COVER PICTURE

The cover picture shows the structural formula of taxol, $R^1 = Ph$, $R^2 = OAc$, superimposed on the needles of the European yew (photograph: S. C. Wilson, TIME–LIFE Magazine, USA). The source of this cytostatic agent till now has been the bark of the Pacific yew; however, about 3000 trees had to be sacrificed to obtain enough taxol to treat 500 patients. As a rapidly regenerable source of a precursor of taxol, the yew needles can help to remedy the situation, since the 10-deacetylbaccatin III isolable from them can be converted into, for instance, taxotere ($R^1 = t$BuO, $R^2 = OH$) or taxol. Nevertheless, more abundant taxol sources and methods to make taxol accessible by semisynthesis or total synthesis are being sought. The fascinating history of taxol, unfolding along the highly interwoven boundary between medicine, cellular biology, and organic chemistry, is summarized by Nicolaou et al. on pages 45–66.

REVIEWS

Contents

Is EXAFS spectroscopy a promising method? Yes, because the element-specific determination of local structures in situ is possible, regardless of the sample's physical state and even at very high dilution. In addition to the principle limitations of this method (differentiation cannot be made between neighboring elements in the periodic table, different backscatterers present at similar distances cannot yield unambiguous results), technical problems (only a few synchrotron radiation sources, data analysis only possible with extensive simulation programs) hinder the development. Although this method has not been in use for very long it has afforded interesting results, for example, in catalysis and the structural characterization of biological systems.

Printed in the Federal Republic of Germany.

A promising antineoplastic chemotherapeutic but hampered by severely limited availability, taxol is described here together with its biological effects and the efforts to increase its accessibility through chemical synthesis. The challenges for the synthetic chemist lie in the eight-membered ring, the densely packed nature of the molecule, and the many oxygen functionalities. An arbitrarily chosen example of an approach to the ABC ring system of taxol is the sequence from **1** through several steps to **2** and finally to **3**.

K. C. Nicolaou,* W.-M. Dai, R. K. Guy 45–66

Chemistry and Biology of Taxol

HIGHLIGHTS

A breakthrough in tailor-made homogeneous catalysts has been achieved by Stanley et al., who synthesized the *rac*-Rh_2 complex **1** with a new tetraphosphane ligand, which catalyzes the hydroformylation of olefins with a high activity and extremely selectively. The combination of these important catalytic properties is traced back to the intramolecular interaction of the two Rh centers fixed by the ligand matrix.

G. Süss-Fink* 67–69

Cooperativity in Rh_2 Complexes: High Catalytic Activity and High Regioselectivity in the Hydroformylation of Olefins

The functionalization of hydrocarbons by selective oxidation is of great technical importance. Two new, effective reagents, (perfluoroalkyl)oxaziridines **1a, b**, hydroxylate the C–H bonds at tertiary C atoms with high selectivity and in good yield. It remains to be seen if they are more economical and efficient than the tried-and-true dioxiranes and $RuCl_3/NaIO_4$.

Oxidation of Weakly Activated C–H Bonds

COMMUNICATIONS

What is the functional relationship between the kinetics and thermodynamics for an elementary reaction in solution? This fundamental question was investigated for unimolecular fragmentations of C–C bonds in radical ions of bibenzylic substrates such as **1**. A Marcus-type free-energy relationship with a parabolic shape fitted the data well. The results imply that mesolytic cleavages have low intrinsic barriers (about 3 kcal mol^{-1}).

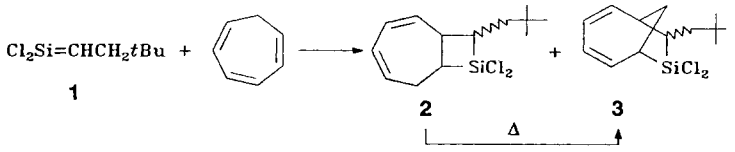
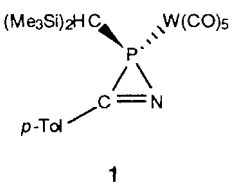
Free-Energy Relationship for Mesolytic Cleavage of C–C Bonds



The seven-coordinate phosphorus atom in the title compound is bound to a slightly distorted square-planar Au_4 array (see structure on the right). Despite the fact that the phosphorus atom is donating all but two of its electrons to the Fe_3 cluster, it is still able to act as a nucleus for the aggregation of four gold fragments.

D. L. Sunick, P. S. White, C. K. Schauer* 75–77

A Cluster-Bound Triply-Bridging Phosphorus Atom Coordinated to Four $(Ph_3P)Au^+$ Units: $[Fe_3(CO)_9P\{Au(PPh_3)\}_4][BAr_4]$



Silabicyclo[4.2.1]nonadienes 3 are two of the products of the reaction of silene **1** and cycloheptatriene. Besides these unusual [6+2] cycloadducts, the [2+2] cycloadducts also arise, which isomerize into **3** upon heating. The [4+2] and [2+2] adducts of 1,3-cycloheptadiene and **1** form competitively; the [2+2] cycloadducts rearrange to give the Diels–Alder products.

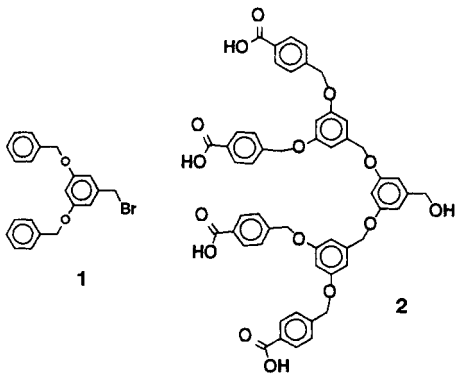
Competing Reactions of Silenes: [2+2], [4+2], and [6+2] Cycloadditions with Cycloheptadiene and Cycloheptatriene



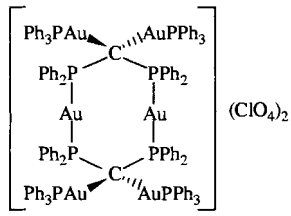
A novel compound with an unsaturated three-membered ring, 2*H*-1-aza-2-phosphirene, is present in complex **1**. This unusual ligand is formed in a surprisingly simple way in the reaction of the corresponding amino(aryl)-carbenepentacarbonyltungsten(0) complex with [bis(trimethylsilyl)methylene]chlorophosphane. The crucial step is the rearrangement of 2-aza-1-phospha-4-tungsta-1,3-butadiene to give the 2*H*-1-aza-2-phosphirene tungsten complex.

R. Streubel,* J. Jeske, P. G. Jones, R. Herbst-Irmer 80–82

Synthesis of the First 2*H*-1-Aza-2-phosphirene Complexes

An accelerated route to the synthesis of dendritic macromolecules through the use of fractal components larger than the repeating unit is described. The first-generation bromide **1** and the second-generation novel branched AB_4 monomer **2** can be used to prepare a highly regular fifth-generation poly(ether ester) dendrimer ($M_r = 9371$) in only three synthetic steps.

K. L. Wooley, C. J. Hawker, J. M. J. Fréchet* 82–85



A "Branched-Monomer Approach" for the Rapid Synthesis of Dendimers

When $Ag_7O_8NO_3$ is heated in an O_2-free atmosphere between 300 and 930 K, its AgO units (300–480 K) are transformed into Ag_2O units (480–580 K) and ultimately into metallic Ag. A strongly chemisorbed O_γ species is found on the Ag surface at temperatures between 580 and 900 K which participates in the catalytic oxidation of methanol to give formaldehyde. The various O species were characterized by Raman spectroscopy.

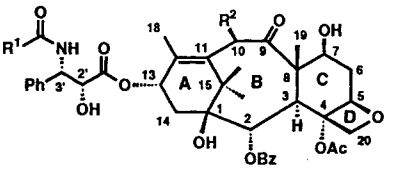
Chemistry and Biology of Taxol

Kyriacos Costa Nicolaou,* Wei-Min Dai, and Rodney Kiplin Guy

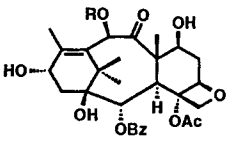
One can view plants as a reference library of compounds waiting to be searched by a chemist who is looking for a particular property. Taxol, a complex polyoxygenated diterpene isolated from the Pacific Yew, *Taxus brevifolia*, was discovered during extensive screening of plant materials for antineoplastic agents during the late 1960s. Over the last two decades, interest in and research related to taxol has slowly grown to the point that the popular press now seems poised to scoop each new development. What was once an obscure compound, of interest only to the most masochistic of synthetic chemists and an equally small number of cellular biologists, has become one of the few organic compounds, which, like benzene and aspirin, is recognizable by name to the average citizen. In parallel, the scientific study of taxol has blossomed. Physicians are currently studying its effects on nearly every known neoplasm. Biologists are using taxol to study the mechanisms of cell function by observing the effects of its interactions with the cellular skeletal systems. Synthetic chemists, absorbed by the molecule's unique and sensitive structure and functionality, are exploring seemingly every available pathway for its synthesis. Indeed, the demand for taxol has risen so in the last five years that alternative sources to the extraction of *T. brevifolia* are being vigorously pursued. Because of the rapidly expanding scope of research in the multifaceted study of taxol, those who are interested in the field may find acquisition of a reasonable base of knowledge an arduous task. For this reason, this account attempts to bring together, for the first time, in a cogent overview the chemistry and biology of this unique molecule.

1. Introduction



Cancer, a disease characterized by unregulated proliferation of cells, is a growing public health problem whose estimated worldwide new incidence is about six million cases per year.[1] In the United States, cancer is second only to heart disease as cause of death.[2] The seriousness of the problem was recognized in the United States in the mid-1960s, studied by the Yarbourogh commission, and addressed legislatively in 1971 by the passage of the National Cancer Act, which attempted to invigorate cancer research through a directed increase in funding.[3] The long-term result of this legislation was the establishment of several national cancer centers and a significant increase in basic research activities aimed at understanding and treating cancer.[4] Considerable progress has been made towards controlling several forms of cancer through a combination of prevention and therapy.[5] Some types of cancer, however, have not yet yielded to the onslaught of research, and breast cancer, in particular, remains a major issue of both scientific[6] and public[7] concern.

Many of the gross causes of cancer, such as dietary, environmental, and occupational exposure to certain chemical substances or forms of electromagnetic radiation, have been elucidated through epidemiological studies.[8] These results have led to a number of prevention programs aimed at reducing exposure to carcinogenic agents (e.g., the US national "Smoke Out" program) and stimulated some controversy over the level of risk involved in such exposures.[9] The biological pathways through which these agents exert their activity as well as the mechanisms of carcinogenesis and metastasis are less well understood and remain the subject of much study and debate.[10] Currently, for example, both genetic[11] and signal transduction[12] models are used to explain carcinogenesis. Although metastasis is well understood at the level of individual tissues, much work remains to be done before the signaling for or the individual biochemical events involved in metastasis can be interrupted.[13]



In the early 1960s the National Cancer Institute (NCI) began an ongoing program to discover new drugs by releasing protocols[14] for widespread screening of substances and extracts from various origins for antineoplastic activity.[15] Following the NCI initiative, United States Forest Service botanist

A. Barclay collected samples of the bark of the pacific yew, *Taxus brevifolia* Nutt, from an Oregon forest in 1962.[16] These samples were sent by the NCI to Wani and Wall, chemists at the Research Triangle Institute in North Carolina. Initial screening of a crude extract of the bark showed cytotoxic activity against leukemia cells and inhibitory action against a variety of tumors. Several years later, the active component of the extract, taxol (**1**, Fig. 1), was isolated by Wall et al. The compound was subjected to an X-ray crystallographic analysis carried out at Duke University, which revealed its molecular structure, including absolute stereochemistry.[17] The beauty of the molecular architecture and the highly congested nature of taxol are appreciated by inspection of molecular models (Fig. 2). Of the more than 110000 compounds from 35000 plant species tested between 1960 and 1981, taxol proved the most interesting.[18] Nevertheless, further investigation of taxol languished for almost a decade due, primarily, to difficulty of extraction from the natural source, problems with the murine screening system, and a belief that taxol was simply another microtubule-destabilizing agent like colchicine and the vinca alkaloids.[19] However, interest in the compound reemerged and rapidly acquired strong momentum when Horwitz et al. at the Albert Einstein College of Medicine reported that taxol did indeed act on microtubules but with a unique mode: it stabilized microtubules instead of destabilizing them like all other known agents.[20]

K. C. Nicolaou

W.-M. Dai

R. K. Guy

K. C. Nicolaou was born in Cyprus and received his Ph.D. degree from the University of London under F. Sondheimer and P. Garratt. After postdoctoral work at Columbia University with T. Katz and at Harvard University with E. J. Corey, in 1976 he joined the faculty at the University of Pennsylvania, where he was promoted to Rhodes-Thompson Professor of Chemistry. In 1989 he accepted joint appointments as Professor of Chemistry at the University of California San Diego and as Darlene Shiley Professor of Chemisty and Chairman of the Department of Chemistry at the Scripps Research Institute. His awards include a Guggenheim Fellowship, a Humboldt Senior American Scientist Award, and the American Chemical Society Award for Creative Work in Synthetic Organic Chemistry. Nicolaou's research interests focus on chemical synthesis, molecular design and recognition, and the biological function of molecules.

W.-M. Dai was born in 1957 in Ninghai, China. He received his B. S. in 1982 from Hangzhou University (China), his M.S. in 1984 at the Shanghai Institute of Organic Chemistry, Academia Sinica under Professor W.-S. Zhou, and his Ph.D in 1990 from Kyoto University (Japan) on asymmetric synthesis utilizing chiral tin(II) enolates, and its application in the total synthesis of alkaloids. He then joined Professor Nicolaou's group as Research Associate. In September 1992 he accepted a teaching post at the Department of Chemistry of the Hong Kong University of Science and Technology. His research interests include the development of novel asymmetric reactions and the synthesis of natural products and biomedically interesting molecules. He is currently engaged in the design, synthesis, and study of novel enediynes.

R. K. Guy, born in 1968 in Ft. Rucker, Alabama, USA, obtained his BA in Chemistry from Reed College, Portland Oregon. He then worked in the Synthetic Development Laboratory of the Almaden Research Center of IBM, San Jose, California on photoresist materials until 1992. At present he is an Office of Naval Research Predoctoral Fellow at the Scripps Research Institute and involved in the total synthesis of taxol program with Professor Nicolaou.

2. The Biological Role of Taxol

2.1. Taxol and Microtubules

Microtubules are involved in many aspects of cellular biology. They are used by the cell to form a static structure, called the cytoskeleton, which helps shape the cell[21] and position the organelles.[22] The dynamic properties of microtubules are used to transmit cellular signals,[23] reorganize organelles,[24] and move the cell.[25] As will be discussed below, they are an absolute necessity for cell division, a process in which they play a central role. Because of their versatility, usage, and importance to growing cells, microtubules have been called "the most strategic subcellular targets of anticancer chemotherapeutics."[26] Figure 3 summarizes the present state of knowledge about the taxol–microtubule connection.

Microtubules are primarily composed of two subunits: α- and β-tubulin, structurally similar protein isofamilies of approximately 440 amino acids each with a molecular weight of about

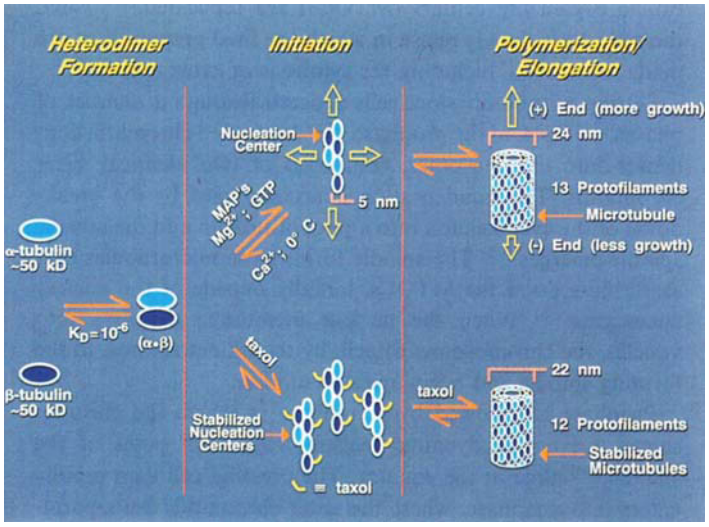

Fig. 3. Microtubule formation and the mechanism of action of taxol. For explanation, see text.

50 kD.[27] The tubulin genes are highly conserved,[28] and there is a 35–40 % homology between the α and β types.[29] Both isofamilies are subject to a variety of posttranslational modifications giving rise to a large number of similar proteins within any given cell. Whether the various cellular functions of microtubules are due to individual tubulins or related groups of tubulins is still unclear.[30] The tubulin dimer binds two molecules of guanosine 5′-triphosphate (GTP), an event involved in the assembly of microtubules. One of the GTP molecules binds exchangeably to a site of the β subunit, called the *E*-site,[31] whereas the other molecule binds tightly to another site, presumed to be on the α subunit and called the *N*-site.[32] The remainder of the mass (up to 20%) of a microtubule is made up by heterogeneous microtubule-associated proteins (MAPs), whose structure and function vary with both organism and tissue.[33]

The tubulin dimer is the binding target of a number of drugs that inhibit the polymerization of tubulin. Although the binding site has been localized to the β subunit for some of these drugs, notably colchicine,[34] most of the others appear to bind to multiple, as yet undefined sites.[35] Competition experiments have shown that colcemid, podophyllotoxin, and nocodazole all bind to the colchicine site, while the vinca alkaloids, vinblastine and vincristine, bind to a different site.[36]

The initial event in the polymerization of microtubules is the formation of a heterodimer comprising one molecule of α-tubulin and one molecule of β-tubulin, which has a dissociation constant K_D of about 10^{-6}.[37] In the presence of magnesium ions and GTP, these dumbbell-shaped heterodimers then join in a head-to-tail fashion to give the nucleation center for protofilament formation. Concomitant growth both along and perpendicular to the axis of the initial protofilament then occurs until the growing molecule curls along the axis of the protofilaments, and the edge filaments join to give a microtubule.[38] From this point, the growth occurs only at the ends of the tubule.

A normal microtubule from brain tubulin is composed of 13 protofilaments and has a diameter of about 24 nm. The protofilaments are assembled in a slightly staggered manner, which gives the microtubule a left-handed three-start helix (in which, in any horizontal unit plane three filaments start).[39] In this configuration, the filaments are aligned in a helical fashion such that one complete turn of the helix results in a vertical rise of three tubulin subunits. The grooves between the protofilaments of the resulting microtubule are much more pronounced on its outer than on the inner surface.[40] The filamentous structure of the microtubule is overlaid with MAPs, some of which appear to have a stimulatory effect on polymerization.[33] Typically, equilibria are set up at both ends of the microtubule with constant loss and gain of tubulin subunits. Often the relative rates of loss/gain at the two ends are different, which gives the microtubule a growing polarity. The faster growing end is termed the "plus" pole and the more slowly growing end the "minus" pole.[41]

In general, microtubules are not static structures. After a certain period of growth, the microtubule and free tubulin will reach relative concentrations corresponding to the equilibrium constant. At this point, disassembly and growth are precariously balanced; this is termed the critical concentration.[42] When the relative tubulin concentration is below the value required for equilibrium, spontaneous assembly will not occur. The tubulin

system then is capable of rapid rearrangement. A number of models, of which the dynamic instability model is currently the most widely accepted, have been proposed[43] to explain this behavior.[44] According to this hypothesis, only tubulin with bound GTP is able to add to the growing end of the microtubule, and the microtubule maintains a "cap" of tubulin·GTP complex. GTP hydrolysis is assumed to be an ongoing background process, and it is proposed that, when a microtubule loses its cap, rapid disassembly ensues. Thus, the model claims that while the mass of assembled microtubules will remain constant, they are represented by constantly growing or shrinking tubules, not by static structures. Establishing the existence of the cap has proven difficult, and the model is currently in dispute.[45]

In 1979 Horwitz et al. demonstrated that taxol affects the tubulin–microtubule equilibrium.[20] Taxol decreases both the critical concentration of tubulin (to almost 0 mg mL^{-1}) and the induction time for polymerization, either in the presence or absence of GTP, MAPs, and magnesium. The microtubules formed by taxol induction proved morphologically distinct from those formed in the control experiments. They exhibited a shorter average length and resistance both to cooling and to ionic calcium, which normally depolymerize microtubules. It was only with the combination of cooling and calcium ions, or cooling and high ionic-strength buffers that taxol-stabilized microtubules could be induced to depolymerize.[46] Changing the pH of the medium to above 7.6 also induced depolymerization,[47] although this may have been due to hydrolysis of the C13 side chain of taxol.[48] Attempts to remove taxol from both microtubules and tubulin after depolymerization indicated that it binds much more strongly to the intact microtubule than to the tubulin dimer and that the molecule does not permanently modify tubulin during the binding interaction.

The maximum effects of taxol occur at a stoichiometry of 1:1 taxol:tubulin dimer.[49] Subsequently, through the use of the tritiated compound, the same workers proved that taxol binds specifically and reversibly to a polymerized form of tubulin with an apparent binding constant K_{app} of 10^{-6}.[50] It was postulated that the effects of taxol were caused by an increase in nucleation events.

The binding site of taxol appears to be distinct from that of other anti-microtubule agents[51] and common MAPs.[52] However, it has been suggested that some spatial overlap exists between the colchicine and taxol binding sites.[53] In addition, taxol does not affect the binding or the hydrolysis of GTP.[54] More recently, the binding site of taxol has been localized to the β subunit of tubulin through direct photoaffinity labeling[55] and analysis of the binding profiles of strains of algae with mutations in tubulin genes.[56] Efforts to locate the binding site more closely are currently under way.[57]

Careful examination of the X-ray scattering patterns and electron microscopy images of microtubules formed by taxol induction revealed several gross structural differences between these tubules and tubules formed in control experiments (see Fig. 3).[58] Taxol induction produces tubules that have a mean diameter of about 22 nm as opposed to 24 nm for those produced by MAP induction and that are composed of 12 protofilaments rather than 13. Time-resolved X-ray scattering data support the idea that taxol promotes sideways growth of tubules in the nucleation center as well as lengthening along the protofilament axis. Taken in conjunction with observations showing that taxol promotes the end-to-end joining of microtubules,[59] these results point to a rather complex mechanism of action for taxol that is not yet completely understood.

French workers have synthesized a highly promising analog of taxol, Taxotere (**2**, see Fig. 1),[60] which promotes the assembly and stability of microtubules with a potency approximately twice that of taxol.[61] Recently, taxol and Taxotere have been shown to compete for the same binding site.[62] While most of the effects of Taxotere mirror those of taxol, it appears that the microtubules formed by Taxotere induction are structurally different from those formed by taxol induction.[63]

2.2. Taxol and the Cell Cycle

Cells have a characteristic life cycle which is depicted schematically in Figure 4. Some of the approximately 10^{13} cells in a human body, such as neurons, are unable to replicate and exist in a state called terminal differentiation. The cells of other tissues spend most of their time in a nonproliferative state called quiescence, or G_0, which is outside the cell cycle.[64] These cells replicate at different rates: skeletal muscle cells less than once a year, liver cells about once a year, and stem cells of the gut about twice a day. They can remain quiescent for long periods and yet switch to rapid proliferation when more cells are needed, such as during the healing of a wound. The different rates of cellular proliferation are related primarily to the fraction of cells in the cell cycle, not to the relative time needed to traverse the cycle. Quiescent cells can be induced to reenter the cell cycle at G_1 either through the action of tissue-specific growth factors[65] or through the influence of internal controls related to differentiation states. While normal cells are inhibited towards proliferation when their population density is high, cancerous cells often lack these control mechanisms and continue to replicate in conditions that normally induce quiescence.[66]

Once induced to reenter the cell cycle, the cells pass through G_1 and initiate, through a complex enzymatic cascade,[67] the S phase.[68] During this phase the DNA, histones, and microtubule organizing centers (MTOCs) are replicated.[69] Next, the cell enters the G_2 phase in which the final preparations are made for mitosis, including the synthesis of extra tubulin.[70]

During mitotic division, cells proceed through a number of phases.[71] First, in the prophase, the duplicated chromatin condenses into chromosomes, composed of two identical sister chromatids. This condensation is accompanied by the breakdown of the cytoskeleton into a pool of tubulin and the mitotic spindle emerges.[72] The spindle forms from microtubules that assemble around the MTOCs, initially outside of the nuclear membrane.[73] When the nuclear membrane dissolves into vesicles, the chromosomes attach, by their kinetochores, to the forming spindle and begin agitated motion.

Prophase is followed by metaphase in which the chromosomes, driven by dynamic tension from both poles of the spindle,[74] align at the equator. The dividing cell then rapidly enters into anaphase, where the sister chromatids are separated,[75] each containing one copy of the genetic message of the chromosome. The chromatids separate slowly, at about

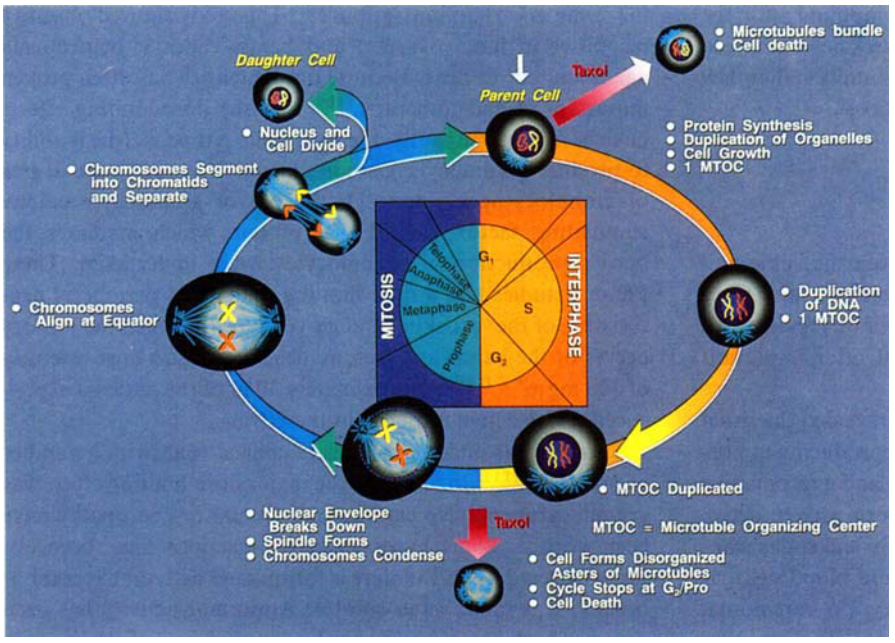

Fig. 4. Taxol and the cell cycle. For explanation, see text.

1 μm min^{-1}. Concomitantly, the poles of the spindle are pushed apart by other microtubules.

Finally, the cell enters telophase during which the chromatids arrive at the poles of the spindle, the nuclear envelope reassembles, and the organelles and cytosol segregate in a process known as cytokinesis. The resulting separated daughter and parent cells continue to grow and synthesize new proteins before either entering G_0 or traversing the cycle.

The events in the cell cycle proceed through a linear pathway in which the initiation of late events require the completion of the early events. Normal cells have control mechanisms, called checkpoints, which enforce this ordering.[76] An example of such a checkpoint is that, when a chromosome is slow to line up at the spindle equator during metaphase, anaphase is delayed until the chromosome arrives.[77] When these checkpoints are abolished, the cell may die or undergo catastrophic alterations to its normal metabolism. Tumor cells are often deficient in checkpoints.

When Horwitz et al. extended their studies on taxol to in vitro cell culture systems, they found that this agent caused HeLa[78] cells to arrest at the transition from interphase to mitosis, (G_2/Pro, see Fig. 4).[79] Morphologically, these cells exhibited unnatural "bundles" of microtubules and no mitotic spindle. Moreover, the investigation showed that taxol inhibited the motility of fibroblasts without affecting their ability to form podia.

These studies were rapidly extended by a number of groups, who found that taxol affects microtubules in all phases of the cell cycle. Cells arrested in mitosis exhibit "asters",[80] which are star-shaped microtubule formations that are not organized around MTOCs and that are formed reversibly.[81] In the other phases of the cell cycle, taxol causes the generally irreversible formation of bundles of microtubules, visually reminiscent of a log jam.[82] The net effect of these phenomena is a sequestration of tubulin as stable structures. The resulting absence of free tubulin prevents the assembly of a normal mitotic spindle. It may be that the cancerous cells lack a checkpoint to detect the absence of a spindle and attempt to continue the cell cycle, which leads to cell death. Other vital cell processes that depend upon microtubules may also be prevented, or checkpoints missed, and the cell remains in interphase. Recent studies have shown that taxol can inhibit the transition of cells out of the quiescent state.[83] Studies with leukemia cell lines indicated that cells may freeze at interphase points in taxol-sensitive lines.[84] Not surprisingly, some fungal cells are also sensitive to taxol.[85]

Taxol has been implicated in the disturbance of many cellular phenomena that are not directly related to cell division. For example, taxol inhibits the locomotion of Walker 256 carcinoma cells,[86] the slow transportation of tubulin, actin, and polypeptides in axons,[87] the intracellular transportation of steroids in MLTC-1 cells,[88] and the immunoreactivity of τ-MAPs in neurons.[89] It should be noted that microtubules are involved in all of these phenomena.

Most intriguing are taxol's effects on protein secretion, a process in which microtubules are intimately involved.[90] The agent inhibits the secretion of insulin from pancreatic cells,[91] catecholamine from adrenal medullary cells,[92] plasma proteins from rat liver cells,[93] and prothrombinase from platelets.[94] In each of these cases, the effect appears to be specific and does not inhibit overall protein secretion. Interestingly, taxol has been shown to increase the secretion of tumor necrosis factor alpha (TNF-α) and interleukin-1 from macrophages in a manner similar to that of bacterial lipopolysaccharide (LPS), an action which may contribute to the antineoplastic activity of taxol.[95] These observations led to the recognition that LPS selectively and specifically binds β-tubulin and MAP-2.[96] The taxol-induced inhibition of collagenase secretion has been linked to a blockage of metastasis of prostate tumor cells (PC-3 ML) in SCID mice.[97]

Likewise, Taxotere has been shown to be active against a wide range of tumor cell lines.[98] As with the microtubule studies, the in vitro cytotoxicity effects of Taxotere are higher than those of

taxol at equivalent doses. The effects of the compound upon the various microtubule-mediated cellular processes have not been reported but one may make the reasonable assumption that they will be similar to those described above for taxol.

2.3. Clinical Applications of Taxol

The clinical usage of taxol has recently been the subject of excellent reviews by Rowinsky et al.[99] Therefore, and since much of the clinical data is beyond the scope of this review, this section will only highlight these studies and offer important recent results.

Preclinical studies on mice, rats, and dogs revealed the usual toxic effects of mitosis inhibitors on tissues reproducing at normal rates, including the blood, lymph, gut, and reproductive systems. Prior to clinical trials, taxol had been proven active against murine B16, L1210, P388, and P1534 leukemias, cancers characterized by overproduction of white blood cells. It also had a demonstrable effect upon Walker 256 carcinoma, sarcoma 180, and Lewis lung tumor cell lines.[100] Taxol was also proven efficacious against a number of leukemias and solid tumors in xenografts (tissue transplanted from one species to another), including those in breast, ovary, brain, and lung.[101] Recently, taxol has proven useful as sensitizer for radiation treatment against cultured astrocytoma cells, which normally serve a structural element in the nervous system.[102] Presumably this effect arises since it holds the cells at G_2/Pro, a phase in which they are known to be quite sensitive to ionizing radiation.[103]

These promising early results led to wide spread Phase I clinical trials in which the clinical safety was established. Initially the trials were hampered by acute hypersensitivity reactions that may be attributable to the vehicle of administration required for solubilization, Cremaphor, a polyoxyethylated castor oil that is known to cause histamine release.[104] Effective protocols, including prophylactic pretreatment with antihistamines[105] and longer infusion times,[105] have emerged to essentially circumvent this problem. In later trials, neutropenia, the inability to produce a certain class of granular white blood cells, has emerged as the major dose-limiting effect, although irregular heart beat rhythms (cardiac arrhythmias),[106] and neuropathy, the deadening of sensory nerves, have also been observed. Due to the sensitivity of the blood to agents which inhibit cellular proliferation and that of the nervous system to cytotoxins, these were not unexpected side effects. In vivo antineoplastic effect was demonstrated with a number of cancers including leukemia, breast, ovarian, and lung tumors, and melanoma. The dose recommendations emerging from these studies were generally in the range of 200–250 mg m^{-2} (of body surface area), administered in about 3 L of isotonic solution over a period of 6–24 hours. Recently several groups have disclosed the development of immunoassays for measuring plasma concentrations of taxol.[107]

Several Phase I trials involving the co-administration of taxol with other drugs are currently under way. Studies with cisplatin, a chemotherapeutic that acts directly upon DNA, have given promising results and demonstrated that the best application sequence is that of taxol (135–170 mg m^{-2}) followed by cisplatin (75 mg m^{-2}) administration.[108] This study showed objective responses in lung, ovarian, and breast cancers; neutropenia again limited the dose. Because dose intensity has often proven important in chemotherapy,[109] and the dose-limiting effects have been predominantly due to granulocytopenia (the inability to produce granulocytes), studies aimed at lowering the degree of granulocytopenia through the use of granulocyte colony stimulating factor (G-CSF), a protein which increases the body's production of granulocytes, were undertaken. These Phase I studies had a dose-limiting toxicity of peripheral neuropathy, of the "stocking and glove" type (in which the sensory nerves of the hands and feet are deadened), at a dose intensity of 300 mg m^{-2}.[110] Approximately 30% of the patients experienced an objective response in these trials.

Taxotere has undergone Phase I clinical trials with a number of protocols.[111] In all cases, the major dose-limiting effect was granulocytopenia. No cardiac arrhythmias or neuropathy have been evident. Some hypersensitivity reactions have been observed, even though Taxotere is formulated without Cremaphor because it is more water-soluble. Antitumor activity has been noted in both breast and ovarian cancers. Phase II studies with Taxotere in which the efficacy of the drug may be established are currently under way.

Phase II clinical trials, limited to those neoplasms that showed preclinical effects because of restricted availability of the drug, have proven the efficacy of treating several cancers with taxol. In the case of ovarian cancer, taxol gave a response with manageable side effects in 30–35% of the cases.[112] These results, which represent the highest reported salvage rate for ovarian cancer, are particularly significant since these patients showed resistance to other therapies.[113] Initial trials involving patients with metastatic breast cancer gave a 56% response rate with manageable granulocytopenia as the dose-limiting side effect.[114] Responses of between 20 and 50% have been demonstrated with non-small-cell lung cancer.[115] A recent Phase II study indicated positive results with G-CSF-mediated dose escalation (30% objective response increases to 60%) in the treatment of recurrent ovarian cancer.[116] This suggests that, in those cases where the dose-limiting toxicity is granulocytopenia, G-CSF co-administration protocols are warranted. These favorable results recently led the Food and Drug Administration (FDA) of the United States to approve taxol for the treatment of patients suffering from advanced recurrent ovarian cancer.[117] It is almost certain that taxol, and very likely Taxotere, will soon be approved for the treatment of other cancers.

2.4. The Issue of Supply

As mentioned above, large scale clinical trials with taxol have been hampered for a long time by relatively low supplies of the drug.[118] Taxol is currently produced by a somewhat tedious extraction from the bark of the Pacific Yew, *Taxus brevifolia* Nutt (Fig. 5a). This extraction, when carried out under good manufacturing practice (GMP) guidelines, is the only method which is currently approved by the FDA as a source of taxol.[119]

The history and biology of the Pacific Yew have recently been reviewed.[120] The yew is a coniferous tree which usually grows

in the understory of old-growth stands of conifer or hardwood (Fig. 5a presents a typical setting). The majority of the trees grow in the coastal regions of the Pacific Northwest from Annette Island, Alaska, to Mendicino County, California, as well as the Cascade Range of Washington and Oregon, the western slopes of the Rockies, and the Lewis Range of Montana. The tree grows slowly and typical mature specimens rarely exceed 12 m in height and 60 cm in diameter. Because of their slow growth and a tendency to grow in dispersed microsites within the larger old-growth ecosystem, the density of the yew is quite low. Prior to the advent of taxol, the trees were regarded primarily as scrub and rarely taken during primary logging operations. Instead they were burned in place during slash disposal fires.

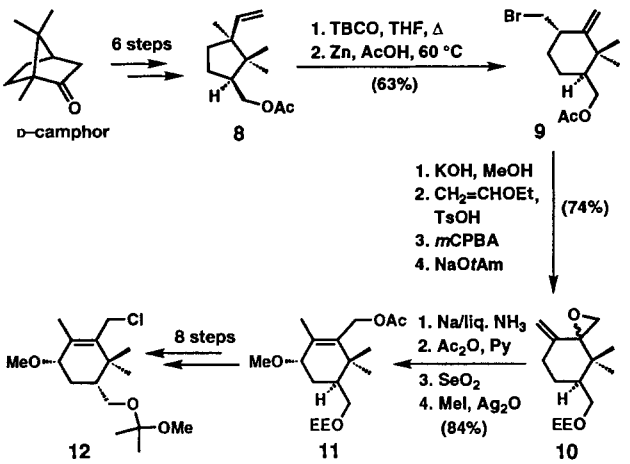
Fig. 5. a) The Pacific Yew, *Taxus brevifolia*. b) The European ornamental shrub *Taxus baccata* (photographs by S. C. Wilson TIME-LIFE Magazine, USA).

To obtain one kilogram of taxol, 10 000 kilograms of bark are required, which, in turn, requires the sacrifice of about 3000 trees. Because of the relatively large amount of taxol needed to treat a patient (under current protocols almost two grams), this kilogram of taxol is enough to treat only 500 patients. A number of groups including SRI International,[121] the Forest Service,[122] and Weyerhaeuser[123] have been exploring the factors that cause variance in taxol concentrations from tree to tree to find growing conditions that will optimize the yield of available taxol from each tree. The Weyerhaeuser group is currently growing the yew in plantations and expect to be producing commercial quantities of taxol by 1994.[124]

The two currently most promising options for large-scale production of taxol are cell culture and semisynthesis. Bristol–Myers Squibb has recently announced that they will begin production of taxol through a semisynthetic route following the methods of Holton's semisynthesis and Hauser's extraction process (see Section 3.5).[125] This route proceeds through the coupling of a suitable side-chain equivalent with a 7-protected baccatin III intermediate obtainable in large quantities from *T. baccata* (Fig. 5b) and currently provided by the Indena company.[119] Taxotere is currently produced by attaching a synthetic side chain to 10-deacetyl baccatin III (**3** in Fig. 1), which is readily available from the European Yew, *T. baccata*, in yields approaching 1 kg of **3** from 3000 kg of needles.[126]

Cell culture has already been used to produce ^{14}C labeled taxol from ^{14}C sodium acetate.[127] The USDA (United States Department of Agriculture) has received a patent for the production of taxol from cultured callus cells of *T. brevifolia*.[128] They have licensed this process to Phyton Catalytic, who estimates that they will begin commercial production within two to five years.[129] The advantage of this system is that the major secretion product of the cells is taxol, which reduces the purification to an ether extraction of the medium. ESCAgenetics has also announced technology for producing high levels of taxol in plant cell cultures, and they project large-scale production in the near future.[130] Additionally, callus cultures of *T. cuspidata* and *T. canadensis* have been sustained in a taxol-producing system for over two months.[131] A fungus, indigenous to *T. brevifolia*, that produces small amounts of taxol has recently been isolated and cultured.[132]

3. Synthetic Approaches to Taxol and Taxol Systems

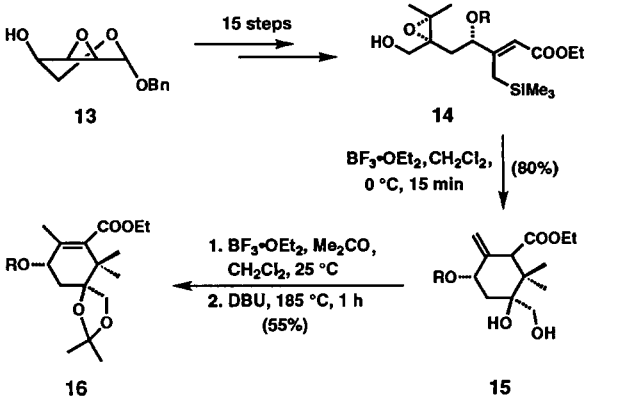


As a target for chemical synthesis, taxol presents a plethora of potential problems. Perhaps most obvious is the challenge presented by the central B ring, an eight-membered carbocycle. Such rings are notoriously difficult to form because of both entropic and enthalpic factors. The normally high transannular strain of an eight-membered ring is further increased in this case by the presence of the geminal dimethyl groups, which project into the interior of the B ring. Then the *trans*-fused C ring with its angular methyl group and another ring (A ring), which is a 1,3 C_3 bridge, must be introduced. The A ring includes a somewhat problematic bridgehead alkene formally forbidden in a six-membered ring by Bredt's rule. If assembling the carbon skeleton alone is not a daunting enough task, one should consider the high degree of oxygenation that must be introduced in a manner which allows the differential protection of five alkoxy groups in a minimum of three orthogonal classes. Additionally, some of the functionality is quite sensitive to environmental conditions. The oxetane ring, for example will open under acidic or nucleophilic conditions, and the 7-hydroxyl group, if left unprotected, will epimerize under basic conditions.

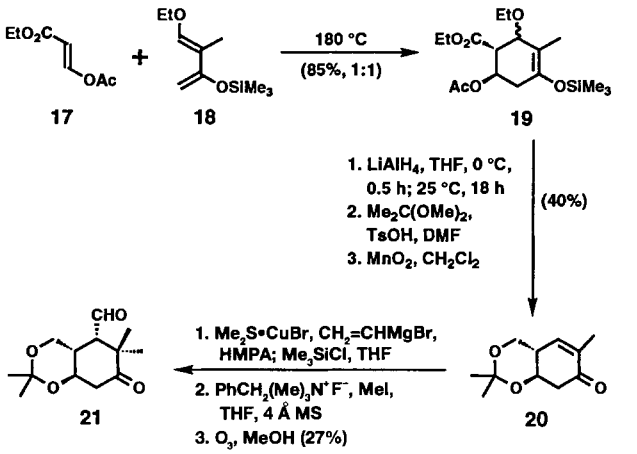
From the time of its structural elucidation, the challenge posed by taxol's unusual molecular architecture and sensitive functionality has fascinated synthetic organic chemists. Despite the many attempts to synthesize taxol, the molecule still remains inaccessible by total synthesis. Much elegant work, however, has been reported in the area. The fruits of these endeavors include the development of new synthetic methodology and strategies, the synthesis of model systems, and the construction of intermediates for projected total and partial syntheses of the natural product. Because an excellent review by Swindell on the synthetic efforts through the middle of 1991 exists,[133] this section will only provide highlights of the synthetic chemistry related to taxol and emphasize the more recent developments. These efforts are discussed under the following subsections: approaches directed at the assembly of the ring A of taxol (Section 3.1), strategies towards the construction of rings C and CD of taxol (Section 3.2), efforts to join the various rings of taxol and the more convergent strategies towards the taxane skeleton (Section 3.3), methods for production of the taxol and Taxotere side

chains (Section 3.4), and semisynthetic approaches to taxol and Taxotere (Section 3.5).

3.1. Approaches to the A Ring System of Taxol



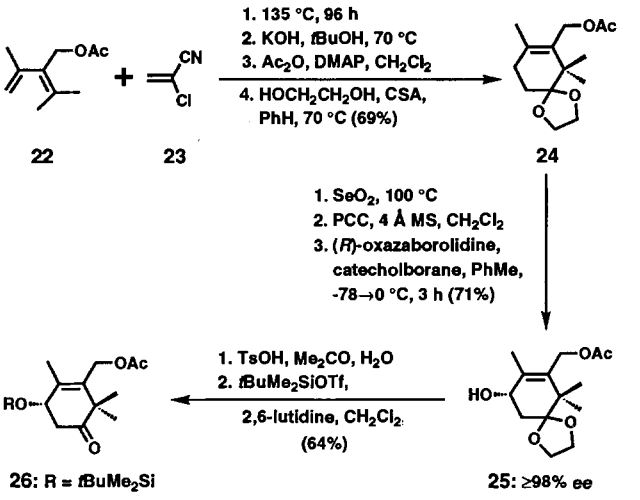
One of the earliest approaches to the ring A of taxol was that of Kitagawa et al.,[134] in which a Wagner-Meerwein rearrangement, induced by a bromonium ion, converted cyclopentane ring **8** into cyclohexane skeleton **9** (Scheme 1). Compound **9** was then transformed into intermediates **11** and **12** in several steps by standard methodology.



Scheme 1. Kitagawa's approach to the A ring system of taxol by ring enlargement (1980 and 1984). TBCO = 2,4,4,6-tetrabromocyclohexa-2,5-dienone, Ts = *p*-toluenesulfonyl, *m*CPBA = *m*-chloroperbenzoic acid, *t*Am = *t*BuCH$_2$, EE = ethoxyethyl, Py = pyridine.

An elegant approach to the A ring of taxol was reported by Frejd et al. in 1987.[135] This method (Scheme 2) involved a Lewis acid promoted cyclization of epoxysilane **14**, prepared from **13**, to afford the key cyclohexane system **15**. Further elaboration of this intermediate provided compound **16**.

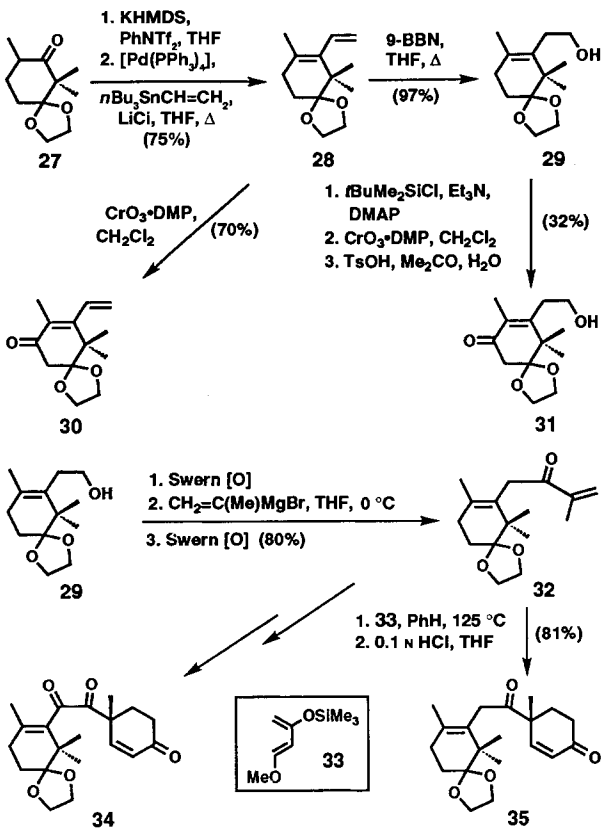
Clark's group[136] reported a synthesis of the A ring system **21** based on a Diels–Alder reaction (Scheme 3). After the cycloaddition process to assemble the cyclohexene ring, the final carbon



Scheme 2. Frejd's approach to the A ring system by intramolecular cyclization (1987). DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene, R = *t*BuMe$_2$Si.

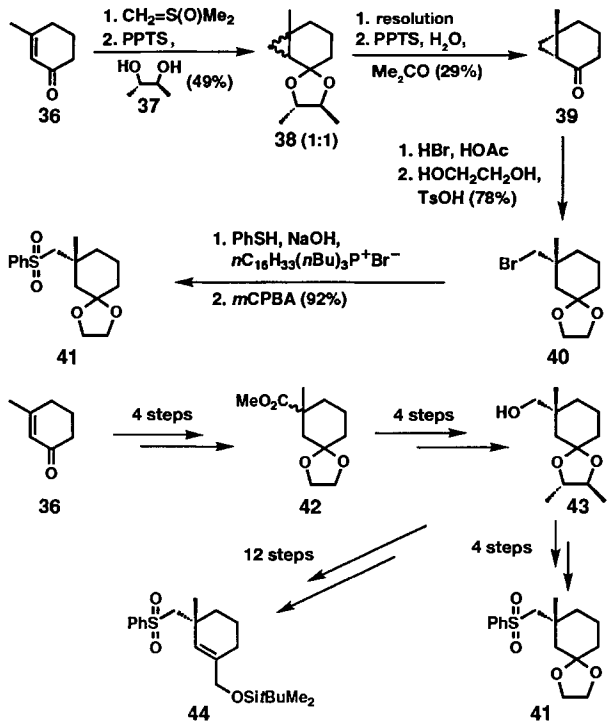
Scheme 3. Clark's approach to the A ring system through a Diels–Alder reaction (1987). DMF = dimethylformamide, HMPA = hexamethylphosphoric triamide, MS = molecular sieves.

framework was produced through further elaboration and a carefully controlled Gilman reaction. While this procedure had the advantage of brevity, it lacked stereocontrol and required the use of unstable starting materials.



Our own Diels–Alder based strategy[137] for the construction of the A ring is shown in Scheme 4. In this rather simple ap-

Scheme 4. Nicolaou's approach to the A ring system through Diels–Alder reactions (1992). DMAP = 4-dimethylaminopyridine, CSA = camphorsulfonic acid, PCC = pyridinium chlorochromate, Tf = trifluoromethanesulfonyl.

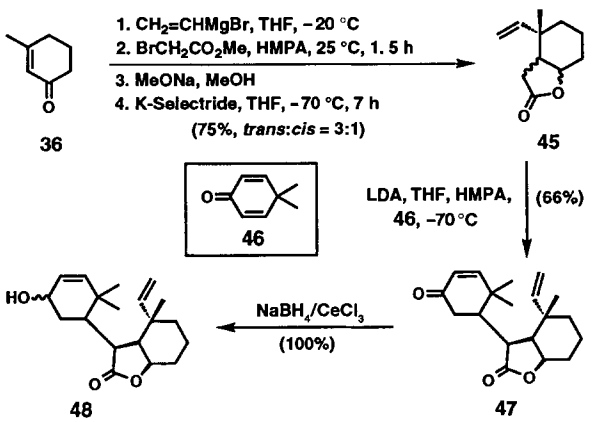


proach the readily available Diels–Alder partners **22** and **23** reacted in a regiospecific manner to afford, after further elaboration, cyclohexene derivative **24**. This intermediate was then smoothly and efficiently transformed into ring A intermediates **25** and **26**. Strategies for the coupling of these systems with fragments containing the C ring of taxol are discussed in Section 3.3.

Scheme 5 depicts the approach of Danishefsky, Queneau et al.[138] to taxol A ring intermediates and model coupling reactions. In this study the known starting material **27**[221] was converted into intermediates **30** or **31** by Stille coupling and subsequent oxidation with chromium(VI) oxide or other

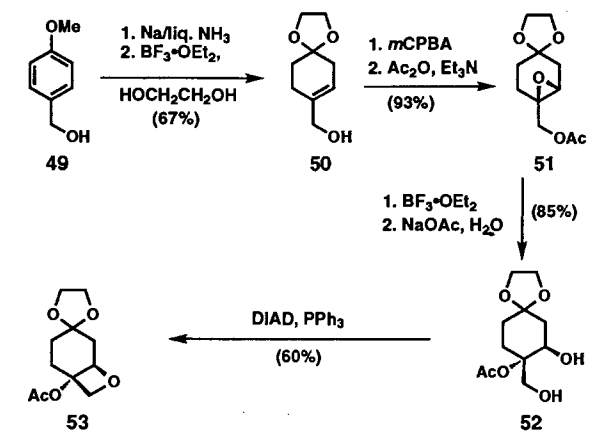
Scheme 5. The Danishevsky–Bornmann approach to A ring systems (1992). HMDS = hexamethyldisilazide, 9-BBN = 9-borabicyclo[3.3.1]nonane, DMP = 3,5-dimethylpyrazole.

standard manipulations. A Diels–Alder reaction of **32** with Danishefsky's diene (**33**) to form **35** demonstrated a possible route for the attachment of the C ring; another potential scenario is the transformation of **32** into **34** in three steps.



Scheme 6. Kitagawa's approach to the C ring system of taxol (1984). PPTS = pyridinium-*p*-toluenesulfonic acid.

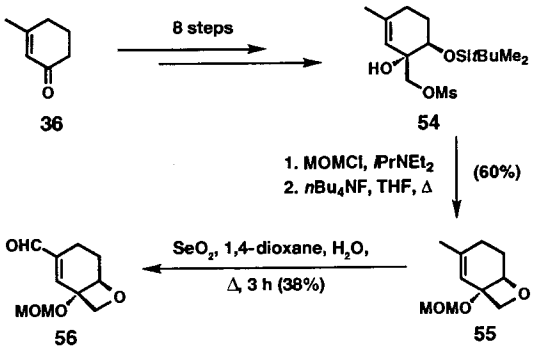
3.2. Approaches to the C and CD Ring Systems of Taxol



Simple model systems for the C ring such as **41** and **44** (Scheme 6) have been synthesized by Kitagawa et al.[139] Compounds **39**–**44**, enriched in the several enantiomers, were obtained through resolution of diastereomeric **38**, which was produced by cyclopropanation of **36** with dimethylsulfoxonium methylide and treatment with **37**. A phenylsulfonyl group was built into the final intermediates to allow for modeling of coupling reactions.

Fetizon et al. demonstrated construction of C ring model system **45** (Scheme 7).[140] Conjugate addition of vinyl magnesium bromide to **36**, followed by enolate trapping with methyl bromoacetate, hydrolysis, and selective reduction gave **45**. A clever approach to ring A–C model systems **47** and **48** was demonstrated by coupling **46** to **45** under basic conditions.

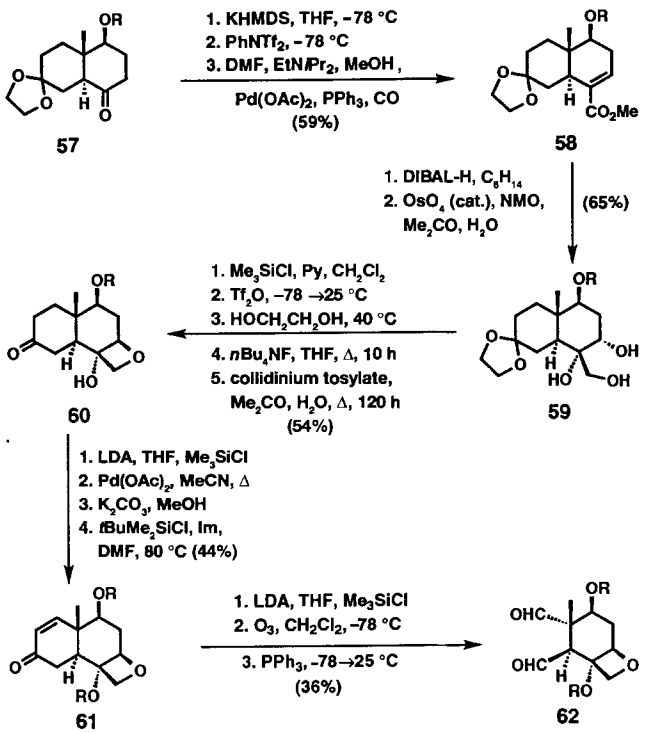
Scheme 7. Fetizon's approach to the A ring system and the B-seco skeleton (1984). K-Selectride = potassium tri-*sec*-butylborohydride, LDA = lithium diisopropylamide.



Berkowitz et al. were the first to report a CD ring model system (Scheme 8).[141] Birch reduction of **49** followed successively by protection of the resulting ketone, allylic epoxidation,

Scheme 8. Berkowitz's approach to the CD ring system (1985 and 1987). DIAD = diisopropylazodicarboxylate.

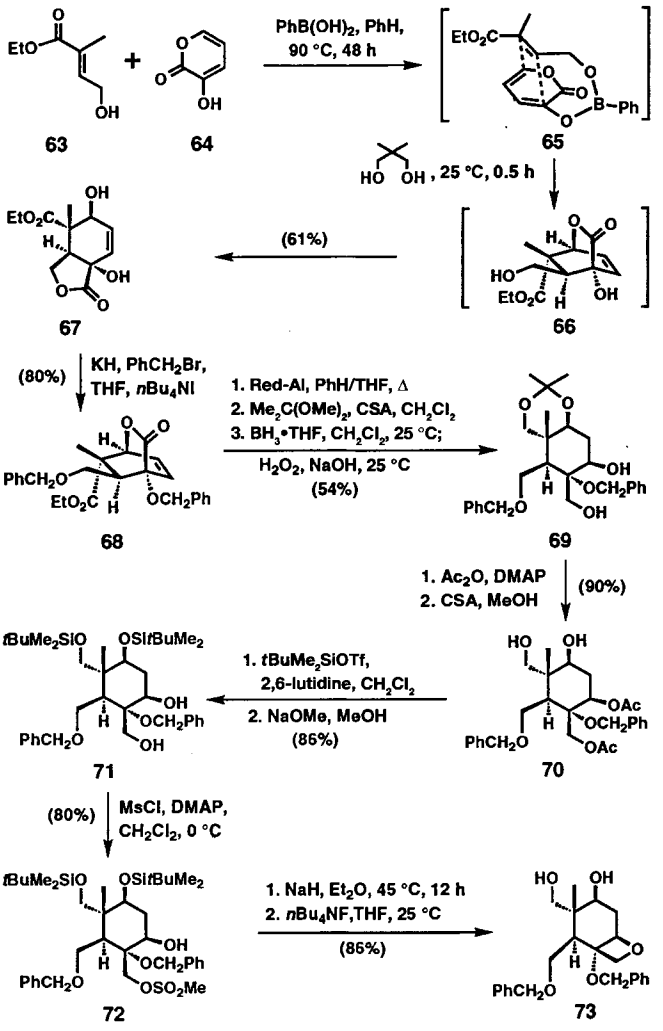
protection, directed epoxide opening, and acyl group migration gave the key intermediate **52**. Finally, an intramolecular Mitsunobu reaction was used to construct the oxetane functionality of **53**.



In a different approach, Clark et al.[136] demonstrated the construction of the CD model systems **55** and **56** (Scheme 9).

Scheme 9. Clark's approach to the CD ring system (1987). MOM = methoxymethyl.

Compound **36** was converted into **54** by oxidation of the trimethylsilyl enolate, protection of the resulting alcohol, Petersen olefination, vicinal dihydroxylation, and selective mesylation. The oxetane **55** was formed by an intramolecular S_N2 type mesylate displacement reaction (**54** → **55**). Finally, allylic oxidation of **55** gave **56**.

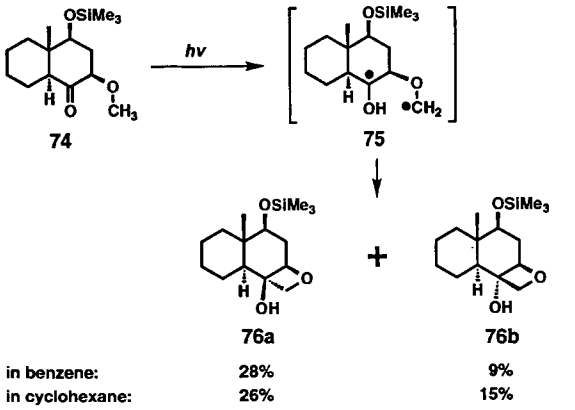


A fully functionalized CD ring system of taxol was synthesized by the Magee–Danishefsky team (Scheme 10).[142] In this effort the Wieland–Miescher ketone was converted into its

Scheme 10. The Magee–Danishefsky approach to CD ring systems (1992). R = tBuMe$_2$Si, DIBAL-H = diisobutylaluminum hydride, NMO = N-methylmorpholine N-oxide, Im = imidazole, collidine = 2,4,6-trimethylpyridine.

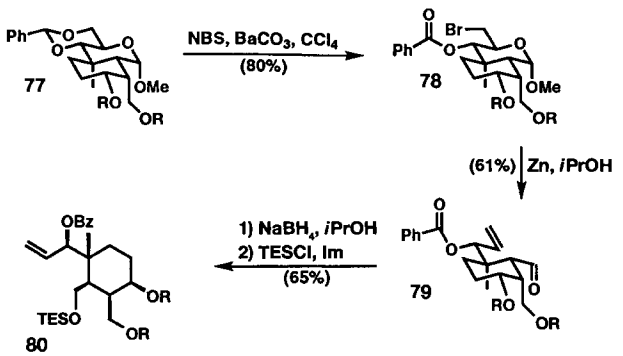
derivatives **57**–**61**. Key transformations in this sequence included a palladium-catalyzed carbonylation, vicinal dihydroxylation, intramolecular displacement of the triflate group to form the oxetane ring, and the formation of an enone through Ito's palladium-mediated process. Compound **61** was converted into **62** by ozonolysis of an intermediate silyl vinyl ether.

In our laboratories a strategy was developed for the construction of the CD ring system **73** (Scheme 11)[143] that took advantage of a boron-mediated Diels–Alder reaction[144] between dienophile **63** and 3-hydroxy-2-pyrone (**64**). The initial product



Scheme 11. Nicolaou's approach to the CD ring system through a Diels–Alder reaction (1992). Red-Al = sodium bis(methoxyethoxy)aluminum dihydride, Ms = methanesulfonyl.

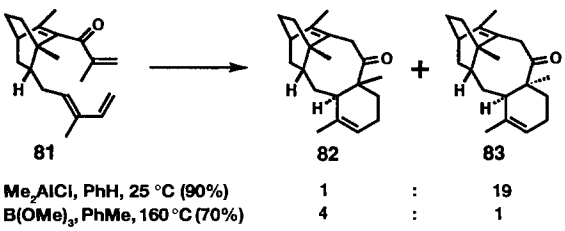
of this reaction, compound **66**, spontaneously rearranged to bicycle **67**, which was transformed into **68** and thence sequentially to **69**, **70**, **71**, and **72**. Finally, the oxetane ring was fused onto the C ring by internal nucleophilic displacement of a mesylate group by an alkoxide (**72** → **73**). This flexible strategy allows entry into a variety of C and CD ring systems suitably protected and functionalized for coupling reactions with appropriate A ring systems.



Wender and Rawlins have recently reported model studies of a Norrish Type II photolysis of α-methoxyketone **74** directed at

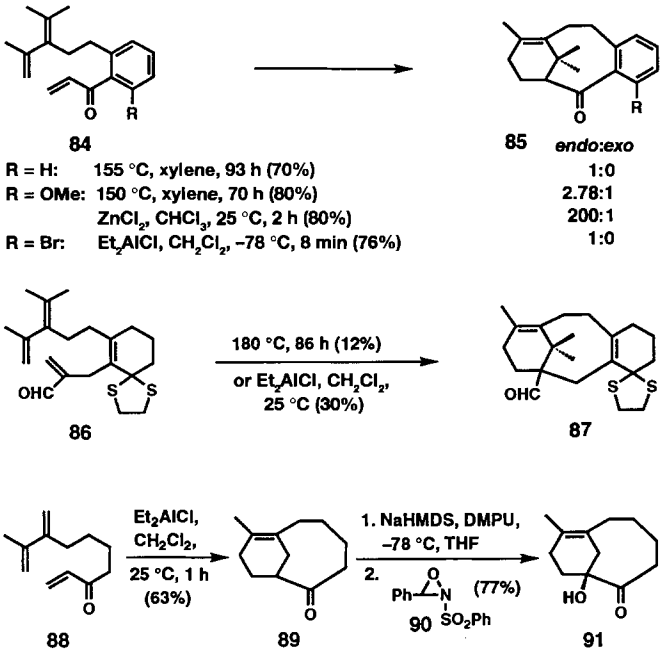
the production of the oxetane ring of taxol (Scheme 12).[145] Unfortunately, and despite the elegance of the method, the yields of the resulting oxetane were rather low, and the predominant stereochemistry corresponded to the undesired *trans* oxetane.

Scheme 12. Wender's photolytic entry into the CD ring model system (1992).



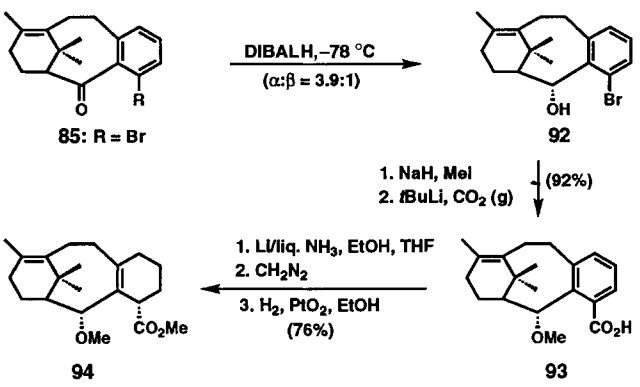
Jenkins et al. have synthesized a functionalized C ring model system (Scheme 13) for use in his convergent approach to the taxane skeleton (see Scheme 17 in Section 3.3).[146] The protected methoxypyranose derivative **77** was converted by a rather clever application of the Vasella fragmentation into the aldehyde **79** and then reduced and protected to give the C ring model **80**. This model can be easily converted into a number of Diels–Alder precursors.

Scheme 13. Jenkin's functionalized C ring model system (1993). R = tBuPh$_2$Si, NBS = *N*-bromosuccinimide, TES = triethylsilyl.



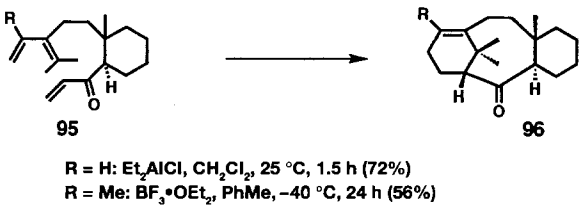
3.3. Approaches to the Taxol Skeleton

One of the earliest and most impressive attempts to construct a taxol-type skeleton was that of Sakan and Craven, who in 1983 reported the intramolecular Diels–Alder reaction shown in Scheme 14.[147] The uncatalyzed reaction gave the desired product **82** but as an intractable mixture with by-products. Catalysis of the crucial Diels–Alder reaction by a strong Lewis acid (Me_2AlCl) gave predominantly the undesired stereoisomer. Finally, success was gained through the addition of $B(OMe)_3$, which gave, in a clean conversion, predominantly the desired product.



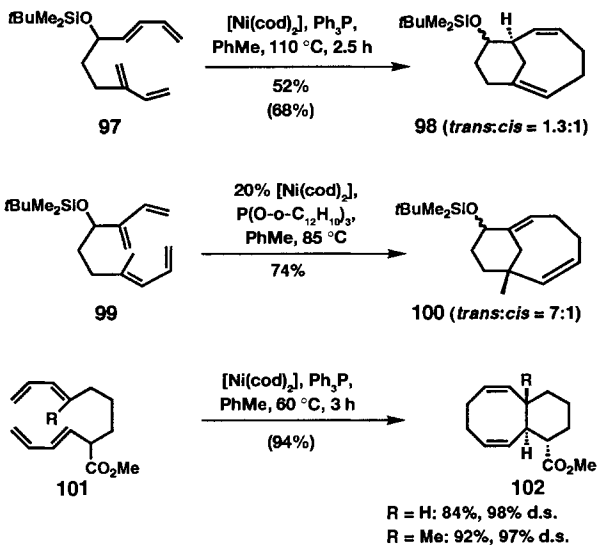
Scheme 14. Sakan's approach to the taxol skeleton through a Diels–Alder reaction (1983). The desired isomer is **82**.

Similarly but independently, Shea and his collaborators developed a number of intramolecular versions of the Diels–Alder reaction starting with **84**, **86**, and **88** and leading to taxol skeleton models **85**, **87**, and **91** as shown in Scheme 15.[148] Atropisomers were observed in these series of compounds. The same group has also demonstrated the viability of establishing the C15 hydroxyl group through trapping of the bridgehead enolate with Davis's reagent. The Diels–Alder product **85** was trans-



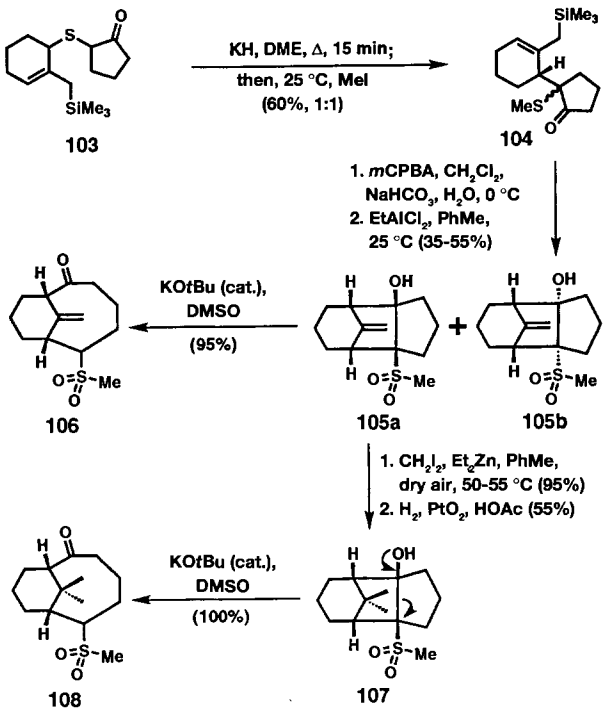
Scheme 15. Shea's approach to the taxol skeletons through a Diels–Alder reaction (1983, 1986, 1988, and 1992). DPMU = *N*,*N*′-dimethyl-*N*,*N*′-propylene urea.

Scheme 16. Shea's approach to taxol skeletons through a Diels–Alder reaction/Birch reduction (1992).



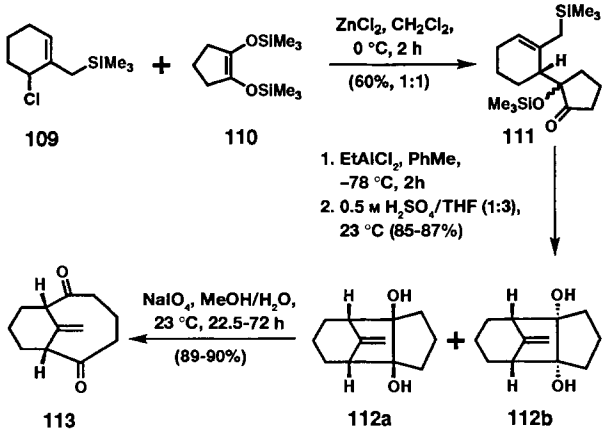
formed into taxol model system **94** possessing the ABC ring skeleton (Scheme 16).[149]

Scheme 17 outlines Jenkins' intramolecular Diels–Alder approach to the taxol skeleton.[150] This methodology was developed concurrently with Shea's and provided entries to compounds such as **96**. Recently, Jenkins et al. synthesized a more functionalized C-ring analog for use in this methodology (see Scheme 13 in Section 3.2).



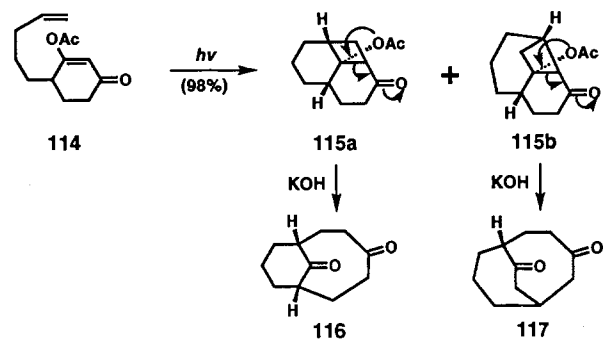
Scheme 17. Jenkin's approach to taxol skeletons through a Diels–Alder reaction (1984–1989).

As part of studies involving nickel-catalyzed cycloadditions of bis(diene)s, the Wender group developed approaches to AB and BC ring model systems **98**, **100**, and **102** (Scheme 18).[151] While these methods provided a relatively unsubstituted system, they did demonstrate the feasibility of forming the B ring of taxol with a direct [4 + 4] cycloaddition process.



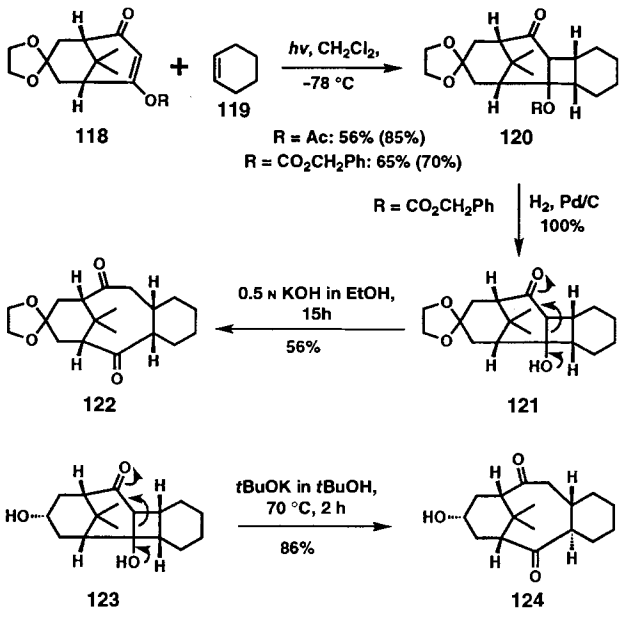
Scheme 18. Wender's approach to the AB and BC ring systems through a [4 + 4] addition (1987). COD = 1,5-cyclooctadiene, $P(O\text{-}o\text{-}C_{12}H_{10})_3$ = tri-*o*-biphenyl phosphite, d.s. = diastereoselectivity. The percentages in parentheses indicate how much starting material was consumed.

Two clever approaches to taxol model systems were reported by Trost et al. In the first approach, shown in Scheme 19, a fragmentation reaction of hydroxy sulfones **105a,b** and **107** leading to the eight-membered ring systems **106** and **108** was utilized.[152] This reaction takes advantage of the stabilization, provided by the sulfone group, of the carbanion intermediates involved. In the second approach, depicted in Scheme 20, an oxidative cleavage of diols **112a,b** led to the formation of a similar bicyclic skeleton (**113**).[153]



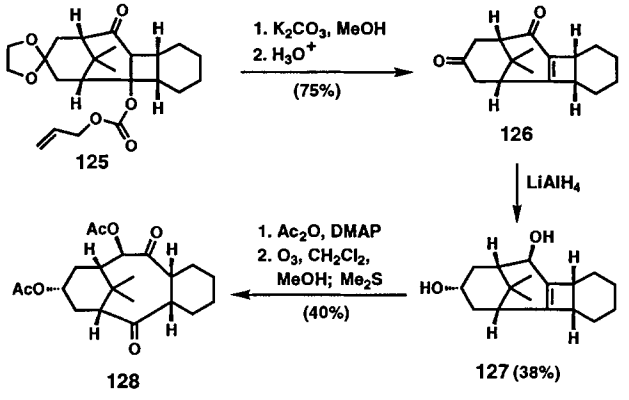
Scheme 19. Trost's approach to the AB ring systems through a fragmention (1982). DME = dimethoxyethane, DMSO = dimethylsulfoxide.

Scheme 20. Trost's approach to the AB ring system through an oxidative cleavage reaction (1984).



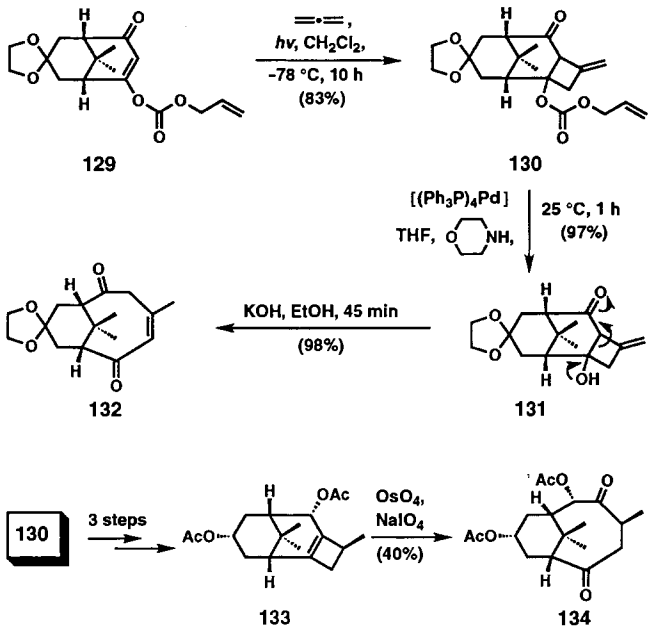
An approach based on a retroaldol type fragmentation was reported by Pattenden in 1983 (Scheme 21).[154] In this strategy,

Scheme 21. Pattenden's approach to the AB ring system through a retroaldol cleavage reaction (1983).



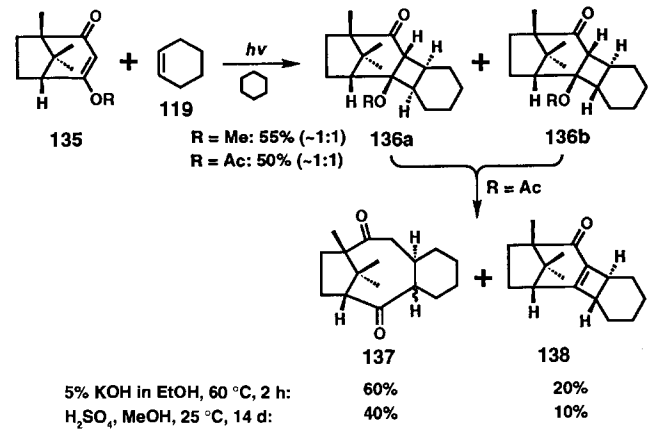
β-acetoxy ketones **115a,b**, derived from the intramolecular [2 + 2] photocycloaddition of **114**, were converted into **116** and **117**, respectively, under the influence of KOH. Unfortunately, the nonregioselective nature of the photocycloaddition reaction led to a mixture of products.

Retroaldol and oxidative ring expansion were also utilized by Blechert et al. in the synthesis of a number of interesting taxoids with biological activity (Schemes 22–24). Substrates **121** and



Scheme 22. Blechert's approach to taxol systems through a retroaldol cleavage reaction (1984 and 1991). The percentages in parentheses indicate how much starting material was consumed.

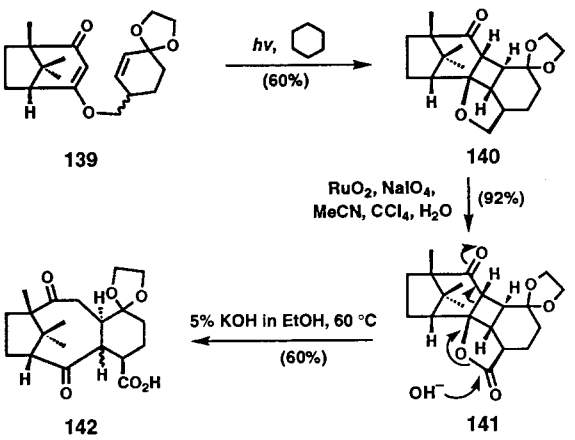
123,[155] and **131**,[156] derived from intermolecular [2 + 2] photocycloaddition reactions and subsequent manipulations, were subjected to basic conditions and afforded tricyclic model systems **122** and **124** (Scheme 22), and **132** (Scheme 24), respectively, on retroaldol-type fragmentations. In an alternative approach, oxidative cleavage of compounds **127**[157] and **133** gave **128** (Scheme 23) and **134** (Scheme 24), respectively. These highly promising ring expansion strategies have the potential of de-



Scheme 23. Blechert's approach to the taxol skeleton through oxidative ring expansion (1992). The reduction of **126** yields isomers of **127** in 33% yield.

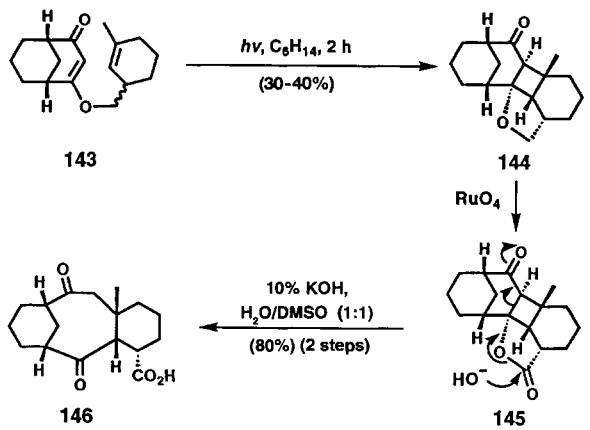
Scheme 24. Blechert's approach to the AB ring system through retroaldol cleavage and oxidative ring expansion (1992).

livering important pointers for the design of mimics of taxol and even the natural product itself.



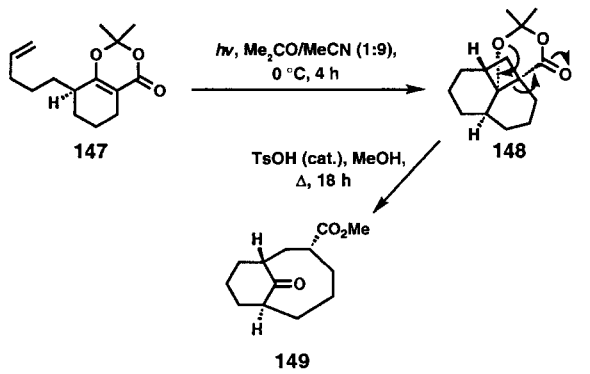
Berkowitz et al. also provided examples of the approach through photocycloaddition–retroaldol reactions to the construction of taxol model systems **137** and **142**, starting from **135** and **139** (Schemes 25 and 26).[158] These models have 5-mem-

Scheme 25. Berkowitz's first approach to the BC ring system through intramolecular photocycloaddition and retroaldol cleavage (1985).



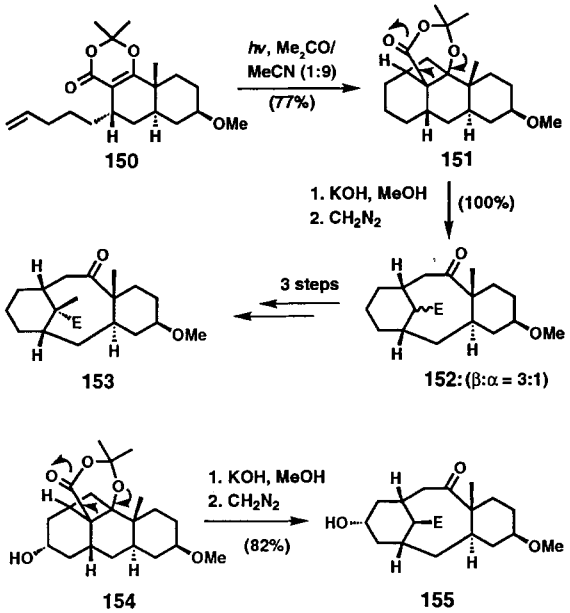
bered A-ring frameworks that, while not functionalized appropriately for conversion to the cyclohexene ring present in the natural product, could provide interesting biological mimics of taxol.

A further example of a synthesis of the taxoid skeleton through photocycloaddition–retroaldol reactions was reported by Inouye's group (Scheme 27).[159] This study could prove particularly useful because of its success in the difficult step of installing the tertiary methyl group and proper functionality for



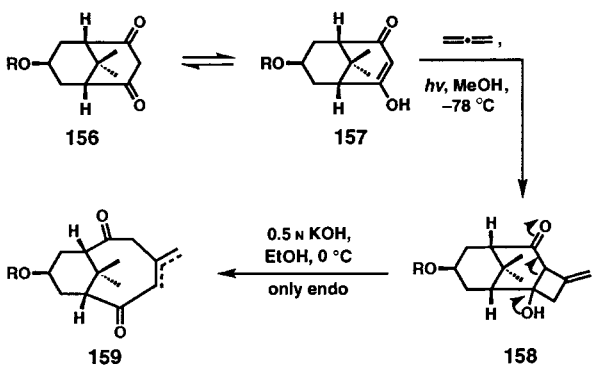
Scheme 26. Berkowitz's second approach to the BC system through intramolecular photocycloaddition and retroaldol cleavage (1985).

further elaboration, even though the synthesized model **146** lacked the *gem* dimethyl groups of taxol.



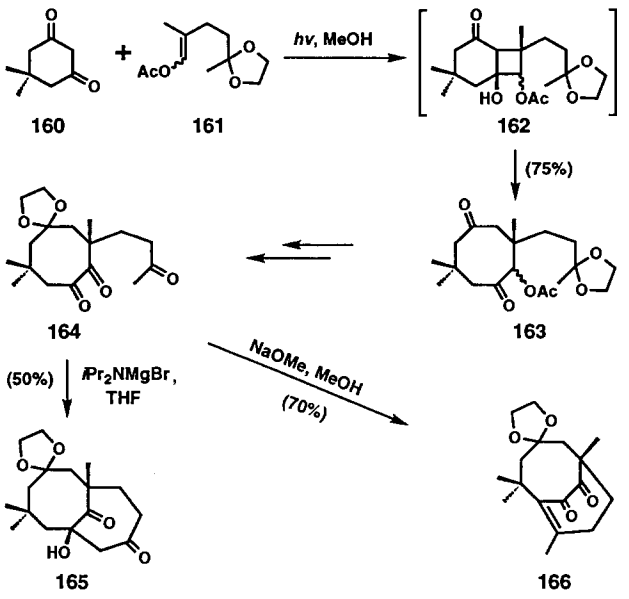
Scheme 27. Inouye's approach to the taxol skeleton through retroaldol cleavage (1985). The yield of **144** is relatively small, because only one isomer of **143** reacts. The other isomer was recovered unchanged.

The Winkler group's studies were also based on photocycloaddition/retroaldol strategies and led to interesting and promising results. As shown in Scheme 28,[160] the original



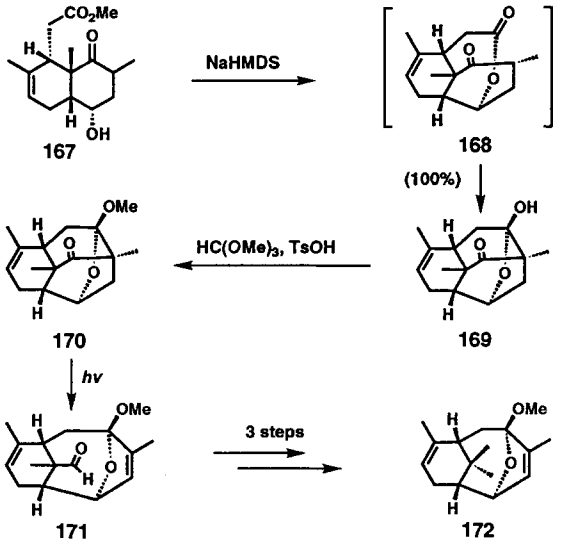
Scheme 28. Winkler's approach to the AB ring system through retroaldol cleavage (1986).

model system **148** was converted into AB ring system **149** by acidic treatment. In a subsequent study, treatment of compounds **151** and **154** with base provided, after methylation, taxol frameworks **153** and **155**, respectively (Scheme 29).[161] These systems could also prove amenable to fruitful elaboration.

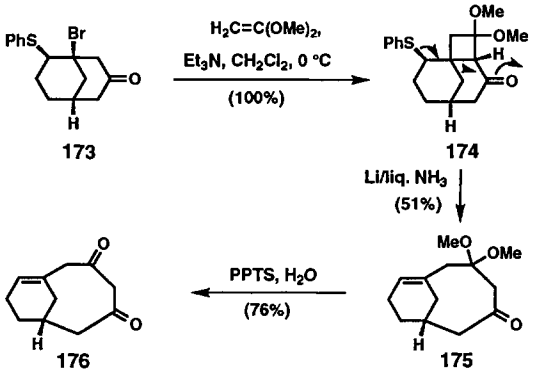


Scheme 29. Winkler's approach to the taxol skeleton through retroaldol cleavage (1989 and 1992). E = CO_2Me

The work of the Fetizon laboratory, depicted in Scheme 30, also involved a combination of photocycloaddition and retroaldol reactions and provided rapid access to interesting taxoid skeletons **159**.[162] The same group reported an unsuccessful

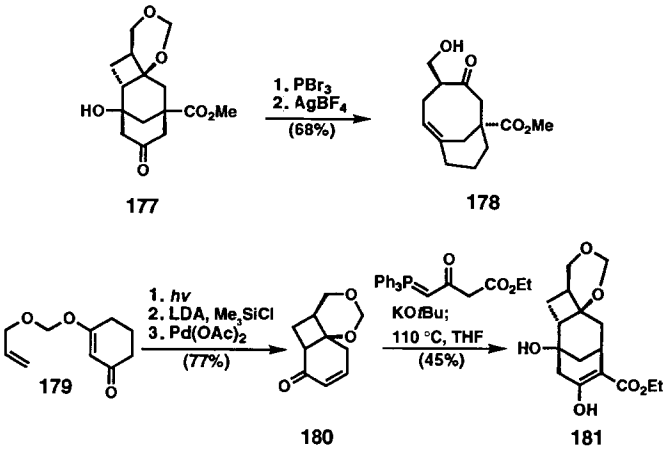


Scheme 30. Fetizon's approach to the taxol AB ring systems through retroaldol cleavage (1987). **156**–**158**, R = PhCO, MOM; **159**, R = H: only endocyclic double bonds (yield 35%), R = MOM: 43% of the product has endo- and 29% exocyclic double bonds.



attempt[163] to prepare the taxol BC ring system by aldol condensation of **164** (Scheme 31). Additionally, ketoester condensation of **168** (Scheme 32)[164] followed by methylation furnished product **170**, which was further elaborated to the AB ring framework by a Norrish II photolytic reaction to provide **172** via **171**.

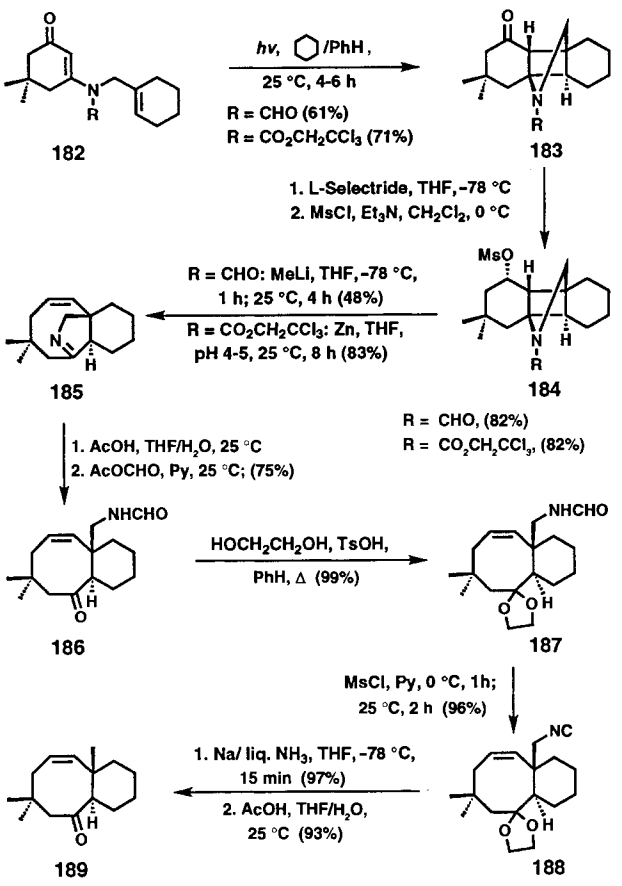
Scheme 31. Fetizon's approach to the AB ring system through a combination of photochemistry and aldol reactions (1992).



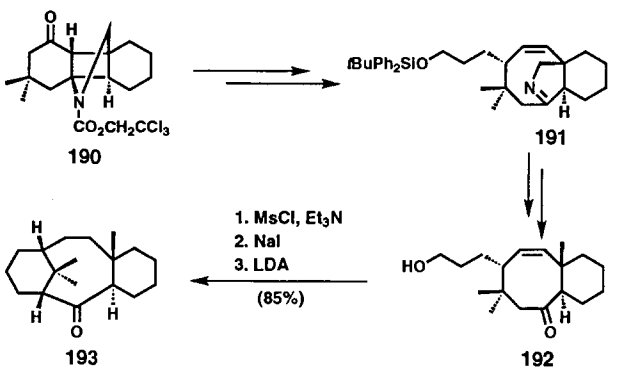
Scheme 32. Fetizon's approach to the AB ring system through ketoester condensation and photolysis (1992).

Scheme 33. Kraus's approach to the AB ring system through reductive cleavage (1987).

Kraus et al. have reported two photocycloaddition–reductive cleavage approaches to the AB ring model systems (Scheme 33 and 34). The first method[165] involves in situ generation of an enone from **173** followed by trapping as **174** with ketene dimethyl acetal. Treatment of **174** with Li/liquid ammonia gave the ring-opened product **175**, which upon deprotection led to **176**. In the second approach,[166] the tetracycle **177** is fragmented by generation of the bridgehead bromide followed by Lewis acid treatment to give bicycle **178**. To move to a more functionalized system, the enone **179** is subjected to intramolecular photocyclization with the vinyl ether to give, after oxidation, tricyclic enone **180**. The enone is then further annulated to give tetracycle **181**. The authors intend to perform a fragmentation analogous to that of **177** on this substrate.



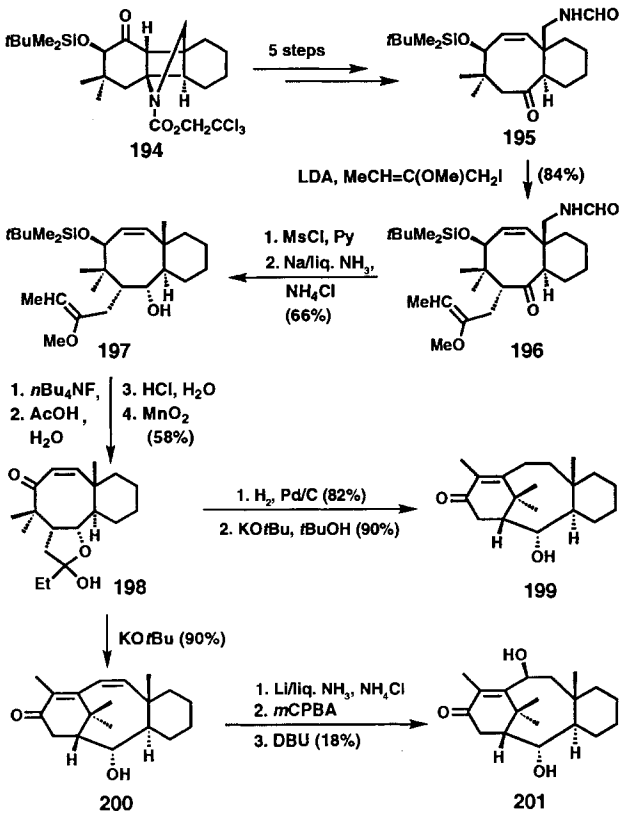
Scheme 34. Kraus's approach to an AB ring system (1993).



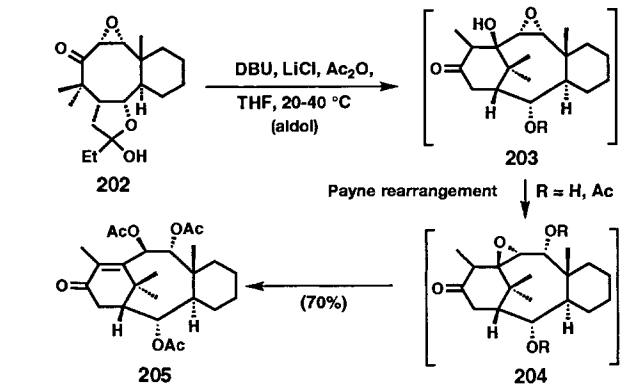
The Swindell group has been very successful in preparing a number of advanced taxol intermediates by a variety of methods. In general, Swindell's strategy involves initial photoinduced construction of a polycyclic system such as **183**, which is then elaborated further to give the desired ring frameworks as shown in Scheme 35.[167] Thus, an amide fragmentation of **184** formed the eight-membered ring system **185**, which was further converted into the BC ring model compound **189** via intermediates **186**–**188**.

In another approach by Swindell et al. (Scheme 36), intramolecular alkylation of **192**, derived from the photoproduct **190** (=**183**, R = $CO_2CH_2CCl_3$) in two sets of seven steps, provided an entry into taxol ABC model system **193**.[168] Alternatively, an aldol reaction was employed to construct ring A (**198** → **199**, Scheme 37) along the route to the advanced ABC ring skeletons **199** and **201** starting from photoadduct **194**.[169] In the same study, highly advanced taxol skeletons such as **205** were constructed (Scheme 38) by photoaddition, amide fragmentation, and aldol condensation.

A reductive fragmentation reaction was used by Ghosh et al. to establish the eight-membered ring compound **207** (Scheme 39) starting with compound **206**.[170] Subsequent ring expansion of **208**, derived from **207**, gave the AB ring skeleton **209**.

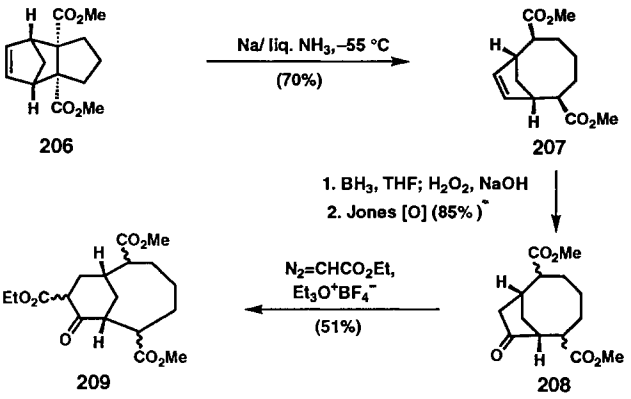


Scheme 35. Swindell's approach to the BC ring system through amide fragmentation (1984 and 1987). L-Selectride = lithium tri-*sec*-butylborohydride.

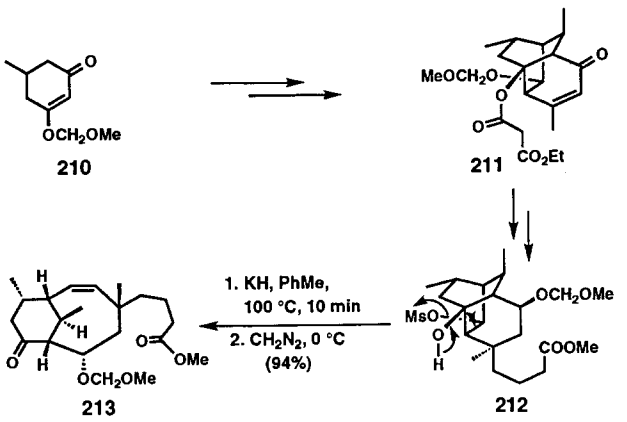


Scheme 36. Swindell's approach to the ABC taxol skeleton through amide fragmentation (1987).

An interesting application of the Grob fragmentation for the synthesis of an AB ring system was devised by Yamada et al. (Scheme 40).[117] In this study, tricyclic substrate **211**, derived from **210** in 17 steps, was converted in eight steps into hydroxy mesylate **212**. Treatment of **212** with potassium hydride followed by methylation furnished **213** in high yield.

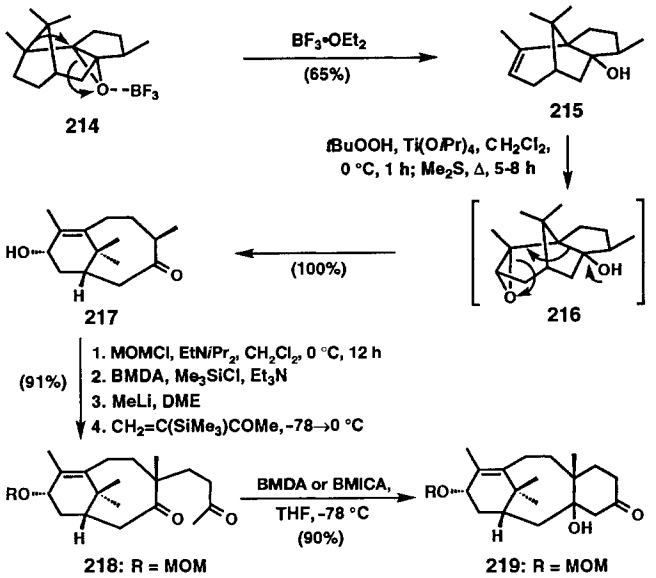


The Holton laboratory has reported a number of advanced studies concerning taxol, including a total synthesis of taxusin (**6**, see Fig. 1), in which they employed the naturally occurring β-patchouline oxide as starting material. Two of these approaches use a hydroxyepoxide fragmentation process as the



Scheme 37. Swindell's approach to the advanced taxol skeletons through amide fragmentation (1990).

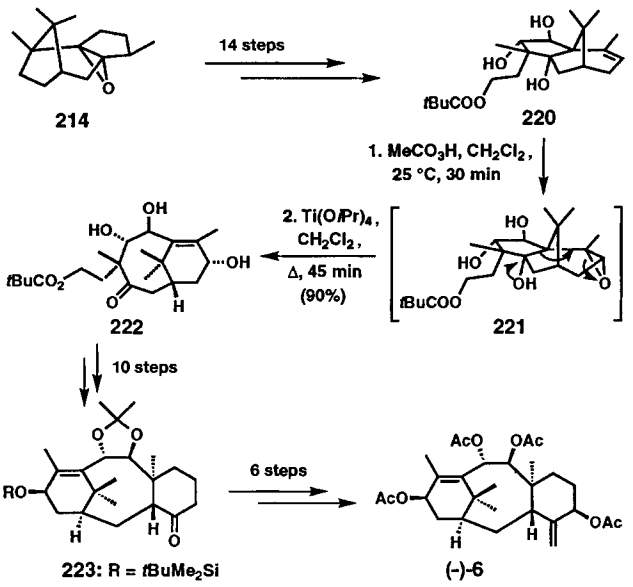
Scheme 38. Swindell's approach to the highly advanced ABC skeleton through amide fragmentation (1990).



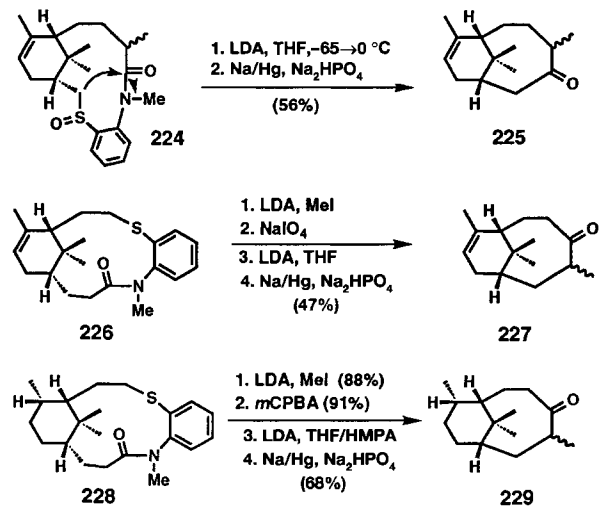
Scheme 39. Ghosh's approach to the AB ring system through reductive cleavage (1990).

Scheme 40. Yamada's approach to the AB ring system through Grob fragmentation (1984).

key step to secure AB ring systems. In the first approach, patchouline oxide (**214**) is subjected to Lewis acid mediated epoxide opening/rearrangement, and the resulting hydroxy alkene is epoxidized to give **217**. An intramolecular aldol condensation within **218** derived from **217** established the ABC ring framework **219** of taxol (Scheme 41).[172] The same strategy was

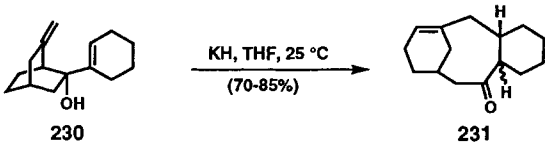


Scheme 41. Holton's approach to the taxol skeleton through fragmentation (1984). MgBr(NRR'), R = R' = *i*Pr (BMDA); R = *i*Pr, R' = cyclohexyl (BMICA).



applied to compound **222** (Scheme 42) leading to a total synthesis of the nonnatural enantiomer of (−)-taxusin [(−)-**6**].[173]

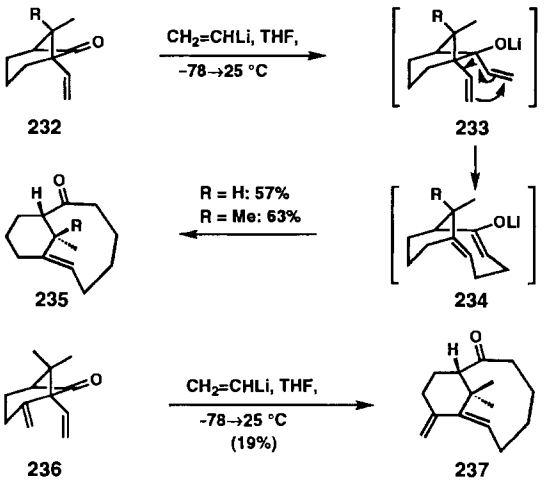
An elegant ring-contraction method has been applied to the synthesis of taxol model systems **225**, **227**, and **229** by Ohtsuka et al.[174] As shown in Scheme 43, this approach involves a base-induced rearrangement after which a sulfoxide moiety is excised by reductive C–S bond cleavage, leading to the eight-membered ring.



An interesting approach to the taxol skeleton **231** based on an oxy-Cope rearrangement reaction of **230** was published by Martin et al. in 1982 (Scheme 44).[175] This approach is most notable

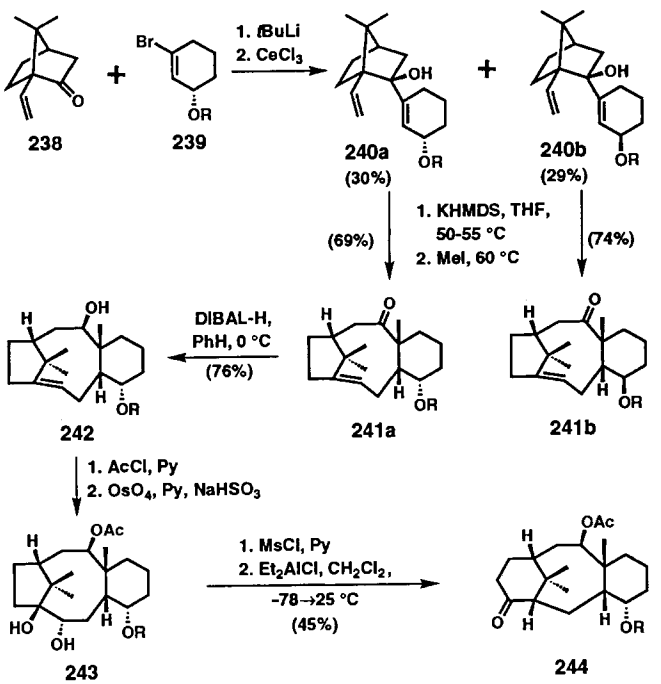
Scheme 42. Holton's approach to the synthesis of (−)-taxusin [(−)-**6**] (1988).

Scheme 43. Ohtsuka's approach to the AB ring systems through ring contraction (1984, 1986, and 1988).



Scheme 44. Martin's approach to the taxol skeleton through anionic or oxy-Cope rearrangement (1982).

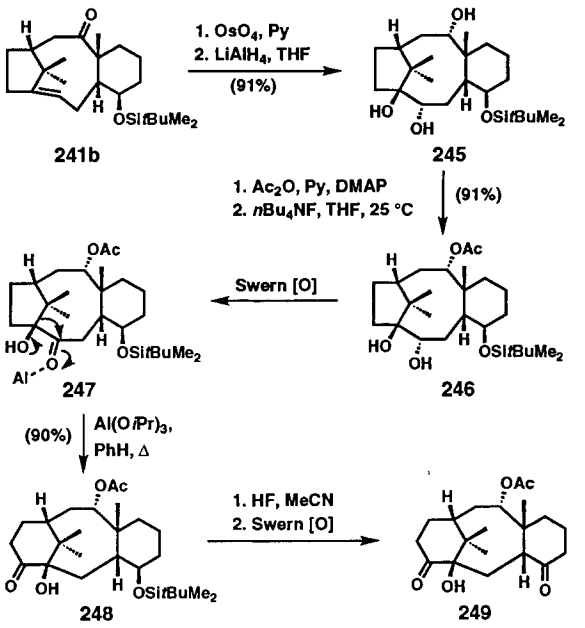
for its brevity: it establishes the ABC ring system in four steps from readily available (3-oxocyclohexyl)acetic acid.



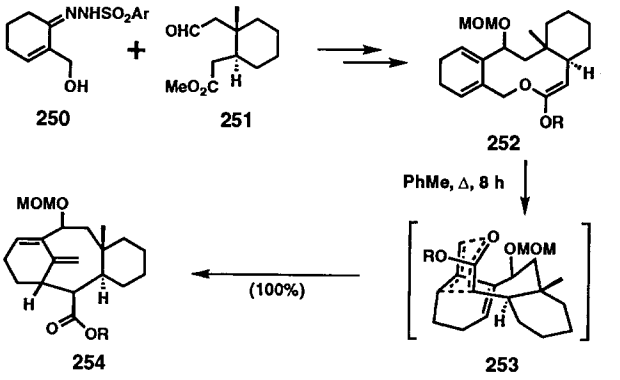
The approach of Snider et al. to model systems **235** and **237** also involved oxy-Cope rearrangements (Scheme 45).[176] While these approaches provide for functionalization at the AB ring junctures, they do not lead to the tricyclic carbon skeleton.

Paquette's group reported a particularly interesting anionic oxy-Cope rearrangement route to the taxol skeleton (Scheme

Scheme 45. Snider's approach to the AB ring systems through anionic oxy-Cope rearrangement (1991).



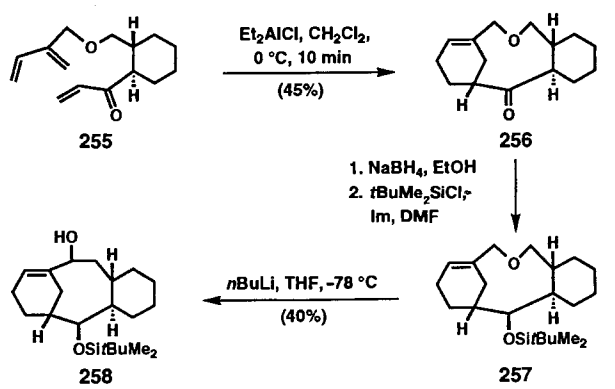
46). Base treatment of isomers **240a,b** gave rearrangement products **241a,b**; **241a** was converted into diol **243** via **242**. Pinacol-type rearrangement of **243** afforded the ABC ring skeleton **244**.[177] An α-hydroxyketone rearrangement of **247**, prepared



Scheme 46. Paquette's approach to the taxol skeleton through an oxy-Cope rearrangement (1989–1991). R = tBuMe$_2$Si.

from the isomeric diol **246** from **241b**, was also reported by the Paquette group to furnish the advanced model system **249** (Scheme 47).[178]

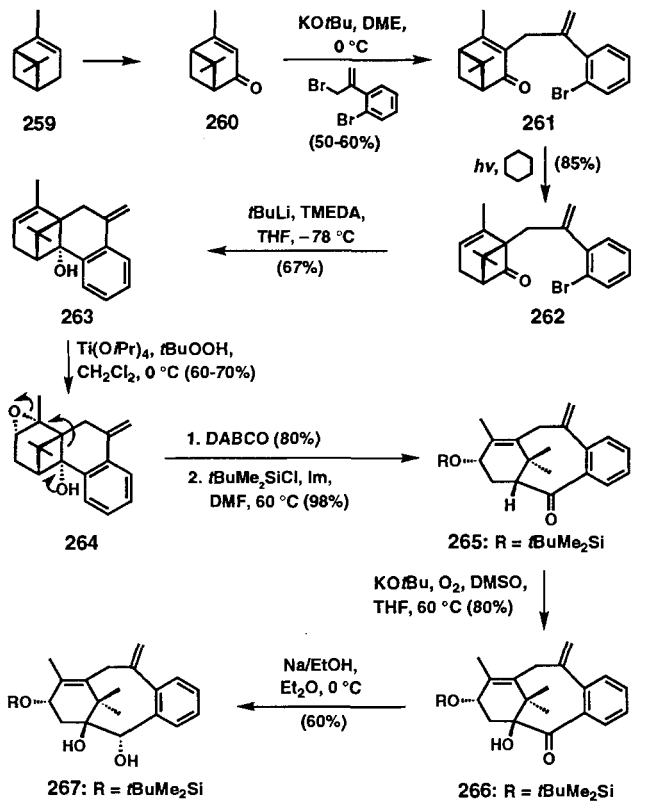
A clever approach to the taxol skeleton based on an intramolecular Claisen rearrangement in which a 10-membered ring is contracted to an eight-membered ring was reported by Funk (**252** → **253** → **254**, Scheme 48). The ten-membered ring was synthesized from **250** and **251** in seven steps.[179] This



Scheme 47. Paquette's approach to the taxol skeletons through an α-hydroxyketone rearrangement (1992).

Scheme 48. Funk's approach to the taxol skeleton through an intramolecular Claisen rearrangement (1988). Ar = triisopropylbenzene, R = tBuMe$_2$Si.

method provides the ABC system with the troublesome angular methyl group already installed.

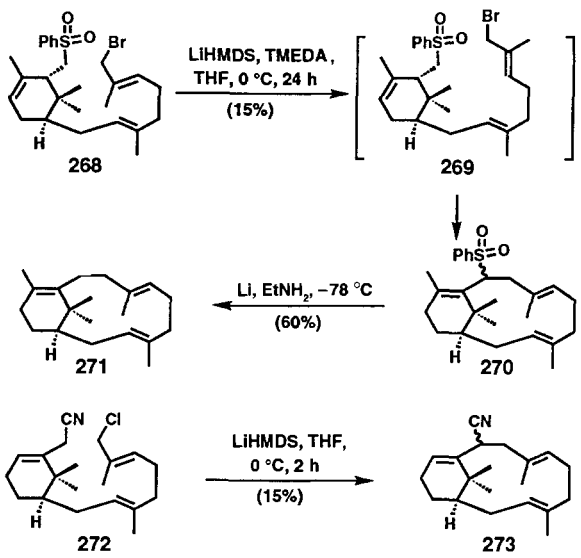


Another interesting strategy towards the taxol skeleton (Scheme 49) based on a Wittig rearrangement was recently pub-

Scheme 49. Yadav's approach to the taxol skeleton through an intramolecular Wittig rearrangement (1991).

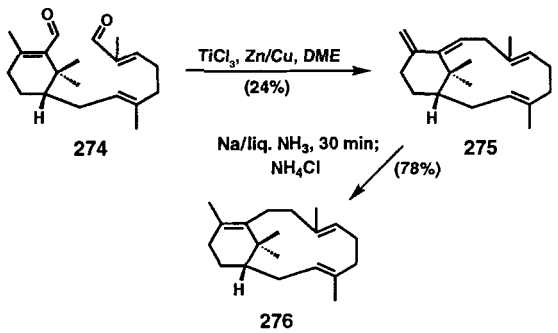
lished by Yadav's group.[180] This approach began with an intramolecular Diels–Alder reaction to construct the A ring model system **256**, which was converted into **257** by standard chemistry. Treatment of **257** with base resulted in a contraction of the nine-membered ring to the eight-membered ring **258**.

An elegant strategy towards the taxol skeleton was recently reported from the Wender group (Scheme 50). In this sequence,



Scheme 50. Wender's approach to the taxol skeleton through rearrangement (1992). TMEDA = *N,N,N',N'*-tetramethylethylenediamine, DABCO = 1,4-diazabicyclo[2.2.2]octane.

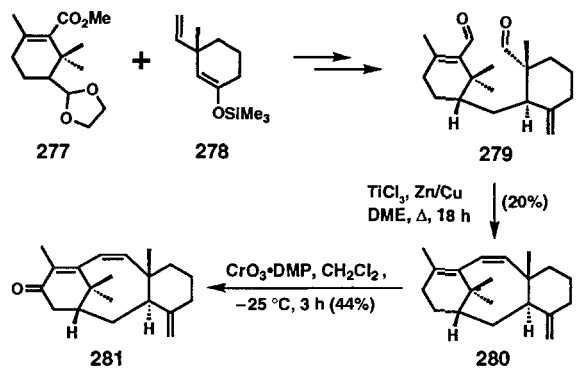
(+)-pinene (**259**) was utilized as a cheap starting material for hydroxyepoxide **264**, which then underwent base-induced fragmentation to afford the tricyclic system **265**. Further elaboration led to the more advanced intermediates **266** and **267** (Scheme 50).[181] Final functionalization of these intermediates to taxol, the ultimate goal of these studies, still remains elusive.



Two approaches to BC secotaxol skeletons **271** and **273** reported by Kato are shown in Scheme 51.[182] Both involved intramolecular alkylation reactions, in which the bromosulfone **269** and chloronitrile **272** were used to construct the 12-membered seco ring systems **271** (after desulfurization) and **273**, respectively. These compounds are analogs of verticillene, a putative biosynthetic precursor to taxol.

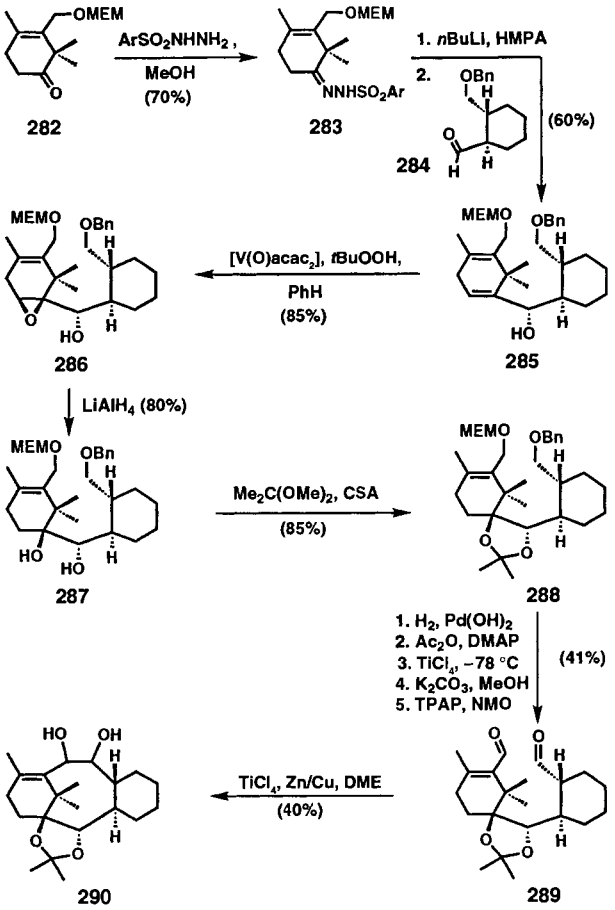
The strategy of Pattenden et al. towards taxoids (Scheme 52) relied on a McMurry-type, intramolecular, reductive pinacol coupling reaction of the dialdehyde **274** to form the macrocyclic ring **275**. This intermediate was further transformed into (*E,E*)-verticillene (**276**) by reduction with Na in liquid ammonia.[183]

In the pioneering work of Kende et al., a McMurry cyclization reaction was successfully applied to form the B ring system



Scheme 51. Kato's approach to the BC secotaxol skeleton through intramolecular alkylation (1978 and 1981).

Scheme 52. Pattenden's approach to the BC secotaxol skeleton through intramolecular reductive coupling (1985 and 1990).

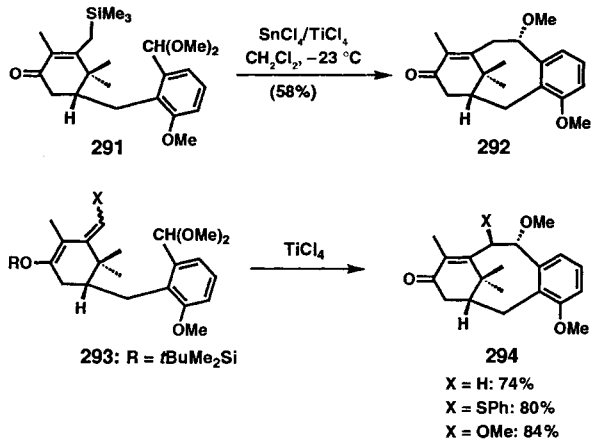


280 from the dialdehyde **279**, obtained from **277** and **278** in twelve steps, as shown in Scheme 53.[184] The low yield of the intramolecular coupling reaction was attributed primarily to competing intramolecular 1,4-addition of the intermediate diketyl.

Scheme 53. Kende's approach to the taxol skeleton through intramolecular McMurry cyclization (1986). DMP = 3,5-dimethylpyrazole.

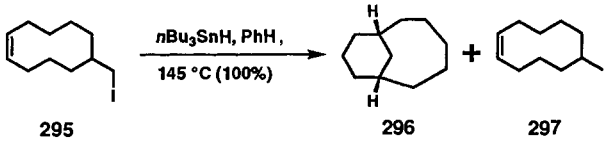
A variety of coupling reactions between A and C ring systems have been carried out in our laboratories. Dithiane and Stille

coupling reactions were demonstrated to be feasible. The hydrazone–vinyllithium chemistry, illustrated in Scheme 54, was found to be exceptionally efficient in coupling A ring and C ring fragments.[185] Addition of the vinyllithium species, generated from **283**, to the aldehyde **284** gave **285**, which was converted into the diol **287** by regioselective epoxidation and subsequent regioselective reduction. Protection of the diol as **288** and further standard chemistry provided the dialdehyde **289**. An intramolecular coupling reaction within **289** gave the diol **290**. We are currently attempting to apply this technology to the total synthesis of taxol.



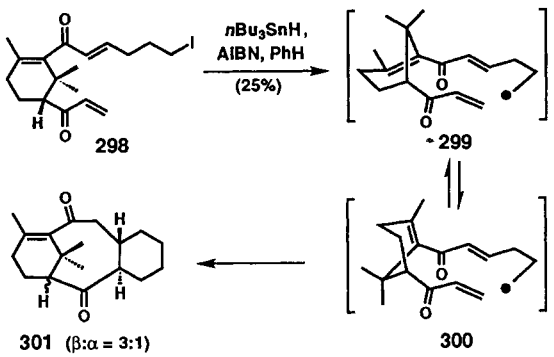
Scheme 54. Nicolaou's approach to the taxol skeleton through intramolecular cyclization (1992). Ar = 2,4,6-triisopropylphenyl, Bn = benzyl, acac = acetylacetonate, TPAP = tetra-*n*-propylammonium perruthenate.

Kuwajima's elegant studies in the taxol area employing acid-promoted intramolecular alkylation reactions culminated in the synthesis of several advanced intermediates (Scheme 55).[186] These workers have carried out careful surveys of the appropriate conditions for these cyclizations and prepared taxoids such as **292** and **294**.

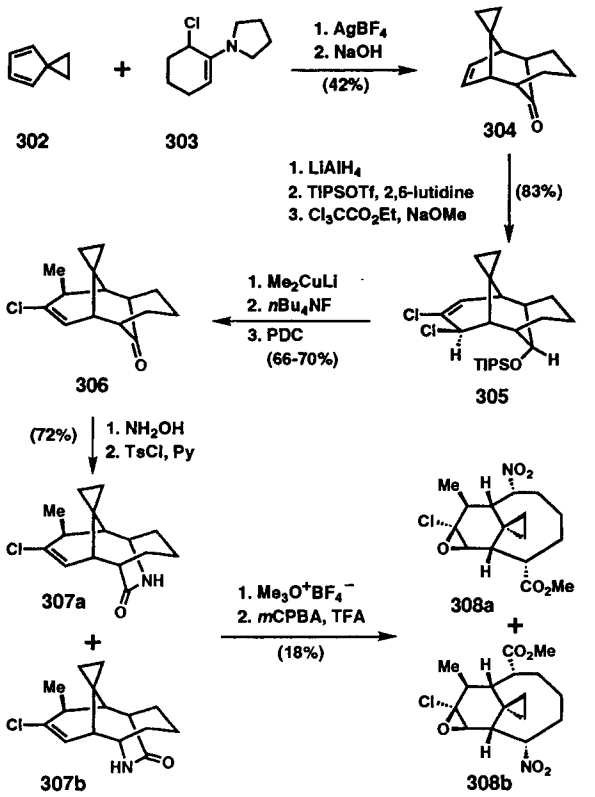


Radical-based approaches to taxol model systems have also been reported. In an attempt by Winkler et al.,[187] a simple cyclic iodoalkene **295** was used to form the AB ring fragment **296** (Scheme 56). Pattenden et al., on the other hand, were able to prepare the ABC ring skeleton **301** through a tandem radical sequence as shown in Scheme 57.[188]

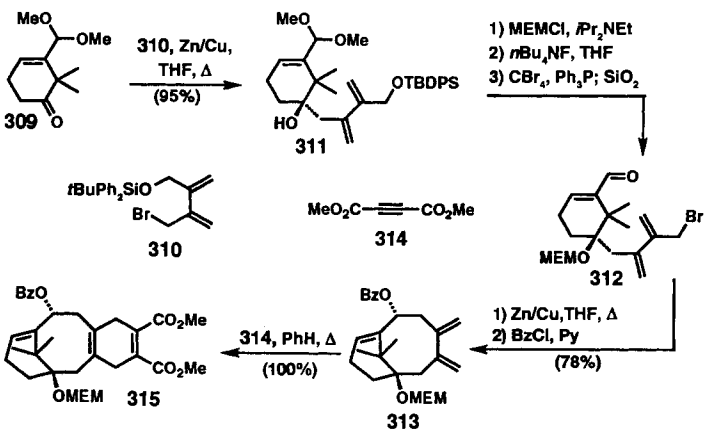
A recent report from Cha's group delineates the synthesis of taxol AB ring model compounds **308a,b** based on a formal [4 + 3] diene–oxyallyl cycloaddition reaction as shown in Scheme 58.[189] The adduct **304**, obtained from **302** and **303**, was subjected to ring expansion (**304** → **305** for A ring), followed by further manipulation to give ketone **306**. Beckmann rearrangement then led to compounds **307a,b** which were converted into the targeted intermediates **308a,b**. Even though the efficiency of the last step needs further improvement, the strategy does provide a novel approach to the bicyclic AB system.



Wang's group has recently disclosed a sequential anionic condensation strategy for establishing the B ring (Scheme 59).[190] Thus, A ring model **309** was condensed with the zinc cuprate formed from **310**. After manipulation, the B ring was closed by applying an intramolecular version of the same method to give **313**. Finally, the C ring was added with a Diels–Alder reaction to give **315**.

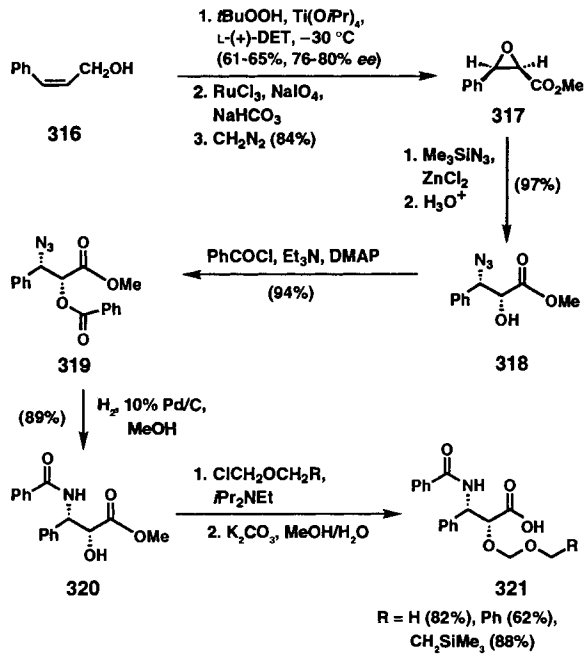


Scheme 55. Kuwajima's approach to taxol skeletons through intramolecular alkylation (1989).



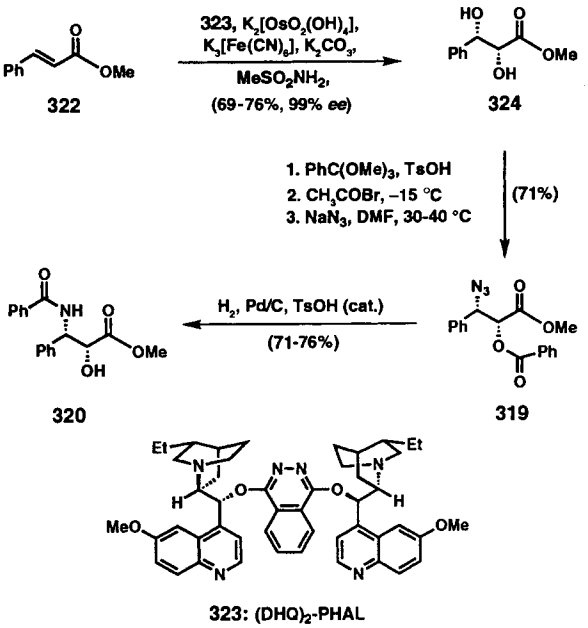
Scheme 56. Winkler's approach to the AB ring system through intramolecular radical cyclization (1989). Product ratio **296**:**297** = 4.1:1.

Scheme 57. Pattenden's approach to the taxol skeleton through intramolecular radical cyclization (1992). AIBN = 2,2'-azobis(isobutyronitrile).



Scheme 58. Cha's approach to AB ring systems through [4 + 3] diene–oxyallyl cycloaddition (1992). TIPS = triisopropylsilyl, PDC = pyridinium dichromate, TFA = trifluoroacetic acid. Product ratio **308a**:**308b** = 3:2.

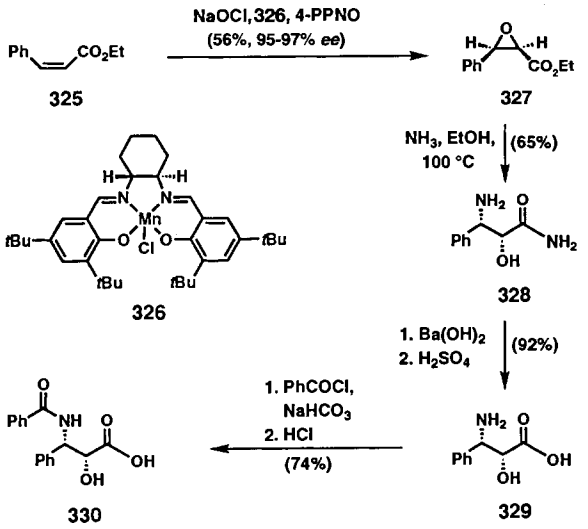
Scheme 59. Wang's approach to the ABC ring system through sequential anionic condensation (1993). MEM = methoxyethoxymethyl, Bz = benzoyl.



3.4. Approaches to the Taxol Side Chain

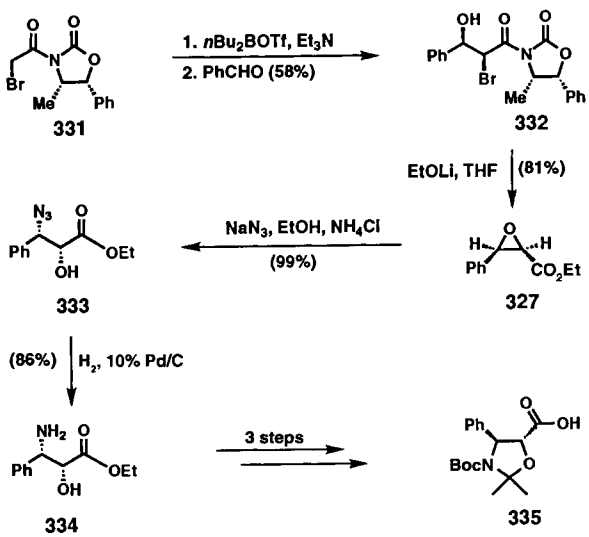
Greene et al. were the first to synthesize the taxol side-chain derivatives **321**, starting from *cis*-cinnamyl alcohol (**316**), for coupling with taxol's polycyclic framework (Scheme 60).[191] Although this strategy relied on the use of Sharpless asymmetric epoxidation to establish the two stereocenters in the molecule, the enantiomeric excess of the product was not particularly high (76–80% *ee*). An alternative route employing Sharpless asymmetric dihydroxylation reaction was later developed by the same group to produce the enantiomerically pure epoxide **317**.[192]

Scheme 60. Greene's approach to the taxol side chain through an epoxidation (1986). DET = diethyl tartrate.



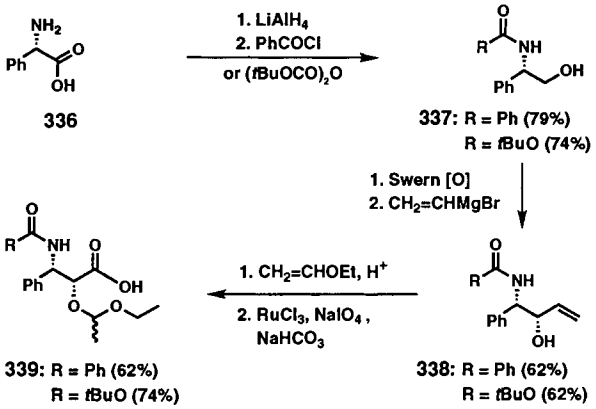
Sharpless and Kolb[193] have applied their latest version of the chiral catalyst $(DHQ)_2$-PHAL (**323**) to the asymmetric dihydroxylation of **322** to give optically enriched **324** in 99% *ee* (Scheme 61). Diol **324** was then converted into the known side-chain derivative **320** via azide **319** in four steps.

Scheme 61. Sharpless's approach to the taxol side chain through asymmetric dihydroxylation (1992).



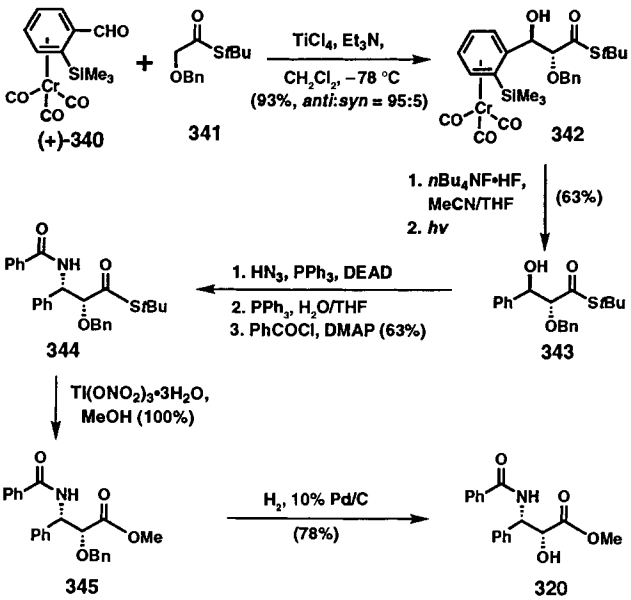
Jacobsen and Deng reported an efficient entry to compound **330** (the free acid of **320**) based on the asymmetric epoxidation

reaction of cinnamate ester **325** that is catalyzed by the chiral catalyst **326**, developed by his group (Scheme 62).[194] This method apparently offers the advantages of both brevity and low cost.



Scheme 62. Jacobsen's approach to the taxol side chain through an epoxidation (1992). 4-PPNO = 4-phenylpyridine *N*-oxide. Besides **327**, 13% of its *trans* isomer is formed from **325**.

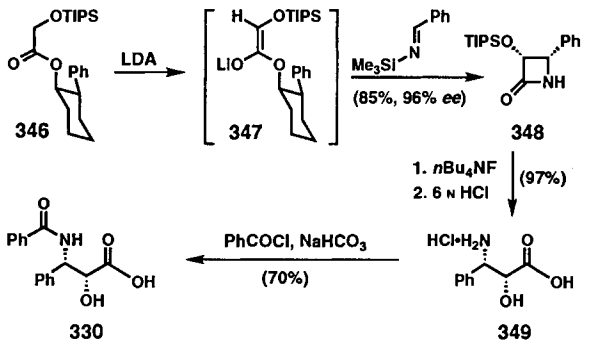
Commerçon et al. used a method based on an Evans-type auxiliary-controlled aldol condensation of chiral imide **331** with benzaldehyde. Treatment of **332** with base afforded the known epoxide **327** (Scheme 63), which was then converted by standard chemistry into the protected taxol side-chain equivalent **335**.[195]



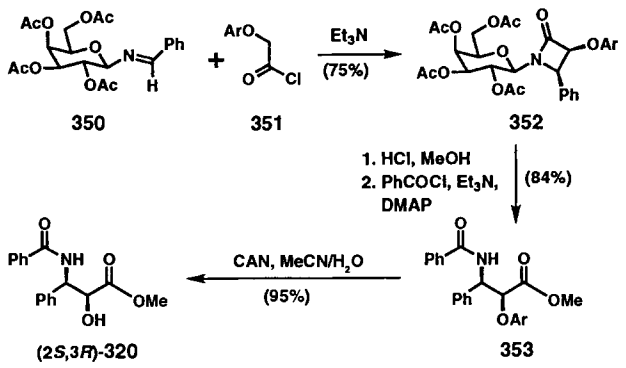
Scheme 63. Commerçon's approach to the taxol side chain through epoxidation (1992). boc = *tert*-butoxycarbonyl.

Greene et al. also introduced a method for the synthesis of the taxol side chain starting with an amino acid (Scheme 64).[196] Reduction, protection, oxidation, and homologation of (*S*)-(+)-phenylglycine (**336**) by standard methods led to the synthesis of compound **339** suitable for synthesis of taxol and Taxotere. A recent synthesis of the Taxotere side chain was achieved by dilithiation of Boc-protected benzylamine.[196b]

Scheme 64. Greene's approach to the taxol side chain starting from phenylglycine (1992).



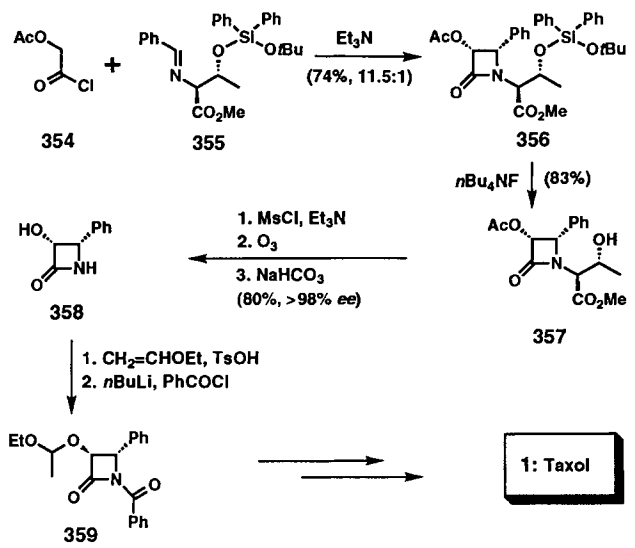
Hanaoka et al.[197] reported an interesting aldol condensation with the chiral chromium(0) complex of a benzaldehyde derivative [(+)-**340**] with **341** to form enantiomerically enriched **342** (Scheme 65). Following standard chemistry, **342** was transformed into the known ester **320**.



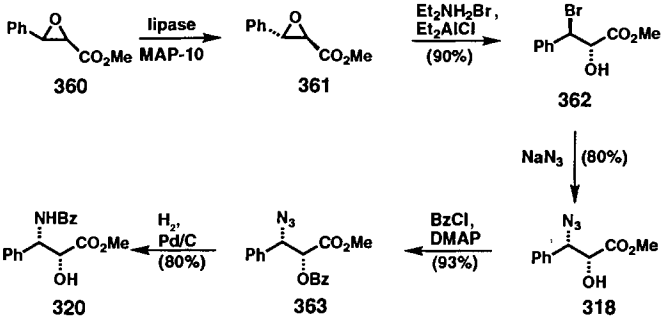
Scheme 65. Hanaoka's approach to the taxol side chain through aldol condensation (1992). DEAD = diethyl azocarboxylate.

β-Lactams have proven to be excellent precursors of the taxol side chain in several procedures. Scheme 66 shows Ojima's synthesis[198] of β-lactam **348** employing chiral ester enolate **347**. Subsequent manipulation of **348** led to the formation of the known hydroxy acid **330**.

An elegant synthesis of β-lactam **352** in optically active form by Georg et al. was based on the use of a carbohydrate chiral auxiliary (Scheme 67).[199] This approach resulted in the preparation of the nonnatural (2*S*,3*R*) enantiomer **320** of the taxol side chain in relatively few steps.

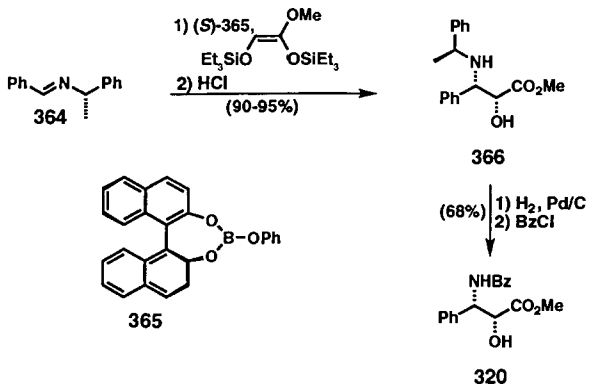


Scheme 66. Ojima's approach to the taxol side chain via a β-lactam (1992).



Scheme 67. Georg's approach to the taxol side chain via β-lactam (1992). Ar = 4-methoxyphenyl, CAN = ammonium cerium(IV) nitrate.

Farina's synthesis of β-lactam **359** was also based on the use of a chiral imine, **355**, prepared from an amino acid derivative (Scheme 68).[200] Following condensation of **354** with **355**, a reaction sequence was developed to remove the chiral auxiliary from the product (**357** → **358**). The protected β-lactam **359** was then treated with a baccatin III derivative to furnish taxol (see Section 3.5, Scheme 72). Racemic taxol side chain was also synthesized by Palomo et al.[201] according to a β-lactam strategy.

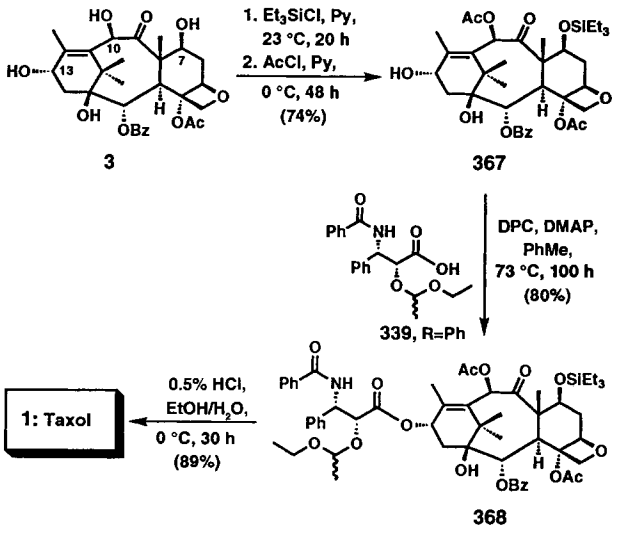


Scheme 68. Farina's approach to the taxol side chain via a β-lactam (1992). The ratio of the two *cis* compounds is 11.5:1.

Chen et al. have recently employed the enzymatic resolution of a chiral epoxy ester (**360**) to produce, after manipulation, the side-chain analog **320** (Scheme 69).[202] Techniques involving enzymatic resolution of other racemic substrates have also been used for the production of the taxol side chain.[203]

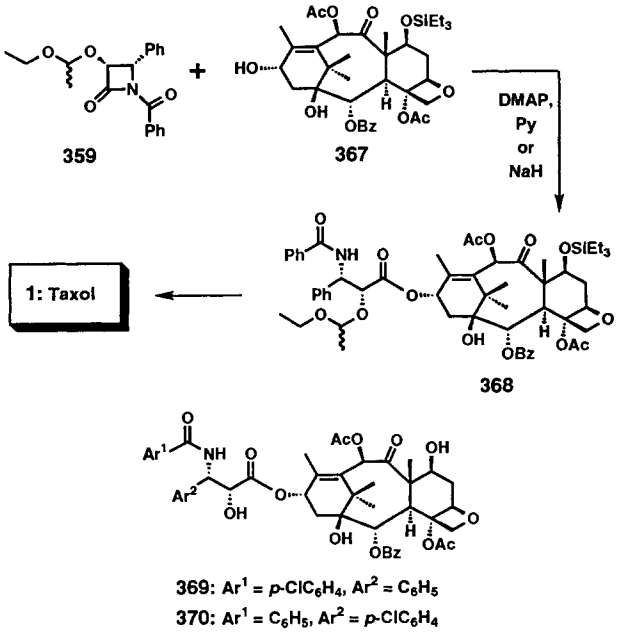
Scheme 69. Chen's approach to the taxol side chain via an enzymatic resolution of a racemate (**360** → **361**) (1993).

Yamamoto et al. have recently disclosed the synthesis of an enantiomerically enriched mixture of side-chain analog **320** (Scheme 70).[204] Their method centers around the aldol condensation of **364** with an enol ether under the mediation of chiral Lewis acid **365**.



Scheme 70. Yamamoto's approach to the taxol side chain (1993).

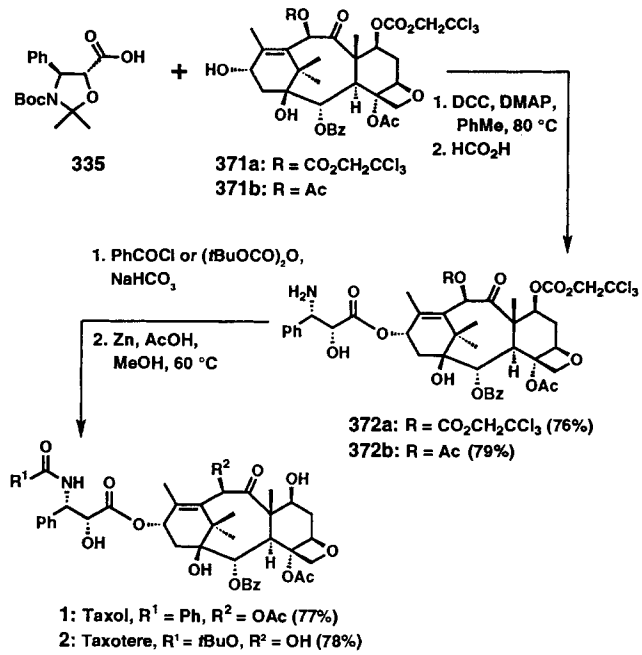
3.5. Semisynthesis of Taxol and Analogs



Despite the many efforts made by scientists during the past two decades, taxol still remains inaccessible by total synthesis. To circumvent the problem of direct extraction from the bark of yew trees, a method for the large scale production of taxol from renewable yew needles and twigs was sought.[125] 10-Deacetylbaccatin III (**3**, see Fig. 1) possesses the basic skeleton and functionality of taxol, and can be isolated from yew needles and twigs in significantly higher yield than taxol itself. This compound has attracted wide attention as a potential starting material for the semisynthesis of taxol and its analogs such as Taxotere.[61b] Since the side chain of taxol is readily available in enantiomerically enriched form by chemical synthesis, the remaining task is reduced to regioselective formation of the C13

ester bond. Several processes have been developed for this purpose.

The groups of Potier and Greene achieved the first successful semisynthesis of taxol[60a] after several preliminary attempts.[205] They found that the four hydroxy groups in **3** exhibited different reactivities towards acylation. Thus, **3** was first converted into its C7- and C10-protected derivative **367** (Scheme 71), which was then coupled with the side-chain equivalent **339** (R = Ph) under the influence of DPC-DMAP. These extreme conditions were essential for ester formation because of the steric hindrance around the C13 hydroxyl group. Acidic treatment of compound **368** provided taxol in high yield. This semisynthesis of taxol from **3** has served as the standard protocol for other modified procedures developed later.



Scheme 71. Potier and Greene's semisynthesis of taxol (1988). DPC = di-2-pyridyl carbonate.

Scheme 72. Holton and Ojima's semisynthesis of taxol (1990–1992).

Holton was successful in coupling baccatin III derivative **367** with optically active β-lactam **359**, made by optical resolution of racemic material, to form the same compound, **368** (Scheme 72).[206] Ojima's group has recently prepared **359** in optically active form by asymmetric reaction analogous to that described in Scheme 66.[198] The combination of Holton's and Ojima's procedures provided another semisynthesis of taxol in a few steps.[198, 200, 203] The same methodology was employed by the groups of Georg and Himes in the preparation of biologically active taxol analogs **369** and **370** with modified side chains.[207]

Commerçon et al. synthesized taxol (**1**) and Taxotere (**2**) by coupling derivatives **371a,b** of baccatin III (**4**) with the side-chain equivalent **335** (Scheme 73).[195] Side chain **335** was prepared by them as described in Scheme 63. The free amines **372a,b**, obtained from this coupling reaction, were then subjected to acylations to provide, after removal of the trichloroethoxycarbonyl group, **1** and **2** in good yields.

Scheme 73. Commerçon's semisynthesis of taxol and Taxotere (1992). DCC = dicyclohexylcarbodiimide.

4. Structure–Activity Relationships

Despite taxol's prospects as an anticancer agent and the global excitement surrounding its potential therapeutic value, several problems associated with the drug still hamper its widespread usage. Central among them is the issue of formulation. As discussed in Section 2.3, taxol's low water solubility ($0.03\ mg\,mL^{-1}$)[208] forces its formulation in a Cremaphor vehicle, which has several difficulties associated with its use. The development of a water-soluble analog or prodrug of taxol could circumvent this problem and greatly facilitate the administration of taxol. In a broader sense, better understanding of

the structure–activity relationships (SARs) of taxol and its derivatives will be pivotal in the design and synthesis of new generations of taxol-based antitumor agents with improved physical, chemical, and biological profiles. Major contributions to the understanding of taxol's SARs have been made by Potier's group in France and Kingston's group in the United States. Readers interested in the details of these studies are referred to Kingston's[209] and Potier's[210] recent review articles. In the following sections, the latest developments and the most important taxol derivatives will be discussed, beginning with the synthesis of water-soluble analogs of taxol.

4.1. Improvement of Water Solubility

As indicated in Figure 6, the C13 side chain is critical for maintaining the biological properties of taxol. The C2′ hydroxyl group is also important, although not as crucial, since acylation results in loss of microtubule stabilization but not cytotoxicy. (This phenomenon, may, however, be explained by ester hydrolysis within the cell.) The C7 hydroxyl group is a good site for derivatization, since blocking of this position causes only minimal loss of activity. A number of derivatives carrying groups at the C2′, C7, or both hydroxyls have been synthesized, including carboxylic acid salts, basic moieties, and other designed functionalities. The most important contributions are discussed below.

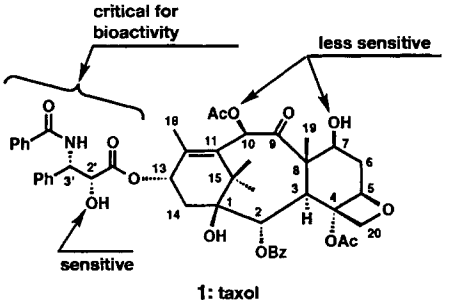


Fig. 6. The significance of selected structural sites for designing taxol analogs and prodrugs.

Deutsch et al. reported a number of taxol compounds (for example, **373**–**375**, Fig. 7),[211] functionalized at C2′, which exhibited improved water solubility. Aqueous solutions of up to 1% of compounds **373**–**375** were obtained. The biological actions of these compounds were also impressive. In assays with B16 melanoma cells, they demonstrated cytotoxicity comparable and even exceeding that of taxol. In particular, compound **375** had a rate of five out of ten cures in mice at dosages of 10 mg kg^{-1}. In the MX-1 breast xenograft test, complete tumor disappearance results were obtained at doses of 40 and 20 mg kg^{-1}, and all surviving mice were tumor free. These compounds may suffer, however, from their tendency to release taxol rapidly in aqueous media and thus cause precipitation problems.

Stella and collaborators have reported the preparation of a series of methanesulfonate salts of derivatives of taxol with amino acids in C2′ and C7 positions whose water solubilities are

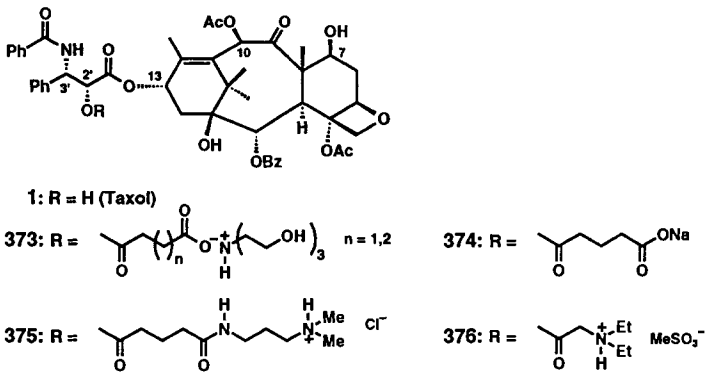

Fig. 7. Structures of water-soluble and biologically active taxol derivatives; Deutsch (1989), Stella (1992).

greater than 2 mg mL^{-1}.[212] For example, they found that the C2′-modified taxol **376** exhibited similar potency to taxol in inhibiting B16 melanoma cell proliferation and as an antitumor agent against breast carcinoma xenografts in mice. The mechanism of action of these water-soluble taxol derivatives was assumed to involve the in vivo release of taxol, an assumption that is supported by the similarity of their biological profiles to those of the natural product.

More recently, our group has been successful in the design and synthesis of two new types of biologically active taxol analogs.[213] The design of these compounds relied on the proposed mechanisms of releasing taxol from its prodrugs (Fig. 8).

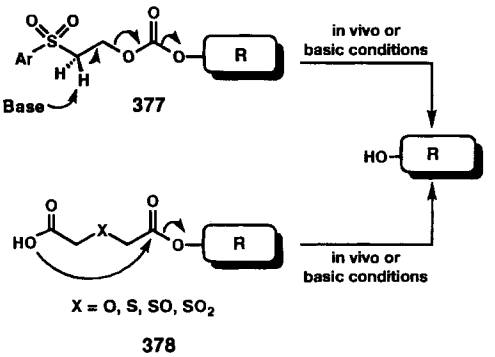

Fig. 8. Proposed mechanism of taxol release from designed protaxols (Nicolaou, 1993). R = taxol residue.

In the first type, the 2-arylsulfonyl ethoxycarbonyl group in **377** was conceived to allow the regeneration of taxol through a base-induced β-elimination reaction. In the second type, the monoester **378** of a dicarboxylic acid was planned to provide the opportunity for cleaving the ester bond through an intramolecular hydrolysis with a assumed cyclic transition state. A polar group X, such as an ether oxygen atom or sulfonyl group, linking the two carboxylic moieties was introduced in order to improve the water solubility of the molecule. These mechanisms allow for the activation of the drug in vivo in the basic microenvironment of certain tumor cells,[214] while maintaining stability in the relatively neutral environment of the fluid systems of the body. To utilize these principles, the derivatives **379**–**384** (Fig. 9) were designed and synthesized in one to three steps from

taxol. Compounds **379–381** exhibited markedly improved water solubility (≈ 1 mg mL^{-1}) and considerable stability at neutral pH and ambient temperature. At basic pH, however, these compounds readily release taxol at a rate depending upon the pH and the medium. In vitro cytotoxicity and microtubule polymerization studies showed profiles consistent with the controlled release of taxol into the system. These profiles demonstrate the high potential for use of these compounds as water soluble prodrugs of taxol in therapy.

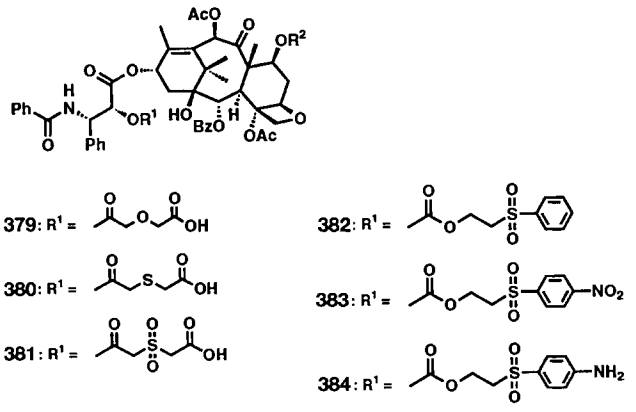

Fig. 9. Designed protaxols (Nicolaou, 1993). $R^2 = H$.

4.2. The Effect of Side-Chain Structures

As indicated in Figure 6, the side chain of taxol plays an important role in the biological functions of this antitumor agent. Protection of the C 2′ hydroxyl group results in major loss of activity but, as discussed in the previous section, those derivatives which possess labile groups in this position exhibit prodrug biological profiles. Structural modifications of the taxol side chain have been recently reported by both the Potier and Swindell groups.[215] These studies revealed a number of interesting features, which are summarized in Figure 10. Important findings include the following: a) the C 3′ acyl group is critical, although the amide's aryl group may be substituted by other aryl or alkyl groups; b) the C 3′ aryl group is required—a replacement by a methyl group reduces the activity 19-fold; c) the C 3′-bound nitrogen can be replaced by an oxygen atom without significant loss of activity; d) one of the C 2′ or C 3′ polar functionalities can be removed without significant effect, but the removal of both or interchange of their positions causes dramatic loss of activity; e) the (2′*S*,3′*R*) isomer is significantly less active than the natural (2′*R*,3′*S*) isomer, but the (2′*S*,3′*S*) and (2′*R*,3′*R*) isomers show comparable activity to that of the natural product.

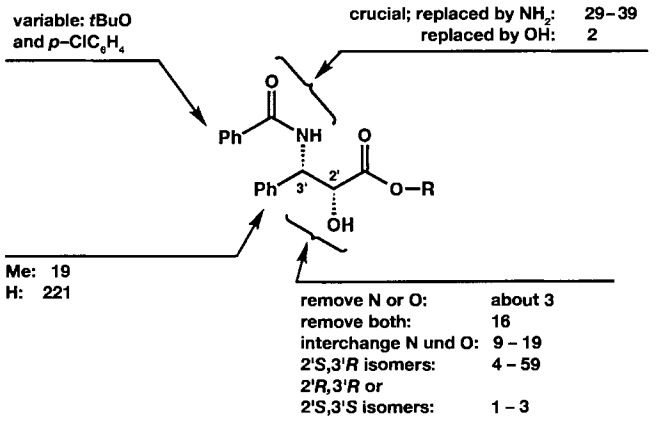

Fig. 10. Effects of structural modifications of the taxol side chain; Potier (1991), Swindell (1991). The numbers indicate the factor by which the activity is decreased.

The role of the taxol side chain in affecting biological activity has not yet been fully determined. However, the structure–activity relationships observed in the studies discussed above have revealed several key features about the mechanism of action of taxol. Based on the fact that the side chain is inactive by itself but essential to the activities of the intact taxol molecule, it is suspected that the principle recognition partner is the taxane skeleton itself. The taxol side chain may be preorganized through hydrogen bonding and may fit into a hydrophobic cleft on the taxane binding site, which stabilizes the drug–tubulin interaction. The details of this mechanism need further exploration. Further studies are needed to elucidate the molecular basis of the mechanism of action of taxol fully.

4.3. Modifications of the Taxol Skeleton

A variety of taxol derivatives, modified on the taxane skeleton, have been prepared by Kingston et al.[216] Figure 11 highlights the effects of structural changes on the biological action of the drug on microtubules. Specifically, these workers have observed that modifications at the C 2, C 7, and C 10 positions have insignificant effects on the biological action of the drug, ranging from doubled to halved activity. The oxetane ring, on the other hand, has proven crucial for maintaining the activity: ring opening led to drastic decrease in both tubulin disassembly (activity

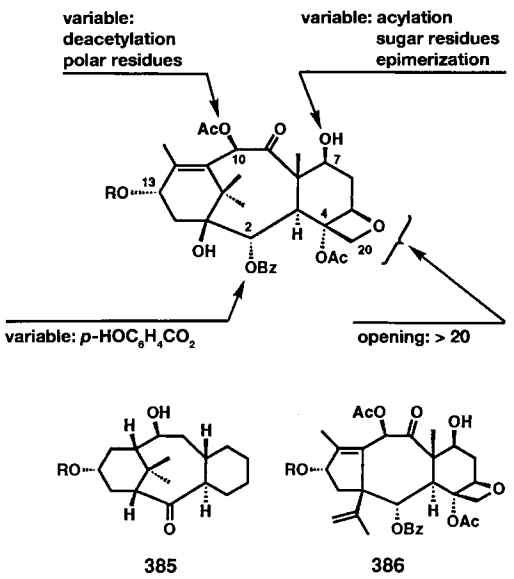

Fig. 11. Taxol derivatives and analogs with modified or rearranged skeletons (Kingston, 1991). See text.

smaller by more than a factor of 20) and cytotoxicity against KB cells ($>10^5$ times smaller IC_{50} values).

Interestingly, the structurally simplified taxane **385** (R = taxol side chain) and taxane analog (**386**) with a contracted A ring,[216] which both possess a properly functionalized side chain, inhibit tubulin depolymerization. Further study in this area could open up new avenues for the design and synthesis of taxol-like compounds. Modification of the taxol skeleton is currently a hot research topic, and several recent efforts have led to the preparation of a number of additional taxane skeletons derived from baccatin III (**4**).[217] Most recently Chen's group has disclosed some studies centered around deleting substituents on the taxol skeleton.[218] This group showed that deletion of the *O*-acetyl group in the 10 position has little if any affect upon the activity. However, deletion of the *O*-benzoyl group in the 2 position causes a drastic reduction in its bioactivity.

One should keep in mind that the different testing systems used by various groups may give different data. Relative values, indexed to taxol, are the most useful for comparison. The correlation between cytotoxicity and antimicrotubular activity has been fairly well established and, with a few exceptions, the trends are usually parallel.

5. Summary and Outlook

The cellular mechanisms by which taxol exerts its effects are beginning to come to light. These studies, as well as those which focus on the supracellular effects of taxol, should remain an area of active study in the coming years. Since the safety and efficiency of taxol and Taxotere are now proven in clinical trials, the way is paved for large-scale evaluations of the clinical usefulness and efficiency of taxol in treating specific neoplasms. At the same time, studies of the synergistic effects of taxol and other drugs may provide even more exciting leads. At the moment these studies are hindered by the lack of a steady and copious stock of taxol. One should expect extensive action in the arena of taxol supply until an efficient, inexpensive, and proprietary process for the production of taxol is developed.

Only a few natural products have excited the extensive level of synthetic effort invested in taxol. While the likelihood of a practical synthetic route for the total synthesis of taxol being developed is relatively low, these studies are sure to provide a wealth of information about taxol's SARs and expand the frontiers of synthetic chemistry. Another exciting prospect is the design and synthesis of simpler biologically active mimics of taxol. With so many groups hard at work, the attainment of a total synthesis of taxol is merely a question of time.

Taxol and its relatives are emerging as yet another class of naturally occurring substances, like the enediyne antitumor antibiotics[218] and the macrocyclic immunophillin ligands,[219] that combine novel molecular architecture, important biological activity, and fascinating mode of action. As such, taxol is bound to continue to stimulate synthetic chemists, molecular designers, molecular and cellular biologists, and clinicians. This deliberate merging of chemistry and biology promises to lead to exciting ventures and discoveries.

We wish to thank our talented collaborators, C. Claiborne, H. Ueno, C. K. Hwang, M. Kerr, J. J. Liu, Y. Mizuno, M. Nakada, C. Riemer, K. Shibayama, E. Sorensen, and Z. Yang for the stimulating discussions and their contributions. We thank J. Hightower and K. Boyd for the art work and M. Egan and S. Conley for undertaking the task of proofreading the manuscript and double-checking the references. Much credit is due to S. Reed for his exacting, informative, and educational comments on the biological sections of this manuscript. Additionally, we wish to thank R. Kelsey of the National Forest Service for a helpful conversation concerning the biology of T. brevifolia. For financial assistance we thank the National Institutes of Health, USA, and the Office of Naval Research, USA.

Addendum

Since the submission of the final version of this article (6/93), more than 100 articles concerning taxol have appeared in the literature. This addendum addresses those that were indexed in Chemical Abstracts Online or Medline by November 15, 1993. The following is a list of those that the authors deem to be both within the scope of this review and particularly important.

Concerning a) microtubules: K. E. Sawin, S. A. Endow, *Bioessays*, **1993**, *15*, 399–407; R. F. Luduena, *Mol. Biol. Cell* **1993**, *4*, 455–457; b) the microtubule organizing center: M. D. Rose, S. Biggino, L. L. Satterwhite, *Curr. Op. Cell Biol.* **1993**, *5*, 105–115.

Concerning the biological effects of taxol: a) the cell cycle: N. M. Lopes, E. G. Adams, T. W. Pitts, B. K. Bhoyan, *Cancer Chemother. Pharmacol.* **1993**, *32*, 235–242; b) metastasis: M. L. Stracke, M. Sorough, L. A. Liotta, E. Schiffmann, *Kidney Int.* **1993**, *43*, 151–157; c) radiation sensitivity: P. B. Schiff, *PCT Int. Appl.* WO 9314787 A1 (August 5, 1993); H. Choy, F. F. Rodriguez, S. Koester, S. Hilsenbeck, D. D. Van Hoff, *Cancer* **1993**, *71*, 3774–3778; A. Steren, B. U. Sevin, J. Perras, R. Ramus, R. Angioli, H. Nguyen, O. Koechli, H. E. Auerette, *Gynecol. Oncol.* **1993**, *50*, 89–93, d) lipopolysaccharide imitation: C. L. Manthey, N. Qureshi, P. L. Stuetz, S. N. Vogel, *J. Exp. Med.* **1993**, *178*, 695–702; e) the pharmacology of taxol: G. N. Kumar, K. V. Walle, K. N. Bhalla, T. Walle, *Res. Commun. Chem. Pathol. Pharmacol.* **1993**, *80*, 337–344; f) the state of art in the clinic: D. Bissit, S. B. Kaye, *Eur. J. Cancer 29A* **1993**, 1228–1231; Paclitaxel (taxol) Investigators Workshop, *Sem. Oncol.* **1993**, *20* (4 Suppl. 3) 1–60.

Concerning the production of taxol through cell culture: A. G. Fett-Neto, S. J. Melanson, K. Sakata, F. Dicosmo, *Bio/Technology* **1993**, *11*, 731–734; R. J. Smith, T. L. Addams, C. R. Burton, R. W. Stahlhut, *PCT Int. Appl.* WO 9310253 A1 (May 27, 1993).

Concerning the synthesis of a) taxoids as photoaffinity label: G. I. Georg, G. C. Hattiman, *Bioorg. Med. Chem. Lett.* **1992**, *2*, 735–738; A. Chatterjee, J. S. Williamson, J. K. Zjawiony, J. R. Peterson, *ibid.* **1992**, *2*, 91–94; b) prodrugs of taxol: D. G. I. Kingston, Z. Y. Zhao, EP-A 537905 (April 21, 1993); c) the taxol CD ring system: R. C. A. Isaacs, M. J. DiGrandi, S. J. Danishefsky, *J. Org. Chem.*, **1993**, *58*, 3938–3941.

Studies on the structure–activity relationships of taxol: a) deletion of the C7 OH group: A. G. Chaudhory, J. M. Rimoldi, D. G. I. Kingston, *J. Org. Chem.* **1993**, *58*, 3798–3799; b) insertion of a C9 OH group: L. L. Klein, *Tetrahedron Lett.* **1993**, *34*, 2047–2050; c) formation of side-chain analogs: G. I. Georg, Z. S. Cheruvallah, *Bioorg. Med. Chem. Lett.* **1992**, *2*, 295–298.

[78] Like most of the cancer cell lines, HeLa cells are the result of culturing cells harvested from a human being. The HeLa line came into being when cancerous cells were removed from the cervix of Henrietta Lacks on February 9, 1951, in Baltimore. Henrietta Lacks died in October of that year: L. X-Ray Absorption Spectroscopy of Amorphous Solids, Liquids, and Catalytic and Biochemical Systems—Capabilities and Limitations

Helmut Bertagnolli* and Teja S. Ertel*

Although the effect on which X-ray absorption spectroscopy (EXAFS spectroscopy) is based has been known for about 70 years, up until about 20 years ago it had not found any application. The reasons for this were on the one hand the shortage of efficient X-ray sources, and on the other hand the lack of a suitable theoretical description. With the advent of synchrotron radiation the situation has changed completely. Today, EXAFS spectroscopy is applied to a variety of very different problems and used more and more frequently to answer chemical questions. The extraordinary behavior of EXAFS spectroscopy that allows the determination of local structures in almost any mixture, independent of the sample's physical state as well as element-specifically with high sensitivity, carries with it the danger that the amount of the obtainable structural information will be overestimated. A realistic estimate of the capability of EXAFS spectroscopy has in the meantime been achieved for crystalline materials, but not for amorphous materials. In this case the viewpoints range from complete rejection to overinterpretation of the EXAFS spectrum. In this article an attempt is made to show how EXAFS spectroscopy can be applied in the investigation of noncrystalline materials. First, the measurement techniques, data analysis procedures, and the simulation of EXAFS spectra are explained. Starting with the simplest systems, the amorphous metals and nonmetals, and using representative but not necessarily current examples, an explanation is given of the structural information provided by EXAFS spectroscopy, of how the local environment about the two components can be determined in binary systems, and of how even the crystallization process and structural changes can be investigated in chemical reactions. Thereafter, EXAFS studies on solutions, molecular liquids, and melts are presented. The final section is concerned with typical applications of EXAFS spectroscopy, the investigation of homogeneous and heterogeneous catalysts as well as the elucidation of active sites in enzymes.

1. Theoretical Foundations

A monochromatic X-ray beam of energy E is attenuated by the passage through a material of thickness d according to Equation (a).[1] $I_0(E)$ and $I(E)$ are the intensity of the incident and transmitted beams, respectively. $\mu(E)$ is the linear absorption coefficient. Its dependence on E is depicted in Figure 1a. $\mu(E)$ decreases with increasing E of the incident X-rays until a threshold is reached at which the energy is sufficient to remove an electron from an inner shell. At this threshold, $\mu(E)$ increases abruptly. Beyond this point, $\mu(E)$ resumes its steady decrease. More precise measurements of the absorption coefficient indicate that the curve shown in Figure 1a is typical only for isolated atoms. When other atoms are in the vicinity of the absorbing atom, the absorption coefficient shows small oscillations up to about 1000 eV above the absorption edge. This is shown schematically in Figure 1b.

$$\frac{I(E)}{I_0(E)} = e^{-\mu(E)d} \qquad \text{(a)}$$

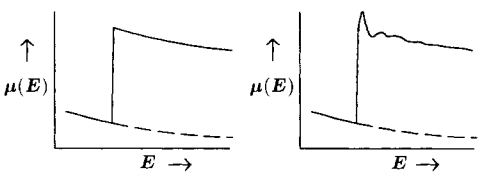

Fig. 1. Graph of the absorption coefficient $\mu(E)$ for an isolated atom (left) and for an atom surrounded by backscattering atoms (right).

This fine structure has been known for a long time—H. Fricke[2] and G. Hertz[3] discovered it in 1920—but the effect could not be explained satisfactorily by theory at the time. R. de L. Kronig[4, 5] already had the correct fundamental ideas in the 1930s, but the interpretation remained confusing until the 1970s when D. E. Sayers, E. A. Stern, and F. W. Lytle[6, 7] formulated

when D. E. Sayers, E. A. Stern, and F. W. Lytle[6, 7] formulated a theory that has remained generally accepted until today. This theory will be briefly outlined below.

The probability for absorption of an X-ray photon by an electron of an inner shell is dependent on the initial and final states of the excited electron. The initial state is that of the core electron, while the final state is more difficult to describe. The absorption of X-ray radiation generates a photoelectron that can be considered as a spherical wave originating from the absorbing atom. This wave is then backscattered by the neighboring atoms. The final state is therefore the superposition of the original and backscattered waves. The resulting constructive and destructive interference leads to the oscillations in the absorption coefficient.

This qualitative description indicates that the oscillations in the absorption coefficient μ are dependent on the distance r_j, the number of neighboring atoms N_j, and the type of backscattering atom j. The backscattering ability of atom j is characterized by the backscattering amplitude F_j, while the effect of j on the phase is determined by the phase shift φ_{ij}. In addition, the finite lifetime of the photoelectron—equivalent to an additional damping with a mean free path length of λ_j—must be taken into account as well as the fact that the backscattering atoms are distributed around a mean distance due to thermal vibrations and static disorder. A good approximation for this distribution is a Gaussian function with a mean square deviation of σ_j^2. In analogy to X-ray and neutron diffraction, the quantity σ_j^2 is called a Debye–Waller-like factor. This terminology indicates that σ_j^2 also contains contributions stemming from the static disorder. This fine differentiation will be ignored in this review and σ_j^2 will be called—as is customary—simply the Debye–Waller factor.

According to the above considerations, precise measurements of the energy dependence of the X-ray absorption coefficient make it possible to determine the local environment around the element which absorbs the X-rays. Methods which are based on this principle are categorized as X-ray absorption spectroscopy or X-ray absorption fine structure (XAFS) spectroscopy. The energy range close the absorption edge is called XANES (X-ray absorption near edge structure), while the range about 30–1000 eV from the edge is called EXAFS (extended X-ray absorption fine structure). XANES yields information about the spatial arrangement of backscatterers. The corresponding theory has not yet been completely developed and, therefore, mostly only qualitative comparisons are employed. In contrast, the theory for EXAFS has evolved to such an extent that reliable conclusions about local structures are possible. Since the positions of the K and L edges are dependent on the element in question, the suitable choice of incident X-ray energies makes it possible to excite one specific element and, hence, to probe its environment. This method is therefore element-specific, independent of the physical state of the sample, and can be employed even for low concentrations of absorbing atoms.

In order to determine the relationship between the quantities characterizing the local environment around the absorbing atom and the X-ray absorption coefficient $\mu(E)$, it is necessary to correct and normalize the modulation of $\mu(E)$ for the background absorption $\mu_0(E)$ [Eq. (b)].[8] The next step is to convert

$$\chi(E) = \frac{\mu(E) - \mu_0(E)}{\mu_0(E)} \qquad \text{(b)}$$

the function $\chi(E)$ into the function $\chi(k)$, in which k is the magnitude of the photoelectron wave vector. k can be calculated

Helmut Bertagnolli, born in 1943 in Baden-Baden, studied chemistry at the Universität Freiburg and received his doctorate there in 1974 in the field of physical chemistry with Prof. Zimmermann. Subsequently, he moved to the Universität Karlsruhe, where he habilitated in 1979 with a work on the scattering of polarized neutrons on ^1H-containing molecular liquids. In 1981 he took up a professorship at the Universität Würzburg; since 1993 he has held the newly founded chair of physcial chemistry at the Universität Stuttgart. The main focus of his research interest lies in the study of the amorphous state, which he characterizes primarily with X-ray and neutron diffraction as well as EXAFS spectroscopy and interprets with statistical mechanical calculations and reverse-Monte-Carlo simulations.

Teja Sebastian Ertel, born in München in 1965, studied chemistry from 1984 to 1985 at the Ludwig-Maximilians Universität München and from 1985 to 1989 at the Universität Würzburg. He received his doctorate in 1992 under the supervision of Prof. Bertagnolli. During his studies he was supported by scholarships from the Stiftung Stipendien-Fonds des Verbands der Chemischen Industrie. In the same year he received the research prize awarded by the Braintrust Gesellschaft für Forschungstransfer München. Since April 1992 he has been working with the aid of a grant from the Dr. Leni Schöninger-Stiftung at the Universität Stuttgart on the structural elucidation of amorphous materials with the help of various spectroscopic techniques.

according to Equation (c) from the energy E of the incident

$$k = \sqrt{\frac{8\pi^2 m_e}{h^2}(E - E_0)} \qquad \text{(c)}$$

X-ray photon and the position of the absorption edge E_0. The mass of the electron is denoted by m_e, h stands for Planck's constant. Equation (d) relates the resulting EXAFS function

$$\chi(k) = \sum_j \frac{N_j}{kr_j^2} \cdot F_j(k) \cdot e^{-2\sigma_j^2 k^2} e^{-\frac{2r_j}{\lambda_j(k)}} \cdot \sin[2kr_j + \varphi_{ij}(k)] \qquad \text{(d)}$$

$\chi(k)$ to the quantities that characterize the environment of the absorbing atom.[6, 7]

The EXAFS function in k space contains all necessary information, however, it is not readily visualized. Fourier transformation of $\chi(k)$ yields a radial distribution function $F(r)$, which has maxima at $R_j = r_j - \alpha_j$ and therefore indicates the distribution of the backscatterers [Eq. (e)]. Generally, only the magni-

$$F(r) = \frac{1}{\sqrt{2\pi}} \int_{k_{min}}^{k_{max}} \chi(k) \cdot k^n w(k) \exp(i2kr)\, dk \qquad \text{(e)}$$

tude of $F(r)$ is plotted, called either the modulo function of the Fourier transformed EXAFS function or simply the structure function $|F(r)|$. During data interpretation it must be taken into account that all maxima are shifted to lower distances—typical shifts are between 0.2–0.3 Å. As the functions are only transformed in the interval $k_{max} - k_{min}$, non-real peaks can appear in the transformed functions. These peaks can be strongly dampened by the use of a window function $w(k)$, which defines the interval to be transformed as well as the weighting of all points. A typical example for $w(k)$ is a step function. While this type of function has the highest resolution, it is not always possible to avoid truncation effects. The use of a Gaussian step function lets the sides of the window slope gently downward at the edges and truncation effects are rarely observed.

The multiplication of the EXAFS function by k^n ($n = 1-3$) is performed to compensate the decrease of $\chi(k)$ with increasing k. This decrease is caused by the functional form of the backscattering amplitude $F_j(k)$ and the factor $\exp(-2\sigma^2 k^2)$. B. K. Teo and P. A. Lee[9] proposed $n = 1$ for backscatterers with atomic number $Z > 57$, $n = 2$ for elements with $36 < Z < 57$, and $n = 3$ for $Z < 36$. Weighting with k^3 requires very high data quality, as for high k values the signal-to-noise ratio is especially unfavorable. This weighting scheme has the advantage, however, that the EXAFS oscillations are evenly weighted over the entire k region. Moreover, the use of different weighting schemes makes it possible to distinguish heavy elements from light ones.

To develop a feel for the characteristics of the EXAFS functions and their Fourier transforms, the structure functions, it is useful to examine some theoretical curves. Figure 2a shows the k^3-weighted $\chi(k)$ function of an Fe–C pair with a typical distance of 2.0 Å (as in ferrocene), coordination number $N_j = 1$, and $\sigma_j = 0.05$ Å, by using theoretical backscattering amplitudes and phases from A. G. McKale et al.[10] The Fourier transformed function (Fig. 2b) shows a maximum which is clearly shifted to smaller distances. This maximum is asymmetric due to the finite transformation interval. Figure 2c shows the EXAFS function of an Fe–Br unit, using the same parameters. A comparison with Figure 2a indicates that the amplitude is significantly larger (also note the different scales). This trend can be generalized: lighter elements are weaker backscatterers, and are therefore more difficult to detect than heavy elements.

How can the element type be recognized? According to Equation (d), the backscattering amplitude and phase are element-specific quantities. The backscattering amplitude is the envelope in the EXAFS function, which results in the clearly different Figures 2a and 2c. The Fourier transformed functions, on the other hand, do not give any indications of the presence of different elements.

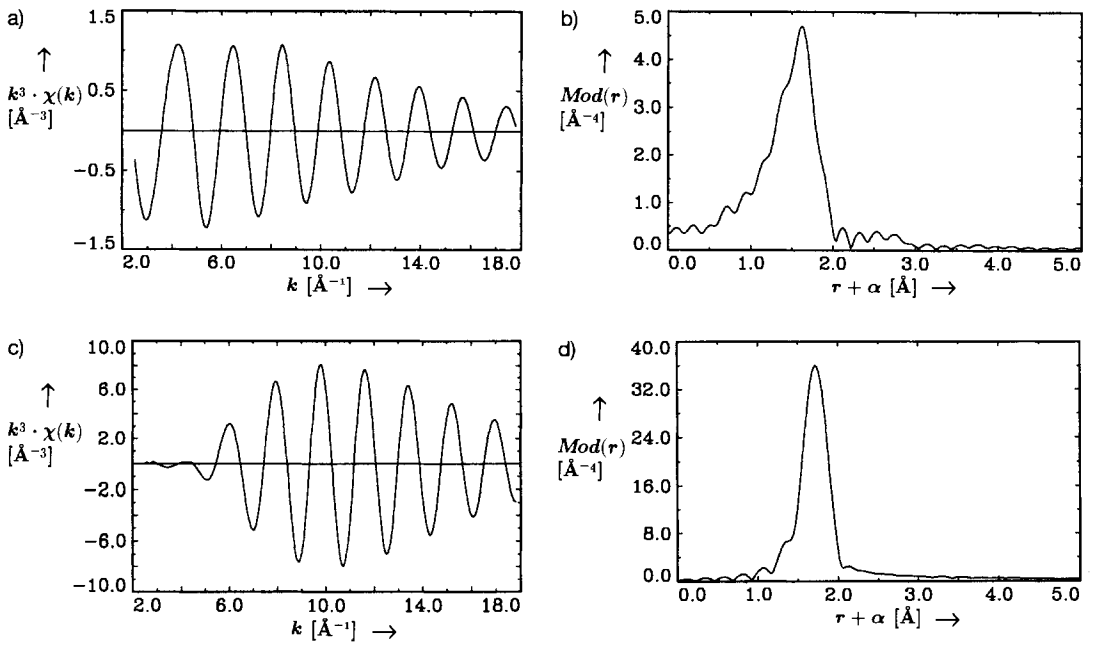

Fig. 2. Theoretical EXAFS functions (a, c) and their Fourier transforms (b, d) for an Fe–C (a, b) and an Fe–Br (c, d) absorber–backscatterer pair. The EXAFS functions were calculated employing McKale amplitude and phase functions [10], by using the following structural parameters: absorber–backscatterer distances $r_{Fe-C} = 2.0$, $r_{Fe-Br} = 2.0$ Å, coordination numbers $N_C = 1.0$ and $N_{Br} = 1.0$, Debye–Waller factors $\sigma_C = 0.05$ and $\sigma_{Br} = 0.05$ Å.

The theoretical calculation of backscattering amplitudes and phases was a problem for a long time and was one of the main reasons why EXAFS spectroscopy did not find wide application. The first extensive calculations of backscattering amplitudes and phases stem from B. K. Teo and P. A. Lee[9] and were based on an electron–atom scattering theory from P. A. Lee and G. Beni.[11] In this theory, the spherical wave originating from the absorbing atom was approximated by a planar wave. This approximation is valid as long as the effective atom size is small compared to the interatomic distance. In the meantime, a number of powerful program packages are available for the calculations, which use spherical waves.[10] A commonly used program is EXCURV90 and its later versions, which was developed by the Science and Engineering Research Council (SERC), Daresbury Laboratory, Warrington, UK. This program uses a formalism by S. J. Gurman et al.[12] to calculate theoretical backscattering amplitudes and phases, as well as the quantity $\lambda_j(k)$ which characterizes the lifetime of the photoelectron. This formalism is based upon an electron scattering theory by P. A. Lee and J. B. Pendry.[13] Moreover, this program is also capable of including multiple scattering effects.[14] In 1986, J. J. Rehr et al. began the development of the program FEFF, which to date allows the most accurate theoretical calculations of mean free wavelengths $\lambda_j(k)$ and amplitude and phase functions for any given pair of absorbing and backscattering atoms.[15, 16]

At this point it must be noted, that the backscattering amplitudes of neighboring elements in the periodic table are only slightly different. This makes an unambiguous differentiation of neighboring elements nearly impossible. In general, however, there is sufficient additional information about the sample to enable identification of the elements involved, provided the theoretically calculated backscattering parameters do correctly model the actual backscattering behavior. Very different chemical environments can lead to deviations. In such cases, it is necessary to employ model compounds.

It is always preferable to use backscattering amplitudes and phases that were obtained from model compounds. In these cases, one measures the EXAFS spectrum of a compound with a precisely known structure. The coordination number N_j and the distance to the absorbing atom r_j are known, and the Debye–Waller factor can be estimated from X-ray data, vibrational frequencies, and variable temperature measurements. The backscattering amplitudes and phases can be then determined from the experimental spectrum. However, not all compounds with known structures are suitable as model compounds, even if they are chemically similar to the system under study. To be suitable, the system must posses a well-defined coordination sphere, that is, the contribution of each term must be clearly separable from all others (cf. Eq. (d)). Model compounds of this kind are very difficult to find and in many cases, the use of calculated backscattering parameters is required.

In most cases, different pairs of atoms at various distances are present and the corresponding EXAFS functions overlap. The overlap of the functions of an Fe–C and an Fe–Br pair with absorber–backscatter distances of 2.0 and 3.5 Å, respectively, is shown in Figure 3a. The Fourier transformed function has separate peaks (Fig. 3b). In such favorable cases, each single peak can be selected separately by a window function and backtransformed from the spatial domain (function $|F(r)|$) to the impulse domain (function $\chi(k)$). The result is shown in Figures 3c and 3d. In comparison to Figures 2a and 2c, it can be seen that the contribution of the Fe–C pair is reproduced. The Fe–Br unit shows the same envelope, but a different period due to the increased Fe–Br distance from 2.0 to 3.5 Å. This example demonstrates how the Fourier filter technique can be used to determine the contribution of a backscatterer. The envelope of the filtered function indicates the type of backscatterer, the amplitude yields the coordination number and the Debye–Waller factor, while the period shows the distance to the absorbing atom.

Figure 3a shows a nearly ideal case. In reality, frequently several distances of comparable magnitude are present. In Figure 4a the results from the overlap of two contributions is shown, an Fe–C and an Fe–Br unit, with $r_{Fe-C} = 2.0$ Å and

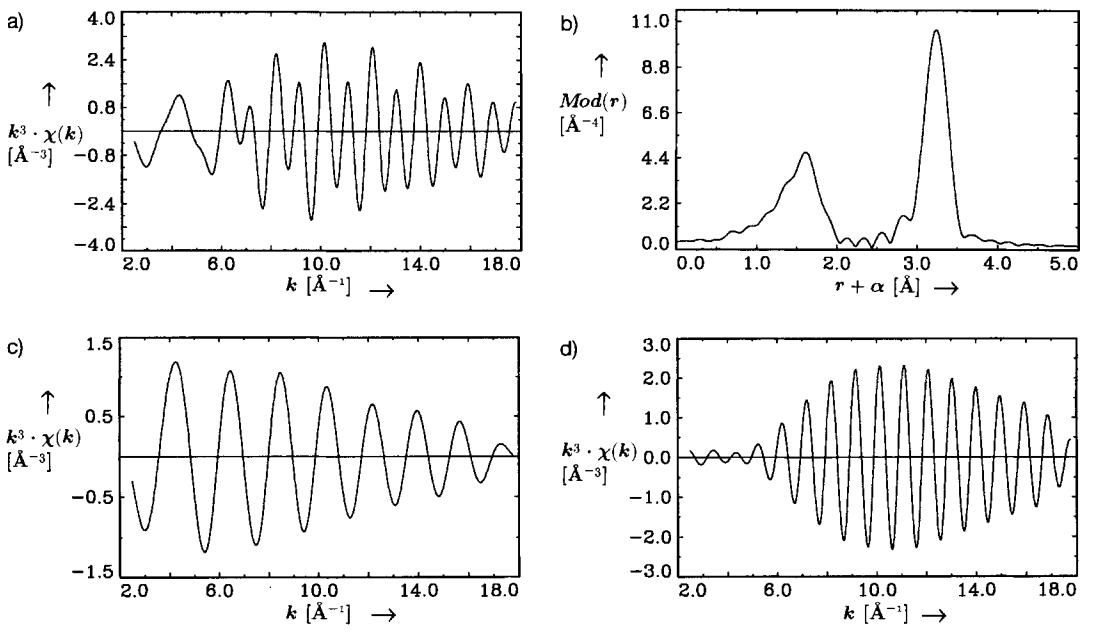

Fig. 3. Theoretical EXAFS function (a) and its Fourier transform (b) for a superpositioned Fe–C and Fe–Br absorber–backscatterer pair. The EXAFS function was calculated employing McKale amplitude and phase functions [10], by using the following structural parameters: absorber–backscatterer distances $r_{Fe-C} = 2.0$, $r_{Fe-Br} = 3.5$ Å, coordination numbers $N_C = 1.0$ and $N_{Br} = 1.0$, Debye–Waller factors $\sigma_C = 0.05$ and $\sigma_{Br} = 0.05$ Å. The EXAFS function was Fourier filtered in the range of 0.5 to 2.5 Å (c) and 2.5 to 4.5 Å (d).

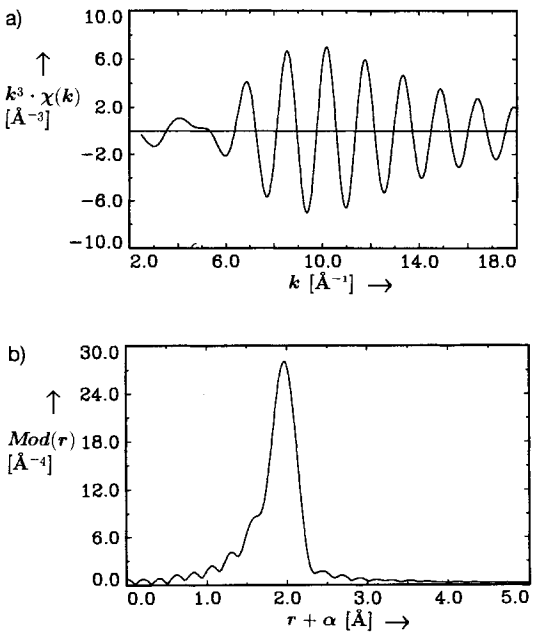

Fig. 4. Theoretical EXAFS function (a) and its Fourier transform (b) for a superpositioned Fe–C and Fe–Br absorber–backscatterer pair. The EXAFS function was calculated employing McKale amplitude and phase functions [10], by using the following structural parameters: absorber–backscatterer distances $r_{Fe-C} = 2.0$, $r_{Fe-Br} = 2.25$ Å, coordination numbers $N_C = 1.0$ and $N_{Br} = 1.0$, Debye–Waller factors $\sigma_C = 0.05$ and $\sigma_{Br} = 0.05$ Å.

$r_{Fe-Br} = 2.25$ Å. As can be clearly seen from the envelope, the contribution of the Br backscatterer dominates, while that of the carbon backscatterer is not discernible. The Fourier transformed function (Fig. 4b) indicates the carbon only as a weak shoulder and a separation into independent coordination spheres is impossible. In such cases, it is necessary to simultaneously fit two shells. Since each shell requires at least three parameters—distance, coordination number, and Debye–Waller factor—the number of parameters increases rapidly with the use of multiple shells. A useful strategy for such cases is to initially fit the experimental EXAFS function to a single shell. If the agreement is poor, the prospect of the presence of a different backscatterer should be explored. If this possibility can be excluded, the existence of another shell can be assumed. In this manner, successive shells can be constructed. In each case, it is necessary to determine the contribution to the total function. If it is small enough to be within experimental error, it is usually better to simply ignore it. In order to analyze the significance of newly added shells of backscatterers, the program EXCURV90 includes a test in which the improvement of a fitting index makes it possible to judge whether the addition of another shell is useful. The fitting of multiple shells frequently leads to overinterpretation of EXAFS measurements and this practice has on occasion led to criticism of the method in general.

Nevertheless, the fitting of a theoretical function to experimental data is in most cases the only way to interpret EXAFS spectra. When appropriate care is taken, the results are very reliable. Distances can be determined with an accuracy of up to 1%, coordination numbers can be ascertained to within 10–30%. When model compounds, optimized measurements, and highly accurate data analysis are employed, the error boundary for the coordination numbers can be significantly reduced.

2. Measurement Fundamentals and Techniques

As can be gleaned from Equation (a), the quantity to be measured by X-ray absorption spectroscopy is the X-ray absorption coefficient $\mu(E)$. The most common technique involves the direct measurement of $\mu(E)$. In order to obtain monochromatic X-rays, a continuous spectrum is employed. According to Bragg's law [Eq. (f)],[17] (λ = wavelength of the incident X-

$$n\lambda = 2d\sin\vartheta \qquad (f)$$

rays; d = interplanar spacing of the crystal; 2ϑ = scattering angle, n = order of diffraction ($n = 1,2,3\ldots$)) a crystal double monochromator, with the second crystal at a slight angle to the first one, selects a beam of wavelength λ, while simultaneously suppressing beams with wavelengths $\lambda/2$, $\lambda/3$, etc. The absorption coefficient is found according to Equation (a) by measuring the intensity of the X-rays before and after the sample. The energy of the incident radiation is adjusted by a stepwise change of the incident angle of the monochromator. The experimental setup is schematically shown in Figure 5a. The sample to be measured, a reference compound, which in many cases is used for calibration purposes, and the ionization chambers for the intensity measurements are arranged in a line. The sample is located between the first and second ionization chamber, and the reference compound is located between the second and third chamber. Typical measurement times are 20–60 minutes, when synchrotron radiation is used. Rapid rotation of the monochromator can reduce these times to a few seconds,[18] however, the experimental effort is increased drastically. The acronym for this measuring technique is QEXAFS (Q = quick). The continuous X-ray spectrum can also be used directly. It is split up by Bragg reflection on a crystal and, after passage through the sample, can be measured by using an array detector.[19,20] This measurement principle is depicted in Figure 5c and is called DEXAFS (D = dispersive).

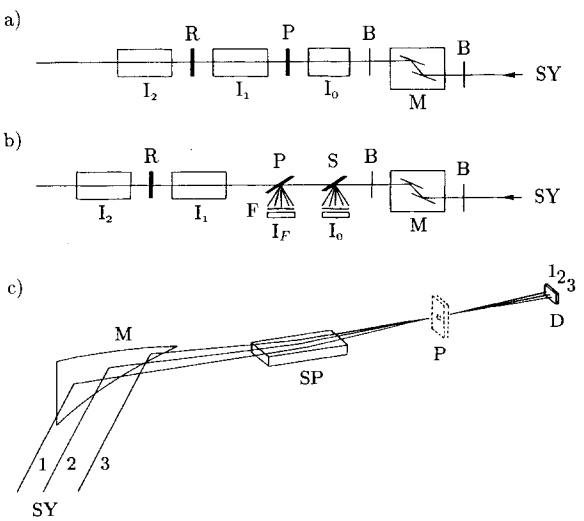

Fig. 5. Experimental setup for transmission (a), fluorescence (b), and energy-dispersive (c) EXAFS measurements (SY = synchrotron radiation, 1,2,3 = beam paths, M = monochromator, I_0,I_1,I_2 = ionization chambers, D = detector (diode array), S = scattering sample, P = sample, R = reference sample, B = slit, F = filter, SP = mirror).

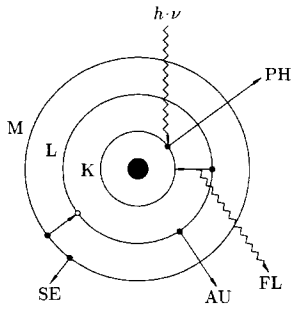

Fig. 6. Subsequent decay processes after creation of a hole in the electron shell by absorption of X-rays $h\nu$ (PH = photoelectron, AU = Auger electron, SE = secondary electron, FL = fluorescence radiation).

Since the absorption of X-rays is linked to the creation of an electron vacancy, it is possible to use all subsequent decay processes to determine the absorption coefficient (Fig. 6). An electron from an outer shell can fill the vacancy, accompanied by the emission of fluorescence radiation (FL) or Auger electrons (AU). These two emissions are competing processes. The fluorescence yield increases with increasing atomic number and this process has the advantage that the background radiation can be removed by using suitable filters, which increases the sensitivity of the method. A typical setup for fluorescence measurements is shown in Figure 5b. In general, the emitted fluorescence is measured at a right angle to the incident beam; the sample is therefore rotated by 45°.

The detection of Auger electrons yields the same structural information as a transmission EXAFS experiment or the fluorescence method described above. Auger measurements are advantageous in situations in which the fluorescence method fails due to low quantum yields—in the case of K-edge measurements for elements with $Z < 30$, and $Z < 80$ for L-edge experiments. Due to the small mean free wavelength of the emitted electrons (ca. 100 Å), the Auger method is especially suited for the study of surfaces (SEXAFS, S = surface). A thorough description of this method can be found in [21]. It is also possible, in principle, to directly detect the photoelectrons generated. This is difficult, however, because their spatial distribution changes with the energy of the incident X-ray beam. This effect can be effectively circumvented by detecting all electrons produced by cascading processes. This includes the Auger and photoelectrons as well as secondary electrons created by inelastic scattering of photoelectrons and the fluorescence radiation.

Three types of devices are available for the detection of X-ray photons: ionization chambers, scintillation counters, and solid-state detectors (Ge, Si, Li-doped Si). The determining criteria for the choice of detector are its energy resolution and recovery period. The energy resolution is defined as the full signal width at half height. The recovery period or dead time is determined by the decay rate of the process used for detection and determines the maximum possible count rate. Ionization chambers have virtually no dead times and can therefore detect high photon intensities with an energy resolution of about 3000 eV. Scintillation counters have a lower resolution and recovery periods between 1.4 (plastic scintillators) and 230 ns (NaI(Tl) scintillator). Solid-state detectors are characterized by a very high energy resolution of 150–400 eV with very short recovery periods. Their maximum count rate is the lowest of the three types, because the semiconductor material used is damaged by high photon fluxes.[22]

EXAFS measurements require an X-ray source which provides a continuous spectrum. The most suitable source is synchrotron radiation, but the bremsstrahlung of conventional X-ray sources can be employed as well.[23–25] In this case, the intensity is lower by a factor of 10^3.[26] This can be partly compensated by the use of focusing X-ray optics and rotating anodes. The experimental effort and financial outlay are enormous, however, and the quality of the obtained spectra is much lower than those obtained with synchrotron radiation. This situation might change once it is possible to better focus X-rays; preliminary experiments in this area have been performed.[27]

Which elements are suitable for an EXAFS study is determined by the spectral region of the X-ray source. If a typical range of 4–26 keV for synchrotron radiation is assumed, K-edge measurements can be used for elements from $Z = 20$ (Ca) to 47 (Ag), while the L_{III} edge can be used for elements from $Z = 51$ (Sb) to 92 (U). Due to the overlap with L_{II} spectra, elements 51 (Sb) to 59 (Pr) are only partially suitable for measurements using the L_{III} edge. Only starting with Nd is there an energy gap of 514 eV between the L_{III} and L_{II} absorption edges and an EXAFS function with a k range of 10 $Å^{-1}$ can be obtained. This leaves a gap between Ag and Nd, which contains important elements such as Sn, Sb, and I. These elements might become accessible for K-edge measurements if it were possible to extend the spectral range of synchrotron radiation to 50 keV. For elements lighter than calcium it is necessary to employ soft X-rays and high-vacuum techniques. This strongly limits the study of liquid samples.

3. Data Analysis

While the measurement of the X-ray absorption coefficient appears to be simple in principle, this is definitely not the case for the data analysis—shown schematically in Figure 7. Extensive discussions of the analysis can be found in references [8, 28]. A few examples shall suffice here to illustrate the main problems. As can be gleaned from Equation (b), the modulation of the X-ray absorption coefficient is normalized for the background absorption $\mu_0(E)$. There is no exact theoretical expression for $\mu_0(E)$, which must therefore be determined empirically. A number of procedures for this are discussed in the literature, for instance the approximation by a polynomial or a spline function.[8] Even though there are criteria for the choice of background, the determination of $\mu_0(E)$ is a critical aspect. The EXAFS oscillations can be dampened too much if $\mu_0(E)$ matches the experimental data too closely. The exact position of E_0—not to be confused with its absolute value—is also not known because E_0 depends on the chemical environment of the absorbing atom. E_0 is necessary (cf. Eq. (c)) for the conversion of the energy E to the magnitude of the wave vector k. These difficulties can be surmounted when model compounds are available for the data analysis.

4. Applications of EXAFS Spectroscopy

Since the nearly coincident development of powerful X-ray sources in the form of synchrotron radiation and the theoretical

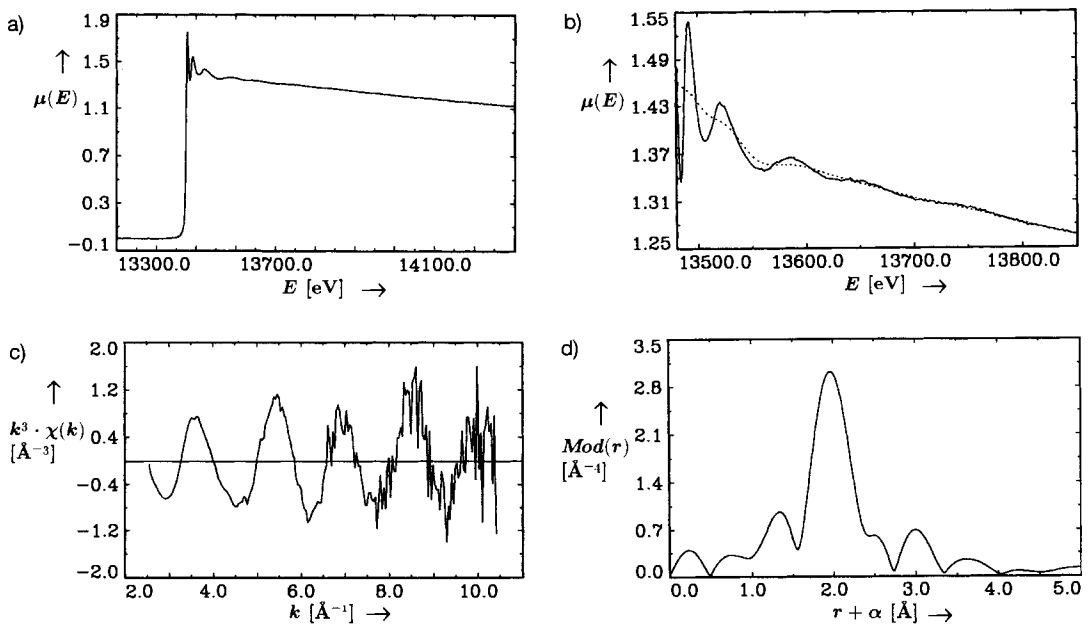

Fig. 7. a) Absorption spectrum $\mu(E)$ after edge correction and removal of pre-edge absorption; b) absorption spectrum $\mu(E)$ (solid line) and background $\mu_0(E)$ (dotted line); c) k^3-weighted EXAFS function and d) modulo function Mod(r) of the Fourier transformed $k^3\chi(k)$ function for methylmagnesium bromide in diethyl ether.

advances in the interpretation of EXAFS spectra, EXAFS spectroscopy has been employed for the study of a variety of very different systems. A Chemical Abstracts literature search for the period up to and including 1992 using the term EXAFS yielded 3423 references. Most of them refer to the study of crystalline systems, for which such powerful methods as X-ray or neutron diffraction are available for structural characterization. In these cases, EXAFS only served to verify the results of conventional methods, or at best to supplement those results. Work of this type will not be discussed in this review. The discussion here will be limited to studies which use the specific advantages of EXAFS, that is, the selective determination of structures in noncrystalline systems. In spite of this limitation, it is impossible to present a complete review. This article deliberately uses representative, not necessarily current examples to demonstrate how EXAFS spectroscopy can be utilized and what kind of limitations are encountered.

4.1. Amorphous Solids

4.1.1. Amorphous Metals and Nonmetals

Atomic systems such as amorphous selenium or germanium are the simplest chemical systems with respect to chemical composition. The determination of local order in these compounds is very important for the understanding of their physical properties and is very amenable to EXAFS studies. These measurements yield coordination numbers, distances to nearest neighbors, and the Debye–Waller term $e^{-2k^2\sigma^2}$. These quantities can then be compared with their analogues in the crystalline phase. The term $e^{-2k^2\sigma^2}$ contains static and dynamic contributions stemming from the static disorder and thermal vibrations, respectively. With increasing temperature, the thermal vibrations of the atoms around their equilibrium positions can become anharmonic and the distribution of atoms becomes asymmetric. Careful variable-temperature EXAFS measurements can yield information about this phenomenon. For amorphous Ge[29] it was found that the short-range local order is not different from the crystalline phase and that the atom distribution is symmetric. The covalent bonds between Ge atoms appear to maintain much of the local order. EXAFS measurements on amorphous Se below and above the glass transition temperature yield a coordination number of 2.[30] This indicates that the atomic arrangement of the Se atoms as chains or Se_8 rings remains intact.

The variation of another thermodynamic variable, namely pressure, is much more difficult to achieve. There is one report[31] that describes studies of amorphous germanium under pressure. The reason behind this study was the observation that amorphous Ge is a semiconductor at ambient pressure, while it shows metallic properties at 6 GPa. Figure 8 shows the Fourier transformed EXAFS functions of amorphous Ge at pressures of 0.0 and 8.9 GPa and, for comparison, of crystalline germanium. In contrast to the EXAFS function of the crystalline phase, the amorphous sample does not show any higher coordination shells. No phase transition from amorphous to crystalline was observed for this sample. It is interesting to note how the pres-

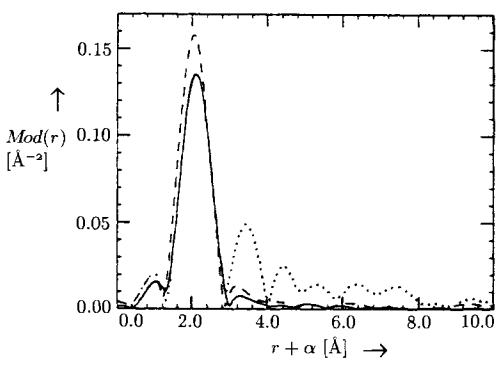

Fig. 8. Modulo function of the Fourier transformed $k\chi(k)$ function (Ge–K absorption edge, $k = 4.0$–10.0 Å^{-1}, multiplied by a Gaussian window function) of amorphous germanium at 0.0 GPa (solid line) and 8.9 GPa (dashed line), as well as of crystalline germanium at 0.0 GPa (dotted line) [31].

sure in the sample was measured. A careful analysis of the pressure dependence of the EXAFS spectrum of a copper foil showed that the variation in nearest neighbor distances and the Debye–Waller factors allow an estimation of the pressure to within 0.2 GPa.[32] For the Ge experiment, a copper foil was measured together with the sample permitting the pressure to be determined.

4.1.2. Amorphous Alloys and Binary Systems

For the systems discussed so far, it was sufficient to use an atomic pair distribution function $g(r)$, which gives a measure of the probability of finding another atom at distance r. For multiatom systems consisting of m atoms, a set of $m \times (m+1)/2$ functions $g_{\alpha\beta}(r)$ is required, which indicate the probability of finding an atom of type β at a distance r from an atom of type α. If standard X-ray or neutron diffraction methods are used to determine the structure, $m \times (m+1)/2$ independent experiments are necessary. In spite of isotopic substitution techniques for neutron diffraction—which are also limited by the small number of suitable isotopes—and the exploitation of anomalous dispersion effects for X-ray diffraction, the determination of the complete set of atomic pair distribution functions is possible only in exceptional cases and only for simple systems. Cases like this are especially suited for EXAFS spectroscopy, as only the environment of the absorbing atom can contribute to the structure function, which reduces the number of atom pair correlation functions to m. It should not be overlooked, however, that because of the finite lifetime of the photoelectron the detectable correlations between atoms are significantly shorter in EXAFS spectroscopy than in the diffraction methods.

The study of amorphous $Ni_{64}Zr_{36}$ serves as an example for the comparison of EXAFS results with those from neutron diffraction experiments.[33] This system allows EXAFS measurements on the K edge of Ni and Zr. The structure functions show only one peak and are consistent with the neutron data if an asymmetric distribution is assumed. The fact that conventional diffraction methods are superior to EXAFS spectroscopy for the determination of long-range correlations can be shown by using a study of amorphous $Ga_{48}As_{52}$.[34] The atom pair distributions determined from anomalous X-ray diffraction show correlations up to distances of 6 Å, while the EXAFS spectra exhibit only one maximum, and do not show any indications of the higher order.[35]

On the other hand, EXAFS spectroscopy has great advantages in cases where minute changes in the first coordination shell are to be detected, for instance for the study of homo- versus hetero-association in binary systems. Fe–K-edge measurements of amorphous $Fe_{0.30}Y_{0.70}$ indicated the tendency of iron atoms to form Fe clusters which are imbedded in an amorphous matrix of yttrium atoms.[36] Amorphous $Cu_{24}Zr_{76}$ supposedly also contains Cu clusters, since fewer Cu–Zr and more Cu–Cu pairs were found than were expected on purely statistical grounds.[37] EXAFS measurements of the As and Se edges indicate that amorphous As_2Se_3 behaves in a similar fashion.[38] The authors of that study differentiate between As–Se and As–As pairs; it is important to recall, however, that it is difficult for EXAFS spectroscopy to distinguish between neighboring elements in the periodic table. In another study that examined the As_xSe_{1-x} ($0.20 \leq x \leq 0.57$) system,[39] the authors admit that EXAFS spectroscopy is definitely not accurate enough to determine the exact ratio of hetero- to homoatomic bonds in As_xSe_{1-x}. For amorphous III/V compounds, the appearance of bonds between the same elements is the dominant defect type, which also strongly effects the electronic properties. Measurements of amorphous InP[40] showed that about one third of all bonds occur between chemically identical elements, indicating that the system is partially chemically disordered.

More of a curiosity is the EXAFS study of alloy formation by mechanical grinding.[41] In agreement with other X-ray studies, the Fe–K-edge EXAFS spectra of a mixture of 75 atom% Fe and 25 atom% C indicate the partial destruction of the crystalline phase and the formation of an amorphous phase which has a short-range order identical to that of cementite Fe_3C.

Light-induced changes in the short-range order can also be studied by EXAFS spectroscopy.[42–44] The effects are very small, however, and are of the same magnitude as measurement uncertainties. For $GeSe_2$,[42] a change in the coordination number upon irradiation has been postulated, while for $As_{50}Se_{50}$ films no structural changes within the first coordination shell could be detected.[44]

4.1.3. Structural Changes upon Crystallization

The previously mentioned sensitivity of EXAFS spectroscopy to changes in the immediate surroundings of the absorbing atom can be employed to determine the crystallization behavior of amorphous samples.[45–47] The studies of thulium/chromium/aluminum oxyhydroxides are an especially instructive example.[48] The samples were prepared by the stoichiometric precipitation of the oxyhydroxides, heating to a certain temperature, and subsequent cooling.

The EXAFS spectra, measured on the L_{III} edge of Tm, and their Fourier transforms are shown in Figure 9. In the vicinity of

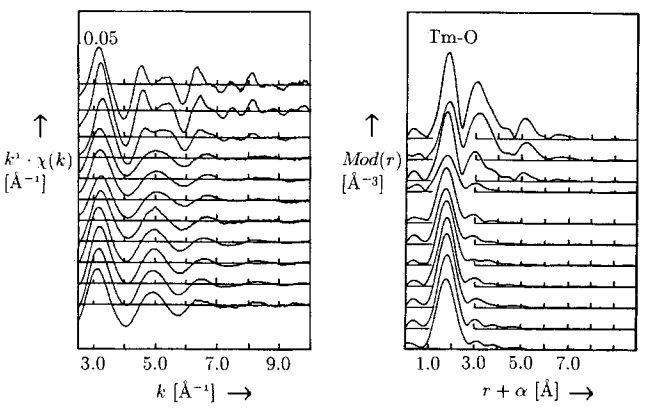

Fig. 9. k-weighted EXAFS functions (left; Tm-L_{III} absorption edge) and modulo functions of the Fourier transformed $k^2\chi(k)$ functions (right) (k = 2.0–9.0 Å, multiplied by Kaiser-Bessel window functions) of 3Tm/2Cr/3Al/xO at the temperatures 1180, 845, 817, 750, 650, 555, 460, 365, 270, 175, and 60 °C (from top to bottom) [48].

the crystallization temperature, the structure functions show the existence of further coordination shells. A definite jump in the Tm–O bond length and a less well-defined change in the coordi-

nation number are observed as well. These data are interpreted to mean that initially Tm(O)OH releases water, forming Tm_2O_3, and then spontaneously reacts at the crystallization temperature to give $Tm_3Cr_2Al_3O_{12}$. During this process, the coordination number of Tm initially decreases from eight to six, and then rises back to eight again.

4.1.4. Structural Changes Induced by Chemical Reactions

EXAFS spectroscopy is also used to determine structural changes that are brought about by chemical reactions. An example is the study of the reaction of amorphous MoS_3 with lithium. This reaction leads to amorphous compounds of the composition Li_xMoS_3 ($0 \leq x \leq 4$).[49] The Fourier transforms of the Mo–K-edge EXAFS spectra of MoS_3, $LiMoS_3$, Li_2MoS_3, Li_3MoS_3, and Li_4MoS_3 are shown in Figure 10. The structure function of MoS_3 shows two maxima. The one at 1.9 Å is assigned to Mo–S, the one at 2.4 Å to a Mo–Mo distance. These assignments are consistent with the results from other X-ray studies on binuclear Mo compounds, once the phase shift is taken into account. The reaction of MoS_3 with lithium leads to a decrease in the maximum assigned to the Mo–Mo distance until the composition Li_2MoS_3 is reached. At higher Li concentrations, a dramatic increase of this peak is observed, which has been interpreted by the authors as a significant structural change involving the formation of Mo clusters.

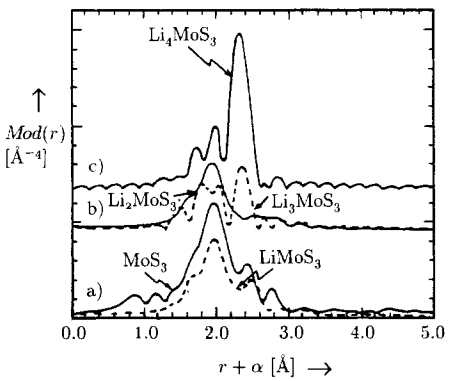

Fig. 10. Modulo function of the Fourier transformed $k^3\chi(k)$ function (Mo–K absorption edge, $k = 4.0$–18.0 Å^{-1}) of untreated MoS_3 (a, solid line), $LiMoS_3$ (a, dashed line), Li_2MoS_3 (b, solid line), Li_3MoS_3 (b, dashed line), and Li_4MoS_3 (c, solid line) [49].

4.1.5. Liquid Crystals

EXAFS spectroscopy can also contribute to the structural elucidation of liquid crystals.[50] In these studies, the short-range order in the liquid phase is compared with that in the crystal. It was shown that in the case of the Cu salts of fatty acids with 6, 12, 18, and 22 C atoms, the crystalline and mesophases have the same short-range order.

4.2. Liquids

X-ray and neutron diffraction methods have been used to study the structure of liquids for about 60 and 30 years, respectively. As has been mentioned in section 4.1.2., diffraction methods have the disadvantage that they can only provide a weighted sum of all atom pair distribution functions, with the scattering ability of each atom pair acting as the weighting factor. The selective determination of the short-range order around specific atom types is only rarely possible—and only then when associated with isotopic substitution methods which require a great deal of effort. This type of study lends itself to EXAFS spectroscopy. The first EXAFS study on a liquid system was published in 1975,[51] but the majority of EXAFS studies of this kind have taken place since 1978.

4.2.1. Solutions of Ionic Compounds

For solutions of salts with concentrations less than 0.1 M it is fairly difficult to employ diffraction methods to determine the structure of the hydration shell because the majority of the scattering is due to solvent molecules. The use of EXAFS spectroscopy is an obvious choice and the first EXAFS studies on solutions of ionic compounds were indeed performed in the mentioned concentration range. The primary goal was to determine the distances of the water molecules of hydration to the cations and anions of the dissolved salts (Table 1). Most subsequent studies dealt with concentrated aqueous solutions of 1:1 and 1:2 electrolytes; mostly halides of Ni, Cu, and Zn were examined. It was postulated that these salts possess a direct metal–halogen bond in addition to the metal–water coordination. There were also indications of cation–cation interactions similar to those found in the corresponding crystalline salts (Table 2).

Table 1. Distances d between cations/anions in dilute solutions of salts and the oxygen atom of the water molecules in the first hydration shell. c = concentration.

Compound	c [mol L^{-1}]		d [Å]	Ref.
$CuBr_2$	0.1	Cu-O	1.97 ± 0.08	[51]
		Br-O	3.14 ± 0.10	[51]
$Ni(NO_3)_2 \cdot 6(H_2O)$	0.1	Ni-O	2.05	[52]
$Ni(NO_3)_2 \cdot 6(H_2O)$	0.1	Ni-O	2.06 ± 0.01	[53]
$Co(NO_3)_2 \cdot 6(H_2O)$	0.1	Co-O	2.08 ± 0.01	[53]
$Cr(NO_3)_3 \cdot 6(H_2O)$	0.1	Cr-O	2.01 ± 0.01	[53]

The measurements were soon extended to more complex solutions of ionic compounds and mixtures of different electrolytes in water. For example, in saturated aqueous mixtures of $ZnCl_2$ and LiCl or $CaCl_2$ it was postulated that there are partially linked, tetrahedral $[ZnCl_4]^{2-}$ units with Zn–Cl distances of 2.24 ± 0.01 Å (LiCl) and 2.25 ± 0.01 Å ($CaCl_2$).[60] The observation that Zn–O backscatterers are also present at 1.89 ± 0.05 Å (LiCl) and 1.92 ± 0.08 Å ($CaCl_2$) led the authors to the conclusion that a partial substitution of Cl in the tetrahedral $[ZnCl_4]^{2-}$ units by H_2O had taken place. The EXAFS measurements on the environment of the Ca^{2+} ions yielded an octahedral solvation by water molecules with a Ca–O distance of 2.45 Å. No metal–halogen association was observed. In the case of mixtures of $CoCl_2$ and $NiCl_2$ in water (0.5 M, enriched in Cl^- by addition of HCl gas), both cations were found to have

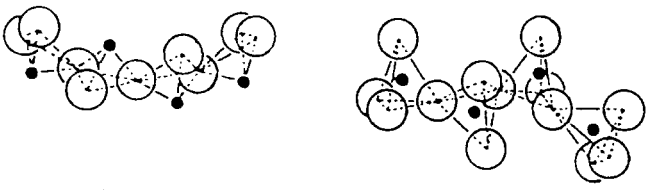

Fig. 11. Models for the local structure of $CdBr_2$ in aqueous solutions. Left: chains of $CdBr_3^-$ pyramids, right: chains of $CdBr_4^{2-}$ tetrahedra [61]. White spheres = Br^-, black spheres = Cd^{2+} ions.

metal–halogen bonds. The tendency for the formation of chloro complexes was higher for the Co^{2+} ions than for Ni^{2+} ions.[62]

Examples for studies of nonaqueous electrolyte solutions can be found in a report about copper halides in dimethylsulfoxide, acetonitrile, pyridine, and water,[63] as well as in pyridine/water mixtures.[64] The determination of the environment of the Ag^+ ions in the N-donor solvents ammonia, pyridine, and acetonitrile[65] also falls into this category. The comparison of EXAFS spectroscopic results of $[UO_2([18]crown-6)](ClO_4)_2$ in the solid state and dissolved in acetonitrile indicated that in solution only two thirds of the UO_2^{2+} ions are present as crown ether complexes, while the remaining UO_2^{2+} ions are coordinated by the acetonitrile solvent molecules. The solvent is apparently capable of removing the UO_2^{2+} ions from the crown ether environment.[66]

4.2.2. *Solutions of Grignard Reagents and of Chloro Complexes*

Upon close examination, it turns out that the majority of EXAFS studies on solutions can be attributed to the field of homogeneous catalysis. This leaves only very few studies that deal with conventional solutions. This group is meant to encompass systems that cannot be classified as solutions of ionic compounds or as belonging to the field of homogeneous catalysis. An example is the study of the structure of Grignard compounds in solution.[67, 68] In spite of their importance in preparative chemistry, their structures in solution had remained uncertain[69] and there have been intense controversies about their correct description. Even though there had been many studies of Grignard compounds, there was basically no information about intra- and intermolecular distances in these reagents in solutions. By using Br–K-edge EXAFS measurements for methyl-, ethyl-, and phenylmagnesium bromide in diethyl ether (3.12 M, 3.04 M, 2.96 M, respectively) and for vinylmagnesium bromide in tetrahydrofuran (1.56 M), it was possible to show that the Grignard compounds methyl-, ethyl-, and phenylmagnesium bromide are present in diethyl ether in the form of tetrahedral monomers as well as octahedral dimers. The amount of dimeric species was 60 ± 7%, 62 ± 8%, and 33 ± 9% for the three compounds. These systems can be described by equilibrium (g). In the case of methyl- and ethylmagnesium bromide, the

$$2\,RMgBr(Et_2O)_2 + 2\,Et_2O \rightleftharpoons RMg(Et_2O)_3Br_2(Et_2O)_3MgR \qquad (g)$$

equilibrium lies more on the right, while for phenylmagnesium bromide it lies more on the side of the monomers. In tetrahydrofuran, vinylmagnesium bromide forms octahedral monomers. No indications for associative tendencies were found. These results are summarized, together with the distances determined by EXAFS spectroscopy, in Figure 12.

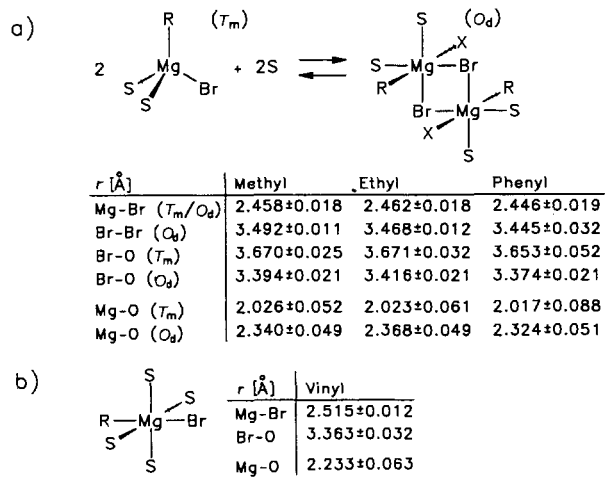

Fig. 12. Equilibrium and structural models for the Grignard compounds a) methyl-, ethyl-, and phenylmagnesium bromide in diethyl ether (3.12, 3.04, 2.96 M; dimer content (O_d) 60±7, 62±8, 33±9%, respectively; distance r[Å]; R = Me, Et, Ph, S = Et_2O, X = Me, Et, Ph, Et_2O) and b) for vinylmagnesium bromide in THF (1.56 M; distance r[Å]; R = vinyl, S = THF) [68].

A study that falls into the conventional solution category dealt with the structure of $[MeEtim]_2[MCl_4]$ ([MeEtim]$^+$ = 1-methyl-3-ethylimidazolium; M = Mn, Co, Ni) in the ionic liquid [MeEtim]-Cl-$(AlCl_3)_x$.[70] The chemical and physical properties of these solutions are primarily determined by the amount x of $AlCl_3$. Liquids with a content of more than 50 mol% $AlCl_3$ are classified as acidic, those with less as basic. For the basic

solutions, a fourfold coordination of the metal center (M = Mn, Co, Ni) by Cl^- ions was found (Mn–Cl = 2.38, Co–Cl = 2.27, Ni–Cl = 2.25 Å), indicating the presence of species of the type $[MCl_4]^{2-}$ in solution. In acidic solutions, however, the immediate environment of the metal atom contains six Cl atoms at very different distances (Mn–Cl = 2.54, Co–Cl = 2.44, Ni–Cl = 2.38) as well as three Al atoms (Mn–Al = 3.33, Co–Al = 3.24, Ni–Al = 3.19 Å). This clearly suggests the presence of complexes of the type $[M(AlCl_4)_3]^-$. The $[AlCl_4]^-$ ligand is bound to the metal center in a bidentate fashion and there appears to be no evidence, in contrast to earlier assumptions, for the chelate-type binding of $[Al_2Cl_7]^-$ species.

4.2.3. *Metal and Semimetal Melts*

The first studies on metal melts were performed to investigate asymmetry effects during the analysis of EXAFS functions. E. D. Crozier and A. J. Seary, for example, studied solid and molten zinc in a temperature range of 273 to 782 K.[71] It turned out that the distribution of the nearest backscatterers is asymmetric at high temperatures. When this asymmetry is neglected and the analysis is performed by using a symmetric distribution function (Debye model), errors occur in the determination of the absorber–backscatterer distance r and the Debye–Waller factor σ. The use of an anharmonic oscillator model, on the other hand, leads to more reliable values for r and σ, with the Debye–Waller factor being about 20% higher than for the symmetric distribution.

Variable temperature studies of crystalline orthorhombic α-gallium, metastable monoclinic β-gallium, and liquid gallium showed that there are very similar short-range orders in the liquid and the crystalline β-structure.[72] The Ga–Ga distances in the first coordination shell are 2.44 and 2.68 Å for the α- and β-forms, respectively. Measurements on tin in a temperature range of 50 to 291 °C were performed to observe structural changes in the immediate vicinity of the Sn atom during the solid–liquid phase transition.[73] The analysis of the EXAFS function, taking asymmetry effects into account, indicated that during the phase transition, the distances increase, but the coordination geometry of the solid state is maintained (four short and two long Sn–Sn distances, Table 3).

Table 3. Sn–Sn distances in the first and second coordination spheres in the element tin at different temperatures (N = coordination number of the Sn atoms) [73].

T [°C]	$r_{Sn-Sn(1)}$ [Å] ($N = 4$)	$r_{Sn-Sn(2)}$ [Å] ($N = 2$)	T [°C]	$r_{Sn-Sn(1)}$ [Å] ($N = 4$)	$r_{Sn-Sn(2)}$ [Å] ($N = 2$)
50	2.997	3.170	232 [a]		
100	2.985	3.156	248	2.974	3.190
150	2.986	3.188	291	3.019	3.282
200	2.978	3.178			

[a] melting point.

An EXAFS study by K. Tamura et al. dealt with Se, Te, and Se–Te mixtures in various phases.[74] Figure 13a shows the Fourier transformed EXAFS functions of crystalline, liquid, and gaseous Se at different temperatures. It is apparent that the intensity of the maximum for the shortest Se–Se bond within a Se_x chain decreases with increasing temperature. An especially strong bond contraction can be observed during the transition to the gaseous phase. At 80 K, it is possible to determine the shortest interchain Se–Se distance (3.38 Å) and the distance to the next-nearest neighbor within a chain (3.73 Å). These values are in good agreement with those obtained from other X-ray studies (3.436 and 3.716 Å, respectively). The authors assume the lack of the maxima for these distances at higher temperatures is due to the greater static and thermal disorder (chain rotation around the Se–Se bonds).

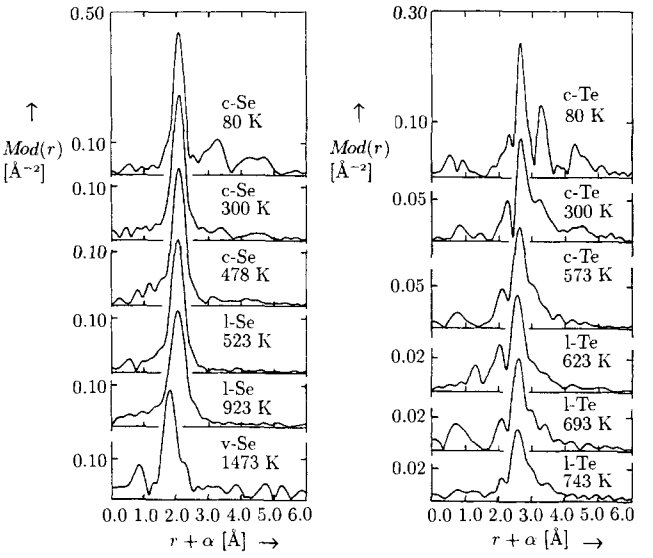

Fig. 13. k-weighted Fourier transformed EXAFS function of crystalline (c-Se), liquid (l-Se), and gaseous (v-Se) selenium (left) and crystalline (c-Te), as well as liquid (l-Te) tellurium (right) at different temperatures [74].

Figure 13b shows the corresponding EXAFS functions of crystalline and liquid tellurium. At first glance, the situation with Te appears to be similar to that found for Se. For crystalline tellurium, the shortest intrachain Te–Te distance at 80 K is found to be 2.84 Å, which is in excellent agreement with the value of 2.835 Å determined by crystallography. The peaks of the structure function at 3.3 and 4.4 Å can be assigned to interchain distances. The next-nearest intrachain distance also contributes to the peak at 4.4 Å. As was found for selenium, at higher temperature these distances can no longer be detected. In the liquid phase of Te, however, two distances are observed, 2.8 and 3.0 Å, while solid Te only showed one distance in that range at 2.84 Å. The authors' explanation for this lies in a chain structure with alternating longer and shorter Te–Te distances. This phenomenon is assumed to be caused by a weakening of the bond by the free electron pairs of neighboring chains (Fig. 14). These results do not support conclusions about a possible threefold coordination of Te atoms, which would result in an As-like pyramidal geometry. This had been postulated by many authors for liquid Te. The investigation of liquid Se–Te mixtures ($Se_{80}Te_{20}$, $Se_{50}Te_{50}$, $Se_{30}Te_{70}$, and $Se_{20}Te_{80}$) was performed by using EXAFS spectra from both absorption edges. The Se–Se distance was found to increase in these compounds with increasing Te content. In addition, the number of longer Te–Te bonds within a chain increases with increasing temperature and Te

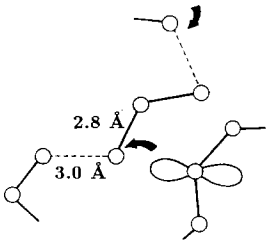

Fig. 14. Schematic structural model for liquid Te, consisting of Te_x chain molecules with shorter and longer bonds. The charge transfer of the lone pair in the neighboring Te_x chain affects a weakening of the covalent bond [74].

content. The authors interpret this as an indication for a semiconductor–metal phase transition.

4.2.4. Salt Melts

There are only a few EXAFS investigations of salt melts, probably due to the amount experimental effort involved. J. Wong and F. W. Lytle studied vitreous and liquid $ZnCl_2$ (melting point 593 K) in the temperature ranges of 120 to 573 K and 603 to 673 K, respectively.[75] Crystalline α-$ZnCl_2$ was used as model compound. It was found that in both the liquid and vitreous phases, the Zn^{2+} ion was surrounded by 5.1 ± 0.8 Cl^- ions at a distance of 2.34 ± 0.01 Å. This is more in accordance with the molecular dynamics calculations of L. V. Woodstock et al. ($N_{Cl} = 4.7$)[76] than with X-ray diffraction results obtained by M. Imoaka et al. ($N_{Cl} = 4.0$).[77] Based on the Debye–Waller factors obtained at different temperatures it appears that the motion of the Zn^{2+} ions is decoupled from their nearest Cl^- neighbors. This effect is especially strong below the glass transition temperature of 375 K. In contrast, EXAFS measurements of vitreous GeO_2 (temperature range 128 to 848 K), which were performed for comparison purposes, indicate strong coupling between the motion of the Ge atoms and the four closest oxygen atoms.

In order to study the salt–metal transition, the two systems RbBr and $Rb_{0.8}(RbBr)_{0.2}$ were examined at 700 °C at the Br–K absorption edge.[78] The coordination number of Rb was calibrated by measuring the EXAFS spectrum of crystalline RbBr at 20 °C. The most important result of this work was that the Rb coordination number decreases from six for liquid RbBr to four in $Rb_{0.8}(RbBr)_{0.2}$.

4.2.5. Molecular Liquids

In 1987, B. X. Yang and J. Kirz performed the first and so far only EXAFS study of liquid water,[79] by using the O–K absorption edge. Due to the low energy of the X-rays employed (500 to 1000 eV), this type of experiment is very laborious and data analysis is difficult. A comparison of the Fourier transformed EXAFS function with atom pair correlation functions $g_{OO}(r)$ and $g_{OH}(r)$ obtained by combining X-ray, neutron, and electron diffraction data of heavy water[80, 81] is shown in Figure 15. The maximum at 2.6 Å can definitively be assigned to an O–O absorber–backscatterer pair. Of interest is the peak at 1.0 Å, which, based on comparison with the $g_{OH}(r)$ function, is assigned by the authors to an H backscatterer rather than an artifact stemming from an incorrect background correction. Usually, H atoms are not observable in EXAFS spectra due to their low backscattering ability (only one electron). The authors note that the backscattering amplitude and phase of the oxygen atom is strongly modified by the H atoms located between the absorbing O atom and the backscattering O atom.

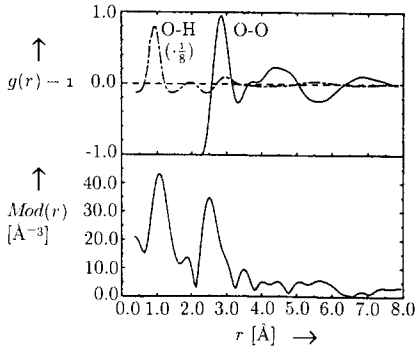

Fig. 15. Top: Atom pair correlation functions (solid line $g_{OO}(r)-1$, dashed/dotted line $(g_{OH}(r)-1)/8$) of D_2O [80,81]. Bottom: k^2-weighted Fourier transformed EXAFS functions of H_2O [79].

The EXAFS study of liquid bromobenzene exemplifies the detailed information that can be obtained through a combination of EXAFS spectroscopy and X-ray and neutron diffraction.[82] The analysis of the EXAFS spectrum indicates a strong interaction between Br atoms and a second one between Br atoms and the aromatic π electron system. It was, however, impossible to unambiguously deduce the relative orientation of the bromobenzene molecules from the observed distances and coordination numbers. This proved possible when using X-ray and neutron diffraction. Figure 16 shows the model for the short-range order in liquid bromobenzene, which is consistent with the results from EXAFS spectroscopy and X-ray and neutron diffraction methods.

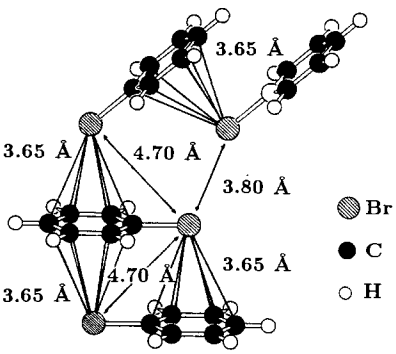

Fig. 16. Three-dimensional structural model for liquid bromobenzene, based on results from EXAFS spectroscopy, and X-ray and neutron diffraction techniques [82].

4.3. Catalysis

The examination of catalysts is one of the main applications of EXAFS spectroscopy. The growing number of available synchrotron sources has over the years led to an enormous increase in the number of publications on this topic. Apart from a number of review articles,[83–85] the biannual reports of the International Conference on X-ray Absorption Fine Structure (EXAFS

and XANES) (since 1986) give an excellent overview of the various applications of EXAFS spectroscopy for catalyst research.[86-88] Since a more thorough discussion of surface studies would go beyond the scope of this article, the reader is referred to two good reviews in the literature.[89, 90]

4.3.1. Heterogeneous Catalysis

The vast majority of all EXAFS studies deals with heterogeneous catalytic systems. In general, heterogeneous catalysts consist of porous oxides, for instance aluminum oxide or silicone oxide, with very large specific surface areas on which extremely finely divided clusters of active metals are adsorbed or chemically bound. The carrier materials are usually loaded with approximately one weight percent of metal. This very low degree of loading, together with the interference from the carrier material, makes the application of conventional spectroscopic methods for the investigation of catalytically active species very difficult. On the other hand, the element specificity and high sensitivity of EXAFS spectroscopy make it comparatively easy to gain information about the environment of the metal atoms.

The properties of catalysts consisting of small metal clusters are critically dependent on the degree of dispersion of the metal.[91, 92] The degree of dispersion is defined as the ratio of metal atoms on the surface to the total number of metal atoms in the cluster. It is typically greater than 0.5, corresponding to a particle size of about 20 Å and a total number of less than 100 atoms per cluster. G. H. Via et al. have studied finely divided osmium, iridium, and platinum clusters on SiO_2 and Al_2O_3 to obtain information about the degree of dispersion, morphology, and size of these metal clusters.[93] The comparison of the EXAFS spectra of the finely divided metal catalysts with those of the pure metals showed that the oscillations of the EXAFS functions are significantly weaker for the catalysts than for the pure metals. In the metal clusters of the catalyst, the metal–metal distances are reduced, the Debye–Waller factor is increased, and the coordination number of the metal centers with respect to the metal–metal bonds (metal–metal coordination number) is decreased (Table 4). The coordination numbers here are clearly averages, as metal atoms can occupy different positions in the cluster (in the interior, on edges, or at corners). In addition, chemisorption studies yielded degrees of dispersion between 0.7 and 1.0. Using the very simplified assumption of cubic clusters (fcc structure), this degree of dispersion led to an average cluster size of 8–15 Å and a corresponding average coordination number of 5–9, in good agreement with the coordination numbers of 7–10 determined by EXAFS spectroscopy (Table 4).

Table 4. Structural parameters (metal–metal distances r, coordination numbers N, Debye–Waller factors σ) for finely divided Os, Ir, and Pt clusters on SiO_2 and Al_2O_3 [93]. The corresponding values for the pure metal are given in parentheses.

Metal	Carrier	r [Å]	N	δ [Å]
Os	SiO_2	2.702 (2.705)	8.3 (12)	0.054 (0.027)
Ir	SiO_2	2.712 (2.714)	9.9 (12)	0.060 (0.030)
Ir	Al_2O_3	2.704 (2.714)	9.9 (12)	0.061 (0.030)
Pt	SiO_2	2.774 (2.775)	8.0 (12)	0.061 (0.044)
Pt	Al_2O_3	2.758 (2.775)	7.2 (12)	0.075 (0.044)

Further similar EXAFS studies by R. B. Gregor and F. W. Lytle, which tested structural models for metal clusters, indicated disc-like structures for osmium clusters, cubic structures for copper, ruthenium, and iridium clusters, while platinum showed different cluster shapes which depended on the preparative conditions.[94] Based on EXAFS results, J. H. Sinfelt et al. reported that the determinations of the degree of dispersion using chemisorption techniques have only limited validity.[95]

The "life cycle" of a metal catalyst can be characterized by three stages: preparation, stationary state and aging, and regeneration. The preparation phase can also be divided into these three steps: impregnation of the carrier material (for instance with isolated complex ions on the oxide surface), drying and annealing (calcination) (removal of water and ionic components stemming from preceding steps), and reduction with hydrogen.

The separate steps of the preparation phase have been studied especially intensively. A nice example is the EXAFS study of a Pd/Al_2O_3 catalyst.[96] Palladium acetylacetonate was used as precursor and deposited onto Al_2O_3 as carrier, followed by drying at 100 °C. The analysis of the EXAFS spectra of the pure $[Pd(acac)_2]$ solution yielded four oxygen atoms at 1.96 Å. The coordination number increases to five in the dried sample. The only possible explanation for this observation is that the metal atom becomes embedded in an octahedral coordination site on the Al_2O_3 surface with concomitant loss of an acetylacetonate moiety. During the annealing step the precursor decomposes further and loses the second acetylacetonate ligand. Annealing at temperatures of 300 to 700 °C leads to an increasing growth of the oxide phase of PdO. This is clearly observable due to the appearance of a second coordination shell (Pd–Pd distance in PdO) in the radial distribution curves of the EXAFS function. The quantitative analysis of the first coordination shell confirms the existence of 4 to 4.5 oxygen atoms with a Pd–O distance of 2.00 Å, which is nearly identical to the Pd–O distance in the structure of pure PdO.

Using palladium nitrate instead of $Pd(acac)_2$ as precursor leads to a catalyst that shows, after annealing under analogous conditions, a Pd–O amplitude that is 2/3 smaller than the one observed for the acetylacetonate sample. This indicates a higher degree of dispersion and hence catalyst activity, since these two quantities are usually correlated. This application clearly demonstrates the sensitivity of the EXAFS method, which in this case enables the development of criteria for precursor selection to target and control specific catalyst properties. It was also possible to demonstrate that with increased loading, the oxide phase becomes more completely formed.

The determination of structural differences between the reduced and nonreduced states of catalysts will be illustrated by using an investigation of a Cu/ZnO catalyst for methanol synthesis.[97] This study dealt with annealed Cu/ZnO catalysts containing different Cu/Zn ratios (10:90, 20:80, 33:67). To gain an insight into the species present, the structural parameters of the model compounds Cu, CuO, Cu_2O, and ZnO were also measured (Table 5). A comparison of the results of the EXAFS analysis of the annealed Cu/ZnO catalysts (Table 6) with those of the model compounds indicates that based on the observed

Table 5. Structural parameters (absorber–backscatterer distances r, coordination numbers N) for the model compounds for Cu/ZnO catalysts [97]. AB = absorber–backscatterer pair.

Model	AB	r [Å]	N	Model	AB	r [Å]	N
Cu (Metal)	Cu-Cu	2.56	12	Cu_2O	Cu-O	1.84	2
CuO	Cu-O	1.96	4		Cu-Cu	3.02	12
	Cu-Cu	3.00	4	ZnO	Zn-O	1.99	4
					Zn-Zn	3.22	12

Cu–O, Cu–Cu, and Cu–Zn distances, Cu^{2+} ions are present in a CuO-like phase, and also substitute Zn in the ZnO lattice. This study yielded the first positive proof of such a Cu–Zn exchange in annealed nonreduced catalysts. An analogous analysis for the reduced state showed that Cu^0 atoms are in a Cu metal-like environment, while the Cu^+ ion surroundings are Cu_2O-like (Table 6). Initially, the observed average Cu–Zn distance at

Table 6. Structural parameters (absorber–backscatterer distances r, coordination numbers N) for annealed and for reduced Cu/ZnO catalysts ($Cat_{cal.}$ and $Cat_{red.}$, respectively) [97]. AB = absorber–backscatterer pair.

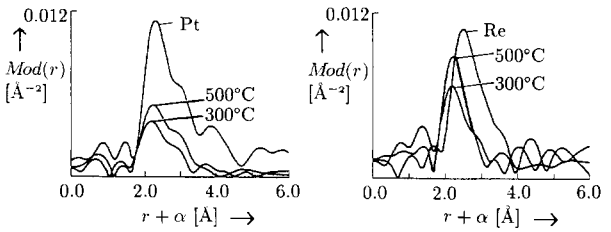
Catalyst	AB	$r_{cal.}$ ($r_{red.}$) [Å]	N ($cat_{cal.}$)
Cu/Zn (10:90)	Cu-O	1.97 (1.86)	4
	Cu-Cu	2.99 (2.53)	3
	Cu-Zn	3.22 (2.25)	10
Cu/Zn (20:80)	Cu-O	1.98 (1.80)	4
	Cu-Cu	2.99 (2.55)	4
	Cu-Zn	3.19 (2.20)	8
Cu/Zn (33:67)	Cu-O	2.00 (1.79)	4
	Cu-Cu	3.01 (2.57)	4
	Cu-Zn	3.26 (2.27)	5

2.24 ± 0.04 Å was difficult to explain. It was possible to exclude replacement of Zn lattice atoms in ZnO by Cu^+ ions, as had been observed for the nonreduced sample. The authors concluded that, in all probability, Cu^+ ions occupy interstitial locations in ZnO. This conclusion is in accordance with all EXAFS results as well as with structural considerations.

The influence of gases on the structural properties of finely divided metal clusters was studied by D. C. Kroningsberger et al.[98] Using an Ir/Al_2O_3 catalyst as example, they were able to show that removal of chemisorbed hydrogen leads to an increased disorder in the Ir clusters and to a reduction in the metal–metal distances. The adsorption of O_2 at 77 K takes place at the surface of the iridium particles. The Ir–O(adsorbed) bonds are of the same type as the bonds of Ir atoms to the O atoms of the carrier material after hydrogen removal. Increasing the temperature to 100 K leads to significant changes in the EXAFS spectrum. It is possible to demonstrate a second, shorter Ir–O distance and a decrease in the Ir–Ir coordination number. This indicates the beginning of the oxidation of the Ir clusters.

In addition to heterogeneous catalysts containing only one type of metal, heterodi- and -trimetallic catalysts play a crucial role, especially in the petroleum industry. EXAFS spectroscopy makes it possible to gain some interesting insights. For example, for the monometallic catalyst H_2PtCl_6 on a carrier, it was found that the drying process does not affect the structure of the $PtCl_6^{2-}$ complex and the slow formation of PtO_2 is observed first during annealing.[99] On the other hand, in a bimetallic Pt/Rh catalyst (made from chlorinated precursors) the platinum is already in a PtO_2 environment after drying. The presence of the Rh metal reduces the temperature necessary to convert H_2PtCl_6 into PtO_2 by several hundred degrees.[100] A systematic investigation using different degrees of impregnation for Pt/Rh or Pt/Re, and Cl led to the following explanation. The Al_2O_3 carrier material employed has two different binding sites: a small number of tight binding sites with Al–O bonds strong enough to resist exchange of O by Cl atoms and a larger number of weaker binding sites with Al–O bonds which permit this exchange. It was observed that an increase in the proportion of Rh or Re metal led to a decrease in the Cl coordination number of platinum and a concomitant increase in the O coordination number. Rhodium and rhenium therefore selectively bind to the sites with stronger Al–O bonds, forcing the Pt atoms to occupy the weaker binding sites.

An EXAFS study of a Pt/Re bimetallic catalyst at different temperatures indicated that the rhenium centers—in contrast to the platinum centers—are not completely reduced (Fig. 17). The



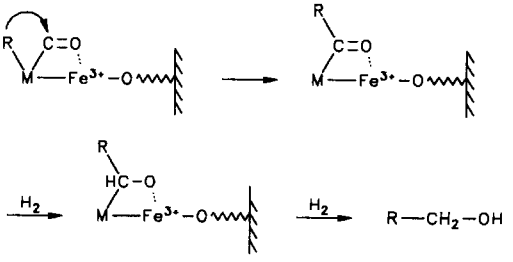


Fig. 17. Fourier transformed EXAFS functions, measured at the Pt-L_{III} (left) and Re-L_{III} (right) absorption edges, of pure platinum and rhenium, respectively, as well as those of bimetallic catalysts reduced at 300 and 500 °C [101].

Re atoms remain partially attached to the carrier by Re–O bonds and act in turn as carrier for platinum clusters.[101] A study employing a variety of analytical methods (EXAFS, FT-IR, ^{57}Fe Mössbauer, and ^{129}Xe NMR spectroscopy as well as transmission electron microscopy (TEM)), examined Rh/Fe, Pt/Fe, and Ir/Fe bimetallic catalysts on SiO_2. Based on the EXAFS data, the authors postulated M-Fe^{3+}-O bonds (M = Rh, Pt, Ir).[102] The M clusters, about 10 Å in size (^{57}Fe Mössbauer spectroscopy), are attached to the SiO_2 carrier by Fe atoms. In this case, the additional metal Fe plays an important role in determining the high activity and selectivity for the catalytic

Scheme 1. Proposed mechanism for the formation of CH_3OH and CH_3CH_2OH under the influence of Rh/Fe, Pt/Fe, and Ir/Fe bimetallic catalysts [102]. R = H, CH_3; M = Rh, Pt, Ir.

preparation of CH_3OH and CH_3CH_2OH from CO and H_2 (Fischer–Tropsch reaction). As an explanation for the role played by iron, the authors presented the mechanistic proposal shown in Scheme 1.

In addition to the analysis of the EXAFS range in the absorption spectrum, the shape of the absorption edge itself can yield valuable information about the structure of catalysts. An example can be found in the study of a SiO_2 catalyst impregnated with titanium oxide.[103] Based on the comparison of the XANES region of differently loaded catalysts with those of the anatase and rutile modifications of TiO_2, it was possible to show that only a selective formation of an anatase-like TiO_2 structure is taking place on the carrier material. The analysis of the EXAFS function of this system confirms this result.

The structure of the L_{III} absorption edge of metals like platinum and rhenium is strongly dependent on the chemical environment of the metal atoms. The reduction of a catalyst can be followed by using the changes in the XANES region. In situ studies of Pt catalysts under realistic chemical and physical conditions (temperature increase of 6 °C min^{-1}, constant H_2 flux) demonstrated that the reduction process is complete after 60 minutes (Fig. 18).[104] Energy-dispersive EXAFS studies are

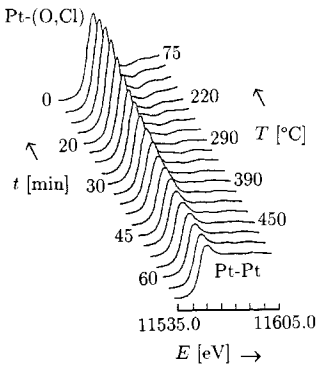

Fig. 18. Changes in the Pt–L_{III} absorption edge as a function of time and temperature, induced by in situ reduction of a 1.5 wt% monometallic platinum catalyst. The immediate coordination sphere of the Pt center consists initially of O and Cl backscatterers. After 60 minutes, the Pt–L_{III} absorption edge is nearly identical with that of pure platinum [101].

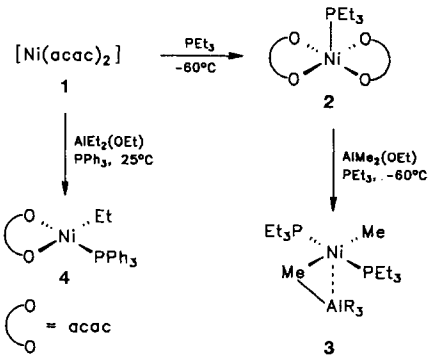
able to follow processes with much faster kinetics. Examples are studies of the activation, poisoning, and regeneration of Pt/Cu and Ir/Cu catalysts.[105, 106]



4.3.2. *Homogeneous Catalysis*

Compared to heterogeneous catalysts, homogeneous ones have the advantage that they can be reproducibly prepared and specifically tailored by variation of the ligands. EXAFS studies in this area are fairly rare and hence not as multifaceted as for heterogeneous catalysts. It is therefore possible to organize them according the catalyzed reaction type.

J. Evans et al. investigated the structure of the alkene metathesis catalyst $[(\eta\text{-}C_5H_5)_2Ti(CH_2AlMe_2)]$ in the solid state as well as in a frozen toluene solution.[107] Based on the EXAFS analysis, no significant structural differences could be observed.

The complexes $[NiX_2(PR_3)_2]$ (X = Cl, Br; R = Ph, Et) can act as precursors for alkene oligomerization and polymerization catalysts. Parameters obtained from EXAFS spectroscopy of polycrystalline samples agree within 3% with those found by X-ray structure determinations. The structure of complexes dissolved in toluene remains unchanged in this case as well.[107]

The same workers did more extensive studies on the activation of these complexes with Lewis acids, and obtained remarkable results.[108] Specifically, the $Al_2Me_3Cl_3$- and $AlEt_3$-activated oligomerization of propene by $[NiCl_2(PEt_3)_2]$ was studied. Initially, model reactions (Scheme 2) were studied by EXAFS spectroscopy to determine to what extent it is possible to gain information about the environment of the Ni atoms in similar systems (for structural parameters, see Table 7). The addition of

Scheme 2. Schematic representation of the studied model reactions, also showing simplified structural models of the complexes formed (**2**–**4**) [108]. Hacac = pentane-2,4-dione.

PEt_3 to trimeric $[Ni(acac)_2]$ (**1**) in diethyl ether leads, at −60 °C, to the disappearance of the Ni–Ni interaction. The paramagnetic pentacoordinated adduct **2** is formed in the process. Further reaction with $AlMe_2(OEt)$ at the same temperature enables the isolation of $[Ni(Me)_2(PEt_3)_2]$ after workup.[109] Even in solution, the analysis of the EXAFS spectrum yields two carbon atoms and two phosphorous atoms at distances of 1.91 and 2.12 Å, respectively, from the nickel center. In addition, a Ni–Al distance of 2.97 Å is detected. The sum of the covalent radii of Ni and Al atoms is 2.4 Å, which is considerably shorter than the observed distance. The authors proposed structure **3**, with a Ni-C-Al interaction, as a possible explanation. The EXAFS study of the preparation of $[Ni(Et)(acac)(PEt_3)]$ (**4**) (an intermediate in the alkylation reaction of the Ni center) in toluene yielded structural parameters similar to those obtained from an X-ray diffraction study of the crystalline compound.[110] These experiments clearly indicate the ease of following in situ reac-

tions and obtaining meaningful structural information about the environment of the nickel centers.

Solutions of $[NiCl_2(PEt_3)_2]$, activated by $Al_2Me_3Cl_3$ or $AlEt_3$, in *p*-fluorotoluene showed, after reaction with propene, a product distribution of 4:2:1 for the C_6:C_9:C_{12} oligomers (determined by GC-MS). The C_6 fraction was primarily composed of 2,3-dimethylbutene, 4-methylpent-1-ene, and 2-methylpent-2-ene. Activation with $ZnEt_2$ leads to face-centered cubic Ni clusters. This was unambiguously shown by EXAFS spectroscopy, which yielded Ni–Ni distances of 2.45, 4.32, 4.14, and 4.87 Å. The solution had only a very limited catalytic activity. The structural parameters (Table 8) for the $Al_2Me_3Cl_3$-activated system indicate the primary presence of complexes of type **5** (Scheme 3). Assuming the existence of a planar Ni-C-Al bridge

with terminal Cl atoms at the Al atom and using the found Ni–Al and Ni–Cl distances, the authors determined Ni-C-Al and Cl-Al-Cl bond angles of 95 and 118°, respectively. The $AlEt_3$-activated system looks somewhat different. Based on the observed Ni–C and Ni–Al coordination numbers, complexes of type **6** form the majority, while only small quantities of **5** are present. The addition of propene to the $[NiCl_2(PEt_3)_2]/AlEt_3$ solution leads to a change in the original EXAFS spectrum. The disappearance of the Ni–Cl distances and the decrease in the Ni–C distance to 1.86 Å are especially remarkable. The influence of the alkene apparently reduces the concentration of species of type **5** dramatically. Finally, it should be mentioned that this study provides the first direct evidence for a Ni-C-Al interaction in solution.

Hydrogenation catalysts have also been studied by EXAFS spectroscopy. For instance, J. Goulon et al. examined nickel and cobalt 2-ethylhexanoate in benzene before and after reduction by $AlEt_3$.[111] The observed Ni–O and Ni–C distances in solution before reduction indicate that four carboxylic acid groups are bound to the metal atom in a monodentate fashion. After the addition of $AlEt_3$, metal–metal distances are observed that are very similar to those in the pure metal, indicating the formation of amorphous, metal-like clusters. The authors note that the detected metal–carbon bonds play a significant role in the catalytic activity of these compounds. A very similar study, performed by C. Esselin et al. with nickel and iron acetylacetonates in benzene, which were reduced by $AlEt_3$ and $GaEt_3$, gave essentially identical results.[112]

The most interesting and extensive study in the area of hydrogenation catalysts has been performed by B. R. Stults et al.[113] They examined optically active rhodium complexes of the type $[Rh(P-P)L]^+X^-$ and $[Rh(P)_2L]^+X^-$ for the asymmetric hydrogenation of the prochiral alkene 2-acylamino-3-methylbut-2-enoic acid. Based on results from previous studies (using X-ray structure determinations, ^{13}C and ^{31}P NMR spectroscopy in solution, and solid-state ^{13}C NMR spectroscopy) and those of other workers, the authors had already proposed the catalytic cycle shown in Scheme 4.[114, 115] EXAFS spectroscopy was

Scheme 4. Proposed catalytic cycle for the asymmetric hydrogenation of prochiral olefins [113].

supposed to yield structural information about solution species formed under realistic reaction conditions. To achieve this goal, a number of crystallographically characterized Rh complexes was examined in solution and in the solid state (Table 9). The distances obtained agreed very well with those obtained by the crystal structure determinations. In general, it was observed that the crystalline compounds had shorter Rh–P and Rh–C distances, which the authors attributed to crystal packing forces.

The compounds $[Rh(dipamp)(cod)]^+$ and $[Rh(camp)_2(cod)]^+$ (for abbreviations see Table 9) were studied in situ in methanol after a 30-minute treatment with H_2. For the interme-

[a] diphos = bis(1,2-diphenylphosphino)ethane, dipamp = (*R*,*R*)-1,2-ethanediylbis[(*o*-methoxyphenyl)phenylphosphene], diop = (*R*,*R*)-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane, camp = (*R*)-*o*-anisylmethylcyclohexylphosphane, L = *cis*-bis(diphenylphosphino)ethylene, cod = 1,5-cyclooctadiene, amb = 2-acylamino-3-methylbut-2-enoic acid, nbd = bicyclo[2.2.1]heptadiene, Hacac = pentane-2,4-dione.

diate **8** (Scheme 4) with dipamp and camp ligands, the analysis of the EXAFS spectra yielded Rh–P distances of 2.34 and 2.35 Å and Rh–O distances (coordinated solvent) of 2.34 and 2.36 Å, respectively. The coordination number was two in all cases. After addition of 2-acylamino-3-methylbut-2-enoic acid to [Rh(dipamp)$(CH_3OH)_2$]$^+$, the following structural parameters were found for **9**: Ph–P1 = 2.36, Rh–P2 = 2.29, Rh–C = 2.26, and Rh–O = 1.86 Å. Scheme 5 shows the proposed structure of the square-planar rhodium complex, which has been confirmed by X-ray structure determinations.[116] The different Rh–P distances are attributed to the position of the P atoms *cis* or *trans* to the alkene and to the O atom. The very short Rh–O distance of 1.86 Å is remarkable when compared to the crystalline compound (2.01 Å, Table 9). The analysis of the EXAFS spectra of [Rh(camp)$_2$$(CH_3OH)_2$]$^+$ in the presence of 2-acylamino-3-methylbut-2-enoic acid was not successful; apparently a large number of different catalyst–substrate species is formed. This is due to the monodentate nature of camp, as opposed to bidentate dipamp, which leads to rapid isomerization in this case. This was also confirmed by NMR experiments.

Finally, a study of the hydroformylation catalyst Na[$(NCCH_2)Co(COOCH_3)(CO)_3$] in methanol should be mentioned here.[117] Na[$Co(CO)_4$] was used as model compound. In solution, the complex has a trigonal-bipyramidal structure, with three C atoms at a distance of 1.83 and two C atoms at a distance of 2.13 Å from the Co atom.

Scheme 5. Schematic representation of the structural model of the square-planar rhodium complex [Rh(dipamp)(amb)] in methanol, based on EXAFS results [113].

4.4. Biochemistry

To demonstrate the application of EXAFS spectroscopy to biological problems, the studies of photosystem II, blue copper proteins, superoxide dismutase, and cytochrome c oxidase will be used as examples.

4.4.1. Photosystem II

Nearly all oxygen required for the energy supply in animals and aerobic bacteria stems from the ability of plants to convert water into the life-sustaining O_2 molecule. This ability is directly linked to photosystem II (PS II). A manganese-containing enzyme complex—the so-called oxygen-evolving complex (OEC)—bound to the thylacoide membrane of chloroplasts catalyzes the oxidation of water to molecular oxygen. In this process, every reaction center in PS II acts independently and accepts, in a stepwise manner, four electrons. Using kinetic studies, it was possible to distinguish five intermediate states of the manganese complex, called S_0 to S_4, with S_0 representing the most reduced state. The stable, resting state of the OEC is the S_1 state.

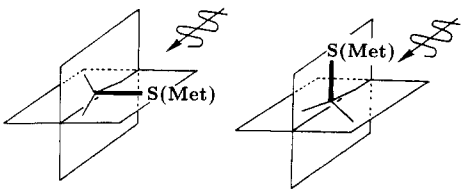
Even though it has been known since 1970 that four specifically bound manganese ions are required for OEC activity,[118] there is controversy over the structure of the cluster and the Mn oxidation states during the electron transfer reaction. In a series of studies[119–127] it was found that in the S_1 state the Mn atoms are surrounded by N or O atoms—it is difficult to distinguish between these two elements—at an average distance of 1.75 and 2.15 Å. In addition, there is a Mn–Mn distance at 2.7 Å. Based on the comparison with binuclear Mn model compounds, the short Mn–(N,O) distance was assigned to a μ-oxo bridge between two Mn centers, while the longer distance was assigned to terminal nonbridging N- and/or O-containing ligands. An additional indication for the presence of a binuclear or multinuclear cluster is the observed Mn–Mn distance of 2.7 Å. However, due to low data quality, the presence of a cluster of higher nuclearity could not be excluded. In addition, the oxidation states of the Mn centers remained unclear. EPR measurements led to the conclusion that μ-oxo-bridged Mn^{III}/Mn^{IV} and Mn^{II}/Mn^{III} dimers are present.[128, 129] A precise analysis of the very broad XANES signal indicated the presence of Mn^{III}/Mn^{IV} centers. No significant changes in the immediate vicinity of Mn ions were observed during the transition to the S_2 state. Even though it is known that inorganic cofactors, such as chloride ions, are required for O_2 production,[130, 131] no indication for Cl coordination to the Mn centers was found.

J. E. Penner-Hahn et al.[132] also investigated the S_1 state of OEC. They were able to significantly improve data quality by increasing the Mn concentration in the sample, accumulating spectra, and by using a solid-state detector array. But even with this improvement it remained impossible to determine whether the Cl^- ions were coordinated to the Mn centers or not. These authors, in contrast to earlier results by other groups, did not find a Mn-(N,O) distance of 1.75 Å, but, in rough agreement with the earlier results, they did observe two O backscatterers at approximately 1.9 and 2.1 Å, two Mn backscatterers at 2.7 Å and, additionally, another Mn atom at 3.3 Å. The presence of two Mn backscatterers at 2.7 Å, together with the analysis of the

XANES spectra and a comparison of EPR spectra, led the authors to propose a trinuclear $Mn^{II}/Mn^{III}/Mn^{IV}$ cluster and a mononuclear Mn^{III} cluster. Three Mn^{III} centers in the trinuclear cluster and one Mn^{III} center in the mononuclear cluster were also in accordance with the EXAFS and EPR results. This oxidation state assignment would require a very distorted environment about the Mn center in order to explain the very broad structure of the XANES signal.

4.4.2. Blue Copper Proteins

Another group of electron carriers in photosynthetic and bacterial redox chains consists of the so-called blue or type I copper proteins. The best known examples are plastocyanin, azurin, stellacyanin, umecyanin, amicyanin, and rusticyanin. The type I copper proteins share a common structural unit, consisting of two histidine and one cystine ligand in a distorted trigonal geometry. The coordination sphere of the Cu center is completed by axial bonds to sulfur atoms (methionine) and in part by oxygen atoms from the peptide chain.



Even though these proteins are by now fairly well structurally characterized, there are still uncertainties regarding the relationship between the redox potential and the Cu coordination environment. In this context, the length of the axial Cu–S(Met) bond appears to play a central role.[133] A large number of EXAFS studies—for instance, the first determination of the bond length of the short Cu–S(Cys) contact[134]—has been performed on this system. Their results are summarized in Table 10.

Table 10. Summary of EXAFS studies of type I copper proteins. Cond. = conditions.

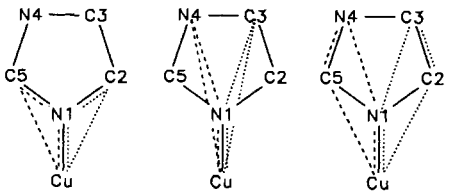
It was mainly possible to demonstrate the existence of two Cu–N(His) contacts between 1.86 to 2.07 Å and a Cu–S(Cys) contact between 2.12 to 2.24 Å. Reduction to the Cu^{I} form leads to a small but significant increase in the Cu–N(His) bonds to an average of 2.05 Å. The Cu–S(Cys) bond remains nearly unchanged by the reduction.

The exact determination of the axial Cu–S(Met) contact by using EXAFS spectroscopy has so far not been successful. In 1982, the research group of R. A. Scott attempted to isolate the contribution of the axial Cu–S(Met) distance to the EXAFS function by using polarized synchrotron radiation and varying the orientation of plastocyanin single crystals (*Populus nigra*) with respect to the polarization vector of the incident X-rays.[140] In the unit cell of plastocyanin, four Cu–S(Met) bonds are aligned parallel to the crystallographic *c* axis.[141] When the *c* axis of the crystal is oriented parallel to the direction of the polarization of the incident beam, the EXAFS function should primarily contain the contribution of the S(Met) backscatterers. If, however, the *b* axis is parallel to the direction of polarization, the contributions of N(His) and S(Cys) backscatterers to the total EXAFS function should be especially high (Scheme 6). The results of this study are in very good agreement with crystallographic data for the Cu–N(His) and Cu–S(Cys) bonds. However, there was no indication for any contribution from the methionine sulfur atom. This was explained by the uncorrelated motion of the atoms involved. The authors stated that the Debye–Waller factor was so large as to make the determination of the Cu–S(Met) distance by EXAFS techniques practically impossible, because the amplitude of any absorber–backscatterer contribution would be dampened too strongly.

Scheme 6. Schematic representation of the orientation of the Cu–S(Met) bond in plastocyanin with respect to the polarization direction of the incident synchrotron radiation. Left: The crystallographic *c* axis and the Cu–S(Met) bond are parallel to the beam polarization. Right: The crystallographic *b* axis is parallel to the beam polarization.

A later study of azurine (*Pseudomonas aeruginosa*)[137] also demonstrated that there are circumstances that make the detection of actual bond lengths by EXAFS spectroscopy difficult or impossible. In the oxidized form of the enzyme, there is destructive interference between the Cu–S(Met) shell and a shell containing imidazole C atoms. This interference does not allow the contribution of the Cu–S(Met) shell to be observed. In the reduced enzyme, however, it was possible to observe this contribution at 2.70 ± 0.05 Å. The reduction and the related shortening of the Cu–S(Met) bond indicate that the methionine ligand plays a central role in the determination of the redox potential.



4.4.3. Superoxide Dismutase

The Cu/Zn superoxide dismutase (Cu/Zn SOD) belongs to the group of type II copper proteins. In contrast to type I Cu proteins, the coordination sphere of type II Cu proteins consists mainly of atoms with low atomic numbers, such as N (histidine) and O atoms (water and O-containing amino acids). Cu/Zn SOD catalyzes the conversion of the superoxide radical to oxygen and hydrogen peroxide, $2H^+ + 2O_2^{\bullet -} \rightarrow O_2 + H_2O_2$. In the crystalline state, the Cu atom in this enzyme is surrounded by four imidazole ligands (histidine) in a flattened tetrahedral ge-

ometry. One of these imidazole ligands forms an N bridge to the neighboring Zn atom. One of the enzyme's characteristics is its ability to bind small anionic ligands, for instance the substrate $O_2^{\cdot-}$ or inhibitors like CN^-, in a surface site between the Cu^{II} center and an arginine residue.[142]

Earlier EXAFS studies on the environment of the Cu ions, using differently prepared samples, indicated the presence of four imidazole ligands at 2.00 Å and an additional solvent molecule at 2.23 Å for native SOD in aqueous solution.[143] These results are in very good agreement with the crystal structure analysis. In the freeze-dried enzyme,[144] the Zn atom is surrounded by three imidazole N atoms at 2.01 Å and one O(Asp) atom at 2.04 Å. Attempts to fit farther-removed C and N atoms, which contribute significantly to the EXAFS function, led to the reduction of some distances by about 0.5 Å. Neither for the used model compounds nor for the actual enzyme samples, was it possible to obtain a convincing fit in the low k range, where multiple scattering effects are particularly significant.

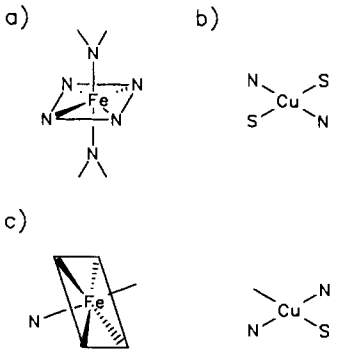
A later study[145] dealt with the native enzyme and its complexes with cyanide and azide ions. Due to the inclusion of multiple scattering effects, it was possible to fit the higher coordination shells very well. It was necessary, however, to assume that the distances between the Cu atom and the C2 and the C5 atoms of the imidazole ring are different. The same assumption was made for the C3 and N4 atoms. The distances obtained indicate an inclination of the imidazole ring of 5–10° with respect to the Cu–N1 axis (Scheme 7). The idealized geometry corresponds to a square pyramid around the Cu atom, with four N atoms at the corners of the basal plane and one axial O atom (from a solvent molecule).

Scheme 7. Atom numbering scheme as well as examples for scattering pathways of multiple-scattering contributions within the imidazole ring.

The characterization of the complexes of SOD with CN^- and N_3^- ions as model substrates presents a very good opportunity to study the structural changes after $O_2^{\cdot-}$ coordination. The analysis of the EXAFS function of the SOD complex with azide ions indicates an equatorial coordination of the N_3^- ion to the Cu atom, presumably in a square pyramidal geometry. A Cu–N(azide) distance and three Cu–N(His) distances of 1.99 Å were observed, as well as a Cu–N(His) contact of 2.27 Å. The coordination of the azide ion leads to a shift of an imidazole ligand from an equatorial to an axial position. The angle between the Cu–N(azide) axis and the molecular axis of the azide ion is less than 135°.

The SOD complex with CN^- ions shows a Cu–C(CN) bond length of 1.97 Å, also indicating an equatorial coordination of the cyanide ion. The CN^- binding also leads to a shortening of the three Cu–N(His) bonds to 1.95 Å. In contrast to the SOD complex with N_3^-, in which an axially coordinated imidazole group with a Cu–N distance of 2.27 Å is retained, the Cu atom in the CN^--SOD complex is surrounded by only four ligands. No additional Cu–imidazole contact could be demonstrated by EXAFS spectroscopy. It appears that the cyanide ion replaces a histidine residue and leads to a higher asymmetry in the orientation of the imidazole ring than is found in the native enzyme.

4.4.4. Cytochrome c Oxidase



Cytochromes are electron-transfer proteins that contain iron phorphyrin moieties. They only exist in aerobic cells. During their catalytic cycle, in all cytochromes the Fe^{II} centers are oxidized to Fe^{III} centers and can therefore no longer be oxidized by molecular oxygen. An exception to this is cytochrome c oxidase which contains additional copper ions. It is the last member in the mitochondrial respiratory chain. Its function is the transfer of four electrons to oxygen, thereby reducing it to water in the process. Each of the four metal centers (two Fe and two Cu) can accept one electron. The Fe(heme a) and Cu_A centers are located in a magnetically insulating environment and are about 12 Å apart. The Fe(heme a_3) and the Cu_B center are a magnetically coupled pair. It is assumed that the oxidized enzyme accepts electrons from heme a and transports them through the Cu_A center to the binuclear heme a_3/Cu_B unit, where the O_2 binding supposedly takes place as well.[146, 147]

EXAFS studies that employ Fe and Cu absorption edges are promising in this case. However, the Fe, as well as the Cu atoms, are present in chemically different environments. The measured EXAFS spectrum is therefore a superposition of the spectra of the Fe center in heme a and heme a_3, or of the Cu ions in the form of Cu_A and Cu_B. Early XAS studies dealt only with a comparison between the absorption edge of the enzyme with those of model compounds.[148, 149] It was found, that the position and the structure of the Cu edge is barely affected by oxidation or reduction. This led to the conclusion, that one of the Cu centers retains its Cu^I oxidation state during oxidation.

The first EXAFS study indicated the average environment around both Cu centers consisted of 1–1.5 S atoms at 2.27 Å and two nitrogen atoms at 1.97 Å.[150] Somewhat later, L. Powers et al.[151] assumed, based on earlier work,[148] that Cu_B is a type I copper center like that found in stellacyanin. Therefore, they subtracted the experimentally determined spectrum of oxidized stellacyanin from the spectrum of oxidized cytochrome c oxidase in order to obtain the EXAFS spectrum of the Cu_A center. In this fashion, it was possible to identify two nitrogen atoms at 1.97 Å and two sulfur atoms at 2.23 Å. The Fe-edge EXAFS spectrum also led to the identification of sulfur backscatterers, a fact that led to the assumption of a sulfur bridge between Fe(heme a_3) and the Cu_B center. These results were later questioned, however. First, no contribution of bridging sulfur atoms could be deduced from the EXAFS spectrum of active cytochrome c oxidase.[152] Second, the EXAFS spectrum of the enzyme did not yield indications about a short Cu–S contact, which is certainly present in stellacyanin.[153] Therefore, the method of L. Powers et al.[151] for obtaining a "pure" Cu_A spectrum was no longer tenable. Even the stated Cu–Fe distance of 3.8 Å in reference [151] is contrary to the 3.0 Å given in reference [153]. Moreover, it was shown that

different enzyme preparation methods yielded different EXAFS spectra.[154, 155]

The most recent study dealt with a form of the enzyme from which the Cu_A center has been selectively removed and which retains up to 75% of its activity.[156] The thus obtained Cu_B EXAFS spectrum yielded three N or O atoms and one S or Cl atom as backscatterers, but no short Cu–S contact was found. This conclusively demonstrated that a stellacyanin-like Cu_B configuration can be excluded. According to these results, the Cu_B center is coordinated by three histidine and one cystine molecule. A—potentially bridging—Cl atom is also possible. The subtraction of the Cu-edge EXAFS spectrum of the Cu_A-depleted enzyme from that of the native enzyme yields selectively the environment of the Cu_A atom. Cu_A is surrounded by two N/O atoms at a distance of 1.97 $\pm$ 0.02 Å and two S atoms at a distance of 2.28 $\pm$ 0.02 Å. This indicates the coordination of two histidine and two cystine molecules to the Cu_A center (Scheme 8). Metal-metal contacts in the Cu_A-depleted enzyme

Scheme 8. Proposed structures for the metal centers in cytochrome c oxidase. a) heme a, b) Cu_A, c) heme a_3-Cu_B. The Cu–S distances in Cu_A and heme a_3-Cu_B are 2.28 Å, the Cu–N distances 1.97 Å.

have so far not been reported in the literature. Fe-edge EXAFS investigations of this enzyme modification have also not yet been reported. Other studies have dealt with the cytochromes b_2,[157] cytochrome P-450-CAM,[158] and the effect of cyanide binding to cytochrome c oxidase.[154]

5. Outlook

Is EXAFS spectroscopy a promising new technique? On first glance, the answer is yes. The element-specific determination of local structures is possible, independent of the sample's physical state and even at very high dilution. The action of catalysts can be investigated and reactions can be studied in situ. On second glance, the answer is no. Experiments must rely on synchrotron radiation, as the laboratory EXAFS methods are not yet far enough developed. This necessitates long-term planning of experiments, short beam times, and dependence on the research policy of the operator. The analysis of spectra is difficult; interpretation is only possible with the help of extensive spectral simulations, which is in contrast to many common spectroscopic techniques. Compared to these efforts, the information obtained is minimal.

Neither of these viewpoints does justice to EXAFS spectroscopy. Its utilization is only sensible when detailed information about the immediate short-range order around a specific atom type is necessary, and when this information is not accessible by other spectroscopic techniques. Even then it is wrong to expect too much of EXAFS spectroscopy. If the short-range order is characterized by a broad distance distribution, or if different backscatterers are present at similar distances, EXAFS spectroscopy cannot yield unambiguous results. As long as these limitations are kept in mind, and systems to be studied are selected accordingly, EXAFS spectroscopy, in combination with other techniques, can supply new observations—maybe even key information. The future will show the potential of this method. The experimental conditions are improving, that is the access to a synchrotron radiation source: in mid-1994 the European Synchrotron source in Grenoble is supposed to begin operation.

We wish to thank the Sonderforschungsbereich 347 ("Selective Reactions Metal-Activated Molecules") and the Dr. Leni-Schöniger Stiftung for financial support. We are grateful for the conscientious reading of this manuscript by Dr. Dieter Leicht and Mr. Uwe Kolb. Ms. Diana Müller is acknowledged for her assistance in preparing the illustrations. A special thanks goes to Ms. Sabine Hückmann who worked on the biological section of this review.

Cooperativity in Rh_2 Complexes: High Catalytic Activity and High Regioselectivity in the Hydroformylation of Olefins

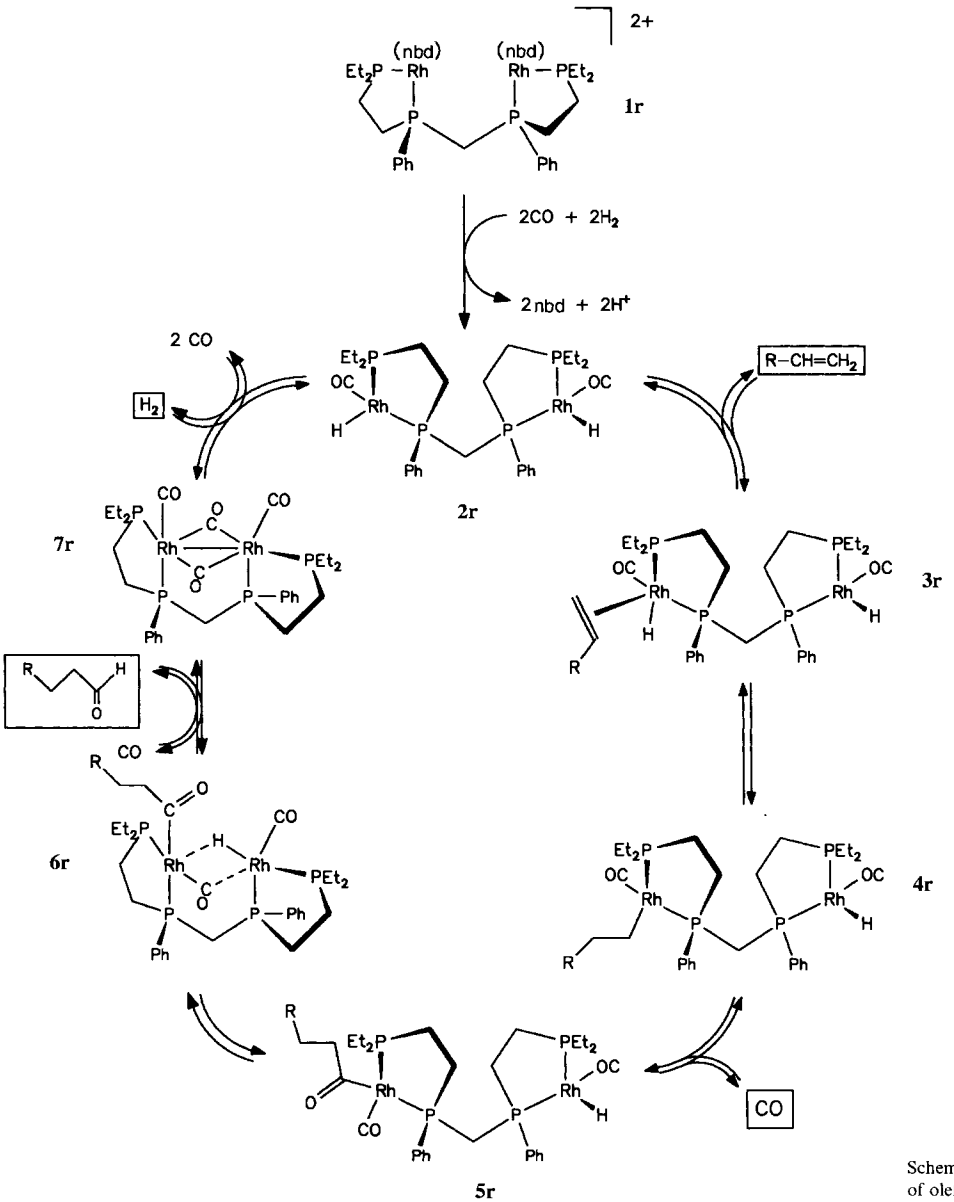
Georg Süss-Fink*

An important step forward in the search for catalytically active polynuclear metal complexes has been made by George G. Stanley's group: The bimetallic complex cations *rac*-$[Rh_2(nbd)_2L]^{2+}$ **1r** and *meso*-$[Rh_2(nbd)_2L]^{2+}$ **1m** (nbd = norbornadiene) which were isolated as tetrafluoroborates (Scheme 1),[1] were obtained by reacting bis(norbornadiene)rhodium tetrafluoroborate with a new tetraphosphane ligand L which exists in *R,R*, *S,S* and *R,S* forms and can be separated into racemic (*R,R*/*S,S*) and *meso* structures (*R,S*).[2]

Scheme 1. The tetraphosphane ligand L and the hydroformylation-active dirhodium complex **1r**.

The racemic complex **1r**, whose structure was determined by single-crystal X-ray crystallography, is an excellent hydroformylation catalyst for olefins such as propylene, 1-hexene, and 1-octene, combining high activity with high regioselectivity. Up to 12000 catalytic cycles (10 cycles per minute) were achieved in a single batch run without observing any decomposition of the catalyst. The conversion of alkene to aldehyde for the hydroformylation of 1-hexene was 85%, and the *n*/*i* ratio was 96.5 : 3.5.[1] The combination of high activity and high selectivity can be explained by cooperativity between both metal centers in the catalytically active bimetallic complex.

The hydroformylation of olefins is the world's most important homogeneous catalytic industrial process with more than six million tonnes of oxo products produced each year.[3] Besides the problem of chemical selectivity, the hydroformylation of higher olefins raises the question of regioselectivity depending on whether the formyl group is added to the terminal or to the inner carbon atom of the double bond. This results in a ratio of linear to branched product (*n*/*i* ratio of the aldehyde formed) [Eq. (a) and (b)]. The industrial processes are all based on monometallic cobalt or rhodium complexes.



$$R\text{-}CH{=}CH_2 + CO + H_2 \longrightarrow \begin{cases} R\text{-}CH_2CH_2\text{-}CHO \quad \textit{n}\text{-aldehyde} & \text{(a)} \\ R\text{-}CH(CHO)\text{-}CH_3 \quad \textit{i}\text{-aldehyde} & \text{(b)} \end{cases}$$

Ever since transition metal clusters have been discussed as catalysts,[4] there have been many attempts to develop polynuclear catalytically active complexes in which the metal centers interact during formation of the target molecule ("cooperativity") to control activity and selectivity. In this way, a highly selective hydroformylation catalyst for propylene was found in the cluster anion $[HRu_3(CO)_{11}]^-$ (linear to branched product ratio of butyraldehyde 98.6 : 1.4), however, its activity is very low with only 57 catalytic cycles in 66 h.[5] The high selectivity and low activity suggest that the catalytic process occurs via a sterically demanding, intact trimetallic structure, for which there is experimental evidence.[6] In contrast to $[HRu_3(CO)_{11}]^-$, the tetrametallic neutral cluster $[Rh_4(CO)_{12}]$ yields high catalytic conversions (84000 cycles) for hydroformylation of 1-hexene, however, the selectivity is unfavorable (*n*/*i* 54: 46).[7] Accordingly, evidence for a catalytic route via monometallic rhodium complex fragments was found.[8] The catalyst **1r** described by Stanley et al. is the only polynuclear metal complex as yet which compares favorably with the hydroformylation catalysts used industrially.

The combination of high catalytic activity and high regioselectivity results from the interaction of the two rhodium centers of **1r** during the hydroformylation cycle (Scheme 2). Under synthesis gas pressure, the complex cation **1r** used as a catalyst precursor is converted into the neutral complex **2r** which is regarded as the active species. Norbornadiene and protons are eliminated in the process. The coordinately unsaturated species **2r** (both Rh atoms have 16 valence electrons) reacts on addition of an olefin to give **3r**, and by insertion of the olefin ligand in the Rh–H bond forms **4r**. The alkyl complex **4r** is converted into

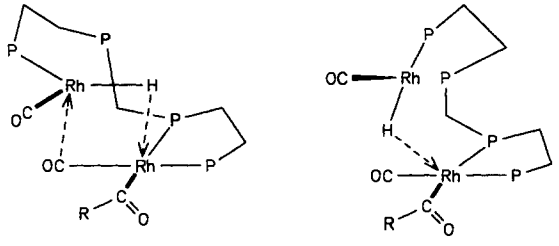
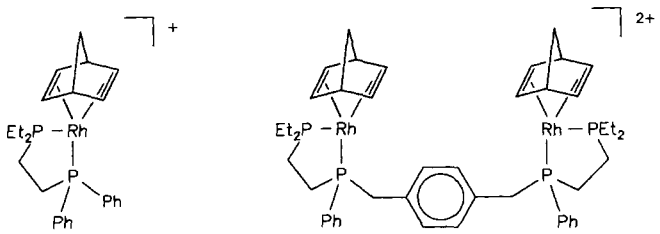


Scheme 2. Proposed catalytic cycle of hydroformylation of olefins with **1r** as catalyst precursor.

the corresponding acyl complex **5r** by incorporation of CO. In what is generally believed to be the rate-determining step, **5r** rearranges into **6r** in which a hydrido and a carbonyl ligand are arranged semi-bridging between the two rhodium atoms. The doubly carbonyl-bridged complex **7r** forms on aldehyde elimination. This is reconverted with hydrogen into the active species **2r** with elimination of carbon monoxide, thus, completing the cycle.

The key step in the catalysis cycle proposed by Stanley et al. is the transfer of the hydrido ligand from one rhodium atom to the other in the bimetallic complex **6r**, in which the interaction of both metal centers is the greatest ("cooperativity") (Scheme 3). The most important evidence for this hypothesis is the observation that if the bimetallic complex **2m** (meso form), a diastereomer of **2r**, is used as the catalyst precursor, the activity and selectivity drop drastically. The meso form **6m** can only form a singly bridged species on hydride transfer because the terminal CO group is unfavorably oriented at the acyl-bound Rh atom. It is assumed that the interaction of the Rh centers across the carbonyl bridge in **6r** favors intramolecular hydride transfer. This assumption was confirmed by SYBYL molecular modeling investigations (molecular dynamics minimizations).



Stanley et al. have attempted to verify the hypothesis of intramolecular hydride transfer in the bimetallic hydroformyla-

Scheme 3. Intramolecular hydride transfer in complexes **6r** (left) and **6m** (right). The complexes are shown without the aldehyde ligands.

tion catalyst through a well-designed systematic investigation. For this, the monometallic complex **8** ("half" complex) and the bimetallic complex **9** ("spacer" complex), both of which are analogous to **1r**, as well as other similar complexes were synthesized. All these model complexes either do not catalyze the hydroformylation or catalyze the hydroformylation with only very low activity and selectivity. Complexes **8** and **9** are comparable

8 **9**

to **1r** both electronically and sterically; however, an intramolecular hydride transfer is not possible either in the monometallic complex **8** or in the bimetallic complex **9**, in which both the Rh atoms are kept further apart by phenylene spacers, which explains the difference in catalytic characteristics compared to **1r**. Finally, the isolation and characterization of the bimetallic complex **7r** (postulated in the catalytic cycle) from the reaction of **1r** with CO and H_2, suggestive of a sensitive equilibrium between **2r** and **7r**, adds additional support to the mechanism proposed by Stanley et al.

The results of Stanley et al. indicate that a breakthrough in the development of tailor-made homogeneous catalysts may be expected. It now seems possible to fix two or more cooperating metal centers in the geometry required for a particular catalytic process with the aid of a suitable ligand matrix, with the aim of controlling selectivity and activity of the catalyst.

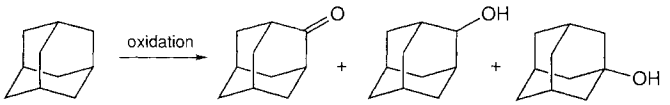
Oxidation of Weakly Activated C–H Bonds**

Oliver Reiser*

The selective oxidation of alkanes remains a challenge in organic synthesis. The development of economical processes for the functionalization of hydrocarbons is of tremendous technical importance. In nature such reactions are mediated efficiently by various enzymes. The systems related to cytochrome P-450, which for example detoxify lipid-soluble compounds in the human liver,[1] have received the most attention.

The fundamental problem in the functionalization of saturated hydrocarbons is that their components, carbon and hydrogen, do not have lone electron pairs, and the molecules do not have orbitals of sufficient energy that are easily accessible. Thus, very reactive reagents and/or extreme reaction conditions are typically required, for example for the oxidation of alkanes. However, the initial products are almost always more reactive than the starting compounds, and undesired side reactions may occur.

Other complications arise if the molecule to be oxidized contains different types of C–H bonds. Since formation of tertiary radicals and carbenium ions is favored and they are also more stable than their secondary and primary analogues, functionalization processes that proceed via these intermediates generally have the selectivity for C atoms in the order tertiary > secondary > primary. For steric reasons, however, the attack of bulky reagents at primary C atoms may be preferred; the best example here is the oxidative addition of transition metal complexes.



The metal-mediated oxyfunctionalization of organic compounds, of olefins in particular, is becoming increasingly important.[2] Research on metal catalysts that activate elemental oxygen and make it usable as a selective oxidizing agent is therefore especially worthwhile. Inspired by the enzyme cytochrome P-450, in which the active center is an oxoiron(IV) unit, researchers have examined numerous iron-containing reagents for the oxidation of alkanes. For example, the so-called Gif systems[3]

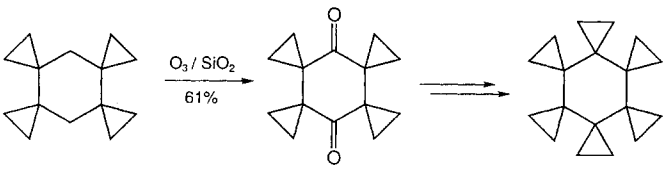
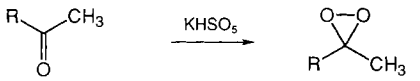
developed by Barton et al., which consist essentially of air, catalytic amounts of iron and/or zinc, acetic acid (HOAc), pyridine (py), and water, oxidize adamantane (**1**) to give adamantanone (**2**) as the major product along with 2- (**3**) and 1-adamantanol (**4**) as side products.



1 **2** **3** **4**

The oxidizing species are postulated to be $[Fe^{II}Fe^{III}_2O(OAc)_6(py)_{3.5}]$[4] and $C_5H_4NO^+$,[5] in keeping with the necessity of a nitrogen base component such as pyridine. Apparently these species attack C–H bonds on secondary C atoms in marked preference to those on primary and tertiary C atoms. Mechanistic studies suggest that the oxidation yielding ketones like **2** does not proceed via the corresponding alcohols **3** and **4**. Turnover rates of over 3000 and almost quantitative reactions have been achieved with several Gif reagents. One disadvantage is that the reactions can be conducted only up to 10–15% conversion to avoid considerable amounts of side products.

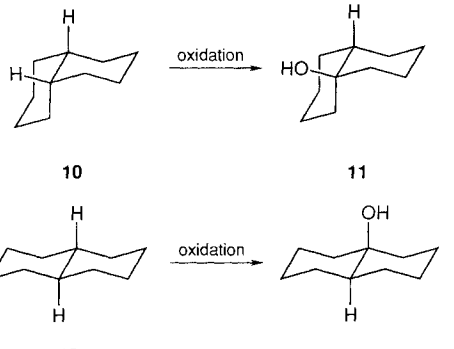
The allotropic form of oxygen, ozone, can also be employed for the oxidation of saturated hydrocarbons. The reactivity of ozone without additional reagents is not sufficient for the preparative functionalization of alkanes in solution; however, its reactivity is increased substantially by the addition of iron(III) chloride[6] or antimony pentafluoride.[7] The dry ozonation variant[8] of Mazur et al.,[9] by which alkanes are hydroxylated at tertiary C atoms with high selectivities and yields, was shown to be especially useful. According to this method, silica gel is coated with roughly 1 wt% of the substrate, cooled to −78 °C, saturated with ozone, and subsequently allowed to warm to room temperature within 0.5–2 h. Adamantane (**1**) is converted almost quantitatively into 1-adamantanol (**4**) in this way (Table 1), and this method of oxyfunctionalization has been applied successfully even on certain steroids.[10]



The selective oxidation of hydrocarbons by dry ozonation is not restricted to reaction at tertiary C atoms: the CH_2 groups adjacent to a cyclopropane ring are smoothly converted into carbonyl groups. This "cyclopropyl activation" can be explained by the well-known ability of the cyclopropyl group to effectively stabilize a neighboring R_3C^+ center. Although in the oxidation of alkanes with ozone the first intermediate, the hydrotrioxide,[11] does not arise from carbenium ions, the effect of polarity upon attack of the electronegative ozone molecule, either as a radical or by 1,3-dipolar addition, at the C–H bond certainly leads to development of a positive charge on the pertinent C atom.[11] Dry ozonation was the first efficient method for the α-functionalization of cyclopropylidene hydrocarbons and served as the key step in the first synthesis of [6]rotane (**7**) via the tetraspiro hydrocarbon **5**.[12]

The ketonation of cyclopropylidene hydrocarbons with ruthenium tetraoxide (generated in situ from $RuCl_3$ and $NaIO_4$ in CH_3CN/CCl_4/aqueous phosphate buffer)[13] proved to be more convenient and better suited for large-scale reactions. This oxidation of organic substrates originally developed by K. B. Sharpless et al.[14] for the oxidative cleavage of alkenes can also be applied for the selective hydroxylation of tertiary C–H groups;[13c,d] for example, adamantane (**1**) is converted into 1-adamantanol (**4**) in 75% yield.[13d]

5 **6** **7**



Since the development of a handy, even large-scale method for the generation of dimethyldioxirane (**9a**), it has become known best as a reagent for the epoxidation of double bonds.[15] Its application for the selective hydroxylation of C–H bonds at tertiary C atoms is less well known. For example, the reaction of **1** with **9a** as the oxidizing agent provides **4** with only minor amounts (<3%) of side products.[16] Oxidations with **9a** pro-

8a: R = CH_3 **9a**: R = CH_3

8b: R = CF_3 **9b**: R = CF_3

ceed stereoselectively with retention, as the reactions with *cis*-decalin (**10**) and *trans*-decalin (**12**) demonstrate. Remarkably, the oxidation of **10** is faster than that of **12**: after a reaction time of 17 h **11** had been formed in 84% yield, **13** in only 20%. This

10 **11**

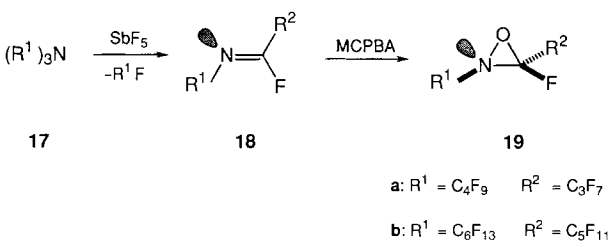
12 **13**

indicates that the oxidation of equatorial positions is preferred to that of axial positions (Table 1).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0070 $ 10.00+.25/0

An oxidizing agent up to 7000 times more reactive than **9a** is methyl(trifluoromethyl)dioxirane (**9b**), which not only hydroxylates tertiary C–H positions (Table 1) but also converts secondary C–H groups into carbonyl functions. As an illustration, the oxidation of cyclohexane at −22 °C afforded cyclohexanone in yields of over 98% in only 18 min.[17] With this reagent not only the monohydroxylation of adamantane (**1**) providing **4** proceeds in excellent yield, but also the two-, three-, and even four-fold hydroxylation of the bridgehead positions of adamantane.[18]

Table 1. Comparison of reagents for the oxidation of adamantane (**1**) and decalins **10** and **12**.



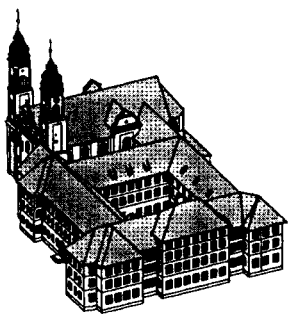
Substrate	Oxidation agent	Product	t [h]/ T [°C]	Yield [%]
1	O_3/SiO_2	**4**	0.5/−78 → 25	99
1	$RuCl_3/NaIO_4$	**4**	3–7/90	75
1	**9a**	**4**	18/22	87
1	**9b**	**4**	1 min/−22	92
1	$F_2/H_2O/CH_3CN$	**4**	−/0	80
1	**19a**	**4**	<1/25	90
1	**19b**	**4**	<1/25	90
10	O_3/SiO_2	**11**	0.5/−78 → 25	99
10	**9a**	**11**	17/22	84
10	**9b**	**11**	0.2/−22	91
10	**19a**	**11**	few/25	85
10	**19b**	**11**	few/25	88
12	O_3/SiO_2	**13**	0.5/−78 → 25	72
12	**9a**	**13**	17/22	20
12	**9b**	**13**	0.1/−22	61
12	**19a**	**13**	many/25	73

Remarkably, **9b** is stable towards acids like trifluoroacetic acid, trifluoromethanesulfonic acid, and sulfuric acid. Based on this observation, Asensio et al. employed **9b** for the oxidation of tertiary C–H positions in the presence of amino groups.[19] Their trick was protecting the amino group as an ammonium tetrafluoroborate by treatment with tetrafluoroboric acid. In the subsequent reaction with **9b**, the C–H bond at a tertiary C atom, which must be at least two C atoms removed from the ammonium group, is converted into a hydroxyl or acetamido function in excellent yield. C–H bonds on secondary C atoms in acyclic amines such as **14** (R = Me, Et, Pr) may also be oxidized in this way to afford the corresponding ketones **15**; the oxygen insertion takes place exclusively at the ε-methylene group. The authors explain the excellent selectivity by the coordination of **9b** to the ammonium group by hydrogen bonding.

Hydroxylation of C–H bonds on tertiary C atoms can be conducted with solutions of fluorine in aqueous acetonitrile.[20] This reagent appears particularly attractive for the synthesis of ^{18}O-labeled compounds; for example, [^{18}O]-1-adamantanol ([^{18}O]-**4**) is prepared in over 80% yield by using a solution of F_2 in acetonitrile and $H_2{}^{18}O$.

The newest reagents for the oxyfunctionalization of hydrocarbons are the di(perfluoroalkyl)oxaziridines **19**,[21] which can be synthesized from commercially available tri(perfluoroalkyl)amines **17** on a large scale[21b] in two steps. The reaction of **17** with antimony pentafluoride produces α-fluoroketimines **18**, which are then epoxidized with *m*-chloroperbenzoic acid (MCPBA) to give **19**. Compound **19** can be purified by vacuum

distillation and stored indefinitely at room temperature. Solutions of hydrocarbons such as **1**, **10**, and **12** in chloroform, carbon tetrachloride, or trichlorofluoromethane are readily monohydroxylated at their tertiary C atoms with only minimal amounts of side products. In addition to the high selectivity for tertiary C atoms over secondary, **19** shows a marked preference for the oxidation of equatorial over axial positions and a high stereospecificity for retention of configuration of the C atoms oxidized (Table 1). The authors propose the concerted O insertion into a C–H bond as the mechanism, since in the reaction of **19** with **1** in CCl_4 no chlorine-containing trapping products are formed from **1** via intermediate radicals, as is observed for the oxidation of **1** in CCl_4 with ozone.



It remains to be seen if the range of application of this latest oxidizing agent for hydrocarbons will surpass that of the other reagents. Besides the selectivity of these reagents, their price, accessibility, and convenient and safe handling are important criteria for application. Based on price and efficiency, the $RuCl_3/NaIO_4$ system and the dioxiranes seem to be ahead of their more recent competitors.

Computational Methods in Chemical Design
Molecular Modeling: Theory and Experiment

Kloster Irsee, May 16 to 20, 1994

The symposium and FEBS course follow the previous three successful meetings on Molecular Modeling and Computer Graphics held in Elmau. The aim continues to bring together investigators interested in elucidating, at the molecular level, interrelationships between structure, physical, chemical and biological properties of molecular materials. "Computational Methods" is intended to be a connecting theme, drawing together various disciplines associated with structural chemistry, as for example: solid state and solution studies, theoretical methods and new developments in computer applications and computer graphics.

Topics: Bio-Crystallography; Protein Modeling; Molecular Recognition and Ligand-Receptor Interactions; Molecular Solid State Systems including Crystal Engineering, Intermolecular Interactions, and Solid State Reactions; Synchrotron Studies, Neutron Diffraction, and Solid State NMR; Polymer Modeling; New Concepts in Structural, Theoretical, and Computational Chemistry; Demonstrations of Hard- and Software.

Invited Speakers: Tore Brinck, Stephen Byrn, Zbigniew Dauter, Gautam Desiraju, Angelo Gavezzotti, Jenny P. Glusker, Andrew D. Hamilton, Gerard Harbison, Kenneth D. M. Harris, William L. Jorgensen, Gerhard Klebe, Jan Kroon, Loes Kroon-Batenburg, Leslie Leiserowitz, Arthur Lesk, Christine Orengo, James Pflugrath, Douglas Rohrer, Mark A. Spackman, John J. Stezowski, a. o.

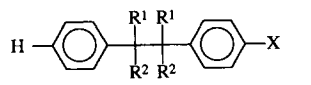
Free-Energy Relationship for Mesolytic Cleavage of C–C Bonds**

Przemyslaw Maslak,* Thomas M. Vallombroso, William H. Chapman, Jr., and Javier N. Narvaez

A full understanding of an elementary reaction must include the functional dependence of the reaction rate (kinetics) on the driving force (thermodynamics), which should include all pertinent variables such as stereoelectronic factors and medium effects. Unimolecular dissociations of radical ions into radicals and ions (mesolytic scissions)[1] provide an opportunity to develop such a quantitative theory for a bond-breaking process. We present here the experimentally determined free-energy relationship for mesolytic cleavages of C–C bonds in π radical ions spanning a range of over 40 kcal mol^{-1} for the driving force and over 17 powers of ten for the rate constants. We show that these fragmentations have low intrinsic barriers if the stereoelectronic factors are optimal, and that a parabolic, Marcus-type free-energy relation may be fitted to the data.

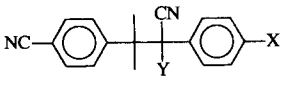
The unpaired electron in the π radical ion resides in a π-type orbital localized on one bonding partner of the scissile bond. The fragmentation reaction is accompanied by the redistribution of electron density to the forming fragments according to one of the modes of electron apportionment[2] [Equations (a)–(d)]. As illustrated by the curved arrows, the processes described by Equations (a) and (c) formally correspond to homolysis; the alternatives (b) and (d) are equivalent to heterolysis.



$$^{-\bullet}A\text{–}B \longrightarrow A^- + B^\bullet \quad \text{(a)}$$

$$^{-\bullet}A\text{–}B \longrightarrow A^\bullet + B^- \quad \text{(b)}$$

$$^{+\bullet}A\text{–}B \longrightarrow A^+ + B^\bullet \quad \text{(c)}$$



$$^{+\bullet}A\text{–}B \longrightarrow A^\bullet + B^+ \quad \text{(d)}$$

We have prepared[1, 3, 4] a series of directly observable radical ions of substrates containing two benzylic units (**1**–**5**) that undergo unimolecular C–C bond scissions according to Equations (a)–(d). The radical ions were designed to provide optimal overlap of the π system bearing the unpaired electron with the scissile C–C bond.[3–5] In all cases probed,[3, 4] the C–C bond cleavage reactions were irreversible under the reaction conditions, as was found in experiments with stereochemically pure *erythro*/*threo* or *meso*/*dl* radical ion precursors. The kinetic data (Table 1) for mesolysis were obtained[3, 4] in polar media to exclude aggregation and ion pairing, by ESR and UV/VIS spectroscopy, flash photolysis, pulse radiolysis, time-resolved fluorescence spectroscopy, and cyclic voltammetry (CV). The primary fragments observed corresponded to the thermodynamically predicted apportionment of electrons.[3, 4] In all cases, the isolated products were consistent with fragmentation of the central C–C bond.[3, 4]

5

The evaluation of the thermodynamics of mesolytic processes was based on a simple thermodynamic cycle.[1, 6, 7] Regardless of the mode [(a)–(d)] of cleavage, the free energy of mesolysis ΔG_m is a function of the free energy of homolysis ΔG_h of the compound A–B and the difference in redox potentials of A–B and the ionic fragment produced ($\Delta G_m = \Delta G_h - 23.06\,\Delta E$, where $\Delta E = E^o_{AB} - E^o_{A^\bullet}$ (or $E^o_{B^\bullet}$) for cleavages of radical cations, and $\Delta E = E^r_{A^\bullet}$ (or $E^r_{B^\bullet}$) $- E^r_{AB}$ for cleavages of radical anions). The thermodynamic factors determine where the unpaired electron is initially localized[3, 4] (A or B), and which of the cleavage modes (homolytic or heterolytic) takes place.[3, 4]

In our systems ΔG_h has been approximated by experimentally accessible $\Delta G_h^{\ddagger}$. The approximation is valid ($\pm$ 3 kcal mol^{-1}) if the radical coupling has only a small activation barrier (that is, the reaction is diffusion-limited) and the thermolysis is carried out under conditions selected to minimize recombination within the solvent cage.[8] These conditions have been established for our compounds.[3, 4] The redox potentials of the radical ions and the ionic fragments have been determined by a technique[9] based on the curvature of the Marcus equations for electron transfer between the electrode and species of interest that gives results comparable to those obtained by other methods.[7]

The kinetic and thermodynamic data at 300 K (Table 1) were used to construct the free-energy relationships of Figure 1. The slope of the solid line corresponds to unity; that is, it depicts endergonic reactions with no kinetic "overhead". The overhead is defined here as the difference between $\Delta G_m^{\ddagger}$ and ΔG_m and represents the barrier to the reverse (exergonic) reaction (that is,

bond-forming coupling of radicals and ions). The examination of Figure 1 yields the following important conclusions: 1) The line through the experimental points in the endergonic region is apparently parallel to the no-overhead line, which implies that the kinetics of these processes closely follows their thermodynamics. 2) The overheads (the vertical separations between the experimental points and the solid line) are small (2–4 kcal mol^{-1}). These observations indicate that the large accelerations[10] of mesolytic bond scissions relative to the homolytic processes in A–B molecules have thermodynamic origins and that the energetic costs of reorganization to attain the transition state (TS) are low.

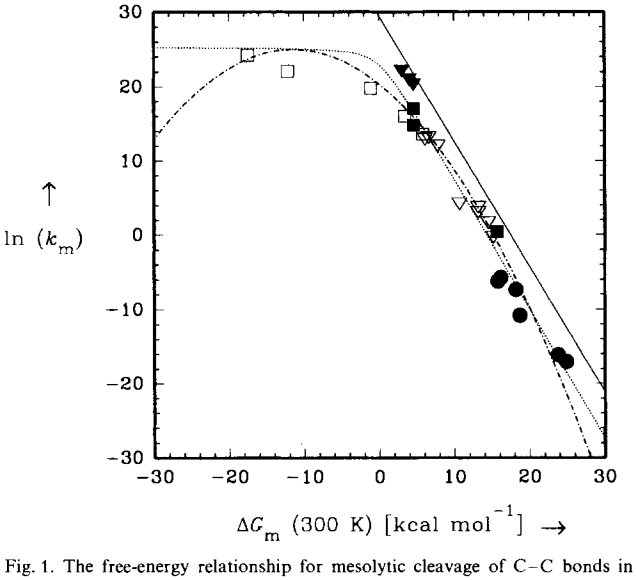

Fig. 1. The free-energy relationship for mesolytic cleavage of C–C bonds in π radical ions of **1c**–**h** (●), **2** (▽), **3** (□), **4a**–**c** (▼), **4d**, **e** and **5** (■). Kinetic measurements were carried out in Me_2SO ($\mathbf{1}^{\bullet-}$), CH_3CN ($\mathbf{3}^{\bullet-}$, $\mathbf{2}^{\bullet+}$), or CH_2Cl_2/MeOH ($\mathbf{2}^{\bullet+}$, $\mathbf{4}^{\bullet+}$, $\mathbf{5}^{\bullet+}$). Addition of electrolytes to these solutions had little effect on the observed rate constants k_m. The solid line represents a hypothetical reaction with no kinetic overhead ($k_m = (k_bT/h)\exp(-\Delta G_m/(RT))$, that is, one with only the thermodynamic barrier). The broken lines are the best fit lines for parabolic and hyperbolic (Weller-type)[11] functions.

A general parabolic and a hyperbolic (Weller-type)[11] equation (broken curves) were fitted to the experimental data. The expected shape of such a relation depends on the shape of the free-energy function. The obvious choices include linear (which is only an approximation), quadratic (Marcus type)[12] or hyperbolic (Weller type).[11] There are precedences for these possibilities in chemistry, and it has been shown that all three can be derived from a unified qualitative treatment based on the Hammond postulate and energy-surface crossing models.[13] The particularly appealing choice is the quadratic, one-parameter, Marcus-type equation (e),[12] in which $\Delta G_0^{\neq}$ is the intrinsic barrier that contains the relevant internal and solvent "reorganization" contributions to the activation energy.[12] It was originally derived for electron-transfer reactions. Recently, analogous models based on a Morse curve description of bond cleavage were developed for dissociative electron-transfer cases and for mesolytic reactions of radical ions.[14]

$$\Delta G_m^{\neq} = \Delta G_0^{\neq}[1 + \Delta G_m/(4\Delta G_0^{\neq})]^2 \quad \text{(e)}$$

Combining the Marcus expression with the Eyring equation ($\ln(k_m/T) = \ln(C) - \Delta G_m^{\neq}/(RT)$) yields Equation (f). The terms

$$\ln(k_m/T) = [\ln(C) - \Delta G_0^{\neq}/(RT)] - \Delta G_m/(2RT) - \Delta G_m^2/(16RT\Delta G_0^{\neq}) \quad \text{(f)}$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0074 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 1

in square brackets reflect a combination of stereoelectronic and statistical factors as well as the energetic costs associated with reorganization of the substrate and solvent to reach the transition state. The term linear in ΔG_m is independent of C and $\Delta G_o^{\ddagger}$. The intrinsic barrier in the quadratic term determines the width of the parabola and the location of the maximum (k_{max} at $\Delta G_m = -4\Delta G_o^{\ddagger}$). Importantly, the best fit, second-order polynomial shown in Figure 1 has the first-order coefficient of 0.81 mol kcal^{-1}, almost equal to that uniquely defined by Equation (f) [$(2RT)^{-1} = 0.84$ mol kcal^{-1}, at 300 K]. This implies that the data are described well by a unique one-parameter, Marcus-type free-energy relationship.

The fit of a parabolic function to the data in Figure 1 spanning a range of over 40 kcal mol^{-1} for the driving force confirms that the intrinsic barrier for mesolytic cleavages is low ($\Delta G_o^{\ddagger} \approx 3$ kcal mol^{-1}). In this treatment any errors in the determination of ΔG_m would shift the curve to the left or right, but the small deviations of the experimental data from a theoretical curve are possibly due to the fact that different modes of cleavage are included. The different modes are expected to differ in the extent of charge delocalization in the transition state and thus have different degrees of TS stabilization.[2-4] Closer scrutiny of this plot indicates that it may contain *four related* data sets corresponding, in order of decreasing intrinsic barriers, to homolytic radical anion cleavage [**1**; Equation (a)], homolytic radical cation cleavage [**2**, **4d** and **e**, **5**; Equation (c)], heterolytic radical anion cleavage [**3**; Equation (b)], and heterolytic radical cation cleavage [**4a** and **c**; Equation (b)]. We are currently testing this hypothesis and searching for the "inverted region" to confirm the parabolic shape of the free-energy relationship for mesolytic cleavage of single bonds.

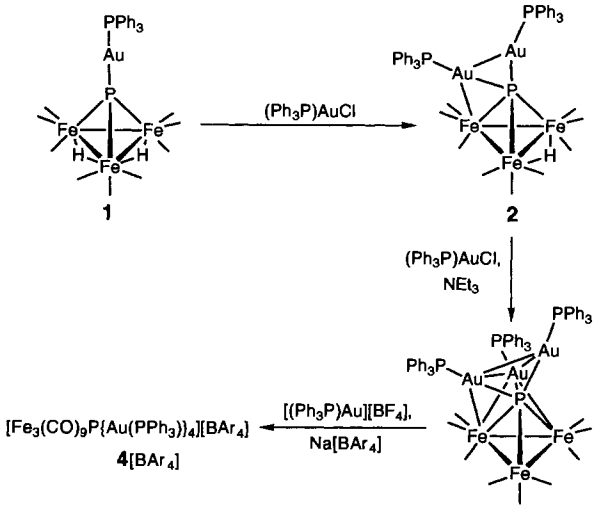
A Cluster-Bound Triply-Bridging Phosphorus Atom Coordinated to Four $(Ph_3P)Au^+$ Units: $[Fe_3(CO)_9P\{Au(PPh_3)\}_4][BAr_4]$**

Deborah L. Sunick, Peter S. White, and Cynthia K. Schauer*

Attractive interactions between metal centers in formally closed-shell d^{10} complexes have been the subject of numerous experimental and theoretical studies.[1] Gold(I), in particular, displays a pronounced tendency to self-associate,[2] and an accurate theoretical description of the $Au^I \cdots Au^I$ attraction requires inclusion of electron correlation and relativistic effects.[3, 4] Such attractive interactions between Au^I ions result in stabilization of the hypercoordinate central atom in a remarkable series of heteroatom-centered gold clusters, $L[Au(PR_3)]_n^{m+}$ (for L = C, n = 5–6;[5] for L = N, n = 5;[6] and for L = P, n = 5–6[7]) that have recently been reported by Schmidbaur et al.

Gold(I) fragments also interact strongly with transition metal carbonyl clusters, and many new clusters have been prepared by the replacement of cluster-bound hydride ligands by $(Ph_3P)Au^+$ units.[8] In the vast majority of cases, a single $(PPh_3)Au$ unit will occupy the same coordination site as the ligand it replaced, but the structures of clusters with more than one $(PR_3)Au$ fragment are dictated by the favored formation of $Au \cdots Au$ bonds. We recently reported the synthesis of the cluster **1**,[9] where the $(Ph_3P)Au$ fragment interacts exclusively with the phosphorus heteroatom of the cluster. This initial μ_3-$PAu(PPh_3)$ interaction

$[(\mu\text{-H})_2Fe_3(CO)_9\{\mu_3\text{-PAu}(PPh_3)\}]$ **1**
$[(\mu\text{-H})Fe_3(CO)_9P\{Au(PPh_3)\}_2]$ **2**
$[Fe_3(CO)_9P\{Au(PPh_3)\}_3]$ **3**



acts as a nucleus for the aggregation of cationic gold fragments, and sequential replacement of the cluster-bound hydride ligands in **1** by $(Ph_3P)Au^+$ fragments produces **2** (with a coordinated $[Au_2(PPh_3)_2]^{2+}$ unit) and **3** (with a coordinated triangular $[Au_3(PPh_3)_3]^{3+}$ unit) (see Scheme 1).[10] An analysis of the X-ray structure of the trigold cluster **3** suggested that there is sufficient space to coordinate a fourth Au^I fragment to the central phosphorus atom. We report here the synthesis and structural characterization of **4**[BAr_4] (Ar = 3,5-$(CF_3)_2C_6H_3$), a

cluster that serves to bring together studies in the areas of heteroatom-centered gold clusters and gold-derivatized transition metal clusters. Of importance in the successful synthesis of **4** is the stability and solubility afforded by the $[BAr_4]^-$ counterion.

Scheme 1.

Following the strategy employed by Schmidbaur et al., $[(Ph_3P)Au][BF_4]$, prepared by reaction of $(Ph_3P)AuCl$ with $Ag[BF_4]$, is employed as an aurating agent. Upon treatment of the Au_3 cluster **3** with a solution of $[(Ph_3P)Au][BF_4]$ in THF, a new deep purple color is observed. The pattern of infrared CO stretching frequencies is shifted by 20 cm^{-1} to higher energy, and the $^{31}P\{^1H\}$ NMR spectrum shows a quintet at $\delta = 82.4$ ($^2J_{P,P} = 129$ Hz), with a corresponding doublet at $\delta = 49.0$ for the phosphane ligands, all suggesting formation of the desired Au_4 cluster. Solutions of $4[BF_4]$, however, decomposed over 1–2 hours, even at $-50\,^\circ C$, to regenerate **3**, together with unidentified gold-containing products. The anion $[BAr_4]^-$ has been recently employed as a replacement for $[BF_4]^-$ to impart increased stability and solubility to cationic, highly electrophilic transition metal complexes.[11] In an attempt to isolate a more soluble and stable salt of **4**, a sample of **3** and 1 equiv of $Na^+[BAr_4]^-$ is treated with $[(Ph_3)Au][BF_4]$. After removal of the solvent, the $[BAr_4]^-$ salt of **4** can be extracted into Et_2O; salts are left behind as by-products. The solubility of $4[BAr_4]$ in ether is especially impressive since the Au_3 cluster **3** is nearly completely insoluble in Et_2O. Crystals of $4[BAr_4]$ are isolated from Et_2O/pentane in 56% yield.

Solutions of $4[BAr_4]$ in THF or CH_2Cl_2 are stable for a day; however, the tetragold cluster **4** readily transfers one $(Ph_3P)Au^+$ fragment in stoichiometric reactions with $[(Ph_3P)_2N]^+\,Cl^-$ or PPh_3 in CH_2Cl_2 solution to regenerate the trigold cluster **3**. To test the possible role of the $[BF_4]^-$ counterion on the low stability of $4[BF_4]$, a solution of $4[BAr_4]$ in THF was added to a flask containing 3 equiv of dry $[NBu_4]^+[BF_4]^-$. At room temperature, complete decomposition of **4** to **3** takes place within 45 minutes, which strongly suggests that $[BF_4]^-$ can be a reactive counterion toward polyaurated cations.

The $^{31}P\{^1H\}$ NMR data for **1**–**4** are summarized in Table 1. At room temperature, sharp, coupled resonances are observed for the central phosphorus atoms (P_c) and the PPh_3 ligands in **1**–**4**, indicating that intermolecular exchange of $(Ph_3P)Au^+$ fragments is not rapid. For the phosphorus-centered gold clusters $[P\{Au(PPh_3)\}_5]^{2+}$ and $[P\{Au(PPh_3)\}_6]^{3+}$,[7] low-temperature ^{31}P NMR spectroscopy was required to observe two-bond P_c-PPh_3 coupling. Successive substitution of gold fragments for hydride ligands in **1** results in a decrease in the average $^2J_{P,P}$ value from 314 Hz in **1** to 129 Hz in **4**, together with a progressive upfield shift of the ^{31}P NMR chemical shift for P_c from $\delta = 390.3$ in **1** to 82.4 in **4**. Similar trends are observed upon addition of a $(Ph_3P)Au^+$ fragment to the pentagold cluster $[P\{Au(PPh_3)\}_5]^{2+}$ ($\delta = 122$ for P_c, $^2J_{P,P} = 186$ Hz) to produce $[P\{Au(PPh_3)\}_6]^{3+}$ ($\delta = -166$ for P_c, $^2J_{P,P} = 167$ Hz).[7] The four gold-bound phosphane ligands in **4** are still equivalent in the $-100\,^\circ C$ ^{31}P NMR spectrum; however, the resonance for P_c is shifted by more than 20 ppm upfield.

Table 1. $^{31}P\{^1H\}$ NMR data for gold clusters **1**–**3** and **4**$[BAr_4]$. The measurements were performed at 25 °C.

	Cmpd	Solvent	$\delta(P_c)$	$\delta(PPh_3)$	$^2J(P,P)$ [Hz]
1		C_6H_6	390.3 (d)	40.8 (d)	314
2		CH_2Cl_2	253.3 (t)	45.3 (d)	192
3		CH_2Cl_2	125.7 (quart)	45.1 (d)	147
4	$[Fe_3(CO)_9P\{Au(PPh_3)\}_4]^+$	$[D_8]$THF	82.4 (quint)	49.0 (d)	129
4	(−100 °C)	$[D_8]$THF	58.9 (quint)	47.7 (d)	130

The structure of $4[BAr_4]$ was determined by a single-crystal X-ray diffraction study (Fig. 1),[12] and consists of a slightly distorted square-planar $[Au_4(PPh_3)_4]^{4+}$ unit ($Au\cdots Au$ = 2.976(1)–3.224(2) Å) coordinated to the $[Fe_3(CO)_9P]^{3-}$ cluster framework. The dihedral angle between the Fe_3 plane and the Au_4 plane is 30°. Three of the four $(Ph_3P)Au^+$ fragments in the Au_4 unit are strongly bound to the central phosphorus atom ($Au-P_c$ = 2.357(6)–2.427(6) Å), while the third $(Ph_3P)Au^+$ fragment (Au3) is at a distance of 2.694(6) Å. Three of the four Au^I ions in the Au_4 square also interact with Fe1 and Fe2 in the Fe_3 triangle: Au3 bridges the Fe1–Fe2 edge, while Au2 and Au4 interact with Fe2 and Fe1, respectively (Fig. 2, right). The stepwise construction of the Au_4 array in **4** can be accessed by evaluating the structures of **2**–**4**. In the digold cluster **2** one $(Ph_3P)Au^+$ fragment (Au1) is bound to the cluster exclusively through P_c, while the second $(Ph_3P)Au^+$ unit (Au2) bridges an

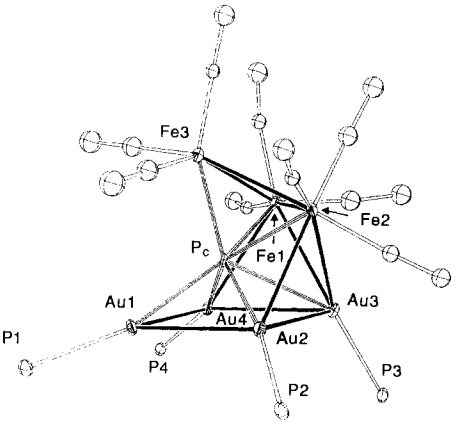

Fig. 1. ORTEP drawing (ellipsoids represent 30% probability) of the structure of the cation **4**. Phenyl rings have been omitted for clarity. Selected distances [Å]: Au1-Au2 2.976(1), Au1-Au4 2.992(2), Au2-Au3 3.224(2), Au3-Au4 2.980(1), Au1-P1 2.302(6), Au1-P_c 2.357(6), Au2-Fe2 2.729(3), Au2-P2 2.299(6), Au2-P_c 2.427(6), Au3-Fe1 2.690(3), Au3-Fe2 2.830(4), Au3-P3 2.287(6), Au3-P_c 2.694(6), Au4-Fe1 2.786(3), Au4-P4 2.296(6), Au4-P_c 2.412(6), Fe1-Fe2 2.674(5), Fe1-Fe3 2.632(5), Fe2-Fe3 2.670(5), Fe1-P_c 2.296(7), Fe2-P_c 2.278(7), Fe3-P_c 2.220(7).

Fe–P edge. The structure of the trigold cluster **3** (Fig. 2 left) is simply derived from addition of a third $(Ph_3P)Au^+$ fragment (Au3) to a Fe_2P face of the cluster As can be seen by comparing the two structures in Figure 2, **4** is formally constructed by "insertion" of Au4 into the Au1–Au3 bond.

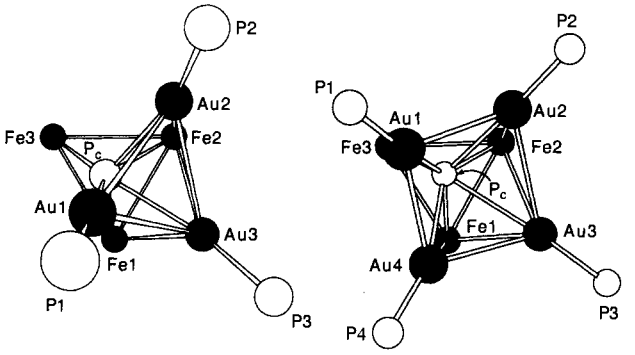

Fig. 2. View onto the Fe_3 plane of the ball and stick drawings of the $Fe_3P[Au_3P_3]$ core of **3** (left) and $Fe_3P[Au_4P_4]$ core of **4** (right).

A C_{4v} symmetry structure (with a square-planar array of Au^I ions) instead of T_d symmetry structure was recently predicted to be the most stable for the hypothetical $[P\{Au(PH_3)\}_4]^+$ cluster,[4e] and is observed experimentally for $[As\{Au(PPh_3)\}_4]^+$.[13] Given the large number of possible other arrangements of gold atoms involving different modes of bonding to the Fe_3 triangle, the configuration adopted by the $[Au_4(PPh_3)_4]^{4+}$ fragment in **4** is likely governed by the stability of the nearly square-planar arrangement of Au^I ions. Remarkably, the geometry of the Au_4 array in **4** is similar to that adopted in the related monoarylphosphorus dication, $[(o\text{-tolyl})P\{Au(PPh_3)\}_4]^{2+}$ (Au···Au = 2.97(5), Au–P_c = 2.37(1), Au–PPh_3 = 2.293(7) Å).[14] Thus, **4** can be viewed either as a $[\{Au(PPh_3)\}_4]^{4+}$ derivative of the $[Fe_3(CO)_9(\mu_3\text{-}P)]^{3-}$ cluster or as an $Fe_3(CO)_9$ derivative of $[P\{Au(PPh_3)\}_4]^+$, in which bonding to the Fe_3 array requires six electrons from the P^{3-} ion. Such a cluster is not readily amenable to classical bonding descriptions.

Experimental Procedure

Reactions were performed under purified nitrogen with standard Schlenk techniques.

4[BAr_4]: Solid samples of purple-red **3** (57.5 mg, 0.031 mmol) and $Na^+[BAr_4]^-$ (27.4 mg, 1 equiv) were combined in a flask, and a freshly prepared solution of [$(Ph_3P)Au$][BF_4] [14] in 10 mL of THF (prepared from 0.031 mmol each of Ag[BF_4] and $(Ph_3P)AuCl$ in the dark) at −70 °C was filtered onto the solids. A new deep purple color was observed as **3** dissolved. After stirring for 5 min, conversion to **4** was complete (as indicated by IR spectroscopy). The solvent was removed under vacuum and **4**[BAr_4] was extracted into Et_2O. The solution was filtered, and then layered with pentane to yield crystals of **4**[BAr_4]. Isolated yields: 56 mg (57%). ^1H NMR (300 MHz, [D_8]THF): δ = 7.9, 7.7 (br s, Ar protons) 7.25, 7.50 (m, Au(PPh_3)); IR (Et_2O): ν_{CO} = 2041 cm^{-1} vs, 1993 vs, 1983 s, 1974 m, 1936 w, br; correct elemental analysis for $C_{113}H_{72}Au_4BF_{24}Fe_3O_9P_5$.

Competing Reactions of Silenes: [2 + 2], [4 + 2], and [6 + 2] Cycloadditions with Cycloheptadiene and Cycloheptatriene**

Wolfgang Ziche, Claudia Seidenschwarz, Norbert Auner,* Eberhardt Herdtweck, and Norbert Sewald

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

(Hetero)olefins usually undergo [2 + 2] and [4 + 2] cycloadditions, while examples of thermal [6 + 2] cycloadditions are comparatively rare.[1] "Dichloroneopentylsilene" **1** is a

$Cl_2Si{=}CHCH_2tBu$ **1**

building block for synthetic organosilicon chemistry, which is characterized by a highly polar Si=C bond and a strongly electrophilic silicon atom. These properties are mainly responsible for its unique reactivity: on the one hand, **1** reacts with relatively unreactive dienes like naphthalene[2] and furans[3] to give Diels–Alder adducts and, on the other hand, it undergoes [2 + 2] cycloadditions with disubstituted acetylenes to give silacyclobutenes.[4] The reaction of **1** with 1,3-butadienes leads selectively to monosilacyclobutanes,[5] and upon treatment of **1** with 1,3-cyclohexadiene the [2 + 2] and [4 + 2] cycloadditions compete with each other;[6] in both cases the [2 + 2] adducts are converted thermally into Diels–Alder and retro-ene products. We report here on the cycloadditions of **1** with 1,3-cycloheptadiene and 1,3,5-cycloheptatriene.

[**] Silaheterocycles, Part 30. This work was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. – Part 29: W. Ziche, V. Popkova, C. Seidenschwarz, N. Sewald, E. Herdtweck, N. Auner, *Organometallics*, submitted.

Reaction of silene **1**, prepared in situ from trichlorovinylsilane and *t*BuLi, with cycloheptadiene produces a mixture of the [2 + 2] and [4 + 2] cycloadduct isomers, **2** and **3**, respectively, which is not separable by distillation.[7] To separate the structural isomers the mixture was treated with phenylmagnesium bromide. In this reaction only the two chloro substituents of the [2 + 2] adducts are replaced by two phenyl groups giving **4**. This selective reactivity is analogous to that of the corresponding cyclohexadiene adducts[6] and is attributed to the angles at the silicon atom in the monosilacyclobutane subunits (see also Fig. 1).[8–10] Compound **4** was recrystallized from pentane and shown by X-ray structure analysis (Fig. 1) to be the diphenyl-substituted [2 + 2] isomer (*E*)-**4**.[8]

(*E*/*Z*)- **2**

exo/*endo*- **3**

4

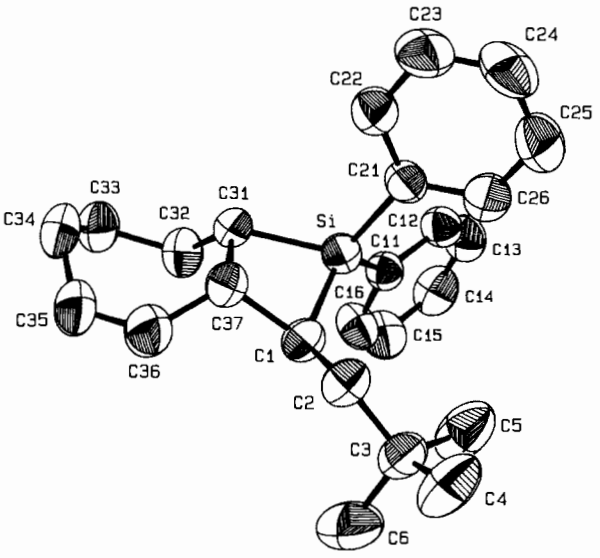

Fig. 1. Crystal structure of (*E*)-**4** (ORTEP representation). Selected distances [pm] and angles [°]: Si-C1 188.0(1), SiC31 188.4(1), Si-C11 187.3(1), Si-C21 187.5(1), C1-C2 152.4(1), C1-C37 158.9(1), C31-C37 156.4(1), C1-SiC31 79.45(5), Si-C1-C37 85.88(7), Si-C31-C37 86.44(7), C1-C37-C31 99.46(9), C11-Si-C21 110.48(5), C31-C37-C36 118.52(11), Si-C1-C2 126.72(9), Si-C31-C32 118.51(9).

The most striking structural features of (*E*)-**4** are the nonplanar central silacyclobutane unit and the small endocyclic angles; the angle at silicon (79.45°) is significantly smaller than at the opposite carbon atom (99.46°). These values are normal for silacyclobutane derivatives.[9]

Surprisingly, the reaction of **1** with 1,3,5-cycloheptatriene leads to four [2 + 2] (**5**) and two [6 + 2] cycloadducts (**6**) (Scheme 1, for relative amounts see Table 1).

Table 1. Selected spectroscopic data[a] for (*E*)-**4**, **5**, **6**, and *endo*-**7**.

[a] ^{1}H NMR: $CDCl_3$, 100, 270, and 360 MHz; ^{13}C NMR: 25.14 MHz, $CDCl_3$, ^{29}Si NMR: 53.64 MHz, $CDCl_3$. GC-MS at 70 eV.

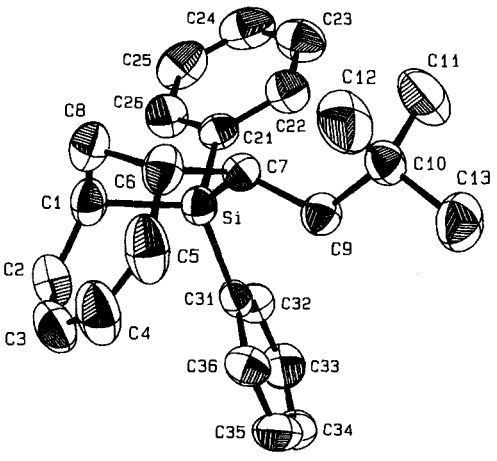
The ^{29}Si NMR chemical shifts of the products, before and after distillation, allow clear assessment of the type of cycloadducts formed. The signals for **5** lie between δ = 12.6 and 18.4, characterizing these compounds as the [2 + 2] cycloadducts. For **6** the signals at δ = 41.7 and 46.5 have chemical shifts typical of dichlorosilacyclopentanes, thus identifying the two compounds as the *exo*/*endo* [6 + 2] cycloadduct isomers. Formation of both the [6 + 2] and the [2 + 2] cycloadducts by a concerted process is forbidden by the Woodward–Hoffmann rules.[11] No [4 + 2] cycloadducts are formed in the reaction sequence shown in Scheme 1; their ^{29}Si NMR signals would be expected in the region $\delta \approx$ 25–30.[6]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0078 $ 10.00+.25/0

Scheme 1. Reaction of **1** with 1,3,5-cycloheptatriene.

The separation of the structural isomers of **5** and **6** into individual components was successfully achieved in a chemical fashion:

- When a mixture of **5** and **6** was stored at room temperature for several months, *endo/exo*-**6** (*endo/exo* 75/25) was formed exclusively. Thermolysis of this mixture in solution (toluene 110 °C, 120 h) or neat (200 °C, 120 h) significantly accelerated the isomerization of **5** into **6**. The *endo/exo* ratio for **6** was then 85/15. Compound **6** was characterized by 2D NMR spectroscopy.
- Derivatizing **5**/**6** with phenylmagnesium bromide gave almost selective isomerization to the diphenyl-substituted [6 + 2] cycloadduct, *endo*-**7**, which is crystalline and was characterized by X-ray structure analysis (Fig. 2).[12]



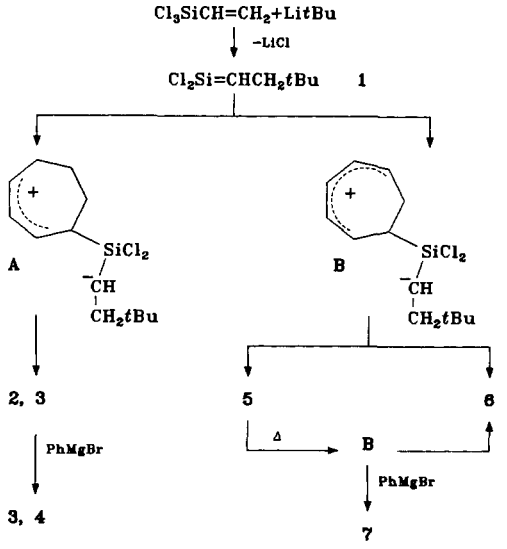


Fig. 2. Crystal structure of *endo*-**7** (ORTEP representation). Selected distances [pm] and angles [°]: Si-C1 190.3(1), Si-C7 190.3(1), Si-C21 187.4(1), Si-C31 186.9(1), C7-C9 153.3(1), C6-C7 155.8(1), C5-C6 149.1(2), C1-C2 148.1(2), C1-C8 153.0(1), C6-C8 153.8(1), C1-Si-C7 96.35(6), Si-C7-C6 103.79(8), Si-C7-C9 118.49(9), Si-C1-C2 113.92(10), C2-C1-C8 113.93(14), C5-C6-C7 114.03(13).

As is clear from Fig. 2, the *endo* isomer of the [6 + 2] cycloadduct **7** shows no striking structural features; the C6–C7 bond length is 155.9(2) pm, a little longer than the average of the other C–C bond lengths ($d = 151.9$ pm). The bicyclo[4.2.1]-2,4-nonadiene unit is somewhat distorted in comparison to the analogous all-carbon framework as a consequence of the larger atomic radius of the Si atom.[13]

The [2 + 2] and [6 + 2] cycloadditions of silene **1** reported here, as well as the isomerizations, can be explained in terms of zwitterionic intermediates (Scheme 2). The strongly polarized

Scheme 2. Possible reaction pathways for the formation and rearrangement of the cycloadducts of **1**.

and electrophilic silene **1** attacks one of the terminal carbons in the conjugated π-electron system of cycloheptadiene and cycloheptatriene, forming the zwitterions **A** and **B**, respectively. Carbocation **B** is more effectively stabilized than **A** by greater delocalization, which thereby allows more time for stereochemical orientation of the dipolar system and a number of possible modes of ring closure. The attack of the carbanion at the terminal carbon atom of the cationic propenyl and pentadienyl moieties leads in both cases to rapid ring closure, giving the [2 + 2] cycloadducts **2** and **5** preferentially. Competing with this is the formation of the Diels–Alder adduct **3**, in a slower step, and the [6 + 2] cycloadduct **6**, which is mainly produced as the thermodynamically more stable *endo* isomer.[14] The greater stability of **B** is also confirmed by the fact that the (*Z*) [2 + 2] adduct **5** does not thermally isomerize to give the retro-ene compound. This isomerization was observed for the related compounds formed from **1** with butadienes,[5] 1,3-cyclohexadiene,[6] and 1,3-cycloheptadiene.[15]

These results open up wide-ranging possibilities for the transformation of the regiospecific but stereoisomeric [2 + 2] adducts of silene **1** into stereochemically pure products with nucleophilic reagents. In this way the whole process becomes stereoselective.

Experimental Procedure

5/**6**: A solution of *t*BuLi (1.7 M in pentane, 36.0 mL, 60.0 mmol) was added dropwise to a mixture of $Cl_3SiCH{=}CH_2$ (9.6 g, 60.0 mmol) and 1,3-cycloheptatriene (11.0 g, 119.6 mmol) in pentane (500 mL) at −78 °C. After the mixture was allowed to warm to room temperature, it was stirred for another 12 h. After filtration the mixture was distilled to give a mixture of **5**/**6** (100 °C, 10^{-2} mbar) as a colorless viscous liquid (9.3 g, 34.0 mmol, 56.6% yield).

4: A mixture of **2**/**3** (2.76 g, 10.0 mmol, prepared analogously to **5**/**6**) was added to phenylmagnesium bromide (60.0 mmol) in THF (50 mL) and heated at reflux for 60 h. The solvent was then distilled off and the residue extracted with pentane. **3** (105 °C, 10^{-2} mbar; 0.85 g, 3.0 mmol, 30% yield) and **4** (185 °C, 10^{-2} mbar; 1.19 g, 3.3 mmol, 33% yield; E/Z = 66/34) were isolated by distillation. (*E*)-**4** solidified in the receiving flask and was recrystallized from pentane to give a white solid (m.p. 85 °C).

7: The derivatization of **5**/**6** with phenylmagnesium bromide (3.40 g, 12.5 mmol) followed that of **4**. Compound **7** was isolated as a thick oil by distillation (200 °C, 10^{-2} mbar), which crystallized in the receiving flask. Recrystallization from pentane gave pure **7** as a white solid (3.58 g, yield 83.3%, m.p. 97 °C).

[7] Nonetheless the assignment of the NMR signals to the individual isomers is possible by comparison to the NMR data from the cycloadducts of **1** with cyclohexadiene[6]; the ^{29}Si NMR spectrum in particular can be used to determine the product type (**2**: δ = 16.45, 16.47 and **3**: δ = 28.90, 29.70) as well as the relative proportions of the individual stereoisomers (*E*)/(*Z*)-**2**, and *exo*/*endo*-**3**). (*E*)/(*Z*) describes the position of the neopentyl group on the silacyclobutanes relative to the vicinal bond of the annulated ring; *exo*/*endo* denotes the stereochemistry of the neopentyl group in the [4 + 2] and [6 + 2] cycloadducts; and *cis*/*trans* refers to the stereochemistry of the fusion of the seven- and four-membered rings in **5**.
[8] X-ray crystal structure analysis of (*E*)-**4** ($C_{25}H_{32}Si$), M = 360.6; colorless prisms (0.51 × 0.18 × 0.26 mm^3); triclinic space group, $P\bar{1}$ (no. 2), a = 993.6(1), b = 1055.5(1), c = 1152.2(1) pm, α = 69.51(1), β = 85.13(1), γ = 76.42(1)°, 25 reflections with high diffraction angles ($2\theta_{min/max}$ = 79.7°/96.8°), V = 1100 × 10^6 pm^3, Z = 2, ρ_{calc} = 1.086 g cm^{-3}, F_{000} = 392, μ = 9.4 cm^{-1}. A crystal suitable for X-ray analysis was mounted in a capillary with perfluorinated polyether. Data were collected on an Enraf-Nonius CAD-4 four-circle diffractometer. Intensity data for 4381 reflections were collected at room temperature (21 ± 1) °C with graphite-monochromated $Cu_{K\alpha}$ radiation, λ = 154.184 pm, $\theta/2\theta$-Scan, 1.0° < θ < 70.0°. From these data 594 reflections with negative intensities were removed. After correction for minor decomposition (99 h, −7.1%) and an empirical absorption correction (8 Psi-scan data, $C_{min/max}$ = 0.959/1.000) there remained, after averaging 414 reflections (R_m = 0.010(F)), 3580 independent reflections. One reflection, obviously a measurement error, was discounted. The structure was solved using a combination of direct and indirect methods, difference-Fourier maps and full-matrix least-squares techniques. All heavy atoms were refined with anisotropic parameters and all hydrogen atom positions with isotropic parameters. Refinement lead to convergence with R = 0.065 and R_w = 0.048 for 3579 reflections and 363 variables. A difference map showed no residual electron density outside + 0.70 and −0.35 e Å^{-3}. All calculations were performed on a micro-Vax-3100 computer with the STRUX IV program package (MULTAN 11/82, ORTEP-II, PLATON, SCHAKAL, SDP and SHELX-86)[16]. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-56657, the names of the authors, and the journal citation.

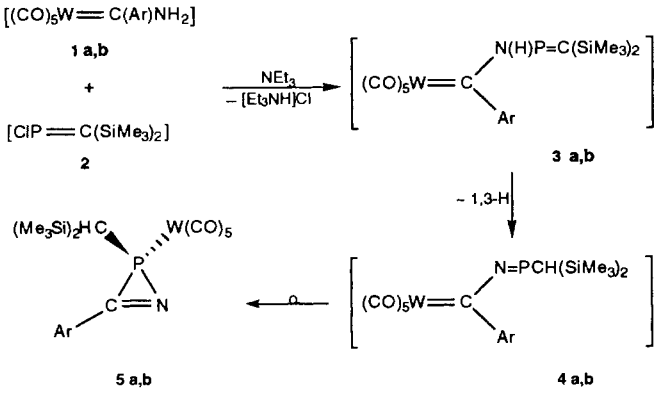
Synthesis of the First 2*H*-1-Aza-2-phosphirene Complexes**

Rainer Streubel,* Jörg Jeske, Peter G. Jones, and Regine Herbst-Irmer

The elucidation of the mechanisms of preparatively important reactions is fascinating, but also often very time-consuming. The rearrangement **I** → **II** of a η^2-cyclopropene into a vinyl carbene complex during the insertion of an alkyne into the metal–carbene carbon bond of an arylidene(pentacarbonyl)-tungsten(0) complex was verified only recently,[1] although this reaction sequence has long been utilized in preparative work.[2] In attempting to synthesize the first derivatives of 2-aza-1-phospha-4-tungsta-1,3-butadiene (**III**), which is isolobal with **II**, we have now surprisingly obtained exclusively 2*H*-1-aza-2-phosphirene tungsten complexes of type **IV**, which are isomeric with **III** (Scheme 1).



Scheme 1.

To the best of our knowledge neither 2*H*-1-aza-2-phosphirenes nor their cyclic isomers are known, nor have there been previous reports of complexes containing these three-membered rings as ligands.[3]

The reaction of amino(aryl)carbene tungsten complexes **1a,b**[4] with chloro[bis(trimethylsilyl)methylene]phosphane (**2**)[5] in the presence of triethylamine under mild conditions gave the 2*H*-1-aza-2-phosphirene-2-pentacarbonyltungsten complexes **5a,b** (Scheme 2). These were isolated from pentane in good yields as yellow crystalline solids.

Scheme 2. Proposed reaction sequence for the formation of the 2*H*-1-aza-2-phosphirene tungsten complexes **5a,b**. **1a**, **3a–5a**: Ar = *p*-tolyl; **1b**, **3b–5b**: Ar = *p*-anisyl.

Table 1. Selected spectroscopic data of **5a,b** and **6** [a].

5a: ^{1}H NMR: $\delta = 0.10$ (s, 9H, $SiMe_3$), 0.29 (s, 9H, $SiMe_3$), 0.71 (d, ^2J(H,P) = 2.8 Hz, 1H, PCH), 2.48 (s, 3H, *p*-CH_3), 7.43 (d, ^3J(H,H) = 8.1 Hz, 2H, *m*-H), 7.91 (d, ^3J(H,H) = 8.1 Hz, 2H, *o*-H); ^{13}C{^{1}H} NMR: $\delta = 1.35$ (d, ^3J(C,P) = 3.13 Hz, $SiMe_3$), 2.14 (d, ^3J(C,P) = 3.04 Hz, $SiMe_3$), 22.02 (s, Ph-CH_3), 27.44 (d, ^1J(C,P) = 24.24 Hz, PCH), 123.79 (d, ^2J(C,P) = 15.08 Hz, Ph), 129.62 (s, Ph), 130.47 (s, Ph), 145.30 (s, Ph), 191.44 (d, ^1J(C,P) = 1.44 Hz, PCN), 195.91 (dd, ^2J(C,P) = 9.11 Hz, ^1J(C,W) = 125.93 Hz, *cis*-CO), 197.87 (d, ^2J(C,P) = 35.91 Hz, *trans*-CO); ^{31}P{^{1}H} NMR: $\delta = -111.19$ (d, ^1J(P,W) = 293.09 Hz).

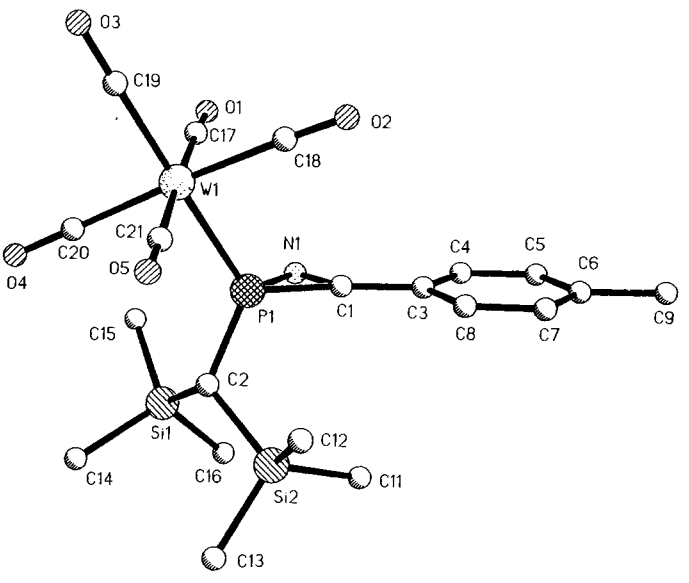
[a] All spectra of **5a** and **6** in $CDCl_3$ and of **5b** in C_6D_6, 25 °C; ^{1}H NMR: 200 MHz, ^{13}C NMR: 50.3 MHz, ^{31}P NMR: 81.0 MHz; the deuterated solvent was used as internal standard and 85% H_3PO_4 as external standard.

Even though none of the intermediates could be isolated or detected spectroscopically, the reaction sequence for the formation of the 2*H*-azaphosphirene tungsten complexes **5a,b** summarized in Scheme 2 still seems plausible. The first step is the formation of the P–N bond to give the 3-aza-2-phospha-5-tungsta-1,4-pentadiene derivatives **3a,b** with the loss of triethylammonium chloride. A subsequent 1,3 hydrogen shift in **3a,b** leads to the formation of the P–N double bond of the bis(trimethylsilyl)methyl-substituted 2-aza-1-phospha-4-tungsta-1,3-butadienes **4a,b**—similar 1,3-hydrogen shifts have already been exploited to synthesize a bis(trimethylsilyl)methyl-substituted iminophosphane[6] and (1-dialkylaminopropylidene)aminocarbene complexes.[7] An immediate valence-isomerization of compounds **4a,b**, possibly via a metallacyclic intermediate, leading to the formation of the C–N double bond, and a subsequent shift of the pentacarbonyltungsten fragment to the phosphorus atom, affords the 2*H*-azaphosphirene complexes **5a,b**. The composition and constitution of compounds **5a,b** are confirmed by elemental analyses, mass spectrometric and IR[8] and NMR spectroscopic investigations (Table 1). The phosphorus atoms in **5a,b** each show one resonance signal in the high-field region of the ^{31}P NMR spectrum (**5a**: $\delta = -111.19$ (^1J(P,W) = 293.09 Hz), **5b**: $\delta = -115.1$ (^1J(P,W) = 292.5 Hz)). The large values of the ^1J(P,W) coupling constants are characteristic for direct bonding of the $[W(CO)_5]$ fragment to the phosphorus atom. The ^{13}C NMR signal of the imine-carbon atom (**5a**: $\delta = 191.44$ (^1J(C,P) = 1.44 Hz); **5b**: $\delta = 190.27$ (^1J(C,P) = 3.05 Hz) is significantly shifted downfield in comparison to the corresponding signals of 3-aryl-2*H*-azirines.[9] The values of the ^1J(C,P) coupling constants of **5a,b** are remarkably small; 1-aryl-1*H*-phosphirine complexes show the same phenomenon.[10]

The proposed constitution of the compounds **5a,b** was confirmed for **5a** by a single-crystal X-ray structure analysis. There are two independent molecules in the asymmetric unit, which, however, do not differ significantly.[11] As shown in Figure 1, the 2*H*-1-aza-2-phosphirene unit in **5a** is characterized by a short C1–N1 bond (126.5(11) and 126.2(11) pm), similar to that observed in 2*H*-azirine palladium complexes. As a result of this short C1–N1 bond in **5a**, a very acute endocyclic angle (41.6(4) and 41.8(4)°) occurs at the phosphorus atom. The very short C1–C3 single bond (145.8(12) and 147.0(12) pm) clearly indicates a π interaction between the two ring systems in **5a** (interplanar angle 2° and 3°). The question then arises whether it is possible to stabilize or destabilize the 2*H*-1-aza-2-phosphirine unit by using suitable substituents at the phenyl ring, and thereby to induce isomerizations of this ring.



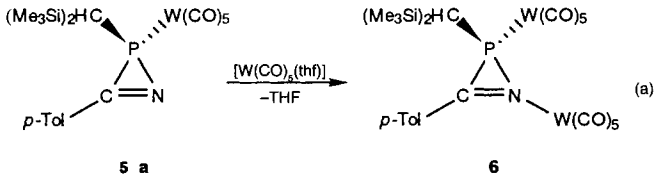


Fig. 1. One of the two independent molecules of **5a** in the crystal. Selected bond lengths [pm] and angles [°] (values for both molecules): P1-C1 176.5(9), 174.9(9), P1-C2 180.1(8), 180.3(8), P1-N1 179.3(8), 178.9(9), P1-W1 247.0(2), 247.9(2), N1-C1 126.5(11), 126.2(11), C1-C3 145.8(12), 147.0(12); C1-P1-N1 41.6(4), 41.8(4), C1-N1-P1 68.0(5), 67.4(6), N1-C1-P1 70.4(6), 70.8(6), N1-C1-C3 134.5(8), 132.6(8), C3-C1-P1 154.9(7), 156.6(6).

The reaction of **5a** with $[W(CO)_5(thf)]$ illustrates the nucleophilic character of the 2 *H*-azaphosphirene complex **5a**.[1,2] The reaction leads smoothly and with retention of the three-membered ring to the orange-colored 1,2-bis(pentacarbonyltungsten)-1-aza-2-phosphirene derivative **6** [Eq. (a)].

(a)

5a **6**

The η^1 coordination of the $[W(CO)_5]$ fragment at the nitrogen atom not only has a considerable deshielding effect on the two other ring atoms, but also on the phenyl-carbon atoms in **6** (cf. NMR data in Table 1). Both the NMR signal of the phosphorus and that of the carbon atom in the three-membered ring of **6** are shifted significantly downfield in comparison to the corresponding signals of **5** (**5a**, **6**: $\delta^{31}P = -111.19, -62.0$; $\delta^{13}C = 191.44, 201.64$); furthermore, the values of the exocyclic $^1J(C,P)$ and $^1J(P,W)$ coupling constants are considerably higher.

As these results show, amino(aryl)carbene tungsten complexes can be used for the synthesis of new phospha heterocycles. The development of additional methods for the synthesis of 2 *H*-1-aza-2-phosphirenes and investigations into the reactivity of this new ring system are planned.

Experimental Procedure

General procedure for the preparation of **5a,b**: A solution of **1a,b** (1.5 mmol) in Et_2O (15 mL) was treated with **2** (0.34 g, 1.5 mmol) and NEt_3 (5 mL) under nitrogen at room temperature and stirred for two days. The orange reaction mixture was concentrated to dryness under reduced pressure. The residue was treated with pentane (30 mL), subsequently filtered and the filtration residue washed twice with pentane (5 mL). The filtrate was concentrated to 10 mL under reduced pressure and cooled to −30 °C. The resulting crystalline solid was washed with a little pentane and then the remaining solvent was removed under high vacuum (10^{-3} mbar). **5a**: yellow crystals, yield 49%, m.p. 104–105 °C (decomp); **5b**: yellow-orange crystals, yield 45%, m.p. 103–104 °C (decomp).

6: **5a** (0.6 g, 0.95 mmol) in THF (20 mL) was treated at 0 °C with a $[W(CO)_5(thf)]$ solution (100 mL, 0.095 M) and stirred at this temperature for 0.5 h. The reaction solution was concentrated to 15 mL under reduced pressure and stirred for a further two hours at room temperature. Subsequently, the solution was concentrated to dryness, the residue taken up in pentane (50 mL), filtered, and concentrated to dryness again. If the residue was taken up in Et_2O (15 mL), **6** remained in the residue. The solid was separated from the solution, washed twice with a little pentane and subsequently dried under high vacuum. Orange powder, yield 69%, m.p. 121 °C (decomp).

[11] Crystal structure analysis of **5a**: $C_{20}H_{26}NO_5PSi_2W$, monoclinic, space group *Cc*, a = 1393.4(5), b = 1392.1(3), c = 2714.1(9) pm, β = 99.58(3)°, V = 5.191(3) nm^3, Z = 8, μ = 4.6 mm^{-1}, T = −130 °C. A yellow crystal (ca. 0.4 × 0.4 × 0.4 mm) was mounted in inert oil (RS 3000, donated by Riedel de Haën). 6276 intensities to $2\theta_{max}$ = 55° were measured with $Mo_{K\alpha}$ radiation on a Stoe-STADI4 diffractometer, of which 6208 were independent after an absorption correction and 6198 were used for all calculations (program SHELXL-93: G. M. Sheldrick, Universität Göttingen **1993**). The structure was solved by heavy atom methods and refined anisotropically on F^2. H atoms were included with a riding model. The final $wR(F^2)$ value was 0.069, with a conventional $R(F)$ 0.032 for 555 parameters and 262 restraints. The structure is characterized by a marked pseudosymmetry; the intenstity statistics and the largest peaks of the Patterson function indicate the centrosymmetric space group *C2/c*, in which, however, only the position of the W atom could be determined. The structure could only be extended in *Cc* (with two independent molecules); the choice of the space group was then confirmed by an *x*-refinement [H. D. Flack, *Acta Crystallogr. Sect A* **1983**, *39*, 876], in which *x* was refined to the value −0.002(8). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-400333, the names of the authors, and the journal citation.

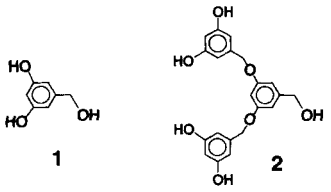
A "Branched-Monomer Approach" for the Rapid Synthesis of Dendimers**

Karen L. Wooley, Craig J. Hawker, and Jean M. J. Fréchet*



The reactivities[1] and properties[2] of dendritic macromolecules are currently being examined both out of scientific curiosity and for potential commercial applications. This has created a demand for the rapid production of dendrimers. However, both of the methods employed in the synthesis of the "perfect" dendritic macromolecules, the "divergent-"[3] and "convergent-growth"[4] approaches, involve stepwise, tedious, and time-consuming processes. Improvements have been made for the convergent growth approach. In an accelerated double-stage process[5] several growth steps are eliminated through the use of large dendritic core molecules (hypercores), allowing the preparation of high molecular weight compounds. Alternatively, in a "two-monomer approach"[6] two generations can be grown in one pot without intermediate purification steps. We now report on the use of more highly functionalized "branched monomers" in the convergent growth approach as a means for the accelerated synthesis of dendrimers.

Conceptually, the simplest repeating unit or "fractal component" used in the convergent growth process is replaced by a larger fractal component of the next generation. Therefore instead of a classical AB_2 monomer (e.g. **1**) a larger AB_4 monomer of the next generation (e.g. **2**) is employed. Use of the larger monomer preserves the convergent-growth concept with a single reactive group (the benzylic hydroxyl group) at the focal point

[**] Financial support of this project was provided by the National Science Foundation (DMR-9224421 and 9121654), the Department of Education (fellowship for K. W.), and the Australian Research Council (fellowship for C. H.).

while maintaining the branching pattern and flexibility of the final dendrimer, and reducing the number of steps required to reach higher generations. In view of difficulties encountered in the preparation of **2** in high yield, the branched monomer **3** was selected for this study.

Preparation of **3** required protection of its carboxy groups as methyl esters. Complete hydrolysis of the starting material $(CH_3O_2C)_4$-[G-2]-OH **4**[7] with potassium hydroxide in a mixed-solvent system of water, ethanol, and 1,4-dioxane at reflux furnished the tetracarboxylate (Scheme 1). Neutralization with glacial acetic acid resulted in precipitation of a partially protonated species, which is insoluble in organic solvents. However, upon addition of chlorotrimethylsilane to a slurry of the collected precipitate in THF, the soluble trimethylsilyl ester of **3** (compound **7**) was formed. Precipitation of this intermediate into water gave the desired tetracarboxylic acid **3**.

Scheme 1. Preparation of branched monomers **3** and **7** and their use in the preparation of a third-generation dendrimer.

As shown in Scheme 1, reaction of the branched monomer **3** with the first-generation dendritic bromide **5** in the presence of potassium carbonate gave a third-generation dendritic benzyl ether **6**, containing four internal ester linkages, in 85% yield after purification by flash chromatography. Because the generation number correlates with the number of layers of monomer units, each generation growth step performed with the second-generation branched monomer **3** results in an increase in size of two generations. Alcohol **6** is a dendritic trilayer block copolymer, since in its construction an outer concentric layer of ether groups surrounds an inner layer of ester groups as well as two layers of ether linkages. It should be noted that the purity of the branched monomer is critical if high yields of pure dendrimer are to be obtained.

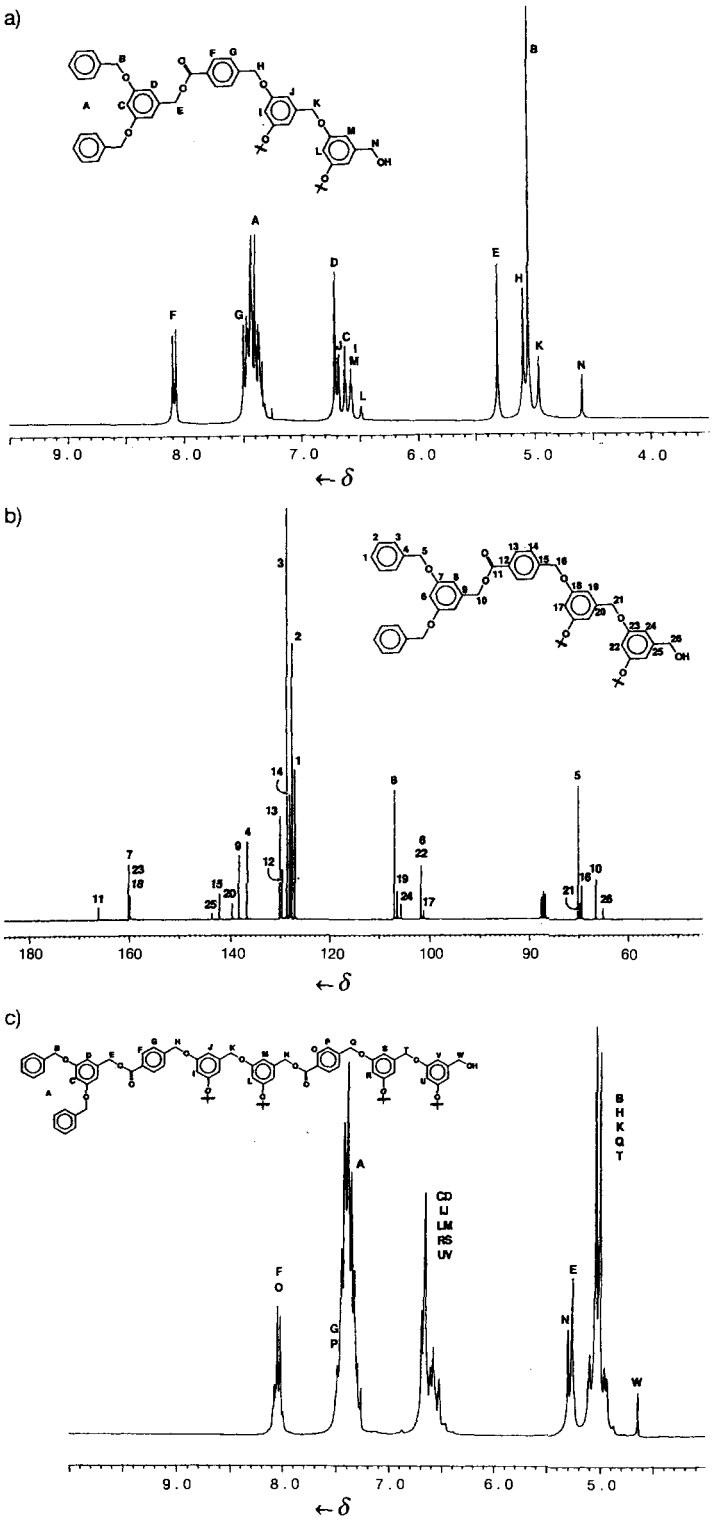

Fig. 1. a) ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of **6**; b) ^{13}C NMR spectrum (75 MHz, $CDCl_3$) of **6**; c) ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of **9**.

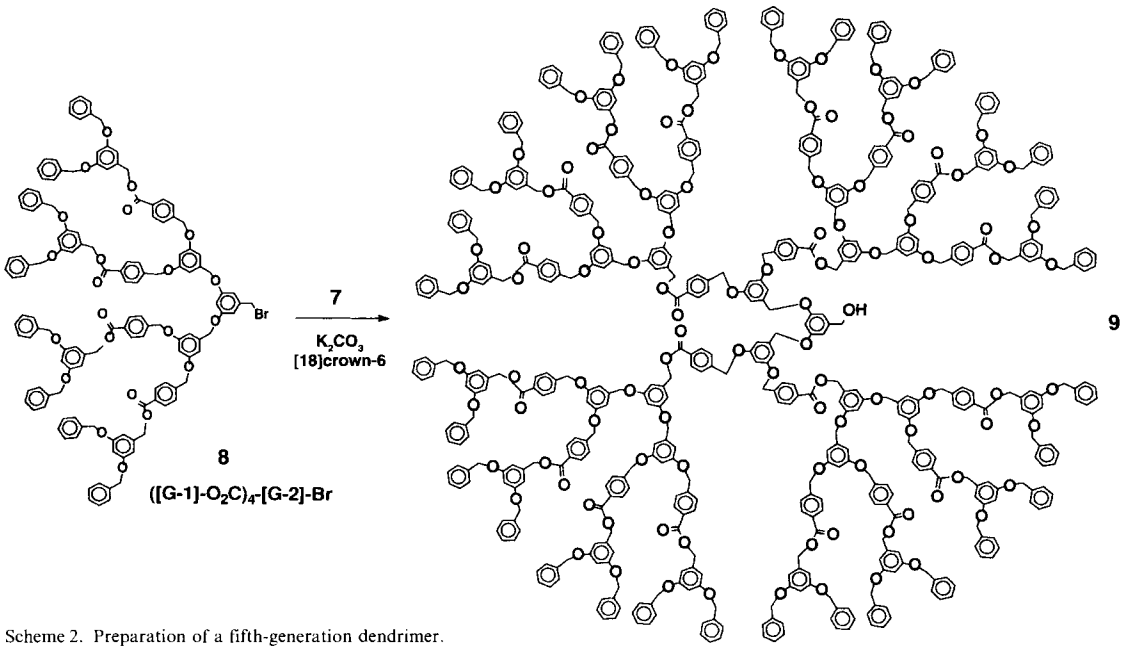
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0083 $ 10.00+.25/0

The reaction between **3** and **5** was found to be quite slow, requiring approximately 60 hours to reach greater than 90% completion. This most likely results from the low solubility of **3** in the basic reaction mixture and its possible aggregation through hydrogen bonding. To increase the efficiency of the synthesis and reduce the reaction time, the tetracarboxylic acid **3** was treated with *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide to give the branched tetrakis(trimethylsilyl) monomer **7**, which was not isolated but treated in situ with the first-generation bromide **5** in the presence of potassium carbonate and [18]crown-6 (Scheme 1). In this way, the desired third-generation alcohol **6** was obtained with 90% conversion after heating at reflux for only 15 hours. Both the ^{1}H and ^{13}C NMR spectra of **6** were extremely well-resolved, and all of the protons and carbon atoms in the structure could be identified and assigned (Fig. 1).

Activation of the focal-point group through transformation of benzylic alcohol **6** to give benzylic bromide **8** was performed with carbon tetrabromide and triphenylphosphane in 91% yield. Coupling of the third-generation dendrimer **8** to the branched monomer **7** generated in situ to afford the fifth-generation dendrimer **9** (Scheme 2) was monitored by gel permeation chromatography (GPC) and found to be roughly 40% complete after 17 hours. Unfortunately, the yield of **9** could not be increased under the conditions selected. This decrease in yield in the coupling reactions leading to higher generation dendrimers was observed previously[4] in the preparation of a sixth-generation dendrimer by the convergent-growth process and is thought to be partly sterically induced, and partly the result of less effective coupling reactions. Despite this shortcoming, the efficiency of this branched-monomer approach is apparent in the synthesis of the dendritic block copolymer **9** which has a molecular weight of 9371, contains eight layers of phenyl rings, and is obtained in only three steps with an overall yield of 31% from the first-generation bromide **5**, which has two layers of phenyl rings and a molecular weight of only 383. In the traditional convergent-growth approach with 3,5-dihydroxybenzyl alcohol as the monomer[4] [G-5]-OH was obtained in 50% overall yield from [G-1]-Br as a result of improved Williamson-type couplings, but the synthesis required seven steps!



As shown in Figure 1c, resonances in the ^{1}H NMR spectrum of **9** are broad compared to those of **6**. Although much fine structure has been lost, important characterization information remains. In particular, one-half of the quartet (AB_q) from the *para*-substituted aromatic rings of the branched monomer units is observed at $\delta = 7.9-8.1$, two resonances at $\delta = 5.25$ and 5.29 are found for the methylene groups of the two layers of benzyl esters, and the benzylic protons of the focal-point group resonate at $\delta = 4.63$.

The synthesis of dendritic poly(ether/ester) layer block copolymers by a novel, rapid branched-monomer approach has been demonstrated. These dendritic macromolecules are interesting since hydrolyzable ester linkages are placed in discrete layers within the structure, such that cleavage or degradation of the dendrimer yielding water-soluble fragments may be possible. By judicious choice of the starting material and the branched monomer a large variety of functionalized dendritic macromolecules and block copolymers can be synthesized.

Experimental Procedure

$(HO_2C)_4$-[G-2]-OH **3**: To a solution of **4** [7] (1.27 g, 1.3 mmol) in 1,4-dioxane (30 mL) was added aqueous KOH (1.10 g, 19.6 mmol, in 12 mL H_2O). The mixture was heated at reflux, 95% ethanol (15 mL) and additional H_2O (18 mL) were added to form a one-phase reaction mixture, and heating was continued for 20 h. The mixture was allowed to cool to room temperature, glacial acetic acid (5 mL) was added, and the precipitate was collected by suction filtration. Upon addition of trimethylsilyl chloride to the slurry of partially protonated product in THF, trimethylsilyl esters formed and the product dissolved. After 20 min at room temperature, the mixture was concentrated under reduced pressure and added to H_2O to give the fully protonated product as precipitate. This precipitate was collected by suction filtration, dissolved in THF, filtered, and concentrated providing tetracarboxylic acid **3** as a white solid, which yellowed with storage over a period of weeks. Yield 96%; T_g 89 °C; m.p. 203–205 °C; ^{1}H NMR ([D$_8$]THF) δ 4.18 (br, 1H; CH_2OH), 4.46 (s, 2H; CH_2OH), 4.96 (s, 4H; $ArCH_2O$), 5.10 (s, 8H; HO_2CPhCH_2), 6.45 (t, 1H, $J = 2$ Hz; ArH), 6.56 (d, 2H, $J = 2$ Hz; ArH), 6.58 (t, 2H, $J = 2$ Hz; ArH), 6.70 (d, 4H, $J = 2$ Hz; ArH), 7.47, 7.97 (AB_q, 16H, $J = 8$ Hz; HO_2CPhH); IR: $\tilde{\nu} = 3500-2400$, 1693, 1597, 1450, 1423, 1373, 1317, 1292, 1160, 1051, 1020 cm^{-1}.

([G-1]-$O_2C)_4$-[G-2]-OH **6**: To a solution of **3** (0.20 g, 0.22 mmol, 1.0 equiv) in THF (25 mL) under nitrogen at room temperature was added *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (0.25 mL, 0.27 g, 1.3 mmol, 5.9 equiv). After 30 min the THF solution was heated at reflux and then **5** (0.42 g, 1.1 mmol, 5 equiv), potassium carbonate (0.30 g, 2.2 mmol, 10 equiv), and [18]crown-6 (0.03 g, 0.11 mmol, 0.5 equiv) were added. The reaction was monitored by GPC. After completion the

Scheme 2. Preparation of a fifth-generation dendrimer.

reaction mixture was evaporated to dryness under reduced pressure and the residue partitioned between water and methylene chloride. The aqueous layer was extracted three times with CH_2Cl_2, and the extracts were combined, dried over $MgSO_4$, and then concentrated under reduced pressure. The crude product was purified by flash chromatography ($CH_3OH/CH_3COOH/CH_2Cl_2$ 2:1:97) to afford **6** as a colorless glass. Yield 85%; T_g 34 °C; ^{1}H NMR ($CDCl_3$) see Fig. 1a; IR: $\tilde{\nu}$ = 3550–3350, 3200–2800, 1719, 1597, 1497, 1453, 1416, 1375, 1343, 1319, 1273, 1215, 1161, 1105, 1061, 1030, 1020 cm^{-1}.

([G-1]-$O_2C)_4$-[G-2]-Br **8**: To a solution of **6** (0.43 g, 0.20 mmol, 1.0 equiv) in THF (20 mL) was added carbon tetrabromide (0.13 g, 0.4 mmol, 2 equiv) and triphenylphosphane (0.10 g, 0.4 mmol, 2 equiv), and the reaction mixture was stirred at room temperature under nitrogen. The progress of the reaction was monitored by thin-layer chromatography. The reaction was quenched by addition of water and CH_2Cl_2. The aqueous layer was extracted three times with CH_2Cl_2, and the extracts were dried over $MgSO_4$ and concentrated under reduced pressure. The crude product was purified by precipitation into ether followed by flash chromatography (2% ether/CH_2Cl_2) to yield **8** as a colorless glass. Yield 91%; T_g 34 °C; ^{1}H NMR ($CDCl_3$) δ 4.35 (s, 2H; CH_2Br), 4.94 (s, 4H; ArCH_2O-), 5.03 (s, 16H; $PhCH_2$), 5.09 (s, 8H; RO_2CPhCH_2), 5.28 (s, 8H; ArCH_2O_2C), 6.4–6.8 (m, 21H; ArH), 7.2–7.6 (m, 40H; PhH), 7.46, 8.05 (AB_4, 16H, J = 8 Hz, RO_2CPhH); IR: $\tilde{\nu}$ = 3200–2800, 1719, 1597, 1499, 1453, 1416, 1373, 1343, 1321, 1273, 1215, 1160, 1105, 1061, 1019 cm^{-1}.

(([G-1]-$O_2C)_4$-[G-2])$_4$-[G-2]-OH **9**: Same procedure as for **6**, however with **8** instead of **5**. The crude product was purified by flash chromatography (3% methanol/CH_2Cl_2) to afford **9** as a colorless glass; T_g 38 °C; ^{1}H NMR ($CDCl_3$) see Fig. 1c; IR: $\tilde{\nu}$ = 3600–3400, 3000–2800, 1719, 1597, 1497, 1453, 1416, 1373, 1343, 1273, 1215, 1159, 1105, 1061, 1019 cm^{-1}.

Thermal Decomposition of Silver Oxide Monitored by Raman Spectroscopy: From AgO Units to Oxygen Atoms Chemisorbed on the Silver Surface

Bruno Pettinger, Xinhe Bao, Ian Wilcock, Martin Muhler, Robert Schlögl, and Gerhard Ertl*

In studies on the catalytic partial oxidation of methanol on silver surfaces it was recently found that the interaction of oxygen at nearly atmospheric pressure with silver at elevated temperatures (> 700 K) leads to the formation of a very stable species, which was identified as O atoms chemisorbed on the surface of the distorted Ag lattice. It is also this species that enters the catalytic oxidation reaction.[1, 2] In order to compare this species, which is associated with metallic silver, to silver oxides, the thermal decomposition of the latter in an oxygen-free atmosphere over the temperature range 300 to 930 K was investigated by Raman spectroscopy. The starting compound was $Ag_7O_8NO_3$ (**1**); in contrast to ordinary silver oxide, which exhibits a pronounced tendency for formation of carbonates in the surface region, **1** is rather stable to the attack of carbon-containing impurity compounds in the gas phase.[3]

Steel-gray $Ag_7O_8NO_3$ powder was prepared by anodic oxidation in a glove box.[4] The experiments were performed in a reaction cell we had constructed which was connected to a Raman spectrometer (SPEX Triplemate) and a diode array detector (OMA II from EG & G).[5, 6] In order to minimize temperature gradients, the powder was pressed into a thin sheet on a silver support which was mounted in a stainless steel sample holder connected to a cylindrical oven. The temperature was monitored by a thermocouple attached to the holder.

Silver oxides are rather sensitive to photochemical reduction and reoxidation, which hampers Raman spectroscopic investigations, in particular, of Ag_2O.[7–9] Hence we reduced the intensity of the laser excitation (λ_{ex} = 514.5 nm) to about 20 mW, and noticeable light-induced changes of the sample were no longer observed.

Raman spectra of **1** reflecting the chemical changes upon heating are reproduced in Figure 1. At T = 300 K the spectrum exhibits essentially only a band at 410 cm^{-1}, which is characteristic for the AgO unit in **1**, and an additional shoulder at around

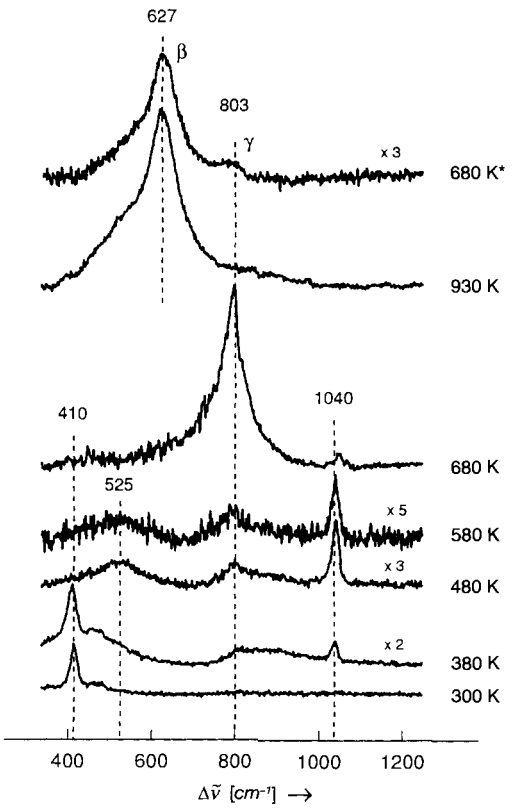

Fig. 1 Raman spectra recorded during the decomposition of $Ag_7O_8NO_3$ (**1**) under a nitrogen atmosphere (1 bar N_2) at different temperatures. The spectrum labeled 680 K* was obtained from a sample of **1** that was first heated to 930 K and then cooled to 680 K.

450 cm^{-1}. The assignment of the band at 410 cm^{-1} is based on the results of previous IR and Raman studies of related compounds (410 $cm^{-1} \leq \nu \leq 430\ cm^{-1}$).[7, 9]

When the temperature is increased to 380 K, the intensity of the band at 410 cm^{-1} decreases. Simultaneously the shoulder at roughly 450 cm^{-1} becomes more pronounced, and additional features between 800 and 1040 cm^{-1} emerge. The latter peak is attributed to the presence of NO_3^- ions which segregate from the lattice and become more Raman intense. The assignment of the feature growing in around 800 cm^{-1} will be discussed later. Heating to 480 K causes the band at 410 cm^{-1} to disappear completely, the broad peak at approximately 450 cm^{-1} to shift continuously to 525 cm^{-1}, and the other features to become more pronounced. When the temperature is increased further to 580 K the situation remains essentially unchanged.

In conflicting reports *on* the spectral data of Ag_2O various bands ranging from 200 to 2000 cm^{-1} are listed.[10-12] From an IR study in vacuo Allen and Scaife[11] concluded that a single band at approximately 530 cm^{-1} is representative of Ag_2O. Since the O atoms in the Ag_2O lattice are located at sites of inversion, first-order Raman scattering is forbidden and the intensity of this band is expected to be rather weak.[7] In addition, Ag_2O undergoes photochemical reoxidation readily upon irradiation with laser light. The absence of the band at 410 cm^{-1} in the spectra recorded at 480 and 580 K prompts us to attribute the band at 525 cm^{-1} to Ag_2O. It decreases in intensity when the temperature is increased to about 600 K, which is the typical temperature for the decomposition of Ag_2O to metallic silver.[4, 13, 14] The relatively high stability of this entity in the present study is presumably a consequence of the specific geometric and electronic structure provided by the presence of the NO_3^- ions.

The continuous shift of the peak initially at 450 cm^{-1} to 525 cm^{-1} with progressing thermal decomposition is attributed to the increasing oxygen deficiency in the AgO lattice and the resulting changes in the coordination of the Ag^+ ions. This contradicts the previous assignment of this shoulder as a satellite peak of AgO.[7] Our conclusion is in line with more recent reports about the importance of oxygen deficiency on the properties of this compound.[15, 16]

The thermal decomposition of silver oxide to bulk silver in an oxygen-free atmosphere is complete at 680 K as is evident from the pronounced increase in intensity of the peak at 803 cm^{-1}. The same Raman band has been found in previous investigations in which a Ag(111) single-crystal surface was exposed to oxygen for long periods at elevated temperature.[1, 2] Investigations with a combination of various techniques led to the conclusion that this band is due to an atomic oxygen species strongly chemisorbed *on* the reconstructed silver surface.

Thermal decomposition of the silver oxide apparently creates a state of the surface similar to that generated by interaction of O_2 with metallic Ag at high temperatures. Apart from reconstruction of the topmost atomic layer into a extended superstructure, the surface becomes rough on a μm-scale with formation of facets.[1] As a consequence, the Raman scattering cross section of chemisorbed oxygen is strongly enhanced (by a factor of about 10^3). Thus, this O species (referred to as O_γ) gives rise to a high-intensity band, although it is confined to the surface layer and hence its amount is much lower than that of an O species in a bulk phase.

The O_γ species *on* the Ag surface are always associated with O_β species *below* the surface, which are characterized by a band at about 630 cm^{-1} in the Raman spectrum.[2, 6] High surface concentrations of the O_γ atoms reduce the Raman cross section for the O_β species to the extent that the corresponding band is not discernible in the spectrum. However, this feature appears after further heating to 930 K, at which temperature the chemisorbed O_γ atoms recombine and desorb. Compared to the Raman line of the O_β species of single-crystal silver surfaces, this band exhibits a significantly larger band width and asymmetry on its low-frequency side. These spectral differences must be attributed to the amorphous/polycrystalline structure of the sample; in other words, the environment of the O_β species is less ordered. The oxygen atoms in the bulk represent a resevoir for the creation of O_γ atoms at the surface. When the temperature is lowered to 680 K, the O atoms diffuse to the surface, and the band at 803 cm^{-1} is reestablished. The intensity of this band is low at the beginning of this process but increases with time.

The band for the O_β species at roughly 630 cm^{-1} is distinctly different from those for AgO and Ag_2O at 410 and 530 cm^{-1}, respectively. Chemisorbed O atoms on the undisturbed Ag surface (i.e. no subsurface O_β species are present) exhibit a Raman band at approximately 950 cm^{-1}; these O atoms recombine and desorb around 600 K, reflecting their relatively low thermal stability. It is the much more stable O_γ species that is present on the surface during the catalytic transformation of methanol to formaldehyde, which is carried out industrially at around 900 K.[17]

The stepwise thermal decomposition of $Ag_7O_8NO_3$ (**1**) thus proceeds by transformation of AgO into Ag_2O structural units and finally into metallic silver, which exhibits a reconstructed surface with strongly chemisorbed O atoms (γ state) that communicate with oxygen atoms in the subsurface region (β state). All states are characterized by distinctly different frequencies for the Ag–O vibrations. It was possible to identify the corresponding band of Ag_2O, amongst others, by Raman spectroscopy for the first time.

A Hexanuclear Gold(I) Complex: $[\{(Ph_3PAu)_2C(PPh_2AuPPh_2)\}_2](ClO_4)_2$**

Eduardo J. Fernández, M. Concepción Gimeno, Peter G. Jones, Antonio Laguna*, Mariano Laguna, and José M. Lopez-de-Luzuriaga

Linearly coordinated gold(I) complexes often display short inter- or intramolecular contacts of about 3 Å between the formally closed-shell (d^{10}) metal centers. This phenomenon is termed "aurophilicity" and is considered to arise from relativistic effects.[1-3] Here we report the synthesis and structure of a new hexanuclear gold complex (**4**) containing three pairs of gold atoms linked by such short contacts. The ligand involved is bis(diphenylphosphino)methanediide, which acts as an eight-electron donor bonded to four gold atoms; the only previously known example in which this ligand bridges four metal centers is the mercury acetate complex $[Hg_2(OAc)_2\{(Ph_2P)C\}\{Hg(OAc)\}_2]$.[4]

The starting complex was the dinuclear methanide **1** (Scheme 1), first prepared by Schmidbaur et al.,[5] which is a suitable precursor for tetranuclear complexes.[6] Complex **1** reacts with $[Au(PPh_3)(tht)]ClO_4$[7] or $[Au(CH_2PPh_3)(tht)]ClO_4$[8] in molar ratio 1:2 in dichloromethane, displacing the tetrahydrothiophene (tht) ligand to give solutions from which the colorless air- and moisture-stable complexes **2** and **3**, respectively, can be isolated in 90% yield. The *trans* configuration of the H atoms attached to the central $Au_2P_4C_2$ ring in **2** and **3** is assumed from the analogous arrangement in $[\{Au(PPh_2)_2CH(AuC_6F_5)\}_2]$.[6]

Scheme 1. Synthesis of the hexanuclear complex **4**. a) $[Au(PPh_3)(tht)]ClO_4$; b) $[Au(CH_2PPh_3)(tht)]ClO_4$; c) $[Au(acac)(PPh_3)]$.

Solutions of **2** and **3** in acetone show conductivities typical of 1:2 electrolytes. Their IR spectra show ν(Au–C) bands at 590 (m; **2**) or 570 (m; **3**) cm^{-1}. The NMR spectra[9] are consistent with the proposed structures in Scheme 1. The $^{31}P\{^1H\}$ NMR spectra show two resonances, one for the P atoms in the central eight-membered ring and one for the PPh_3 groups; the spectrum of **3** shows two singlets, that of **2** a triplet and quintet, probably because of virtual coupling between the two different phosphorus atoms. The ^1H NMR signal of the CH group in the central eight-membered ring appears as a triplet at $\delta = 5.38$ (**2**) or as a multiplet at $\delta = 3.63$ (**3**), indicating that the CH proton is more shielded in **3**.

The reaction of **2** with $[Au(acac)PPh_3]$[10] in molar ratio 1:2 leads after 10 d at room temperature to the pale yellow complex **4**, an air- and moisture-stable solid and 1:2 electrolyte, in 87% yield. (No analogous reaction was observed with **3**). The acetylacetonate (acac) ligand is able to deprotonate the CH group of the methanide ligand, whereby acetylacetone is formed and the methanediide C atom can coordinate to the $[AuPPh_3]^+$ fragment. The IR spectrum of **4** shows a ν(Au–C) band at 590 (m) cm^{-1}; the $^{31}P\{^1H\}$ NMR spectrum shows two singlets, one for the PPh_3 and one for the PPh_2 groups.

Crystals of **4** suitable for X-ray diffraction studies[11] were obtained from dichloromethane/hexane. Figure 1 shows the structure of the cation of **4**, which contains an eight-membered $Au_2P_4C_2$ cycle with two additional $AuPPh_3$ groups coordinated to each peripheral carbon atom. Crystallographic inversion symmetry imposes a chair configuration. Short gold–gold contacts are observed [Au1···Au1′ (transannular) 2.920(2), Au2···Au3 2.987(2) Å], and all gold atoms are linearly coordinated (maximum deviation 5°).

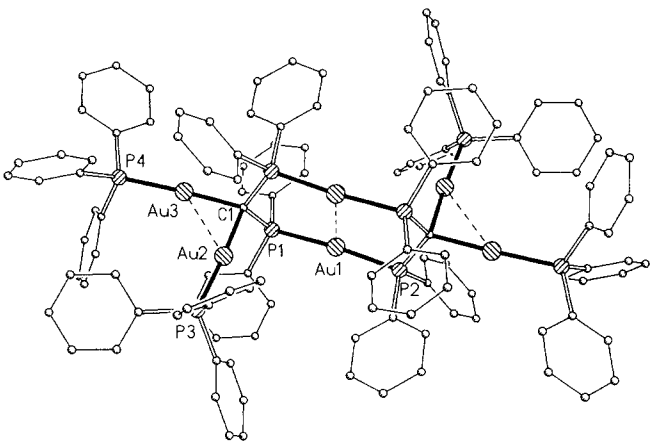

Fig. 1. The cation of complex **4** in the crystal. Radii are arbitrary. H atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Au3-C1 2.104(10), Au2-C1 2.112(10); P2-Au1-P1 175.0(1), P3-Au2-C1 176.1(3), C1-Au3-P4 177.2(3); other values see text.

The $(PPh_3Au)_2C$ moiety has been observed in other complexes, and a three-center, two-electron (3c-2e) bonding system has been postulated for the Au_2C group[12-15] on the basis of the small Au-C-Au angle [Au3-C1-Au2 90.2(4)° in **4**], the slightly shortened P–C bonds [P1-C1 1.810(10), P2-C1′ 1.757(11) Å in **4**; compare with P–CH_2 1.83(1), 1.80(1) Å in $[Au_2(dppm)_2]^{2+}$[16]], and the large angle opposite the CAu_2

Aleuria aurantia Agglutinin Recognizes Multiple Conformations of α-L-Fuc-(1 → 6)-β-D-GlcNAc-OMe**

Thomas Weimar and Thomas Peters*

The molecular mechanisms underlying specific recognition reactions between oligosaccharides and receptor proteins such as antibodies and lectins have been the subject of numerous studies during past years.[1] Here, we report the use of 2D transferred NOE (TRNOE) experiments[2] to study the complexation of an α-L-fucose-specific lectin, *Aleuria aurantia* agglutinin (AAA),[3] with a synthetic *N*-glycoprotein-type disaccharide α-L-Fuc-(1 → 6)-β-D-GlcNAc-OMe (**1**).[4] Disaccharide **1** is a rather flexible molecule which samples at least two distinct regions in conformational space roughly characterized by different values for the exocyclic dihedral angle ω (O6-C6-C5-O5), *gt* ($\omega = 60°$), and *gg* ($\omega = -60°$). Additional variation of the dihedral angles ϕ (H1′-C1′-O1′-C6) and ψ (C1′-O1′-C6-C5) leads to a complex conformational equilibrium in **1**. Because of the high selectivity of AAA for disaccharide **1** as compared to α-(1 → 2)-, α-(1 → 3)-, or α-(1 → 4)-linked fucose residues,[3c] selection of a single conformer of **1** upon binding appears reasonable. However, TRNOE experiments and specific line-broadening effects indicate flexibility of the reducing β-D-GlcNAc unit in liganded **1**.

1

^1H NMR spectra of free **1** and **1** complexed with AAA were recorded in D_2O at 600 MHz[5] (Fig. 1). For free **1** the amount of *gg*, *gt*, and *tg* conformers could be estimated on the basis of vicinal coupling constants $J_{5,6\text{-}pro\text{-}R}$ (5.7 Hz) and $J_{5,6\text{-}pro\text{-}S}$ (2.0 Hz). Assignments of prochiral protons H6-*pro-R* and H6-*pro-S* were assumed to be analogous to D-glucose.[6] Different parametrizations[7-9] of the Karplus relation gave the following *gg*:*gt*:*tg* ratios: 56:43:1,[7] 66:37:−3,[8] and 58:54:−12.[9] Regardless of the parametrization used, *gg* orientations were found to be preferred over *gt*, and *tg* orientations could be almost excluded. In the presence of lectin (Fig. 1b) it was observed that all resonances of **1** were broadened, but those of the fucose residue were significantly more broadened to an extent that even spin-spin couplings in the order of 7 Hz (C6′ methyl protons) could no longer be resolved (cf. Fig. 1a and 1b).[10] This could be explained by faster transverse relaxation of a more immobilized fucose residue, or by an incomplete averaging of slightly different chemical shifts for free and complexed molecules, or both. Both explanations would indicate a fucose residue bound more tightly than the *N*-acetyl glucosamine residue. This conclusion was further substantiated by the results of NOESY[11] experiments for free and liganded **1**.

For free disaccharide **1** positive NOEs were observed because of fast molecular tumbling (Fig. 2a). The NOE patterns observed can only be understood on the basis of a complex conformational equilibrium about the glycosidic linkage. Nevertheless, conformers can roughly be categorized as belonging to the *gg* or *gt* family. Strong interglycosidic NOEs were observed between H1′ and H6-*pro-S* and H6-*pro-R* and between H5′ and H6-*proS* (Fig. 2a). Additionally, several medium to weak interglycosidic NOEs were observed (Fig. 2a: H1′/H5, H1′/H4, H5′/H5, H5′/H4, H5′/OMe).

The NOEs observed for disaccharide **1** in the presence of AAA were negative (Fig. 2b), a clear indication of transferred NOEs (TRNOEs). TRNOEs reflect the conformation of the ligand in the bound state. Since the mixing time used (100 ms) was rather short, spin diffusion is unlikely to play a role. Qual-

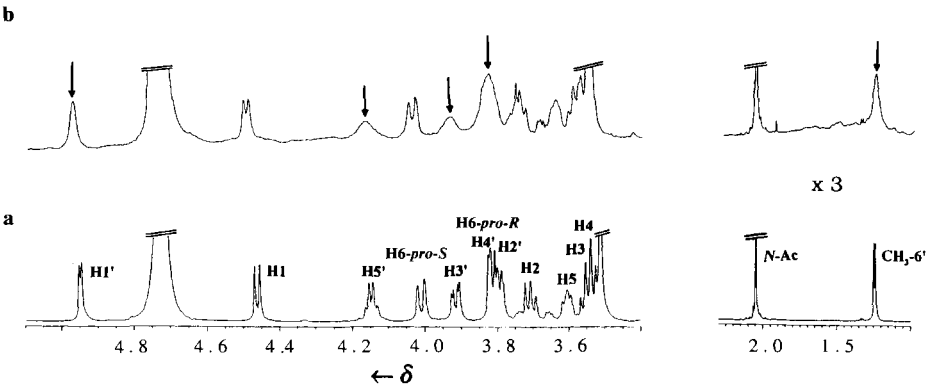

Fig. 1. ^{1}H NMR spectra of free and liganded **1** recorded in D_2O at 303 K and 600 MHz. a) ^{1}H NMR spectrum of free **1** (10 mg dissolved in 0.5 mL D_2O, 52 mM). b) ^{1}H NMR spectrum of **1** (0.64 mg, 1.7 μmol) in the presence of AAA (4 mg, 0.11 μmol), dissolved in 0.5 mL D_2O (3.4 mM **1**, 0.22 mM AAA). Broadened fucose resonances are indicated by arrows.

itatively, strong interglycosidic TRNOEs (H1′/H6-*pro-R*, H1′/H6-*pro-S*, H5′/H6-*pro-S*) matched corresponding NOEs observed for unliganded **1** (cf. Fig. 2a and 2b), only the comparison of weak and medium effects revealed differences. For instance, free **1** showed dipole-dipole contacts of medium intensity between H5′ and protons H5 and H4 (Fig. 2a). For bound **1** only a rather weak TRNOE between H5′ and H4 and assumption leads to contradictions. If one single conformer was selected upon binding, the orientation about the C5–C6 linkage had to be *gt* because strong TRNOEs of similar magnitude were observed between H4 and both protons at C6, H6-*pro-R* and H6-*pro-S* (Fig. 2b). This can neither be expected for *gg* nor for *tg* conformations which both place one of the protons H6 at a distance of about 4 Å to H4, which is above the upper distance

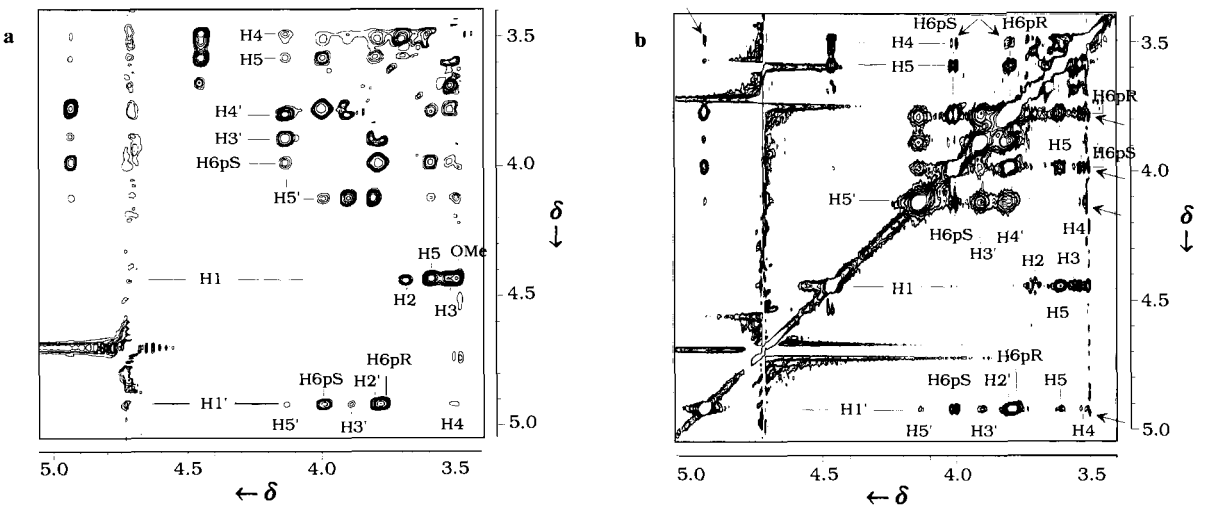

Fig. 2. 2D NOESY ^{1}H NMR spectra (600 MHz, 303 K, D_2O) of free and liganded **1**. Sample concentrations were as in Figure 1. 512 experiments were performed in t_1 with 2 K data points each to yield a final data matrix after 2D Fourier transform of 2 K × 1 K data points. Prior to Fourier transformation the data matrix was multiplied with $\pi/3$ shifted squared sine bell functions in both directions, t_1 and t_2. A third-order baseplane correction (UXNMR, standard Bruker software) was applied after 2D Fourier transform and phase correction. Protons H6-*pro-S* and H6-*pro-R* are abbreviated as H6pS and H6pR, respectively. a) Free **1**. The mixing time was 900 ms and 32 scans were recorded for each experiment. The relaxation delay was 4.0 s. NOEs are positive and only positive levels are shown. b) Liganded **1**. The mixing time was 100 ms and 150 scans were recorded for each experiment. The relaxation delay was 1.5 s. The cross peaks are negative and represent transferred NOEs (TRNOEs) which reflect the bound conformation of **1**. TRNOEs labeled with arrows indicate the presence of *gt and gg* conformations of **1** in the bound state (see text for details).

no TRNOE between H5′ and H5 was observed. For the following qualitative discussion it is useful to have a gauge which defines an upper limit for proton–proton distances up to which TRNOEs may be expected. The weak intraglycosidic TRNOE between H1′ and H5′ which corresponds to a H1′–H5′ distance of 3.7 Å can serve as such a standard. Thus, if a TRNOE is observed the corresponding distance will be assumed to be $\leq$3.7 Å.

Is it possible to explain the TRNOEs observed with a model which assumes that **1** is bound as a single conformer with a fixed orientation of the (1 → 6) linkage? It is easily shown that this limit as estimated above. On the other hand, weak TRNOEs between H1′ and H4 and between H5′ and H4 (Fig. 2b) are expected only for *gg* conformers. This is easily checked by simple model building: both proton pairs, H1′/H4 and H5′/H4, cannot be brought closer than about 4.5 and 6.0 Å, respectively, with the C5–C6 bond locked in a *gt* conformation. These two TRNOEs are also incompatible with a *tg* conformation of the C5–C6 linkage. Table 1 gives a summary of the TRNOEs discussed and their pertinence to *gt*, *gg*, and *tg* conformations of the C5–C6 bond. Evidently both *gt* and *gg* conformers are bound by AAA. Additionally, Metropolis Monte Carlo (MMC)

Table 1. TRNOEs observed in liganded **1** and their relation to *gt*, *gg*, and *tg* orientations at the C5–C6 bond. "+/–" indicates that a TRNOE can/cannot be observed in this conformation.

Conformation	TRNOE		
	H4/H6-*pro-S* and H4/H6-*pro-R* (strong)	H1′/H4 (weak)	H5′/H4 (weak)
gt	+	–	–
gg	–	+	+
tg	–	–	–

simulations[12] of unliganded **1** yielded minima **A**–**D**[13] which represent major conformations within the *gt* and *gg* family (Fig. 3). All *tg* conformations possess a high energy mainly because of unfavorable van der Waals interactions and thus play no significant role (vide supra). On the basis of our experimental findings these simulations support the understanding of the complex conformational equilibrium of **1** for both the liganded and the unliganded form: the TRNOE H1′/H4 can only be expected for the region around minimum **D** (*gg* family), the one between H5′ and H4 only for the region around minimum **B** (*gg* family), and the one between H5′ and H5 only for the region around minimum **A** (*gt* family). On the whole, it appears that multiple conformations of **1** are bound by AAA which is consistent with the observation of specific line broadenings described above.

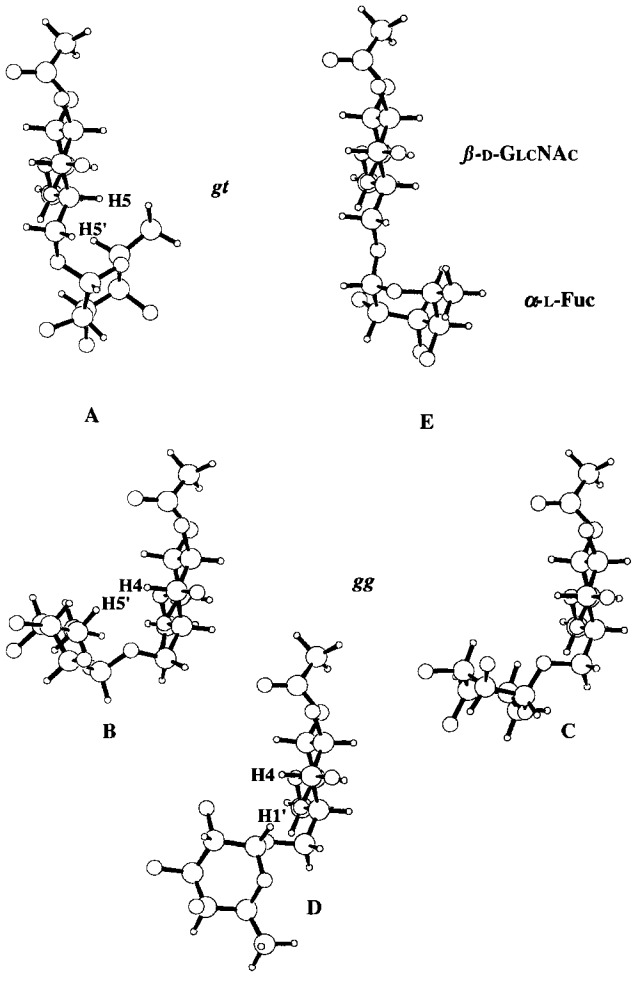

Fig. 3. Ball and stick models (plot program Schakal-88B, E. Keller, University of Freiburg, **1988**) of the major minimum energy conformations **A**–**D** [13] of **1** portraying the *gt* and *gg* conformational families.

It is concluded that although AAA specifically recognizes the (1 → 6)-linked fucose in **1**,[3c] the orientation of this linkage is not fixed in liganded **1**; the reducing *N*-acetyl glucosamine unit having relatively more conformational freedom than the fucose residue. Because of the differences that were observed between the weak to medium interglycosidic NOE and TRNOE patterns it can be assumed that the conformational equilibrium of **1** is disturbed upon binding to AAA. There are two other studies where the binding of (1 → 6)-linked disaccharides to a monoclonal antibody k is disturbed upon binding to AAA. There are two other studies where the binding of (1 → 6) linked disaccharides to a monoclonal antibody[14] and to lectin[15] was investigated. In one case it was found that a monoclonal antibody binds the saccharide, methyl *O*-β-D-galactopyranosyl-(1 → 6)-4-deoxy-4-fluoro-β-D-galactopyranoside, in a single well-defined conformation which does not belong to any of the major conformational families identified for the free disaccharide.[14] In the other case of β-methylmelibiose (α-D-Gal-(1 → 6)-β-D-Glc-OMe) binding to Ricin B,[15] it was concluded that a predominant conformer of the free disaccharide is selected upon binding. We suggest that specific recognition of flexible carbohydrate epitopes by receptor proteins may involve rather different binding modes, not necessarily involving selection of a single conformer.

[10] After completion of all experiments ethylenediaminetetraacetate (edta) was added and a ^{1}H NMR spectrum was obtained to make sure that the line broadening effects were not due to specific complexation of the carbohydrate with impurities of cations such as Ca^{2+}. Since AAA has no Ca^{2+} or other metal ion binding sites it can be assumed that edta efficiently removes such impurities from the protein surface.

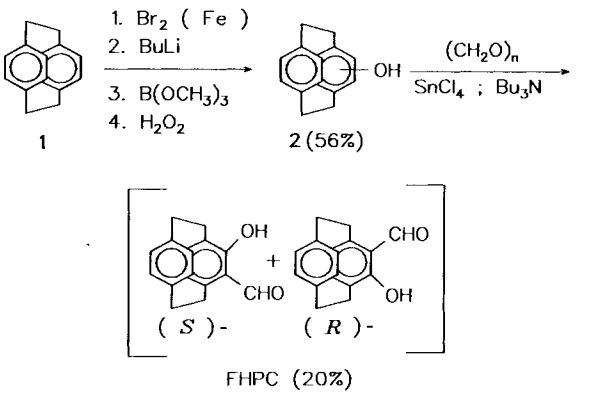
Scalemic 2-Formyl-3-hydroxy[2.2]paracyclophane: A New Auxiliary for Asymmetric Synthesis**

Valeria Rozenberg, Vladimir Kharitonov, Dimitri Antonov, Elena Sergeeva, Andrei Aleshkin, Nickolai Ikonnikov, Svetlana Orlova, and Yuri Belokon'*



Among the most successful chiral ligands employed in asymmetric synthesis, catalyzed or promoted by transition metals, are molecules with planar chirality, such as derivatives of ferrocene.[1] These feature prominently as chiral ligands in palladium-catalyzed Grignard cross-coupling reactions,[1a] palladium-catalyzed allylic alkylation reactions,[1b] gold-catalyzed aldol condensations of α-isocyanoacetates,[1c] and hydrogenation of enamides.[1d] Chiral arenechromium complexes have been used in many stoichiometric asymmetric reactions,[2a] and also very recently to catalyze the addition reactions of organozinc compounds to aldehydes.[2b] Furthermore, a chiral pyridoxal derivative was shown to function as an auxiliary in the asymmetric synthesis of amino acids.[3]

Unfortunately, the compounds with planar chirality derived from arene or cyclopentadiene transition metal complexes are either readily oxidized or are unstable under certain reaction conditions.

We have therefore investigated whether other compounds with planar chirality, derived from [2.2]paracyclophane, are also suitable as chiral auxiliaries, since here the starting material is very stable towards light, oxidation, acids, bases, and relatively high temperatures.[4] We report here the synthesis and resolution of 2-formyl-3-hydroxy[2.2]paracyclophane (FHPC), a chiral analogue of salicylaldehyde, as well as an example of its application as a chiral auxiliary for the synthesis of β-hydroxy-α-amino acids.

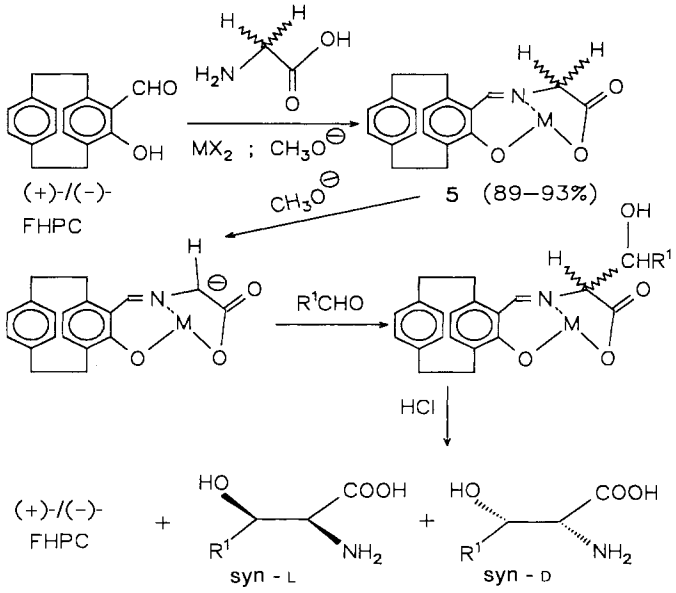

Scheme 1. Synthesis of racemic FHPC.

Racemic FHPC was synthesized in a multistep reaction (Scheme 1): bromination of the parent paracyclophane **1**, Li–Br exchange,[5] reaction of the organometallic intermediate with trimethylborate, and oxidation with H_2O_2 furnished the phenol **2**.[6] The *ortho* formylation with $(CH_2O)_n$, catalyzed by $SnCl_4$ and Bu_3N, gave the expected racemic FHPC.[7] The differing solubility of the diastereomeric Cu^{II} complexes (**3** and **4**) of the Schiff bases derived from (*S*)-FHPC and (*R*)-FHPC and (*S*)-valyl-(*S*)-valine in 2-propanol were used for the resolution of racemic FHPC (Scheme 2). The diastereoisomers can be separated by chromatography on SiO_2. The enantiomers of FHPC were recovered from the complexes with aqueous HCl (Scheme 2); their enantiomeric purity reached 94%, as determined by ^{1}H NMR spectroscopy in which [Eu(hfc)$_3$] was employed as a shift reagent.

Scheme 2. Resolution of racemic FHPC.

Scheme 3. Asymmetric synthesis of β-hydroxy-α-aminoacids employing scalemic FHPC. $MX_2 = Cu(OAc)_2$; R^1 = *i*Pr, Ph.

Scalemic FHPC can now be used for the asymmetric synthesis of β-hydroxy-α-amino acids, as shown in Scheme 3. This involves the condensation of the chiral Cu^{II} complexes **5** of the Schiff bases, derived from (+)- or (−)-FHPC and glycine, with isobutyraldehyde or benzaldehyde. The enantiomeric purity of the isolated amino acids was greater than 90%, and the *syn*/*anti* ratio was over 30:1 (see Table 1). FHPC was recovered almost quantitatively and with unchanged optical purity from the reaction mixture.

Table 1. Condensation reaction of **5** with isobutyraldehyde and benzaldehyde in MeOH, catalyzed by MeONa under Ar, $T = 50\,^{\circ}C$.

[a] GLC enantiomeric analyses of the *syn*-β-hydroxy-α-amino acids were performed on a Chirasil-Val-type phase [13], by using their *N*-trifluoroacetylisopropyl esters. Experimentally observed enantiomeric excesses *ee* of the amino acids were recalculated, assuming 100% *ee* of the chiral auxiliary FHPC. The chemical yields were in the range of 60–80%. [b] The analysis of the ^1H NMR spectrum (with $[Eu(hfc)_3]$ as a shift reagent) gave an enantiomeric purity of 86%. [c] The analysis of the ^1H NMR spectrum (with $[Eu(hfc)_3]$ as a shift reagent) gave an enantiomeric purity of 85%. [d] The amount of *anti* isomer was too small to carry out any meaningful measurements.

In our opinion FHPC compares favorably with other stoichiometric chiral auxiliaries currently used for the asymmetric syntheses of β-hydroxy-α-amino acids.[8]

Moreover, we believe that scalemic FHPC could also be used in numerous reactions, catalyzed by metal complexes of the salicylaldehyde-derived Schiff bases.[8–11] Cyclopropanation,[9] oxidation of sulfides,[10] epoxidation of olefins,[11] and silylcyanation of aldehydes[12] are just several examples of catalytic reactions in which the chiral analogue of salycilaldehyde might be used either to improve the enantiomeric excess of the reactions or to simplify the synthetic procedure.

Experimental Procedure

Synthesis of FHPC: The formylation of **2** in 20% yield was carried out according to a literature method for the *ortho* formylation of phenols [7]. M.p. 201–204 °C. ^1H NMR (200 MHz, C_6D_6, 25 °C): $\delta = 2.24$–3.62 (m, 8H; CH_2), 5.98 (d, $^3J(H,H) = 8$ Hz, 1H), 6.16–6.26 (m, 2H), 6.30 (d, $^3J(H,H) = 8$ Hz, 1H), 6.40 (dd, $^3J(H,H) = 8$, $^4J(H,H) = 1.8$ Hz, 1H), 7.00 (dd, $^3J(H,H) = 8$, $^4J(H,H) = 1.8$ Hz, 1H), 9.47 (s, 1H; CHO), 12.61 (s, 1H; OH); UV/VIS (benzene): $\lambda_{max}(\varepsilon) = 304(4493)$, 399 nm (2310); IR ($CDCl_3$): $\tilde{\nu} = 1630\ cm^{-1}$ (C = O); correct C,H analyses.

Resolution of racemic FHPC into enantiomers: The diastereoisomeric complexes **3** and **4** were obtained by heating FHPC (0.347 g, 1.38 mmol), *i*PrONa (13.8 mL of 0.3 N solution in *i*PrOH), $Cu(ClO_4)_2 \cdot 6H_2O$ (0.512 g, 1.38 mmol) and (*S*)-valyl-(*S*)-valine (0.298 g, 1.38 mmol) in *i*PrOH (15 mL) under reflux for 3 h. The reaction mixture was cooled down and left overnight at room temperature. The resulting precipitate of [(+)-FHPC-(*S*)-Val-(*S*)-Val]Cu^{II} (0.14 g, 0.32 mmol, 23%) was filtered off and treated (see below) to give 0.060 g (0.24 mmol, 17% based on the initial racemic FHPC) (+)-FHPC ($[a]_D^{25} = +513$ ($c = 0.2$ in benzene), 86% *ee*). The filtrate was concentrated to dryness and the residue chromatographed on SiO_2 (Kieselgel-60, $d = 1.9$ cm, $l = 20$ cm). Partially resolved, unreacted FHPC (0.030 g, 0.12 mmol, 8.6%, $[a]_D^{25} = +253$ ($c = 0.2$ in benzene), 40% *ee*) was eluted with benzene/methanol (10/1) as the first fraction. Elution with MeOH/AcOEt furnished 0.25 g (0.57 mmol, 43%) of [(−)-FHPC-(*S*)-Val-(*S*)-Val]Cu^{II} whicb was treated to give 0.060 g (0.24 mmol, 17%) of (−)-FHPC ($[a]_D^{25} = -505$ ($c = 0.2$ in benzene), 85% *ee*). More careful chromatographic separation may afford (−)-FHPC with 94% *ee* ($[a]_D^{25} = -556$ ($c = 0.2$ in benzene)).

Synthesis of **5**: Condensation of (+)-FHPC or (−)-FHPC (0.15 g, 0.595 mmol) with glycine (0.05 g, 0.67 mmol) and $Cu(OAc)_2 \cdot H_2O$ (0.14 g, 0.7 mmol) in MeONa (5.2 mL of 0.23 N solution in MeOH) under argon afforded **5**, which was purified on a Sephadex LH-20 column (benzene/methanol 3/1). The yield was 89–93% (0.206–0.215 g, 0.53–0.55 mmol).

Synthesis of β-hydroxyleucene and phenylserine: To (+)- or (−)-**5** (0.027 g, 0.59 mmol) was added a solution of MeONa (6 mL of 0.28 N solution in MeOH), followed by isobutyraldehyde (0.22 mL, 2.36 mmol) [or benzaldehyde (0.24 mL, 2.36 mmol)] under argon. The mixture was stirred at 50 °C for several hours and the reaction mixture was worked up as described below.

General procedure for the recovery of FHPC and amino acids from the Cu^{II} complexes: To a solution of the complex in MeOH was added 2 N HCl (8–10 mol equiv) and the mixture was heated to reflux until FHPC precipitated from the solution. The mixture was extracted with benzene, and FHPC was purified on SiO_2 (benzene). The amino acids were obtained from the aqueous solution by ion-exchange chromatography on Dowex-50 (H^+).

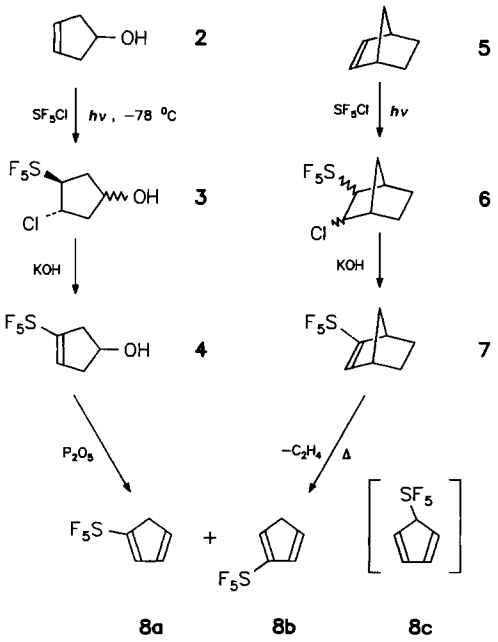
(Pentafluoro-λ^6-sulfanyl)cyclopentadiene and Cyclopentadienylidenetetrafluoro-λ^6-sulfane**

Axel Klauck and Konrad Seppelt*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday



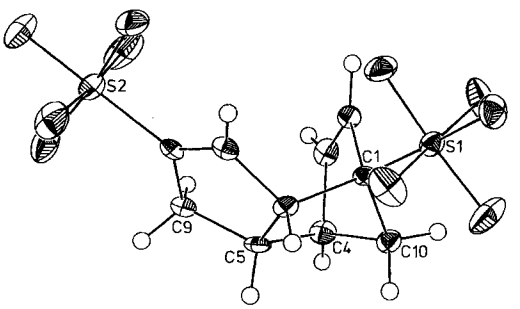
The alkylidene sulfur tetrafluorides $R_2C{=}SF_4$ have a short and rigid C–S bond with anisotropic electron density distribution such that it can reasonably be referred to as a C–S double bond.[1] We wondered if the same would be true for cyclopentadienylidenetetrafluoro-λ^6-sulfane (**1**), since the equilibrium could lie in the direction of the ylide-type resonance structure because of aromatization. Since the torsion at the C–S bond is linked to the conformational equilibration of the different fluorine atoms, this question can be answered qualitatively by using ^{19}F NMR spectroscopy.[1]

1 ?

The parent compound cyclopentadienethione is an unstable compound,[2] which can only be stabilized by introducing substituents that exert large steric and electronic effects.[3] The steric and electronic protection afforded by four fluorine substituents at the sulfur atom should make compound **1** sufficiently stable for its thorough investigation. In this regard one only needs to consider the stability of $H_2C{=}SF_4$[1] versus $H_2C{=}S$.[4]

The synthetic route to **1** initially requires the preparation of (pentafluoro-λ^6-sulfanyl)cyclopentadiene **8**, which can form three isomers and which is in itself a worthwhile target compound on account of its expected high reactivity. We prepared **8** by two routes, from 3-cyclopenten-1-ol (**2**) and from norbornene (**5**). As with almost all syntheses of highly fluorinated organosulfur compounds, the first step involves the radical addition of SF_5Cl to a C–C double bond.

It is clear from the NMR data (^1H, ^{13}C, ^{19}F) of **8** that the isomers **8a** and **8b** formed in a ratio of about 60:40. The assignment of the spectra to **8a** and **8b** is based on the different $^{13}C{-}^{19}F$ coupling constants and is not totally certain. Evidence for the formation of **8c** was not observed. The related trifluoromethylcyclopentadiene occurs in a corresponding isomer ratio of 70:30.[5] Since the isomers are easily interconverted through a [1,5]-sigmatropic hydrogen shift, we assume that the ratio **8a**:**8b**:**8c** of 60:40:0 also reflects the relative stabilities. Compounds **8a, b** have the typical properties of cyclopentadienes. Interestingly the mixture dimerizes to give a single product **12**, whose structure was determined by a single-crystal X-ray analysis (Fig. 1). Since the dimer is formed from two molecules of **8a** and is obtained in high yield without any other dimers present according to NMR spectroscopy, the conversion **8a** $\rightleftharpoons$ **8b** is essential. The exclusive formation of this one enantiomer pair from 32 theoretically possible ones can be explained only by the combination of steric and electronic effects of the large and rigid SF_5 groups.[6] In contrast trifluoromethylcyclopentadiene dimerizes to produce a mixture of four isomers.[5]



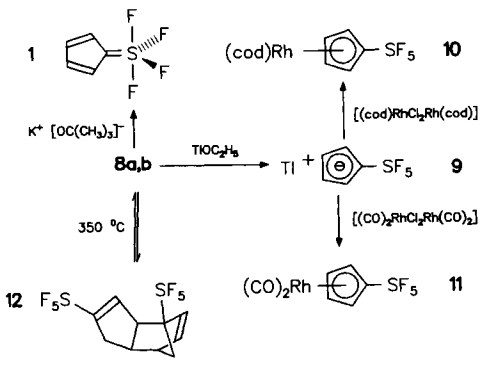


Fig. 1. Crystal structure of the dimer **12**. $a = 935.1(1)$, $b = 1083.8(2)$, $c = 1292.9(2)$ pm, $\beta = 91.77(2)°$, $V = 1310.3(3) \times 10^6$ pm^3, $T = -143$ °C, $P2_1/c$, $Z = 4$; 1883 measured, 1718 unique reflections, of which 1613 had $F > 3\sigma(F)$, 229 parameters; all non-hydrogen atoms refined anisotropically; $R = 0.033$, $R_w = 0.030$; full matrix, SHELX 76 and 86[11].

The reaction of **8a, b** with thallium ethanolate gives thallium (pentafluoro-λ^6-sulfanyl)cyclopentadienylide (**9**), which was isolated as the crystalline THF adduct. In its NMR spectrum only a single anion of **9** is observed. The crystal structure analysis of **9**·THF reveals the bent chain of rings linked through the Tl^+ ions, which is typical for thallium cyclopentadienides.[7] The coordination number at the thallium center is increased by the coordinated THF molecule (Fig. 2). The Tl–C distances indicate a largely ionic compound.[7]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Hoechst AG, Frankfurt, for fluorinated solvents.

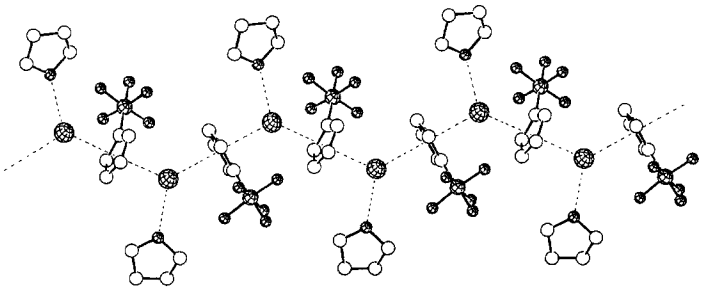

Fig. 2. Crystal structure of **9**·THF. The hydrogen atoms have been omitted for clarity. $a = 1214.4(5)$, $b = 1015.7(4)$, $c = 1075.1(3)$ pm, $\beta = 113.95(3)°$, $V = 1212.1(8) \times 10^6$ pm^3, $T = -143\,°C$, $P2_1/c$, Z = 4; 4181 measured reflections, 2646 unique reflections, of which 2373 had $F > 3\sigma(F)$, 185 parameters; all non-hydrogen atoms refined anisotropically; $R = 0.035$, $R_w = 0.026$. Tl–C 302.7(6)–314.9(5), Tl–O 287.7(4) pm[11].

Starting from **9** many organometallic cyclopentadienyl complexes should now be accessible by simple metathesis reactions. In this way, for example, the complexes **10** (cod = 1,5-cyclooctadiene) and **11** were produced. The crystal structure analysis of **10** shows it to be a typical η^5-cyclopentadienyl complex (Fig. 3).

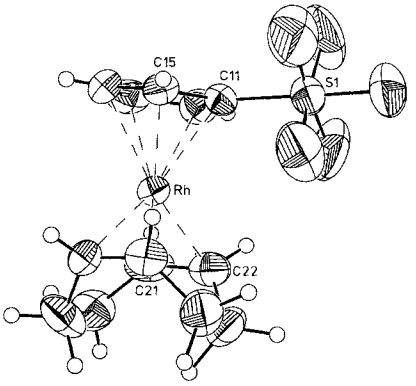

Fig. 3. Crystal structure of **10**. $a = 917.4(1)$, $b = 1318.2(1)$, $c = 1177.4(2)$ pm, $\beta = 101.84(2)°$, $V = 1386(3) \times 10^6$ pm^3, $T = 20\,°C$, $P2_1/c$, Z = 4. 2335 measured reflections, 2184 unique reflections, of which 1934 had $F > 3\sigma(F)$, 226 parameters, all non-hydrogen atoms refined anisotropically; $R = 0.036$, $R_w = 0.031$. Rh–C(Cp) 220.9(6)–228.1(6), Rh–C(cod) 207.9(6)–209.9(6) pm[11].

Disturbances in the fivefold symmetry of the cyclopentadienyl unit arising from the SF_5 group are evident only to a small degree in the Rh–C bond lengths. In spite of repeated efforts we have not succeeded in synthesizing the corresponding ferrocene, even though the formation of bis(trifluoromethyl)ferrocene from $FeCl_2$ and $Tl(CF_3C_5H_4)$ is possible.[8]

The deliberate fluoride abstraction from **8** by elimination of KF from the intermediate $K^+(C_5H_4SF_5)^-$ at $-55\,°C$ gives **1** as a yellow liquid, which is stable as a diluted solution for several days at room temperature. Compound **1** was characterized by ^1H and ^{19}F NMR spectroscopy as well as by mass spectrometry. If one ignores the small HF coupling in the ^{19}F NMR spectrum, the A_2B_2 system known for alkylidene sulfur tetrafluorides is observed. This spin system does not coalesce to a single line even when a highly dilute sample is heated to 180 °C. From this one can conclude that the zwitterionic mesomeric resonance structure is not significant despite the potential stabilization of the aromatic five-membered ring. It is known that the axial and equatorial fluorine atoms of alkyltetrafluorosulfonium cations $R-SF_4^+$ exchange even at $-80\,°C$.[9] In our proposed structure for **1** the plane of the five-membered ring is coplanar with the axial fluorine atoms, and the structure is rigid in analogy to the known alkylidene sulfur tetrafluoride.[1]

Experimental Procedure

3 (Mixture of isomers): In a glass ampule 1.87 g (22.2 mmol) **2**[10], 1.70 g CCl_3F, and 3.64 g (22.4 mmol) $SClF_5$ were irradiated with a high-pressure Hg vapor lamp at $-78\,°C$ for ca. 16 h. The volatile components were removed at 80 °C/0.1 mbar leaving 3.55 g (65%) **3**. M.p. $-65\,°C$; ^{19}F NMR (84 MHz, $CDCl_3$): 2 sets of AB_4-type signals in the ratio 70:30. $\delta = 85.3$, 61.0 ($^2J(AB) = 143.3$ Hz), 85.3, 60.1 ($^2J(AB) = 143.2$ Hz); IR: strong bands at 3386, 906, 847 (vs), 750, 651, 596 cm^{-1}.

4: 2.25 g (9.12 mmol) **3** reacted at room temperature within several h upon stirring with 2.50 g powdered KOH in 50 mL ether. After neutralization, extraction with ether, drying with $MgSO_4$, and fractional condensation (25 °C/−78 °C/−196 °C) in dynamic vacuum at 10^{-3} mbar, 1.07 g (56%) **4** was isolated in the trap at −78 °C. M.p. 5 °C; ^{19}F NMR ($CDCl_3$): AB_4 type, $\delta = 85.26$, 62.82 ($^2J(AB) = 145.8$ MHz); IR: strong bands at 3352, 824 (vs), 774, 663 cm^{-1}.

8 (from **3**): 3.87 g (18.4 mmol) **4** was layered with P_2O_5 in a glass flask. The reaction vessel was attached to a cold trap system (−78 °C/−196 °C) and warmed to 50 °C. 2.60 g (73%) **8a**, **b** was obtained in the trap at −78 °C under a dynamic vacuum. M.p. −75 °C; ^{19}F NMR ($CDCl_3$): two sets of AB_4-type signals in the ratio 60:40, $\delta = 86.44$, 67.92 ($^2J(AB) = 150.1$ Hz, isomer A), 84.84, 65.09 ($^2J(AB) = 146.5$ Hz, isomer B); IR(gas): strong bands at 1097, 893 (vs), 871 (vs), 805 (vs), 673, 605 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$): $\delta = 3.2$ (isomer B), 3.5 (isomer A), (-CH_2-), 6.4–6.5, 6.6–6.7, 6.8, 7.0; $^{13}C\{^1H\}$ NMR ($CDCl_3$): 40.6 (B), 42.7 ($J(CF_{eq}) = 2.0$ Hz, A), 128.8 ($J(CF_{eq}) = 3.5$ Hz), 129.8, 133.4–135.2, 155 (-$C(SF_5)$, A and B); MS (*m/z*: 192 (M^+, 98.2%), 173 ($[C_5H_5SF_4]^+$, 15.0%), and smaller fragments.

6: In a sealed glass ampule 1.50 g (15.9 mmol) **5** dissolved in 2.8 g CCl_3F reacted with 2.85 g (17.5 mmol) $SClF_5$ under irradiation with a high-pressure Hg vapor lamp. Fractional condensation (25 °C/−78 °C/−196 °C) in dynamic vacuum gave 4.00 g (98%) **6** in the trap at −78 °C. M.p. 5.5 °C; ^{19}F NMR ($CDCl_3$): AB_4 type, $\delta = 85.7$, 58.8 ($^2J(AB) = 141.6$ Hz); IR: strong bands at 2917, 1305, 890 (vs), 869 (vs), 831 (vs), 814 (vs), 797 (vs), 786 (vs), 758, 636 (vs), 590 cm^{-1}.

7: A mixture of 3.50 g (13.6 mmol) **6** and 10 g finely powdered KOH in 50 mL pentane was heated at reflux for two weeks. Fractional condensation (25 °C/−78 °C/−196 °C) in dynamic vacuum gave 2.36 g (79%) pure **7** in the trap at −78 °C. M.p. −52 °C; ^{19}F NMR ($CDCl_3$): AB_4 type, $\delta = 85.5$, 64.3 ($^2J(AB) = 148.9$ Hz); IR: strong bands at 2977, 2929, 1309, 1067, 917, 831 (vs), 791 (vs), 770 (vs), 686, 658 (vs), 597 (vs) cm^{-1}.

8 (from **5**): 0.42 g (1.9 mmol) **7** was pyrolyzed at 10^{-3} mbar and 400 °C in a glass tube, and the volatile components were fractionally distilled in a cold-trap system (−78 °C/−196 °C). 0.10 g (27%) **8** was isolated in the trap at −78 °C.

9: 0.44 g (1.8 mmol) $Tl(OC_2H_5)$ was dissolved in 50 mL dry THF (or pentane, Et_2O, EtOH) and cooled to −196 °C. 0.36 g (1.9 mmol) **8** was added by condensation. The mixture was slowly warmed to −20 °C. Recrystallization from THF at −78 °C gave 0.51 g (61%) **9**·THF. M.p. 65 °C (decomp); ^{19}F NMR ([D_8]THF): AB_4 type, $\delta = 95.9$, 79.3 ($^2J(AB) = 150.4$ Hz); ^1H NMR ([D_8]THF): $\delta = 5.9$, 6.5; MS (*m/z*): 396 ([*M*]$^+$, 6.7%), 332 ([$TlSF_5$]$^+$, 0.6), 225 ([TlHF]$^+$, 1.4), 205 (Tl^+, 100.0) and smaller fragments; IR: strong bands at 1522 (vs), 1036, 903, 849 (vs), 839 (vs), 800 (vs), 757 (vs), 658 cm^{-1}.

10: On addition of 235 mg (0.477 mmol) $[Rh_2Cl_2(cod)_2]$ to a suspension of 0.64 g (1.45 mmol) **9** in 30 mL THF at −78 °C, an orange solution and a precipitate of TlCl was obtained. The solvent was removed under vacuum, the residue dissolved in pentane and centrifuged to give after recrystallization 0.28 g (0.70 mmol, 74%) **10**. M.p. 89.4 °C; ^{19}F NMR ($CDCl_3$): AB_4 type, $\delta = 76.0$, 87.8 ($^2J(AB) = 148.9$ Hz); $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 31.9$ ($^1J(CRh) = 0.5$ Hz), 66.6 ($^1J(CRh) = 13.9$ Hz), 84.9 ($^1J(CRh) = 4.0$ Hz, $J(CF_{eq}) = 4.0$ Hz), 87.2 ($^1J(CRh) = 3.5$ Hz, $J(CF_{eq}) = 1.3$ Hz), 93.3 ($^2J(CF_{eq}) = 11.4$, $^1J(CRh) = 3.1$, $^2J(CF_{ax}) = 1.1$ Hz); MS (*m/z*): 402 (*M*$^+$, 100%), 372 ($[C_{11}H_{10}F_5RhS]^+$, 4.4), 348 ($[C_9H_{10}F_5RhS]^+$, 3.4), 275 ($[C_{13}H_{16}Rh]^+$, 10.1), and smaller fragments; IR: strong bands at 901, 871 (vs), 826 (vs), 785 (vs), 775 (vs), 734, 625, 587 cm^{-1}.

11: 0.30 g (0.78 mmol) $[Rh_2Cl_2(CO)_4]$ in THF reacted with 1.2 g (3.0 mmol) **9** at −78 °C, whereupon the solution turned red. The reaction mixture was warmed to room temperature, the THF removed in vacuo and replaced with pentane, and the resulting solution centrifuged. Fractional condensation of the crude product (25 °C/−78 °C/−196 °C) under a dynamic vacuum gave 0.40 g (71%) in the trap at −78 °C. M.p. −3 °C; ^{19}F NMR ($CDCl_3$) : AB_4 type, $\delta = 74.9$, 83.2 ($^2J(AB) = 146.5$ Hz); ^1H NMR ($CDCl_3$): $\delta = 5.45$ ($^3J(HH) = {}^2J(HRh) = 2.45$ Hz, $J(CF_{eq}) = 1$ Hz), 5.87 ($^3J(HH) = {}^2J(HRh) = 2.45$ Hz, $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 86.92$ ($J(CF_{eq}) = 4.0$, $^1J(CRh) = 0.7$ Hz), 87.22 ($J(CF_{eq}) = 1.8$ Hz), 123.67 ($^2J(CF_{eq}) = 23.6$, $^1J(CRh)/^2J(CF_{ax}) = 2.6/4.4$ Hz), 188.28 ($^1J(CRh) = 84.84$, $^4J(CF_{eq}) = 1.3$ Hz); MS (*m/z*): 349.89064 calc. 349.89073 (*M*$^+$, 84.4%), 322 ([M − CO]$^+$, 68.4), 294 ([M − 2CO]$^+$, 13.5), 223 ([M − SF_5]$^+$, 6.2), and smaller fragments; IR: strong bands at 2061 (vs), 1999 (vs), 906, 852 (vs), 798 (vs), 670, 599, 570, 514, 493 cm^{-1}.

12 (Dimer of **8**): 0.26 g (1.4 mmol) **8** at 25 °C produced 0.25 g (0.65 mmol, 96%) **12** after several days. M.p. 31.6 °C; ^{19}F NMR ($CDCl_3$) : two sets of AB_4-type signals, $\delta = 86.12$, 62.22, 83.51, 59.13 ($^2J(AB) = 146.5$, 141.6 Hz); $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 35.83$ ($^3J(CF_{eq}) = 2.4$ Hz), 41.05, 42.35 ($J(CF_{eq}) = 2.0$ Hz), 54.78 ($J(CF_{eq}) = 3.4$ Hz), 55.83 ($J(CF_{eq}) = 2.0$ Hz), 102.03 ($^2J(CF_{eq}) = 11.2$, $^2J(CF_{ax}) = 1.5$ Hz),

Facile Reduction of a Dialkyl Zirconium(IV) Octaethylporphyrin (OEP) Complex by H_2: Crystal Structure and Spectroscopic Characterization of $[(OEP)ZrCH_2SiMe_3]$**

Holger Brand and John Arnold*

During our recent studies of the homogeneous catalytic hydrogenation of olefins by $[(OEP)ZrR_2]$ (OEP = octaethylporphyrin, R = alkyl) we observed degradation of the catalyst in the absence of olefin to a green paramagnetic compound that we have now isolated in pure form for $R = CH_2SiMe_3$ and show here to be the reduced monoalkyl complex $[(OEP)ZrCH_2SiMe_3]$ (**2**).[1–3] Formally, this compound contains Zr in the +III oxidation state which is remarkable since: i) alkylzirconium(III) compounds are extremely rare,[4] and ii) reduction of Zr^{IV} to Zr^{III} by H_2 is, to the best of our knowledge, unprecedented. A combination of spectroscopic techniques shows, however, that this simple view of the complex does not fully account for the observed data, and that a more accurate picture is obtained by considering a second resonance form involving a neutral Zr^{IV}–porphyrin radical anion.[5] As similar arguments were made some time ago by Reed et al. to explain related data for reduced iron porphyrins, our results provide an interesting comparison between early transition metal porphyrin radicals with these more well-studied late metal derivatives.[6, 7]

Reaction of $[(OEP)Zr(CH_2SiMe_3)_2]$ (**1**)[1] with H_2 (1 atm) in toluene at 20 °C results in a color change from red to green and affords a quantitative yield of $[(OEP)ZrCH_2SiMe_3]$ (**2**) after filtration and removal of the solvent [Eq. (a), OEP is denoted as a circle]. Crystallization from pentane at −40 °C gave blue crystals of analytically pure **2** suitable for X-ray crystallography. The crystal structure of **2** (Fig. 1) shows the zirconium atom to be five-coordinate with the alkyl group in the axial position.[8] The zirconium atom is displaced by 0.63 Å out of the mean plane generated by the four nitrogen atoms, towards the carbon atom of the alkyl group. This value is similar in magnitude to the related five-coordinated (OEP)Sc compounds[9, 10] but is significantly smaller than that for the dialkyl precursor **1** (in which the Zr is displaced by 0.93 Å[1]) and related *cis*-coordinated (OEP)Zr derivatives.[2] This is no doubt due to relief of steric strain brought about by the loss of the *cis* ligand, a view which is further supported by the shortening of the Zr–C bond in **2** (2.216(8) Å) relative to that in **1** (2.287(4) Å). A slight lengthen-

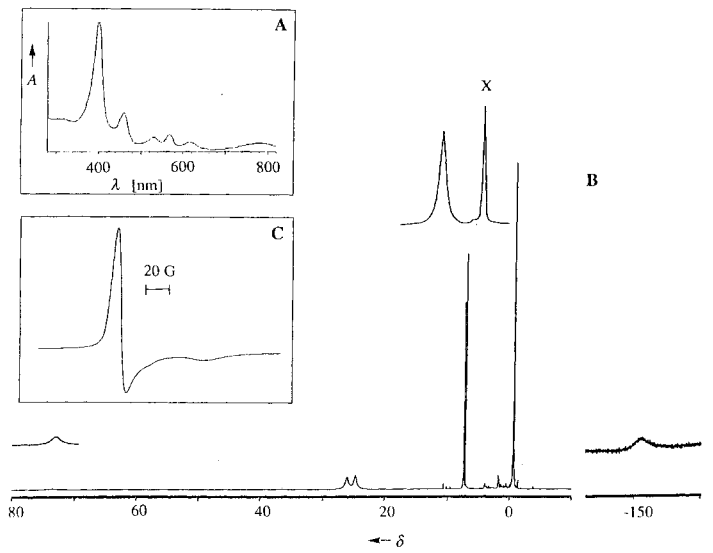
ing of $N-C_a$ and C_b-C_b and shortening of C_a-C_b bonds is apparent when the average bond lengths in the porphyrin core of **2** are compared with those of other d^0 transition metal OEP derivatives (Table 1). Similar results have been reported for reduced Fe–porphyrin compounds and these have been rationalized in terms of partial population of the porphyrin LUMO of e symmetry.[7, 11]

Table 1. Comparison of average bond lengths [a].

Compound	$N-C_a$	C_a-C_b	C_b-C_b	C_a-C_m
2 [b]	1.395(7)	1.428(11)	1.373(7)	1.388(12)
(OEP)M derivates [c]	1.382(7)	1.447(6)	1.361(6)	1.390(9)

[a] These are averaged values with the calculated standard deviations given in parentheses. [b] Data from the two independent molecules in the unit cell. [c] Averaged values from $[(OEP)ZrMe_2]$, $[(OEP)ZrCl_2]$, $[(OEP)Zr(O\,t\,Bu)_2]$ (all ref. [2]), **1** (ref. [1]), and [(OEP)ScMe] (ref. [10]).

The UV/VIS, ^{1}H NMR, and EPR spectra of **2** are shown in Figure 2. The UV/VIS spectrum shows a Soret band (Fig. 2A) that is reduced in intensity relative to that in the spectrum of the starting material **1** and extra bands at 458 and above 600 nm, typical of a porphyrin radical anion.[6, 12] In comparison, most of the isoelectronic d^1 Ti–porphyrin compounds display a "normal" UV/VIS spectrum, since the single electron in these species resides in a metal d_{xy} orbital.[13, 14] We note, however, that if back-bonding from the axial ligand to the metal raises the energy of this orbital,[15, 16] green porphyrin radical anions are observed.[17, 18]



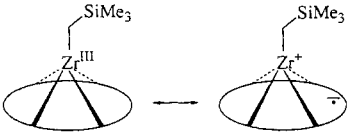


Fig. 2. A) UV/VIS, B) ^{1}H NMR, and C) EPR spectra of **2**. A = absorbance.

The ^{1}H NMR spectrum (Fig. 2B) provides more information about the electronic nature of **2**. The proton resonances have been assigned by integration and by selective deuteration at the *meso* positions,[19] and follow Curie–Weiss behavior between 5 and 80 °C. The large upfield shift and temperature dependence of the signal corresponding to the *meso* hydrogen atoms is indicative of high spin density at the *meso* carbon atoms.[20, 21] Since the methylene protons of the CH_2SiMe_3 group also experience a strong, temperature-dependent paramagnetic shift (down field in this case) there must also be considerable spin density at the Zr atom.[20, 21] This ambiguity of spin density is best explained by assuming single occupancy of a molecular orbital of e symmetry,[7, 11] delocalized over the porphyrin ring *and* the transition metal. Such an orbital has the right symmetry to overlap with the metal d_{xz} and d_{yz} orbitals, and its wave function has a large coefficient at the *meso* carbon atoms.

No EPR signal is detected at 293 K; however, at 77 K an isotropic signal typical of a metal-centered radical, with $g_\perp = 2.001$ G and $g_\parallel = 1.989$ G, is observed (Fig. 2C).[22] The fact that an isotropic signal with no ^{14}N hyperfine coupling[14, 17, 23, 24] is observed at low temperature, yet no signal is detected at 293 K is also consistent with single occupation of an e orbital and not of the metal d_{xy} orbital as is the case with a Ti^{III} system. Porphyrin radical anions of late transition metals show g values around the spin only value; in these compounds the electron is confined to the porphyrin ring since the metal d_{xz} and d_{yz} orbitals are occupied.[25] The electronic structure of $[(OEP)ZrCH_2SiMe_3]$ (**2**) is therefore best described by two resonance formulae, a Zr^{III} metal-based radical *and* a zwitterionic porphyrin radical anion.

2

Experimental Procedure

Toluene (25 mL) was vacuum transferred onto $[(OEP)ZrCl_2] \cdot 0.5$ toluene (0.500 g, 0.675 mmol) [2] and $LiCH_2SiMe_3$ (0.127 g, 1.350 mmol). After 2 h all the starting materials were dissolved and H_2 (1 atm) was admitted, resulting in a color change to dark green. The solution was filtered after 2 h and the volatiles were removed under reduced pressure. The compound was crystallized from pentane to afford blue crystals: M.p. 100 °C (decomp.); ^{1}H NMR (C_6D_6, 300 MHz): $\delta = 73.5$ (2H, br s, $h_{1/2} = 610$ Hz; CH_2Si), 26.1 (8H, br s, $h_{1/2} = 250$ Hz, CH_2CH_3), 24.7 (8H, br s, $h_{1/2} = 250$ Hz, CH_2CH_3), 7.39 (9H, s, $h_{1/2} = 15.4$ Hz; $Si(CH_3)_3$), −0.64 (24H, s, $h_{1/2} = 25$ Hz; CH_2CH_3), −154 (br s, $h_{1/2} = 3000-3500$ Hz, *meso*-H); UV/VIS (pentane): λ_{max} (ε) = 316 (14100), 398 (56200), 458 (15800), 530 (9300), 566 (10700), 614 (7600), 786 (6600); MS (70 eV): m/z 711 (50%, M^+); μ_{eff} (C_6D_6) = 1.88 BM; EPR ($C_6H_{11}CH_3$, 77 K): $g_\perp = 2.001$, $g_\parallel = 1.964$; Anal. calcd. for $C_{47}H_{55}N_4SiZr$: C, 67.55; H, 7.79; N, 7.88; found: C, 67.58; H, 7.78; N, 7.87.

[11] This is equivalent to the e_g orbital (for D_{4h} symmetry) as described by the four-orbital diagram in: M. Gouterman in *The Porphyrins* (Ed.: D. Dolphin), Academic Press, New York, **1978**, *Vol. III*, Chapter 1, p 93.
[12] A reviewer pointed out that the peaks in the UV/VIS spectrum may in fact result from a mixture of the following species: $(OEP)Zr^{IV}$, $(OEPH)Zr^{IV}$, $(OEPH_2)Zr^{IV}$, and $(H_2OEP)Zr^{IV}$ formed by disproportionation and subsequent protonation and rearrangement. At such high dilution we cannot rule out such reactions, however, we note that the relative intensities of the peaks are reproducible and that an identical UV/VIS spectrum is produced by generation of $[(OEP)ZrCH_2SiMe_3]$ (**2**) from $[(OEP)Zr(CH_2SiMe_3)_2]$ (**1**) and dihydrogen in situ in the UV cell. For explanation of the nomenclature used and the UV/VIS features for the species mentioned above see ref. [5].

Trialkylstibanes as Bridging Ligands: Synthesis and Structure of the Dinuclear Complexes $[Rh_2Cl_2(\mu\text{-}Sb\mathit{i}Pr_3)(\mu\text{-}CR_2)_2]$**

Peter Schwab, Norbert Mahr, Justin Wolf, and Helmut Werner*

Dedicated to Professor Carl Krüger on the occasion of his 60th birthday

Owing to recent investigations particularly by Huttner et al.[1] the existence of dinuclear transition metal complexes containing Sb, SbR, and SbR_2 units as bridging ligands is well established.[2] In contrast, stibanes SbR_3 as well as arsanes AsR_3 and phosphanes PR_3 were considered to be able only to form terminal $M-ER_3$ bonds.[3] We have now discovered the first examples of SbR_3-bridged dinuclear complexes which are not only easily accessible but are also surprisingly thermally stable.

The carbenerhodium(I) compounds **1**–**3**, prepared from *trans*-$[RhCl(C_2H_4)(Sb\mathit{i}Pr_3)_2]$ and diaryldiazomethanes,[4] react on warming in benzene by partial loss of the $Sb\mathit{i}Pr_3$ ligands to give complexes **4**–**6** in about 80% yield. Complexes **4**–**6** are red crystalline solids which are soluble in C_6H_6 and CH_2Cl_2 and thermally decompose only above 180 °C. The composition was confirmed by elemental analysis. The spectroscopic data of **4**–**6** differ significantly from those of the mononuclear compounds **1**–**3** insofar as in the ^1H NMR spectra the signal of the SbC*H* protons appears at *higher* field than that of the $SbCHCH_3$ protons [see Table 1 and cf. **1**: $\delta(SbCH) = 2.08$ (sept, $J(H,H) = 7.3$ Hz), $\delta(SbCHCH_3) = 1.31$ (d, $J(H,H) = 7.3$ Hz)], while in the ^{13}C NMR spectra the Sb*C*H resonance is observed at *lower* field than that of the $SbCHCH_3$ carbon atoms [see Table 1 and cf. **1**: $\delta(SbCH) = 19.07$ (d, $J(RhC) = 3.4$ Hz), $\delta(SbCHCH_3) = 21.90$ (s)]. Another characteristic feature is that in compound **1** the phenyl groups are spectroscopically equivalent, whereas in compound **4** they are different, as is illustrated by the double set of signals for the C_6H_5 carbon atoms. The ^{13}C NMR spectrum of **6** reveals that all three possible isomers with

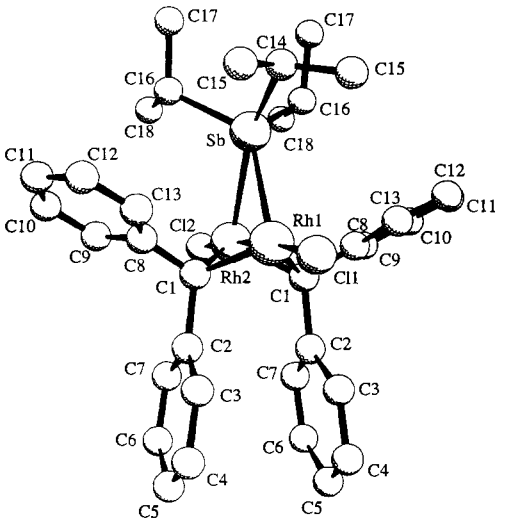
different orientations of the aryl groups are present. The more unsymmetrical complex **7** which contains two different carbene ligands (see Scheme 1) is formed either on treatment of **1** with di(*p*-tolyl)diazomethane or on reaction of equimolar amounts of **4** and **5**. In the latter case the yield is quantitative.

The X-ray crystal structure analysis of **4**[5] (Fig. 1) confirms the hitherto unknown capability of trialkylstibanes to behave as bridging ligands, that is to form *two* M–Sb bonds. The Rh–Rh distance (2.5349(5) Å) is relatively short and is indicative of a direct metal–metal interaction. Equally short Rh–Rh bond



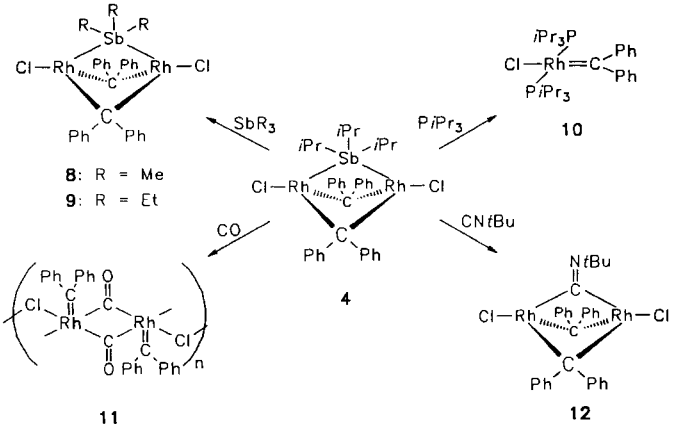


Fig. 1. Crystal structure of **4**. Selected bond lengths [Å] and angles [°]: Sb-Rh1 2.6868(5), Sb-Rh2 2.6695(5), Rh1-Rh2 2.5349(5), Rh1-Cl1 2.300(1), Rh1-C1 2.003(1), Rh2-Cl2 2.294(1), Rh2-C1 2.007(3); Rh1-Sb-Rh2 56.49(1), Sb-Rh1-Rh2 61.41(1), Sb-Rh2-Rh1 62.10(1), Sb-Rh1-C1 90.24(9), Sb-Rh2-C1 90.59(9), Rh1-Rh2-Cl2 176.35(4), Rh2-Rh1-Cl1 175.45(4), C1-Rh1-C1 87.7(2), C1-Rh2-C1 87.3(2), Rh1-C1-Rh2 78.5(1), Rh1-Rh2-C1 50.63(9), Rh2-Rh1-C1 50.9(1), Rh1-C1-C2 115.5(2), Rh1-C1-C8 114.8(2), Rh2-C1-C2 114.5(2), Rh2-C1-C8 118.4(2), C2-C1-C8 111.5(3).

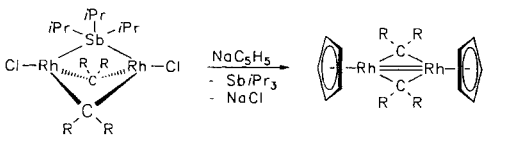
lengths have been found in other carbene-bridged dirhodium complexes of the type $[Rh_2Cl_2(py)_2(\mu\text{-}CO)(\mu\text{-}CPh_2)_2]$[6] and $[(C_5H_5)_2Rh_2(\mu\text{-}CO)(\mu\text{-}CPh_2)_2]$.[7] Noteworthy are the significantly larger (ca. 0.1 Å) Rh–Sb distances in **4** compared with those in **1**,[4] which is in agreement with the bridging position of the Sb*i*Pr$_3$ ligand. The Cl-Rh-Rh-Cl unit is almost linear; the somewhat slight bending away from the Sb atom is possibly due to the steric repulsion between the chloro ligands and the bulky isopropyl groups.

A series of interesting reactions of compounds **4** is outlined in Scheme 2. We note in particular the smooth and almost quantitative exchange of the stibane ligand which provides a route to other SbR_3-bridged dinuclear rhodium complexes. Compound **8** is even more stable than **4** and decomposes only above 240 °C.



Attempts to replace the Sb*i*Pr$_3$ ligand in **4** by a bridging P*i*Pr$_3$ unit failed. Compound **4** reacts with one equivalent of triisopropylphosphane to give the mononuclear carbenerhodium(I) complex **10** in 25% yield.[4] However, compound **10** may be obtained almost quantitatively by reaction of **4** with four equivalents of P*i*Pr$_3$. Treatment of **4** with CO also leads to the displacement of the stibane accompanied by cleavage of the $Rh(CPh_2)Rh$ bridges. The resulting polymeric complex **11** was previously prepared by Sonogashira et al.[8] from $[\{Rh(CO)_2Cl\}_2]$ and diphenylketene; the structure of the reaction product from **11** and NaC_5H_5, namely $[(C_5H_5)_2Rh_2(\mu\text{-}CO)(\mu\text{-}CPh_2)_2]$ has been determined by X-ray analysis.[7] In

Scheme 2.

contrast to the reaction with CO, treatment of **4** with *tert*-butylisonitrile leads to a displacement of Sb*i*Pr$_3$ by the CN*t*Bu ligand; in this process, the carbene bridges remain intact.

The lower stability of the $Rh(SbR_3)Rh$ bridges over the $Rh(CPh_2)Rh$ bridges is equally illustrated in the reactions of **4** and **5** with NaC_5H_5. In these reactions, the dinuclear complexes **13** and **14**, respectively, (see Scheme 3) are formed in excellent yields (89%); compound **13** is also accessible by thermolysis of $[(C_5H_5)_2Rh_2(\mu\text{-}CO)(\mu\text{-}CPh_2)_2]$.[6–8]

Scheme 3.

The conversion of **13** on treatment with Sb*i*Pr$_3$ to the mononuclear carbene complex $[(C_5H_5)Rh(=CPh_2)(SbiPr_3)]$, which was recently prepared by us from **1** and NaC_5H_5,[4] was not successful. We assume that the attack of the bulky stibane upon the Rh–Rh double bond is significantly hindered by the four phenyl groups of the bridging carbene ligands.

Experimental Procedure

4: A solution of **1** (98 mg, 0.12 mmol) in benzene (10 mL) was stirred for 4 h at 60 °C. After cooling to room temperature, the solvent was removed. The residue was washed with pentane and dissolved in ether (10 mL). The product mixture was separated by chromatography on Al_2O_3 (neutral, activity grade V, 3 cm column) with ether/benzene (1:2). The red fraction was evaporated to dryness, and the residue was recrystallized from acetone (−78 °C) to give red crystals which were stable in air for short periods. Yield 42 mg (81%); m.p. 190 °C (decomp). Compounds **5** and **6** were prepared in a similar way. Yield about 78%. **5**: m.p. 190 °C (decomp); **6**: m.p. 178 °C (decomp).

7: a) A solution of **1** (81 mg, 0.10 mmol) in ether (10 mL) was treated with a solution of di(*p*-tolyl)diazomethane (22 mg, 0.10 mmol) in ether (5 mL) and stirred for 3 h at room temperature. The solvent was removed, the residue repeatedly washed with pentane and dried in vacuum; red microcrystalline solid. Yield 34 mg (76%); m.p. 183 °C (decomp). b) A solution of **4** (47 mg, 0.06 mmol) and **5** (49 mg, 0.06 mmol) in benzene (10 mL) was stirred for 5 h at room temperature, and was then worked up as described for a). Yield 93 mg (96%).

8: A solution of **4** (82 mg, 0.10 mmol) in benzene (10 mL) was treated with $SbMe_3$ (16 µL, 0.10 mmol) and stirred for 30 min at room temperature. The solvent was removed, the residue was washed with pentane and dissolved in benzene (2 mL). The solution was chromatographed on Al_2O_3 (see **4**) with C_6H_6/CH_2Cl_2 (1:1) and from the red fraction dark red crystals were isolated which were stable in air for short periods. Yield 66 mg (89%); m.p. 242 °C (decomp). Compound **9** was prepared analogously; yield 87%; m.p. 152 °C (decomp).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0098 $ 10.00+.25/0

12: A solution of **4** (71 mg, 0.08 mmol) in benzene (10 mL) was treated with CN*t*Bu (9 μL, 0.08 mmol) and stirred for 1 h at room temperature. The solvent was removed, the residue repeatedly washed with acetone and dried in vacuum. An orange-red solid was isolated which was stable in air for short periods; yield 56 mg (98%); m.p. 222 °C (decomp).

13: A solution of **4** (87 mg, 0.10 mmol) in THF (15 mL) was treated with NaC_5H_5 (44 mg, 0.50 mmol) and stirred for 1 h at room temperature. The solvent was removed, the residue was extracted with pentane/benzene (1:1; 3 mL), and the solution chromatographed on Al_2O_3 (see **4**). With ether a violet fraction was eluted from which after evaporation of the solvent and recrystallization from ether/pentane violet needles were isolated; yield 53 mg (80%); m.p. 208 °C (decomp). Compound **14** was prepared analogously; yield 78%; m.p. 132 °C (decomp).

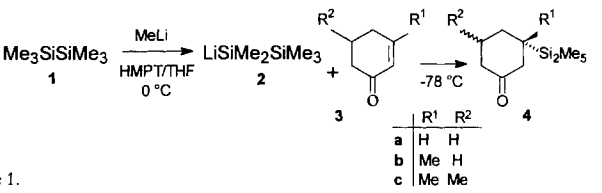
First Total Synthesis of (±)-Rabelomycin**



Karsten Krohn* and Karamali Khanbabaee

Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

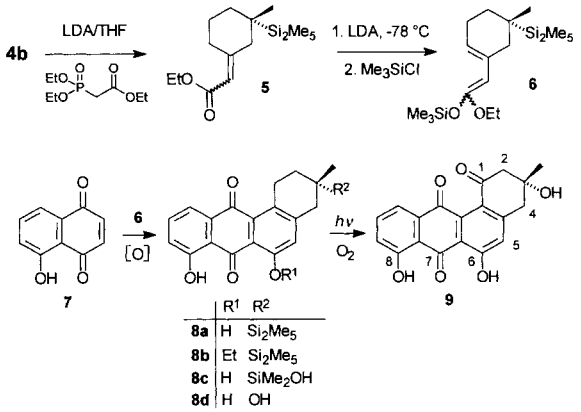
Rabelomycin (**9**), known since 1970,[1] is a structurally simple member of the rapidly expanding class of angucyclin antibiotics.[2] The name angucyclins was given to the class on the basis of the analogy with the anthracyclins and the angular benz[*a*]-anthracene framework.[3] In particular, angucyclin antibiotics are characterized by antifungal,[4] antiviral,[5] enzyme inhibitory,[6] and antitumor activity.[7] Most of the biologically active compounds, which include **9**, carry a labile tertiary hydroxyl group β to the C1 carbonyl group. This inherent lability is one of the reasons that, with the exception of the biomimetically oriented urdamycin-B synthesis of Yamaguchi et al.,[8] no total synthesis of angucyclins is known.

We now present the first synthesis of racemic rabelomycin (*rac*-**9**), in which the synthetic problem is solved in a simple and productive manner with the help of a Diels–Alder reaction and a new type of photooxygenation of a nonfunctionalized C-atom. Previously, only model compounds lacking the tertiary hydroxyl group could be prepared with the Diels–Alder reaction.[9, 10]

Retrosynthetic analysis yielded a diene (OH instead of Si_2Me_5 in **6**, see Scheme 2) which, as preliminary experiments indicated, is probably extremely labile and, furthermore, not easily accessible. We therefore had the idea of replacing the hydroxyl group in the diene with a substituent that is a poorer leaving group. Our original intention was to use the dimethylphenylsilyl group, which could be replaced by a hydroxyl group in a later step.[11] However, to study the Michael addition of lithiated silanes to Michael acceptors such as 3-methylcyclohexenone, the cheaper trimethylsilyllithium was chosen. This reagent is prepared by Still by treatment of hexamethyldisilane (**1**) with methyllithium in hexamethylphosphoric triamide (HMPT).[12] However, on carrying out the reaction on a larger scale, it was discovered that the C–Si bond and not the Si–Si bond in **1** is broken, leading to the formation of pentamethyldisilyllithium (**2**, Scheme 1). This result is in agreement with an observation of Hudrlik[13a] and was recently confirmed for cyclic silanes by Allred et al.[13b] Under the conditions described in the Experimental Section the cleavage of the C–Si bond in hexamethyldisilane by alkyllithium compounds to afford **2** is a general reaction which takes place not only with methyllithium in ether, but also, for example, with *n*-butyllithium. Obviously, the negative charge on the silicon is stabilized by the second silicon atom in the α position. This effective stabilization is also noticeable in the reactivity of the species. The "soft" anion adds to the α,β-unsaturated carbonyl compounds cyclohexenone (**3a**), 3-methylcyclohexenone (**3b**), and 3,4-dimethylcyclohexenone (**3c**) to give exclusively the 1,4 addition products (Scheme 1).[14a] The adducts **4a**–**4c** that are formed are chiral, and further evidence for the presence of a $SiMe_2SiMe_3$ unit is provided by the splitting of the signal of the diastereotopic methyl groups in the $SiMe_2$ group in both the ^1H and ^{13}C NMR spectra (see Experimental for **4b**).

Scheme 1.

Thus, the reagent is already sufficiently selective towards 1,4-addition that the formation of silylcuprates, through the addition of copper salts to the reagent (cf. ref. [11]), is not necessary. The reagent even adds smoothly to sterically hindered enones. The easily accessible pentamethyldisilyllithium (**2**) is a new synthetic reagent, whose usefulness in the synthesis of tertiary alcohols is demonstrated by this first synthesis of rabelomycin.



The first advantage of having a silyl group on the tertiary carbon atom is shown in the next step of the synthesis. Chain

[**] Synthetic Angucyclins, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 1: K. Krohn, F. Ballwanz, W. Baltus, *Liebigs Ann. Chem.* **1993**, 991–913.

extension of the β-silylketone **4b** to the unsaturated ester **5** in a Wittig-Horner reaction with triethylphosphonoacetate can be carried out without the risk of a base-catalyzed β elimination in 95% yield. The presence of two signals in the ^{29}Si NMR spectrum at $\delta = -7.63$ ($SiMe_2$) and at $\delta = -19.51$ ($SiMe_3$) confirms that the Si–Si bond survives the transformation intact.[15]

The silyl group provides a further benefit in the next step through its property of destabilizing anions in the β position to the silicon atom. Theoretically, two regioisomeric dienolates can be formed by the deprotonation of **5** with lithium diisopropylamine (LDA). Our plan assumed, however, that proton abstraction α to the tertiary carbon atom in **5** would be suppressed by a combination of the steric shielding afforded by the methyl and silyl groups and the β-effect of the silicon. This expectation was completely fulfilled, and after selective enolate formation with LDA and trapping with trimethylsilyl chloride only the desired regioisomer of the diene **6** (76%) could be isolated. The subsequent Diels–Alder reaction proceeded regiospecifically to give a 1:1 mixture of the phenol **8a** (32%) and the ethyl ether **8b** (33%) (Scheme 2). However, the formation of

Scheme 2.

this mixture is not a disadvantage, since the ethyl ether can be quantitatively converted into the phenol by treatment with aluminum trichloride. Under these conditions the Si–Si bond is also cleaved, and after hydrolytic workup the silanol **8c** is obtained (76% over both steps). Alternatively, the Si–Si bond can be cleaved under mild conditions with bromine.[14b] Silyl groups with electronegative substituents can be oxidatively replaced with hydroxyl groups.[11b] In this way **8c** could be converted into the tertiary alcohol 1-deoxyrabelomycin (**8d**, 78%) by mild treatment with potassium fluoride and hydrogen peroxide.[16]

Due to the initially mentioned instability of the tertiary alcohol, the introduction of the oxygen at C1 of **8d** was carried out in the last step of the synthesis. The oxygenation of **8d** to give rabelomycin **9** was successfully carried out in a new type of photooxygenation, in which a dilute solution of **8d** was exposed to daylight (70%). This photochemical introduction of oxygen at the angular benzylic position at C1 to form labile β-hydroxyketones has already proved successful in the synthesis of angucyclin analogues.[17] This reaction will, in our opinion, be an important step in future angucyclin syntheses, because base-catalyzed oxygenation[10] of compounds with tertiary hydroxyl groups such as **8d** invariably leads to decomposition.

Experimental Section

Preparation of **2** and Michael addition to **3b** to form **4b**: A solution of hexamethyldisilane (50.0 mL, 0.34 mol) in HMPT (200 mL) was cooled to 0 °C and treated with a 5% solution of methyllithium in ether (88 mL, 0.2 mol) under nitrogen. After 15 min dry THF (0.5 L) was added over 10 min, the reaction mixture cooled to −78 °C, followed by treatment with a solution of **3b** (16.5 g, 0.15 mol) in dry THF (100 mL). After 15 min the reaction was quenched by the addition of dry methanol (20 mL), and the mixture then warmed to 0 °C. The product was extracted with *n*-pentane (1 L), the pentane solution washed twice with water (a total of 1 L) and dried over magnesium sulfate. The solution was concentrated under vacuum, and the residue fractionally distilled under oil pump vacuum; yield 21.2 g (58%) (95–99 °C; 1.3 Torr), colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = -0.07$ (s; 3H, $SiMe_2$), 0.08 (s; 3H, $SiMe_2$), 0.00 (s; 9H, $SiMe_3$), 0.86 (s; 3H, CH_3), 1.39–1.47 (m; 1H), 1.61–1.80 (dt; 1H), 1.84–1.94 (m; 3H), 2.14–2.35 (m; 3H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = -5.57$ (prim.), −5.42 (prim.), −0.94 (3 × prim.), 20.46 (prim.), 22.95 (sec.), 27.02 (quat.), 32.12 (sec., 41.46 (sec.), 49.55 (sec.) 213.31 (quat.) (Assignments from DEPT).

Photooxygenation of **8d** to **9**: A solution of **8d** (30 mg, 0.092 mmol) in dichloromethane (6 mL) was exposed to diffuse daylight for 10 hours in three NMR tubes. After plate chromatographic purification on silica gel (dichloromethane:ether = 80:20) orange crystals of **9** were obtained from the fraction of medium polarity. (22 mg, 70%); M.p. 192 °C (decomp.); (ref. [1] for (+)-rabelomycin: M.p. 193 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 1.49$ (s; 3H, CH_3), 2.95 (d, $J_{2e,2a} = 15$ Hz; 1H, 2-H_e), 3.04 (d, $J_{2e,2a} = 15$ Hz; 1H, 2-H_a), 3.08 (s; 2H, 4-H_2), 6.99 (s; 1H, 5-H), 7.25 (dd, $J_{9,11} = 2.0$, $J_{9,10} = 7.3$ Hz; 1H, 9-H), 7.65 (dd, $J_{9,11} = 2.0$, $J_{9,10} = 7.3$ Hz; 1H, 11-H), 7.67 (t, $J_{9,10} = J_{9,11} = 7.3$ Hz; 1H, 10-H), 11.65 (s; 1H, -OH), 12.30 (s; 1H, OH); ^{13}C NMR: $\delta = 30.05$ (prim.), 44.26 (sec.), 53.89 (sec.), 76.95 (quat.), 115.03 (quat.), 116.83 (quat.), 120.10 (tert.), 122.04 (tert.), 124.02 (tert.), 128.04 (quat.), 135.46 (quat.), 137.82 (tert.), 138.06 (quat.), 150.63 (quat.), 162.06 (quat.), 163.77 (quat.), 183.19 (quat.), 192.57 (quat.), 196.05 (quat.). Synthesis of *N*-Glycopeptide Clusters with Lewis^x Antigen Side Chains and Their Coupling to Carrier Proteins**

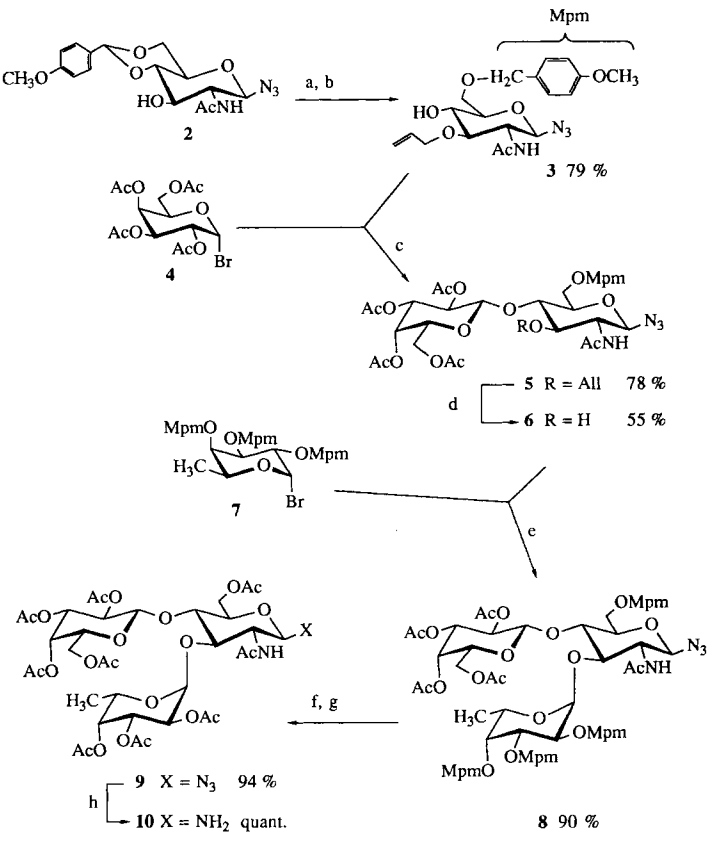
Karsten von dem Bruch and Horst Kunz*

Dedicated to Professor Erich Wünsch on the occasion of his 70th birthday

The trisaccharide determinant 3-*O*-α-fucosyl-*N*-acetyllactosamine (**1**), known as the Lewis^x antigen, has been found both in glycoproteins and in membrane glycolipids of mammalian cells.[1] It is formed during embryonic development and cell differentiation at the 8-cell stage by α-1,3-fucosylation of the I determinant as SSEA-1 antigen (SSEA = stage-specific embryonic antigen), and later it is almost completely masked by further fucosylation (Lewis^y antigen) and/or sialylation.[1, 2] The glycan with an α(2-3)- or α(2-6)-sialylated galactose unit (sialyl Lewis^x) is widely distributed and is an important signal in cell–cell recognition by lectins responsible for cellular adhesion (E-selectin, ELAM-1).



1

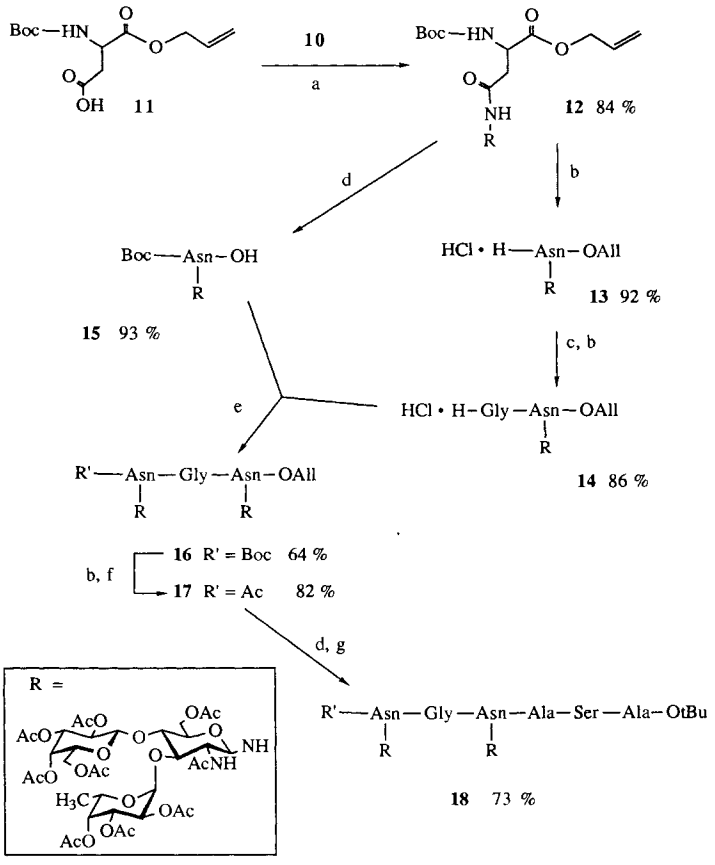
The recognition of sialyl Lewis^x by E-selectin leads, for example, during inflamation to the recruitment of neutrophilic granulocytes and their subsequent invasion into the focus of inflammation.[3] In contrast to sialyl Lewis^x antigen, in healthy adults the occurrence of the Lewis^x antigen is confined to certain specific regions such as the kidney tubules, gastrointestinal epithelial cells, and cells of the spleen and brain.[4, 5]

In tumors the degree of accumulation of Lewis^x antigen in the cell membrane has been shown to correspond directly to the extent of loss of cell–cell recognition, which normally acts to control growth. Therefore, glycoconjugates with Lewis^x antigen structure are of special interest as tumor-associated antigens. Because cluster structures show increased antigenicity[6] and in addition, in natural glycoproteins the antennary oligosaccharide side chains enable a multiple presentation of the saccharide determinants, our aim was the synthesis of glycopeptides with two Lewis^x antigen side-chains, which can simulate a biantennary Lewis^x antigen structure.

We have used two methodological principles during the synthesis of the Lewis^x trisaccharide: a) An azide function serves as an anomeric protective group for the glucosamine unit and at the same time as precursor for the anomeric amino group, required later for the formation of the *N*-glycosidic linkage to the peptide. b) The α-fucose was added in the Mpm-protected form (Mpm = 4-methoxyphenylmethyl) to achieve the acid stability necessary for formation of the glycosidic linkage.[7] The Mpm groups can be selectively removed in the presence of the azido function and replaced by acetyl groups.[7, 8]

The 4,6-(4-methoxybenzylidene)-protected *N*-acetylglucosaminylazide **2**[7, 8] was converted into the corresponding 3-*O*-allyl ether with allyl bromide in the presence of barium hydroxide[9] in dimethylformamide (DMF). The allyl ether was then converted into the glucosaminazide **3** containing a selectively deblocked 4-OH function through a regioselective reductive acetal opening[10] by treatment with sodium cyanoborohydride/trifluoroacetic acid (Scheme 1). Since 6-*O*-Mpm groups are labile in acid, the glycosylation of **3** required carefully chosen conditions. The glycosylation with 2,3,4,6-tetra-*O*-acetyl-galactopyranosyl bromide (**4**)[11] (1.2 equiv) with silver trifluoromethanesulfonate (2.3 equiv) in the presence of 2,6-di-*tert*-butylpyridine (1 equiv) was successful and afforded the β-glycoside **5**. An alternative procedure in the presence of mercury cyanide, which was used successfully in the synthesis of the Lewis^a glycopeptide,[12] yielded the unwanted orthoester only. The allyl ether cleavage was achieved by isomerization with palladium chloride and sodium acetate[13] in acetic acid. The azido function was stable under these conditions; however, the lability of the Mpm groups in acidic milieu reduced the yield of **6**. The allyl cleavage can be optimized by using a lactosamine analogue of **5** that has benzoyl groups in position 6 instead of Mpm groups; the synthesis of this derivative, however, requires two additional steps. The α-fucoside unit was added as the Mpm-protected fucopyranosyl bromide (**7**),[12] which was treated with the acceptor **6** in a stereoselective in situ anomerization procedure[14] to give the protected Lewis^x trisaccharide **8**.

Scheme 1. a) CH_2=CH-CH_2Br, $Ba(OH)_2$/DMF; b) $NaCNBH_3$, CF_3COOH, DMF; c) AgOTf, 2,6-*t*Bu-pyridine, CH_2Cl_2, toluene 1:1) d) $PdCl_2$, NaOAc, AcOH, 50 °C; e) Et_4NBr, 2,6-*t*Bu-pyridine, CH_2Cl_2/DMF 1:1; f) $(NH_4)_2Ce(NO_3)_6$, CH_3CN/H_2O 9:1; g) Ac_2O, pyridine; h) H_2/Raney Ni, *i*PrOH, 20 °C.



With cerium ammonium nitrate[10b] the Mpm groups can be removed from **8** without affecting the azide function.[7, 12] Acetylation of the deblocked OH groups yielded the *O*-acetyl-protected Lewis^x azide **9**. Catalytic hydrogenation of **9** with neutral Raney nickel in isopropyl alcohol yielded the trisaccha-

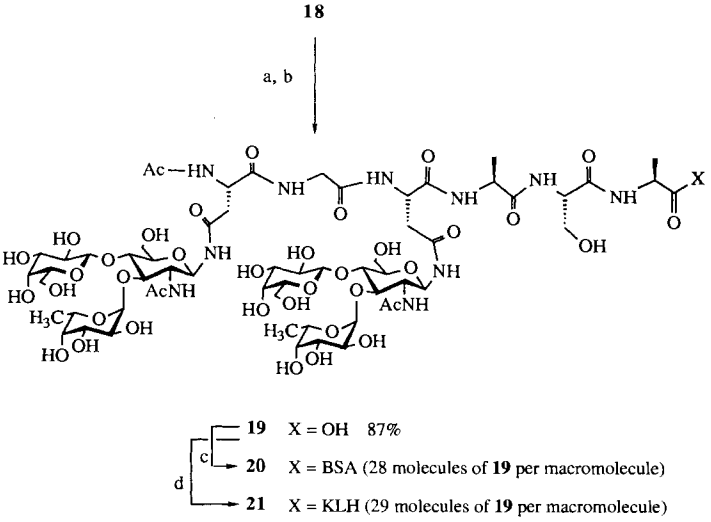
ridamine **10**.[15] These conditions were designed to prevent a O → N acyl transfer.



The protected trisaccharidamine was coupled with α-allyl Boc-asparaginate (**11**)[16] to yield the *N*-glycosylasparagine conjugate **12**; isobutyl-2-isobutoxy-1,2-dihydroquinoline-1-carboxylate (IIDQ)[17] proved itself as condensation agent. The Boc groups can be completely and selectively removed from **12** without saccharide cleavage by using HCl/diethyl ether. This demonstrates that the *O*-acetyl protective groups stabilize the *O*-glycosidic bonds against attack by acids.[7] Chain extension of the product **13** and removal of the Boc groups yielded the N-deblocked Lewis^x dipeptide allyl ester **14** in an overall yield of 86%. Alternatively, the allyl ester **12** was selectively cleaved by Rh^I-catalyzed isomerization.[16] Condensation of **15** and **14** under the influence of the water-soluble 1-ethyl-3-(3-dimethylamino)propylcarbodiimide (EDC) in the presence of 1-hydroxybenzotriazole (HOBt)[18] gave a tripeptide linked to two Lewis^x units (**16**).

Scheme 2. a) IIDQ, CH_2Cl_2; b) HCl/Et_2O; c) Et(iPr_2)N, Boc-Gly-OH, IIDQ, CH_2Cl_2; d) [(Ph_3P)$_3$RhCl], EtOH/H_2O 9:1, 70 °C; e) Et(iPr_2)N, EtN=C=N(CH_2)$_3$$NMe_2$ (EDC), HOBt, CH_2Cl_2; f) Ac_2O/pyridine; g) TBTU, HOBt, H-Ala-Ser-Ala-O*t*Bu, CH_3CN.

Replacement of the Boc groups with the biocompatible *N*-acetyl groups, another Rh^I-catalyzed allyl ester cleavage on **17**, and condensation of the product with a spacer tripeptide ester under the influence of *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU)[19] led to the glycohexapeptide **18**, which has two Lewis^x side chains suitably placed to simulate biantennary presentation.

For deblocking, first the C-terminal *tert*-butyl ester of **18** was cleaved by formic acid. The *O*-acetyl groups were removed by Zemplén saponification by using a very dilute sodium methanolate solution in methanol,[20] which gave a pH of 8.5 on moist pH paper. The glycohexapeptide **19** obtained with two Lewis^x antigen side chains was purified by gel-filtration chromatography on Sephadex G15 and characterized by high-field NMR as well as fast atom bombardment mass spectrometry (FAB-MS).[21] The coupling of the Lewis^x glycopeptide **19** to bovine serum albumin (BSA) to give the synthetic glycoprotein antigen **20** was carried out analogously to a procedure already used with T antigen glycopeptides[22] involving the use of water-soluble carbodiimide/*N*-hydroxysuccinimide[23] in water at a pH of 5.7. To test the antibodies induced against **20**, a second neoglycoprotein (**21**) was created from **19** and hemocyanin from *Megathura crenulata* (KLH, keyhole limpet hemocyanin). The content

Scheme 3. a) HCOOH, 20 °C; b) MeOH/NaOMe, pH 8.5 with air-moist pH paper; c) bovine serum albumin (BSA), EDC, *N*-hydroxysuccinimide, water, pH 5.7; d) KLH, EDC, *N*-hydroxysuccinimide, water, pH 5.7.

of Lewis^x antigen glycopeptide **19** in the glycoproteins was determined photometrically according to the phenol–sulfuric acid method.[24] The assay was calibrated with completely deblocked Lewis^x trisaccharidazide from **9** as standard. It was found that both glycoproteins contain about 30 molecules of synthetic Lewis^x antigen glycopeptide per protein molecule. Thus, clearly defined glycoconjugates that imitate glycoproteins with biantennary Lewis^x determinant structure are now available as models for immunological investigations of tumor-associated recognition signals.

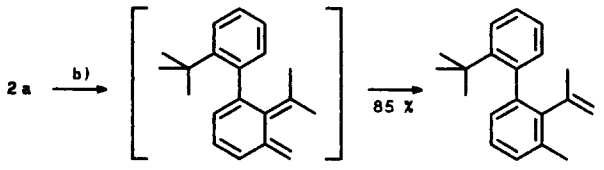
Palladium-Catalyzed C–H Activation of *tert*-Butyl Groups: A Simple Synthesis of 1,2-Dihydrocyclobutabenzene Derivatives**

Gerald Dyker*

Metalation reactions are often chosen to activate C–H bonds which would otherwise be too unreactive. In this context special mention should be made of transition metals in catalytic reactions. Whereas the palladium catalyzed C–H activation at sp^2 carbon centers is now established as a key step in the selective functionalization of alkenes and arenes,[1] such reactions at sp^3 hybridized carbon atoms, which could open up many synthetic possibilities, have hardly been examined.[2] A new domino coupling reaction is described here in the course of which a palladium-catalyzed C–H activation at a *tert*-butyl group is observed for the first time.

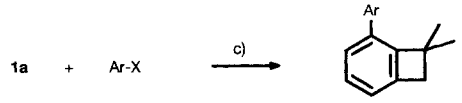
1-*tert*-Butyl-2-iodobenzene (**1a**)[3] is condensed with palladium catalysis to give the strained 1,2-dihydrocyclobutabenzene derivative **2a** in 75% yield. (Scheme 1; for the spectroscopic data of this and other new compounds see Table 2).[4] For a similar coupling reaction of 2-iodoanisole[2a] it is still not clear whether the heteroatom makes a decisive contribution towards the C–H activation or not. The findings now presented confirm the generality of the reaction principle that the intramolecular



1a **2a**

Scheme 1. Homo coupling of **1a**: a) 2.5 mol% $[Pd(OAc)_2]$, K_2CO_3, nBu_4NBr, *N,N*-dimethylformamide (DMF), N_2, 4 d, 105–110 °C.

C–H activation at alkyl groups is not dependent upon additional activation by a heteroatom.



In order to confirm the structure of **2a** chemically, it was thermolyzed at 200 °C (Scheme 2). From this reaction the substituted biphenyl **4** is formed as a result of a pericyclic reaction cascade (1. ring opening to give the *ortho*-quinone compound **3**; 2. [1,5]hydrogen shift with rearomatization).[5]

3 **4**

Scheme 2. Thermolysis of **2a**: b) 1,2-dichlorbenzene, 24 h, 200 °C.

The range of applications offered by this new annelation reaction was explored by experiments involving cross coupling reactions. The aryl halides **1b–g** were added in excess as the second coupling components (Scheme 3). Whereas with 4-bromotoluene (**1b**) und 4-bromoanisole (**1c**) (X = Br) the coupled products **2b** and **2c**, respectively, were produced in satisfactory yields (Table 1), the domino coupling process was inhibited by the more reactive aryl halides 4-iodoanisoles **1c, d** (X = I) and

1b-g (5 equiv) **2b-g**

Scheme 3. Cross coupling of **1a** with the aryl halides **1b–g**; c) 10 mol% $[Pd(OAc)_2]$, K_2CO_3, nBu_4NBr, DMF, N_2, 4 d, 105–110 °C. Ar see Table 1.

Table 1. Cross coupling of **1a** with aryl halides **1b–g** to produce the corresponding 1,2-dihydrocyclobutabenzene derivatives **2**.

Coupling partner	Ar	X	Yield [a] [%]
1b	4-methylphenyl	Br	56
1c	4-methoxyphenyl	Br	59
		I	0
1d	3-methoxyphenyl	Br	37
1e	ethyl phenyl-4-carboxylate	Br	0
1f	4-nitrophenyl	Br	0
1g	2-naphthyl	Br	11

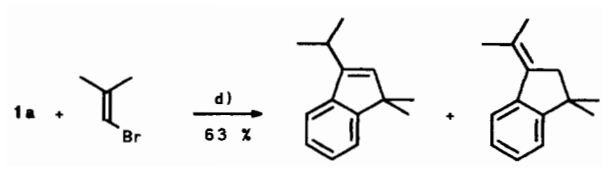
ethyl 4-bromobenzoate (**1e**). In this case the palladium-catalyzed Ullmann reaction [6] of **1c** (X = I) and **1e** predominates; 1-*tert*-butyl-2-iodobenzene (**1a**) hardly reacts.

Vinyl arenes **5**[7] and the triphenylene derivative **6b** (Table 2) were isolated as the side products of the cross coupling reactions (Scheme 4). These products are indicative of a multistep formation mechanism. A possible mechanism for the main reaction shall now be discussed which can be developed in accordance with the experimental results and in analogy to the similar coupling reaction of 2-iodoanisole[2c] (Scheme 5). The cyclometalation of **7** to give **8**, in which the intramolecular C–H activation at the *tert*-butyl group is postulated as the decisive reaction step, might initiate a $Pd^{II}-Pd^{IV}-Pd^{II}$ catalytic cycle[8] involving **9** and **11** as additional reactive intermediates. The formation of 1,2-dihydrocyclobutabenzene **10** by the reductive elimination of Pd^0 from **8** was not detected. Apparently the aryl substituent of **12** exerts the required steric influence to facilitate the formation of the strained 1,2-dihydrocyclobutabenzene derivatives **2**.



Scheme 4. Side products of the cross coupling of **1a** with the aryl halides **1b**, **1c**, **1g**. Ar see Table 1.

Scheme 5. Possible mechanism for the coupling reaction of **1a** to afford **2**. Pd^0 complexes were postulated as the active catalysts.

The bromoolefin **13** is also suitable as a coupling component (Scheme 6). In this case the domino process is terminated by ring closure, resulting in the formation of indene derivatives **14**[9] and **15**.

13 (10 equiv) 14 (9:1) 15

Scheme 6. Cross coupling of **1a** with vinyl bromide (**13**); d) 10 mol% $[Pd(OAc)_2]$, K_2CO_3, nBu_4NBr, DMF, N_2, 3 d, 105–110 °C.

The palladium-catalyzed C–H activation of *tert*-butyl neighboring groups described here for the first time is a new fundamental process for cross coupling reactions, which should allow the simple synthesis of selectively substituted 1,2-dihydrocyclobutabenzene and indene derivatives. The variation of neighboring groups, in particular the inclusion of silyl groups, with a

view to explaining the relationship between the structural parameters and the course of the coupling reaction are the subject of investigations that are currently in progress.

Experimental Procedure

2a: A mixture of **1a** (520 mg, 2 mmol), $[Pd(OAc)_2]$ (11 mg, 0.05 mmol), K_2CO_3 (1.1 g, 8.0 mmol), and nBu_4NBr (645 mg 2.0 mmol) in DMF (10 mL) was stirred for 4 d at 105–110 °C under nitrogen in a closed reaction vessel. After the addition of water (50 mL), the mixture was extracted three times with ether (50 mL), the organic phase filtered through silica gel, and the solvent distilled off. The least polar fraction ($R_f = 0.34$) was isolated by flash chromatography (silica gel, petroleum ether). Kugelrohr distillation at 100 °C/0.1 Torr afforded **2a** as a colorless oil (197 mg, 75%).

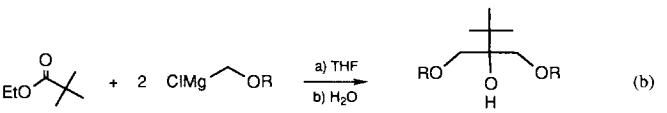
Solvent-Free Volatile Alkoxides of the Alkaline-Earth Elements**

Wolfgang A. Herrmann,* Norbert W. Huber, and Thomas Priermeier

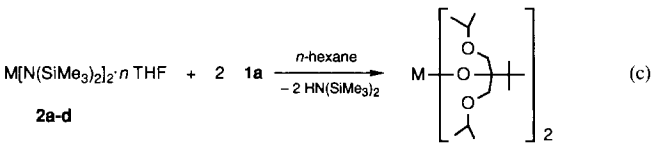
Since the discovery of oxidic high-temperature superconductors interest in volatile calcium, strontium, and barium alkoxides of type $M(OR)_2$ has increased.[1a–c] These compounds are needed for the deposition of thin oxide layers of the respective elements from the gas phase. As cadmium is used as a substitute for yttrium (up to 30 atom%) in YBaCu-type superconductors, cadmium alkoxides also deserve attention.[1d]



How are volatile $M(OR)_2$ compounds obtained? The widely employed concept of steric shielding of reactive molecular centers by means of bulky ligands has not been particularly successful in the chemistry of the metals in question. Even ligands as sterically demanding as $^-OSi(C_6H_5)_3$ form oligo- and polynuclear complexes of low volatility[2] sometimes still containing solvent.

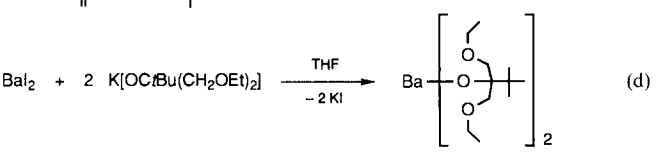
Complexes with the ligand "tritox" ($^-OCtBu_3$) are less stable as a result of steric crowding.[3] Upon sublimation above 185 °C and 10^{-3} mbar, the new complex $[Ca_2(tritox)_4]$ decomposes to give $[Ca_3(ditox)_6]$[4] (ditox = $^-OCHtBu_2$) and isobutene according to Equation (a).

In our approach to the problem, donor functionality and steric bulk are combined within the same ligand.[5] We have prepared a series of donor-functionalized alkoxy ligands and, after adjusting them to charge and ionic radius of the metal in question, used them to synthesize the most volatile alkoxides of the alkaline-earth elements and of cadmium known so far.



The trifunctional alcohols **1a**,**b** are obtained from common precursors in 75% yield after distillation [Eq.(b)]. The metal

1a : R = $CH(CH_3)_2$
1b : R = C_2H_5



amides **2a–c** react with **1a** at room temperature in *n*-hexane according to Equation (c) and form alkoxides **3a–c** almost quantitatively. Alternatively, the barium derivatives, in particular, can be obtained by transmetalation [Eq.(d)], or directly from metallic barium [Eq.(e)].

The colorless metal complexes **3a–c** and **4c** have excellent solubility even in nonpolar solvents like *n*-pentane. Elemental analyses and NMR spectroscopic data show them to be solvent-free, a rarity for this type of compounds.[6] Their most remark-

able property, however, is the high volatility reflected by the sublimation temperatures of 150 °C (**3a**, **4c**), 170 °C (**3b**), and 185 °C (**3c**) at 10^{-2} mbar. The compounds are thermally stable under these conditions and do not leave a significant residue. A thermogravimetric study carried out on **3c** shows that the residue at 600 °C/6 mbar (resulting from traces of moisture in the measuring apparatus) is less than 3 wt%. From chemical ionization (CI) mass spectra and single-crystal X-ray structure analyses we find that the new alkaline-earth metal alkoxides are dimeric both in the gas phase and in the solid state in spite of their high volatility (possibly also a consequence of molecular shape).

As an example, the crystal structure of the calcium complex **3a** (Fig. 1)[7] shows that three alkoxy groups serve as μ-O ligands bridging the two metal centers. Peripheral ether-type oxygen atoms complete the coordination sphere, such that both metal centers achieve the favorable coordination number (CN) 6 through coordinative and ionic bonds. We attribute the extreme pyramidality at the oxygen atoms of the three bridging alkoxy ligands as well as the bending of the terminal Ca2-O41-C405 unit to the steric hindrance within the chelate structure.

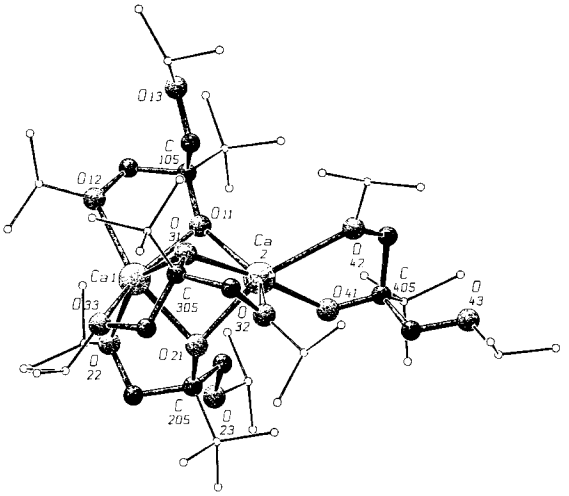

Fig. 1. Molecular structure of the binuclear calcium alkoxide **3a** at −110 °C (SCHAKAL plot). For clarity, the isopropyl and *tert*-butyl groups are only sketched. Selected distances [pm] and angles [°]: Ca2–O41 218.1(4), Ca1–μO 226.9(8), Ca2–μO 236.2(8), Ca1–O_{ether} 246.9(9), Ca2–O_{ether} 259.4(6), Ca1–Ca2 312.3(2); Ca2-O41-C405 132.1(4), Ca1-μO-Ca2 84.8(2), μO-Ca1-μO 81.2(3), μO-Ca2-μO 77.4(2); sum of the angles at O11: 343.3(6), at O21: 343.1(6), at O31: 331.0(6).

The few volatile alkoxides of the alkaline-earth metals reported previously do not have well-defined sublimation temperatures. They are much less volatile, and because of the unfavorable choice of ligands (e.g. containing silicon or fluorine), they cannot serve as molecular precursors for superconductors.[8]

Though the concept presented here does not use commercially available ligands, it can be generalized nonetheless. Thus, **3d**, the first volatile cadmium alkoxide, is synthesized following Equation (c).[9, 10] Crystalline **3d** is also composed of dimeric units, but in the gas phase it is a monomer according to CI mass spectra.

Each cadmium atom is coordinated by five oxygen atoms which form a distorted trigonal bipyramid. The metal atoms are bridged by two alkoxy groups, and the μO-Cd-μO planes are tilted by an angle of 19° with respect to each other, resulting in a coordination number of 3. The coordination sphere (CN 5) is completed by two axial donor functions from ether-type atoms. As in **3c** the alkoxy ligands in **3d** have strongly pyramidalized bridging oxygen atoms and narrow Cd-O_{term}-C angles.

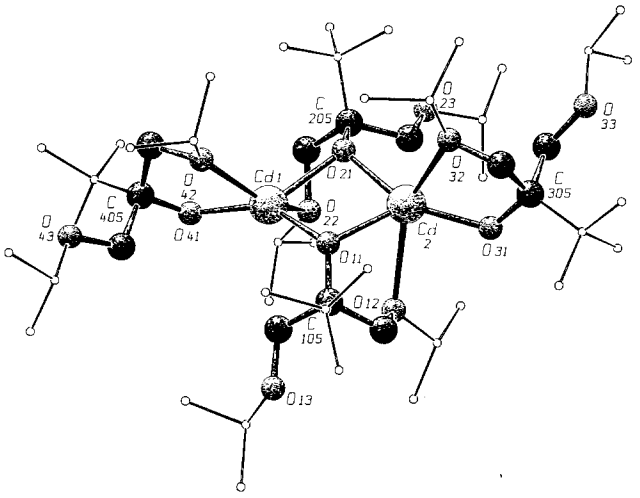

Fig. 2. Molecular structure of the binuclear cadmium alkoxide **3d** at −80 °C (SCHAKAL plot). The disorder of two of the isopropyl groups (see ref. [7]) is not shown. Selected distances [pm] and angles [°]: Cd–O_{term} 206.2(11), Cd–μO 218.2(13), Cd–O_{ether} 251.8(15), Cd1–Cd2 328.6(1); Cd-O_{term}-C 120.9(9), Cd1-μO-Cd2 97.7(4), μO-Cd-μO 80.4(4), sum of the angles around O11: 340.6(7), around O21: 342.9(8).

Our results show that stable metal alkoxides with little tendency toward aggregation and with high volatility can be obtained easily and economically by using tailored ligands. With **1a** as the ligand, we have also prepared the first volatile alkoxides $M(OR)_2$ of divalent manganese, iron, and cobalt (sublimation temperatures: 70–90 °C/10^{-2} mbar), which will be reported on in due course.[10]

Experimental Procedure

1a: To a solution of $ClMgCH_2OCH(CH_3)_2$ (0.26 mol) in THF (150 mL) at −10 °C was added $EtOCOCMe_3$ (8.46 g, 65 mmol) dropwise within 30 min. After stirring for 20 h, the reaction mixture was poured onto ice (50 g), neutralized with aqueous NH_4Cl, and extracted with diethyl ether (3 × 100 mL). The ether phase was washed with aqueous $NaHCO_3$ and H_2O, and subsequently dried with $MgSO_4$. After removal of the ether under vacuum, the residue was distilled at 76 °C/7 mbar. Yield: 11.53 g (76%). – **1b** was prepared analogously, but the reaction was conducted at −20 °C for 3 d (b.p. 52–56 °C/2 mbar, yield: 78%). The batch size can be increased without any loss in yield.

3c: To a solution of **2c** (2.02 g, 3.35 mol) in 35 mL *n*-hexane at −30 °C was added dropwise **1a** (1.56 g, 6.69 mmol). The mixture was stirred for 16 h at 25 °C. After removal of the solvent under vacuum, the colorless product was sublimed at 185 °C/10^{-2} mbar. Yield: > 98%.

4c: A mixture of potassium alkoxide (0.86 g, 3.54 mmol; prepared from KH and **1b** in THF) and BaI_2 (0.69 g, 1.77 mmol) was charged with 50 mL THF (added by vacuum condensation). The pure white suspension was stirred for 16 h at 25 °C. The solvent was removed under vacuum and the product dried under vacuum for 3 h. The isolated product was charged with 50 mL *n*-pentane (added by vacuum condensation), and after stirring for another 15 h the suspension was filtered. The filtrate was concentrated under vacuum, and **4c** was obtained as a yellowish oily product which crystallized upon standing. Yield: 0.55 g (57%).

3d: To a solution of **2d** (1.00 g, 2.30 mol) in 20 mL *n*-hexane at −30 °C was added **1a** (1.07 g, 4.60 mmol) dropwise. The mixture was stirred for 11 h at 25 °C. The solvent was removed under vacuum, and the colorless crystalline product was sublimed at 95 °C/10^{-2} mbar. Yield: > 98%.

[4] Dimeric $[Ca(OCtBu_3)_2]$ is synthesized from **2a** and $HOCtBu_3$ by analogy to Equation (c); colorless crystals, moderately soluble in *n*-pentane, readily soluble in toluene and diethyl ether. Warming under high vacuum (185 °C/10^{-3} mbar) gives a moderate yield of trimeric $[Ca(OCHtBu_2)_2]$ as a colorless sublimate, soluble in toluene and THF. The properties of the sublimate are identical to those of a sample prepared from **2a** and $HOCHtBu_2$. The trimeric structure of $[Ca(OCHtBu_2)_2]$ results from chemical ionization (CI) mass spectrometry.

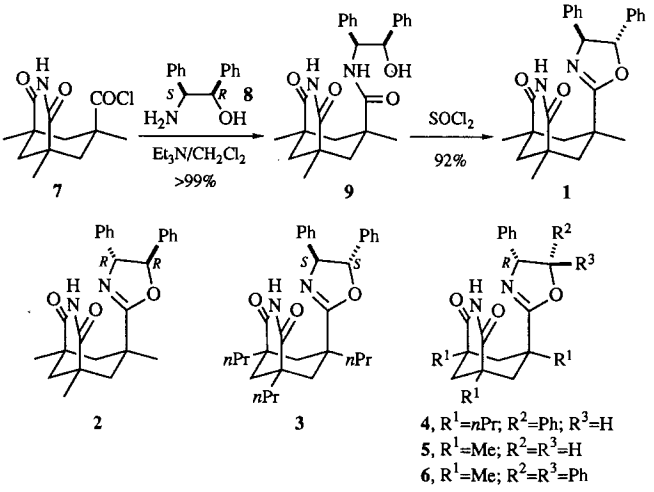
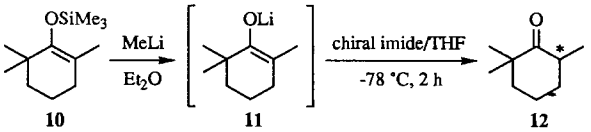
Enantioselective Protonation of Simple Enolates: Chiral Imide as a Chiral Proton Source**



Akira Yanagisawa, Takeshi Kuribayashi, Tetsuo Kikuchi, and Hisashi Yamamoto*

The enantioselective protonation of prochiral enolates is one of the most effective methods of preparing optically active α-substituted carbonyl compounds. Numerous successes have been reported in the last twenty years; however, most of these have used substrates bearing polar substituents such as amino, hydroxyl, or phenyl groups,[1–3] and few succeeded in the asymmetric induction of simple enolates.[4] Here, we report a general solution to this problem in which we use the new chiral proton sources, (*S,S*)-imide **1** and (*R,R*)-imide **2**, which possess an asymmetric 2-oxazoline ring, and describe their application to the enantioselective protonation of metal enolates derived from α-monoalkylated cycloalkanones [Eq. (a)].



(a)

Selective *C*-protonation is expected to occur in the reaction of an enolate with an imide because of the relatively weak acidity of the imide proton.[5] The chiral imide was prepared (see Scheme 1) from a readily available derivative of Kemp's tricarboxylic acid[6] in two steps and in more than 90% overall yield. The synthesis avoided the cumbersome resolution step. The imide acid chloride **7**[7] was condensed with (1*R*,2*S*)-2-amino-1,2-diphenylethanol (**8**) to afford amide **9** (>99% yield), and cyclization to form a 2-oxazoline ring with thionyl chloride completed the synthesis of (*S,S*)-imide **1** ($[\alpha]_D^{26} = -21.9$ ($c = 0.73$ in $CHCl_3$)).[8, 9]

Scheme 1. Top: Synthesis of (*S,S*)-imide **1**. Bottom: Structural formulas of the (*R,R*)-imide **2** and the imides **3**–**6**.

Using the chiral imides derived from a variety of amino alcohols, we examined the asymmetric protonation reaction of lithium enolate [Eq. (b)].[10] Treatment of lithium enolate **11**, gener-

(b)

ated from the silyl enol ether **10** and methyllithium in diethyl ether,[10] with (*S,S*)-imide **1** (1 equiv) in THF at −78 °C for 2 h afforded (*R*)-2,2,6-trimethylcyclohexanone (**12**) with 87% *ee* (Table 1, entry 1). Use of the enantiomer (*R,R*)-imide **2** afforded (*S*)-**12** with a similar enantioselectivity (entry 2). Substitution of the methyl groups of **1** with *n*-propyl groups[11] had no effect

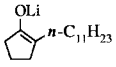
Table 1. Protonation of the lithium enolate **11** with chiral imides **1**–**6** [a].



Entry	Imide	*ee* [%] [b]	Configuration [c]
1	**1**	87	*R*
2	**2**	88	*S*
3	**3**	88	*R*
4	**4**	60	*S*
5	**5**	54	*S*
6	**6**	85	*S*

[a] Yields of isolated **12** were 97–60%. [b] Determined by GC analysis with chiral column (Chrompack). [c] Determined by comparison with published data; (*R*)-isomer (46% *ee*): $[\alpha]_{578}^{RT} = -36.3$ ($c = 1.8$ in $CHCl_3$) [4b]. Observed $[\alpha]_D$ value of (*R*)-isomer (69% *ee*): $[\alpha]_D^{22} = -41.0$ ($c = 3.1$ in $CHCl_3$). RT = room temperature.

(compare entries 1 and 3). The *cis* arrangement of the two phenyl groups of imide **4** decreased the enantioselectivity (compare entries 2 and 4). The configuration of the product **12** was reflected by the absolute configuration of the C4 stereogenic center of the oxazoline ring (entries 2, 4, 5, and 6). Consequently, (*S,S*)-imide **1** and (*R,R*)-imide **2** were found to be the most effective proton sources.

Selected results of the reaction of various lithium enolates with (*S,S*)-imide **1** or (*R,R*)-imide **2** are summarized in Table 2.

Table 2. Enantioselective protonation of lithium enolates with **1** and **2** [a].

Entry	Lithium enolate	Imide	Ketone [b] *ee* [%]	Configuration
1		**1**	68 [c]	*R* [d]
2		**2**	70 [c]	*S* [d]
3		**1**	87 [e]	*R* [f]
4		**2**	88 [e]	*S* [f]
5		**1**	96 [c]	*R* [g]
6		**2**	97 [c]	*S* [g]
7		**1**	78 [c]	–

[a] Unless otherwise noted, lithium enolate was generated from the corresponding silyl enol ether (1 equiv) and MeLi (1.2 equiv) in diethyl ether at room temperature. The protonation was carried out by adding a chiral imide (1.2 equiv) in THF at −78 °C (duration 2 h). [b] Yields of isolated products were 94–45%, depending on the generation of the enolate anion. The only by-product is the starting silyl enol ether. [c] Determined by HPLC analysis of the α-methyl-α-trifluoromethylphenylacetic acid (MTPA) ester of *trans*-2-methylcyclohexanol derived from the corresponding ketone by reduction ($NaBH_4/CH_3OH$) and esterification. [d] Determined by comparison with published data; pure (*S*)-isomer: $[\alpha]_D = +14$ ($c = 0.23$ in MeOH) [12]. Observed value of (*R*)-isomer (36% *ee*): $[\alpha]_D^{24} = -5.9$ ($c = 0.50$ in MeOH). [e] Determined by GC analysis with chiral column (CHROMPACK). [f] See footnote [b] in Table 1. [g] Observed $[\alpha]_D$ value of (*S*)-isomer (93% *ee*): $[\alpha]_D^{25} = +77.3$ ($c = 1.2$ in Et_2O). Reported $[\alpha]_D$ value of (*S*)-isomer (97% *ee*): $[\alpha]_D^{24} = +81.0$ ($c = 1.0$ in Et_2O) [13].

The following features are characteristic: 1) The (*R*)- and (*S*)-enriched ketones could be prepared with equal optical purity with either (*S,S*)-imide **1** or (*R,R*)-imide **2**. 2) The existence of two methyl groups at the C6 position of the enolate of 2-methylcyclohexanone raised the enantioselectivity (entries 1–4). 3) An exceedingly high *ee* was achieved with the enolate of a cyclopentanone that possessed a long alkyl chain (entries 5 and 6).

A proposed model of the transition state of this protonation is shown in Figure 1. The lithium atom of the enolate coordinates to both the nitrogen atom of the 2-oxazoline ring and the oxygen atom of the imide. An eight-membered ring that avoids steric repulsion between a phenyl substituent of oxazoline ring and the alkyl ring of the enolate is formed. Thus, (*S,S*)-imide **1** protonates selectively at the *si* face of the lithium enolate. In addition, steric bulkiness of alkyl substituents at the C6 position seems beneficial for the enantioface discrimination. Further study on asymmetric protonation with this chiral imide and its precise reaction mechanism is currently underway.

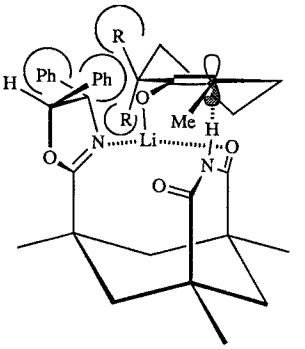


Fig. 1. Proposed model of the transition state of the asymmetric protonation of lithium enolates with (*S,S*)-imide **1**.

Experimental Procedure

Silyl enol ether **10** was derived from 2,2,6-trimethylcyclohexanone (**12**). To a solution of **10** (104 mg, 0.49 mmol) in dry Et_2O (2.5 mL) at 0 °C was added a solution of MeLi (1.5 M, 0.35 mL, 0.53 mmol) in Et_2O under argon atmosphere [10]. After the reaction mixture had been stirred for 2 h at 20 to 25 °C, protonation was carried out at −78 °C by addition of a solution of (*S,S*)-imide **1** (211 mg, 0.51 mmol) in dry THF (2.5 mL). The reaction solution was held at −78 °C for 2 h. Then a saturated NH_4Cl solution (10 mL) was added, and the organic material was extracted twice with Et_2O (2 × 10 mL). The combined extracts were dried over anhydrous Na_2SO_4 and concentrated in vacuo. The crude product was purified by column chromatography on silica gel (hexane/Et_2O, 5:1) to afford (*R*)-(−)-**12** [4b] (59 mg, 86% yield) with 87% *ee*. The imide **1** was recovered without significant loss of optical purity.

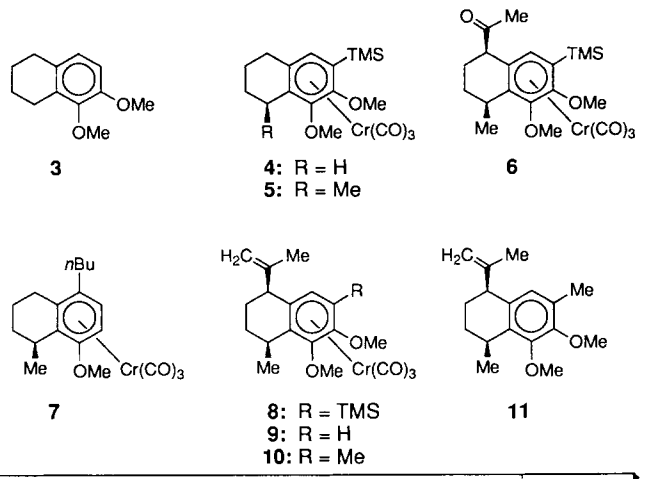
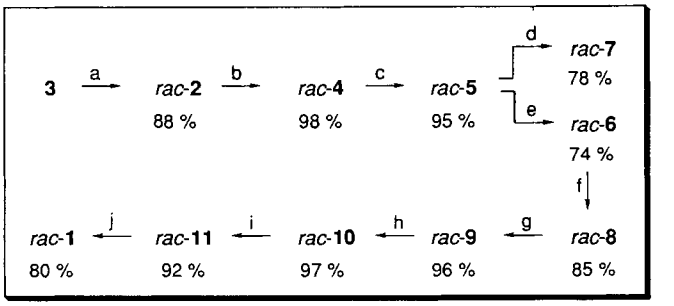
The Total Synthesis of *cis*-7,8-Dihydroxy-11,12-dehydrocalamenene by Regio- and Diastereoselective Alkylation of Chiral η^6-Arenetricarbonylchromium Complexes: An Unexpected Case of Nucleophilic Aromatic *tele*-Substitution with Methoxide as a Leaving Group**

Hans-Günther Schmalz,* Markus Arnold, Jens Hollander, and Jan W. Bats

In the course of our work on chiral transition metal π complexes as synthetic building blocks[1] we have found an efficient total synthetic route to the potential antiinfective sesquiterpene *cis*-7,8-dihydroxy-11,12-dehydrocalamenene (**1**).[2] Our synthetic strategy (Scheme 1) is founded on the chemistry of η^6-benzene–$Cr(CO)_3$ derivatives.[3] Starting with the chiral complex **2**, all three side chains are introduced by successive deprotonation–alkylation steps during which both the increased acidity of the complexed ligand (especially in the benzylic positions)[4] and the steric shielding effect of the $Cr(CO)_3$ fragment are exploited.



1 **2**

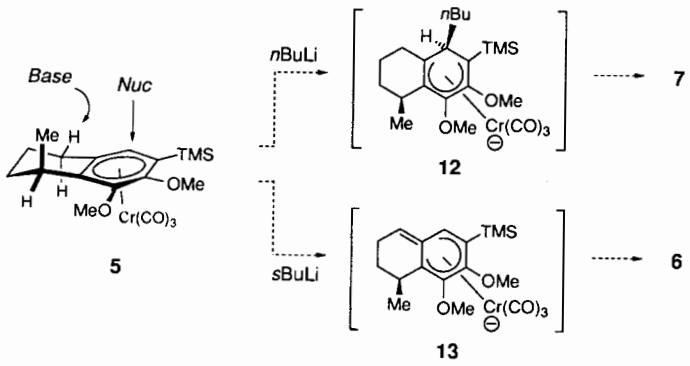


Scheme 1.

The synthetic route was first worked out and optimized employing racemic compounds (Scheme 2).[5] The complex *rac*-**2** was obtained by direct complexation of 5,6-dimethoxytetralin (**3**)[6] with $[Cr(CO)_6]$ under standard conditions.[7] After protection of the (relatively) acidic aryl position adjacent to the methoxy substituent by silylation (*rac*-**2** → *rac*-**4**), benzylic methylation of *rac*-**4** led with complete regio- and diastereoselectivity to *rac*-**5**, whose constitution and relative configuration were established by a crystal structure analysis (Fig. 1).[8] The conversion of *rac*-**5** into the acylated compound *rac*-**6** was also achieved in good yield though only when *sec*-butyllithium (*s*BuLi) was employed as base and hexamethylphosphoric acid triamide (HMPT) was not used as cosolvent. In contrast, treatment of *rac*-**5** with *n*BuLi in THF/HMPT unexpectedly gave high yields of *rac*-**7**,[9] which can be considered as the product of a nucleophilic aromatic *tele* substitution[*] with methoxide as the leaving group (see below). For the further transformation of *rac*-**6** in the direction of the target compound it was next methylenated by the method of Lombardo.[10] After fluoride-induced desilylation, the still-missing methyl group was introduced by *ortho* deprotonation/alkylation. Oxidative decomplexation with iodine in ether yielded *rac*-**11**, which was finally deprotected by treatment with thioethanolate[11] to provide *rac*-**1**[12] (overall yield from *rac*-**2**: ca. 40% over 8 steps!).

The selective formation of *rac*-**6** or *rac*-**7**, which can be controlled by the choice of reaction conditions, deserves a comment: With *n*BuLi *rac*-**5** probably undergoes nucleophilic addition to give the anionic intermediate *rac*-**12**, whereas with the stronger base *s*BuLi (and in the absence of HMPT as the cosolvent which promotes nucleophilic addition[13b]) the intermediate deprotonated at the benzylic position, *rac*-**13**, is formed (Scheme 3).[14]

3 **4**: R = H, **5**: R = Me **6** **7** **8**: R = TMS, **9**: R = H, **10**: R = Me **11**



Scheme 2. Synthesis of *rac*-**1**. a) 1.1 equiv. $[Cr(CO)_6]$, nBu_2O/THF (10:1), reflux, 45 h; b) *n*BuLi, THF, −60 °C → −40 °C, 30 min, then Me_3SiCl, 0 °C, 1 h; c) *n*BuLi, THF/HMPT, −60 °C, 10 min, 0 °C, 2 h, then MeI, −40 °C, 10 min, 0 °C, 1 h; d) *n*BuLi, THF/HMPT, −40 °C → 0 °C, 2 h, then CH_3COCl, −70 °C → 0 °C, 0.5 h; e) *s*BuLi, THF, −65 °C, 10 min, −10 °C, 2.5 h, then CH_3COCl, −25 °C, 10 min, 25 °C, 0.5 h; f) CH_2Br_2/Zn/$TiCl_4$, THF, 0 °C → 25 °C, 25 °C, 2.5 h; g) nBu_4NF, THF, room temperature, 3 h; h) *n*BuLi, THF, −50 °C → −30 °C, 1.5 h, then MeI, −30 °C → −10 °C, 20 min; i) I_2, Et_2O, 25 °C, 1 h; j) NaSEt, DMF, reflux, 20 h. For selected physical and spectroscopic data see Table 1.

The conversion of *rac*-**4** into *rac*-**5** is a rare example of a nucleophilic aromatic *tele* substitution[*] in which the entering group takes a position more than one atom distant from the position to which the leaving group was attached.

Scheme 3. Mechanistic consideration: benzylic deprotonation versus nucleophilic addition.

The surprising ease with which *rac*-**5** is nucleophilically attacked under conditions that lead to smooth benzylic deprotonation in the case of *rac*-**4** can be explained: The crystal structure of *rac*-**5** shows the saturated six-membered ring in a half-chair conformation with the benzylic methyl substituent in a pseudo-axial position (Fig. 1 top).[8] The only benzylic H atom available for deprotonation (*exo* to the $Cr(CO)_3$ group) is thus in a pseudo-equatorial position. Its abstraction should therefore be relatively disfavored for stereoelectronic reasons.[14] The crystal structure shows further that the $Cr(CO)_3$ tripod prefers an eclipsed conformation (relative to three C atoms of the arene ring; Fig. 1, bottom) such that one of the CO ligands is located exactly "under" the ring atom attacked by *n*BuLi. That this attack should be comparatively favorable is inferred from investigations that have shown that (charge-controlled) nucleophilic additions to arene–$Cr(CO)_3$ complexes occur especially readily at those ring atoms whose charge density is lowered by eclipsing CO ligands.[13, 15] In this way the originally unexpected reactivity of *rac*-**5** towards *n*BuLi can be attributed to the structurally well-established interplay of two stereoelectronic effects (disfavored benzylic deprotonation and facilitated nucleophilic addition).[16]

racemic series.[20] Thus, the absolute stereochemical information brought into the synthetic scheme by the chiral metal complex could be transferred without any loss to the two newly generated chiral centers.

The synthesis presented here is attractive because it has only a few steps and a remarkably high efficiency (total yield, selectivity), and it opens up an easy route to multi-gram quantitites of optically active 7,8-dihydroxy-11,12-dehydrocalemenene derivatives with a given absolute configuration. The underlying concept[21] has proved to be very effective and will now be used in the enantioselective synthesis of other compounds.[1b]

[16] The transformation of the initial nucleophile adduct *rac*-**12** into *rac*-**7** could take place in analogy to the mechanism suggested by Rose-Munch et al.[17] (for nucleophilic *tele* substitution on halobenzene–$Cr(CO)_3$ derivatives). Nevertheless, the selective formation of *rac*-**7** is remarkable for several reasons. Not only is the smooth attack of the nucleophile adjacent to the bulky TMS group unique, but also the complete regioselectivity of the methoxide expulsion and the ease with which the methoxide acts as a leaving group. Further investigations are in progress to clarify these phenomena and to determine the synthetic potential of nucleophilic addition to *rac*-**5** and analogous compounds.

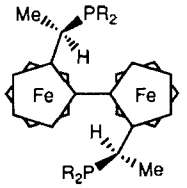
Singh, *ibid.* **1987**, *109*, 7925–7926; b) We have found that the enantioselectivity of the Corey–Bakshi–Shibata (CBS) reduction of **14** as described in ref. [1] can even be increased (from 94 to 97% *ee*) if the $BH_3 \cdot Me_2S$ reagent is added slowly by means of a syringe pump.

[20] The *ee* values given were determined by ^{1}H NMR spectroscopy (with $Eu(hfc)_3$ in $CDCl_3$); **15** was employed as the acetate. The conversion of **15** into **6** (Scheme 4) was performed without recrystallization steps so that a possible (partial) racemization would have been recognized.

[21] A completely different strategic concept for the synthesis of (exclusively racemic) monohydroxycalamenenes also using arene–$Cr(CO)_3$ complexes for relative stereocontrol at the benzylic positions was followed by Uemura: a) M. Uemura, K. Isobe, K. Take, Y. Hayashi, *J. Org. Chem.* **1983**, *48*, 3855–3858; b) M. Uemura, K. Isobe, Y. Hayashi, *Chem. Lett.* **1985**, 91–94.

trans-Chelating Chiral Diphosphane Ligands Bearing Flexible *P*-Alkyl Substituents (AlkylTRAPs) and their Application to the Rhodium-Catalyzed Asymmetric Hydrosilylation of Simple Ketones

Masaya Sawamura, Ryoichi Kuwano, and Yoshihiko Ito*



The design and synthesis of new chiral ligands for transition metals are essential for the development of catalytic asymmetric synthesis.[1, 2] We recently showed that the *trans*-chelating chiral diphosphane ligand PhTRAP (Fig. 1a)[3] is an excellent ligand for the rhodium-catalyzed asymmetric Michael addition of 2-cyanopropionates.[4] The concave chiral surroundings provided by the four Ph groups on the *trans*-positioned phosphorus atoms in the ligand are crucial for high enantioselectivity. Most chiral phosphane ligands to date were designed to bear bulky and conformationally rigid substituents such as Ph or cyclohexyl groups on the phosphorus atoms in order to force the resulting chiral environment to extend to the reaction site.[5] However, molecular modeling studies of TRAP–metal complexes suggested that the bulkiness and rigidity of the substituents on phosphorus atom are not always required for asymmetric reactions and may contribute negatively when the substituents are too large for the effective interaction of reactants and catalyst. This prompted us to synthesize new TRAPs bearing less bulky and more flexible alkyl substituents.

The new *trans*-chelating chiral peralkyldiphosphanes[6] (*R*,*R*)-(*S*,*S*)-*n*BuTRAP, -*n*PrTRAP, and -*i*PrTRAP (Fig. 1a), which bear different alkyl groups instead of the Ph groups of PhTRAP, were synthesized in four steps and in 25–34% overall yield from the readily available (*R*)-*N*,*N*-dimethyl-1-ferrocenylethylamine by essentially same procedure as that used for PhTRAP.[3] The X-ray crystal structure of *trans*-[RhCl(CO)-{(*R*,*R*)-(*S*,*S*)-*n*BuTRAP}] (Fig. 1b)[7] reveals that Rh has a nearly planar coordination geometry with a P-Rh-P bite angle of 164.4°. The conformation of the ligand is essentially C_2-symmetric, and the four *n*Bu groups are arranged in a C_{2v}-symmet-

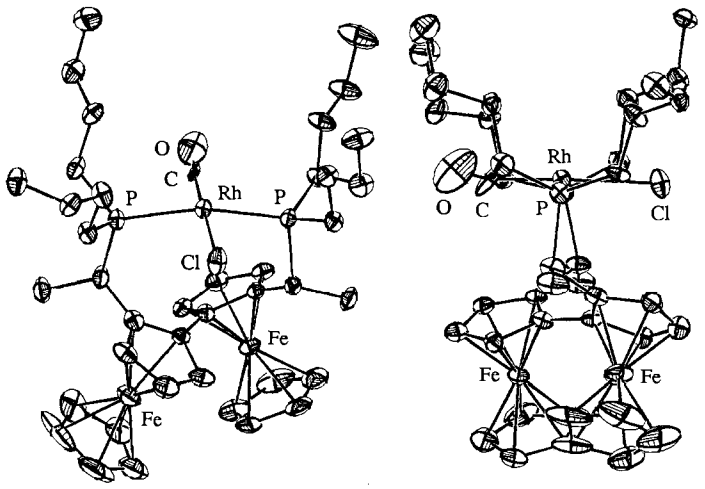

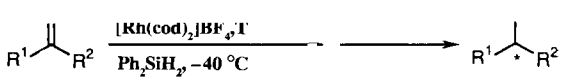

Fig. 1. a) The new (*R*,*R*)-(*S*,*S*)-TRAPs. b) ORTEP plots (two views) of the X-ray crystal structure of *trans*-[RhCl(CO){(*R*,*R*)-(*S*,*S*)-*n*BuTRAP}] (ellipsoids at the 30% probability level). The structure with 0.55 occupancy is shown. In the structure with 0.45 occupancy the Cl and CO ligands are interchanged.

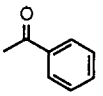

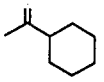

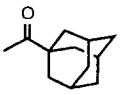

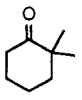

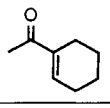

ric fashion with the exception of one of the four terminal carbon atoms (Fig. 1b). The torsion angle between the two linked Cp rings is 123°. The chloro and carbonyl groups on rhodium, which may be replaced by a prochiral substrate in a catalytic asymmetric reaction, are completely buried in the chiral cavity created by the biferrocenyl backbone and the *n*Bu groups, suggesting that the alkylTRAPs may display a high degree of chiral recognition.

Indeed, *n*PrTRAP and *n*BuTRAP were found to be excellent chiral ligands for the rhodium-catalyzed asymmetric hydrosilylation of simple ketones.[8, 9] Thus, to a solution of the catalyst precursor prepared in situ by mixing $[Rh(cod)_2]BF_4$ (0.01 mmol) (cod = cyclooctadiene) and (*R*,*R*)-(*S*,*S*)-TRAP (0.011 mmol) in THF or dimethoxyethane (DME) (1 mL) at room temperature, was added ketone (1.0 mmol) and diphenylsilane (1.5 mmol) at −40 °C. The mixture was stirred at this temperature until the reaction was complete, and the resulting silyl ether was then solvolyzed [Eq. (a)]. The *trans*-chelating ligands bearing prima-

ry alkyl groups on phosphorus atoms, *n*BuTRAP and *n*PrTRAP, were equally effective in the hydrosilylation of acetophenone (Table 1, runs 1, 2) in terms of both enantioselectivity (92% *ee*, *S*) and catalytic activity. This indicates that the terminal Me groups of *n*BuTRAP are not important for stereoselectivity. On the other hand, the reduction of acetophenone in the presence of *i*PrTRAP and PhTRAP, which carry bulkier substituents on the phosphorus atoms, was much less

Table 1. Asymmetric hydrosilylation of ketones catalyzed by TRAP–Rh complexes [a].

Run	Ketone	Ligand [b]	Time [h]	Yield [%] [c]	*ee* [%]	config. [d]
1		*n*BuTRAP	11	88 [f]	92 [j]	*S*
2		*n*PrTRAP	5	89 [f]	92 [j]	*S*
3		*i*PrTRAP	48	78 [f]	1 [j]	*S*
4		PhTRAP	9	85 [f]	15 [j]	*S*

6		*n*BuTRAP	48	92 [g]	91 [k]	*S*
7						
8			12	71 [g, i]	95 [j]	*S*

[a] Reactions were carried out in THF unless otherwise noted. The mol ratio $[Rh(cod)_2]BF_4$/TRAP/ketone/Ph_2SiH_2 was 1/1.1/100/150. [b] (*R*,*R*)-(*S*,*S*)-TRAP was used. [c] No starting material was recovered after workup; hydrosilylation was almost quantitative. [d] Determined by optical rotation. [e] DME was used as solvent. [f] Isolated yield by preparative thin-layer chromatography. [g] Isolated yield by medium-pressure liquid chromatography. [h] Isolated yield by bulb-to-bulb distillation. [i] Obtained with traces of 1-cyclohexylethanol, which seems to be produced during the methanolysis of the silyl ether. [j] Determined by GLC analysis of the alcohol with Chiraldex G-TA. [k] Determined by HPLC analysis of *N*-(3,5-dinitrophenyl)carbamate with Sumichiral OA-4500. [l] Determined by GLC analysis of trifluoroacetate with Chiraldex G-TA.

enantioselective (1% *ee*, *R*, and 15% *ee*, *S*, respectively; runs 3, 4). These results suggest that the chiral environment created by the *trans*-spanning biferrocenyl backbone of the ligands is the critical element for stereocontrol. *n*BuTRAP was also effective in the reduction of hindered saturated ketones (runs 5–7). Reaction of 1-acetylcyclohexene gave allylic alcohols with 95% *ee* accompanied by traces (<1% by gas-liquid chromatography (GLC)) of the 1,4-reduction product (run 8). To the best of our knowledge, *n*BuTRAP and *n*PrTRAP are the first chiral phosphane ligands effective for the rhodium-catalyzed asymmetric hydrosilylation of simple ketones lacking secondary coordinating functional groups.[8]

Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[8] The enantioselectivities in the asymmetric hydrosilylation of simple ketones lacking secondary coordinating functional groups catalyzed by chiral rhodium–phosphane complexes still remain at most about 60%, but high enantioselectivities over 80% are obtained with α- and γ-keto esters, see: a) I. Ojima, T. Kogura, M. Kumagai, *J. Org. Chem.* **1977**, *42*, 1671–1679; b) I. Ojima, T. Kogure, *Tetrahedron Lett.* **1974**, 1889–1892; c) I. Ojima, T. Kogure, M. Kumagai, S. Horiuchi, T. Sato, *J. Synthesis and Structure of the Disilagermirane $R_2Ge(SiR_2)_2$ and the Solvent-Separated Ion Pair $[Li([12]crown-4)_2][GeR_3]$; (R = $SiMe_3$)**

Andreas Heine and Dietmar Stalke*

Up until the beginning of the 1980s three-membered ring systems of the heavier elements of group 14 were considered unobtainable, and in fact even today not many of these compounds are known. However, the use of very bulky ligands stabilizes these tricyclic systems kinetically and protects the reactive center with an organic layer. This prevents further reaction and dimerization. In 1981 Masamune et al.[1] isolated the unprecedented hexakis(2,6-dimethylphenyl)cyclotrisilane by reduction of dichlorobis(2,6-dimethylphenyl)silane with lithium naphthalenide. In a related reaction Weidenbruch et al.[2] obtained the even more sterically crowded hexa-*tert*-butylcyclotrisilane. Hexakis(2,6-dimethylphenyl)-[3] and hexa-*tert*-butylcyclotrigermane[4] have also been obtained by reductive cyclization of diorganodihalogengermanes with lithium naphthalenide. To date six cyclotrisilanes[1, 2, 5–7] and four cyclotrigermanes[3, 4] have been structurally characterized.[8] Recently Baines et al.[9] published the structure of the siladigermirane $Mes_2Si(GeMes_2)_2$, which was also synthesized by reductive cyclization.[10] Three-membered ring systems containing silicon have also been thoroughly investigated by MO calculations.[11–13]

We report here on the synthesis and structure of **1**, the first disilagermirane. Compound **1** was synthesized from germanium dichloride and tris(trimethylsilyl)silyllithium at −78 °C [Eq. (a)].[14, 15]

(a)

The reaction mechanism for the formation of **1** has not been confirmed unequivocally. It seems possible, however, that initially a germylene is formed intermediately by simultaneous LiCl elimination and migration of two Me_3Si groups. The $(Me_2Si)_2Ge$: then reacts with the intermediately formed disilene $(Me_3Si)_2Si{=}Si(SiMe_3)_2$ to give **1**. This seems feasible, since stable dialkylgermylenes have been synthesized and characterized previously.[16–18] This reaction provides a novel and easy access to mixed tricyclic ring systems containing heavier elements of group 14. We are currently trying to synthesize other derivatives from the reaction of $EHal_2$ (E = Ge, Sn, Pb; Hal = Cl, Br) with $(Me_3Si)_3ELi$ (E = Si, Ge, Sn).

Compound **1** has D_{3h} symmetry[19] (Fig. 1). The three ring atoms lie on a crystallographic mirror plane. A threefold axis is perpendicular to the mirror plane intersecting the center of the $GeSi_2$ triangle. This causes a disorder of the single germanium atom over all three ring positions; however the disorder could be solved and refined reasonable well. The site occupation factor of the Ge atom converged at 1/3. As expected the two exocyclic Ge–Si distances (235.6 pm) are shorter than the endocyclic Ge–Si distances (239.1 pm). This is also valid for the Si–Si distances (236.6 pm exocyclic, 237.7 pm endocyclic). The Si–Si and Si–Ge distances in the three-membered ring are consistent with the results of recently published ab initio calcula-

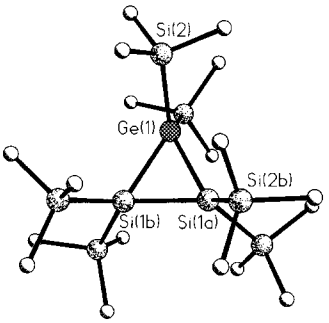

Fig. 1. Structure of **1** in the solid state. Selected bond lengths [pm] and angles [°]: Ge(1)-Si(2) 235.6(4), Ge(1)-Si(1a) 239.1(1), Si(1a)-Si(2b) 236.6(5), Si(1a)-Si(1b) 237.7(14); mean exocyclic Si-Si-Si angle 105.2(3), mean exocyclic Si-Ge-Si angle 105.8(3)°.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank one of the referees for valuable comments.

tions.[12] In comparison, the endocyclic Si–Si distances in hexakis(2,6-dimethylphenyl)cyclotrisilane are 238 pm and 242 pm,[1] whereas in the sterically even more crowded hexa-*tert*-butylcyclotrisilane they are 251 pm.[2] The Ge–Ge bond lengths in $[(2,6\text{dimethylphenyl})_2\text{Ge}]_3$[3] and $(t\text{BuGe})_3$[4] are 254 pm and 256 pm, respectively.

In order to obtain, for example, hexakis(trimethylsilyl)-digermastannirane in analogy to the reaction described above, we synthesized tris(trimethylsilyl)germyllithium-([12]crown-4)$_2$ (**2**). The preparation of **2** [Eq. (b)][20] was carried out analogously to that of the silicon compound,[14, 15] the only difference being the presence of [12]crown-4.

$$(Me_3Si)_4Ge + MeLi \xrightarrow[2\text{ d stirring}]{[12]\text{crown-4}} \underset{\mathbf{2}}{[Li([12]\text{crown-4})_2][Ge(SiMe_3)_3]} + Me_4Si \qquad (b)$$

Compound **2** crystallizes as expected as a solvent-separated ion pair.[19] In Figure 2 only the structure of the $[Ge(SiMe_3)_3]$ anion is depicted. The mean Ge–Si bond length (236.7 pm) is in good agreement with the exocyclic Ge–Si bond in **1** (235.6 pm). The Ge–Si distance in $[Cp^*Cl_2HfGe(SiMe_3)_3]$ ($Cp^* = C_5Me_5$),[21] the only other known structurally characterized compound with this moiety, is 240.9 pm.

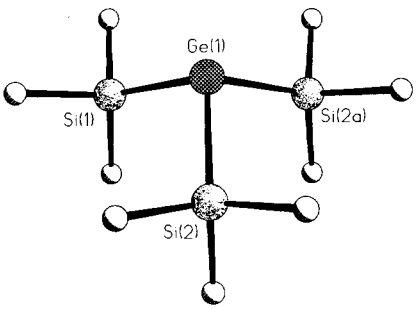

Fig. 2. Structure of the anion in **2**. Selected bond lengths [pm] and angles [°]: Ge(1)-Si(1) 236.6(1), Ge(1)-Si(2) 236.9(1); Si(1)-Ge(1)-Si(2) 102.66(3), Si(2)-Ge(1)-Si(2a) 100.53(4).

The most remarkable structural feature in the anion of **2** is the Si-Ge-Si angle (average of 101.6°; Ge1, Si1, and C2 lie on a crystallographic mirror plane, so that there are only two independent angles). This angle is more acute than the Si-Si-Si angle in the tris(trimethylsilyl)silyllithium derivatives $R_3SiLi(thf)_3$ (102.1°)[15] and $R_3SiLi\text{-}(dme)_{1.5}$ (104°),[22] (R = $SiMe_3$, dme = dimethoxyethane), which both crystallize as contact ion pairs. The reason for this is the increasing energetic separation of *ns* and *np* orbitals for the heavier elements of the group. This decreases the participation of electrons in s orbitals in σ bonds. Therefore, in the $[Ge(SiMe_3)_3]$ anion the three orthogonal p orbitals are chiefly used for bonding to the three Me_3Si substituents, whereas the lone pair possesses mainly s character. Recent investigations on $Ph_3SnLi(pmdeta)$[23] and $Ph_3PbLi(pmdeta)$,[24] (pmdeta = $(Me_2NCH_2CH_2)_2NMe$) show that with increasing atomic number this effect becomes more pronounced (C-E-C- angle in $Ph_3E\text{-}Li$; E = Sn: 96.1° and for E = Pb: 94.3°). The reduction in the Si-Ge-Si angle in the $[Ge(SiMe_3)_3]$ anion is even more remarkable, because the steric demand of a $(thf)_3Li$ group such as in $(Me_3Si)_3SiLi(thf)_3$ on the Si-Si-Si angle[25] as well as a (pmdeta)Li group such as in $Ph_3SnLi(pmdeta)$ and $Ph_3PbLi(pmdeta)$ on the C-Sn-C and C-Pb-C angles, respectively, are not applicable for the $[Ge(SiMe_3)_3]$ anion. The Si-Ge-Si angle in $(Me_3Si)_3GeLi(thf)_3$ should be even smaller for these reasons. In $Ge(pz)_3Na(thf)_3$ (pz = pyrazol-1-yl) the germanium atom is likewise not coordinated by the alkali metal, because the sodium atom is coordinated by the three pyrazolyl ligands, which decreases the N-Ge-N angle to 96.2°.[26]

Experimental Procedure

1: A solution of $GeCl_2$ (0,3 g, 2.1 mmol) in *n*-hexane (25 mL) was cooled to −78 °C and treated with $(Me_3Si)_3SiLi(thf)_3$ (2,0 g, 4.2 mmol). The solution was warmed to 0 °C and stirred for 12 h. The solvent was removed under reduced pressure (10^{-2} bar) and the solid residue taken up in *n*-pentane (25 mL). The insoluble components were filtered off and the solution was cooled to −90 °C. After 2 d colorless crystalline plates were obtained that were suitable for X-ray diffraction. Yield: 0.57 g (48%), decomposition at $T \geq 140$ °C. ^{1}H NMR (C_6D_6, 25 °C): $\delta = 0.43$ (s, 36H; $Si(SiMe_3)_2$), 0.45 (s, 18H; $Ge(SiMe_3)_2$); ^{29}Si NMR (C_6D_6, 25 °C): $\delta = -6.65$ ($Si(SiMe_3)_2$), −22.1 ($Ge(SiMe_3)_2$), −159.98 ($Si(SiMe_3)_2$; IR: $\tilde{\nu}$[cm^{-1}] = 1260 m, 1243 m, 1093 m, 1021 m, 838 vs; FI-MS: *m/z* (%): 568 (100) [M^+].

2: To a solution of (1.35 g, 3.7 mmol) $(Me_3Si)_4Ge$ in *n*-hexane (25 mL) was added [12]crown-4 (1.3 mL) and slowly methyllithium (2.5 mL, 4 mmol) in Et_2O. The white suspension was stirred for 24 h at room temperature and then THF (5 mL) was added to dissolve the white precipitate. The solution was stirred for an additional 24 h and subsequently stored at −35 °C. After approximately 7 d colorless needles were obtained that were suitable for X-ray diffraction. ^{1}H NMR ([D$_8$]toluene, 25 °C): $\delta = 0.27$ (s, $Ge(SiMe_3)_3$), 3.59 (s,$[O(CH_2)_2]_4$); ^{7}Li NMR ([D$_8$]toluene, 25 °C): $\delta = 0.27$ (s).

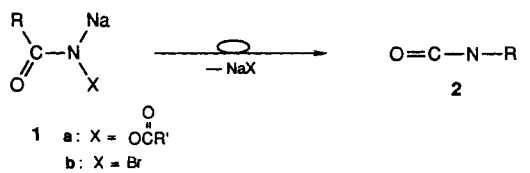
[19] Crystal Data of **1**: $C_{18}H_{54}Si_8Ge$, $M = 567.9$, rhombohedral, space group $R\bar{3}c$, $a = b = 1051.4(1)$, $c = 5435.4(11)$ pm, $V = 5.203$ nm^3, $Z = 6$, $\varrho_{calcd} = 1.087$ Mg m^{-3}, $F(000) = 1836$, $\lambda = 71.073$ pm, $T = -120$ °C, $\mu(Mo_{K\alpha}) = 1.165$ mm^{-1}, crystal size: $0.5 \times 0.5 \times 0.3$ mm, $8° \leq 2\theta \leq 55°$; of the 3513 collected reflections 1339 were independent and used for refinement; largest difference peak and hole: 550 e nm^{-3}, $R1(F > 4\sigma(F)) = 0.028$ and $wR2 = 0.066$ (all data) with $R1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR2 = (\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2)^{0.5}$; **2**: $C_{25}H_{59}LiO_8Si_3Ge$, $M = 651.5$, monoclinic, space group $P2_1/m$, $a = 939.4(1)$, $b = 1433.5(2)$, $c = 1395.7(3)$ pm, $\beta = 104.56(1)°$, $V = 1.819$ nm^3, $Z = 2$, $\varrho_{calcd} = 1.189$ Mg m^{-3}, $F(000) = 700$, $\lambda = 71.073$ pm, $T = -80$ °C, $\mu(Mo_{K\alpha}) = 0.978$ mm^{-1}, crystal size: $0.5 \times 0.4 \times 0.4$, $8° \leq 2\theta \leq 55°$; of the 7864 reflections collected 4370 were independent and used for refinement, largest differ-



ence peak and hole: 310 e nm^{-3}, $R1$ ($F > 4\sigma(F)$) = 0.040 and $wR2$ = 0.095 (all data); R values as defined above. Data of both structures were collected on a Stoe-Siemens-AED diffractometer. The intensities of the rapidly cooled crystals in an oil drop [27] were collected by the $2\theta/\omega$ method. Both structures were solved by direct methods (SHELXS-90) [28] and refined by full-matrix least-squares on F^2 [29]. The silicon/germanium disorder in **1**, which is caused by symmetry could be resolved. The refinement of occupancy for the central silicon atoms and the germanium atom resulted in values of 2/3 and 1/3, respectively. The refinement in the space group $C2/c$ was not successful. Due to the disorder of the crown ether molecule caused by the mirror plane, two crown ether molecules with an occupancy of 1/2 each were refined. 1–2 and 1–3 distances of chemically equivalent bonds were refined by using distance restraints. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), by quoting the full journal citation.

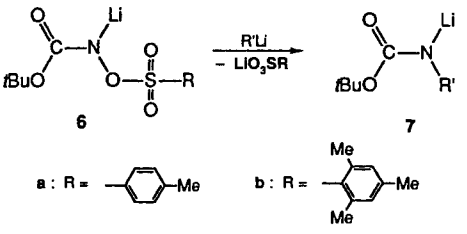
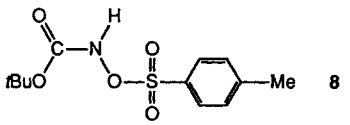
[(*N*-Lithio-*N*-mesitylsulfonyloxy-*tert*-butylcarbamate)$_2$·(thf)$_3$]: Crystal Structure of a Nitrenoid**

Gernot Boche,* Christiane Boie, Ferdinand Bosold, Klaus Harms, and Michael Marsch



Nitrenoids **1** and their reactions have been known for a very long time. In 1872 Lossen described compounds of type **1a**,[1, 2a, b] which like compounds **1b**[2a, b, 3] prepared by Hofmann in 1881, are converted into isocyanates **2** by the shift of the R group to the N atom and α elimination of NaX.



The observation made by Schverdina and Kotscheschkov in 1938 was particularly remarkable and long not understood: in the amination of organolithium compounds R'Li the *electrophilic* species is not *O*-methylhydroxylamine (**3a**) but rather the N-lithiated species **3b**. Primary amines **5** are then obtained via **4**.[4] The dimerization of a nitrenoid,[5] which proceeds analogously, and its α elimination to provide a nitrene[6] were also described. What are the structural requirements for these nitrenoid reactions?

One of the insights obtained from quantum chemical calculations of **3b** and its reaction with R'Li[7] was that the N–O bond in **3b** is bridged by Li and *longer* than the related bond in its nonlithiated counterpart **3a**. This would explain the relatively facile cleavage of the N–OCH$_3$ bond in **3b**[8] and the N–X bonds in other nitrenoids such as **1a,b**. In 1991 Genet, Mallart, Greck, and Piveteau showed that nitrenoids of type **6** are also suited for the electrophilic amination of R'Li to give **7**.[9] The corresponding Boc-protected primary amine is obtained from protonation of **7**.

We report here on the crystal structure of *N*-lithium *N*-mesitylsulfonyloxy-*tert*-butylcarbamate (**6b**), which crystallizes as a dimer with three equivalents of THF, and we compare this structure to that of the dimer of the nonlithiated *N*-toluenesulfonyloxy-*tert*-butylcarbamate (**8**). Compound **6b** is the first nitrenoid characterized by X-ray structure analysis.[10]

The two anions in [(**6b**)$_2$(thf)$_3$] (Fig. 1) are linked by two Li cations, such that Li1 (Li1A) is bound to N1A (N1) and O4 (O4A). The strong donor O4A prevents the bridging of, for example, the N1–O3 bond by Li1A. The two Li centers are tetracoordinate; each interacts with two terminal (O6, O6A) and one shared THF molecule (O7), an unusual type of THF coordination. It is amazing that the oxygen atoms O1 (O1A) and O2 (O2A) of the sulfonyloxy unit are not bound to lithium, considering their excellent donor properties.[11, 8] The shortening of the N1–C10 bond in [(**6b**)$_2$(thf)$_3$] to 133.1(4) pm relative to the analogous bond in (**8**)$_2$ (N1–C8, 140.6(7) pm, Fig. 2) and the lengthening of the C10–O4 bond in [(**6b**)$_2$(thf)$_3$] (123.9(4) vs. 120.6(7) pm for C8–O4 in (**8**)$_2$) are as expected. In [(**6b**)$_2$(thf)$_3$] C10 has planar coordination, in (**8**)$_2$ C8 (sum of angles 360.0 and 359.8°, respectively). O3 in [(**6b**)$_2$(thf)$_3$] is almost in the plane formed by N1, C10, O4, and O5 (torsion

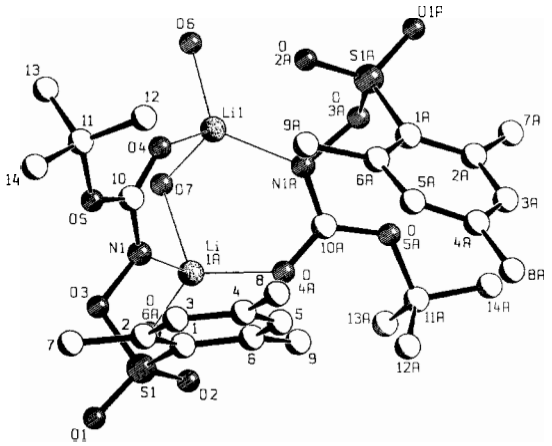

Fig. 1. Crystal structure of $[(\mathbf{6b})_2(thf)_3]$[11]; for clarity only the O atoms O6, O7, and O6A of the three THF molecules are shown; the C atoms are numbered. Important bond lengths [pm] and angles [°]: N1-O3 148.5(3), C10-N1 133.1(4), C10-O4 123.9(4), C10-O5 134.7(3), N1-Li1A 201.5(6), Li1-O4 189.5(5), Li1-O6 195.9(6), Li1-O7 215.9(6); N1-C10-O4 119.3(2), O4-C10-O5 123.0(5), O5-C10-N1 117.7(3); O3-N1-C10-O5 3.9(3), O3-N1-C10-O4 −176.1(2); Li1A-N1-C10-O4 −2.0(5).

angle O3-N1-C10-O5 3.9(3)°), whereas O3 in $(\mathbf{8})_2$ projects 46(2) pm out of the plane defined by N1, C8, O4, and O5. Dimer $(\mathbf{8})_2$ is held together by two hydrogen bonds (N1–H1 88(5) pm, H1–O4A 199.8(5) pm, N1–O4A 287.3(5) pm[19]). The following changes in bond lengths are important for the reactivity of **6b**: 1) C10–O5 in $[(\mathbf{6b})_2(thf)_3]$ is 5 pm longer than C8–O5 in $(\mathbf{8})_2$. Thus **6b** should eliminate LiO*t*Bu relatively easily to give

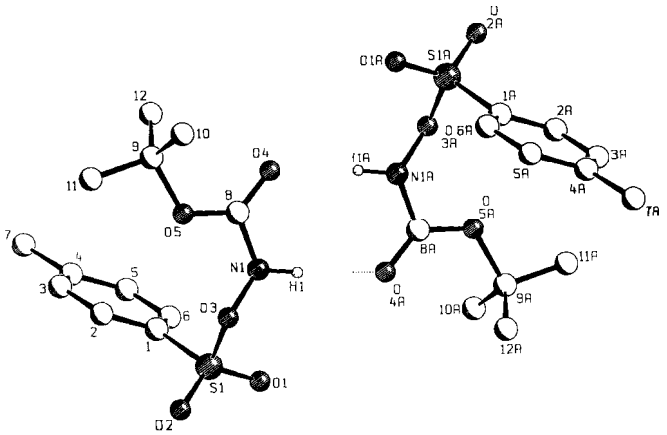

Fig. 2. Crystal structure of $(\mathbf{8})_2$[17]; the C atoms are numbered. Important bond lengths and distances [°]: N1-O3 142.3(5), C8-N1 140.6(7), C8-O4 120.6(7), C8-O5 129.7(6), N1-H1 88(5), H1-O4A 200(5), N1-O4A 287.3(5); N1-C8-O4 118.2(5), O4-C8-O5 129.8(5), O5-C8-N1 111.8(5), N1-H1-O4A 174.2(47); O3-N1-C8-O5 −23.9(6), O3-N1-C8-O4 160.5(4).

the corresponding isocyanate. The analogous formation of a ketene from Li ester enolates by elimination of LiOR is as well known as the corresponding lengthening of the C–OR bond in these compounds.[20] 2) The lengthening of the N1–O3 bond by 6.2 pm relative to that in the neutral compound $(\mathbf{8})_2$ has particular significance for the nitrenoid character of **6b**. This structural change is in accord with the remarkably facile substitution of the RSO_3^- group in **6b** (as well as other leaving groups X^- in nitrenoids) by R′Li, is supported by the previously mentioned calculations,[7] and is analogous to the results from studies on carbenoids $R_2C(Li)X$ (X = Hal, OR), for which the facile replacement of X^- by R′Li is also accompanied by the lengthening of the C–X bond.[8]

Experimental Procedure

$[(\mathbf{6b})_2(thf)_3]$: *N*-mesitylsulfonyloxy-*tert*-butylcarbamate (164 mg, 0.52 mmol) was dissolved in THF/pentane (2 mL, 1/1), cooled to −78 °C, and treated with *n*BuLi in hexane (0.33 mL, 1.6 M). After 48 h at −50 °C colorless prisms of $[(\mathbf{6b})_2(thf)_3]$ suitable for X-ray structure analysis had formed. Yield: 115 mg (52%).

$(\mathbf{8})_2$: A solution of *tert*-butyl-*N*-hydroxycarbamate (7.5 g, 56.5 mmol) and *p*-toluenesulfonic chloride (10.7 g, 56.5 mmol) in anhydrous diethyl ether (ca. 450 mL) at 0 °C was treated with a solution of triethylamine (7.9 mL, 0.1 mol) in anhydrous diethyl ether (5.0 mL). The reaction mixture was stirred for 30 min at 0 °C and the ammonium salt formed removed by filtration. The solvent was removed on a rotary evaporator and the resulting yellow solid washed with petroleum ether until it was colorless[21]. Recrystallization of the crude product from diethyl ether produced colorless crystals after four days at 20 °C that were suitable for X-ray structure analysis. Yield: 12.2 g (75%).

Isopagodanes—Precursors of Unusual Cage Ions**

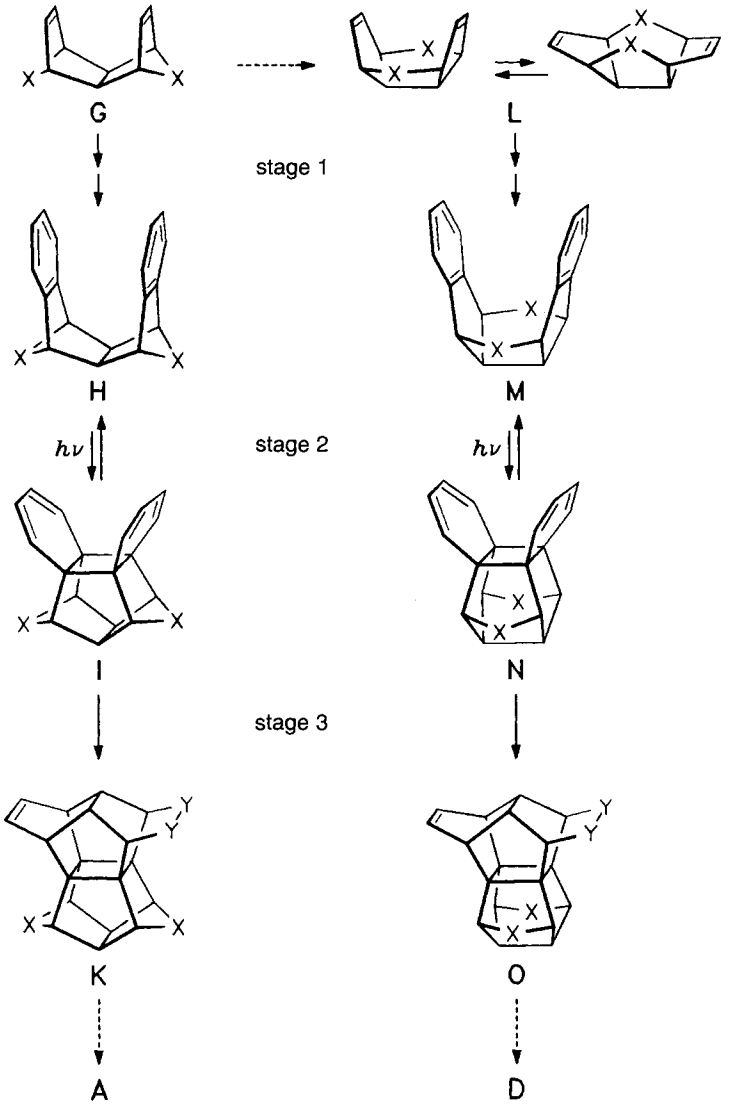
Markus Wollenweber, Rolf Pinkos, Jürgen Leonhardt, and Horst Prinzbach*

The highly strained, polycyclic pagodanes **A** have a high preparative potential, notably as intermediates in the synthesis of dodecahedranes[1] and of the unusual radical cations **B** and dications **C**.[2] The "isopagodanes" **D**[4] were expected to contribute significant information for the quantitative evaluation of the factors responsible for the nature and extent of the transannular electron delocalization (σ-homoaromaticity[2, 3]) in these cage ions. By rotating the two "halves" of the molecules by 90° with respect to each other, D_{2d} symmetry is enforced in the [1.1.1.1] and [2.2.2.2] skeletons (X = Y = CH_2 and $(CH_2)_2$, respectively). A favorable structure is thus provided for the formation of the corresponding ions **E** and **F** in potentially square configurations. According to calculations, the analogous ions **B**/**E** and **C**/**F** should differ considerably with regard to the influence exerted by the bridges X and Y on stability and nature of bonding.[5, 6] We report here on a versatile approach to the synthesis of compounds of type **D** and, in particular, on the preparation of the parent [1.1.1.1] and [2.2.1.1] skeletons **1** and **2**.[7] Compounds **1** and **2** are expected to resemble the pagodane analogues[1] as far as strain energy and rigidity as well as high thermal stability are concerned. MMX calculations predict strain energies for **1** and **2** of 113.8 and 103.6 kcal mol^{-1}, respectively.

1

2

As can be seen from Scheme 1, our original conceptual approach to the construction of isopagodanes **L** → **D**, subdivided into three stages, had been designed in close analogy with the optimized pagodane route **G** → **A**.[8] The prerequisites were seemingly fulfilled when dienes of type **G** (including isodrin) could be "metathesized" efficiently to give dienes **L**. However, an a priori analysis of the individual steps had to take into consideration that the frameworks **L** and **M**, in contrast to **G** and **H**, are conformationally mobile. Even in the favored "closed" conformations the distance between the π systems in **L** and **M** is larger than in **G** and **H**.[4] The chances of success in the two key steps—the benzo/benzo photocycloaddition **M** → **N** and the domino Diels–Alder addition **N** → **O**—were further jeopardized by the fact that very minor structural changes, X = $(CH_2)_2$ for example, are sufficient to prevent the model reaction **H** → **I** from taking place.[4, 9] Moreover, **N** could not be expected to have the high structure-specific kinetic stability of the *syn-o,o'*-dibenzo compound **I** (X = CH_2, $\Delta H^{\neq}(206\,°C) = 37.8$ kcal mol^{-1}; $\Delta S^{\neq} = 2.9$ cal mol^{-1} K^{-1})[10], which was essential for step **I** → **K**.



Experimentally, the analogy to the pagodane route did indeed end with the attempt to bring about photochemical four-membered ring formation in the dibenzo compound **3** (**M**, X = CH_2)[4] to give **4**. Compound **3** remained unchanged under widely varied conditions of direct irradiation (with poly- and monochromatic light) and sensitized irradiation. No adduct (e.g. **6**) was detected on irradiation at low temperatures (−70 °C) in the presence of 4-methyl-1,2,4-triazoline-3,5-dione. Equilibration of **3** with **4** as a very low-percentage equilibrium component was thus thought to be unlikely, especially in view of the fact that the photoadduct in the photoequilibrium **H** ⇌ **I** (X = CH_2, 7:3) was trapped almost quantitatively by use of the above reagent.[9]

Eventually, a way out of this dilemma was found with the reaction sequence **3** → **[5]** → **7** → **9** → **11(12)** → **4** (Scheme 2)—

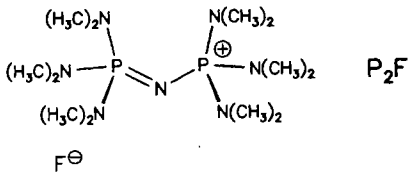
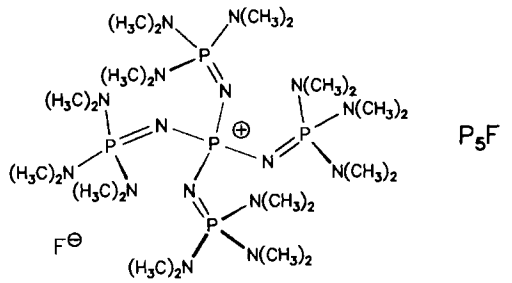
Scheme 1.



the transannular four-membered ring formation was brought about through a geometrically less demanding $[2_\pi + 2_\pi]$ photocycloaddition. The double Birch reduction of **3** to **7** (possibly via the diradical anion **5**), which had failed in the case of the dibenzo analogue **H**[11] (X = CH_2; the distance between the two benzene rings is here shorter than in **3**), was achieved in the presence of very high ethanol concentrations; however, overreduction of **3** was unavoidable. A procedure was provisionally adopted by which the reaction was stopped at around 90% conversion. After chromatographic separation **7** was then isolated in approximately 65% yield [with respect to converted **3**, colorless crystals, UV (*n*-hexane): $\lambda_{max}(\varepsilon) = 198$ nm (7520), $\varepsilon_{254} \approx 1$]. Byproduct **8** was not reduced to **7** when subjected to analogous conditions. However, dehydrogenation of **8** back to **3** by irradiation in acetone (Solidex filter, high-pressure Hg lamp, 0 °C) or, preferably, by reaction with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) proved possible, thus allowing **8** to be recycled. A selective $[2_\pi + 2_\pi]$ cycloaddition of **7** to give **9** could not be effected by using carbonyl-containing sensitizers with various triplet energies; dehydrogenation providing **8** and **3** was the main reaction observed with acetone, xanthone, or benzophenone. On irradiation in benzene the addition **7** → **9** did take place, but the following step **9** → **10** was comparatively rapid, and some dehydrogenation also occurred. Direct irradiation with monochromatic 254-nm light proved to be more selective despite the fact that **7** has a low extinction coefficient at this wavelength; the reaction was stopped at around 90% conversion, because polymerization became increasingly detractive with longer reaction times. After chromatographic separation from the relatively small quantities of **8** and **10**, cycloadduct **9** [λ_{max}(*n*-hexane) = 196 nm (ε = 6170)] was isolated in 74% yield (with respect to reacted **7**). Titration with bromine resulted in quantitative addition to give an approximately 1:1 mixture of tetrabromides **11** (C_2) and **12** (C_s), which was used in the next step without further purification. Transannular Br_2 addition was obviously not competing. Fears that the kinetic instability of pho-



Scheme 2. (1) 150 mL NH_3, 600 mg (2.32 mmol) **3** in 64 mL ether and 34 mL (580 mmol) ethanol, 4.53 g (650 mmol) Li, −78 °C, 1 h, 12% **3**, 58% **7**, 12% 4,5-dihydro-**7**, 12% **8**; (2) 835 mg (3.18 mmol) **7**, 250 mL cyclohexane, Rayonet reactor (254 nm), 3.5 h, 12% **8**, 12% **7**, 6% **10**, 65% **9**; (3) 0.1 M Br_2 solution in CH_2Cl_2, −78 °C, 100%; (4) 2.46 g (2.59 mmol) 80% P_2F in 10 mL THF, 164 mg (0.28 mmol) **11**/**12** in 6 mL THF, N_2 atmosphere, −78 °C, 1 h, up to 80% **4**.

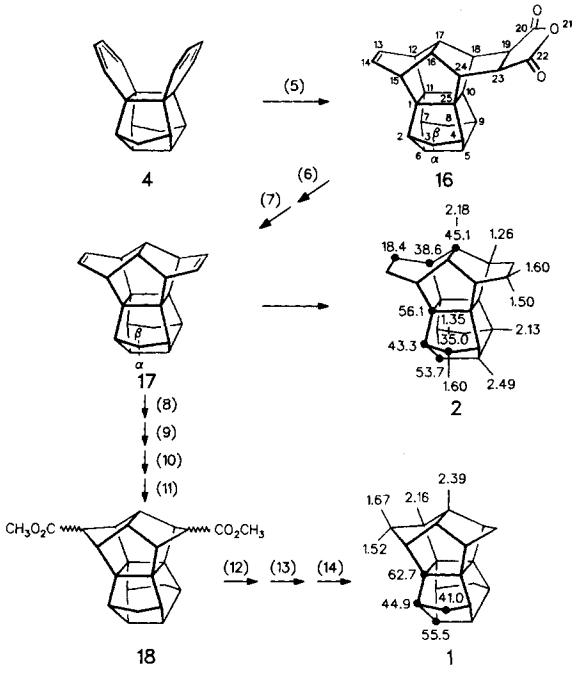
toadducts of type **N** might lead to complications in step **11/12** → **4** with its multiple HBr eliminations proved to be well justified. The necessary temperatures were either too high (potassium *tert*-butoxide/dimethyl sulfoxide (DMSO), 1,5-diazabicyclo[4.3.0]non-5-ene (DBN)/THF), or other elimination pathways leading back to **3** or to **14** were favored (*tert*-butyl-P_4 base,[12] −78 °C). A breakthrough was accomplished with the "naked" fluoride recently developed by Schwesinger et al.;[13] under these conditions **4** was formed rapidly even at −78 °C. By using carefully prepared batches of base (2.3 equivalents P_5F or P_2F per HBr), **4** could be secured reproducibly on a gram scale in yields of up to 80% besides **3**. It was established that **3** does not arise from



4; a plausible mechanism is a competing 1,8-HBr-(*cis*)-elimination in **13**. The thermally labile compound **4** could be purified by rapid chromatography on deactivated silica gel. Evidence for the C_{2v} symmetry of **4** includes the six signals observed in its ^{1}H NMR spectrum. The UV spectrum (*n*-hexane) with $\lambda_{max}(\varepsilon) = 292$ nm (2570) confirms the presence of the σ-coupled tetraene chromophore. Upon treatment with acid, irradiation (with 254-nm light instantaneously; with 350–400-nm light within hours), and upon heating in benzene, **4** was smoothly converted into **3** [$t_{1/2}$(24 °C) = 32.7 h, $t_{1/2}$(44 °C) = 97.5 min, $t_{1/2}$(50 °C) = 26.2 min; $E_a = 23.9 \pm 1.5$ kcal mol^{-1}]. The activation energy for this cleavage, in good agreement with the enthalpy of formation calculated for the intermediate diradical **15** (Scheme 3,

Scheme 3. The enthalpies of formation ΔH_f° for **4**, **15**, and **3** derived from MM2 calculations are 112.5, 133.0, and 37.7 kcal mol^{-1}, respectively.

MM2),[4] is approximately 10 kcal mol^{-1} less than the value quoted above for the **I** isomer and comparable with the fragmentation barriers of *syn*- and *anti*-*o*,*o*'-dibenzene (E_a = 26.7 and 24.8 kcal mol^{-1}, respectively).[14]

The addition of maleic anhydride (MA) to **4** provides the entry into the third stage of our synthesis (Scheme 4). Because of the limits set by the lability/reactivity of the reactants, the following procedure was adopted: The fluoride base was extracted from the crude solution from the HBr elimination step (mixture of **4** and **3**). The solution was concentrated in vacuo below room temperature and the solid residue mixed thoroughly with approximately 30 equivalents of freshly sublimed, finely ground MA. After rapid heating to 100 °C the domino adduct **16** formed in yields of 50–60% (based on **11/12**) was separated from **3** without loss of material; no adduct other than **16** could be detected (TLC, ^{1}H NMR). The oxidative degradation of **16** to give the [2.2.1.1]isopagodadiene **17** turned out to be problematic. A yield of only a few percent was obtained under the conditions optimized for the pagodane route. However, with a modified two-step procedure the yield was increased to 70–75%. The catalytic hydrogenation of **17** to give the parent [2.2.1.1] skeleton **2** and the twofold ring contraction **17** → **18** proceeded as expected.[8] Nearly equal proportions of the three possible methyl esters **18** emerged from the photo-Wolff rearrangement in methanol/CH_2Cl_2; the final protonation at C-4(9) of the intermediate ketene is clearly not sterically controlled. In a deviation from the model reaction scheme[8] the ester was converted into **1** according to the method of Barton et al.[16] (The overall yield for the sequence of saponification, formation of the acid chloride, esterification, and thermolysis approached ca. 50%.)

Scheme 4. (5) Molten MA, 100 °C, 15 min, 22% **3**, 50–60% **16**; (6) KOH, methanol/H_2O (1:1), reflux, 1 h, 100%; (7) Cu_2O, 2,2'-dipyridyl, quinoline a) room temperature, 7 d, b) 185 °C, 17 h, 72% **17**; (8) BH_3·THF, 25 °C, 4 h; NaOH, H_2O_2, 25 °C, 18 h, 100% crude product; (9) CrO_3, acetone, H_2SO_4, 25 °C, 1 h, 56%; (10) NaH, THF, HCO_2CH_3, methanol (cat.), 25 °C, 22 h; glacial acetic acid, 4-methylphenylsulfonylazide, triethylamine, CH_2Cl_2, 25 °C, 30 h, 52%; (11) methanol/CH_2Cl_2 (10:1), high-pressure Hg lamp, Duran filter, 25 °C, 45 min, 98% **18**; (12) KOH, ethanol, H_2O, reflux 3 h, 72%; (13) oxalyl chloride, dimethylformamide (DMF), toluene, 100%; (14) sodium mercaptopyridine-1-oxide, 4-dimethylaminopyridine (DMAP), *tert*-butylthiol, toluene, reflux, 3 h, 68% **1**. – The numbers shown on the skeletons of **1** and **2** are the ^{1}H and ^{13}C NMR chemical shifts (δ values).

The four (8:4:4:4) ^{1}H NMR and four ^{13}C NMR signals confirm the D_{2d} symmetry of **1**. The H,H coupling constants ($J_{3,4a} \approx J_{3,4s} \approx 1$, $J_{4a,4s} = 10.0$, $J_{3,7} \approx 4$ Hz) are generally somewhat smaller than the calculated values (MM2). The smaller

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0119 $ 10.00+.25/0

chemical shifts observed for the carbon atoms of the cyclobutane ring in **2** point to the (calculated) reduction in strain.

The colorless crystals of **2** melt at 198 °C without decomposition, those of **1** at 90–92 °C. In the mass spectra of **1** and **2** a dominant molecular ion peak and only weak fragmentation peaks are observed.

The key step in the synthesis of pagodanes, the benzo/benzo photocycloaddition, exhibits a very subtle dependency on structure. For that reason it was necessary to modify the original synthetic scheme for the isopagodanes, which had been designed by direct analogy with the pagodane route. The reaction sequence described above, which starts from **3** (and thus originally from isodrin) and leads to the parent [2.2.1.1]- and [1.1.1.1]isopagodane skeletons, can also be applied to the synthesis of functionalized derivatives. Preliminary results from electrochemical and ESR studies are stimulating in that they reveal one of the astonishing peculiarities of the isopagodane series: In line with calculations,[6] **2** undergoes two-electron oxidation via a cyclically delocalized radical cation **E** to give a dication **F**, which is persistent enough to allow observation of the two-electron reduction.[5, 17]

A Novel Reaction Sequence for the Coupling of Nucleophiles to Agarose with 2,2,2-Trifluoroethanesulfonyl Chloride**

Anastasios Demiroglou,
Cornelia Bandel-Schlesselmann
and Herbert P. Jennissen*

Sulfonyl chlorides such as tosyl chloride and 2,2,2-trifluoroethanesulfonyl chloride (tresyl chloride[11]) are among the most widely employed nucleophilic reagents. Over ten years ago tresyl chloride was also introduced in the synthesis of supports for affinity chromatography[2] and is now widely used for the activation of solid phases containing primary hydroxyl groups for subsequent coupling with primary amines or thiols.[3–14] Equation (a) was proposed to describe the tresylation of a solid support, for example, the polysaccharide agarose (tresyl agarose, tresyl Sepharose).[2] The subsequent coupling of amines and thiols to tresyl Sepharose was thought to follow Equations (b)

$$\text{-}CH_2\text{-}OH + ClSO_2CH_2CF_3 \xrightarrow{\text{pyridine}} \text{-}CH_2\text{-}O\text{-}SO_2CH_2CF_3 + HCl \quad (a)$$

$$\text{-}CH_2\text{-}O\text{-}SO_2CH_2CF_3 + R\text{-}SH \longrightarrow \text{-}CH_2\text{-}S\text{-}R + HOSO_2CH_2CF_3 \quad (b)$$

$$\text{-}CH_2\text{-}O\text{-}SO_2CH_2CF_3 + R\text{-}NH_2 \longrightarrow \text{-}CH_2\text{-}NH\text{-}R + HOSO_2CH_2CF_3 \quad (c)$$

and (c), respectively;[2] however, these reactions, in which 2,2,2-trifluoroethanesulfonic acid acts as the leaving group, were never proven.[2–5, 10] The unexpected protein binding properties of thioalkyl agaroses prepared by the tresyl chloride method[14–16] prompted us to reinvestigate the putative reaction mechanism [Eqs.(a)–(c)] by performing systematic elemental analyses of the synthesized alkyl Sepharose products. We found that the elemental analyses of the coupling products obtained from tresylated agarose are not in agreement with Equations (b) and (c),[16] which we show here to be wrong.

A typical analysis of the coupling products obtained from Sepharose 4B activated with tresyl chloride is shown in Table 1. In experiments 1–5 the covalent tresylation of Sepharose can be easily followed by an elemental sulfur analysis. These results are in accord with those reported by Mosbach and Nilsson.[1] In the SIMS analyses for experiments 1 and 2 a signal corresponding to the fluorine of the tresyl residue was also detected. Coupling with butanethiol (expts 1–5) leads to a reduction of the SIMS fluorine signal by a factor of 45 in experiment 1 and by a factor of 10 in experiment 2, which is still in agreement with a release of the 2,2,2-trifluoroethanesulfonic acid moiety. However, the further product analysis (Table 1) shows that the elemental sulfur content does not remain constant after the coupling as ex-

[a] Activation of Sepharose 4B with tresyl chloride and the coupling with butanethiol and with amine are described in ref. [14] and in the text. For elemental analysis (S,N) see Experimental Procedure, and for ^{14}C tracer see ref. [22]. For further details see Experimental Procedure and the text. ND: not determined. [b] The control values for unsubstituted Sepharose 4B (see Table 2, expt 1) have been subtracted.

pected. In fact it increases by roughly a factor of 2 in all the experiments. The increase in sulfur content of the gel corresponds to the amount of ^{14}C-butyl thiol incorporated covalently, which indicates that the ratio of original tresyl chloride sulfur to alkylthiol sulfur is 1:1. A very similar result was obtained when butylamine was coupled to tresyl Sepharose (expts 3–5). Here the sulfur content before and after coupling is practically constant, whereas the nitrogen content and ^{14}C-butyl amine incorporation are stoichiometric. Similar results were obtained when the coupling was conducted at pH 8.0 under the conditions described in ref.[2], rather than in NaOH solution (pH 13.3). These experiments demonstrate that the sulfur atom of tresyl chloride is not part of the leaving group in the coupling reaction.

Table 2 shows that alkaline treatment (0.5 M NaOH, 24 h) alone leads to a loss of fluorine atoms, as reflected by the decrease in the intensity of the SIMS signal by a factor of 70 (expts 2 and 3), whereas the sulfur content is unaffected (expts 3 and 4). ^{14}C-Butanethiol cannot be coupled to alkali-treated tresyl Sepharose (expt 3). Alkali treatment of the coupling product, butyl Sepharose, for 24 hours results in a relatively small loss of 14–17% of sulfur and ^{14}C-butyl residues. This indicates that the covalent bond between the matrix and the alkyl residues is quite stable.

Since impurities in the employed tresyl chloride could be excluded (the ^1H NMR and ^{19}F NMR spectra of tresyl chloride show only the expected quartet and triplet, respectively, indicating 99% purity), a novel leaving group had to be involved. One possibility was that 1,1,1-trifluoroethane, an insoluble and practically inert gas, was released. However, manometric measurements in a Warburg apparatus[16] of various tresyl Sepharoses during alkaline hydrolysis disproved gas development. Therefore the liquid phase obtained after NaOH hydrolysis of tresyl Sepharose and after coupling of butanethiol and butylamine was analyzed by ^{19}F NMR spectroscopy. Only one singlet at $\delta = -119.5$ to -119.7 in scans covering a range from $\delta = +115$ to -235 is evident (Fig. 1A–D), demonstrating that inorganic fluoride is the only fluorine product of the hydrolysis of tresyl Sepharose under the conditions examined. The additional peak at $\delta = -75.5$ in Figure 2D is due to a contamination in the butylamine employed for coupling. This contamination accounts for 6.7% of the total F^- signal.

After the ^{19}F NMR analyses had proved that the fluoride ion is the only fluorine product released from tresyl Sepharose, quantitative F^- determinations were performed (Table 3). Fluoride was found to be generated in a F/S ratio of approximately 3:1, which demonstrates the quantitative conversion of organic into inorganic fluoride (Table 3). The appearance of fluoride during the hydrolysis of tresyl Sepharose was also recently noted by Ohata et al.[17] However, the "classical" reaction sequence of tresyl chloride activation and coupling [Eqs. (a)–(c)] was not queried by this group.

Table 2. SIMS Fluoride analysis of tresyl and butyl Sepharose before and after treatment with NaOH[a].

	Sulfur analysis	SIMS analysis			Sulfur analysis	Incorporated butyl residues	SIMS analysis	
		F^- intensity	F^-/CH_2			^{14}C analysis	F^- intensity	F^-/CH_2
	[μg-atom/g dry gel]				[μg-atom/g dry gel]	[μmol/g dry gel]		
1. Sepharose 4B control	0	30	0.010	–	–	–	–	–
2. tresyl Sepharose	469 [b]	2824		NaOH	ND	–	40	ND
3. tresyl Sepharose	328	2070	0.497	NaOH [c]	294 [d]	9	29	0.007
4. butyl Sepharose	1628	382		NaOH	1359	522 [e]	134	ND

[a] Sepharose 4B was activated and coupled with butanethiol as described in the Experimental Procedure, in the text, and in the legend to Table 1; ND = not determined. The gels were incubated in 0.5 M NaOH for 24 h. For further details on the analysis of the gels see the Experimental Procedure, the text, and the legend to Table 1. SIMS analysis: In experiments 2–4 the control values for unsubstituted Sepharose (expt 1) were substracted. [b] Calculated from the incorporation of ^{14}C butanethiol (605 μmol/g dry gel) and the ratio of 1.29/1 for tresyl Sepharose for butyl residues incorporated/elemental sulfur analyzed (expt 1, Table 1). [c] Reaction with NaOH was followed by coupling with butanethiol. [d] Calculated based on the dry weight of the corresponding tresyl Sepharose. [e] Before treatment with NaOH the amount of incorporated ^{14}C-butanethiol was 604 μmol/g dry gel (see expt 2, Table 1).

Table 3. Determination of inorganic fluoride in the liquid phase after the coupling of Sepharose tresylate with butanethiol and butylamine[a].

2	1.67	butanethiol	3.50	0	1.96	5.11
3	1.67	butylamine	1.81	1.73	1.58	5.77

[a] For further details on preparative and analytical procedures (determination of inorganic fluoride) see the Experimental Procedure, legends to Tables 1 and 2, Figure 1, and the text.

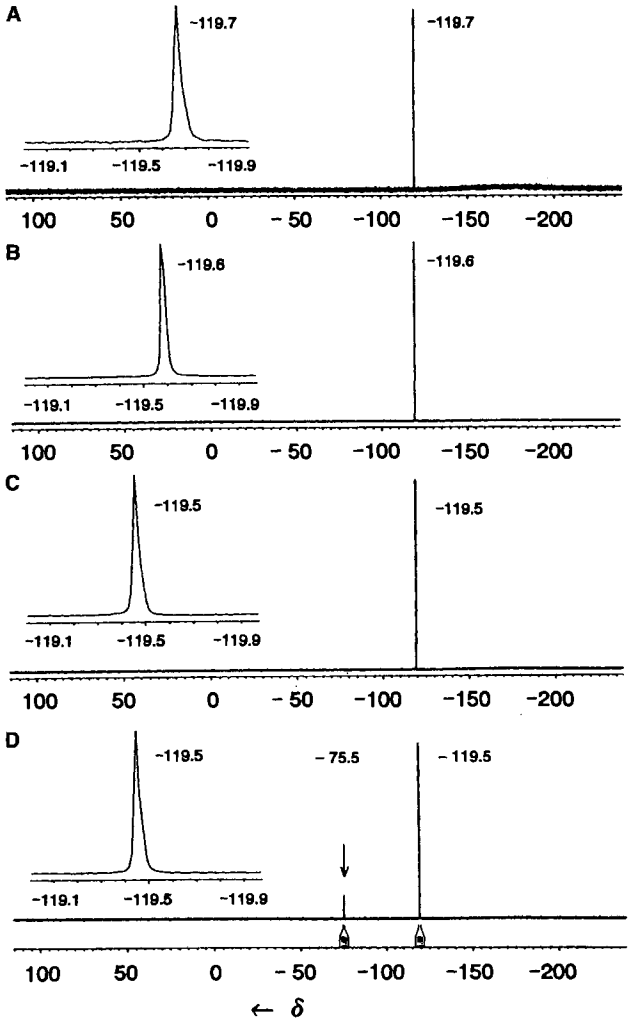

Fig. 1. ^{19}F NMR spectra of the liquid phase obtained from reaction mixtures of tresyl Sepharose in alkaline medium. The spectra were measured with $CFCl_3$ as external standard. The inserted spectra were measured with a resolution of 30 Hzcm^{-1}. The numbers refer to the chemical shifts. The arrow in D indicates the signal due to a contaminant of the butylamine solution. For further details see Table 3 and the text. A) 48 mM NaF in 1 M NaOH; B) liquid phase of tresyl Sepharose (1.67 mg-atom sulfur/g dry gel) after hydrolysis in 0.5 M NaOH; C) liquid phase of tresyl Sepharose (1.67 mg-atom sulfur/g dry gel) after coupling in 0.21 M butanethiol and 0.5 M NaOH; D) liquid phase of tresyl Sepharose (1.67 mg-atom sulfur/g dry gel) after coupling in 0.21 M butylamine and 0.5 M NaOH.

The question now remained what organic residue constitutes the leaving group in the tresyl chloride reaction. In this context the papers of Jones[19] and Buxton et al.[20] are of great interest, since they showed that in alkaline media the trifluoromethyl groups of *o*- and *p*-substituted benzotrifluorides[19] and α-trifluoromethylpropionic acid[20, 21] undergo a combined addition–elimination reaction with the formation of a carboxyl group and sodium fluoride. We therefore infer from their work that acetic acid is the organic product formed during the coupling reaction.

We conclude from the data presented here that during the reaction of tresyl Sepharose with nucleophilic agents in alkaline medium an addition–elimination reaction takes place generating acetic acid and fluoride ion. Equations (d)–(f) describe the novel reaction of tresyl Sepharose in alkali with thiols and amines in which esters of sulfuric acid (checked by acid titration), *S*-alkylthiosulfuric acid, and *N*-alkylamidosulfuric acid are produced, respectively.

$$|\text{-CH}_2\text{-O-SO}_2\text{CH}_2\text{CF}_3 + 3\text{NaOH} \longrightarrow |\text{-CH}_2\text{-O-SO}_3\text{H} + \text{CH}_3\text{COOH} + 3\text{NaF} \quad \text{(d)}$$

$$|\text{-CH}_2\text{-O-SO}_2\text{CH}_2\text{CF}_3 + \text{R-SH} + 3\text{NaOH} \longrightarrow |\text{-CH}_2\text{-O-SO}_2\text{-S-R} + \text{CH}_3\text{COOH} + 3\text{NaF} + \text{H}_2\text{O} \quad \text{(e)}$$

$$|\text{-CH}_2\text{-O-SO}_2\text{CH}_2\text{CF}_3 + \text{R-NH}_2 + 3\text{NaOH} \longrightarrow |\text{-CH}_2\text{-O-SO}_2\text{-NH-R} + \text{CH}_3\text{COOH} + 3\text{NaF} + \text{H}_2\text{O} \quad \text{(f)}$$

Experimental Procedure

Preparative Methods: The conditions for the activation of agarose (Sepharose 4B, Pharmacia/LKB Freiburg) with tresyl chloride (Fluka, Neu Ulm) are described in ref.[14]. For environmental reasons anhydrous acetone was used in the incubation mixture instead of anhydrous dioxane[14]. Tresyl Sepharose was coupled to butanethiol and butylamine according to the general procedure described in ref.[14]. In a typical preparation 10 g (wet weight) of tresyl Sepharose was added to 18 mL of 0.43 M thiol or 0.43 M amine in 1 M NaOH in a closed flask. The final concentrations in the mixture after addition of Sepharose were 0.28 M for both thiol and amine and 0.64 M for NaOH. The mixtures with the thiols were incubated for 60 min at room temperature, those with the amines for 60 min at 5 °C. Practically identical results were obtained when the amines were coupled at room temperature. After coupling the gel was washed on a Büchner funnel with ca. 20 vol water, acetone/water (1:3, v/v), acetone/water (3:1, v/v), and finally with pure acetone until the thiol or amine smell had disappeared. A reversal of this washing procedure was used to transfer the gel back into aqueous medium.

For the alkaline hydrolysis 15 g tresyl Sepharose (wet weight[22]) was added to 15 mL 1 M NaOH and incubated at room temperature between 2.5 and 24 h. In the initial experiments the reaction mixture was incubated for 24 h until it was found that the reaction was complete after 1–2.5 h. The solid phase (gel) was then separated from the liquid phase on a Büchner funnel for separate analysis. All other methods concerning the preparation and handling of agarose are given in ref.[14].

Analytical Methods: 1. Elemental sulfur and nitrogen analysis (double analysis) was performed by gas chromatography on a Carlo Erba Strumentzione Elemental Analyzer model 1106. 2. ^1H NMR spectra were recorded on a high-resolution Bruker AMX-300 NMR spectrometer (282 MHz) in $CDCl_3$. The ^{19}F NMR spectra were recorded on the same instrument with $CFCl_3$ as external standard (max. resolution: 30 Hzcm^{-1} for the spectra inserted in Fig. 1). 3. Fluoride was determined with a modified flow injection halide sensor based on a lanthanum fluoride solid-phase electrode[23]. The sensitivity exceeded 10^{-7} M fluoride. 4. The SIMS analyses were carried out with a Belzers SIMS apparatus with a QMG 511. The Ar^+ ions (3 keV, 10^{-9} A/0.1 cm^2) were directed towards the sample in an angle of 60°. There was charge compensation by an additional electron beam. The Sepharose bead samples were lyophilized and affixed to conducting solvent-free, double-sided adhesive tape.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0122 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 1

The mass spectrum was obtained for positive and negative secondary ions in a range of 0–100. 5. The degree of substitution of the gel was monitored by adding 0.05–0.25 μCi mL^{-1} *n*-[1-^{14}C]-butanethiol (NEN)[14] or *n*-[1-^{14}C]-butylamine (Hoechst AG) to the coupling mixture (as described in ref.[22]). The amount of coupled alkyl residues was determined by liquid scintillation counting[22] after acid hydrolysis of the *n*-[1-^{14}C]-butyl-labeled agarose (colorless hydrolysate). Analyses were done in triplicate.

An Extraordinarily Violent Molecular Dissociation: The Unprecedented Kinetic Energy Release in the Decomposition of $HONF^+$, a Singly Charged Metastable Ion**

Fulvio Cacace, Felice Grandinetti,* and Federico Pepi

The kinetic energy associated with the separation of the fragments from the decomposition of a metastable species constitutes an integral component of the reaction dynamics and is therefore of fundamental interest.[1] In the case of charged species the translational energy of the fragments can be measured with experimental techniques such as mass-analyzed ion kinetic energy (MIKE) spectrometry,[2–5] whose application has provided a large amount of data and has proved a useful tool in the determination of the structures of ions.[6]

The kinetic energy release (KER) spans over several orders of magnitude, from a few hundredths of the one eV to large energies of 10 eV and above, measured in the decomposition of certain multiply charged ions. The latter, however, generally undergo charge-separation reactions, and their KER is not simply related to the intrinsic dynamics of the dissociation reaction, since most of the translational energy of the charged fragments arises from their coulombic repulsion.[7] The KER associated with the decomposition of a singly charged ion provides a more direct insight into the potential energy hypersurface of the decomposing species.

A survey of the experimental results, customarily expressed by the $T_{1/2}$ energy calculated from the metastable peaks widths at their half heights, indicates that the KER associated with the decomposition of singly charged ions falls in general well below 2 eV, rarely exceeding 1.5 eV. This is hardly surprising, since large translational energies of the fragments require a combination of several factors, including a much higher stability of the fragments with respect to their parent, a high barrier for the dissociation, and a partition of the energy released that favors the translational over the rotational and/or internal degrees of freedom of the fragments.

The loss of HX from simple ions containing the $(X-N-Y)H^+$ moiety (X, Y = O or F) which leads to metastable ions $(N-Y)^+$ is characterized by an appreciable barrier for the reverse reaction and by a large KER, for example in the case of protonated nitric acid,[8] nitrogen trifluoride,[9] methyl[10] and ethyl nitrate.[11]

A recent theoretical study of a closely related system has pointed to the large exothermicity of the unimolecular dissociation (shown in [Eq. (a)]) estimated to be 68 kcal mol^{-1} (2.95 eV)

$$H-O-N-F^+ \longrightarrow HF + NO^+ \qquad (a)$$

at the (CISD + Q) (CISD + Q = configuration interaction limited to single and double excitations corrected for unlinked quadruple excitations) level of theory with a double-zeta plus polarization quality basis set.[12] This has prompted a reinvestigation of the system at the GAUSSIAN-1 level of theory,[13] aimed at evaluating the barrier for dissociation [Eq. (a)]. The results summarized in Table 1, and illustrated in Figures 1 and 2 agree quite well with those from the previous theoretical study with regard to the exothermicity of the dissociation [Eq. (a)] and indicate, in addition, that the barrier for the dissociation process, which requires molecular reorganization, is as high as 24.2 kcal mol^{-1}. The latter is an interesting finding, showing that the total energy released in the decomposition of those $HONF^+$ ions which are sufficiently excited to overcome the barrier exceeds 80 kcal mol^{-1}, some 3.5 eV. Furthermore, the nature of the NO^+ and HF fragments suggests that only a limited fraction of the energy released should be partitioned in

Table 1. GAUSSIAN-1 absolute energies [Hartree] and relative stabilities, ΔE [kcal mol^{-1}] of the investigated $(F,H,N,O)^+$ ions and their fragments.

Species (*n*) [a]	*E* (GAUSSIAN-1)	ΔE (298 K)

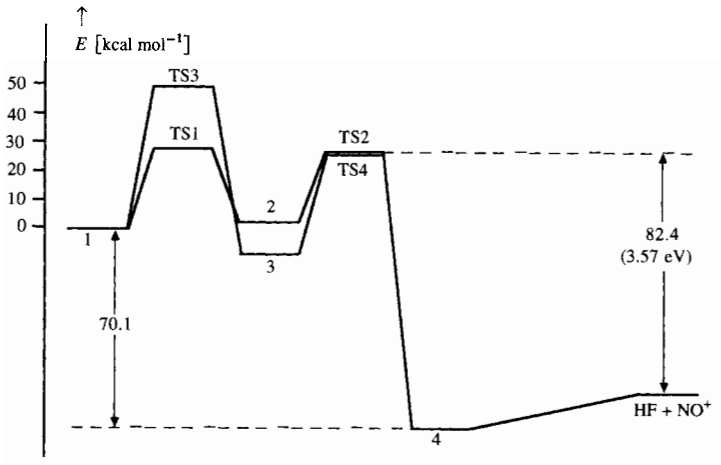

Fig. 2. Schematic energy profile of dissociation of $HONF^+$ [Eq. (a)]

their rotational and/or internal degrees of freedom, which justifies the expectation of an exceptionally large KER.

In order to verify the above-mentioned theoretical predictions experimentally, a suitable route must be found to ions of the required H-O-N-F^+ structure, containing excess internal energy sufficient to allow decomposition according to Equation (a). $HONF^+$ ions have been successfully obtained upon ionization of a NF_3/H_2O mixture, under chemical ionization (CI) conditions. A plausible explanation for the formation of $HONF^+$ is based on the reaction sequence summarized in Equations (b)–(d).

$$NF_3 + e \longrightarrow NF_2^+ + F^\cdot + 2\,e \quad (b)$$

$$NF_2^+ + H_2O \longrightarrow [H_2O{-}NF_2]^+_{exc} \quad (c)$$

$$[H_2O{-}NF_2]^+_{exc} \longrightarrow [HONF]^+_{exc} + HF \quad (d)$$

The adduct from the highly exothermic reaction (c) dissociates yielding $HONF^+$ ions of the desired structure, containing, as required, excess internal energy. In fact, apart from the evidence provided by the formation route, the H-O-N-F connectivity of the ions obtained from Equation (d) is demonstrated by their collisionally activated dissociation (CAD) spectrum, which displays signals for the fragments NO^+ (56.2%), NF^+ (31.1%), NOH^+ (9.7%), OH^+ (1.8%), and N^+ (1.2%). The fact that the $HONF^+$ ions are formed in an excited state is suggested by the considerable (1.36 eV) KER of dissociation [Eq. (d)], since it is most reasonable to assume that a proportionately large amount of energy is deposited into the internal degrees of freedom of the $HONF^+$ fragment. Moreover, a fraction of the energy of the ionizating electrons may contribute to excited $HONF^+$ ions.

The MIKE spectrum of the $HONF^+$ ions obtained from the sequence (b)–(d), displays the single transition [Eq. (a)], whose KER ($T_{1/2} = 2.68 \pm 0.1$ eV) fully meets, and perhaps exceeds, the theoretically based expectations, being unprecedented for the decomposition of a metastable monocation (Fig. 3). From

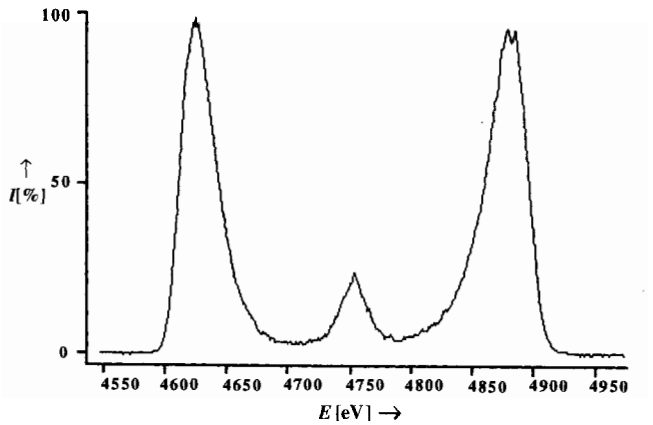

Fig. 3. The NO^+ peak from the decomposition of the metastable $HONF^+$ [Eq. (a)]. The kinetic energy of the precursor ion is 7921 eV. I = relative intensity.

the study of a large number of simple ions, it has been found that $T_{1/2}$ generally exceeds the mean kinetic energy release by 15–20%.[5] Under this assumption, the mean kinetic energy of the fragments would account for 60 to 70% of the total energy released from process (a) which in Figure 2 corresponds to the energy difference of about 3.57 eV, between **TS2** and the separate NO^+ and HF fragments; the remaining fraction is contained in their rotational and internal degrees of freedom. The narrow gaussian component of Figure 3, centered at $m/z = 30$, can be ascribed to the decomposition of metastable ions **4** formed from the isomerization of $HONF^+$ ions, and stabilized by collisional deactivation in the ion source. From Figure 2, and consistent with the MIKE spectrum, the fragmentation of **4** into NO^+ and HF is a simple bond cleavage, occurring with no energy barrier, for the reverse reaction.

In conclusion, apart from the intrinsic interest of (X–N–Y)H^+ systems, several of which play an important role in such fields as chemical reactivity and catalysis, environmental, flame, and atmospheric chemistry, the present results underline the powerful interplay between high-level calculations and MIKE spectrometry in gathering direct insights into relevant details of the potential energy hypersurface of simple ions in the gas phase.

Experimental Procedure

MIKE and CAD spectra of the $(F,H,N,O)^+$ ions were recorded by using a ZAB-2F mass spectrometer from VG Micromass Ltd. Typical operating conditions of the CI

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0101-0124 $ 10.00+.25/0

source were as follows: bulk gas pressure 0.1–0.2 Torr, source temperature 180 °C, emission current 1 mA, repeller voltage 0 V, electron energy 100 eV. The MIKE spectra were recorded by using an accelerating potential of 8 KeV at a typical energy resolution of 8×10^3, and represent the average of at least 100 scans. CAD spectra were taken by admitting He into the collision cell at such a pressure to reduce the main beam intensity to 30% of its initial value.

Computational Details: Ab initio quantum-mechanical calculations were performed by using a RISC/6000 version of the GAUSSIAN 92 program package [14]. The standard internal 6-31G* [15a], 6-311G** [15b], 6-311 + G** [16], and 6-311G** (2 df) [16] basis sets were employed. Geometry optimizations were performed in the full space of the coordinates by analytical gradient-based techniques [17], in the framework of the second-order Møller-Plesset perturbation theory [18], with the 6-31G* basis set. The MP2 method was used with full (FU) electron correlation (including inner-shell electrons). The geometries obtained (Fig. 1) in this way are denoted by MP2(FU)/6-31G*. The corresponding vibrational frequencies were computed for all of the species investigated, in order to characterize them as true minima, transition structures, or higher order saddle points on the potential energy hypersurface. The zero-point energy of the various species was accounted for in this way. The GAUSSIAN-1 procedure, as outlined in ref. [13], was employed to obtain the total energies of the investigated species.

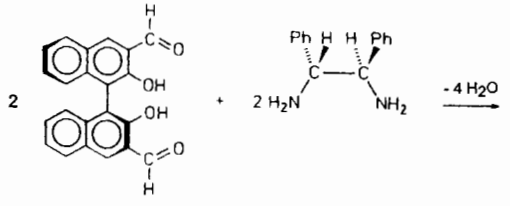
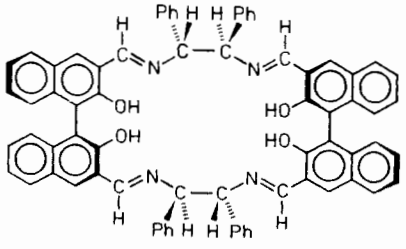
Dialdehyde + Diamine—Polymer or Macrocycle?

Henri Brunner* and Hubert Schiessling



Dedicated to Professor Otto J. Scherer on the occasion of his 60th birthday

Schiff bases derived from salicylaldehyde (**1**) and primary amines are common chelating ligands in complex chemistry.[1] Optically active salicylaldiminates have, for some time, also been employed successfully in enantioselective catalysis (e.g. cyclopropanation).[2] The optically active compounds (*R*)-**2** and (*S*)-**2** contain two salicylaldehyde residues in a chiral binaphthyl system.[3,4] The synthesis of 2,2′-dihydroxy-1,1′-binaphthyl-3,3′-dialdehyde (**2**) proceeds by 1,1′-coupling of the commercially available 3-hydroxy-2-naphthoic acid, acetylation of the phenolic OH groups, reduction of the acid chloride, and cleavage of the protecting groups, in an overall yield of about 20%.[3] Enantiomeric resolution takes place at the 2,2′-dihydroxy-1,1′-binaphthyl-3,3′-dicarboxylic acid stage.[5]



1 (*R*)-**2** (*S*)-**2**

The condensation of salicylaldehyde (**1**) with the difunctionalized amine 1,2-diaminoethane yields the known tetradentate salen ligand. In contrast to the monofunctionalized aldehyde **1**, the binaphthyl derivatives **2** are difunctionalized, and should therefore react with (*R*,*R*)-1,2-diamino-1,2-diphenylethane[6,7] (**3**) to give polymeric Schiff bases. This supposition is confirmed by the reaction of (*R*)-**2** with **3**, but not by the reaction of (*S*)-**2** with **3**, in which two molecules of dialdehyde undergo condensation with two molecules of diamine to form the 24-membered macrocycle **4**. Compound **4** is a yellow solid that may be purified by chromatography on silica gel.[8] An *m*/*z* value of 1037 in the mass spectrum confirms the above formulation. Obviously during the condensation of (*R*)-**2** with **3**, the ends of the growing chain are so far apart from one another that the anticipated polymer forms, whereas in the reaction of (*S*)-**2** with **3**, the 24-membered ring closes.

(*S*)-**2** **3**

4

A simple enantiomeric separation exploits the observation that with the given optically active diamine **3**, only the *S* enantiomer of aldehyde **2** gives rise to a macrocycle, whereas the *R*

enantiomer forms a polyimine. When the products of the reaction of (*R*)-**2** and (*S*)-**2** with **3** are subjected to column chromatography on silica gel, the macrocycle formed from the reaction of (*S*)-**2** with **3** is eluted with dichloromethane/toluene as an orange band, whilst the polyimine arising from (*R*)-**2** is left as a residue on the column. Stirring of **4** with hydrochloric acid liberates (*S*)-**2**, which may then be isolated enantiomerically pure.

The large-scale synthesis of racemic **2** is achieved from the commercially available 1,1′-binaphthyl-2,2′-diol.[9] This is first methylated with NaH/dimethylsulfate, and then formylated *ortho* to the methoxy groups with BuLi/DMF/HCl, before the methoxy groups are cleaved with boron trichloride. With the procedure described, **2** may be obtained optically pure without laborious recrystallization. This new enantiomeric separation of **2** is considerably less costly than the original synthetic route.[3]

The new macrocycle **4** should be able to form complexes of defined stereochemistry with up to four metal centers on both sides of the molecule.

Experimental Procedure

4: Racemic **2** (4.39 g, 12.8 mmol) and **3** (2.80 g, 13.2 mmol) were stirred together in dichloromethane (100 mL) at room temperature for 24 h. Monitoring by thin-layer chromatography (dichloromethane as eluent) showed complete consumption of **2**. The solvent was removed, and the residue chromatographed on silica in portions of 1 g (column 1 m × 3 cm, dichloromethane/toluene 9:1, temperature −18 °C). The band containing the macrocycle **4** is distinguished by its orange color. Yield: 1.40 g (1.35 mmol; 42% based on a single enantiomer of **2**); yellow powder, turning brown >270 °C. Macrocycle **4** contains approximately 0.5 moles of dichloromethane, which is in agreement with the ^{1}H NMR spectrum and elemental analysis. MS (FD, CH_2Cl_2): 1037 MH^+; ^{1}H NMR ($CDCl_3$, 250 MHz, TMS): δ = 12.62 (s, 4H), 8.42 (s, 4H), 7.34–6.72 (m, 40H), 4.96 (s, 4H): IR (KBr): $\nu_{C=N}$ = 1635 cm^{-1}.

2: For the liberation of (*S*)-**2**, the yellow powder **4** is dissolved in dichloromethane (50 mL) and stirred for 24 h with 5 *N* HCl (100 mL), after which the dichloromethane is distilled off. The dialdehyde (*S*)-**2** is then filtered off and washed free of acid. Purification is accomplished by column chromatography on silica/dichloromethane, with the isolation of 830 mg (2.42 mmol, 90%) (*S*)-**2**, $[\alpha]_{20}^{D} = -250$ (literature value: −248 [3]), (c = 0.3, CH_2Cl_2).

After elution of **4**, the polyimine can be washed from the column with acetone. Liberation of aldehyde from the polyimine with 5 *N* HCl affords a mixture containing all of the (*R*)-**2** and 50–60% of the (*S*)-**2** initially present.

Nanostructures Based on Molecular Materials. Edited by *W. Göpel* and *C. Ziegler*. VCH Verlagsgesellschaft/VCH Publishers, Weinheim/New York, 1992. X, 377 pp., hardcover DM 168.00.—ISBN 3-527-28416-8/1-56081-210-9

The control of structure and function of materials on the nanometer scale is becoming increasingly feasible and important. Scientists are fascinated by the prospects of molecule-based electronics, electrooptic elements, and sensor structures rivalling nature in size and selectivity. The notion of molecule-based nanostructures was the theme of a workshop held in Germany (in Monrepos Castle, Ludwigsburg) in October 1991, from which this book was developed. As with many emerging areas of interdisciplinary scientific activity, a definition of what constitutes nanostructures based on molecular materials is difficult. The scope of this book emphasizes the design of molecules for "molecular electronics", and their assembly in Langmuir–Blodgett (LB) films. Several additional contributions deal with liquid crystals, photoelectric processes, nonlinear optical systems, and sensors. Other fields of research activity on nanostructures, such as self-assembled monolayers, host–guest chemistry in layered compounds and zeolites, organic inclusion chemistry, and nanocomposites, are not covered in detail. However, for those interested in a current overview of concepts and realized systems in molecular electronics, this book is a valuable resource. Most articles provide short reviews (some quite brief) on the author's research, with references to the original literature. Many readers would probably have appreciated a subject index.

An overview of the topics of the book (Göpel) presents an optimistic view on the rapid development of nanometer structures on a broad basis, including the controlled preparation of 0–3 dimensional structures, scanning probe microscopies, and important applications such as those mentioned above, as well as catalysts, ordered polymers, and membranes. The important difference between bottom-up approaches (based on molecular assemblies) and top-down approaches (based on high resolution patterning of solids and films) is also emphasized.

Electron transfer, both at low field ("molecular wires"), and resulting from optical or redox excitations, plays a key role in concepts of molecular electronic devices. Proteins from the photosynthetic center can teach us about electron transfer paths and how they can be turned on (Ulstrup). Once important features of the photosynthetic reaction center are understood, one can attempt to mimic its molecular machinery for solar energy conversion. Fujihira describes elegant developments in this field, including the assembly of electron acceptor (viologen), sensitizer (porphyrin), and donor (ferrocene) functions in LB heterostructures, and photoelectric conversion by these structures. Ambitious information processing schemes based on organic nanostructures functioning as molecular shift registers (electric field and optically driven) are described by Wilson. Layers that are of nanometer scale in one dimension only can be assembled with present technology, and can be interfaced to existing silicon devices; they can reduce space charge effects. Light driven molecular triads that represent cellular automata could form the building blocks of computing networks, as discussed by Roth. Problems such as the probability of errors as a function of energy differences of the electronic states involved might require the design of sophisticated triads where the center group can be modulated.

The transition from conventional microelectronics towards molecule-based electronics is envisaged as occurring through an increasing contribution of molecular components to the total system (Näbauer). Molecular electronics is expected to make possible greater integration, lower power consumption, and faster switching times, and to allow simplified fabrication. This latter assertion remains to be demonstrated, given the inherent problem of how to interface with individual moleules. Lithographic techniques have recently been refined to such an extent that quantum dots and wires could be fabricated (Jay), and similar techniques should make it possible to pattern thin films of organic molecules, provided the lithographic technique is compatible with the organic systems.

Molecules with second-order and third-order optical nonlinearities can be understood and possibly predicted from quantum chemical calculations (Bredas, Ratner). Various push–pull molecules with high first-order hyperpolarizability and polyacetylene oligomers with third-order response are described. In many cases the theoretical predictions of trends are in reasonable agreement with experiment. Elegant self-assembly techniques have been used by Marks to form multilayer thin films for second harmonic generation.

In addition to wires, molecular switches are basic components of potential molecular electronic devices. A collaboration between several groups described by Schaumburg et al. aims at developing molecules which can change under external influence to a metastable state with suitable lifetimes and distinct properties that permit "read" operations. Interesting examples include photo redox switches (e.g., ferrocene-Ru(bpy)$_3$ changes its fluorescence on oxidation), and push–pull systems containing bianthrone for optical switching.

As mentioned above, this book emphasizes the Langmuir–Blodgett technique as a means of fabricating molecular-scale thin films. Peterson discusses the role of parasitic capacitance, defects, and other parameters in films intended as rectifiers, and proposes optimized structures based on poly(phenylenevinylene) for this purpose. Supramolecular assemblies based on LB films of amphiphilic porphyrins and phthalocyanines, made by using ordering principles to achieve face-to-face dimers and flat ionic networks, are discussed by Palacin. LB films are also of interest for aligning liquid crystals (Wei). New developments in the design of ferroelectric liquid crystals and LB films with spontaneous polarization are reported by Blinov.

Molecule-based materials that have a small band gap and an intrinsic conductivity, and can be doped to form n- and p-type materials, are classified as intrinsic molecular semiconductors (Andre). An example is the radical lutetium bisphthalocyanine, which has been used in field effect transistors. Discotic mesophases are interesting liquid crystalline systems that offer enormous flexibility in the design and physical properties of the disk-like cores which are stacked together. For example, phthalocyanines with alkyl side chains form a spine of aromatic cores favoring one-dimensional charge transport (Simon), while binuclear complexes of fatty acids with transition metals have related but distinct features (Marchon). The latter can also form lyotropic mesophases and gels in hydrocarbon solvents.

The last part of the book adds several useful articles on methods for the characterization of complex structures such as

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

those described earlier. These include current–voltage measurements of partially ordered metal/functionalized polythiophene/metal structures (Umbach), and the characterization and modification of molecular materials by scanning tunneling microscopy (Rabe). The morphology and electronic structure of conducting polymers and the structure and dynamics of monolayers of long-chain alkyl derivatives are being studied with the latter technique. Investigations of molecular packing, epitaxy with the substrate, defect and domain mobility, and the ability to modify materials on the nanometer scale will be of critical importance for the rational design of thin film structures. An important aspect of nanoscale materials is their chemical characterization, e.g., to obtain information about composition, valence states, and molecular energy levels. Photoemission spectroscopy provides detailed information on these aspects, with nanometer vertical sensitivity and lateral resolution at the micron scale. A useful overview of the technique and examples, including conjugated polymer films on metals, is given by Salaneck. The final chapter by Göpel deals with the preparation of molecular thin film structures by vapor deposition and their characterization under ultra-high vacuum (UHV) conditions, in particular the changes of structural and electronic properties observed when one varies the coverage from submonolayer to monolayer and multilayer thickness, and on exposure to gases such as oxygen. Electron energy loss, photoemission spectroscopy, and conductivity measurements of molecular sandwich structures such as phthalocyanine films are discussed.

In summary, this book provides a timely overview of research activities and concepts in the field of molecular electronics and will be useful to readers with various interests.

Magnetic Resonance Microscopy. Edited by *B. Blümich* and *W. Kuhn*. VCH Verlagsgesellschaft, Weinheim, 1992. X, 604 pp., hardcover DM 268.00.—ISBN 3-527-28403-6

Magnetic resonance (MR) microscopy is an old idea which has only recently started to attract increasing interest. It arose out of the rapid development of MR tomography for medical applications, but it was not until quite late that efforts to adapt the MR imaging principle to observe small volumes with high spatial resolution were begun. The technique that has developed from this work not only gives high resolution in the μm range, but has the further advantage of "speed". Thus, unlike routine MR imaging in medicine, it is possible to obtain images from substances with large natural linewidths (solids in the extreme case) with useful spatial resolution. These two properties of an MR microscope make possible a wide variety of applications.

This book collects together the papers presented at the first International Conference on MR Microscopy, held in September 1991 in Heidelberg. Thus it is not a textbook in the conventional sense, but gives a picture of the state of the art in this relatively new field. The contributions are grouped in five chapters.

The first chapter deals with the fundamental principles of forming images of substances with large natural linewidths. All the authors are concerned with the same subject, and consequently some repetition is unavoidable. In the second article of this chapter W. S. Veeman gives a lucid explanation of the problems of MR imaging of solids and the various approaches to solving them. Readers with a particular interest in the theory are well served by the article by R. Kimmich, which explains in detail many different ways of generating three-dimensional images. Those who make the effort to work carefully through this article will then have an understanding of how "simple" experiments can yield images of solid samples, and how even chemical shift imaging is possible. The chapter ends with two interesting articles on imaging by electron spin resonance (ESR).

The second chapter is concerned with applications of the various imaging techniques to polymers and other solid-like substances, and indicates the present limitations on resolution. Although there is much repetition, the articles contain important information, for example on the problem of artefacts caused by inclusions in solids, which can make the experiments difficult to perform successfully. There are also interesting contributions describing dynamic studies of processes such as photopolymerization and the imaging of "chemical waves".

The third chapter deals with measurements of flow and diffusion. Everyone involved in carrying out flow and diffusion experiments (including routine tomography measurements) will benefit from the help with theoretical and experimental problems offered by these articles.

The fourth chapter shows, with examples of the images obtained, how the high resolution capability of MR microscopy is being applied to studies of plants.

The book concludes with a chapter showing how the high spatial resolution of MR microscopes and the very high sensitivity attainable by using high magnetic field strengths can be used in biomedical research. Possible applications include those based on imaging of heteronuclides, and localized spectroscopy of very small volumes (also by ESR spectroscopy).

Who will benefit from this book? Newcomers to MR microscopy will not find it easy to get to grips with the methodology if they start here; they should first learn something about conventional MR imaging before reading this book. On the other hand, the reader wishing to learn about the potential uses of an MR spectrometer for the imaging of small specimens will find all the relevant techniques and experiments described here. This book cannot, of course, offer a systematic and exhaustive treatment of the capabilities and problems along the lines of a textbook. Here it might have been useful if the editor had supplied an introduction or a summary at the end of each chapter. Also the omission of the names of the authors of the individual contributions from the list of contents is rather unhelpful.

Chemistry and Crystal Growth

Jürg Hulliger*

Dedicated to Professor Hanns Thomas Arend on the occasion of his 70th birthday

Single-crystal materials, along with other forms of condensed matter (ceramics, polymers, liquid crystals, etc.) are fundamental to modern technology. The basic research and production of new materials with "tailored" solid-state physical properties therefore necessitate not only chemical synthesis but also the production of single crystals of a particular morphology (either bulk or thin layer crystals) and well-defined crystal defects (doping). In this review, an attempt is made to broaden the traditional synthetic concept of chemistry to the process of single-crystal synthesis. The methods of the resulting approach, which takes into account the specific properties of solid materials, are discussed and illustrated by experimental set-ups for the solution of a range of problems in chemical crystallization. Also included is recent work on the growing of single crystals of high-temperature superconductors, organic nonlinear optical compounds, and proteins.

1. Introduction

Solve et Coagula![1]

1.1. Chemistry and Crystal Growth: The Evolution and Significance of Crystallization

The endeavor to transform liquid and gaseous substances into the solid, pure state, thereby immobilizing them (coagulation), permeates the whole of chemistry, from the early uncertain attempts of the alchemists[1, 2] to present day methods of purification and crystal growth (Fig. 1).[3, 4] Coagulation, in the modern sense, means the bonding of atoms, ions, and molecules to form supramolecular solid-state structures.[5] Therefore, the formation of crystal nuclei of molecular substances would seem to be an ideal case of molecular self-organization,[6] in which the generation of a multiplicity of system-determined morphological forms can be interpreted, for example, within the framework of pattern formation theory.[7]

In the course of the development of chemistry, chemists have been primarily concerned with the synthesis of low molecular weight and macromolecular substances and the building up of extended solid-state structures, basically by molecular accretion. This led to the fact that "crystal nucleation and growth ... remained virtual areas of darkness on the map of the chemical knowledge".[8] Somewhat belatedly, great interest in supramolecular chemistry became apparent very recently. This has been strongly motivated, for example, by the development of functional solid materials (for molecular electronics,[9] for sensors,[10] and for applications based on their mechanical and other properties[11]). Traditionally, however, the physical properties of single-crystal materials (e.g., cooperative phenomena such as magnetism,[12] ferroelectricity,[13] or superconductivity,[14] etc) did not occupy the center of interest. In this context Lüttringhaus commented:[15] "The more chemistry expanded, the more the chemist concerned himself with chemical reactions, and the less with the state of his substances. In particular, he entrusted the study of crystals to crystallographers or structural physicists."

When the anisotropy of physical phenomena in single crystals was discovered, the peculiarities of their physical properties, however, became a topic of physics. The Neumann Principle enabled an increasing number of properties represented by tensors to be qualitatively classified by point symmetry groups.[16] The direction of solid-state physics had been pointed towards the "high tech" age by important discoveries including the technologies of high frequencies, semiconductors, magnetic storage, and lasers, and by the physics of solid phases characterized by nonlinear properties. This could not have been contemplated without experiments with increasingly complex single crystals. The necessary crystal growth technique had taken its place in the field of crystal physics alongside crystallography and experimental mineralogy.

Significantly, the above passage can be found in the introduction to general laboratory practice (crystallization) in Volume 1 of the textbook *Methoden der Organischen Chemie* (Houben-

Weyl);[15] crystallization had not become a theme of modern chemistry. Obviously, crystallization processes have always played an important role in chemistry, and crystallization has been exhaustively described in the older chemical literature.[17, 18] Nevertheless, crystallization, in the conventional chemical sense, is merely a useful laboratory technique even today, whereas crystal growth in the true sense, that is, the science of producing large single crystals for a particular purpose, is a topic mainly found in the field of physics research. A glance at the many general chemistry textbooks available today reinforces this impression (Scheme 1). On average, the subject of

Scheme 1. References to crystal growth in chemical textbooks: 60 recent general textbooks of organic, inorganic, and physical chemistry were searched for references to crystallization, recrystallization, and crystal growth [19]. The histogram shows the frequency of these references. S = number of pages on crystallization (K); n = number of books: out of approximately 43000 pages, about 50 pages covered this theme ($c_K \approx 0.12\%$). If the c_K value is compared with the corresponding value of 50 old *organic* chemistry textbooks, the value of c_K today is considerably smaller.

crystallization forms only about 0.1% of the total.[19] The majority of current chemistry textbooks do not describe it at all, nor do they describe the solid-state properties of the interesting types of materials mentioned above. (The review of well-known chemical journals (1968–1991) gives a similar picture.) Compared with textbooks written 20–40 years ago, the relative amount of space devoted to the special science of crystallization has clearly decreased. One can only assume that the situation with respect to solid-state chemistry could be improved; however, in a recent summary of views on the theme "Is Everything O.K. with Solid-State Chemistry?"[20] it is stated: "... there is no textbook on solid-state chemistry adequate for modern science...",[20] and the reviewer summarizes the results of an opinion poll involving 50 specialists in solid-state chemistry:

"It is high time to recognize that besides classical chemistry, which deals with individual molecules and atoms or ions,

Jürg Hulliger was born in 1953 in Zürich. He studied chemistry at the ETH, Zürich, and graduated in physical chemistry. He took his Doctorate at the anorganisch-chemisches Institut der Universität Zürich under Prof. J. H. Ammeter. After spending a year at the Pennsylvania State University, he succeeded Prof. H. Arend at the ETH, Zürich, at the Institut für Festkörperphysik (later Quantenelektronik). There, between 1987 and 1993, he led a group working on crystal growth. In 1993, he accepted the offer of a Professorship at the Institut für anorganische, analytische und physikalische Chemie der Universität Bern. His research fields are: chemistry, crystal growth, and physical properties of inorganic and organic solid materials, and the development of special methods for the synthesis of crystals and for the in situ characterization of crystal growth.

there exists chemistry where chemical transformation has a collective character. This chemistry cannot be equated with classical chemistry nor extrapolated from it."[20]

In the case of solid-state chemistry, the collective character of the process which leads to the formation of complex solids is stressed, but, even in this connection, the general importance of processes and mechanisms of crystal growth and their characterization by instrumental analysis have not been mentioned. We have to say, with no exaggeration: solid-state properties (as considered by physics) in association with crystal growth (synthesis of single crystals—as distinct from molecular synthesis or the usual kind of synthesis of solid materials) has not been the concern of chemistry, or has only been on the fringe.

On the other hand, how are developments progressing in the field of materials research (see, for example, the recently founded (1988) journal *Advanced Materials*, VCH, or papers in *Issues and Opportunities in Materials Research*[21]) whose success depends to a large extent on the contribution from chemical synthesis? The concept of crystal engineering was given an identity after 1945 by von Hippel,[22] and in its further development (Hahn,[23] Kitaigorodski,[24] Arend,[25] Willet,[26] F. Hulliger,[27] Kaldis,[28] Leiserowitz et al.,[29] Schmidt,[30] McBride et al.,[31] Desiraju,[32] Etter,[33] Fagan et al.,[6] etc.) is to be regarded as a solid-state analogue of "molecular engineering", the well-known system of synthesis. One of the great challenges of modern chemistry thus concerns the reinforcing of ways of thinking about supramolecular structures and developing methods for their construction, in particular the synthesis of single-crystal materials with "tailored" physical properties (see Tables in refs. [3, 34]).

In this context, a new topochemical subject known as nanochemistry[35] deserves special attention (see, for example, Ozin[36]). Thus, a series of methods of extremely wide application are available to the modern grower of crystals, enabling the targeted construction of solid-state structures or molecular syntheses, impossible by the classical route. These include (in addition to the possibilities discussed by Ozin,[36] and the fullerene syntheses) molecular beam epitaxy (MBE),[37] metal-organic chemical vapor deposition (MOCVD), chemical beam epitaxy (CBE)[38] CVD, or plasma-assisted deposition techniques, the Langmuir–Blodgett process,[39] and special applications of topochemistry.[40] There is also an analogy between the mechanistic concepts of molecular synthesis and controlled crystallization. Kahr et al.[31], for example, have compared the production of true growth locations of a crystal nucleus with the starting point of a radical chain reaction (see Section 2.1). The term chemospecificity in crystallization corresponds to the selective choice of a particular guest molecule, regiospecificity is shown by alteration of crystal habit, and stereospecificity in the spatial distribution of crystal defects.

Modern achievements in synthetic chemistry such as superconducting oxides,[41] magnetically-ordered organic or organometallic compounds,[42] fullerenes and their derivatives,[43] and organic, strongly nonlinear, optical compounds[44] are of interest for their distinctive solid-state physical properties. The detailed investigation of these subjects requires well-defined single crystals, and, increasingly, also epitaxial thin films. In general, a detailed investigation of the physical properties of a new substance discovered by classical synthesis is only possible after single-crystal samples of known real structure have been prepared. Single crystals, epitaxial thin films, and fibers made from an increasingly large number of different compounds are today undeniably a part of the fundamental research into material science and technology. Here, where success largely depends on an interdisciplinary method of thought and work, the elucidation of complex plans of materials research requires the interlinking of chemistry and physics. The modern science of crystal growth is active in the promising areas in which chemistry and physics overlap, that is, where growth processes are investigated, and special methods for producing solid single crystals, epitaxial layers, and fibers with tailored properties are developed.

To quote but one example: "Materials are really the key to new solid-state lasers" (Chai).[45] Following the first phase of development of solid-state lasers in the 1960s and 1970s, a more vigorous search for other matrix lattices has recently been started,[46] which, along with high power short wavelength semiconductor laser diodes, has the main aim of producing tunable light sources and "up-conversion" systems.[47] This involves, for example, the crystal growth of fluorides ($LiYF_4$, KYF_4, etc.) and oxides (silicates, garnets, etc.) as well as fluoride glasses.[48]

From today's viewpoint, the basic question for chemists is to what extent chemistry should integrate solid-state properties and single-crystal synthesis as one of its new leitmotifs into research and teaching in the future.

Single crystals play a decisive role not only in the context of complex materials research. Single-crystal X-ray structural analysis still represents the definitive proof of structure for the chemist. The discussion of molecular and other properties depends upon it, especially for a comparison with structures calculated from quantum chemistry.

Based on this outline, two subjects are dealt with in the following sections: 1) an introductory description for the chemist of the basic principles of crystallization and crystal growth from the modern viewpoint (see especially refs. [3, 34, 49]), and 2) a practical discussion of methods which can contribute to progress in mass crystallization (on the laboratory scale), or the production of small single crystals (for structural investigations), and the preparation of larger single crystals (for the investigation of the physics of the solid state).

1.2. From Crystallization to Single-Crystal Growth

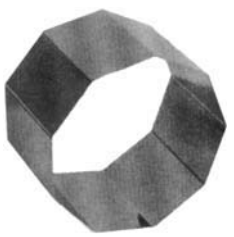
Crystallization is one of the most perfect purification operations...[17b]

In practice, crystallization was, for organic chemistry, one of the most effective methods of purifying substances for a long time, especially for the separation of enantiomers (resolution of racemates). With the development of chromatography and other methods of separation (including chiral stationary phases), crystallization itself lost some importance as a laboratory technique, which must be the main reason why it is not treated at all in the newer textbooks of general chemistry, or at least only briefly, although methods for the preparation of small single crystals or polycrystalline materials, mainly for complete crystal structure analysis by X-ray or neutron diffraction, have remained in use.

The special techniques summarized in Scheme 2, for which crystallization processes were developed or used, have attained importance in chemical research and technology. Industrial crystallization is undoubtedly most important.[50] Because of the necessity for quality control of bulk production, as well as a technically feasible user-friendly crystal morphology[51, 52] and defined particle size distribution of agglomerates,[53] the process control system must be based on extensive knowledge of the mechanisms of nucleation and growth for a given hydrodynamic regime and set of surface-active agents (crystal habit modifiers[62]). In the industrial production of mainly large single crystals with defined real structure, extremely pure starting materials are required on the one hand, and very closely controlled crystal growth technology on the other (Fig. 2).[2, 4, 55, 63]

1. Industrial crystallization [50–53]
   Sales of a) polycrystalline bulk materials in which each product is estimated to exceed 10^6 t per year, for example, NaCl, urea, sugar, or zeolite Linde A with 10^5 t per year [54]; b) single-crystal production of elements (e.g., Si with no dislocations: 10^4 t per year) [55] and compounds (e.g., cubic stabilized ZrO_2: 300 t per year) [56]
2. Determination of structures of crystals and molecules
   (about 8000 new crystal structures per year)
3. Separation, purification, and purity determination of fine chemicals, pigments, and natural products
4. Racemate separation and determination of absolute configurations [29, 57]
5. Crystallization of macromolecular substances (proteins, polymers) [58, 59]
6. Measurement of physical properties by spectroscopic and other physical methods
7. Biocrystallization (also in the medical field: osteoporosis (see ref. [3]: kidney stones and gall stones)) [60]
8. Synthesis under topochemical control [40, 61]
   (e.g., cracking catalysts based on zeolites [54])

Scheme 2. Areas where crystallization processes are important in chemical research and technology.



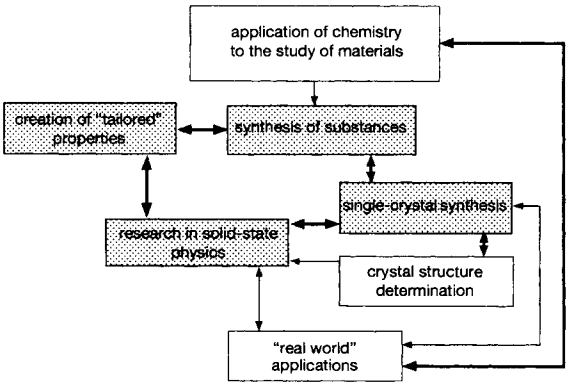


Fig. 2. Special technology ("edge-defined film-fed growth") for the economic production of silicon solar cells. Eight- or nine-sided thin-walled single crystals, several meters long, are obtained from the molten material by crystal pulling [63].

In the laboratory, the elucidation of structure has had to take second place in view of the demand for small single crystals (linear dimensions d less than one mm); about 8000 new crystal structures per year currently result either from the purification of various compounds or the separation of racemates. As a more detailed discussion of all recent relevant fields would go far beyond the scope of this article, the reader is referred to the recent literature on this subject in some cases.

To recapitulate, most types of chemical crystallization can be divided into three classes, which differ in the method used: a) large-scale production of small crystals, b) crystallization of individual single crystals (d less than one mm), and c) growth of single crystals (1 mm $\lesssim d \lesssim$ 1 m). As modern materials research and crystal growth are oriented towards the same stages of the processes, this classification will be used for the planning of Section 3. That is to say, for newly synthesized compounds, the desired solid-state properties are at first investigated with polycrystalline (for example, ceramic) and small single-crystal samples, and are then optimized (see Scheme 3) by developing specific methods of crystal growth (bulk, thin film, and fiber single crystals). From the viewpoint of materials research, the usual synthetic methods at this point give way to methods of single-crystal growth to achieve the desired solid-state properties.

Scheme 3. Chemistry and crystal growth: interlinking of the processes in materials science including single-crystal synthesis.

In view of the continually increasing number of initially poorly characterized compounds, the question of simple but effective strategies of crystallization arises. A cost estimate ("man-years investments") based on "response theory" (Tiller, 1991)[49] shows that the implementation of the "black box" assumption (a current view of crystal growth!) leads to an "art-based technology" (crystal growth = a collection of recipes) based on the multidimensional parameter space j + k, where j = the number of materials and k = the number of experimental parameters, whereas a "system approach", which always presupposes some sort of prestructuring "clustering", leads to a "science-based technology" (strategies for proceeding with a minimum of experiments). A proposed plan for an intelligently organized laboratory crystallization process is discussed from a practical point of view in Sections 3.2 and 3.3. This contains the exploratory methods of crystallization and the advanced methods of single-crystal growth.

All methods must be termed exploratory when they systematically use a phenomenological approach with a minimum of experimental work, for example, by the deliberate use of self-regulating mechanisms. In many cases, crystals produced in a first stage are used as nuclei in a second stage of advanced crystal growth. The so-called temperature-difference method of solution growth (see Section 3.2) should be regarded as a simple example of a "science-based technology". Here it should be mentioned that H. T. Arend contributed greatly to the research and development work on exploratory strategies of crystallization during the course of his activity as a crystal grower at the Eidgenössische Technische Hochschule (ETH), Zürich.

In the future, the electronic storage and handling of data concerning methods and materials should provide the chemist

with a database, in which the knowledge about crystallization is stored ("computer knowledge base for crystallization"[64]). A first attempt at this has been in existence since 1990,[64] and it is to be hoped that its usefulness and shortcomings will become apparent through continual use. However, data systems will certainly not be able to replace the specialist in the foreseeable future. If a problem is too difficult for the crystal growth expert to solve, existing electronic strategies will also fail. "The expert then falls back on his intuition and far more wide background knowledge."[64] There is another electronic data bank that stores information on the crystallization of biological macromolecules.[65] This contains data on more than 1000 crystalline forms of over 600 biological macromolecules. The use of this when attempting systematic protein crystallization (e.g. "successive automated grid searches") is discussed by Weber.[58]

In addition to the electronic media, it should not be forgotten that a rich experience of the solution of crystallization problems exists, for example, in the older organic chemical literature. This can now be extended in a methodical manner.[15, 18]

This article has so far been aimed at throwing some light on the significance of crystallization in chemistry, and preparing the reader for the specific nature of the later part of the discussion which describes experiments in modern crystal growth. After a general outline of the theory (Section 2), a very practically oriented systematic approach is set out in Section 3. In Section 4, the crystal growth of three classes of materials of topical interest is briefly discussed.

2. Fundamentals of Crystal Growth

2.1. Energetics and Kinetics of Nucleation and Volume Growth

A crystal is nothing but a large molecule.
Van Vleck[66]

Crystallization leads to the buildup of supraatomic and supramolecular ordered states, whose microscopic real structure and macroscopic morphology are determined by energetic, kinetic, and transport (mass and heat) mechanisms; thus, lattice components are attached. This means that, as a nonequilibrium process of a heterogeneous system ($\Delta G(\mathrm{N} \rightarrow \mathrm{C}) = G_\mathrm{C} - G_\mathrm{N} < 0$; C: crystal, N: nutrient phase), the final condition of a macroscopic crystal is the result of a transition process due to a local thermodynamic deviation from equilibrium, $\Delta G(x, y, z; \Delta p, \Delta T, \Delta X_i)$, the removal of the heat of crystallization, the inflow of lattice components, and the outflow of dispersive and other components which are not taken up into the lattice or are only taken up in small amounts.[49] If the crystal growth takes place at a high or low temperature (or pressure), attention must also be paid to defect equilibria on changing to normal conditions (e.g. Schottky defects[67]). It is today widely recognized that crystal growth must be regarded as a complex process (Neuhaus[68]) whose mechanism is divided into stages. This has consequences for the experimental methods of producing single crystals with "tailored" physical properties.

Kinetic effects (in processes involving a large deviation from equilibrium, e.g., in MBE or MOCVD technology[69]) make possible the buildup of heteroepitaxial layers,[70] superlattices, or mechanically strong strained thin films,[70, 71] and also affect the distribution equilibrium of dopants[49] and dominate the morphology.[72] An example of kinetically controlled crystal growth is provided by optically anomalous crystals in which a regular incorporation of foreign components or a disorientation of the lattice components disturbs the symmetry of individual growth sectors.[31]

Whereas, in the 1960s and 1970s, crystal growth was mainly studied phenomenologically,[73] during the 1980s the development of new experimental techniques for investigating growth in situ introduced the possibility of "taking a picture" at the atomic/molecular level (transmission electron microscopy (TEM),[74] reflection high-energy electron diffraction (RHEED), low-energy electron diffraction (LEED),[75] synchrotron radiation and light scattering experiments at the crystal–nutrient phase interface (CNI),[76] scanning tunneling microscopy (STM),[77] and atomic force microscopy (AFM)[78]). Light scattering experiments have shown that, for example, in a supercooled melt, the growing crystal is surrounded by a partially ordered layer that can be several μm thick, depending on the degree of supercooling.[76] In situ observations of the properties of metallic clusters (Pt, Au, Pb) in vacuo have been carried out by TEM (video recording).[79]

Turning now to the theory,[73] (for historical information, see refs. [2, 34]) the early contributions of Gibbs (1878), Wulff (1895), Volmer (1926), Kossel (1927), Stranski (1928), and others have been fundamentally extended by the discovery of the energetically favorable growth by screw dislocations (Burton, Cabrera, Frank (BCF theory) 1949[80]), the treatment of morphological stability/instability criteria (Mullins and Sekerka, 1963[81]) for the crystal–nutrient phase interface, and the incorporation of impurities into the lattice (Burton, Prim, Slichter, 1953[82]). More recently, Monte Carlo methods,[83] "molecular modeling", and ab initio simulations (for Si, GaAs, noble gases, etc.)[84] illustrate space and time aspects of the growth steps at a crystal surface. Also, progress has been made in the calculation of the expected binding energy of macroscopic (*hkl*) surfaces[85] (for the general consideration of theoretical models, see literature quoted, for example, in ref. [3, 34]).

An understanding of the mechanism of homogeneous nucleation is of fundamental interest.[53, 86] Starting from the statistically disordered nutrient phase N ($T > T_{\mathrm{equilibrium}}$), the structure-forming self-organization of the components (Fig. 3) takes place in the supercooled or supersaturated state in several stages,[87] leading to a reaction principle (with a part played by molecular recognition mechanisms) whose elementary steps, infinitely repeated, lead to the "macromolecular" crystal. Homogeneous nucleation and crystal growth can be described in analogy to chemical reactions according to Scheme 4.[49, 86a] As an illustration of stepwise buildup by nucleation, Figure 3 shows structures calculated from quantum mechanics of associates and clusters ($\mathrm{Na^+(NaCl)_n}$) up to the formation of a "first" NaCl ordered structure of a unit cell (gas phase).[87a]

In the classical capillary approximation, the transition of small molecular agglomerates to clusters (C) of increasing size leads to the formation of a phase boundary surface (outer surface), for which the cluster formation energy ΔG_C consists of a volume and surface area term. For a nucleus, assumed to be

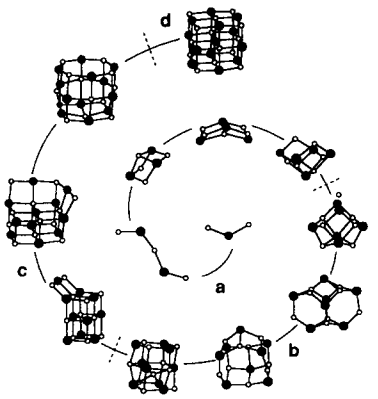

Fig. 3. Quantum-mechanical calculation of the stepwise development of structures leading to the formation of an NaCl lattice cell structure (from ref. [87a] with additions from the author). a) Small aggregates; b) cluster formation; c) transition to an NaCl lattice structure unit; d) first "unit cell".

spherical, in solution, ΔG_C[53] is described by Equation (a), where the cluster radius r^* [Eq. (b)] represents the critical size, and ΔG_C^* [Eq. (c)] represents the activation energy to overcome the critical size of the nucleus. The molar volume of the cluster is represented by v; $\sigma = (X - X_o)/X_o$ represents the relative supersaturation,[88] X_o represents the equilibrium concentration, γ represents the interface surface energy per unit area, and k_B is the Boltzmann constant.

$$\Delta G_C = \Delta G_C(r) = -\frac{4\pi}{3} r^3 [k_B T \ln(\sigma + 1)]/v + 4\pi r^2 \gamma \quad \text{(a)}$$

$$r^* = 2v\gamma/[k_B T \ln(\sigma + 1)] \quad \text{(b)}$$

$$\Delta G_C^* = 16\pi v^2 \gamma^3/[3k_B^2 T^2 \ln^2(\sigma + 1)] \quad \text{(c)}$$

The transition into growth of macroscopic crystals (Reactions 3 and 4 in Scheme 4) can take place by energy fluctuations in the system; thus, r^* and ΔG_C^* are overcome.

1) Formation of associates from monomer A

$A + A \rightleftharpoons A_2$
$A_2 + A \rightleftharpoons A_3$
...

2) Buildup of clusters

$A_n + A \rightleftharpoons A_{n+1}$
...
(coalescence of clusters also possible)

3) Formation of critical nucleus A_m^* and its growth

$A_{m-1} + A \rightleftharpoons A_m^*$
$A_m^* + A \rightleftharpoons A_{m+1}$

4) Molecular accretion on macroscopic crystal surfaces (Ω)

$\Omega + A \rightleftharpoons \Omega A$

Scheme 4. Reaction scheme for homogeneous nucleation (see text).

According to Larson et al.,[89] consideration of surface curvature anisotropy (for example, by the attachment of clusters to macroscopic surfaces) leads to a thermodynamic stabilization of small clusters with $r < r^*$. Therefore, in real systems (in the supersaturated state), there exists a specific distribution of metastable or stable but subcritical nuclei of varying size r. Since r^* depends on σ, the construction of the first ordered lattice cell does not in general lead to a production of the critical nucleus size. Statistical thermodynamic models confirm the capillary approximation [Eq. (a)] down to cluster sizes of approximately 10–30 atoms/molecules.[86a] Gas-phase experiments by Volmer et al. have shown that condensed droplets of organic compounds have a diameter of $r^* = 0.8$–1.5 nm, and $n = 30$–130 molecules,[50] which would be expected to be a realistic description of the capillary model. For liquid–solid phase systems, there is some experimental data about the size distribution and concentration of clusters, but a great lack of structural information. The size of clusters in solutions is in the range 1–10 nm, with up to 1000 molecules.[89]

According to Boltzmann statistics, the number of clusters that exist in the state with ΔG_C^* is proportional to $\exp(-\Delta G_C^*/k_B T)$. The nucleation rate J [$cm^{-3} s^{-1}$] therefore follows Arrhenius's Law. This is true when the activation energy for the diffusion is appreciably less than ΔG_C^*, as, for example, for molten materials, in which nucleation takes place just below the liquidus temperature. Including the contribution made by diffusion ΔG_D^*, J (for solutions) is given by Equation (d), in which v_L represents the molar volume of the solvent, and h is Planck's constant.

$$J = \exp(-\Delta G_D^*/k_B T) \exp(-\Delta G_C^*/k_B T)\, k_B T/h v_L \quad \text{(d)}$$

As shown by measurements by Tammann (1898) and others,[18, 34, 86b] $J(\sigma)$ can show a fairly sharp maximum, where the temperature range for maximum nucleation and that for maximum growth rate do not in general overlap to a great extent. In the crystallization of proteins, one of the main problems can be that conditions for nucleation and those for growth are optimized separately.[58]

In many systems, nucleation proceeds heterogeneously, as interactions with solid items of equipment or vessel walls reduce activation energy and nucleation temperature. If the critical nucleus size is reached, the continuing process of accretion of materials becomes the growth of macroscopic crystals (in analogy with polymerization reactions), for which various mechanisms can be effective within the CNI.[34, 73, 86b] Both experimentally and theoretically, the distinction must be made between growth on an atomically rough or smooth (in this case stepped) surface, and growth by means of screw dislocations. The step velocity v and the macroscopically measurable surface growth velocity R (R: linear or nonlinear) are functions of the supersaturation σ, and depend on the transport mechanisms; thus, lattice components are added, and are incorporated into the "kink position" preferentially for energy reasons. In the case of a growth mechanism driven by adsorption onto the growth surface and by screw dislocations (BCF Theory[80]) the growth rate R of macroscopic faces can be described (in solution) by Equation (e) where k_1 and k_2 represent kinetic, temperature-dependent constants.[90]

$$R = k_2 \sigma^2 \tanh(\sigma^{-1} k_1/k_2) \quad \text{(e)}$$

For small values of σ a parabolic rate relationship would be expected, and for larger values of σ it would be linear

(v is linearly dependent on σ). Detailed measurements[91] of $R(\sigma)$ and $v(\sigma)$ on, for example, KH_2PO_4, have shown considerable deviations from the expected parabolic relationship for small values of σ, attributed to the effect of foreign materials. Above a critical supersaturation value σ', the growth velocity R increases considerably (suppression of growth for a small deviation from equilibrium). This shows once again the importance of prior purification of materials before mechanisms of crystallization can be investigated and interpreted. Because specific impurities are active down to the ppm level, this presents no easy task for preparative and analytical chemistry. This helps to understand why, in some cases, even when seed nuclei are used and the supercooling and/or supersaturation is relatively large ($\Delta T, \sigma$), no crystal growth, or very slow crystal growth is observed. From general experience with solid materials of various types, it can be said that the problems of chemical crystallization are not with the crystal growth, but with the nucleation. This happens in many systems where nucleation takes place at a high degree of supersaturation, so that the volume growth proceeds too quickly. Separate production of seed nuclei for a later crystallization process is therefore to be recommended.

Foreign materials can reduce the rate of accretion, even without adsorption onto growth-active locations. When $k_0 < 1$ (Nernst distribution coefficient $k_0 = X_C/X_N$), the foreign material (including dispersive components) becomes concentrated in the vicinity of the growing faces,[34] which leads, for example, to a reduction in the liquidus temperature in accordance with the phase diagram of a two-component system (see Section 2.2, Fig. 6, Type I, III). Thus, when the temperature is kept constant (provided that the system is thermally homogeneous), the supercooling ΔT or the supersaturation σ decreases, and the growth proceeds more slowly. It is therefore useful to reduce the thickness of the diffusive matter transfer zone by a suitable flow profile in the nutrient phase, and thorough mixing throughout its volume. Regarding the incorporation of foreign material into the lattice, an increase in the concentration X_C due to kinetic effects is observed. Depending on the growth rate R and the hydrodynamic condition, $k_{kinetic} > k_0$, and in extreme cases reaches 1, where $X_C \approx X_N$. In analogy to the result of comparable work, the theory of Burton et al. gives the Equation (f),[82]

$$k_{kinetic} = k_{CNI}\,[k_{CNI} + (1 - k_{CNI})\exp(-R\delta/D)]^{-1} \qquad (f)$$

where D denotes the diffusion constant, δ the thickness of the crystal–nutrient interface (CNI), and k_{CNI} the Nernst distribution coefficient in the CNI (approximation: $k_{CNI} \approx k_0$).

The well-known rule that, in purification by crystallization, the crystallization process must take place slowly is therefore confirmed in one respect. Since too rapid a growth rate can lead to a macroscopic inclusion of nutrient phase, a suitably slow growth rate is always advisable (see earlier comment on nucleation at high σ values).

2.2. Phase Diagrams and a Systematic Classification for General Methods of Crystal Growth

Experimental crystal growth requires exact knowledge of the relevant phase diagram, at least in the region of existence ($\Delta p, \Delta T, \Delta X$) of the primary product to be crystallized. As the necessary thermodynamic data are known in relatively few cases, or their accuracy may be inadequate with respect to the values of p, T, X, limited-range phase diagrams often have to be specially determined under conditions comparable to those to be used in the crystal growth work (containers, purity requirements, time scales,[92] etc.). (For experimental methods, see ref. [93], and, for data, ref. [94].) In the thermoanalytical investigations, visual observation of the liquefaction and crystallization processes should be included. In this way, information is commonly obtained that may well be irrelevant in pure phase diagram work, but can be very important in crystal growth (existence of small amounts of undissolved solid materials or cloudiness, melt–solution segregation, morphological aspects, color effects during crystal growth, etc.). As an example from high-temperature solution growth, an experimental procedure is briefly described here. This was used as an exploratory technique (see Section 3.2) in the determination of growth conditions for the production of epitaxial layers of $KTa_{1-x}Nb_xO_3$.[95]

High-melting materials (e.g. ABO_3 perowskites) can be brought into solution by fluxes (that is, lower melting oxides or halides) at much lower temperatures than the melting point of the pure substances, and crystallized.[96, 97] Here, it is necessary to know at least part of the quasi-binary phase diagram (see Figs. 6, 7). Solution and crystallization processes for temperatures up to about 1200 °C can be investigated in situ by visual observation and/or thermoanalytical measurements by using the system shown schematically in Figure 4. By simultaneously using six platinum crucibles (diameter: 8 mm, $l = 15$ mm) illuminated with a fiber-optical light guide, morphological and chemical information can be obtained and color effects observed. In the case of the $KTa_{1-x}Nb_xO_3$ referred to above, this led to a simple determination of the phase diagram (Type I, see Fig. 6) with potassium fluoride as the solvent. Moreover, useful basic information for the later development of an epitaxial process[98] was obtained from experiments on $KTaO_3$ substrates, which were several mm^2 in size. The growth of the $KTa_{1-x}Nb_xO_3$ layers is accompanied by the formation of a strong blue color, noticeable even at the early stage of the growth process (Fig. 5).

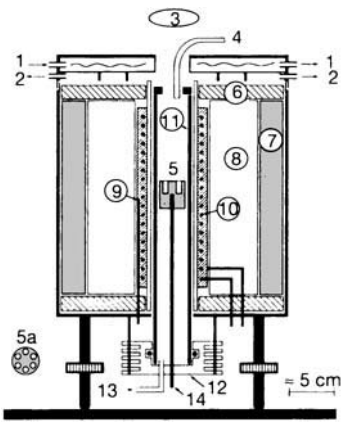

Fig. 4. Furnace for visual observation of dissolution and crystallization phenomena [95]. In the arrangement shown, six Pt crucibles can be charged with samples simultaneously. Alternative arrangement: Two crucibles + DTA. 1: Water cooling. 2: Exit for gaseous emissions. 3: Binocular microscope. 4: Quartz lamp for illuminating the samples. 5: Inconel 600 crucible container. 6–8: Insulation materials (ceramic powder and fiber materials). 9: Control thermocouple. 10: Kanthal A1 heating coil. 11: Inconel 600 or ceramic protective tube. 12: Replaceable floor plate (sealed). 13: Gas inlet. 14: Sample thermocouple. Maximum operating temperature: 1200 °C. (Example of use: see Fig. 5.)

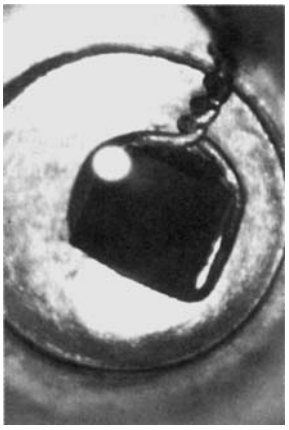

Fig. 5. In situ observation (see furnace in Fig. 4) of epitaxial growth of dark blue $KTa_{1-x}Nb_xO_3$ crystals on a $KTaO_3$ substrate from KF flux at 920 °C after 10 min (110) orientation with macroscopically rough growth surface [95]. Crucible diameter $\varnothing = 8$ mm.

Three phase diagrams (T, X, at constant p) are shown schematically in Figures 6 and 7 to help in understanding the later discussion of the crystal growth of many substances: 1) The two-component system A/B without formation of solid solutions, as a basis for solution growth from dilute or concentrated solution, 2) the melting diagram for crystal growth of a congruently melting compound AB from the pure melt or from the self-fluxing mixture (incongruently melting compounds are usually obtained from nonstoichiometric melt solutions, that is an excess of one of the components (self-fluxing mixtures)), and 3) the two-component system forming solid solutions $A_{1-x}B_x$, which requires special techniques for growing macroscopic homogeneous mixed crystals. The diagram illustrating the most commonly used solution growth method (Fig. 7) is discussed in more detail: In the A/B system (no solid solutions), to enable as wide a range of T (largest value of ΔT) on the solubility curve to be utilized practically, the eutectic temperature T_E should be reached at a low concentration of $X_{substance}$. Below the liquidus curve and adjacent to it, there is a metastable state, such that when this is crossed, spontaneous nucleation takes place. In the metastable region of the phase diagram, the reactions of Scheme 4 take place. These reactions have so far been very little investigated experimentally. A complex array of processes and conditions determine the width (ΔT) of this important zone. These include cooling velocity, hydrodynamic state, concentration of dissolved and undissolved foreign substances, type of solvent and extent of solvation, dwell times, etc. In the case of mass crystallization (see Section 3.1), the attempt should be made to cause nucleation in the system without too large a step beyond the metastable zone. If seed nuclei are used, it is advantageous to superheat the system, and then to keep it always within the metastable zone, so that controlled growth is then possible without the formation of secondary nuclei.

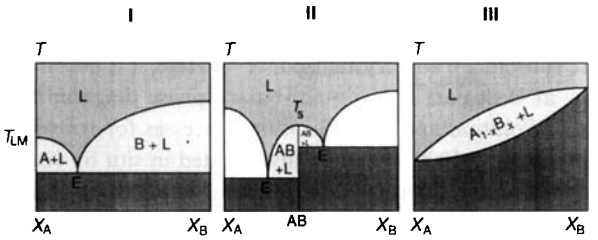

Fig. 6. (T,X) Phase diagram for two-component systems (A/B) as a basis for: solution growth of B (I; see also Fig. 7); the melt growth or flux growth of a congruently melting compound AB (II); the growth of mixed crystals $A_{1-x}B_x$ (III). L: liquid phase, E: eutectic point; T_{LM}, T_S: melting points of solvent and of substance AB, respectively.

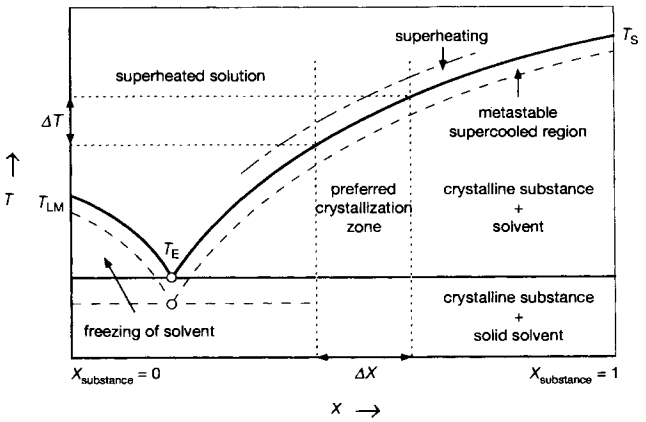

Fig. 7. Phase diagram (T,X) of solution growth, showing optimum crystallization zone (ΔT,ΔX), and metastable region of supersaturation and of superheating. The region of freezing of the solvent is shown on the left of the diagram (see Sections 3.1.1 and 4). T_{LM}, T_S: melting points of solvent and substance S, respectively; T_E: eutectic temperature.

With regard to the classification of crystallization processes to be described later, it should be said that if crystallization is regarded as a phase change of a system of one or more components, this leads to a systematization of the general methods (Laudise,[99] Arend[100]). Sections 3 and 4 give more details of individual processes.

2.3. Morphology as a Property

Growth processes lead not only to the formation of the real structure of a crystalline solid (which largely determines its physical properties), but also to the creation of a morphology, which determines the real structure by means of the growth mechanisms of the individual faces, and also creates additional properties. The scale of this effect extends to large three-dimensional crystals with specific crystal habit, two-dimensional epitaxial thin films, one-dimensional fiber crystals or whiskers, and "zero-dimensional" "quantum dots". For about 15 years, methods of two-dimensional crystallization (liquid-phase epitaxy (LPE), MBE, and MOCVD) have enabled functional semiconductor structures to be produced.[70, 71] Homo- and heteroepitaxy increasingly includes other classes of materials such as oxides (ABO_3 ferroelectric materials,[98, 101] magneto-optic garnets[102]), and even organic compounds. Also in the area of three-dimensional crystals, process control of the morphology has become important. The Stephanov process,[103] for example, enables crystals of sapphire and $LiNbO_3$ in the form of plates, tubes, and other shapes to be pulled. Silicon single crystals for solar cells have recently been produced with a profile in the form of a thin-walled polygon (see Fig. 2).[63]

In industrial mass crystallization and general crystal growth, those molecular processes are of interest which lead to the formation of a specific growth morphology. Here, the distinction

must be made between mechanisms for pure substances and those influenced by surface-active [(*hkl*)-specific or site-specific] foreign materials. For pure substances, the morphology is determined by stability/instability criteria in the crystal–nutrient interface (CNI), and is essentially controlled kinetically. Depending on the extent of supersaturation and on the mass and heat flow, polygonal, hopper-shaped, dendritic,[49] and irregular (even fractal)[7] growth is observed (Fig. 8).[72]

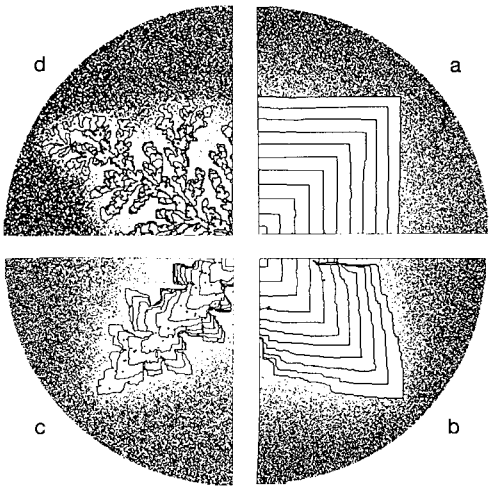

Fig. 8. Monte Carlo simulations of growth in two dimensions as a mathematical function of the driving potential (from [72]). a) Polygonal surface growth, b) transition to hopper-shaped growth, c) dendritic growth, d) irregular growth.

In general, the end morphology of a faceted crystal is determined by the slowest growing faces. The theory of Hartman and Perdok can be used to predict flat crystal surfaces ("periodic bond chains", so-called PBC vectors;[104] for new developments see ref. [85]), according to which, the (*hkl*) faces with the lowest energy of attachment of a growth layer show the lowest face growth rate R.

Even small concentrations (ppm) of suitable foreign substances can influence growth, for example, by molecular recognition mechanisms, and can retard rapidly growing surfaces. With the synthesis of tailored additives ("habit modifiers"), the formation of a desired crystal habit or form of agglomerates is realized in industrial crystallization,[52, 62b] enabling the properties of a large number of products in powder form to be controlled (purity, bulk density, dissolution rate, etc.). The activity of foreign substances is deduced experimentally from the form of the function $R(\sigma, X_{\text{foreign substance}})$. Here, it is certain that in situ atomic force microscopy will yield interesting results within the next few years.[78] As well as the effect of the foreign substance on R, the effect on the nucleation rate J is of practical as well as theoretical interest. The majority of the well-known crystallization problems in organic synthetic chemistry must to some extent be caused by small or large amounts of mainly unknown foreign substances.

Considerable progress in the understanding of molecular recognition processes achieved during the last decade,[29, 35] have, according to Davey et al., had the result that "tailor-made additives for the control of specific processes are now a reality".[62b]

3. Experimental Methods of Crystallization

Crystal growth is a science and an art. The scientists' role in the crystal growth process is that of an assistant who helps molecules to crystallize. Most molecules, after all, are very good at growing crystals. The scientific challenge is to learn how to intervene in the process in order to improve the final product.
Etter[105]

Following the classification made in Section 1, the techniques of mass crystallization and of true methods of crystal growth (exploratory and advanced) are treated separately. We shall therefore collate the crystallization techniques described in the chemical literature, briefly discuss them, and hence elucidate the basic principles of the most commonly used process of solution crystallization. The obvious consequences for methods of mass crystallization on the laboratory scale are set out in Sections 3.1 and 3.2. As examples of bulk growth, three crystal growth processes are described in Section 3.3. These are used in materials research into molecular substances for nonlinear optics.

3.1. Mass Crystallization on the Laboratory Scale

The processes listed in Sections 3.1.1–3.1.5 are described in the extensive literature on industrial crystallization[50, 106] and chemical laboratory practice :[15, 17, 18]

3.1.1. Crystallization from Solution

Crystallization from solutions has mainly two aims: the isolation of a solid, which was synthesized in solution, and the stepwise purification of a soluble solid. Isolation: Crystallization is achieved by 1. complete, usually rapid (isothermal) evaporation of the solvent (rotary evaporator); 2. partial or complete, usually slow (isothermal) evaporation of the solvent (crystallizing dishes, open to the atmosphere or in a desiccator); 3. slow or rapid reduction of the temperature of a saturated solution (without evaporation); 4. freezing of the solvent; 5. precipitation by the (isothermal) addition of reactive components or solvent components to reduce solubility (addition by diffusion or with stirring); 6. salting out by the (isothermal) addition of a strong electrolyte; 7. spray drying by rapid evaporation of the solvent by pressure reduction (flash evaporation); 8. freeze drying; 9. electrocrystallization; 10. molten salt synthesis (at high temperatures);[107] 11. hydrothermal synthesis.[108]

Here, in practice, crystallization is essentially performed more rapidly than with single-crystal growth, the purity of the substances obtained is rather less, and the crystallized material often shows inclusions of solvent. Success depends greatly on the choice of solvent,[109] and on the nature of the impurities present. Van der Sluis et al.[110] have used statistical analysis methods to determine which solvent molecules are preferentially included in the crystal lattices of known organic compounds: water to 61%, dichloromethane to 6%, benzene to 5%, methanol to 4%, acetonitrile to 2%, and dimethyl sulfoxide to

0.5%. These figures indicate the proportion of the structures that can include solvent molecules or form solvates. It should also be noted that the concentration and frequency of the inclusions are strongly dependent on the growth conditions (kinetic effects, see Section 2.1), which are usually not discussed in this connection.

Even if the aim of the crystallization is the isolation of a compound, the principle applies that the material should be purified by other methods before crystallization, and analysis for trace elements or molecules for control purposes should be included.

If a compound needs to be purified in a stepwise manner, this can be achieved by crystallization with rejection of mother liquor or by fractional crystallization with reuse of mother liquor.

3.1.2. Crystallization from the Melt

Crystals that form from molten substances can be obtained by zone melting carried out one or more times, by Bridgman techniques or by solidification of a supercooled melt. Whereas solution processes cover almost the entire range of classes of materials, melt crystallization is restricted to those that are thermally stable in the liquid state at their melting point, and where chemically inert vessels are available (a problem with high-temperature superconductors, see Section 4.2). Zone melting has been of great importance for the purification of thermally stable materials for a long time.[111] Bridgman techniques have been applied in many cases.[34]

3.1.3. Crystallization from the Gas Phase

Crystals form from the gaseous state by 1. sublimation and desublimation in a vacuum or in a gas flow, 2. chemical transport, 3. reactive deposition from the gas phase (chemical vapor deposition CVD). Quantitative crystallization from the gas phase is usually of limited application due to the low vapor pressure of the component being transported. With semiconductor materials (Si, ZnSe, ZnS, SiC, etc.), CVD is an important process.

3.1.4. Crystallization in the Solid State

Crystals form likewise from solids by 1. recrystallization, 2. devitrification (slow crystallization of supercooled organic and inorganic glasses), 3. reactive solid-state diffusion and ceramic synthesis, 4. sol-gel syntheses of ceramic materials.[112]

The crystallization of the so-called oils of organic compounds (glassy, high viscosity condensed phases), which is often described as difficult, is here discussed in more detail. The fundamental investigations of Tammann have led to the formulation of rules for the nucleation behavior of organic melts (see Section 2).[15, 18] According to these, for complex molecular materials, the temperature T_N of the maximum rate of nucleus formation J can be considerably below the temperature T_G of the maximum rate of crystal growth. As exemplified by glycerine, this difference can be as much as 65 K in exceptional cases.[34] It is generally known that many organic melts that are thermally fairly stable (benzophenone, salol, benzil, etc.) can be strongly supercooled,[113] without producing growth nuclei within a reasonably short time. As the nucleation rate J is in general reduced by dissimilar dissolved materials, prior purification and trace analysis are of the greatest importance, and active impurities must be limited to the ppm concentration range. To bring about the crystallization of analytically pure, stable, but difficult to nucleate supercooled melts (see ref. [15], therein Fig. 1, 2), the samples are preferentially heated above the melting point, slowly supercooled (1 K min^{-1} to 1 K h^{-1}), and repeatedly subjected to temperature cycling at temperatures just below the melting point (5–20 K), so that the oily substance does not completely harden in the supercooled region (insufficient diffusion, Eq. (d), Section 2.1). Slow heating and cooling, with periods of constant temperature (hours to days), at various temperatures (induction periods) can be helpful in finding the regions for T_N and T_G, which sometimes do not overlap. For most real systems (material + its surroundings), heterogeneous nucleation is more probable than homogeneous nucleation. Therefore, purification of the melts should only involve the removal of dissolved impurities. The introduction of a matrix with a similar lattice structure can lead to crystallization by heteroepitaxial processes. For other induction possibilities (e.g., by ultrasound), see references [18, 50].

3.1.5. Crystallization by the Formation of Derivatives

Several organic compounds crystallize better 1. as salts (alkali metal or ammonium salts), 2. as hydrochloride, 3. as metal–salt complex, 4. as molecular compounds (diastereomeric reaction partners for racemate separation), or 5. as inclusion compounds.[114]

3.1.6. Basic Principles of Chemical Crystallization from Solution

Although many methods are available, for most newly synthesized substances, only crystallization from solution (temperature reduction or evaporation) is used. (For a critical review of crystallization from solutions and melts, see Matz.[50]) The further development of efficient and versatile laboratory methods of solution crystallization that take advantage of established knowledge of nucleation and growth mechanisms are therefore still important for synthetic chemistry.

If one wishes to obtain crystals from solution efficiently, the following points should be taken into consideration:

1) Choice of a chemically stable two-component or multicomponent system without formation of solid solutions and with a eutectic temperature T_E for small values of $X_{substance}$ (see phase diagram in Fig. 7; solvents: see refs. [34, 109]).
2) Exclusion of components that inhibit nucleation and growth (which may include solvents).
3) Suitable concentration range for crystallization: $\approx 5\,wt\% \lesssim X_{substance} \lesssim 30\,wt\%$ (for systems showing good nucleation properties, superheating for a short period at 5–20 K above saturation temperature is recommended; otherwise not). When growing large single crystals, the $X_{substance}$ concentration should be as high as possible.
4) The optimum nucleation and growth temperatures (in particular for molecular crystals) are usually considerably below

the melting point of the pure material, and considerably above the eutectic temperature or the melting point of the pure solvent.

5) After successful nucleation (N) at $T_N < T_G$ (Fig. 7), volume growth (G) should be carried out closer to the saturation temperature (but always within the metastable region) and with increasing depletion of the solution at a temperature that is reduced in a controlled manner with thorough mixing (maintenance of constant supersaturation). The chemical laboratory equipment normally available is not suitable for these operations. A heating bath with programmable temperature is required (see Section 3.2).
6) When working with spontaneous nucleation, small amounts of insoluble solids should not be removed for the first crystallization of the compound, as these usually reduce the nucleation threshold. However, for later crystallization, solid particles can lead to macrodefects (inclusions of solution and particles), and are to be avoided.

If careful attention is paid to the complex relationships during crystallization and to systematic working methods, a solution to many difficult problems can be found, sometimes quite quickly. This implies that proficiency in crystallization should always remain a part (preferably increasing) of theoretical and practical chemical education.

This results in the following approach for chemical mass crystallization:

1) The first nuclei are prepared by exploratory methods of crystal growth (see Section 3.2).
2) Mass crystallization (on the laboratory scale) is carried out by using process control comparable to that used in growing bulk single crystals. This increases the chance (in the sense of Section 1) that the synthetic chemist will, on average, obtain significantly larger crystals than hitherto, and that (in special cases) it will be possible to use these for an initial determination of solid-state physical properties.

By this "trick of the trade", the area of interest and the experimental practice of traditional synthesis may be extended in the direction of single-crystal synthesis and solid-state properties of interesting classes of substances. So-called "exploratory" methods of crystal growth can be of further assistance, as these attempt to give maximum control of the process at minimum cost.

3.2. Exploratory Methods of Crystal Growth

Compared with the major improvements of the last decade in almost all structure-determination steps of X-ray crystallography, crystallization lags behind.
Van der Sluis et al.[115]

In Section 1 we commented on the significance of crystallization for chemistry. Crystal structure investigations must today be the largest (nonindustrial) consumer of small single crystals. The preparation of suitable samples ($d \approx 0.1-0.3$ mm, as isometric as possible) is therefore becoming more and more *the* rate-determining step. Initial attempts at designing a versatile set of apparatus for purposeful crystallization are already in existence.[100, 115, 116]

Exploratory techniques have the advantage that they require relatively simple equipment in the chemical laboratory and that only small amounts of substance are necessary. The process operation has the best possible control of crystallization parameters, preferably self-regulating. During the measurements the solution and crystallization phenomena can be visually observed. The crystals can be removed without mechanical and thermal stress and without serious surface contamination.

With the aim of applicability over as wide a range of substances as possible, the following should be considered:

1) Isothermal evaporation (Fig. 9), 2) temperature reduction (also in a gel, Fig. 10), 3) temperature difference methods (Figs. 12, 13), 4) isothermal diffusion (in droplets (Fig. 14a), using membranes (Fig. 14b), in a gel (Fig. 14c), or through a coating), 5) melt growth in capillaries, 6) sublimation/desublimation (evaporation from Knudsen cells, Fig. 17), 7) chemical transport and reactive evaporation, 8) high-temperature solution growth (see Section 2.2, Fig. 4), and 9) hydrothermal solution growth (miniaturized equipment, see Fig. 18).

For methods 1–5, it is necessary to have chambers with temperature control, homogeneous heating, and controlled atmospheres (commercial ovens are not always suitable), which incorporate visual observation by a binocular microscope, and where small crystals can be removed.

The important features of these techniques are illustrated in Figures 9, 10, and 12–19. For example, for controlled isothermal evaporation (Fig. 9), the walls of the vessels should be such that the solutions do not creep up them to a great extent (silanated glass or polytetrafluoroethylene (Teflon) should be used), unless it is intended to use this as an effective method of promoting nucleation. The junction of the walls to the floor should be

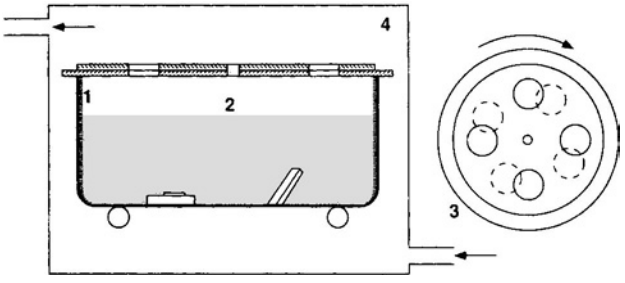

Fig. 9. Crystallization vessel with flat or slightly convex bottom for isothermal evaporation of the solvent. 1: Silanization to prevent creeping of the solution. 2: Supersaturated nutrient phase. 3: Lid with turnplate with apertures for the regulation of evaporation rate. 4: Arrangement in homogeneously heated chamber with through flow of gas and access for observation and removal of samples; T = constant.

gently rounded and it is advantageous when the floor is convex (the vessel being held vertical by standing it on a ring), and the clearance of the loosely fitting lid can be adjusted by a turnplate. A saturated solution of the substance to be crystallized should be prepared in a separate vessel at the evaporation temperature, and, before charging, 5–10 vol% solvent should be added to reduce the concentration below saturation. When the first crystals become visible, the solution is usually too strongly supersaturated, causing rapid growth to start. This should be retarded by a slight increase in temperature (if $\partial X_{substance}/\partial T > 0$). The

gas flow through the evaporation chamber should be reduced at the same time. It is recommended that the first crystals should be almost completely redissolved in the solution, so that they can then be allowed to grow slowly as has been described. The removal of small crystals ($d \approx 0.1-0.3$ mm) requires great care. A thin-walled capillary can be used with a mechanical means of applying reduced pressure (with fine adjustment), so that the small crystal brings with it a minimal amount of solution. The nutrient phase and the crystal are then ejected into a large volume of preheated liquid in which the crystallized compound is less soluble (only for stable hydrates and solvates). After a small amount of etching of the crystal, it is again picked up and transferred to the absorbent base of a preheated container, which also serves for the removal and slow cooling of the crystal. Meanwhile, the growth of the remaining crystals continues fairly undisturbed. The other crystallization methods also require an equal amount of care. In general, isothermal evaporation is the preferred choice if $\partial X_{\text{substance}}/\partial T < 0$. High-temperature variations of the method are discussed by Elwell et al.[96] and Wanklyn.[97]

Crystallization in a gel by reducing the temperature (Fig. 10 right): Crystallization from gels is usually used for sparingly soluble salts, by using counter-current diffusion.[34, 117, 118] For

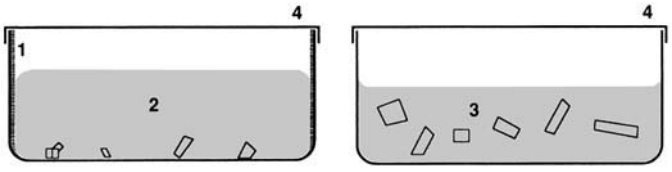

Fig. 10. Crystallization vessels for lowering the temperature of a solution (left) or of a gelled solution (right). 1: Silanization. 2: Solution. 3: Gelled solution (in superheated state). 4: Lid with observation facility (similar to Fig. 9).

substances of normal solubility, an aqueous or ethanolic/aqueous solution can, for example, be gelled in the supersaturated state by adding 5–10 vol% tetramethoxysilane (Arend et al.[119]) in the superheated state. Nucleation takes place normally in a strongly supercooled state. This is retarded by increasing the temperature, and the process then changes to slow growth of single crystals. The crystallization from gels by reducing the temperature has the advantage that phenomena associated with convection are prevented; thus, growth takes place purely by diffusional matter transfer. If gels are absent, the crystals grow preferentially at the bottom of the vessel and are fed from one direction only. For the same reason, the growing nuclei in a gel tend to be more widely separated (self-regulating mechanism), so that fewer agglomerates are produced. Typical growth times after the induction phase are weeks or months. Small crystals are picked up together with a piece of gel, and then treated in the manner already described. By using flat (closable) dishes and a relatively thin layer of gel, the continued growth of remaining crystals is possible. The gel growth method has recently been used successfully for nonlinear optical organic compounds (Fig. 11).[120a] This very simple method provides serious competition to the technique of growing molecular substances in space (removal of gravitational convection).[120b] Also, experiments with gels should be valuable for the investiga-

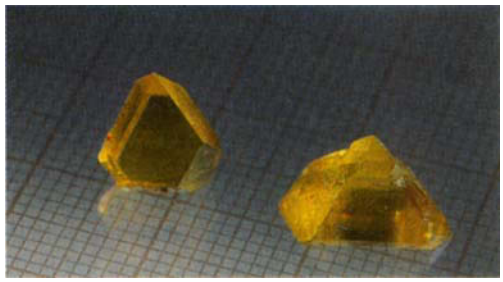

Fig. 11. Solution growth of PNP (B. Březina, ETH, Zürich): Gel growth by lowering the temperature (left: maximum crystal size $d \approx 1$ cm), and by growth in a solution moving with laminar flow (right: starting from a *b* platelet seed crystal, the crystal grew preferentially in the direction of the pyroelectrically negative pole ($\Delta T > 0$) of the polar twofold axis; see Fig. 21). Use: measurement of nonlinear optical and electro-optical effects [169].

tion of deviations from the 1:1 distribution of D and L crystals ("chiral symmetry breaking"[121]) as the mobility of secondary nuclei is here much reduced.

Temperature-difference method (Fig. 12): This system has a wide application spectrum (provided that $5 \lesssim X_{\text{substance}} \lesssim 30$ wt%, $\partial X_{\text{substance}}/\partial T > 0$[122]). The separately saturated solu-

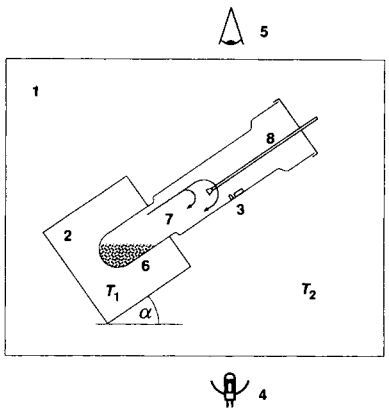

Fig. 12. Crystallization by the temperature-difference (ΔT) process (from [122], modified). Arrangement for the observation of spontaneous crystallization or growth upon nuclei. 1: Thermostatically controlled air bath. 2: *T*-controlled Al block inclined at angle $\alpha = 10-30°$ ($\Delta T = T_1 - T_2 = 1-5$ K). 3: Glass vessel with rectangular center section [123] and screw lid, 4: Cold light illumination. 5: Observation by binocular microscope. 6: Supply of solid phase. 7: Flow due to thermal convection. 8: Holder for seed crystal (eccentrically mounted) for seed-growth experiments.

tion at T_2 is placed in the glass vessel (with a small excess of solid phase at the bottom), so that, in the temperature gradient $\Delta T = T_1 - T_2 < 1-5$ K, the solution, rising by natural convection, becomes supersaturated, and begins to form nuclei spontaneously (self-regulating mechanism). The central part of the closed vessel should preferably be a smooth rectangular glass vessel (inside dimensions: 12, 15, 23 mm),[123] so that the faceted growth of the crystals is not disturbed by the curvature of the vessel wall. Two conditions are recommended to give the most favorable crystallization parameters: a) Single-sample operation, as described in Figure 11, while observing with a binocular microscope and slowly increasing ΔT, b) series operation in a crystallization matrix (Fig. 13). Around 50 crystallizing

vessels can be placed in conventionally heated cabinets fitted with the appropriate equipment. As indicated, crystallization can also be carried out by using seed nuclei. The small crystals should be removed in the manner described. Typical crystallization times can be several weeks. As this process operates after reaching a stationary state of constant supersaturation, it can also be used to produce macroscopic homogeneous single crystals of solid solutions.[122]

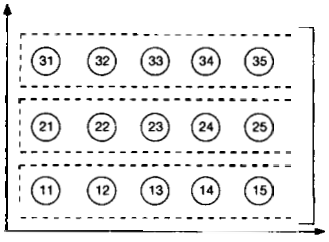

Fig. 13. Crystallization matrix for the determination of optimum growth conditions; on the y axis the temperature difference ΔT is varied and on the x axis the solvent is varied. Series arrangement using sample tubes in a matrix [123] PR_{ij} (i: ΔT, j: solvent) in a heated cabinet [122]. The temperatures of the blocks (shown by dashed lines) are individually controlled, so that a constant $\Delta T(i)$ with respect to the ambient temperature (i.e. of the heated cabinet) is obtained. The blocks have several holes (numbered) for the sample tubes PR_{ij}. ΔT influences the supersaturation and flow velocity.

Based on many years of experience (Arend, Hulliger) with a wide range of classes of substances, the chance of success of crystallization with the ΔT method is over 90%. It is possible to extend the process to large crystals[122a] and to the use of high temperatures (approximating to hydrothermal in subcritical pressure ranges).

The isothermal diffusion method (Fig. 14) also has a wide application spectrum, and the "sitting-drop" version of this is reported to be most successful.[115] Also included here is gel crystallization by counter-current diffusion of two components

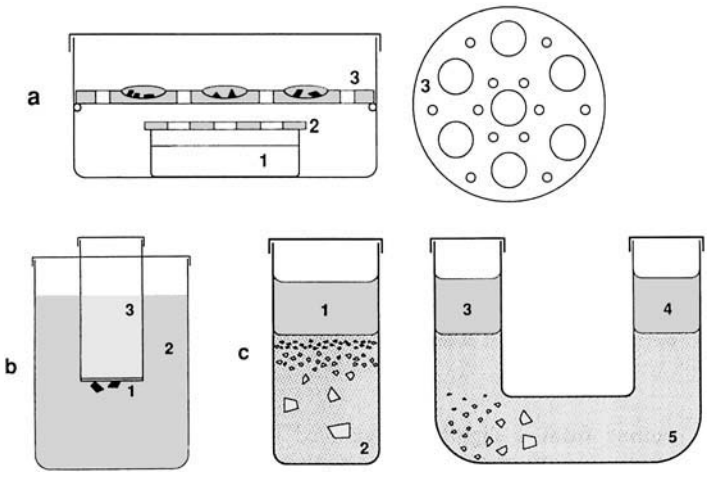

Fig. 14. Crystallization by isothermal diffusion a) "sitting drop" method. 1: Precipitating agent, 2: control of evaporation rate, 3: plate with hollows for receiving the drops (see also commercial products for protein crystallization); b) diffusion through a membrane. 1: Membrane, 2/3: solution/precipitating agent; c) two types of diffusion in the gel (see also [34, 117]): mostly unidirectional diffusion into the gel (left-hand diagram 1: precipitating agent or second component) or counter-current diffusion (right-hand diagram 3, 4: components A and B in solution), 2: gel with crystallizing substance, 5: initially pure gel.

(a slow precipitation reaction), in general using inward diffusion of components that reduce solubility or change pH (substance example:[124], see Fig. 15). It is also possible to work with the help of a **membrane.**[125]

Fig. 15. Gel growth of silver periodate by pH reduction ($AgNO_3$, H_5IO_6, and sodium silicate gel). **Yellow crystals: $Ag_2H_3IO_6$, red-brown crystals (black in photograph): Ag_2IO_5 [124].**

Melt growth in capillaries may be used if, for example, only small amounts of material are available. The cylindrical crystallizates formed can be used for X-ray work, either together with the capillary (Lindemann glass) or after etching. A modern application of melt growth in glass capillaries is in the production of nonlinear optical organic fibers (Fig. 16).[126]

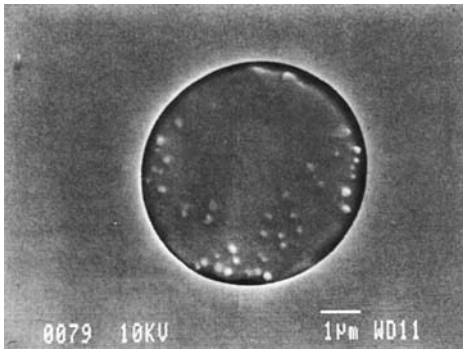

Fig. 16. Modern application of melt growth in glass capillaries. Fiber single crystal of 4-(*N*,*N*-dimethylamino)-3-acetamidonitrobenzene (DAN). Internal diameter = 6 µm. With DAN fibers, a high efficiency was obtainable in optical frequency doubling experiments (Nd:YAG, 1064 nm) (Kerkoc et al. [126]).

Sublimation and Desublimation (Fig. 17): In addition to the well-known variations of gas-phase crystallization, the technique of controlled evaporation from Knudsen cells should be mentioned here.[127] This system (Fig. 17) can be used for crystallization by forming derivatives, but particularly for producing macroscopically homogeneous solid solutions (other processes are given in ref. [34] and by Karl[111]).

Possible processes for crystal growth by using chemical transport reactions are described in the well-known work of Schäfer.[128]

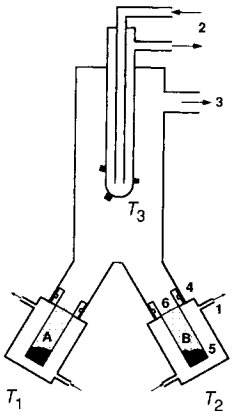

Fig. 17. Growth from the gas phase by controlled evaporation from Knudsen cells [127]. (T_1, T_2: cell temperatures, T_3: temperature of deposition (cold finger). Suitable for the growth of mixed crystals $A_{1-x}B_x$ by separate evaporation of $A(T_1)$ and $B(T_2)$, and for low temperatures (unstable compounds). 1: Inlet or outlet for heating liquid. 2: Connections for coolant. 3: To high vacuum pump with cold trap. 4: Knudsen cells sealed with O-rings. 5: Supply of solid phase. 6: Aperture for controlled evaporation rate at cell pressure $p(T)$.

The hydrothermal crystallization process involves considerable cost.[34, 129] Moret has developed a small apparatus for exploratory work (Fig. 18),[130] which was used in reactive counter-current diffusion experiments for forming single crystals of a series of compounds, including $NiFe_2O_4$, $KFeF_4$, Te_4O_9, $PbCu_6O_8$, Cu_2I_2. The construction of autoclaves, in general, is described by Laudise et al.;[131] the hydrothermal synthesis of inorganic substances by Rabenau.[108]

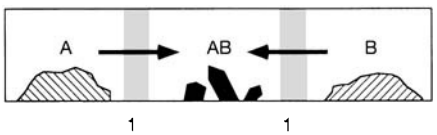

Fig. 18. Schematic diagram of a hydrothermal reactor for the synthesis of AB by counter-current diffusion of the starting materials A and B through a diaphragm (1). Miniaturized, easily operated equipment for the synthesis and single-crystal growth of small crystals is described by Moret [130]. (Reactor dimensions: $l \approx 15$ cm, internal diameter ≈ 0.7 cm; see also [108]).

This discussion of the practical aspects of exploratory crystal growth is deliberately not oriented towards particular classes of substances, but has attempted to propose a developable range of basic equipment whose design must be optimized in individual cases. The classification of processes according to substances is based only on distinctions such as low melting point, high melting point, stability/instability, etc. The substance-based approach, which corresponds more closely with chemical thought, has not proved useful in crystal growth. Chemically unimportant differences in the structure of the molecules or in associated impurities can affect crystal growth disproportionately, and can influence the choice of process decisively. The present approach should provide useful guidelines and should enable crystallization to be carried out by the most adequate means as the *last synthesis step*. It should also lead to an improvement in the reproducibility of crystallization results in the majority of cases.

3.3. Discussion of Modern Methods of Advanced Chemical Crystallization

A fairly complete overview of advanced methods used today can be obtained from the following articles: Gilman (Ed.),[132] Pamplin (Ed.),[133] Laudise,[99] Elwell et al.,[96] Dryburgh et al. (Eds.),[134] Wilke et al.,[34] Arend et al. (Eds.),[135] and Hurle et al. (Eds.).[136]

Three processes will be described in more detail. These are currently used for growing single crystals of nonlinear optical molecular crystals. Their applicability to other classes of compounds depends on specific properties which cannot be discussed in general terms.

3.3.1. *Crystallization from Slightly Supercooled Organic Melts*

Under certain conditions, the strong tendency of organic melts to supercool (Section 3.1.4) can be successfully used for the synthesis of single crystals of cm^3 dimensions, and for making single crystals that are almost perfect crystallographically. For this, pure materials are required that are sufficiently thermally stable for long periods (days or weeks). These are melted, preferably degassed, superheated (10–20 K), slightly supercooled ($\Delta T \approx 0.1$–2 K), and can then be crystallized by the complete immersion of a seed crystal. Scheffen-Lauenroth et al. and Klapper[137] have recently demonstrated the usefulness of this method with salol, benzophenone, and benzil. Using equipment similar to that shown in Figure 19 (left), a strongly nonlinear optical compound (COANP: 2-cyclo-octylamino-5-nitropyridine) could be crystallized (Fig. 19 right).[138] Crystal

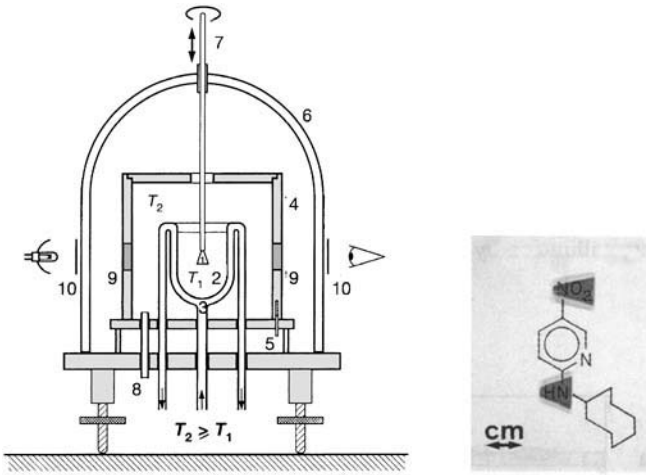

Fig. 19. Left: Crystallization from a supercooled melt (Hulliger et al. [138]). 1: Seed crystal (completely immersed: crystal pulling also possible). 2: Isothermally heated melt. 3: Glass vessel with water cooling. 4: Heating for gas atmosphere. 5: Pt-100 control thermocouple. 6: Vacuum hood. 7: Equipment for moving seed crystal (translation or rotation). 8: Inert gas inlet. 9: Red glass (protection against short wave light). 10: Polarizer, analyzer, and cold light illumination (IR filter not shown). Right: COANP single crystals (1 mm thick platelets) produced by crystal growth from slightly supercooled melts by complete immersion of the seed crystal [138]. Growth time: 1–2 weeks. Application: frequency doubling experiments and measurement of electro-optical effect [169].

pulling from a slightly supercooled melt produced cm^3-size single crystals of COANP which had not been obtainable by other methods.[139] Moreover, the same growth method has led to the discovery of the first purely organic photorefractive crystal.[139, 140] The investigation of the physical state (vitreous state and cluster formation) of supercooled COANP melts is described by Kind et al.[141] Crystal growth from supercooled melts has at least two important advantages over normal meth-

ods (zone melting and Bridgman techniques)[34]: The growing crystal is surrounded only by the liquid phase (as well as by the seed holder), and the growth takes place under virtually isothermal conditions.

3.3.2. Crystallization by Isothermal Evaporation with Resaturation

The principle of controlled isothermal evaporation and resaturation has attractive advantages compared with temperature-reduction methods. This method is 1) possible when $\partial X_{substance}/\partial T \lesssim 0$ and for relatively small values of $X_{substance}$; 2) single-crystal synthesis is possible when the evaporation temperature is constant and as low as necessary (unstable compounds). Bösch et al.[142] and Hesse et al.[143] crystallized alkali metal hyperoxides, peroxides, as well as ozonides from liquid ammonia by this technique. Fuith et al.[144] discussed the design of the apparatus shown in modified form in Figure 20 (and the growth of, for example, sulfate crystals). This apparatus is also used by the present author for organic compounds.

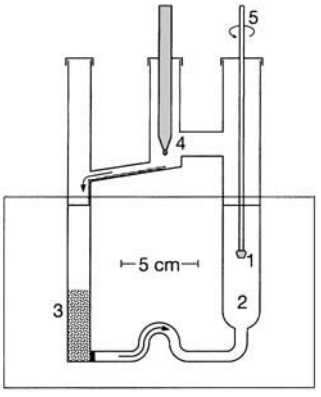

Fig. 20. Crystal growth by isothermal evaporation (arrangement placed in a thermostatically heated water bath) with resaturation (Fuith et al. [144], modified). 1: Seed crystal. 2: Solution with hydrostatic equilibration. 3: Nutrient material. 4: Cold finger (thermostat or Peltier element) for condensation of solvent. 5: Rotational movement of crystal (for relatively rapid growth).

3.3.3. Crystal Growth in Laminar Flow by Lowering the Temperature of a Solution

Convection phenomena or other uncontrolled flow conditions in the nutrient phase can reduce the width of the metastable area of supercooling[68] and lead to the formation of undesired growing crystal surfaces (defect formation and morphological instabilities).[91, 145] The hydrodynamic state of the system is more easily controlled by a directed, almost laminar flow over a seed nucleus (stationary or intermittently rotated, Fig. 21). Furthermore, thorough mixing is ensured by the careful selection of the method of propelling the solution. In some cases, growth rate by the solution process is considerably increased at increased flow velocities (several $cm\,s^{-1}$). This has been used for the relatively rapid growth of very large crystals of KH_2PO_4 (see Fig. 1).[146] Also, in cases of strongly anisotropic growth, the directed flow improves deposition on slowly growing surfaces. This should have many small-scale applications. At the present time, the author is crystallizing nonlinear optical compounds, such as 2-(*N*-(L)-prolinol)-5-nitropyridine (PNP) (Fig. 11) and 4′-dimethylamino-*N*-methyl-stilbazonium-*p*-tosylate (DAST: one of the strongest electro-optical organic compounds known today) by this method.

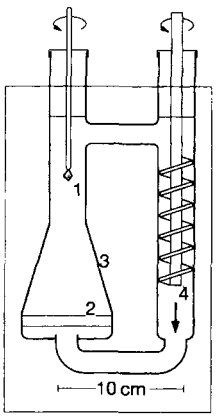

Fig. 21. Crystal growth by lowering the temperature (arrangement placed in a temperature-controlled water bath) under smooth fluid flow: 1: Seed crystal in a zone with almost laminar flow. 2: Diaphragm or glass spheres (disturbance of stream lines). 3: Cone (smoothing and compression of the flow). 4: Propulsion helix (Delrin).

4. Progress in the Single-Crystal Growth of Materials of Topical Interest

4.1. Special Literature Information

A wide-ranging review of developments in the crystal growth of approximately 2000 compounds is available in the latest edition (1988) of the highly regarded standard work of Wilke and Bohm (349-pages index of materials information and literature).[34] Another compendium will be available in 1993, namely the first handbook of crystal growth, including the newer methods and materials (MBE, MOCVD, superconductors, proteins, etc.).[136] Current work (e.g., CA selects, "crystal growth", etc.) is reported in the *Journal of Crystal Growth*, which also publishes the reports of the conferences held by the ICCG (International Conferences on Crystal Growth) that take place every 3–4 years. Journals of national speciality groups[147] may also be of interest, since they publish lists of grown crystals (special materials), and name indexes from time to time.

4.2. High-Temperature Superconductors: Oxocuprates

Up to three or four years ago oxocuprates were a class of chemical compounds no more remarkable than countless others.
Müller-Buschbaum[148]

With the discovery of the relatively high transition temperature of $La_{2-x}Ba_xCuO_4$,[149] the superconductivity of several oxides [NbO, $SrTiO_3$ (doped), $LiTi_2O_4$ ($T_c = 13.7$ K), $BaPb_xBi_{1-x}O_3$ ($T_c = 13$ K), known for quite a long time] became the center of interest of solid-state science virtually overnight.[41, 150] Where is the challenge of growing crystals of this type of material?

It was soon realized that for $La_{2-x}M_xCuO_4$ (M = Ba, Sr) and the related compounds of Y-Ba-Cu-O, Bi-Ca-Sr-Cu-O, Tl-Ca-Ba-Cu-O, etc., the controlled three- and two-dimensional crystal growth (see Section 2.3) of the oxocuprates requires detailed knowledge of the stability regions (primary crystallization fields) of incongruently melting substances within a pseudo-ternary or pseudo-quaternary phase diagram, including oxygen pressure, so that the pure compounds can be crystallized from

nonstoichiometric melt solutions.[151a] The determination of phase diagrams and the crystal growth itself are made more difficult by complex reaction equilibria that are established kinetically slowly.[152] Moreover, the Ba-Cu-O liquid phase has extremely corrosive properties, which require the development of resistant crucible materials:[153] "Corrosion of the crucible is the most basic problem for crystal growth of the high T_c superconductors" (Changkang[151a]). The determination of the phase diagram of YBCO has given very variable results (Fig. 22).[152e] Also, the use of foreign fluxing agents, in analogy to the usual process of flux growth, gives mainly negative results. Watanabe has tested nearly 100 flux compositions at various temperatures,[154a] and concludes: "The present results suggest that a more extensive and detailed search for a suitable flux may be worthwhile: but there may be no suitable flux"[154a] (apart from self-fluxing[154b]).

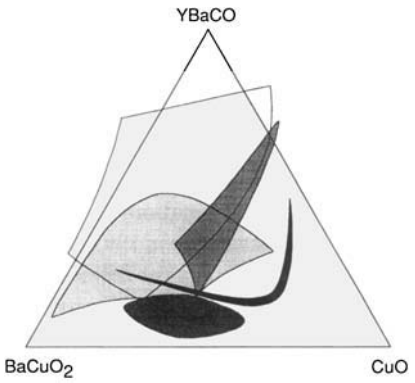

Fig. 22. Graphic design or the key to YBCO crystallization? Primary crystallization fields from the results of several authors (from [152e]).

Nevertheless, mm-size single crystals were occasionally produced. However, the still-awaited breakthrough in oxocuprate crystal growth depends on: 1) the chemical stability of liquid phases towards crucible materials yet to be developed[151b] (cold crucible processes are conceivable), 2) knowledge of the phase diagram (T, X_i, p) and of the purity of the phases (effects of impurities), 3) the establishment of equilibrium (oxygen pressure) and the homogenization of the liquid phase (mixing, superheating), 4) the control of growth kinetics within the metastable region of supercooling. The solution of the crucible problem is of the greatest importance, and not only from the practical point of view: side reactions disturb the equilibration of the oxocuprate, so that relatively narrow existence and stability regions change continuously during phase diagram or crystal growth work.

Even if all these problems were solved (including problems of phase changes during cooling), large oxocuprate crystals may soon be of minor importance technologically; this does not apply to epitaxial and polycrystalline thin films. In this area, as well as LPE,[155] gas-phase techniques[156] have mainly been used, including laser ablation,[157] RF sputtering,[158] MBE,[159] MOCVD, and even sol-gel techniques. This has stimulated developments in the epitaxy of other oxides, for example, in ferroelectricity.[101] Just as the epitaxy of other materials (semiconductors and magneto-optic garnets) was achieved in a similar way, a parallel development of substrate crystals is required for thin film growth of oxocuprates.[160]

The known hurdles in three- and two-dimensional crystal growth of oxocuprates reveal themselves primarily as a chemical problem, and high-temperature and solid-state chemistry will be able to contribute greatly to its solution. In conclusion, it may be mentioned that advances have been made in the last 12 years in the crystal growth of organic superconductors (ambient pressure, $T_c(\max) = 11.4$ K).[161, 162] The future may well have some big surprises in store directly stemming from the merging of these two worlds of chemistry (alkali metal-C_{60},...?).[163] A real challenge for crystal synthesis!

4.3. Nonlinear Optical Molecular Crystals

Special donor-substituted and acceptor-substituted π-electron systems[44] show optical frequency doubling or an electro-optical effect in crystals. These effects have appreciably higher or comparable values compared with those observed with inorganic substances known for a long time, such as $LiNbO_3$,[164] $KNbO_3$,[165] KH_2PO_4 (see Fig. 1).[4, 166]

During the past 15 years, about 300 more or less strongly hyperpolarizable organic compounds were rediscovered for modern optics. Some of these were modified existing compounds and some were newly synthesized ("molecular and crystal engineering"), and were investigated as single crystals[44] or Langmuir-Blodgett (LB) films,[39b, 167] and in the form of poled polymers.[168] In frequency doubling experiments with the Nd:YAG laser ($\lambda_0 = 1064$ nm), for three-[138, 169] and one-dimensional crystals[126, 170] (see Figs. 16, 19 right), efficiencies of over 25% producing green light were reached. Reviews of compounds, crystal growth, and optical characteristics have been published by Zyss et al.[44a] and in reference [171].

In three-dimensional crystal growth, it was necessary to work mainly with solutions (and gels) for stability reasons.[120] By the method of temperature reduction and isothermal evaporation, cm^3-sized crystals were produced of MBANP (2-(α-methylbenzylamino)-5-nitropyridine),[171c] POM (methyl-3-nitro-4-pyridine-1-oxide),[171a] NPP (N-(4-nitrophenyl)-(L/D)-prolinol),[171a] PNP,[172] DAST,[173] and other compounds. Melt growth was used only infrequently (for example, for *m*-dinitrobenzene, *m*-nitroaniline, methyl-(2,4-dinitrophenyl)-amino-2-propanoate,[171a] COANP,[138] and DAN,[126]), where the best conditions for obtaining the desired optical quality should be provided by slow growth from the homogeneously supercooled melt (see Section 3.3.1).

In analogy to other topical subjects, interest in two-dimensional crystallization is also increasing. With the achievement of growing μm-thick crystal platelets[174] in a smooth (sometimes wedge-shaped) fissure, development is clearly proceeding in the direction of heteroepitaxy from the gas phase (MBE).[175]

Faced with the wide variability of organic compounds, the salient question is not what can be achieved but whether the class of materials shows sufficient long-term stability after incorporation into an optical component. It is well known that the optical damage threshold of organic compounds is lower than with oxides or semiconductors. Also, in this field, a further chemically interesting task presents itself, namely, to find hyper-

polarizable systems that are significantly more stable photochemically and thermally than the amino- or hydroxy- and nitro- or cyano-substituted π-electron systems that have been used for a long time. Here, the resulting nonlinearity would be expected to be less, which reduces one of the important advantages compared with oxides. However, for electro-optical use, organic crystals and thin films of significantly more stable compounds should have a chance (a general discussion of application areas is given in [176]). The newly discovered photorefractive effects in organic crystals are even less researched.[140]

4.4. Protein Crystallization

Many protein crystallographers believe that the growth of protein crystals is much more complicated than the growth of inorganic crystals
Rosenberger[177]

The fact that it has taken so long to produce proteins whose crystals have sufficiently good diffraction properties (Bernal and Crowfoot, 1934) "... is undoubtedly partly due to prejudice..." (Lüttringhaus[15]) although the crystallization of hemoglobin was first reported in 1840 (McPherson, historical review).[178]

From the modern point of view, it is generally accepted that, as regards nucleation and growth behavior, proteins do not differ in principle from lower molecular weight substances.[58, 179] Some differences arise from the biological origin of the samples and the fact that a protein crystal contains 30–80 vol% combined water. Hence, crystallization is carried out from water ($T \leq 30\,^{\circ}C$), usually after adding a controlled quantity of a precipitating agent [$(NH_4)_2SO_4$, 2-methyl-2,4-pentanediol, polyethylene glycol, etc.[65, 180]] so that, for a given total system, the solubility behavior of the protein becomes a critical parameter of the process. When salts are used, the solubility decreases with increasing ionic strength. Although solubility properties have been widely researched, there is still no model that can explain what takes place when the type of precipitating agent or its concentration is changed. According to Sieker,[180] experiments on 70 proteins produced crystals with a 60% success rate, although crystals of a quality good enough for X-ray structural analysis could be produced from only 70% of the crystallizable samples after further development of the crystallization techniques used.

The main difference in behavior compared with lower molecular weight substances is that a higher degree of supersaturation ($\sigma \approx 5-20$) is often necessary, together with a long induction period (lysozyme: 1–200 days depending on the concentrations of protein and NaCl).[181] Because of the molar volume, r^* is approximately 500 times as large for proteins as for lower molecular weight substances. For some years, induction periods have been investigated with dynamic light scattering, leading to conclusions about the diffusion and size of the scattering centers. This method could also be used diagnostically to establish the effectiveness of precipitation agents.[179]

Work on the growth kinetics of macroscopic protein crystals has led to the conclusion that the rate-determining step depends on processes on the growth surface. The measured growth rates R are of the order of a few 10^{-3} cm per day. In comparison with typical R values for other solution growth processes, protein crystals do not grow appreciably more slowly. On the other hand, at the molecular level, the mass transfer rate is approximately 10^{-3} times less[116b] (a recent discussion of growth mechanisms is given by Weber[58]). One of the remaining problems in the mechanistic investigation lies with the poor reproducibility of the data. Apart from the effects of impurities (including bacteria), this is certainly associated with the slow establishment of complex equilibria (folds and water inclusions, etc.). However, the use of the atomic force microscopy (AFM) method by Durbin et al.[182] showed that the well-known BCF (see Section 2) mechanism[80] for low molecular weight materials is in fact also valid for protein crystals.

Experimental methods of protein crystallization have been described by many researchers.[58, 116b, 179, 180] In analogy to the methods described in Section 3, the following are available: 1. Isothermal diffusion, a) over the gas phase (5–50 μL, "hanging or sitting drop" method—the commonest), b) by using a membrane, c) in a gel ("hanging drop"),[183] and d) by diffusion across the interface between the protein solution and the precipitant solution, and 2. temperature reduction (rare).

In addition to the literature mentioned previously, four conference reports *Crystal Growth of Biological Macromolecules* (1985, 1987, 1989, 1992) are worthy of note.[184]

5. Summary and Future Prospects

It has become increasingly evident in the last few years that scientific aspects of crystal growth have attracted the attention of physicists, chemists, metallurgists, ceramists, materials scientists, mineralogists, geologists, as well as a small number of biologists, and that a substantial number of these people regard crystal growth as their special field of competence and interest.[185]

Although these lines were written 25 years ago, large areas of synthetic chemistry have not yet adopted crystal growth as a possible special method of synthesis for building supramolecular structures with specific physical properties. Nevertheless, the development of a large number of single-crystal materials since the general upsurge in solid-state physics and materials science has shown the way towards the possibility of a chemistry that encompasses both the classical synthesis of new compounds and the formation of single-crystal phases with interesting properties. As well as giving an account of interdisciplinary cooperation and the theoretical side of the science of crystal growth, it seemed to me that the central topic was a discussion of recent developments in the systematic practical solution of crystallization problems. Here, the distinction has been made between exploratory methods, which are as simple and self-regulating as possible, and advanced methods of crystal growth. Crystallization is no longer an "outdated laboratory technique" for the chemist, but a modern and novel method of carrying out chemical syntheses in new areas of materials research.

I should like to thank my colleagues Hermann Wüest, Marcel Ehrensperger, Lucien Pauli, Dr. Roland Gutmann, Dr. Primoz Kerkoc, and Dr. Bohuslav Březina (Prague) for their collaboration in the development of a large number of methods of crystal growth. My special thanks are due to Prof. Dr. Dr. hc Hanns Arend, who introduced me to crystal growth and who has given me great support ever since. The ETH Zürich and the Swiss National Science Foundation are acknowledged for financial support.

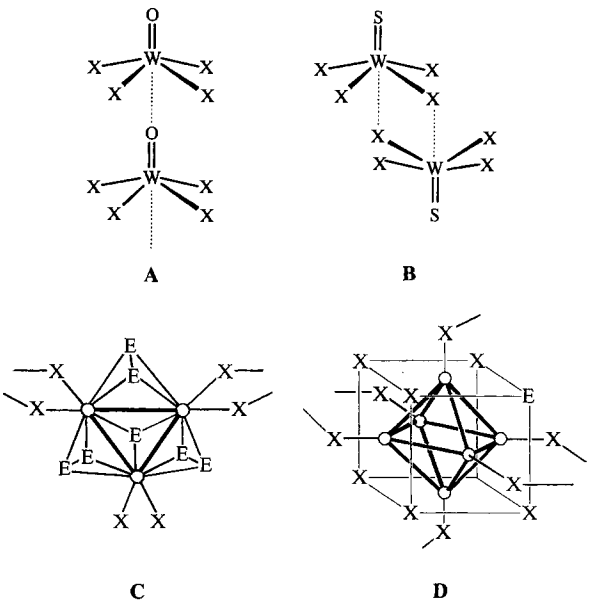
Just what does a referee system achieve?

Regular readers of "Angewandte" are well aware that Dr. Hans-Dieter Daniel has researched this question using *Angewandte Chemie* as example. The preliminary results were presented in a communication on this topic (Issue 2/93). Now the complete analysis by Daniel is available in book form: "The Guardians of Science: Fairness and Reliability in Peer Review" by H.-D. Daniel, foreword by H. Nöth (VCH, Weinheim, 1993, ISBN 3-527-29041-9, DM 78.—).



New Forms and Functions of Tellurium: From Polycations to Metal Halide Tellurides

Johannes Beck

Metal chalcogenides and metal chalcogenide halides are distinguished by their structural diversity and by their very different physical properties. Therefore, the synthesis of novel compounds from this class is always a rewarding goal for the preparatively oriented solid-state chemist. Over the past few years, many syntheses and structural investigations have stimulated the field. The emphasis of the research has been placed on selenium-rich and tellurium-rich compounds, which are characterized by directed covalent bonds between the chalcogen atoms. Compounds with novel chalcogen polycations have also become accessible during the past few years by reacting the chalcogen elements with transition metal halides, or from chemical vapor deposition in the sense of chemical transport reactions. In these compounds, tellurium differs from its lighter homologues by a pronounced tendency towards greater covalence. This article attempts to provide an overview of new developments in the field of compounds with chalcogen polycations and of metal chalcogenide halides, with an emphasis on compounds containing molybdenum and tungsten as the transition metals and tellurium as the chalcogen.

1. Introduction

Metal chalcogenide halides are ternary compounds, that is compounds containing three different chemical elements. These are formed with main group and subgroup metals, the elements oxygen to tellurium (chalcogens), and fluorine to iodine (halides). The metals behave very differently with respect to the formation of chalcogenide halides. Niobium, for example, forms a large number of such compounds with compositions like NbS_2Cl_2[1] or $Nb_2Te_2I_6$.[2] For zirconium, however, although it is the immediate neighbor of niobium in the periodic table, no halide sulfides, halide selenides, or halide tellurides are known. For the elements of group 8 (chromium, molybdenum, and tungsten), the chemistry of halide oxides, halide sulfides, and halide selenides is well-developed. Trivalent chromium forms a chloride oxide CrOCl,[3] a bromide oxide CrOBr,[4] and a bromide sulfide CrSBr,[5] all of which crystallize with the FeOCl type structure.[6] CrSBr is highly antiferromagnetic with a Neél temperature of 132 K.[5, 7] For tungsten, a large number of halide oxides, halide sulfides, and halide selenides are known, which have also been structurally characterized. Often isotypic series are encountered, in which the different halogens and/or chalcogens can replace each other without changing the structure type. An example for this are the chalcogenide halides of hexavalent tungsten. The compounds $WOCl_4$[8] and $WOBr_4$[9] are isotypic; their columnar structure is built of square pyramids of monomers associated along the W–O axis to form chains (Scheme 1, **A**). α-$WSCl_4$ and $WSBr_4$[10] form dimers held together by bridging halogen atoms (Scheme 1, **B**). In the structure of β-$WSCl_4$,[11] these dimers are "docked" by additional pyramidal $WSCl_4$ molecules. This polymorphism has so far not been

observed for $WSeCl_4$, which crystallizes in the β-$WSCl_4$ type structure (Fig. 1) only.[12] All these compounds are constructed from square pyramidal monomers in which the chalcogen atom is in the apical position. The tungsten–chalcogen bonds are very short (mean W=O = 180, W=S = 210, W=Se = 220 pm), and may be formally regarded as double bonds. It is noteworthy that this series of closely related compounds ceases with the halide selenides, that is tungsten halide tellurides are unknown.

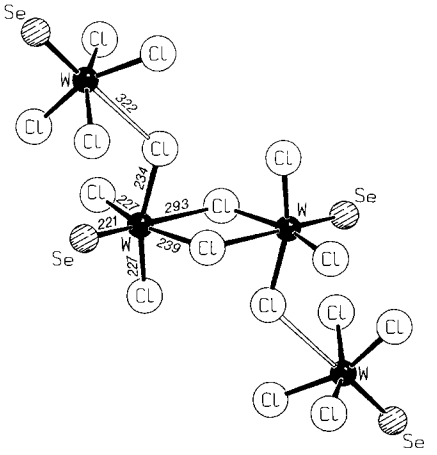

Fig. 1. Structure of $WSeCl_4$ with important distances in pm.

For molybdenum, the situation is similar. Several molybdenum halide sulfides and halide selenides are known.[13] This is exemplified by compounds of the type $Mo_3E_7X_4$ (E = S, Se; X = Cl, Br, I),[14] which feature triangular Mo_3 clusters with dichalcogenide dianions bridging the edges (Scheme 1, **C**). All compounds with E = S and Se, and X = Cl, Br, and I, have been prepared, but no corresponding tellurium compounds are known. The only known halide tellurides of the group 8 elements are derived from the cluster compounds of divalent molybdenum. One of the eight inner halogen atoms of the $[Mo_6X_8]X_4$ cluster can be substituted by a tellurium atom, which is distributed statistically over all eight possible positions[15] (Scheme 1, **D**). The $Mo_6Te_{8-y}X_y$ type compounds with X = Br, I and $0 \leq y \leq 3$, which fall into the class of the superconducting Chevrel compounds, are of special interest because of their physical properties.[16] This review reports on the authors' efforts to synthesize halide tellurides of molybdenum and tungsten. The somewhat surprising results are discussed with respect to current findings of other research groups.

2. An Initial Route to the Ternary Molybdenum/Tellurium/Halogen System: Compounds with Trihalotelluronium Ions TeX_3^+

The tetrahalides of sulfur, selenium, and tellurium have partially ionic character, which enables them to form trihalochalcogenonium ions EX_3^+ (E = S, Se, Te, X = Cl, Br and for E = Se, Te, X = I).[17] Chalcogen tetrahalides react with strong Lewis acids to form ionic adducts. The role of the halide ion acceptor can be filled not only by halides of main group elements like $AlCl_3$ or SbF_5, but by metal halides of the subgroup elements as well, such as $TiCl_4$, $NbCl_5$, $FeCl_3$, UCl_5, or $AuCl_3$. $MoOCl_3$ also proved to be a suitable Lewis acid. The compounds $SCl_3^+MoOCl_4^-$[18] and $SeCl_3^+MoOCl_4^-$[19] were obtained from MoO_3 and a mixture of SCl_2/Cl_2 or directly from $SeCl_4$ and $MoOCl_3$. This series is completed by the preparation of the corresponding tellurium compound $TeCl_3^+MoOCl_4^-$,[20] which turned out to be isostructural with $SeCl_3^+MoOCl_4^-$.

Likewise, $MoCl_4$ reacts with $TeCl_4$ and accepts two chloride ions, thus forming $MoCl_6^{2-}$. Depending on the amount of $TeCl_4$ used, two different compounds, $MoTe_2Cl_{12}$ and $MoTe_3Cl_{16}$ could be obtained.[21] Their structures feature almost ideally octahedral $MoCl_6^{2-}$ ions and trigonal-pyramidal $TeCl_3^+$ ions. Figure 2 shows a section from the structure of $MoTe_3Cl_{16}$. In addition to the three short Te–Cl distances (230–232 pm) there are three longer Te–Cl contacts (287–302 pm); the result is that

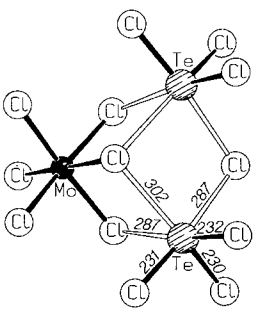

Fig. 2. A section from the structure of $MoTe_3Cl_{16}$ which can also be formulated as $(TeCl_3^+)_3(MoCl_6^{2-})(Cl^-)$. Short covalent bonds are represented by black rods, longer weak Te–Cl contacts by white rods. The Mo–Cl distances are between 224 and 249 pm, the Te–Cl bonds are given in pm.

Johannes Beck was born in 1956 in Hornberg/Schwarzwald. From 1976–1982 he studied chemistry at Tübingen, where he received his doctorate under the supervision of J. Strähle with a thesis on pentaazadienido metal complexes. Subsequently, he moved to work with H. Bärnighausen at the Universität Karlsruhe, where he completed his habilitation in 1991. In 1992 he accepted a call to the Universität Giessen to succeed R. Hoppe to the chair for Inorganic and Analytical Chemistry. His research interests include crystal structure analysis, polycations of the chalcogens, halides, oxyhalides, and chalcogenides of the transition metals, as well as metal complexes with polyazenido ligands.

each Te atom is surrounded by a distorted octahedron of Cl atoms. This distortion of the polyhedron around the Te atom is found in almost all compounds of TeX_3^+ ions and halide metalate ions and is caused by the lone pair of electrons at the Te^{4+} ion. The stereochemically active lone pair points from the Te ion towards one of the faces of the coordination polyhedron and thereby effects the typical separation into three normal and three elongated Te–X distances.[22] $MoTe_3Cl_{16}$ is thus regarded as $(TeCl_3^+)_3(MoCl_6^{2-})(Cl^-)$, and $MoTe_2Cl_{12}$ as $(TeCl_3^+)_2(MoCl_6^{2-})$. The two compounds may also be described as mixed tetrahalides $3\,TeCl_4 \cdot MoCl_4$ and $2\,TeCl_4 \cdot MoCl_4$. The chlorine atoms form closest-packed structures with different stacking sequences, in which Mo and Te atoms occupy a quarter of the tetrahedral interstices in an ordered fashion.

Although both $MoTe_2Cl_{12}$ and $MoTe_3Cl_{16}$ are ternary compounds of the Mo/Te/Cl system, they do not belong to the category of molybdenum chloride telluride compounds. In the latter one would expect not only to find Mo–Cl bonds, but also Mo–Te bonds, which occur in neither $MoTe_2Cl_{12}$ nor in $MoTe_3Cl_{16}$.

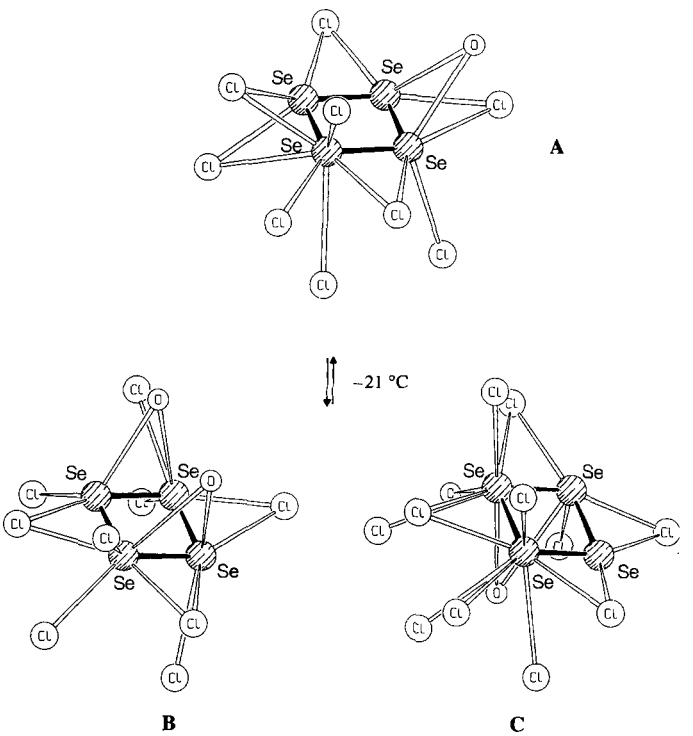
3. The Oxidation of Chalcogen Elements by Transition Metal Halides: A New Route to Chalcogen Polycations

One of the historical discoveries in the chemistry of the early nineteenth century was the observation that sulfur, selenium, and tellurium were soluble in concentrated sulfuric acid. The composition of the ensuing intensely colored solutions, however, remained unknown until the mid-1960s.[23] From preliminary investigations by the research groups of Bjerrum,[24] Gillespie,[25] and Corbett,[26] it became apparent that chalcogen polycations were responsible for the coloring. This was corroborated by the first crystal structure analyses of the tetrachloroaluminates of the Se_8^{2+}[27] and Te_4^{2+} ions.[28] Convenient preparations for these ions are the oxidation of the chalcogen elements with $S_2O_6F_2$ in HSO_3F, or with AsF_5 or SbF_5 in liquid SO_2, or the symproportionation of the chalcogen elements with a higher chalcogenide halide in the presence of a halide ion acceptor. In this way, saltlike compounds are formed whose AsF_6^-, SbF_6^-, SO_3F^-, or $AlCl_4^-$ anions, as weak conjugate bases of very strong Lewis acids, stabilize the chalcogen polycations. So far, only one compound with a halide metalate anion of a transition metal has been reported: Tellurium and $TeCl_4$ react in a $NbCl_5/NbOCl_3$ melt to form $Te_4^{2+}Nb_2OCl_{10}^{2-}$.[29] The reaction does not change the oxidation state of the niobium atom; the $NbCl_5/NbOCl_3$ mixture acts as a Lewis acid and elemental tellurium is oxidized by $TeCl_4$. A more recent finding is that chalcogen elements can be oxidized directly and selectively to chalcogen polycations by transition metal halides whose metal atoms are in high oxidation states. The metal halides are reduced to halide metalate anions and a solvent is unnecessary. Rather, the components react in sealed glass or quartz ampoules under vacuum, along a defined temperature gradient, in the sense of a chemical transport reaction. Using reaction temperatures between 150 and 250 °C and temperature gradients of approximately 20 °C, these ionic compounds are successfully deposited (mostly quantitatively) from the vapor phase in the colder part of the reaction ampoule.

3.1. Se_4^{2+} and Te_4^{2+}: Well-known Ions in New Environments

Tellurium reacts smoothly with $MoOCl_4$ or WCl_6 to form $Te_4^{2+}(MoOCl_4^-)_2$[30] and $Te_4^{2+}(WCl_6^-)_2$,[31] respectively. For selenium, the reaction with $MoOCl_4$ leads to the analogous selenium compound $Se_4^{2+}(MoOCl_4^-)_2$.[21] The structures of these compounds feature square-planar E_4^{2+} ions (E = Se, Te), which have been synthesized during the past few years with various counterions. Strong cation–anion interactions are characteristic for these saltlike compounds.

In each case four halogen or four halogen and oxygen atoms bridge the edges of the E_4 square, and additional neighboring atoms are arranged above and below the E_4 square plane.[32] Though the chalcogen–halogen distances in these compounds are longer than covalent bonds, they are often noticeably shorter than the sum of the van der Waals radii. The E_4^{2+} ions can be perceived as aromatic systems with 6π electrons and have repeatedly been subject of molecular orbital calculations.[33–35] They possess a lowest unoccupied, weakly antibonding molecular orbital, which extends above the ring edges. Partial transfer of electron density to neighboring anions causes a slight elongation of the bonds within the E_4^{2+} ion. In $Se_4^{2+}(MoOCl_4^-)_2$, such



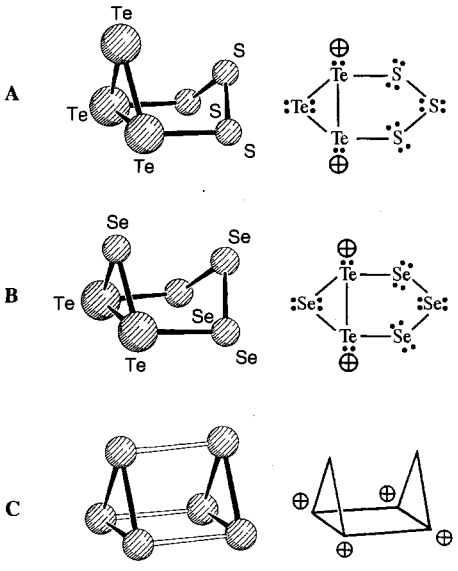


Fig. 3. Structure of the Se_4^{2+} ion in $Se_4(MoOCl_4)_2$. The Cl and O atoms from neighboring $MoOCl_4^-$ ions that are not more than 360 pm from a Se atom are represented in the structures **A**–**C**. At −21 °C, a reversible phase transition (ΔH = 0.2 kJ mol^{-1}) occurs. The room temperature phase has only one crystallographically independent Se_4^{2+} ion (**A**). In the low-temperature phase this is split into two independent cations (**B** and **C**) as a result of a doubled lattice parameter, and thus a doubled unit cell volume.

interactions are the driving force for a solid-state phase transition. Whereas the structures of the Se_4^{2+} and $(MoOCl_4^-)_2$ ions do not change, their relative orientation changes at $-21\,^{\circ}C$ in such a way that the Se centers show a higher coordination number in the low-temperature phase (Fig. 3).

3.2. Te_6^{2+}: Another Prismatic Chalcogen Polycation

The chalcogen polycations with six atoms known so far, for example, $Te_3S_3^{2+}$,[36] $Te_2Se_4^{2+}$,[37] and Te_6^{4+},[38] have structures that can be derived from a hexagonal prism (Scheme 2). In the heteroatomic ions $Te_3S_3^{2+}$ and $Te_2Se_4^{2+}$, two edges of the prism are unconnected. In both polycations there are two tellurium atoms that are three-bonded (cross-ring bond) which formally carry the positive charges, according to the Zintl–Klemm concept.[39] The Te_6^{4+} ion has six very short bonds of 267 pm between the Te atoms of the triangular faces and three very long Te–Te bonds of approximately 312 pm which link the triangular faces of the prism. If these long bonds are assigned a bond order of 2/3, this ion also obeys the Zintl–Klemm concept, which predicts four three-bonded Te atoms for Te_6^{4+} ions. In the homoatomic Te_6^{4+} ion, the four charges are distributed equally over the six Te atoms.

Scheme 2. Structures of the hexaatomic chalcogen cations $Te_3S_3^{2+}$ (**A**), $Te_2Se_4^{2+}$ (**B**), and Te_6^{4+} (**C**), and their corresponding Lewis structures. For the Te_6^{4+} ion only one of the three possible resonance structures is shown.

The Te_6^{2+} ion has been postulated several times[25, 26] but has so far not been characterized by crystal structure analysis. At 210–230 °C, tellurium and $WOCl_4$ selectively react to form Te_3WOCl_4, a compound built of discrete Te_6^{2+} ions and one-dimensional strands of $WOCl_4^-$ ions.[21] The Te_6^{2+} ion (Fig. 4) has a prismatic Te_6 structure with one prism edge, which joins the triangular faces, not connected by a bond, and only weak Te–Te contacts (mean 328 pm) in the two Te_3 triangles. The other Te–Te bonds (mean 272 pm) fall within the range of covalent

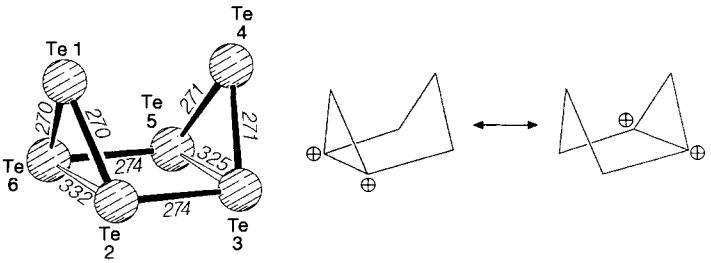

Fig. 4. Structure of the Te_6^{2+} ion in $Te_6^{2+}[(WOCl_4^-)_2]_n$, and its corresponding resonance structures; bond lengths given in pm.

Te–Te bonds. In the homoatomic Te_6^{2+} ion, the two positive charges are localized at four Te centers. This can be expressed by the resonance structures shown in Figure 4. Even though in the structure of $Te_6(WOCl_4)_2$ the Te_6^{2+} ions form strands (see Fig. 6, **A**), there is no interaction between the single polycations. The shortest interionic distance between Te atoms is 461 pm, which is longer than the sum of the van der Waals radii (440 pm).[40]

3.3. The Bicyclic Te_8^{2+} Ion: Final Member of the Homologous Series E_8^{2+} (E = S, Se, Te)

The octaatomic polycations S_8^{2+}[41] and Se_8^{2+}[27] were prepared by using the classical methods for synthesis of chalcogen polycations as AsF_6^- and $AlCl_4^-$ salts, respectively. The unusual structures of these ions, which both form eight-membered rings with weak transannular intramolecular interactions, and their bonding have already been discussed several times.[42, 43] More modern concepts of chemical bonding interpret these transannular bonds as six-center, two-electron $\pi^*-\pi^*$ bonds.[44]

The final member of the series of E_8^{2+} cations, Te_8^{2+}, was obtained in the compound $Te_8^{2+}(WCl_6^-)_2$ by reacting WCl_6 with tellurium.[45] The formation of ionic products with WCl_6 to date remains restricted to tellurium. Sulfur reacts with WCl_6 either to give $WSCl_4$ or to give the adduct $WCl_6 \cdot S_8$, depending on the reaction conditions. The structure of $WCl_6 \cdot S_8$ is built of alternate layers of neutral S_8 rings and WCl_6 molecules.[46] The reaction of selenium with WCl_6 is presently under investigation.[12] The structure of the Te_8^{2+} ion (Fig. 5) can be described as a bicyclic species consisting of two condensed five-membered rings, each of which assumes an envelope configuration. The Te–Te distances around the eight-membered ring are on average 275 pm, the transannular bond is 299 pm. The two bridgehead

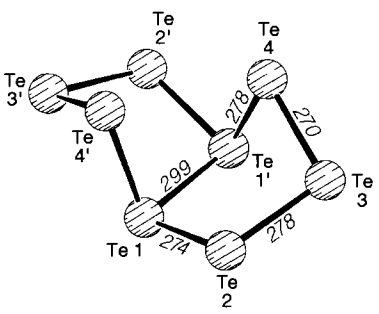

Fig. 5. Structure of the Te_8^{2+} ion in $Te_8(WCl_6)_2$. The ion has a twofold rotational axis perpendicular to the Te1–Te1′ bond. The bond lengths are given in pm.

atoms Te1 and Te1′ are three-bonded and are trigonal-pyramidally coordinated. The two positive charges in the Te_8^{2+} ion are predominantly localized at these two Te atoms. In contrast to its two lighter homologues S_8^{2+} and Se_8^{2+}, the bicyclic character in the Te_8^{2+} ion is more pronounced due to the short transannular bond. Moreover, in the structure of $Te_8(WCl_6)_2$ (Fig. 6, **B**) the association of chalcogen polycations was observed for the first time. The individual Te_8^{2+} ions are linked by Te–Te contacts of 342 pm to form a folded band. Interionic contacts of a similar size are also observed in the chainlike tellurium polyanions Te_4^{2-} and Te_5^{2-}, in which polyanionic units associate and form polymeric strands of tellurium.[47,48]

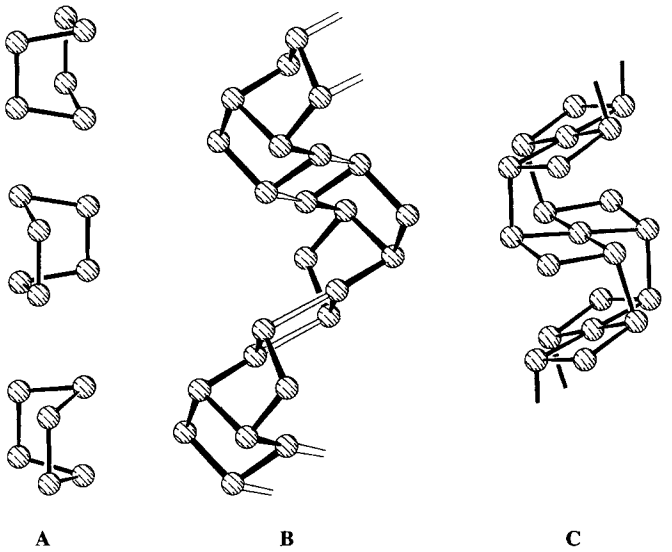

Fig. 6. The arrangement of the Te_6^{2+} (**A**), Te_8^{2+} (**B**), and $(Te_7^{2+})_n$ ions (**C**) in the structures of $Te_6(WOCl_4)_2$, $Te_8(WCl_6)_2$, and Te_7WOBr_5, respectively. This structural comparision illustrates the increase of interionic interactions, culminating in the polymeric structure (**C**).

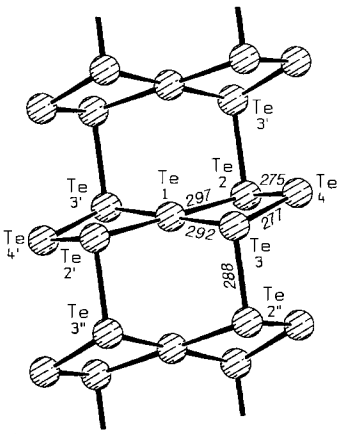
3.4. Te_7^{2+}: A Polymeric Tellurium Polycation

The polymeric $(Te_7^{2+})_n$ tellurium cation occurs in the Te_7MOX_5 type structure, for which four examples are known so far: Te_7WOBr_5,[49] Te_7WOCl_5,[50] and Te_7NbOX_5 (X = Cl, Br).[51] These compounds are built of one-dimensional strands of square-pyramidal $(MOX_4^-)_n$ ions, isolated X^- ions, and polymeric $(Te_7^{2+})_n$ ions, in which nearly planar Te_7 units are linked to give a folded band (Fig. 7). The charge distribution in the Te_7MOX_5 type structure can be unambiguously clarified by preparing the niobium-containing compounds (but not by preparing those containing tungsten). The diamagnetism of aTe_7NbOBr_5 shows that the niobium atom is in the oxidation state + v, the $NbOBr_4^-$ group carries one negative charge, and the correct ionic formulation of the compound is $(Te_7^{2+})_n(NbOBr_4^-)_nBr^-$. Already on going from the Te_6^{2+} ion (discrete) to the Te_8^{2+} ion (significant interionic interaction), the increasing tendency towards association between the tellurium polycations becomes apparent. In the polymeric $(Te_7^{2+})_n$ ion, the Te_7 units are connected by covalent Te–Te bonds of 288 pm (see Fig. 6, **C**).



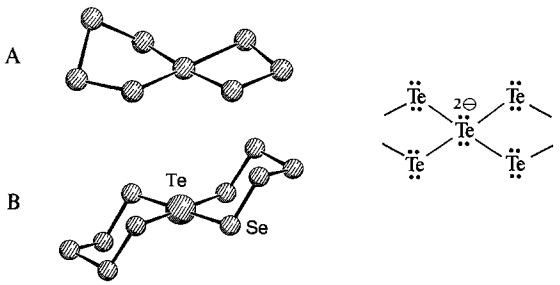


Fig. 7. Structure of the polymeric Te cation $(Te_7^{2+})_n$; bond lengths given in pm.

Structural motifs of the $(Te_7^{2+})_n$ ion are realized in various ways in compounds with tellurium polyanions.[52] Thus, for example, the central square-planar $TeTe_4^{6-}$ unit is common to the discrete Te_5^{6-} ion in Ga_2Te_5,[53] the polymeric $(Te_5^{2-})_n$ ion in Rb_2Te_5 and Cs_2Te_5,[54] the spirocyclic anions in Te_7^{2-}[55] and Te_8^{2-},[56] (Scheme 3, **A**) and the $(Te_7^{2+})_n$ ion. Compounds with the same structural motif containing selenium are also known with the spirocyclic anions $TeSe_{10}^{2-}$ (Scheme 3, **B**)[57] and Se_{11}^{2-}.[58] The $TeTe_4^{6-}$ unit contains 36 valence electrons and is isostructural with XeF_4 or ICl_4^- (Scheme 3). The Gillespie–Nyholm valence shell-electron pair repulsion model[59] regards the central tellurium atom in an ψ^2 octahedral (psedo-octahedral) coordination, in which the two lone pairs are *trans* to each other. Extended-Hückel calculations[60] interpret the bonding in terms of a three-center, four-electron model. In this model, the significant elongation of the four Te–Te bonds by approximately 8% (as compared with the sum of the covalent radii of 274 pm) can be explained in terms of the antibonding character of the highest occupied molecular orbitals.

Scheme 3. Structures of the spirocyclic anions Te_8^{2-} (**A**), $TeSe_{10}^{2-}$ (**B**), and a Lewis formula for the central $TeTe_4^{2-}$ unit.

3.5. $Te_6I_2^{2+}$ and $(Se_6I^+)_n$: A Discrete and a Polymeric Iodochalcogen Polycation

Under ambient conditions, sulfur and selenium do not form stable binary iodides. With the exception of the SeI_6^{2-} ion, no compounds with S–I or Se–I bonds were known until a few

years ago. The first successful synthesis of a neutral compound with a Se–I bond was achieved in 1987 with 2,4,6-tri-*tert*-butylphenyl(iodo)selenide.[61] Here, the bulky phenyl substituent affords kinetic stabilization. In their cationic forms, however, bound into a crystal lattice with AsF_6^- or SbF_6^- anions, S–I and Se–I bonds are stable. Since the first preparation of an (iodo)sulfur cation in $S_2I_4^{2+}(AsF_6^-)_2$ in 1980 by Passmore et al.,[62] the same group has synthesized a whole series of other cations such as S_7I^+, $[(S_7I)_2I]^{3+}$, SeI_3^+, $Se_2I_4^{2+}$, $(Se_6I^+)_n$, and $Se_6I_2^{2+}$.[63]

TeI_3^+ was hitherto the only known (iodo)tellurium cation.[64] From the reaction of Te, I, and WCl_6, another (iodo)tellurium cation, $Te_6I_2^{2+}(WCl_6^-)_2$ has now become accessible.[21] This cation is centrosymmetric and the Te atoms form a six-membered ring with chair conformation, in which the two iodine atoms are bound to the ring at positions 1 and 4 in such a way that an *endo-endo* conformation results (Fig. 8). The $Te_6I_2^{2+}$ ion

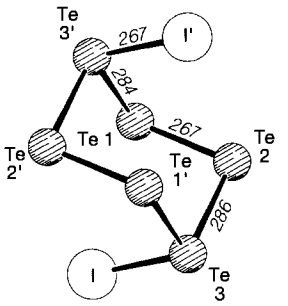

Fig. 8. Structure of the centrosymmetric $Te_6I_2^{2+}$ ion in $Te_6I_2(WCl_6)_2$; bond lengths given in pm.

is thus isostructural with its selenium analogue $Se_6I_2^{2+}$.[65] Both ions have distinctly alternating bond lengths. In the $Te_6I_2^{2+}$ ion, the Te–I bonds as well as the Te1–Te2 bonds, and the Te1′–Te2′ bonds (all 267 pm) are unusually short. Conversely, the other Te–Te bonds (mean 285 pm) are clearly longer than a Te–Te single bond (expected value 274 pm). Formally, the two positive charges are localized at the two three-bonded Te3 and Te3′ atoms. If the shortened bonds are assigned some degree of double bonding, however, delocalization ensues and the positive charges are distributed over all atoms in the cation, including the iodine atoms.[65] This interpretation is made plausible from the occurrence of several short distances between the I atoms of the cations and the Cl atoms of the WCl_6^- anions in the $Te_6I_2^{2+}(WCl_6^-)_2$ structure.

The reaction of selenium, iodine, and WCl_6 selectively leads to the polymeric (iodo)selenium cation $(Se_6I^+)_n$ in the compound $(Se_6I^+)_nWCl_6^-$.[66] The cation (Fig. 9) is an infinite one-dimensional chain of Se_6 rings in a chair conformation, connected by iodine bridges formed by *endo* iodine atoms at *para* Se ring atoms. The linear environment of the iodine atoms is best understood under the assumption of a three-center, four-electron bond. The Se–I distances (278 pm) are significantly longer than the sum of the covalent radii (250 pm). The structure of the polymeric cation is very similar to that of the corresponding cations in $(Se_6I)AsF_6$ and $(Se_6I)SbF_6$.[65] The difference lies in the identical orientation of the Se_6 rings in $(Se_6I)WCl_6$, as opposed to a twisted orientation of adjacent rings in $(Se_6I)MF_6$ (M = As, Sb).

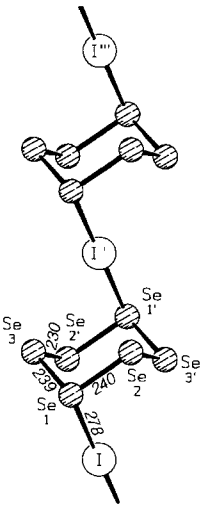

Fig. 9. Structure of the polymeric $(Se_6I^+)_n$ ion in $(Se_6I)WCl_6$. There are inversion centers at the iodine atom positions and at the centers of gravity of the Se_6 rings; bond lengths given in pm.

Has the original goal of synthesizing molybdenum and tungsten halide tellurides been achieved with the compounds presented in this section? At a first glance, the overall formulas of $MoOTe_2Cl_4$, WTe_2Cl_6, $MoOSe_2Cl_4$, $WOTe_3Cl_4$, WTe_4Cl_6, $WOTe_7Br_5$, $WOTe_7Cl_5$, $NbOTe_7Cl_5$, $NbOTe_7Br_5$, WTe_3Cl_6I, and WSe_6Cl_6I seem to suggest this. The structural principle common to all these compounds is their construction from chalcogen polycations and halide metalate anions; however, these compounds have no metal–chalcogen bonds. Thus, the compounds presented so far cannot be counted among the desired class of metal halide tellurides compounds.

4. Halogen-Containing Tellurides and Halide Tellurides of Molybdenum and Tungsten

In this section the emphasis will again be placed on compounds of the ternary system metal/tellurium/halogen (metal = molybdenum, tungsten), but which are based on structural principles totally different from those considered so far.

4.1. $MoTe_4Br$: A Molybdenum Telluride with a Chain Structure, Containing Bromine

$MoTe_4Br$ forms as crystals with a silver luster from $MoTe_2$, Te, and $TeBr_4$ at 440 °C.[21] The structure of $MoTe_4Br$ is characterized by infinite one-dimensional $Mo(Te_2)_2$ chains with intercalated bromide ions (Fig. 10). $MoTe_4Br$ is isotypic with $TaTe_4I$, which is closely related to $NbTe_4I$.[67] Mo_2 pair formation occurs along the linear molybdenum chain. The short Mo–Mo distance (300 pm) is still within the range of a metal–metal bond. For comparison, the formal Mo–Mo single bond in the structure of $[Mo_6Cl_8]Cl_4$ is 261 pm,[68] and in the structure of $MoTe_2$, in which the Mo atoms form zigzag chains, the metal–metal distance is 290 pm.[69] The larger distance of 382 pm to the adjacent Mo_2 pairs in $MoTe_4Br$ is no longer considered as a Mo–Mo interaction. This pair formation indicates that the molybdenum atoms in $MoTe_4Br$ still possess available d electrons. As expected, in $NbTe_4I$ and $TaTe_4I$, which formally con-

tain Nb^{5+} and Ta^{5+}, respectively, and thus have a d^0 configuration, the metal–metal distances within the chain are equidistant.[67]

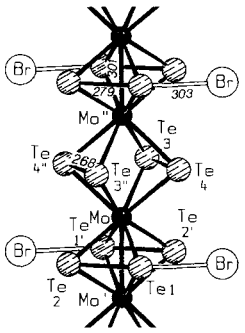

Fig. 10. A section from the $Mo(Te_2)_2$ chain in the structure of $MoTe_4Br$ with the most important bond lengths given in pm. The Mo–Te bonds range between 273 and 287 pm.

The tellurium atoms in $MoTe_4Br$ form Te_2^{2-} ions which bridge two adjacent Mo atoms in such a way that each Mo atom achieves a coordination number eight and a square antiprismatic coordination polyhedron results. The bromide ion forms close contacts to several Te atoms, of which the Te1–Br distance of 303 pm is the shortest. Since the sum of the covalent radii of Te and Br atoms is 251 pm,[40] a Te–Br bond of 303 pm is very weak, but still partially covalent. The Te–Br distances of 290 and 302 pm in the tellurium subhalide Te_2Br fall into a similar range.[70] Whether the distance between the atoms Te1 and Br in the $MoTe_4Br$ structure is regarded as a covalent Te–Br bond, or as a close contact of a bromide ion with a Te atom from a positively charged $Mo(Te_2)_2$ chain, results in two limiting ionic formulas: $(Mo^{3+})(Te_2^{2-})(Te_2Br^-)$ or $[(Mo^{5+})(Te_2^{2-})_2]^+(Br^-)$. Since $MoTe_4Br$ shows only a weak, temperature-independent paramagnetism, the coupling of unpaired electrons is very strong, and thus a decision on the oxidation state of the molybdenum centers is not possible on the basis of magnetic properties. A comparison with the isostructural $TaTe_4I$ favors the existence of Mo^{5+} ions with a d^1 configuration in $MoTe_4Br$; in $TaTe_4I$ the Ta oxidation state appears certain, since in the chain of Ta atoms there are no Ta–Ta pairs. The Te–Te bonds within Te_2 groups taking part in the short Te–halogen contacts are lengthened in both $TaTe_4I$ and $MoTe_4Br$. For $TaTe_4I$ this increase is approximately 4 pm, for $MoTe_4Br$ it is 11 pm. This shows that the Te–halogen interactions are slightly bonding, a result which was confirmed by band structure calculations on $TaTe_4I$.[67] The Te_2Br fragment is also encountered in the $[(C_5H_5)(CO)_2MoFe(CO)_3(Te_2Br)]$ complex[71] (Fig. 11), in which Te–Br distance and the Te–Te distance are 281 pm. The complex is only weakly dissociated in solution, which indicates the stability of the Te–Br bond; however, it reacts with $AgSbF_6$ to give the 1:1 electrolyte $[(C_5H_5)(CO)_2MoFe(CO)_3(Te_2)]^+SbF_6^-$.

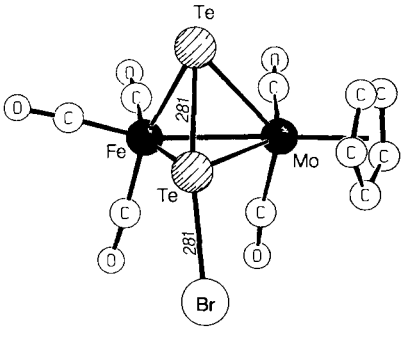

Fig. 11. Structure of the $[(C_5H_5)(CO)_2MoFe(CO)_3(Te_2Br)]$ complex [71]; bond lengths given in pm.

4.2. $MoTe_6Br_3$: A Molybdenum Telluride with Te_4^{2+} Ligands, Containing Bromine

$MoTe_6Br_3$, like $MoTe_4Br$, forms as crystals with a silver luster from $MoTe_2$, Te, and $TeBr_4$, but at a lower temperature (300 °C).[21] The structure of $MoTe_6Br_3$ (Fig. 12) is built from bromide ions and dimeric cationic complexes which can be perceived as fragments from the chain structure of $MoTe_4Br$. The dimers are centrosymmetric and consist of Mo_2 pairs (Mo–Mo distance 296 pm) bridged by two Te_2^{2-} pairs (Te1–Te2 and Te1'–Te2'). Two almost planar Te_4 rings, bound in an η^4–π fashion, complete an octacoordinate environment around each Mo atom in the form of a square antiprism. The average Te–Te bond length in the Te_4 rings is 279 pm. If the Te_4 ring is assumed to be a complexing Te_4^{2+} ion, $MoTe_6Br_3$ can be formulated ionically as $[(Mo^{3+})_2(Te_2^{2-})_2(Te_4^{2+})_2]^{6+}(Br^-)_6$. Thus far, there are only a few examples of chalcogen polycations acting as complex ligands. For instance, the reaction of $[M(CO)_6]$ (M = Mo, W) with Se_4^{2+} in liquid SO_2 affords a complex cation $[(CO)_5MSe_4M(CO)_5]^{2+}$,[72] in which the Se_4^{2+} ion is bound as an η^2 ligand along two of the edges of the four-membered ring to two $M(CO)_5$ fragments (Fig. 13, **A**). The same reaction with Te_4^{2+} yields the cationic complex $[(CO)_4M(Te_3)]^+$,[73] which contains the triangular Te_3^+ ion (unknown as a noncomplexed species) as a π-bound η^3 ligand (Fig. 13, **B**). The structure of $Nb_3OTe_8I_7$ contains complex cations, in which a Te_4^{2+} ion bridges two niobium atoms (Fig. 13, **C**).[74] The consideration of Te_4^{2+} as a ligand is also supported by the coordination of neighboring halide ions, which in $Nb_3OTe_8I_7$ (Fig. 13, **C**) and $MoTe_6Br_3$ (Fig. 12) typically bridge the edges of the Te_4 ring. In $MoTe_6Br_3$ some of these Te–Br distances are very short, and, in particular, the Te3–Br and the Te5–Br distances (mean 281 pm) must be interpreted as considerably covalent Te–Br bonds.

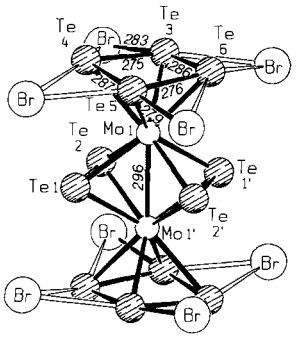

Fig. 12. Structure of the $[Mo_2(Te_2)_2(Te_4)_2]^{6+}$ complex in $MoTe_6Br_3$ with the most important bond lengths given in pm. The adjacent bromide ions which bridge the edges of the Te_4 rings are also shown. The weaker Te–Br contacts are represented by white rods. The Mo–Te bonds range between 273 and 286 pm.

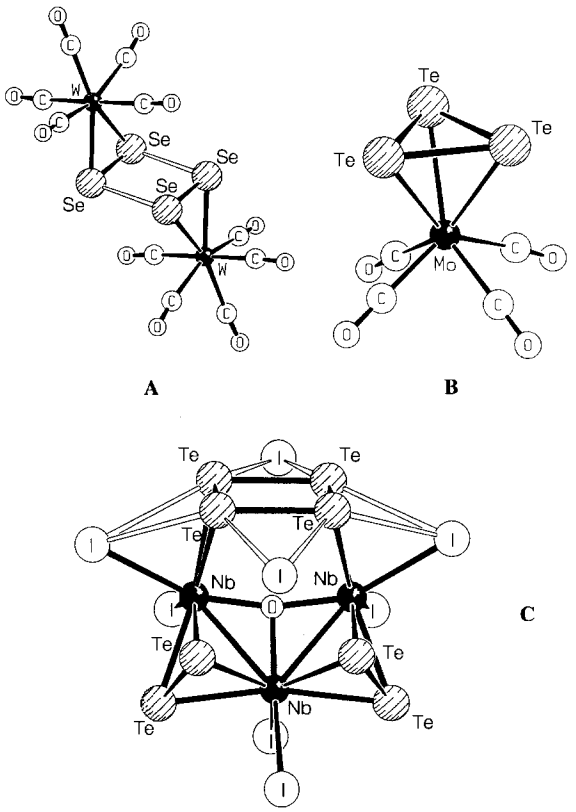

Fig. 13. Structures of compounds containing chalcogen polycations that complex metal atoms. **A**: $[(CO)_5MSe_4M(CO)_5]^{2+}$ [72], **B**: $[(CO)_4Mo(Te_3)]^+$ [73]. **C** shows a section from the $Nb_3OTe_8I_7$ structure [74].

4.3. $Mo_4Te_7X_8$ (X = Cl, Br): A Molybdenum Halide Telluride with a Structure Containing Two Different Chains

At 500 °C, the isostructural compounds $Mo_4Te_7Cl_8$ and $Mo_4Te_7Br_8$ are formed in the ternary molybdenum/tellurium/halogen (halogen = Cl, Br) system.[21] Both compounds appear as shining black needles. $Mo_4Te_7Br_8$ is a semiconductor with a small specific conductivity of 4×10^{-5} $(\Omega cm)^{-1}$ at room temperature. The structures are built from two different one-dimensional chains between which there are no significant interactions (Fig. 14). One of the chains, $(Mo_2X_7)_n$, contains only molybdenum and halogen atoms. Each Mo atom is hexacoordinated by an octahedron of six halogen atoms. The MoX_6 octahedrons connect by alternately sharing edges and faces along the chain. Furthermore, the Mo atoms form Mo_2 pairs with distances of 275 pm for X = Cl and 282 pm for X = Br. The other chain, $[Mo_2(Te_2)_3(TeX)]_n$, contains Mo atoms surrounded only by Te atoms. The Mo_2 pair formation is much less pronounced, and the Mo–Mo distances alternate only slightly with 292 and 301 pm for X = Cl and 296 and 310 pm for X = Br. Along the chain, two neighboring Mo atoms are each coordinated alternately by two μ_2-Te_2^{2-} pairs, or by one μ_2-Te_2^{2-} pair and the Te atom of a bridging TeX group. The TeX groups, hitherto unknown, are a peculiarity in the $Mo_4Te_7X_8$ structures. The Te–X distances are 244 pm for X = Cl and 260 pm for X = Br; thus, they are only slightly longer than the sum of the covalent radii of Te and Cl atoms (236 pm) and Te and Br atoms (251 pm), respectively. It is thus a reasonable to consider the TeX group as the isoelectronic tellurium analogue of the hypochlorite ion OCl^-. The ionic formula $[\{(Mo^{4+})_2(Te_2^{2-})_3(TeX^-)\}^+]_n$-$[\{(Mo^{3+})_2(X^-)_7\}^-]_n$ for $Mo_4Te_7X_8$ therefore seems appropriate.[75]

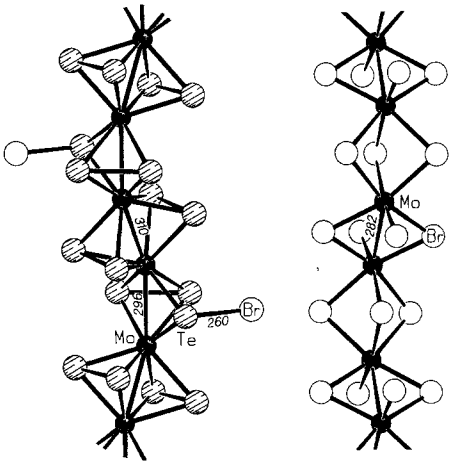

Fig. 14. Sections from the $Mo_2(Te_2)_3(TeX)$ and Mo_2X_7 chains in the structures of $Mo_4Te_7X_8$ (X = Cl, Br). The distances given pm are valid for $Mo_4Te_7Br_8$. The Mo–X bonds range from 238 to 252 pm for X = Cl, and from 251 to 268 pm for X = Br, the Mo–Te bonds are between 270 and 283 pm.

For these four new compounds from the ternary molybdenum/tellurium/halogen systems, the more or less pronounced proximity of tellurium atoms and halogen atoms is a characteristic observed in addition to the ever-present Mo–Mo interactions. With Te–Br contacts between 260 and 303 pm, a broad spectrum of distances is observed ranging from ionic contacts to covalent bonding. Since $MoTe_4Br$ and $MoTe_6Br_3$ contain only Mo–Te bonds and no Mo–Br bonds, they can be classified as bromine-containing tellurides. For $Mo_4Te_7X_8$ (X = Cl, Br), both Mo–Te and Mo–X bonds are present, so that the classification as metal halide tellurides is therefore justifiable. Admittedly, the tellurium and the halogen atoms are not bound to the same molybdenum atom—rather a separation into Mo–X chains and Mo–Te chains occurs. This may be perceived as a segregation in the solid.

4.4. $W_2O_2Te_4Br_5$: The First Tungsten Halide Telluride

$W_2O_2Te_4Br_5$ can be obtained by reacting $WOBr_4$ and tellurium at 400 °C.[21] Similar to $Mo_4Te_7X_8$, the structure of $W_2O_2Te_4Br_5$ is also composed of two different infinite one-dimensional chains (Fig. 15). In the $(WOBr_4)_n$ chains are square-pyramidal monomers which are associated through almost linear, strongly assymetric W-O-W-O bridges. The W=O distances (174 and 205 pm) are distinctly different. The second chain contains an almost linear W-O-W-O chain with identical W–O distances of 190 pm. The tungsten atoms have the coordination number seven and are pentagonal-bipyramidal surrounded. In addition to the two oxygen atoms at the apical positions, two Te_2 groups and one terminal bromine atom are coordinated to each W atom. Between the Te_2 groups of neighboring tungsten

atoms, Te–Te bonds (295 pm) exist, so that U-shaped, planar Te_4^{2-} ions are present, which each bridge one W-O-W unit. This way, for $W_2O_2Te_4Br_5$, the formal ionic formulation $[\{W^{6+}OBr(Te_4^{2-})\}^+]_n[(W^{5+}OBr_4)^-]_n$ results. Thus, in $W_2O_2Te_4Br_5$, in contrast to the previously described molybdenum compounds, for the first time, Te and Br atoms are both bound to a tungsten atom.

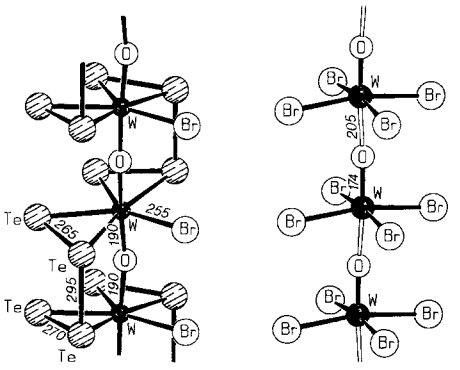

Fig. 15. Sections from the $(WOTe_4Br)_n$ and $(WOBr_4)_n$ chains in the $W_2O_2Te_4Br_5$ structure; bond lengths given in pm. The W–Br bonds in the $(WOBr_4)_n$ chain are between 248 and 255 pm, the W–Te bonds between 272 and 283 pm.

5. Summary and Outlook

The barely researched ternary M/Te/X systems with M = Mo, W and X = Cl, Br, I, turn out to be a very rich field with respect to structural chemistry, where many different structural principles are realized. Compounds such as $Mo_4Te_7X_8$ and $W_2O_2Te_4Br_5$, which simultaneously contain metal–tellurium and metal–halogen bonds and thus can be classified as halide tellurides, are still in the minority. Rather, compounds built from tellurium polycations and halide metalate anions dominate. The halide tellurides do not show the structural characteristic of terminal M=E bonds (M = Mo, W; E = O, S, Se) with a formal double bond character typical for the halide oxides, halide sulfides, and halide selenides. Apparently, this kind of bonding becomes unfavorable for the heaviest of the chalcogens used here—tellurium—and for the metal atoms in their higher oxidation states. In recent times, however, complexes with terminal tellurido ligands have become known,[76] including a tungsten complex $[WTe_2(PMe_3)_4]$ containing a linear Te=W=Te group.[77] These results have provided fresh impetus to the search for other halide tellurides of molybdenum and tungsten. The potential of the synthesis route for preparing chalcogen polycations from chalcogen elements and metal halides is by no means exhausted. The observation that different metal halides specifically generate different polycations provides hope for obtaining other new chalcogen polycations with metal halides not yet employed. Investigations with rhenium halides and uranium halides are already under way, as well as experiments to oxidize mixtures of chalcogens with suitable metal halides. It is conceivable that in this way the great number of mixed polycations, among them the octaatomic and decaatomic species $Te_2Se_6^{2+}$ and $Te_2Se_8^{2+}$,[78] respectively, synthesized in Gillespie's group, may be further increased.

The compounds available thus far raise many questions about their method of formation and their types of bonding. An interesting problem is the elucidation of the reaction mechanisms during chemical transport. For example, what is the nature of the tellurium-containing species in the gas phase above a continuously growing crystal of Te_7WOBr_5 and what effects the buildup of the polymeric tellurium substructure? Compounds such as $MoTe_4Br$ and $Mo_4Te_7Br_8$ contribute to the current topic of low-dimensional solids,[79] for which the bonding cannot be described satisfactorily by simple ionic formulas. Modern methods applied in the theory of chemical bonding will be helpful for a deeper understanding of these solids.

The results presented in this article were obtained for the most part during the authors' work on his habilitation thesis at the Universität Karlsruhe from 1988–1991. The author is very much indebted to Professor Hartmut Bärnighausen for continuous support during this period and for many helpful discussions. The results of G. Bock, T. Marschall, and J. Wetterau, my first coworkers at the Universität Giessen, have also been included in this article, and I owe them many thanks for their commitment. Thanks also go to Dr. M. Serafin for his help with the SCHAKAL plots [80] and to the Fonds der Chemischen Industrie for generous financial support.

[75] An alternative formulation assumes neutral chains; that is the Mo atoms in both chains must have mixed-valence: $[(Mo^{3+})(Mo^{4+})(Te_2^{2-})_3(TeX^-)]_n[(Mo^{3+})(Mo^{4+})(X^-)_7]_n$. No decision between the two formulations can be made from magnetic properties, since the two $Mo_4Te_7X_8$ compounds show only a weak, temperature-independent paramagnetism.

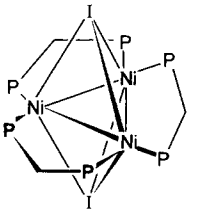
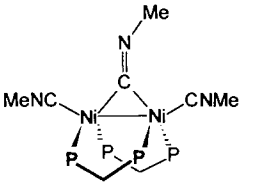
The Photochemical Activation of Carbon Dioxide Using a Nickel Complex



Walter Leitner

Carbon dioxide is in many ways a remarkable starting material in chemical syntheses.[1] It is cheap and easy to purify, presents no problems in handling, and is virtually nontoxic. Furthermore, its availability is almost inexhaustible since the quantity of carbon released by combustion of fossil fuels in the form of CO_2 far exceeds that used up in technical and chemical processes.[2] Of special interest in this context are processes that avoid the use of fossil fuels for the generation of the energy required for CO_2 activation.

Unlike chemists, plants are capable of synthesizing organic compounds from sunlight, CO_2, and a cosubstrate. Photosynthesis, optimized over millions of years of evolution and estimated to convert about 10^{11} tons of carbon per year, is the most important chemical process on our planet and forms the basis of life. It is only in the last ten years that man has begun to search intensively for molecular systems which allow the photochemical activation of carbon dioxide.[3]



The fundamental problem of photochemical activation of CO_2 is the first step, namely the formation of the radical anion $CO_2^{\bullet -}$. For this purpose it is essential to generate the necessary powerful reducing agent through irradiation. The first successful examples of this approach were achieved with, among others, metal-free redox-active systems,[4] dipyridine complexes,[5] semiconductor materials,[6] and a combination of such components.[7] In some cases small amounts of C_2 products were detected.[6b] Kubiak et al. of Purdue University have now shown that the new and exceptionally efficient photochemical reducing agent **1** also allows photoreduction of CO_2.[8] Their findings deserve special attention since for the first time the generated $CO_2^{\bullet -}$ radical anion is available for C–C coupling reactions with cosubstrates.

Cluster **1** is a result of detailed investigations of similar bi- and trinuclear nickel complexes by the same group during the last couple of years.[9] These complexes are derived from the binuclear complex **2**, in which no iodine is present and the nickel atoms are in the zero oxidation state. The authors described this and other similar binuclear Ni^0 complexes as "cradle complexes",[9a] not knowing that they were indeed an extremely promising starting point in the photochemical activation of CO_2. Thermal, electrochemical, or photochemical excitation of **2** resulted in activation of CO_2, but reactions of $CO_2^{\bullet -}$ with the isocyanide ligands finally led via structurally interesting intermediates to the stable carbonyl complex **3**, which exhibits no further reactivity towards CO_2.[9a–b] Treatment of **2** with CH_2I_2 or NiI_2 gave the first trinuclear iodine-containing complex[9c] in a rather complicated but smooth reaction. The highly symmetrical

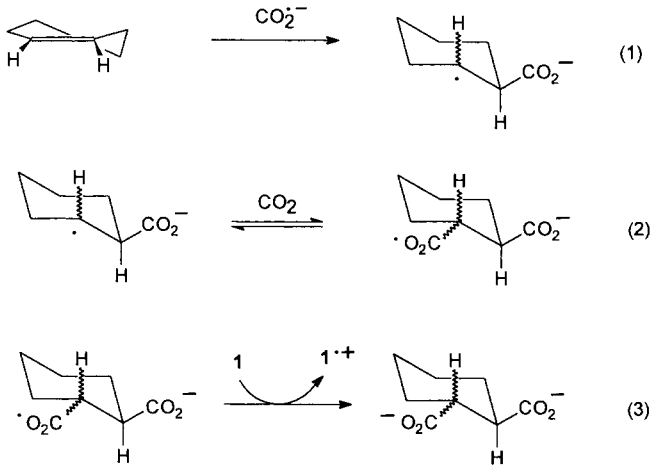
P⌒P = Ph_2P-(CH_2)-PPh_2

2

3



cluster **1** was obtained directly by the comproportionation of $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) and NiI_2 in the presence of 1,2-bis(diphenylphosphino)methane (dppm). Cluster **1** finally allowed the photochemical formation of free $CO_2^{\bullet -}$, which was detected with different methods.[8]

The violet **1** can be oxidized electrochemically at $E_{1/2}$ ($\mathbf{1}^{\bullet +}/\mathbf{1}$) = −0.69 V (vs. SCE) to the green radical cation $\mathbf{1}^{\bullet +}$. Crystal structure analyses of both compounds indicate that oxidation causes negligible structural changes in the cluster. The edges of the equilateral triangle formed by the nickel atoms are bridged by dppm ligands. Both faces of the triangle are capped by a μ_3-iodo ligand. Diffuse daylight is sufficient to bring about photochemical oxidation of **1** in solvents such as THF or CH_2Cl_2. In an atmosphere of CO_2, the photolysis of a THF solution of **1** leads to the formation of CO and CO_3^{2-} in the absence of proton sources, or to HCO_2^- in the presence of toluene. These products indicate intermediate formation of $CO_2^{\bullet -}$. In addition to these classical reactions of $CO_2^{\bullet -}$, the radical anion was trapped by cyclohexene. Equations (1)–(3) demonstrate a plausible mechanism for the observed formation of cyclohexane dicarboxylic acid; the reversibility (Kolbe reaction) of step (2) readily explains the *cis*/*trans* ratio of 37:63 in the isolated product. This is the first proof of a photochemically induced

C–C coupling with CO_2, and the first example of an addition of $CO_2^{\bullet-}$ to an olefinic double bond.

It is quite remarkable that once more a nickel complex can be considered a milestone in CO_2 chemistry. Since the first successful structural characterization of a CO_2 complex $[(Cy_3P)_2Ni(CO_2)]$ (Cy = cyclohexyl)[10] by Aresta et al., nickel complexes have been setting the pace in this branch of organometallic chemistry. Amine–nickel complexes have been reported recently to bind even atmospheric CO_2.[11] Other nickel complexes are versatile synthetic reagents in stoichiometric coupling reactions of CO_2 with unsaturated substrates.[12] Furthermore, nickel complexes are used as catalysts in the formation of cyclic carbonates from epoxides and CO_2,[13] and of 2-pyrones from alkynes and CO_2.[14a] The latter reaction was applied recently in the synthesis of novel polymers.[14b] Electrochemically generated Ni^0 species may also effect C–C coupling between alkynes and CO_2, and α,β-unsaturated carboxylic acids are produced under these conditions.[15]

The $\mathbf{1}/\mathbf{1}^{\bullet+}$ system, like all other approaches to the photochemical activation of CO_2, suffers from an unfavorable total energy balance. The C–C coupling has undoubtedly been proved, but, the authors do not comment on the yields or on the possibilities of realizing a catalytic cycle. Nevertheless, the opportunity of using photochemically activated **1** in some of the already mentioned reactions and the excellent work of Kubiak et al. are grounds enough for optimism that, in the near future, catalytic variations of photochemical C–C coupling reactions with CO_2 will be reported.

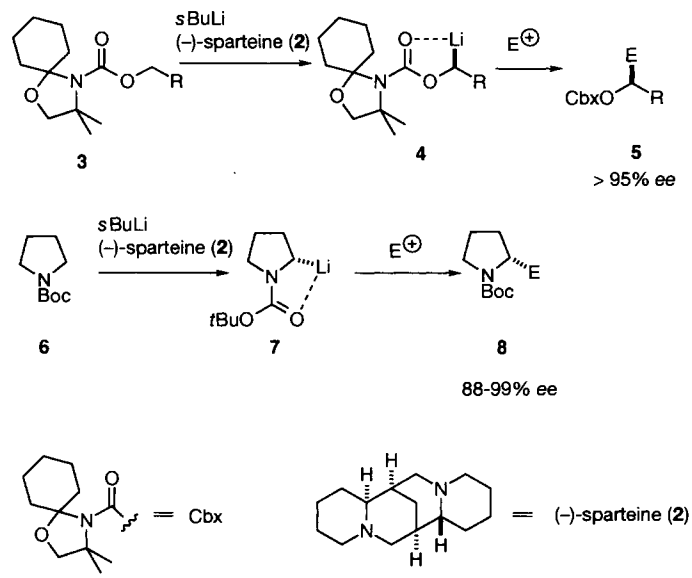
Enantioselective Transformations and Racemization Studies of Heteroatom Substituted Organolithium Compounds

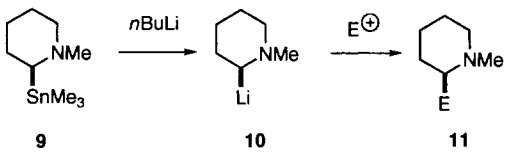
Varinder Kumar Aggarwal*



Disconnection of C–C bonds adjacent to heteroatoms is of central importance in organic synthesis. This disconnection can lead to either an organometallic reagent and a C=X group (Scheme 1, path a) or to a carbon electrophile and an α-hetero-

Scheme 1.

atom-substituted organolithium compound (path b). Both pathways can be useful for asymmetric synthesis. For successful asymmetric synthesis using path b the following traditional criteria need to be fulfilled: 1) good methods for the synthesis of the α-lithio compounds in high enantiomeric excess must be available, 2) the α-lithio compounds must be configurationally stable, and 3) either complete retention or inversion of configuration should occur upon quenching with an electrophile.



For α-alkoxy- and α-aminoorganolithium compounds there are now several processes that meet the above criteria, and the most notable examples are shown in Scheme 2. These examples utilize the chiral base derived from *s*BuLi and (–)-sparteine (**2**) to effect asymmetric deprotonation.[1–3]

Scheme 2.

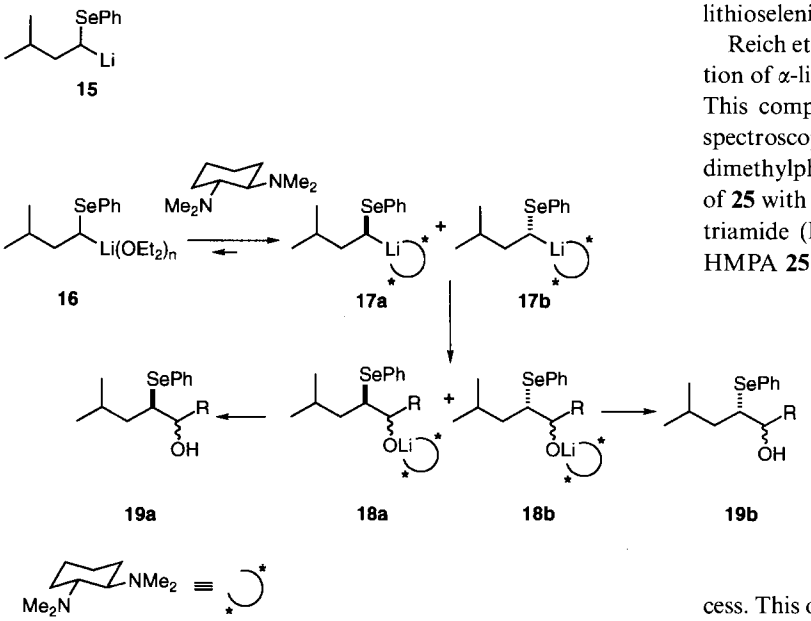
In these and all other successful cases the intermediate chiral organolithium species is stabilized by chelation to a donor group.[3, 4] The only example of an α-aminoorganolithium compound that is not stabilized by chelation but is still configurationally stable has recently been discovered by Gawley et al.[5] They have shown that cyclic α-aminostannanes without chelating groups can be transmetalated with *n*BuLi, and that such α-aminoorganolithium compounds are configurationally stable at –78 °C and can be trapped with electrophiles with complete retention of stereochemistry (Scheme 3).

Scheme 3.

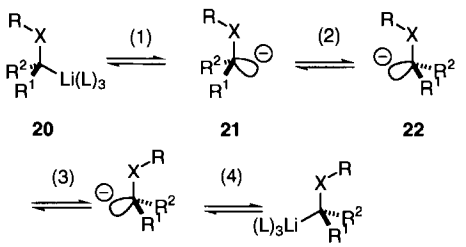
However, in contrast to oxygen- and nitrogen-stabilized carbanions, those stabilized by sulfur or selenium are much less configurationally stable.[6–8] Reich et al.[8] have shown that the α-lithioselenides **13a,b** rapidly equilibrate and that subsequent trapping with a range of electrophiles is faster than equilibration (Scheme 4). Consequently, the product ratio (**14a**:**14b**) reflects



Scheme 4.

the equilibrium ratio of the α-lithioselenides **13a**/**13b**. By considering ratios of enantiomeric and diastereomeric products obtained in reactions of racemic and nonracemic α-lithioselenides **15** (see Scheme 5) with aldehydes, Hoffmann et al. have recently shown that in acyclic systems α-lithioselenides are also trapped more rapidly than they equilibrate.[9] In contrast to the above-formulated criteria, this result demonstrates the possibility of using *configurationally labile* organolithium compounds in stereoselective synthesis by forming diastereomeric complexes with chiral additives.

In this study[9] Hoffmann et al. discovered that the equilibrium constant for formation of the amino complexes **17** was large and that these complexes react with aldehydes more rapidly

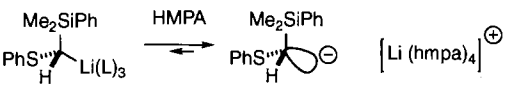


than the uncomplexed organolithium compound **16**. The ligand-induced acceleration in the rate of addition to aldehydes suggests possibilities for asymmetric catalysis. However, it was found that the intermediate **18** obtained from trapping **17** with aldehydes complexes the diamine more strongly than the α-lithioselenides **17** (Scheme 5). This means that stoichiometric amounts of diamine are required for asymmetric synthesis of **19**. The products **19** obtained showed an enantiomeric excess that was comparable to the diastereomeric ratio of **17** (7:3). This is expected when trapping of the complexed α-lithioselenides **17** is more rapid than their interconversion. If alternative diamines could be found that give rise to high thermodynamic ratios of the complexes **17a,b**, then it might be possible to obtain higher enantioselectivities. Alternatively, if trapping of the complex by electrophiles is slower than their interconversion, then higher enantioselectivities may be obtained through kinetic resolution, as has been shown by Beak et al. for a related system.[10]

Scheme 5.

Hoffmann et al.[11a] and Reich et al.[11b] have both addressed the issue of understanding the mechanism of racemization of α-lithioselenides. In α-heterosubstituted alkyllithium compounds the negative charge is partially stabilized by $n_C \rightarrow \sigma^*_{X-R}$ delocalization in the X–R bond. Thus, the starting α-lithioselenide (X = Se) **20** and the enantiomeric α-lithioselenide **24** must both possess C–Li bonds antiperiplanar to the X–R bonds. The process of racemization shown in Scheme 6 fulfills these requirements and can be discussed as a sequence of several distinct steps: 1) loss of Li from C to give either separated or contact ion pairs, 2) inversion of the pyramidal carbon atom, 3) rotation about the C–X bond, and 4) recombination of the carbanion with the Li atom.[11a]

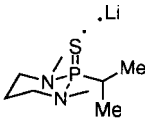
Kinetic data for the racemization of **20**, R = Ph, R^1 = $PhCH_2$, R^2 = H, ($\Delta G^{\neq}$ = 12.4 kcal mol^{-1}, $\Delta H^{\neq}$ = 11.9 kcal mol^{-1}, $\Delta S^{\neq}$ = − 2.5 kcal mol^{-1}) has now been determined.[11a]



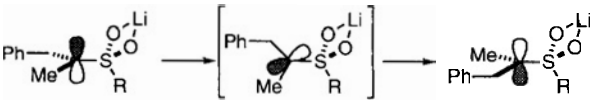
Scheme 6.

Based on comparisons with the activation energies estimated for loss of Li and inversion of pyramidal carbon, and from other observations, the authors suggested that rotation of the C–X bond was the rate-determining step (step 3). This proposal was supported by the observation that increasing substitution either at R or at the carbanion center, which reduces conformational mobility, results in greater configurational stability of the α-lithioselenide.

Reich et al. have recently studied the mechanism of racemization of α-lithioselenides using **25** as an example (Scheme 7).[11b] This compound contains several nuclei observable by NMR spectroscopy and a diastereotopic probe in the form of the dimethylphenylsilyl group. By following the ^{7}Li NMR spectrum of **25** with increasing concentrations of hexamethyl phosphoric triamide (HMPA), they found that with three equivalents of HMPA **25** was converted to the solvent-separated ion pair **26**. The diastereotopic probe showed that this species was still chiral even though significant planarization at the carbanionic center had occurred. Intuitively, one would expect the solvent-separated ion pair **26** to racemize more rapidly than the contact ion pair **25**. However, the rate of racemization is roughly twenty times slower for **26** compared to **25**, which immediately indicates that ion separation is not the rate-determining step in the racemization process. This observation fits the hypothesis that the rate-determining step is associated with rotation about the carbanion–S bond. The solvent-separated ion pair **26** should show greater $n_C \rightarrow \sigma^*_{S-R}$ delocalization than **25**, and this leads to a greater barrier to rotation about the C–S bond. Intuitively, one might expect the rate of racemization to increase with increasing concentrations of HMPA. In fact the rate of racemization is reduced. This suggests that racemization of the solvent-separated ion pair **26** might actually proceed via the contact species **25**, and recoordination of the lithium ion to carbon center, accompanied by loss of one or more HMPA molecules, explains the rate-retarding effect with increasing concentrations of HMPA.



A similar effect of HMPA is seen on the rotation about the C_α–P bond in lithiated thiophosphonamides; as in the previous



Scheme 7.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0176 $ 10.00+.25/0

ly discussed example, the presence of HMPA slows down the rate of rotation[12] (Scheme 8). Finally, the importance of

27 $\Delta G^{\ddagger}$ = 9.8 kcal mol^{-1} (THF)
$\Delta G^{\ddagger}$ = 11.4 kcal mol^{-1} (THF-HMPA)

28 **29** ent-**28**

a R = *t*Bu; $\Delta G^{\ddagger}$ = 13.0 kcal mol^{-1} (THF-DMPU)
b R = CF_3; $\Delta G^{\ddagger}$ = 17.3 kcal mol^{-1} (THF-DMPU)

Scheme 8.

$n \rightarrow \sigma^*$ delocalization of the carbanionic lone pair for configurational stability is underscored by a study of the mechanism of epimerization of α-lithiosulfones.[13, 14] The increasing barrier to racemization (**28a**: $\Delta G^{\ddagger} = 13.0$; **28b**: $\Delta G^{\ddagger} = 17.3$ kcal mol^{-1}) with increasing ability of the S–R group to accept negative charge is indicative of $n_C \rightarrow \sigma^*_{S-R}$ hyperconjugation in stabilizing the α-lithio species **28** and of the rate-determining step involving rotation about the C_α–S bond (Scheme 8).

These experiments clearly indicate that rotation of the C–X bond plays a dominant role in racemization of S-, Se-, and P-stabilized carbanions. If we are to extend the application of heteroatom-substituted anions in asymmetric synthesis to more general cases, this new understanding of the mechanism of racemization will play a crucial part.

The Sialyl Lewis^X Group and its Analogues as Ligands for Selectins: Chemoenzymatic Syntheses and Biological Functions

Athanassios Giannis*

White blood cells or leukocytes are components of blood that play a vital role in the immune response. Neutrophils, for example, are responsible for rapid and unspecific immune defense by ingesting invading bacteria, while B and T lymphocytes are responsible for the specific immune response. As part of the immune response leukocytes leave the blood vessels and migrate to the zone of infection and the secondary lymphatic organs. The cells leave the blood through the endothelium of the postcapillary venules in the area of the target tissue.

The complex multistage event leading to migration of leukocytes into the zone of infection occurs during normal chronic inflammation as well during acute inflammation and is mediated by a specific and regulated cell–cell recognition process between leukocytes and endothelial cells. This cell–cell recognition takes place by means of the interaction of a number of membrane-bound adhesion receptors with the corresponding membrane-bound ligands. The following receptors are known to be involved:[1] a) selectins, b) integrins, and c) members of the immunoglobulin superfamily.

The selectin family consists of three members, which are all glycoproteins and which mediate the initial stage of leukocyte adhesion (Fig. 1), namely, L, E, and P selectin. L selectin is constitutively expressed on the surface of leukocytes. It is involved in the recirculation of lymphocytes in peripherial lymph nodes as well as in the recruitment of leukocytes at the zone of inflammation. E selectin is expressed on the surface of endothelial cells a few hours after stimulation with interleukin 1 or tumor necrosis factor α. P selectin is kept in intercellular stores in blood platelets (thrombocytes) and endothelial cells. Within a few minutes of exposure to thrombin, histamin, substance P, peroxide radicals, or complement factors, P selectin is mobilized from these stores and transported to the cell surface. The exact structure of the membrane-associated carbohydrate ligand for L selectin is not known. However, it is known that the L selectin ligand is located at the postcapillary endothelium of the high endothelial venules (HEV) of the peripheral lymph nodes. According to the available data it is a sialic acid containing, sulfated, and possibly fucosylated oligosaccharide.[2]

The sialyl Lewis^X group (SLe^X) (**1** without R in Fig. 1) serves as a common ligand for all three selectins and is a component of glycosphingolipids and glycoproteins, which are also found on the surface of the leukocyte membrane. The importance of this oligosaccharide group for leukocyte adhesion was recently underlined by investigations into a hereditary disease, namely, leukocyte adhesion defiency type 2.[3] Owing to a defect in the biosynthesis of the SLe^X group, which is not understood yet in detail, the neutrophils are not able to adhere to stimulated endothelium and thus to migrate into the zone of inflammation. Patients with this condition suffer from repeated severe bacterial infections. On the other hand, there is also a series of acute and chronic diseases whose course is negatively influenced when too many leukocytes migrate to the area of the infection or in the area of the pathological process itself. These include cardiogenic shock, stroke, thrombosis, rheumatism, psoriasis, dermatitis, adult respiratory distress syndrome, bacterial meningitis, and encephalitis. In addition, metastasis formation in a number of tumors seems to be linked to the expression of SLe^X and other closely related oligosaccharides on the membrane surface of the tumor cells and the interaction of these groups with endothelial selectins. Efforts have thus been directed towards the development of adhesion blockers as new antiphlogistics, antithrombotics, immunosuppressants, and as drugs to prevent the formation of metastases.

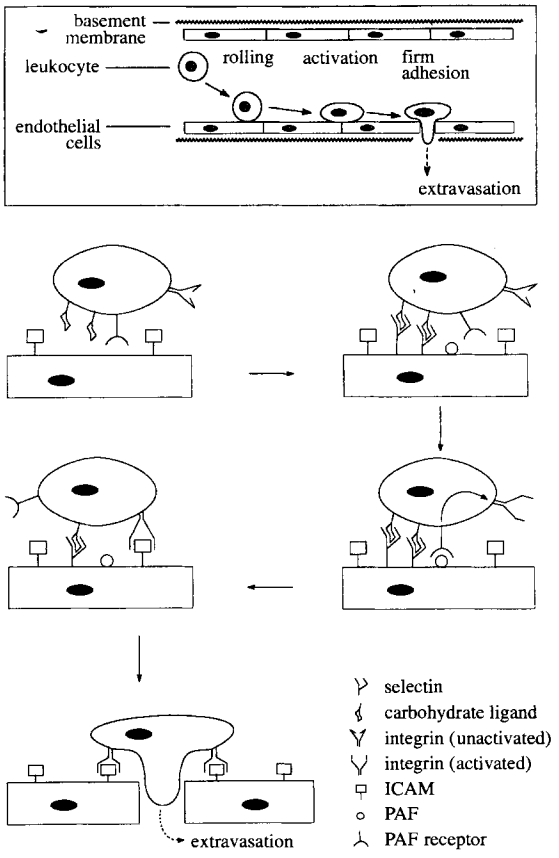

Fig. 1. Interaction between leukocytes and endothelial cells of blood vessels (modified from ref.[1e]). Top: overview; bottom: single steps with explanation of the symbols. Stimulation of endothelial cells by various mediators and factors leads to the expression of selectins and platelet-activating factor (PAF). The extravasation of leukocytes from the postcapillary venules starts with a weak, low-affinity, selectin-mediated adhesion of the leukocytes to endothelial cells, which leads to a slowing down of the leukocyte velocity (rolling). In the second phase a PAF-mediated activation of the leukocyte integrins occurs. In the third phase the activated integrins bind with high affinity to their ligands which are located on the endothelial cell surface. These ligands are called intercellular cell adhesion molecules (ICAM) and are members of the immunoglobin superfamily. The firm adhesion of the leukocyte cells to the endothelium and finally their departure from the blood vessel (extravasation) results.

A topic of currently high priority is the synthesis of the SLe^X group and analogues thereof, which could act as alternative selectin ligands and thus block the interaction between endothelium and leukocytes. Such an oligosaccharide synthesis must meet a number of criteria; it must be efficient, highly regio- and stereoselective, and suitable for large-scale production. In addition, the synthesis of a potential pharmaceutical must fulfill economic and ecological requirements (e.g. reagents containing heavy metals should be avoided). The groups of J. C. Paulson and C.-H. Wong have gone a long way towards solving these problems through the development of a clever (though not uncomplicated) enzyme-catalyzed synthesis of SLe^X (Fig. 2).[4] They employ the glycosyl transferases involved in the biosynthesis of SLe^X. A number of difficulties had to be overcome before the synthesis became viable:

a) although galactosyl transferase was available, neither the Neu5Ac transferase (Neu5AcT) nor the Fuc transferase (FucT) were;
b) the pertinent glycosyl donors (sugar nucleotides) are too expensive to be used in stoichiometric amounts in large-scale synthesis;
c) the glycosyl transferases are inhibited by the final products and/or intermediates.

The first problem was overcome by cloning and expressing the genes for Neu5Ac transferase and Fuc transferase[5] in Sf9 or COS 1 cells. In this way both transferases could be produced in large amounts. A new method for cofactor regeneration in situ allowed the sugar nucleotides (UDP Gal, CMP Neu5Ac, GDP Fuc) to be easily generated and also largely suppressed the inhibition of the enzymes by the products. To enable easy isolation, the SLe^X group was synthesized as the *O*-allylglycoside **1** ($R = CH_2CHCH_2$). In the original paper the oligosaccharide was produced in mg amounts; however, in the meantime the synthesis in g amounts has apparently been achieved.[6]

^{13}C-labeled SLe^X derivatives were also synthesized for NMR spectroscopic studies. These studies showed that the SLe^X group has a folded, low-energy conformation, in which the L-fucose residue lies above the D-galactose unit. Therefore it appears that the tetrasaccharide forms a well-defined hydrophilic surface along the Neu5Ac-Gal-Fuc structural unit, while a hydrophobic region exists below the Neu5Ac-Gal-GlcNAc structural unit.

The fact that the transferases show some flexibility with regard to the glycosyl residues they will accept allowed the synthesis of a series of SLe^X analogues (Fig. 3) such as the glucal derivative **2**[7] and the di(SLe^X) derivative **3**, which were used for investigtions into structure–activity relationships.[8] The affinity of **2** for E selectin was found to be similar to that of SLe^X; in contrast, **3** proved to be a fivefold better ligand. Based on these results and the fact that the sulfatides **4** and **5** isolated from biological material demonstrated a higher affinity for E selectin,[9] Gaeta, Wong, et al. postulated the following model of the E selectin–SLe^X interaction:[8]

a) the interaction is multivalent;[10]
b) the structural elements of the SLe^X unit essential for recognition by E selectin include the carboxyl function of *N*-acetylneuraminic acid, part of the galactose residue (possibly only the 4- and 6-hydroxyl functions),[11] and the three hydroxyl

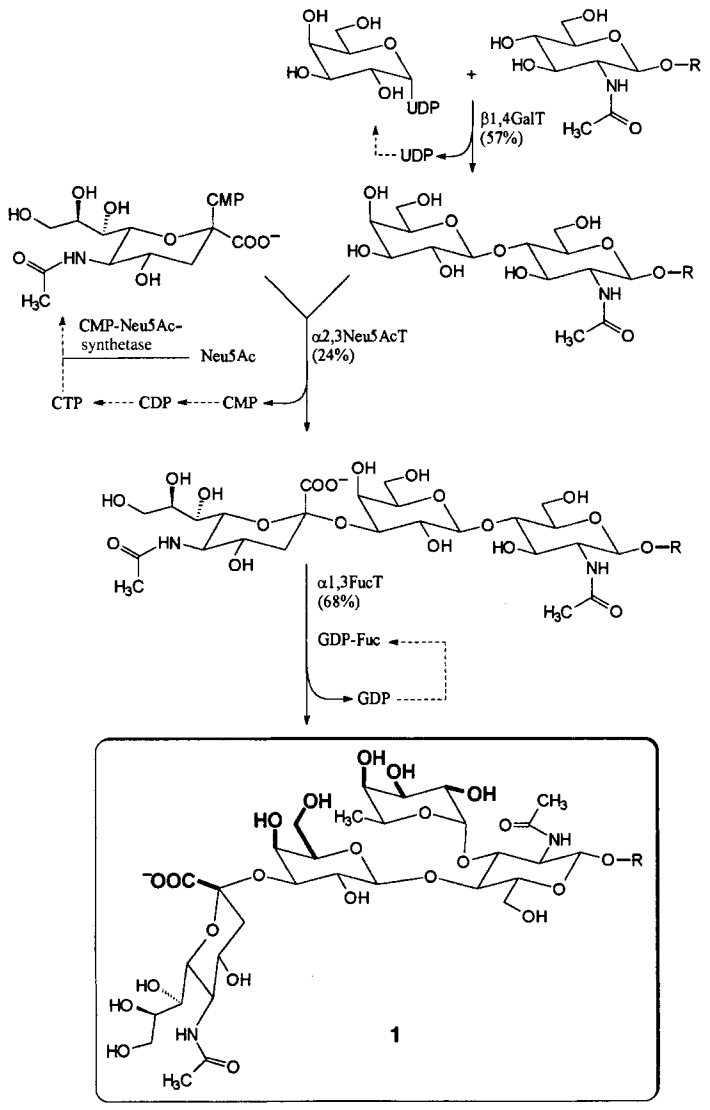

Fig. 2. Chemosynthetic SLe^X synthesis according to Paulson, Wong, et al. ($R = CH_2{-}CH{=}CH_2$).

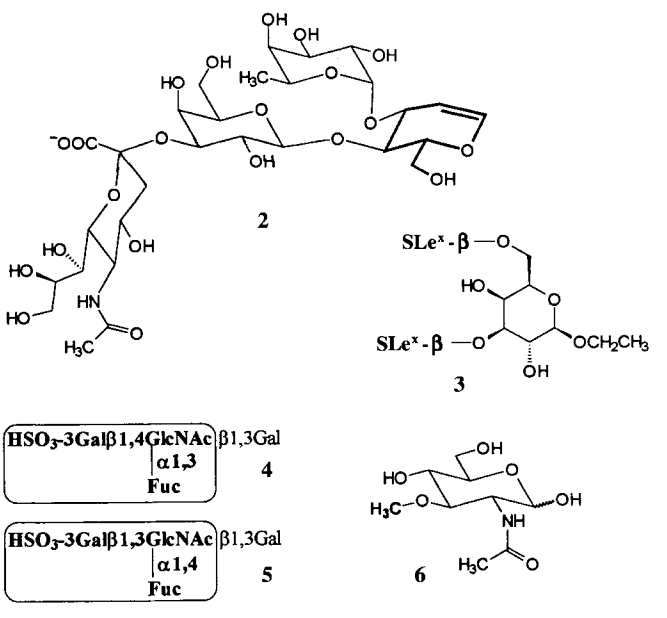

Fig. 3 Chemical structures of the selectin ligands **2**–**5** and of *N*-acetyl-3-*O*-methyl-D-glucosamine (**6**), a potent inhibitor of *N*-acetylneuraminic (sialic) acid biosynthesis.

groups of the fucose residue. The CH_3 group of this L sugar seems to be nonessential;

c) the bioactive conformation of the oligosaccharide, in other words, its conformation when bound to E-selectin, is identical with the low-energy conformation determined in aqueous solution by NMR spectroscopy.

Direct confirmation of this last hypothesis is still lacking, since investigations into the structure of the E-selectin–SLe^X complex have not been carried out. The structure–activity relationships found are largely in accordance with those found by Tyrrell et al.[11] The pharmacophores are highlighted in the chemical formula of SLe^X-R **1** (Fig. 2).

The final confirmation of the efficacy of **1** (R = H) as an antiinflammatory drug was provided by Mulligan et al.[12] with animal models. Rats were injected with a poison isolated from cobras (cobra venom factor, CVF), which led to a P-selectin induced adhesion of neutrophils to the endothelium of blood vessels of the lungs. This in turn resulted in a massive accumulation of neutrophils in the tissues of the lungs as neutrophils left the blood vessels and invaded the surrounding tissues. The accompanying increase in the permeability of the blood vessels led to lung edemas, bleeding in the alveoli, and severe damage to the lungs. An intravenous injection of SLe^X **1** (R = H) into the animals drastically reduced the level of damage observed. The effect was dose dependent and time dependent in relation to the CVF infusion. For example, when a dose of 200 μg of SLe^X **1** (R = H) was given shortly before application of the snake venom, a 50% reduction in the amount of bleeding in the lungs and accumulation of neutrophils in lung tissues was observed compared to that in untreated animals. In contrast, the same dose given after the application of snake venom was less effective in reducing the damage. Other, nonfucosylated oligosaccharides such as Neu5Acα2,3Galβ1,4GlcNAc proved to be inactive. The fact that such a low dose induces this protective effect is surprising: a single dose of 200 μg of **1** (R = H) corresponds to a concentration of less than 1 μmol L^{-1} in the blood! The experimentally induced lung damage in rats is equivalent to adult respiratory distress syndrome in humans, which is still difficult to treat, has a high mortality rate (60%), and affects in the USA alone around 150000 people per year.[13]

Based on these results, the hope that SLe^X-containing oligosaccharides and their analogues may prove to be effective antiinflammatory drugs seems to be well founded. However, it should be borne in mind that many aspects of the selectin–leukocyte interaction remain unexplained[1d] and that the selectins have overlapping ligand specificity and indeed that a variety of compounds can serve as selectin ligands. For example, the sulfatides **4** and **5** (Fig. 3) are not only potent E-selectin ligands, they also have a high affinity for L-selectin.[9b] The discovery that the sulfooligosaccharides **4** and **5**[14] can serve as selectin ligands also indicates that the SLe^X group may be replaced by simpler analogues that would be easier to synthesize. A long-range goal is the replacement of the SLe^X group with mimetics that are effective when taken orally, have better pharmacokinetics, and are metabolically more stable.

Crucial to the development of such carbohydrate mimetics is the determination of the conformation of the carbohydrate ligand when bound to selectin, that is to say the biologically active conformation. A suitable molecule could then be created by attaching the structural units essential for recognition to an appropriate scaffold. The methods that have been developed for the construction of peptide mimetics[15] could also be applied to the design of carbohydrate mimetics. Recent results indicate that a carbohydrate structure is not an absolute requirement: screening showed that small peptides act as monosaccharide mimetics and block the interaction of the lectin concanavalin A with its carbohydrate ligands.[16] Finally, since the SLe^X-induced leukocyte adhesion could also be blocked by inhibiting the enzymes responsible for the biosynthesis of this oligosaccharide group, intensive efforts are underway to develop such inhibitors.[17] In this context it is of interest that an inhibitor of Neu5Ac biosynthesis has recently become available: the simple D-glucosamine derivative **6** (Fig. 3) is a specific and potent inhibitor of both GlcNAc kinase and ManNAc kinase (K_i = 17 and 80 μM, respectively) and thus inhibits Neu5Ac biosynthesis.[18]

These developments show clearly that "knowledge of carbohydrate synthesis, structure and function can serve the medicinal chemist well in the design of new drug candidates".[19]

Proton-Transfer-Dependent Reversible Phase Changes in the 4,4′-Bipyridinium Salt of Squaric Acid**

Manfred T. Reetz,* Sigurd Höger, and Klaus Harms

Proton-transfer-mediated electron transfer in organic materials is a way to regulate the electronic properties of solids.[1] Intramolecular proton transfers are responsible for the photo- and thermochromic properties of the crystal forms of *N*-salicylidene anilides.[2] Proton transfers under hydrostatic pressure in quinhydrones are known to be accompanied by changes in the absorption spectrum.[3] In the phase change of dimethyl 3,6-dichloro-2,5-dihydroxyterephthalate, the color change is associated with a proton transfer.[4] For this reason, investigations on crystal structures of self-assembling, hydrogen-bonded aggregates are gaining in importance.[5] We report here on a new hydrogen-bonded system which undergoes a thermally induced reversible single-crystal–single-crystal phase change. This process is associated with a proton transfer and a concomitant change in color.

The reaction of 4,4′-bipyridine (**1**) (colorless) and squaric acid (**2**) (colorless) in water leads to a pale yellow-brown precipitate **3** (Scheme 1).[6] On recrystallization the bulk of the material is obtained as pale ochre colored [λ_{max} (solid) = 390 nm] rectangular crystals (**4**). A few individual crystals of an additional polymorph (**5**), which appears to be slightly darker [λ_{max} (solid) = 460 nm], are also formed.[7]

Scheme 1.

The (extended) asymmetric units of salts **4** (monoclinic) and **5** (triclinic) are shown in Figure 1.[8] They consist of infinite chains connected by hydrogen bonds and are arranged in stacks. These are aligned with the crystallographic *c* axis. The position of the ordered protons in these chains can be explained by the acidity constants of both components (squaric acid: pK_1 = 1.2–1.7, pK_2 = 3.2–3.5; 4,4′-bipyridinium dihydrochloride: pK_1 = 2.73, pK_2 = 4.87).[9] Each asymmetric unit in salt **4** contains one bipyridine unit (torsion angle 24°), while two different bipyridine units are contained in **5** (C301 to C310, torsion angle 8°; C201 to C210, torsion angle 12°). Figure 2 shows a view of **4** along the stack.

Characteristic for both structures are the strong hydrogen bonds of the type N–H···O and O–H···N (Table 1). The

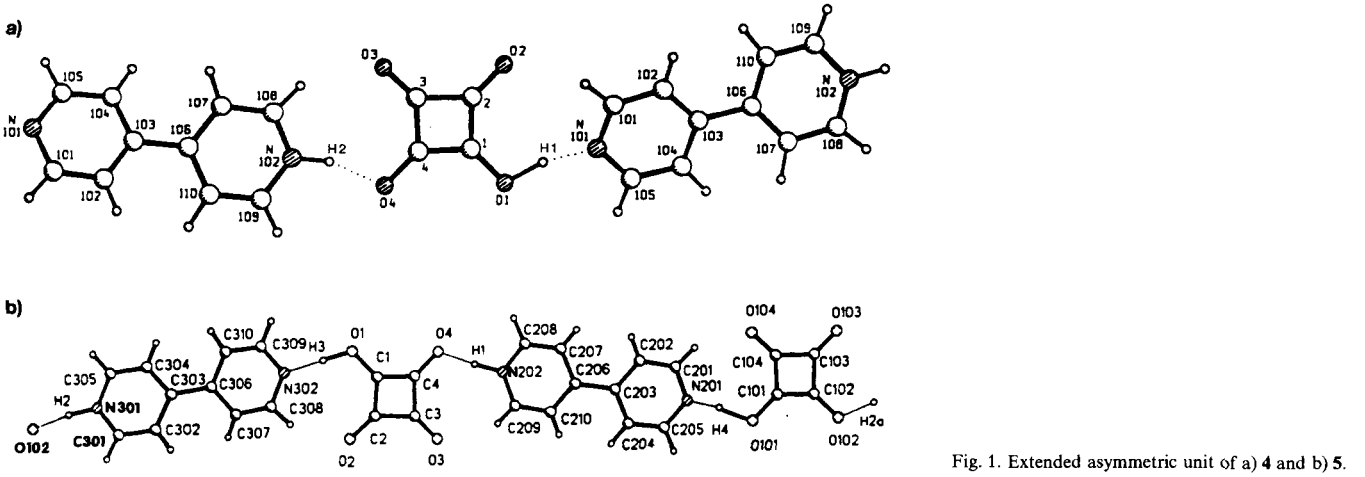

Fig. 1. Extended asymmetric unit of a) **4** and b) **5**.

atomic distances within the anions (Table 2) show that the geometry of the anions in salts **4** and **5** is strongly influenced by these hydrogen bonds. The formal mirror plane of an uncomplexed squaric acid monoanion does not occur. Such an ideal geometry is found in oxamide-dioxonium-dihydrosquarate (monodeprotonated squaric acid anion).[10] Our structures are "intermediates" between unperturbed monohydrogen squarate and free squaric acid. Thus, they are examples of the correlation

5	C104	C101	1.464(5)	C104	O104	1.237(5)

Equally unusual is the thermally reversible phase transition of the monoclinic form **4**. On heating to 180 °C, crystals of **4** change from yellow to red. This phase transition always orginates at the end of the crystal and then moves along the length of the crystal in fractions of a second (Fig. 3, left). A determination of the orientation of the unit cell axes relative to the outer edges of the crystal reveals that the longest edge of the crystal corresponds to the shortest unit cell axis, the shortest edge (plate thickness) to the longest axis, and the plate width to the middle axis.

Differential scanning calorimetric (DSC) measurements show that this transformation is accompanied by an energy uptake of 19.8 $J g^{-1}$. When this high-temperature phase (which is still present as a single crystal) is cooled below 150 °C, the color of the crystal changes back to yellow (Fig. 3, right). The apparent reversal into the original phase is, however, not complete, since the system releases only 15.7 $J g^{-1}$ of energy. The crystal thereby

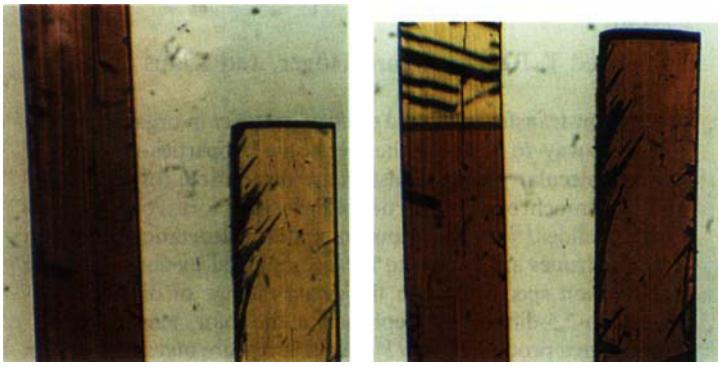

Fig. 3. Left: The initial heating of a crystal sample of **4** to 180 °C. The red crystal is already in the high-temperature modification. Right: Initial cooling below 150 °C.

fractures into several smaller pieces, and it was not possible to perform a single-crystal X-ray stucture determination on this product. When this new phase is reheated, it changes back into the red high-temperature phase at 173 °C. This change is accompanied by the uptake of 15.7 $J g^{-1}$. Subsequent cooling to below 150 °C again releases 15.5 $J g^{-1}$ and results in a transformation to the yellow modification. Further heating or cooling changes neither the transition temperature nor the energy balance. The original and the newly-formed room temperature modifications are different not only in the higher energy content of the latter (approximately 4 $J g^{-1}$), but also in the absorption coefficients in the UV region and the signal intensities in the X-ray powder diffractogram: The relative intensity of the absorption band in the UV region (maximum at 240 nm) is markedly increased in comparison with the intensity of the charge transfer (CT) band (390 nm) in the solid-state UV/VIS spectrum of the monoclinic form when it is recooled after being heated. While the ratio of the intensities of the maxima is initially approximately 3:4 (UV:CT), it changes to approximately 6:5 after the crystals have been heated; the position of the bands, however, remains unaltered. The relative intensities of the signals in the powder diffractogram also differ in going from the original sample to the heated and cooled sample. Thus, since the position of the signals is unchanged, the dimensions of the unit cell must have remained constant and only the atomic positions within this unit cell have altered. It was not possible to isolate sufficient quantities of **5** to perform analogous experiments. It is nevertheless remarkable that upon heating no color change such as that for **4** was observed for **5**.

When **3** is recrystallized from D_2O the acidic protons in **4** are replaced by deuterium. The single-crystal X-ray crystallographic examination of this form (**6**) at room temperature shows that the O1–N101 distance has increased from 2.620(3) to 2.641(4) Å when compared with the protonated form **4** at the same temperature.[8] At the same time the O4–N102 distance increases from 2.593(2) to 2.623(2) Å. This is reminiscent of the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0182 $ 10.00+.25/0

increase in the O–O distance of free squaric acid when it is deuterated[12] and is an indication for the presence of a double minimum potential.[13] When the deuterated form **6** is heated, no color change is observed up to the decomposition temperature of about 225 °C.

Such a strong isotope effect (increase of the phase-transition temperature) is also known for free squaric acid.[14] This supports the assumption that in our case the red high-temperature modification is formed from the yellow room temperature modification by proton transfer. This influences the electron donor–acceptor properties of the participating ions.

Preliminary experiments show that **4** also undergoes a reversible phase change under hydrostatic pressure. The solid-state UV/VIS spectrum and the X-ray powder diffractogram of a powdered sample of **4** that had been pressurized to 11 kbar for 60 s are, after relaxation, similar to those of the previously heated form.

Calicheamicin θ_1^I: A Rationally Designed Molecule with Extremely Potent and Selective DNA Cleaving Properties and Apoptosis Inducing Activity**

K. C. Nicolaou,* T. Li, Masahisa Nakada, Conrad W. Hummel, A. Hiatt, and W. Wrasidlo

A biologically active and selective enediyne[1] molecule, calicheamicin θ_1^I (**1**) (Fig. 1 A) has been rationally designed on the basis of chemical principles and the mechanism of action of the naturally occurring calicheamicin γ_1^I (**2**) (Fig. 1 A).[2] Unlike its natural counterpart, this new enediyne was designed to undergo activation under mildly basic conditions[3] by hydroxide ion (Fig. 1 B), leading to 1,4-benzenoid diradicals[4] which are capable of causing double strand cleavage of DNA. Prepared by total synthesis, calicheamicin θ_1^I (**1**) exhibits potent (concentrations $< 10^{-9}$ M) and sequence-selective (TCCT, TTTT, and CTCT sites) DNA cleavage at pH 7.5 and 37 °C, initiates programmed cell death (apoptosis)[5] at concentrations $< 10^{-10}$ M, and kills cells with potencies ($< 10^{-12}$ M) exceeding, in certain cases, those of natural calicheamicin γ_1^I (**2**),[1] CN-MRA,[6] and ricin,[7] compounds which have been claimed as some of the most toxic substances known.

Guided by the mechanism of action (Fig. 1 B) of calicheamicin γ_1^I (**2**)[8] in which a powerful nucleophile, such as a thiolate ion, initiates a cascade of reactions that leads to DNA damage,[9, 10] and with the intention of designing a molecule that would be activated under a different set of conditions, we focused on calicheamicin θ_1^I (**1**), which is equipped with a thioacetyl group instead of the trisulfide moiety as a triggering device. Compound **1** was expected to undergo ready activation by attack from oxygen nucleophiles, such as hydroxide ion (as well as from sulfur and nitrogen nucleophiles); compound **2** is normally activated by thiols. Due to the simplicity of activation of the designed compound, certain advantages were expected for calicheamicin θ_1^I (**1**) both for in vitro and in vivo action.

Although structurally related to the naturally occurring compound, the designed molecule (**1**) is unique in its projected mode of activation. Furthermore, despite the structural similarity between the natural (**2**) and designed (**1**) compounds, the targeted calicheamicin θ_1^I (**1**) could not be synthesized from the natural product (**2**) because of the overlap of the required chemistry with the mechanism of activation (and therefore destruction) of **2**. The significance of the reported findings, therefore, extend over molecular design[11] [rational mechanism of action], chemical synthesis (preparation of a highly complex molecule), and biology (impressive biological properties) (vide infra).

Calicheamicin θ_1^I (**1**) was obtained by total synthesis following a variation of the sequence recently described[12–15] for the construction of calicheamicin γ_1^I (**2**). Thus, the previously synthesized intermediate **3**[12–15] was treated with *para*-toluenesulfonic acid in aqueous tetrahydrofuran at ambient temperature

B) Mechanism of the activation of **1**.

for 48 h. Subsequent exposure to aqueous diethylamine furnished **1** in 75% overall yield. Selected physical properties for calicheamicin θ_1^I (**1**) are summarized in the legend for Figure 1.

In order to gain insight into the DNA cleaving profile of calicheamicin θ_1^I (**1**), its ability to cut supercoiled plasmid DNA was examined and compared to that of the natural product (**2**). ΦX174 supercoiled DNA was incubated with **1** and **2** in buffer solutions of varying pH values at 37 °C and cleavage was assayed by agarose gel electrophoresis (Fig. 2). The synthetic

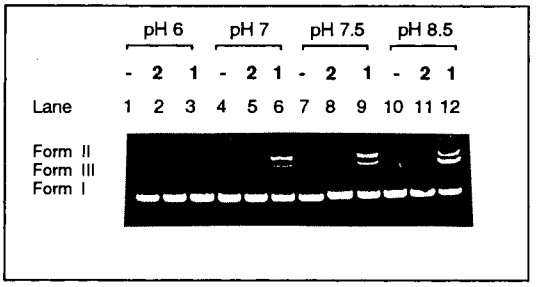

Fig. 2. Interaction of calicheamicin θ_1^I (**1**) with double stranded DNA. Agarose gel electrophoresis patterns of supercoiled ΦX174 DNA cleavage by **1** and **2**. Designed calicheamicin θ_1^I (**1**) causes double strand cleavage of supercoiled DNA with higher potencies that natural calicheamicin γ_1^I (**2**) under mildly basic conditions. Methods: Supercoiled closed circular form I ΦX174 DNA (200 ng) was incubated with 10 nM of **1** or **2** in different pH buffer solutions in a total volume of 10 μL [dimethylsulfoxide (DMSO)/4 mM Tris buffer (1:99), 4 mM ethylenediaminetetraacetic acid (EDTA)] for 12 hours at 37 °C. Electrophoresis was carried out by using 1% agarose gel with added ethidium bromide. Lanes 1, 4, 7, and 10 are controls. Form I: supercoiled DNA; Form II: nicked DNA; and Form III: linear DNA.

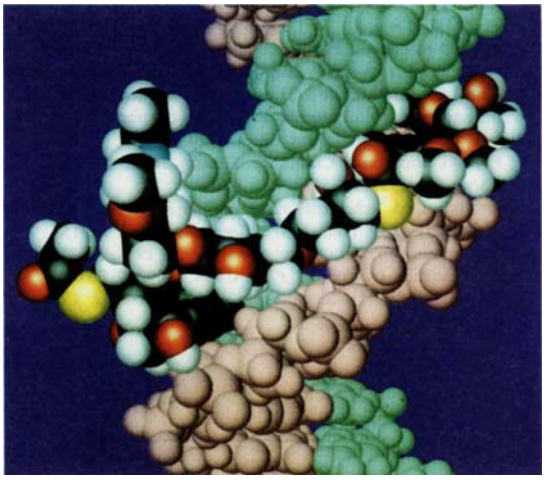
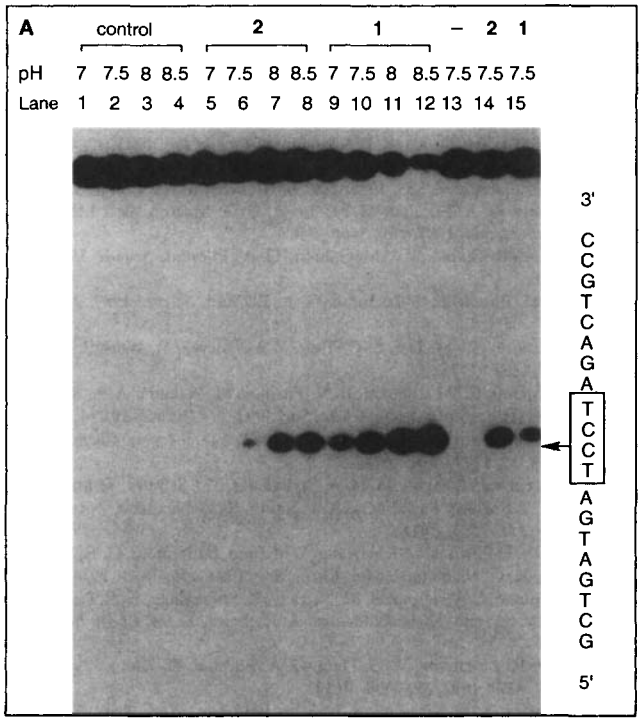
calicheamicin θ_1^I (**1**) exhibited double and single strand cuts at very low concentrations in neutral or basic media in the absence of any additives, overshadowing in this respect calicheamicin γ_1^I (**2**), which was essentially inactive under similar conditions. In the presence of thiols, however, **2** was the more potent compound (data not shown); an observation which is in accord with the proposed mechanism of activation for the two compounds. It is also interesting to note that the potency of **1** as a DNA cleaving agent in neutral or basic media is further potentiated by thiols as expected from the higher nucleophilicity of sulfur nucleophiles as compared to that of oxygen-centered nucleophiles.





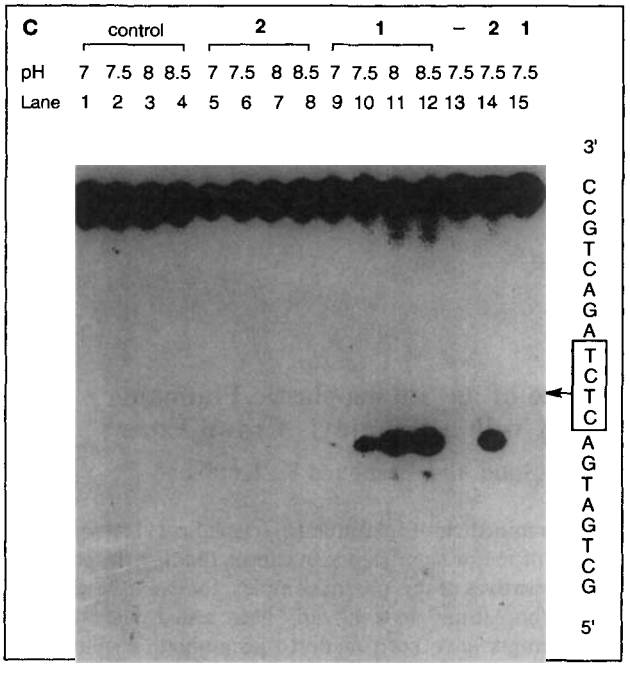


Fig. 3. Computer-generated space-filling model of calicheamicin θ_1^I (**1**) bound in the minor groove of double helical DNA along a TCCT site [Sybyl molecular modeling program; modeling and photography by Manos Pitsinos, University of California, San Diego, and The Scripps Research Institute].

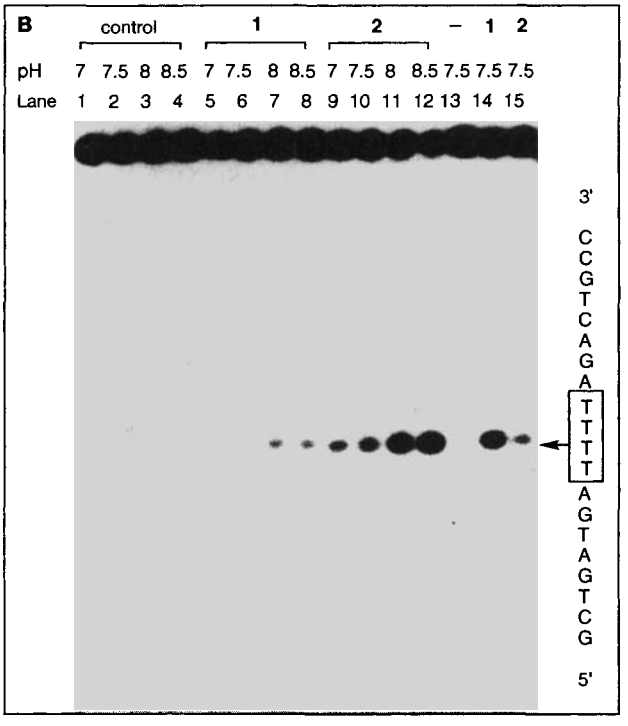

Fig. 4. Autoradiograms of denaturing gels showing selective cleavage of double stranded 5'-end-labeled 20mer DNA containing A) a TCCT/AGGA B) a TTTT/AAAA, and C) a CTCT/GAGA sequence. DNA is cleaved selectively at the designated site. Methods: The synthetic DNA duplex (100 pM, Operon Technologies) was incubated in solutions of various pH values with 400 μM **2** (lanes 5–8) or **1** (lanes 9–12) for 4 hours and with 1 μM **2** (lane 14) or 1 μM **1** (lane 15) for 20 mins followed by addition of β-mercaptoethanol (5 mM) and further incubation for 15 mins. Lanes 1–4 and 13 are controls. All incubations were carried out in 50 mM Tris · HCl buffer/DMSO (97:3) solutions at 37 °C, and the DNA in each reaction mixture was resolved by electrophoresis and autoradiography.

By analogy to its natural counterpart,[9, 10, 16] calicheamicin θ_1^I (**1**) was expected to recognize and cleave along TCCT, CTCT, and TTTT sites of helical DNA. Responsible for this striking recognition is the oligosaccharide tail of these molecules which assists them to bind tightly and selectively[17, 18] in the minor groove of double stranded DNA along these sequences (Fig. 3). Indeed this expectation was confirmed by incubating compounds **1** and **2** with three synthetic 20mers containing a TCCT, TTTT, or CTCT sequence, respectively (Fig. 4A–C). Again, it is noteworthy that **1** exhibited higher potency that **2** in the absence of additives, an order that was reversed, however, in the presence of β-mercaptoethanol as expected.

Calicheamicin θ_1^I (**1**) was tested against a broad spectrum of cell lines ranging from the relatively resistant melanoma cell line SK-MEL 28 to the highly sensitive leukemia cell line MOLT-4 and including a number of untransformed cell lines (Table 1). In

Table 1. Cytotoxicities [a] of calicheamicins θ_1^I (**1**) and γ_1^I (**2**) against a panel of cancer and untransformed cell lines.

Cell type	Cell line	IC_{50} [M]–**1**	IC_{50} [M]–**2**
	Cancer cell lines		
Breast carcinoma	BT-549	$<10^{-12}$	1.0×10^{-9}
Pancreatic carcinoma	CAPAN 1	$<10^{-12}$	1.3×10^{-9}
Lung carcinoma	H322	1.0×10^{-9}	1.7×10^{-8}
B-cell leukemia	HL-60	$<10^{-12}$	$<10^{-12}$
T-cell leukemia	MOLT-4	$<10^{-12}$	$<10^{-12}$
Colon carcinoma	HT-29	$<10^{-12}$	7.0×10^{-9}
Breast carcinoma	MCF-7	1.2×10^{-11}	4.1×10^{-8}
Ovarian carcinoma	OVCAR-3	$<10^{-12}$	2.2×10^{-9}
Lung carcinoma	UCLA-P-3	$<10^{-12}$	1.7×10^{-9}
Prostate carcinoma	PC-3	$<10^{-12}$	4.4×10^{-9}
Squamous carcinoma	SIHA	$<10^{-12}$	6.7×10^{-10}
Melanoma	SK-MEL 28	$<10^{-12}$	1.6×10^{-9}
Melanoma (metastatic)	M24 MET	$<10^{-12}$	1.0×10^{-9}
CNS cancer	U251	9.9×10^{-9}	1.1×10^{-9}
Perirenal carcinoma	786-0	$<10^{-12}$	1.0×10^{-8}
	Untransformed cell lines		
Chinese hamster ovary	CHO	4.3×10^{-9}	1.2×10^{-9}
Human mammary epithelial	HMEC	$<10^{-12}$	1.0×10^{-9}
Human dermal fibroblast	NHDF	$<10^{-12}$	1.0×10^{-9}
Peripheral blood lymphoblast	RPMI 7666	$<10^{-12}$	1.6×10^{-9}

[a] Cytotoxicities were determined by using the sulforhodamine B assay method (see ref. [20]); IC_{50} is the final molarity at which 50% of cell viability was observed after 72 h incubation under standard tissue conditions (37 °C, 5% CO_2 in air).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0185 $ 10.00+.25/0

several cases the synthetic compound (**1**) was found to be superior to the naturally occurring calicheamicin γ_1^I (**2**) in terms of potency (Table 1). Furthermore, experiments with other known highly cytotoxic agents such as CN-MRA[6] and ricin[7] (data not shown) revealed comparable or higher potencies for **1**. Particularly significant is the powerful effect of this compound on breast, colon, ovarian, prostate, and the SK-MEL 28 melanoma cell lines.

In order to gain further insight into the mechanism of action of **1**, cells were examined after exposure to compounds **1** and **2** for signs of apoptosis.[5, 19] Indeed, the typical signs of this phenomenon (condensed chromatin and DNA degradation into nucleosomal fragments, Fig. 5) were observed for MOLT-4 leukemia cells upon exposure to low concentrations of both **1** and **2**, with the designed calicheamicin (**1**) inflicting a more severe apoptotic morphology than the natural compound **2** (Fig. 5F and D). In addition, a higher proportion of cells were affected by compound **1** (ca. 66%) than by compound **2** (ca. 28%) under the same conditions, resulting in a more pronounced degradation of DNA (Fig. 5G and E).

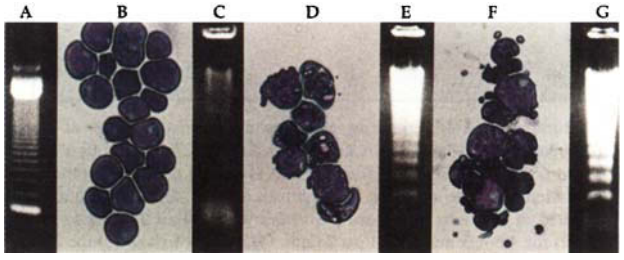

Fig. 5. Apoptotic morphology and nuclear DNA degradation induced by calicheamicin θ_1^I (**1**) and its natural counterpart, calicheamicin γ_1^I (**2**). A) Molecular weight markers consisting of multiples of a 123 base-pair fragment (Gibco BRL); B) untreated MOLT-4 leukemia cells; C) DNA extracted from untreated MOLT-4 cells; D) MOLT-4 cells incubated with 10^{-10} M **2**; E) DNA extracted from MOLT-4 cells exposed to 10^{-8} M **2**; F) MOLT-4 cells incubated with 10^{-10} M **1**; G) DNA extracted from MOLT-4 cells exposed to 10^{-8} M **1**. Methods: Solutions of calicheamicin **1** or **2** in DMSO (10^{-3} M) were diluted in culture medium to the appropriate concentrations and added to cell cultures. MOLT-4 cells (10^5) were incubated with 10^{-10} M final concentrations of **1** or **2** for apoptosis morphology assays, and with 10^{-8} M final concentrations for DNA degradation assays. After incubation for 4 h at 37 °C, cells were harvested and processed as described in ref. [18] to visualize apoptotic morphology and DNA degradation.

The described chemical and biological results demonstrate the power of organic chemistry in the design and synthesis of sophisticated molecules for specific biological actions. The availability of calicheamicin θ_1^I (**1**) by total synthesis and its highly potent and selective DNA cleaving, apoptosis-inducing, and cytotoxic properties represent significant advances in the areas of DNA cleavage and cell death. As a powerful biological tool, compound (**1**) may find useful applications in specific DNA cutting and in investigating the phenomenon of apoptosis. As a highly potent cytotoxic agent and potential antiticancer agent, calicheamicin θ_1^I (**1**) deserves further investigation. Further improvements and variations in the biological properties of **1** may result by incorporation of other designed delivery systems and activating devices.

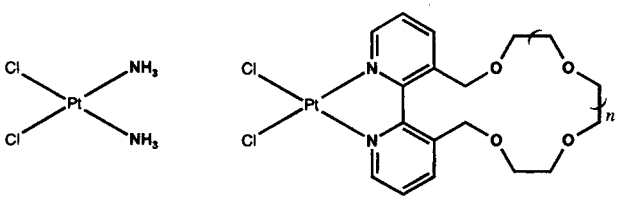
Structure of an Antineoplastic Platinum Complex with a Bipyridyl–Crown Ether**



Andreas Gund and Bernhard K. Keppler*

Cis-diamminedichloroplatinum(II) (cisplatin **1**) has for a long time been of major significance in cancer therapy. In addition, several derivatives of this parent complex, for example iproplatin and carboplatin,[1] have already been tested clinically. Recently attempts have been made to accumulate cisplatin and other pharmacologically important compounds selectively in certain body tissues by binding the substances agent to carrier molecules ("drug targeting"), thereby increasing efficacy. For example, binding cisplatin to phosphonic acids that show a high affinity for the inorganic bone matrix hydroxylapatite resulted in higher accumulation and therefore increased therapeutic efficacy for bone tumors.

The same goal of reducing toxic side effects while maintaining therapeutic efficacy can also be accomplished by improving the

Scheme 1. Cisplatin (**1**) and the pertinent structurally analogous complexes between bipyridyl-crown ether and platinum (**2a–e**).

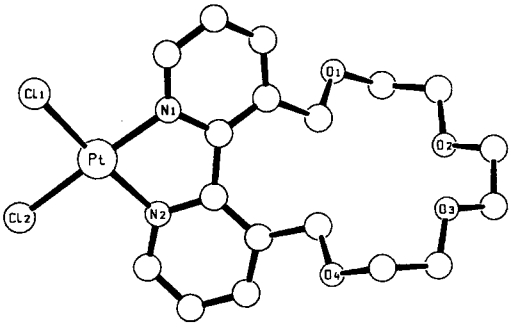

Fig. 1. SCHAKAL drawing of the crystal structure of **2a**. Selected bond lengths [pm] and angles [°]: Pt–Cl1 230.1(3), Pt–Cl2 229.5(3), Pt–N1 200.3(7), Pt–N2 202.0(8); Cl1-Pt-Cl2 89.0(1), Cl1-Pt-N1 95.6(2), Cl2-Pt-N2 95.2(2), N1-Pt-N2 80.4(3).

solubility of the complexes, by slowing down degradation processes through shielding of the platinum with bulky ligands, and by increasing membrane permeability with more lipophilic ligands. Here, crown ethers are especially promising as novel, complex building blocks, as they fulfill the last two requirements: they are bulky and soluble in both hydrophilic and lipophilic media. Complexation of platinum with bipyridyl-crown ethers yields the novel compounds **2a–c** with structures analogous to cisplatin (Scheme 1), which have shown good antitumor activity in vivo as well as in vitro. Notably, these compounds not only showed the expected activity for a human ovarian carcinoma cell line in concentrations of 10–30 $\mu g\,mL^{-1}$, but also almost complete growth inhibition in human colon and rectal cancer cell lines.[2] Two platinum complexes with crown ethers are known. In one of them, [([18]crown-6) · $\{cis$-$[PtCl_2(NH_3)_2]\}_2$ · $(MeCONMe_2)_2$],[3] two molecules of cisplatin are bound by hydrogen bonds between the ammine ligands and the oxygen atoms of the polyether [18]crown-6. In the second, [Pt(bpy)-$(NH_3)_2$(dibenzo[30]crown-10)]$(PF_6)_2$ (bpy = 2,2′-bipyridine),[4] the platinum complex forms a 1:1 adduct with dibenzo[30]-crown-10. In both cases binding of platinum to the polyether occurs through dipolar interactions. Thus, these compounds must be regarded as adducts of the metal complex with the macrocycle and therefore are probably not stable in solution. The smallest of our platinum complexes with a bipyridyl-crown ether containing four oxygen atoms (**2a**) can be prepared in water at 60 °C by reaction of K_2PtCl_4 with the appropriate macrocycle.[8] It was obtained in form of a light yellow powder, which was subsequently characterized by IR, ^1H, and ^{13}C NMR spectroscopy. The higher homologues **2b** and **2c** were prepared analogously. Crystals suitable for X-ray structure analysis were obtained as yellow needles by dissolving **2a** in warm methanol and subsequent slow evaporation of the solvent. In this way the alcohol is incorporated into the crystal lattice in a 1:1 ratio, but no interaction with platinum complex fragment or the crown ether is observed.[6] As shown in Figure 1, the platinum atom of this highly symmetrical molecule is in a square planar environment surrounded by two chloride ions and the two *cis* nitrogen atoms of the bipyridyl unit. This *cis* arrangement of pairs of groups, such as halogenide or carboxylate (that can easily be hydrolyzed under physiological conditions) and more strongly coordinating (nitrogen-containing) ligands, is an important prerequisite for tumor-inhibiting activity in these platinum compounds.

The bond lengths and angles for the bipyridyl–platinum fragment (Fig. 1) are in good agreement with those for planar [(bpy)$PtCl_2$] (red form).[7] However, in **2a** the two pyridine rings are not planar, but instead are twisted by $\theta = 31.1°$. This is a result of steric interactions in the crown ether moiety, especially between the two methylene groups, which are bonded directly to the bipyridyl fragment. In solution the two rings rapidly "flip". This process proceeds through a transition state in which the aromatic ring systems are coplanar. One can follow this racemization by dynamic ^1H NMR spectroscopy: At high temperatures at which racemization occurs, a sharp singlet is observed for the diastereotopic CH_2 protons of the two methylene groups bonded to the ring, while at low temperature a quartet (AB spin system) results. The coalescence temperature for the racemization of **2a** is 22 °C (200 MHz); this in turn translates into a value for $\Delta G^{\neq}$ of about 13.7 $kcal\,mol^{-1}$. The twofold ability of these bipyridyl-crown ether complexes to coordinate transition metal ions with the outward facing N atoms and alkali metal ions inside the cavity of the crown ether has already been studied by Rebek et al. by means of ^1H NMR spectroscopy.[8] He concluded the presence of an "allosteric effect": Binding of a transition metal ion to the outer sphere of the bipyridyl-crown ether levels the pyridine rings. This exerts an unfavorable effect on the conformation of the whole system to such an extent that the ability of the crown ether to complex cations is reduced relative to that of "deplatinated" macrocycles. This reduced tendency of compounds **2a–c** to bind alkali metal ions can also be recognized in the ^1H NMR spectrum: All signals, but in particular that of the benzylic CH_2 protons of the crown ether ($\delta = 4.6$, s, 4H), remain unchanged even several hours after addition of Li, Na, and K salts to solutions of **2a–c**. In contrast, addition of alkali metal ions to solutions of crown ethers whose bipyridyl unit has

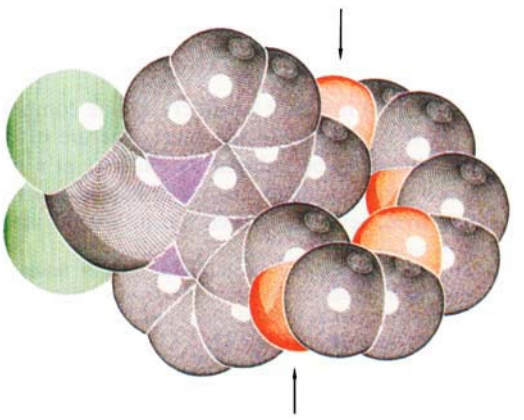

Fig. 2. Space-filling model **2a**. To perceive precise structural details a comparison with Figure 1 is necessary. The oxygen atoms O1 and O4 (arrows) face away from the crown ether cavity. Twisting of the two pyridine rings ($\theta = 31.1°$) can also be seen.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0202-0187 $ 10.00+.25/0*

not been complexed, and which show a much larger conformational flexibility and therefore a higher binding tendency, results in a change of the benzylic CH_2 proton's singlet to a quartet (AB spin system).[8]

In a space-filling model of **2a** (Fig. 2) derived from the X-ray data, two oxygen atoms of the polyether face away from the crown ether cavity and are in an unfavorable arrangement for complexation of alkali metal ions. This model, however, certainly does not represent the structure in solution, but it shows that flexibility is decreased by complexation with platinum.

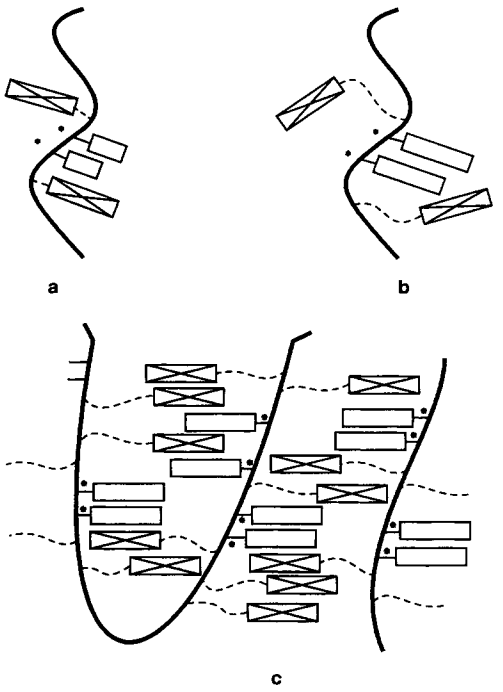
Cooperativity and Transfer of Chirality in Liquid-Crystalline Polymers**

Günter Wulff,* Harald Schmidt, Hartmut Witt, and Rudolf Zentel*

In memory of Günther Snatzke

The interest in chiral liquid-crystalline compounds is due to the fact that chirality in the superstructure of the liquid-crystalline phase can be induced by chirality at a molecular level. This can result in the formation of helical superstructures with pitches from several hundred nm to several μm. The material properties of such phases are also of particular interest, for example, the selective reflection of light by the cholesteric phase or the ferroelectricity of the smectic C* phase. Such thermotropic phases of compounds of low molecular weight are well-known, as are those of side chain polymers.[1] In the latter case, the chiral group is mainly found in the branch group.[1] It is rarely seen in the spacer[2] or in the mesogen.[3] On the other hand, thermotropic side chain polymers with chirality in the main chain are as yet unknown.

Our intention was to synthesize liquid-crystalline polyvinyl compounds, which have chirality that arises from the configuration of the main chain.[4, 5] It is thus possible to investigate the coupling and decoupling of the chiral polymer chains with the achiral mesogens. From this we found a surprisingly distinct relationship between the structure of the groups at the uniquely defined stereochemical centers of the main chain and the transfer of chirality onto the mesogens (Fig. 1).



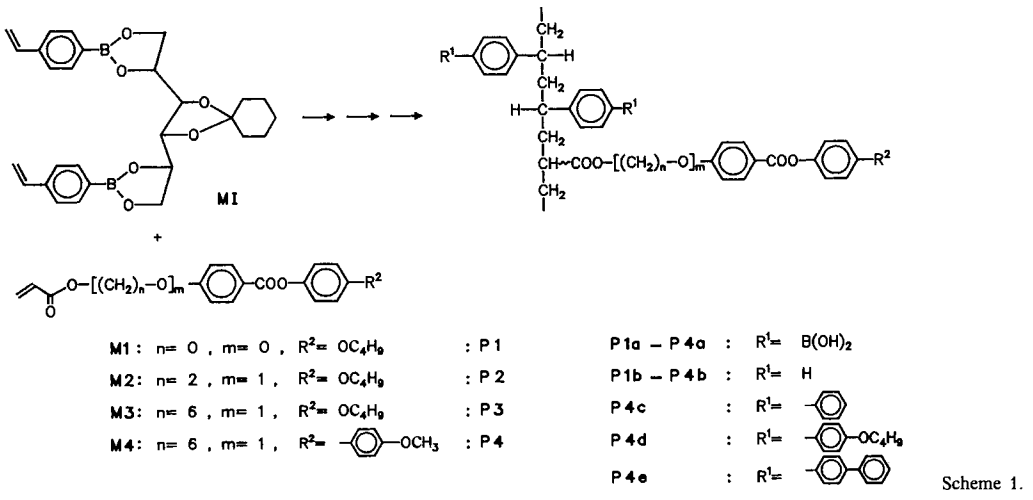


Fig. 1. Schematic representation of the configuration of the mesogen groups from the comonomer (⊠) and the substituents in the chiral diad (□) on the polymer chains. a) Behavior in solution of polymers of the type **P1b** and **P2b** with a short spacer at the mesogen and phenyl groups at the diad. The chromophore in the mesogen is placed in a preferred chiral conformation by the neighboring diad. b) Behavior in solution of polymers of the type **P4c–4e** with a long spacer at the mesogen and diad units lengthened to biphenylyl or terphenylyl groups. A transfer of chirality between the diad and the mesogen chromophore is not observed. c) Behavior in liquid-crystalline phase of polymers of the type **P4c–4e** with a long spacer at the mesogen and mesogen-like diad units. A strong inter- and intramolecular interaction and transfer of chirality occurs due to the general orientation of both groups in the liquid crystal.

Main chain chiral polyvinyl compounds were synthesized using a method[4, 5] in which chiral diads in the main chain are produced by means of a template. The optically active polymers **P1a–4a** with 4-vinylphenylboronic acid diads, which show predominantly (*S,S*) configuration, were obtained by radical cyclocopolymerization of the template monomer **MI** with the liquid-crystalline monomers **M1–M4** (Scheme 1) and subsequent removal of the template. Once the boronic acid groups have been eliminated with $AgNO_3/NH_3$, the liquid-crystalline poly-

Scheme 1.

mers **P1b**–**4b** are obtained (Table 1). These liquid-crystalline polymers have a clearing point which is somewhat lower than and a liquid-crystalline range which is somewhat narrower than that of the homopolymers synthesized from **M1**–**M3**[6] and **M4**.[7] This is because of the influence of the non-mesogenic comonomer.

Table 1. Composition and selected properties of the newly synthesized liquid-crystalline copolymers which have chirality arising from the configuration of the main chain.

[a] Mole ratio of the component of mesogen monomer to the component of diad yielded by **MI** (determined by ^{1}H NMR spectroscopy). [b] Phase transitions determined by differential scanning calorimetry (DSC) (Mettler TA4000). g: glassy, k: partially crystalline, lc: liquid crystalline, not identified precisely, s: smectic, n: nematic, n*: cholesteric, i: isotropic. Parameters; temperature in °C. [c] Due to the chirality in the main chain of the polymers, chiral liquid-crystalline phases are expected. These were however difficult to determine for **P1b** and **P2b** and were not detectable for **P3b** and **P4b**.

Possible interactions between the chiral configurations in the main chain and the achiral mesogens of the side chains should be detectable by circular dichroism (CD) of the solution of polymers **P1a**–**4a** (Fig. 2). A negative Cotton effect at 230 nm was observed for the chiral diad in each case. However, in the mesogen absorption region (≈260 nm), an additional positive Cotton effect was only obtained for **P1a** (spacer $n = 0$) and **P2a** (spacer $n = 2$). For a longer spacer ($n = 6$), this effect does not occur, that is, no chiral induction takes place in the mesogen. This is consistent with earlier findings for main chain chiral polymers[5] and also with the model for the decoupling of the mesogen and polymer chain by the flexible spacer[8] (cf. Fig. 1a and 1b).

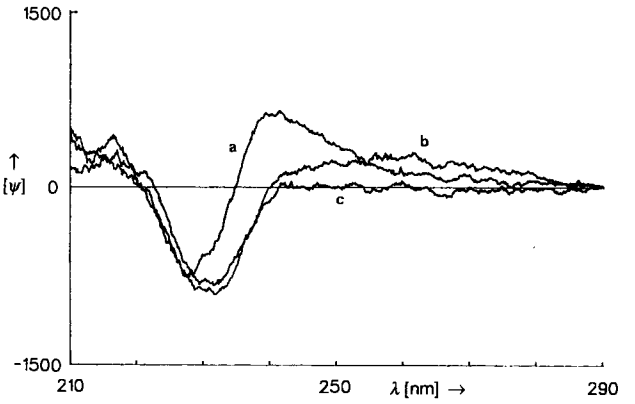

Fig. 2. Circular dichroism of polymers **P1a** (a), **P2a** (b), and **P4a** (c) in tetrahydrofuran. Polymers with a long spacer (**P4a** and almost identical spectrum for **P3a**) show no induced Cotton effect in the region of the mesogen chromophore. The specific ellipticity [Ψ] is given (unit °dm^{-1}g^{-1}mL).

Texture investigations of the liquid-crystalline phase, which should yield information about the influence of chirality of the main chain on the superstructure of the liquid-crystalline phase, were only possible for polymers with a long spacer (**P3b** and **P4b**).[9] In these cases, no chiral superstructure was observed, that is, if a chiral superstructure exists, its pitch is greater than the sample thickness and is therefore not detectable. The texture appears typically nematic and not cholesteric (Fig. 3 top). This was consistent with the results of the CD measurements, which means that for polymers with a long spacer, there is no noteworthy interaction between the chiral configuration in the main chain and the mesogen. This is the case not only in solution, but also in the densely packed liquid-crystalline phase in which van der Waals interactions would have had to take place between the mesogens and the chiral diad in the main chain. This result is all the more surprising as there is formation of distinct cholesteric textures on dissolving small amounts of chiral doping agent.[10]

In order to strengthen the interaction between the chiral structural elements in the polymer chain and the mesogen groups, the individual structural groups of the chiral diads were lengthened by the Suzuki reaction.[11] Polymers **P4c**–**4e** were

synthesized from polymer **P4a** by reaction with bromobenzene, 1-bromo-4-butoxybenzene, or 4-bromobiphenyl under Pd^0 catalysis (see Table 1). The yields of these polymer-analogous reactions are around 60–70%. The polymers thus synthesized with mesogen-like structures at the chiral diads (biphenylyl and terphenylyl groups) show distinctly cholesteric textures unlike **P3b** and **P4b** (Fig. 3 bottom). This behavior is evidence for a

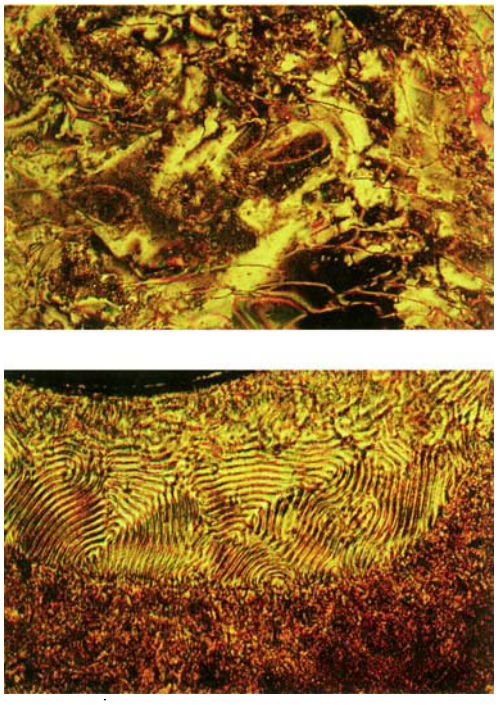

Fig. 3. Polarization microscopy photographs of (top) the schlieren texture of the nematic phase **P4b** and (bottom) the fingerprint texture of the cholesteric phase of **P4e**, synthesized from **P4a** by the Suzuki reaction. Magnification 100×.

distinct interaction between the modified chiral diads and the original mesogens in the liquid-crystalline phase. However, CD measurements in solution (Fig. 4) showed no interaction between the chiral diad and the mesogens for these polymers (**P4c–4e**).

In order to explain this discrepancy, CD measurements were carried out in bulk. For this, thin films (20–30 nm) of polymers

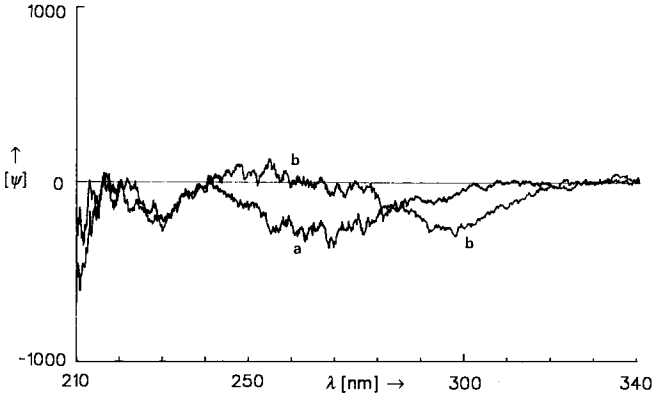

Fig. 4. Circular dichroism of polymers **P4d** (a) and **P4e** (b) in tetrahydrofuran. The weaker negative Cotton effect at 230 nm is due to unreacted 4-vinylphenylboronic acid.

P4c–4e in the cholesteric phase were tempered and then quickly cooled to room temperature. The CD spectra obtained from these films[12] (Fig. 5) differ distinctly from the solution spectra. After heating the films to temperatures above the clearing point, the CD signal disappears completely, only to reappear unaltered on cooling.[13] It can be stabilized in the glassy state by rapid cooling of the liquid-crystalline phase. We could rule out the possibility that this phenomenon may be attributed to birefringence effects by carrying out exhaustive measurements at various orientations of the films in the spectrometer, and by checking the reproducibility of the measurements for various films.[13]

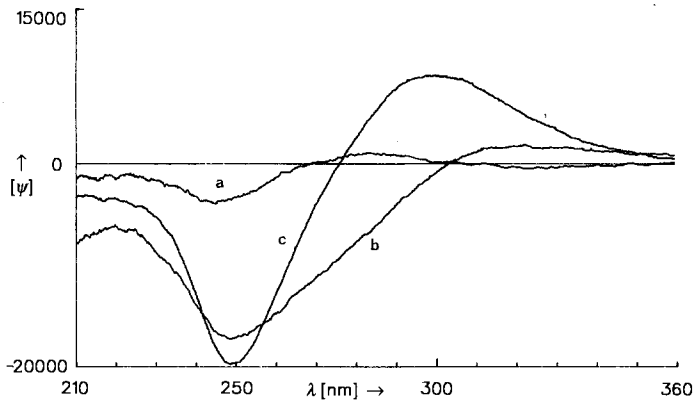

Fig. 5. Circular dichroism of polymers **P4c** (a), **P4d** (b), and **P4e** (c) measured as films. The films were tempered at 180 °C and quickly cooled. The specific ellipticity [Ψ] was calculated from the determined film thickness of 20–30 nm.

The CD signals described earlier prove unambiguously that the chromophores of the mesogens in the liquid-crystalline state are in a chiral environment. The extent to which the CD signals may be discussed at a molecular level in terms of interactions between different chromophores cannot yet be answered. Neither is it known if to some extent an existing helical superstructure in the thin films (thickness 20–30 mm compared to a pitch of a few μm) contributes to the effects described here.[14] Positive Cotton effects in the region 280–325 nm together with strongly negative Cotton effects at 245–250 nm may be interpreted as circular dichroism. The zero passage of **P4e** at 276 nm is in the region of the absorption maxima of the mesogen (268 nm) and the terphenyl (300 nm), so that it may be treated as a positive exciton couplet. In comparison to this, **P4e** in solution shows only a weak negative Cotton effect for the terphenyl diad at 300 nm (see Fig. 4).

If the textures of the liquid-crystalline phases of polymers **P3b** and **P4b** (with distyryl diads) are compared with those of polymers **P4c–4e** (with lengthened mesogen-like diads), a distinct chiral induction is detected only in those of the latter. However, both **P3b** and **P4b** as well as **P4c–4e** show no interaction between the chiral diads and the mesogen chromophore in solution by circular dichroism. This verifies a particular mechanism for the transfer of chirality through space for polymers **P4c–4e** in the liquid-crystalline phase, as is shown schematically in Figure 1c for inter- and intramolecular transfer. Figure 1c should be understood in such a way that the interaction between chiral diads and mesogens forces the latter into a helical superstructure. By comparison with CD spectra in solution, this transfer can be clearly differentiated from the conventional transfer mechanisms along the polymer chain (Fig. 1a). This differentiation was possible because optically active liquid-crystalline side chain polymers, whose chirality is derived from

the configuration of the main chain, were successfully synthesized for the first time. With such a structure, the influence of the chiral configurations on the different chromophores and on the formation of the liquid-crystalline phase may be understood separately.

$[K([18]crown\text{-}6)]^+ [Mo_4(\mu_4\text{-}H)(OCH_2tBu)_{12}]^-$, the First Alkoxidohydrido Cluster of Molybdenum, Evidence for a Rare, if not the First, Example of a μ_4-Hydride**

Theodore A. Budzichowski, Malcolm H. Chisholm,* John C. Huffman, and Odile Eisenstein*

The dimetal hexaalkoxides $[M_2(OR)_6]$ ($M{\equiv}M$) are weakly Lewis acidic and this affords entry into all of the chemistry associated with the M–M triple bond (M = Mo, W).[1] We have recently been studying the reactions of $[M_2(OR)_6]$ compounds with a variety of anions in hydrocarbon solvents [Eq. (a)].[2]

$$[M_2(OR)_6] + [Q]^+[X]^- \rightleftharpoons [Q]^+[M_2(OR)_6X]^- \quad (a)$$

Q = NBu^n_4 or K

When X is a halide the equilibrium lies well to the left but for $X = OR^-$ it lies well to the right and salts containing the anion $[M_2(OR)_7]^-$ may be isolated.[2a] When $X = CN^-$ the equilibrium can be monitored by NMR spectroscopy and thus the strength of the bonding of CN^- to the W_2^{6+} center and to the Mo_2^{6+} center can be compared directly based on the thermodynamic parameters.[2b] The reaction involving $X = H^-$ occurs readily ($Q^+ = K^+$), but is quite different for molybdenum versus tungsten, and the nature of the products depends upon the ratio (alkoxide:hydride) of the two starting materials used. The title compound is formed by the reaction shown in Equation b

$$2\,[Mo_2(OCH_2tBu)_6] + KH/[18]crown\text{-}6 \xrightarrow[THF]{22\,^\circ C} [K([18]crown\text{-}6)]^+\,[Mo_4(\mu\text{-}H)(OCH_2tBu)_{12}]^- \quad (b)$$

and is best prepared (88% isolated crystalline yield) by using a deficiency of the hydride reagent (45 mol% $K[B(sBu)_3H]$). The reaction may be viewed to proceed in two steps. The first step formally involves addition of H^- to yellow $[Mo_2(OCH_2tBu)_6]$ to form the anionic complex $[Mo_2(OCH_2tBu)_6H]^-$, which then attacks another equivalent of coordinatively unsaturated $[Mo_2(OCH_2tBu)_6]$ to afford the Mo_4 cluster anion. It should be noted that $[Mo_2(OR)_6]$ compounds where R = *i*Pr and $R = CH_2tBu$ do not undergo cluster formation, in contrast to their tungsten analogues.[3] By ^1H NMR spectroscopy we find no evidence for the $[Mo_2(OCH_2tBu)_6H]^-$ anion which implies that the second addition of $[Mo_2(OCH_2tBu)_6]$ occurs at a much faster rate than the initial adduct formation.

The X-ray structure analysis (space group $P\bar{1}$) shows there is one unique Mo_4 cluster anion in the unit cell and two cationic $[K([18]crown\text{-}6)]^+ \cdot (THF)_2$ moieties each lying on a crystallographic inversion center.[4] It should be emphasized that there is only one potassium ion per cluster and the two independent cations are each of half weight. A difference Fourier synthesis with phases based on the non-hydrogen atoms revealed approximately one half of the hydrogen atoms of the anion, including H(A) which is in the appropriate position for a μ_4-hydride. In the first cycles of refinement its positional and thermal parameters were allowed to vary along with the non-hydrogen atoms. An ORTEP view of the anion is given in Figure 1 and the central $[Mo_4(\mu_4\text{-}H)O_{12}]$ skeleton is shown in Figure 2.

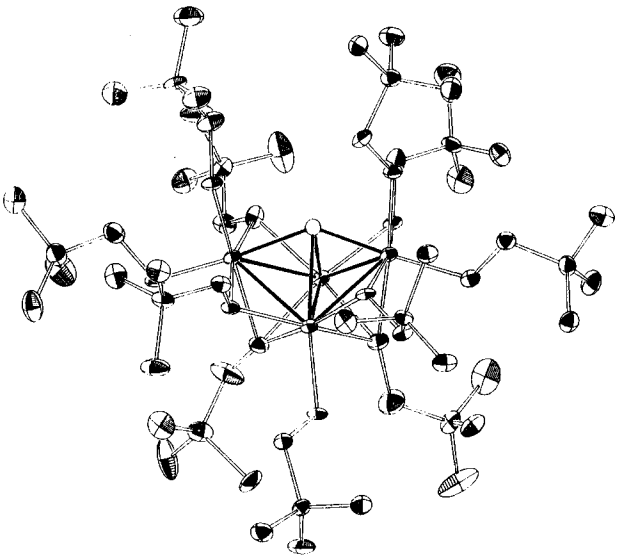

Fig. 1. ORTEP diagram for the $[Mo_4(OCH_2tBu)_{12}(\mu_4\text{-}H)]^-$ anion. Ellipsoids are at the 30% probability level, (the μ_4-hydrido ligand is shown as an arbitrary sphere). Atom labels and the terminal alkoxido ligand bound to the rear hinge Mo atom have been omitted for clarity.

Despite the inherent difficulties associated with locating hydrogen atom positions near transition metals by X-ray diffraction, as well as several minor disorder problems associated with this crystallographic study,[4] we are confident of the assignment of a μ_4-hydride for several reasons. Inspection of the Mo–O distances shows the expected trend d(M–O terminal) < d(Mo–μ_2-O) < d(Mo–μ_3-O) and no evidence of coordinated ROH ligands was observed.[5] Preliminary reactivity studies further support this view: The complex is inert towards tBuCH$_2$OD (10-fold excess, 40 °C, 12 h), suggesting neither hydridic behavior, which would liberate HD, nor acidic behavior, which would result in H/D exchange. Placement of the hydrido ligand within bonding distance of all four metal atoms completes a nearly octahedral coordination sphere (excluding M–M bonding) for each of the molybdenum centers, and is most reasonable considering the steric congestion within the molecule. As a structural consequence of the μ_4-hydride, the Mo_4-butterfly unit opens considerably [Mo(1,2,3)–Mo(1,2,4) dihedral angle 117.8°] compared to two structurally related analogues $[Mo_4(OiPr)_9Br_3]$ (dihedral angle 97.6°) and $[Mo_4(OiPr)_8Br_4]$ (dihedral angle 97.4°) which do not possess bonded ligands in this domain.[6] Furthermore, the nonbonded wingtip-to-wingtip distance is considerably longer for the title compound (3.741 Å) than for the other two structurally characterized Mo_4^{12+} butterfly clusters (3.284 and 3.287 Å, respectively).[6]

Since the framework of the molecule has virtual C_{2v} symmetry five groups of alkoxido ligands with relative integral intensities of 2:2:2:2:4 are found by NMR spectroscopy. All of the terminal and both of the μ_3-OR ligands lie on mirror planes but the four μ_2-OR ligands do not. The methylene protons of the latter are diastereotopic and appear as an AB quartet in the ^{1}H NMR spectrum. The signal for the hydrido ligand occurs at $\delta = -15.2$, *upfield* of Me_4Si in contrast to the signals of the hydrido ligands of all the previously characterized alkoxidohydrido tungsten clusters that are downfield from Me_4Si. Thus, the ^{1}H NMR data[7] are consistent with the maintenance of the structure found in the solid state. We have been unable to locate an IR absorption band assignable to either a μ_4-H or a μ_4-D ligand. The absorption bands associated with this moiety are either too weak to be observed or are obscured by other IR active modes of the OR ligands.

Although M_4-butterfly clusters are known to capture μ_4-carbido,[8] -nitrido,[9] and -oxido ligands,[10] to our knowledge this is the first complex with a μ_4-hydrido ligand. While there are numerous μ_2-H, μ_3-H, and μ_6-H moieties reported in the Cambridge Crystallographic Data Center, this data base does not contain the $M_4(\mu_4$-H) moiety. As a check on the viability of the proposed μ_4-hydrido ligand we investigated the possible interactions of a hydrido ligand with the hypothetical cluster $[Mo_4(OH)_{12}]$, whose structural parameters are related to those in the title compound, but which are idealized to C_{2v} symmetry.

A study of the interaction of a hydrido ligand with the model cluster $[Mo_4(OH)_{12}]$ by extended Hückel calculations[11] strongly supports the proposed μ_4 coordination of H^-. It is found to be considerably more stable than a μ_2 coordination to the molybdenum atoms of the back-bone of the butterfly. The preference for the μ_4 coordination comes from the shape of the LUMO of $[Mo_4(OH)_{12}]$ (Scheme 1). The LUMO is low in energy and has a_1 symmetry. It is therefore ideally suited to stabilize the hydrido 1 s orbital in a μ_4 position, since it can overlap with the orbitals of the four metallic centers. (The HOMO of the cluster being of a different symmetry is not affected by the coordination of the hydrido ligand.) Coordination to the backbone molybdenum atoms leads to a total overlap which is half of that with a hydrido ligand in a μ_4 position (0.32). An interesting aspect of the problem is why is the LUMO of $[Mo_4(OH)_{12}]$ low in energy (HOMO–LUMO gap 0.04 eV). The LUMO is the in-phase combination of the LUMOs localized on each metal center. Each Mo is surrounded by five ligands that are arranged in an octahedral geometry, one site (the center of the butterfly) being vacant. Such a metallic fragment is characterized by a low-lying LUMO pointing towards the empty site of the octahedron. The in-phase combination of the four LUMOs is therefore lower in energy and points toward the center of the butterfly structure.

Scheme 1. LUMO of $[Mo_4(OH)_{12}]$.

In conclusion, we find it most intriguing that addition of hydride to $[Mo_2(OCH_2tBu)_6]$ should induce the coupling of two Mo≡Mo units to give what appears to be the first example of a cluster containing $M_4(\mu_4$-H). Further studies are in progress.

Experimental Procedure

A solution of $[K([18]crown\text{-}6)]^+[B(sBu)_3H]^-$ was prepared by mixing [18]crown-6 (175 mg, 0.66 mmol) and potassium tri-*sec*-butylborohydride (0.65 mL of 1.0 M solution in diethyl ether, 0.65 mmol) in 10 mL of dry, degassed THF. This was cooled to −78 °C and added by cannula dropwise to a stirred solution of $[Mo_2(OCH_2tBu)_6]$ (1.00 g, 1.40 mmol) in 5 mL THF at −78 °C. The reaction was allowed to warm to room temperature and stirred an additional 15 minutes. The solvent was removed in vacuo to afford a dark purple microcrystalline solid, which was washed with 3 × 10 mL dry, degassed C_6H_6 and filtered to afford an 88% yield of brown product. X-ray quality crystals were grown from a THF solution by hexane diffusion. The

reaction may also be performed with solid KH, but a substantially longer reaction time is necessary (>24 h) owing to the low solubility of this reagent. The analogous $[Mo_4(\mu_4\text{-}D)(OCH_2tBu)_{12}]^-$ anion was prepared in a similar manner from commercially available KD.

The reaction is extremely sensitive to the presence of trace amounts of H_2O. Both KH and K[B(*s*Bu$_3$)H] and H_2O react to give H_2 and KOH/K[B(*s*Bu$_3$)OH] and the latter react with $[Mo_2(OCH_2tBu)_6]$ to give the green $[Mo_4O(OCH_2tBu)_{11}]^-$ anion and pentyl alcohol. The alcohol and KH/K[B(*s*Bu$_3$)H] react to generate [KOCH$_2$*t*Bu] which in turn reacts with $[Mo_2(OCH_2tBu)_6]$ to form the purple $[Mo_2(OCH_2tBu)_7]^-$ anion [2a]. Both of these by-products have been synthesized by independent routes which will be described in a later publication.

[4] Crystal data for $[K([18]crown\text{-}6)]^+[Mo_4(\mu_4\text{-}H)(OCH_2tBu)_{12}]^- \cdot 2THF$. X (solvent) $T = -171\,^\circ C$; $a = 15.767(17)$, $b = 24.173(28)$, $c = 15.094(17)$ Å, $\alpha = 90.01(2)$, $\beta = 115.87(2)$, $\gamma = 91.02(3)^\circ$, $Z = 2$, $\rho_{calcd} = 1.21\ g\,cm^{-3}$, space group $P\bar{1}$. Final residuals are $R(F) = 0.075$ and $Rw(F) = 0.072$. During the refinement of the structure an area which contained numerous peaks of electron density 1.2 to 3.8 $e\,Å^{-3}$ well separated from the ions was observed. Attempts to identify this apparent solvent were unsuccessful and it was modeled by using 10 half weight carbon atoms. A disorder was present in one OR group of the cluster [O(65)–C(70)] as well, but this was easily modeled by using six half-weighted carbon atoms. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57854, the names of the authors, and the journal citation.

$[Re_2I_2(CO)_6(Se_7)]$, a Coordination Compound of Elemental Selenium with a Transition Metal: a Solution- and Solid-State Study**

Alessia Bacchi, Walter Baratta, Fausto Calderazzo,* Fabio Marchetti, and Giancarlo Pelizzi

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

It has recently been found[1] that *cyclo*-octasulfur coordinates to a transition element; coordination compounds with elements in their polyatomic form are also known for dihydrogen[2] and diiodine.[3] Coordination of *cyclo*-octasulfur may be regarded as the primary stage prior to the irreversible oxidation to sulfides and metallacyclopolysulfides,[4] resulting from sulfur-sulfur bond cleavage. The first labile coordination compounds of S_8 ($[Re_2X_2(CO)_6(S_8)]$, X = Br, I) were isolated and suggested, on the basis of their chemical and spectroscopic properties,[1] to have a dinuclear structure with bridging halides and η^2-coordinated *cyclo*-octasulfur.

We now report the isolation and crystallographic characterization of $[Re_2I_2(CO)_6(Se_7)]$, which can be regarded as a coordination compound of Se_7, one of the known[5] cyclic compounds of elemental selenium. These new findings indirectly confirm the earlier structural assignment of the sulfur analogue, show that an oligonuclear cyclic form of elemental selenium can coordinate to a transition metal, and define the structural parameters of coordinated Se_7.

Treatment of a CS_2 solution of $[Re_2I_2(CO)_6(THF)_2]$[6] with elemental selenium[7] at room temperature [Eq. (a)] followed by THF removal by repeated evaporation of the volatiles in vacuo, yielded the brown crystalline diamagnetic coordination compound, which analyzed (C, H, Se) satisfactorily as $[Re_2I_2(CO)_6(Se_7)]$. In its IR spectrum, the compound has carbonyl

$$[Re_2I_2(CO)_6(THF)_2] + 7/n\,Se_n \rightleftharpoons [Re_2I_2(CO)_6(Se_7)] + 2\,THF \qquad (a)$$

stretching bands (CS_2 solution) at 2045, 2030, 1960, and 1934 cm^{-1}, in accord with a C_{2v} symmetry of the $Re_2(CO)_6$ core ($2A_1$, $2B_1$, B_2). The ^{13}C NMR spectrum of the compound in CS_2 at room temperature shows three resonances in 1:1:1 ratio at $\delta = 187$, 184, and 182, assigned to three pairs of nonequivalent carbonyl groups. Finally, the ^{77}Se NMR spectrum at room temperature in CS_2 solution (C_6D_6 lock) shows four resonances in 2:2:2:1 ratio at $\delta = 1150$, 1011, 973, and 927 (relative to $SeMe_2$ in $CDCl_3$[9]), suggesting the presence of four nonequivalent groups of selenium atoms in the molecule. In comparison, free Se_7 (in admixture with Se_6 and Se_8) is fluxional and shows a single resonance at $\delta = 998$ relative to neat $SeMe_2$.[10] The resonance at $\delta = 1150$ is assigned to the Re-bonded selenium

atoms on the basis of their relaxation times. Thus, strong evidence for a dinuclear structure in solution with bridging iodides, a bidentate heptaselenium ligand, and two sets of three carbonyl groups in *fac* arrangement exists. However, only X-ray diffraction can unambiguously distinguish the two possibilities: a) a rhenium(I) complex of *cyclo*-heptaselenium, or b) a complex of rhenium(II) with a metal–metal bond and a bidentate heptaselenide ligand.

The X-ray structural analysis carried out on a single crystal of the heptane-solvated compound[11] has definitely established the former formulation. A perspective view of the molecule is shown in Figure 1. Each metal atom is in an almost octahedral

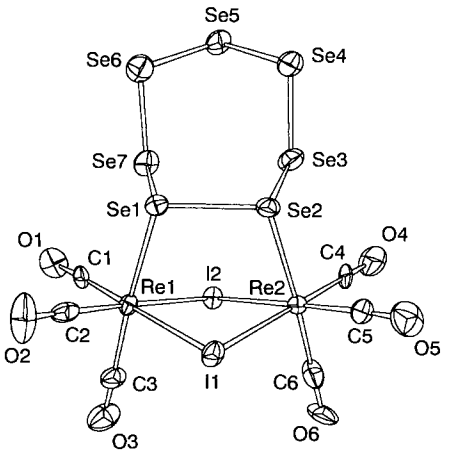

Fig. 1. ORTEP view (50% probability ellipsoids) of $[Re_2I_2(CO)_6(Se_7)]$. Ranges for bond distances in Å (number of bonds in parenthesis): Re–I(4), 2.820–2.826; Re-Se(2), 2.586–2.587; Re-C(6), 1.890–1.974; Se–Se(6), 2.309–2.346, Se1–Se2, 2.558(3). Ranges of selected bond angles [°], number of angles in parenthesis: Re-I-Re(2), 92.44–92.50; I-Re-I(2), 84.12–84.27; Re-C-O(6), 176–179; Se-Se-Se(7), 99.3–104.3.

environment coordinated to three terminal carbonyl groups, two bridging iodides, and one selenium atom of the *cyclo*-heptaselenium ligand. The Re···Re nonbonding distance is 4.077(3) Å, in agreement with the 3.90(4) Å distance in the rhenium(I) dimer $[Re_2Br_2(CO)_6(Se_2Ph_2)]$.[13] The angular distortions from ideal octahedral geometry are less than 6.5°. The Re–Se distance (average 2.586 Å) compares well with the Re–Se distance of 2.604(4) Å in the diphenyldiselenide complex.[13] The two coordination polyhedra share the two iodo ligands, and the apical selenium atoms are bonded at a distance of 2.558(3) Å. The rhenium-coordinated *cyclo*-heptaselenium ligand adopts a chairlike conformation defined by the planes Se1-Se2-Se3-Se7 (maximal deviation of atoms from best plane: $d_{max} = 0.036$ Å, plane 1), Se3-Se4-Se6-Se7 ($d_{max} = 0.016$ Å, plane 2), and Se4-Se5-Se6 (plane 3); the dihedral angles are 78.11(5)° between plane 1 and 2, and 74.90(9)° between plane 2 and 3. Plane 2 is almost parallel to the Re1-Re2-Se1-Se2 plane ($d_{max} = 0.07$ Å); the dihedral angle is 5.89(4)°. The molecular symmetry is close to C_s; the mirror plane contains the atoms Se5, I1, and I2.

To our knowledge, no examples of a discrete molecule of an allotropic modification of elemental selenium coordinated to a transition metal center have been established previously; on the other hand, selenium and tellurium complexes of d^{10} copper(I) and gold(I) halides are known,[14] which contain screw-type chalcogen ligands[15] or *cyclo*-Se_6 as ligand,[16] interconnected in the crystal lattice at bonding metal–chalcogen distances (e.g., Cu–Se bond distance 2.447(4) Å;[16a] average Cu–Se bond distance 2.460(2) Å[16b]). Copper selenide clusters stabilized by tertiary phosphanes are also known.[17] Although Se_7 does not appear to have been studied crystallographically as yet, the structural parameters of Se_7 interlayered with Se_6 in $(NEt_4^+)_2[Se_5^{2-} \cdot 1/2\ Se_6 \cdot Se_7]$ have been reported:[18] the Se_7 moiety adopts a chairlike conformation whose symmetry is approximately C_s and Se–Se bond distances range from 2.323(7) to 2.365(7) Å; the unique Se–Se bond bisected by the symmetry plane is significantly longer [2.409(7) Å]. Thus, coordination of Se_7 to a rhenium(I) center would correspond to a lengthening of the bond by only about 0.15 Å with respect to uncoordinated *cyclo*-heptaselenium. A theoretical study[19] of some selenium clusters has predicted that the chairlike conformation of Se_7 is the ground state of the molecule and that the unique Se–Se bond (2.48 Å) would be significantly longer than the others.

Experimental Procedure

IR spectra were recorded on a Perkin-Elmer FT-IR 1725 X, and NMR spectra on Bruker AC 250 and Varian Gemini 200 HVC instruments. Under a dinitrogen atmosphere the rhenium(I) complex $[Re_2I_2(CO)_6(THF)_2]$ (0.476 g, 0.507 mmol) was treated with sublimed [7] Se_n (0.345 g, 4.37 mmol for $n = 1$) in CS_2 (15 mL). The suspension was stirred in the dark for 21 h at room temperature; throughout this time, the volatiles were removed in vacuo. The dry residue was dissolved in fresh CS_2, and this operation repeated three times until the IR spectrum of the supernatant solution in the carbonyl stretching region showed that the starting metal carbonyl had disappeared. The final suspension was filtered, and the brown complex washed with heptane and dried *in vacuo* (44% yield). The *cyclo*-heptaselenium rhenium(I) complex is readily soluble in CS_2 (about 4% w/v) and stable in air if dry; by addition of THF to its CS_2 solution, a slow separation of α-Se_8 [8] was observed (Unit cell parameters: $a = 9.072$, $b = 9.097$, $c = 11.625$ Å, $\beta = 90.99°$).

[7] Commercial gray selenium (20 g) was pyrolyzed in vacuo (about 10^{-2} Torr) at about 240 °C in a 1-L flask equipped with a central cold finger (cooled with liquid nitrogen). The red sublimed Se_n was scraped from the cold finger and kept at about −30 °C until it was used for the subsequent reaction with the rhenium(I) complex. A solution of the sublimed Se_n in CS_2 at room temperature slowly deposited monoclinic α-Se_8, as shown by comparison of the cell constants of the precipitate ($a = 9.068$, $b = 9.080$, $c = 11.572$ Å, $\beta = 90.75°$) with the literature data [8]. No or incomplete reaction was observed between the rhenium(I) carbonyl complex and gray elemental selenium. Commercial selenium carefully prewashed with carbon disulfide did not react.

Spectroscopic and Reactivity Studies of a Copper-Containing Metallacrown**

Alexander J. Blake, Robert O. Gould, Craig M. Grant, Paul E. Y. Milne, David Reed, and Richard E. P. Winpenny*

Crown ethers were first discovered more than twenty years ago,[1] and since that time their utilization in all fields of chemistry has been extensive. More recently a related class of compounds, named metallacrowns, has begun to appear,[2] in which the carbon backbone of the macrocyclic ligand has been replaced by metal-containing entities. Recently we reported on the cation of **1**, a potentially new member of this small class of

$[Cu_6(MeL)_{12}Na][NO_3]$ **1**

compounds, a hexanuclear copper complex of 2-hydroxy-6-methylpyridine (MeLH),[3] in which a sodium cation was found at the center of a macrocyclic cavity created by a hexanuclear copper complex of MeL. Before claiming that **1** was a metallacrown, we felt that two criteria needed to be satisfied: firstly that the structure is retained in solution, and secondly that the sodium cation at the center of **1** could be replaced by another metal without gross alteration of the structure. Here we report spectroscopic studies of **1**, which indicate that the structure is largely retained in solution, and reactions of **1**, which show that the sodium can be replaced by copper or magnesium to open up further new chemistry.

Compound **1** is synthesized from the reaction of the potassium salt of MeLH and hydrated copper nitrate in the solid state, followed by crystallization from CH_2Cl/ether. X-ray structural analysis[13] (the structure of the cation is identical with that of **2** except that the central copper atom Cu1 is replaced by a sodium atom) led to the conclusion that a sodium cation was at the center of the cavity, despite the apparent absence of sodium from the reactants.[4] This is further confirmed by the mass spectrum, in which a peak is seen for $[Cu_6(MeL)_{12}Na]^+$. Interestingly, strong fragment peaks are seen for $[Cu_4(MeL)_8Na]^+$, $[Cu_3(MeL)_6Na]^+$, $[Cu_2(MeL)_4Na]^+$, $[Cu_2(MeL)_3Na]^+$, and $[Cu(MeL)_2Na]^+$; no strong peaks are seen which indicate ready loss of sodium from **1**.

^{1}H NMR spectroscopy suggests that the structure of **1** is largely retained in solution. Eight paramagnetically shifted resonances reflect the presence of two inequivalent ligand types in **1**. Six of the signals of relative intensity 1 are due to aromatic protons and are shifted to higher frequency than commonly observed. Two signals of relative intensity 3 are shifted to low frequency and are due to the methyl protons. The ^{23}Na NMR spectrum of **1** showed a single peak at $\delta = -165.2$ and with a line-width of several hundred Hz. The chemical shift range of ^{23}Na is normally quite narrow,[5] and therefore this shift is indicative of a strong influence from the paramagnetic coppers. Additionally, the linewidth is consistent with a quadrupolar sodium atom in a highly symmetrical site. Thus both ^{1}H and ^{23}Na NMR spectra are consistent with the crystal structure.

We have shown that reaction of **1** with solid lanthanum nitrate leads to a highly unusual La_8Cu_{12} metal complex.[3] We have investigated similar reactions with a series of other metal nitrate salts. Treatment of a dichloromethane solution of **1** with solid lead nitrate over a period of ten weeks at 3 °C caused the solution to darken. Unchanged lead nitrate was removed from the mixture, and very dark green crystals grown by addition of ether. X-ray structural analysis[6] shows that compound **2** has

$[Cu_6(MeL)_{12}Cu][Pb(NO_3)_4]$ **2**

formed (Fig. 1). The cation in **2** is almost identical to that in **1**, except that the Na atom in **1** has been replaced by a Cu atom.

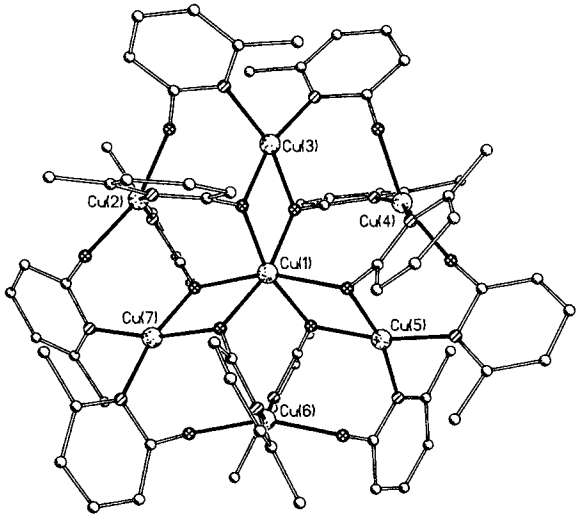

Fig. 1. The crystal structure of the heptametallic cation of **2**. Bond length ranges [Å] (average, standard deviations 0.014 Å): Cu–N 1.963–2.036, Cu1–O 1.994–2.210, other Cu–O distances 1.913–2.003.

The metallacrown consists of six copper atoms in a six-pointed star array. Each is four coordinate, with a *trans* arrangement of 2 O and 2 N donors from MeL units for Cu2, Cu4 and Cu6, and a *cis* arrangement of the same donor set for Cu3, Cu5, and Cu7. The *cis* oxygens form the cavity in which the seventh copper atom is bound. The coordination geometry of this copper is distorted from an octahedron towards a trigonal prism. This distortion is caused by the small angle (about 74°) between each pair of oxygen atoms which bridge to the peripheral coppers, and its effect is to cause a rotation about a molecular threefold axis, so that the upper triangle of oxygens in the "trigonal prism" is twisted with respect to the lower triangle by 41° from its eclipsed position in an ideal trigonal prism rather than by the 60° required for an octahedron.

The anion of **2**—$[Pb(NO_3)_4]^{2-}$—is also, to our knowledge, new. $Sn(NO_3)_4$ has been reported[7] and contains Sn(IV) with a regular coordination geometry based on a dodecahedron. Here the anion contains Pb^{II}, and the coordination geometry is extremely irregular.

The mass spectrum of **2** shows a peak for the cation $[Cu_6(MeL)_{12}Cu]^+$ and similar structural fragments to those in the spectrum of **1**; that is, again it appears that the central metal atom is largely retained. Peaks are also seen at *m/z* greater than that of the cation, consistent with addition of fragments of the $[Pb(NO_3)_4]^{2-}$ anion. The ^1H NMR spectrum indicates that **2** is unstable in solution.[8]

To a large extent **1** did not react with solid magnesium nitrate. However, a very small number of lighter green crystals suitable for X-ray analysis[6] also formed. The crystallographic study revealed a new mixed-metal compound **3** (Fig. 2). The three cop-

$[Cu_3Mg(MeL)_6(NO_3)_2(MeLH)_2]$ **3**

per atoms in the structure retain much the same spatial arrangement as the corresponding unit in **1** and **2**; the structure resembles **1** or **2** but cut in half. The coordination geometry of magnesium is much nearer octahedral than that of the central atoms in **1** and **2**; only one angle [O3-Mg1-O3a = 72.05(11)°] differs dramatically from the expected value. As was the case in **2**, this acute angle is between two μ_2-oxygens, in this case bridging Cu1 and Mg1. The more regular geometry reflects a requirement of the metal, and perhaps explains why **3** is formed in such a low yield, and why the Mg atom is not at the center of a macrocycle: the geometrical preferences of Mg^{2+} and the conformational inflexibility of the metallacrown do not match, whereas for metal ions such as Na^+ and Cu^{2+}, which can support distorted coordination geometries, they do. Under these conditions **1** does not react with other s-block salts.

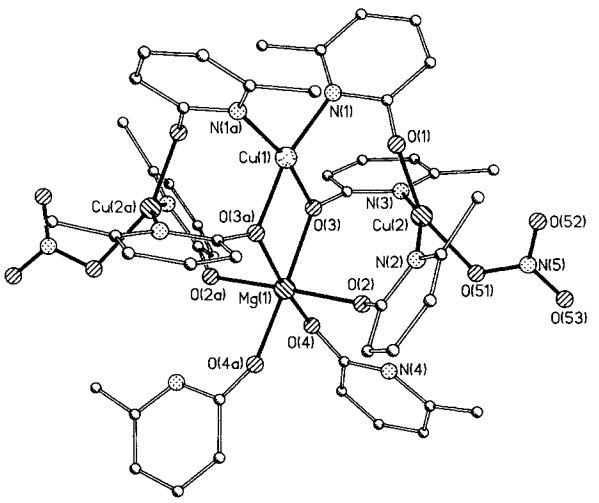

Fig. 2. The crystal structure of **3**. A crystallographic twofold axis passes through Cu1 and Mg1. Bond lengths [Å] (average standard deviations 0.03 Å): Cu1–N1 2.001, Cu1–O3 1.985, Cu2–O1 1.936, Cu2–N2 1.998, Cu2–N3 2.015, Cu2–O51 2.020, Mg1–O2 2.042, Mg1–O3 2.132, Mg1–O4 2.064. Bond angles [°] (average standard deviations 0.13°): N1-Cu1-N1A 95.75, N1-Cu1-O3 93.86, N1-Cu1-O3a 166.56, O3-Cu1-O3a 78.34, O1-Cu2-N2 91.72, O1-Cu2-N3 93.07, O1-Cu2-O51 157.41, N2-Cu2-N3 159.08, N2-Cu2-O51 90.35, N3-Cu2-O51 92.97, O2-Mg1-O2a 178.28, O2-Mg1-O3 87.77, O2-Mg1-O3a 93.62, O2-Mg1-O4 89.52, O2-Mg1-O4a 89.28, O3-Mg1-O3a 72.05, O3-Mg1-O4 89.28, O3-Mg1-O4a 89.52, O4-Mg1-O4a 89.52°.

Several aspects of the synthetic work remain to be explored. It is unclear how addition of $Pb(NO_3)_2$ to **1** leads to compound **2**. Obviously it is not merely replacement of Na^+ by Cu^{2+}, as the source of Cu must be other metallacrowns. This suggests that lead nitrate may disrupt the structure of **1** completely. Unfortunately in this case the paramagnetic nature of the compounds hinders extensive investigation of the reaction chemistry by NMR spectroscopy.

Experimental Procedure

1: Hydrated copper nitrate (6.9 mmol) and the potassium salt of MeLH (3.4 mmol) were intimately mixed. The green paste which resulted was extracted with dichloromethane (20 mL), and slow diffusion of ether vapor caused dark green cubic crystals to form. Yield (after one month): 19%. Use of NaMeL led to isolation of a light green powder, rather than to an increased yield of **1**. ^1H NMR for **1** (CD_2Cl_2): δ = 40.8, 40.4, 29.0, 22.0, 21.3, 18.3 (each a singlet of intensity 1); −6.9, −13.8 (each a singlet of intensity 3). Additional peaks due to free ligand and solvent were also observed. ^{23}Na NMR ($CDCl_3$): δ = −165.2 (s). FABMS: *m/z*: 1704, $[Cu_6(MeL)_{12}Na]^+$; 1141, $[Cu_4(MeL)_8Na]^+$; 862, $[Cu_3(MeL)_6Na]^+$; 581, $[Cu_2(MeL)_4Na]^+$; 473, $[Cu_2(MeL)_3Na]^+$; 302, $[Cu(MeL)_2Na]^+$; 131, $[(MeL)Na]^+$.

2: $Pb(NO_3)_2$ (2.8 mmol) was added to a solution of **1** (0.06 mmol) in CH_2Cl_2 (4 mL), and the reaction mixture stored at 3 °C. Over a period of ten weeks the solution changed from green to very dark green, and a yellow precipitate was noticed among the solid $Pb(NO_3)_2$. The solution was filtered through Celite, and an equal volume of ether was added to the filtrate. Long (4–7 mm) crystals of **2** formed in one day. Yield: 12% based on **1**. Slow diffusion of ether vapor leads to formation of a dark green oil rather than crystalline material. FABMS: *m/z*: 2133, $[\{Cu_6(MeL)_{12}Cu\}Pb(NO_3)_3]$; 2070, $[\{Cu_6(MeL)_{12}Cu\}Pb(NO_3)_2]^+$; 2007, $[\{Cu_6(MeL)_{12}Cu\}Pb(NO_3)]^+$; 1805, $[\{Cu_6(MeL)_{12}Cu\}(NO_3)]^+$; 1742, $[Cu_6(MeL)_{12}Cu]^+$; 1181, $[Cu_4(MeL)_8Cu]^+$; 1075, $[Cu_4(MeL)_7Cu]^+$; 1010, $[Cu_3(MeL)_7Cu]^+$; 900, $[Cu_3(MeL)_6Cu]^+$; 794, $[Cu_3(MeL)_5Cu]^+$.

3: $Mg(NO_3)_2 \cdot 6H_2O$ (2 mmol) was added to a solution of **1** (0.07 mmol) in CH_2Cl_2 (4 mL), and the reaction mixture stored at 3 °C. After eight weeks the reaction solution was filtered, and ether vapor allowed to diffuse into the green filtrate. In the main, dark green crystals of **1** were recovered, plus a very small number of light green crystals of **3**. Yield: 5%.

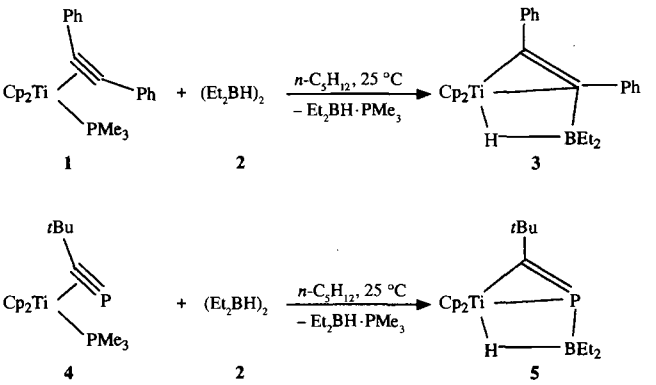
[8] In CD_2Cl_2 intense peaks are seen for MeLH in addition to a large number of paramagnetically shifted peaks, eight of which are also seen for **1**. In $CDCl_3$ very intense peaks for MeLH are seen, plus the eight peaks for **1** which are very weak.

New Titanium–Boron Complexes with a Planar Tetracoordinate Carbon or a Planar Tricoordinate Phosphorus Center**

Paul Binger,* Frank Sandmeyer, Carl Krüger, Jörg Kuhnigk, Richard Goddard, and Gerhard Erker



Dedicated to Professor Otto J. Scherer on the occasion of his 60th birthday

C–C double and C–C triple bonds as well as multiple bonds including heteroatoms are very rapidly hydroborated by alkyldiboranes at 0–20 °C.[1] Hydroboration also occurs in the reaction of (1-alkenyl) chlorozirconocenes with 9-borabicyclo[3.3.1]nonane (9-BBN).[2] However, nothing is known about the nature of the interaction between alkyldiboranes and alkenes or alkynes π-bonded to titanocene. In connection with the synthesis and reactivity of bimetallic complexes containing titanocene and zirconocene groups, we have now investigated the reaction of tetraethyldiborane (**2**) with diphenyl acetylene (tolane) coordinated η^2 to titanocene and the analogous reaction with *tert*-butylphosphaalkyne coordinated η^2 to titanocene.

In the reaction of the trimethylphosphane-stabilized titanocenes **1** and **4**, containing η^2-bonded tolane or phosphaalkyne ligands, respectively (see Scheme 1), with **2**, we observe no B–H addition to either the C–C or C–P triple bond. Instead a special class of dimetallabicyclopentenes is formed, the suitability of which for stabilizing unusual coordination geometries of carbon has previously been reported by Erker et al.[3] and theoretically studied by Gleiter et al.[4] Bimetallic systems, consisting of a main group element (Al, Ga) and a transition metal of the fourth subgroup (Zr, Hf), which contain a planar tetracoordinate carbon as central structural feature have recently aroused a great deal of interest.

Thus we have not only succeeded in transferring the simple synthetic method of G. Erker et al. to Ti/B complexes, but we have also been able to prepare and structurally characterize a representative of this class of compounds in which a phosphorus atom takes the position normally reserved for the planar tetracoordinate carbon atom.

The dinuclear complex **3** with a titanium and boron center is obtained in a spontaneous reaction in 94% yield from the tolane complex **1** and the equivalent amount of tetraethyldiborane (**2**) at room temperature as an orange powder (Scheme 1). Under identical conditions the dinuclear complex **5** is obtained from the phosphaalkyne complex **4** and **2** in 46% yield over 20 h (Scheme 1). The particularly remarkable feature of both reactions is that in the products **3** and **5** a Et_2BH fragment is found exclusively, even though the reagent **2** consists of an equilibrium mixture of several diboranes of the general composition $(Et_xBH_{3-x})(Et_yBH_{3-y})$ ($x = 1, 2$; $y = 1, 2$) and Et_3B.[5] A zirconium complex analogous to **3** was recently obtained from (η^2-tolane)(trimethylphosphane)zirconocene, 9-BBN, and triethylborane in about 12% yield.[6]

Scheme 1. Syntheses of the bimetallic complexes **3** and **5**.

The structures of **3** and **5** cannot be assigned unambiguously from spectroscopic data. The ^{13}C NMR shift of the planar tetracoordinate carbon atom in **3** ($\delta = 115$ ([D_8]THF, 25 °C, 75.5 MHz))[7] lies within the resonance range of aromatic carbon atoms and is not very characteristic. The NMR signal of the boron atom at $\delta = 25.2$ ([D_8]THF, 25 °C, 64.2 MHz) lies within the region for boranes with B–H bridges.[8] The X-ray structure investigations,[9] however, conclusively show the planar geometry of the five-membered skeleton in complex **3**, comprising Ti, the two olefinic C atoms, B, and H and thus confirm that **3** belongs to the class of "anti-van't Hoff/le Bel" compounds obtained by Erker et al.

The ^{31}P NMR signal of complex **5** at $\delta = 34.8$ is clearly shifted upfield in comparision to the corresponding signal of the starting material **4** ($\delta = 122.7$). The strong shielding of the phosphorus atom suggests that the lone pair of electrons on the phosphorus atom is not involved in the bonding. Thus, this type of coordination is clearly different from the known $\eta^2:\eta^1$ coordination of phosphaalkynes,[10] and from the η^1 coordination of phosphaalkenes,[11] which also may lead to planar-coordinated phosphorus. In these cases the ^{31}P NMR signals are at very low field in comparison to the signal of complex **5**. The NMR signal of the boron atom in **5** is found at $\delta = 35.6$. The boron atom is thus slightly more deshielded than in the analogous tolane complex **3**. This observation together with the high-field position of the ^{31}P NMR signal give the impression that in **5** boron serves as an electron donor to the phosphorus atom, which in turn may transfer electron density in the plane containing the σ bonds to titanium. Thus, the bonding would be clearly different from that

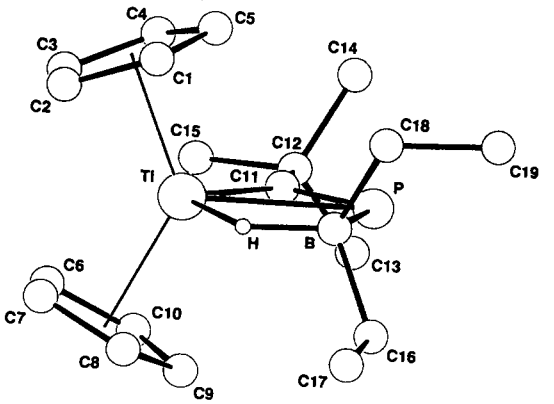
calculated by Hoffmann et al.[12] for compounds with a planar tetracoordinate carbon atom, which could not function as a donor due to its electron deficiency. The results of electron density measurements as well as ab initio calculations should reveal the exact nature of the bonding.

The crystal structure analysis provides the conclusive evidence for the planar environment of the tricoordinate phosphorus atom in complex **5** (Fig. 1).[13] According to the structure



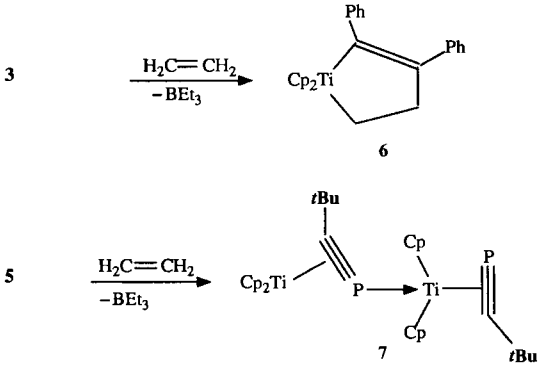


Fig. 1. Crystal structure of **5**. Selected distances [Å] and angles [°]: Ti–P 2.648(1), Ti–C11 2.099(2), Ti–H 1.81(3), P–C11 1.666(2), P–B 2.054(3), B–H 1.25(3); H-Ti-P 72.9(9), C11-Ti-P 39.0(1), B-P-Ti 64.6(1), C11-P-Ti 52.4(1), H-B-P 109(1), B-H-Ti 113(2).

analysis, the basic framework of complex **5** consists of a planar dimetallabicyclo[2.1.0]pentene unit which contains a Cp_2Ti and a Et_2B group as well as C11, P, and H as bridging ligand. The phosphaalkyne ligand is η^2 coordinated to the transition metal and η^1 coordinated to the boron atom. The phosphorus atom functions as a bridgehead atom; the three bonds emanating from it lie exactly in a plane. The bonds P–C11 (1.666(2) Å) and Ti–P (2.648(1) Å) are slightly longer than those in the starting material, whereas the Ti–C11 distance (2.099(2) Å) is clearly shorter,[10] so that this bond can be ascribed partial double bond character. The Ti-H-B unit has bond lengths similar to those found in tetrahydroborate–titanium complexes.[14] No bonding interaction is observed between the titanium atom and the boron atom (Ti–B 2.563(2) Å). Overall we have therefore proven that complex **5** has the same structural features as complex **3** and numerous known zirconium and hafnium complexes with planar tetracoordinate carbon.[3]

Scheme 2. Reactivity of the complexes **3** and **5** with ethylene.

In spite of their thermal stability, complexes **3** and **5** are highly reactive towards unsaturated substrates. Thus **3** reacts at room temperature with ethylene to form the titanacyclopentene **6** (as yet unreported), together with triethylborane (Scheme 2). Under the same conditions complex **5** disintergrates under the influence of ethylene into the components (η^2-*tert*-butylphosphaalkyne)titanocene and diethylborane; the latter reacts with ethylene to give triethylborane. The titanocene unit does not undergo oxidative coupling, instead it dimerizes to give the known dinuclear complex **7**.[10]

Experimental Procedure

3: To a suspension of **1** (1.49 g, 3.5 mmol) in pentane (55 mL) was pipetted **2** (0.85 mL, 7.0 mmol) at room temperature. The color changed to orange immediately. After 3 min the orange solid **3** was filtered off. The mother liquor was concentrated (50% volume) and cooled to −20 °C from which additional **3** was obtained (total yield 94%). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1685 (BH); ^{1}H NMR (200 MHz, [D$_8$]THF, 25 °C): δ = 7.07–6.54 (m, 10H; Ph), 5.92 (s, 10H; Cp), 1.14–0.84 (m, 10H; Et), −4.06 (broad, μ–H). Correct elemental analyses.

5: Complex **5** was prepared analogously to complex **3** from **4** (1.8 g, 5.2 mmol) and **2** (1.8 mL, 15.6 mmol) in pentane (35 mL). The mixture was stirred for 20 h at room temperature, filtered over Celite, and the mother liquor cooled to −20 °C. Compound **5** crystallized in form of orange-red platelets in 46% yield. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1700–2000 (BH, not unambiguously assignable); ^{1}H NMR (200 MHz, [D$_8$]THF, 25 °C): δ = 5.52 (s, 10H; Cp), 1.49 (s, 9H; *t*Bu), 1.15–0.83 (m, 10H; Et), the signal of the μ–H atom could not be found. Correct elemental analyses.

$[P_4(Cp^*Al)_6]$: A Compound with an Unusual P_4Al_6 Cage Structure**

Carsten Dohmeier, Hansgeorg Schnöckel,* Christian Robl, Uwe Schneider, and Reinhart Ahlrichs*

Recently we reported on the synthesis and characterization of pentamethylcyclopentadienylaluminum (Cp*Al, **1**), the first organometallic compound with monovalent aluminum.[1] These results were followed by a great number of investigations concerning the properties and the reaction behavior of the compound. Of particular interest was the association behavior of **1** in solution. It could be demonstrated that tetrameric **1** is in equilibrium with monomeric Cp*Al in solvents such as toluene [(Eq. (a)].[2]

$$[(Cp^*Al)_4] \rightleftharpoons 4\,Cp^*Al \qquad (a)$$

The compound $[(Cp^*Al)_4]$ in solution is thus a "continuous" source for a carbene analogous alanediyl.

At first we investigated the oxidation of **1** ($Al^I \rightarrow Al^{III}$) with white phosphorus [Eq. (b)], since the compounds between the heavy elements of the third and fifth main group are of current interest with regard to both bonding theory (e.g. in multiple bonding or cage systems[3]) and industrial applications (semiconductor precursors[4]). If **1** is allowed to react with P_4, cleavage of the P_4 tetrahedron into four P building blocks leads to the formation of $[P_4(Cp^*Al)_6]$ (**2**) in high yield according to Equation (b).[5] Compound **2** forms bright yellow air- and moisture-

$$1.5\,\underset{\mathbf{1}}{[(Cp^*Al)_4]} + P_4 \xrightarrow{\text{toluene/25 °C}} \underset{\mathbf{2}}{[P_4(Cp^*Al)_6]} \qquad (b)$$

sensitive rhombuses, which are almost insoluble in all common solvents. Thus, no indication of the structure of the species present in solution can be obtained by NMR spectroscopic methods. In contrast, the molecular structure of solid **2** (Figs. 1 and 2) is obtained by a crystal structure analysis.[6] This shows

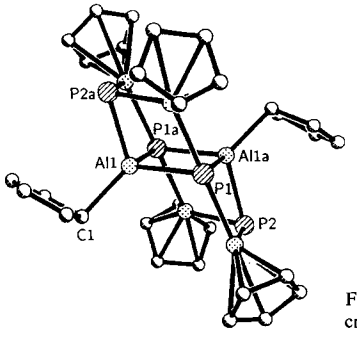

Fig. 1. Molecular structure of **2** in the crystal (methyl groups are not shown).

that centrosymmetric molecules occur, in which five edge-sharing Al_2P_2 rings form a P_4Al_6 framework alternatingly occupied with aluminum and phosphorus (Fig. 2). It can be described by two face-sharing, distorted Al_4P_4 cubes which lack two P atoms at diametral corners.[7]

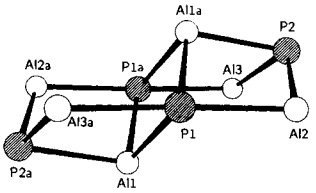

Fig. 2. P_4Al_6 framework of crystalline **2**.

The Al–P bond lengths are—depending on the coordination number of the participating atoms—between 231 pm (e.g. P2–Al2) and 242 pm (e.g. P1–Al1) (see Table 1). Thus, they vary

Table 1. Selected distances and angles in crystalline $[P_4(Cp^*Al)_6]$ (**2**), calculated molecular parameters of $[P_4(CpAl)_6]$ (**3**) (numbering corresponds to that in **2**, Fig. 2), and shared electron numbers (SEN) [12].

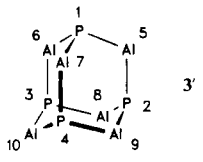
about the value of 235 pm in the crystalline AlP (zinc blend structure). Depending on whether the aluminum atoms have two or three phosphorus neighbors, the Cp* groups are linked η^5 and η^1, respectively. As expected, the π-like backbonds from the Cp* ligands to aluminum are in competition with the formation of additional Al–P bonds. The σ-Al–C bond is relatively long (205.7 pm). The distance between aluminum and the π-bound C atoms (mean 227.6 pm) lies between the distances found in $[(Cp^*AlCl_2)_2]$ (ca. 222 pm)[8] and $[(Cp^*Al)_4]$ (**1**) (233.4 pm). Also of interest are the "nonbonding" Al–Al distances in **2**: five short (4×302 pm, 1×310 pm) and four long Al–Al contacts (4×386 pm), bonding interactions can be assumed for the former (see below) (d_{Al-Al} in the metal: 286 pm). In contrast, the P–P distances in **2** (364–372 pm) are found which lie in the range of van der Waals distances.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0199 $ 10.00+.25/0

In order to get a deeper understanding of the unexpected bonding in **2** we carried out quantum chemical calculations on the model compound $[P_4(CpAl)_6]$ (symmetry C_{2h}) **3**.[9] The calculated Al–P distances in the P_4Al_6 cage of **3** is also shown in Table 1. The discrepancy between the latter and the values determined from experiments with **2** is always less than 2%.



There are 32 electrons available for the bonds in the P_4Al_6 framework: two from each Cp*Al unit, five per P atom. These 16 electron pairs result in one pair of electrons for each of the 14 Al–P bonds of the framework in addition to the lone pair of electrons at the tricoordinate P atoms. If covalent bonds are assumed, the two tetracoordinate P atoms (P1/P1a) would formally carry a single positive charge and the two Al atoms Al1 and Al1a would carry a single negative charge. This would require a perfect $3s$-$3p_y$ hybridization at the P atoms (y = P1–Al2 direction), which is unusual for phosphorus (promotion energy $3s \rightarrow 3p$: 8 eV).

This model contradicts chemical intuition and is not confirmed by the analysis of the wave function. The Mulliken atomic charges[10] (P1/P1a: −1.09, P2/P2a: −0.68, Al1/Al1a: + 0.90, Al2/Al3/Al2a/Al3a: + 0.98) and the high occupation of the $3s$ orbitals on P1/P1a (1.81e) as well as on P2/P2a (1.83e) can be explained as follows: Each P atom carries a lone pair of electrons, which has predominantly s character and is only weakly delocalized in the cage.[11] Thus, **3** is an electron-deficient compound, in which 12 occupied MOs describe 14 bonds. This is also consistent with the shared electron numbers (SEN)[12] (Table 1) and thus with the significant bond contributions for the "nonbonding" Al–Al contacts.

In order to understand the bonding in **2** we investigated the adamantane-analogous isomer **3'** (Table 2) with quantum mechanical methods for comparison. The geometric parameters and the SENs are given in Table 2. Depending on the method of calculation **3** is more stable by 30 to 80 kJ mol^{-1} than **3'**.[13]

Table 2. Calculated molecular parameters of **3'** (symmetry C_{3v}).

	Distance [pm]	SEN
P1-Al5	234.7	1.39
P2-Al5	231.0	1.47
P2-Al9	237.4	1.27
Al5···Al9	361.2	0.16
Al5···Al6	353.1	0.23
Al8···Al9	378.3	0.10
P1···P3	418.7	–
P4···P3	411.3	–

3'

Apparently, the lacking or very weak Al–Al interactions in **3'** lead to the calculated destabilization in comparison to **3**. However, the difference in energy is not very large and thus a thermal rearrangement of **2** into **2'** (adamantane-analogous isomer of **2**) can be expected.[14] In this context the thermochromic properties of **2**, whose interpretation is the subject of current investigations, are of interest.

Experimental Procedure

In order to record the Raman spectrum (Bruker-FRA-106 (Nd:YAG laser 1.06 μ)) solid **2** was sealed in an evacuated tube. The KBr disk for the IR spectrum (Nicolet 520-FT-IR) was prepared in a glove box.

2: **1** (0.43 mmol, 70 mg) was dissolved in toluene (22 mL). The pale yellow solution was then slowly layered with a solution of freshly sublimed P_4 (0.39 mmol) in toluene (4 mL) at room temperature. The reaction mixture turned intense yellow within an hour. After approximately 4 d, bright yellow crystals of **2** (68 mg, 87%) were isolated. These crystals were air- and moisture-sensitive and showed thermochromic behavior (yellow↔orange) above 115 °C and sublimed at 290 °C (decomp). FT-Raman spectrum: [cm^{-1} (rel. int.)]: 2915(10), 2855(4), 2724(1), 1600(0.50), 1533(1.5), 1456(1.5), 1426(2), 1384(2), 1038(0.5), 800(1), 679(1.5), 596(3), 557(1), 502(1), 462(0.5), 431(1.5), 383(1.5), 358(2), 348(1.5), 287(1), 241(1.5), 173(2), 141(4), 113(4). – FT-IR (KBr) [cm^{-1} (rel. int.)]: 2967(5), 2916(10), 2872(7), 2850(8), 2726(1), 1661(0.5), 1596(1), 1495(2), 1442(7), 1430(6), 1375(9), 1273(4), 1143(1), 1034(3), 940(2), 850(2), 797(3), 728(1), 657(4), 623(1), 591(3), 562(1), 489(7), 455(7), 437(9), 368(5), 318(3).

[9] All calculations were carried out with the TURBOMOLE program (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, *162*, 165) on IBM RISC 6000 workstations. The structure of **3** was obtained by geometry optimization at the SCF level with fully optimized basis sets for the atoms (Al, P, C: SVP; H: DZ) (A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571).
[10] R. Mulliken, *J. Chem. Phys.* **1955**, *23*, 1833.
[11] The distorted trigonal-bipyramidal coordination at P1 and P1a here corresponds to the geometry, which is to be expected according to the VSEPR model for a PR_4^- anion (for example K. B. Dillon, A. W. G. Platt, A. Schmidpeter, F. Zwaschka, W. S. Sheldrick, *Z. Anorg. Allg. Chem.* **1982**, *488*, 7).
[12] Shared electron numbers are a measure for the covalent bond order; see for example C. Ehrhardt, R. Ahlrichs, *Theor. Chim. Acta* **1976**, *42*, 33, and references therein.
[13] The SCF method affords a stabilization of **3** by about 106 kJ mol^{-1}. This value is probably too large, since **3'** could only be optimized in C_{3v} symmetry and lowering the symmetry can lead to a stabilization of **3'**. Therefore the two corresponding isomers of $[P_4(AlCl)_6]$ (**4** and **4'**) (C_{2h} and T_d, respectively) were investigated. The SCF method affords only a stabilization of 36 kJ mol^{-1} for **4** in comparison to **4'**. In order to estimate the influence of the electron correlation on the stability additional MP2 calculations on these model examples were carried out. Here the closer packing of the C_{2h} structure leads to a greater influence of the electron correlation and thus to an additional preference of **4** by 44 kJ mol^{-1}.
[14] The thermal conversion of two P_4X_6 isomers has been reported for $[P_4(NiC_3H_7)_6]$; O. J. Scherer, K. Andres, C. Krüger, Y.-H. Tsay, G. Wolmershäuser, *Angew. Chem.* **1980**, *92*, 563; *Angew. Chem. Int. Ed. Engl.* **1980**, *19*, 571.

(Iminoboryl)borates $[(t\mathrm{BuN}{\equiv}\mathrm{B})\mathrm{B}t\mathrm{Bu}_2\mathrm{R}]^-$ from the Azadiboriridine $\mathrm{NB}_2t\mathrm{Bu}_3$ (R = Me, Bu)

Ellen Eversheim, Ulli Englert, Roland Boese, and Peter Paetzold*

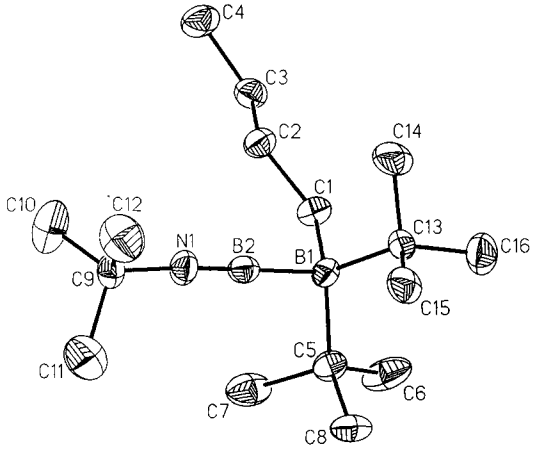
The azadiboriridine $\mathrm{NB}_2t\mathrm{Bu}_3$ (**1a**) reacts with CO[1] and BH_3[2] at the B–B bond to give unexpected products. We have now treated **1a** with the alkyllithium compounds LiMe and LiBu in the presence of *N,N,N',N'*-tetramethylethylenediamine (tmeda) and observed a B–N ring opening and the migration of one of the *t*Bu groups [Eq. (a)].

(a)

1a

2a, R = Me
2b, R = Bu

In accord with the proposed structure of the colorless, solid products **2a, b**, the ^{11}B NMR signal of **1a** ($\delta = 51.9$) is replaced by two significantly upfield-shifted signals at $\delta = 17.7, -15.9$ (**2a**) and $\delta = 16.3, -13.4$ (**2b**), whereas the two B–*t*Bu groups of each of the products remain equivalent in the ^{1}H and ^{13}C NMR spectra. The crystal structure analysis of **2b** (Fig. 1)[3] shows that in the anion a two- and a four-coordinated boron atom are bonded to each other with an interatomic distance in the range expected for B–B single bonds (1.725 Å). The length



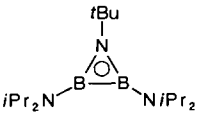


Fig. 1. Crystal structure of the anion of **2b**. Selected bond distances [Å] and angles [°]: B1-B2 1.725(5), B2-N1 1.250(5), N1-C5 1.473(4), B1-C1 1.679(5), B1-C5 1.710(5), B1-C13 1.707(5); B1-B2-N1 178.7(3), B2-N1-C9 174.7(3), C1-B1-B2 108.5(3), C5-B1-B2 107.7(3), C13-B1-B2 116.2(3).

of the B–N bond in the anion (1.250 Å) is typical for the B–N triple bond of iminoboranes.[4] Accordingly the B1-B2-N1-C9 chain deviates only slightly from linearity.

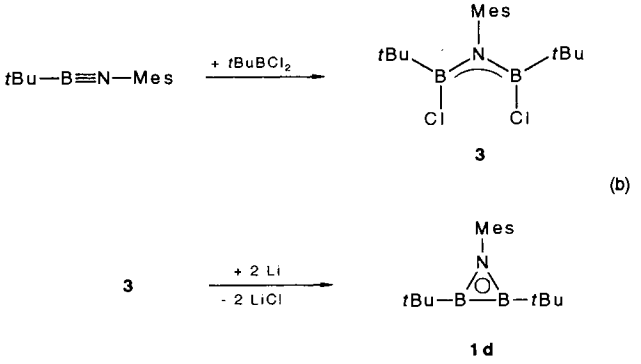
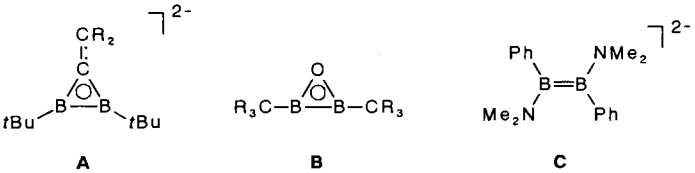
The anions **2** are isoelectronic with alkynyl borates of the type $[\mathrm{R_3BC}{\equiv}\mathrm{CR}]^-$. However, they can also be considered adducts of the Lewis acids $\mathrm{BR}t\mathrm{Bu}_2$ with the anion $\mathrm{B}{\equiv}\mathrm{N}t\mathrm{Bu}^-$, which is isoelectronic with *tert*-butyl isocyanide $\mathrm{C}{\equiv}\mathrm{N}t\mathrm{Bu}$. We presume that $\mathrm{BN}t\mathrm{Bu}^-$ is both a strong σ donor and a π acceptor as a result of the lone pair at the boron atom and the nitrilium group, respectively, and is therefore expected to act as a strongly bound ligand in transition metal complexes. Our attempts to trap the presumably reactive anion with unsaturated complexes after separation of the $\mathrm{BR}t\mathrm{Bu}_2$ moiety by means of bases such as pyridine have been unsuccessful.

We had not expected the ring opening according to Equation (a), because atom B1 is sterically overcrowded. The crystal structure of the ring compound **1a**, from which we wanted to deduce its unexpected reactions,[1, 2] could not be determined because of disorder.[5] The azadiboriridine compounds **1b** and **1c** with B-bound amino groups, the structures of which are known,[6, 7] do not react as unexpectedly as **1a** because of their different electronic properties. Therefore, we tried to synthesize



1b



1c

a azadiboriridine with sterically demanding organic ligands which, like **1a**, would not rapidly dimerize to *nido*-diazahexaborane,[8] but in contrast to **1a** should crystallize without disorder. This was achieved by chloroboration of the known iminoborane $t\mathrm{BuB}{\equiv}\mathrm{NMes}$[9] (Mes = 2,4,6-$\mathrm{Me_3C_6H_2}$) to form compound **3** and subsequent ring closure to give **1d** in a hetero-Wurtz synthesis, as shown in Equation (b).

The crystal structure analysis (Fig. 2)[10] shows that the B–B distance of 1.558 Å in **1d** represents a particularly short B–B bond, which is comparable with the quite short bonds in the similar compounds **A** (1.58 Å),[11] **B** (1.60 Å)[12] (R = $\mathrm{SiMe_3}$),

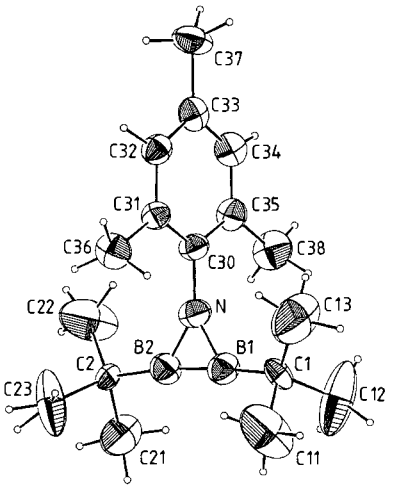

Fig. 2. Crystal structure of **1d**. Selected bond distances [Å] and angles [°]: B1-B2 1.558(9), B1-N 1.373(6), B2-N 1.356(6), B1-C1 1.483(7), B2-C2 1.482(7), N-C30 1.398(5); B1-N-B2 69.6(4), N-B1-B2 54.7(3), N-B2-B1 55.7(3), C1-B1-B2 176.0(4), C2-B2-B1 172.3(5).

and **C** (1.631 Å)[13] or in both the 2,3-diaminoazadiboriridines **1b** (1.604 Å)[6] and **1c** (1.610 Å)[7]. The B–N bonds (1.373 and 1.356 Å) and the B–C bonds (1.483 and 1.482 Å) are also rather short. All these distances in **1d** are reminiscent of corresponding structural parameters in the isoelectronic tri-*tert*-butylcyclopropenyl cation $C_3tBu_3^+$, with its short ring C–C distance of 1.372 Å and the short C–C distances of 1.485 and 1.489 Å between the ring and the *t*Bu groups.[14] The C1-B1-B2-C2 chain in molecule **1d** is essentially linear, with angles of 176.0 and 172.3°, respectively, at B1 and B2. This and the short B–B distance may be compared with similar structural features of the oxadiborirane **B**. Ab initio calculations on three-membered ring systems composed of BH, BH, and Y show an increasing shortening of the B–B bond and an increasing linearization of the HB–BH chain in the series Y = BH, CH_2, NH, O. This was rationalized in terms of the σ-bridged π-bonding model.[15] In the hypothetical parent compound H_2B-BH_2 the B–B single-bond length is calculated to be 1.71 Å, and the double bond in HB=BH to be 1.51 Å.[16] Thus the B–B distance in **1d** suggests strong double-bond character.

Preliminary experiments in NMR tubes have shown that **1d** reacts with CO, BH_3, and LiR analogously to **1a**. Apparently the structure of **1a** is closely related to that of **1d**. We are currently trying to elucidate the relationship between the unique reactivity of the triorganoazaboriridines and their structure.

Experimental

2a: A solution of methyllithium in diethyl ether (3.20 mL, 1.6 M) was added dropwise to a solution of **1a** (1.07 g, 5.17 mmol) and tmeda (1.6 mL) in THF (10 mL) at −78 °C. The mixture was stirred for 30 minutes at room temperature, volatiles were removed in vacuo (25 °C/1 Torr), and the residue was taken up in ether. At −30 °C, 2.03 g (84%) of **2a** crystallized.

NMR spectra in [D_8]THF at 25 °C; ^{1}H NMR (499.843 MHz, TMS): $\delta = -0.59$ (q, ^2J(HB) = 3.3 Hz; BMe), 0.75 (q, ^3J(HB) = 2.8 Hz; B*t*Bu$_2$), 1.13 (s; N*t*Bu), 2.14 (s; 4 NMe_2), 2.29 (s; 4 NCH_2); ^{11}B NMR (150.364 MHz, $Et_2O \cdot BF_3$): $\delta = -15.9, 17.7$ (2s, 1:1); ^{13}C NMR (125.697 MHz, TMS): $\delta = 31.1$ (q; BMe), 34.8, 36.1 (2q; *t*Bu), 46.0 (q; NMe), 50.6 (s; NC), 58.7 (t; NCH_2).

2b: Similarly 1.88 g (78%) of **2b** were obtained from 0.99 g of **1a** (4.78 mmol) and 3.00 mL of BuLi (1.6 M) in hexane.

NMR spectra (as for **2a**); ^{1}H NMR: $\delta = -0.01$ (t/q, ^3J(HH) = 7.9 Hz, ^2J(HB) = 4.3 Hz; BCH_2), 0.75 (q, ^3J(HB) = 2.4 Hz; B*t*Bu$_2$), 1.10 (t, ^3J = 7.0 Hz; Me(Bu)), 1.13 (s; N*t*Bu), 1.26, 1.38 (2m; CH_2(Bu)), 2.14 (s; NMe), 2.30 (s; NCH_2); ^{11}B NMR: $\delta = -13.4, 16.3$ (2s, 1:1); ^{13}C NMR: $\delta = 15.5$ (q; Me(Bu)), 28.1, 28.8 (2t; CH_2(Bu)), 35.1, 36.1 (2q; *t*Bu), 46.4 (q; NMe), 50.2 (s; NC), 58.6 (t; NCH_2).

3: Gas-phase thermolysis of Cl(*t*Bu)B=N(Mes)$SiMe_3$ (5.78 g, 18.7 mmol) yielded the iminoborane *t*BuB≡NMes, [9] which was frozen out at −196 °C with 5 mL of pentane. *t*BuBCl_2 [17] (2.10 g, 15.1 mmol) was added dropwise to the resulting solution at −78 °C. Distillation of this solution at 74 °C/0.003 Torr gave 4.63 g (90%) **3**.

NMR spectra in $CDCl_3$ at 25 °C (standards as for **2a**); ^{1}H NMR (80.13 MHz): $\delta = 1.01$ (s; *t*Bu), 2.18, 2.26 (2s; Me), 6.84 (s; CH); ^{11}B NMR (32.08 MHz): $\delta = 55.4$; ^{13}C NMR (67.88 MHz): $\delta = 20.0, 20.3$ (2q; Me), 29.1 (q; *t*Bu), 129.3 (d; CH), 135.3, 136.2, 140.9 (3s; Mes).

1d: Compound **3** (1.95 g, 6.20 mm) was added dropwise to a suspension of lithium powder (0.16 g, 22.4 mmol) in THF (10 mL) at −78 °C. After stirring for 1 h at −30 °C, the solvent was removed at 25 °C/10 Torr, and the residue taken up in pentane (50 mL). The filtered solution was reduced in volume. At 60 °C, 1.27 g (70%) of **1d** crystallized (m.p. 80 °C).

NMR spectra (conditions as for **3**); ^{1}H NMR: $\delta = 0.98$ (s; *t*Bu), 1.98, 2.26 (2s; Me), 6.85 (s; CH); ^{11}B NMR: $\delta = 49.3$; ^{13}C NMR: $\delta = 19.1, 20.9$ (2q; Me), 26.1 (q; *t*Bu), 128.5 (d; CH), 132.3, 134.8, 138.8 (3s; Mes).

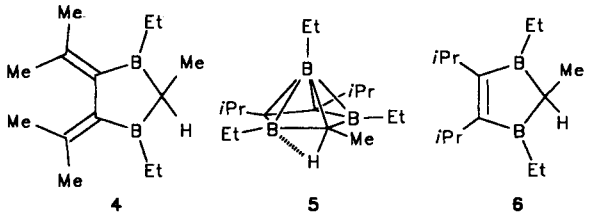
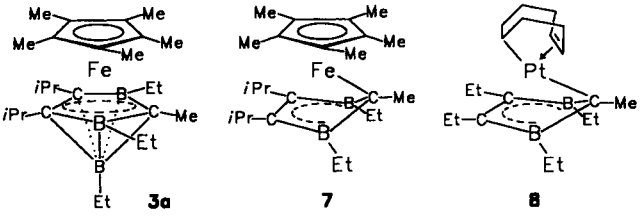
(η^5-Pentamethylcyclopentadienyl)iron Complexes with η^5-2,3,5-Tricarbahexaboranyl and η^5-2,3-Dihydro-1,3-diborolyl Ligands**



Walter Siebert,* Ralph Hettrich, and Hans Pritzkow

Dedicated to Professor M. Frederick Hawthorne on the occasion of his 65th birthday

Hawthorne et al reported the syntheses of the first complexes containing *nido*-$C_2B_9H_{11}$ ligands in 1965,[1] thus heralding the beginnings of metallacarborane chemistry which they then systematically elaborated.[2] Of the smaller carboranes, the *nido*-$C_2B_4H_6$ ligand, which contains five less BH groups, also displays a high synthetic potential.[3] The metallacarborane clusters **1** and **2** (M = Fe, Co) are well-known complexes containing these ligands, and may—if regarded as π complexes—be considered as forming a bridge to the metallocenes. The iron compounds **1**[4] and **2**[5] (M = Fe) are paramagnetic complexes (17 valence electrons (VE)), which react by taking up one additional electron to form the diamagnetic anions $\mathbf{1}^-$ and $\mathbf{2}^-$ (M = Fe), the analogues of ferrocene. The buildup of neutral 18 VE complexes requires either the substitution of the C_5H_5 ligand by C_6H_6, or the replacement of the C_2B_n carboranes ($n = 4$, 9) by the 5e ligand *nido*-$C_3B_3R_6$, which would lead to the formation of **3**. We report here on the (tricarbahexaboranyl)iron complex **3a** which is analogous to ferrocene, and on the first 16 VE iron sandwich compound **7**.



We have observed the metal-induced formation of 2,3,5-tricarbahexaboranylnickel complexes[6] by rearrangement of bis(2,3-dihydro-1,3-diborole)nickel complexes at room temperature and have recently been able to synthesize the unknown 2,3,5-tricarbahexaborane **5** by two different routes. The hydroboration of 1,3-diethyl-2-methyl-4,5-diisopropylidene-1,3-diborolane (**4**)[7] with $(HBEt_2)_2$ leads rather surprisingly to a 2:1 mixture of the carborane **5**[8] and the 1,3-diborole **6**, which can be deprotonated to the corresponding anions $(\mathbf{5}-H)^-$ and $(\mathbf{6}-H)^-$ by the action of NaH or LiMe, respectively.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, and the BASF AG.

A mixture of the green, air-sensitive complexes **3a** and **7** is obtained by reaction of the anions with $[(C_5Me_5)FeCl]$ (formed in situ); complex **7** can be separated from **3a** by crystallization. After separation of **5**/**6** by distillation, both complexes can also be separately synthesized and spectroscopically characterized. The ^{11}B NMR spectrum provides evidence for the presence of the 2,3,5-tricarbahexaboranyl ligand in **3a**; signals at $\delta = 6.6$ and $\delta = -1.8$ can be assigned to the basal boron atoms and the apical boron atom, respectively. The ^{11}B resonance signals are

strongly shifted in comparison to the signals for the free carborane **5** [$\delta = 22$ (2B), -36 (1B)] (the signal for the apical boron atom being shifted downfield, whereas that for the basal boron atoms is shifted upfield). This observation has also been made for other metal complexes.[8] The $\delta(^{11}B)$ value of 19.4 for the 16 VE sandwich complex **7** lies within the expected range for monofacially coordinated 1,3-diborolyl ligands; this rules out a *closo* structure with 14 framework electrons for the C_3B_2Fe framework atoms, which should be possible according to cluster formalism.

The result of the crystal structure analysis[9] on **7** confirms the sandwich arrangement with a severely folded 2,3-dihydro-1,3-diborolyl ring, in which the planes C3-C3′-B1-B1′ and B1-C2-B1′ form an angle of 41.3° (Fig. 1). The following deviations

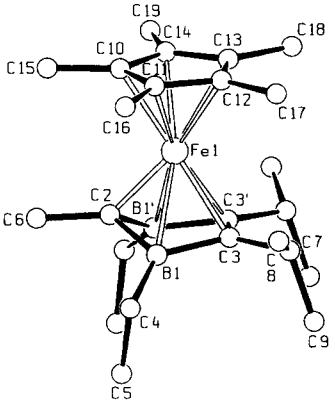

Fig. 1. Molecular structure of **7**. Selected distances [Å] and angles [°]: Fe1-B1 2.249(5), Fe1-C2 1.899(6), Fe1-C3 2.121(4), B1-C2 1.549(7), B1-C3 1.573(6), C3-C3′ 1.406(8); C2-B1-C3 110.1(4), B1-C2-B1′ 89.5(5), B1-C3-C3′ 104.3(2).

from the plane of best fit through the C_3B_2 ligands result: C2 + 0.29, B1 −0.24, C3 + 0.09, Fe +1.71 Å; the distance of the Fe1 atom to the plane through the C_5Me_5 ring is 1.73 Å. The 16 VE complex **7** has a small B1-C2-B1′ bond angle of 89.5(5)°, a short Fe1−C2 bond length of 1.899(6) Å, and a long Fe1−B1 distance of 2.249(5) Å, whereas the Fe1−C3, B1−C3, and C2−B1 bond lengths lie in the usual range. In comparison to this, a significantly larger B-C-B angle of 108.8(2)°, a longer Ni−C(B_2) bond length of 2.091(3) Å, and a shorter Ni−B distance of 2.172(3) Å was determined for the 18 VE nickel complex $[(\eta^5\text{-}C_5H_5)Ni\{\eta^5\text{-}(CEt)_2(BEt)_2CMe\}]$.[10] The position of the methyl group on C2 is quite remarkable; this atom can be

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0203 $ 10.00+.25/0

regarded as approximately sp^3 hybridized. In contrast to **7**, the heterocycle in the corresponding 18 VE nickel complexes is only folded to the extent of 10–12°. A larger fold angle (28°) of the heterocyclic C_3B_2 ligand can be found in the 16 VE complex (η^3-cyclooctenyl)(η^5-1,3,4,5-tetraethyl-2-methyl-2,3-dihydro-1,3-diborolyl)platinum (**8**).[11] However, the $\delta(^{11}B)$ value of 50 signalizes a weaker interaction between the boron and the metal atom than that in **3a** ($\delta = 19.4$).

Complex **7** is the first structurally characterized 16 VE iron sandwich complex, which does not allow stacking with an additional $(C_5Me_5)Fe$ fragment (resulting in the formation of a triple-decker complex). This is due to the stabilizing electronic effects of the methyl groups on the C_5 ring, and the steric shielding effected by the substituents of the heterocycle. In the course of the synthesis of $[\{(\eta^5\text{-}C_5H_5)Fe\}_2\{\mu,\eta^5\text{-}(CEt)_2(BEt)_2CMe\}]$,[12] we were able to isolate a reactive green mononuclear complex, but were not able to characterize it fully. Our results show that the 16 VE iron sandwich complex **7** is stabilized by an extreme folding of the heterocycle. This folding is cancelled when the electron-poor complex reacts with addition of a $(C_5H_5)M$ (M = Fe, Co) fragment to give a triple-decker (29 or 30 VE, respectively), or is capped by a boranediyl building block (R^4B:) to formally give the carboranyl iron complex **3** (18 VE).

Experimental Procedure

3a/**7**: A mixture of **5** and **6** (0.470 g, 1 mmol of each component) was added to a suspension of NaH (0.130 g, 5.4 mmol) in THF (5 mL) at −20 °C and then stirred at room temperature for 2 h. The solution was then separated from excess NaH and added to a solution of $[(C_5Me_5)FeCl]$ at −75 °C, prepared from C_5Me_5H (0.270 g, 2.0 mmol), BuLi solution and $FeCl_2 \cdot 2THF$ (0.530 g, 2.0 mmol) in THF (10 mL).]. The reaction mixture was stirred for 20 h at 20 °C, after which Et_2O/THF was removed under vacuum. The green residue was dissolved in a mixture of 0.5 mL toluene and 0.5 mL hexane and passed through a chromatography column packed with Al_2O_3 using hexane as eluant. The green fraction obtained contained **3a**, **7**, and a small amount of $[(C_5Me_5)_2Fe]$. **7** crystallized at −30 °C after concentration of the solution.

7: Yield: 170 mg (42%); m.p. 216–218 °C (decomp); ^{1}H NMR (200 MHz, C_6D_6): $\delta = 0.42$ (m, br, 4H; BCH_2CH_3), 0.53 (t, br, 6H, $^3J(H,H) = 6$ Hz; BCH_2CH_3), 1.26 (d, 6H, $^3J(H,H) = 6.5$ Hz; $CHCH_3$), 1.45 (s, 15H; C_5CH_3), 1.91 (d, 6H, $^3J(H,H) = 6.5$ Hz; $CHCH_3$), 2.77 (s, 3H; CCH_3), 4.21 (sept. 2H; $CH(CH_3)_2$; ^{11}B NMR (29 MHz, C_6D_6): $\delta = 19.4$; ^{13}C NMR (75 MHz, C_6D_6): $\delta = 6$ (br; BCH_2), 10.0 (BCH_2CH_3), 10.5 (C_5CH_3), 20.2 (CCH_3), 23.7, 24.3 ($CH(CH_3)_2$), 33.6 ($CHCH_3$), 80.3 (C_5CH_3), 133 (br; C4,5), C2 (CCH_3, not observed); EI-MS: *m/z* (%) = 408 (M^+, 100), 393 ($M^+ - CH_3$, 4), 379 ($M^+ - C_2H_5$, 5), 365 ($M^+ - C_3H_7$, 10).

3a: Yield: 45 mg (10%) green, air-sensitive oil (isolated from the mother liquor of **7**); ^{1}H NMR (200 MHz, C_6D_6): $\delta = 0.62$ (m, br; $B(CH_2CH_3)$, 0.91 (m, br; $B(CH_2CH_3)$, 1.2–1.5 (several incompletely resolved signals), 1.63 (s; C_5Me), 1.82 (s; CCH_3), 2.12 (sept; $CHCH_3$); ^{11}B NMR (29 MHz, C_6D_6): $\delta = -1.8$ (1B), 6.6 (2B); EI-MS: *m/z* (%) = 448 (M^+, 34), 443 ($M^+ - CH_3$, 24), 420 ($M^+ - C_2H_4$, 100).

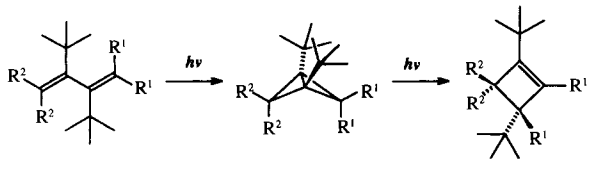
Photoisomerization of Highly Alkylated Butadienes**

Henning Hopf,* Helmut Lipka, and Marit Traetteberg



It has long been known that highly substituted acyclic 1,3-dienes prefer nonplanar molecular structures rather than the flat s-*trans* and s-*cis* conformations.[1] In contrast, how this deviation from planarity, which in the extreme case can lead to the orthogonal arrangement of the two "double bond halves", effects the chemical behavior of these compounds has hardly been investigated. With the development of a simple and versatile method for preparing highly alkylated (including *tert*-butyl-substituted) butadienes, we have recently[2] reached the stage where we are able to investigate the relationship between orthogonality and the reactivity of acyclic compounds. We report here on the photoisomerizations of selected polyalkyldienes, which were irradiated directly (450 W Hg high-pressure lamp) in dilute solutions (0.05–2%) in inert solvents (pentane, cyclohexane, etc.) at room temperature. The parent compound 1,3-butadiene rearranges under these conditions into a mixture of cyclobutene and bicyclobutane, in which the monocyclic product predominates,[3] and the yield of bicyclobutane is at best a few percent. Addition of copper(I) chloride leads to an increase in the proportion of the bicyclobutane component, without, however, making the process of any significant preparative value.[4]

The situation is quite different for polyalkylated dienes: According to X-ray structural analysis[5] and electron diffraction[6] the orthogonal 2,3-di-*tert*-butyl-1,3-butadiene (**1a**) isomerizes exclusively (60%) upon irradiation (60 min) to the bicyclobutane **2a**. The even more highly substituted butadiene **1b** is converted into the corresponding dimethyl derivative **2b**.[7]

Both photoproducts are not stable to further irradiation: **2a** rearranges to **3a**; **2b** to **3b**,[7] which are again the sole reaction products. In this ring opening the central bond of **2** is presumably broken and the resulting 1,3-diyl is then stabilized by a hydrogen shift. If one reduces the steric strain in the interior of the molecule by shifting one of the bulky susbtituents to the periphery of the diene system, as for example in *trans*-1,3-di-*tert*-butyl-1,3-butadiene (**4**), an s-*cis* conformation can appar-

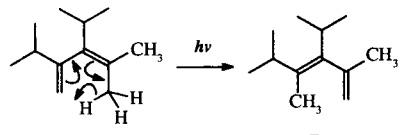
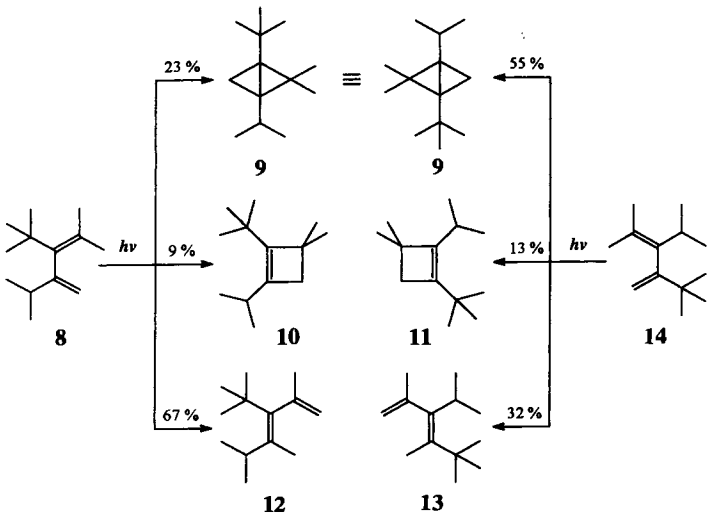
1 **2** **3**



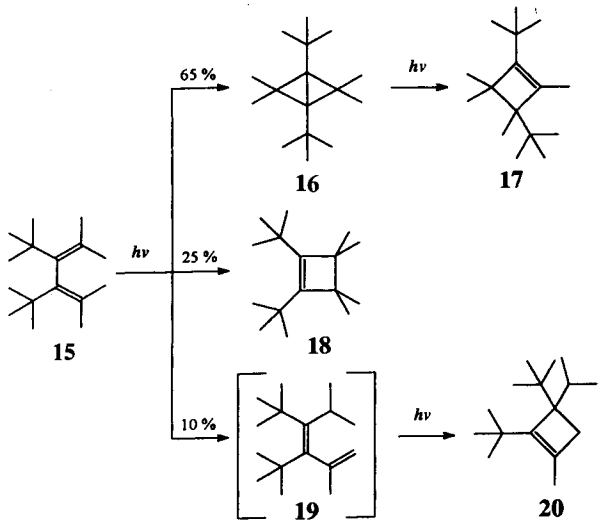
a: $R^1=R^2=H$; **b:** $R^1=H$, $R^2=CH_3$

ently be attained,[8] since the only photoproduct obtained after 45 minutes is the cyclobutene **5**,[7] which upon heating to about 200 °C is converted back into the expected product **4**.



4 **5**

A third reaction pathway for highly alkylated dienes is made available, when these have terminal methyl substituents and central substituents which are not too bulky, so that an orthogonal structure is either not enforced or can be left readily via comparatively low-lying transition states. The major rearrangement product (80%) from **6** is isomer **7**,[7, 9] which results from a 1,5-hydrogen shift.



6 **7**

The variability of the diene synthesis[2] makes it possible to introduce desired alkyl groups into the four olefinic positions of the diene system, so that the contributions of each photoisomerization pathway can be controlled. Thus, irradiation of the diene **8** gives a mixture of the three photoisomers **9** (23%), **10** (9%), and **12** (67%).[10] If the isopropyl and the *tert*-butyl groups in the molecule's interior (compound **14**) are interchanged, **9** becomes the major rearrangement product (55%), while the amount of the 1,5-hydrogen migration isomer **13** is significantly reduced (32%); the amount of the cyclization product **11** (13%) is scarcely altered in comparision with **8**. From these results it can be concluded that for an arrangement of substituents as in **14** (flanking *tert*-butyl groups), the orthogonality of the starting material is much greater than in the isomer **8**, with its centrally bound *tert*-butyl substituents.

8 **9** **9** **10** **11** **12** **13** **14**

Finally, the completely substituted diene **15** is also interesting, since because of the two *tert*-butyl groups in the interior of the molecule, it should be orthogonally configurated. In fact, the bicyclobutane **16** is the major product (65%) of the photoisomerization.[7] Nevertheless, the other two rearrangements also compete; the cyclobutene **18** is formed in 25% yield and the 1,5-hydrogen shift product in 10% yield.[7] However, in this case, the primary product **19** is not isolated, but rather its cycloisomer **20**. As expected, compound **16** is not photostable; upon longer irradiation it is converted into **17** (main product) which is formally formed from **16** by the migration of a methyl group.

15 **16** **17** **18** **19** **20**

To what extent these isomerization reactions can be applied to dienes with bulky but removable substituents, (e.g. trialkylsilyl groups) is currently under investigation.[11]

[6] M. Traetteberg, H. Hopf, H. Lipka, unpublished results; dihedral angle: 82°.
[7] All new compounds were characterized by the usual spectroscopic and analytical methods.
[8] According to MM3 calculations the torsion potentials for **1** and **4** are very different; **1** shows a deep potential minimum (orthogonal configuration) with high barriers in both directions (*syn*: ca. 22 kcal mol^{-1}, *anti*: ca. 13 kcal mol^{-1}). The torsion potential curve for **4**, on the other hand, is relatively flat (maximum energy difference ca. 2 kcal mol^{-1}; M. Traetteberg, unpublished results).
[9] The configuation of **7** has not been established. NOE spectra (NOE = nuclear Overhauser effect) do not provide clear indication for an assignment of the configuration, and under the irradiation conditions it cannot be ruled out that it can undergo *E*/*Z* isomerization in a secondary reaction. In the photolysate one diastereoisomer clearly predominates (85%, NMR analysis). According to NMR spectra the by-products found are derivatives of bicyclobutane and cyclobutene.
[10] The configuration shown is derived from NOE measurements (strong interactions between the *tert*-butyl and the isopropyl groups.)
[11] Note added in proof (November 26, 1993): Bis-2,3-trimethylsilyl-1,3-butadiene also photoisomerizes to give a bicyclobutane analogous to **2**. (H. Hopf, R. Hänel, unpublished results).

Fullerene Dications as Initiators for Gas-Phase "Ball-and-Chain" Polymerization of Ethylene Oxide; Termination by Cyclization**

Jinru Wang, Gholamreza Javahery, Simon Petrie, Alan C. Hopkinson, and Diethard K. Bohme*

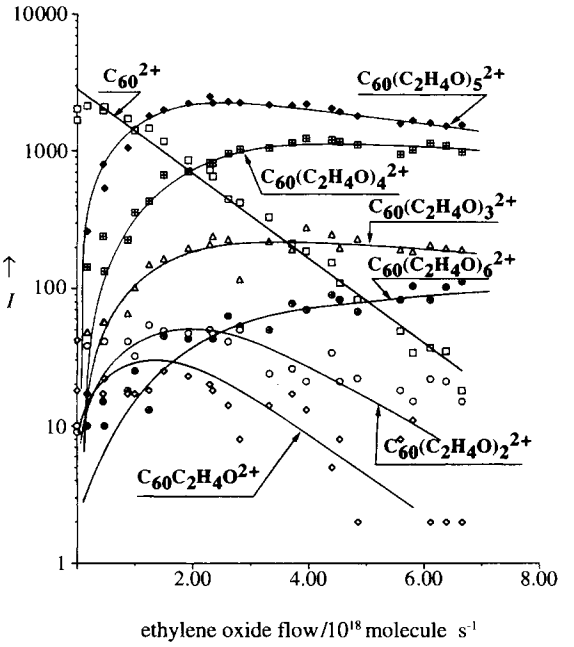
Multiply charged cations of buckminsterfullerene, C_{60}^{n+}, are remarkably stable, easily generated (up to at least $n = 3$), and readily subjected to chemical reaction in the gas phase.[1] This control over the number of charges on a molecule is unique and provides an unprecedented opportunity for exploring the role of charge in directing intramolecular reactions. For example, Coulombic repulsion between two positive charges has been postulated to drive the "ball-and-chain" polymerization of 1,3-butadiene initiated by C_{60}^{2+} away from the surface of C_{60} into the surrounding space.[2, 3] An almost exponential decrease in the rate of polymerization is observed at 294 ± 2 K in helium at 0.40 ± 0.01 Torr for the proposed sequential addition leading to a chain of six units of 1,3-butadiene.[2] We report here on a second possible feature of such polymerization: termination by cyclization at chain lengths at which Coulombic repulsion is weaker than chemical forces. We have chosen to investigate this possibility experimentally with the C_{60}^{2+}-initiated polymerization of ethylene oxide which, unlike butadiene, has a strong tendency for cyclization.

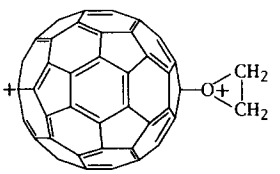
Figure 1 displays the remarkable observation that a series of rapid sequential addition reactions attach up to six molecules of ethylene oxide to C_{60}^{2+} in helium buffer gas at 0.35 Torr and 294 K [Eq. (a)]. The initiation reaction of C_{60}^{2+} with ethylene

$$C_{60}(C_2H_4O)_n^{2+} + C_2H_4O \longrightarrow C_{60}(C_2H_4O)_{n+1}^{2+} \quad n = 0 - 5 \qquad (a)$$

oxide proceeds relatively slowly with a rate constant of $(5.3 \pm 1.6) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, which corresponds to a reaction efficiency of 0.019.[4] The subsequent oligomerization reactions are characterized by larger rate coefficients: we estimate the second step to be more than ten times faster than the first step, and the rate constants drop by a factor of 2 to 3 with each successive step (in the reaction of C_{60}^{2+} with butadiene the rate constants drop by a factor of 3 to 4). Also, more significantly and unlike the case of 1,3-butadiene, the observed rate of addition of ethylene oxide shows a sharp drop at $n = 5$ by about a factor of 10. In contrast to the dication, the monocation of C_{60} did not react with ethylene oxide with a measurable specific rate ($k \leq 3 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}).

The slow first step, which is presumed to proceed in a termolecular fashion by collisional stabilization (He is the stabilizing third body) under our experimental conditions, is not atypical: we have found other oxygen-containing compounds to add slowly to C_{60}^{2+} under similar conditions. In analogy to these reactions we expect the first step to be nucleophilic addition leading to the formation of a product **I** in which the charge is formally localized on the oxygen atom.[1d] This addition is accompanied by a loss in charge delocalization energy of the C_{60}^{2+},





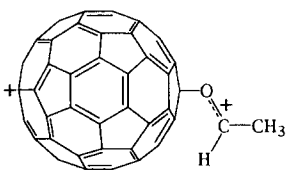


Fig. 1. Variation in the ion signals I upon addition of ethylene oxide into the reaction region of the SIFT apparatus in which C_{60}^{2+} has been established as the dominant ion in helium buffer gas. $p = 0.35$ Torr, $\bar{v} = 6.4 \times 10^3$ cm s^{-1}, $L = 47$ cm, and $T = 294$ K. C_{60}^{2+} is produced by electron impact at 60 eV of C_{60} vapor entrained in argon carrier gas. Signal intensities for the first three adducts $C_{60}(C_2H_4O)_n^{2+}$ ($n = 1, 2, 3$) at low ethylene oxide flows, suggest that the rate constants for reaction of these adducts substantially exceed that for reaction of "bare" C_{60}^{2+}. However, the signal intensities observed for these adducts at high flows ($\geq 4 \times 10^{18}$ molecules s^{-1}) are substantially higher than would be expected if these adducts reacted rapidly with ethylene oxide. This apparent discrepancy suggests that higher order adducts may undergo chemical or thermal dissociation. Alternatively, fragmentation may be induced by the electric field gradient in the vicinity of the product ion sampling nosecone, or different isomeric forms of the adducts may be present, some of which react rapidly while others remain essentially unreacted. A detailed kinetic model would require a better understanding of these factors.

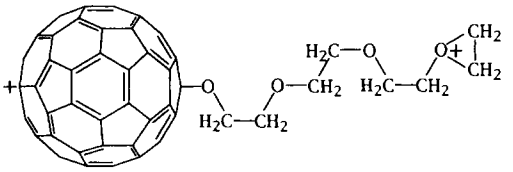
which will act to disfavor association, as will the accompanying distortion at the C_{60} bonding site, which is required for tetrahedral coordination with the nucleophile.[6] If the excess energy associated with C–O bond formation is sufficiently large, we can expect subsequent ring opening and a hydride shift to generate structure **II**.[7]

I

II



Addition of the second molecule of ethylene oxide can now occur at a site with a localized charge without a distortion requirement, which is more favorable than addition at the site of the remaining charge on the C_{60} surface (recall also that C_{60}^{+} is unreactive).[9] This would explain the considerably higher rate of addition of the second, third, and fourth molecules of ethylene oxide leading either to the propagation of a chain as indicated in structure **III** (for addition to structure **I**)[10] or as indicated in structure **IV** (for addition to structure **II**).

Coulombic repulsion between the propagated charge and the remaining charge on the surface of C_{60} will tend to drive the

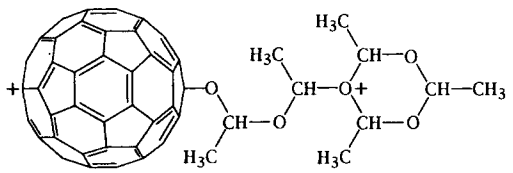
III



IV

molecular growth away from the surface in a similar fashion to that envisaged for the C_{60}^{2+}-induced polymerization observed with 1,3-butadiene; however, ethylene oxide oligomers should show an increasing tendency for unimolecular cyclization to form a relatively stable six-membered ring at the end of the chain as Coulombic repulsion weakens with increasing charge separation. Structures **V** and **VI** show the products of this cyclization which would inhibit further chain propagation.

V

VI

The observed discontinuity in the addition rate between the fifth and sixth addition is consistent with such a mechanism. However, while the data indicates that most chains do not contain more than five ethylene oxide units, some have six units, and termination after four and perhaps even three additions is probable also. Moreover we cannot rule out cyclization beyond dimers and trimers, to form larger rings, and the dissociation to form cyclic oligomers.

The mechanism of cationic cyclooligomerization of ethylene oxide with BF_3 in CH_2Cl_2 has been investigated in detail by Dale and Daasvatn.[11] These authors have demonstrated the requirement of a minimum chain length for direct cyclization (in the absence of Coulombic repulsion), the termination of the growing chain by direct cyclization beyond dimers and trimers, the competition between formation of a cyclic trimer and dimer, and the possible expulsion of cyclic oligomers. We are currently investigating the chemistry of C_{60}^{n+} with other small epoxides.

Experimental Procedure

The reaction of C_{60}^{2+} with ethylene oxide was monitored with a Selected-Ion Flow Tube (SIFT) apparatus [12, 13]. C_{60}^{2+} was produced by the electron bombardment of 60 eV of C_{60} vapor entrained in argon carrier gas. The dications were selected with a quadrupole mass filter, injected into a flowing helium gas at 295 ± 2 K and 0.35 ± 0.01 Torr, allowed to reach thermal equilibrium by collisions with helium atoms, and finally exposed to ethylene oxide further downstream. The progress of the reactions was followed with a second quadrupole mass filter in the usual fashion [12, 13]. The ethylene oxide had a purity of ≥99.0% (Matheson). The fullerene powder was a mixture of C_{60} and 2–12% C_{70} (Strem Chemicals).

[7] It is interesting to note that acetaldehyde, which might be expected to form the secondary carbocation adduct **II** directly, was observed not to add to C_{60}^{2+} with a measurable rate ($k < 1 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}) [8].
[8] S. Petrie, G. Javahery, H. Wincel, J. Wang, D. K. Bohme, *Int. J. Mass Spectrom. Ion Processes* **1993**, submitted.
[9] The observed 10-fold increase in the rate of addition of the second ethylene oxide molecule compared to the first suggests very strongly that the first addition activates the dication in some manner. The first addition most likely generates an activated site because the C_{60} substituent carries a localized charge. Previous experiments in our laboratory have shown that sequential addition to the surface of the C_{60} (to form a double-handled adduct) is characterized by essentially identical rates for the first and second addition steps [1].
[10] Addition in this manner is considered to involve concomitant ring opening of the ethylene oxide monomer previously added.

$[(Ph_3PAu)_6(dppeAu_2)(AuCl)_4Pd]$, an Icosahedral Au_{12} Cluster with a Central Pd Atom**

Martin Laupp and Joachim Strähle*

The photolysis of $[Ph_3PAuN_3]$ leads to the formation of homometallic gold clusters by reductive elimination of the azide group.[1, 2] The heterodimetal clusters $[(Ph_3PAu)_xM(CO)_y]^{n+}$ ($n = 0,1,2$) are formed in the presence of metal carbonyls. The composition of the cluster is governed by the electron requirements of the transition metal M, that tries to achieve a stable noble-gas electron configuration. This simple approach to the synthesis of new clusters, encouraged us to carry out the photolytic reaction on other azide complexes. Although the photol-

ysis of Ag^I and Cu^I complexes does not lead to the formation of stable clusters, we could produce the cluster $[(dppe)PtCo_2(CO)_7]$ (dppe = 1,2-bis(diphenylphosphino)ethane) from the azido platinum(II) complex $[(dppe)Pt(N_3)_2]$ and $[Co_2(CO)_8]$. From $[(Ph_3P)_2Pt(N_3)_2]$, $[Ph_3PAuN_3]$, and $[Ph_3PAuCl]$ we obtained the cluster $[(Ph_3PAu)_6(AuCl)_3Pt(CO)]$.[3] In this cluster the nine gold atoms form a polyhedron which can be described as an incomplete icosahedron in which one triangular face is missing. The platinum atom is located in the center of the incomplete icosahedron and its CO ligand points towards the middle of the missing icosahedral face. Since gold-palladium clusters are relatively rare, we carried out the analagous cophotolysis with $[Ph_3PAuN_3]$ and the azido palladium complex $[(dppe)Pd(N_3)_2]$ and obtained the cluster **1**, in which the twelve gold atoms form a complete icosahedron with a palladium atom in the center. The presence of the palladium atom was confirmed by energy dispersive X-ray microanalysis and mass spectrometric analysis. Moreover, the structure refinement[4] shows that the palladium atom is in the center of the cluster.

$[(Ph_3PAu)_6(dppeAu_2)(AuCl)_4Pd]$ **1**

The photolysis product of $[(Ph_3P)_2Pd(N_3)_2]$, $[Ph_3PAuN_3]$ and $[Ph_3PAuCl]$ presumably has a structure analagous to **1**. A crystal structure analysis has not been done yet; nevertheless, the constitution of this cluster was shown by mass spectrometry to be $[(Ph_3PAu)_8(AuCl)_4Pd]$ (**2**). To date, only one cluster with a complete Au_{12} icosahedron around a central atom was known—that of $[(PhMe_2PAu)_{10}(AuCl)_2Au]^{3+}$.[5] In this cluster, the center of the icosahedron is occupied by a Au atom. We now announce the first isoelectronic clusters **1** and **2** that contain a heteroatom in the center.

The gold–palladium clusters synthesized by Pignolet et al.[6, 7] exhibit Au_6Pd and Au_8Pd polyhedra. The crystal structure analysis shows that the eight gold atoms in $[(Ph_3PAu)_8Pd]^{2+}$[6] form a crownlike structure centered by a Pd atom, whereas in $[(Ph_3PAu)_8Pd(CO)]^{2+}$ and $[(Ph_3PAu)_6\{(MeO)_3PAu\}_2Pd\{P(OMe)_3\}]^{2+}$, the eight Au atoms are arranged as hemispherical icosahedral fragment.[7]

In the photolytic synthesis of **1** [Eq. (a)], a mixture of $[Ph_3PAuN_3]$ and $[(dppe)Pd(N_3)_2]$ are irradiated for 2 h with a high-pressure Hg vapor lamp. Then $[Ph_3PAuCl]$ is added, and the irradiation continued for one hour. After chromatographic separation of the products of photolysis, deep red columnar crystals of **1**, which deteriorate very quickly out of the mother liquor, are isolated in about 15% yield.

$$8[Ph_3PAuN_3] + 4[Ph_3PAuCl] + [(dppe)Pd(N_3)_2] \longrightarrow \underset{\mathbf{1}}{[(Ph_3PAu)_6(dppeAu_2)(AuCl)_4Pd]} + 15\,N_2 + 6\,PPh_3 \quad (a)$$

During the cluster formation from mononuclear units it is curious that the diphosphane ligand is transfered to the gold atom, although the synthesis of **2** shows that the diphosphane ligand is not necessary to stabilize the cluster.

The cluster **1** lies on the C_2 axis of the monoclinic space group $C2/c$.[4] The axis passes through the Pd atom and the center of the ethylene bridge of the diphosphane ligand (Fig. 1). The Au–Au distances of 285.2(2) to 293.5(2) pm lie in the typical range for distances between peripheral gold atoms as found in the homometallic cluster $[(PhMe_2PAu)_{10}(AuCl)_2Au]^{3+}$.[5] The Pd–Au distances (272.2(2) to 276.7(1) pm) are, in contrast, clearly shorter and indicate strong bonding interaction. They resemble the Au–Au distances to the central atom in the previously mentioned homometallic Au_{13} cluster.[5]

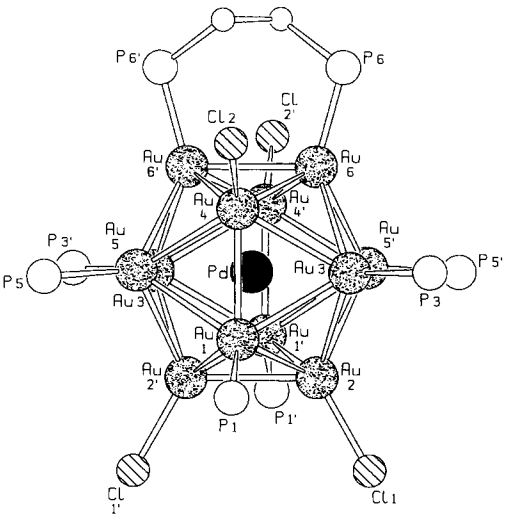

Fig. 1. Structure of **1** in crystal [12]. Only the P atoms of the phosphane ligands and in the case of dppe, only the ethylene bridge was drawn. Important interatomic distances [pm]: Au1-Au2 285.4(2), Au1-Au2' 287.3(1), Au1-Au3 289.7(2), Au1-Au4 288.9(2), Au1-Au5 291.4(1), Au2-Au2' 289.9(2), Au2-Au3 288.2(2), Au2-Au5' 293.5(2), Au3-Au4 290.2(2), Au3-Au5 290.5(1), Au3-Au6 287.4(2), Au4-Au5 287.8(1), Au4-Au6 292.0(1), Au5-Au6' 287.8(2), Pd-Au1 272.2(2), Pd-Au2 274.0(4), Pd-Au3 276.7(1), Pd-Au4 275.2(2), Pd-Au5 276.7(2), Pd-Au6 273.5(3), Au-P_{PPh_3} 229.0(8)–230.5(7), Au6-P_{dppe} 227.9(9), Au2-Cl1 237.5(7), Au4-Cl2 239.2(9).

Large homometallic gold clusters characterized by one central and n peripheral gold atoms can, according to Mingos,[8, 9] be classified by their topology as spherical type with $12n+18$ valence electrons, and as flattened toroidal type with $12n+16$ valence electrons. In the spherical clusters whose n peripheral Au atoms lie approximately on the surface of a sphere, the $10(n+1)$ nonbonding electrons are found in the fully occupied d orbitals of the $n+1$ gold atoms; $2n$ electrons are required for bonding to the ligands of the peripheral gold atoms. The remaining eight electrons are thus reserved for bonds between the metal atoms in the polyhedron. They are located in the four bonding MOs of the cluster; in the toroidal clusters six bonding MOs are required. The cluster **1** belongs to the spherical type clusters. With $12n+18 = 162$ valence electrons as well, it is isoelectronic with $[(PhMe_2PAu)_{10}(AuCl)_2Au]^{3+}$[5] and has eight bonding electrons in the polyhedron, which are contributed by the eight gold(0) centers of the $[Au_{12}]^{4+}$ polyhedra.

Experimental Procedure

1: $[(dppe)Pd(N_3)_2]$ (491 mg, 0.8 mmol) are first mixed with $[Ph_3PAuN_3]$ (423 mg, 0.8 mmol) in freshly distilled THF (70 mL) for 2 h while stirring under a weak stream of N_2 and irradiating at room temperature with a high-pressure mercury vapor lamp. The solution turns deep red. Then $[Ph_3PAuCl]$ (410 mg, 0.8 mmol) is mixed into the reaction solution, which is irradiated for another 1 h. Thereafter, the solvent is completely removed in vacuum, and the residue redissolved in CH_2Cl_2 and chromatographed in an Al_2O_3 column. A red fraction can be seperated with CH_2Cl_2/THF (1:1). This is evaporated to dryness and dissolved in CH_2Cl_2 again. After overlaying of the solution with diisopropylether, deep red columnar crystals of **1** form within 14 days at 0 °C in approximately 15% yield. The crystals presumably contain solvate molecules and because of this, deteriorate quickly outside of the solvent. The presence of Pd was confirmed by energy-dispersive X-ray microanalysis. FAB-MS: m/z (%): 4548.2 (15) $[M^+ - Cl]$, 4285.3 (30) $[M^+ - Cl - PPh_3]$, 4088.8 (100) $[M^+ - Cl - PPh_3 - Au]$, 4054.0 (40) $[M^+ - 2Cl - PPh_3 - Au]$, 3792.5 (35) $[M^+ - 2Cl - 2PPh_3 - Au]$. $^{31}P\{^1H\}$ NMR (32.39 MHz, CD_2Cl_2, −30 °C, H_3PO_4): δ = 65.05 (PPh_3), 28.74 (dppe).

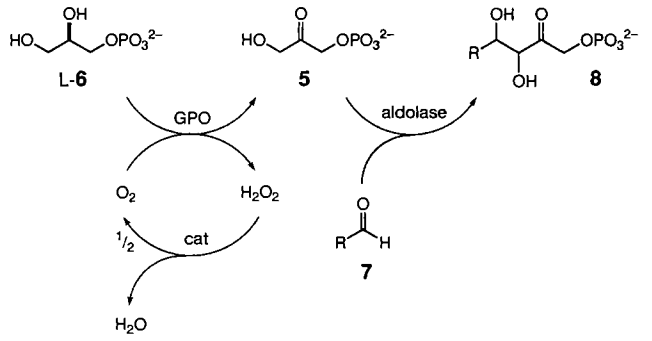
Synthesis of Dihydroxyacetone Phosphate (and Isosteric Analogues) by Enzymatic Oxidation; Sugars from Glycerol**

Wolf-Dieter Fessner* and Gudrun Sinerius

Enzyme-catalyzed aldol additions are currently of great interest because of their broad potential for application in asymmetric syntheses.[1] In particular, the dihydroxyacetone phosphate (DHAP) dependent aldolases, which are available as a complete stereochemical set for the generation of all four possible types of diastereomeric DHAP–aldehyde adducts (D-fructose 1,6-bisphosphate aldolase = FruA, [EC 4.1.2.13]; D-tagatose 1,6-bisphosphate aldolase = TagA, [EC 4.1.2.-]; L-fuculose 1-phosphate aldolase = FucA, [EC 4.1.2.17]; L-rhamnulose 1-phosphate aldolase = RhuA, [EC 4.1.2.19]),[2] are characterized by preparative efficiency, high chiral induction for two stereocenters, and a broad substrate tolerance for the aldol acceptor component. In addition, the FucA and RhuA enzymes have the capacity for an almost complete kinetic differentiation of racemic 2-hydroxyaldehydes.[3] Problematic is the fact that DHAP **5**, the essential donor component, is commercially too expensive for preparative syntheses[4] and relatively unstable in solution. The published procedures for its chemical synthesis (acid hydrolysis of the dimethyl acetal **1**, eight steps from 3-chloro-1,2-propanediol,[5] overall yield 17%; hydrolysis of the dimeric diethyl acetal **2**, three to five steps from dihydroxyacetone, phosphorylation by diphenyl chlorophosphate,[6a] phosphoroxy chloride,[6b] or *O,O'*-dibenzyl *N,N*-diethyl phosphoramidite,[6c] up to 50% overall yield) and enzymic synthesis (phosphorylation of dihydroxyacetone **3** by glycerol kinase/ATP, 83%;[7] cleavage of fructose 1,6-bisphosphate **4** by FruA/TPI (TPI = triosephosphate isomerase), ca. 100%[8]) have serious disadvantages with respect to expenditure (number of steps, cost of reagents) and purity of product. Here we describe a novel enzymic procedure that generates **5** practically quantitatively and in high chemical purity from inexpensive starting materials and its use in situ with different DHAP aldolases in a coupled reaction with aldehydes. This procedure also proved adaptable to the synthesis of DHAP analogues modified at the phosphate group, which are likewise accepted by the aldolases.



In the metabolism of several bacteria L-glycerol 3-phosphate (L-**6**) is oxidized to DHAP by a flavine-dependent glycerol phosphate oxidase (GPO, [EC 1.1.3.21]).[9] In contrast to the oxidation mediated by glycerol phosphate dehydrogenase [EC 1.1.1.8], a separate cofactor regeneration step[10] is not necessary because the reduced cofactor $FAD(H_2)$ remains tightly bound to the enzyme and is rapidly reoxidized by elemental oxygen with liberation of hydrogen peroxide. Since the latter can be used for the indirect quantification of glycerol in optical tests, GPO is a common and inexpensive enzyme. However, its obvious application to the preparative synthesis of **5** had to the best of our knowledge not been realized previously. We have found that the oxidation of L-**6** indeed proceeds smoothly and practically without competing side reactions if the buildup of a considerable stationary concentration of the coproduct H_2O_2, known to destruct enzymic activities, is suppressed by added catalase (cat, [EC 1.11.1.6]; Scheme 1). GPO exclusively oxidizes the L enantiomer,[11] which preparatively is best obtained by enzymic phosphorylation of glycerol.[7] This latter reaction, however, cannot be coupled with the oxidase reaction because of the low oxygen tolerance of glycerol kinase.

At higher concentrations **5** acts as a competitive GPO inhibitor. Out of the seven different commercial GPO preparations from at least three different organisms that we have inves-

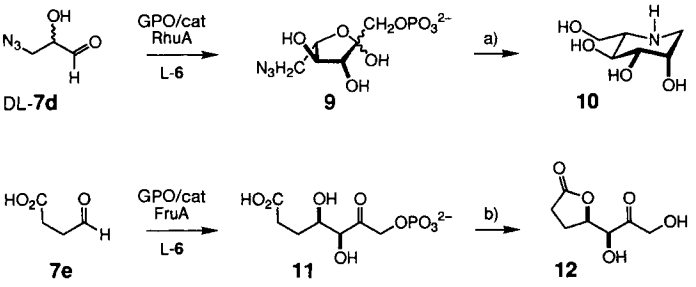
[**] Enzymes in Organic Synthesis, Part 7. This research was supported by the Deutsche Forschungsgemeinschaft (Grant Fe 244/2-2), the Fonds der Chemischen Industrie, and the Wissenschaftliche Gesellschaft Freiburg. We thank Dr. P. Rasor, Boehringer Mannheim GmbH, for the generous gift of several enzymes, and Dr. W. Deck for ^{31}P NMR spectra.—Part 6: [3b].



Scheme 1. Multienzymic synthesis of ketose-1-phosphates **8** from L-glycerol 3-phosphate (L-**6**).

tigated[12] the ones from *Streptococcus* species showed the lowest product inhibition (residual activity ca. 20% at 100 mM **5**). At this concentration preparative reactions can thus be run up to roughly 90–95% conversion to furnish **5** without further contaminants.[13] These particular enzyme preparations also displayed the highest stability in solution ($t_{1/2} \geq 3$ d at 25 °C; 2 U mL^{-1}),[14] which makes immobilization unnecessary, and only minimal sensitivity to higher concentrations of substrate (0.5 M), organic cations (e.g., cyclohexylammonium salts, 1.0 M), and inorganic phosphate (0.1 M; residual activity $\geq 70\%$ in each case), as well as the highest tolerance against H_2O_2 ($t_{1/2} \approx 1.5$ h at 150 mM). On the preparative scale, a sufficient oxygen supply at room temperature could be easily provided by shaking or mechanical stirring without noticeable enzyme deactivation. Scheme 1 suggested further that oxygenation could be sustained by careful addition of H_2O_2, which was indeed verified experimentally.

Rather unexpectedly, the oxidative generation of **5** could be smoothly coupled to its consumption by enzyme-catalyzed addition to aldehydes **7** (Scheme 1). This not only prevents inhibition of the GPO by **5** and thus assures rapid and quantitative conversion of L-**6**, but also suppresses almost completely any decomposition of the labile **5** since it does not accumulate. Neither the (limited) occurrence of H_2O_2 nor the application of oxygen-saturated solutions—even at an elevated oxygen partial pressure of up to 5 bar—led to the feared deactivation of the several tested DHAP aldolases from rabbit muscle (FruA) and *E. coli* (FruA, FucA, RhuA). The coupled reactions were preferably run at slightly acidic pH to assure that **5** is sufficiently stable and to maintain a high conversion rate. Compared to the established procedures[6–8] the GPO method usually furnishes adducts **8** of higher purity and in equal or higher yields. An interesting observation is that when the cyclohexylammonium salt of **6** is used, some particular aldol adducts (e.g. L-**8e**) crystallize in high yield and purity already upon concentration of the crude product solution, which significantly simplifies the work-up.

In spite of the sensitivity of aldehydes for air oxidation, this anticipated competing reaction was negligible under the usual reaction conditions; we interpret this inter alia as resulting from hydrate formation in aqueous solution. Simple (acetaldehyde, **7a**) and hydroxylated aliphatic aldehydes (glycolaldehyde, **7b**; L-glyceraldehyde, **7c**) were transformed smoothly into the known ketose phosphates[2a] (Table 1). In a one-flask reaction starting from L-**6** and racemic 3-azido-2-hydroxypropanal **7d** only the L-configurated aldehyde was converted by the RhuA as expected, owing to efficient kinetic control.[3a] The resulting pure adduct **9** was transformed into the non-naturally configurated alkaloid 1-deoxy-L-mannojirimycin **10** by dephosphorylation and hydrogenolysis (overall yield 60%; Scheme 2).[15]

Scheme 2. Chemoenzymic syntheses of 1-deoxy-L-mannojirimycin (**10**) and chiral γ-lactones like **12**. a) Acid phosphatase [EC 3.1.3.2], H_2, Pt/C; b) H_3O^+.

Particularly advantageous is the GPO reaction in combination with FruA-catalyzed conversions of anionic aldol acceptors, because in this case the thermodynamic relationships are far more favorable than those involving **4**, which is most often applied as the starting material.[1c] Thus, succinic semialdehyde **7e** and L-**6** gave adduct **11** in good yield (81%; only 40% from **4**[16]). Acidic conditions effected a cyclization furnishing the optically pure γ-lactone **12** (Scheme 2; RhuA provides *ent*-**11**/**12**, see Table 1) which, because of its differentiated funtionalization, is of interest as a potential precursor to a range of biologically active compounds.

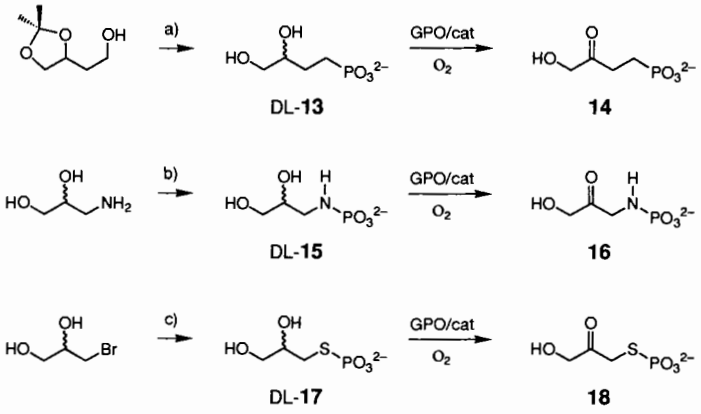


Table 1. Aldol reactions coupled with the GPO-catalyzed, in situ generation of DHAP and its analogues [a].

The positive results with the GPO method suggested a possible extension to the preparation of suitable DHAP analogues. Earlier work employing FruA from rabbit muscle had shown that modification of the free hydroxymethylene moiety in **5** generally leads to a complete loss of activity, whereas phosphonate **14**, which is derived from isosteric replacement of the phosphorylated subunit in **5**, is converted in enzymic assays at 10% of the rate of the reaction of **5**.[17] Ketone **14** had been accessible previously only by a multistep route of low efficiency,[18a,d] and its preparative use restricted to the assay scale.[18b] However, phosphonate **13**,[18c,e] isosteric to diol **6**, is readily obtained by the route illustrated in Scheme 3, as are the corresponding phosphoramidate and phosphorothioate analogues **15**[19] and **17**, respectively.

Scheme 3. Chemoenzymic syntheses of isosteric DHAP analogues. a) Ph_3PBr_2/dimethylformamide (DMF), $P(OEt)_3$, Me_3SiBr, H_2O; b) ref. [19]; c) aq. Na_3PO_3S (pH 8).

Indeed, upon treatment with GPO all three compounds were converted into the corresponding DHAP analogues which, for practical reasons (hydrolytic instability[19] of **15**–**18**), were directly converted in situ by coupled aldol additions into the sugar derivatives **19**–**21** (Table 1). As expected only up to 50% of the

racemic precursors **13** and **17** was converted. Thus, the adducts were characterized only as mixtures with remaining starting material (Table 2). The analysis of the reaction of **15**/**16** was complicated by competing rapid phosphoroamidate hydrolysis and potentially competing oxidative side reactions and subsequent reactions (plausibly via enamine tautomers[20]). For a more detailed investigation of the latter system and to facilitate product isolation the synthesis of enantiomerically pure L-analogues is highly desirable.

In the last two years the GPO procedure has completely replaced the competing methods for DHAP generation for almost all types of applications in our labs. In particular, the extension of the product spectrum through the use of DHAP analogues[21] is an advantage of this procedure.

Table 2. NMR data of selected compounds [a].

[a] NMR spectra were recorded in D_2O at pH 7.0 after ion exchange giving the Na^+ salts. ^{1}H NMR data (400.1 MHz) are referenced relative to sodium 3-trimethylsilyl-[$^2H_4$]propionate (TSPNa) (δ = 0.00), ^{13}C NMR (100.6 MHz) to CH_3CN (δ = 1.30), and ^{31}P NMR (80 MHz) to D_3PO_4 (δ = 0.00); coupling constants in Hz. [b] Indices: H = hydrate, K = ketone.

Experimental Procedure

To a solution containing **6** (as its bis(cyclohexylammonium) salt; 370 mg, 1.0 mmol) and L-glyceraldehyde **7c** (110 mg, 1.2 mmol) in 10 mL of oxygen-saturated water at pH 6.8 was added 70 U of GPO, 1000 U of catalase, and 50 U of RhuA. The mixture was shaken at 20 °C under an oxygen atmosphere at 100 Upm. Conversion was monitored by enzymic assay for equivalents of DHAP produced, as well as by ^{1}H and ^{31}P NMR spectroscopy. After the solution was filtered through charcoal, the pH was adjusted to 7.5 by addition of 1.0 M cyclohexylamine in ethanol, and the solution was concentrated to dryness by rotary evaporation at $\leq$20 °C in vacuo. The solid residue was taken up in 0.5 mL of water, and the resulting solution was filtered. Anhydrous ethanol was added (2.5 mL) followed by anhydrous acetone until a faint turbidity remained. Recrystallization at 4 °C furnished the bis(cyclohexylammonium) salt of L-fructose 1-phosphate **8e** as colorless needles; chemical yield 370 mg (85%).

Neutral Gold(I) Fluoride Does Indeed Exist**

Detlef Schröder, Jan Hrušák,
Inis C. Tornieporth-Oetting, Thomas M. Klapötke,
and Helmut Schwarz*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The chemistry of gold and its compounds still receives considerable attention.[1] This interest is not only caused by the potential catalytic activity of gold; it also reflects the fascinating coordination chemistry of gold(I) compounds.[2] Although several gold halides in various oxidation states are described in the literature,[1, 3] there is no unambiguous experimental evidence for the existence of the neutral AuF.[4] The only *indirect* characterization of gaseous AuF is based on the analysis of emission spectra of species generated in the etching of gold films in O_2/CF_4 and O_2/SF_6 rf glow-discharge plasmas.[5] Although the title of that contribution[5] implies that evidence for the existence of AuF had been found, in the discussion of the experimental results the authors leave no doubt that besides AuF the diatomic molecules AuO, AuO^+, and AuF^+ cannot be definitively ruled out as the emitting species, and the hope for additional investigations is explicitly expressed. Actually, it has been stated recently that "there is still no evidence for the existence of a definitively characterized gold(I) fluoride."[4b] Recent theoretical calculations, using a correlated relativistic approach, predict solitary AuF as a stable entity with a calculated bond dissociation energy of 59 kcal mol^{-1}.[6] Here for the first time, we will provide evidence for the existence of this long-sought molecule, and we also will report an estimate of the bond dissociation energy of AuF.

Neutralization–reionization mass spectrometry (NRMS) has been established as a versatile tool in the study of elusive molecules in the gas phase.[7] The inability to generate the corresponding bulk materials in the condensed phase often does not reflect an intrinsic instability of the neutral species; rather, the "non-existence" is due to facile bi- or termolecular reactions, such as isomerization, disproportionation, or solvolysis, which prevent experimental detection and characterization of the molecule in solution or in a matrix. Recently, NRMS has been successfully applied to the study of many unusual organometallic molecules, none of which is viable in the condensed phase.[7, 8]

Upon collisional activation[9] of AuF^+ with oxygen as a stationary gas, the formation of Au^+, corresponding to the loss of the fluorine ligand, is the only singly charged product observed (Fig. 1). Due to the high ionization energy of fluorine (IE(F) = 17.4 eV, IE(Au) = 9.2 eV)[16] as well as the reduced kinetic energy of the resulting fragment ion, the intensity of the signal corresponding to the fluorine cation was below the detection limit. In addition to atomic Au^+, dications are formed by charge stripping of AuF^+ in collision with oxygen. The observation that the doubly charged Au^{2+} gives rise to a signal about 25 times more intense than that of the AuF^{2+} dication indicates that the lifetime of AuF^{2+} is short; most likely upon charge stripping an electron is removed from the σ bond of AuF^+, thus making the incipient AuF^{2+} quite susceptible to fragmentation.[17] By means of high-resolution translational energy loss spectroscopy (HRTELS)[18] we ascertained that excited electronic states of AuF^+ do not contribute to the cations originating from electron impact ionization (EI) of AuF_3; this is evidenced by the absence of peaks at the high-energy side, which would result from superelastic collisions of excited AuF^+ in an HRTELS experiment (inset in Fig. 1).

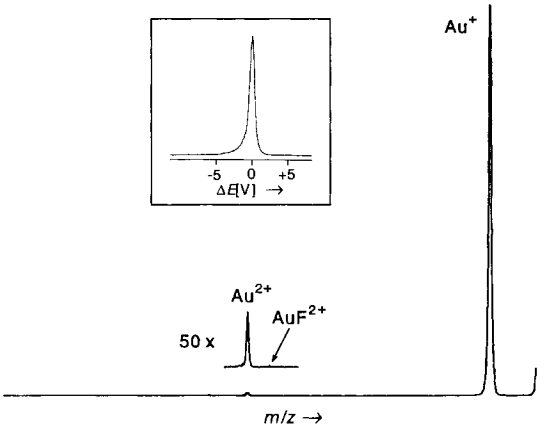

Fig. 1. Collisional activation spectrum of mass-selected AuF^+ with oxygen (70% *T*). The inset shows the HRTEL spectrum of AuF^+ with oxygen (50% *T*); see text and [9] for details.

If AuF^+ is subjected to a NRMS experiment, a distinct recovery signal is observed, which corresponds to the reionized neutral AuF molecule (Fig. 2). This provides for the first time un-

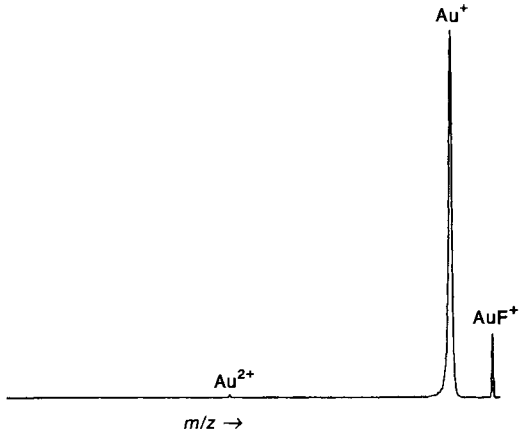
ambiguous experimental evidence that neutral AuF is a stable gas-phase species as predicted by theory[6] and conjectured in the analysis of emission spectra.[5] From the distance between the two collision cells (10 cm) the *minimal* lifetime of neutral AuF is calculated to exceed 25 μs. The NR spectrum is dominated by a large signal corresponding to Au^+, which largely originates from the dissociation of the neutral molecule followed by reionization; furthermore, a weak signal for Au^{2+} is observed. We note in passing that also in the NR spectrum of the AuF^- anion, generated by electron import of AuF_3 in the presence of the electron-moderating agent N_2O,[19] a recovery signal corresponding to reionized AuF is observed. These NR experiments demonstrate beyond doubt that AuF resides in a potential minimum. Thus, the elusiveness of the species in the condensed phase[1] does not reflect an intrinsic instability of AuF; rather, our results point to the operation of facile intermolecular reactions, which as yet preclude the generation of bulk AuF.



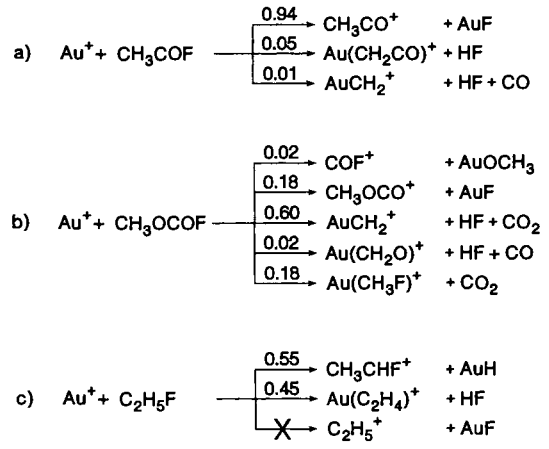


Fig. 2. Neutralization–reionization mass spectrum of mass-selected AuF^+ (xenon, 85% *T*/oxygen 85% *T*).

Once the existence of neutral AuF had been established, we were interested in the determination of the bond dissociation energy (BDE) of this molecule. One possibility of elucidating the thermochemistry of *neutral* species in a mass spectrometric setup is provided by the study of ion–molecule reactions of thermalized ions with appropriate neutral substrates. These experiments allow the determination of upper and lower bounds for the heat of formation of neutral as well as ionic species, provided thermochemical information for the remaining reaction partners is available.[16] To this end we have performed Fourier transform ion cyclotron resonance (FTICR) experiments,[9] in which thermalized Au^+ cations were subjected to reaction with various fluorine-containing organic compounds R–F (Scheme 1). Since an abstraction of a fluoride anion is believed to occur fast and without a significant barrier,[20] the occurrence of the corresponding R^+ cations permits the determination of the upper and lower limits of BDE(AuF).

When Au^+ is treated with acetyl fluoride, the predominant reaction channel corresponds to the formation of CH_3CO^+ and neutral AuF (Scheme 1a). This observation implies that BDE(AuF) > 68 kcal mol^{-1}. Similarily, neutral AuF is formed in the reaction of Au^+ with methyl fluoroformate, which yields a lower bound for BDE(AuF) of 73 kcal mol^{-1} (Scheme 1b). As other reaction channels compete effectively with this reaction, abstraction from methyl fluoroformate is believed to occur near threshold. However, because $\Delta H_f(FCO_2CH_3)$[21] is not as reliably known as $\Delta H_f(CH_3COF)$, the BDE value based on process (1b) is subject to further refinement. The observation that various other fluorinated organic compounds R–F do *not* give rise to neutral AuF and the corresponding organic cations R^+ (e.g., R=CH_3, C_2H_5, $CFCl_2$, CF_2Cl, CF_2Br, CHF_2, CF_3, *c*-C_6F_5, CH_2CH_2OH, and SF_5)[24] permits an estimate of the upper limit of BDE(AuF). An upper bound for BDE(AuF) of 85 kcal mol^{-1} results from the absence of the formation of $C_2H_5^+$ in the ion–molecule reaction of Au^+ with ethyl fluoride (Scheme 1c). Furthermore, since in this reaction $C_2H_5^+$ is not even formed if excited Au^+ cations are used, the upper bound of 85 kcal mol^{-1} will be considerably too high.

Scheme 1. Ion–molecule reactions with Au^+.

In conclusion, the existence of AuF has been unambiguously established by means of a NRMS experiment. From the results of ion–molecule reactions of thermalized Au^+ cations with various substrates, lower and upper bounds for the bond dissociation energy of AuF can be obtained, which are in reasonable agreement with the theoretical predictions.[6a,c,25]

[9] Experimental details: All experiments were performed with a modified VG ZAB/HF/AMD four-sector mass spectrometer in *BEBE* configuration (*B* stands for magnetic and *E* for electric sector), which has been described previously [10]. The ion source was passivated by pretreatment with gaseous fluorine, generated in situ by thermolysis of AgF_2 (Alfa Ventron), and heated to 300 °C in order to minimize condensation of AuF_3 vapor on the instrument walls. Anhydrous AuF_3 was admitted to the ion source through the solid probe inlet system (sample temperature 330–380 °C) [11] and subsequently ionized by a beam of electrons (kinetic energy 70 eV) in an electron impact ion source (repeller voltage ≈ 20 V). Collisional activation was performed by colliding the beam of *B*(1) mass-selected AuF^+ cations with oxygen (70% transmission *T*); the cationic fragments were recorded by scanning *E*(1). For the NRMS study the ions of interest were mass-selected by means of *B*(1) and subjected to a double-collision experiment in the field-free region preceding *E*(1). Neutralization of the cations was brought about by collision with xenon (85% *T*); the remaining ions in the beam were deflected by a 1000 V potential, and the fast neutral species were subsequently reionized by collision with oxygen (85% *T*). The spectrum of the reionized species was recorded by scanning *E*(1). Due to the relatively low vapor pressure of AuF_3 and its readiness to undergo pyrolysis, maximum sensitivity in the collision experiments could only be achieved by using the first two sectors at a mass resolution of $m/\Delta m = 2.000$. All spectra were accumalted and processed on-line with the VG 250/11 data system, and 15–30 scans were averaged to improve the signal-to-noise ratio. Additional experiments were performed with a Spectrospin CMS 47X Fourier Transform ion cyclotron resonance (FTICR) mass spectrometer, which has been described in detail elsewhere [12]. In brief, Au^+ cations were generated in the external ion source by laser desorption/laser ionization of a pure gold target and, by using a system of electric potentials and lenses, the ions were transferred to the FTICR cell, which was situated within a 7 Tesla magnetic field. For the determination of ΔH_f, the isolated Au^+ cations were thermalized by multiple collisions with pulsed-in argon gas and reisolated by the FERETS (FERETS = front-end resolution enhancement using tailored sweeps) technique [13].

AuF_3 was prepared by treating a gold wire with an excess of elemental fluorine ($p_{F_2} = 15$ bar) in a quartz reactor at 1000 °C; since AuF_3 is extremely sensitive to atmospheric moisture, all handling was done under utmost anhydrous conditions [11]. The ion source mass spectrum of the AuF_3 so-formed was in excellent agreement with the previously reported one [14]. The organic fluorine compounds were either commercially available or synthesized and purified by well-known literature procedures [15].

[11] In order to obtain maximal ion currents, the AuF_3 samples were slowly heated during the measurement (heating rate ≈ 2 (K) min^-, starting at 330 °C); this procedure represents a compromise between conditions at which AuF_2 is not volatile enough and those at which it is pyrolyzed.

"Head-to-Tail" Linkage in Double Calix[4]arenes

Wojciech Wąsikiewicz, Gabriel Rokicki, Jędrzej Kiełkiewicz, and Volker Böhmer*

Calixarenes are macrocyclic compounds[1] which are readily available in large quantities, above all by condensation of *p-tert*-butylphenol with formaldehyde under alkaline conditions.[2] Numerous compounds are then accessible by substitution at the *para* positions (in some cases after prior elimination of the *tert*-butyl groups) and by reaction at the phenolic OH groups.[3] The synthesis of larger structures can also be achieved by covalently linking calixarene subunits.

Until now, the subunits have either been linked through the phenolic OH groups[4–12] or through the *para* positions.[13–15] When two calix[4]arenes in the *cone* conformation are coupled cyclically by two bridges X, two types of macrotricycles are formed in which either the two cavities (**1**)[13–15] or the two hydroxylated sides (**2**)[4, 5, 7] face each other. These alternatives can be described as "head-to-head" or "tail-to-tail" arrangements. We report here on the first double calix[4]arenes linked in a "head-to-tail" arrangement (**3**), in which both calixarenes have the same orientation. In contrast to compounds of type **1** or **2** in which the dipole moments of the calix[4]arene units cancel one another out, the dipole moments in **3** add up. This

may be of significance for the potential application of similar compounds in areas such as nonlinear optics.[16]

In order to obtain stable compounds of type **3**, we chose to link the moieties by ether bonds. The synthesis was achieved by analogy with the method described for the preparation of bridged calix[4]arenes.[17] *tert*-Butylcalix[4]arene **4** reacted smoothly with tosylates **5** in a mole ratio 1:2 to give diethers **6** in yields of 89 and 70% after purification. After cleavage of the benzyl groups (H_2/Pd, 85–92%), diphenols **7** were reacted with bisbromomethylated *p*-cresol in glacial acetic acid in the presence of zinc acetate (as Lewis acid and Brønsted base). Finally, the double calix[4]arenes **8** were isolated in yields of 4–5% after a simple column-chromatographic purification.

4 **6** R = Bz, **7** R = H

7 **8**

The structures of **8a** and **8b** were confirmed by their mass and NMR spectra (see Table 1). The presence of two pairs of doublets assigned to the Ar–CH_2–Ar methylene protons shows that both calix[4]arene subunits are in the *cone* conformation.

Table 1. ^{1}H NMR data ($CDCl_3$, 400 MHz, δ values, coupling constants in Hz in parentheses) for the double calixarenes **8**.

Proton	**8a**	**8b**	
–OH	9.352	10.180	(br s, 4H)
	7.228	6.135	(s, 2H)
Ar–H	6.997	6.998	(s, 4H)
	6.980	6.897	(s, 4H)
	6.764	6.821	(s, 4H)
	6.742	6.568	(s, 4H)
Ar–CH_2–Ar	4.189 (14.0)	4.209 (13.8)	(d, 4H)
	4.116 (12.9)	4.155 (13.1)	(d, 4H)
	3.407 (14.1)	3.422 (13.9)	(d, 4H)
	3.262 (13.0)	3.205 (13.2)	(d, 4H)
–$(CH_2)_n$–	3.777	3.84	(m, 4H)
	2.338	2.591	(m, 4H)
	1.405	1.805	(m, 4H)
		1.645	(m, 4H)
–CH_3	2.209	1.897	(s, 6H)
–$C(CH_3)_3$	1.250	1.290	(s, 18H)
	0.923	0.806	(s, 18H)

This is further supported by the low-field OH signal corresponding to four protons. The rest of the spectrum is also consistent with the postulated structure: two singlets for the *tert*-butyl groups, one singlet for the methyl groups, and four singlets for the aromatic protons. Thus, the conformation adopted by **8a** and **8b** corresponds to that depicted.

A comparison of the NMR spectra of **8a** and **8b** leads to the conclusion that the hydrogen bonds in **8a** are somewhat weakened. This is an effect generally observed in *p*-bridged calixarenes with decreasing length of the bridge.[18] The distortion of the "newly formed" calixarene is also reflected in the position of the singlet corresponding to the methyl groups. Compared to the methyl groups in **8b** ($\delta = 1.90$), those in **8a** ($\delta = 2.21$) are rotated further out of the shielding region of the benzene rings below, belonging to the "original" calixarene.

We are now in the process of synthesizing further calix[4]arenes of type **3**. A different strategy in which the calix[4]arene units are synthesized prior to linkage should also allow access to compounds with three or more calixarenes in the "head-to-tail" arrangement.

Experimental Procedure

The synthesis of **8a** is described as a typical example; all compounds gave correct elemental analyses and molecular peaks with 100% relative abundance in the FD mass spectra.

6a: A solution of **4** (4.0 g, 5.4 mmol) (1:1 complex with toluene) and **5a** (4.8 g, 12.1 mmol) in anhydrous acetonitrile (180 mL) was heated under reflux with K_2CO_3 (0.82 g, 5.9 mmol) (argon, stirring). After 40 h, the solvent was removed by distillation, and the residue was taken up into CH_2Cl_2 (30 mL) and water (20 mL). The organic phase was washed with dilute hydrochloric acid and water, and then dried. The brown residue was purified by flash chromatography (silica gel, $CHCl_3$). Finally, recrystallization from acetone gave **6a** as colorless crystals (5.27 g, 89%), m.p. 194–197 °C; ^{1}H NMR ($CDCl_3$, 200 MHz): $\delta = 7.90$ (s, 2H, OH), 7.34–6.84 (*m*, 26H, ArH), 4.99 (s, 4H; O–CH_2–Ar), 3.97 (t, $J = 7$ Hz, 4H; CH_2–CH_2–Ar), 4.29 and 3.30 (d, $J = 12.9$ Hz, 4H each; Ar–CH_2–Ar), 2.94 (t, $J = 7$ Hz, 4H; Ar–O–CH_2), 2.32–2.25 (m, 4H; CH_2–CH_2–CH_2), 1.28 and 0.99 (s, 18H each; $C(CH_3)_3$).

7a: Compound **6a** (2.6 g, 2.37 mmol) was dissolved in glacial acetic acid (100 mL), and 5% Pd/C (2.1 g) was added to the solution, which was then stirred under hydrogen at room temperature and atmospheric pressure. After the mixture had been stirred vigorously for about 7 h, hydrogen was no longer taken up. After removal of the catalyst, the filtrate was concentrated by evaporation, the residue dissolved in CH_2Cl_2 (50 mL), and the resulting solution washed with $NaHCO_3$ solution. The crude product was finally purified by chromatography over a short column (silica gel, $CHCl_3$/diethyl ether 50:1) to yield **7a** as a colorless, amorphous product (1.99 g, 92%); ^{1}H NMR ($CDCl_3$, 200 MHz): $\delta = 6.68$–7.07 (m, 16H; ArH + 2H; OH), 5.50 (br s, 2H, OH), 3.96 (t, $J = 7$ Hz, 4H; CH_2–CH_2–Ar), 4.30 and 3.30 (d, $J = 12.9$ Hz, 4H each; Ar–CH_2–Ar), 2.81 (t, $J = 7$ Hz, 4H; Ar–O–CH_2), 2.28–2.23 (m, 4H; CH_2–CH_2–CH_2), 1.28 and 0.98 (s, 18H each; $C(CH_3)_3$).

Double calixarene **8a**: A solution of **7a** (1.5 g, 1.64 mmol) and 2,6-bis(bromomethyl)-4-methylphenol (0.964 g, 3.28 mmol) in glacial acetic acid (50 mL) was added dropwise with stirring to a boiling solution of zinc acetate (0.72 g) in glacial acetic acid (250 mL) over 24 h. After the mixture had refluxed for a further 45 h, the solvent was removed by distillation, and the dark green residue was taken up in $CHCl_3$ (40 mL) and water (30 mL). The organic phase was washed with $NaHCO_3$ solution and water, and was then concentrated by evaporation. Pure **8a** (75 mg, 3.9%), m.p. > 400 °C, was finally obtained by flash chromatography (silica gel, $CHCl_3$ and *n*-hexane/CH_2Cl_2 2:3) (for ^{1}H NMR see Table 1).

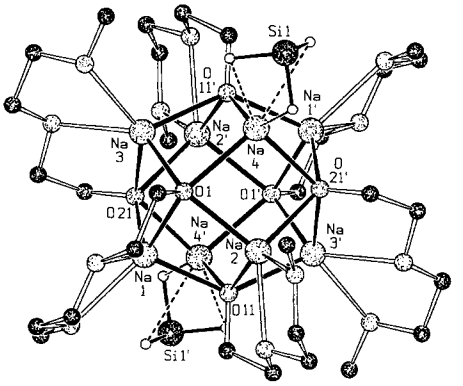
Inversely Coordinating Silanide Ions in an Oligomeric Sodium Alcoholate**

Hans Pritzkow, Thomas Lobreyer, Wolfgang Sundermeyer,* Nicolaas J. R. van Eikema Hommes, and Paul von Ragué Schleyer



In 1961 Ring and Ritter succeeded in characterizing the molecule $KSiH_3$.[1] Their results were confirmed by Weiss et al.[2] in 1970 and extended by structural analyses on the alkali metal silanides $MSiH_3$ (M = Rb, Cs). All three compounds crystallize in the NaCl structure, and according to NMR spectroscopic studies the SiH_3 groups rotate freely at their lattice sites down to a temperature of −100 °C. Becker et al.[3] were able to detect an orthorhombic low-temperature modification of $KSiH_3$ for the first time in 1989 (β-$KSiH_3$).

In contrast, according to ab initio calculations[4] the molecule $LiSiH_3$ should have a remarkable structure with inverted C_{3v} geometry, which is favored over the conventional tetrahedral van't Hoff structure by 10 kJ mol^{-1}. Thus the silyl anion H_3Si^- is expected to bind to the lithium cation through the negatively polarized hydrogen atoms and not in the usual way. The calculated structures of the analogous $NaSiH_3$ isomers (**1a**, **b**; see Fig. 2) are very close in energy,[5, 6] but the van't Hoff structure is the more stable by about 4–8 kJ mol^{-1}. Experimental proof of these theoretically predicted molecular structures did not exist previously. We now report the X-ray crystal structure of an oligomeric sodium alcoholate to which two H_3Si^- anions are coordinated with inverted C_{3v} symmetry, as well as the ab initio calculation of a simplified model of this compound.

Treatment of monosilane with dispersed sodium in diethyleneglycol dimethyl ether (diglyme) leads at 100 °C to sodium silanides of composition $NaSi(SiH_3)_nH_{3-n}$ ($n = 0-3$).[7] After about 20 days a few reproducible, colorless crystals separate as by-product from the filtered yellowish solution of the silanides. The X-ray structure analysis[9] showed that it was the sodium–oxygen cage compound $[Na_8(O_3C_5H_{11})_6(SiH_3)_2]$ (**2**, Fig. 1).[10] Apparently the methyl–oxygen bond of the solvent diglyme is cleaved by the alkali metal sodium to a small extent under these drastic conditions.[11]

2

Fig. 1. Crystal structure of the neutral complex **2** [14]. Selected distances [Å] and angles [°]: Na–Na 3.013–3.055(2), Na–$O_{alcoholate}$ 2.300–2.427(3), Na–O_{ether} 2.389–2.457(2), Na4–Si1 3.048(2), Si–H 1.38–1.42(3), Na4–H 2.52–2.67(3); H-Si-H 96.0, 97.1, 91.3(18).

The eight sodium atoms form a cube, the faces of which are capped by alcoholate oxygen atoms of the six monomethyl diethyleneglycolate ions, which are each bonded to four sodium atoms [Na–O 2.300–2.417 Å]. Together these fourteen atoms form an approximate rhombododecahedron. The two ether oxygen atoms of each monomethyl diethyleneglycolate ion are bound to a common sodium atom (Na–O 2.389–2.457 Å). Thus six of the eight sodium atoms are fivefold coordinated to oxygen atoms. The coordination of the other two sodium atoms is completed by a SiH_3^- ion. The silyl hydrogen atoms were localized in a difference Fourier synthesis, and their positions subsequently refined; they are situated on the side facing the sodium atom. The determined Na–Si distance [3.048 Å] is clearly longer than the distance calculated by us for the isolated $NaSiH_3$ molecule **1a** (2.71 Å); the Si–H distances (1.38–1.42 Å) are shorter (calculated: 1.56 Å). The SiH_3 unit forms a steep pyramid in which the H-Si-H angles vary between 91 and 96° (calculated for **1a**: 92°). The Na-Si-H angles in the crystal [57.7–62.0(13)°] are slightly larger than the calculated angles (56°). Besides the bonds to the hydrogen atoms and the interaction with the sodium atom, the silicon atom has no other contacts to neighboring atoms closer than 3.2 Å.

Although according to calculations[5, 6] the van't Hoff isomer **1b** of the monomeric, gaseous $NaSiH_3$ is more stable than the inverted isomer **1a**, for **2** the inverted structure is apparently energetically favored. To determine whether this is a contradiction of theory or whether **1a,b** are not suitable models for **2**, calculations were performed on a $[(NaOH)_3NaSiH_3]$ complex as model (that is, on a species which reflected half of the crystallographically studied sodium–oxygen cage **2**). The MP2/6-31G* geometries of the inverted structure **3a** and the van't Hoff structure **3b** are depicted in Figure 2 and contrasted with the structures of the isomeric molecules **1a** and **1b**. The Na–Si distance in **3** is longer than in the corresponding isomers of **1**,

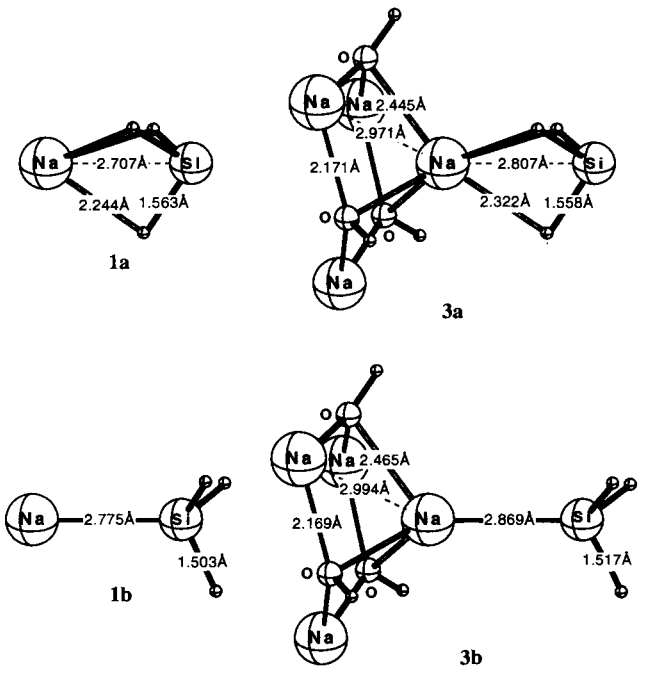

Fig. 2. Structures of **1a** and its van't Hoff isomer **1b** calculated with ab initio methods (MP2/6-31G*) and of the $[Na(OH)_3NaSiH_3]$ complexes **3a** and **3b**. Whereas **1a** is 6.5 kJ mol^{-1} less stable than **1b**, **3a** is 6 kJ mol^{-1} more stable than **3b** (data from MP4sdq/6-31* calculations).

but is still shorter than in solid **2**. Such deviations in the molecular geometry in the gas phase and in the solid state can be explained by dielectric effects in the crystal field.[12] The elongation of the bond in this case is certainly attributable to the higher coordination of the alkali metal atom in **2**. However, most important for the comparison between **3a** and **3b** are the relative energies, which show that in **3** the complexation reverses the order for stability from that found for **1**. On the highest level used for the calculations (MP4sdq/6-31G*//MP2/6-31G*), the inverted complex **3a** is 6 kJ mol^{-1} more stable than **3b**. The results of the calculations are thus in accord with the experimentally determined data.

For gaseous lithium silanide the inverted structure is, according to calculations,[4] more favorable than the van't Hoff structure on account of the contributions of the agostic Li–H interactions. In contrast, for gaseous sodium silanide the corresponding Na–H interactions are weaker, with the result that the contribution of the metal–silicon bond energy that favors the van't Hoff structure increases in importance. The inversion of stabilities in the isomeric complexes **3a** and **3b** is a consequence of the additional electrostatic interaction ($H^{\delta-}\cdots Na^{\delta+}$) of the SiH_3 group with the three sodium atoms of the $(NaOH)_3$ fragment. The preferred conformation of the SiH_3 groups in **2** is therefore attributable to these interactions.

Experimental Procedure

Sodium (10 g, 0.44 mol) was dispersed in diglyme (500 mL) at 100 °C in a reactor fitted with a hollow stirrer and baffle plate and converted into sodium silanides of the composition $NaSi(SiH_3)_nH_{3-n}$ ($n = 0-3$) by treatment with continuously added monosilane [7]. After 4 h the monosilane addition was stopped, and the contents of the reactor allowed to cool to room temperature under nitrogen. The resulting yellow solution was filtered over a G-4 frit. After about 20 days colorless crystals precipitated from the solution of sodium silanides. The solution was removed by syringe, and the crystals were selected manually.

Syntheses of Cyclopentanols by a Silicon-Induced Cascade Reaction**

Michael-Ralph Fischer, Andreas Kirschning, Tycho Michel, and Ernst Schaumann*

The synthesis of chiral cyclopentane derivatives is a component of many natural product syntheses.[1] The diverse synthetic possibilities include the chemistry of the trimethylenemethane equivalent,[2, 3] ring expansion reactions of three-[4] and four-[5] membered rings as well as radical cyclization reactions.[6] Extending our work on the synthesis of cyclopropanes with the homo-Peterson reaction[6] we have now developed a simple route to cyclopentanes including optically active examples. In this route the lithium derivatives **1a–c**, which are easily obtained from silylated thioacetals,[6] react with the epoxy *para*-toluenesulfonate **2** to afford the silyl ethers **5a–c** (Scheme 1, Table 1). Apparently the carbanion of **1** attacks the unsubstituted carbon atom of the epoxide in **2** chemoselectively and regioselectively to give **3**. Finally, a 1,4-carbon to oxygen shift of

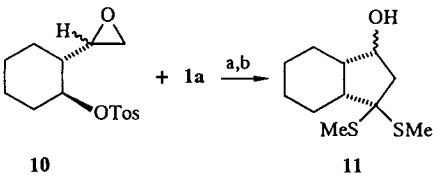
the silyl group (1,4-Brook rearrangement)[7, 9] to afford **4** generates a new carbanion, which displaces the *para*-toluenesulfonate group in an S_Ni reaction. The free alcohols **6a, c** can be obtained from the trimethylsilyl derivatives **5a, c** under acidic conditions.

The ease of formation of **5b** shows that the sterically demanding *tert*-butyldimethylsilyl group rearranges without problems[10] and thus may serve as a stable protecting group in subsequent reactions. However, in this case an oxetane (< 10%) was also produced in the cyclization of **3b**.



Following the same principle, the reaction of the lithium derivative **7** of a 1,3-disilylated propene with (S)-**2**[11] synthesized from (L)-hydroxysuccinic acid gives rise to a mixture (1:1) of optically active diastereomers **8**. In the second step rearrangement of the allylic trimethylsilyl group leads to a less stable carbanion, and therefore a crown ether and high temperatures are necessary. The sluggishness of silyl migration in this case causes formation of 14% of the oxetane **9** as a mixture of diastereomers from the alkoxide (Scheme 2, Table 1).

The efficiency of the cascade reaction[12] is documented in the synthesis of the annelated cyclopentane compound **11** from the

Scheme 2. a) (*S*)-**2**. b) [12]Crown-4, $-78 \rightarrow 0\,^\circ C$, ca. 2 h (monitored by TLC). c) 2 M HOAc/MeOH.

substituted epoxy *para*-toluenesulfonate **10**[13] (Scheme 3, Table 1). These reactions, which afford good yields, offer a promising alternative to the already known [4 + 1] cycloaddition reactions,[14] particularly as the reaction can be undertaken with an enantiomerically pure epoxy *para*-toluenesulfonate compound such as **2**.

Scheme 3. a) $-78 \rightarrow -40\,^\circ C$, ca. 2 h, monitored by TLC. b) 2 M HOAc/MeOH.

Experimental Procedure

3,3-Bis(methylthio)cyclopentanol **6a**: To a solution of protonated **1a** (397 mg, 2.2 mmol) in 6 mL of anhydrous THF was added *n*BuLi (2.49 mmol, 1.6 M in hexane) under an inert gas atmosphere at $-78\,^\circ C$. This solution was stirred at 0 °C for 30 min. At $-78\,^\circ C$, **2** (500 mg, 1 mmol) in 5 mL of anhydrous THF was slowly added dropwise. The yellow reaction solution was warmed to $-50\,^\circ C$ and then hydrolyzed with a mixture of ether, water, and saturated ammonium chloride solution (1:1:1). The aqueous phase was separated and extracted again with ether. The combined organic phases were dried over magnesium sulfate and concentrated in vacuo. The crude product was taken up in 0.5 mL methanol, and 0.5 mL 2 M acetic acid was added. The solution was stirred at 20 °C for 12 h, and finally the phases were separated after addition of an ether–water mixture. The organic phase was neutralized with saturated sodium hydrogen carbonate solution, washed with saturated sodium chloride solution, dried over magnesium sulfate, and concentrated in vacuo. The product was purified by column chromatography on silica gel with petroleum ether/ethyl acetate (7:1) as eluent (Table 1).

New Porphyrinoid Macrocycles Containing Pyridine

Kurt Berlin and Eberhard Breitmaier*

New structural variants of porphyrins are not only interesting as Hückel aromatic compounds and chromophores, they have potential applications as ligands and in medicine as well.[1] Thus we were encouraged to replace one five-membered ring in this macrocycle with a larger heteroarene. Exchange of a pyrrole ring in porphyrin with pyridine would provide cycle **3**, which has only one possible 18 π aromatic resonance structure. We propose the designation pyriporphin for the unsubstituted framework and the numbering shown.[2] The obvious question is whether the aromaticity of the pyridine ring is sacrificed in favor of the [18]annulene. We planned to synthesize **3** by condensation of pyridine-2,6-dicarbaldehyde (**1**) with the "tripyrranedicarboxylic acid" **2b**[3,4] and subsequent oxidation.

Pyridine-2,6-dicarbaldehyde (**1**)[5] reacted with dicarboxylic acid **2b**[3] as expected to provide the isolable, dark blue pyriporphyrinogen **4**. However, treatment of **4** with an excess of tetrachloro-*p*-benzoquinone (*p*-chloranil) did not furnish the desired pyriporphyrin **3** but the green pyriporphyrinone **6** as the single isolable product in roughly 5% yield. In contrast to the analogous oxophlorines[6] this compound does not show downfield shifts for the alkyl and *meso* protons in its ^{1}H NMR spectrum, which would indicate the enolization of the ketone and in turn 18 π aromaticity. To avoid oxidation of **4** to give pyriporphyrinone **6** we employed an equimolar amount of *p*-chloranil and obtained, in addition to **6**, a product with almost twice the molecular weight (M = 926.6) of pyriporphyrinogen **4** (M = 464.3). NMR experiments confirmed our suspicions that this compound is the didehydro dimer of **4**. After the connectivity of the rings was determined by CH-COLOC and CH-COSY experiments, the presence of a bridging C–C single bond was secured by the coupled ^{13}C NMR spectrum and NOE experiments. Selected data are listed in Table 1.

Table 1. Selected physical and spectroscopic data of **4**, **5**, and **6**[8]

The formation of dimer **5** depends on the amount of oxidant used, which indicates that two radicals arising from pyriporphyrinogen **4** recombine. When lower concentrations of *p*-chloranil are used, the reaction of the radical with the oxidant to yield pyriporphyrinone **6** is just as likely as the reaction with another radical to give dimer **5**. Fuhrhop et al. reported an analogous dimerization in the oxidation of 5,15-dioxoporphodimethenes.[7]

Although two asymmetric centers are formed in the reaction of pyriporphyrinogen **4** to provide dimer **5**, only one compound is evident in the NMR spectra. This indicates that the steric requirements of the radicals determine the course of the reaction. The *anti* conformation of the *meso* compound shown in Figure 1 is sterically least hindered (Fig. 1).

Owing to the hindered rotation about this single bond, the methyl groups can only be equivalent when the conformation is symmetric. Thus most of the other possible conformations can be discounted. This assumption was confirmed by NOE differ-

ence experiments, which indicate the proximity of the marked CH_3 groups (Fig. 1) to the pyridine protons, and by the small chemical shift of the pyridine protons which reflect the anisotropy of the pyridine ring.

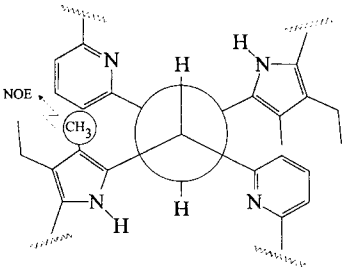

Fig. 1. Proposed configuration of the bridging C–C single bond in dimer **5**.

Experimental Procedure

Solution of **4**: Diester **2a** (635 mg, 1 mmol) was dissolved in anhydrous THF (100 mL), charged with triethylamine (0.1 mL) and 10% Pd/C (200 mg), and hydrogenated at atmospheric pressure. The catalyst was removed by filtration and washed with THF. The filtrate was then added dropwise to a solution of pyridine-2,6-dicarbaldehyde (**1**) (135 mg, 1 mmol) in dichloromethane (800 mL). Argon was bubbled through the reaction mixture before a solution of HBr in glacial acetic acid (1.8 mL, 33%) was added dropwise.

4: The solution of **4** was stirred for 20 h under argon and exclusion of light, then washed with dilute ammonia solution and water, and dried over K_2CO_3. The solvent was removed under vacuum and the residue purified by chromatography first on silica gel (ethyl acetate:cyclohexane 1:3) and then on neutral alumina (activity III; ethyl acetate:cyclohexane 1:9). The intensely colored turquoise fraction furnished dark blue, shiny, microcrystalline **4** (38 mg, 8.2%).

6: The solution of **4** (see above) was stirred under exclusion of light for 4 h then treated with *p*-chloranil (750 mg, ca. 3 mmol). After 15 min the reaction mixture was neutralized with triethylamine (2.5 mmol) and left to stand for 12 h. The solvent was removed under vacuum and the residue purified by chromatography first on silica gel (ethyl acetate:cyclohexane 1:3) then on alumina (activity III; ethyl acetate:petroleum ether 1:4) and recrystallized from dichloromethane/petroleum ether. Yield: 28 mg (5.9%) green, shiny, microcrystalline **6**.

5: The reaction was carried out analogously to that leading to **6**, but only 246 mg (1 mmol) *p*-chloranil was employed. The crude product was purified by chromatography on alumina (activity III; petroleum ether:ethyl acetate 95:5). Yield: green-black, shiny microcrystalline **5** (21 mg, 4.5%) and **6** (14 mg, 2.9%).

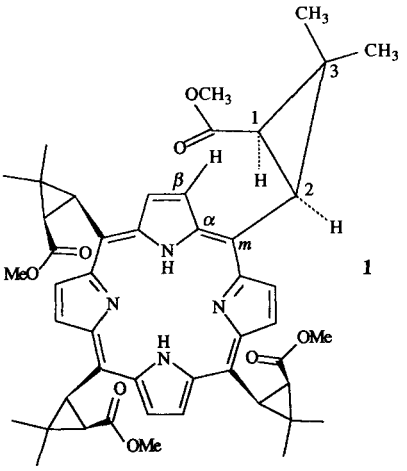
Chiroporphyrins: An Approach to Asymmetric Catalysts with Stereocenters Near the Plane of the Porphyrin Ring**

Marc Veyrat, Olivier Maury, Frédéric Faverjon, Diana E. Over, René Ramasseul, Jean-Claude Marchon,* Ilona Turowska-Tyrk, and W. Robert Scheidt*

The utility of chiral appendages attached to *meso*-tetraarylporphyrinato ligands in the enantioselective control of metal-catalyzed epoxidation of olefins[1] has encouraged us to seek new porphyrin types that would achieve selectivity through close proximity of the substituents at the stereogenic centers to the reactive oxometal group.[2] We envisaged the possibility that a D_2-symmetric "chiroporphyrin" complex of generalized structure **A** could facilitate the oxygen transfer pathway represented by the transition-state assembly **B**.[3] In this geometry,

A B

Scheme 1. Generalized structure **A** of a chiroporphyrin catalyst and schematic representation of the structure **B** of the epoxidation transition state.



steric repulsion near the plane of the porphyrin ring between a bulky *meso* group and a substituent (R = C_6H_5) on the olefin would favor epoxidation at the *Re* face. Herein we report two chiroporphyrins of this novel class, which are obtained in a single step from pyrrole and easily available chiral aldehydes: **1** from (1*R*)-(−)-*cis*-caronaldehydic acid methyl ester, and **2** from (1*R*)-(−)-myrtenal. Among the four atropisomers that can be expected on account of the restricted rotation[4] of the bulky chiral substituents around the bonds to the *meso* carbon atoms of **1** and **2**, the D_2-symmetric $\alpha\beta\alpha\beta$ isomer appears to be the most stable and abundant. The nickel(II) complex of **2** is the first chiral porphyrin for which a crystal structure determination unambiguously establishes the distribution and symmetry of its atropisomers and their absolute configuration. Moreover, the chloromanganese(III) derivatives of **1** and **2** are efficient asym-

1

metric catalysts in the epoxidation of unfunctionalized aromatic olefins with iodosylbenzene; **1** gives optical yields of up to 70% *ee* for the conversion of dihydronaphthalene to its epoxides.

2

The chiroporphyrin free base **1** was obtained in 4% yield from pyrrole and the bulky (1*R*)-(−)-*cis*-caronaldehydic acid methyl ester[5] under Lindsey condition,[6] and gives one major and two minor spots by thin-layer chromatography. The pyrrole protons of the major product (ca. 50% of total porphyrin) appears as two sharp singlets at $\delta = 9.07$ and 9.18 in the 200 MHz and 400 MHz ^{1}H NMR spectra at room temperature, leading to its unambiguous identification of an $\alpha\beta\alpha\beta$ atropisomer.[4c] The high relative abundance of this D_2-symmetric atropisomer is likely to result from the interaction of the porphyrin with its very bulky *meso* substituents.[7] The moderate upfield shift of the N–H resonance ($\delta = -1.66$) indicates a decreased ring current and a nonplanar conformation of the porphyrin.[8] It is important to note that the coupling constant of the vicinal cyclopropyl protons of **1** ($J' = 8.9$ Hz) is similar to that found in the starting aldehyde ($J' = 8.6$ Hz), indicating a *cis* configuration and the absence of epimerization during acid-catalyzed porphyrin formation.

(1*R*)-(−)-Myrtenal (≥98% *ee*)[9] was allowed to react with pyrrole,[6] and the resulting *meso*-tetrakis[(1*R*)-apopinen-2-yl]porphyrin **2** was isolated in 11% yield after chromatographic purification on alumina. In contrast to **1**, the ^{1}H NMR signal of the pyrrole protons of **2** appears as a broad singlet in [D_8]toluene at 20 °C, turns into a sharp peak at 60 °C, and splits into an asymmetric pair of peaks at −20 °C. This behavior suggests the presence of slowly interconverting atropisomers[4] at room temperature. The chemical shift of the N–H resonance indicates a nonplanar conformation of the porphyrin.[8]

Reaction of **2** with nickel acetate tetrahydrate in chloroform–ethanol afforded the nickel complex **3** in 80% yield. The ^{1}H NMR spectrum of this complex exhibits partially resolved signals at room temperature, even at 400 MHz. Heating **3** to 60 °C in [D_8]toluene induced fast exchange and gave a well-resolved spectrum which could be completely assigned on the basis of selective decoupling and 2D correlation experiments. The stereochemistry found for the *meso* groups is in full agreement with that of the starting myrtenal.[10] A crystalline sample was obtained by slow evaporation to dryness of a solution of **5** in a chloroform/acetone/acetonitrile mixture. Single crystals suitable for X-ray diffraction were selected from this homogeneous crystalline material.

In addition to confirming the nonplanar conformation of the porphyrin ring and the *R* absolute configuration, the structure of the nickel complex **3** determined from diffraction data[11] reveals an unusual feature. Two atropisomers ($\alpha\beta\alpha\beta$ and $\alpha\alpha\beta\beta$) are present in the crystal lattice: they are found as two independent molecules in the asymmetric unit (Fig. 1). The porphyrin macrocycle shows substantial ruffling[12] in both molecules. This deformation results from the severe nonbonding interactions between the very bulky geminal dimethyl groups in the *meso* position and the pyrrole hydrogen atoms.[13] The small size of the nickel atom, which tends to form short Ni–N bonds with a concomitant ruffling of the core, may also be a contributing factor.[14] The saddle distortion bends opposite *meso* substituents towards each other, resulting in a very similar overall shape for the two atropisomers.

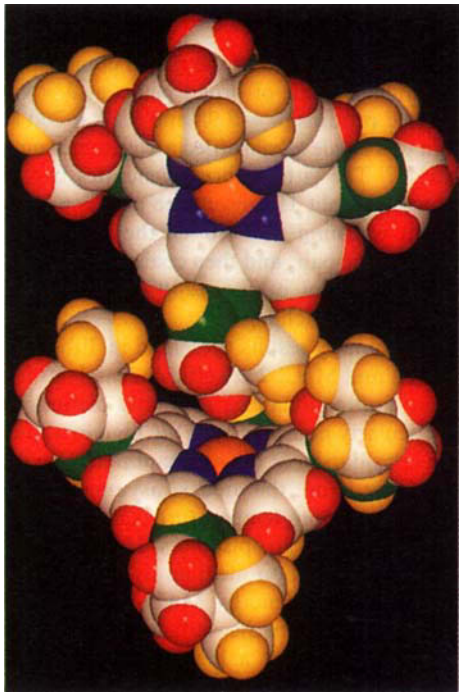

Fig. 1. Structures of the two atropisomers of **3** in the asymmetric unit. The ruffled conformation of the porphyrin is apparent in the side view of the $\alpha\beta\alpha\beta$ atropisomer at the bottom. The $\alpha\alpha\beta\beta$ atropisomer at the top is viewed perpendicular to the plane of the porphyrin ring. Color coding: carbon is white except in double bonds of *meso* substituents in which it is green; hydrogen is red except in vinylic and geminal dimethyl groups of *meso* substituents in which it is yellow; nitrogen is blue; nickel is orange.

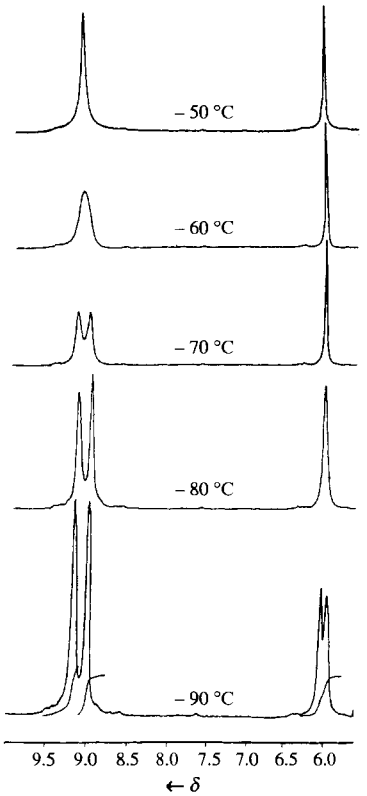
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0221 $ 10.00+.25/0

The question obviously arises whether the porphyrin ruffling observed in the crystal is retained in solution. The conformation of **3** was therefore examined in solution by variable-temperature high-resolution ^{1}H NMR spectroscopy (Fig. 2). The 300 MHz



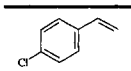


Fig. 2. Variable-temperature 300 MHz ^{1}H NMR spectra of **3** in CD_2Cl_2 showing the evolution of the β-pyrrole H and H3 resonances from −90 to −50 °C.

^{1}H NMR spectrum of the nickel complex **3** at −90 °C exhibits a symmetric pair of broad peaks at $\delta = 9.01$ and 9.19 for the pyrrole protons ($\delta = 8.98$ and 9.17 at 200 MHz), which we assign to a single $\alpha\beta\alpha\beta$ ruffled atropisomer undergoing slow inversion.[15] The latter process generates two distinct conformers, hence the split H3 resonance at $\delta = 6.17$ at this temperature. Upon warming to −80 °C, the pyrrole signals turn into an asymmetric pair, and then coalesce at −60 °C, suggesting gradual population of the $\alpha\alpha\beta\beta$ conformation and concomitant atropisomer exchange.

Preliminary results presented in Table 1 indicate that MnCl-$\alpha\beta\alpha\beta$-**1** and MnCl-**2** are efficient catalysts for the epoxidation of some unfunctionalized aromatic olefins with iodosylbenzene. Particularly noteworthy is the high *ee* value (70%) obtained in the epoxidation of dihydronaphthalene with MnCl-$\alpha\beta\alpha\beta$-**1**. On the other hand, the modest asymmetric induction found with MnCl-**2** at room temperature is not surprising for a mixture of interconverting atropisomers. However, lowering the temperature of the reaction medium to −10 °C for the epoxidation of dihydronaphthalene by MnCl-**2** unambiguously results in an improved asymmetric induction. This encouraging result is assumed to reflect a higher relative abundance of the $\alpha\beta\alpha\beta$ atropisomer of the active Mn complex of **2** at low temperatures, as suggested by the variable-temperature NMR spectra of **3** (see above).

In summary, the chiroporphyrin concept combines several appealing features that are seldom found together among previously described asymmetric epoxidation catalysts. By its inherent simplicity, the synthesis of **1** is comparable to that of asymmetric salen complexes,[16] but it leads to a more chemically robust porphyrin catalyst. Moreover, enantioselectivity can be adjusted by choosing appropriate esters of *cis*-caronaldehydic acid. The open structure of **1** and **2** allows in principle higher turnover rates than most sterically shielded tetraphenylporphyrins with chiral "pickets", "walls", "vaults", or "straps".[1a-h, 17] Compared to the latter, an added bonus is the high relative abundance of the $\alpha\beta\alpha\beta$ atropisomer upon self-assembly of the porphyrin catalyst. Studies are under way on the implications of this concept which we believe will be of wide interest for the design of asymmetric porphyrin catalysts with improved properties.

Table 1. Asymmetric epoxidation of aromatic olefins with MnCl-$\alpha\beta\alpha\beta$-**1** and MnCl-**2** [a].

Substrate	Catalyst	T [°C]	Epoxide yield [%]	*ee* [%] [b]	Configuration [c]	Byproduct yield [%]
	MnCl-$\alpha\beta\alpha\beta$-**1**	25	77	15	*R*(+)	10 [d]
	MnCl-**2**	25	62	8	*R*(+)	35 [d]
	MnCl-$\alpha\beta\alpha\beta$-**1**	25	70	21	(−) [e]	11 [f]
	MnCl-**2**	25	65	6	(−)	–
	MnCl-$\alpha\beta\alpha\beta$-**1**	25	73	29	1*S*,2*R*(+)	16 [g]
	MnCl-**2**	25	71	11	1*R*,2*S*(−)	11 [g], 9 [h]
	MnCl-**2**	−10	67 [i]	15	1*R*,2*S*(−)	7 [g], 19 [h]
	MnCl-$\alpha\beta\alpha\beta$-**1**	25	83	67	1*S*,2*R*(−)	5 [j]
	MnCl-$\alpha\beta\alpha\beta$-**1**	25	75 [k]	70	1*S*,2*R*(−)	4 [j]
	MnCl-**2**	25	90	2	1*S*,2*R*(−)	0

[a] Reactions were generally run for 1 h with 1.0 μmol of catalyst, 100 μmol of iodosylbenzene, 250 μmol of pyridine, 20 μL of nonane, and 1.00 mmol of olefin in 2 mL of CH_2Cl_2. Yields are based upon iodosylbenzene and were determined by GC analysis. [b] Determined by gas chromatography (Cyclodex-B chiral capillary column). [c] Assigned by comparison with results described in ref. [1g]. [d] *p*-Chlorophenylacetaldehyde. [e] The absolute configuration was not determined. [f] 2-Naphthylacetaldehyde. [g] *trans*-β-Methylstyrene epoxide. [h] Benzylmethylketone. [i] Reaction time: 2 h. [j] β-Tetralone. [k] Reaction time: 10 min.

Experimental Procedure

The porphyrins **1** and **2** and the nickel complex **3** were prepared by standard methods. New compounds were characterized by mass spectrometry (VG ZAB-VEQ), UV/VIS (Perkin Elmer Lambda 9), and NMR spectroscopy (Bruker AC 200, AM 300, and AM 400).

1: MS (EI, Fe complex generated in situ): *m/z*: found. 868.810 ($M - 2H + Fe$), calcd. for $C_{48}H_{52}N_4O_8Fe$: 868.808. UV/VIS (CH_2Cl_2), λ_{max} [nm] = 428, 565, 605, 663. ^{1}H NMR (200 MHz, $CDCl_3$, TMS, 20 °C): $\delta = -1.66$ (s, 2H, NH), 0.79 (s, 12H, CH_3), 1.87 (s, 12H, CH_3), 2.69 (d, 4H, $J' = 8.9$ Hz, H_1), 3.07 (s, 12H, CO_2CH_3), 4.75 (d, 4H, $J' = 8.9$ Hz, H_2), 9.07 (s, 4H, pyrrole H), 9.18 (s, 4H, pyrrole H); ^{13}C NMR (50 MHz, $CDCl_3$, TMS, 20 °C): $\delta = 18.2$ (CH_3), 27.7 (C_3), 29.3 (CH_3), 33.2 (CH), 38.3 (CH), 51.0 (OCH_3), 110.1 (*Cm*), 127.2 (*Cβ*), 131.1 (*Cβ*), 143.7 (*Cα*), 148.6 (*Cα*), 170.9 (C = O).

2: FAB$^+$-MS: *m/z* 791.7 (M^+). Correct C,H,N analysis. UV/VIS (CH_2Cl_2), λ_{max} [nm] (lg ε) = 427 (5.52), 528 (4.03), 568 (4.12), 664 (3.82). ^{1}H NMR (200 MHz, $CDCl_3$, TMS, 20 °C): $\delta = -2.70$ (s, 2H, NH), 1.54 (s, 12H, CH_3), 1.68 (s, 12H, CH_3), 2.33 (d, 4H, $J = 8.6$ Hz, H7), 2.58 (m, 4H, H5), 3.06 (m, 12H, H4, H4′, H7′), 3.45 (m, 4H, H1), 6.39 (m, 4H, H3), 9.36 (m, 8H, pyrrole H); ^{1}H NMR (200 MHz, [D_8]toluene, TMS, 20 °C): $\delta = -2.07$ (s, 2H, NH), 1.39 (s, 12H, CH_3), 1.63 (s, 12H, CH_3), 2.29 (d, 4H, $J = 8.6$ Hz, H7), 2.37 (m, 4H, H5), 2.95 (m, 12H, H4, H4′, H7′), 3.44 (t, 4H, H1), 6.35 (m, 4H, H3), 9.53 (m, 8H, pyrrole H); ^{13}C NMR (50 MHz, $CDCl_3$, TMS, 20 °C): $\delta = 22.4$ (CH_3), 26.9 (CH_3), 33.1 (C4), 33.8 (C7), 39.1 (C6), 40.6 (C5), 54.3 (C1), 122.4 (*Cm*), 130.1 (C3), 130.8 (*Cβ*), 146.0 (*Cα*), 149.0 (C2).

3: FAB$^+$-MS: *m/z* 848.4 (M^+). Correct C,H,N,Ni analysis. UV/VIS (CH_2Cl_2), λ_{max} [nm] (lg ε) = 425 (5.34), 541 (4.06), 580 (3.67). ^{1}H NMR (200 MHz, $CDCl_3$, TMS, 20 °C): $\delta = 1.41$ (s, 12H, CH_3), 1.42 (s, 12H, CH_3), 2.14 (d, 4H, $J = 8.6$ Hz, H7), 2.45 (m, 4H, H5), 2.86 (m, 12H, H4, H4′, H7′), 3.03 (m, 4H, H1), 6.17 (m, 4H, H3), 9.17 (m, 8H, pyrrole H); ^{1}H NMR (200 MHz, [D_8]toluene, TMS, 20 °C): $\delta = 1.31$ (s, 12H, CH_3), 1.46 (s, 12H, CH_3), 2.15 (d, 4H, $J = 8.6$ Hz, H7), 2.29 (m, 4H, H5), 2.72 (t, 8H, H4, H4′), 2.77 (m, 4H, H7′), 3.08(t, 4H, H1), 6.18 (m, 4H, H3), 9.35 (m, 8H, pyrrole H); ^{1}H NMR (200 MHz, [D_8]toluene, TMS, 60 °C): $\delta = 1.31$ (s, 12H, CH_3), 1.46 (s, 12H, CH_3), 2.15 (d, 4H, $J = 8.6$ Hz, H7), 2.29 (m, 4H, H5),

Coexistence of Mobile and Localized Electrons in Bis(ethylene)dithiotetrathiafulvalene (BEDT-TTF) Radical Salts with Paramagnetic Polyoxometalates: Synthesis and Physical Properties of $(BEDT\text{-}TTF)_8[CoW_{12}O_{40}] \cdot 5.5H_2O$**

Carlos J. Gómez-García, Lahcène Ouahab,*
Carlos Gimenez-Saiz, Smaïl Triki, Eugenio Coronado,*
and Pierre Delhaès

One of the challenges in materials science is to prepare new molecular compounds with unusual combinations of properties as, for example, compounds coupling magnetic and conducting sublattices. Choosing as molecular building block the π donor bis(ethylene)dithiotetrathiafulvalene (BEDT-TTF or ET), which is the most widely used molecule in the synthesis of molecular superconductors,[1] and polyoxometalate anions,[2] which show a very well-known ability to accommodate magnetic metal ions at specific sites, we have prepared a radical salt in which mobile electrons from the organic component coexist with localized electrons from the magnetic Co^{II}-containing polyoxometalate $[Co^{II}W_{12}O_{40}]^{6-}$, and other related polyanions.

Diamagnetic polyoxoanions have been recently used by us[3] and by other groups[4] as inorganic electron acceptor components of charge-transfer salts, with the aim of examining the novel structural and electronic properties in the organic moiety induced by the sizes, shapes, and charges of these inorganic clusters. In some cases the polyoxoanion is reduced by the organic molecule to give a material in which delocalized electrons coexist in both the organic and the inorganic components.[5] However, no structural analyses have been reported for these salts with paramagnetic polyoxoanions.[6] In this communication we report the structure and physical properties of the first example of this kind.

The structure[7] of the title compound shows the presence of alternating layers of the anions and the ET molecules (Fig. 1).

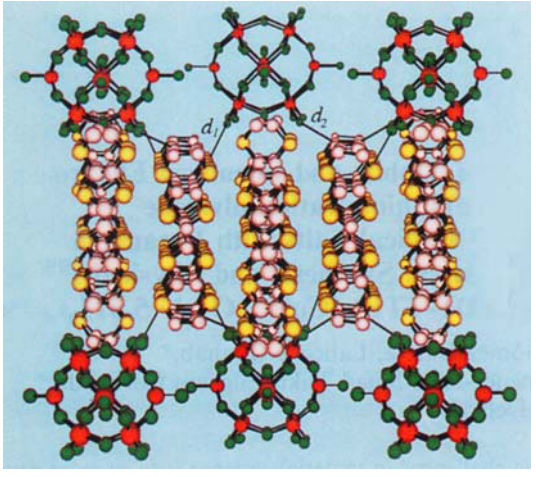

Fig. 1. Perspective view of the organic and inorganic layers showing the chains of eclipsed ET molecules and chains of dimers, as well as the interactions between the anions and the organic C-type molecules [Å]: d_1 (O–S) = 3.04(3), d_2 (O–C) = 3.08(5).

This structure is similar to that found for $ET_8[SiW_{12}O_{40}]$, but in that case the structure is acentric[4a] and the compound does not contain water molecules. In our case the anion displays the well-known Keggin structure containing a Co^{II} ion in its tetrahedral cavity. The anion is disordered (rotation of 90° around the C_2 axis), which makes it appear to be a centrosymmetric unit. This kind of disorder has been unambiguously described by Pope and Evans.[8] The organic layers are formed by three crystallographically independent molecules of ET noted as A, B, and C (Fig. 2a). These molecules are arranged in two different kinds of chains (types I and II, Fig. 2a). Type I chains are formed by alternating B and C type molecules packed eclipsed with S-S distances of 4.04(2) Å. Chains of type II consist of A type molecules packed as dimers with S-S distances within a dimer of 3.86(2) and between dimers of 3.98(1) Å (Fig. 2b). The two types of chains alternate parallel to the direction [$\bar{1}$01] and give rise to an α phase[1a] with a dihedral angle of 46.5° between the ET molecules. The interchain connections (Figure 2a) (ranging from 3.46(2) to 3.52(2) Å), which are much shorter than the intrachain ones, are close to those commonly observed in the quasi 2-D materials based on ET.[1a] Moreover, two kinds of interactions between the organic and inorganic layers can be observed (Fig. 1). The first occurs between the sulphur atoms of the C-type molecules (in the eclipsed chain) and the terminal oxygen atoms of the anion (shortest S–O distance of 3.04(3) Å). The second type of interaction is a hydrogen bond between oxygen atoms of the anion and the carbon atoms of both ethylene groups in the ET molecules of the A type (shortest C–O distance, 3.08(5) Å; Fig. 1). Note that interactions through the ethylene groups have been shown to play an important role in the conducting properties of solid ET.[9] Indeed, this donor arrangement is one of the classical types, called the α phase, in 2-D molecular superconductors.[10]

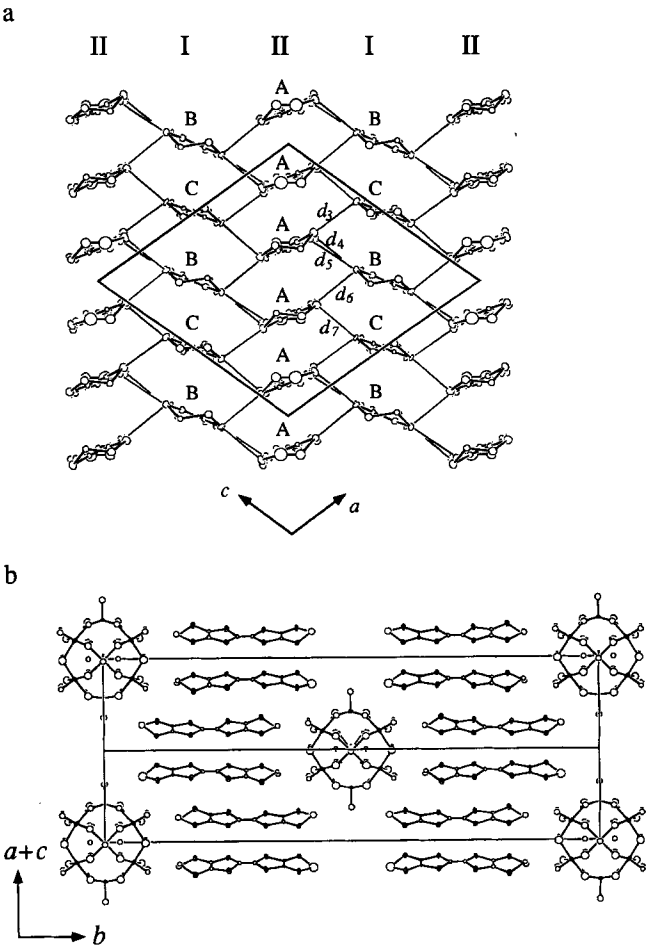

Fig. 2. a) Projection of the organic layer onto the *ac* plane showing the mode of packing of the α phase and the intrachains interactions [Å]: $d_3 = d_4 = 3.51(2)$, $d_5 = d_6 = 3.52(2)$, and $d_7 = 3.46(2)$. b) View of the positions of the anions in the unit cell and the A-type molecules of ET stacked in the chains of dimers (type II) along the [101] direction.

The electrical properties of a single crystal of $ET_8[CoW_{12}O_{40}] \cdot 5.5\,H_2O$ are illustrated through a plot to the normalized resistance versus T in Figure 3. The compound is a semiconductor ($\sigma \leq 0.1\ Scm^{-1}$ at room temperature) showing two different semiconducting behaviors with activation energies of 120 and 27 meV (at high and low temperatures, respectively), and a transition temperature of about 170 K (estimated from the intersection of the two semiconductive regimes).

The IR and visible absorption spectra recorded at room temperature shows the presence of two charge transfer bands and a doublet for the associated vibronic modes. The electronic bands

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0224 $ 10.00+.25/0

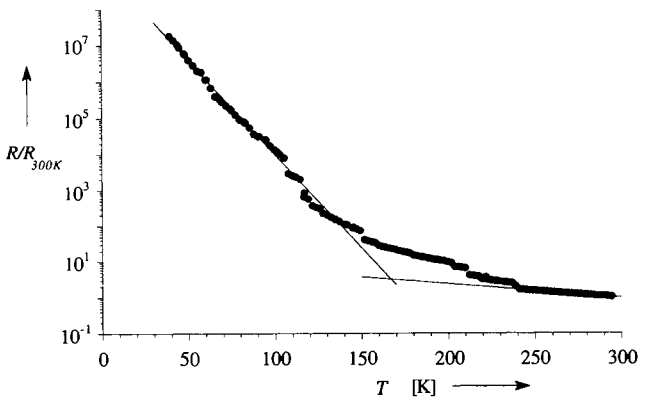

Fig. 3. Plot of the normalized resistance versus T for a single crystal of the title compound. Straight lines represent the fit for the two semiconductive regimes (see text).

are located at 4500 and 9900 cm^{-1}: the first one is associated with a mixed-valence system, whereas the second one accounts for a doubly occupied site.[11] Besides, we observe vibronic lines due to the classical electronic–molecular vibrational coupling with two pairs of lines at 1405 and 1344 cm^{-1} for the $a_g\nu_4$ C=C central stretching mode and at 450 cm^{-1} with a shoulder around 480 cm^{-1} for the $a_g\nu_{10}$ C–S–C stretching mode. In analogy to assignments made for other ET salts[12] we conclude that two different organic stacks are present, as already observed from the X-ray crystal structure data: on one hand, the stack including B- and C-type ET molecules appears to be completely ionized, and on the other, the A-type dimeric molecular arrangement is be a mixed valence system with $+1/2$ charge on each ET molecule (to yield the total anionic charge of -6).

In a wide temperature range (40–300 K), single-crystal EPR measurements show one homogeneous signal at $g \approx 2$ that appears to be mainly related with the organic radical cations. A second signal becomes observable at lower temperatures, which is very sensitive to the orientation of the crystal (the g value of this line varies between 4 and 6 when the static magnetic field is perpendicular or parallel to the long axis of the needle-shaped crystal). This signal is due to the tetrahedral Co^{II} ions. The observation of two signals indicates that the exchange interaction between the two spin sublattices is small. Further indication of magnetic interactions can be obtained from the plot of the dependence of temperature on the spin susceptibility, the g value, and the signal width derived from the radical signal (Fig. 4). Thus, the plot of the χT vs. T decreases continuously on lowering the temperature, and at 4 K reaches a value that is 3% of the room temperature value, which indicates short-range antiferromagnetic interactions in the organic sublattice. On the other hand, both g and line-width parameters do not change, within the experimental error, down to about 80 K, and at lower temperatures a progressive increase of these parameters is observed. This behavior is reminiscent of that previously observed in two other organic/inorganic salts for which magnetic interactions between the localized moments of the inorganic part and the itinerant electrons of the organic moiety have been proposed.[13] However, in our case the presence of a very small organic–inorganic exchange interaction does not seem to be sufficient to justify the strong variability of the experimental parameters. A more plausible explanation arises from the possibility of magnetic interactions between the two kinds of organic chains present in the structure: one probably contains completely ionized ET molecules, and therefore localized spins, while the other is in a delocalized mixed-valence state. In fact, magnetic measurements carried out on the related silicon-containing salt, $ET_8[SiW_{12}O_{40}]$, show a maximum in χ at about 60 K, which indicates the presence of significant antiferromagnetic interactions in the organic sublattice.[14]

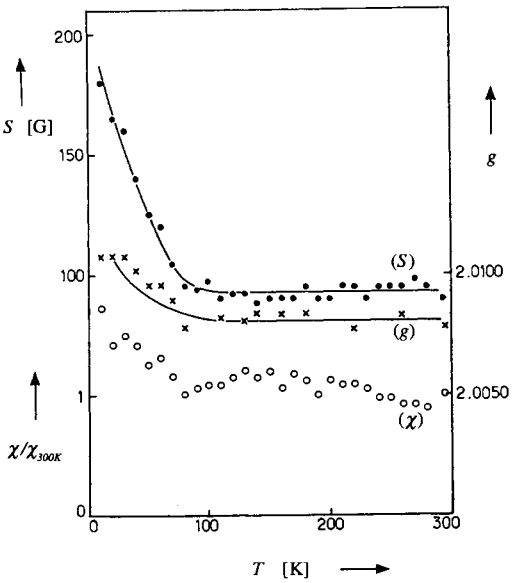

Fig. 4. Temperature dependence of the linewidth S of the ESR signal, the g factor, and the relative spin susceptibility χ for a given position of the single crystal within the resonance cavity.

From the above results we conclude that the two spin sublattices are quasi-isolated. The only significant interaction seems to occur within the organic component. The bulk susceptibility measurements confirm this conclusion: The product χT remains constant in the range 150–300 K and shows a slight decrease from 3 to 2.2 emu mole K^{-1} on lowering the temperature to 4 K. This decrease should arise from the antiferromagnetic interaction in the organic component, while the low temperature value is in good agreement with the presence of isolated Co^{II} ($S = 3/2$ and $g \approx 2.2$).

The material presented here constitutes the first example of organic/inorganic salts made with both magnetic polyoxometalates and π-type organic donors. It opens the possibility of synthesizing new molecular compounds in which the coupling between magnetic and conducting sublattices should lead to new and interesting properties. Radical cation salts containing other polyoxometalates $XW_{12}O_{40}$ are under current investigation in our groups. Preliminary results show that other paramagnetic (X = Co^{III}, Fe^{III}, Cu^{II}, etc.) and diamagnetic (X = H_2^{+2}, Zn^{II}, B^{III}) anions with the Keggin structure present the same α phase. Furthermore, we have also found the existence of two other related phases for almost all the mentioned polyanions.[15] These results now open the possibility of trying other Keggin polyanions having magnetic ions on the surface in order to favor the magnetic interactions with the organic part. Moreover, they show the rich structural polymorphism of this kind of inorganic/organic association and the existence of isostructural series in which different anionic charges (from -4 to -8) and different spins can be accommodated with ease, thus constituting ideal supports for the investigation of systems combining conducting and magnetic behaviors.

Experimental Procedure

Single crystals of the title compound were obtained from the electrochemical oxidation of ET (3.5×10^{-3} M in a mixture of $CH_2Cl_2/CH_3CN/H_2O$ 10:2:1) in the presence of the tetrabutylammonium salt of the polyoxoanion $[CoW_{12}O_{40}]^{-6}$ [16] (5×10^{-3} M in a mixture of CH_2Cl_2/CH_3CN 1:1) in a U-shaped cell with Pt electrodes (0.5 mm diameter) separated by a sintered-glass frit. The intensity of the current was fixed at 1 μA. After 2 or 3 weeks, amber, platelike single crystals of the title compound were collected carefully and air dried.

Magnetic measurements were carried out on single crystals with a magnetometer (905 VTS, SEH Corporation) equipped with a SQUID sensor (SQUID = *s*uperconducting *q*uantum *i*nterference *d*evice). EPR measurements of the X band at variable temperature were recorded on a Bruker ER 200D spectrometer equipped with a helium cryostat. In the experiment the static magnetic field is perpendicular to the long axis of the needlelike single crystal. Infrared spectra in the range 400–4700 cm^{-1} were made on KBr pellets with a FT-IR interferometer Nicolet MX1. Conductivity measurements were performed using the four-probe method on approximately 4-mm long-needlelike single crystals.

Amides as a New Type of Backbone Modification in Oligonucleotides**

Alain De Mesmaeker,* Adrian Waldner, Jacques Lebreton, Pascale Hoffmann, Valérie Fritsch, Romain M. Wolf, and Susan M. Freier

Considerable efforts have been made recently in the structural modification of oligonucleotides.[1] Several properties of the natural 2′-deoxyoligoribonucleotides must be improved for potential therapeutic application of the antisense strategy. For example, the stability of the antisense oligonucleotides towards nucleases must be substantially increased, while the affinity and the specificity for the complementary RNA target is maintained (or even increased). So far, most of the replacements of the phosphodiester linkage that lead to an increased resistance towards nucleases are also connected with a decrease in the affinity for a complementary RNA strand.[1, 2] Two exceptions to this were recently reported in which either an *N*-methylhydroxylamine or a thioformacetal unit was used as a PO_4 replacement.[2a, c]

We proposed to replace the natural phosphodiester linkage in **1** (Scheme 1) by an amide function (as in **2**–**4**), which offers several advantages compared to previously reported modifications.[3] The amide unit is compatible with conditions required

Scheme 1. Structural isomers of oligonucleotide backbones modified by amide linkages.

for solid-phase oligonucleotide synthesis and is also more stable under physiological conditions than the phosphodiester linkage. Furthermore, the lower overall charge of oligonucleotides containing neutral amide groups should facilitate penetration of the negatively charged cell membranes.[4] The amide moiety is readily accessible by simple synthetic methods and is achiral. Thus the formation of diastereomeric mixtures after incorporation into oligonucleotides is avoided.

We disclose here the synthesis of the thymidine dimers **10** (see Scheme 2) having the same substitution pattern in the nucleotide backbone as that in **2**. The incorporation of **10** into oligodeoxynucleotides is described, together with the thermodynamic stability (melting temperatures T_m) of the corresponding duplexes

formed with the RNA and DNA complements, and the resistance of these oligonucleotides towards 3′-exonucleases.

The synthesis of the amide dimers **10** is depicted in Scheme 2. The oxidation of aldehyde **5**[5] to give the corresponding acid **6** was initially performed in two steps: **5** was oxidized with pyridinium dichromate (PDC) in dimethylformamide (DMF) in the presence of methanol to give the methyl ester in 60% after chromatography;[6] subsequent hydrolysis with sodium hydroxide furnished the desired carboxylic acid **6** in almost quantitative yield. Later on, we found that **5** could be oxidized very efficiently with sodium chlorite to provide **6**.[7] Amines **8a–c** were obtained by treatment of **7** with methyl- or isopropylamine (for **8b, c**) or with lithium azide[8] followed by the reduction of the resulting azide with tin dichloride (for **8a**).[9]

Scheme 2. Synthesis of the phosphoramidites **10a–c**. TBDPSi = *tert*-butyldiphenylsilyl. a) $NaClO_2$, 2-methyl-2-butene, NaH_2PO_4, *t*-BuOH, H_2O, room temperature (RT), 2 h (87%); b) R = H, see [8]; RNH_2, THF, RT, 27 h (R = Me (83%), R = *i*Pr (75%)); c) **6**, *N*-methylmorpholine, TBTU, *N*-hydroxybenzotriazole, MeCN, RT, 0.5 h, then **8**, *N*-methylmorpholine, MeCN, RT, 20 h (R = H (86%), R = Me (80%), R = *i*Pr (85%)); d) nBu_4NF, AcOH, THF, RT, 20 h (85%); e) DMTCl, pyridine, RT, 40 h (85%); f) $(iPr_2N)_2POCH_2CH_2CN$, $iPr_2NH_2^+$ tetrazole$^-$, CH_2Cl_2, RT, 40 h (75%).

Carboxylic acid **6** was activated with *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU) and *N*-hydroxybenzotriazole[10] and then coupled with amines **8a–c**. Only the rotamer depicted in Scheme 2 was detected by ^{1}H NMR spectroscopy in the case of the amide dimer **9a** (R = H). However, both rotamers of the N-disubstituted amides **9b**, **9c** were found in solution and identified by ^{1}H NMR NOE experiments.[11] The major rotamer was, in both cases, the one shown in the Scheme 2 (rotamer ratio ca. 4:1 in $CDCl_3$ at room temperature).

The removal of the silyl protective groups with tetra-*n*-butylammonium fluoride in the presence of acetic acid was followed by the selective introduction of the 4,4′-dimethoxytrityl group (DMT) at the 5′ end and the phosphoramidite function at the 3′ end with standard procedures.[12] The solid-phase synthesis of the oligodeoxynucleotides (Table 1) and their purification were performed by standard methods.[13]

Table 1. Melting temperatures T_m of duplexes of modified oligonucleotides and their RNA and DNA complements [a].

[a] **A–D** with RNA complement, **E–F** with DNA complement. [b] **a** = 3′-CH_2–NR–CO–CH_2-4′, (R = H, a_1; R = Me, a_2; R = *i*Pr, a_3). [c] ΔT_m = [T_m(modified oligonucleotide) − T_m(wild-type)]/(number of modifications). [d] Not measured.

The melting temperatures of the duplexes formed between these oligodeoxynucleotides and their RNA and DNA complements are summarized in Table 1.[14] The incorporation of a single amide modification in the middle of the oligonucleotide (**A**) led to an increase in the thermal stability of the duplexes with RNA (+0.9 to +1.0 K). An analogous increase in the affinity for the RNA target is also observed in the case of modification a_1 in the sequences **B** and **D**. A. slight decrease of the stability of the duplex was observed (− 0.3 K per modification) when five a_1 units were introduced in the oligonucleotide (**C**). The same trend was followed by the N-substituted amides a_2 and a_3. However, the destabilization of the duplexes in these cases is rather small, even for the sterically demanding isopropyl group (in a_3). These results indicate that the amide unit a_1 is a good modification in the oligonucleotide backbone and that the introduction of additional substituents on the nitrogen atom does not significantly disturb the structure and the stability of the duplex formed with an RNA complement. The amide modification in **2** also displays a good affinity for a complementary DNA strand (**E** and **F** in Table 1).

These binding data are quite different from the ones we obtained for amides **3**[3b] and **4**:[3c] their incorporation into the same oligonucleotides led to an average drop in the T_m of the duplexes with RNA by −2.9 K per modification for **3** and by −1.6 K per modification for **4**. Molecular dynamics studies (see below) confirmed that the amide modification in **2** adopts a more favorable geometry in the duplex with an RNA complement than those in analogues **3** and **4**. Interestingly, the amide modifications a_1–a_3 destabilize the duplexes formed with the complementary DNA strand (entry **E–F**) more than those with the complementary RNA strand (**A–D**).

Molecular mechanics and molecular dynamics (MD) investigations were undertaken in order to gain insight into the structural features of the modified oligonucleotide backbones.[15] No counterions and solvent molecules were included explicitly at this stage. The permittivity was modulated by the use of a distance-dependent dielectric constant $\varepsilon = 4 \times r_{ij}$, where r_{ij} is the distance separating point charges. In a first step, a hybrid duplex d(CTT**TaT**TTC) · r(GA_6G) composed of an A-form octamer was analyzed with respect to the various possible conformations adopted by the amide linkage 3′-CH_2–CO–NH–CH_2-4′. For this purpose the torsion angles ζ and β (Fig. 1) were changed in 30° increments, and the structure was allowed to relax each time.

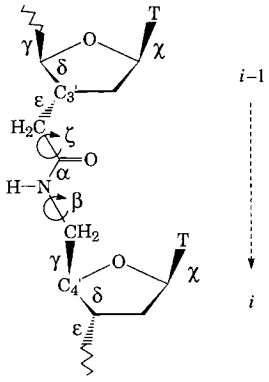

Fig. 1. Definition of torsion angles in a DNA fragment with an amide linkage.

Table 2. Torsion angles [°] at the amide linkage (see also Figs. 1 and 2) [a].

Conformer	Energy [b] [kcal mol^{-1}]	Residue	α	β	γ	δ	ε	ζ	χ
I	0	*i*-1	−75	177	60	77	**178**	**−79**	−157
		i	**170**	**−157**	**166**	85	−155	−62	−169
II	0.5	*i*-1	−74	178	59	75	**171**	**55**	−159
		i	**−172**	**73**	**170**	77	−158	−65	−171
III	2.9	*i*-1	−75	176	58	71	**92**	**81**	−159
		i	**−171**	**157**	**71**	77	−173	−67	−148

[a] Torsion angles in the modified portion C3'-CH_2-CO-NH-CH_2-C4' are in boldface. [b] Relative Amber energy of octamer duplex structure.

Torsion angles ε and γ were left free to adjust during this procedure, the amide bond (torsion angle α) was kept in the *trans* conformation but was allowed to deviate from the default value of 180° from the force field constraints.[16] This approach allowed the identification of several local minima for the conformation of the amide linkage without disrupting the duplex structure at any point during the conformational scanning. Three clearly distinct conformations are shown in Figure 2,[17] and their structural details are listed in Table 2.

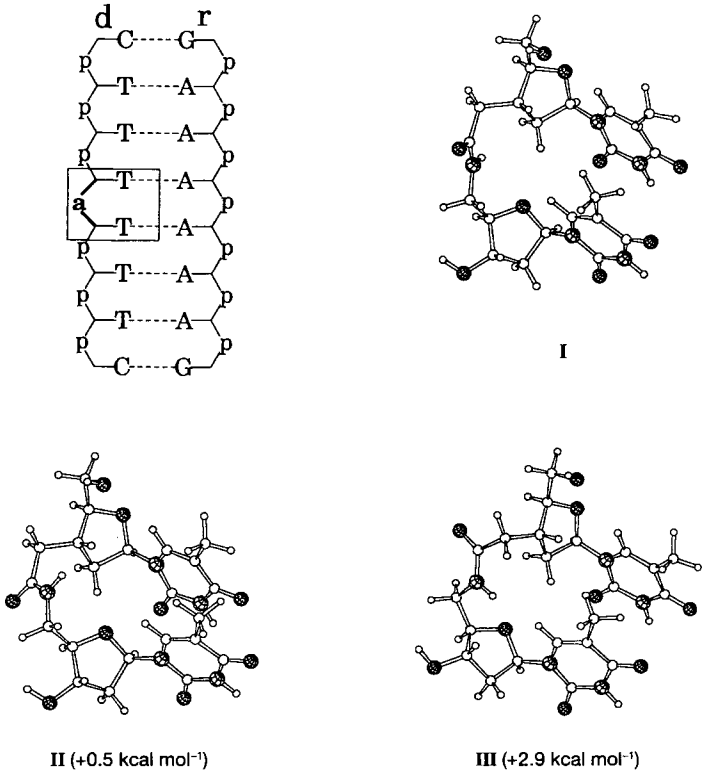

Fig. 2. Structures corresponding to local energy minima for the amide linkage which are cut out of the middle of the octamer duplex (modified DNA) · (RNA) (top left). Energy values are AMBER energies, normalized to the lowest-energy conformer **I**.

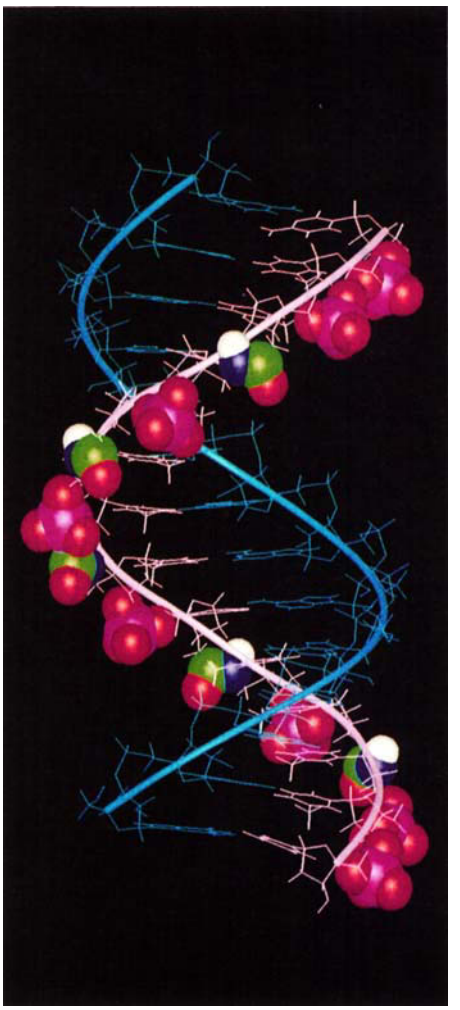

Fig. 3. Fully minimized structure of the 14mer duplex d(CT(**TaT**)$_5$TC)·r(G(A)$_{12}$G). All amide linkages are in the **I** conformation (see Fig. 2 and Table 2 for structural details).

Molecular dynamics studies on 14mer duplex structures with an alternating modified d(CT(**TaT**)$_5$TC) strand and a natural complementary RNA strand (Fig. 3) were carried out for 100 ps at 300 K (progressive heating up to equilibrium in 24 ps). Figure 4 shows the superimposed backbone ribbons of structures spaced by 10 ps for a wild-type d(CT$_{12}$C) · r(GA$_{12}$G) (left) and the duplex depicted in Figure 3, in which all amide linkages are in the conformation **I** at the start of the calculation (right). The dynamic behavior is very similar in both cases, which suggests that the two structures undergo similar oscillations around an equilibrium geometry. Detailed accounts on MD simulations conducted with different starting geometries and the conformational transitions observed will be given in due course.[18]

Compared to the unmodified oligomer, the modified oligonucleotides TCCAGGTGTT**TaT**C exhibit an enhanced resistance

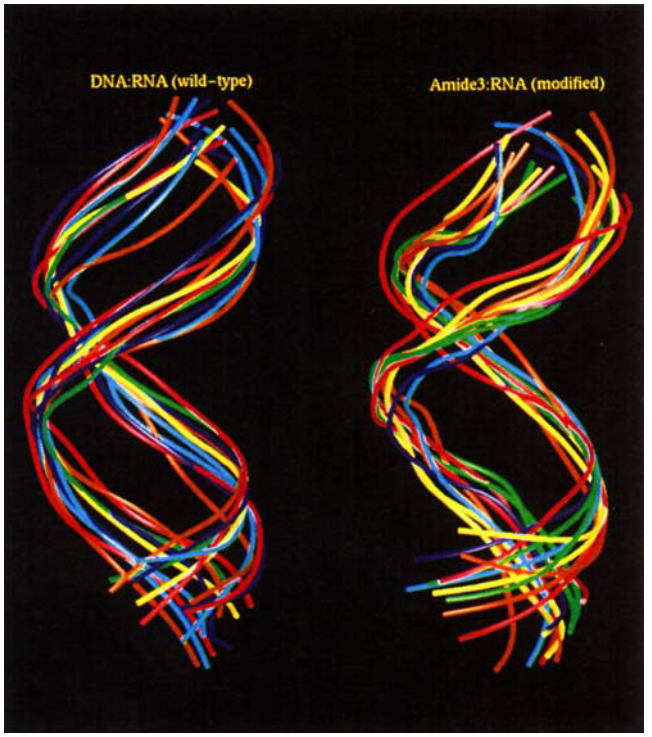

Fig. 4. Superposition of the backbone ribbons of duplex structures. Left: the 14mer DNA · RNA hybrid duplex $d(CT_{12}C) \cdot r(GA_{12}G)$; right: the modified duplex $d(CT(\mathbf{TaT})_5TC) \cdot r(G(A)_{12}G)$ shown in Figure 3. The modified DNA strands start at the upper right.

to hydrolysis by 10% fetal calf serum[19] (predominantly 3′-exonuclease) at 37 °C by factors of 9 and 17 for $\mathbf{a}_2$ and $\mathbf{a}_3$, respectively.

In summary, modified oligonucleotides having the new amide modification in **2** not only display a similar or even slightly higher affinity for an RNA target than the natural analogues, but they are also substantially more stable towards 3′-exonucleases. The introduction of the backbone modification in **2** into biological relevant sequences is under current investigation.

[13] The oligonucleotides were prepared on an ABI 390 DNA synthesizer by using standard phosphoramidite chemistry according to M. J. Gait, *Oligonucleotide Synthesis: A Practical Approach*, IRL, Oxford **1984**, but with prolonged coupling times (10 min). DMT oligonucleotides were purified by reversed-phase HPLC (column: Nucleosil RPC_{18}, 10 μm, 10 × 250 mm; eluent A: 50 mM triethylammonium acetate (TEAA), pH 7.0; eluent B: 50 mM TEAA, pH 7.0 in 70% acetonitrile; elution with gradient from A:B = 85:15 to 55:45 in 45 min). After purification by HPLC the oligodeoxynucleotides were checked by capillary gel electrophoresis (concentration: 35 μg oligonucleotide mL^{-1}; injection: 2 kV, 3; separation: 9 kV; capillary: effective length 30 cm, inner diameter 100 μm, polyacrylamide 10% T; buffer: 100 mM H_3PO_4, 100 mM 2-amino-2-hydroxymethyl-1,3-propanediol (Tris), 2 mM ethylenediaminetetraacetate (EDTA), 7 M urea, pH 8.8). The molecular weight of each oligodeoxynucleotide was checked by mass spectrometry (MALDI-TOF: U. Pieles, W. Zürcher, M. Schär, H. Moser, *Nucl. Acids Res.* **1993**, *21*, 3191). The oligodeoxynucleotide was desorbed from a matrix of 2,4,6-trihydroxyacetophenone (detection of megatively charged ions) with diammonium hydrogen citrate as additive (25 mM final concentration).

[14] The thermal denaturation of DNA/RNA hybrids was performed at 260 nm with a Gilford Response II Spectrophotometer (Ciba-Corning Diagnostics, Oberlin, OH, USA) or a Varian Cary 3 UV/Vis spectrophotometer. The extinction vs. temperature profiles were measured for each strand (4 μM) in 10 mM phosphate (pH 7.0, Na salts) with 100 mM total $[Na^+]$ (supplemented as NaCl) and 0.1 mM EDTA). T_m values were obtained from fitting the extinction vs. temperature curves to a two-state model with linear slope baselines (S. M. Freier, D. D. Albergo, D. H. Turner, *Biopolymers* **1982**, *22*, 1107). All values are averages from at least three experiments. The absolute experimental error of the T_m values is ±0.5 K.

[15] AMBER force field (S. J. Weiner, P. A. Kollman, D. T. Nguyen, D. A. Case, *J. Comp. Chem.* **1986**, *7*, 230), as incorporated in the Insight II (version 2.2.0)/DISCOVER (version 2.9) software from BIOSYM Technologies, San Diego, CA 92121 (USA).

[16] The same procedure was applied with the *cis*-configurated amide group. In this case, the local minima were definitely higher in energy than those obtained with the amide in the standard *trans* conformation.

Inductively Coupled Plasmas in Analytical Atomic Spectrometry. 2nd Edition. Edited by *A. Montaser* and *D. W. Golightly*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. XXII, 1017 pp., hardcover £ 111.00, DM 296.00.—ISBN 1-56081-514-0/3-527-28339-0

Inductively coupled radiofrequency plasmas (ICPs) now play an important role in elemental trace analysis, as radiation sources for optical emission spectrometry and as ion sources for mass spectrometry. This book edited by Montaser and Golightly (which is a revised version of one first published in 1987) gives a comprehensive treatment of the principles and applications of atomic spectrometry using ICP sources. It has been written by a team of 32 authors who have made fundamental contributions to the development and use of ICP atomic spectrometry. The basic principles and different aspects of ICP atomic spectrometry are treated comprehensively, with a wealth of references to the literature on individual topics and applications.

The introduction explains how the ICP, as a source for atomic spectrometry, is related to other types of plasmas. The essential principles and analytical capabilities of direct current (DC) plasmas, microwave plasmas, graphite furnace thermal plasmas, and both DC and radiofrequency glow discharges are all briefly described. The first part of the book is concerned specifically with aspects relevant to atomic spectrometry. The chapter on the fundamentals of atomic emission spectrometry deals mainly with the concepts and methods of plasma physics and plasma diagnostics. Aspects given special attention include the concept of temperature, line-broadening mechanisms, and thermal equilibrium. The chapter on instrumentation for atomic emission spectrometry discusses the principles of spectral dispersion, optical systems, and radiation detection in modern spectrometers. As well as conventional systems some newer developments are discussed, including Fourier transform atomic emission spectrometry and new types of radiation detectors such as charge-coupled (CCD) and charge-injection (CID) devices. The next chapter describes the radiofrequency generators and plasma torch systems used in ICP atomic spectrometry. The chapter on the analytical performance of ICP atomic emission spectrometry gives a clear explanation of optimization procedures, including the simplex method, and of detection limits and interferences. The very important problem of line selection in atomic emission is treated in a separate chapter. High-resolution variants of plasma emission spectrometry and their use in applications such as the analysis of actinides are also discussed as a special topic. This is followed by a chapter on plasma diagnostics and on spectroscopic reference data for ICP atomic emission spectrometry. The first part ends with a chapter describing important applications.

The second part, entitled "Complementary ICP Techniques", begins by describing applications in which an ICP serves as an atomization cell for atomic fluorescence spectrometry. Next comes a detailed description of inductively coupled plasma mass spectrometry (ICP-MS). The importance and performance capabilities of ICP-MS for elemental analysis are discussed, as also are optimization procedures and interferences. Fundamental topics such as the formation of cluster ions and the importance of plasma potentials are then treated. This part ends with a survey of the applications of ICP-MS.

The third part of the book deals with the problems of sample introduction, plasma generation, and mathematical modeling of plasmas. The principles of generating aerosols from liquid samples are treated in detail. A separate chapter then deals with the direct generation of aerosols from solids, including laser vaporization techniques. The injection of gases and vapors, including coupling to chromatography, is also discussed with examples from recently published work. Further chapters deal with the development of plasmas with low gas consumption, the potential for ICPs using gases other than argon, and mathematical modeling of ICPs.

The overall structure of the original edition has essentially been retained, but the part dealing with ICP-MS has been considerably enlarged to take account of recent developments. The authors have also clearly described the current development trends in all the aspects covered. In its updated form this is a standard work that can be recommended to everyone who is either concerned with research on the techniques of plasma spectrometry or uses these methods to solve analytical problems for research or routine purposes.

Sourcebook of Advanced Organic Laboratory Preparations. By *S. R. Sandler* and *W. Karo*. Academic Press/Harcourt Brace Jovanovich, New York, 1992. X, 332 pp., ring-bound $ 59.95—ISBN 0-12-618506-9

Practical laboratory sessions alongside lecture courses are an indispensable part of chemistry training. As well as providing the necessary support to theoretical studies and equipping students with the practical skills that are essential in later professional work, they allow them to experience successes which can keep up their motivation during parts of the course where enthusiasm temporarily wanes. Thus there is a need for a well-chosen and proven collection of preparations. It is satisfying for the student when a preparation works and provides a sudden insight ("aha effect"); if it also affords an opportunity to work on the semi-micro or even micro scale, the satisfaction is still greater. A good collection of student laboratory preparations should include an appropriate amount of introductory theoretical background, information about potential dangers, and brief instructions about the disposal of waste products.

A number of good practical workbooks for the teaching of organic chemistry already exist, and that reviewed here is a useful addition to these. The two authors have already established their reputation with six larger volumes of preparative methods: *Organic Functional Group Preparations I*, **1983**; *II*, **1986**; *III*, **1989** and *Polymer Syntheses I*, 2nd Edition, **1992**; *II*, **1977**; *III*, **1980**. Some well-proven methods have now been taken from these and collected together in a convenient form in a ring-binder. Most of the preparations are also suitable for carrying out on a semi-micro scale. Significantly, some polymerizations have also been included. A short explanation of the theory precedes each one of the 41 sections, arranged by compound classes as follows: Paraffinic/Aromatic Hydrocarbons, Olefins, Acetylenes, Alcohols/Phenols, Ethers/Oxides, Halides, Aldehydes,

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0202-0231 $ 10.00+.25/0*

Ketones, Carboxylic Acids, Esters, Amides, Cyanates/Isocyanates/Thiocyanates/Isothiocyanates, Amines, Hydrazine Derivatives/Hydrazones/Hydrazides, Diazo and Diazonium Compounds, Nitro Compounds, Nitriles, Mercaptans/Sulfides/Disulfides, Sulfoxides, Sulfones, Sulfonic Acids, Allenes, Ortho Esters, Sulfites, Enamines, Ynamines, Ureas/Polyureas, Carbodiimides, *N*-Carbamates, *O*-Carbamates, Imines, Azides, Azo-/Azoxy Compounds, Acetals/Ketals, Anhydrides, Monoalkyl Sulfates, Amidines, Imides, Oximes, Hydroxamic Acids, Polymer Preparations. The 172 preparations for which detailed laboratory recipes are given are based on original papers (with references). Other analogous preparations are also listed in tables together with literature references and data on the conditions. Where appropriate the authors draw attention to special features and/or dangers. However, in a future edition they should, right at the start, substitute safe alternatives for chemicals that carry special risks, for example benzene as substrate or solvent (the carcinogenicity of which is mentioned in the preface).

Measured against the requirements of German university courses, this "Sourcebook of Advanced Organic Laboratory Preparations" should be regarded as a good basis for organic chemistry practical work rather than a book for advanced students. It is mainly suitable for students of chemistry (including those training as teachers) and of pharmacy, and it can also be used to advantage, as the authors suggest, for training people in industrial laboratories. Many of the examples could also be used in practical courses for students of neighboring disciplines, since the authors have evidently taken into consideration the time restrictions that affect many practical classes. Important general working techniques of organic chemistry are explained on the basis of typical examples, and many of the preparations afford opportunities for combining with practice in the use of modern analytical methods. Unfortunately, however, some traditional and well-proven methods are missing (e.g., in the synthesis of mercaptans and ureas), nor are there any examples of natural products syntheses. The Appendix contains very useful advice and explanations regarding standard laboratory practices.

The authors' chosen system of classifying the preparative methods according to compound classes and functional groups is a long proven one. However, in a future edition perhaps more emphasis could be put on the second most practicable method of classification, by reactions of functional groups; this could be done by providing an index on this basis instead of the present "Name Reaction Index". In summary, the book by Sandler and Karo is well suited for organic chemistry practicals in universities and colleges, and departments should add it to their range of teaching resources.

der Universität Rostock (FRG)

Die Allianz von Wissenschaft und Industrie. August Wilhelm Hofmann (1818–1892). Edited by *C. Meinel* and *H. Scholz*. VCH Verlagsgesellschaft, Weinheim, 1992. X, 375 pp., hardcover DM 148.00.—ISBN 3-527-29009-5

This book was published to mark the centenary of the death of August Wilhelm Hofmann, which coincided with the 125th anniversary of the foundation, through Hofmann's initiative, of the German Chemical Society (Gesellschaft Deutscher Chemiker, GDCh). It contains a loosely structured collection of 22 essays (14 in German and 8 in English) by an international team of authors, in which they discuss the many different aspects of the work of this great patriarch of modern organic chemistry.

In the introductory chapter Heindirk tom Dieck (Frankfurt) gives a brief account of the development and aims of the GDCh, whose early stages were decisively influenced by the personality of A. W. Hofmann. Here one already becomes aware of the close collaboration between academic and industrial chemistry, and this is examined in more detail in the following chapter ("Wissenschaft, Industrie und Kultur zur Zeit A. W. Hofmanns", by Lothar Burchardt, Konstanz). It is sobering to find that many of the problems of concern to university chemists at that time still persist today with only minor shifts of emphasis, even though their dimensions are now quite different: growing student numbers, the degree of autonomy of the universities and of professors, the interplay between research and teaching, the demarcation between the universities and the Technische Hochschulen, the setting up of new faculties, and so on. Even the quite ardently displayed cultural pessimism that is now so fashionable, not only among many intellectuals but also among some politicians, and which is manifested in vaguely expressed criticisms of technology, was already active in that period when scientific societies were being founded and the large-scale chemical industry was becoming established. Despite this, more farsighted minds recognized in good time that the development of culture and civilization is closely related to scientific and technological progress, resulting in a promotion of scientific and cultural studies that was unique throughout the world. It is only against this background that one can appreciate the importance of Hofmann's contribution as a pioneer of new forms of cooperation between universities and industry.

Christoph Meinel (Regensburg) then examines in greater depth the social and political environment within which Hofmann, the reigning "Chief Chemist" of his time, pursued a career which took him from Liebig's laboratory in Gießen on to Bonn and London, back again to Bonn, and finally to Berlin. Hofmann soon came to be recognized as *the* standard-bearer for the revolutionary ideas of Liebig, which were concerned with a teaching based on experimental research that also attracted much attention in England. It was therefore quite consistent when in 1845, at the age of 27, he was appointed as the Principal and first Professor of the Royal College of Chemistry in London, where he was to set up a science-orientated teaching institution. Chemical research too was at that time undergoing a change of emphasis, from analysis towards the development of directed syntheses. In this context Hofmann used the concept of compound classes or substitution and type theory as a sort of template to systematically identify new structures. He became a prominent public figure through his wide-ranging activities in helping to organize world exhibitions, as President for a time of the Chemical Society, and as a lecturer on popular scientific themes. Following his return to Berlin in 1865, Hofmann used his influence, based on the scientific reputation built up while in England, to place chemistry in a key position in the modernization of the universities. Nevertheless, Meinel does not forget to mention that Hofmann's pompous conceit and self-adulation, though perhaps understandable in view of the "zeitgeist" of the time, earned him severe criticism, even from close colleagues.

In the next three chapters British authors discuss the influence of A. W. Hofmann and the Gießen academic tradition on scientific culture in Britain. Colin A. Russell (Milton Keynes) emphasizes the role of Hofmann as cosmopolitan scientist, in his friendships with the top European scientists of the time, and even with the British Royal Family. Through his fluency in the English language he contributed to the Journal of the Chemical

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0232 $ 10.00+.25/0

Society becoming internationally recognized, and later in his homeland he modeled the GDCh on the pattern of the Chemical Society of London. Unfortunately Russell is guilty of an annoying lapse in forgetting to mention Georg Wittig in his gallery of Hofmann's successors; Wittig worked with Hofmann's former student K. von Auwers in Marburg at the same time as Karl Ziegler. Next William A. Brock (Leicester) analyzes several of Hofmann's lectures aimed at popularizing chemistry, in which time and again, in language illuminated by many metaphors, he emphasized the importance of his subject to culture and the standard of living and argued for greater state support. Gerrylynn K. Roberts (Milton Keynes) takes the view that Hofmann's twenty years in England mirror an "uneasy balance between pure and applied science", and that he also felt this in his work at the Royal School of Mines. He persisted in his efforts to replace the practically- and analytically-orientated teaching in these institutions by chemistry studies with a greater scientific content, but it was not until the time of his return to Berlin that these courses were introduced at the then newly founded Royal College of Science in Dublin.

In the first of the strictly science-orientated chapters Michael N. Keas (Norman, USA) discusses Hofmann's work on the nature of organic bases, which led to the development of a theory of the ammonia type. Keas describes how, from 1865 onwards, Hofmann went on from this to propose a "truly natural chemical classification system, a structurally-interpreted type theory consisting of the hydrochloric acid, water, ammonia, and methane types."

Under the title "Science and Technology for an Empire", Anthony S. Travis (Jerusalem) examines the significance of Hofmann's work to the chemistry of the coal-tar and aniline dyes and their commercial development. Important contributions were made in this area by other German chemists who also worked in England at that time (Heinrich Caro, Carl Alexander Martius, Peter Griess, etc.) and, of course, by William H. Perkin, the discoverer of mauveine who was also one of Hofmann's former students. Travis identifies the wide-ranging exchange of ideas between Hofmann and Caro (who was influenced by Hofmann to switch from being a colorist to a chemist) and several British and German dye manufacturers as the starting point for the rise of the first ever science-based industry.

The discussion by Hans-Werner Schütt (Berlin) of the state of chemistry in Prussia before A. W. Hofmann, which comes next, should actually be read immediately after the chapters by Burchardt and Meinel, as this too is concerned with the sociopolitical and educational environment of the times. It deals mainly with Liebig's criticisms against the view taken by the Prussian cultural administration that chemistry was not a fundamental science, and therefore did not justify treatment as an independent area of study. Liebig's arguments seem to have made a considerable impression in Berlin, because after the death of his adversary Eilhard Mitscherlich, A. W. Hofmann was appointed in his place to bring into this region too the new ideas of an inquiring way of teaching. Next is a study by Regine Zott (Berlin) of the ideas that Liebig and Hofmann had in common and those that were unique to each one; like the previous chapter, this really belongs with the introductory essays. The central thesis is that although the two scientists had much in common and both fought with great tactical skill for the independence of their subject, chemistry, they differed quite substantially in their attitudes towards theoretical, philosophical, and political matters. Although the younger of the two, Hofmann was more conventional and bound by the mores of his time than was his more ambitious teacher and friend Liebig.

According to Willem J. Hornix (Nijmegen), the assessment by Hofmann's contemporaries and biographers of his role in the development of the dyestuffs industry has assumed almost mythical dimensions. Hornix then critically analyzes Hofmann's scientific contributions in the dyestuffs field; here again the wider social context and the international ramifications of these studies become apparent. It is interesting to note that Hofmann's influence continued to dominate even when his incorrect ideas regarding the structure of the aniline dyes, based on an ammonia-type analogy, came into conflict with Kekulé's (correct) triphenylmethane structures.

Jeffry A. Johnson (Villanova, USA) contributes another view from abroad on "Hofmann's Role in Reshaping the Academic–Industrial Alliance in German Chemistry", in a detailed and informative discussion including the political background. He deals sympathetically with Hofmann's concerns about the needs for modern teaching establishments with the ability to undertake pure research, for an effective German patents system, and for arranging collaboration between universities and industry through the medium of the scientific learned societies. These efforts eventually won important advantages for Germany's chemists and industry, indicating certain causal connections of which people need to be reminded, especially now.

A quite different topic is addressed by Elisabeth Christine Vaupel (Munich) in her article on Hofmann's role in relation to chemistry at the world exhibitions. We learn how Hofmann, through his brilliant reporting as an adjudicator, systematically worked himself up into a position of authority which gave him a wider forum in which to propagate his views on the balance between pure and applied research. However, these clever tactics were strongly criticized by many of his colleagues, who accused him of seeking prestige, collecting positions of authority, and misusing power ("shameless" patronage, e.g. in the awarding of honors), and viewed these as evidence of serious human weaknesses. From the environmental standpoint it is interesting to learn that even then (about 1855) there were already worries about the toxicity of pigments containing lead and arsenic.

Soná Strbánová (Prague) describes how the influence of Hofmann's work spread into eastern Europe, in her article on the Liebig and Hofmann schools at the Prague universities and the development of chemistry in Bohemia. The Czech University and the independent German Technical University, both in Prague, modeled their chemistry teaching departments directly or indirectly on Hofmann's ideas. Of course, as Hartmut Scholz (Berlin) recounts, Hofmann also took part in the controversial discussions that went on during the latter third of the 19th century regarding the reform of chemistry teaching in the German schools, colleges, and universities. The questions of status that were at issue then were basically similar to those of today, with arguments about the relative merits of the Gymnasium and the Realschule, of the academic and technical universities, of state examinations and the dissertation system, or about the separation of the sciences from the philosophical faculties.

In view of Hofmann's numerous connections with color chemistry and the dyestuffs industry, the next two chapters occupy a key position in this collection of essays. In a historical sketch entitled "Farbstoffe zu Hofmanns Zeiten und heute" (Dyestuffs in Hofmann's Time and Today) Peter Suchanek (Bayer, Leverkusen) discusses the most important discoveries and processes in this field from an industrial standpoint. His account includes the latest developments in color printing inks, laser dyes, color formers,

and ink-jet printers, and highlights the increasing emphasis on environmental aspects in product-orientated research. Siegfried Dähne (Berlin-Adlershof) then considers the theoretical aspects of dyes under the title "Structur-Farbe-Beziehungen im Wandel der Zeit" (Structure-Color Relationships Through the Changing Times). After pointing out that because Hofmann clung to the type theory throughout his life he was unable to arrive at a deeper understanding of the relationship between structure and color, Dähne systematically describes how the different dye color theories developed, from the chromophore theory through the mesomeric school and the polymethine concept to the modern methods based on quantum-chemical calculations. The unavoidable sacrifice of transparency with the latter methods is offset by the following explanation of the heuristically impressive triads principle with its simple color rules.

The reactions that carry Hofmann's name are still used in modern synthetic chemistry, as Hans-Georg Henning (Berlin) shows by describing several examples; unfortunately a slight mix-up has occurred here in the correspondence between text and formulas. But only when we come to the article by Herbert Teichmann (Berlin-Adlershof) with the title "Phosphorchemie bei A. W. Hofmann und heute" (Phosphorus Chemistry in A. W. Hofmann's Time and the Present) are we reminded that Hofmann, in addition to his "great" reactions and investigations, also carried out fundamental studies on phosphorus chemistry which contributed significantly to our present knowledge in this area. In reviewing this work, Teichmann reveals among other facts that in his synthetic studies in this field Hofmann used the Umpolung principle for the first time. Next Günther Wess (Hoechst, Frankfurt) discusses synthetic methods for pharmaceuticals and aspects of medicinal chemistry, and shows that here too there are many fascinating connections with Hofmann's work. This is not only because some of the pharmaceutical compounds known in Hofmann's day were based on the aniline structure; in addition a number of the compounds and reactions that he discovered are still used nowadays in medicinal chemistry. Moreover, the author maintains that in his conceptions of organic chemistry in relation to medicines Hofmann correctly predicted some important later developments.

The chapter entitled "Geschichte der Schering AG—Von der grünen Apotheke zum Chemiekonzern" by Gerd J. Wlasich (Berlin) tells the story of the development of Schering AG from its origins as a small Berlin pharmacy during Hofmann's period in the city, a pattern of development that is typical of many of the major present-day chemical companies. A central theme of the article, and one that again underlines the leitmotif of this book, is the close contacts that existed between the industrialist Ernst Schering and the chemists at Berlin University. Schering also participated in the formation of the GDCh in 1867, and he continued to serve as the Society's treasurer until 1880.

The final essay by Uwe Biethan (Marl) discusses Hofmann's work in relation to modern polymer chemistry. It could well have been entitled "Missed Opportunities", as it shows that on many occasions Hofmann was very close to a breakthrough into polymer chemistry, but failed to follow through the crucial chain of perception. For example, although he described polystyrene he was not the first to discover it, and although he made formaldehyde and oligomerized it he did not follow this up further. Similarly, in his work on (iso)cyanate chemistry he passed within a hair's breadth of stumbling upon the polymer concept, but the polyamine and polyaniline plastics that were later to be derived from his favorite objects of research lay beyond his horizon of experience.

This extensive account of the personality and work of A. W. Hofmann—who is rightly described at several points as the "first Eurochemist"—is in my view an unqualified success. By bringing together the contributions of authors who approach their material from the widely different backgrounds of the academic scientist, the science historian, and the industrial chemist, the book gives us a very complete, though also critical, picture of one of the leading figures in the early development of our science, and of his interactions with the scientific, economic, and sociopolitical network of the time, which already then extended throughout Europe. However, it would have been useful to have some more views about the spread of the influence of Hofmann's work into the cultures of southern and eastern Europe. Also it would have been a good idea to include short biographical notes about the authors, especially as there is in fact enough space for this at the ends of the chapters. I can thoroughly recommend this book to everyone with a serious interest in chemistry. Professional chemists might spend a few contemplative hours away from the hectic activity of their everyday work, and students could well benefit from the relaxation that it offers during the toughest periods of preparing for examinations. The book is suitable for dipping into to read individual chapters to suit one's interests and mood. Readers who appreciate the special appeal of centenaries might like to recall that just a century *before* Hofmann's period of work in England (1845-1865) another great German, the master of baroque music Georg Friedrich Händel, celebrated his triumph there, whereas exactly 100 years *after* Hofmann's arrival in Britain another great innovator of chemistry, Otto Hahn, together with his colleagues from the German atomic research fraternity, became a rather unwilling guest of that nation and there witnessed the end of the war.

Immunosorption Techniques. Fundamentals and Applications. By *P. Mohr, M. Holtzhauer* and *G. Kaiser*. Akademie Verlag, Berlin, 1992. VIII, 173 pp., hardcover DM 112.00.—ISBN 3-05-501350-6

The authors of this book have set out to give a comprehensive review of immunosorption techniques. They describe the basic principles of the methods in an easily understandable way and discuss the various applications. In particular the compilation of examples from the literature makes the book required reading for all who would like to apply this modern methodology but lack experience of their own to draw on.

In the first chapter the authors give a concise and informative explanation of the basic features of the immune system. The structure of antibodies, their interaction with antigens, the concepts of affinity and avidity, and other relevant topics are all treated in adequate depth.

Chapter 2 discusses in considerable detail the choice of substrate and methods of activation and coupling. The extensive tables giving details of the functional groups of the various substrate materials, different methods of activation, and reactive groups in biomolecules that can be used for coupling, together with relevant literature references, provide the beginner with a very useful overview. Ways in which the biological activity of biomolecules can be altered by coupling or modification are also discussed, using antibody binding properties as an example. The favorable impression conveyed by this chapter is reinforced when the authors give details of laboratory procedures for the activation of substrates and for determining the degree of activa-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0234 $ 10.00+.25/0

tion. The relationship between the pretreatment of an affinity column (for example), the coupling method chosen, and the conditions for adsorption and desorption of the protein to be isolated is clearly explained. The various methods and buffer systems are usefully summarized in tables. Lastly the authors discuss the avidin–biotin system, but their treatment of this standard system is very brief.

Chapter 3 deals with the isolation of antibodies, haptenes, and antigens. Nearly 50 pages are devoted mainly to a very detailed treatment of the isolation of antibodies. As well as immunosorption chromatography the authors discuss precipitation methods and ion exchange chromatography with a degree of detail that seems inappropriate for a book of this kind. Although it is true that antibodies are an important element in immunosorption methods, this book would certainly not be one's only source of help on isolation techniques if the required antibodies were not commercially available and had to be prepared in one's own laboratory.

The final chapter is concerned with immunoassay, immunoblotting, and immunosensors. Immunoassay techniques especially are now very important and widely used, and are based on the principle of immunosorption. It would therefore have been useful to give some guidelines for potential users of these techniques, but unfortunately the various detection systems are only listed in a table, without a more detailed discussion of their advantages and disadvantages. In contrast the second section deals with immunoblotting in considerable detail. The different blotting techniques are compared and general procedures are given. There is a very useful survey, in the form of a table with literature references, of the various membranes, transfer buffers, etc. The authors also discuss important questions such as the sensitivity of different dyeing methods. The last section deals briefly with immunosensors and their classification according to the different detection principles. The depth of treatment here is adequate, since immunosensor techniques have not yet become established in routine use, partly because the detection systems are very complicated.

To summarize, this is a useful book within certain limitions. It can be recommended to everyone who seeks a review of immunosorption techniques. Specialists in the field must decide for themselves whether the information presented in the tables is worth the price.

Crown Compounds: Toward Future Applications. Edited by *S. R. Cooper*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. 325 pp., hardcover DM 218.00.—ISBN 1-56081-024-6/3-527-28073-1

This book aims to discuss the potential applications of crown ethers and related synthetic macrocycles. As the editor states in the preface, there are now a number of excellent books and reviews on the fundamental aspects of macrocyclic chemistry, or on the broader perspectives of supramolecular chemistry. The book attempts to give a *prospective* view of the field and to answer the question: "Where are these research fields going?". In fact there are two different aspects: future applications and future *developments* which need not necessarily lead to applications. The result of this concept is a mixture of everything, which is not surprising with 16 different (groups of) authors.

Applications, current and future, are clearly addressed in seven of the 16 chapters. In Chapter 2 Chen and Echegoyen briefly discuss the separation of isotopes by redox-switched ligands. An excellent contribution by D. Parker (Chapter 4) gives an overview of the use of macrocycles as ligands for immobilizing radioisotopes with medical applications. He briefly discusses clinical analysis and in more detail diagnostic and therapeutic agents.

Martell describes in Chapter 7 the possibilities of selective complexation (and transport) of molecular oxygen by binuclear macro(bi)cyclic complexes, in the context of a more general overview of this class of compounds. Frabbrizzi et al. include the transport across liquid membranes in their contribution on cyclams (Chapter 9). The same application is dealt with more specifically for enantiomeric recognition by Izatt et al. in Chapter 12. Applications of molecular recognition in sensors are probably the most advanced at present. Sutherland describes one possible application of this kind to chromogenic reagents and chromoionophores. The recognition process is transduced via a light signal in an optical fiber based sensor. The more widely studied potentiometric sensors (ISE and CHEMFET based) are not represented.

In Chapter 16 T. W. Bell describes his planar macrocyclic ligands, the torands, and their possible application in discotic liquid crystalline materials. In Chapter 15 the editor, S. R. Cooper, has succeeded well in his aim to discuss future applications. The coordination chemistry of 99Tc, applied in nuclear medicine, is a good example of the advantages gained by using a specific ligand. Together with Parker he has covered this area very nicely.

Most other chapters review the current status of the authors' individual research topics. Since there are several recent books and review articles, some duplication of existing literature is unavoidable. Gokel and Nakano describe cation complexation, ion channels, and the different chemical structures that introduce selectivity. According to these authors future developments in this field will eliminate artificial barriers between disciplines, such as organic/inorganic or biological/synthetic. In Chapter 3 G. R. Newkome presents a short outline of the development of the research on macrocycles in his group, from the early pyridocrown ethers to the recently described arborols.

Several chapters (5, 6, 8, and 10) deal with different aspects of nitrogen macrocycles. The authors, Adam and Lindoy (Chapter 5), Kimura (Chapter 6), Kaden (Chapter 8), and Hannock (Chapter 10) emphasize the influence of the ligands on the properties of the complexed metal ions. In Chapter 11 Seel and Vögtle describe large tailor-made molecular cavities. The analogy with the natural siderophores, inclusion of neutral guest species, and photophysical properties of complexed ions are the topics discussed. The sulfur analogues of crown ethers have received less attention than the all-oxygen macrocycles. However, in Chapter 14 Kellogg describes how these ligands can be synthesized and their role in the complexation of metal ions such as Ag, Hg, and Pb.

In conclusion, this book offers a random selection of topics in the rapidly growing field of supramolecular chemistry. As a consequence the picture is far from complete. The quality of the individual chapters varies from good to excellent and there is no doubt that the authors are experts in their fields. I would have preferred to have more applications-oriented chapters, in accordance with the expectation raised by the title. This book is a good choice for those entering specific areas of supramolecular chemistry.

Chemical Communication. The Language of Pheromones. (Scientific American Library Series, Vol. 41.) By *W. C. Agosta*. Scientific American Library, New York/Freeman, Oxford, 1992. IX, 179 pp., hardcover £ 17.95.—ISBN 0-7167-5036-8

The term "semiochemicals" refers to substances that transmit signals and are used by living organisms to exchange information. This book is concerned with the isolation and identification of such substances, their chemical structures, and their biological functions. The seven chapters contain lively and exciting accounts of how chemical communication is achieved in microorganisms, animals, and humans. In each case the author first explains the biological background to the phenomena described, then goes on to the isolation of the biologically active compounds, and lastly the elucidation of their structures and the effects of the corresponding synthetic products. He has taken particular care to emphasize general principles, and has not been afraid to introduce a number of simplifications (and even inaccuracies) in the interests of a unified and rounded overall presentation. For example, the word "pheromone" in the title strictly includes only intraspecific signal transmitting substances, but fortunately this restriction has been relaxed in the text. It was sensible to omit details of the synthesis of the relevant substances in this context, but it would have done no harm to include more information about biosynthesis and sensing mechanisms.

The book begins with a brief introduction to "molecular messengers", which is followed by a chapter on gamete attractants in brown algae and molds and on bacterial pheromones. Chapter 3 describes tracking and alarm substances, and attractants and concealment substances relevant to sea anemones, snails, crabs, mites, and ticks. Chapter 4 is the longest with 40 pages, and describes the various ways in which insects use chemical substances for communication. The topics include the structures and mechanisms of the sexual pheromones of female butterflies. Also included, of course, is the remarkable story of the male butterfly, which feeds on pyrrolizidine alkaloids, firstly to protect itself from enemies, and secondly to ensure successful reproduction and protect the offspring (one really must read this!). Compounds that regulate the aggregation behavior of bark beetles are discussed, as also are the complex systems of bees and ants in the formation of colonies. This chapter also explains the importance of pheromones in selective pest control. Chapter 5 is concerned with fishes and amphibians, and Chapter 6 with pheromones in mammals, a subject which is not yet clearly understood due to the experimental difficulties. Chapter 7 ("Human Attractions") deals with the delicate subject of pheromone communication in humans, covering perfumes as well as odor substances of human origin. (It is interesting that humans wash to remove the individual odors that they undoubtedly possess, then strangely seek to give their "neutralized" bodies a new "individual aura" by the use of a perfume.)

Chapter 7 is followed by a glossary, an important aid for the non-specialist reader. However, if this had been made more comprehensive and had been better integrated into the book by appropriate references in the text, it would have avoided the need to interrupt the latter with explanations (mostly of common chemical terms), thus improving the flow. Also the index could have been made more useful by including a greater number of keywords. The figures vary from good to very good (although some of the drawings seem a little childish). The formula diagrams are (almost) free from errors, although those of brevicomin on page 77 (an aggregation-controlling substance in certain species of bark beetles) and dehydrobrevicomin on page 144 (inactive in itself but a component of an aggression-inducing pheromone complex in mice) both lack the methyl group on the acetal carbon atom. Although *cis–trans* isomerism is explained twice (pp. 7 and 161), it is startling to find that the concept of chirality is neither mentioned nor taken into account, even pictorially, in the formula diagrams of the relevant compounds—this despite the fact that the absolute configuration of chiral natural products is often essential to their biological activity!

However, the author has produced a book which is a pleasure to read and should find friends even at school level. It presents in a small space a great wealth of information, and clearly shows the interdisciplinary nature of research into the fascinating subject of chemical communication. Everyone interested in this field, whether as an expert or an outsider, a biologist or a chemist, should buy this attractive book.

Phthalocyanines. Properties and Applications. Vol. 2. Edited by *C. C. Leznoff* and *A. B. P. Lever*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XI, 305 pp., hardcover DM 268.00.—ISBN 3-527-89544-2/1-56081-544-2

In 1983 Moser and Thomas's two-volume text on phthalocyanines provided an excellent summary of the chemistry, properties, and applications of this remarkable series of macrocycles known up to that time. Attention was drawn to their well established importance as industrial pigments and dyes and their use as oxidation catalysts. Now, ten years on, Leznoff and Lever have produced the second volume of their most welcome series "Phthalocyanines—Properties and Applications", reviewing more recent developments in the field. These have been extensive, stimulated to a considerable degree by the growing interest in the new disciplines of molecular electronics and materials chemistry. Such are the unique properties of the phthalocyanine ring system that there is now world-wide research into its use in gas sensors, displays, data storage systems, fuel cells, solar cells, electrophotography, and photodynamic therapy. This in turn has stimulated a renewed interest in probing the fundamental science of the phthalocyanine ring, in designing new derivatives with particular properties, and in investigating new formulations of phthalocyanines as thin films and mesophases.

The second volume of this new series maintains the high standard set by the first (1989), providing in this case a glimpse of the range of phthalocyanine and phthalocyanine-type structures available, some detailed spectroscopic evaluations, new studies of catalytic function, and investigations of thin film formulations and mesophase behavior. The six chapters are written by authorities in their particular areas, with an interesting mix of general overviews and accounts of work from the authors' own laboratories.

Chapter 1 by Ercolani and Floris ("Metal Phthalocyanine Single-Atom Bridged Dimers", 41 pp., 101 references) surveys derivatives containing five- or six-coordinate metal ions linked via an oxygen, nitrogen, or carbon atom. The review covers aluminum, titanium, manganese, ruthenium, and iron derivatives with particular emphasis given to the complex chemistry of the last of these, unravelling sometimes conflicting information. Mössbauer spectroscopy has been useful in this regard, and the application of this technique to variously substituted iron

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0236 $ 10.00+.25/0

phthalocyanines is dealt with in greater depth by Hanack, Keppeler, Lange, Hirsch, and Dieing in Chapter 2 ("Mössbauer Spectroscopy of Phthalocyaninato-Metal Complexes", 53 pp., 157 references). These authors present extensive data, collected from the standpoint of the organic chemist viewing the method as a means of characterizing materials. As well as work on iron derivatives, the authors also survey the much less extensive data available for tin complexes and iodine-doped complexes.

There are a number of macrocycles related to phthalocyanines by benzofusion, including naphthalocyanines and anthracyanines, and others containing features which help forge a continuum of molecular structures between the phthalocyanines and the porphyrins, eg. the tetraazaporphyrins and the benzporphyrins. These and a host of other ring systems are discussed by Kobayashi in Chapter 3 ("Synthesis and Spectroscopic Properties of Phthalocyanine Analogues", 65 pp., 255 references). Many deserve more extensive investigation but their synthesis requires both skill and patience; a researcher new to the area should heed the author's closing comment to the effect that few, if any, of the systems are synthesized as easily as the parent phthalocyanine ring.

In Chapter 4 ("Thin Film Phthalocyanine Chemistry and Technology", 30 pp., 59 references) Saji gives an account of his group's work on the electrochemical formation of thin films by disruption of micellar aggregates (the MD method). Phthalocyanine particles are released when surfactant molecules adsorbed on them are electrochemically oxidized, allowing the pigment particles to be deposited as an even film on the electrode. Spectra of the films are similar to those of the original particles, indicating that the method provides a means of generating good quality films of different polymorphic forms. Chapter 5 ("Catalytic Functions and Applications of Metallo-Phthalocyanine Polymers", 25 pp., 13 references), by Hanabusa and Shirai, provides another account of research undertaken primarily within the authors' own laboratories and highlights a number of enzyme-like catalytic functions of metallo-phthalocyanines. One of the intriguing potential applications of the chemistry lies in its deodorant action; metallophthalocyanines effectively catalyze the decomposition of offensively smelling gases.

The final chapter by Simon and Bassoul ("Phthalocyanine Based Liquid Crystals: Towards Submicronic Devices", 76 pp., 174 references) gives an overview of those heavily substituted phthalocyanine derivatives that exhibit discotic mesophase behavior and offers a thoughtful analysis of factors controlling mesophase formation. Drawing heavily on their own substantial contributions in this area, including analysis of energy transport and charge transport within columnar mesophases, the authors have provided a chapter which will be of interest to those working on both phthalocyanine and non-phthalocyanine based liquid crystals.

With regard to the production of the present text, purists may regret the move from the typesetting of Volume 1 to the camera-ready copy of Volume 2, a consequence of 'the fiscal realities of the early nineties'. This has resulted in small variations in the typeface between chapters and has favored retention of minor idiosyncracies in style and presentation introduced by the different contributors; at the extreme, one chapter contains structural representations of the phthalocyanine nucleus in which just four of the nitrogens are drawn in. But these are minor quibbles over a text which will certainly be much referred to and cited in years to come. In short, it should prove invaluable to those working directly with this class of compounds, academics and industrialists alike, and will be of interest to those involved more generally in research into advanced materials.

The Chemical Bond. Structure and Dynamics. Edited by *A. Zewail.* Academic Press, New York, 1992. XV, 313 pp., hardcover $ 49.94.—ISBN 0-12-779620-7

This book is based on a symposium held on 28 February 1991 at the California Institute of Technology (Caltech) to celebrate the 90th birthday of Linus Pauling. What could be more appropriate than to honor the author of the famous book "The Nature of the Chemical Bond" by publishing a book on the same subject? For this purpose the organizers brought together a number of eminent scientists who have made important contributions to the understanding of the chemical bond. Naturally Linus Pauling himself contributed papers, not only one on the historical aspects but also a report on recent progress with a problem of structural chemistry. There could be no better demonstration that the Linus Pauling era certainly does not yet belong to the past.

The nine articles are arranged under two headings: "Structure" and "Dynamics". The structure group is opened by Linus Pauling with a brief historical survey of the development of crystal structure analysis by X-ray diffraction. As early as 1922, scarcely nine years after the discovery of this method, Pauling began his own researches in this area. During the following years many structural principles were discovered and these have contributed significantly to the understanding of the chemical bond. The discovery of the alpha helix in 1948 was undoubtedly a high point. However, the computation times needed then were enormous, amounting to years for difficult structures. Although many thousands of structures have since been determined, Pauling is rather disappointed that this has revealed few new structural principles. He sees an exception to this in the field of metals and intermetallic compounds.

In the second article Max Perutz reviews structural studies on hemoglobin, myoglobin, and related proteins. He was motivated to begin work in this area by predictions made by Pauling, who postulated that hydrogen bonds had an important influence on the stability of proteins, and suggested that hemoglobin would be a very interesting system for structural analysis. Both these views were to be subsequently confirmed, although the structural analysis was not completed until 30 years later. Experiments with naturally occurring mutants and variants made by genetic engineering methods yielded detailed information about the mechanism whereby oxygen becomes bonded to the heme molecule. This work eventually led to the discovery of a new type of hydrogen bond that could be formed between a heteroatom and a benzene ring.

Hydrogen bonding also plays a key role in the subject of the third article, in this case between DNA and proteins. Certain proteins are apparently able to recognize particular types of sites on the DNA and to bind specifically to these. In his article Alexander Rich first describes the different forms of DNA helices and identifies the parts of the base pairs that are accessible from outside; these lie in different types of depressions in the DNA helix, the minor and major "grooves". From steric considerations one can then predict which amino acid sequences can attach to these sites by hydrogen bonds. The greater the number of possible hydrogen bonds, the more specific are the interactions whereby the DNA and protein can recognize each other. However, the variety of types of

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0202-0237 $ 10.00+.25/0*

such recognition interactions is extremely great, and it has not yet been possible to classify these into a simple scheme.

In the fourth article Francis Crick considers the many important initiatives that Linus Pauling has provided for molecular biology, and concludes that he should be regarded as a co-founder of this area of science. The first important initiative was the recognition that weak forms of bonding (hydrogen bonds and dispersive interactions) are extremely important in biology. The second important idea was that biological molecules such as proteins have a definite shape (and are therefore not simply "colloids"), and that this is intimately related to their catalytic function. Another important concept was that attractive interactions are a result of complementarity, and this eventually led to the discovery of the structure of DNA. The interpretation of sickle cell anemia as a "molecular disease", in which the hemoglobin structure has been altered by a mutation, was the first example of a connection between protein chemistry and genetics. Another contribution in this field was the suggestion that the number of mutations that have accumulated in a certain protein can serve as a measure of "evolutionary time".

Pauling himself appears for a second time as the author of the fifth article. Even before he began his formal studies he was interested in minerals, and looked for general relationships between the properties of different substances and their composition. From 1922 onwards he worked on X-ray structural analysis at Caltech, and during this period he also studied theoretical methods of statistical thermodynamics. At that time quantum mechanics was being developed, and the ideas of physicists such as Bohr and Millikan, involving the motion of electrons in circular orbits, seemed to be irreconcilable with those of chemists such as Lewis and Langmuir, who assumed that the electron pairs occupied fixed positions. Pauling tried to find a solution that would unify these views. On the basis of Sommerfeld's work he suggested that the electron pairs in neon or methane moved in highly eccentric elliptical orbits. Thus it came about that he spent a year with Sommerfeld in Munich, and there he was able to become immersed in the new quantum mechanics in its initial phases. After returning to Pasadena he continued, through both experimental and theoretical studies, to seek a better understanding of the chemical bond, and in 1939 he summarized the results of this work in his celebrated book "The Nature of the Chemical Bond".

The part of the book concerned with dynamics is introduced by Sir George Porter, who presents a historical outline, beginning with the Arrhenius equation for the rate of a chemical reaction. The activation energy that appeared in the equation was subsequently assigned to an activated complex (Nernst) or to the transition state (Eyring, Polanyi). In general a chemical reaction proceeds via several stages, and it is therefore necessary to clarify the mechanism before a comparison with theory becomes possible. In order to prove the existence of short-lived species the method of flash photolysis was developed from about 1946 onwards. This led to the detection of a great variety of diatomic and aromatic free radicals and triplet-state molecules. The development of pulsed (Q-switched) lasers improved the time-resolution of this pump-and-probe method to a few nanoseconds. Further advances in laser physics (mode-locking and colliding pulse mode [CPM] ring lasers) mean that one can now achieve a time-resolution of 100 femtoseconds or less.

The progress of a chemical reaction is crucially dependent on the height of the energy barrier and its position on the potential surface. As the barrier height is typically only about 10% of the bond energy, the breaking of the original bond and the formation of the new bond occur simultaneously. Pauling postulated that in this process the sum of the bond orders should remain constant. In the seventh article John C. Polanyi describes how he and his group obtained experimental data on energy barriers from detailed measurements of the rate constants $k(V,R,T)$ for reactions of the type A + B–C $\rightarrow$ A–B + C. Here V, R, and T represent the vibrational, rotational, and translational energies respectively for the product molecules. The populations of the product states were determined by chemiluminescence measurements in the infrared. The distribution of the reaction energy between the different degrees of freedom is clearly indicated by colored triangle diagrams. To obtain even more detailed information it is necessary to impose limits on the initial geometry for the reactive collision. This can be achieved by using photoreactions in which both reacting species are adsorbed at a surface and thus have a fixed orientation. Furthermore, by inducing photodissociation of such adsorbed molecules with different photon energies one can perform a local scattering experiment to probe the potential in the neighborhood of the adsorption site.

In the eighth article Dudley R. Herschbach discusses the important contributions that Pauling made to the development of reaction dynamics. He then turns to some relevant topics in his own field of work. By studying bimolecular reactions between species in crossed molecular beams and measuring the velocity and angular distribution of the product trajectories one obtains a very detailed picture of the reaction dynamics. A highly anisotropic distribution indicates that the reaction has a large degree of "recoil" character, which can be explained in terms of the nodal structure of the frontier orbitals. Further extension of this concept leads to an electronegativity rule, which states that in complexes of the type X–Y–Z the favored structure is that in which Y is the least electronegative element. Scattering experiments of this kind yield results that are averaged over all the collision variables and molecular orientations. By simultaneously measuring and correlating the vector variables the orientational averaging can be partly eliminated. However, a better method is to align the molecules before the collision. Herschbach explains in detail how this can be achieved for cold molecules in strong external fields.

A quite different topic being studied by Herschbach is the calculation of the energies of atoms and molecules with many electrons. If the Schrödinger equation is formally extended to an arbitrary number of dimensions D, exact solutions are possible for the two limiting cases $D \rightarrow 1$ and $D \rightarrow \infty$. If one treats $1/D$ as the expansion parameter in a perturbation calculation and interpolates for $D = 3$, the results are in remarkably good agreement with those from laborious ab initio calculations. The case $1/D = 0$ corresponds to the limiting case where the electrons have an infinitely large mass, which means that the system behaves quasi-classically with the electrons at fixed positions in space. Thus one obtains a higher-dimensional analogue of the "Lewis structures" that were postulated by G. N. Lewis in 1916. Transitions between different Lewis structures can be represented by trajectories along an imaginary time axis, and interpreted as tunneling between different canonical structures.

The methods described in the two preceding articles allow one to determine asymptotic properties of the trajectories that pass through the transition state. The corresponding observable quantities are integrated over the reaction time, and yield only indirect information about the lifetime of the activated complex. For many reactions the lifetimes are in the range from 10 to 1000 femtoseconds. Flash photolysis measurements with this

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0202-0238 $ 10.00+.25/0

order of time resolution ("femtochemistry") are the subject of the ninth article by Ahmed Zewail and Richard Bernstein. The aim here is to observe the passage of the system through the transition state directly as a function of time. After describing the apparatus used in their laboratory at Caltech, the authors discuss the most important results that femtochemistry has yielded up to now. So far the technique has been applied to the study of rapid decomposition reactions and oscillating intermediates (quasi-bound states). A brief update section reporting on progress with the method since about 1988 is also included.

The nine articles are followed by short biographical notes on each of the authors with photographs. The book is completed by an index, which also lists the names of other people mentioned in the text.

The book is equally suitable for specialists and for laypersons with an interest in the subject. It contains a wealth of information for everyone wishing to learn something about the current state of knowledge in this field. Complex topics are clearly explained without too much glossing over of details, and mathematical derivations are avoided completely. Thus the book is primarily concerned with concepts and methods, and should appeal to a wide readership.

Frontier Orbitals and Properties of Organic Molecules. (Ellis Horwood Series in Organic Chemistry. Series editor: *J. Mellor.*) By *V. F. Traven.* Ellis Horwood, Chichester, 1992. XVI, 401 pp., hardcover $ 111.00.—ISBN 0-13-327487-X

I expected to find here an up-to-date book covering the most recent literature in this field. Instead I found an English translation of an obviously older Russian work. It mainly covers work published from the 1950s to the 1970s, with just a few references to 1980s publications. For the subject treated here that is quite inadequate.

The contents are arranged under two broad areas. First is a section of about 60 pages dealing with the various methods of describing the electronic structures of molecules. The main part then begins with an introduction to orbital structure and the properties of organic molecules (30 pp.), which is followed by a systematic treatment of individual classes of organic compounds (250 pp.). The book ends with an appendix listing HMO data for selected molecules (10 pp.) and a bibliography containing 471 references.

The first chapter presents in a very cursory and superficial way some basic principles of physical organic chemistry, and is really of little value. This is followed by an introduction to the methods of quantum chemistry, beginning with the Bohr model of the atom and ending with some concepts of the MO theory. The HMO theory is then introduced, followed by a description of the state of ab initio methods as it was twenty years ago then, as semiempirical methods, the CNDO, NDDO, and PPP approaches. The MNDO, AM1, and PM3 methods appear to be as yet unknown. Next comes a very brief introduction to the experimental methods for investigating the electronic structures of organic molecules: photoelectron spectroscopy (PES), electron transmission spectroscopy (ETS), electron spin resonance (ESR) spectroscopy, UV spectroscopy, polarography. It becomes apparent in this chapter that photoelectron spectroscopy is the author's special field, and one can guess that it is likely to figure prominently in the later chapters. The pleasure of reading this first part is marred by the incomplete and superficial treatment and by the very poor standard of English.

The second part begins with a treatment of orbital structure and reactivity, with special emphasis on frontier orbitals. We read that: "The rules for concerted cycloaddition reactions proposed by Woodward and Hoffmann were a further development of the frontier orbitals concept." In a similarly uncritical vein the author then goes on to consider how the orbital structure is related to biological activity, color, and phototropic behavior.

The treatment of individual compound classes follows the conventional structure of a textbook of organic chemistry. Now we come to the turn of photoelectron spectroscopy, including calculations, some of which are ab initio calculations of the type used in the 1970s. There are many tables listing ionization potentials; however, these are easily available from other sources.

One might expect that the "properties of organic molecules" referred to in the book's title would be limited to structural features, but this turns out not to be so. For example, in the chapter on "Alkenes" certain aspects of the Woodward–Hoffmann rules are discussed. Under "Annulenes" one is disappointed to find that this attractive topic is treated from a completely outdated standpoint.

And so it goes on for one compound class after another. The reader with a special interest in photoelectron spectroscopy will perhaps find something of value here and there, but the average organic chemist will gain little from the book. To summarize, although the title sounds very promising, it would have been better if this book had not been translated into English. The book *Frontier Orbitals and Organic Chemical Reactions* by Fleming (1976), which is not cited by Traven, is more reliable and up-to-date than this book published in 1992.

Supported Reagents. Preparation, Analysis and Applications. By *J. H. Clark, A. P. Kybett* and *D. J. Macquarrie.* VCH, Weinheim, 1992. XI, 152 pp., hardcover DM 108.00.—ISBN 3-527-28043-X

We have probably all at some time read in a publication a sentence claiming that by immobilizing the reagent on a support one can improve the yield and selectivity, facilitate the work-up procedure, etc. These reports often leave some practical questions unanswered: what pretreatment and after-treatment of the support is needed?—how does one get the reagent on to the support? (and which support should be chosen?)—how can the supported reagent be analyzed?—how does one use such supported reagents to perform reactions?—and so on. This book aims to tell the reader how to prepare and use supported reagents, illustrating this by practical examples.

It consists of five chapters as follows. A general introduction to the subject is followed by separate chapters on the preparation of supported reagents and on their analysis. The last two chapters then describe practical examples. One of these discusses in detail, based on a few examples, the factors that need to be optimized for successful work with such reagents. An appendix contains a table listing various types of supported reagents and the reactions that can be carried out using them.

The introduction sets out to stimulate the reader's interest by reviewing the general field of supported reagents and the problems. The importance of the choice of support material is illustrated by a three-page table giving details of some reactions chosen as examples. Unfortunately one becomes aware here of a weakness that

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0202-0239 $ 10.00+.25/0*

persists throughout the book: the information in the table is not arranged according to reaction types, nor according to support materials or reagents, and this considerably reduces the usefulness of a book which has been written for the practical user. Also it is unfortunate that the examples in this table are not repeated in the much more detailed table in the appendix; a combined table would have been more useful for quick reference. In the table in the appendix an attempt has been made to arrange the examples according to reaction types, but this has not turned out very successfully: for example, the oxidation of diphenylcarbinol to benzophenone using potassium permanganate appears in three places. A commendable attempt has been made to provide additional notes on the examples in the table, but often these contain no more information than is already evident from the reaction equation. Only rarely is one given information about yields or the compatibility of the reagents with other functional groups, which would have been of interest to every user.

The initial approach to describing the different methods of preparing supported reagents is good. The authors'aim is to outline general procedures for these methods and to explain them by examples. Unfortunately, however, the recipes are too general to be used in practice for the preparation of reagents.

The chapter on techniques for the analysis of supported reagents is well written. The authors describe a wide variety of methods, mainly spectroscopic, illustrated by practical examples. In addition to the conventional spectroscopic methods they describe some recently developed techniques such as electron tunneling microscopy, thermogravimetry, and differential scanning calorimetry.

The "case studies" in Chapter 4 include detailed accounts of the use of supported fluorides, thiocyanates, and catalysts for Friedel–Crafts alkylations and acylations. The section on thiocyanates is especially interesting and comprehensive, with detailed information on the composition of the reagents and a table giving examples of reactions with data on reaction times, yields, etc.

Despite all the above criticisms this is a useful book for readers who wish to gain a general understanding of supported reagents. It is important to take the time to read the whole book, but as it consists of only 152 pages that should not be a problem. In that way the reader will gain a clear impression of the potential of the reagents described and of how they might be applied to his or her own problems. However, as a "comprehensive reference source" (according to the claim on the dustjacket) the book leaves something to be desired, both in form and arrangement of material.

Just what does a referee system achieve?

Regular readers of "Angewandte" are well aware that Dr. Hans-Dieter Daniel has researched this question using *Angewandte Chemie* as example. The preliminary results were presented in a communication on this topic (Issue 2/93). Now the complete analysis by Daniel is available in book form: "The Guardians of Science: Fairness and Reliability in Peer Review" by H.-D. Daniel, foreword by H. Nöth (VCH, Weinheim, 1993, ISBN 3-527-29041-9, DM 78.—).

Organizing Principle of Complex Reactions and Theory of Coarctate Transition States

Rainer Herges*

The majority of concerted reactions proceeds by a simultaneous breaking and making of only one bond at each atom involved in the reaction. If this process follows an alternating cyclic sequence, the reactions are called pericyclic. However, there is a hitherto never consistently characterized class of reactions that proceeds by breaking and making two bonds at one or more atoms at a time. The striking relationships that are purely descriptive and formal in the first instance are explained by a common physical principle. Theoretical insight not only permits predictions of mechanisms and stereochemistry; the qualitative theory is also used as an organizing principle for the known reactions and as a tool for predicting unprecedented reactions of this type.

1. Introduction

In principle, any chemical reaction can be described as a sequence of concerted elementary steps. For the theoretical treatment of these elementary processes, molecular orbital (MO) theory has proven to be most fruitful. Among the qualitative descriptions the Woodward–Hoffmann rules[1] are the most prominent example. Quantitative treatment is feasible with smaller systems by using quantum chemical calculations. Particularly geometries and thermodynamic and kinetic energies[2] are predicted with high accuracy.[3]

It is common practice to describe these reactions in a mechanistically simplified manner as a sequence of arrows that indicate the electron shift (that is, the alternating sequence of bond making and breaking). In spite of its lower content of information, the simplistic valence bond (VB) notation has advantages over MO methods because of its higher level of abstraction, and this not only from the aspect of ease of communication.[4] VB theory also forms a suitable basis for organizing principles[5] and for the prediction of unprecedented reactions.[6] The simple structural formula notation in the following is therefore used to demonstrate the formal unity of the "complex reactions". Qualitative MO models explain the striking, descriptive relationships and enable the prediction of mechanisms and stereochemistry. With the aid of quantum chemical calculations (and experimental data if available) the qualitative statements are verified and quantified. The hierarchy of the three levels of abstraction at the same time describes, in correct chronological order, the heuristic that led to the following article.

[*] Priv. Doz. Dr. R. Herges
Institut für Organische Chemie der Universität Erlangen–Nürnberg
Henkestrasse 42, D-91054 Erlangen (FRG)
Telefax: Int. code + (9131)85-9132

Starting point was a systematic classification of about 80000 reactions from the reaction databases ORAC[7] and REACCS[8] and a number of carbene reactions from the literature.[9] According to this study, most of the organic reactions can be described by a linear sequence of electron-pushing arrows; that is, bonds are made and broken in an alternating

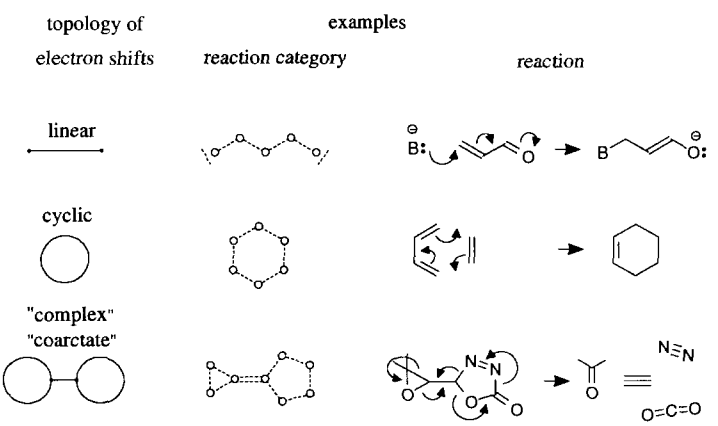

Fig. 1. Topologies of the electron shifts in organic reactions.

sequence (Fig. 1). The linear topology of "electron-pushing" necessarily results in a shift of charges and corresponds to the common way of thinking in organic chemistry (for example, in a nucleophilic or electrophilic attack of a reagent at a substrate that reacts by a double bond shift or by elimination of a leaving group).

The second largest class is formed by reactions that can be described by a cyclic sequence of electron-pushing arrows. They are called pericyclic if the electron shifts are concerted. Within

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0303-0255 $ 10.00+.25/0

the remaining data record, a group of reactions attracts attention that never were described in a coherent context, even though they exibit a number of formal similarities. We class them under the general term "complex reactions" because of their intricate mechanism.

2. Definition and Formal Description of Complex Reactions

Common to these reactions is that at one atom, at least, two bonds at a time are made and broken. The linear succession of bond making and breaking is finished by "terminators" at both ends. Suitable terminators are atoms with a lone pair that is formed or removed in the course of the reaction, or a cyclic shift of electrons over several atoms (Fig. 2). In principle, any combi-

Fig. 2. Formal description of complex reactions. In the terminology used in the following, T and T' are terminators that bound the linear subsystem of length n ($n \geq 1$).

nation of different terminators is possible. The length n of the linear subsystem is variable as well (however, $n \neq 0$). According to this description, complex reactions with $n = 0$ are pericyclic. Most frequent are reactions with $n = 1$, and 2, and with terminators containing lone pairs or three- and five-membered rings.

Figure 3 illustrates the principle by means of examples from important categories of these reactions.

The descriptive treatment disregards mechanistic details and particularly ignores the question whether the reactions are concerted. Nevertheless, the striking formal relationships suggest similarities on the level of physical chemistry as well. In order to find the physical principle that obviously favors these reactions or transition states, we made the following two ad hoc assumptions:

- The reactions are concerted.
- The transiton states are stabilized by conjugation (similar to the pericyclic reactions).

Starting point of our theoretical approach is the traditional qualitative treatment for pericyclic reactions and especially the topological methods of Zimmerman,[27] which therefore should be briefly summarized.

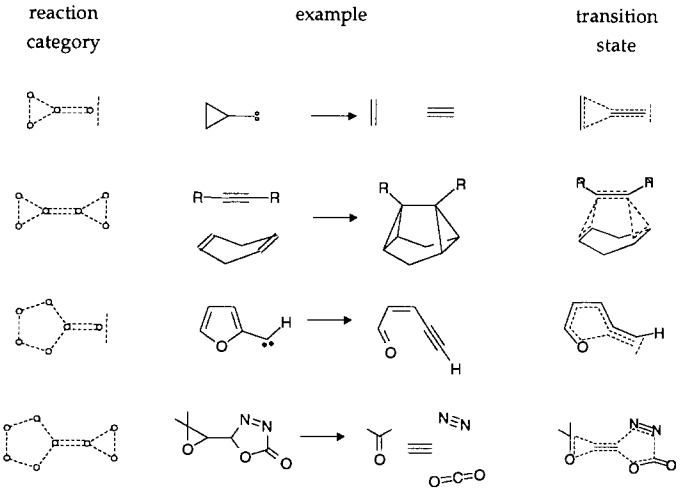

Fig. 3. Examples of complex reactions. The reactions are categorized according to the topology of the electron shift; the transition state is given for a concerted mechanism.

3. The Theory of Coarctate Transition States

3.1. Qualitative Methods for Treating Concerted Reactions

There are three qualitative methods for the theoretical treatment of concerted and, in particular, pericyclic reactions:

1. Conservation of orbital symmetry
   (correlation[10] and state diagrams)
   by Woodward–Hoffmann[1, 11–14] and Longuet-Higgins et al.[15]
2. Frontier orbital method
   (perturbation theory)
   by Oosterhof et al.[16, 17] and Fukui et al.[18–20]
3. Aromaticity of transition states
   (topological methods)
   by Evans and Dewar[21–25] and Zimmerman[26–28]

For the nontheorist, the topological method of the aromaticity of transition states is the easiest to apply. The method was introduced almost concurrently by Dewar as the "Evans principle" and by Zimmerman as the "Hückel–Möbius" method. Notwithstanding the fact that both methods are based on different theoretical grounds, they are almost identical in their formalism. A. C. Day[29] proved later that the general Woodward–Hoffmann rules (based on the number of supra- and antara-

Rainer Herges, born in 1955 in St. Ingbert (Saar), studied Chemistry at the Universität des Saarlandes in Saarbrücken, where he completed his Diplom under the supervision of H. Dürr. He then moved to the research group of I. Ugi at the Technische Universität München and obtained his doctorate there for a dissertation on the systematic, deductive search for new reactions and their experimental realization. As postdoctoral fellow with G. A. Olah in Los Angeles he performed calculations and syntheses for cations and dications (1985). He completed his habilitation on the topic of reaction planning in 1992 at the Universität Erlangen-Nürnberg. He was awarded the prize for doctoral candidates by the TU München for his dissertation, the ADUC-Jahrespreis 1992 for habilitands for the work on rational planning of new chemical reactions, and the CSA Trust Award 1993 (CSA = Chemical Structure Association) for his contributions to the processing by computer of chemical structures and reactions.

facial reacting components) are equivalent to the topological Hückel–Möbius method, because in a certain context the concepts antarafacial and sign inversion imply the same physical meaning. Because of its simple and general applicability and the lack of dependence on explicit knowledge of the MOs of starting materials and products, this "paper-and-pencil method" found favor with most organic chemistry textbooks.

It is evident, but nonetheless very important, to discriminate between the terms "orbital basis" and "molecular orbital".[10b] The basis orbitals that form the orbital basis set are atomic orbitals (for example, atomic functions or hybrid orbitals). Molecular orbitals are formed by mixing the basis orbitals according to the rules of the LCAO method. The resulting number of MOs equals the number of basis orbitals prior to the interaction. (For example, the four π orbitals of butadiene are derived from the four carbon p orbitals perpendicular to the molecular plane.)

In analyzing pericyclic reactions one starts out from the idea that in a first approximation the "mobile" electrons participating in the reaction and the corresponding basis orbitals can be distinguished from the remaining system and treated separately. These basis orbitals are written in arbitrary phase, and a closed curve is drawn (in the following figures in red), which depicts the overlap of neighboring orbitals. Only two aspects are crucial for whether a reaction is allowed: the number of mobile electrons and the topology of the overlap of the basis orbitals. An even number (including 0) of negative overlaps (overlap of orbital phases with opposite sign) indicates a system with Hückel topology that is aromatic with $4n + 2$ electrons and antiaromatic with $4n$ electrons. Möbius systems[30] with an odd number of negative overlaps are aromatic with $4n$ electrons and antiaromatic with $4n + 2$ electrons. Reactions with an aromatic transition state are thermochemically allowed and while those with antiaromatic transition states are forbidden. Fig. 4 illustrates the topological analysis by means of the Diels–Alder reaction and the conrotatory ring opening of cyclohexadiene.

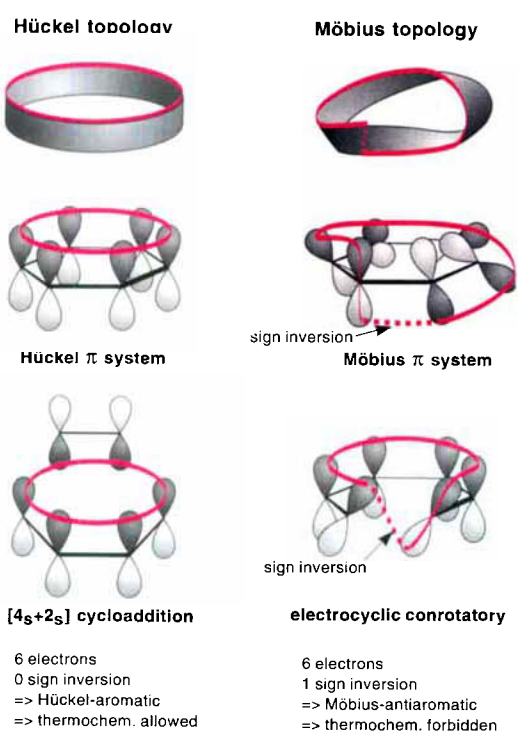

Fig. 4. Topological method for treating pericyclic reactions. The delocalized system of electrons in the transition state of pericyclic reactions is isoconjugate to the π system of aromatic or antiaromatic compounds. Reactions with an "aromatic transition state" are thermochemically allowed, and those with an antiaromatic one are thermochemically forbidden.

3.2. Extension of the Topological Method to Coarctate Transition States

In its original form the topological method, based on the aromaticity of transition states, is solely applicable to pericyclic reactions. Complex reactions, for instance the cyclopropylcarbene fragmentation (first example in Fig. 3), elude this analysis, because in the usual notation there is no cyclic overlap of the basis orbitals. Concerning these reactions Zimmerman and Sousa write in their article about the fragmentation of cycloheptatrienylidene:[31]

> "In analyzing the present reactions, we find that the usual methods do not generally apply. For only one of the reactions is there any symmetry to allow construction of a correlation diagram. The Hückel–Möbius methods presented by us earlier require a cyclic array of orbitals; however, the present reactions consist of linear arrays of orbitals instead."

To solve the problem, Zimmerman et al. proposed a modified version of correlation diagrams that do not rely on symmetry criteria but on the nodal properties of the MOs. Since these correlation diagrams are not suitable for categorizing the diversity of complex reactions and cannot explain the striking relationships, we tried to develop a topological method, which will be presented in this article.

Ad hoc assumption and starting point of our considerations was the claim that the topology of the orbital basis of complex reactions corresponds to the topology of pericyclic reactions: they are both cyclic. Hence the orbital basis of the transition states of complex reactions should be "isoconjugate" to aromatic systems, like the one of pericyclic reactions. In contrast to the situation with pericyclic reactions, the aromaticity of the transition states of complex reactions cannot be directly recognized. However, it can be impressively illustrated by means of topology. Figure 5 shows, as example, the topological transformation[32] of the orbital basis of the π system of the cyclopentadienyl anion into the delocalized system in the transition state of the cyclopropylcarbene fragmentation. (Topological equivalence or homoeomorphism in the following is depicted with the double arrow $\curvearrowleftrightarrow$.[33]) For illustration of the homoeomorphism of the two systems, centers 3 and 5 of the cyclopentadienyl anion are brought together in such a way that their basic orbitals are orthogonal, and the orbital basis of the cyclopropylcarbene fragmentation is thus obtained directly. Neither the topology of the orbital basis nor the number of electrons is changed during the transformation, because the overlap integral of the orthogonal basic orbitals 3 and 5 is zero, and the mutual overlap of all basis orbitals was maintained. As a result both physical preconditions for the topological analysis remain unaltered. This means that the transition state of the cyclopropylcarbene fragmentation is Hückel-aromatic and therefore the

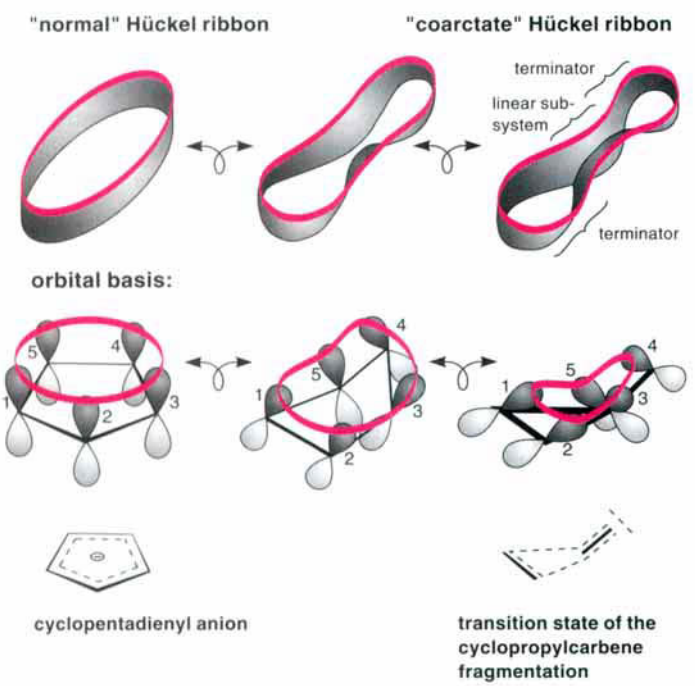

Fig. 5. A topological transformation proves that the delocalized system of electrons in the transiton state of complex reactions is isoconjugate to the π system of arenes. The example shows the topological transformation of the orbital basis of the π system of the cyclopentadienyl anion to the transition state of the complex cyclopropylcarbene fragmentation. The number of electrons as well as the topology of the basis orbital overlap remain unchanged during the operation [38]. In the same way as the topology of the orbital basis in transition states of pericyclic reactions corresponds to a Hückel ribbon (top left) or a Möbius ribbon, the orbital basis in the transition state of complex reactions can be viewed as an intersecting ribbon, the ribbon planes being perpendicular where they intersect (complex, coarctate Hückel ribbon, top right). The two "loops" represent the terminators, and the section where the ribbon intersects forms the linear subsystem.

reaction is thermochemically allowed, which agrees with the experimentally observed facts and with comprehensive theoretical calculations (for the details see Section 4.1). At this point it should be reemphasized that Figure 5 shows the orbital basis and not molecular orbitals. It is therefore not allowed to vectorially sum up the independent basic orbitals 3 and 5 to give one resultant orbital (which would be allowed with molecular orbitals). However, an arbitrary rotation of the orbitals 3 and 5 around the axis that intersects both orbital axes perpendicularly leads to the same physical result, as long as the orbitals remain orthogonal and are pure p functions.

Upon setting up the basis orbitals of complex reactions, it is important to assume a set of two p orbitals at the centers at which two bonds are made and broken simultaneously (which are thus not terminators). They have to be orthogonal to each other but not to the remaining basis.

The same topological transformation that we carried out with the orbital basis (in Fig. 5) can also be applied to the molecular orbitals. Figure 6 shows, on the left, the three occupied π orbitals of the cyclopentadienyl anion (the E_1'' orbitals are degenerate). By topological transformation they are converted into the three corresponding molecular orbitals of the transition state of the cyclopropylcarbene fragmentation (the A'' and A' orbitals are not degenerate). The topology of the overlap including the nodal properties is preserved. Because we are treating molecular orbitals, both components at the central carbon atoms are allowed to be added vectorially.

A comparison of the MOs obtained with this simple paper-and-pencil method and those from a high level ab initio calculation (Fig. 6, right column) demonstrates not only qualitative but also excellent quantitative agreement.

With respect to the topology of the transition state, the complex cyclopropylcarbene fragmentation is, therefore, isoconjugate to the 5-center, 6-electron pericyclic reactions (for example, 1,3 dipolar cycloaddition,[35, 36] 1,5 cyclization,[37] chelotropic reaction of sulfolenes) that are also derived from the cyclopentadienyl anion according to the classical method. Though the mechanisms appear totally different on first inspection, the transition states profit from the same kind of stabilization.

Because the transition states of complex reactions are formally derived from pericyclic reactions by constriction (see Fig. 20) we termed them coarctate.[38] The coarctations correspond to

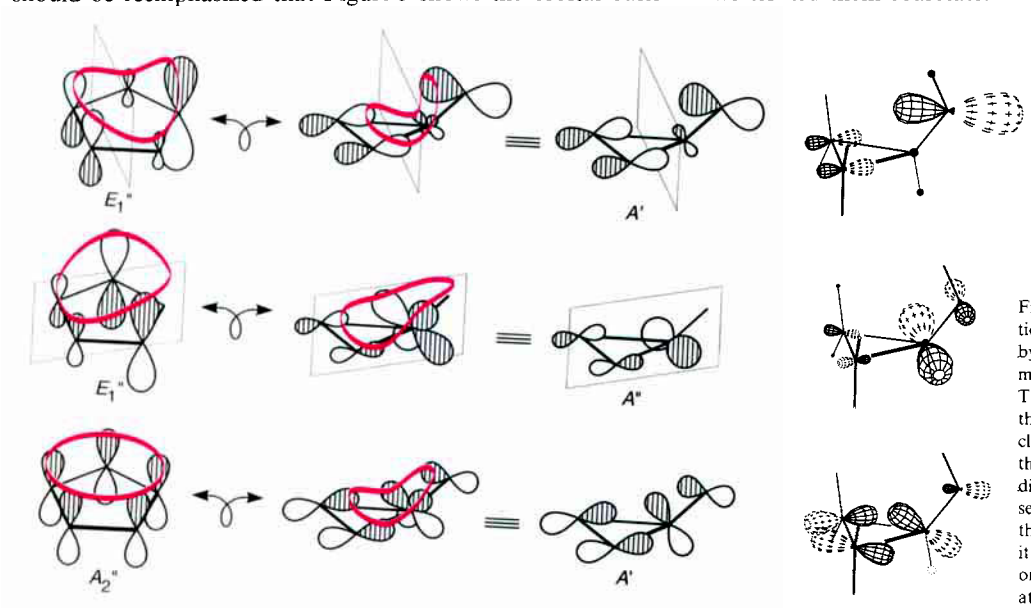

Fig. 6. The molecular orbitals of the transition state of complex reactions are derived by topological transformation from the molecular orbitals of the π system of arenes. The example illustrates the derivation of the three highest occupied π orbitals of the cyclopropylcarbene fragmentation from the three occupied π orbitals of the cyclopentadienyl anion. The nodal properties are preserved during the operation. In contrast to the procedure for deriving the orbital basis, it is now allowed to vectorially add the two orthogonal p orbitals at the central carbon atom. The MOs thus obtained agree well with those of an ab initio calculation (MP2/6-31G*//MP2/6-31G* level, right column).

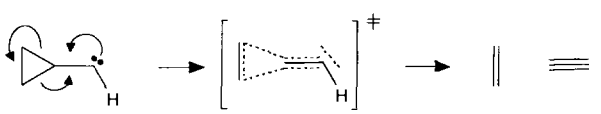
the atoms where two bonds are broken and made (see formal description, Fig. 2).

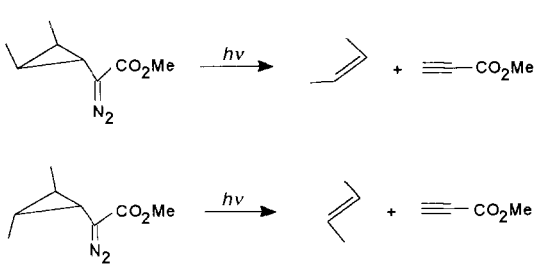
In principle, the extended topological method allows the prediction of the stereochemistry and mechanism of complex reactions in a way similar to the traditional method for pericyclic reactions. In the following section the approach is outlined with the aid of a number of known complex reaction types with coarctate transition states.



4. Application of the Model to Different Categories of Complex Reactions

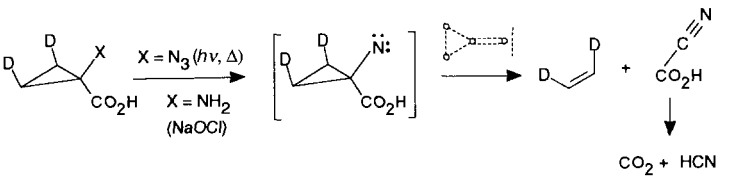
4.1. Reactions with Lone-Pair Terminators and Three-Membered Ring Terminators

4.1.1. The Cyclopropylcarbene Fragmentation



Most thoroughly investigated and the prototype of complex reactions is the cyclopropylcarbene fragmentation (Scheme 1). Formally, two bonds are made between the carbene carbon atom and the three-membered ring. The carbene center with the lone pair and the two cyclopropane carbon atoms 2 and 3 act as terminators.

Scheme 1. Fragmentation of cyclopropylcarbene to acetylene and ethylene.



The reaction was discovered in 1960 by Friedman and Shechter.[39] Presumably because of its unusual mechanism it has been thoroughly investigated, both experimentally[40] and theoretically.[31,41,42] The fragmentation of the corresponding cyclopropylnitrenes is also known.[43–49] In both the carbene[50,51] and the nitrene fragmentation[45,46] stereochemistry is preserved (Scheme 2), and for both reaction types a singlet carbene[52] or nitrene[46] intermediate was proposed.

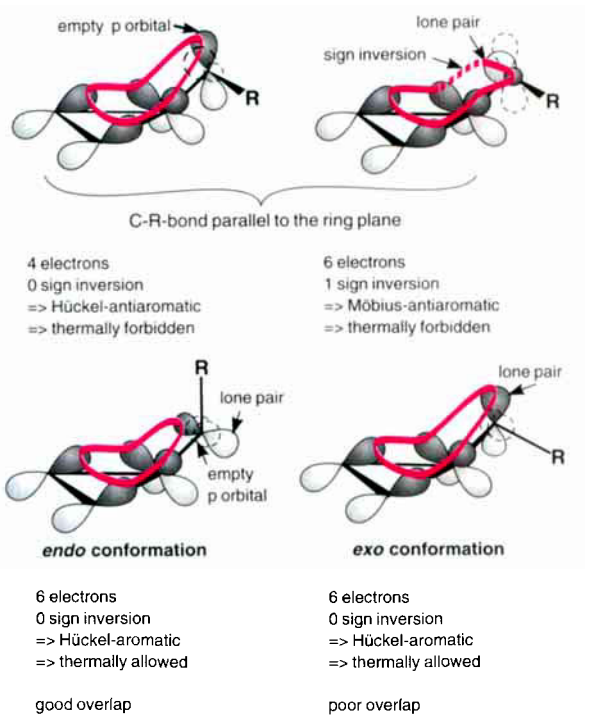
Presumably the biologically important, enzymatic oxidation of the 1-aminocyclopropylcarboxylic acid to ethylene, carbon

Scheme 2. The cyclopropylcarbene fragmentation. The reaction proceeds via the singlet spin state of the carbene and with retention of stereochemistry. (The competing reaction is the likewise allowed ring enlargement affording the four-membered ring.)

dioxide, and cyanide[52] does not pass a cyclopropylnitrene but proceeds via radical intermediates. Oxidation of the acid with sodium hypochlorite[53] and the irradiation of the corresponding azide,[54] however, are stereospecific and share the nitrene as a common intermediate (Scheme 3).

Scheme 3. Fragmentation of derivatives of the 1-aminocyclopropylcarboxylic acid.

With our qualitative topological analysis the stereochemistry of this fragmentation is easily comprehended without any calculation. Additionally, further stereochemical details can be predicted (Fig. 7).



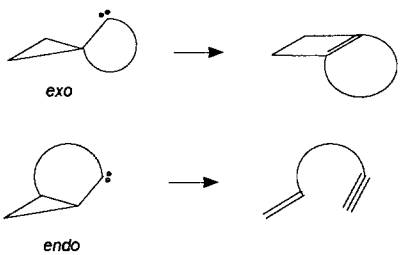


Fig. 7. Topological analysis of the cyclopropylcarbene fragmentation according to Scheme 1. For details, see text.

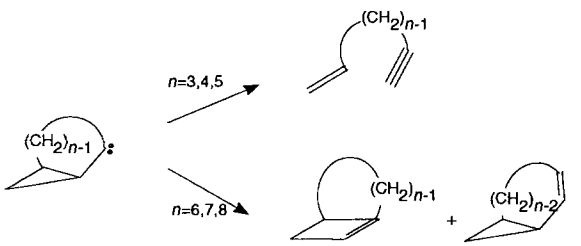
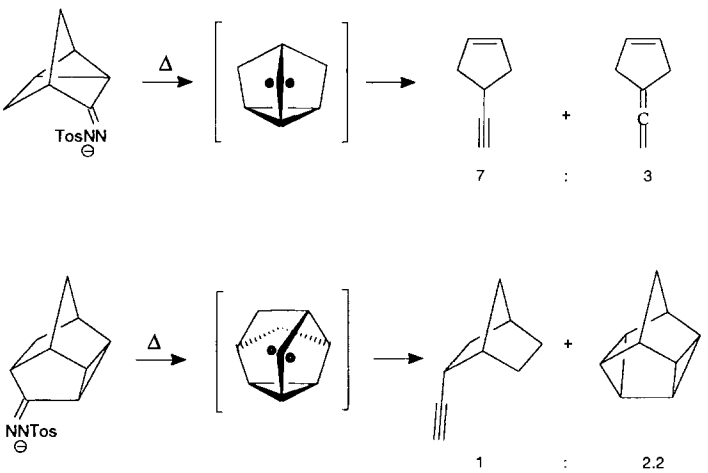
From the orbital basis of Figure 7, derived in Figure 5, it follows that the overlap is best if the orbital containing the lone pair is parallel to the plane that bisects the plane of the three-membered ring. Under this prerequisite the transition state is aromatic, and the reaction is therefore thermochemically allowed. With the substituent C–R bond parallel to the forming ethylene fragment, the empty lone-pair orbital of the carbene center interacts with the remaining orbital basis, and the transition state with four electrons is Hückel-antiaromatic, which is energetically unfavorable. An alternative view, which, however, yields the same result, is provided by the overlap of the lone-pair orbital at the carbene center with the remaining basis orbitals:

The system includes six electrons; however, because of the sign inversion it is Möbius-antiaromatic and therefore forbidden.



An analysis of the cyclopropylcarbene fragmentation by correlation diagrams leads to the same results. However, the advantage of our method is provided in its ability to discriminate between two or more stereochemically allowed reaction modi. With the substituent either *endo* or *exo* to the cyclopropane ring, C_s symmetry is conserved, and the reaction is thermochemically allowed. As illustrated in Fig. 7, the lone-pair orbital of the carbene overlaps more efficiently with the remaining basis orbitals in *endo* conformation than in *exo* conformation. The fragmentation should therefore proceed preferentially in *endo* systems. Theoretical calculations as well as experiments confirm this prediction. Instructive are investigations of systems in which the carbene is sterically fixed in a particular conformation. Carbenes fixed in *exo* conformation exclusively afford ring enlargement products[55–59] and *endo*-fixed carbenes fragment preferentially.[60–64] (Scheme 4).

Scheme 4. Reactions of *exo*- and *endo*-fixed cyclopropylcarbenes.



The comparison is unfair for small and medium spiro-annelated rings, because highly strained alkynes would be formed by fragmentation. However, spiro[2.11]tetradec-2-ylidene also does not undergo fragmentation,[65] even though the dodecyne formed as product would be almost unstrained.

Moreover, *endo*-fixed systems do not exclusively afford fragmentation. The yield of fragmentation product critically depends on the alignment of the carbene center relative to the cyclopropane ring. In *endo*-fixed bicyclo[*n*.1.0] systems the larger annelated ring determines the preferred reaction modus. Whereas five-, six, and seven-membered rings steer the reaction in direction of the fragmentation,[60–64] larger ring systems afford 1,2 shifts and ring enlargement[66–68] (Scheme 5). The different reactivity is presumably due to the forcing of the system into *endo* position by small annelated rings; larger rings allow more conformational flexibility.

Scheme 5. Reaction modi of bicyclo[*n*.1.0]alk-2-ylidenes depending on the ring size *n*. Smaller annelated rings force the system into *endo* conformation and favor the fragmentation affording alkynes.

Fragmentations of tricyclo[2.2.1.$0^{2,6}$]-hept-3-ylidene and tetracyclo[4.3.$0^{2,4}$.$0^{3,8}$]non-5-ylidene[69] illustrate the striking effect of small changes in conformation on the product ratio (Scheme 6). In the first system the substituent of the carbene carbon atom is exactly *endo* to the cyclopropane and the orbital of the carbene lone pair lies in the plane that bisects the plane of the three-membered ring. Thus fragmentation dominates.[70, 71] In the second system the lone pair is twisted relative to the bisecting plane by about 30°, and the insertion product prevails.[72]

Scheme 6. Dependence of the proportion of cyclopropylcarbene fragmentation on the conformation in the polycyclic ring system.

Besides these experimental findings, detailed theoretical calculations performed by Shevlin and McKee[73] and also by my group[74] impressively confirm the predictions of the qualitative topological analysis. Figure 8 shows the relative energies of the stationary points on the potential energy surface of the cyclopropylcarbene fragmentation. There are two conformational

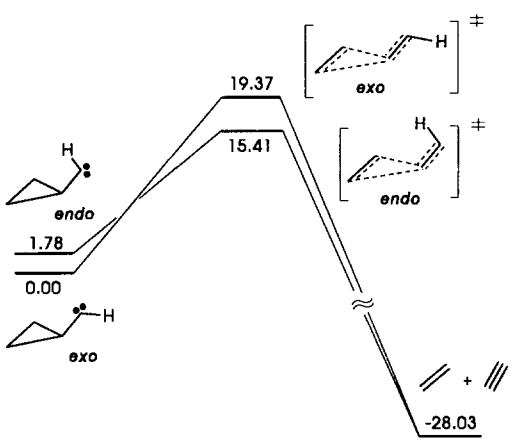


Fig. 8. Relative energies, calculated by ab initio methods, of stationary points on the potential energy surface of the cyclopropylcarbene fragmentation in kcal mol^{-1} [74].

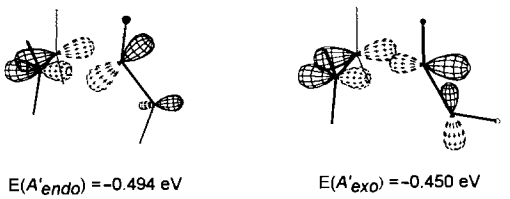
minima of the carbene: in one the carbene H is in *exo* position; in the other it is in *endo* position. In agreement with our qualitative picture, the *endo* transition state of the fragmentation is

almost 4 kcal mol^{-1} lower in energy than the corresponding transition state of the *exo* conformer.

According to the topological analysis in Figure 7, this is due to the better overlap of the carbene lone-pair orbital with the basis orbitals of the neighboring carbon atom. This is also convincingly confirmed by ab initio calculation (Fig. 9).



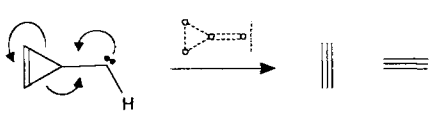


Fig. 9. Comparison of the HOMO-2 orbitals [75] in the transition state of the cyclopropylcarbene fragmentation (ab initio calculation on the MP2/6-31G*// MP2/6-31G* level; orbital plot with PERGRA [76]). The overlap in *endo* conformation is more effective. The other two MOs (HOMO-1 and HOMO) are similar in energy in both conformations because of their nodal properties.

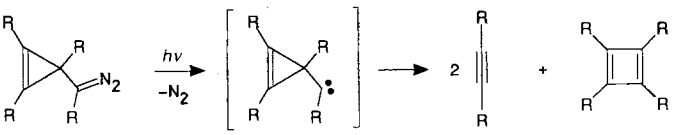
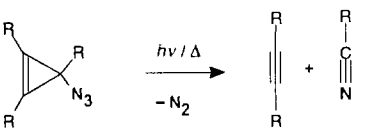
The symmetrical MO of the orbital basis containing no nodes that has the lowest energy (A', HOMO-2,[75] see also Fig. 6) is 0.04 eV more favorable in the *endo* transition state than in the *exo* transition state. The better overlap of the back lobes does not completely compensate for this effect.



All theoretical considerations presented so far assume that a singlet carbene is the reactive species. The conservation of the stereochemistry in cyclopropylcarbene fragmentations of substituted systems could also be explained by a triplet carbene and a very short-lived, ring-opened, biradical species, whose cleavage to ethylene and acetylene proceeds faster than the isomerization of the double bond. According to our ab initio calculations on QCI level,[77] the cyclopropylcarbene (contrary to conclusions by Shevlin and McKee[73]) definitely has a singlet ground state. The triplet state of lowest energy lies 2.15 kcal mol^{-1} higher. As demonstrated by a comparison of results of ab initio calculations with experimental data of the singlet–triplet splitting in methylene,[78] our level of electron correlation probably still describes the singlet species less adequately than the triplet species. It is reasonable to predict that the singlet state in cyclopropylcarbene lies at least 4 kcal mol^{-1} lower than the triplet state. This explains the experimental findings of Gallucci and Jones,[51] according to which cyclopropylcarbenes generated by triplet-sensitized excitation from diazo compounds fragment stereoselectively (Scheme 2). Presumably the carbene generated in the triplet state changes to the singlet state prior to the elimination and fragments stereoselectively.

4.1.2. Other Fragmentations



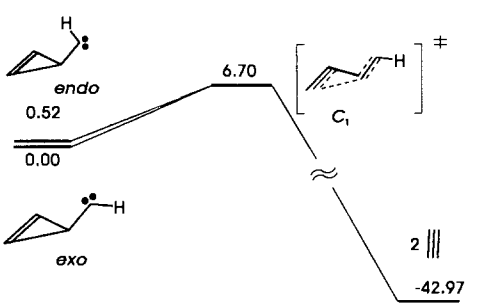
Related to the cyclopropylcarbene fragmentation is the decomposition of cyclopropenylcarbene[79] into two molecules of acetylene[80] (Scheme 7). Cyclopropenylcarbenes have been thoroughly investigated, mainly in the vain hope of gaining access to tetrahedrane by intramolecular carbene addition to the double bond or of generating cyclobutadiene by ring enlargement; for example, see refs. [81,82] (Scheme 8). Apart from some exceptions[83–86] fragmentation was observed in high yields depending on the reaction conditions.[80, 82, 87–91] The fragmentation of cyclopropylnitrenes is also known (Scheme 9).[92–94]

Scheme 7. Fragmentation of the cyclopropenylcarbene into two molecules of acetylene.

Scheme 8. Example of the cyclopropenylcarbene fragmentation (R = *t*Bu). Depending on the experimental conditions, ring enlargement to cyclobutadiene is observed in addition to the fragmentation products.

Scheme 9. Example of the fragmentation of a cyclopropenylnitrene [92]. R = Me.

It would be rash to conclude that the mechanism is concerted and follows a coarctate transition state analogous to the cyclopropylcarbene fragmentation. Our ab initio calculations[95] on the singlet potential energy surface of the cyclopropenylcarbene show at least that the reaction is not synchronous. The transition state is unsymmetrical[96] and has a strong biradical character.[97] The *exo* and *endo* conformations are almost equal in energy (Fig. 10).[98, 99] Since both fragment with low activation energy via the same transition state, the conformation should not have a large effect on the fragmentation of the carbene. (The same is not necessarily true for ring enlargement or the not yet observed, intramolecular carbene addition.)



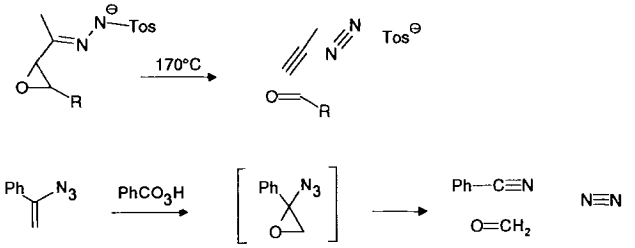


Fig. 10. Relative energies calculated by ab initio methods at the MP4SDTQ/6-31G*//MP2/6-31G* + ZPE level for stationary points on the potential energy surface of the cyclopropenylcarbene fragmentation, in kcal mol^{-1}.

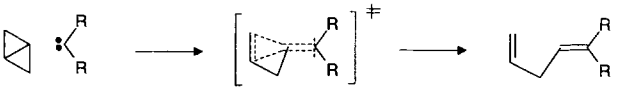
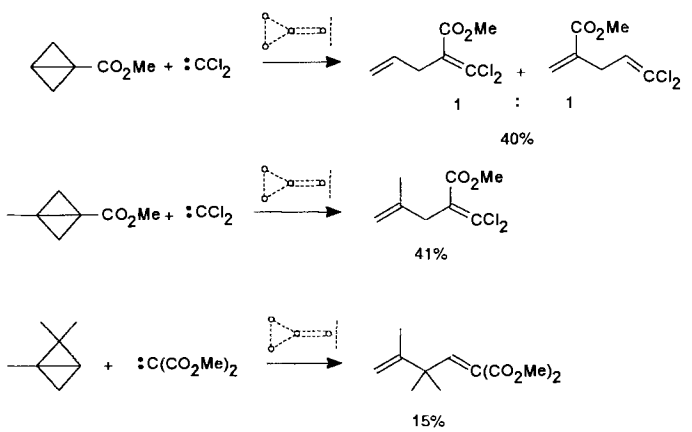
Also related to the cyclopropylcarbene fragmentation are the fragmentation reactions of some oxiranes. The α,β-epoxyhydrazone fragmentation described by Eschenmoser,[100] like the cyclopropylcarbene fragmentation, proceeds preferentially in ster-



ically *endo*-fixed systems.[101] Based on the reaction conditions (room temperature, acid and base catalysis), a carbene intermediate (and most probably also a diazo compound) can be almost definitely excluded.[102] Presumably, polar intermediates, and thus other mechanisms, determine the stereochemical characteristics. The analogous fragmentations of the sodium salts of tosylhydrazones under Bamford–Stevens conditions[103] and of azidooxirane,[104] however, proceed under pyrolytic or nonpolar conditions. Concerted mechanisms via diazo compounds, carbenes, or nitrenes are therefore plausible (Scheme 10).

Scheme 10. Heteroanalogues of the cyclopropylcarbene fragmentation.



4.1.3. Carbene Additions to Bicyclobutanes

The addition of carbenes to bicyclobutanes to form 1,4-dienes was termed "a pathway without parallel in the chemistry of ... carbenes" by its discoverers (Scheme 11).[105] The parent

Scheme 11. Schematic representation of the addition of carbenes to bicyclobutanes.

compound, bicyclobutane, reacts with methylene affording 1,4-pentadiene in 21% yield.[106] Substituted bicyclobutanes were treated by Wiberg et al.,[106] Applequist et al.,[107] and Jones, Jr. et al.[108] with dichlorocarbene and dimethoxycarbonylcarbene to give the corresponding 1,4-pentadienes (Scheme 12). Doering et al.[105] and Wiberg et al.[106] proposed a diradical mechanism. Detailed experimental investigations and semiempirical calculations of Jones, Jr. et al.[108] suggest a concerted attack of the singlet carbene.

Scheme 12. Examples of carbene addition to bicyclobutanes.

Formally the reaction corresponds to the attack of a carbene at a cyclopropane ring in such a way that two cyclopropane ring bonds are broken simultaneously and two bonds are attached to the carbene center. Besides the least motion process (Fig. 11a), other modes of attack with lower symmetry are conceivable. The point group given in Figure 11 is derived from the symmetry elements that are conserved during the reaction. All the

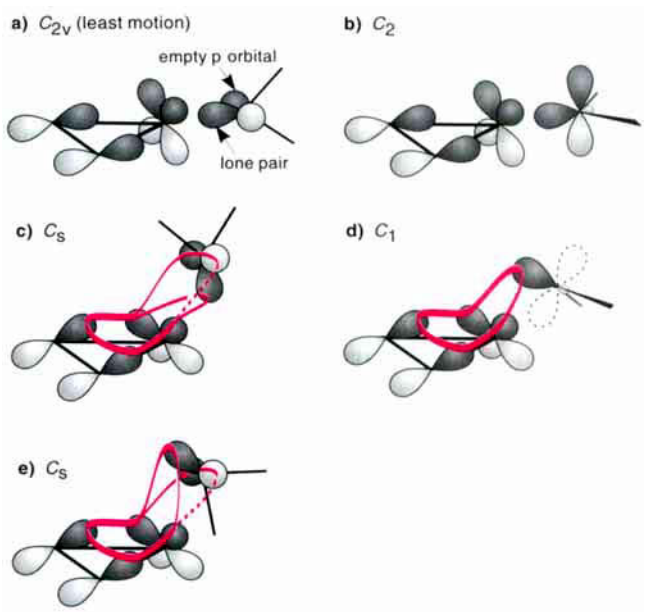


Fig. 11. Topological analysis of the carbene addition to cyclopropanes as given in Scheme 11. For details, see text.

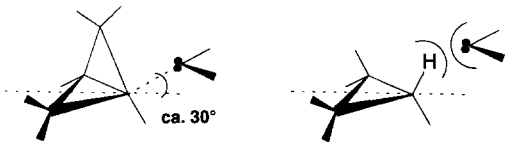
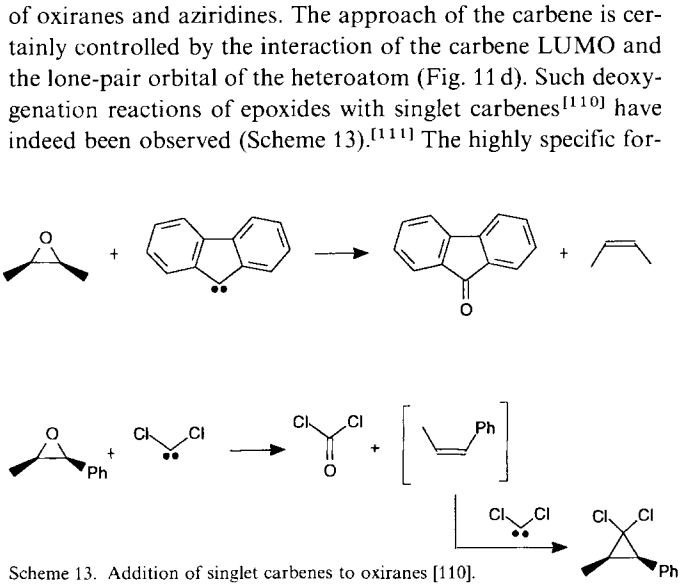
trajectories indicated are allowed according to the rules of the conservation of orbital symmetry. Topological analysis, however, maintains that attacks a) and b) are energetically less favorable than c), d), and e), because there is no way of forming a cyclic topology of the orbital basis. Most favorable are approaches c) and e), since both the lone-pair as well as the empty p orbital at the carbene center form aromatic systems with the remaining orbital basis (a Hückel system with the lone-pair and a Möbius system with the empty p orbital). The attack of the carbene therefore takes place from above the ring plane. This is confirmed by MNDO calculations of Jones, Jr. et al.[108] Examining the addition of methylene to bicyclobutane, they found two transition states of almost equal energy that correspond to the attacks c) and e) in Figure 11. According to the calculations, the angle between the bisector of the three-membered ring and the forming bond of the carbene center with the cyclopropane ring in the transition state is about 30°.[109] This explains why even highly strained cyclpropanes like spiropentane exclusively undergo C–H insertion in contrast to the bicyclobutanes. In cyclopropanes the attacks c) and e) (Fig. 11) are not feasible on steric grounds (because of the impeding H atom), whereas in bicyclobutanes the cyclopropane carbon atom at which the attack occurs is sterically deshielded by the three-membered ring bridge (Fig. 12), and addition is thus possible.





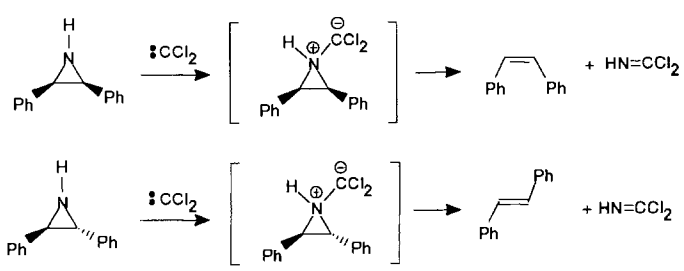


Fig. 12. According to MNDO calculations [108] and in accordance with the topological analysis, the attack of the carbene does not follow the least motion principle (approaches a) or b) in Fig. 11), but starts from above the ring plane with an angle of about 30° and from inside the flap of the bicyclic system. In cyclopropane the corresponding approach is hindered by the cyclopropane H atom.

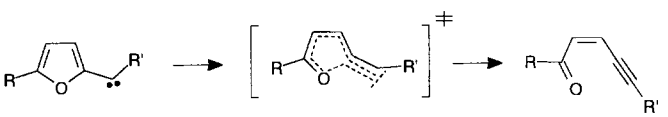
Similarly there are no steric problems to be expected during the attack of the carbene from above the ring plane in the case of oxiranes and aziridines. The approach of the carbene is certainly controlled by the interaction of the carbene LUMO and the lone-pair orbital of the heteroatom (Fig. 11d). Such deoxygenation reactions of epoxides with singlet carbenes[110] have indeed been observed (Scheme 13).[111] The highly specific formation of the alkene and the small acceleration of the reaction by substituents that stabilize carbenium ions make ring-opened, dipolar intermediates implausible. In principle, an ylide intermediate is conceivable besides the concerted pathway. Most probably, the fragmentation of aziridines found by Hata and Watanabe proceeds via an ylide intermediate and does not follow a complex mechanism[112] (Scheme 14).

Scheme 13. Addition of singlet carbenes to oxiranes [110].

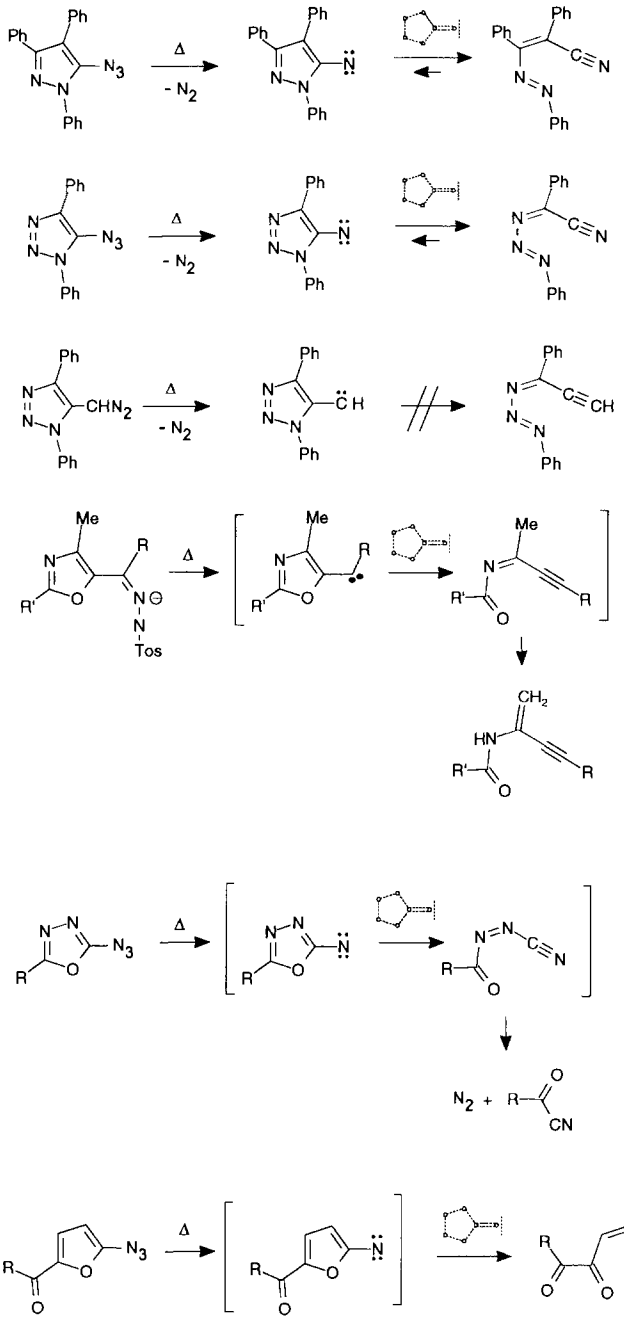
Scheme 14. The carbene addition to aziridines is not concerted but passes an ylide intermediate.



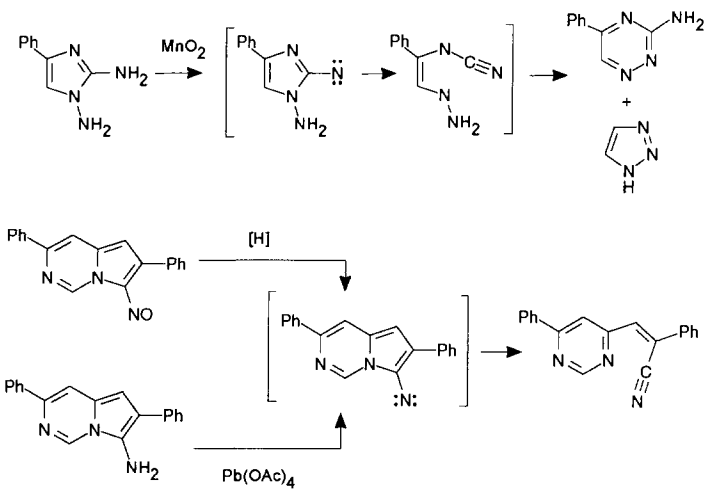
4.2. Reactions with Lone-Pair Terminators and Five-Membered Ring Terminators

The stereochemical relationships in reactions with a five-membered ring and a lone pair as terminators are different to those in which the terminators are three-membered rings and lone pairs. With two more electrons delocalized in the transition state but the same stereochemical constraints, the selection rules are inverted. This is illustrated in this section by the example of the rearrangement of furfurylidene and its heterocyclic analogues.

4.2.1. Rearrangement of Furfurylidene and Its Heterocyclic Analogues

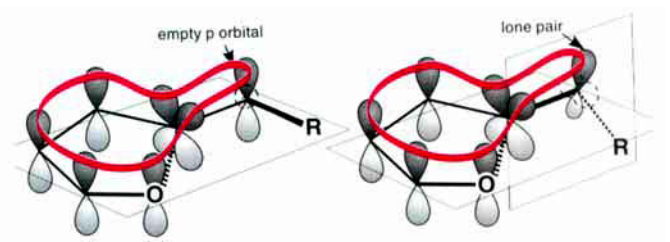


The 2-furfurylcarbene rearrangement was discovered by Hoffman und Shechter.[113-117] In a reaction that seems unusual at the first glance, furfurylidenes rearrange stereoselectively by cleavage of the furan ring to afford *cis*-2-penten-4-ynals (Scheme 15). Dry salts of tosylhydrazones or diazo compounds have served as carbene precursors.[118] Highly interesting are the fragmentations of some heterocyclic analogues of furfurylidene. There are indications that the fragmentation products of both the 5-aminopyrazoles[119] and the 5-azidotriazoles[120, 121] are open-chain nitriles that are in equilibrium with the corresponding cyclic nitrenoid forms; the equilibrium, however, lies for to the side of the nitriles (Scheme 16, first and second examples).[122] The small activation barrier and the consistent stereochemistry is explained by a stabilized coarctate transition state. The cyclic carbenoid form of the analogous 5-triazolylcarbene, however, is so stable that no open-chain alkyne could be detected (Scheme 16, third example).[121]



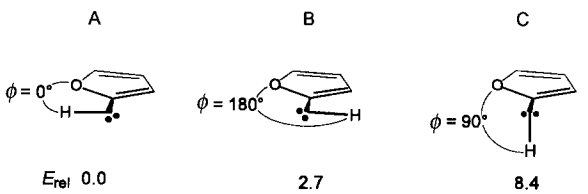
Scheme 15. Schematic representation of the furfurylidene rearrangement.

Similarly analogous to the furfurylidene rearrangement are the reactions of 5-oxazolylcarbenes (Scheme 16, example 4),[123] 5-acyl-2-azidofurans (Scheme 16, example 5),[124-126] and azidooxadiazoles (Scheme 16, example 6).[127]



The rearrangements of 1,2-diamino-4-phenylimidazole[128] and 3,6-diphenylpyrrolo[1,2-*c*]pyrimidine derivatives[129] (Scheme 17) most probably proceed via nitrenes or nitrenoide intermediates and therefore are analogous to the furfurylidene rearrangement as well. The ease of the rearrangement despite the annihilation of the aromaticity of the five-membered heterocyclic arenes during the reaction, as well as the *cis*-configuration of the olefinic product, can be explained by topological analysis (Fig. 13). Moreover, the analysis of the coarctate transition state supplies information about the most favorable position of the carbene carbon with respect to the plane of the ring. In contrast to the situations for the three-membered ring in the cyclopropylcarbene fragmentation and the carbene addition to bicyclobutanes, the furan ring makes six electrons available for delocalization in the transition state. Therefore, the empty p orbital of the carbene carbon atom should be included in the orbital basis in the transition state in order to allow Hückel-aromatic topology with six electrons, isoconjugate to the tropylium

Scheme 16. Examples of the rearrangement of heteroanalogues of furfurylidene. In the 4th reaction R′ = H, R = CH_3 or R′ = R = CH_3 or R′ = CH_3, R = Ph; in the 5th reaction R = Ph; in the 6th reaction R = *t*Bu, *i*Pr, H.



Scheme 17. Rearrangements that presumably proceed via nitrenes or nitrenoid intermediates, which are thus thus analogous to the furfurylidene rearrangement.

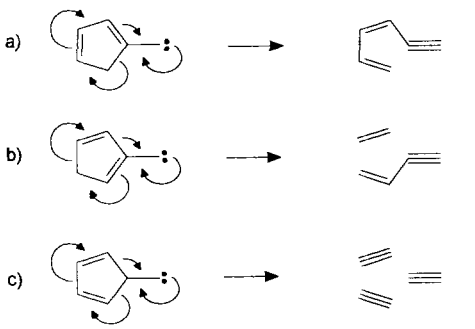
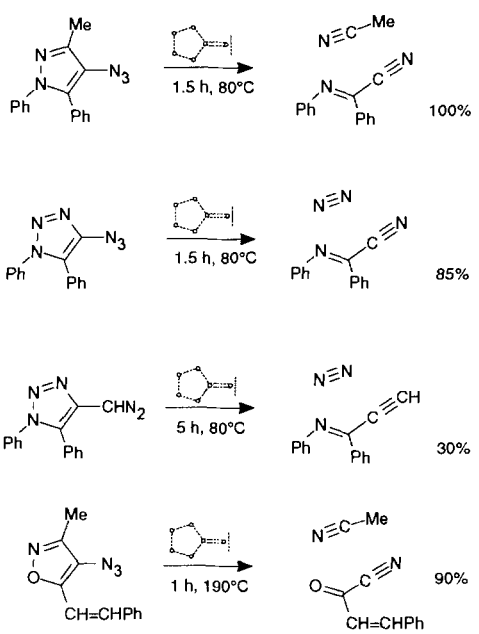
Scheme 18. MNDO calculations of different conformations of furfurylidene. In both conformative minima, the carbene H atom lies within the plane of the furan ring ($\phi = 0$, 180°). The transition state of the rotation around the C–C bond between the carbene and furan is described by C. Relative energies are given in kcal mol^{-1}.

cation. The bond axis between substituent and carbene center has to be parallel to the plane of the furan ring, and C_s symmetry has to be conserved during the reaction. Simple semiempirical calculations show that this is indeed the case. According to our MNDO calculations,[130] furfurylidene has two conformative minimima in C_s symmetry (Scheme 18).[131] The energetically most favorable conformation of the carbene in the starting material at the same time is the most suitable for the rearrangement to proceed.



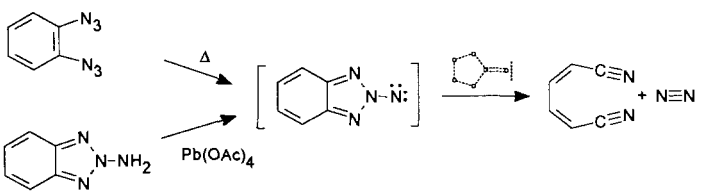
In agreement with the topological analysis, the energy maximum on the reaction path for the rearrangement[132] with a fixed angle of $\phi = 90°$ lies indeed more than 16 kcal mol^{-1} higher in energy than the one with $\phi = 0°$ (Scheme 19). (As to be expected for a forbidden reaction the energy maximum with $\phi = 90°$ is not a true transition state, but a stationary point of higher order.)



Scheme 19. Energy maxima on the reaction path [132] of the furfurylidene rearrangement, calculated by MNDO. The values E_{rel} [kcal mol^{-1}] are given relative to the energy of furfurylidene with $\phi = 0°$ (Scheme 18).

4.2.2. *Other Reactions*

In principle, three different positional isomers of cyclopentadienyl carbenes or nitrenes that are capable of undergoing complex reactions with five-membered ring and lone-pair terminators are conceivable (Scheme 20). The furfurylidene rearrangement in which the substitutent bearing the lone pair is in 1-position has already been mentioned. Additionally there is an elimination to give two and a fragmentation to afford three unsaturated fragments. In all-carbon systems these reactions have not yet been observed. Examples for nitrenes, however, are known. They derive their driving force mainly from the thermodynamically favorable formation of molecular nitrogen or a CN triple bond. 4-Azidopyrazoles like 4-azido-3-methyl-1,5-diphenylpyrazole react smoothly and in high yields to afford the corresponding nitriles and iminonitriles.[133, 134] Heteroanalogous are the elimination reactions of 4-azido-,[133] 4-diazomethyl-1,2,3-triazoles,[135] and 4-azido-3-methyl-5-styrylisoxazole (Scheme 21).

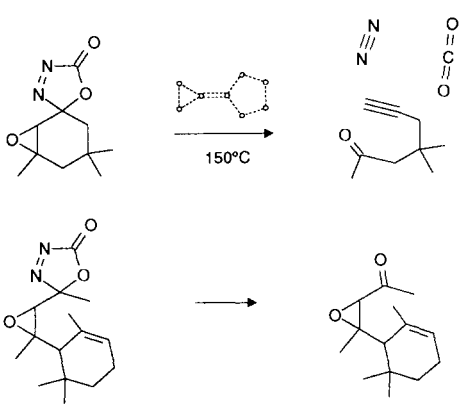


Scheme 20. Three types of complex reaction with five-membered ring and lone-pair terminators. The reactions differ only in the position of the substitutent bearing the lone pair relative to the double bonds in the five-membered ring. a) Furfurylidene rearrangement, b) elimination, c) fragmentation.

Scheme 21. Examples of elimination reactions analogous to mechanism b) in Scheme 20.

The fragmentation c) in Scheme 20 probably occurs in the pyrolysis of *o*-diazides[136] and the oxidation of 1- and 2-aminobenzotriazole[137] (Scheme 22). In agreement with a complex mechanism, *cis,cis*-muconitrile is formed stereoselectively as the product of this unusual fragmentation reaction.

Scheme 22. Example for a fragmentation reaction analogous to mechanism c) in Scheme 20.



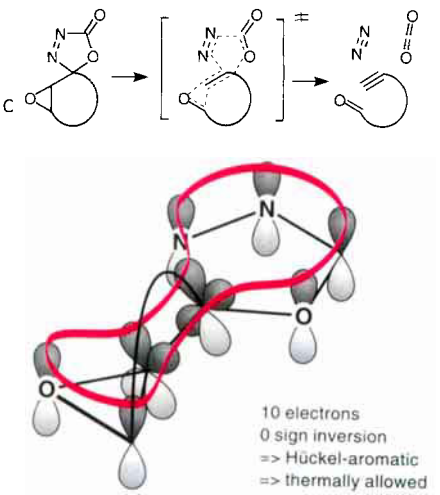
4.3. Reactions of Systems with Three- and Five-Membered Ring Terminators

4.3.1. *Oxirane Fragmentations*

Most of the fragmentation reactions with three-membered ring terminators rely on the principle of the elimination of a ketone from an epoxide. Depending on the length of the linear system of bond-breaking and -making and the size of the other terminator, a number of stereochemical consequences can be derived from a topological analysis of the transition state.

MacAlpine and Warkentin,[138] for instance, found that the fragmentation of oxirane-substituted [5H]-oxadiazolones is observed only if the oxirane and oxadiazolidine rings are fixed in a coplanar conformation by a spiro bridge (Scheme 23). If a concerted mechanism is assumed,[139] this fact can be easily explained by a topological analysis of the transition state (Fig. 14). With ten electrons and Hückel topology the reaction

Scheme 23. The fragmentation of oxirane-substituted oxadiazolones is observed only if the oxadiazol and oxirane rings are fixed in a coplanar orientation by a spiro bridge.



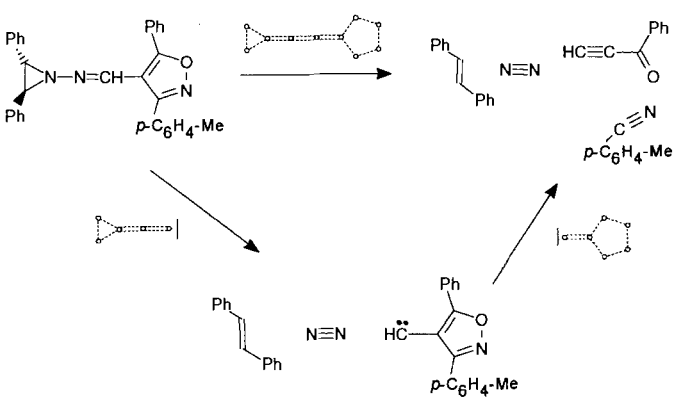


Fig. 14. Schematic representation and topological analysis of the oxirane-substituted oxadiazolone fragmentation.

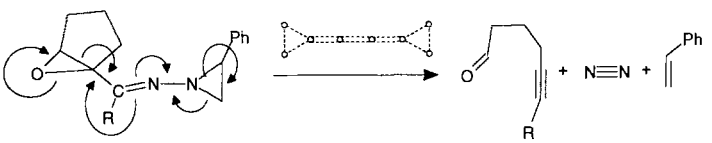
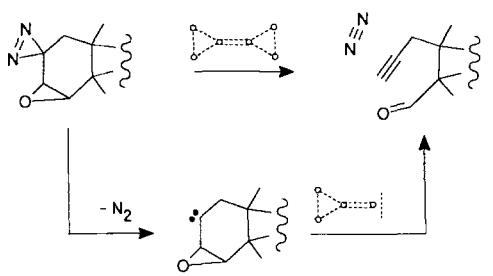


is thermochemically allowed. Oxirane and oxadiazole rings are fixed in a coplanar geometry, and thus the most suitable overlap of the orbital basis and an optimal stabilization of the transition state is attained. The same arguments concerning the stereochemistry are valid for the alternative mechanism via an oxiranyl carbene (see Scheme 26).

Likewise endowed with a three- and a five-membered ring terminator but containing a larger linear system ($n = 4$) is the fragmentation of 4-(aziridine-1-yliminomethyl)isoxazole, discovered by Gilchrist and Pearson.[140] Alternative to a one step mechanism and, considering the size of the system, more probable[141] is a two-step process consisting of two consecutive complex reactions. Both reaction pathways are allowed according to the topological analysis (Scheme 24), and both are favored by a coplanar orientation of the three- and five-membered ring.

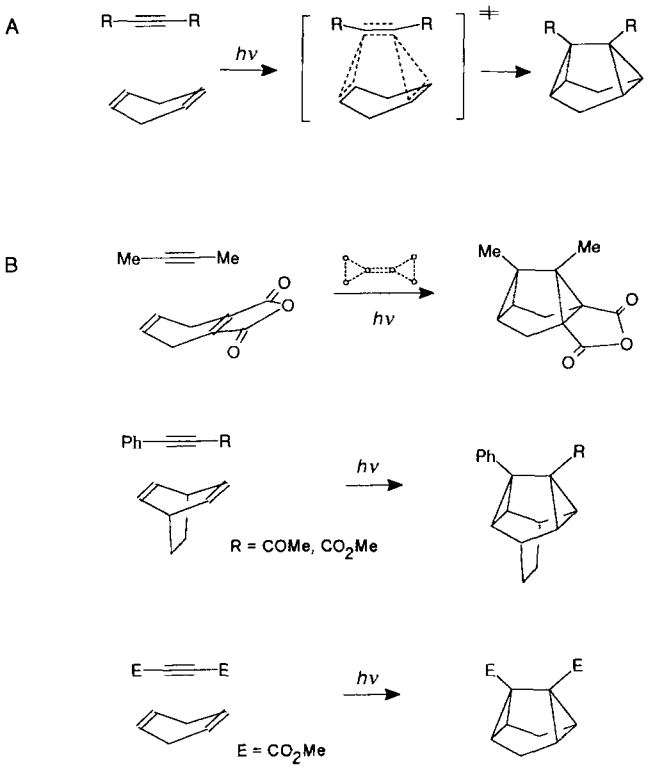


Scheme 24. If formulated as a one step reaction, the fragmentation of 4-(aziridine-1-yliminomethyl)isoxazole proceeds via a complex mechanism with a three- and a five-membered ring terminator and a linear system of $n = 4$. The Hückel aromatic transition state with 14 electrons is favored by a coplanar arrangement of the aziridine and isoxazole ring. Both steps of the alternative two-step mechanism via the 4-isoxazolylcarbene also proceed by complex mechanisms.

Stereochemical relationships should be reversed if a three-membered ring terminator (for example, aziridine ring) replaces the five-membered ring terminator (oxazole ring). Scheme 25 depicts the *N*-aminoaziridine version of the Eschenmoser reaction as example of such a reaction.[142] With 12 electrons and Hückel topology the reaction is thermochemically forbidden. Furthermore, sterically nonfixed systems of such a size rarely react in a concerted way. In some cases diazo compounds have indeed been detected as stable intermediates.[143] Also contradicting a concerted pathway and thus in agreement with the topological analysis is the fact that the reaction occurs in sterically nonfixed systems with high yields.

Scheme 25. The aminoaziridine version of the Eschenmoser reaction with 12 electrons is forbidden as a coarctate Hückel process.

Similarly forbidden according to a toplogical analysis is the fragmentation of the spiro-annelated diazirine shown in Scheme 26. Presumably after elimination of molecular nitrogen a carbene is passed as intermediate. The fragmentation of this intermediate is allowed, since it is an oxirane analogue of the cyclopropylcarbene fragmentation. It is even favored by the imposed *endo* conformation (Scheme 26, bottom).



Scheme 26. Fragmentation of a spiro-annelated diazirine. Top: The fragmentation that has been observed in a steroid system is forbidden as concerted process. Bottom: The fragmentation of the diazirine in a two-step mechanism is allowed.

4.3.2. *Cycloadditions of Acetylenes to 1,4-Cyclohexadienes*

Formally the photochemical addition of acetylenes to 1,4-cyclohexadienes can be viewed as a coarctate addition with two three-membered ring terminators (Scheme 27 A). Three experimental investigations have been published (Scheme 27 B).[145–147]

This is one of the few complex reactions that do not need topological transformation to be analyzed with the Hückel–Möbius method. In the linear part of the reaction (acetylene) there are already two orthogonal π systems present. Consequently, this simplifies the choice of the basis orbitals. The reaction was already used as an example for illustrating the application of the Hückel–Möbius method by Zimmerman[27] and treated by Woodward and Hoffmann according to the rules of the conservation of the orbital symmetry.[1] By using the topological approach the reaction can be analyzed without explicitly constructing a correlation diagram (Fig. 15). With eight elec-

trons and without sign inversion, the orbital basis is Hückel antiaromatic, and the reaction, in agreement with experiment, is photochemically allowed. Topological transformation shows that the transition state is isoconjugate to the antiaromatic cyclooctatetraene.

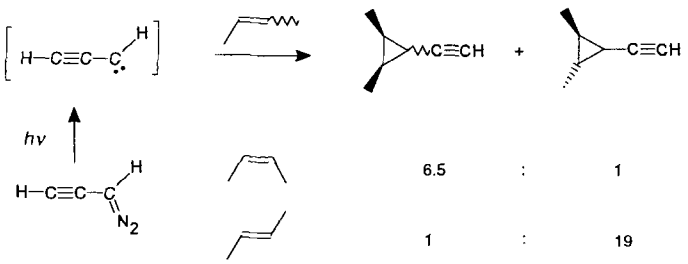
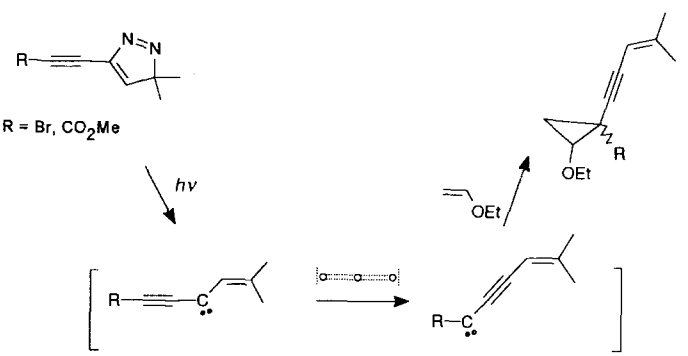
4.4. Reactions in Systems with Two Lone-Pair Terminators

4.4.1. Bond-Shift Reactions



The "bond-shift" reactions in which triple bonds are formally moved, can be considered models for complex reactions. Prototype of these rearrangements is the propynylidene (propargylene") automerization (Scheme 28). Here two bonds are broken and made simultaneously at the central carbon atom. Carbene centers act as lone-pair terminators. Such a 1,3-carbene shift has already been postulated by Skell et al. for propynylidene.[148] In the parent system and in symmetrically substituted

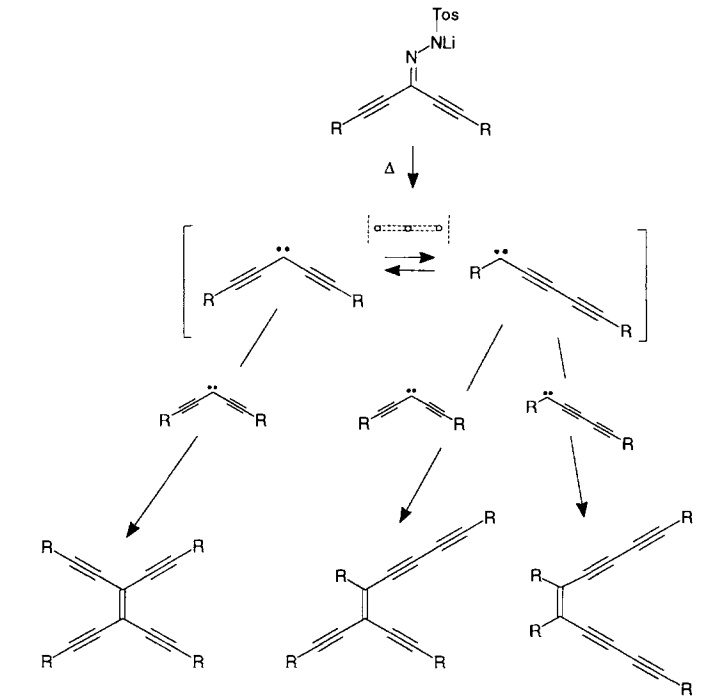
?



Scheme 28. General schematic representation of the bond-shift reaction of propynylidene.

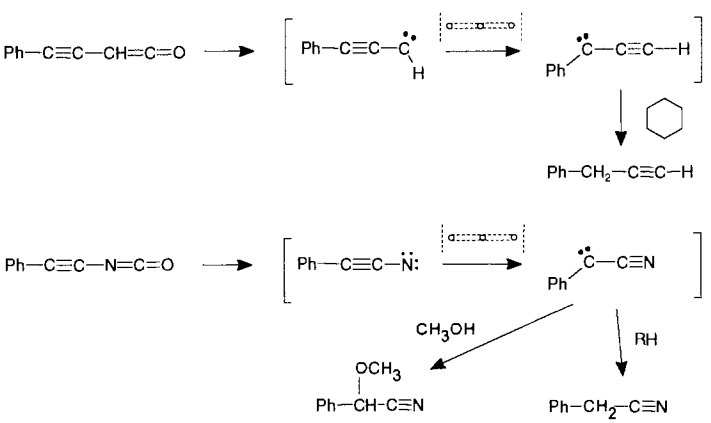
systems, however, the shift is not detectable. Trapping reactions with *cis*- and *trans*-butene prove that the stereochemistry of the olefin is not completely preserved.[148] Presumably part of the formed propynylidene converts into the more stable triplet state prior to the addition step. The nonstereoselective addition of the triplet then is responsible for the formation of the other stereoisomer (Scheme 29). The work of Franck-Neumann et

Scheme 29. Stereochemistry of the addition of propynylidene to alkenes.



al.,[149, 150] in particular, on vinylsubstituted propynylidenes suggest that a fast bond-shift reaction in the singlet state of the carbene (Scheme 30) takes place. Even though the photolysis was carried out in pure vinyl ether as trapping reagent, the trapped product exclusively derives from the rearranged carbene intermediate.

Scheme 30. Bond-shift reactions of vinylpropynylidenes.



Another bond-shift reaction, though not necessarily in the singlet state, was observed by Hauptmann while generating diethynyl carbenes.[151] All three conceivable dimeric products derived from a 1,3-carbene shift were formed. Because the

dimerization presupposes a long-lived carbene species, the transition to the potential triplet ground state is possible prior to the recombination with another carbene (Scheme 31).

Scheme 31. Bond-shift reactions of diethynylcarbenes.

According to Boyer and Selvarajan the trapped products of phenylpropynylidene[152, 153] and (phenylethynyl)nitrene[154] also derive from a rearranged carbene. In the case of the nitrene, the isomeric carbene species should be favored thermodynamically because of the relative stability of the C≡N bond over the C≡C bond[155] (Scheme 32).

Scheme 32. Bond-shift reactions of phenylpropynylidene and (phenylethynyl)-nitrene.

If the lone-pair orbitals on both potential carbene centers are parallel, the delocalized system of electrons in the transition state of the bond-shift reaction is topologically equivalent to the π system of the cyclobutadiene dianion, according to topological analysis (Fig. 16). With six electrons and Hückel topology, the reaction is thermochemically allowed. An optimal overlap of the orbital basis is attained if the transition state adopts a W shape (C_s symmetry). A transition state with C_2 symmetry, that is, the participation of an empty p orbital and a lone-pair orbital in the delocalized system, would have four electrons and would therefore be forbidden.

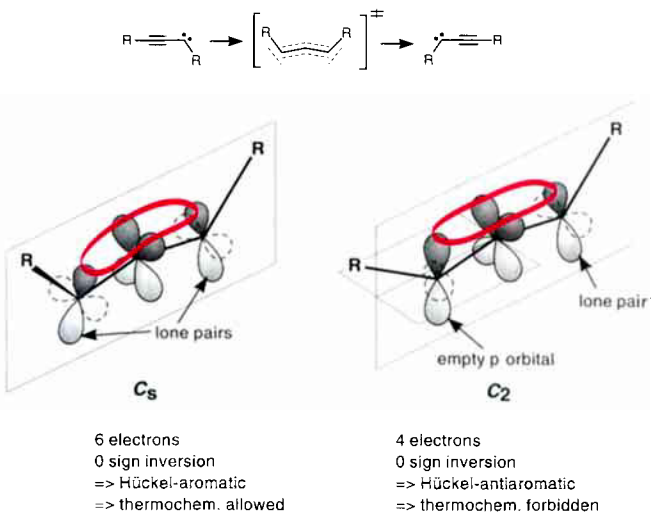


Fig. 16. Schematic representation and topological analysis of the bond-shift reaction of propynylidene.

Ab initio calculations of the singlet propynylidene on a reasonable theoretical level[156] confirm our qualitative predictions (Table 1, Fig. 17).[157] Highly interesting is the fact that on a high level of correlation the postulated "transition state" of the bond-shift reaction is more stable than the carbene species. The C_{2v} symmetrical form thus is not a transition state but an energy minimum on the singlet potential energy surface and accordingly the most stable structure of singlet propynylidene.

Table 1. Calculated relative energies of propynylidene with C_s and C_{2v} symmetry in kcal mol^{-1} (all values with for correction for the zero point energy).

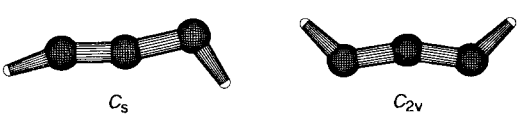
[a] See Fig. 17.



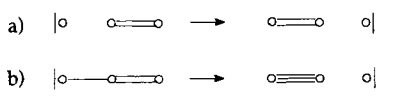


Fig. 17. Structures of propynylidene in C_s and C_{2v} symmetry, calculated with ab initio methods (QCISD/6-31G* level).

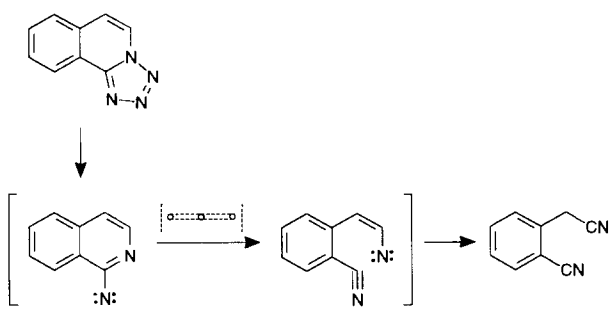
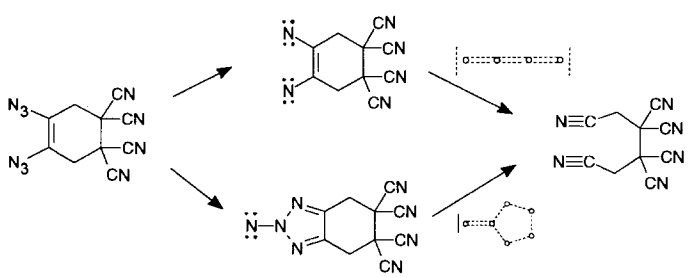
The ground state according to matrix investigations[158–162] and ESR studies[163] is the triplet spin state of propynylidene.



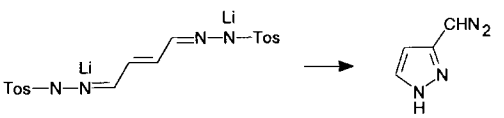
According to calculations[164–169] the triplet is more than 5 kcal mol^{-1} lower in energy than the lowest singlet state. Our calculations, however, suggest that the bond-shift reaction in the singlet state is faster than the spin inversion to the more stable triplet state.

4.4.2. Other Reactions

Theoretically two further complex reactions besides the bond-shift reaction are conceivable with two lone-pair terminators and $n = 1$ (Scheme 33). Reaction a) is rare as a concerted process; most of these abstraction reactions proceed via ylide intermediates.[170] Reaction b) presumably is the crucial step in some nitrene–nitrene and carbene–nitrene rearrangements,[171] such as, for example, those in Scheme 34.[172, 173]

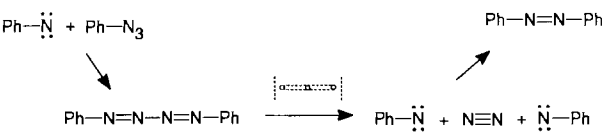


Scheme 33. Formal reaction schemes possible for complex reactions with lone-pair terminators and $n = 1$ (The sign ° represents an arbitrary element and | a lone pair.) Reaction c describes the bond-shift reaction.



Scheme 34. Rearrangement of the (2-quinolyl)nitrene as an example of a complex nitrene–nitrene rearrangement.

Whereas in reactions with an odd number n (for example, bond-shift reaction $n = 1$) the lone pair of the starting compound is formally pushed to the other end of the linear system, reactions with an even number n imply the occurrence of two lone pairs in the starting compound or product. At least for bis(carbene)s or bis(nitrene)s, such coarctate processes are very unlikely (or only observable under exotic conditions). The fragmentation of *o*-phenylene diazides and vicinal vinyl diazides[174] most probably proceeds (as mentioned in Section 4.2.2) via a triazole intermediate and not a bis(nitrene) (Scheme 35).



Scheme 35. The thermal and photochemical decomposition of vicinal vinyl azides leads to 1,4-dicyano compounds. Both the reaction path via the bis(azide) as well as that via the triazolylnitrene may be described as coarctate processes.

The fragmentation of the dilithio salt of the *trans*-butenedial ditosylhydrazone, published by Rodewald and Lee,[175] could not be reproduced by Maier and Wolf.[176] In place of the anticipated acetylene via the bis(carbene), 3-pyrazolediazomethane was formed from the intermediates of the Bamford–Stevens reaction (Scheme 36).

Scheme 36.

More probable, however, is an isoelectronic, coarctate process with lone-pair terminators and $n = 2$ for the photolysis of phenyl azide. Waddell et al. found a quantum yield of $\Phi = 300$ for the formation of azobenzene from phenyl azide in acetonitrile.[177–179] The chain mechanism of Scheme 37 was proposed as a conceivable explanation.

Scheme 37. Mechanism of the photolysis of phenyl azide. Phenylnitrene formed by photolysis adds to phenyl azide to afford diphenyltetraazadiene, which decomposes into two molecules of phenyl azide. The chain reaction leads to a quantum yield of $\Phi \gg 1$. Alternatively, the reaction of phenylnitrene with phenyl azide could lead directly to two molecules of phenylnitrene.

5. Back to Theory

5.1. Topology and Symmetry

In all examples shown so far, at those centers where two bonds are broken or made simultaneously, a set of two orthogonal p orbitals, twisted relative to the coordinate system of the remaining basis by 45°, were used for the construction of the orbital basis. The choice of the local coordinate system for the basis orbitals is arbitrary;[180] however, the orientation used in the above cases is neither coincidental nor purely empirical. It can be justified within the scope of qualitative MO theory. In symmetrical systems, the interrelation between qualitative MO theory based on the Hückel approximation and the topological analysis presented in this article can be directly illustrated.

The proper choice and orientation of the basis orbitals at these centers involves creating a set of orthogonal basis orbitals that are interconvertible by symmetry operations within the point group of the molecule, and that are not orthogonal relative to the remaining orbital basis. If one derives the symmetry-adapted MOs from this basis, *all* basis orbitals are included in each MO that is part of the delocalized system.[181] The totally

symmetrical MO without nodes is consequently topologically equivalent to the orbital basis of the topological analysis. Provided that there is a cyclic overlap of the orbital basis, the topology and nodal properties of the π orbitals of the corresponding aromatic or antiaromatic compounds are obtained directly by constructing the symmetry adapted MOs. This will be outlined in the following by means of the hypothetical[182] cycloaddition of two acetylene molecules to form tetrahedrane (Fig. 18).

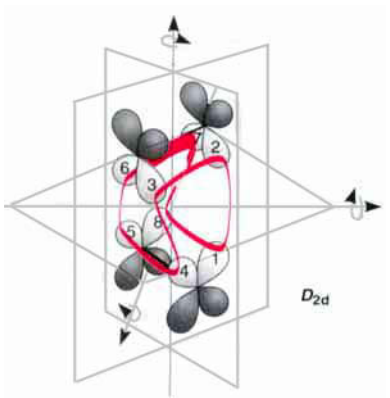


Fig. 18. Orbital basis of the photochemically allowed (hypothetical) addition of two acetylene units to form tetrahedrane. If the orbital axes basis orbitals form an angle of 45° with the corresponding mirror planes, all p functions are interconvertible by symmetry operations within the point group D_{2h}. The symmetry adapted MOs derived from this basis each contain all basis orbitals. Their topology of overlap and nodal properties correspond to those of the antiaromatic cyclooctatetraene (see text).

The point group of the whole system is D_{2d}. By rotating around the C–C bond axis the orientation of each p orbital ϕ is chosen in such a way that all basis orbitals are interconvertible by symmetry operations of the point group D_{2h}.[183] In this way all atomic orbitals that participate in the reaction are used as the basis for the reducible representation Γ of the point group D_{2h}. The reducible representation can be written as a linear combination of irreducible representations [Eq. (a)]. For the sake of simplicity we assume equal resonance integrals between all basis orbitals. The symmetry-adapted molecular orbitals then are derived by applying the projection operator method according to Scheme 38. Their topology and nodal properties exactly correspond to the antiaromatic, hypothetical D_{8h} cyclooctatetraene.[184] The reaction is thus thermochemically forbidden and photochemically allowed.[185]

$$\Gamma = A_1 + A_2 + B_1 + B_2 + 2E \qquad \text{(a)}$$

	Number of Nodes

Scheme 38. Symmetry-adapted MOs of the (hypothetical) dimerization of acetylene to tetrahedrane (see Fig. 18).

The topological method leads to the same result. It shows directly, and without explicit calculation of the MOs, a cyclic overlap of the basis orbitals (sequence -1-2-3-4-5-6-7-8-) without sign inversion. With eight electrons the transition state is antiaromatic and the reaction is thermochemically forbidden.

5.2. Simplified Rules

Because pericyclic and complex reactions profit from the same kind of stabilization in the transition state, the formal and descriptive relationship (described above in Section 2) has a sound physical foundation. Vice versa, the method of orbital transformation can be reduced to a descriptive level that allows the analysis of complex reactions on a purely formal basis. First the transition state is written in the form given in Figure 2. Each center p and q, at which one bond is broken and made or a lone pair is made or removed, is furnished with one basis orbital. The centers n, at which two bonds are broken or made simultaneously, receive each a set of two orthogonal p orbitals that are twisted by 45° relative to the other orbitals (Fig. 19).

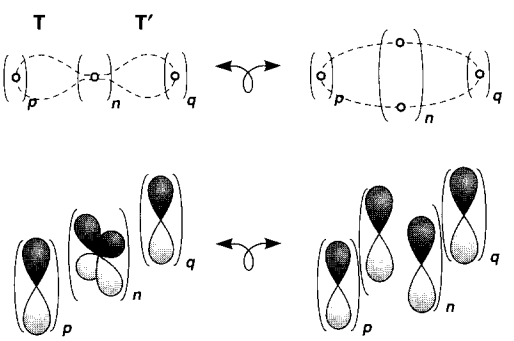

Fig. 19. Formal method to construct and analyze the orbital basis of complex reactions.

Subsequently the transformation to the corresponding cyclic system is performed, which is then analyzed according to the rules of the Hückel–Möbius method:

Complex reactions with $4n + 2$ electrons preferably proceed via Hückel-aromatic transition states and those with $4n$ electrons via Möbius-aromatic transition states.

If there are several stereochemically different, allowed reaction pathways, the following rule is used to select the energetically most favorable:

Of several allowed processes the one with the maximum overlap of the orbital basis is favored.

There is a special rule for carbene reactions:

There is always an allowed reaction path for carbene reactions if the orientation of the carbene center is not stereochemically fixed! If the remaining orbital basis (without the orbitals from the carbene) contains $4n$ electrons, the carbene center replenishes the system to $4n + 2$ electrons with its lone pair. In systems with $4n + 2$ electrons in the remaining orbital basis, the empty p orbital participates at the delocalized sys-

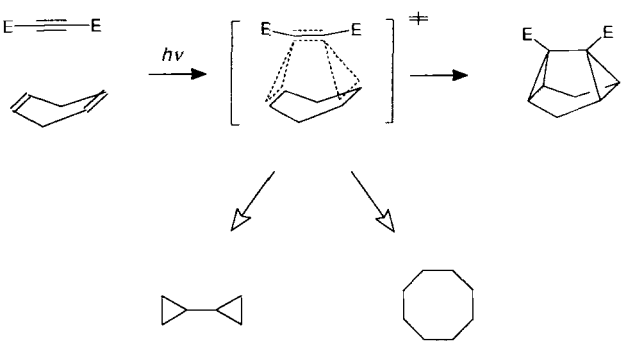
tem in the transition state. Stereochemical and mechanistical consequences only arise if the free orientation of the carbene center is hindered.

5.3. Comparison of the Topological Method with Alternative Methods

As mentioned in Section 3.1, there are three theoretical approaches for the qualitative treatment of pericyclic reactions, namely, correlation and state diagrams, frontier orbital considerations, and topological methods.

Advantages and disadvantages of the different methods have been discussed in detail by Dewar[25] and Zimmerman[27] and should just briefly be mentioned at this point. Being a perturbation method, the frontier orbital theory only is useful for reactions with an "early transition state", since a correct treatment of the interactions is restricted to the beginning of the reaction coordinate. Furthermore, a simple and useful application is limited to interactions between separated components. The extension to intramolecular reactions is rarely used in the literature. It suffers from the fact that first-order perturbations arise that are equal for all MOs (and not relevant exclusively for the frontier orbitals). On the other hand, the energies of the frontier orbitals and the size of the coefficients provide important information on reactivity and regioselectivity.[186] The application of the frontier orbital method presupposes the knowledge of the frontier orbitals, which are accessible only in symmetrical cases with paper-and-pencil methods.

Both the Woodward–Hoffmann rules, which are based on the number of supra- and antarafacial components, as well as the Hückel–Möbius method, are topological methods that are solely applicable to pericyclic reactions, or more precisely to a cyclic arrangement of orbitals. *The extension of the Hückel–Möbius method by topological transformation of the orbital basis, described in this article, offers the advantage that it is applicable to nonpericyclic reactions as well.* This has been illustrated by means of some examples of complex reactions.



The only feasible alternative in the case of nonpericyclic reactions is the construction of correlation and orbital interaction diagrams. However, the analysis by correlation diagrams is restricted to symmetrical systems[187] and requires the knowledge of the MOs of starting materials and products. Our topological analysis in symmetric and multicomponent reactions is faster than other methods and easier for a nontheorist to apply. In many concerted reactions two or more symmetry-allowed pathways are conceivable. Whereas the rules of the conservation of orbital symmetry provide only yes/no statements,[188] the topological analysis additionally discriminates between several stereochemically allowed pathways (see the cyclopropylcarbene fragmentation, Fig. 7, or carbene addition to bicyclobutanes, Fig. 11).

The most important advantage of the topological method, however, is not provided by its simpler and more general applicability, but by the fact that reaction principles derived from it can be used as organizing principles for known reactions and for the prediction of new reactions. Starting from the principle of topological transformation, new coarctate transition states can thus be derived from cyclic orbital topologies. By combination with the algorithms for the generation of reactions,[189–192] it should be possible to predict a large number of new reactions.

6. Prediction of Reactions

6.1. Create your Own Transition State

Correlation and orbital interaction diagrams allow prediction whether a known reaction is allowed or forbidden; however, there is no way of prediciting an unprecedented symmetry-allowed reaction from a correlation diagram. Innovative achievements in chemistry usually do not rely on abstract, quantum theoretical deliberations but on a topological way of thinking.[4] The topological way of thinking in chemistry manifests itself in its most simple form in the structural formula. The synthetic chemist's customary combinatorial problem of setting up chemical structures, for example to evaluate the products of a reaction, is carried out by manipulation of structural formulas in form of graphs. The same way of thinking is not applicable to designing novel transition states of complex reactions or mechanisms. The reason for this is that the constitutional topology of the participating bonds of a reaction and the topology of the delocalized system of electrons in the transition state are not identical, as the example of the photochemical addition of acetylenes to 1,4-cyclohexadiene illustrates (Scheme 39).

Scheme 39. Comparison of the topology of the newly formed or broken bonds (bottom left) with the topology of the orbital overlap in the delocalized system of the transition state (bottom right) for the addition of methyl acetylenedicarboxylate to 1,4-cyclohexadiene. E = CO_2Me.

However, novel transition states can be predicted by topological transformation of known transition states. Figure 20 shows the derivation of the set of eleven conceivable coarctate transition states from the transition states of pericyclic reactions with six and eight centers (and illustrates the term coarctate). Each transition state again represents a general category of complex reactions comprising a number of specific reactions. They can also be systematically deduced by formal methods.

6.2. Generation of Reactions

By means of graph theory and under defined boundary conditions the complete set of conceivable reactions that proceed via the coarctate transition states can be generated (cf. Fig. 20). For

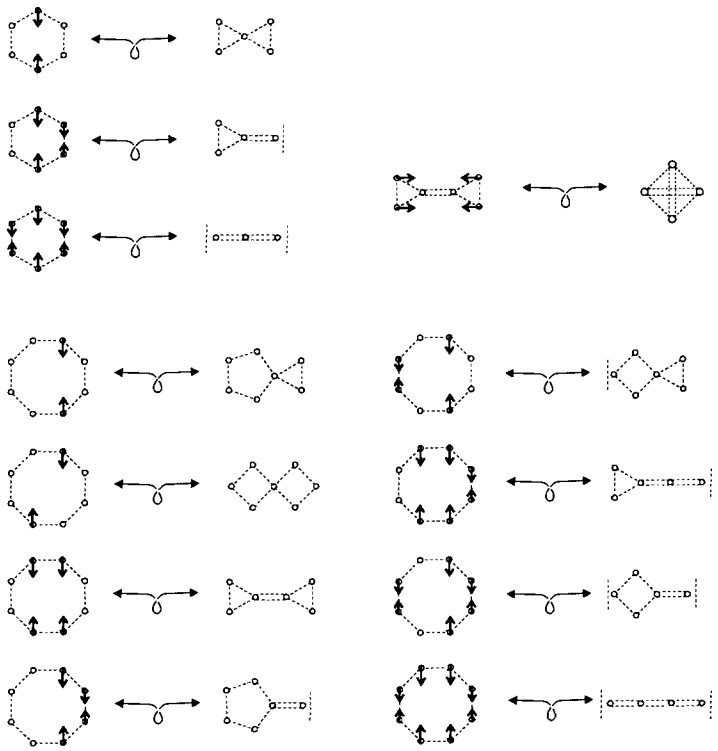


Fig. 20. Derivation of coarctate transition states from pericyclic transition states by topological transformation. The coarctate transition states can be further formally contracted by the same procedure (see last example).

that purpose we used the computer program IGOR[191] and our algorithm for generating subgraphs.[193] A similar approach with the program SYMBEQ was published by Zefirov et al.[194–196] Part of the reactions that are generated on a combinatorial basis should be known. The yet unknown reactions can be predicted as being theoretically conceivable and possibly verified in the laboratory.[5, 190, 197–200]

As an illustrative example we selected the complex reaction category with a three-membered ring terminator, a lone-pair terminator, and $n = 1$. The number of combinatorially possible solutions is restricted, since we are dealing with a small system with only four atoms in the reaction center. Moreover, systems of this size are still conveniently treated even with high-level ab initio methods. Thus the plausibility of the novel reactions can already be theoretically evaluated prior to the experimental verification.

As a boundary condition for the "chemistry" of the four atoms in the reaction center, it is useful to stipulate the "valence schemes" of carbon including carbene structures, because these valence schemes include the coordination properties of the most important heteroatoms. By substituting the not yet specified reaction centers with heteroelements in a second step, heteroanalogues are generated.[201] Structures with allene systems or triple bonds in three-membered rings are excluded as not chemically meaningful. Figure 21 shows the twelve "basic reactions"[202] that are conceivable and comply with these boundary conditions. Four of the twelve reactions are known: reaction 1 corresponds to the cyclopropylcarbene fragmentation, reaction 2 to the cyclopropenylcarbene fragmentation, reaction 3 to the addition of carbenes to bicyclobutanes, and reaction 4 to the known rearrangement of phenylcarbenes to ethynylcyclopentadienes.[171] Reactions 5-12 are unprecedented according to a careful search of the literature.

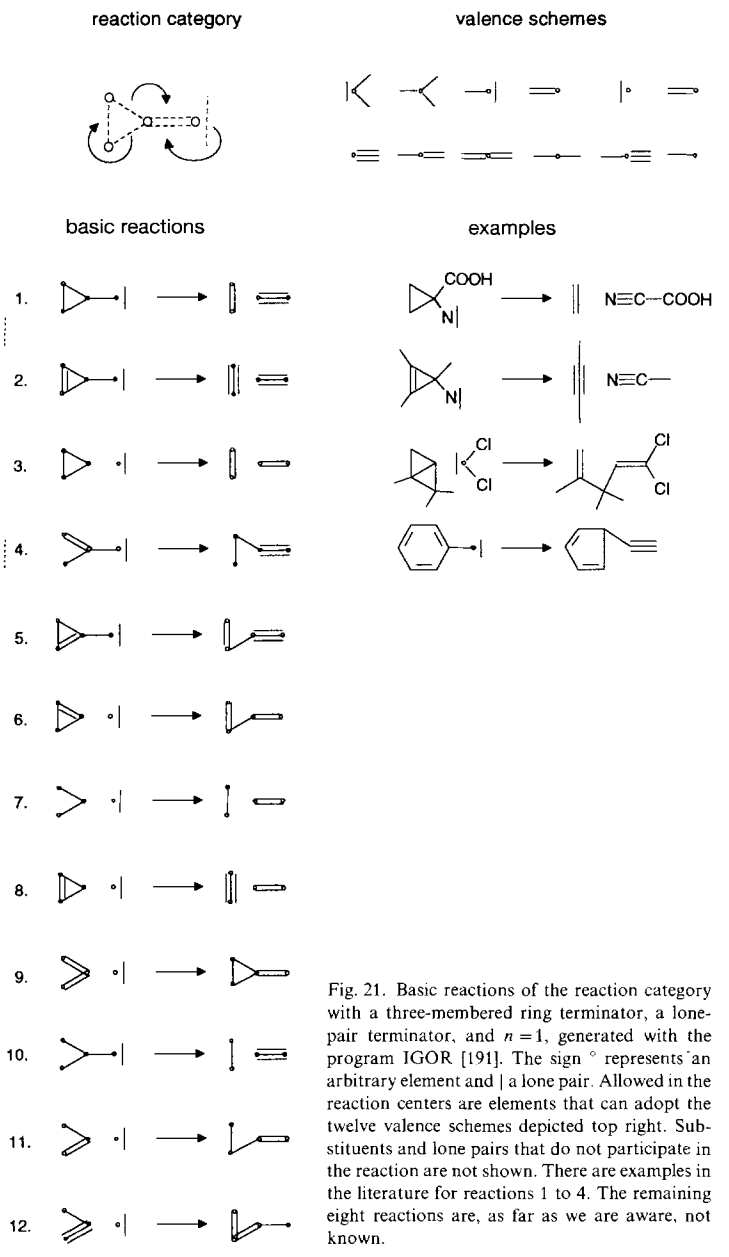

Fig. 21. Basic reactions of the reaction category with a three-membered ring terminator, a lone-pair terminator, and $n = 1$, generated with the program IGOR [191]. The sign ° represents an arbitrary element and | a lone pair. Allowed in the reaction centers are elements that can adopt the twelve valence schemes depicted top right. Substituents and lone pairs that do not participate in the reaction are not shown. There are examples in the literature for reactions 1 to 4. The remaining eight reactions are, as far as we are aware, not known.

The algorithms for the generation of reactions on a pure combinatorial basis do not give an indication for the practical feasibility of the reactions. Plausibility and possible side reactions have to be considered empirically. Thermodynamic and kinetic data in these small systems are predicted by ab initio methods with reasonable reliability. Reactions 6, 8, 9, 11, and 12, for instance, are bimolecular, and the addition of the carbene to the double bond most probably would compete with the coarctate process. In reactions 7 and 10 two sp^3-hybridized centers react with each other, which is unfavorable on sterical grounds. Only reaction 5 remains as a plausible prediction and therefore was selected for further investigations. In the parent

system (with four carbon atoms in the reaction core) the reaction corresponds to a rearrangement of 1-cyclopropenylcarbene to vinylacetylene.

Extensive ab initio calculations on the potential energy surface of C_4H_4[203] revealed only two stationary points with the 1-cyclopropenylcarbene structure (Fig. 22). Neither, however,

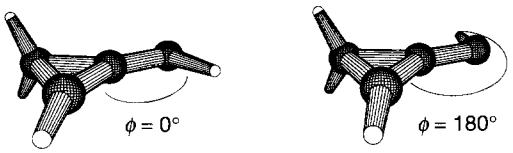

Fig. 22. C_s symmetric structures of 1-cyclopropenylcarbene calculated by ab initio methods (MP2/6-31G*//MP2/6-31G* level).

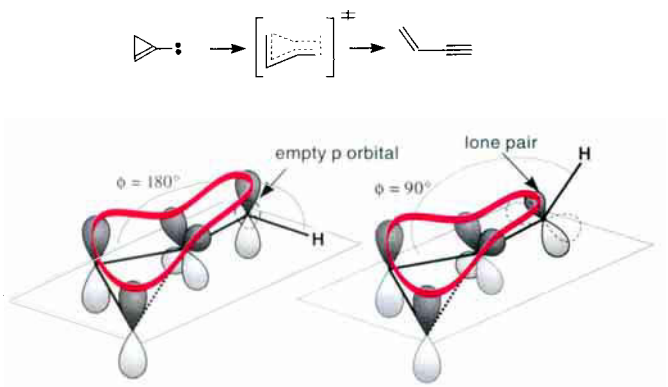
are minima; instead, according to a harmonic frequency analysis, they are transition states for the rotation around the carbene–cyclopropene C–C bond. If, starting from these two structures, the carbene H-atom is rotated around this bond while all other geometry parameters are optimized, the energy decreases continuously for both cases. At a torsional angle ϕ of $0 \pm 14°$ (or $180 \pm 14°$) the molecule rearranges spontaneously, as predicted, to vinylacetylene. This is likewise in accordance with the topological analysis of the coarctate transition state[204] of the reaction (Fig. 23). At a torsional angle of $\phi = 0°$, the empty



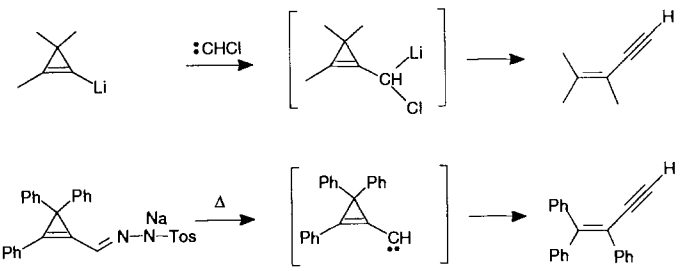


Fig. 23. Schematic representation and topological analysis of the rearrangement of 1-cyclopropenylcarbene to vinylacetylene.

p orbital of the carbene center overlaps with the remaining orbital basis to form a Hückel antiaromatic system; the reaction consequently is forbidden. If the carbene lone pair is turned out of the plane of the three-membered ring, a Hückel system with six electrons is formed, and the reaction therefore is thermochemically allowed.

Because the singlet state of the 1-cyclopropenylcarbene, according to our calculations, does not represent a minimum on the C_4H_4 energy surface but rearranges to vinylacetylene without an activation barrier, no side reactions are anticipated during experimental realization. No obstacles should thus bar the way of a practical verification, apart from potential problems in synthesizing the starting materials.

6.3. Experimental Verification

Trimethylcyclopropenyllithium was synthesized according to the methods of Closs et al.[205–207] and treated with dichloromethane. The intermediate carbenoid[208] formed by insertion of the incipient chlorocarbene into the C–Li bond, indeed rearranges to the corresponding vinylacetylene in 85% yield (Scheme 40). To test the mechanism further, another car-

Scheme 40. Experimental verification of the rearrangement of 1-cyclopropenylcarbene to vinylacetylene.

bene precursor, the tosylhydrazone of triphenylcyclopropene aldehyde,[209] was synthesized. The Bamford–Stevens reaction affords the corresponding vinylacetylene in 85% yield (Scheme 40)[189] in this case as well.

7. Outlook

In contrast to almost any other concerted organic reaction, the constitutional topology of the changing bonds and the overlap of the corresponding basis orbitals in the transition state of complex reactions are not identical[210] (see Scheme 39). This fact complicates not only the analysis of the mechanism, but also in particular, the prediction of unprecedented reactions of this type. Certainly not least for that reason, a large number of complex reactions are still waiting to be discovered. The insight into the formal relationships and physical principles presented here should help to develop this scarcely studied field of organic chemistry.[211, 212] Alongside linear (polar) and cyclic (pericyclic) reactions, the complex reactions form a third, smaller but important and cohesive class of concerted processes.

I would like to thank Professors R. Hoffmann, I. Ugi, and P. von R. Schleyer for helpful comments and discussions, and Molecular Design Ltd., the Fonds der Chemischen Industrie, and the Deutsche Forschungsgemeinschaft for financial support. I am particularly grateful to my wife. In intensive discussions and from the unbiased view of a nonchemist she suggested a number of improvements that contributed to the clearness of the article.

[32] Topological transformations, according to the mathematical definition, are continuous deformations of figures, whose geometrical properties are not changed thereby, for example, streching, pressing, or turning (not tearing, cutting, or folding). Geometrical figures that can be transformed by topological transformations are called homoeomorphous. Cube and sphere, for instance, are homoeomorphous; however, sphere and torus are not homoeomorphous. The surface of a cube or of a sphere can be divided in two differently colored parts by a closed curve; this is not possible with a torus. A Hückel and a Möbius ribbon (Fig. 5) are not homoeomorphous, because for transformation the ribbon has to be torn (not a topological transformation), twisted by 180°, and pasted.
[33] The symbol for homoeomorphism resembles R. Hoffmann's isolobality symbol (*Angew. Chem.* **1982**, *94*, 725; *Angew. Chem. Int. Ed. Engl.* **1982**, *21*, 711), because there are also similarities in meaning.
[34] The orbital at center 4 in the transition state of the cyclopropylcarbene fragmentation is the orbital that corresponds to the carbene lone pair in the starting material and to a p orbital in the product, acetylene.

[95] MP4SDTQ/6-31G*//MP2/6-31G* + ZPE level; R. Herges, unpublished; all stationary points were characterized by harmonic frequency analysis as minima or transition states.
[96] On the SCF level and without consideration of correlation (6-31G*//6-31G*), the transition state is calculated to be symmetric (C_s symmetry). The corresponding structure optimized on the MP2/6-31G* level in C_s symmetry, however, yields two imaginary frequencies. It is therefore not a transition state, but a stationary point of second order ("hill top"). Only after removal of the symmetry restrictions does optimization afford a strongly asymmetric structure, which turns out to be a transition state according to frequency analysis. Upon better treatment of the correlation (e.g., MCSCF), the transition state might prove to be more unsymmetrical or even a diradical intermediate might be found. A synchronous reaction can be ruled out on the grounds of these data.
[97] An UHF calculation of the transition state shows a high-spin contamination ($\langle S^2 \rangle = 0.911$).

[118] The intermediacy of the carbene is not proved in all cases. Ethyl(2-furyl)diazoacetate reacts already at room temperature in solution quantitatively within 12 h to give (*Z*)-hex-4-ene-2-yn-6-al-1-carboxylate. The reaction conditions suggest a concerted elimination of nitrogen and rearrangement; see ref. [117]. The statements from the topological analysis, however, are still valid.

[210] Another exception is the concerted di-π-methane rearrangement. Only one of the two double bonds is affected by the photorearrangement, even though both of them are involved in the transition state and both are essential for the reaction: a) S. S. Hixson, P. S. Mariano, H. E. Zimmerman, *Chem. Rev.* **1973**, *73*, 531; b) H. E. Zimmerman, *Acc. Chem. Res.* **1982**, *15*, 312.
[211] With the boundary conditions valid in Figure 21, 74 basis reactions are conceivable for the category of complex reactions with lone-pair and five-membered ring terminators and $n = 2$. Most of them are yet unknown.
[212] Some of the most important epoxidation reactions also proceed via coarctate transition states. Prediction of the mechanism and stereochemistry of these reactions would be of practical interest and will be subject of further studies.

Protein Structure Determination with Three- and Four-Dimensional NMR Spectroscopy

Hartmut Oschkinat,* Thomas Müller, and Thorsten Dieckmann

Structural biology has made important contributions to the understanding of biological processes. In recent years an increasing amount of structural information has also been derived from NMR spectroscopic studies, often with special emphasis on dynamic aspects. The introduction of three- and four-dimensional techniques has greatly simplified protein structure determination by NMR spectroscopy, which has in fact become routine. In the past it was more of an art to interpret the complicated NOESY spectra of proteins, but the application of three-dimensional techniques now makes the interpretation of protein spectra straightforward.

In this review we discuss the most important multidimensional NMR techniques along with suitable applications. The emphasis is put less on the discussion of individual pulse sequences than on their application to the structure determination of proteins.

1. Introduction

NMR spectroscopy is now well established as a method for the structure determination of small proteins and DNA fragments.[1] Since it allows the investigation of biological macromolecules in solution and offers additional insight into dynamic phenomena, NMR spectroscopy has proved to be a complementary method to X-ray crystallography. The most important prerequisite for this development was the introduction of two-dimensional (2D) NMR spectroscopy.[2–6] This enabled the interpretation of the complex NMR spectra of proteins and DNA and the determination of the parameters needed for structure calculation, for example, nuclear Overhauser effects (NOEs)[7] and coupling constants.[8, 9] These parameters correlate with distances between nuclei and dihedral angles, which provide the basic data for the calculation of three-dimensional structures using distance geometry[10, 11] and molecular dynamics[12, 13] programs.

The investigation of proteins by NMR spectroscopic methods was first limited to small molecules up to a size of 80 amino acids,[14–20] since the signal overlap in 2D spectra of larger proteins was too extreme. The development of three-dimensional (3D)[21–26] and four-dimensional (4D) NMR techniques[27] overcame this barrier. It is now possible to examine systems with molecular weights of up to 35 kDa when the proteins are uniformly labeled with ^{13}C and ^{15}N. The size of the proteins that can be investigated is still restricted by the transverse relaxation time, which becomes shorter with increasing molecular weight. An additional restriction may be caused by the complexity of the spectra; if a protein is composed of more than 250 amino acids, its 3D spectra will also show strongly overlapping signals. Examples of larger proteins whose structures have been investigated by multidimensional NMR spectroscopy include interleukin-1β,[28] the cyclophilin/cyclosporin complex,[29] and the calmodulin target peptide complex.[30]

The principles applied in 3D and 4D spectroscopy do not differ greatly from those already known from 2D spectroscopy.[6] We will therefore not discuss the pulse sequences here in detail, but rather their application in connection with the structure determination of proteins. After a short introduction to 3D and 4D NMR spectroscopy, a basic set of experiments will be illustrated by studies on interleukin-4 (IL-4)[31, 32] and chicken albumin cystatin (cystatin),[33, 34] whose structures were determined by NMR spectroscopy.

2. Multidimensional NMR Spectroscopy

The basic elements of 3D and 4D NMR spectroscopy are already included in 2D NMR spectroscopy. The general term "multidimensional NMR spectroscopy" applies for all of these techniques. In a typical 2D pulse sequence, given as

preparation – evolution (t_1) – mixing – detection (t_2)

the crucial step is the "coherence transfer".[5] During the evolution time, a nucleus A precesses with its characteristic frequency. A second nucleus B, which interacts with nucleus A by coher-

ence transfer during the mixing time, is excited, and its frequency is subsequently detected.

A set of experiments can be acquired in which the evolution time is increased for each experiment in suitable steps. Detection in t_2 and Fourier transformation gives a signal of nucleus B that is modulated with the frequency of nucleus A. The signals resulting from different t_1 settings are ordered in a 2D matrix. A second independent Fourier transformation of the orthogonal data vectors provides a signal with two different frequency coordinates, a 2D cross peak. It is obvious that at the end of such a pulse sequence another mixing time can be added before detection. This gives us the general form of a multidimensional NMR experiment:

preparation–(evolution–mixing)$_n$–detection

The individual multidimensional NMR experiments are distinguished by the applied excitation and mixing procedures (Fig. 1). Most of these are the same as those used in 2D spectroscopy and are combined like building blocks to give a 3D or 4D sequence.[6] The COSY (correlated spectroscopy)[3, 35–38] and TOCSY (total correlated spectroscopy)[39–41] sequences give the correlations through chemical bonds, while the NOESY (nuclear Overhauser and exchange spectroscopy)[42] and ROESY (rotating frame Overhauser effect spectroscopy)[43] mixing sequences identify neighboring nuclei through space by means of cross relaxation. The HMQC (heteronuclear multiple quantum coherence)[44, 45] and HSQC (heteronuclear single quantum coherence) sequences[46, 47] are analogous to the COSY sequence but correlate different nuclei (e.g. protons and carbon nuclei). In principle the multidimensional experiments can also be understood as a combination of 2D techniques. For this reason in the nomenclature of the 3D techniques the names of the underlying 2D techniques are combined (e.g. TOCSY-NOESY, NOESY-HMQC) or, as is practiced for most triple-resonance experiments, the participating nuclei are listed. A 3D-HCACO experiment, for example, gives a correlation between the α proton, the α carbon atom, and the carbonyl carbon atom of a single amino acid in the protein. Nuclei given in parentheses are not detected but are involved in coherence transfer (e.g. 3D-HCA(CO)N). A selection of pulse sequences used for structure analysis of proteins is given in Table 1. Figure 2 shows a region of the 3D-TOCSY-NOESY spectrum of interleukin-4.

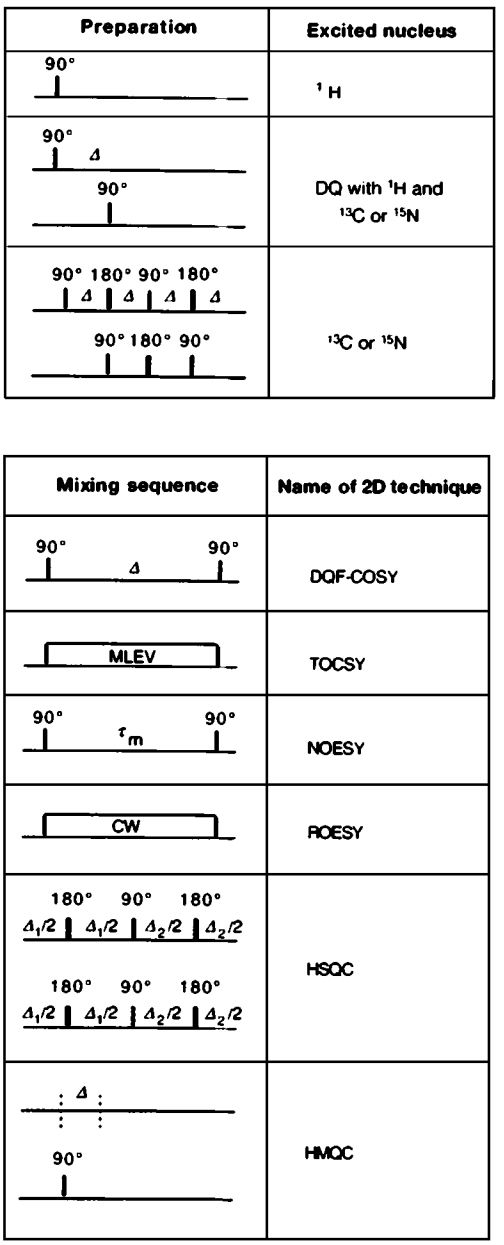

Fig. 1. Some common pulse sequences for excitation and mixing in multidimensional NMR experiments. DQ = double quantum, DQF = double quantum filtered, CW = continuous wave, MLEV = composite pulse mixing sequence. Other abbreviations are explained in the text.

Hartmut Oschkinat, born February 28, 1957, in Frankfurt am Main, studied chemistry in Frankfurt starting in 1975. His studies were interrupted by time spent in community service and with Ray Freeman's research group in Oxford. He earned his Ph.D. in 1985 under the direction of Horst Kessler. Following postdoctoral research with Geoffey Bodenhausen in Lausanne, he worked as an NMR spectroscopist at the Max-Planck-Institut für Biochemie in Martinsried from 1987 to 1991. Has has been a group leader at the EMBL in Heidelberg since 1991. His research interests focus on the determination of protein structures in solution and the study of structures and functions of membrane-bound proteins.

Table 1. A selection of 3D and 4D NMR techniques used in protein structure determination.

Experiment	Information/linkage obtained	Ref.
a) *unlabeled proteins—homonuclear experiments*		
3D-TOCSY-TOCSY	^{1}H spin systems/amino acids	[66]
3D-TOCSY-NOESY	sequential assignment of the spin systems, identification of NOEs	[122]
3D-NOESY-NOESY	identification of NOEs	[82–86]
b) *^{15}N labeled proteins*		
3D-TOCSY-^{1}H-^{15}N-HMQC/HSQC	^{1}H spin systems, ^{15}N shifts	[96–100]
3D-NOESY-^{1}H-^{15}N-HMQC/HSQC	sequential assignment of the spin systems, identification of NOEs with amide protons	[96–100]
3D-HNHB	$H_N(i)$-N(i)-$H_\beta(i)$, stereospecific assignment of methyl protons	[111]
c) *^{13}C-^{15}N labeled proteins*		
3D-TOCSY-^{1}H-^{13}C-HMQC/HSQC	^{1}H spin systems, ^{13}C shifts	[96–100]
3D-NOESY-^{1}H-^{13}C-HMQC/HSQC	sequential assignment of the spin systems, in particular identification of NOEs between side chains	[96–100]
3D-HCCH-COSY	^{1}H spin systems, ^{13}C shifts	[117, 118]
3D-HCCH-TOCSY	^{1}H spin systems, ^{13}C shifts	[119]
3D-HC(C)NH-TOCSY	connection of H_N and side-chain ^{1}H and ^{13}C	[114]
3D-H(CCO)NH	correlation of all side-chain ^{1}H and ^{13}C of amino acid i with $H_N(i+1)$	[112, 113]
H(CA)NH	$H_\alpha(i)$-N(i)-$H_N(i)$	[27]
3D-HCACO	$H_\alpha(i)$-$C_\alpha(i)$-CO(i)	[101]
3D-HNCA	$H_N(i)$-N(i)-$C_\alpha(i)$/$C_\alpha(i-1)$	[101, 102]
3D-HNCACB	$H_N(i)$-N(i)-$C_\alpha(i)$/$C_\alpha(i-1)$/$C_\beta(i)$/$C_\beta(i-1)$	[103]
3D-HN(CA)NNH	$H_N(i)$-N($i+1$)-$H_N(i+1)$	[105]
3D-HA(CA)NNH	$H_\alpha(i)$/$H_\alpha(i-1)$-N(i)-$H_N(i)$	[105]
3D-HN(NCA)NNH	$H_N(i)$-N($i+1$)-$H_N(i+1)$	[104]
3D-HCA(CO)N	$H_\alpha(i)$-$C_\alpha(i)$-N($i+1$)	[101, 106]
3D-HNCO	$H_N(i)$-N(i)-CO($i-1$)	[101]
3D-HN(CA)HA	$H_N(i)$-N(i)-$H_\alpha(i)$/$H_\alpha(i-1$)	[107]
3D-HN(CO)CA	$H_N(i)$-N(i)-$C_\alpha(i-1$)	[108]
3D-HN(COCA)HA	$H_N(i)$-N(i)-$H_\alpha(i-1$)	[109]
3D-H(N)CACO	H_N-$C_\alpha(i)$/$C_\alpha(i-1)$-CO(i)/CO($i-1$)	[110]
3D-H(C)(CO)NH-TOCSY	correlation of side-chain ^{1}H and ^{13}C with $H_N(i,i-1)$ and N($i,i-1$)	[144]
4D-HCANNH	$H_\alpha(i)$-$C_\alpha(i)$-N(i)-$H_N(i)$	[115, 116]
4D-HCA(CO)NNH	$H_\alpha(i)$-$C_\alpha(i)$-N($i+1$)-$H_N(i+1)$	[115, 116]
4D-HNCAHA	$H_N(i)$-N(i)-$C_\alpha(i)$-$H_\alpha(i)$	[115, 116]
4D-HCCH-TOCSY	^{1}H spin systems, ^{13}C shifts	[120]
4D-^{1}H-^{13}C-HMQC-NOESY-^{1}H-^{13}C-HMQC	identification of NOEs between side-chain	[121]
4D-^{1}H-^{15}N-HMQC-NOESY-^{1}H-^{13}C-HMQC	identification of NOEs with amide protons	[27]
$^2J_{CO(H_\alpha)}$-E.COSY	^2J(CO,H_α)	[89]
3D-HNCA	^3J(HN,H_α), ϕ angle	[90]
3D-HMQC-J_{HH}-TOCSY	^3J(HN,H_α), ϕ angle	[88]
3D-H,C-COSY-ct-C,C-COSY-β-INEPT	vicinal ^{1}H-^{1}H couplings	[91]
Soft-HCCH-COSY	^3J(H_β,CO)	[92]
Soft-HCCH-E.COSY	^3J(H_α,H_β)	[92]

Three- and four-dimensional NMR experiments have many qualitative advantages over two-dimensional techniques. At least three dimensions are needed for correlations between heteronuclei in macromolecules, because the magnetization of the protons must be detected for reasons of sensitivity. This technique is indispensable for proteins, as the sequence assignment of the signals can be made independently of the secondary structure analysis. Three dimensions are also needed if the chemical shifts of heteronuclei are used for the resolution of signal overlap in NOESY spectra. This increase in resolution is probably the most important advantage of multidimensional NMR spectroscopy and is shown schematically in Figure 3. Two pairs of

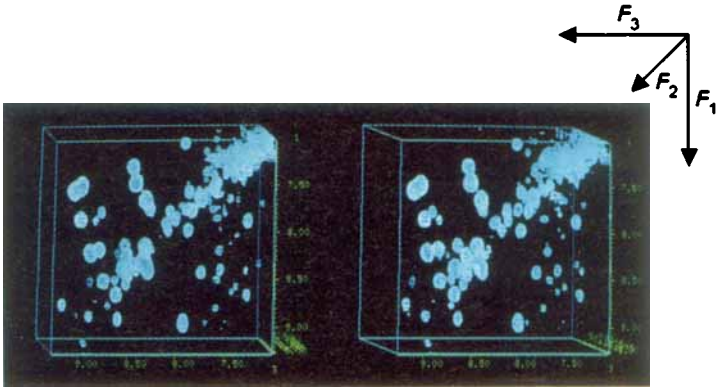

Fig. 2. Section of a 3D-TOCSY-NOESY spectrum of IL-4. In F_1 and F_3 the section with the chemical shifts of the amide protons was chosen, in F_2 the α-proton region.

interacting protons have the same chemical shifts (A), and the NOESY spectrum shows only one signal (B). Application of a third dimension, comprising the different chemical shifts of the ^{13}C nuclei, allows the distribution of the 2D cross peaks into different layers and facilitates the assignment of the blue signals (C).

Despite this increase of resolution, the protons with the "green" frequency in Figure 3 cannot be assigned unambiguously. It is obvious that the introduction of one more frequency dimension, in other words, detection of the carbon atoms connected to those protons, would solve this problem.

2.1. Basics

Owing to the modular construction of multidimensional pulse sequences from units known from 2D spectroscopy (Fig. 1), the events occurring in a higher order pulse sequence are completely analogous. A full description of the individual sequences using the product operator formalism[49] and coherence transfer pathways will therefore not be given here; the reader is referred to articles by Ernst[5] and Kessler et al.[6] for more information. In the following we will discuss some particular problems that arise when switching from two to three or more dimensions.

2.1.1. Sensitivity

The 3D data set is a function of three independent time variables. If the terms describing relaxation during the evolution period are neglected, a single 3D signal can be described by Equation (1).[51] $Z_{(pq,rs,tu)}$ is the amplitude of the coherence transfer [Eq.(2)]. The superoperator element $R^{(n)}_{(pq,rs)}$ describes

$$S_{(pq,rs,tu)}(t_1,t_2,t_3) = Z_{(pq,rs,tu)} \exp(-\omega_{pq} t_3) \exp(-\omega_{rs} t_2) \exp(-\omega_{tu} t_1) \quad (1)$$

$$Z_{(pq,rs,tu)} = D_{pq} R^{(2)}_{(pq,rs)} R^{(1)}_{(rs,tu)} \sigma(0)_{(tu)} \quad (2)$$

the n^{th} coherence transfer between the coherences pq and rs, the operator $D_{(pq)}$ corresponds to the effectiveness of the detection of the transition pq, and $\sigma(0)_{(tu)}$ is the ground state of the density operator for the transition tu. Equation (2) thus describes the integral intensity of the signal.

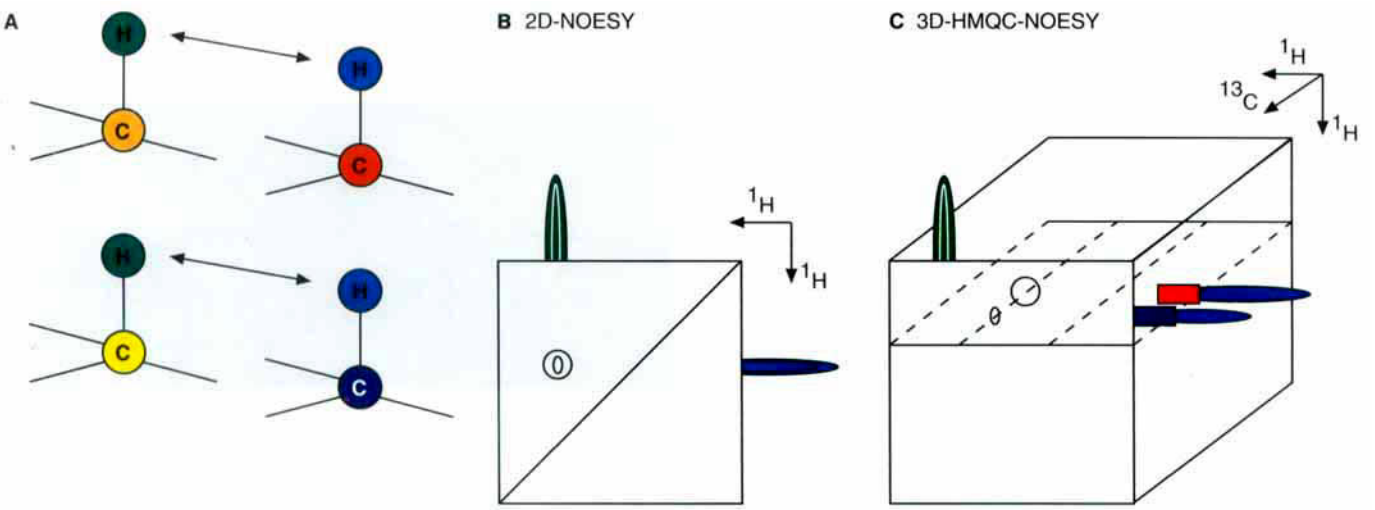

Fig. 3. Schematic representation of the resolution advantages of 3D NMR spectroscopy. Two pairs of protons have the same resonance frequency (same color) (A), which results in an overlap of cross peaks in the 2D NOESY spectrum (B). When the frequency of the carbon atoms is plotted as the third dimension, the problem is solved, since their resonance frequencies are different. The NOESY cross peaks are thus distributed in different planes (C).

Increasing the number of dimensions from two to three may, though not necessarily, result in a much lower signal/noise (S/N) ratio. This can be caused by two main factors: the intensity may be distributed into several multiplet lines occurring in the third dimension, or the coherence transfer steps are not efficient, which results in weak 3D cross peaks. It can be shown that the difference in the signal/noise ratio of a 2D cross peak involving the two protons i and k and that of a 3D cross peak ijk depends on the efficiency of the additional transfer T_{ij} and on the number of multiplet lines of nucleus i, N_i [Eq.(3)]. In the best case, when the signal of nucleus i consists of only one line and

$$\frac{(S/N)^{ijk}_{3D}}{(S/N)^{jk}_{2D}} = T_{ij}/N_i \qquad (3)$$

the transfer is quantitative, no substantial decrease in intensity will be observed compared to the 2D spectrum. This is the basis of techniques that use the chemical shifts of heteronuclei as additional frequency parameters. If there is no relaxation, the signal intensities in a ^{15}N-resolved NOESY spectrum should correspond to those in the 2D-NOESY spectrum. However, if homonuclear 2D techniques are combined, the intensities of the 1D, 2D, and 3D signals is 100:10:1, given a 10% efficiency of each coherence transfer and not taking into account the effect of the increasing number of multiplet lines.

2.1.2. Resolution and Acquisition Time

The advantages of multidimensional NMR spectroscopy can only be made use of if sufficient data points can be accumulated in all dimensions. If the resolution is poor, the spectra are difficult to interpret and will show broad, overlapping signals, which offsets the advantages of higher dimensional NMR experiments. Since the acquisition time increases exponentially with the number of experiments in the indirectly detected dimensions, a compromise must be found between good resolution and acquisition time. The acquisition of a 3D-NOESY-^{1}H-^{15}N-HMQC spectrum, for example, with 196 × 96 × 1024 data points in $F_1(^1H)/F_2(^{15}N)/F_3(^1H_N)$ and accumulation of 16 transients per time increment requires 70–80 hours. Several procedures are therefore applied to obtain sufficient resolution in a reasonable acquisition time, for example backfolding of signals, selective excitation of small spectral regions, use of pulsed field gradients, and the application of mathematical algorithms to enhance the resolution.

Backfolding of Signals: The spectral width of an NMR spectrum is defined by the time increment used in data acquisition. Normally signals lying outside the spectral range are "folded back" after a Fourier transformation of the digitized signal.[4, 52] Carefully planned folding of the spectrum in one frequency domain may make it possible to record a sufficiently resolved spectrum without any loss of information. Multidimensional ^{13}C NMR carbon spectra, in particular, can be improved by this method.[47]

Selective Excitation: A smaller spectral width and hence sufficient resolution in an acceptable time can also be obtained by selective excitation of nuclei, whose signals are found in separate regions of the spectra. Generally, shaped pulses with low power are used.[51, 53, 54] For heteronuclear spectra, multiplicity selection may also be applied.[55–57]

Gradients: The total time required for a multidimensional experiment mainly depends on the phase cycling used to select the desired coherences. In many cases at least 4, 8, or 16 transients are needed for spectra with a minimum of artifacts, which results in long acquisition times. If pulsed field gradients are used, selection of the desired coherence transfer steps is potentially possible in one scan.[58–61] Therefore, no addition of free induction decays (FIDs) is needed as is usually required for selection by phase cycling. As a consequence, more data points can be acquired.[62–64]

Linear Prediction: To improve resolution, the FIDs can be extended by calculating more data points before Fourier transformation by the application of a linear prediction. This is helpful if only a few data points can be acquired in the indirectly detected dimensions. New data points are usually calculated from the measured data by using the Burg algorithm.[65–67]

2.2. What Three-Dimensional Spectra Look Like

In a three-dimensional spectrum the basic 2D spectra of which it is composed appear as diagonal planes. When all three diagonal planes are present, as is the case in homonuclear 3D spectroscopy, the line of intersection of the three diagonal planes is the main diagonal, which is equivalent to the one-dimensional spectrum. The signals are classified according to the number of coherence transfer steps and therefore according to the number of different frequencies contained (Scheme 1).

Diagonal peaks	A → A → A
Cross diagonal peaks	A → A → B
	A → B → B
Back transfer peaks	A → B → A
Cross peaks	A → B → C

Scheme 1. Signal classification in multidimensional NMR spectra.

Diagonal signals containing three identical frequencies correspond to the one-dimensional spectrum, signals with two identical frequencies (cross-diagonal and back transfer signals) represent the 2D spectra. Only from the 3D cross peaks can one extract more information than from the 2D spectra. The type of signal that may appear depends on the kind of 3D experiment. A homonuclear 3D-TOCSY-NOESY spectrum will typically display all three types of signals, whereas 3D-TOCSY or 3D-NOESY-HMQC spectra contain only signals with two or more different frequencies. A triple-resonance experiment such as a 3D-HCACO will give rise exclusively to 3D cross peaks.

2.3. Evaluation of Multidimensional NMR Spectra

The evaluation of a multidimensional NMR spectrum consists of the search for correlations between cross peaks, which have one or more frequencies in common. 3D and 4D NMR spectroscopy has the advantage of yielding cross peaks that have more than one coordinate in common. Thus the combinatory problem is greatly simplified compared to the analysis of the same spin system by 2D cross peaks with only one common frequency. This is illustrated in Figure 4 for six different chemical shifts belonging to one spin system. The frequencies of the spin system in A can be connected only in one way by using 3D cross peaks (B), whereas the 2D cross peaks allow an incorrect assignment (C) as well.

The 3D and 4D spectra are usually evaluated manually by using a set of 2D planes. These planes obtained from various 3D experiments with the same or with a symmetrical frequency in the third dimension are evaluated in parallel; the desired correlation is then given by a second common coordinate.

This procedure is quite time-consuming, since several 3D or 4D data sets must be taken into account simultaneously. Consequently, multidimensional NMR spectra are often analyzed with the help of computer programs.[68-71] Completely automated assignment of spectra, however, is not yet possible, although several steps have already been made in this direction.[72-74] It has proved difficult to transfer the thought processes of an experienced spectroscopist to a computer. The main difficulties are distinguishing artifacts from real cross peaks, and the incomplete information obtained. Despite these problems, automated evaluation seems to be much easier with 3D and 4D techniques, as the data sets are more specific.

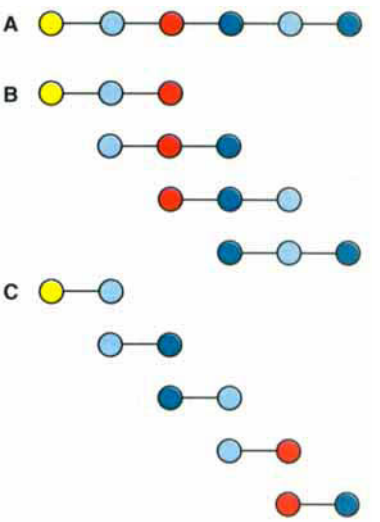

Fig. 4. Assignment of a spin system with six chemical shifts. The system of six nuclei illustrated schematically in A can be linked only in the way shown by using the 3D cross peaks illustrated in B. If only 2D cross peaks are used, an incorrect connection can also result, as shown in C.

2.4. Quantitative Evaluation of Multidimensional NMR Spectra

2.4.1. Determination of Distances

The calculation of protein structures requires estimated distances between proteins which are obtained from quantitative evaluation of NOE- and ROE-dependent cross peaks. The various strategies to quantify distances vary from a general classification of NOEs[1] to a method that treats the problem by using a relaxation matrix formalism.[75-78]

Until now, a classification of the observed NOEs was carried out in most cases, or the distances were calculated after integration of the cross peaks from NOESY spectra with a short mixing time by using a known reference distance.[79,80] In the first method NOESY cross peaks are separated into several classes according to their intensity or their occurrence in NOESY spectra recorded with different mixing times. These classes are assigned an upper distance limit, (e.g. high intensity: distance <2.8 Å; medium intensity: distance <3.5 Å; low intensity: distance <5.0 Å. With the second method the distances r_{ij} are calculated by using Equation (4) from the intensities I_{ij} of the

$$r_{ij} = r_{\mathrm{ref}}\left(\frac{I_{\mathrm{ref}}}{I_{ij}}\right)^{\frac{1}{6}} \qquad (4)$$

signals and a reference distance r_{ref}. The proportionality of Equation (4) holds, however, only if the NOESY spectra are recorded with a sufficiently short mixing time.

Since in 3D and 4D spectra more than one transfer process [see Eq.(2)] contributes to the intensity of a cross peak, there is

no direct correlation between cross peak intensity and interproton distance. The amplitude of a 3D cross peak is determined by the product of the efficiency of each single step. This can be described with a vector diagram, in which the efficiency of the single steps is given by vectors and the amplitude of the 3D cross peak by an extended plane.[81]

The prerequisite for a quantitative evaluation of NOESY-type 3D spectra is that all contributions to the cross peaks are known (except the distance to be determined) or can be considered as constant. The latter can be assumed if one of the contributions is caused by a heteronuclear ^1J coupling, as in NOESY-HMQC or NOESY-HSQC spectra. The range of variation for these couplings is quite small (90–96 Hz for J_{NH}, 125–160 Hz for J_{CH}). The different transverse relaxation times of protons can, however, cause a problem. For biological macromolecules the time of free precession necessary for the evolution of a heteronuclear coupling cannot be ignored and could be quite different for chemically related groups. This means that the signal amplitudes can be distorted by relaxation effects.

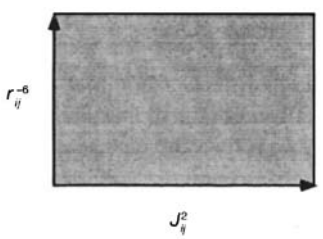

Fig. 5. Vector diagram describing the intensity of TOCSY-NOESY cross peaks. The lengths of the vectors represent the efficiency of the individual coherence transfer steps, the extended plane the intensity of the 3D cross peaks.

The situation becomes more complicated if the efficiency of both coherence transfer steps depends on the conformation of the molecule, as in homonuclear 3D experiments.[81,82] The 3D cross peaks in TOCSY-NOESY spectra, for example, depend to a first approximation on J^2 and r^{-6} (Fig. 5). As $^3J_{NH-H_\alpha}$ is heavily dependent on the backbone angle ϕ, several specific cross peaks can be found in those spectra whose amplitudes are determined by the kind of secondary structure (Fig. 6). It can be seen that for α helices only weak cross peaks are expected with the shifts of H_N and H_α as F_1/F_2 coordinates, whereas β structures lead to very intense signals.

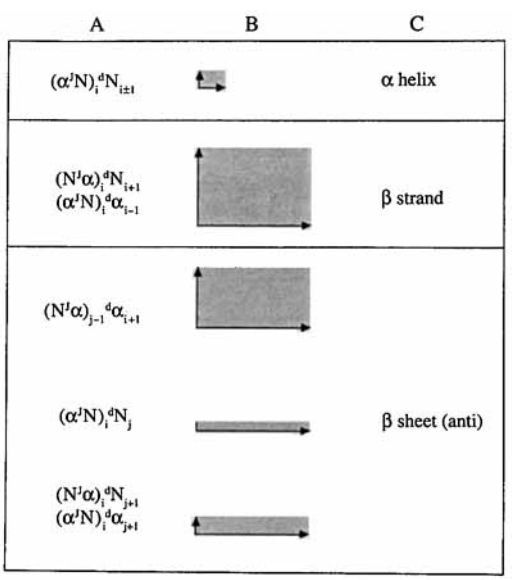

Fig. 6. The dependence of the intensities of cross peaks in TOCSY-NOESY spectra on the secondary structure of a protein (C). A gives the underlying transfer; for example, $(N^J\alpha)_i{}^d N_{i+1}$ is a TOCSY transfer from H_N to H_α in amino acid i followed by a NOESY transfer (distance dependent) to the NH of the next amino acid. B shows vector diagrams of intensities (see Fig. 4) for the various types of cross peaks. Amino acids i and j are adjacent to each other in a β sheet.

The quantitative evaluation of NOESY-NOESY spectra shows some interesting aspects. In a first approximation the amplitude of a cross peak I_{ijk} is influenced by two cross relaxation rates σ [Eq.(5)], where $\tau_m^{(1)}$ and $\tau_m^{(2)}$ are the two applied

$$I_{ijk} \approx \sigma_{ij}\sigma_{jk}\tau_m^{(1)}\tau_m^{(2)} \quad (5)$$

mixing times. If $\tau_m^{(1)} = \tau_m^{(2)}$, then the expression for I_{ijk} corresponds to the second-order terms obtained from a series expansion of the exponential function that describes the magnetization transfer in the NOESY experiment [Eq.(6)].[8] In principle this fact can be used to calculate higher order contributions to 2D and 3D cross peaks.[51,84–86]

$$[e^{-R\tau_m}]_{ij} \approx 1 + \sigma_{ij}\tau_m + \sum_k \sigma_{ij}\sigma_{jk}\tau_m^{(2)} \quad (6)$$

2.4.2. *Determination of Dihedral Angles*

The determination of dihedral angles requires the measurement of coupling constants. For this reason several 3D techniques have been developed that yield multiplets with an e. COSY-type fine structure (e. COSY = exclusive correlation spectroscopy).[87–92] The main problem that must be faced is achieving a sufficiently high resolution. In order to measure small coupling constants with satisfactory accuracy, separate planes of a multidimensional spectrum must usually be calculated with high digital resolution. The coupling constants can then be taken directly from the splitting in the observed e. COSY-type multiplet.

3. Strategies and Experiments for Protein Structure Determination

The choice and combination of multidimensional experiments and the simultaneous decision as to which isotopes should be used depend on various factors such as the size of protein, its secondary structure, the distribution of signals in the ^{1}H NMR spectrum, and availability of labeled protein, which is normally produced by biotechnological methods. These factors must be considered when the isotopic labeling and the NMR experiments are selected so that the information required for structure determination can be obtained. Three tasks must be completed, specifically

- the complete sequence assignment
- the complete assignment of side-chain signals
- the collection of a sufficient number of precisely measured NOEs.

For each labeling strategy a basic set of experiments can be defined (Table 2).

If the protein is not labeled, a conventional concept for the assignment may be chosen which relies on secondary structure analysis by means of ^{1}H techniques (Fig. 7A). The proton sig-

Table 2. NMR experiments and the types of labeling suited for protein structure determination.

	without isotopic labeling	with ^{15}N labeling	with ^{15}N and ^{13}C labeling
assignment of spin systems	TOCSY-TOCSY	TOCSY-HMQC TOCSY-TOCSY	3D/4D-HCCH-TOCSY HCCH-COSY HC(C)NH-TOCSY
sequential assignment	TOCSY-NOESY	NOESY-HMQC TOCSY-NOESY	HCACO HNCA HNCO HCA(CO)N
identification of NOEs	NOESY-NOESY TOCSY-NOESY	NOESY-HMQC NOESY-NOESY TOCSY-NOESY	3D-NOESY-HMQC 4D-HMQC-NOESY-HMQC

nals of the side chains are collected with TOCSY and COSY techniques by utilizing the scalar couplings, and these signal sets are then ordered sequentially by using NOEs between neighboring amino acids. The structure determination is based on distances derived from the 2D-NOESY spectra or from homonuclear 3D spectra.[32, 84, 85, 93–95]

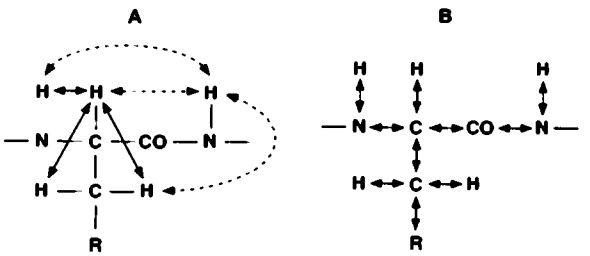

Fig. 7. Identification of spin systems and sequence assignment in proteins. A) For unlabeled proteins the assignment relies on homonuclear spectroscopy utilizing ^3J couplings (solid lines) and NOEs between the protons of neighboring amino acids (broken lines). B) In the case of labeling with ^{15}N and ^{13}C, the assignment is achieved by heteronuclear techniques using the relatively large ^1J couplings ($^1J(H,C) \approx 125$. $^1J(H,N) \approx 90$, $^1J(N,C) \approx 10-17$, $^1J(C,C) \approx 40-60$ Hz).

In ^{15}N-labeled proteins the chemical shifts of the heteronuclei can also be used for the three-dimensional resolution of the NH region of TOCSY and NOESY spectra,[96–100] always relying on the relationships from ^1H NMR experiments (Fig. 7A). The application of ^{15}N labeling and 3D techniques makes the assignment easier, and a larger number of NOEs can also be interpreted. However, the enhancement of resolution resulting from ^{15}N labeling only affects the amide protons. Overlaps in the aliphatic region must therefore be solved by homonuclear 3D techniques,[32] especially for the assignment of NOEs between side-chain protons.

For doubly labeled proteins (^{13}C and ^{15}N) the complete assignment can be carried out without recourse to conformation-dependent parameters (Fig. 7B).[101–116] The assignment of the side chains is achieved with experiments relying on ^1J couplings between ^1H and ^{13}C and between neighboring carbon atoms.[117–120] Two advantages are gained from this procedure. The participating couplings are relatively large and can also be resolved for larger proteins. In addition, the signal overlap always observed in 2D ^1H NMR spectra is largely avoided for some types of amino acids.

The sequence-specific resonance assignment, commonly referred to as the sequential assignment, can now also be carried out with the conformation-independent ^1J couplings (Fig. 7B). A large number of 3D and 4D techniques are available for the correlation of chemical shifts of heteronuclei in the protein main chain. The NOEs needed for structure calculation are extracted from ^{15}N- or ^{13}C-resolved NOESY spectra or may be interpreted from the 2D-NOESY spectrum. In addition, four-dimensional spectra may be recorded[27, 121] to obtain unambiguous assignments of NOEs in analogy to the situation depicted in Figure 3.

Although doubly labeling a protein with ^{15}N and ^{13}C is considered the best approach for NMR spectroscopic structure analysis, good results are often also obtained without complete labeling. However, the size of molecule that can be investigated decreases. Proteins larger than 10 kDa are rarely examined with homonuclear 3D methods, and the investigation of ^{15}N-labeled proteins with a combination of ^{15}N-resolved and homonuclear 3D spectroscopy would be ineffective for proteins with a size greater than 13–15 kD.

3.1. Investigation of Unlabeled Proteins and Peptides

The application of homonuclear 3D techniques for the structure determination of small proteins is particularly useful for proteins that are derived from natural sources and cannot be labeled. Sequential assignments can be made with the TOCSY-NOESY technique,[122] and the NOESY-NOESY technique has mainly been applied in the past to measure a large number of distances and to determine them more precisely.[84, 85] In addition, it has been shown that homonuclear 3D spectra are better suited for the automated assignment of NMR signals than 2D spectra.[72]

In the past heteronuclear methods were only applied to unlabeled biomolecules in cases of smaller proteins or peptides.[55, 56, 123]

3.2. Investigation of a ^{15}N-Labeled Protein: The Structure of Interleukin-4

The complete labeling of a protein is not always practicable, especially if variants are to be examined in addition to the wild-type and not all of them can be labeled with ^{13}C. In such cases ^{15}N labeling and the combined application of ^{15}N-resolved and homonuclear 3D NMR spectroscopy enables the determination of the required parameters. The strategy for investigating a ^{15}N-labeled protein is discussed here with IL-4 as an example.

The structure of IL-4[124–128] consists of four helices which form a four-helix bundle (Fig. 8). The spatial relationship of the four helices can be determined from the NOEs between the side-chain protons in the hydrophobic amino acids that are colored yellow. The sequential assignment is based on the characteristic NOEs between amide protons. Both kinds of interactions are difficult to measure with 2D techniques, as overlapping signals are expected in the region of the signals for NH and the methyl groups. In order to resolve them, the ^{15}N-NOESY-HMQC technique[96] is applied for sequential assignment,

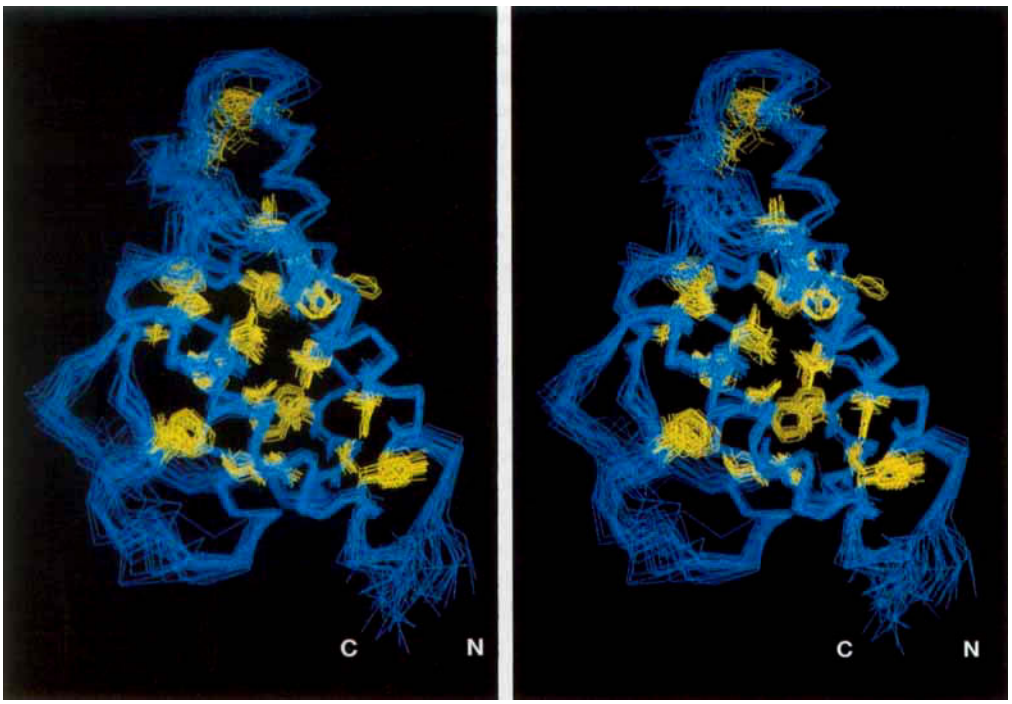

Fig. 8. Superposition of 21 structures of interleukin-4 calculated from NMR data. The atoms of the protein main chain are given in blue, the side chains of the hydrophobic amino acids in yellow.

which gives additional resolution for the amide region. The TOCSY-NOESY technique[32, 122] is used for the detection of NOEs between the side chains. In addition, the H_N, H_α, and H_β resonances of the individual amino acids can be correlated by the ^{15}N-TOCSY-HMQC technique,[96] thus giving the basis for the side-chain assignment.

3.2.1. *Assignment of ^{1}H Signals with ^{15}N-TOCSY-HMQC and ^{15}N-NOESY-HMQC Experiments*

The ^{15}N-TOCSY-HMQC and ^{15}N-NOESY-HMQC techniques (Fig. 9) are among the most useful in 3D NMR spectroscopy. It must be pointed out that HSQC experiments give

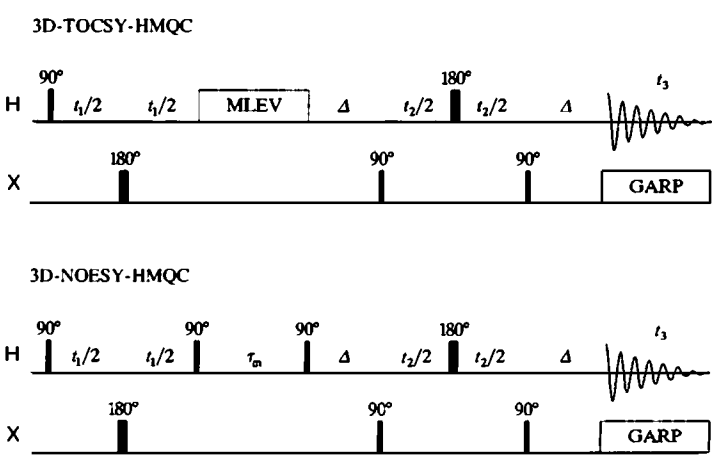

Fig. 9. Pulse sequences for the 3D-^{15}N-TOCSY and -^{15}N-NOESY-HMQC experiments. GARP = composite pulse decoupling sequence.

the same spectra as HMQC experiments. In analogy to the situation shown in Figure 3, degenerate NH signals are distributed onto several planes by the different chemical shifts of the directly connected ^{15}N nuclei. In these 3D spectra a vector is present for each amino acid on the coordinates of the amide proton and amide nitrogen resonances, where all TOCSY or NOESY cross peaks of the amide proton are lined up. The ^{15}N-TOCSY-HMQC technique makes the assignment of the side-chain signals much easier, and ideally all the side-chain protons of an amino acid are given in the corresponding vector.

The sequential assignment of α-helical regions in proteins can be solved very elegantly with only the ^{15}N-NOESY-HMQC technique by finding cross peaks between the NH signals of neighboring amino acids. This is problematic with only a 2D spectrum if, for example, two NH signals from an α helix are degenerate. In this case four cross peaks to other amino acids are expected at this frequency, and an unambiguous assignment is not possible. On the other hand, in the ^{15}N-NOESY-HMQC spectrum the corresponding signals are found on different ^{15}N planes if the ^{15}N nuclei show different chemical shifts. Sequential residues are found by looking for NH–NH cross peaks that are symmetrical to the diagonal in the NOESY spectrum. A successful sequential assignment is usually displayed by showing stripes from the 3D-NOESY-HMQC spectra (Fig. 10). These stripes correspond to the ^{H}N/^{15}N vectors mentioned earlier.

To assign β structures with this technique, a slightly different evaluation strategy should be applied. The superposition of planes with the same ^{15}N frequency from the ^{15}N-NOESY-HMQC and ^{15}N-TOCSY-HMQC spectra makes it possible to locate the corresponding NOESY and TOCSY peaks in the H_α region (Fig. 11). For a particular residue, both 3D cross peaks show the same ^{15}N and H_N chemical shifts and give the connec-

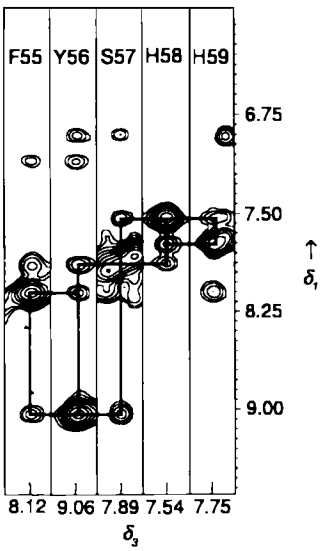

Fig. 10. Example of a sequential assignment for an α-helical region with a 3D-NOESY-HMQC spectrum, shown for the connection between amino acids F55 to H59 in IL-4, by using NOEs of the type $NH_i-NH_{i\pm1}$. The strips are each taken at the frequencies of the amide nitrogen (F_2) and amide protons (F_3).

tion $H_\alpha(i-1) \rightarrow H_\alpha(i)$. For further sequence assignments, planes must be found that contain the corresponding NOESY peak with the appropriate $H_\alpha(i)$ frequency or the TOCSY peak with the frequency of $H_\alpha(i-1)$. In the ideal case only one suitable plane is found, but several H_α signals are usually degenerate. The practicability of the ^{15}N-HMQC-NOESY technique for sequence assignment is therefore restricted to proteins with a large proportion of α helices (see Section 3.2.2).

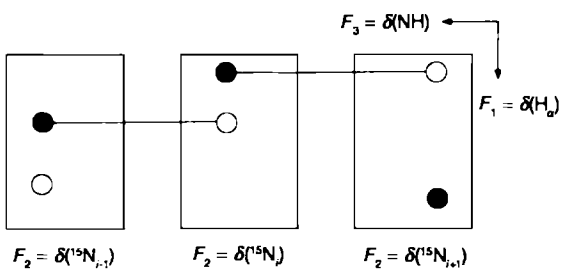

Fig. 11. An example of the sequence assignment in ^{15}N-resolved TOCSY and NOESY spectra based on H_N-H_α correlations. The TOCSY signals (black) and NOESY signals (white) with the coordinates $H_\alpha(i)/H_N(i)$ and $H_\alpha(i-1)/H_N(i)$ belong to the same H_N and are found on the plane with the same ^{15}N frequencies. The neighboring amino acids can be found by searching slices with appropriate TOCSY signals (left) or NOESY signals (right).

3.2.2. *Completing and Checking the Sequence Assignment with TOCSY-NOESY Data*

Overlapping signals in the H_α region also caused problems in the assignment of NOESY and TOCSY spectra of interleukin-4. For example, the H_α signals of some amino acids belonging to the β sheet are degenerate. The 2D spectra and ^{15}N-resolved 3D spectra did not provide unambiguous correlations. 3D-TOCSY-NOESY spectra, however, contain the necessary information. In these spectra signals with the coordinates $H_N(i)/H_\alpha(i)/H_N(i+1)$ and $H_\alpha(i)/H_N(i)/H_N(i+1)$ in $F_1/F_2/F_3$ are observed which contain the desired correlation. This is pointed out in Figure 12, where the region of the 2D-TOCSY and 2D-NOESY spectrum suitable for assignment is shown schematically. The filled circles represent TOCSY signals, the empty ones the NOESY signals. The assignment cannot be made unambiguously, as the chemical shifts of two H_α signals are degenerate. Both possible assignments are indicated, starting from amino acid *i*. The 3D cross peaks mentioned above can be seen as correlation lines between 2D cross peaks, drawing a line between the two NH shifts at the level of the H_α shift (Fig. 12 right). In this way a definite assignment of the 2D cross peaks can be made.

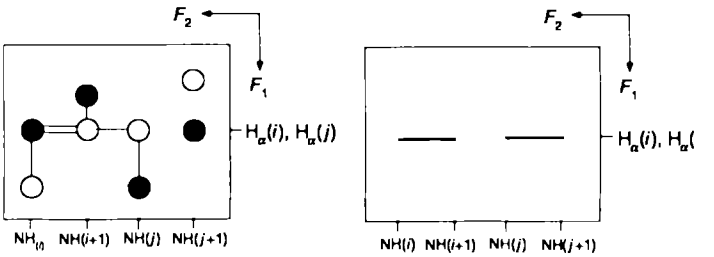

Fig. 12. An example of the use of 3D-TOCSY-NOESY data for the assignment of protein NMR spectra. Left: The assignment procedure with 2D spectra is normally done by connecting cross peaks containing coupling information (black) with those containing distance information (white), which occur, for example, in TOCSY and NOESY spectra. If signals of different α protons occur at the same frequency, several linkages are possible. Right: In a TOCSY-NOESY spectrum the cross peaks with coordinates $H_N(i)/H_\alpha(i)/H_N(i+1)$ or $H_N(i)/H_N(i+1)/H_\alpha(i+1)$ in $F_1/F_2/F_3$ correspond to the correlations depicted in A. In the 2D spectrum they can be depicted as correlation lines at the level of the H_α frequency. The lines connect the frequencies of the amide protons of amino acids *i* and *i* + 1.

In practice the relevant parts of the 3D spectra are calculated separately, then a peak-picking routine gives a list of the signals, and these are entered graphically into the spectrum as described above. This is shown for interleukin-4 in Figure 13. The TOCSY spectrum is shown in turquoise and the NOESY spectrum in red. The correlation lines drawn by the assignment program give horizontal correlations for the sequence assignment. This figure shows correlations that mainly originate from the nonhelical

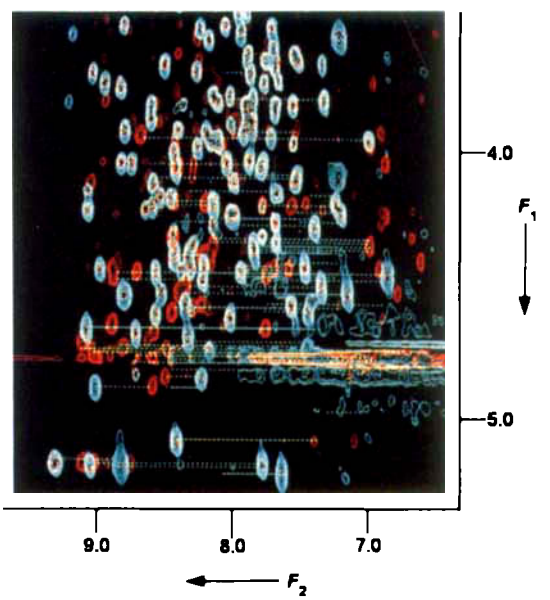

Fig. 13. Superimposed 2D-TOCSY (turquoise) and 2D-NOESY spectra (red) of IL-4 with indicated correlations derived from cross peaks in the 3D-TOCSY-NOESY spectrum (see Fig. 12).

region. Owing to their small couplings between H_N and H_α, amino acids in helices give only very weak cross peaks which were not considered.

3.2.3. *Assignment of Signals in NOESY Spectra*

One of the main problems encountered in the assignment of NOESY spectra is the identification of NOEs between methyl groups or other side-chain atoms. Figure 14 shows an example from the structure determination of IL-4. It is possible to resolve these NOEs based on the couplings of the methyl groups to directly neighboring protons by using a TOCSY-NOESY spectrum. However, it is essential that the cross peaks between the methyl groups of the valine residues and their H_β, as well as those between the methyl groups of the leucine residues and their H_γ, are resolved in the 2D-TOCSY spectrum and are already assigned.

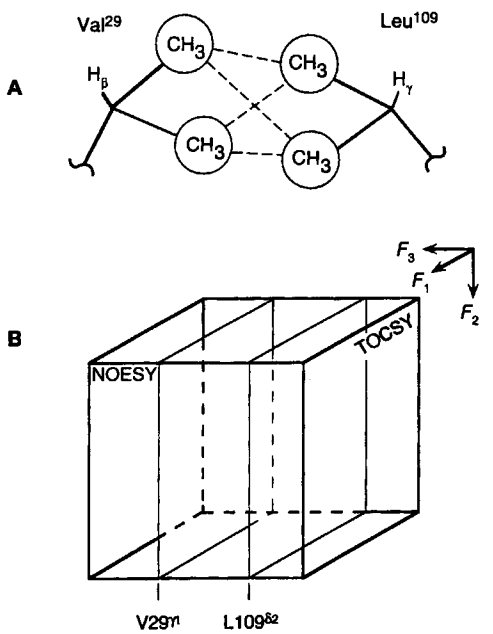

Fig. 14. Identification of NOEs between side-chain protons of IL-4 with the 3D-TOCSY-NOESY technique. The NOEs between the side chains of Val29 and Leu109 in A could be assigned unambiguously by evaluating the TOCSY planes (F_1/F_2) taken at the frequencies of the protons of the methyl groups (F_3) (B; see also Fig. 15).

The 3D spectrum is evaluated conveniently by using TOCSY planes and comparing them with the NOESY spectrum. The NOESY spectrum is investigated in the F_2 direction. The planes with the same F_3 frequencies are taken from the 3D spectrum (Fig. 14B). The F_1 frequencies of the cross peaks in the 2D spectrum can be used to identify the 3D cross peaks necessary for the assignment. They can be found in the TOCSY planes of the 3D spectrum at the same F_2 coordinates as the F_1 coordinate in the NOESY spectrum. The F_1 coordinates of the 3D cross peak give the chemical shift of the coupling partner, and therefore, after comparison to the TOCSY spectrum, also the assignment.

An example is given in Figure 15 showing the assignment of the NOEs between the methyl groups of L109 and V29. The signal of one of the methyl groups of L109 does not overlap with any other signal in the proton spectrum, which makes the problem easier to solve. The F_1/F_2 plane shown here has two cross peaks with the coordinates of V29-H_β in F_1 and the coordinates of the methyl groups of V29 in F_2 (Fig. 15a). This is the proof that the corresponding cross peaks in the NOESY spectra result from NOEs between L109 and V29. If the signal of L109 overlapped with other signals, the interpretation would have to be proved by the symmetrical signals which are found in an F_3

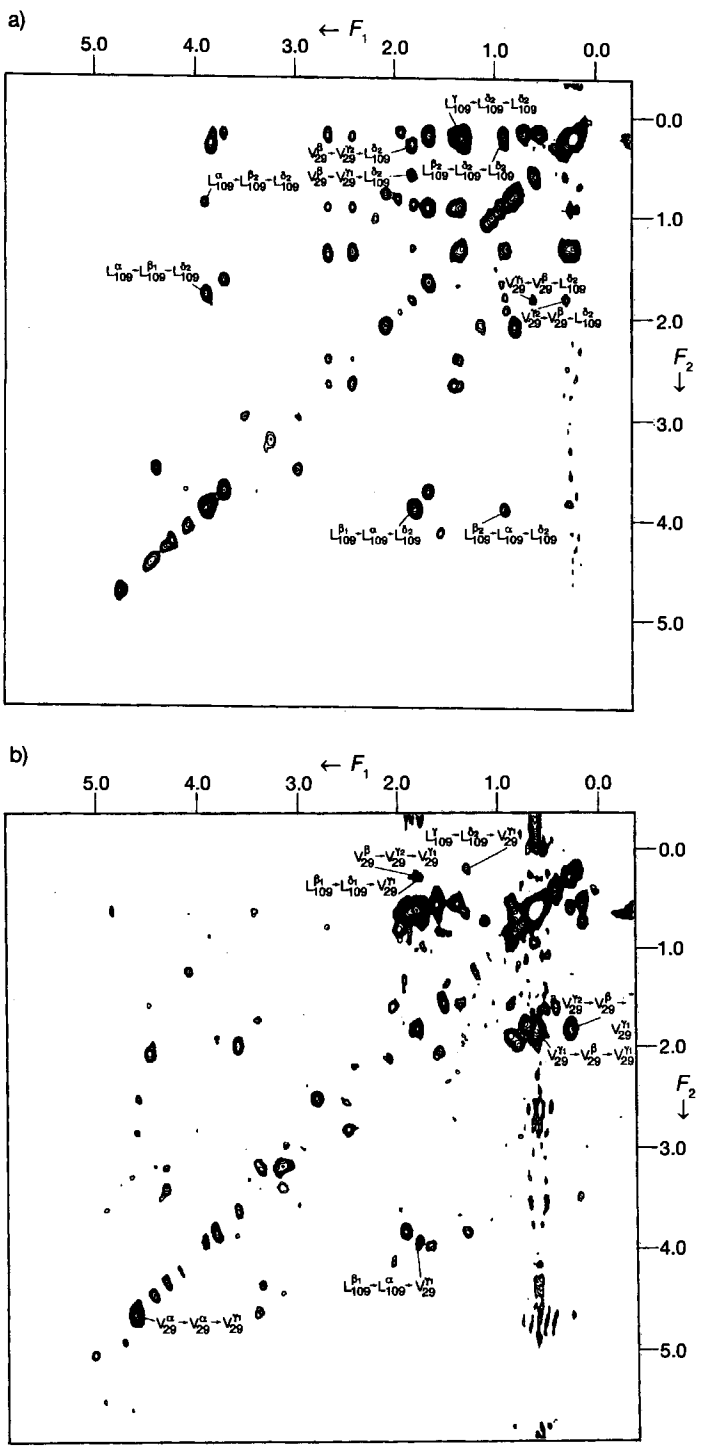

Fig. 15. TOCSY planes (F_1/F_2) from the 3D-TOCSY-NOESY spectrum of IL-4 taken at the positions shown in Figure 14B. a) At $\delta(F_3) = 0.22$, b) at $\delta(F_3) = 0.61$.

plane with the frequency of the methyl group of V29 and which contain the coupling between L109 H_δ and H_γ. These signals are indeed found, as is shown in Figure 15b.

3.2.4. *Measurement of $^3J_{H_\alpha H_N}$ Coupling Constants*

In order to determine the local conformations within the main chain and the conformations of the side chains in proteins, dihedral angles are derived from coupling constants by means of the Karplus equation and used in the structure calculations. The determination of coupling constants for larger proteins is not feasible with 2D experiments, as signal overlap often hides some components of the cross peaks. However, several multidimensional techniques have been developed for the measurement of coupling constants.[88-92]

For IL-4 the 3D-HMQC-J_{HH}-TOCSY technique[88] was used to determine the H_N-H_α couplings, and from that, the ϕ angles of the protein main chain. Small values (<5 Hz) indicate α-helical structures and large values (>9 Hz) suggest stretched conformations. Coupling constants of intermediate values (5 to 9 Hz) indicate conformational averaging from a fast rotation around the $N-C_\alpha$ bond or an unusual conformation of the main chain (e.g. positive ϕ angles). Figure 16 shows a plane from the HMQC-J_{HH}-TOCSY spectrum of IL-4. The H_α-H_N-N cross peaks are split in F_2 by the $^1J_{NH}$ coupling and in F_3 by the $^3J_{H_NH_\alpha}$ coupling.

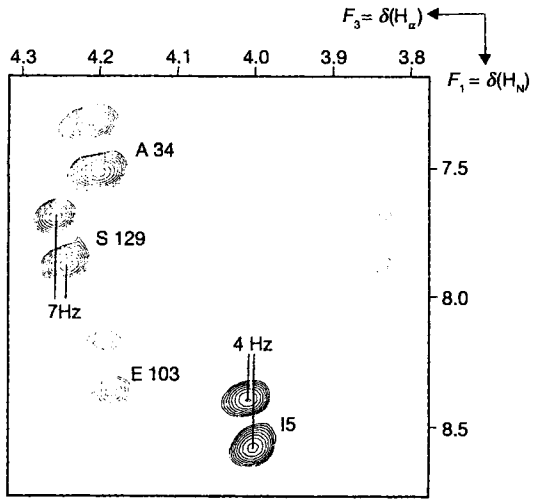

Fig. 16. F_2 section of the 3D-HMQC-J_{HH}-TOCSY spectrum of IL-4. The H_α-H_N-N cross peaks of I5, A34, E103, and S129 are shown. The coupling constants correspond to the separation of cross peak components in the F_3 direction.

3.3. Techniques for the Assignment of ^{15}N,^{13}C-Labeled Proteins; The Structure of Cystatin in Solution

Without ^{13}C labeling, insufficient spectral resolution often hinders the investigation of proteins with more than 100 amino acids. One example is provided by the structures of phosphorylated and nonphosphorylated cystatin.[129-131] The phosphorylated protein was isolated from egg white[132] and could not be isotopically labeled. Its structure is poorly defined in specific regions (Fig. 17 left). The nonphosphorylated form (Fig. 17 right) could be overexpressed in *E. coli*[34] and hence was available for ^{13}C- and ^{15}N-labeling. The structure of the large loop at the lower left of the protein was therefore much better determined by the measurement of a larger number of distances.

The advantages of ^{13}C labeling are manifold. The assignment of the side chains is often simplified because several amino acids are easy to identify by their characteristic chemical shifts in the ^{13}C region. The sequential assignment is additionally simplified by triple-resonance experiments.

In our first investigations of the structure of cystatin we used unlabeled samples, and most of the signals were assigned by

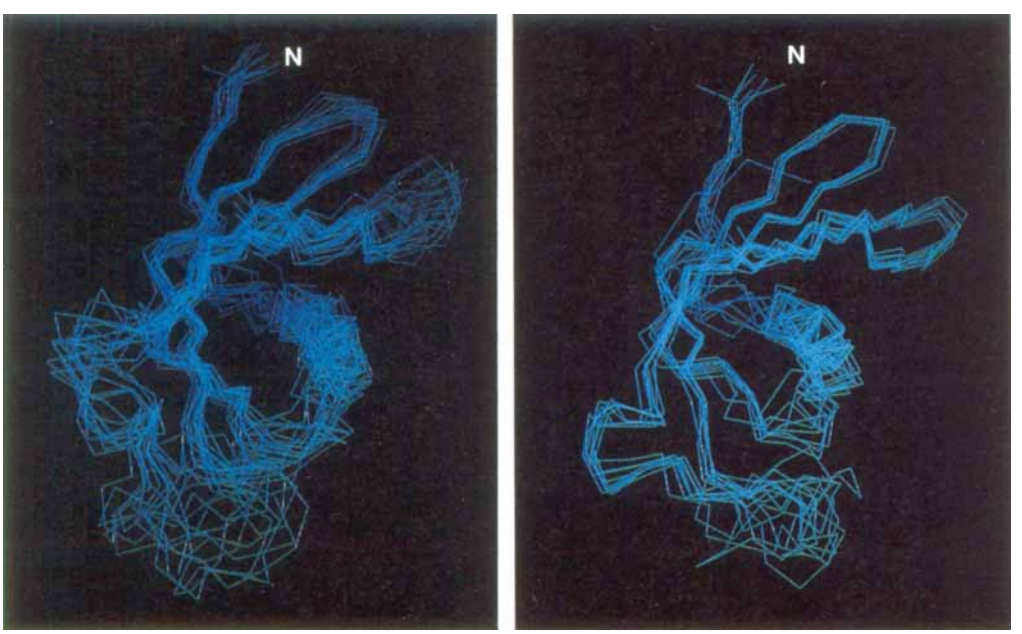

Fig. 17. C_α plot of the calculated structures of phosphorylated albumin cystatin (left) and a recombinant synthesized mutant (right). The structures on the left are based on homonuclear data, those on the right on data from ^{13}C,^{15}N-labeled samples. N denotes the N terminus.

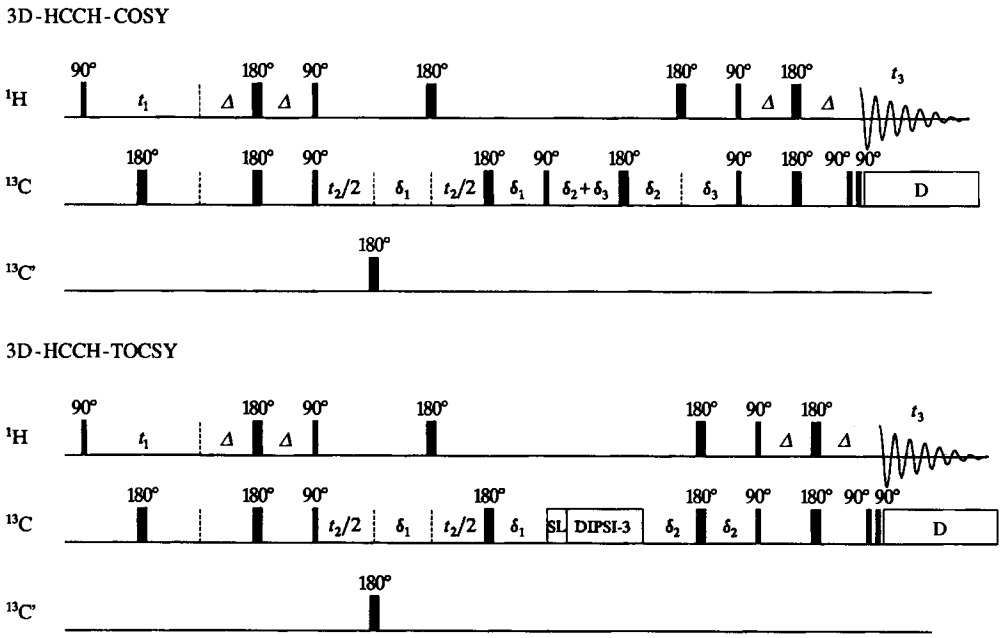

Fig. 18. Pulse sequences for the 3D-HCCH-TOCSY and 3D-HCCH-COSY techniques. D = decoupling.

conventional techniques. For the solution of several problems, however, ^{13}C labeling was absolutely necessary. A major question was whether the N terminus is flexible (up to G9) and also whether there is a large loop (up to residue 10 in the region 69–80), as only poor NOEs were observed for these regions. A complete description of the structure required the measurement of heteronuclear relaxation parameters (especially for ^{15}N), which provided information about the mobility of the peptide chain. For this reason the determination of these parameters will be discussed briefly in Section 4.

3.3.1. Assignment of Side Chains

The assignment of side chains in doubly labeled samples relies mainly on experiments of the HCCH-type, the 3D-HCCH-COSY[117, 118] and 3D-HCCH-TOCSY techniques[119] (Fig. 18).

The latter allows the correlation of all side-chain protons and carbon nuclei with the α proton and α-carbon nucleus of the corresponding amino acid, which is a linking point for the sequential assignment (Fig. 19).[133, 134]

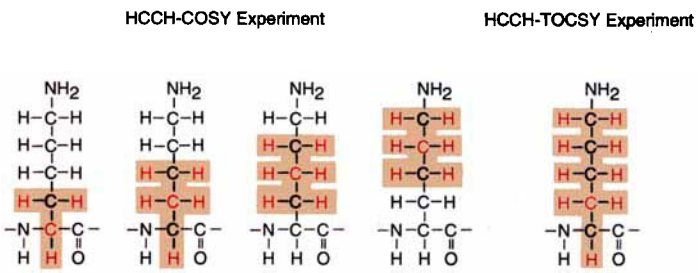

Fig. 19. Schematic view of the "building blocks" obtained in HCCH experiments for assigning side chains, as illustrated for lysine residue. If planes are taken from the HCCH-COSY spectrum at the frequencies of carbons (red), correlations to the directly bound protons and to protons from neighboring carbon atoms (on gray background) can be found. The entire side chain can be assigned by combining the information obtained from the individual planes. In the 3D-HCCH-TOCSY spectrum the plane of one carbon atom contains correlations to all protons of a side chain, in the ideal case.

The pulse sequences generally involve excitation and detection of protons. The excitation of the carbon nuclei proceeds by means of the C–H couplings, such that the $^1J_{CC}$ couplings can be used (see also Fig. 7B). For detection the protons must be excited once more by means of a C–H coupling. As the participating couplings are large (125, 40, 125 Hz), the maximum amplitude for the coherence transfer is reached in a shorter time than when proton–proton couplings are used in homonuclear sequences (TOCSY, COSY). In many cases this helps in finding the side-chain signals, especially of large proteins, for which the transverse relaxation time of the protons is too short for ^1H techniques to be used. The 3D spectra gained from the pulse sequences from Figure 18 have two coordinate axes with ^1H chemical shifts (F_1 and F_3) and one with ^{13}C chemical shifts (F_2). The spectra correspond to a COSY or TOCSY spectrum that is resolved by the ^{13}C chemical shifts.

In the HCCH-COSY spectrum ^{13}C chemical shifts are found in a single F_2 plane, frequencies of the directly bonded protons are found on the F_1 axis, and frequencies of the protons on the adjacent carbon atoms on the F_3 axis. The complete assignment of the side chains is given by the combination of F_2 planes with symmetrical ^1H signals. In the HCCH-TOCSY spectra all protons of a side chain can be found in one F_2 plane ($\delta(^{13}C)$), which makes work much easier (Fig. 19 right).

The HCCH-TOCSY spectrum of cystatin is shown in Figure 20. This plane is defined by the shifts of the α carbons of T70, T96, T94, V99, and the β carbon of S56. The frequency of the directly bonded proton can be found in the F_1 direction, while the frequencies of all protons belonging to the spin system of the relevant amino acid would ideally be found in the F_3 direction. Starting from the C_α/H_α diagonal signal of T96, the 3D cross peaks to H_β as well as to the protons of the γ-methyl group are found.

Both techniques are also suitable for a four-dimensional experiment. In the pulse sequence shown in Figure 18 the excited carbon nucleus is detected first. In principle, the frequency of the second carbon nucleus to which the magnetization is trans-

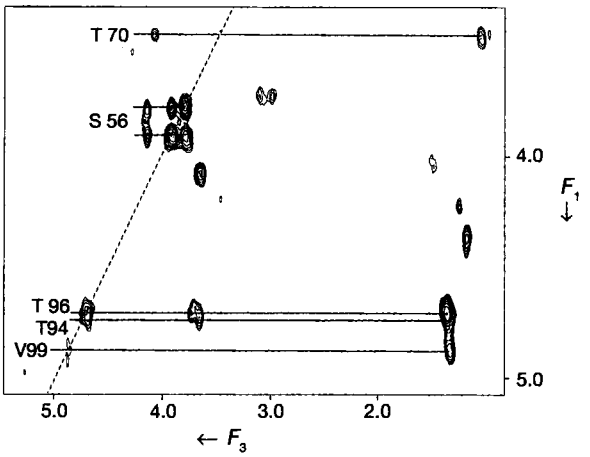

Fig. 20. Plane from a 3D-HCCH spectrum of cystatin. The spin systems of T70, S56, T96, T94, and V99 are indicated.

ferred can also be detected simply by inserting a second evolution time after the COSY or the TOCSY transfer.

3.3.2. *Sequential Assignment with ^1J Couplings between Atoms of the Protein Main Chain*

The sequential assignment of a doubly labeled protein is normally achieved by a combination of so-called triple-resonance experiments,[135-137] which correlate the chemical shifts of the protein main-chain atoms. Each experiment potentially identifies an additional unit of the protein sequence (Fig. 21). These

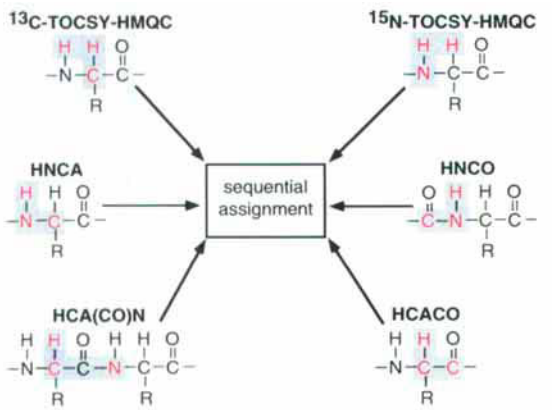

Fig. 21. Schematic representation of units (correlations) in the protein main chain derived from triple-resonance experiments. The spectra show cross peaks with frequencies of the nuclei given in red. A combined evaluation of these spectra gives a sequential assignment.

experiments are characterized by relatively large pulse sequences, which require a well-equipped NMR spectrometer. Two examples that require four frequency channels are shown in Figure 22.

Although a small number of experiments may suffice to obtain a complete sequence-specific resonance assignment, it is helpful to ensure good results by recording all possible kinds of correlations. The sequential assignment is most reliable when it is given by a set of cross peaks always having two frequencies in

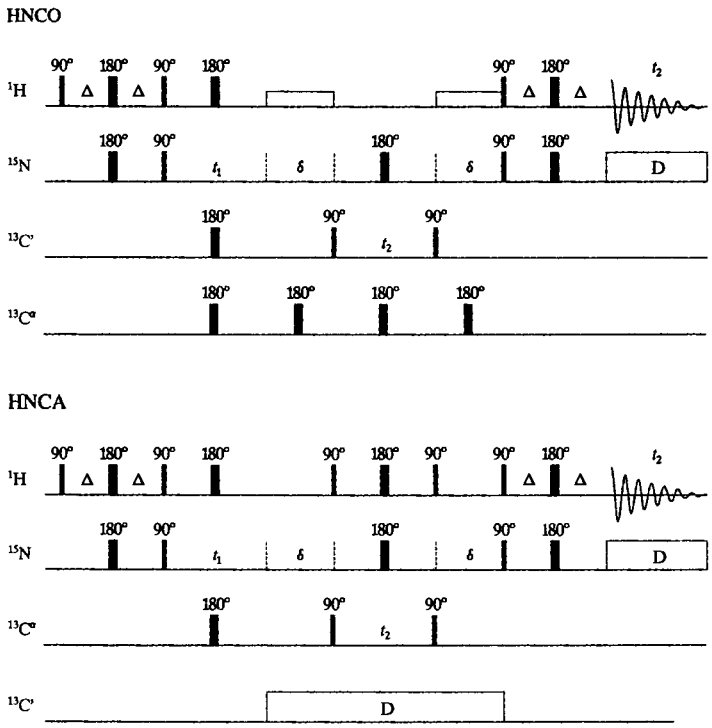

Fig. 22. Pulse sequences for the 3D-HNCO and 3D-HNCA experiments.

common. Such a combination of experiments is shown in Figure 23. HNCA[101,102] and HCACO experiments[101] are used to assign all of the backbone atoms of an amino acid. The connection of the next amino acids in the sequence can be achieved by several correlations. The cross peaks in the HNCO

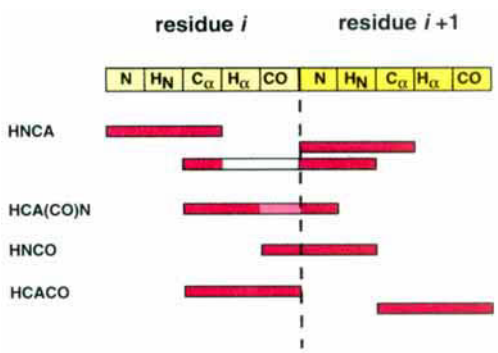

Fig. 23. Correlation of the amino acid i and $i+1$ by means of a basis set of 3D triple-resonance experiments. The red bars give the frequencies that are contained in 3D cross peaks. Nuclei colored pink are not detected but only used for magnetization transfer during the pulse sequence.

spectrum, for example,[101] contain the H_N and ^{15}N frequencies of amino acid i as well as the frequency of the carbonyl carbon atom of amino acid $i-1$. The HCA(CO)N spectrum[101] links H_α and C_α of amino acid i with the amide nitrogen atom of amino acid $i+1$ in an analogous fashion. The sequential assignment can thus be achieved by combining units that partly overlap. Besides the experiments mentioned above, several alternative pulse sequences are available (see Table 1).

The main advantage of this group of experiments is the relatively small number of cross peaks in the spectra; each amino acid shows only one or two cross peaks. This not only simplifies the manual evaluation but also facilitates automated assignment.

Figure 24 shows a three-dimensional view of the 3D-HCACO spectrum of cystatin. Most cross peaks are well resolved in all three frequency dimensions, and about 90% of the expected correlations can be observed.

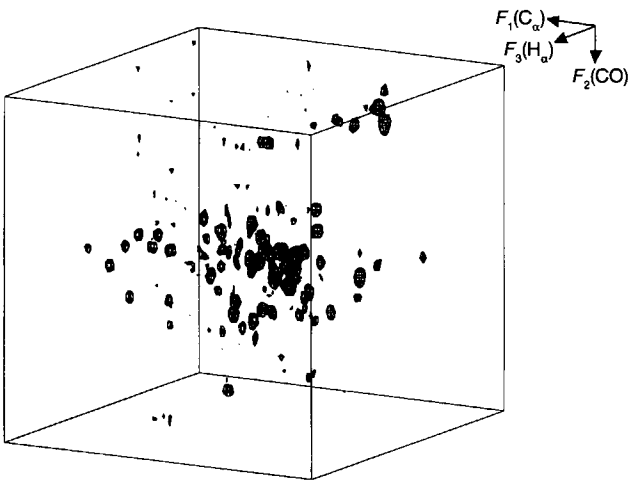

Fig. 24. Three-dimensional representation of the 3D-HCACO spectrum of cystatin.

3.3.3. *Identification of NOEs Using 3D- and 4D-HMQC-NOESY Techniques*

The experiments of the 3D-HMQC/HSQC-NOESY type discussed previously (Section 3.2.1) are especially important for ^{13}C-labeled proteins, as they can be used for the assignment of NOEs between protons in the amino acid side chains. The 3D spectra correspond to 2D-NOESY spectra resolved by means of the frequencies of the directly attached carbons. The NOE signals that occur symmetrically with respect to the diagonal of the 2D spectrum are distributed in two different planes of the 3D spectrum according to the frequencies of the directly bonded carbon atoms. The identification of NOEs is based on the known ^{13}C assignment by using a combination of these planes. This is shown in Figure 25 for the assignment of the NOE between F83-H_α and T69-H_α of cystatin. It is interesting to note that both side chains are clearly identified by their NOE patterns.

The assignment of long-range NOEs to side-chain protons follows the same principle and is shown in Figure 26 for the methyl groups of several alanine, valine, and isoleucine residues. The cross peak identified with a question mark could not be assigned despite the use of a 3D spectrum, because the H_α and C_α signals overlapped with other signals. In cases in which the three-dimensional spreading is not sufficient to make an assignment, a four-dimensional variant of the experiments can be used. Here all protons that contribute to an NOE are correlated with the directly connected heteronuclei, and 4D-HMQC-NOESY-HMQC spectra are obtained.[27, 121] One such experiment (4D-$^1H/^{13}C$-HMQC-NOESY-$^1H/^{13}C$-HMQC [121]) was

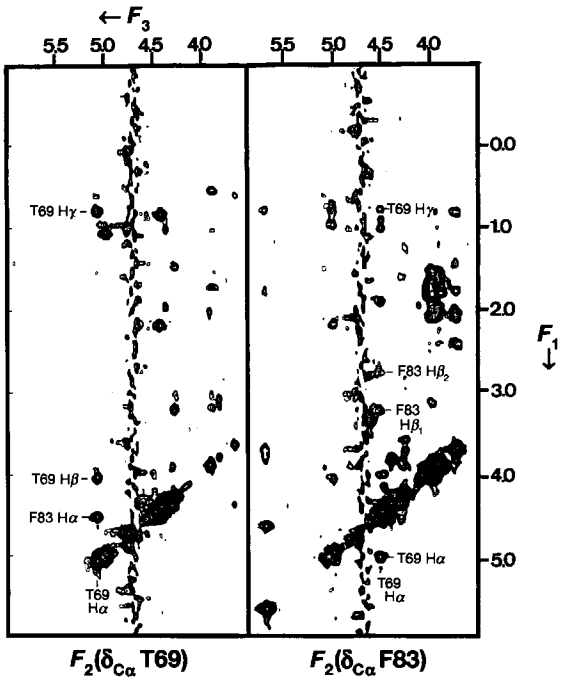

Fig. 25. Sections of two F_3 planes of the 3D-NOESY-^1H-^{13}C-HMQC spectrum of cystatin, which allow the identification of the H_α–H_α NOE between T69 and F83.

used to resolve the ambiguous assignment of the cross peak in Figure 26. The corresponding 4D cross peak appears at the coordinates H_β-(A90)-C_β(A90)-H_α(P87)-C_α(P87), which identifies the NOE as an interaction between the β-methyl group of alanine 90 and the α proton of P87.

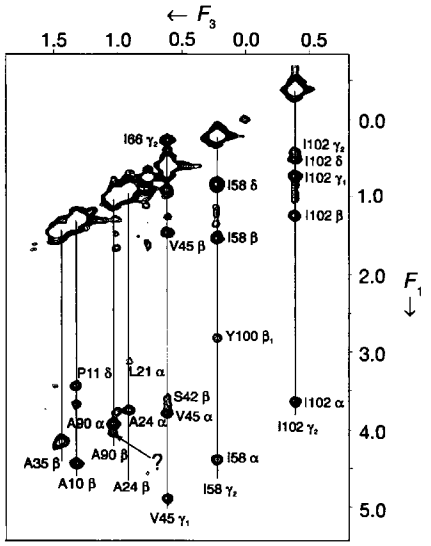

Fig. 26. The plane for $F_2 = 17.5$ (^{13}C) from the 3D-NOESY-^1H-^{13}C-HMQC spectrum of cystatin. The NOE signals of the methyl groups of some valine, isoleucine, and alanine residues are indicated. The signal labeled with a question mark could be assigned only by means of a 4D experiment as an NOE between P87 H_α and A90 H_β.

4. NMR Experiments for the Investigation of Backbone Dynamics of Proteins

The techniques developed for the structure determination of small- and medium-size proteins in solution by NMR spec-

troscopy also enable us to investigate their dynamic properties.[138-142]

The mobility of the peptide chain is reflected in the way protons and heteronuclei relax. As a consequence, the measurement of relaxation parameters (longitudinal relation time T_1, transverse relaxation time T_2, and hetero-NOE) give information concerning the inner dynamics of the protein. For the determination of the relaxation time of heteronuclei and the hetero-NOEs, slightly different H–X correlations of the HSQC-type are used.[143] For each parameter a series of measurements with different relaxation delays must be recorded. The plot of the intensities obtained provides a curve with exponential decay for each heteronucleus and can be used to determine the relaxation time. For the determination of the hetero-NOE, NOESY experiments with and without presaturation of the protons are performed. The NOE results from the relationship between the measured intensities of the cross peaks in both spectra. Figure 27 shows the derived T_1, T_2, and NOE values for cystatin.

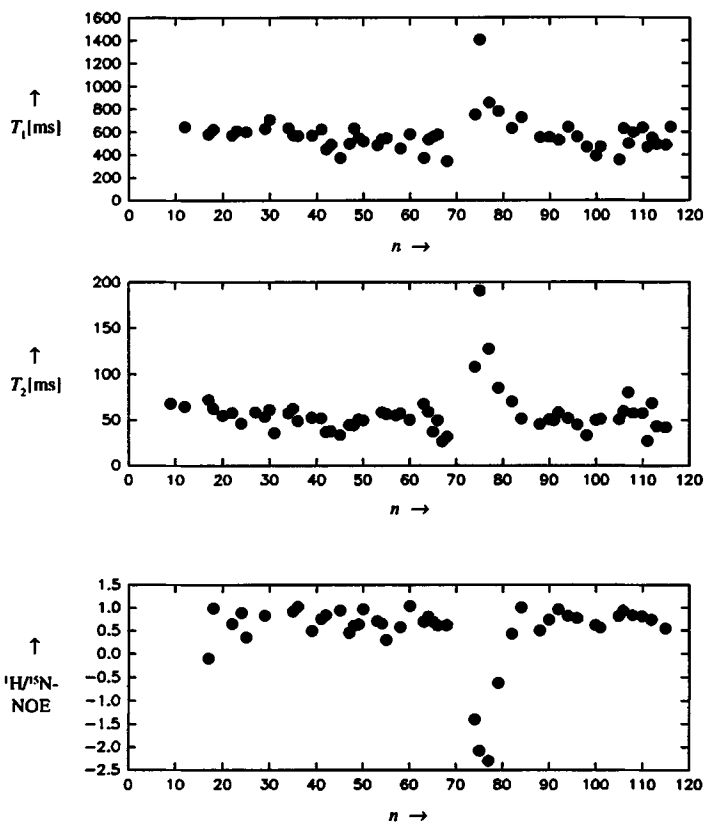

Fig. 27. Values for T_1, T_2, and the $^1H/^{15}N$ NOE of the individual amino acids in cystatin (n = position of the amino acid). There are strikingly different values in the region between C71 and C81, which indicates the higher mobility of the protein main chain in this region.

It clearly demonstrates the very different relaxation times of the ^{15}N nuclei, and as a result, the various mobilities of the protein main chain. In the region of amino acids 72–80, in particular, the relaxation behavior of the amide nitrogen nuclei resembles that of a small peptide more than that of a protein with more than 100 amino acid residues. The high mean variation in this region of the peptide chain (shown in the structures in Figure 17) is therefore no artifact caused by insufficient data but results from the real flexibility of the protein main chain.

5. Summary and Outlook

The introduction of multidimensional NMR techniques together with suitable labeling of recombinant synthesized proteins has made the structure determination of biologically important macromolecules ($M > 10$ kDa) in solution a straightforward matter. The methods described in this article are only a few of the experiments that can be used for the structure determination of proteins by NMR spectroscopy. With these techniques it is now possible to investigate structures of proteins with molecular weights of 20–35 kDa.

The ultimate size limit for proteins studied by NMR spectroscopy may not yet have been reached. Since the transverse relaxation time decreases with increasing molecular size, the applicability of experiments is strongly restricted to proteins with molecular weights < 35 kDa. We therefore assume that, at least with regard to a complete structure determination by NMR spectroscopy, a "natural upper limit" exists.

This work was supported by the Deutsche Forschungsgemeinschaft and the Sonderforschungsbereich 207. The authors thank Dr. E. A. Auerswald, Munich, and Prof. W. Sebald, Würzburg, for the preparation of labeled protein samples, and Dr. P. Neidig for the modification of the program AURELIA. We are also grateful to Bruker for technical support (8-mm probe). Plots of molecules were prepared with the program QUANTA (Molecular Simulations, Inc.).

Time-Resolved Photoacoustic Calorimetry: From Carbenes to Proteins

Kevin S. Peters*

Why have molecules only been seen but not heard? For over a century chemists have probed reactions with various spectroscopic methods to learn about structures, dynamics, and reactivities of their molecules. What they have not done is to listen to their molecules react. Although the photoacoustic phenomenon has been known since 1880, it is only in the last twenty years that technology has developed to the point where sound waves produced by reacting molecules can be time resolved and the information contained within the waves deciphered. The information content within the photoacoustic wave is indeed rich, for one can learn about the dynamics and the magnitude of enthalpy changes associated with the reaction as well as the changes in molecular volume. This review article chronicles the development of time-resolved photoacoustic calorimetry and its application to a variety of reactions encountered in organic and organometallic chemistry and biochemistry.

1. Introduction

The realization that molecules produce sound following the absorption of light, the photoacoustic effect, dates back to 1880 when Alexander Graham Bell focused mechanically chopped sunlight upon a sample contained within a cell and listened to the sound by placing his ear against an open tube whose other end made contact with the sample cell.[1] The frequency of the sound that he heard corresponded to the frequency of the mechanical chopping. Today, we can listen to the sound produced by reacting molecules with the time resolution of one nanosecond.

The application of the photoacoustic effect to the study of the dynamics of enthalpy and volume changes originates with the experiments of Callis, Parson, and Gouterman in the early 1970s.[2] The experiment that was used to study *Chromatium vinosum* chromatophores utilized a capacitor microphone that measured the expansion and contraction of the solution caused by a change in the enthalpy and molecular volume upon the evolution of the reactants into the products. The time resolution approached 100 μs.

In 1985 we extended the time resolution of photoacoustic calorimetry onto the 100 ns timescale.[3] The increased time resolution resulted from employing piezoelectric transducers composed of lead zirconate/lead titanate for the detection of acoustic waves and a nanosecond laser for light initiation of the reactions. The photoacoustic calorimetry technology was adapted from the photoacoustic spectroscopic methods developed by Patel and Tam.[4] During this same period Braslavsky et al.[5] independently developed photoacoustic calorimetry. More recently the time resolution of photoacoustic calorimetry has been extended onto the 1 ns timescale by Caldwell, Melton, et al.[6]

In this review article we will discuss the theory, design, and application of time-resolved photoacoustic calorimetry as it has been developed in my laboratory and the laboratories of my former associates. The review is not comprehensive but instead attempts to convey the nature of the problems in organic and organometallic chemistry and biochemistry that can be addressed by this technique. An extensive review of photoacoustic calorimetry and related methodologies has recently appeared.[7]

2. Theory of Photoacoustic Calorimetry

The theory of the photoacoustic effect is well developed and has been thoroughly reviewed.[8] When a chemical reaction in solution is initiated by the absorption of light, the reacting molecules transfer their excess internal energy to the solvent. This sudden increase in the internal energy of the solvent causes its expansion, producing an acoustic wave that propagates through the medium. The amplitude of the acoustic wave is directly proportional to the amount of energy released by the reacting molecules. Acoustic waves are also produced by the increase or decrease in the molecular volume of the reacting molecules. This may be brought about by the cleavage of a covalent bond, (→ increase in the molecular volume) or the creation of charged species leading to electrostriction of the solvent about the charged centers (→ decrease in the molecular volume). Thus both a thermal expansion, ΔV_{th}, and a change in the molecular configuration of the system, ΔV_{con}, contribute to the production

of the acoustic wave. The amplitude of the acoustic wave, S, measured by the microphone is given by Equation (1), where K is a parameter which is a function of the instrument response.

$$S = K(\Delta V_{th} + \Delta V_{con}) \quad (1)$$

Since the amplitude of the acoustic wave is a measure of contributions of both ΔV_{th} and ΔV_{con}, the problem then arises as to how S is partitioned into the individual components. The volume change attributed to the thermal component is related to the thermal energy, Q, released to the solvent according to Equation (2), where β is the thermal expansion coefficient of the

$$\Delta V_{th} = (\beta/C_p\rho)Q \quad (2)$$

solvent, C_p is the heat capacity, and ρ the density of the solution. Since for aqueous solutions $\beta/C_p\rho$ is highly temperature dependent and approaches 0 at 3.9 °C for water, ΔV_{th} is a function of temperature. By contrast, ΔV_{con} is independent of temperature over a limited interval. Therefore in aqueous media the contributions of ΔV_{th} and ΔV_{con} can be separated by examining the temperature dependence of the acoustic wave amplitude, S. Unfortunately, for organic solvents $\beta/C_p\rho$ is virtually independent of temperature such that the temperature dependence of S cannot be used to separate the contributions of ΔV_{th} and ΔV_{con}. However, one approach to separating these terms is to examine the reaction in a variety of organic solvents with similar solvating abilities but different thermoexpansion coefficients β (see Section 4.1). To date, most photoacoustic studies of reactions in organic solvents have assumed that ΔV_{con} makes only a minor contribution to the overall acoustic wave amplitude and can thus be neglected.

The instrument response function parameter K may be eliminated from the analysis by employing a calibration compound that converts the entire energy of the photon, $E_{h\nu}$, into heat, and undergoes no changes in its molecular structure ($\Delta V_{con} = 0$) on the timescale of the instrument resolution. The acoustic wave amplitude for the calibration compound, S_{cal}, is given by Equation (3). K is eliminated by dividing the acoustic wave amplitude S by S_{cal} [Eq. (4)]. If ΔV_{con} is negligible, then the heat released

$$S_{cal} = K(\beta/C_p\rho)E_{h\nu} \quad (3)$$

$$\phi = S/S_{cal} = (Q/E_{h\nu}) + \{\Delta V_{con}/[(\beta/C_p\rho)E_{h\nu}]\} \quad (4)$$

during the reaction, Q, equals $E_{h\nu}\phi$. For aqueous solutions the correlation of ϕ with $1/(\beta/C_p\rho)$ yields both Q and ΔV.

The transducers used in the detection of acoustic waves are sensitive not only to the amplitude of the acoustic waves but also to their temporal profile. If a reaction involves two sequential decay steps [Eq. (5)], then the observed time-dependent voltage

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \quad (5)$$

produced by the transducer, $E(t)_{obs}$, will reflect both decay processes, $H(t)$. $E(t)_{obs}$ is produced by the convolution of $H(t)$ with the instrument response function, $T(t)$, which may be independently determined from the calibration compound [Eq. (6)]. For

$$E(t)_{obs} = H(t) * T(t) \quad (6)$$

the two sequential decays in Equation (5), $H(t)$ is expressed according to Equation (7), where ϕ_i is defined by Equation (4).[3] Numerous algorithms have been developed for obtaining the parameters ϕ_i and k_i.[9]

$$H(t) = \phi_1 \exp(-tk_1) + [\phi_2 k_1/(k_2 - k_1)][\exp(-tk_1) - \exp(-tk_2)] \quad (7)$$

3. Photoacoustic Calorimeter

Numerous designs of photoacoustic calorimeters have appeared.[3, 6, 7] Their basic components are a laser for excitation and a transducer for detection of the acoustic waves. The transducers are composed of either polyvinylidene difluoride (PVF_2) thin films or piezoelectric ceramics. PVF_2 thin films have been used as broad-band detectors that directly follow the real time propagation of the acoustic waves. An intrinsically more sensitive detector is the piezoelectric transducer composed of lead zirconate/lead titanate. The output of the transducer is normally passed through a pre-amplifier and then time resolved by a transient digitizer. The arrangement is very sensitive to small temperature changes; for a 10 μJ laser pulse with a beam diameter of 1 mm passed through a 1 cm cuvette, the temperature change along the cylinder defined by the laser beam that generates the acoustic wave is on the order of 10^{-6} °C. The corresponding volume change is 10^{-10} mL.

The plot in Figure 1 illustrates how kinetic phenomena are manifested in the acoustic waves. Irradiation (λ = 365 nm) of

Kevin S. Peters was born in 1949 in Ponca Cita, Oklahoma, USA, received his B. S. in chemistry in 1971 from the University of Oklahoma, and earned his Ph.D. in 1975 for his work with Kenneth Wiberg at Yale. Following postdoctoral research with Fred Richards (Yale), Meredith Applebury (Princeton), and Peter Rentzepis (Bell Laboratories), he accepted a position as professor at Harvard in 1978. He has been a professor of chemistry in the Department of Chemistry and Biochemistry at the University of Colorado at Boulder since 1984. He is a recipient of the Alfred P. Sloan Fellowship and the Henry and Camille Dreyfuss Teacher–Scholar Award. His research focuses on the dynamics and energetics of reactive intermediates in organic and organometallic chemistry and biochemistry.

the calibration compound ferrocene in benzene produces acoustic wave A. This curve represents the response of the piezoelectric transducer to an impulse. Curve B is produced following irradiation ($\lambda = 365$ nm) of benzophenone in benzene. The shift in curve B relative to curve A reflects kinetic phenomena of the reaction of benzophenone on the timescale of the response of the transducer. The first event is the formation of the triplet state of benzophenone from the decay of its singlet state, which occurs in less than 20 ps and thus cannot be temporally resolved. The

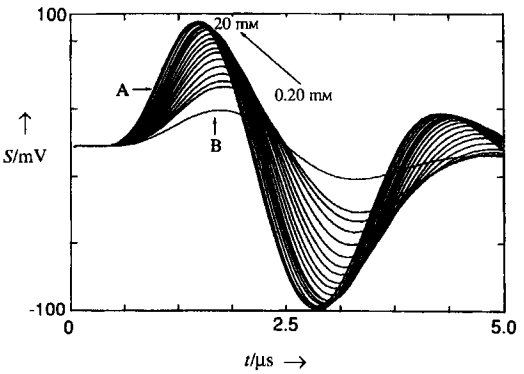

Fig. 1. Acoustic waves generated by the irradiation ($\lambda = 365$ nm) of ferrocene (calibration compound, optical density $OD_{365} = 0.3$, curve A), benzophenone ($OD_{365} = 0.3$, curve B), and benzophenone in the presence of 2,3-dimethyl-2-butene (0.2 mM–20 mM). See text for details.

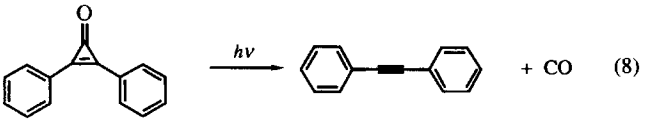


second event is the decay of the triplet state of benzophenone on the 10 μs timescale. The acoustic waves between curve A and curve B are produced when the triplet state of benzophenone is quenched by 2,3-dimethyl-2-butene (0.2 to 20 mM). Analysis of these acoustic waves reveals that the rate constant for the quenching of the triplet state of benzophenone by 2,3-dimethyl-2-butene is $1.30 \pm 0.02 \times 10^9$ L mol^{-1} s^{-1}. These waves are produced by kinetic events within the time range of 38 ns to 3.8 μs.

4. Organic Reactions

Photoacoustic calorimetry allows organic chemists for the first time to directly measure the reaction enthalpies for highly reactive species such as radicals, diradicals, and carbenes in the condensed phase. Prior to this development the energetics for these species could only be estimated. With direct measurements chemists can begin to critically examine the theoretical predictions for the heats of formation and the heats of reaction of highly reactive species.

4.1. Decomposition of Diphenylcyclopropenone

One of the first applications of photoacoustic calorimetry in organic chemistry was an estimation of the resonance energy of diphenylcyclopropenone.[10] The resonance energy was derived from the heat of reaction for the photoinduced decomposition of diphenylcyclopropenone to form diphenylacetylene and carbon monoxide [Eq. (8)], and the heats of formation of the constituent molecules using Benson's group additivity method.

(8)

Irradiation ($\lambda = 337$ nm) of diphenylcyclopropenone in benzene produces diphenylacetylene and CO with quantum yield 1.0. The experimentally derived heat of reaction is -9.9 ± 2.9 kcal mol^{-1}, which leads to an estimate for the resonance energy of -11 kcal mol^{-1}.[10]

In the original study it was assumed that the change in volume due to a change in molecular configuration, ΔV_{con}, was negligible and thus that the resulting acoustic wave was produced only by a release of heat. Recently, Hung and Grabowski have examined the magnitude of the contribution of ΔV_{con} in the decomposition of diphenylcyclopropenone.[11] The contribution of ΔV_{con} was obtained by studying reaction (8) in a homologous series of alkane solvents, whose thermal expansion coefficient, β, varied with chain length. It was implicitly assumed that H_{rxn} and ΔV_{con} are constant in the series of alkane solvents. Their analysis revealed that $H_{rxn} = -6.7 \pm 1.2$ kcal mol^{-1} and $\Delta V_{con} = 23 \pm 4$ mL mol^{-1}. The magnitude of this volume change is that expected for the cleavage of two carbon–carbon bonds; the average volume change associated with the cleavage of one carbon–carbon bond is 10 mL mol^{-1}.[11]

This more recent study reveals that neglecting the contribution of ΔV_{con} led to an overestimation of H_{rxn} by 3 kcal mol^{-1} for reaction (8) in the original study. Clearly for reactions that involve the formation or cleavage of covalent bonds, ΔV_{con} can make a significant contribution to the acoustic wave amplitude in organic solvents.

4.2. Reactions of Carbenes

In recent years there has been a renewed interest, both theoretical and experimental, in the reactivity of carbenes.[12a] Although there have been a variety of methods developed for determining the reactivity of carbenes, until the development of photoacoustic calorimetry there had been little progress in obtaining the energetics for these reactions. Now one is able to measure the enthalpy change for the formation of carbenes and their reactions with a great variety of substrates.

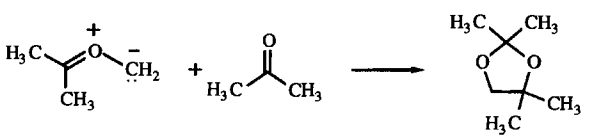
4.2.1. Diphenylcarbene

The dynamics, structural characteristics, and reactivity of the spin states of diphenylcarbene have been well characterized. Eisenthal et al. have shown that the photolysis of diphenyldiazomethane produces singlet carbene within 25 ps which undergoes intersystem crossing to the triplet carbene on the 100 ps timescale [Eq. (9)].[12b] The kinetics of this latter process are de-

$$Ph_2CN_2 \xrightarrow{h\nu} {}^1Ph_2C: + N_2 \xrightarrow{k_{isc}} {}^3Ph_2C: + N_2 \qquad (9)$$

pendent upon solvent polarity. Little is known regarding the energetics for the formation of diphenylcarbene and its associated reactions.

Employing photoacoustic calorimetry we have measured the enthalpy change for the formation of triplet diphenylcarbene from diphenyldiazomethane in benzene [Eq. (10)].[13] The enthalpy change associated with the intersystem crossing of singlet diphenylcarbene to triplet diphenylcarbene was not time resolved, as this process occurs on the 100 ps timescale and the time resolution of the photoacoustic calorimeter was approximately 50 ns. The analysis of the acoustic data to obtain the heat of reaction did not take into account the contribution due to the increase in the molecular volume of the system that accompanied the molecular dissociation. Based upon the experiments of Grabowski,[11] the reported enthalpy change may be in error by as much as 3 kcal mol^{-1}.

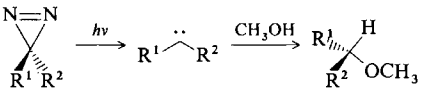


$$Ph_2CN_2 \longrightarrow {}^3Ph_2C: + N_2 \quad \Delta H = 0 \pm 1.7\ \text{kcal mol}^{-1} \qquad (10)$$

Following the formation of triplet diphenylcarbene, a subsequent reaction with molecular oxygen forms benzophenone oxide, the "Criegee intermediate" [Eq. (11)].[13] In oxygen-saturated benzene this reaction occurs within 220 ± 29 ns.

$$^3Ph_2C: + O_2 \rightarrow Ph_2COO \quad \Delta H = -34.7 \pm 2.4\ \text{kcal mol}^{-1} \qquad (11)$$

4.2.2. *Alkylcarbenes*



Goodman et al. have developed an extensive research program examining the dynamics and energetics for the reactions of carbenes.[14–20] In one of their first studies they examined the reaction of ylide **1** with acetone to form 2,2,4,4-tetramethyl-1,3-dioxolane (**2**); ylide **1** was produced by the photolysis of diazomethane in acetone.[14] The enthalpy change ΔH is -57.1 ± 13.4 kcal mol^{-1} for the addition reaction giving **2**. From the heat of formation of acetone and the calculated heat of formation of dioxolane **2**, the heat of formation of ylide **1** is derived, $\Delta H_f(\mathbf{1}) = 4.5 \pm 9.9$ kcal mol^{-1}.

1 **2**

One of the proposed reactions of ylide **1** is bond cleavage to form singlet methylene and acetone.[14] From the heats of formation of ylide **1**, methylene (102 kcal mol^{-1}), and acetone (-52.1 kcal mol^{-1}), the enthalpy change for this dissociation is estimated to be 45 kcal mol^{-1}. Given the endothermicity of this reaction it is unlikely that fragmentation of ylide **1** occurs to a significant extent. This value for the enthalpy of fragmentation is in close agreement with the value of 38 kcal mol^{-1} calculated by Houk et al for the fragmentation of formaldehyde *O*-methylide.[21]

In a subsequent study Goodman et al. measured the enthalpy changes associated with the photolysis of diazirines **3a–d** to form the corresponding carbenes **4a–d**, which then insert into the O–H bond of methanol to form the ethers **5a–d**.[15] The enthalpy changes are given in Table 1; the heats of formation for carbenes **4a–d** were deduced from these values. When the experimental heats of formation were compared with the values obtained from MNDO calculations, the experimentally determined values were consistently lower by 10–20 kcal mol^{-1}.[15] The proposed rationale for this discrepancy is that the ΔV_{con} makes a significant contribution to the acoustic wave amplitudes or that the solvation energy for the carbene is high. Alternately, the MNDO calculations may be in error. Clearly, this will be a fruitful area for further investigation.

3 **4** **5**

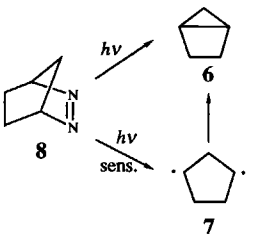
c, R^1 = Ph, R^2 = Br; **d**, R^1 = OMe, R^2 = Cl

Table 1. Enthalpy changes for the reactions **3a–d** → **4a–d** (ΔH_1) and **4a–d** → **5a–d** (ΔH_2), and the heats of formation of **4a–d** (ΔH_f).



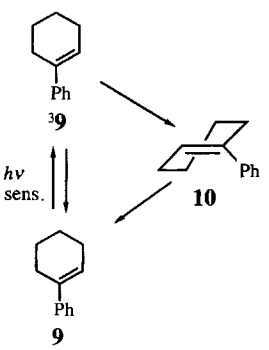
Cmpd.	ΔH_1 [kcal mol^{-1}]	ΔH_2 [kcal mol^{-1}]	ΔH_f [kcal mol^{-1}]
3a	-7.9 ± 2.1	-49.4	27.3
3b	-11.1 ± 1.6	-50.9	67.1
3c	-11.4 ± 2.0	-50.6	79.8
3d	-39.9 ± 2.9	-31.2	-21.6

Goodman and his associates also have used photoacoustic calorimetry to study 1,2 intramolecular hydrogen shifts in halomethylcarbenes, which are produced photochemically from the corresponding diazirines, to form vinyl halides.[17, 19] For chloromethylcarbene the enthalpy change for the 1,2 hydrogen shift is -59.5 kcal mol^{-1}; for bromomethylcarbene this value decreases to -48.9 kcal mol^{-1}. These values are in good agreement with AM1 calculations for the heats of these reactions.

4.3. Reactions of 1,3-Diradicals*

Diradicals are often postulated to be intermediates in thermal rearrangements of cycloalkanes, and thus it is important to be able to estimate their heats of formation.[22] However, there is little direct thermochemical data for diradicals. For example in the thermal isomerization of bicyclopentane (**6**) the heat of formation of the transition state is 76 kcal mol^{-1}. The estimate for the heat of formation of the 1,3-diradical **7** is 67 kcal mol^{-1}. This suggests that the enthalpy of activation for the closure of **7** to form **6** is 9 kcal mol^{-1}. However, the experimental energy of activation for the ring closure is only 2.3 kcal mol^{-1}, which calls into question the validity of the calculated heat of formation for **7**.[23]

Herman and Goodman have determined the heat of formation of **7** by time-resolved photoacoustic calorimetry.[24] The direct irradiation of diazene **8** produces bicyclopentane (**6**) in less than 10 ns; the heat of reaction ΔH_{86} is -20.4 kcal mol^{-1}. Under conditions of triplet sensitization **8** decomposes to form the long-lived triplet state of **7** with a heat of reac-



8 **6** **7**

tion of $\Delta H_{87} = 14.1$ kcal mol^{-1}. The heat of formation $\Delta H_f(7)$ is then obtained from relationship $\Delta H_f(7) = \Delta H_f(6) - \Delta H_{86} + \Delta H_{87}$. With $\Delta H_f(6) = 37.0$ kcal mol^{-1}, the value of $\Delta H_f(7)$ is 71.5 ± 2.3 kcal mol^{-1}. This higher value for the heat of formation of **7** is consistent with the experimentally determined energy of activation for the ring closure of **7** and the heat of formation for the transition state for the isomerization of **6**.

These experiments also revealed that the lifetime for the triplet state of **7** is 316 ns, which is significantly shorter that deduced by using oxygen trapping (720 ns).[24] This was the first measurement of the lifetime of a nonconjugated diradical in solution.

4.4. Strain Energy of *trans*-1-Phenyl-cyclohexene

Although there have been numerous attempts to quantify the strain energy in a variety of organic compounds, little is known regarding the magnitude of the torsional strain about double bonds in cyclic systems.[25] One such molecule is *trans*-1-phenylcyclohexene (**10**). Triplet sensitization of *cis*-1-phenylcyclohexene (**9**) with benzophenone produces its triplet state ^{3}**9**, whose lifetime is 65 ns. *trans*-1-Phenylcyclohexene (**10**) is produced from ^{3}**9** with a quantum yield of 0.36, and it in turn rearranges into **9** in 9 μs.

Employing photoacoustic calorimetry we have determined the strain energy of **10**, defined as the difference in the enthalpies of **10** and **9**, to be 44.7 ± 5.0 kcal mol^{-1}.[25] The energy of the triplet state ^{3}**9** is 56.0 ± 3.4 kcal mol^{-1}. This latter value was the first directly measured energy for the relaxed triplet state of an alkene. More recently several photoacoustic calorimetry studies of the relaxed triplet state energies for alkenes and dienes have been published.[26–29]

4.5. O–H Bond Enthalpies

Another application of time-resolved photoacoustic calorimetry has been in the determination of substituent effects upon the enthalpy of the O–H bond in phenols.[13, 30] These bond enthalpies can be derived from the heat of reaction associated with the abstraction of the OH hydrogen atom by *tert*-butoxy radical and the known enthalpy of the O–H bond in *tert*-butyl alcohol as outlined in Equations (12) and (13).

$$t\text{BuO–O}t\text{Bu} \xrightarrow{h\nu} 2\ t\text{BuO}^{\bullet} \quad (12)$$

$$t\text{BuO}^{\bullet} + \text{X–C}_6\text{H}_4\text{OH} \longrightarrow t\text{BuOH} + \text{X–C}_6\text{H}_4\text{O}^{\bullet} \quad (13)$$

The O–H bond enthalpies have been measured for several substituted phenols along with the kinetics for hydrogen atom abstraction (Table 2).[13] The value for phenol, 84.4 ± 1.1 kcal mol^{-1}, is in good agreement with the value determined by gas-phase methods, 86.5 ± 2.0 kcal mol^{-1}.[13] There is a correlation between the kinetics of hydrogen atom abstraction and the bond dissociation energy.

Table 2. Bond dissociation energies (BDE) for hydrogen atom abstraction from substituted phenols (0.06 M in benzene) by *tert*-butoxy radical and the associated half-lives τ.

Phenol	BDE [kcal mol^{-1}]	τ [ns]
4-cyanophenol	88.2 ± 1.1	227
phenol	84.4 ± 1.1	175
4-*tert*-butylphenol	83.2 ± 0.8	213
4-phenylphenol	83.0 ± 1.1	151
4-methoxyphenol	77.9 ± 0.9	128

5. Organometallic Reactions

To develop an understanding of the reactivity and selectivity in organometallic chemistry it is important to have a measure of metal–ligand and metal–metal bond enthalpies. To date there have only been a few thermochemical studies of bond energies for organometallic compounds in solution. With the advent of photoacoustic calorimetry a number of metal–ligand, metal–hydrogen, and metal–metal bond enthalpies have been obtained.

5.1. Metal–Ligand Bond Enthalpies

The first organometallic compound to be studied by photoacoustic calorimetry was $[Cr(CO)_6]$.[31, 32] Upon irradiation ($\lambda = 337$ nm) in heptane, $[Cr(CO)_6]$ undergoes CO dissociation followed by complexation with the solvent within picoseconds. In the presence of a ligand L the coordinated solvent molecule is then displaced [Eq. (14)]. The values for ΔH_1, ΔH_2, and k for a variety of ligands are given in Table 3. From gas-phase stud-

$$[Cr(CO)_6] \xrightarrow[\text{heptane},\ \Delta H_1]{h\nu} [Cr(CO)_5(\text{heptane})] \xrightarrow[\Delta H_2]{k[L]} [Cr(CO)_5L] \quad (14)$$

ies the enthalpy of CO dissociation from $[Cr(CO)_6]$ is 36.8 kcal mol^{-1}.[33] The enthalpy ΔH_1 for the substitution of

Table 3. Reaction enthalpies for the substitution of CO in $[Cr(CO)_6]$ by heptane (ΔH_1) and for the substitution of heptane in $[Cr(CO)_5(\text{heptane})]$ by L (ΔH_2), and the associated rate constants k.

L	ΔH_1 [kcal mol^{-1}]	ΔH_2 [kcal mol^{-1}]	k [10^{-7} L mol^{-1}]
THF	27.2 ± 1.2	-12.4 ± 1.2	11.8
2,5-dimethyltetrahydrofuran	27.1	−10.8	5.3
ethanol	26.5	−13.8	3.6
acetone	27.3	−13.5	15.9
acetonitrile	26.8	−18.2	27.1
N*n*Bu$_3$	27.3	−12.2	1.2
P*n*Bu$_3$	26.3	−21.6	–
1-hexene	27.2	−12.2	3.0
2,3-dimethyl-2-butene	27.2	−9.6	2.6

CO by heptane is 27.0 kcal mol^{-1}. The difference between the two values, 9.8 kcal mol^{-1}, is the enthalpy for the coordination of heptane to [Cr(CO)$_5$]. As expected, the most strongly binding ligands are P*n*Bu$_3$ and acetonitrile. The binding energies for the remainder of the ligands are very similar with the notable exceptions of 2,5-dimethyltetrahydrofuran, which binds 1.6 kcal mol^{-1} less strongly than THF, and tetramethylethylene, whose binding energy is 2.6 kcal mol^{-1} less than that of 1-hexene. These differences are attributed to increased steric interactions.

The kinetics for the displacement of heptane from [Cr(CO)$_5$(heptane)] do not correlate with the reaction enthalpies. The primary factor that governs the rate of substitution would appear to be steric requirements for the incoming ligand. However, there are some notable exceptions; the rate constants for ethanol, for example, appear to be too small based on steric considerations. This anomaly may be a consequence of hydrogen bonding.

In a similar study Klassen and Yang determined the enthalpy change ΔH_2 for the replacement of heptane in [Cr(CO)$_5$(heptane)] by *cis*-cyclooctene to be -14.2 ± 0.9 kcal mol^{-1}, and by *trans*-cyclooctene to be -19.5 kcal mol^{-1}.[34] The greater binding enthalpy of *trans*-cyclooctene relative to *cis*-cyclooctene ($\Delta H_2 = -5$ kcal mol^{-1}) is attributed to the release of the strain energy in *trans*-cyclooctene upon binding to the metal center as a result of a change in hybridization at the olefinic carbon atoms.

Yang et al. have also examined metal–ligand bond dissociation energies for [CpMn(CO)$_2$L] complexes [Eq. (15), Table 4).[35–37]

$$[CpMn(CO)_3] \xrightarrow[\text{heptane, } \Delta H_1]{h\nu} [CpMn(CO)_2(\text{heptane})] \xrightarrow[\Delta H_2]{k[L]} [CpMn(CO)_2L] \quad (15)$$

Table 4. Reaction enthalpies for the substitution of CO in [CpMn(CO)$_3$] by heptane (ΔH_1) and for the substitution of heptane in [CpMn(CO)$_2$(heptane)] by L (ΔH_2), and the associated rate constants *k*.

L	ΔH_1 [kcal mol^{-1}]	ΔH_2 [kcal mol^{-1}]	k [10^{-6} L mol^{-1}]
THF	46.2 ± 1.2	−16.1 ± 1.4	4.4 ± 0.1
acetone	47.8 ± 1.7	−17.4 ± 1.0	3.6 ± 0.4
cis-cyclooctene	47.6 ± 1.4	−24.5 ± 2.3	2.3 ± 0.4
Bu_2S	45.3 ± 1.4	−28.7 ± 2.2	8.2 ± 0.5
Et_3SiH	46.7 ± 2.2	−20.1 ± 2.1	2.5 ± 0.5

In comparisons of the metal–CO bond enthalpies in [Cr(CO)$_6$] and [CpMn(CO)$_3$], the Mn–CO bond enthalpy is 20 kcal mol^{-1} greater than the Cr–CO bond enthalpy. Since the enthalpy of the Mn–CO bond is not known in the gas phase, it is not possible to determine the heptane binding enthalpy in [CpMn(CO)$_2$(heptane)].

5.2. Metal–Metal Bond Enthalpies

A variety of methodologies have been utilized in obtaining the enthalpy of the metal–metal bond in [Mn$_2$(CO)$_{10}$].[38] A wide range of values have been determined: 16 kcal mol^{-1}, 22.5 kcal mol^{-1}, and 34 ± 13 kcal mol^{-1} from thermochemical measurements, values ranging from 19 to 28 kcal mol^{-1} from electron-impact mass spectrometry, 36.8 kcal mol^{-1} from kinetic measurements in solution, and 41 ± 9 kcal mol^{-1} from ICR-photoelectron spectroscopy (ICR = ion cyclotron resonance). This range of values indicates the difficulty of obtaining good thermochemical data for metal–metal bond enthalpies.

In a kinetic study of the photodissociation of [Mn$_2$(CO)$_{10}$] on the picosecond timescale we found that there are two dissociation pathways: cleavage of the metal–metal bond to form two [Mn(CO)$_5$] units and dissociation of CO to give [Mn$_2$(CO)$_9$]. Both reactions occur within 25 ps of excitation.[38] The dominant pathway is cleavage of the metal–metal bond, as the quantum yield for CO dissociation is 0.1. When a previously determined value of 36 kcal mol^{-1} is used for the Mn–CO bond enthalpy,[38] the value obtained for enthalpy of the Mn–Mn bond in [Mn$_2$(CO)$_{10}$] is 38.0 ± 5.0 kcal mol^{-1}.

5.3. Metal–Hydrogen Bond Enthalpies

Reactions involving metal–hydrogen bonds are fundamental in organometallic chemistry and yet little is known about these bond enthalpies. A general approach for obtaining this thermochemical information is by studying the abstraction of the hydrogen atom from a metal hydride by *tert*-butoxy radical [Eq. (16), see also Section 4.5).

$$L_nM{-}H + t\text{BuO}^{\cdot} \longrightarrow L_nM^{\cdot} + t\text{BuOH} \quad (16)$$

We have used this approach to measure the enthalpy of the metal–hydrogen bond in [(η^5-C$_5$Me$_5$)(PMe$_3$)IrH$_2$].[39] The Ir–H bond enthalpy is 72.9 ± 4.3 kcal mol^{-1}, which is in excellent agreement with value of 74 kcal mol^{-1} derived from kinetic measurements.[39] The method should be generally applicable for the determination of metal–hydrogen bond enthalpies.

6. Reactions of Proteins

Understanding the relationship between the molecular motion of a protein and its function is essential for the development of models for enzyme action. Protein structures provided by X-ray crystallography have provided a wealth of information for understanding protein function. However, the picture is incomplete without full characterization of the intermediates that intervene in protein action. One would like to understand how the dynamics and energetics of substrate binding and catalytic function are controlled by protein structure. A number of methodologies have been developed that provide information relating to the intermediates in the reactions of proteins. These techniques include time-resolved absorption spectroscopy, Raman, EPR, NMR, and IR spectroscopy. Information has been notably lacking on the dynamics of the enthalpy changes and the associated molecular motions for protein function on short timescales. Photoacoustic calorimetry is beginning to provide such insights for proteins.

Photoacoustic calorimetry has been used to study the dynamics of photodissociation of carbon monoxide from carboxymyoglobin[40-42] and carboxyhemoglobin,[43] the energetics of the intermediates formed in the bleaching of the visual protein rhodopsin,[44] the dynamics of proton pumping in bacteriorhodopsin,[45] electron transfer in reaction centers, and the photophysics and photochemistry of the plant photosensor pigments phytochrome and chlorophyll.[46,47]

6.1. Myoglobin

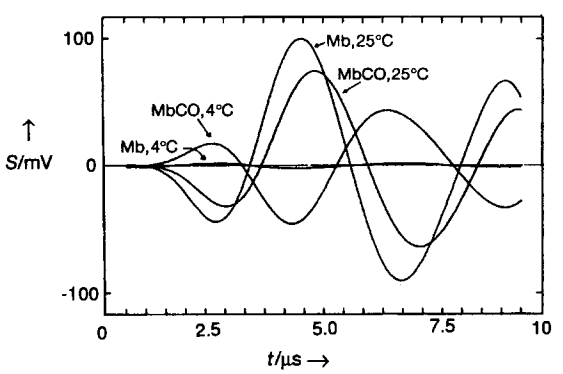
One of the most extensively investigated proteins is sperm whale myoglobin, an oxygen storage protein. Although the mechanism of myoglobin function has been addressed by numerous experimental and theoretical studies, two fundamental points are still not understood. The first is the pathway by which a ligand diffuses between the heme pocket and the solvent. The second is how the protein structure modulates the binding energy of the ligand. X-ray studies reveal that there are no channels for ligand diffusion that directly connect the heme pocket with the solvent. Therefore, the protein must undergo significant structural changes to allow ligand diffusion. The dynamics and energetics of these processes are unknown. With the development of photoacoustic calorimetry, we are beginning to gain insight into the nature of these processes.

The photophysics of carboxymyoglobin (MbCO) have been well characterized [Eq. (17)].[48] After MbCO absorbs a photon,

$$\mathrm{MbCO} \xrightarrow{h\nu} (\mathrm{MbCO})^{*} \xrightarrow{350\ \mathrm{fs}} \mathrm{Mg{:}CO} \xrightarrow{180\ \mathrm{ns}} \mathrm{Mb{:}::CO} \xrightarrow{???} \mathrm{Mg} + \mathrm{CO} \quad (17)$$

its excited state decays by cleavage of the Fe–CO bond within 350 fs to create the geminate pair Mb:CO, in which the ligand is located within the heme pocket. Within 180 ns at room temperature CO diffuses out of the heme pocket into the protein matrix (Mb:::CO) and then into the solvent (Mb + CO). The dynamics of this latter process are unknown.

Time-resolved photoacoustic spectra of MbCO in 0.1 M Tris-HCl buffer following irradiation ($\lambda = 510$ nm) are shown in Figure 2. Also displayed is the spectrum of the calibration compound, deoxymyoglobin (Mb), which converts the entire photon energy into heat and undergoes no conformational changes.



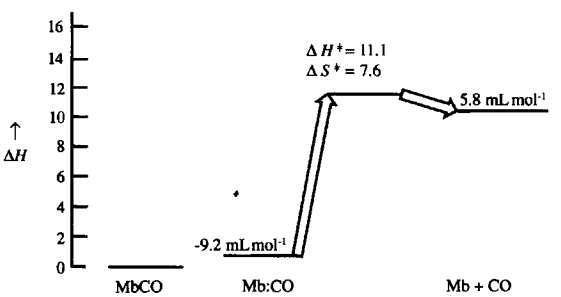


Fig. 2. The temperature dependence of the photoacoustic signal from carboxymyoglobin (MbCO), (1.6×10^{-5} M), and deoxymyoglobin (Mb) (1.6×10^{-5} M) in 0.1 M Tris-HCl, pH 8.0. $T = 25$ and 4 °C, irradiation with $\lambda = 510$ nm.

At 25 °C there is a pronounced shift in the MbCO acoustic wave relative to the Mb acoustic wave, revealing that dynamical processes are occurring on the nanosecond timescale. To probe the dynamics of conformational changes the temperature of the aqueous solution was lowered to 4 °C. At this temperature the thermal expansion coefficient for the system approaches 0, and only changes in the protein structure, ΔV_{con}, will produce acoustic waves. Indeed, at 4 °C the acoustic wave amplitude for Mb is practically 0, since this calibration compound undergoes no structural changes on the nanosecond timescale. However, MbCO has a pronounced acoustic wave at 4 °C with a negative initial amplitude, which results only from structural changes within the protein–solvent system. The analysis of the temperature dependence of the acoustic waves indicated that there are at least two decay processes, and the enthalpy and volume changes for these decay process were resolved.[40] Also, from the temperature dependence of the kinetics for the second decay, the thermodynamic activation parameters were derived.

The results are summarized in Scheme 1. Following the absorption of light, MbCO decays to form the geminate pair Mb:CO in less than 10 ns. The enthalpy change for this process is 0.6 ± 2.2 kcal mol^{-1} and the volume change -9.2 ± 0.5 mL mol^{-1}. At 22 °C a second decay occurs within 700 ns which has an enthalpy change of 10.7 ± 1.8 kcal mol^{-1} and a volume change of 15.0 ± 0.4 mL mol^{-1}. For this second process the enthalpy of activation ΔH^{*} is 11.1 ± 0.3 kcal mol^{-1}, and the entropy of activation ΔS^{*} is 7.6 ± 1.9 cal K^{-1} mol^{-1}.

Scheme 1. Energy diagram for the release of CO from carboxymyoglobin MbCO. ΔH in kcal mol^{-1}, ΔS in cal K^{-1} mol^{-1}.

The most surprising finding is that the enthalpy change for the formation of the geminate pair is 0.6 kcal mol^{-1} and the volume change is -9.2 mL mol^{-1}. Since formation of the geminate pair entails cleavage of the Fe–CO bond, we expected that the enthalpy change would reflect the Fe–CO bond enthalpy, approximately 20 kcal mol^{-1}, and that the volume change would be positive. However, it has recently been proposed, based upon X-ray structural studies, that the pathway by which the ligand diffuses out of the protein entails the breaking of a salt bridge formed between arginine-45 and the propionate side chain.[48] The breaking of a salt bridge and accompanying solvation of the resulting two charged centers releases heat to the solution and causes electrostriction of the water about the charged centers producing a negative volume change for the system.

To probe for the involvement of the arginine-45 salt bridge, this amino acid in sperm whale myoglobin was replaced by

asparagine, which does not form a salt bridge, and the photoacoustic spectrum of this derivative was examined.[41] With the salt bridge deleted, the volume change for the formation of the geminate pair increases from -9.2 to $-4.7\ mL\,mol^{-1}$. The enthalpy change for the formation of the geminate pair increases to $8.7\ kcal\,mol^{-1}$. Clearly, the breaking of the arginine-45 salt bridge is involved in the diffusion of the ligand out of the protein.

These experiments as well as analogous studies of horse carboxymyoglobin[42] and human carboxyhemoglobin[43] are beginning to provide detailed information on the dynamics of enthalpy and volume changes for CO diffusion in heme proteins on the nanosecond timescale.

6.2. Rhodopsin

The visual protein rhodopsin is an integral membrane protein (39 kD) in the disk membranes in the outer segments of the retinal rod cells. Owing to its heterogeneous membrane environment, the study of the dynamics of the enthalpy and volume changes associated with the bleaching of rhodopsin is particularly challenging.[44]

Upon absorption of light, rhodopsin evolves through a series of spectroscopically distinct intermediates that reflect changes in the protein structure important to its function, namely, initiating visual transduction [Eq. (18)]. The intermediate meta-

$$\underset{498\ nm}{\text{rhodopsin}} + h\nu \xrightarrow{<6\ ps} \underset{540\ nm}{\text{batho}} \xrightarrow{50\ ns} \underset{497\ nm}{\text{lumi}} \xrightarrow{0.3\ ms} \underset{478\ nm}{\text{meta I}} \xrightarrow{10\ ms} \underset{380\ nm}{\text{meta II}} \quad (18)$$

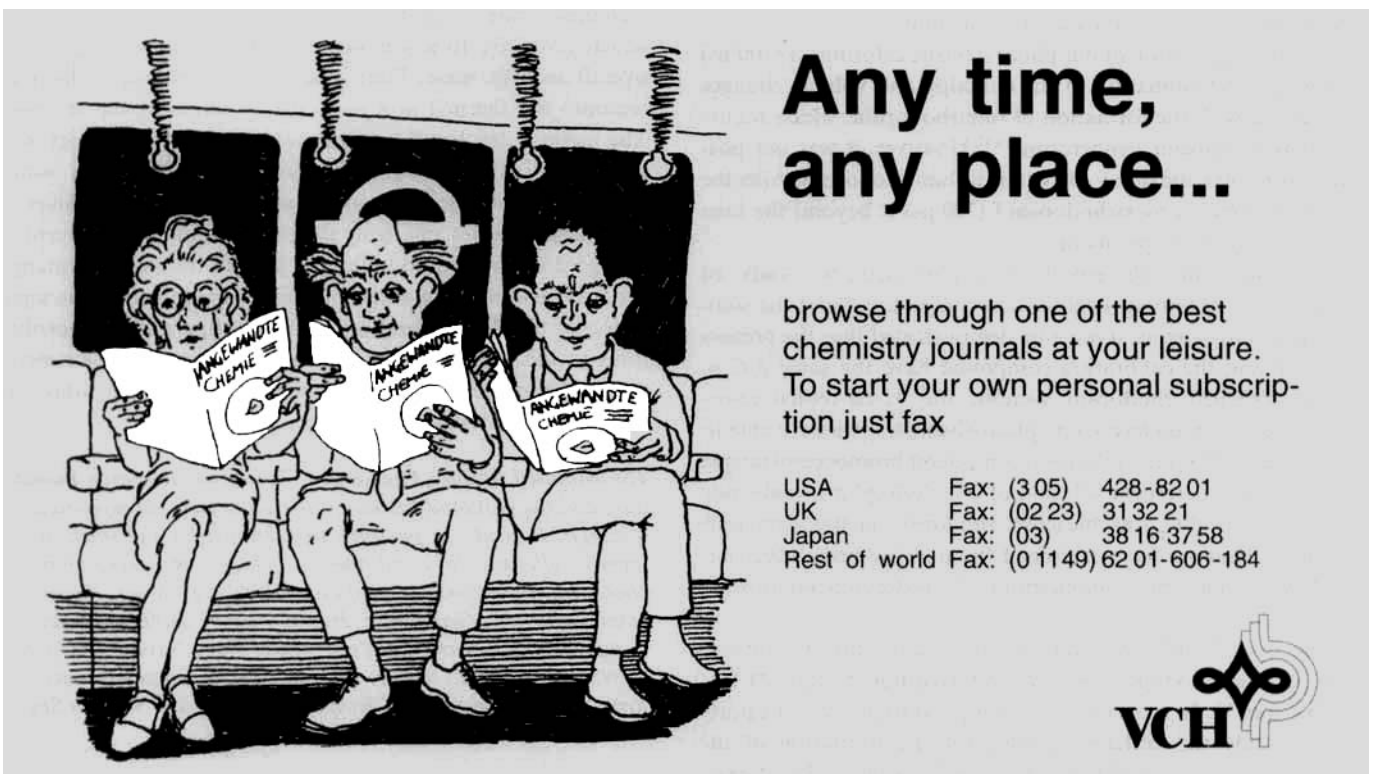
rhodopsin II activates the G protein transducin, which initiates the enzyme cascade for visual transduction.

The time resolution of our photoacoustic calorimeter (100 ns) allows the determination of the enthalpy and volume changes associated with the formation of lumirhodopsin, which occurs in 50 ns at ambient temperature.[44] However, it was not possible to resolve the decay of batho- to lumirhodopsin. Also the decay of lumi- to metarhodopsin I (300 μs) is beyond the time resolution of the experiment.

The most difficult aspect of a photoacoustic study of rhodopsin is obtaining a calibration compound. Since the solution is heterogeneous, it must be demonstrated that the protein solution and the calibration compound have the same $\beta/C_p\rho$. Using bleached rhodopsin without the 11-*cis*-retinal chromophore, which undergoes no photochemistry, we were able to demonstrate that the calibration compound bromocresol purple dissolved in a detergent solution of 2% dodecyl-β-D-maltoside has the same $\beta/C_p\rho$ as bleached rhodopsin in this detergent solution. Thus we have examined the photoacoustic spectrum for bovine rhodopsin solubilized in 2% dodecyl-β-D-maltoside solution.[43]

The overall enthalpy and volume change for the formation of lumirhodopsin is $3.9 \pm 5.9\ kcal\,mol^{-1}$ and $29.1 \pm 0.8\ mL\,mol^{-1}$. In a previous low-temperature ($-75\,^{\circ}C$) calorimetric study the enthalpy change for the formation of lumirhodopsin was found to be $26.3 \pm 4.2\ kcal\,mol^{-1}$.[44] A possible explanation for this difference in the values of the enthalpy change for the formation of lumirhodopsin is that the low-temperature matrix perturbs the energetics of lumirhodopsin. When rhodopsin is photoactivated it undergoes a series of conformational changes as evidenced by the changes in the chromophore absorption spectrum. The volume change of $29.1\ mL\,mol^{-1}$ observed in photoacoustic calorimetry may reflect some of these conformational changes. In a low-temperature glycerol–water glass photoactivated rhodopsin may not be able to undergo reorganization of its protein structure which would induce strain within the protein and lead to an increase in enthalpy for the system. Clearly it is important to study the dynamics of enthalpy and volume changes of proteins under conditions that approximate physiological.

7. Summary and Outlook



Although time-resolved photoacoustic calorimetry has provided many new insights into organic and organometallic reactions as well as protein dynamics, there is a clear need for the extension of the time resolution into the picosecond time domain. With polyvinylidene difluoride thin film transducers, picosecond lasers, and gigahertz transient digitizers, a time resolution of 100 ps should be possible in the very near future. Increasing the time resolution to the 10 ps timescale is more problematic and will require a different technology. The methods of picosecond optical calorimetry developed by Zimmt et al. are the most promising for this timescale.[49, 50]

Reactions in organic and organometallic chemistry that have been the subject of only a limited number of photoacoustic investigations are those involving the creation or annihilation of charge in nonaqueous solvents. Accompanying the creation of a charged center is electrostriction of the solvent about the ion which gives rise to a significant contribution of ΔV_{con} to the overall acoustic wave. Thus it becomes exceedingly difficult to separate the thermal and molecular configurational changes. The method developed by Grabowski et al.[11] may work well for alkane solvents, but for more polar solvents, in which specific solvation becomes important to the overall stability of the charged species, changing the composition of the solvent to change $\beta/C_p\rho$ would undoubtedly perturb the overall enthalpy for the reaction. Until a new method is developed for the separation of the thermal and molecular configurational contributions to the overall acoustic wave, photoacoustic calorimetry cannot be applied to a very important class of reactions, the creation or annihilation of charged centers.

The National Science Foundation, Petroleum Research Foundation, and the National Institutes of Health have all supported my research. It is also a pleasure to acknowledge the work of my former colleagues who did much to advance the development of photoacoustic calorimetry: Lewis Rothberg, Mark Bernstein, John Simon, Joe Grabowski, Jeanne Rudzki, Josh Goodman, Gil Yang, Judy Westrick, Kathleen Marr, Gary Snyder, and Chris Norris. In addition I wish to acknowledge my collaborations with Professors Veronica Vaida, Richard Caldwell, and Stephen Sligar.

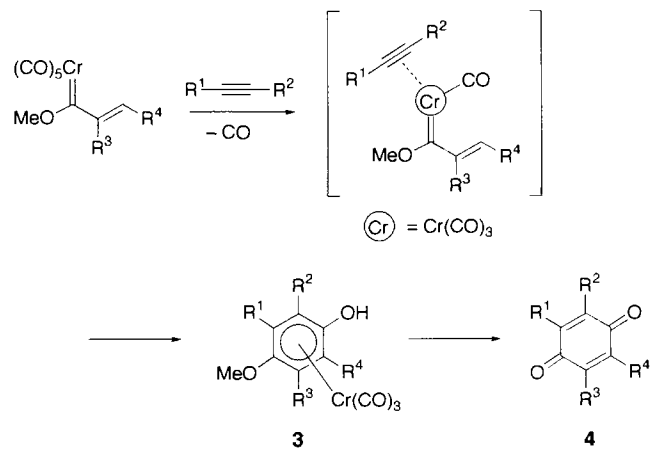
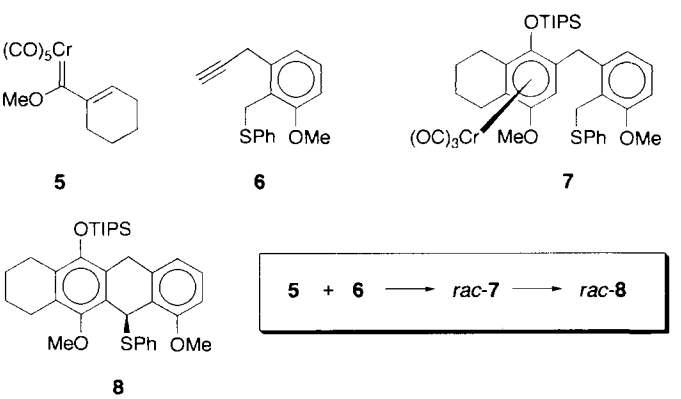
Chromium Carbene Complexes in Organic Synthesis: Recent Developments and Perspectives

Hans-Günther Schmalz*



Complexes of the type $[(CO)_5M{=}CR^1R^2]$, M = Cr, Mo, W, which are also known as Fischer carbene complexes, after their discoverer, have found widespread application in organic synthesis in recent years.[1] Heteroatom-stabilized chromium complexes of type **1** have especially played a major role.[2] These compounds can be prepared in good yield by reaction of $[Cr(CO)_6]$ with organolithium reagents followed by O-alkylation. Alternatively, the anionic intermediate **2** can also be generated by reaction of acyl chlorides with $Na_2[Cr(CO)_5]$.[3]

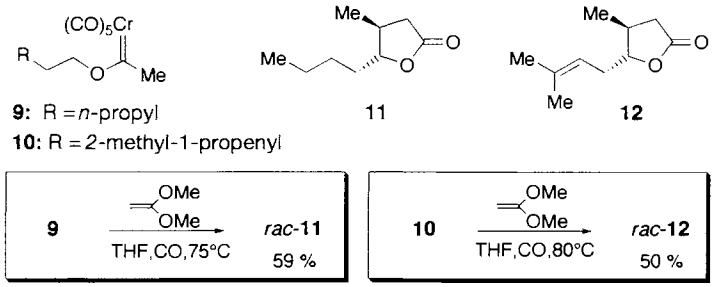


Among the synthetically useful reactions of chromium carbenes, benzannulations certainly are the most prominent.[2] In particular, the so-called Dötz reaction is an efficient synthetic method, which has already proved its worth numerous times within the context of natural product synthesis.[2] In this reaction α,β-unsaturated complexes **1** (R = aryl or alkenyl) are allowed to react with alkynes under thermal conditions to give (in the sense of a formal [3+2+1] cycloaddition) $Cr(CO)_3$-complexed hydroquinone derivatives **3** or, after oxidative workup, *p*-benzoquinone derivatives **4**.

As recently shown by Harrity et al., the typically long reaction times for the Dötz reaction can be drastically reduced by the application of high-intensity ultrasound.[4] Dry-state adsorption of the reaction partners on silica followed by warming to 40–70 °C is an other attractive preparative alternative, which results in markedly improved yields in many cases.[4]

In an effort to further broaden the synthetic scope of the Dötz reaction, S. Chamberlin, W. D. Wulff, and B. Bax succeeded in trapping the free phenol function of the initial products **3** (in situ) as a silyl ether.[5] This in turn allowed them to take advantage of the characteristic reactivity of the resulting arene–$Cr(CO)_3$ complexes, especially towards nucleophiles[6] (tandem

Dötz/Semmelhack reactions). For example, the reaction of the carbene complex **5** with the alkyne **6** in the presence of triisopropylsilyl triflate (TIPS-OTf) and 2,6-lutidine in dichloromethane gave the complex *rac*-**7** (77%), which was then converted to the anthracycline derivative *rac*-**8** in 84% yield by deprotonation with lithium diisopropylamide followed by workup of the reaction mixture with iodine.[5a]



The research group headed by W. D. Wulff also reported on the thermal reaction of chromium carbene complexes with ketene acetals to yield substituted γ-butyrolactones.[7] This reaction, which probably proceeds through insertion of a carbenoid

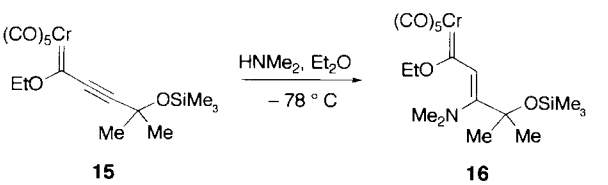
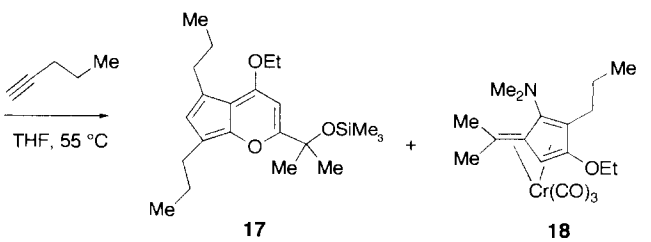
into a C–H bond, was successfully applied to a diastereoselective synthesis of the (albeit racemic) natural products quercuslactone *rac*-**11** and eldanolide *rac*-**12**.[7]

A whole new range of applications of Fischer carbenes in organic synthesis has been developed by L. S. Hegedus et al. after they discovered that the photolysis of chromium carbene complexes produces, under CO insertion, species with a ketene-like reactivity. These intermediates react with nucleophiles to form derivatives of carboxylic acids and with imines (or enol ethers) to form [2+2] cycloaddition products.[8, 9] The introduction of chiral substituents at the carbene carbon atom even allows the control of the absolute configuration of the reaction products. For example, the chiral aminocarbene complex **13** served as the starting point for a quite efficient synthesis of optically active β-lactams.[10]





Photolysis of chiral (aminocarbene) complexes of type **14** in the presence of alcohols proceeds with high diastereoselectivity (in the protonation step) and provides an efficient entry to a broad spectrum of optically active, natural and unnatural amino acids,[11] including optically active [2-$^2H_1$]-glycine.[12] A remarkable feature of this chemistry is the possibility of preparing compounds with two neighboring ^{13}C-labeled carbon centers, which are of considerable interest for the investigation of biological problems by NMR spectroscopic methods.[13] For this purpose the starting complexes (e.g. **14**) are prepared from ^{13}C-enriched chromium hexacarbonyl.

Photolysis of (aminocarbene) complexes of type **14** in the presence of carboxyl-protected amino acids allows the (diastereoselective) construction of dipeptides in a one-pot reaction.[14] This process is remarkable for several reasons: firstly, both the peptide bond *and* the new stereogenic center are established in a single preparative operation; secondly, visible light acts as the "coupling agent". This permits the direct incorporation of all kinds of amino acids into peptides without the amino acids themselves having to be presynthesized separately.

The number of publications concerning reactions of Fischer carbene complexes is growing rapidly. Preparative as well as mechanistic aspects of this chemistry are under intense investigation worldwide—and the discovery of unexpected reaction pathways and products does not seem to be a rare exception. In a recent example, A. de Meijere et al. treated complex **16** (which is easily prepared from **15**) with 1-pentyne and obtained considerable amounts of the fulvene–$Cr(CO)_3$ complex *rac*-**18** in addition to the cyclopenta[*b*]pyran **17**.[15]

W. D. Wulff et al. reported the formation of cyclopentenones (by C–H activation) when alkyl chromium carbenes were treated with alkynes.[16] A new entry to cyclopentenones was also discovered by the research group of J. W. Herndon in the reaction of cyclopropyl carbene complexes with alkynes—a reaction which was (rather daringly!) classified by the authors as a [4+2+1–2] cycloaddition[17].

Which of the many new reactions of chromium carbene complexes (only a few have been mentioned here) will stand the test of real-life application in multistep syntheses, is, of course, still uncertain. However, one can certainly expect that Fischer carbene complexes will be good for many more surprises in the future, and that their potential for organic synthesis will be more and more recognized, researched, and utilized. Thus, every synthetic chemist is well advised to follow this fascinating field with appropriate attention.

A New Application of Modified Peptides and Peptidomimetics: Potential Anticancer Agents

Rob M. J. Liskamp*

Wide applications of (unmodified) peptides as drugs are limited by the disadvantages affiliated with their use in biological systems. An unmodified linear peptide is easily degraded by, for example, proteases, it is often too water-soluble to pass through the cell membrane and therefore unable to pass through the blood–brain barrier and is rapidly excreted. In addition, a peptide has a flexible structure and the bioactive conformation is usually only one of several thousand possible conformations.

The desire to remedy these disadvantages and thereby to obtain meaningful pharmaceutical compounds has led to the development of modified peptides and peptidomimetics.[1, 2] All major pharmaceutical companies nowadays are carrying out major research and development in this area, and the number of applications of these substances is steadily increasing. The importance of modified peptides and peptidomimetics is evident from several applications. So far they have been applied for example in the development of drugs regulating blood pressure and blood clotting, in the development of HIV-protease inhibitors and immunosuppressive agents as well as in the development of neuropeptide (ant)agonists.

Two recent reports have described a new promising application of modified peptides and peptidomimetics as potential anticancer agents for the treatment of tumors in which oncogenic Ras proteins (see below) contribute to transformation and abnormal growth.[3, 4] Two aspects of the results presented in these reports are especially noteworthy:
– the inhibition of malignant transformation was achieved on a level other than the DNA level;
– the inhibition originated from inhibition of a post-translational modification process of proteins.

In many conventional chemotherapeutic regimens of cancer, the drug displays its activity on the DNA level. The interference with or damage to the genetic material leads to the arrest of cellular growth and halting of uncontrolled cell division. However, these drugs are often deleterious for other rapidly dividing cells involved in the formation of, for example, bone marrow, gastrointestinal mucosa, and hair follicles, causing the well-known side effects. In addition, interference with the genetic code means that these reagents are inherently carcinogenic and/or mutagenic. Therefore attempts directed towards the development of drugs acting on other cellular levels are especially interesting.

The most direct approach is to employ modified peptides or peptidomimetics for the inhibition of the cleavage of an amide bond in an amino acid sequence, present in a peptide or protein involved in a biological process, which one wants to suppress. For example, HIV-protease inhibitors are supposed to inhibit the cleavage of the amide bond between phenylalanine and proline in a precursor polyprotein of HIV. As a result the formation of proteins necessary for the assemblage of new virus particles is inhibited, and the spread of HIV is diminished. More indirect—perhaps better tunable—approaches focus on the use of modified peptides and peptide mimetics for the inhibition of modification processes which the protein has to undergo once it has been biosynthesized at the ribosome and before it can fully perform its function. These processes are referred to as post-translational modification processes. Since there are many of these processes,[5] often with high selectivity with respect to the protein(s) being modified, interference with a particular post-translational modification process offers a means for very specific intervention in undesired cellular processes. Inhibition of the post-translational modification process by phosphoryla-

tion catalyzed by protein kinase C (PKC) or tyrosine kinases has been an approach employed to interfere with the carcinogenic process, since, for example, PKC is presumably involved in carcinogenesis.[6] However, inhibition of phosphorylation catalyzed by PKC may also be disastrous for normal cells, since many other proteins are phosphorylated by PKC in addition to those possibly involved in the transformation process. Therefore interference with such a specific post-translational modification process as farnesylation seems a more promising and perhaps an even more viable approach for the development of anticancer drugs.

Eukaryotic polypeptides with a cysteine residue located at the fourth position (counting from the C terminus) are, in principle, candidates for a post-translational modification involving the cysteine-SH. In a reaction catalyzed by farnesyl protein transferase (FPTase), this SH can be alkylated by farnesylpyrophosphate (FPP), an isoprenoid compound also involved in the biosynthesis of cholesterol. This step can be followed by the subsequent post-translational modifications of cleavage of the three C terminal amino acid residues and methyl esterification of the carboxylic acid terminus.[7] The role of farnesylation or geranylgeranylation is not clear at present. The hydrophobic isoprenyl tail may be responsible for membrane association of proteins. Alternatively, the isoprenyl tail and methyl ester may promote binding of the protein to specific membrane associated receptors.[8]

The Ras protein is an intriguing example of an eukaryotic protein which is farnesylated (Scheme 1). Ras is a guanosine triphosphate (GTP) binding protein. When GTP is bound to Ras, cell division is triggered. Normal Ras possesses GTPase activity, this leads to the hydrolysis of the bound GTP to GDP, so that the mitogenic signal is terminated in time. There are, however, mutant forms of Ras, found in about 50% of human colon carcinomas and 90% pancreatic carcinomas, which have an impaired GTPase activity. This impaired GTPase activity has as a consequence that the mutant Ras protein remains constitutively complexed to GTP, leading to unregulated cell proliferation and malignant transformation. Farnesylation of both normal and oncogenic Ras proteins is necessary for attachment to the cell membrane and the resulting biological effects. For the mutant Ras protein farnesylation appears to be required for efficient cell-transforming activity. Therefore a straightforward, albeit elegant, approach to inhibit transformation would be to interfere with Ras membrane localization by preventing farnesylation.[9]

Tetrapeptides with amino acid sequences identical to the COOH terminus of protein substrates for farnesylation by FPTase can compete with Ras for farnesylation. Selectivity of inhibition of farnesylation as opposed to inhibition of the other isoprenylation process of attachment of a geranylgeranyl moiety can be obtained by using peptides of the consensus sequence CAAX in which C is cysteine, A is an aliphatic amino acid, and X is serine or methionine.

In the modified peptides designed by the group at Merck the N-terminal amide bonds were reduced to introduce resistance to hydrolysis by aminopeptidases.[3] In addition, serine or methionine at the C terminus were replaced by homoserine or its lactone. It was also expected that the lactone could penetrate more easily into cells, because of the absence of a charged carboxylic acid moiety. The two compounds L-731,735 and L-731,734 (see Scheme 1) were potent inhibitors of partially purified FPTase, the homoserine compound being the more active in-

Scheme 1. Post-translational modification by farnesylation. The cysteine residue in the consensus sequence CAAX (C, cysteine; A, aliphatic amino acid residue; X, serine or methionine) near the C terminus in the Ras protein is farnesylated by farnesylpyrophosphate (FPP) catalyzed by farnesyl protein transferase (FPTase). The farnesylated protein can then attach itself to the plasma membrane. If mutated Ras proteins are farnesylated and attached to the cell membrane, this leads to transformation. Modified peptides [3] (L-731,735 and L-731,734) based on the consensus sequence CAAX, as well peptidomimetics [4] (BZA-2B and BZA-5B) based on both the consensus sequence and a presumed turn of CAAX act as potent competitive inhibitors of Ras farnesylation.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0303-0306 $ 10.00+.25/0

hibitor (IC_{50} 18 nM as compared to 282 nM for the lactone derivative). By isolating only soluble—not isoprenylated and therefore not membrane associated—Ras from cells transformed with the *ras* gene, which were treated with L-731,734, it was proven that the modified peptide did in fact interfere with the farnesylation post-translation modification. The cytostatic activity was evident from the inhibition of anchorage-independent growth of Rat1 cells transformed with v-*ras*. At a concentration of 1 mM the modified peptide was capable of inhibiting the growth of these cells in soft agar.

The University of Texas and Genentech groups went a step further.[4] Besides realizing that one needed a tetrapeptide sequence corresponding to the CAAX consensus sequence to obtain alternative substrates, thereby competitively inhibiting the farnesylation of Ras proteins, they hypothesized that the tetrapeptide binds to the FPTase in a turn conformation. This would place the NH_2-terminal cysteine and the COOH-terminal methionine in close proximity to the Zn^{2+} ion that is known to be essential for peptide binding by FPTase. To mimic a turn-like structure of the two middle amino acids in the consensus sequence, they used the benzodiazepine skeleton to which the N-terminal cysteine residue and a C-terminal methionine, serine, or leucine residue were attached.[10] Several structural features in the peptidomimetics (see Scheme 1) were essential for effective inhibition of farnesylation: a) the amino function connecting the cysteine had to be *N*-methylated, b) the configuration at the C-3 atom needed to be the correct one (not determined as yet): only one of the two diastereomers was active, c) methionine at the C terminus was most effective and d) although the free acid (BZA-2B) produced the best results in the in vitro assay (IC_{50} 0.85 nM), the ester (BZA-5B), and to a somewhat lesser extent the amide, were more active in a Chinese hamster ovary cell line, suggesting that the latter compounds may more easily penetrate into cells, because of their reduced polarity. Almost complete inhibition of farnesylation was achieved at a concentration of 25 μM by using the ester, whereas a concentration of 250 μM of the acid was required for the same inhibition.

BZA-2B also displayed selectivity in its inhibition of farnesylation as compared to inhibition of geranylgeranylation and was not itself farnesylated.

Reversal of the transformed phenotype of multilayered clumps to a monolayer system was observed by incubating Rat1 fibroblasts, transformed with an activated mutant of H-Ras, with 200 μM of the peptidomimetic BZA-2B for five days. In the presence of 25 μM of the ester BZA-5B the growth of Ras-transformed Rat1 fibroblasts was inhibited for about 90% after ten days.

The use of modified peptides and peptidomimetics to selectively inhibit Ras farnesylation and thereby transformation and ultimately possible the carcinogenic process is an important and new application of these compounds.[11, 12] It also shows that they can be employed for a finely tuned intervention in complex biochemical and biological processes. It is therefore expected that as the understanding of cellular processes (e.g. protein trafficking, intracellular signal transduction) progresses, it will be possible to intervene in, or selectively inhibit these processes using carefully designed modified peptides and peptidomimetics.

The design, synthesis, and applications of modified peptides and peptidomimetics as well as peptide-like compounds such as peptoids is one of the rapidly growing and increasingly important areas,[13] but it is also important to emphasize that this field can and only will continue to flourish by a close interplay of many disciplines, as was also evident from the research discussed here.

German version: *Angew. Chem.* **1994**, *106*, 313

[1] Modified peptides are defined as peptides in which, in essence, the amino acid sequence is unchanged but the peptide contains, for example, some unnatural amino acids, a modification of a cysteine residue, or a phosphorylated amino acid. Peptidomimetics are compounds which imitate the structure and/or imitate or block the biological effect of a peptide at the receptor level [2]. As a consequence peptidomimetics span the whole range of compounds varying from peptide isosteres to compounds without an identifiable amino acid or peptide moiety.

Rationally Designed Inorganic Catalysts for Environmentally Compatible Technologies**

John Meurig Thomas* and Kirill Ilyich Zamaraev*

In a recent analysis[1] of the future prospects pertaining to the design of new catalysts and to the improvement of the performance of existing ones, Schlögl viewed the world through the prism of ammonia synthesis. He traced the heroic work that started with Haber, continued with Mittasch, and which has since been the subject of intense study by generations of subsequent investigators, all of whom, in their respective ways, have struggled to understand the behavior of the iron-based catalyst for the large-scale manufacture of ammonia. But Schlögl's assertions must be challenged, especially the following: "All of the catalytic processes vital to industry were developed by purely empirical methods and countless screening experiments". "This heuristic approach has led to the opinion that catalysis research is not a science but rather 'black magic'". Schlögl further asserts that "...industrial chemists tend to be rather sceptical toward inductive-scientific strategies in heterogeneous catalysis, since it is evident that our understanding of *the relationship between structure and reactivity is inadequate*" (our italics). These are strong, strident words with which we disagree for the reasons given below.

Whilst it is true, as Schlögl describes, that the laboratory world of iron single-crystals, cleaned in ultrahigh vacuum and studied under modest pressure, is vastly different from that of the catalyst in the ammonia synthesis reactor, and whilst it is undeniable that, as yet, no new industrially viable ammonia synthesis catalyst (with the possible exception of the recently commissioned, supported ruthenium catalyst) has emerged as a direct consequence of the de novo investigations of single-crystal metal catalysts, his statements cited above are untrue when applied to other important classes of catalysts. There are numerous examples in which causal relationships between crystalline structure and catalytic performance have been incontrovertibly established.

Some examples of the veracity of our claims are contained in a number of recent publications.[2-11] One of these,[2] published in *Angewandte Chemie* five years ago, is entitled "Uniform Heterogeneous Catalysts: The Role of Solid-State Chemistry in their Development and Design". In another,[3] numerous chapters support the view that designed catalysts have already been commercialized and are likely to play a pivotal role in the chemistry of the 21st century. Yet other publications[4, 5] address the timely question of designer catalysts in the quest for cost-effective, environmentally compatible technologies. If Schlögl's claims were true, future employers and boardroom protagonists could well underestimate or misjudge the contributions that the research chemist could make to the future of their industry, and employment prospects for numerous highly trained physical scientists would be bleak.

Examples of intentional design in the genesis and evolution of new catalysts are quite numerous. So relevant and progressive is this sector of solid-state chemical research in devising environmentally acceptable catalysts and processes that we summarize four distinct categories of catalysts:

1) An ever-expanding family of monophasic, microporous, microcrystalline solids, some members of which already function on the industrial scale as essentially shape-selective catalysts.
2) Multiphasic systems embracing supported metals, supported oxides, mixed oxides, and mixed sulfides of "designed" solids nowadays function as robust industrial catalysts.
3) Proven examples where new concepts in the design of molecular and extended (solid-state) catalysts have been demonstrated.
4) Improvements on preexisting industrial catalysts which stemmed from a fundamental reexamination of chemical engineering practice; worthwhile commercial and environmental improvements have already been achieved.

Whilst some amplification of all four theses is given in a recent book,[3] we present here the salient points that constitute our rebuttal of the assertions made by Schlögl.[1]

Shape-selective inorganic catalysts[9] are in extensive commercial use worldwide for the conversion of methanol to gasoline, the isomerization of xylene (maximizing yield of the *para* isomer), the conversion of ethene and benzene to ethyl benzene, the disproportionation of toluene to benzene and paraxylene, and the conversion of phenol to hydroquinone and catechol.[12] Many other processes currently being tested at either the pilot plant or laboratory stage entail the use of shape-selective solid

catalysts. These include the production of ε-caprolactam by the isomerization of cyclohexanone oxime, the conversion of cyclohexanone into its oxime, the transformation of methanol into light olefins, the selective production of dimethylamine from ammonia and methanol, the isomerization of 1-butene to 2-methylpropene, and the production of diisopropylnaphthalene (DIPN) isomers. The particular monophasic catalysts used for these processes all have well-defined crystal structures possessing channels and cavities lined with active sites of known identity. Typical examples are H-ZSM-5, H-ferrierite, Theta-1, zeolite rho, HZSM-23, acidic clays, mordenite, and the silicoaluminophosphates H-SAPO-34, H-SAPO-11, etc., which, like ZSM-5, are Brönsted solid acids.[5, 8–12] They are all examples of so-called uniform heterogeneous catalysts in which the active sites are distributed in a spatially uniform way throughout their bulk. Another uniform shape-selective catalyst designed for the function it now has industrially (in the selective oxidation of phenol to hydroquinone) is Ti-silicalite, which is nonacidic.

The germ and genesis of the rational concept of shape-selective molecular sieves was the work of Weisz et al.,[9] who demonstrated that by a *controlled* variation of cavity size—exercised by simple application of the principles of crystal engineering—the selectivity of the catalytic dehydration of alkanols could be profoundly changed. In the thirty years that have elapsed since Weisz and his colleagues first reported their results, numerous successful attempts have been made to adapt the structures of naturally occurring molecular sieves (e.g. the well-known zeolite mordenite) and to synthesize a host of new ones. SAPOs and MeAlPOs in which some of the phosphorus or aluminum atoms of the aluminum phosphate microporous framework are replaced by silicon (in SAPO) or divalent ions (in MeALPO), respectively -are now being designed and synthesized for specific catalytic reactions.[4, 10–16] One strong thrust is in the area of large-pore solid acid catalysts, many of which have recently been prepared[14] with the reactions of bulky molecules in mind.

We agree that the statement "No correlation exists between the bulk X-ray diffraction data and catalytic performance" was convincingly demonstrated by Schlögl[1] in the case of ammonia synthesis (iron-based) catalysts. But for the uniform shape-selective catalysts discussed here there is an indisputable link between the powder diffraction pattern, on the one hand, and the catalytic activity, on the other. See, for example, the published correlation between diffraction pattern, crystal structure, and catalytic performance for the Ni^{2+} ion-exchanged zeolite Y catalysts in the cyclotrimerization of acetylene.[17]

Indeed, so well understood is the correlation between crystal structure and selectivity among acidic shape-selective catalysts that computational chemistry has already contributed significantly to the evolution of superior catalysts for a given task. We cite two examples: the acid-catalyzed isomerization of 1-butene into 2-methylpropene, which is calculated[5, 18] to be facilitated better by Theta-1 than by ZSM-5, and the alkylation of naphthalene by propene to yield 2,6-diisopropylnaphthalene as the desired product.[4] Using computational procedures[18–20] that are by now quite routine for evaluating the energetics of docking of reactants and products inside zeolites, and for diffusion of species out of such shape-selective catalysts, Cusumano reports[4] that acidic mordenite is the favored catalyst to replace the environmentally harmful $AlCl_3$ now used for this reaction. (The $AlCl_3$ catalyst yields both the 2,6- and 2,7-disubstituted isomers as well as undesirable tri- and tetrasubstituted products.) DIPN can be selectively oxidized (Fig. 1) to give a number of monomers which may then be copolymerized into speciality high-performance polymers such as polyethylene naphthanate[4] which are of great potential in the liquid crystal and synthetic polymer markets.

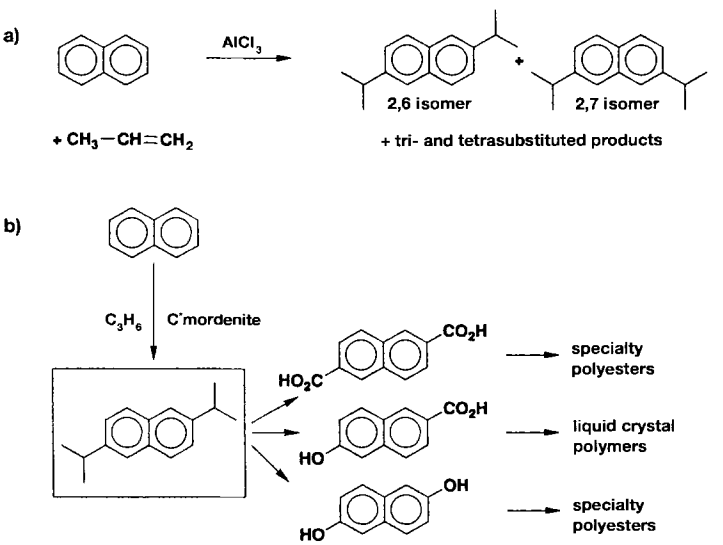

Fig. 1. Alkylation of naphthalene by propene catalyzed by a) $AlCl_3$ to give a mixture of products, b) by mordenite to give 2,6-diisopropylnaphthalene cleanly which can be converted to a number of monomers for specific polymers.

The second category consists of designed multiphasic catalysts. As a typical example, consider a new family of carbon-supported palladium catalysts[21] developed at the Boreskov Institute of Catalysis, Novosibirsk, by Likholobov, Yermakov, et al. These catalysts are prepared by the successive accretion of Pd atoms attached to certain functional groups of the support. A typical procedure is shown schematically in Figure 2. Supported

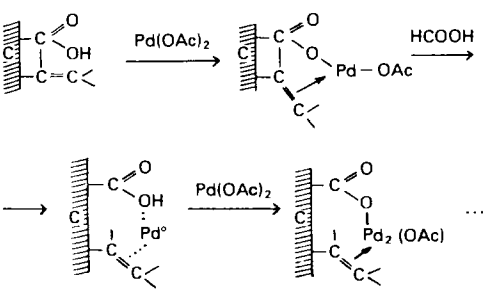

Fig. 2. Accretion of Pd atoms for the production of carbon-supported palladium catalysts.

particles of Pd (crystalline or amorphous) of remarkably uniform size can be obtained in this way. Based on laboratory tests to ascertain the activity of such supported catalysts (for reactions such as the hydrogenation of trifluoromethylnitrobenzene to provide the corresponding aniline), industrial catalysts for large-scale reductions are now in operation with particle sizes in

the range 10 to 30 Å. It is also noteworthy that a new high-strength (ca. 400 kg cm^{-2}) carbon support containing essentially no micropores was especially designed[21] for this catalyst preparation and is already in use industrially.

Designer multiphasic catalysts have also been commercialized to alleviate environmental problems caused by H_2S. This pollutant is found as an impurity in many sources of natural gas, and also in many natural bodies of water, the Black Sea in particular. One popular method of eliminating H_2S has been to use a stoichiometric then a catalytic reaction sequentially [Eq. (a)].

$$H_2S \xrightarrow{+O_2} SO_2 \xrightarrow[\text{cat.}]{+H_2S} S\downarrow + H_2O \qquad \text{(a)}$$

A superior method now on the verge of commercialization for the purification of natural gas[22] is based on a mixed-metal oxide that catalyzes the conversion of H_2S directly into S_2 at such a low temperature that methane remains unoxidized. Natural gas "poisoned" by H_2S may soon by purified efficiently with this designer oxide catalyst.

For removing H_2S from natural bodies of water inorganic photocatalysts that mimic natural bacterial photosynthesis have been designed, prepared, and proven effective.[24] Reaction (b) was demonstrated to proceed quite smoothly in pilot plants upon illumination of semiconductors with visible light.[23]

$$H_2S \xrightarrow{h\nu} H_2 + \tfrac{1}{2}S_2\downarrow \qquad \text{(b)}$$

With the heterojunction arrangement of Figure 3 the whole solar light spectrum is captured, and the efficiency achieved is comparable with that of living organisms.

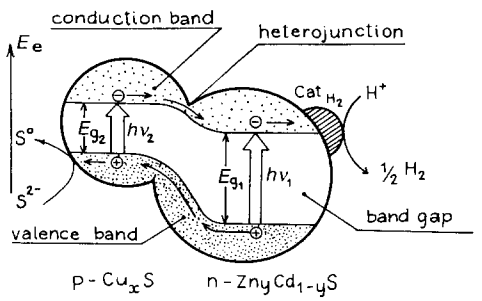

Fig. 3. Energy diagram for the photoseparation of charges and scheme for the catalytic process in a suspended semiconductor particle with the microheterojunction $CuS_x/Zn_yCd_{1-y}S$. E_e is the electrochemical potential of an electron; E_{g1} and E_{g2} are the widths of the band gaps of the semiconductor phases; $h\nu_1$ and $h\nu_2$ are the corresponding quanta of light required to promote an electron into the conduction band.

Another example is the heterogeneous Ziegler–Natta $TiCl_3/MgCl_2$ catalyst for stereoselective polymerization of propene and its copolymerization with other alkenes. Once the mechanism of its mode of action was rationally established, it became possible to tune the catalyst structure and morphology, and the reaction conditions for predominant production of stereoregular polymers with desired physical and mechanical properties.[3] With these carefully designed catalysts one can maximize the yield of the commercially required product and minimize the formation of wastes and consumption of raw material and energy.

A well-known family of inorganic molecular catalysts consists of metal complexes dissolved in liquids (homogeneous) or anchored to solid supports (heterogeneous). Among them, catalysts with chiral ligands for stereocontrolled organic synthesis are particularly noteworthy. The most renowned is the Monsanto rhodium-based catalyst for synthesis of L-dopa, a drug for treating Parkinson's disease (see ref. [4] for further details). Numerous other examples of rationally designed metal complex catalysts are known.[3,4] The active site of one, a bimetallic $(Pd + Co)/SiO_2$ catalyst for hydroformylation of olefins, has been designed by Likholobov and co-workers.[3]

The third category of catalysts includes proven examples in which molecular systems and extended solids have been tailored for a specific catalytic purpose. We cite several noteworthy examples, the first of which relates to the rational development of a system for the photocleavage of water.[23] Here vesicles, microspheres several hundred Å in diameter with walls composed of a bi- or monolayer membrane of amphiphilic molecules, are employed. Aqueous solutions of the appropriate composition are found on either side of this membrane, and the photocatalyst may be "placed" inside the vesicle. The membrane serves to prevent recombination of the photogenerated, energy-rich electron–hole pair. In this way, with the agency of the encapsulated inorganic catalyst—which could be CdS particles of nanoscopic dimension that could serve as a quantum solid with energy levels different from those in the continuous solid—oxidation of water to oxygen and reduction to hydrogen may be smoothly effected.

But inorganic membrane catalysts are already occupying a central role in the development of new catalysts. Palladium-based membranes have been designed by Gryanznov and co-workers[24] at Moscow for numerous selective hydrogenations. In the current industrial production of vitamin K_4[24] a membrane made of a palladium alloy is used that permits facile passage of hydrogen from one compartment to other reactants at the membrane interface. The fundamental principle that governs the mode of operation of a membrane catalyst, be it metal alloy or inorganic (such as a zeolite[25] or a mixed-oxide electrolyte), is that it enables one (or more) crucial reactant(s) to be delivered to an interface in such a manner as to circumvent thermodynamic or other restrictions. Many potentially viable commercial applications, including fuel cells for the direct conversion of chemical into electrical energy in the presence of the appropriate electrocatalyst, are currently being tested.

With the goal of combating the greenhouse effect stemming from the buildup of carbon dioxide in the atmosphere and also exploring new ways of producing alternative feedstocks for C_2-C_3 production, Russian scientists[26] have developed catalytic membranes not based on precious metals for the conversion $CH_4 + CO_2 \longrightarrow 2CO + H_2$; here syn gas is produced with an advantageous $CO:H_2$ ratio.

The fourth category of catalyst research encompasses advances in the application of rationalized new ideas relating to the design and mode of operation of catalytic reactors. The most environmentally useful example to cite here emerged from a recent analysis conducted by Boreskov and Matros of the optimal conditions for the catalytic oxidation of SO_2 to SO_3,[27,28] the basis of sulfuric acid production. Instead of pursuing the traditional practice of operating the catalytic reactor under steady-state conditions, Matros[28] explored the merits of run-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0303-0310 $ 10.00+.25/0

ning a so-called unsteady-state operation. This entails oxidation of the SO_2 under "forced" conditions for the passage of the reaction mixture through the catalyst bed. The principal advantage of this approach is that, compared with the conventional methods for the production of sulfuric acid, more dilute feedstocks (of SO_2) may be handled, and the size of the plant itself is significantly reduced, thereby limiting the required capital expenditure. Thanks to this work, copper and nickel refining in Russia, which hitherto released its sulfur by-products into the atmosphere as SO_2 leading to acid rain, now produces some 600000 tons of sulfuric acid and processes over 3 billion cubic meters of waste gases per annum.

Numerous other reactor design features have already been implemented commercially. One important example, reactive distillation (otherwise known as catalytic distillation), is the basis of a viable method of etherifying alkenes to produce gasoline additives such as methyl *tert*-butyl ether[29] by the addition of methanol to 2-methylpropene (now readily produced by the isomerization 1-butene[7, 30]).

It is also relevant to note that the pore structure in multiphasic catalysts can be rationally designed to optimize their performance. For example, the new high-strength (ca. 400 $kg\,cm^{-2}$) carbon support, containing predominantly mesopores and almost no micropores and macropores, was especially designed for the Pd catalysts described in Figure 2. Likewise the honeycomb-shaped monolithic catalyst supports for pollution control in power plants and vehicles are the product of rational design.

It is simply not true that the quest for new catalysts is tantamount to black magic. Still less valid is the assertion that all the catalytic processes vital to industry were developed by empirical methods. We concede, however, that although it is already possible, de novo, to compute the rates of diffusion[19] of reactants and products into and out of the pores of shape-selective catalysts, a great deal more must be done before the prospect of computing and accurately predicting catalytic rate coefficients for bond rupture and formation is realized.

Reply

Robert Schlögl*

In our original highlight article[1] we described the possibilities and limitations of in situ experiments as a modern tool for unraveling the relationships between the structure of a working catalyst and its reactivity. Our conclusion was that although tremendous insight into the complexities of this problem has been gained, our knowledge about the crucial structure–reactivity relationship is, in general, still inadequate for the rational design of a catalyst for a given reaction.

In the immediately preceding correspondence[2] our conclusions are criticized as being only applicable to simple reactions such as the ammonia synthesis (which was not the main subject of the highlight article). Thomas and Zawaraev give an expert description of recent ingenious developments in heterogeneous catalysis; however, proof that these developments are based upon an understanding of the structure–reactivity relationship is lacking.

[*] Prof. Dr. R. Schlögl
Institut für Anorganische Chemie der Universität
Marie-Curie-Strasse 11, D-60439 Frankfurt am Main (FRG)

Their main example of shape-selective, monophasic, zeolite-based catalysts is admittedly a development in which rational ideas about the spatial requirements for diffusion of reactants or transition states in reactions allow the control of reactivity in favorable cases in which the reactant molecules have large structural differences. For any given general case with more subtle structural differences in the desired reactants, the concept of shape selectivity finds its current limits in details such as undisputed "kinetic openings", the influence of the crystallite size on mass transport, and the zeolite lattice dynamics under reaction conditions. A number of empirically derived chemical modifications such as that of the external surface and pore openings were applied, which indicates how chemical intuition can be used to solve problems without a rigorous analysis of the physical background of the application problem.

The second example of "designed multiphasic catalysts" is a further illustration for the general problem. It is simply not feasible to inductively design a catalyst for a reaction, the mechanism of which is not known in detail, and use components with unknown synergetic functions for the catalyst. The important field of selective oxidation catalysis is characterized by the existence of qualitative concepts[3] such as "remote control" which summarize the practical experience of researchers over about 25 years. These concepts are, however, not based on fundamental chemical principles nor can they be used in a quantitative way like a theory.

In view of the formidable complexity of mechanisms for any selective oxidation reactions, such working concepts are of great practical value in guiding the chemical intuition required in developing catalytic processes such as those mentioned by Thomas and Zamaraev. The successful search for such qualitative guiding rules which are commonly used also in other fields of chemistry was inspired by the rational approach of surface physics to the problem of interface reactivity. It is the invaluable contribution of surface science[4] to catalysis that provides guiding ideas and concepts such as that of the active site, geometric reaction control, surface thermodynamics, surface restructuring, and the dynamic nature of reactive systems. The large pool of detailed knowledge about surface reactions under surface-science conditions serves as a source of background information for the development of practical catalyst systems. In this way catalysis has gained a scientific basis in the form of a set of intuitively founded, qualitative working rules. This is, however, not to be mistaken as a quantitative, physically exact, and scientifically proven theory with the predictive power required for the "design approach" in catalysis. The efforts in conducting increasingly complex in situ experiments on existing catalyst systems may find one justification in providing arguments to rationalize the working rules with practical, operating examples.

The "possibilities and limitations of a deductive approach to the development of industrial catalysts" was also analyzed from the viewpoint of a technical chemist.[5] Riekert concludes that it should be in principle impossible to design a catalyst owing to the inherently metastable and kinetically heterogeneous nature of an active catalyst material. This statement may be too restrictive, as we may not require starting catalyst design from first principles and we are also allowed to use some empirical testing in a rational design approach. In his analysis Riekert advocates an evolutionary approach mimicking the controlled "trial-and-error" strategy of nature.

In a recent analysis of the impact of surface science on catalysis[6] it was stated that the direct (rational) impact of surface science in the timeframe of a decade is limited. The indirect impact along the lines of providing working rules and modifying the thinking in catalyst development was, however, estimated as highly important. Catalysis is defined in this analysis as an "interesting mixture of science, engineering, and art". This conclusion is rather similar to that as reached in the initial highlight article.

It is obvious, and I fully agree with Thomas and Zamaraev, that significant progress has been made in selected cases in elucidating a number of aspects of the structure–reactivity relation. We do need, however, a great deal more hard facts about this relation to supplement our set of qualitative rules. There is no need to be pessimistic about an ever-increasing efficiency of catalyst development by the influx of scientific elements, and the semantic polarization of catalyst development strategies into either "scientific" or "intuitive" should also be avoided. Creating unjustified expectations about the potential of rational catalyst design by overestimating the state of our undisputed knowledge about operation principles in catalysis is unproductive and potentially detrimental to the field of catalysis science. Closing the experimental gaps between surface science and catalysis as described in the highlight article is one way to efficiently contribute towards the ideal of a rational approach in catalysis.

The Effect of Fusion of Angular Strained Rings on Benzene: Crystal Structures of 1,2-Dihydrocyclobuta[*a*]cyclopropa[*c*]-, 1,2,3,4-Tetrahydrodicyclobuta[*a*,*c*]-, 1,2,3,4-Tetrahydrodicyclobuta[*a*,*c*]cyclopropa[*e*]-, and 1,2,3,4,5,6-Hexahydrotricyclobuta[*a*,*c*,*e*]benzene**

Roland Boese*, Dieter Bläser, W. Edward Billups*, Michael M. Haley, Andreas H. Maulitz, Debra L. Mohler, and K. Peter C. Vollhardt*

Recent crystallographic studies of arenes that contain fused strained rings have found a marked difference in the structures of cyclopropabenzene ("benzocyclopropene", **1**)[1] and 1,2-dihydrocyclobutabenzene ("benzocyclobutene", **2**)[2]. Although the bond of annelation as well as the bonds adjacent to it are influenced by the effects of strain, the aromatic framework of **2** has undergone a fundamental change from that of **1**. In benzocyclopropenes the annelated bond is always the shortest; in benzocyclobutenes the adjacent bond is the shortest.[3] Incorporating two strained-ring features into a single system, such as **3** and **4**, resulted in structures which reflect a summation of the distortions found in each of the parent systems.[2, 4] The linear [*a*,*d*] annelation did not allow the two effects to influence one another significantly; only the bond angle at C2 was altered noticeably. Combining strained-ring features in a nonlinear [*a*,*c*] fashion (as in **5** and **6**) or [*a*,*c*,*e*] fashion (as in **7** and **8**), however, should result in an overlap of the effects of strain, and thus the structures are expected to be more distorted. In order to determine the extent of structural deformation in **5**–**8**, X-ray analyses were carried out.

While calculations on **5**[5] and **6**[6] are limited and have never been performed on **7**, **8** has been the subject of a burgeoning number of theoretical studies in recent years.[6, 7] This molecule has become the quintessential test case for theoreticians in the long-standing debate over strain-induced bond alternation in benzenoid molecules, now commonly known as the Mills–Nixon effect.[8] Fueled by conflicting theoretical papers, this argument now focuses on two specific approaches: the first postulates control of bond alteration by the σ electron system, the second by the π electron system.[6c, 7c–d] The difference between the alternating interatomic distances in the benzene ring of **8** calculated by different methods varies widely: it is as large as 0.132 Å for the semiempirical AM1 calculations but as little as 0.013 Å at the ab initio 6–31 G* level.[7e] Although syntheses of **8** have been known for some time,[9] the only crystal structure determination was performed on the perfluoro derivative **8**-F_{12}.[10] Fluorine substituents on small rings are known to alter their structures.[11] Therefore, the extrapolation of the data of **8**-F_{12} to **8** is tenuous.[6a] At the end of this paper we will show that only at the highest level of theory can calculations accurately reproduce experimental results.

The arenes were synthesized by published procedures.[9, 12–14] Single crystals of **5** (m.p. −12 °C) and **6** (m.p. 35 °C), prepared by previously described methods,[15] were used for analysis. Suitable crystals of **7** were grown by sublimation directly from the reaction vessel. The structure determinations were performed at 255, 120, and 105 K, respectively, and the molecular structures are presented in Figure 1.[16–18] The structure determination for **8** proved to be suprisingly complex. Crystals were grown from pentane in a computer-controlled device which adjusts the temperature of the solution to optimal crystallization conditions. Most of the crystals were destroyed upon cooling on the diffractometer for low-temperature data collection, which indicated a solid-state phase transition at 205 K.[20] Therefore, the structure of **8** was determined at room temperature, and in the following this "high-temperature" phase is termed **8**-HT.[21] The crystal was then cooled very slowly (1 °C h^{-1} cooling rate) through the transition temperature to 125 K, and a second determination was made (termed the low-temperature phase **8**-LT).[22] As one independent molecule is present in the HT cell and two independent molecules in the LT cell, Figure 2a shows a pair of molecules of **8**-HT, coupled by the inversion centers, and Figure 2b the two independent molecules of **8**-LT.

Common with all benzocyclopropenes,[1, 3] the bond of cyclopropene fusion is found to be the shortest bond in **5** (1.351 Å, see Fig. 1, left)[23] and is in good agreement with that found in **3** (1.349 Å). The bond in **5** between the cyclopropene and cyclobutene rings (C1–C2), however, is significantly shortened because of the added strain of nonlinear fusion (1.363 Å). This additional strain is demonstrated at the bridgehead atom C1; to our knowledge the angle at C1 is the largest yet found at an

Welch Foundation, and the Fonds der Chemischen Industrie. M.M.H. is the recipient of an NSF Postdoctoral Fellowship (1991–93).

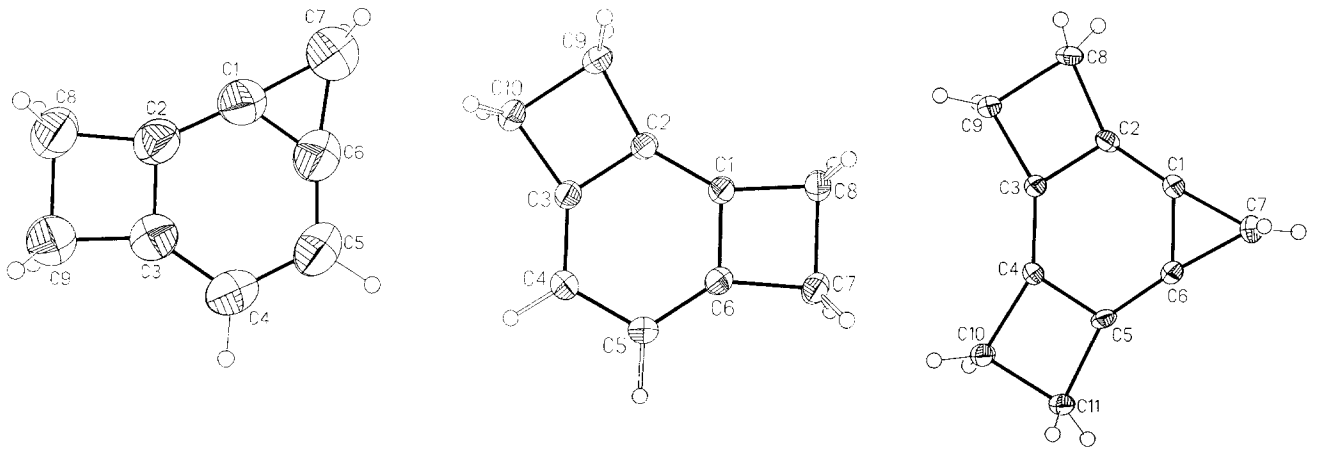

Fig. 1. Molecular structures of **5**–**7** with thermal probability plots of 50%. Distances [Å] and angles [ ] (standard deviations), values after a libration correction [19] in parentheses (mean values for the molecules): Left: **5**: C1-C2 1.363(2) (1.368), C2-C3 1.393(1) (1.401), C3-C4 1.384(2) (1.390), C4-C5 1.401(4) (1.405), C5-C6 1.368(2) (1.376), C1-C6 1.351(3) (1.357), C1-C7 1.507(2) (1.512), C6-C7 1.499(2) (1.508), C2-C8 1.510(3) (1.516), C3-C9 1.516(2) (1.521), C8-C9 1.565(2) (1.574); C1-C2-C3 116.3(2), C1-C2-C8 150.1(1), C1-C6-C5 125.7(2), C1-C7-C6 53.4(1), C2-C1-C6 120.0(1), C2-C1-C7 176.9(1), C2-C3-C4 123.7(2), C2-C8-C9 86.7(1), C3-C4-C5 118.8(1), C3-C9-C8 86.9(1), C4-C3-C9 143.5(2), C4-C5-C6 115.6(2), C5-C6-C7 170.7(2); center: **6**: C1-C2 1.385(1) (1.387), C2-C3 1.402(1) (1.405), C3-C4 1.392(1) (1.395), C4-C5 1.413(1) (1.414), C6-C7 1.522(1) (1.524), C7-C8 1.582(1) (1.585), C1-C8 1.518(1) (1.520); C1-C2-C3 118.1(1), C1-C2-C9 148.4(1), C2-C3-C4 124.3(1), C2-C3-C10 93.2(1), C2-C9-C10 86.5(1), C3-C2-C9 93.8(1), C3-C10-C9 86.8(1), C3-C4-C5 117.7(1), C4-C3-C10 142.5(1); right: **7**: C1-C2 1.372(4) (1.373), C2-C3 1.411(3) (1.412), C3-C4 1.385(4) (1.386), C1-C6 1.363(4) (1.364), C1-C7 1.506(4) (1.507), C2-C8 1.517(3) (1.518), C3-C9 1.521(4) (1.522), C8-C9 1.580(3) (1.581); C1-C2-C3 117.7(2), C1-C2-C8 149.0(3), C1-C6-C5 121.9(3), C1-C7-C6 53.8(2), C2-C1-C7 174.9(3), C2-C3-C4 120.4(2), C2-C8-C9 86.8(2), C3-C9-C8 86.9(2), C4-C3-C9 146.6(3).

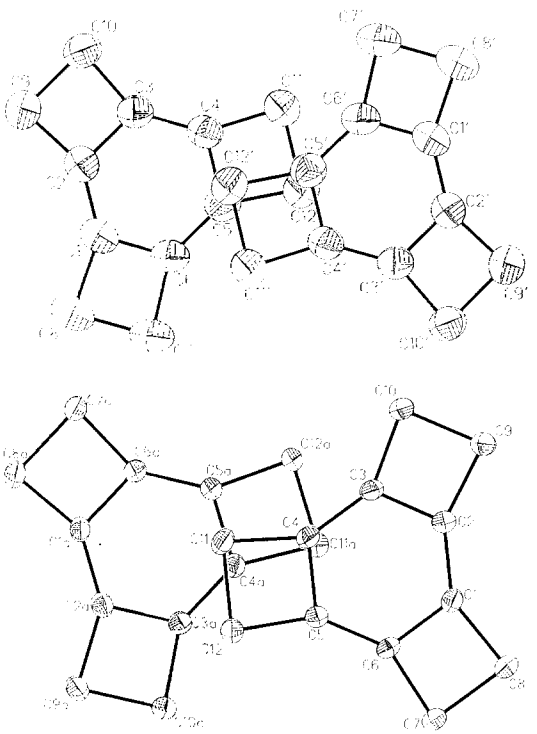
sp^2-carbon center—176.9 °C. The remaining bond lengths and angles in **5** are consistent with previously determined structures.



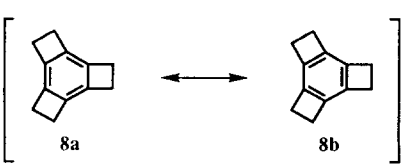


Fig. 2. Molecular structure of a pair of molecules of **8**-HT (top) and of the two independent molecules of **8**-LT (bottom) with thermal probability plots of 50%. Distances [Å] and angles [ ] (maximum standard deviations 0.002 Å and 0.2 , respectively, for **8**-HT: 0.001 Å and 0.1 , respectively, for **8**-LT), values after a libration correction [19] in parentheses (mean values): Top: **8**-HT: C1-C2 1.383 (1.387), C2-C3 1.401 (1.405), C6-C7 1.519 (1.523), C7-C8 1.566 (1.570); C1-C2-C3 120.0, C1-C2-C9 147.0, C2-C9-C10 87.0, C3-C2-C9 93.0; bottom: **8**-LT: C1-C2 1.390 (1.391), C2-C3 1.413 (1.414), C6-C7 1.527 (1.528), C7-C8 1.579 (1.580); C1-C2-C3 120.0, C1-C2-C9 147.0, C2-C9-C10 87.0, C3-C2-C9 93.0.

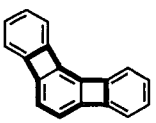
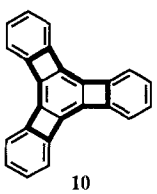
As in other benzocyclobutenes,[2, 3] the annelated bonds (C1–C6, C2–C3) in **6** (Fig. 1, center) have lengths usual for arenes (1.402 Å and 1.402 Å). The bonds in the benzene ring adjacent to the annelated bonds (C1–C2, C3–C4, C5–C6) are shortened (1.385 Å, 1.392 Å), and the C4–C5 bond is significantly lengthened (1.413 Å). This elongation can be attributed to the strain of nonlinear [*a*,*c*]-fusion of two ring systems. As the sole aromatic bond not connected to a cyclobutene moiety, the strain in the other bonds is imparted to C4–C5, which results in a lengthening of 0.010–0.015 Å.



At 1.363 Å, the bond of the three-membered ring annelation in **7** (Fig. 1, right) is the longest of all benzocyclopropenes.[3] The addition of a third strained ring to the system forces a significant lengthening (0.010–0.020 Å) in the otherwise short bond. Similarly, the bonds of four-membered ring annelation are lengthened by 0.010–0.022 Å with respect to benzocyclobutenes.[3] The bridgehead atoms C1 and C6 in **7** also possess unusually large angles (174.9 °) at the sp^2-carbons.

As with **7**, the benzenoid nucleus of **8** (Fig. 2) tries to "breathe" under the "weight" of triangular ring fusion, that is, the ring expands since no bonds can be shortened. The aromatic bond between the cyclobutene rings (e.g., C1–C2) varies between 1.383 (HT) and 1.390 Å (LT), the bond of fusion (e.g., C2–C3) between 1.401 (HT) and 1.413 Å (LT). The resulting differences in bond lengths (0.018 and 0.023 Å, respectively) suggest an approximate difference of 0.026 Å when the data are extrapolated to 0 K. Thus, from the experimentally determined distances, the Kekulé structure **8a** appears to contribute slightly more to the molecule than **8b**.



The fusion of equivalent cyclobutene rings induces the minor bond alternation observed in **6** and **8**. [*N*]Phenylenes **9** and **10**,

structural analogues containing the structural units **6** and **8**, have been shown by X-ray crystallography to exhibit pronounced bond alternation in the central six-membered ring.[24] The 0.098–0.159 Å difference in bond lengths within **9** and **10** results in an increased olefinic reactivity of the central ring, as demonstrated by the ease with which **10** can be hydrogenated, epoxidized, and cyclopropanated.[25] The 0.010–0.023 Å difference observed in **6** and **8** (that is, the small preference of **8a** over **8b**) is, however, chemically insignificant, because the central ring in **8** appears to be much less reactive than that of **10**. Hydrogenation required more severe conditions than those employed for **10** and gave a complex mixture of products; attempts at cyclopropanation have failed so far. Although annelation of one additional benzene ring to each cyclobutene moiety alters the structure of the four-membered ring and produces more strain in the molecule, it appears that avoidance of anti-aromatic cyclobutadienoid circuits (π effect) contributes to a much greater degree, thus inducing the larger bond alternation observed in **9** and **10**.

9

10

The ring strain of the cyclobutene moieties of **6** and **8**-LT is clearly evident in Figure 3: the electron-density maxima in the molecular plane (that is, the σ frame) are shifted outside the four-membered ring, and as a consequence the annelated bonds are shifted toward the center of the benzene ring. This results in an outward shift of the electron densities of the neighboring bonds. The outward shift is especially prominent in C1–C2, since this bond is connected to both cyclobutene rings; it results in a shortening of the interatomic distance. The accuracy of the data do not enable the determination of exact amounts of shifts, but they are as depicted qualitatively in Figure 4. These findings are wholly consistent with the concept of bent bonds ("banana" bonds), in which the σ frame dominates the structures of small-ring annelated benzenes, as pointed out by Stanger on the basis of theoretical work.[7c] Structures for **5**–**8** calculated with a variety of methods at different levels are summarized in Tables 1–4, respectively. Although the data also do not allow for estimation of the π contribution to the molecular structure, the detailed study of Baldridge and Siegel[7d] does a splendid job of addressing the issue of σ vs. π control of bond alternation[6, 7] (Mills–Nixon effect). Their work seems at last to bring into line experiment and theory, as illustrated by their calculations for **8**

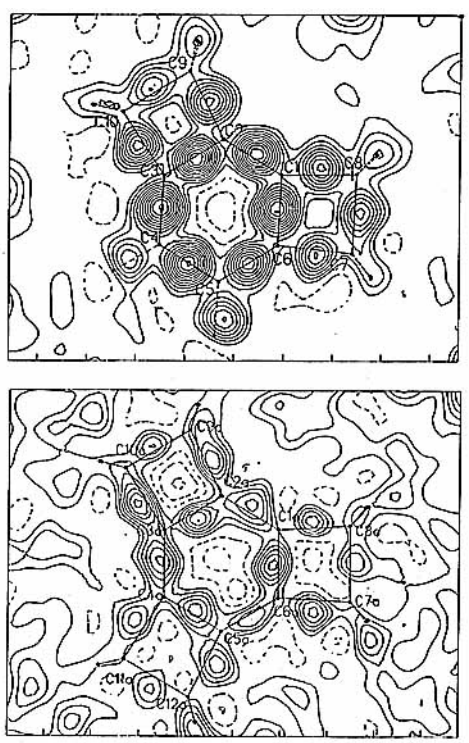


Fig. 3. X–X difference electron densities of **6** (top) and **8**-LT (bottom) in the plane of the molecular framework; distances of 0.05 e Å^{-3} (positive and zero, solid lines) and 0.1 e Å^{-3} (negative, dotted lines).

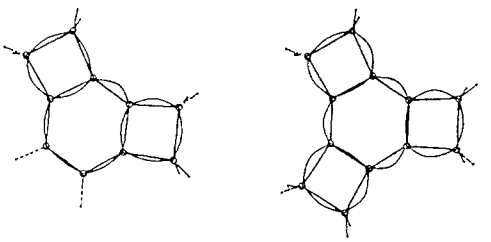

Fig. 4. Shifts of electron-density maxima for **6** (top) and **8**-LT (bottom); the arcs join nucleus to nucleus through the electron density maximum.

(Table 4, entries 6 and 9). From the tables, it appears that only the ab initio 6–31G or higher levels accurately reproduce the experimental values. Interestingly, the highest level of theory (MP2/6-31G*) almost duplicates the experimental structures of **6**–**8**, yet it overestimates bond lengths in **5**. Since the structure determination of **5** was conducted at 255 K, the better comparison is with librationally corrected values (Fig. 1, left); with these data the MP2 (full) 6–31G* level gives excellent agreement.

The results for the crystal structures of **5**–**8** complete the series of structure determinations for known strained-ring annelated benzenes. From our findings three conclusions can be readily drawn: 1) strained-ring fusion to the benzenoid nucleus leads to the formation of "banana" bonds in the molecule, and thus interatomic distances seem to be somewhat misleading; 2) bond alternation, if present, is very minor (< 0.025 Å) and appears to be chemically insignificant; thus it should not be taken as support for Mills–Nixon arguments; and 3) only the highest level ab initio calculations are able to replicate experimental structures, and of these, the best agreement is found with MP2/6-31G*, therefore, studies at lower levels of theory possibly lead to misleading or erroneous conclusions. Finally, we conclude that benzene, even if distorted in the σ-frame, simply wants to remain "aromatic".

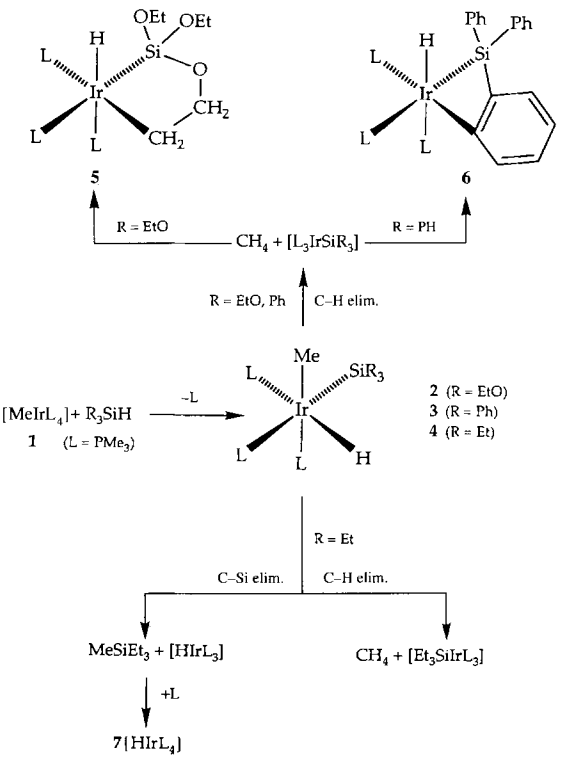
Competitive Generation of C–H and C–Si Bonds by Reductive Elimination: Formation of Silametallacycles by Metalation of Silyl Ligands**

Michael Aizenberg and David Milstein*



Transition metal catalyzed transformations of organosilicon compounds[1] may sometimes involve either C–Si or C–H bond formation in the product-forming step. For example, the Chalk–Harrod mechanism[2] for the synthetically important hydrosilation of alkenes, in which product formation by C–Si reductive elimination is postulated, has been discussed in many papers.[1, 3] In an alternative mechanism proposed by Wrighton,[4] silyl migration to the coordinated alkene takes place, and the product is released by C–H reductive elimination. A two-silicon cycle for Rh-catalyzed olefin hydrosilation, recently proposed by Perutz,[5] also involves C–H reductive elimination in preference to C–Si elimination. Whereas formation of C–H bonds by reductive elimination is well documented,[6] examples for generation of C–Si bonds that may proceed by this process are very rare.[7–11] Of particular interest is the question of competitive C–H vs. C–Si reductive elimination. Relevant to this is the generation of methane upon reaction of $[MeCo(CO)_4]$ with Me_3SiH[4] and of $[MeRh(PMe)_{3,4}]$ with $HSiPh_3$,[8] although the presumed oxidative addition intermediates have not been observed and the relative disposition of the hydrido, silyl, and methyl ligands in these complexes is not certain. Reactions of $[MPhCl(CO)(PPh_3)_2]$ (M = Ru, Os) with silanes yield benzene,[12] again no intermediates are observed.

We report here for the first time on elimination reactivity of fully characterized complexes which possess the necessary all *cis* arrangement of the hydrido, silyl, and methyl ligands. We find that, depending on the electronic properties of the silyl ligand, C–Si and C–H reductive elimination can be competitive. This study has led to rare examples of metalations of silyl ligands, including the metalation of sp^3-C–H bonds.

The facial hydrido-silyl-methyl iridium complexes **2**–**4**[13] are readily formed (in >90% yield) upon addition of one equivalent of the corresponding silane to a solution of $[MeIr(PMe_3)_4]$ (**1**)[14] in benzene at 25 °C (Scheme 1). Although these complexes are stable at 25 °C, quantitative elimination takes place when they are heated for one day at 100 °C in C_6D_6 in a closed vessel; complexes **2** and **3** undergo exclusive quantitative C–H elimination of methane, as detected by ^1H NMR spectroscopy and by gas chromatography (GC). The resulting iridium(I) complexes, which were not observed, undergo unusual intramolecular C–H activation of the silyl ligands, yielding the novel complexes **5** (in >98% yield) and **6** (in >90% yield). Complex **5** is unambiguously characterized by ^1H, ^{31}P, ^{13}C, and ^{13}C DEPT135 NMR spectroscopy. The iridium-bound methylene group appears in the $^{13}C\{^1H\}$ NMR spectrum as a doublet of triplets at $\delta = 3.0$ (^2J(C, P, *trans*) = 59.3 Hz, ^2J(C, P, *cis*) = 5.7 Hz); this signal is negative in the DEPT spectrum, indicating an even number of hydrogen atoms. The second methylene in the iridacycle gives rise to a doublet of triplets at $\delta = 68.7$ (^3J(C, P, *trans*) = 10 Hz, ^3J(C, P, *cis*) = 2.6 Hz), which also appears as a negative signal in the DEPT spectrum. This excludes the possibility of a four-membered iridacycle in which the metal is bound to the carbon atom of the CH_2O group. To our knowledge **5** is the first isolated complex formed by metalation of a silyl ligand not involving an aryl group.[15] This can be contrasted with the several examples known for remote intramolecular metalation by iridium.[16] Interestingly, specific metalation at the δ position takes place, probably as a result of the more stable five-membered ring.

Scheme 1.

Complex **6** was identified spectroscopically and by single-crystal X-ray diffraction[17] (Fig. 1); **6** crystalizes in $P2_1/n$ space group. The iridium atom is surrounded by a distorted octahedron; the silairidacycle is clearly visible. The Ir–Si bond length of 2.404(3) Å lies in the normal range.[18] The bonds Ir–P1 and

Ir–P3 are the same length and both longer (by 0.03 Å) than the bond Ir–P2 (P *trans* to C). The strong *trans* influence of silyl ligands has been previously noted;[19] it is expected to be higher than that of hydrido ligands. Apparently, the effect is not fully manifested here because of the large deviation of the Si-Ir-P_3 angle from linearity (157.3°), perhaps as a result of ring constraints.

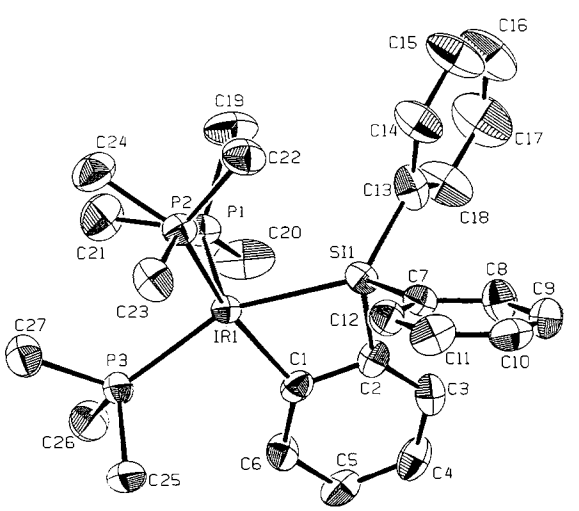

Fig. 1. Crystal structure of **6** (ORTEP: hydrogen atoms are omitted for clarity, thermal ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: Ir1-P1 2.342(3), Ir1-P2 2.314(3), Ir1-P3 2.343(3), Ir1-Si1 2.404(3), Ir1-C1 2.16(1), C1-C2 1.41(1); Si1-C2 1.87(1), P2-Ir1-C1 164.2(3), P3-Ir1-Si1 157.3(1).

To our knowledge, this is the first structural characterization of a complex resulting from metalation of a silyl ligand. Although orthometalation involving arylphosphanes is well documented,[20] we are aware of only one other example of an isolated adduct resulting from the orthometalation of an arylsilyl ligand, namely $[(dcpe)Pt(C_6H_4)Si(SiMe_3)_2]$ (dcpe = 1,2-bis(dicyclohexylphosphano)ethane).[21] As noted in that work, orthometalation may be sterically promoted due to the large substituents on Pt and Si. However steric effects are very unlikely to play a significant role in the formation of the PMe_3 complexes **5** and **6**. It is not clear why metalation of silyl ligands is so rare in comparison with that of phosphane ligands, especially since Si and P have similar covalent radii. Nevertheless, we show here that metalation to form stable silametallacycles can occur readily, not only with aryl groups but even with nonactivated sp^3-C–H bonds in remote positions.

Interestingly, heating a solution of the Et_3Si complex **4** in C_6D_6 at 100 °C for one day in a closed vessel results in both C–H and C–Si reductive elimination. Complex **4** completely disappears, yielding CH_4 (ca. 80% yield, by GC) and $MeSiEt_3$ (ca. 20% yield). Although $[Et_3SiIr(PMe_3)_3]$ and $[HIr(PMe_3)_3]$ could not be detected because of subsequent reactions of these reactive intermediates with the solvent,[22] $[HIr(PMe_3)_4]$[23] was observed when **4** was heated in the presence of PMe_3.[24] Since reductive elimination of CH_4 and $MeSiEt_3$ is very likely irreversible, these processes are probably under kinctic control and a rough estimate of their relative rates is $k_{C-H}/k_{C-Si} \approx 4$.

C–H reductive elimination is generally much more facile than C–C reductive elimination. This has been attributed to kinetic factors, resulting from the need to reorient the direction of p orbitals in the case of C–C elimination, whereas the symmetrical s orbital involved in C–H elimination results in a lower barrier for this process.[25] Our observation that Si–C elimination can be competitive with C–H elimination may be attributed to the notion that the electropositive metal directs a high degree of s character in the silicon contribution to the M–Si bond,[26] as has been discussed also for stannyl derivatives.[27]

The difference in elimination reactivity between complexes **2** and **3**, which undergo only C–H reductive elimination, and **4** may be influenced by the effect of the substituents attached to silicon on the degree of M–Si s character, but the main factor seems to be due to the M–SiR_3 bond strength which increases with the electronegativily of R and follows the order M–$Si(OEt)_3$ > M–$SiPh_3$ > M–$SiEt_3$.[28] This may result not only in a higher kinetic barrier but also in a thermodynamically less favorable C–Si reductive elimination process when groups of higher electronegativity are attached to silicon. Steric factors are probably not important here since $SiEt_3$ is intermediate in size between $Si(OEt)_3$ and $SiPh_3$.

In conclusion, we have unambigously shown that C–H reductive elimination is the most favorable process, especially with electron-withdrawing substituents on Si, whereas C–Si elimination can become competitive when the silyl ligands carry alkyl substituents. The implication of this for the product-forming step in the hydrosilation reaction should be borne in mind. With such a fine balance between C–H and C–Si elimination, generalization of the hydrosilation mechanism is difficult and should take into consideration, among other factors, the particular silane reactant.

Another important aspect of this study is the observation that, although very rare, metalation of silyl ligands, including

sp^3-C–H bonds is possible. This C–H activation process can be regioselective, leading to the specific δ metalations. The synthetic implications of this approach for the generation of novel silametallacycles, like those reported here, are being explored.

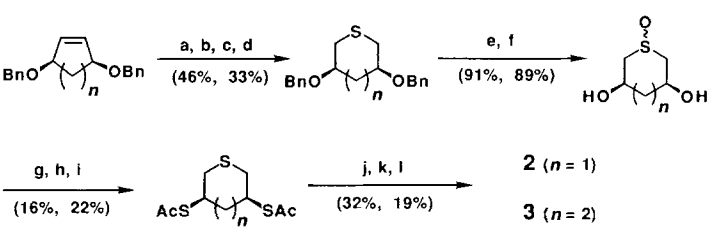
Strategies for Nonmacrocyclic Polythioether Ligands: New Pentacoordinating Architectures**



John M. Desper and Samuel H. Gellman*

Polythioethers are of interest as complexing agents for late transition metal ions.[1] Most prior efforts to enhance the chelating efficacy of polythioether arrays have involved construction of a macrocyclic ligand skeleton.[2–5] We have recently demonstrated that peripheral substituents on macrocyclic tetrathioethers can improve metal ion binding.[6] Here we report an approach for preorganization of a nonmacrocyclic pentathioether framework.

Ethylene sulfide oligomers such as, **1** are not well suited for multidentate coordination, because of the strong *anti* conformational preference of SC–CS bonds, the weak preference of the *gauche* conformation about the CS–CC bonds, and the intrinsic flexibility of the acyclic backbone.[7] We reasoned that the latter two problems might be alleviated by incorporation of thiane or thiepane rings into the backbone to generate **2** or **3**. These target

structures require control of configuration at the exocyclic C–S bonds, because the *cis*-disubstituted ring systems are required for pentacoordination. The stereospecific preparations of **2** and **3** from known benzyl-protected *cis*-dihydroxycycloalkenes[8, 9] are outlined in Scheme 1. Construction of the *cis*-dihydroxythiane and -thiepane rings involved ozonolysis of the double bond, activation of the resulting primary hydroxyl groups, and cyclization with Na_2S. Activation of the secondary hydroxyl groups for nucleophilic displacement was not practical with the ring sulfur atom in its reduced form, because of rearrangements

[**] This research was supported by the U.S. National Science Foundation (Presidential Young Investigator Award to S. H. G), Eastman-Kodak, Procter & Gamble, and Rohm and Haas. J. M. D. was the recipient of a fellowship from the U.S. Department of Education's Graduate Assistance in Areas of National Need Program.

that are known to occur in such systems.[10] "Temporary" oxidation to the sulfoxide decreased intramolecular nucleophilicity sufficiently to allow generation of the required *cis*-ditosylates (as mixtures of compounds epimeric at the sulfur center).[11] Double displacement with thioacetate provided the core with three sulfur atoms and the required configuration. After reduction of the sulfoxide,[12] completion of the syntheses was straightforward.[13]

The structures of **2** and **3**, and their ability to serve as pentadentate ligands, were verified by crystallographic analyses of Ni^{II} and Cu^{II} complexes of each new ligand. Both complexes of **2** and the Ni^{II} complex of **3** were crystallized with perchlorate counterions; the Cu^{II} complex of **3** was crystallized with tetrafluoroborate counterions. The complex $[\mathbf{2}\text{-}Ni^{II}]^{2+}$ (Fig. 1) has five Ni–S bonds of similar length (2.36–2.42 Å); one perchlorate ion serves as a sixth ligand (Ni–O = 2.227(5) Å). In the

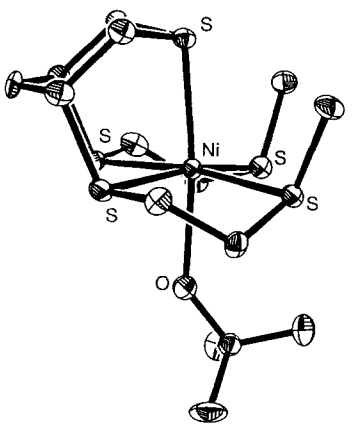

Fig. 1. Crystal structure of $[\mathbf{2}\text{-}Ni^{II}(ClO_4)]^+$; the noncoordinating ClO_4^- counterion is not shown. Hydrogen atoms have been omitted for clarity. Crystals were obtained by vapor diffusion of 1,2-dichloroethane into a solution of the product in nitromethane. Data were collected with $Mo_{K\alpha}$ radiation at 123 K: 1791 unique reflections, 1535 observed reflections. $R = 0.0371$, weighted $R_w = 0.0469$ (observed data); residual electron density minimum = −0.43, maximum = 0.84 e Å^{-3} [16].

analogous Cu^{II} complex (Fig. 2) the thiane sulfur atom forms a distinctly longer bond to the metal ion (2.581(2) Å) than the other four sulfur atoms (Cu–S = 2.32–2.35 Å). The copper ion forms a weak sixth bond to one perchlorate ion (Cu–O = 2.746(6) Å). In both complexes of **2** the thiane ring adopts a chair conformation with the substituents axially disposed, as expected.

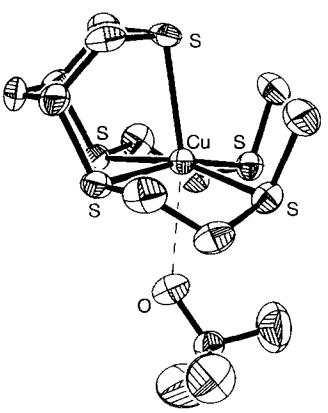

Fig. 2. Crystal structure of $[\mathbf{2}\text{-}Cu^{II}(ClO_4)]^+$; the noncoordinating ClO_4^- counterion is not shown, and the dotted line indicates the long Cu–O bond to the weakly coordinated ClO_4^- anion. Hydrogen atoms have been omitted for clarity. Crystals were obtained by slow evaporation of a solution of the product in methanol–water. Data were collected with $Mo_{K\alpha}$ radiation at 113 K: 3678 unique reflections, 2328 observed reflections, $R = 0.0509$, weighted $R_w = 0.0516$ (observed data); residual electron density minimum = −0.48, maximum = 0.72 e Å^{-3} [16].

The Ni^{II} complex of **3** (Fig. 3) shows octahedral coordination at the metal ion, as observed for $[\mathbf{2}\text{-}Ni^{II}]^{2+}$, but now the sixth ligating atom is an oxygen atom from a water molecule (Ni–O = 2.092(5) Å). The five Ni–S bonds of $[\mathbf{3}\text{-}Ni^{II}]^{2+}$ (2.38–

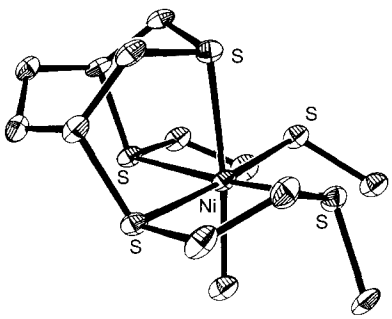

Fig. 3. Crystal structure of $[\mathbf{3}\text{-}Ni^{II}(H_2O)]^{2+}$; the noncoordinating ClO_4^- counterions are not shown. Hydrogen atoms have been omitted for clarity. Crystals were obtained by vapor diffusion of 1,2-dichloroethane into a solution of the product in nitromethane. Data were collected with $Cu_{K\alpha}$ radiation at 113 K: 2895 unique reflections, 2632 observed reflections, $R = 0.0571$, weighted $R_w = 0.0784$ (observed data); residual electron density minimum = −0.85, maximum = 1.09 e Å^{-3} [16].

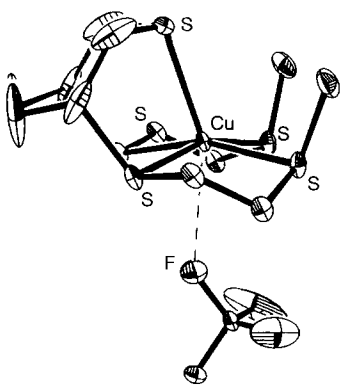
2.43 Å) are of similar length to one another and to the Ni–S bonds of $[\mathbf{2}\text{-}Ni^{II}]^{2+}$. The $[\mathbf{3}\text{-}Cu^{II}]^{2+}$ complex (Fig. 4) is bisected by a crystallographic mirror plane through the copper and thiepane sulfur atoms. As a result of this symmetry, the conformation about the thiepane C–C bond furthest from the sulfur atom is formally eclipsed, but the high thermal parameters observed for the carbon atoms in the thiepane ring suggest disorder in this part of the structure, which presumably reflects the avoidance of torsional strain in individual molecules. As observed for $[\mathbf{2}\text{-}Cu^{II}]^{2+}$, one of the Cu–S bonds in $[\mathbf{3}\text{-}Cu^{II}]^{2+}$ is longer than the other four: the bond involving the thiepane sulfur atom is 2.510(2) Å in length, while the others are all approximately 2.34 Å. The metal ion forms a weak sixth bond to one of the tetrafluoroborate counterions (Cu–F = 2.735(4) Å).



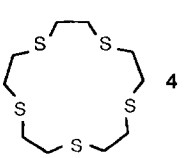


Fig. 4. Crystal structure of $[\mathbf{3}\text{-}Cu^{II}(BF_4)]^+$; the noncoordinating BF_4^- counterion is not shown. Hydrogen atoms have been omitted for clarity. Crystals were obtained by vapor diffusion of 1,2-dichloroethane into a solution of the product in nitromethane. Data were collected with $Cu_{K\alpha}$ radiation at 113 K: 1485 unique reflections, 1368 observed reflections, $R = 0.0456$, weighted $R_w = 0.0646$ (observed data) residual electron density minimum = −0.71, maximum = 0.69 e Å^{-3} [16].

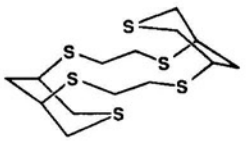
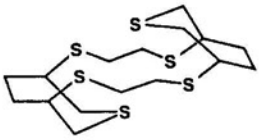
The consistent elongation of one of the Cu–S bonds in the complexes of **2** and **3** is similar to the selective elongation previously observed in the complex between Cu^{II} and pentathia-[15]crown-5 (**4**).[14] In that case, the elongation was less pronounced: four of the Cu–S bonds had lengths in the range 2.29–2.34 Å, and the fifth was 2.40 Å long. Interestingly, the authors of this previous study speculated that the intrinsic preference of Cu^{II} coordinated to five sulfur atoms would be for a greater elongation of the fifth bond than they observed, and that the relatively small elongation with **4** reflected ligand backbone constraints. Our data support this proposition.



4



The methodology developed by Rorabacher et al.,[4] in which UV measurements are used to quantify Cu^{II} complexation, is one of the few reliable methods that have been reported for determining stability constants of polythioether–metal complexes. With $CH_3OH:H_2O$ (4:1) containing 0.1 M $HClO_4$ as a solvent, this method gave a stability constant of 88 M^{-1} for $[\mathbf{2}\text{-}Cu^{II}]^{2+}$, which is an order of magnitude lower than that reported for macrocycle **4** in this solvent.[4] We were unable to evaluate the Cu^{II}-binding properties of **3** in $CH_3OH:H_2O$ (4:1)/0.1 M $HClO_4$ because of the low solubility of this thioether. A stability constant of 93 M^{-1} for $[\mathbf{3}\text{-}Cu^{II}]^{2+}$ could, however, be determined in $CH_3OH:H_2O$ (19:1)/0.025 M $HClO_4$. In this solvent system the stability constant for $[\mathbf{2}\text{-}Cu^{II}]^{2+}$ is 55 M^{-1}. Thus, the thiepane-based ligand seems to have a marginally greater affinity for Cu^{II} than the thiane-based ligand.

Attempts to determine a stability constant for the Cu^{II} complex of acyclic pentathioether **1** with the method of Rorabacher et al.[4] were unsuccessful. The data suggested that **1** and Cu^{II} do not form a 1:1 complex; instead, it appeared that higher order complexes were present. This behavior is consistent with the acyclic ligand's expected resistance to wrapping around a single metal ion, a resistance that stems at least in part from the intrinsic conformational preferences of the SC–CS and CS–CC bonds.[7] Thus, the preorganizational strategy underlying the design of **2** and **3** has been successful: the thiane and thiepane ligands enforce 1:1 complexation in solution.

We have developed a stereospecific route to polythioethers containing *cis*-disubstituted thiane and thiepane rings. Our data show that nonmacrocyclic pentathioethers based on these units are predisposed towards pentacoordination with a single metal ion, which represents an improvement in preorganization relative to acyclic ethylene sulfide oligomers. While the new ligands

5

6

do not chelate Cu^{II} as strongly as thiacrown ether **4** does, the synthetic route we have developed for **2** and **3** should provide access to a new type of thiacryptand architecture,[15] exemplified by **5** and **6**, which may lead to very effective complexing agents for late transition metal ions.

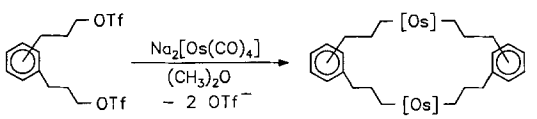
18-, 20-, and 22-Membered Dimetallaortho-, -meta-, and -para[7.7]cyclophanes—The First Typical Metallaphanes**

Ekkehard Lindner,* Walter Wassing, Riad Fawzi, and Manfred Steimann

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday



The rapid development of cyclophane chemistry[1] has produced compounds with special cage or niche structures capable of storing extraneous molecules (host–guest compounds).[2, 3] Cyclophane frameworks containing heteroatoms (e.g. N, O, S) have complexation properties which, in cooperation with specific structural parameters, make possible molecular recognition.[3, 4] In contrast to metallocenophanes[5] such as ferrocenophanes, metallaphanes are still unknown, apart from simple benzometallacycloalkanes.[6] The incorporation of transition metal com-

[**] Preparation and Properties of and Reactions with Metal-Containing Heterocycles. Part 87. This research was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We thank BASF Aktiengesellschaft and Degussa AG for gifts of chemicals. Part 86: E. Lindner, T. Schlenker, C. Haase, *J. Organomet. Chem.*, in press.

plex fragments gives rise to new structural elements and reactive centers which form the basis for the synthesis of further cyclophanes.

With the application of the bistriflate method,[7] we have now achieved the synthesis of the first metallacyclophanes **2**, **4**, and **6**, each with four M–C σ bonds. These are formed in good yields by the cationic alkylation of $Na_2[Os(CO)_4]$ with the bis(trifluoromethanesulfonates) **1**, **3**, and **5**, respectively, in dimethyl ether.[7] The clearly favored formation of the "dinuclear" diosma[7.7]cyclophanes, as opposed to oligo- or polymerization, is supported by entropic effects.[8] The latter are also in competition with steric influences. Thus, as a result of the short distance between the terminal C atoms in **5**, its reaction with $Na_2[Os(CO)_4]$ also leads to the "mononuclear" 4,4,4,4-tetracarbonyl-4-osma-[7]orthocyclophane [MS (FD, 8 kV, 34 °C): *m/z* 462.2 (M^+)].

[Os] = $Os(CO)_4$, OTf = OSO_2CF_3

In crystalline form, the diosma[7.7]paracyclophane **2** has C_2 symmetry (Fig. 1).[9] The two phenylene groups give rise to an interplanar angle of 50.3°, and together with the metal centers these mark out the corners of a distorted tetrahedron [Os1–Os1a distance 10.07(2) Å, C13–C13a distance 5.64(3) Å]. The basic cyclophane framework has a bowl-shaped structure, above which the oxygen atoms O3 and O3a are 4.61(2) Å apart.

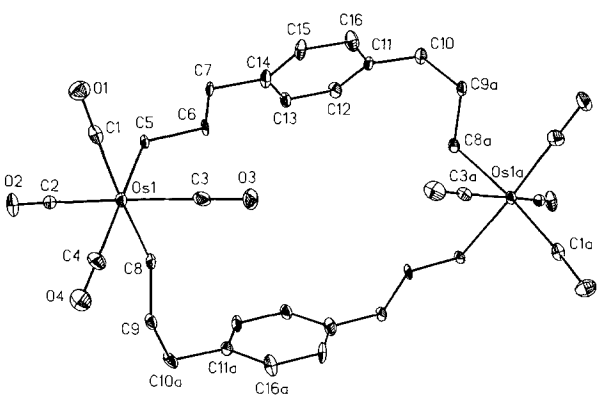

Fig. 1. Crystal structure of **2**. Selected bond lengths [Å] and angles [°]: Os1-C5 2.202(12), Os1-C8 2.182(12), mean Os1-(CO) distance 1.938(14), mean C-O distance 1.152(17); C1-Os1-C2 93.0(4), C1-Os1-C3 96.1(5), C1-Os1-C4 95.9(5), C2-Os1-C3 166.9(5), C5-Os1-C8 84.2(4) (cf. [9]).

Compound **6** is centrosymmetric in the crystal (Fig. 2),[9] and displays two parallel planes (distance 3.2 Å), defined by the phenylene carbon atoms and the chains C10, C9, C8, and Os1 and C10a, C9a, C8a, and Os1a, respectively. The likewise parallel best-fit planes stipulated by the bridging atoms Os1, C5, C6, and C7 and Os1a, C5a, C6a, and C7a (distance 7.3 Å), respectively, are tilted at an angle of 83.6° relative to the arene rings.

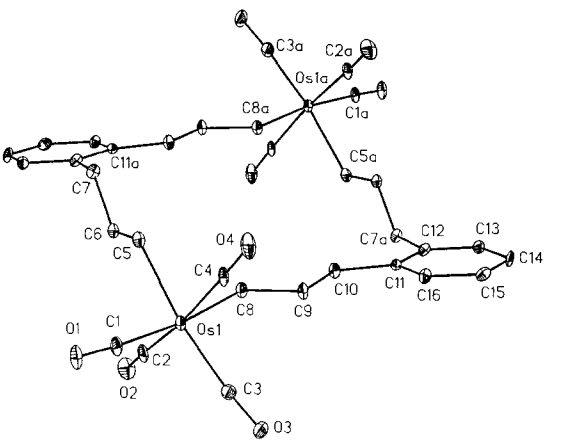

Fig. 2. Crystal structure of **6**. Selected bond lengths[Å] and angles [°]: Os1-C5 2.214(5), Os1-C8 2.218(6), mean Os1-(CO) distance 1.959(7), mean C-O distance 1.122(9), C1-Os1-C2 93.9(3), C1-Os1-C3 99.5(3), C1-Os1-C4 93.2(3), C2-Os1-C4 169.3(2), C5-Os1-C8 85.3(2) (cf. [9]).

In **2** and **6**, the bulky $Os(CO)_4$ groups lead to an angularity at the metal centers of the arene-bridged chains. In **4b** or other metal-free cyclophanes such as 9,12,22,25-tetramethoxy[7.7]-paracyclophane-4,17-dione,[10] the arene is, on the other hand, connected by an "elongated" zigzag chain.

In the $^{13}C\{^1H\}$ NMR spectra of **2**, **4**, and **6**, the ^{13}C signals occurring at highest field correspond to the C atoms adjacent to the metal centers (Table 1). The two, four, and three ^{13}C-resonances of the phenylene groups of **2**, **4**, and **6**, respectively, and the corresponding ^1H NMR signals are comparable to those of the open-chain systems, and are not influenced by cyclization.[7]

[a] $^{13}C\{^1H\}$ NMR spectra (62.90 MHz, $CDCl_3$, 25 °C, referenced internally to TMS).

The colorless, slightly soluble metallacyclophanes **2**, **4**, and **6** are strikingly stable to heat.[11] In the presence of carbon monoxide, a slow insertion of CO takes place only above 70 °C, leading to the formation of cyclic mono- and diacyl species [IR (*n*-pentane): ν(>C=O) = 1671 cm^{-1}; FD-MS: *m/z* 954 and 982, respectively].[12] A further increase in temperature generates the corresponding [7.7]cyclophanedione in low yield by reductive elimination of $Os(CO)_4$.

The diferracyclophanes **4a** and **6a**, analogous to **4** and **6**, are accessible by a similar route. They are thermally labile (decomp

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0303-0322 $ 10.00+.25/0

> -30 °C), and react with CO, as depicted for **4a** → **4b** (Table 1), to give the cyclic diketones in much higher yield. The molecular structure of **4b** has been confirmed by an X-ray crystal structure analysis.[9]

[Fe] = $Fe(CO)_4$, OTf = OSO_2CF_3

Experimental Procedure

2, **4**, **6**: A solution of **1**, **3**, or **5** (580 mg, 1.27 mmol), respectively in dimethyl ether (20 mL) was added to a suspension of $Na_2[Os(CO)_4]$ (550 mg, 1.58 mmol) in dimethyl ether (30 mL), and the mixture was allowed to react under reflux for 3 d. After removal of the solvent (−70 °C), the residue was taken up in *n*-pentane (70 mL) at 20 °C, and the solution was filtered (P4). Following concentration of the filtrate to 5 mL and cooling to −70 °C, the product was recrystallized twice from *n*-pentane. Yields: **2**: 458 mg (78%), **4**: 417 mg (71%), **6**: 270 mg (46%); correct elemental analyses; m.p. 127, 113, and 122 °C, respectively.

4a and **6a** were synthesized analogously at −70 °C, worked up at −50 °C, and characterized by IR spectroscopy (Table 1).

Thermolysis of **4a**: A solution of $Na_2[Fe(CO)_4]$ (338 mg, 1.58 mmol) and **3** (580 mg, 1.27 mmol) in dimethyl ether (50 mL) was stirred for 2 h at −70 °C, and then CH_2Cl_2 (50 mL) was added. The mixture was warmed to 20 °C with passage of CO, stirred for 2 h, and then concentrated. Purification on a silica gel column, eluting with CH_2Cl_2, followed by acetone gave **4b**. Yield: 90.8 mg **4b** (38% based on **3**); correct elemental analysis; m.p. 79 °C.

Difluoromethyl Compounds of Chalcogens: A NMR Study of the Reactions of $Cd(CF_3)_2 \cdot 2MeCN$ and $ZnBr(CF_3) \cdot 2MeCN$ with Dialkyl Chalcogenides and Boron Trifluoride**

Dieter Naumann,* Regina Möckel, and Wieland Tyrra

$Zn(CF_3)$ and $Cd(CF_3)$ derivatives have established themselves as polar reagents for the transfer of trifluoromethyl groups.[1, 2] A further possibility for the employment of these derivatives is as difluorocarbene sources at higher temperatures.[3] Products have been identified, however, which indicate a carbenoid or carbene reaction even under extremely mild conditions – in particular in the transfer of CF_3 groups to strong Lewis acid systems.

Based on these findings, we were able to open a simple route to chalcogenides with difluoromethyl groups by optimizing the reaction conditions.[4] Whereas difluoromethyl ethers and difluoromethyl sulfides may already be prepared by base-initiated reactions of chlorodifluoromethane and the corresponding alcohols and thiols[5] or by reactions of difluorodiazirine[6] or fluorosulfonyldifluoroacetic acid[7] with alcohols, the difluoromethyl compounds of the heavier elements—with the exception of aryl(difluoromethyl) compounds[8]—were not known until now.

The alkyl(difluoromethyl) chalcogenides **3a**–**8a** are formed by the BF_3-initiated reaction of **1** or **2** with dialkyl ethers (**3** and **4**), dialkyl sulfides (**5** and **6**), dimethyl selenide (**7**), or dimethyl telluride (**8**), at −30 °C (Eq. (a)). The products were identified by NMR spectroscopic techniques.

$$\underset{\mathbf{1,2}}{M(CF_3)X} + \underset{\mathbf{3-8}}{R_2E} + BF_3 \rightarrow \underset{\mathbf{3a-8a}}{RECF_2H} + [MX]^+ + [BF_4]^- \qquad \text{(a)}$$

$M(CF_3)X$: $Cd(CF_3)_2 \cdot 2MeCN$ **1**, $ZnBr(CF_3) \cdot 2MeCN$ **2**;
R_2E: Me_2O **3**, Et_2O **4**, Me_2S **5**, Et_2S **6**, Me_2Se **7**, Me_2Te **8**

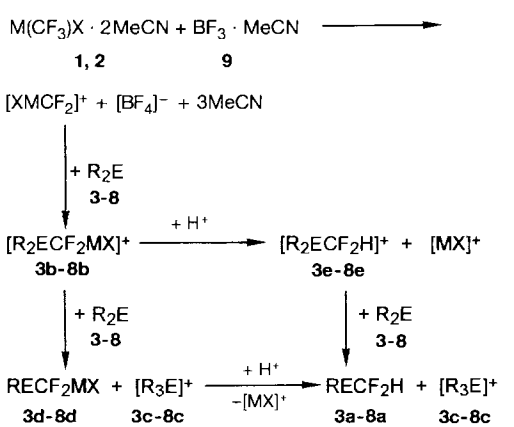
[**] Carbenoid Reactions of Trifluormethyl Element Compounds, Part 1. This work was supported by the Fonds der Chemischen Industrie and by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.



The reactions are selective in dichloromethane between $-78\,^{\circ}C$ and room temperature. The products formed indicate the following reaction mechanism: On the assumption that trifluoromethyl derivatives of cadmium and zinc, analogous to the intensively investigated lithium carbenoids,[10] may be written in the mesomeric forms **1a** and **1b** (see Eq. (b), without MeCN), it would seem apparent that the removal of a fluoride ion by the use of a Lewis acid, such as BF_3, should be possible. The electron deficit that thereby arises on the carbon atom is compensated by a Lewis base, for example, a dialkyl chalcogenide, under formation of an onium intermediate (**3b**–**8b**) (see Scheme 1).

$$\underset{\mathbf{1}}{CF_3CdCF_3} \longleftrightarrow \underset{\mathbf{1a}}{[CF_3Cd]^+[CF_3]^-} \longleftrightarrow \underset{\mathbf{1b}}{[CF_3CdCF_2]^+\,F} \qquad \text{(b)}$$

Intermediates of this type can be identified in the reaction of **1** with cyclic sulfanes by using ^{19}F NMR and ^{113}Cd NMR spectroscopic techniques,[11] and have already been detected by ^{113}Cd NMR spectroscopy in reactions of $Cd(CF_3)_2$ complexes with $I(CF_3)(OCOCF_3)_2$ in the presence of $B(OCOCF_3)_3$.[12]

A two-step reaction involving alkyl group transfer and protolysis can be assumed for the formation of alkyl(difluoromethyl) chalcogenides **3a**–**8a** from **3b**–**8b**. The onium intermediates **3b**–**8b** react with an excess of the dialkyl chalcogenides **3**–**8** to give the trialkylchalcogenium ions **3c**–**8c**, which can be detected by NMR spectroscopy, and the neutral intermediates **3d**–**8d**. The ensuing protolysis of **3d**–**8d** leads to the formation of the alkyl(difluoromethyl) chalcogenides **3a**–**8a**.

The intermediates **3b**–**8b** could initially be protolyzed to give the dialkyl(difluoromethyl)chalcogenium ions **3e**–**8e**. The sulfonium ions **5e** and **6e** were identified. Compounds **3e**–**8e** react with an excess of the chalcogenides **3**–**8** to form **3a**–**8a** and **3c**–**8c** (Scheme 1).

Scheme 1. Suggested course of the title reaction. For M, X, R, E, see Equation (a).

The source of the protons in the reactions of the dialkyl ethers, **3** and **4**, cannot be determined unequivocally. The alkyl cations released in the reaction could further react with the acetonitrile present in the system to form ketenimines under proton abstraction.[13] The possible formation of an intermediate trialkyloxonium ion, which subsequently decomposes to give an ether, an alkene and a proton[14] cannot be ruled out, but appears to be improbable in the system described.

The identification of the alkene and other by-products can be made by the reaction of **1** with $BF_3 \cdot t$BuOMe in *tert*-butylmethyl ether, where $MeOCF_2H$ (**3a**) is formed as the main product. Side-products include hydrogen fluoride, isobutene, *tert*-butylfluoride, and 1,1-difluoro-2,2-dimethylcyclopropane. All products were identified by ^{19}F NMR and $^{13}C\{^1H\}$ NMR spectroscopic techniques. $MeOCF_2H$ (**3a**) is formed according to the mechanism proposed above. The proton needed for the cleavage of the metal–carbon bond originates from reaction of the *tert*-butyl cation yielding isobutene. The formation of *tert*-butylfluoride can be explained by either the decomposition of the intermediate $[t\text{Bu}][BF_4]$, or by a Markovnikov addition of HF to isobutene. The 1,1-difluoro-2,2-dimethylcyclopropane, also identified in the reaction, can be considered as a product of a carbenoid reaction of **1** with isobutene. The absence of tetrafluoroethene or perfluorocyclopropane, the trimer of difluorocarbene, confirms the assumption of a carbenoid reaction pathway and all but completely rules out the formation of the products by a difluorocarbene insertion or [2 + 2] cycloaddition reaction.

In the case of the heavier elements, the complexed acetonitrile functions as a proton source—this was confirmed by deuteration studies.[15] These studies could not ascertain as to how far fluoride ions or tetrafluoroborate ions make the hydrogen abstraction from acetonitrile[16] possible in these systems. However, the ^1H NMR spectra of the reaction mixtures do enable the identification of (*E*)-3-amino-2-butenenitrile as a product of this proton abstraction (cf. [17]).

Table 1. NMR spectroscopic data of the compounds **3a**–**8a**, **5c**–**8c**, **5e** and **6e**. (Measurements made at 21 °C in CH_2Cl_2 unless otherwise stated). Product mixtures were used.

$MeOCF_2H$ **3a**: ^{19}F NMR (188.3 MHz, THF, CCl_3F): $\delta = -86.93$ (d, $^2J(F,H) = 75.4$ Hz, $^1J(F,C) = 259.4$ Hz) [a]

$EtOCF_2H$ **4a**: ^{19}F NMR (188.3 MHz, $MeCN/Et_2O$, CCl_3F): $\delta = -83.86$ (d, $^2J(F,H) = 75.9$ Hz, $^1J(F,C) = 257.9$ Hz) [b]; ^1H NMR (200.1 MHz, $CDCl_3$, TMS): $\delta = 6.15$ (CF_2H, t, $^2J(F,H) = 75.5$ Hz, 1 H), 3.88 (CH_2, q, 2 H), 1.22 (CH_3, t, 3 H); $^{13}C\{^1H\}$ NMR (50.5 MHz, $CDCl_3$, TMS): $\delta = 115.8$ (CF_2H, t, $^1J(F,C) = 260.0$ Hz), 59.0 (CH_2, t, $^3J(F,C) = 5.0$ Hz), 18.5 (CH_3, s)

$MeSCF_2H$ **5a**: ^{19}F NMR (188.3 MHz, CCl_3F): $\delta = -96.38$ (d, $^2J(F,H) = 56.9$ Hz, $^1J(F,C) = 270.6$ Hz); ^1H NMR (200.1 MHz, TMS): $\delta = 6.80$ (CF_2H, t, $^2J(F,H) = 56.6$ Hz, 1 H), 2.23 (CH_3, s, 3 H)

$EtSCF_2H$ **6a**: ^{19}F NMR (188.3 MHz, CCl_3F): $\delta = -93.45$ (d, $^2J(F,H) = 56.3$ Hz, $^1J(F,C) = 271.1$ Hz); ^1H NMR (200.1 MHz, TMS): $\delta = 6.84$ (CF_2H, t, 1 H, $^2J(F,H) = 56.5$ Hz), 2.78 (CH_2, q, 2 H), 1.29 (CH_3, t, 3 H)

$MeSeCF_2H$ **7a**: ^{19}F NMR (282.4 MHz, CCl_3F): $\delta = -94.37$ (d, $^2J(F,H) = 55.1$ Hz, $^2J(Se,F) = 34.2$ Hz); $^{77}Se\{^1H\}$ (57.3 MHz, Me_2Se): $\delta = 289.77$ (t, $^2J(Se,F) = 34.4$ Hz)

$MeTeCF_2H$ **8a**: ^{19}F NMR (282.4 MHz, CCl_3F): $\delta = -91.75$ (d, $^2J(F,H) = 52.5$ Hz, $^2J(Te,F) = 61.0$ Hz); $^{125}Te\{^1H\}$ NMR (94.8 MHz, Me_2Te): $\delta = 534.72$ (t, $^2J(Te,F) = 60.8$ Hz)

$[Me_3S]^+$ **5c**: ^1H NMR (200.1 MHz, TMS): $\delta = 2.89$, s

$[Et_3S]^+$ **6c**: ^1H NMR (200.1 MHz, TMS): $\delta = 3.25$ (CH_2, q, 6 H), 1.43 (CH_3, t, 9 H) [c]

$[Me_3Se]^+$ **7c**: $^{77}Se\{^1H\}$ NMR (57.3 MHz, Me_2Se): $\delta = 255.84$ (s) [d]

$[Me_3Te]^+$ **8c**: $^{125}Te\{^1H\}$ NMR (94.8 MHz, (Me_2Te): $\delta = 446.66$ (s) [e]

$[Me_2SCF_2H]^+$ **5e**: ^{19}F NMR (188.3 MHz, CCl_3F): $\delta = -110.77$ (d, $^2J(F,H) = 52.9$ Hz)

$[Et_2SCF_2H]^+$ **6e**: ^{19}F NMR (188.3 MHz, CCl_3F): $\delta = -104.43$ (d, $^2J(F,H) = 52.5$ Hz, $^1J(F,C) = 291.0$ Hz); ^1H NMR (200.1 MHz, TMS): $\delta = 7.54$ (t, $^2J(F,H) = 52.5$ Hz) [f]

[a] Cf. [6]. [b] Cf. [7]. [c] Cf. [18]. [d] Cf. [19]. [e] Cf. [20]. [f] The signals from the ethyl groups are eclipsed by those from **6c**.

The new reaction type discussed here makes it possible to synthesize alkyl(difluoromethyl) chalcogenides in a very simple manner, and under mild conditions, starting from trifluoromethyl compounds of cadmium and zinc. An elaboration of the reaction principle, using other organometallic and organic derivatives, should open simple routes to the synthesis of both new compounds containing CF_2H groups, and compounds which are otherwise extremely difficult to obtain.

Experimental Procedure

All manipulations were carried out under nitrogen with the careful exclusion of moisture. **1** (1.0 mmol) or **2** (2 mmol) was dissolved (or suspended) in dichloromethane (6 mL) at −78 °C. After addition of **9** (2.0 mmol), the reaction mixture was stirred for several minutes and **3**–**8** (ca. 6 mmol) was added. The mixture was stirred at −78 °C for five hours and then warmed to room temperature. Reactions with $BF_3 \cdot t$BuOMe were carried out in *t*BuOMe. The NMR spectra (Table 1) were recorded at room temperature using the product mixtures. The molar ratios of **5a**–**8a** to **5c**–**8c** were calculated from the NMR spectra and found to be 1:1 in all cases.

Synthesis and Structure of an Oxovanadium(v)–Organophosphonate Cluster Encapsulating a Chloride Ion: $[ClV_7O_{12}(O_3PC_6H_5)_6]^{2-}$**

Yuan-Da Chang, Jose Salta, and Jon Zubieta*

Recent developments in metal organophosphonate coordination chemistry[1, 2] have received considerable impetus from the applications of such materials as sorbents, catalysts, and catalyst supports.[3, 4] Oxovanadium–organophosphonate chemistry includes numerous new materials such as binuclear coordination compounds,[5] fully oxidized[6] and mixed-valence clusters,[7, 8] and layered compounds.[9, 10] The solid oxovanadium organophosphonates with alternating organic and inorganic layers have been shown to recognize and selectively discriminate between alcohols.[10] The large mixed-valence polyoxovanadium–organophosphonate ions $[(Me_4N)^+ \subset H_6(VO_2)_{16}(CH_3PO_3)_8]^{7-}$,[7] $[(H_2O)_x \subset H_{12}(VO_2)_{12}(PhPO_3)_8]^{4-}$,[8] and $[2\,NH_4^+, 2\,Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$[11] form inclusion compounds with cationic units, neutral molecules, and even anionic/cationic aggregates, respectively. While an expansive coordination chemistry of organophosphonates with primarily V^{IV}-oxo units is emerging, oxovanadium(v)-organophosphonate chemistry remains relatively unexplored and to date the only example of this class of compound previously reported is the pentanuclear cluster $[V_5O_7(OCH_3)_2(PhPO_3)_5]^-$.[6] We report here the synthesis and structure of a novel oxovanadium(v)–organophosphonate (**1**). This anion exhibits a cage

$(Ph_4P)_2[ClV_7O_{12}(PhPO_3)_6]$ **1**

structure formed by the corner-sharing of V^v/O square pyramids and $PhPO_3$ tetrahedra, in which a Cl^- ion is encapsulated. The anion of **1**, while best described as spherical, shares common structural motifs with the layered phase $VO(C_6H_5PO_3) \cdot H_2O$, and both of these structures may be related in turn to simple binuclear oxovanadium(IV) species such as **2** and **3**.

$(Ph_4P)_2[(VO)_2Cl_4(t\text{-}C_4H_9PO_3H)_2]$ **2**
$[(VO)_2Cl_2(H_2O)_2(RPO_3H)_2]$ **3a**; R = C_6H_5; **3b**; R = CH_3

Red parallelepiped crystals of **1** were prepared by the reaction of $(Ph_4P)VO_2Cl_2$[12] and $PhPO_3H_2$ in acetonitrile. The X-ray structure analysis of **1**[13] revealed the presence of discrete $(Ph_4P)^+$ cations and $[ClV_7O_{12}(O_3PC_6H_5)_6]^{2-}$ anions (Fig. 1 top). The V/P/O framework consists of a spherical shell of corner-sharing vanadium/oxygen square pyramids and organophosphonate tetrahedra. This $[V_7O_{12}(O_3PC_6H_5)_6]^-$ cage acts as a host for the chloride ion, which serves as a template for the organization of the cluster during the condensation process.[14] While the structure of **1** is somewhat reminiscent of that of $[V_{15}O_{36}Cl]^{6-}$,[15, 16] the topological details are quite distinct. The cluster cage of $[V_{15}O_{36}Cl]^{6-}$ is constructed exclusively from vanadium/oxygen square pyramids; this results in the formation of a highly symmetrical spheroid of approximate D_{3h} symmetry. The "facets" of the spheroid consist of two six-membered $\{V_3O_3\}$ rings, three $\{V_4O_4\}$ rings, and eighteen four-membered $\{V_2O_2\}$ rings. In contrast, cluster **1**, which is constructed from vanadium/oxygen square pyramids and phosphorus/oxygen/carbon tetrahedra and displays irregular geometry with approximate C_2 symmetry, exhibits six-membered $\{V_2PO_3\}$ rings, eight-membered $\{V_2P_2O_4\}$ and $\{V_3PO_4\}$ rings, and ten-membered $\{V_3P_2O_5\}$ rings defining four, four, two, and two faces of the cage, respectively.

All illustrated in Figure 1 middle, the cage is constructed from the fusing of a trinuclear $\{V_3O_5(O_3PC_6H_5)_6\}$ unit to a tetranuclear $\{V_4O_7\}$ moiety through bridging organophosphonate groups. While neither unit exists independently in the V/O/organophosphonate system, the trinuclear unit is reminiscent of the $\{V_3O_5(O_3PC_6H_5)_5\}$ unit in $[V_5O_7(OCH_3)_2(O_3PC_6H_5)_5]^-$,[6] and the cage of **1** shares common structural features with the solid phase $VO(O_3PC_6H_5) \cdot H_2O$[9] and with simple binuclear species of the type $[(VO)_2Cl_2(HO_3PR)_2Y_2]^n$ (**2**: R = *t*-C_4H_9, Y = Cl, *n* = 2; **3a** and **3b**: Y = H_2O, *n* = 0, R = C_6H_5 and CH_3, respectively).

The compositions of the binuclear complexes of the V/O/organophosphonate system are dependent on reaction conditions

Selected bond lengths [Å] and angles [°]: V1-Cl1 2.351(2); V1-Cl2 2.371(2); V1-O6 1.571(6); V1-O3 1.980(5); V1-O4 1.974(4); P1-O4 1.504(4); P1-O3 1.497(8); P1-O2(H) 1.585(5); Cl1-V1-O4 155.8(2); Cl2-V1-O3 145.9(2). Bottom: The structure of $[(VO)_2Cl_2(H_2O)_2(CH_3PO_3H)_2]$ (**3b**). Selected bond lengths [Å] and angles [°]: V1-Cl1 2.330(7); V1-O1 1.64(1); V1-O3 1.99(1); V1-O5 1.98(1); V1-O8 1.93(1); V2-Cl2 2.321(6); V2-O2 1.58(1); V2-O4 2.01(1); V2-O6 2.01(1); V2-O9 1.94(1); Cl1-V1-O8 150.6(3); O3-V1-O5 149.2(4); Cl2-V2-O6 155.5(4); O4-V2-O9 144.0(5).

sharing V^V/O square pyramids and organophosphonate tetrahedra. Both orientations of the $\{V{=}O\}$ groups relative to the cyclic $\{V_2P_2O_4\}$ unit have been isolated; **2** and **3a** adopt the *anti* configuration, while **3b** exhibits *syn* geometry (Fig. 2). The structures of **2** and **3a** may be viewed as fragments of the $VO(O_3PR)\cdot H_2O$ layered materials, which may be constructed by linking binuclear units, in such a way that $\{V{-}O\cdots V\}$ interactions with alternating short and long distances are formed along the chains and the pendant {P-OH} groups coordinate to adjacent units. Similarly, **3b** possesses the required *syn* configuration to provide a structural motif for **1**.

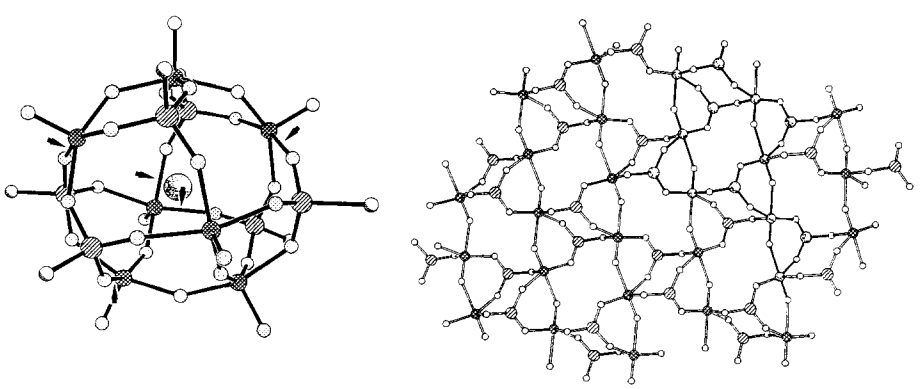

Fig. 3. Left: A view of the anion of **1**. The arrows indicate the V–O(P) bonds that may be broken to provide the $\{V_7O_{12}(O_3PC_6H_5)_6\}$ moiety which is subsequently unfolded and flattened. Right: A view of the *bc* plane of $VO(O_3PC_6H_5)\cdot H_2O$; phenyl carbon atoms and H_2O molecules are omitted for clarity. The unfolded and flattened $\{V_7O_{12}(O_3PC_6H_5)_6\}$ unit derived from **1** is highlighted.

The structure of **1** is also reflected in the layered phase, such that cleavage of V-phosphonate–oxygen bonds, coordination of H_2O to the sixth coordination site on vanadium, and flattening of the cage produces the motif shown in Figure 3 (right). The structural relationships of the cluster **1** to the related binuclear species **2** and **3** and to the layered solid $VO(O_3PR) \cdot H_2O$ are not only striking but extend beyond topological similarities to the chemical behavior of the cluster. Protic degradation and reduction of **1** by alcohol in MeOH/HCl yields the binuclear species **3a**, which in turn serves as a precursor for fragment condensation reactions by mild hydrolysis[5] to give $[V_6O_{10}(PhPO_3)_4(PhPO_3H)_2]^{2-}$, $[(CH_3CN)_2(VO)_{14}O_8(OH)_4(O_3PPh)_8]^{6-}$,[20] and other as yet unidentified oligomers. Under more forcing conditions of hydrolysis/condensation, both **1** and **3a** yield solid phases of composition $VO(O_3PPh) \cdot H_2O$.

The polyvanadate system adopts complex structures based on cage, basket, belt, bowl, and barrel motifs which are topologically and chemically related to the V_2O_5 layer structure.[19] A similar structural diversity may be expected for the V/O/organophosphonate system whose molecular clusters exhibit certain analogous relationships to the solid $VO(O_3PR) \cdot H_2O$ phases. However, the introduction of the organophosphonate tetrahedral unit into the polyhedral backbone clearly expands the structural possibilities as indicated by the $[H_6(VO_2)_{16}(CH_3PO_3)_8]^{8-}$, $[H_{12}(VO_2)_{12}(PhPO_3)_8]^{4-}$, and $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$[11, 20] frameworks, which exhibit structural motifs related to both V_2O_5 and $VO(O_3PR) \cdot H_2O$ phases.

Experimental Procedure

All reactions were carried out in an atmosphere of N_2.

1: A solution of $PhPO_3H_2$ (1.3 g, 8.2 mmol) in acetonitrile (5 mL) was added to a solution of $(Ph_4P)[VO_2Cl_2]$ (2.0 g, 4.1 mmol) in CH_3CN (15 mL). After stirring for 48 h, the original translucent lime-green color associated with $[VO_2Cl_2]^-$ changed to an intense red-orange. The volume of the reaction mixture was reduced to 10 mL and layered with diethyl ether to give 0.6 g of a fine red precipitate of **1**. Recrystallization was effected by slow evaporation from acetonitrile solution. IR(KBr pellet): $\tilde{\nu}[cm^{-1}] = 1484(m)$, 1438(m), 1178(m), 1132(s), 1039(s), 1019(s), 990(vs), 831(m), 753(m), 722(m), 689(m), 553(m), 526(m), 492(m); $\{PO_3\}$ group vibrations: 1178, 1132, 1039, and 1019.

2: $tBuPO_3H_2$ (0.59 g, 4.27 mmol) was added to a solution of $(Ph_4P)[VO_2Cl_2]$ (2.24 g, 4.54 mmol) in methanol (20 mL). After stirring at room temperature for 48 h, the resultant dark green solution was concentrated to 12 mL and layered with diethyl ether. Blue-green crystals of **2** were recovered after standing at room temperature for 18 days. Yield: 0.40 g. IR(KBr pellet): $\tilde{\nu}[cm^{-1}] = 1585(m)$, 1483(m), 1436(m), 1313(w), 1187(w), 1164(w), 1109(vs), 1013(s), 997(s), 756(s), 722(vs), 688(s), 526(vs); $\{PO_3\}$ group vibrations: 1187, 1164, 1109, 1013.

3b · $2Ph_4PCl$: $(Ph_4P)[VO_2Cl_2]$ (2.51 g, 5.1 mmol) and $CH_3PO_3H_2$ (0.443 g, 4.61 mmol) were allowed to react at room temperature in methanol (20 mL). Conditions and workup were identical to those reported for **2** (yield: 0.56 g of blue crystals). IR(KBr pellet): $\tilde{\nu}[cm^{-1}] = 1609(w)$, 1585(m), 1483(m), 1436(s), 1315(m), 1193(s), 1108(s), 1068(s), 1018(s), 996(s), 949(s), 757(m), 722(s), 688(s), 527(vs). $\{PO_3\}$ group vibrations: 1193, 1108, 1068, 1018. The synthesis of **3a** is reported in reference [5].

Macrotricyclic Borane–Amine Adducts: The First Uncharged Synthetic Host Compounds Without Lewis Acid Character, for Anionic Guests**

Karin Worm, Franz P. Schmidtchen,* Annette Schier, Andrea Schäfer, and Manfred Hesse*

Two alternative concepts have been used to date for the supramolecular binding of anions in solution to synthetic molecular hosts:[1] A high, positive charge density, such as that found in macrocyclic polyammonium salts, ensures host–guest complexation even when the guest experiences marked protic solvation.[2] The selectivity of molecular recognition certainly suffers from unavoidable competition with the counterions, which are subject to the same electrostatic attraction. In principle, formation of uncharged hosts for anions would be more favorable. Such hosts could be regarded as analogs to the cation-binding crown ethers. Since most anions possess lone electron pairs, the grouping of

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie.

several Lewis acid centers as complementary binding sites in a preorganized molecular lattice is obvious. A series of successful hosts has already been prepared according to this principle,[3] although they must thereby accept as guests the Lewis base solvent molecules, present in high concentration.

We envisaged a better, third way in the use of anion–dipole interactions, similar to those presumably employed in natural receptors. In numerous crystal structures of enzyme–substrate complexes, protein helices are aligned with the amino terminal directed toward negatively charged groups in the substrate, thereby illustrating the stabilizing effect of this orientation of the macrodipole.[4]

The ion–dipole interaction is nevertheless considerably weaker than the direct ion–ion interaction, decreases more rapidly with increasing distance, and is also dependent on orientation. In order to be able to use the ion–dipole interaction in synthetic hosts, the host must be perfectly preorganized for anion binding. This requirement could be fulfilled by formation of an adduct of the macrotricyclic amine **1**[5] with boron derivatives (cf. **2**). The dipoles of the dative boron–nitrogen bonds converge with the positive dipole terminals towards the center of the molecular cavity. Thus, the highly linked structure guarantees the fixed, unperturbed orientation of the dipoles, whilst the hydrocarbon bridges ensure a nonpolar environment with a low dielectric constant and thus the maximum electrostatic attraction for negatively charged molecular species. As shown by the analogous example of the quaternary ammonium salt,[6] obtained from **1** by Menshutkin alkylation, the molecular cavity is large enough even to bind iodide ions (ionic radius 2.16 Å) as guest in an inclusion complex. In addition, force field calculations in vacuo indicate negative enthalpies of formation for inclusion complexes **3** of the adduct **2** with bromide and cyanide[7] [ΔH ($Br^- \subset$ **2**) = -16 kcal mol^{-1}; ΔH ($CN^- \subset$ **2**) = -26 kcal mol^{-1}].

Preparation of the borane adduct **2** was achieved by reaction of **1** with $BH_3 \cdot THF$ (77%). Crystals from CH_2Cl_2/ether had the molecular structure shown in Figure 1;[8] surprisingly, only two carbon atoms in one of the hydrocarbon bridges are disordered. Unlike the inclusion complexes of tetraalkylated **1** with iodide[6] the borane adduct **2** is distorted from tetrahedral symmetry in the crystal, with the result that the molecular cavity in **2** is markedly smaller than the cavity that the iodide ion occupies in tetracationic hosts.[6] The host **2** must therefore change its equilibrium conformation on migration of a guest into this cavity.

The borane adduct **2** was titrated with a series of quaternary ammonium and phosphonium salts in $CHCl_3/CH_2Cl_2$, during

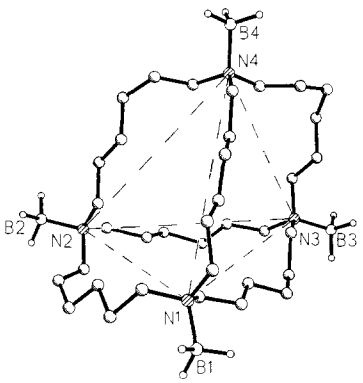

Fig. 1. Crystal structure of the borane–amine adduct **2** [8]; selected distances [Å]: N1–N2 6.92, N1–N3 8.10, N1–N4 7.35, N2–N3 7.08, N3–N4 6.65, N2–N4 7.86.

which procedure the ^{1}H NMR signals of the α-CH_2 group in **2** were observed to be sensitive probes of conformation. The signal pattern of **2** does not change; instead concentration-dependent shifts of the signals appear. These shifts are typical of those found for supramolecular complex formation governed by rapid host–guest exchange kinetics. The change in chemical shift ($\Delta\delta$) is thus a function both of the ratio of free host to host–guest complex and of the maximum value ($\Delta\delta_{max}$), the latter being dependent on the guest anion.[9] For the five anions examined, Figure 2 shows variable but linear dependences for the concentration ratios selected. As absolutely no effect was detected for the analogous triethylamine–borane adduct **4** in titrations under the same conditions, the observed signal shifts cannot be due to unspecified salt effects but must be a result of the macrotricyclic cage structure of **2**. The graduation can therefore be explained without further ado according to the model of an inclusion complex: large anions (PF_6^-, I^-) show no or only very weak shifts, because the concentrations of the host–guest complexes are small. As a result of their size these guests can only be taken up in the molecular cavity with difficulty and therefore have very small binding constants. In contrast, small negatively charged guests (Cl^-, CN^-) migrate easily into the cage of the host and form stable complexes. Since this process, however, requires only a very small adaptation in the conformation of the host, the measured effect is small; for cyanide it is even smaller than for iodide. These counter influences lead to an optimal result for bromide as guest.

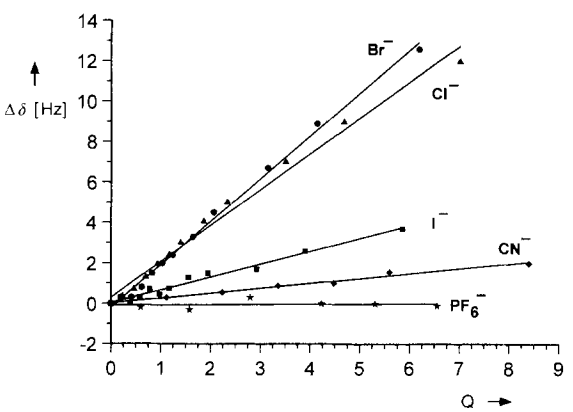

Fig. 2. ^{1}H NMR titrations (360 MHz) of **2** (9.45×10^{-3} M) with five salts at 297 K in 20 vol% $CD_2Cl_2/CDCl_3$; the change in chemical shift $\Delta\delta$ of the α-CH_2 signal in the host is plotted against the host–guest ratio Q. ▲ $(C_6H_5)_4P^+Cl^-$, ● $(C_4H_9)_4N^+Br^-$, ■ $(C_4H_9)_4N^+I^-$, * $(C_4H_9)_4N^+PF_6^-$, ◆ $(C_2H_5)_4N^+CN^-$.

The formation of a host–guest inclusion complex should give a saturation isotherm with 1:1 stoichiometry. The linear dependences in Figure 2 indicate that the dissociation constants of the host–guest complexes must be considerably greater than can be determined from the host and guest concentrations used hitherto in the titrations. The apparent host–guest dissociation constants of **2** with bromide as guest were determined from ^{1}H NMR titrations (360 MHz) with a large excess of bromide (Fig. 3). Under these conditions the unspecific ion-pairing of the salt becomes more important, and the host–guest binding constant is systematically underestimated as a result of this competition. A nonlinear regression function that fits the data well represents a 1:1 binding model with $K_{diss} = 80 \pm 8 \times 10^{-3}$ M (20% CD_2Cl_2/$CDCl_3$; $\Delta\delta_{max} = 80.3 \pm 3$ Hz; complexation range 18–74%) for the bromide complex of the electrically neutral host **2**.

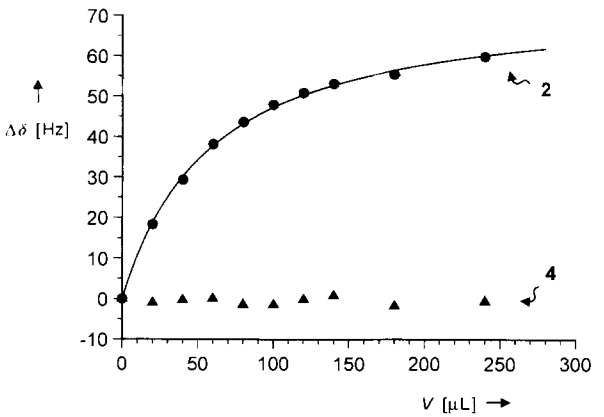

Fig. 3. ^{1}H NMR titration (360 MHz) of **2** (●) (13.6×10^{-3} M) and of triethylamine · BH_3 **4** (▲) with $(C_6H_5)_4P^+Br^-$ (0.78 M) at 297 K in 20 vol% CD_2Cl_2/$CDCl_3$ (500 μL). The change in chemical shift of the α-CH_2 signal is plotted against the volume of the guest solution. The continuous line shows the calculated regression curve. Repeating the titration with [**2**] = 5.8×10^{-3} M gave the same values for K_{diss} and for $\Delta\delta_{max}$ as those found at higher concentration.

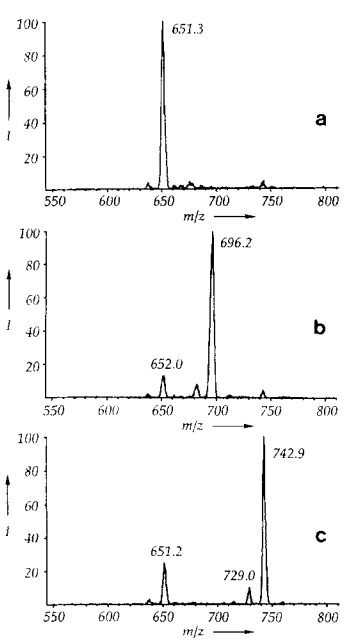

Fig. 4. Electrospray mass spectra of **2** (negative ion mode) in $CHCl_3/CH_3OH$ (1:3, $c = 10^{-4}$ M); a) without additive; b) with addition of $(C_4H_9)_4N^+Br^-$; c) with addition of $(C_4H_9)_4N^+I^-$.

Additional support for the formation of 1:1 host–guest complexes with halide ions in solution is provided by electrospray mass spectra (ESI-MS).[10] Recording the negative ions in $CHCl_3/CH_3OH$ solution yields almost exclusively the chloride complex of **2** (molecular mass 651 = 616 (**2**) + Cl^-;[11] Fig. 4a). The chloride apparently arises from the solvent, which emphasizes the affinity of the host **2** for this anion. On addition of bromide or iodide to the solution (as tetrabutylammonium salt), included Cl^- is replaced by Br^- or I^-, (the extent depends on the concentration of the added halide), and host–guest complexes are recorded at *m/z* 696 (616 (**2**) + Br^-[11]) and 743 (616 (**2**) + I^-)(Figs. 4b and 4c).

The macrotricycle **2** is thereby the first example of a new class of uncharged synthetic host compounds, in which the binding affinity for anions arises essentially from ion–dipole interactions. The success of the host compounds depends on the precise preorganization of the dipole, on the dipole strength, and on the stability and solubility of the abiotic host. Improvements in these properties will provide excellent perspectives for applications.

[7] Calculations with the CVFF force field of the Insight/Discover molecular modeling program in vacuo. The partial charges in **2** were taken from a semiempirical MOPAC calculation of a tripropylamine · BH_3 adduct. To overcome kinetic barriers on inclusion of the guest, molecular dynamics calculations were carried out at 500 K, and the total energy of the configuration was minimized every 1 ps. Cyanide was found in the molecular cavity of **2** after only one ps, whereas bromide was found there only after 16 ps. Tetrafluoroborate remained only externally associated with **2**, even after 100 ps at 1000 K.

[8] Crystal structure of **2**: $C_{36}H_{84}B_4N_4$, $M = 616.706$; Enraf–Nonius CAD4 diffractometer; $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å); graphite monochromator; the lattice constants were obtained with 25 reflections; orthorhombic cell, $a = 12.368(1)$, $b = 14.003(1)$, $c = 24.294(2)$ Å, $V = 4208.1$ Å^3, space group $P2_12_12_1$ [no. 19], $Z = 4$, $\rho_{calcd} = 0.974$ g cm^{-3}, $F(000) = 1392$ e, $\mu(Mo_{K\alpha}) = 5.08$ cm^{-1}, ω scan, measured range of reciprocal space: $-14 < h < +14$, $0 < k < 16$, $0 < l < 27$; of 3674 independent reflections, 2608 were regarded as observed [$F_0 > 4\sigma(F_0)$]; structure solution was by direct methods (SHELXS-86), refinement according to the method of full-matrix least squares and difference Fourier synthesis (SHELX-76); all non-hydrogen atoms except the (disordered) atoms C33 and C34 were refined with anisotropic displacement parameters; all hydrogen atoms were placed in calculated positions; $R(R_w) = 0.0778$ (0.0512, with $w = 1/(\sigma^2(F_0) + 3.8103\ F_0^2)$); 411 parameters; maximum residual electron density: + 0.45/−0.46 e Å^{-3}. Refinement of the inverse coordination set produced no changes in the *R* values and geometries. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57735 and the journal citation.

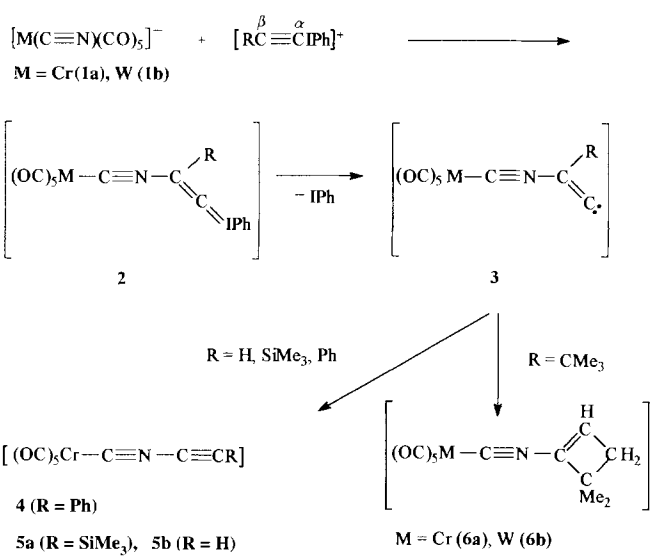
Complex-Stabilized Alkynyl and Cycloalkenyl Isocyanides**

Rainer Kunz and Wolf P. Fehlhammer*



Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday.

For some time now, we have been interested in particularly simple functional isocyanides which – although unstable to various degrees as free molecules—can be readily prepared at the "protecting metal". In this form, these isocyanides are then available as stable molecules. Examples can be found in the proven or postulated interstellar isocyanides CNH,[1] $CNNH_2$,[2] and CNCN.[3, 4] In the meantime, a separate organometallic chemistry has begun to emerge around CNH ("chemistry of hydrogen isocyanide"[4]).

The situation is similar for the poly- and perchloroalkyl isocyanides, for example, $CNCCl_2-CCl_2R$ and $CNCCl_3$,[5, 6] which can be obtained by radical alkylations of cyano complexes. In its coordinated form, $CNCCl_2-CCl_2R$ appears to be a promising precursor for vinyl and also alkynyl isocyanides, a group of compounds which was unknown until recently. However, whereas the 1,2-elimination of two chlorine atoms posed no problem, the complex resisted further elimination to form a C-C triple bond.[7] Recently, Lentz et al. successfully achieved this elimination by flash pyrolysis of $[Cr(CO)_5CNCCl{=}CHCl]$, however, the metal-ligand bond was cleaved in the process as well.[8] The instability and low yield of the free ethynyl isocyanide thus obtained hinder the development of its chemistry.

We have therefore searched for other pathways to alkynyl isocyanide complexes and found one in the reaction of cyano complexes with alkynyl(phenyl)iodonium salts. One should be aware, however, that the advantage of stabilization by complexation carries with it the disadvantage of interference by the metal. Alkynyl(phenyl)iodonium salts are masked acetylene cations and, owing to their electrophilic character, react with cyano complexes according to Scheme 1.

The first step is probably an attack of the cyano complex *N* atom at the β-C atom, yielding the ylide **2**, which readily cleaves off iodobenzene. This reaction sequence has also been observed for other nucleophilic substitutions at alkynyliodonium salts.[9, 10] Depending on the nature of R, the formed isocyanovinylidene complex **3** is stabilized either by migration of the R group, yielding an alkynyl isocyanide complex (**4**, **5a**,**b**), or by insertion into a C–H bond of the alkyl chain, leading to a coordinated cycloalkenyl isocyanide – in this case cyclobutenyl isocyanide (**6a**, **b**). This last reaction step is reminiscent of the tandem Michael carbene insertions, which have been used by Ochiai et al. for elegant and efficient syntheses of cyclopentene derivatives.[9a] Complex **3** can also be used to prepare cyclopentenyl isocyanide complexes.[11]

Scheme 1. Proposed mode of formation of alkynyl and cyclobutenyl isocyanide complexes from cyanometalates and alkynyliodonium salts.

The finding that the use of $MeC{\equiv}ClPh^+$ does not lead to either propynyl or cyclopropenyl isocyanide complexes can serve as further evidence for the proposed mode of reaction, as apparently the primary adduct **2** (M = Cr, R = Me) is isolated. This is indicated by the molecular ion peak and the CO loss pattern in the mass spectrum, as well as by the IR spectrum that exhibits distinctly lower ν(CN) and ν(CO)[E] bands, an observation which is in accordance with the proposed vinyl isocyanide/iodonium ylide structure **7**.[12] A complete characterization has failed so far due to the ready decomposition of this species.

$[(OC)_5Cr{-}C{\equiv}N{-}C(Me){=}\ddot{C}{-}\overset{+}{I}Ph]$ **7**

The reaction of $NEt_4[Cr(CN)(CO)_5]$ with $[HC{\equiv}ClPh]OTf$ (OTf = OSO_2CF_3) leads to **5b**, which contains the simplest complex-bound alkynyl isocyanide. The use of $[Me_3SiC{\equiv}ClPh]BF_4$ allows – after separation by column chromatography—the isolation of two products. According to NMR, IR, and mass spectra, these are the trimethylsilyl derivative **5a** and its hydrolysis product **5b**.

Complex **4** is the first alkynyl isocyanide complex characterized by X-ray crystallography.[13] The C≡N, ≡N–C≡, and C≡C distances along the main molecular axis (Fig. 1) indicate isolated triple bonds, the corresponding bond angles are normal and in agreement with the description of the ligand as a linear isocyanoacetylene. The essentially equal Cr–C(O) bond lengths indicate a *trans* influence of the C≡N–C≡CPh ligand that is similar to that of CO, while it is very much weaker than that of cyano isocyanide C≡N–C≡N, one of the strongest π-acceptor ligands (see below).[3]

The fact that the signals of the axial and equatorial CO carbon atoms are coincident in the ^{13}C NMR spectrum of **5b** also supports the assertion that C≡N–C≡CH acts like a sixth carbonyl ligand.

Ad hoc assignments of the IR vibrational bands in the triple bond region are not feasible due to the various possible couplings between four species with A_1 symmetry ($2\times\nu$(CO), ν(CN), ν(C≡C)). Also ^{13}C labeling of the isocyanide carbon atom in **5b** did not lead to the desired clarity. Surprisingly, none of the original bands shows a truly significant isotopic shift, the only notable difference in the IR spectrum of **5b′** to that of **5b** con-

[**] Metal Complexes of Functional Isocyanides. Part 22. This work was supported by the Fonds der Chemischen Industrie and the Bundesministerium für Bildung und Wissenschaft in the context of the Graduiertenkolleg "Synthese und Strukturaufklärung niedermolekularer Verbindungen". We thank Priv.-Doz. Dr. D. Lentz for valuable assistance with the X-ray structure analyses. Part 21: W. P. Fehlhammer, R. Metzner, R. Kunz, *Chem. Ber.*, in press.

cerns the low energy shoulder of the ν(CO)[E] absorption. A previously hidden band was shifted by about $-15\ cm^{-1}$, which indicates a significant ν(CN) component. Interestingly, similar isotope effects have also been observed for pentacarbonylchromium complexes of particularly electron-deficient isocyanides, such as $CNCCl_3$, CNCN, and CNC(O)NC.[4, 5b] In these compounds, the new band appears at even lower wavenumbers, namely 1936, 1929, and 1830 cm^{-1}, respectively.

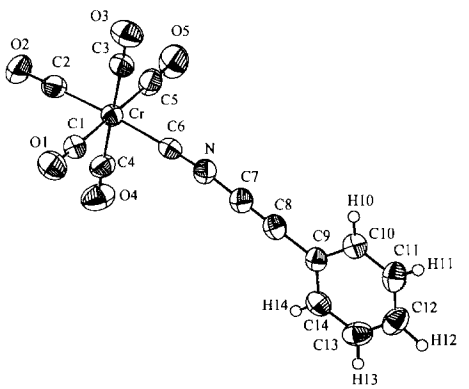

Fig. 1. Crystal structure of **4** (ORTEP, 50% probability ellipsoids), space group $P2_1/n$, $a = 6.044(3)$, $b = 7.403(3)$, $c = 30.667(14)$ Å, $\beta = 91.95(4)°$, $V = 1371.3$ Å^3, $Z = 4$; 2412 measured reflections, 1876 observed ($I > 3\sigma(I)$), 211 refined parameters, $R = 0.039$, ($R_w = 0.039$). Selected bond lengths [Å] and angles [°]: Cr-C2 1.896(4), Cr-C(O)$_{cis}$ (average) 1.891, Cr-C6 1.926(4), C6-N 1.169(5), N-C7 1.314(5), C7-C8 1.179(5); Cr-C6-N 175.7(3), C6-N-C7 175.1(4).

$[(OC)_5Cr\text{-}{}^{13}C{\equiv}N\text{-}C{\equiv}CH]$ **5b′**

The mass and ^{13}C NMR spectra of **4** and **5**, on the other hand, were straightforward. They confirm the formulation as alkynyl isocyanide. The position of the isocyanide carbon atom in **5b′**, which can be unambiguously assigned due to the ^{13}C label, is especially conclusive, but it is still not shifted as far downfield (≈ 200 ppm) as the corresponding C atoms in $[Cr(CO)_5CNCN]$ and $[Cr(CO)_5CNCCl_3]$ (cf. Experimental Procedure).[3, 6]

Preliminary experiments showed that the alkynyl isocyanide synthesis presented here can also be transferred to other cyano complexes ([Fe(CN)Cp(dppe)], [Ru(CN)Cp(dppe)]; dppe = 1,2-bis(diphenylphosphino)ethane). This gives us a very favorable basis for the development of subsequent chemistry, which, according to early results, appears to be primarily a chemistry of functionalized alkynes. For instance, reactions with $[Co_2(CO)_8]$ and $[Pt(\eta\text{-}C_2H_4)(PPh_3)_2]$ lead to the typical μ_2- and η^2-coordination compounds, respectively.

The cyclobutenyl isocyanide complexes **6a, b** also represent a new class of coordinated functional isocyanides. As expected, their IR spectra exhibit bands at 2140 s cm^{-1} (ν(CN)) and 1620 w cm^{-1} (ν(C=C)), and the mass spectra show the appropriate molecular ion peaks. The NMR data permit an unambiguous structure assignment, which is based on the δ values of other vinyl isocyanide complexes synthesized by us.[7]

The X-ray crystal structure analysis of **6a**[13] indicates a Cr-$(CO)_5$ fragment that exhibits a reduced Cr–CO_{trans} distance, when compared to the average value of the Cr–CO_{cis} bonds. This is generally observed for complexes incorporating donor ligands. In general, the geometric parameters reflect the unusual steric conditions at the unsaturated *gem*-disubstituted four-membered ring. Its spontaneous formation is therefore surprising also from this point of view (Fig. 2).

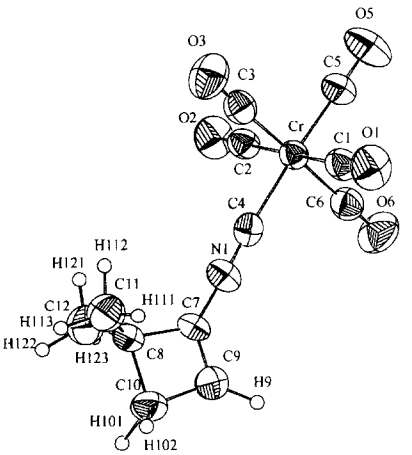

Fig. 2. Crystal structure of **6a** (ORTEP, 50% probability ellipsoids), space group $P2_1/c$, $a = 11.073(3)$, $b = 6.114(2)$, $c = 20.538(5)$ Å, $\beta = 90.60(2)°$, $V = 1390.25$ Å^3, $Z = 4$; 2143 measured reflections, 1547 observed ($I > 3\sigma(I)$), 208 refined parameters, $R = 0.036$, ($R_w = 0.038$). Selected bond lengths [Å] and angles [°]: Cr-C5 1.840(5), Cr-C(O)$_{cis}$ (average) 1.891, Cr-C4 1.968(5), C4-N1 1.165(6), N1-C7 1.371(6), C7-C9 1.316(7), C7-C8 1.496(6), C8-C10 1.587(7), C9-C10 1.500(8); Cr-C4-N1 176.0(4), C4-N1-C7 178.3(4), N1-C7-C8 129.4(4), C8-C7-C9 97.1(4), C7-C9-C10 93.3(4), C9-C10-C8 86.2(4), C10-C8-C7 83.4(3).

Experimental Procedure

4: A solution of $NEt_4[Cr(CN)(CO)_5]$ (3.00 g, 8.62 mmol) and [PhC≡ClPh]OTs (OTs = *p*-$MeC_6H_4OSO_2$) (4.10 g, 8.62 mmol) [14] in dichloromethane (30 mL) was heated to reflux for 60 minutes, after which the solvent was removed and the dark brown residue was extracted with several 50 mL portions of *n*-hexane. The solvent was removed again and the oily residue was separated by column chromatography (10 × 5 cm column, Kieselgel 60 (Merck), solvent *n*-hexane). The product was eluted first as a yellow band. The yellow solid that remained after solvent removal was recrystallized from diethyl ether at 0 °C. This resulted in colorless rod-shaped crystals, which melted under decomposition at about 60 °C. Yield: 0.7 g (25%). Correct elemental analyses for C, H, and N. IR (KBr): ν[cm^{-1}] = 2235 s, 2020 s, 1941 vs, ^1H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 7.45 (m, Ph); $^{13}C\{^1H\}$ NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 54.7 (α-C), 70.6 (β-C), 119.4, 128.6, 129.9, 132.9 (Ph), 174.4 (C≡N), 213.3 (CO_{eq}), 213.8 (CO_{ax}).

5a, 5b: These compounds were prepared as described for **4** from $NEt_4[Cr(CN)(CO)_5]$ (2.00 g, 5.75 mmol) and $[Me_3SiC{\equiv}ClPh]BF_4$ (2.23 g, 5.75 mmol) [15]. The chromatographic separation (same conditions as for **4**) yielded two fractions. The first fraction contained 0.3 g of **5a** (17% yield, m.p. 42 °C (decomp)). IR (KBr): ν[cm^{-1}] = 2215 s, 2162 s, 2094 s, 2029 s, 1941 s, 1250 s, 850 s; ^1H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 0.25 (s, $SiMe_3$); $^{13}C\{^1H\}$ NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = −1.02 ($SiMe_3$), 30.0, 60.3 (C≡C), 171.6 (C≡N), 213.1 (CO_{eq}), 213.3 (CO_{ax}). The second fraction contained 0.2 g of **5b** (14% yield). Both compounds gave correct elemental analyses for C, H, and N.

5b: This compound was obtained in the same manner as **4** from $NEt_4[Cr(CN)(CO)_5]$ (2.00 g, 5.75 mmol) and [HC≡ClPh]OTf (2.17 g, 5.75 mmol) [16]. After the chromatographic separation (same conditions as for **4**), complex **5b** was obtained in 29% yield; m.p. ≈ 30 °C (decomp). IR (polyoil): ν[cm^{-1}] = 3315 m, 2187 s, 2089 s, 2011 s, 1973 vs. $^{13}C\{^1H\}$ NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 44.9 (α-C), 63.5 (β-C), 174.2 (C≡N), 213.6 (CO_{ax} + CO_{eq}).

5b′: IR (polyoil): ν[cm^{-1}] = 3314 m, 2087 s, 2011 s, 1975 vs, 1962 vs.

6a: This compound was prepared as described for **4** from $NEt_4[Cr(CN)(CO)_5]$ (2.00 g, 5.75 mmol) and [*t*BuC≡ClPh]BF_4 (2.66 g, 5.75 mmol) [17]. The chromatographic separation (same conditions as for **4**) and subsequent workup afforded 0.4 g (23%) of product. Colorless crystals in the form of platelets were obtained from toluene at room temperature: m.p. 65 °C. IR (KBr): ν[cm^{-1}] = 2137 s, 2060 s, 1921 vs. ^1H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 1.28 (s, 6H, Me), 2.16 (s, 2H, CH_2), 5.8 (s, 1H, CH); ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 23.5 (Me), 39.8 (CMe_2), 48.9 (CH_2), 125.4 (α-C), 130.2 (β-C), 174.8 (C≡N), 214.3 (CO_{eq}), 216.4 (CO_{ax}).

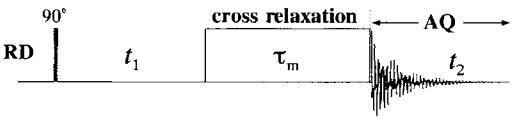
FAST NOESY Experiments— An Approach for Fast Structure Determination**

Matthias Köck and Christian Griesinger*

The determination of cross-relaxation rates by NMR spectroscopic methods[1] provides interproton distances. Two-dimensional experiments like NOESY[2] and ROESY[3] (Fig. 1) are gradually taking the place of classical one-dimensional saturation NOE experiments, since they allow the simultaneous measurement of all interproton distances in a molecule, irrespective of their number. Long longitudinal relaxation times (T_1) often determine the total measurement time. Normally, the relaxation delay between consecutive scans is on the order of two to three times the relaxation time of those protons with the longest T_1 values.[4] For molecules in the extreme narrowing limit (molecular weight below 500 D), in particular, the relaxation delay constitutes the major part of the entire measurement time. In this communication we introduce a post-processing procedure for NOESY and ROESY spectra allowing the acquisition time to be shortened with a marginal loss in the signal-to-noise ratio and the accuracy of the integration of the cross-relaxation peaks. A similar procedure was described for the accelerated measurement of heteronuclear T_1 values in 1975.[4]



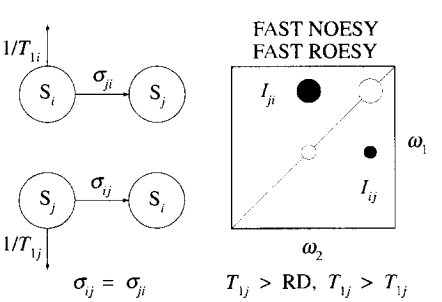


Fig. 1. Pulse sequence of NOESY and ROESY experiments with relaxation delay RD, mixing time τ_m, and acquisition time AQ = t_2(max).

NOESY and ROESY spectra contain cross peaks whose integrals reflect the cross-relaxation rate between magnetically active nuclei in the initial rate approximation.[5] The cross-relaxation rates depend on the correlation time τ_c and the distance r between the interacting nuclei according to r^{-6}. However, this relation only holds if the spin system relaxes back to thermal equilibrium after each scan. An exact solution for incomplete relaxation between scans in a FAST NOESY experiment can be obtained from the Liouville-von-Neumann equation.[1a, 6] The integral of the cross-peak between spin i and j (I_{ij}^F) is dependent on the relaxation delay (RD) between scans, the mixing time τ_m, the acquisition time AQ, and the relaxation matrix $\boldsymbol{\Gamma}$ as given in [Eq. (a)].

$$I_{ij}^F = [\exp(-\boldsymbol{\Gamma}\tau_m)]_{ij} \sum_{k=1}^{N} [\mathbf{1} - \exp(-\boldsymbol{\Gamma}(\mathrm{RD} + \mathrm{AQ})]_{jk} = I_{ij} \sum_{k=1}^{N} [\mathbf{1} - \exp(-\boldsymbol{\Gamma}(\mathrm{RD} + \mathrm{AQ})]_{jk} \quad \text{(a)}$$

The first factor I_{ij} is due to the cross relaxation during the mixing time τ_m, and the second is due to the relaxation to thermal equilibrium during the relaxation delay and the acquisition time. When the T_1 value of a proton is approximately equal or longer than RD + AQ, the integrals in the NOESY are too small owing to incomplete relaxation. The second term in Equation (a) is asymmetric with respect to the permutation of spins i and j, in contrast to the first term I_{ij}. Therefore the cross-peak integrals in NOESY and ROESY spectra above and below the diagonal can be different for short recovery delays (Scheme 1).

Scheme 1. Representation of the cross relaxation σ between spins S_i and S_j. Despite the identity of the cross-relaxation rates σ_{ij} and σ_{ji}, asymmetric NOESY and ROESY spectra result for short recovery delays when the T_1 values of the spins S_i and S_j are different.

This asymmetry is most notable for nuclei with strongly differing T_1 values. This effect has prevented the recording of NOESY spectra with short recovery delays.[7]

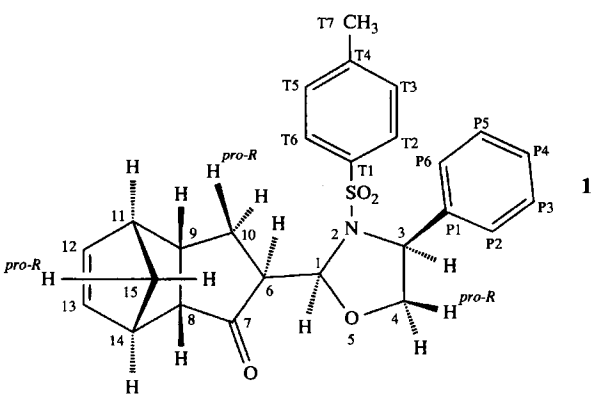
An exact compensation for incomplete relaxation including the effects of spin diffusion by complete relaxation matrix approaches[8] in FAST NOESY will be presented elsewhere.[9] Here we describe a procedure that allows the cross-peak integrals, I_{ij}, of a NOESY spectrum with full relaxation to be obtained from the cross-peak integrals of a FAST NOESY experiment, I_{ij}^{F}. For small molecules the diagonal elements of the relaxation matrix Γ determine the T_1 values. Therefore the multiexponential relaxation $\sum_{k=1}^{N}[\mathbb{1}-\exp(-\Gamma(\mathrm{RD}+\mathrm{AQ})]_{j,k}$ can be simplified to Equation (b).

$$\sum_{k=1}^{N}[\mathbb{1}-\exp(-\Gamma(\mathrm{RD}+\mathrm{AQ})]_{jk}=\mathbb{1}-\exp(-(\mathrm{RD}+\mathrm{AQ})/T_{1j}) \qquad \text{(b)}$$



The T_{1j} values of the protons must be determined by Inversion–Recovery before the 2D cross-relaxation experiment is recorded (Table 1). The evaluation of all T_1 values requires a resolved 1D NMR spectrum.

Table 1. T_1 relaxation times for the protons in compound **1** [a].

Proton	T_1	Proton	T_1
1	1.684 (<0.1%)	12	2.533 (<0.1%)
3	1.724 (<0.1%)	13	3.041(<0.1%)
$4^{pro\text{-}R}$	0.782 (0.2%)	14	2.070 (<0.1%)
$4^{pro\text{-}S}$	0.665 (1.6%)	$15^{pro\text{-}R}$	0.758 (0.1%)
6,8	1.593 (0.1%)	$15^{pro\text{-}S}$	0.611 (1.8%)
9	1.064 (0.1%)	P2-P6, T3, T5	3.200 (<0.1%)
$10^{pro\text{-}R}$	0.598 (0.9%)	T2, T6	2.375 (<0.1%)
$10^{pro\text{-}S}$	0.603 (0.8%)	T7	1.184 (0.5%)
11	1.794 (0.2%)		

[a] The assignment of the protons is shown in Scheme 2. The T_1 relaxation times are given in s, the statistical errors in parentheses. The Inversion–Recovery experiment was recorded with 79 different recovery delays and evaluated with the T_1 routine of the Bruker UXNMR program.

We demonstrate this procedure on a complex organic micromolecule (**1**, molecular weight 450 D, Scheme 2) with positive NOEs.[10] A series of NOESY spectra at 400 MHz with relaxation delays of 5.0, 3.0, 1.5, 1.0, 0.75, 0.5, and 0.25 s were recorded. The measurements were performed at a temperature of 300 K in $CDCl_3$ with AQ = 0.53 s and τ_m = 0.5 s.[11] This mixing time is still in the linear region of the NOE build-up (cf. ref. [10]).

Scheme 2. Structure of **1**.

Figure 2 shows sections of NOESY spectra with the cross peaks between H-12/H-13 and H-$15^{pro\text{-}R}$/H-$10^{pro\text{-}S}$. For RD = 5 s (Fig. 2a, b) the cross-peak integrals above and below the diagonal of the NOESY spectrum are almost identical; for RD = 0.25 s (Fig. 2c, d) they differ by up to a factor of 3. Above the diagonal (Fig. 2a, c) the cross-peak integrals remain almost unchanged for RD = 5 s and RD = 0.25 s, because the T_1 values of the protons H-$10^{pro\text{-}S}$ and H-$15^{pro\text{-}R}$ are smaller or equal to RD + AQ (see Table 1).

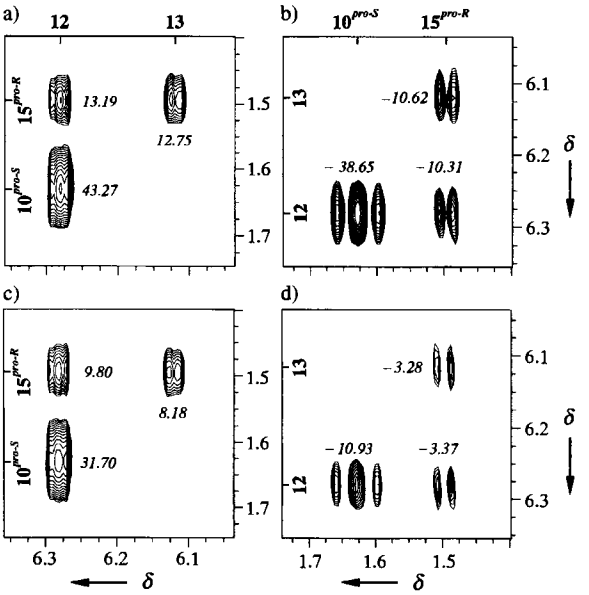


Fig. 2. Cross peaks in NOESY (a and b, RD = 5 s) and FAST NOESY spectra (c and d, RD = 0.25 s) between H-12/H-13 and H-$15^{pro\text{-}R}$/H-$10^{pro\text{-}S}$ above (a and c) and below (b and d) the diagonal. The integrals of the cross peaks are given in italics.

Figure 3a shows a statistical evaluation of the integrals as a function of the relaxation delay RD: $I_{ij}^{F}(\mathrm{RD})/I_{ij}(\mathrm{RD}=5\ \mathrm{s})$. The systematic error of the integrals obtained from the FAST NOESY experiments relative to those obtained from the experiment with RD = 5 s is dramatic, especially for the very short recovery times.

$$I_{ij}=I_{ij}^{F}/[1\text{-}\exp(-(\mathrm{RD}+\mathrm{AQ})/T_{1j})] \qquad \text{(c)}$$

Compensation of the integrals in the FAST NOESY experiment according to Equation (c) provides the integrals, I_{ij}, of an NOESY experiment with full relaxation. This is demonstrated in Figure 3b by a statistical evaluation of the ratio between the compensated integrals from the FAST NOESY and the integrals from the NOESY experiment with RD = 5 s. The ratios are centered around 1 as expected. This is even true for the experiment with RD = 0.25 s, which had a relaxation delay 20 times shorter than the reference experiment (RD = 5 s). The interproton distances obtained from the uncorrected FAST NOESY integrals I_{ij}^{F} deviate from the values obtained from the NOESY spectrum by up to 15%. With compensation for incomplete relaxation, the interproton distances obtained from the FAST NOESY are similar to those obtained from the fully relaxed NOESY to within ±2%.

The acquisition time for NOESY and ROESY experiments can be reduced by a factor of 5 to 10, and the determination of interproton distances is almost as accurate as that based on an NOE spectrum with full relaxation. This allows spectrometer

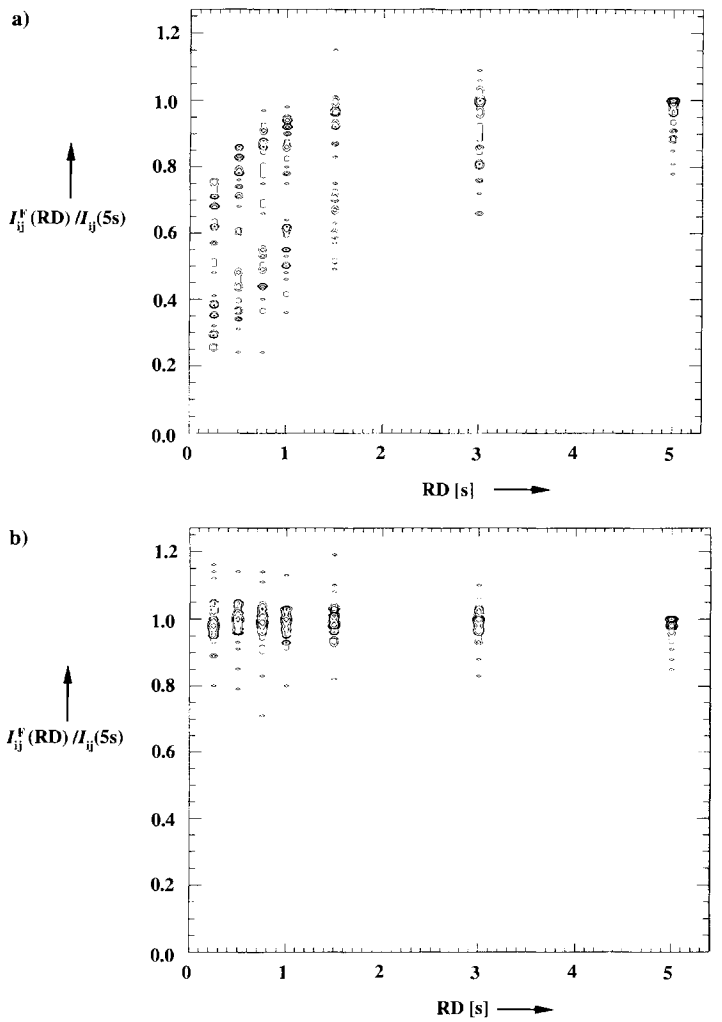

Fig. 3. a) Integral ratios for the cross peaks of **1** obtained from a FAST NOESY, I_{ij}^{I}, (RD) and from a NOESY experiment, I_{ij}, (RD = 5 s) in percent. A contour representation with a factor of 2 for the level spacing was chosen to indicate the number of integral ratios within a given range of percentage. If a value of $I_{ij}^{I}(RD)/I_{ij}(5\ s)$ occurs only once, it is represented by one contour line. If it occurs n times it is represented by trunc($\lg_2 n$) contour lines. Only those 46 cross peaks were evaluated that showed no overlap in the NOESY and whose T_1 values could be determined in the 1D spectrum. The integrals obtained from the FAST NOESY experiments are reduced to 1/5 of those from the fully relaxed NOESY. This corresponds to an error in distance of up to ± 15%. b) Same representation as in a) but with compensation of incomplete relaxation during RD + AQ according to Equation (c). The deviations of the integrals obtained from the FAST NOESY are reduced to ±10%, which corresponds to an error in distances of ±2%.

time to be used much more effectively and reduces the time for the structure determination. If the recovery delay (RD + AQ) approaches or is smaller than the transverse relaxation times T_2, B_0 spoil gradients should be used during the relaxation delay RD.

[11] The spectra were recorded with 16 scans, a spectral width of 3846.15 Hz, 384 real points in t_1 (TPPI) and 4096 points in t_2. TPPI was used in order to obtain pure phase spectra. Processing yielded a matrix of 1024 × 2048 points. Before Fourier transformation a squared cosine function was applied. A baseline correction with a fifth-grade polynomial was applied.

Small Molecules Stabilized in Inorganic Frameworks: NbI_5 Monomers in the Novel Layered Compound $Nb_7S_2I_{19}$**

Gordon J. Miller* and Jianhua Lin

Many types of inorganic extended solids can stabilize and, perhaps, "solubilize" molecular species that may not be thermodynamically stable in either the gaseous state or liquid solution. These extended structures can also serve as reaction templates (heterogeneous catalysts) for reactions that are otherwise kinetically unfeasible. Zeolites and clays are just two examples of a number of interesting materials with such applications, because they exhibit large channels or open layers for insertion of molecular entities.[1] We are presently investigating the possibilities of early transition metal cluster compounds,[2, 3] especially ternary niobium and tantalum chalcogenide halides, for such purposes.

When small molecules are introduced in a solid-state host, often the structure and, in particular, the topology of the host remains unchanged (except for shifts in lattice parameters) or undergoes small displacive transformations. Seldom does one observe major topological changes in the extended solid, although there may certainly be a synergistic relationship between the structures adopted by the extended framework and the enclosed molecule. In $Nb_7S_2I_{19}$ (more precisely $[Nb_3S_2I_7][NbI_5]$), we have found this type of structural synergism.

A (001) projection of the structure of $Nb_7S_2I_{19}$ is shown at the top of Figure 1.[4] This compound forms nearly level sheets composed of Nb_3 triangular clusters, according to the description $[NbS_{1/3}I_{1/3}I_{2/2}I_{2/2}]_3 \triangleq Nb_3SI_7$, which are stacked perpendicular to the monoclinic *ab* plane. In these layers, each Nb atom is octahedrally coordinated by one S and five I atoms, and these coordination polyhedra share faces to form a bicapped Nb_3 triangle with one S and one I atom as the capping atoms. The twofold capping leads to significantly shorter Nb–Nb dis-

[**] This research was supported both by the Chemical Sciences Division, Office of Basic Energy Sciences, U.S. Department of Energy, under Contract D-7405-Eng-82 and the Donors of the Petroleum Research Fund, administered by the American Chemical Society. We thank Dr. L. Miller, Ames, for the resistivity and magnetic susceptibility measurements, and Prof. Dr. U. Müller for several suggestions.

tances (2.776(5) Å) within the cluster than those found in other binary and ternary niobium iodide phases containing monocapped Nb_3 clusters (ca. 3.00 Å).[7] The two-dimensional network forms through two intercluster bridging I atoms; in other words, the coordination polyhedra about each Nb atom in two adjacent clusters share an edge. The Nb–Nb distances between clusters average greater than 4.20 Å. This particular layered framework represents a new structural motif for M_3X_8 compounds[7] but cannot as yet be stabilized in the Nb-S-I system without any inserted species.

The other component in the structure of $Nb_7S_2I_{19}$ is a trigonal-bipyramidal monomer of NbI_5 (Fig. 1 bottom). These NbI_5 molecules pack between the Nb_3SI_7 layers within nearly hexagonal channels along the *c* axis (see Fig. 1 top). In the solid state, brass-colored NbI_5 has been reported to form complex chains of *cis*-vertex-sharing octahedra, $NbI_4I_{2/2}$,[8] which differ from the *trans*-edge-sharing octahedra in $NbCl_5$ and $NbBr_5$.[9, 10] However, since only the I positions and not the Nb positions were determined, another structure involving $(NbI_5)_2$ molecules is also possible.[11]

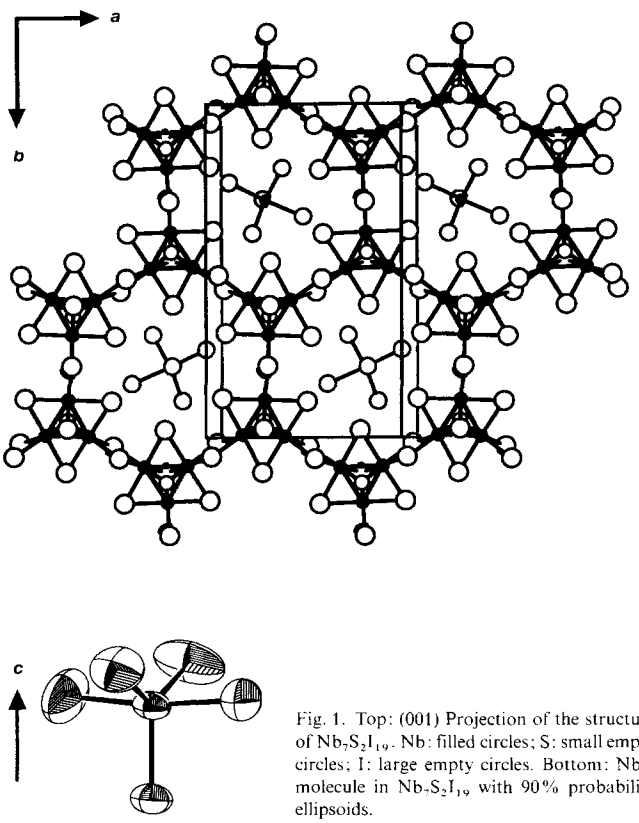

Fig. 1. Top: (001) Projection of the structure of $Nb_7S_2I_{19}$. Nb: filled circles; S: small empty circles; I: large empty circles. Bottom: NbI_5 molecule in $Nb_7S_2I_{19}$ with 90% probability ellipsoids.

Electron diffraction studies on the vapors of $NbCl_5$ and $NbBr_5$ indicate trigonal-bipyramidal structures,[12] but NbI_5 is thermally unstable, and decomposes into reduced niobium iodides.[13] To our knowledge, this is the first example of monomeric NbI_5 molecules in the solid state. The average Nb–I distance of 2.671(6) Å is consistent with a higher formal oxidation state for these Nb atoms than those in the $^2_\infty[Nb_3SI_7]$ framework ($d(Nb-I)_{av}$ = 2.780(5) Å). In addition, there is an excellent correlation between Nb–X distances (X = Cl,[9] Br,[10] I) in NbX_5 and the ionic radii of X^-.[14] A revised value of $r(Nb^{5+})$ based upon these data is 0.51 Å.

As evident in the upper structure in Figure 1, one example of structural synergism between the two-dimensional Nb_3SI_7 layer and the NbI_5 molecules is the formation of a monoclinic lattice, which is only slightly shifted from hexagonal symmetry. In the Nb_3SI_7 partial structure, simple electron counting assigns two valence electrons per Nb atom, which means that the six electrons suffice for three two-center, two-electron bonds in each Nb_3 triangle. Thus, the electronically neutral, two-dimensional layer corresponds to a closed-shell configuration, and adopts a structure that is nearly hexagonal. However, since one equatorial Nb–I bond in the NbI_5 unit is parallel to the stacking axis, the highest rotational symmetry allowed is a twofold axis. Furthermore, minimization of I···I nonbonding repulsions between the NbI_5 molecules and the two-dimensional framework precludes orthorhombic (*mmm*) symmetry and allows at most a monoclinic (2/*m*) lattice.

The structural hierarchy outlined in Scheme 1 gives further insights into the intricacies of the interactions between layer and molecule, and lends support to the twinning mechanism.[15]

Scheme 1.

$P6/m2/m2/m$ ← hypothetical Nb_3I_8
↓ *t*3
$C2/m2/m2/m$
↓ *k*2
$P2_1/m2_1/m2/n$ ← Nb_3SI_7 layer
↓ *k*2, *a*, *b*, 2*c*
$P2_1/c2_1/c2/n$ ← doubled *c* axis
↓ *t*2
$P12_1/c1$ ← $Nb_7S_2I_{19}$

The highest allowed symmetry group for the two-dimensional framework is $P6/mmm$ (a hypothetical Nb_3I_8). If S atoms replace I as the capping atoms of the Nb_3 clusters, an orthorhombic cell with symmetry $Pmmn$ and the metric relations $a_{ortho} = \sqrt{3}a_{hex}$, $b_{ortho} = a_{hex}$, $c_{ortho} = c_{hex}$ is obtained. Doubling along the *c* axis produces the subgroup $Pccn$, and then introducing the NbI_5 monomers such that one Nb–I_{eq} bond lies parallel to *c* lowers the symmetry of the space group to $P2_1/c$ by means of a *t*2 step. The resulting monoclinic cell is given in Scheme 2. Since there are two possible orientations of the trigonal bipyramid with respect to the mirror plane perpendicular to the a_{mono} axis, twinning results.

Scheme 2. The subscripts mono, ortho, and hex denote monoclinic, orthorhombic, and hexagonal, respectively.

$a_{mono} \approx b_{ortho} = a_{2,hex}$
$b_{mono} \approx a_{ortho} = 2a_{1,hex} - a_{2,hex}$
$c_{mono} \approx c_{ortho} = 2c_{hex}$

Calculations of the electronic structure[16] of $Nb_7S_2I_{19}$ reveal that Nb–Nb bonding interactions within each cluster are maximized and that the occupied levels are separated from the unoccupied levels by an energy gap of ca. 0.2 eV (Fig. 2). This result is confirmed by both the diamagnetic and semiconducting behavior of $Nb_7S_2I_{19}$. Nb 4d levels dominate the density of states (DOS) above −11 eV, and the effect of the octahedral ligand field is seen by the separation of Nb 4d orbitals into t_{2g} and e_g sets. Nb–Nb orbital overlap splits these states further, and the nature of this overlap is shown by the Nb–Nb crystal orbital overlap population (COOP) curve. In particular, the t_{2g} levels split into three distinct bands, which correspond to Nb–Nb bonding ($E \approx -10$ eV), nonbonding ($E \approx -9$ eV), and antibonding states ($E \approx -8$ eV). Just above the calculated Fermi level ($E_F = -9.4$ eV) we find Nb 4d levels from the NbI_5 mole-

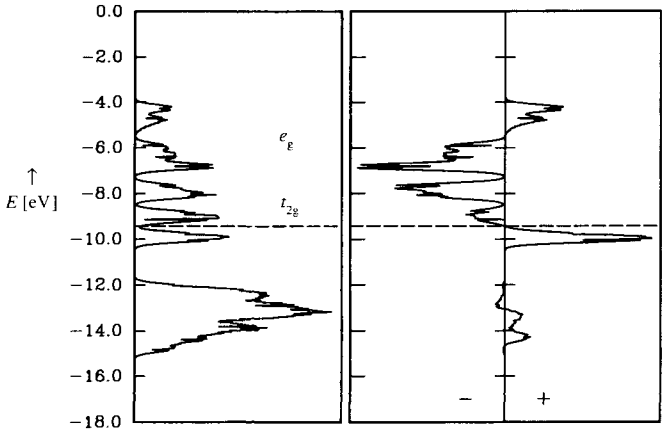

Fig. 2. Total density of states (left) and Nb–Nb overlap population (right) for $Nb_7S_2I_{19}$. (+): bonding Nb–Nb interactions; (−): antibonding Nb–Nb interactions. Dashed line indicates the Fermi level (highest occupied orbital), which occurs at a small energy gap (0.2 eV) in the DOS that is not completely visible on this scale.

cule, which indicates a d^0 configuration for these Nb atoms. If we compare these energies with those for a *trans*-vertex-sharing chain of NbI_6 octahedra,[8] which give rise to a broad Nb 4d band by significant through-bond coupling with the bridging I atoms, this band would overlap with the Nb–Nb bonding band in the Nb_3SI_7 layer. Our calculations strongly suggest, therefore, that the monomers form so as to optimize Nb–Nb interactions within the two-dimensional framework, but with little charge transfer between the two components. Thus, van der Waals and other London dispersion forces are the dominant interactions holding these two structural components together.

Similar calculations on the alternative structure of Nb_3SI_7 expected from earlier work on ternary Nb_3YX_7 compounds in this family[19] reveal that the bicapped Nb_3 cluster is energetically less favorable than the monocapped alternative.[20] All of our attempts to remove the NbI_5 molecules from $Nb_7S_2I_{19}$ have resulted in the formation of NbI_4, I_2, and the Nb_3SI_7 trigonal variant. Thus, a significant structural synergism exists between these two components, each of which is unstable with respect to either another structure (Nb_3SI_7) or towards decomposition (NbI_5), but are stabilized when they "cocondense."

Experimental Procedure

Elemental Nb (foil, Alfa; washed HF/HNO_3 and dried under vacuum), S, and I (sublimed; Alfa) in the molar ratio 7:2:19 were sealed under Ar in a quartz ampule ($\varnothing$ = 10 mm; l = 60 mm) and heated at 1100 K for 2 d. The product forms black, needle-shaped crystals. Chemical analysis with the Volhard method [21] gave I: 75.0% and S: 2.0%. Nb analysis (as Nb_2O_5) gave Nb: 20.2%. X-ray powder diffraction using an Enraf-Nonius Guinier camera indicates the phase $Nb_7S_2I_{19}$ is accompanied by a small amount of a hexagonal phase we identify as Nb_3SI_7 [19]. Magnetic susceptibility measurements show a small Curie–Weiss contribution (0.018 cm^3 K mol^{-1}) from a paramagnetic impurity. Two-probe electrical resistivity measurements indicated ρ(300 K) > 10^4 Ω cm.

[4] Crystals of $Nb_7S_2I_{19}$ were always found as twins; space group $P2_1/c$ (No. 14), Z = 4, a = 1283.0(1), b = 2209.8(2), c = 1465.0(1) pm, β = 94.025(9)° (Siemens P4 diffractometer): $Mo_{K\alpha}$, 6659 unique reflections, 3366 reflections with $F_o^2 \geq 3\sigma(F_o^2)$. The structure was solved with direct methods (SHELXTL PLUS, [5]) and refined with the program SFLS [6] to R(aniso) = 0.054, R_w(aniso) = 0.058. The initial structural model found by direct methods [5] could be refined to $R \approx 0.10$. Systematic deviations occurred for reflections with $h = 6n$, which allowed us to elucidate a twin-law involving planes perpendicular to the monoclinic a axis [6]. The resulting effect produces small but significant shifts in the stacking pattern of the two-dimensional layers along the c direction. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57736, the names of the authors, and the journal citation.

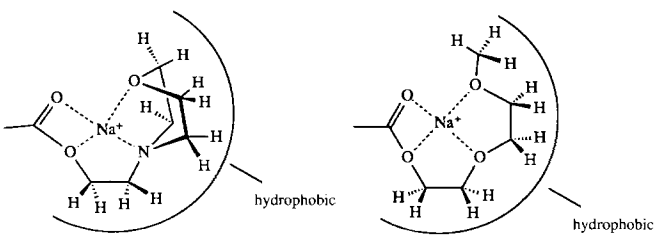
Enzymatic Hydrolysis of Hydrophilic Diethyleneglycol and Polyethyleneglycol Esters of Peptides and Glycopeptides by Lipases**

Horst Kunz,* Danuta Kowalczyk, Peter Braun, and Günther Braun

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

The esters of primary alcohols were used as protective groups for carboxyl groups quite early in peptide synthesis.[1] However, alkaline hydrolysis of these esters bears a high risk of racemization. In glycopeptide synthesis[2] with *O*-glycosyl-serine and -threonine derivatives the β elimination of the carbohydrate constitutes an additional problem.[3]



New perspectives open up with enzymatic methods that are carried out in neutral media,[4] as is shown by the selective hydrol-

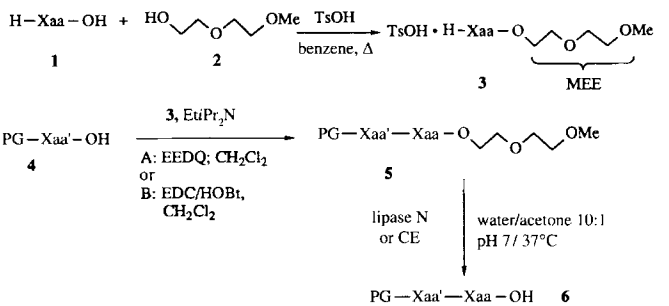
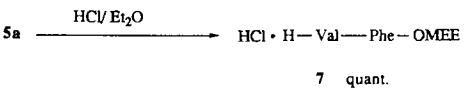
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank the Amano Pharmaceutical Co. for donating enzymes.



ysis of the heptyl esters of amino acids and peptides by lipases.[5] In peptide synthesis lipases have the advantage that they do not attack the peptide linkage. A limitation is the substrate selectivity of the enzymes; for example, the heptyl esters of hydrophobic dipeptides such as -Val-Phe- are attacked by lipases either very slowly or not at all.[5a] Similarly the heptyl esters of peptides with C-terminal proline,[5a] *O*-azidogalactosyl-threonine, or *O*-galactosaminyl-serine[5b] are not hydrolyzed by either lipase M (Amano) from *Mucor javanicus* or lipase N (Amano) from *Rhizopus niveus*. This lack of reactivity can be explained not only by the fact that the substrate structure is not suited to the active center of the enzyme, but also by simple physical factors such as the poor solubility and water-repelling properties of the heptyl ester in water. Heptyl[5] and similar alkyl esters were originally chosen for the reaction with lipases, since their hydrophobic properties simulate those of the natural substrates for these enzymes.[6] Many researchers have found that lipases incorporate the lipid boundary surface during the catalytic process.[7] Hence, it was generally accepted that compounds containing a polar region and a hydrophobic region provided suitable substrate properties for lipase-catalyzed hydrolysis.

During glycopeptide synthesis, however, we have observed that 2-morpholinoethyl esters (MoEt ester) of peptides, which do not contain any especially hydrophobic regions, are cleanly hydrolyzed by lipases.[8] This surprising result can be interpreted by postulating that complexation of the amphiphilic morpholino ester, for example with Na^+, causes the exposure of a hydrophobic surface which functions as a recognition region for the interaction with the lipase (Scheme 1).



Scheme 1.

By generalizing this interpretation we came to the conclusion that diethyleneglycol esters as well as oligo- and polyethyleneglycol esters of amino acids and peptides ought to be enzymatically cleavable protective groups.[9] To test this hypothesis, the hydrotosylates of esters **3** (2-[2-methoxyethoxy]ethyl ester; MEE) were prepared from amino acids **1** and diethyleneglycol monomethyl ether **2** by azeotropic esterification. Esters **3** were formed almost quantitatively, but the products still contained traces of **2** after drying at 80 °C under high vacuum and washing with diethyl ether. The impure products were therefore converted into the protected dipeptide esters **5** by treatment with N-protected amino acids under the usual peptide condensation conditions. The enzymatic hydrolysis of the dipeptide MEE esters **5** was carried out in water/acetone (10:1) at 37 °C; the reaction mixture was maintained at pH 7 with 0.2 M sodium phosphate buffer solution. Lipase N (Amano) from *Rhizopus niveus* proved to be suitable. Only in the case of alanyl-proline MEE ester **5d** was it necessary to use lipase CE (Amano) from *Humicola lanuginosa* (Scheme 2 and Table 1).

Scheme 2. PG = protective group, EEDQ = ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate, EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, HOBt = 1-hydroxybenzotriazole.

The MEE esters are stable under the cleavage conditions for most N-terminal protective groups. For example the Boc group in **5a** can be removed quantitatively with HCl/diethyl ether without the MEE ester bond in **7** being attacked.

In accord with this stability and the favorable solubility of the amino acid and peptide MEE esters, peptide syntheses with these components can be conducted without complications (cf. the total yields of **5** for the two-step sequence in Table 1). In lipase-catalyzed hydrolyses the MEE esters have proved to be superior to all the other esters hitherto investigated.[4, 5, 8] Thus, the completely selective and practically quantitative hydrolysis of the MEE ester **5a** was achieved with lipase N (Amano), whereas the corresponding heptyl ester[5] did not react with any of the lipases investigated. It should be emphasized that even the proline-

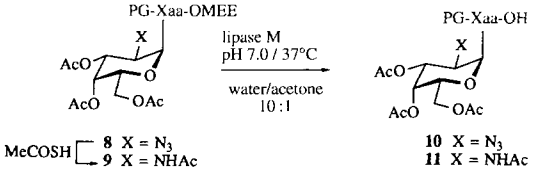


Table 1. Synthesis of amino acid MEE esters **3** from **1** and **2**, conversion of **3** with protected amino acids **4** to provide MEE esters, and the hydrolysis of **4** with lipases to give **6**.

terminated MEE ester **5d** was hydrolyzed not with lipase N but with lipase CE (Amano). **5d** is the first proline ester for which a lipase hydrolysis has been found.

To test the MEE esters in glycopeptide syntheses, the *O*-glycosyl amino acid esters **8** were prepared from serine and threonine MEE esters by the introduction of Aloc,[10] Fmoc,[11] or Z protective groups by known literature methods, and subsequent glycosylation with 2-azido-2-deoxy-3,4,6-tri-*O*-acetyl-α-D-galactopyranosyl bromide[12] or ethyl-2-azido-2-deoxy-3,4,6-tri-*O*-acetyl-β-D-1-thiogalactoside.[13] Compounds **8** were converted

into their galactosamine conjugates (T_n-antigen) **9** with thioacetic acid. The MEE esters once again have more favorable properties than the corresponding heptyl and bromoethyl esters[4, 5] in lipase-catalyzed hydrolyses (Table 2).

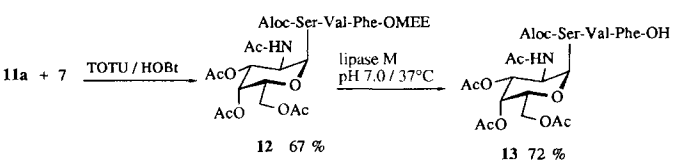

Table 2. Hydrolyses of *O*-glycosyl amino acid MEE esters **8** and **9** catalyzed by lipase M (Amano) from *Mucor javanicus* to give **10** and **11**.

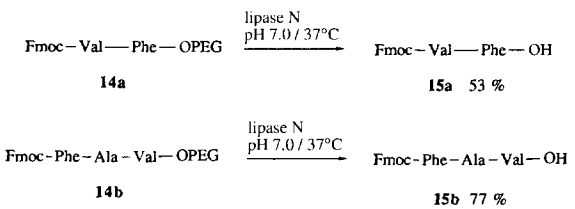
[a] The products **10a**, **10b**, and **11b** were characterized by their correct elemental analyses and 400 MHz ^{1}H NMR spectra consistent with the proposed structures. [b] (*c* 1, $CHCl_3$).

The differently protected azidogalactosyl-serine MEE esters **8a** and **8b** were hydrolyzed smoothly with lipase M to give **10a** and **10b**, respectively. The corresponding threonine MEE ester **8c** reacted too slowly for preparative purposes. The acetamidogalactosyl-serine and -threonine MEE esters **9a** and **9b**, whose heptyl and bromoethyl ester analogues showed no reactivity with lipases, were hydrolyzed sufficiently fast to be useful. This reaction was not optimized further, since in the meantime it had been shown that glycosyl amino acid MEE esters can be effectively deblocked at the C-terminus with the protease papain.[15]

For glycopeptides whose saccharide side chains are not C-terminally located, and for which deblocking with papain is restricted because of its protease activity, the lipase-catalyzed cleavage of the MEE ester is quite efficient (Scheme 3). The T_n-antigen glycopeptide ester **12** prepared from **11a** and **7** by condensation



Scheme 3. TOTU = 2-[(ethoxycarbonylcyanomethylene)amino]-1,1,3,3-tetramethyluronium tetrafluoroborate[16].

with TOTU[16] was smoothly and selectively hydrolyzed to **13**.[17] The reaction was quantitative according to thin-layer chromatography. All other protective groups and the glycosidic bond remained untouched.

Encouraged by these results we have prepared the Fmoc-peptide polyethyleneglycol esters (PEG esters) **14** by the method of Mutter and Bayer[18] and hydrolyzed them with lipase N. The loading of the polyethyleneglycol in conjugate **14** was verified by calibration with Fmoc-Phe-OH. According to the first results, the highly hydrophilic peptide PEG esters were hydrolyzed by lipases in practically neutral media. The base-sensitive Fmoc group in **15** remained intact in the polymer-free peptide.

The results obtained in lipase-catalyzed hydrolysis of polar, solubilizing MEE and PEG esters open up new possibilities in both peptide and glycopeptide syntheses as well as syntheses on polymer-bound substrates. The lipases have no protease activity and do not attack peptide linkages. The MEE esters confer wettability and solubility in water and so ensure that the esters of hydrophobic peptide sequences will be hydrolyzable. Some of these polar peptide esters, for example **14a** and **14b**, form clear

solutions in water. Their hydrolysis (see above) brings into question the general validity of the postulate that lipases are only effective on heterogeneous surfaces.[19] The exposed hydrophobic surface resulting from complexation (see Scheme 1) is obviously sufficient for the formation of the enzyme–substrate complexes with lipases. Since the hydrolyses take place in neutral media, sensitive structural elements of the deblocked products, such as protective groups and glycosidic bonds, remain intact.

Experimental Procedure

General method for the hydrolysis of MEE esters: A solution of lipase N or CE (200 mg) in 0.2 M aqueous sodium phosphate buffer (2 mL; pH 7) was stirred with phenylmethylsulfonyl fluoride (PMSF; 3.5 mg) for 1 h at 0 °C to inhibit residual protease activity. After the addition of more sodium phosphate buffer solution (18 mL), the mixture was shaken at 37 °C for another 1 h. (With lipase M this preparatory treatment is not necessary.) A solution of peptide ester **5** (0.5 mmol) in acetone (2 mL) was added dropwise to 20 mL of the lipase solution prepared as above. The mixture was well shaken for 24 h at 37 °C. The solution was saturated with NaCl and extracted five times with ethyl acetate. The combined organic phases were dried over $MgSO_4$ and concentrated. The N-protected peptide **6** was obtained by flash chromatography (petroleum ether/ethyl acetate→ethyl acetate), dissolved in diethyl ether, and converted to its dicyclohexylammonium salt. The precipitated salt was pure according to its elemental analysis and 200 MHz ^{1}H NMR spectra.

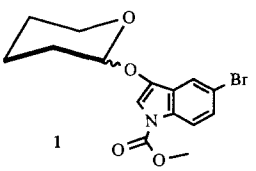
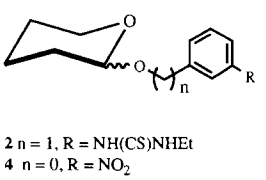
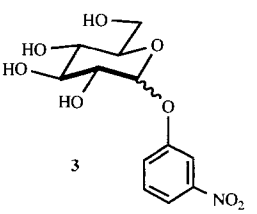
Progress toward an Antibody Glycosidase**



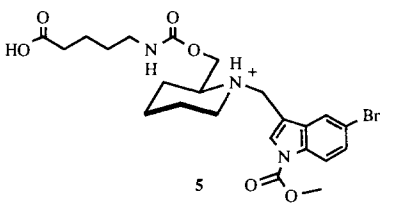
Jaehoon Yu, Linda C. Hsieh, Lynn Kochersperger, Shirlee Yonkovich, James C. Stephans, Mark A. Gallop,* and Peter G. Schultz*

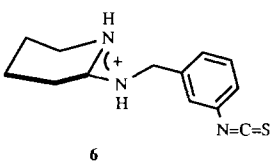


The development of catalysts for sequence-specific oligosaccharide cleavage would have a significant impact on the study of carbohydrate structure and function.[1] Catalytic antibodies may be particularly well-suited for this task, since antibody specificity may be programmed through hapten design. Mechanistic studies of enzymatic oligosaccharide hydrolysis suggest that a catalytic antibody combining site would need to stabilize the delocalized positive charge and/or the half-chair conformation of the high-energy oxocarbenium ion formed by acid-catalyzed leaving group expulsion [Eq. (a)].[2] As part of a program for generating glycosidase antibodies, we have elicited monoclonal antibodies against several transition state analogues for the hydrolysis of model acetal and glycoside substrates (**1**–**4**).

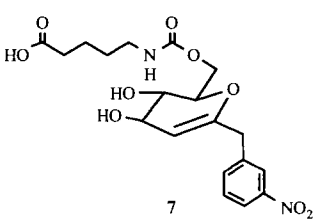


The design of hapten **5** is based on known cyclic amine glycosidase inhibitors such as nojirimycin and castanospermine.[3] The positively charged ammonium ion is expected to induce functional groups in the antibody combining site that stabilize the charge-





delocalized transition state in the hydrolysis of substrate **1** and/or assist in the acid-catalyzed expulsion of the leaving group. The 5-bromoindolyl leaving group, which is rapidly oxidized in air to form bromoindigo, provides a simple, direct assay of cell culture supernatants for catalytic activity, greatly facilitating the screening process during hybridoma production.[4] In addition, this group serves as a common recognition element between substrate and hapten to ensure substrate binding. Hapten **6** is based on the potent amidine-containing glycosidase inhibitors which are thought to mimic both the half-chair conformation and the positive charge of the high-energy oxocarbenium ion.[5] The less activated benzylic leaving group in substrate **2** ensures protonation of the amidine group in the corresponding hapten and provides the common recognition element. For comparison, antibodies were also raised against the D-galactal derivative **7**, a neutral analogue of the half-chair oxocarbenium ion intermediate formed in the hydrolysis of substrate **3**.[6]



The first step in the synthesis of hapten **5** was formylation of 5-bromoindole with $POCl_3$ in dimethylformamide (DMF), followed by protection of the indole nitrogen with dimethyl pyrocarbonate. The formyl group was then converted to the corresponding primary bromide by sequential treatment with $NaBH_4$ and PPh_3/Br_2, and the resulting bromide was used to alkylate 2-hydroxymethylpiperidine. Derivatization of the primary hy-

droxyl group with methyl 5-isocyanovalerate and subsequent saponification afforded hapten **5**. Hapten **5** was linked to carrier proteins keyhole limpet hemocyanin (KLH) and bovine serum albumin (BSA) through an *N*-hydroxysuccinimide (NHS) ester.[7] Hapten **6** was synthesized by treatment of δ-valerothiolactam with *m*-nitrobenzylamine under anhydrous methanolic conditions.[5] After acidification, the nitro group was reduced with $H_2/Pd(OH)_2$ and the resulting amine treated with thiophosgene. Hapten **6** was coupled to KLH and BSA through thiourea linkages.[8] Hapten **7** was synthesized from the coupling reaction of 1-tributylstannyl-3,4,6-tri-*O*-*tert*-butyldimethylsilylglucal with *m*-nitrobenzyl bromide using a Pd^0 catalyst, followed by desilylation with tetrabutylammonium fluoride.[9] Treatment with methyl 5-isocyanovalerate as described above afforded hapten **7**, which was coupled to KLH and BSA.[10]

Balb/c mice were immunized with the KLH conjugates of haptens **5**–**7**, and monoclonal antibodies were obtained by standard protocols.[11] Twenty-eight hybridoma cell lines specific for hapten **5**, twenty-nine specific for hapten **6**, and sixty specific for hapten **7** were isolated.

Cell culture supernatants and crude ascites from cell lines producing antibodies against hapten **5** were directly assayed for hydrolytic activity by using substrate **1**.[12] Ten monoclonal antibodies showed activity in cell culture supernatants, and eight of these antibodies retained activity in ascites fluid. One antibody, AA71.17, was characterized in further detail after purification by protein A affinity chromatography and ion (MONO-S) exchange chromatography.[13] Hydrolysis of substrate **1** by antibody AA71.17 was monitored by reversed-phase high-performance liquid chromatography (RP-HPLC) and assayed in 10 mM 2-(*N*-morpholino)ethanesulfonic acid (MES) or *N*-(2-hydroxyethyl)piperazine-*N'*-3-propanesulfonic acid (EPPS) buffer at pH 5.5, 7.0, or 8.5 with the ionic strength adjusted to 100 mM NaCl.[14] The antibody-catalyzed hydrolysis showed saturation kinetics with $k_{cat} = 0.904\ h^{-1}$ and $K_M = 324\ \mu M$ (pH 5.5), corresponding to an apparent second-order rate constant of $2.3 \times 10^3\ M^{-1}h^{-1}$ (Fig. 1). For comparison, the second-order rate constant for the background hydrolysis of substrate **1** by the general acid, AcOH, was found to be $1.3 \times 10^{-1}\ M^{-1}h^{-1}$. The antibody reaction was competitively inhibited by hapten **5**, which is consistent with the reaction occurring in the antibody combining site. Dixon analysis with hapten **5** afforded a K_i of 35 μM. The k_{cat} and K_M values at pH 7.0 and 8.5 are $k_{cat} = 0.0913\ h^{-1}$, $K_M = 154\ \mu M$ and $k_{cat} = 1.00\ h^{-1}$, $K_M = 178\ \mu M$, respectively, demonstrating that the antibody reaction is both general acid and base catalyzed. The second-order rate constant for the hydrolysis of substrate **1** by AcO^- was determined to be less than $1.6 \times 10^{-2}\ M^{-1}h^{-1}$. Chemical modification of the antibody with diazoacetamide in the absence of hapten **5** showed a 33% reduction in catalytic activity relative to antibody modification in the presence of 2 mM hapten, suggesting some involvement of an active site carboxylate group.[15]

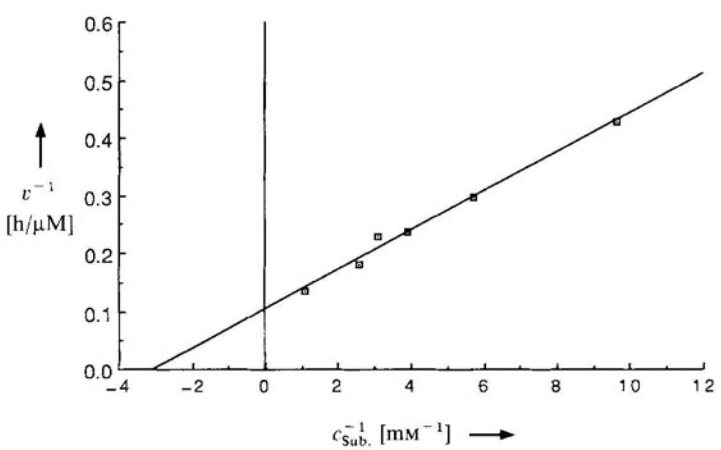

Fig. 1. Lineweaver–Burk plot for the hydrolysis of substrate **1** at pH 5.5 catalyzed by the antibody AA71.17. $c_{Sub.}$ = substrate concentration.

Twenty-nine antibodies specific for hapten **6** were purified to homogeneity as described above[13] and assayed for the ability to catalyze the hydrolysis of substrate **2** both in 50 mM MES, 50 mM NaCl, 0.02% NaN_3 at pH 5.5 and in 10 mM borate, 100 mM NaCl at pH 8.25.[16] These antibodies were also assayed using substrate **4** (pH 5.5 and 8.25), since hapten **6** might represent an "exploded" transition state analogue for the hydrolysis reaction.[16] No activity above the uncatalyzed rate was observed with either substrate. Sixty antibodies specific for hapten **7** were purified to homogeneity[13] and assayed for the ability to catalyze the hydrolysis of the α and β isomers of *m*-nitrophenyl-D-glucoside **3**.[17] Again, no activity above the uncatalyzed rate was observed.[18]

Both this study and recent work by Reymond et al. show that haptens containing a positive charge corresponding to the anomeric center of a cyclic acetal can elicit antibodies with hydrolytic activity.[19] However, two attempts to accommodate the half-chair transition state structure were unsuccessful. The absence of catalytic activity in the antibodies specific for haptens **6** and **7** may result from the fact that the planar structure of these haptens does not permit a favorable axial leaving group geometry in the corresponding substrates. In the case of hapten **7**, the difference in unsaturation compared to the oxocarbenium ion may also be significant.[20] Improvements in hapten design that better accommodate the transition state and leaving group structure should lead to antibody glycosidases. We are currently examining a number of five-membered aza sugars as haptens for oligosaccharide hydrolysis.

[12] Substrate **1** was synthesized by coupling 1-acetyl-5-bromoindole with 2-chloropyran under basic conditions followed by deacylation and purification by RP-HPLC. Cell supernatants or ascites fluid were diluted with an equal volume of MES buffer (pH 5.5) containing 2 mM substrate and 20% (v/v) DMF. After incubation at 37 °C for 12 h, indigo color was observable.

[13] a) J. Jacobs, R. Sugasawara, M. Powell, P. G. Schultz, *J. Am. Chem. Soc.* **1987**, *109*, 2174; b) K. M. Shokat, *Dissertation*, University of California, Berkeley, CA, **1991**.

[14] Assays were initiated by adding a stock solution of substrate **1** in DMF to the antibody in the assay buffer at 37 °C (final antibody concentration 6.67 μM; 20% (v/v) DMF). Hydrolysis was monitored with a Microsorb C18 reversed-phase column (4.6 mm × 25 cm) using a 10–60% acetonitrile/water gradient and an internal standard (3-nitrobenzonitrile). Reaction velocities were measured at less than 10% conversion.

[15] A. L. Grossberg, D. Pressman, *J. Am. Chem. Soc.* **1960**, *82*, 5478.

[16] Substrates **2** and **4** were synthesized by condensing 3,4-dihydro-2*H*-pyran with *m*-nitrobenzyl alcohol and *m*-nitrophenol, respectively. Hydrogenation of the former product with palladium on carbon, followed by reaction with thiophosgene in the presence of Hünig's base produced the isothiocyanate. Reaction of the isothiocyanate with ethyl amine afforded substrate **2**. Assay conditions: 6.67 μM antibody, 250 μM substrate, 10% (v/v) CH_3CN in reaction buffer, 22 °C. Product formation was monitored by RP-HPLC as described with 2,4-dimethoxybenzamide as an internal standard.

[17] Substrate **3** was synthesized by condensing α-D-glucose pentaacetate with *m*-nitrophenol in the presence of a catalytic amount of $TiCl_4$ in CH_2Cl_2 at room temperature, followed by deacylation in K_2CO_3/CH_3OH. The ratio of anomers was 3:1 (α:β). Assay conditions: 6.67 μM antibody, 2.5 mM substrate, 10% (v/v) DMF. Product formation was monitored with a Microsorb phenyl column (4.6 mm × 15 cm).

[18] Enzyme-linked immunosorbent assays (ELISAs) with substrate–BSA conjugates indicated that 71 and 63% of the antibodies against haptens **6** and **7**, respectively were capable of binding their substrates.

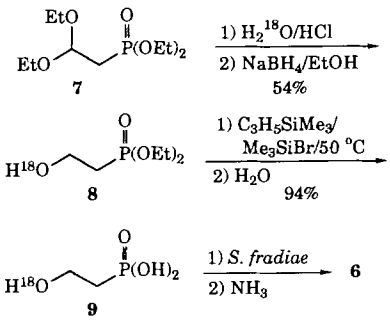
Incorporation of L-[Methyl-$^2H_3$]methionine and 2-[Hydroxy-^{18}O]hydroxyethylphosphonic Acid into Fosfomycin in *Streptomyces fradiae*—An Unusual Methyl Transfer

Friedrich Hammerschmidt*

Fosfomycin (**5**) is a clinically used antibiotic which belongs to the group of natural products with a P–C bond.[1] Its biosynthesis has two most interesting steps: the extension of a P–C_2 unit by a C_1 unit and the formation of an oxirane. The biogenesis of fosfomycin begins with the isomerization[2] of phosphoenolpyruvate (**1**) to give phosphonopyruvic acid (**2**), which presumably decarboxylates to afford phosphonoacetaldehyde (**3**),[3] which in turn is methylated to provide (*S*)-2-hydroxypropylphosphonic acid (**4**).[3–5] The latter is converted into fosfomycin (**5**); the oxirane oxygen originates from the hydroxyl group.[4] This paper provides further experimental evidence for the assumption previously made[6] that in the transformation of **3** into **4** a methyl group, formally CH_3^-, adds to the carbonyl carbon. There is no biosynthetic precedent for this step.[7]



Both the methyl group[3] of [methyl-^{14}C]methionine and the 2-hydroxy[2,2-$^2H_2$]ethylphosphonic acid (cf. **9**)[6, 8] are incorporated into fosfomycin. The latter is incorporated with retention of one of the deuteriums via a postulated aldehyde intermediate,[5, 6, 8] which is indeed plausible in the general context of biosynthesis of natural products with a P–C bond. Umpolung of the C=O functionality via a thiamine pyrophosphate adduct must be ruled out. Hence, a feeding experiment with L-[methyl-$^2H_3$]methionine (300 mg L^{-1}) with *Streptomyces fradiae* was undertaken to determine whether the methyl group was transferred intact, that is, without replacement of any of the deuteriums by protium. The fosfomycin produced (8 mg L^{-1}) was transformed into the labeled 2-amino-1-hydroxypropylphosphonic acid (**6**),[9] which was easily isolated and analyzed by NMR spectroscopy. In the ^{1}H NMR spectrum (400.1 MHz, D_2O) the pattern of signals and their integration show that **6** consists of 19% unlabeled and 81% trideuteriated compound. This can be deduced from the sharp doublet (^3J(H,H) = 7.0 Hz) at δ = 1.54 for 3-H and from the triplet (^3J(P,H) = ^3J(H,H) = 5.0 Hz) at δ = 3.72 for 2-H. In the ^{13}C{^{1}H} NMR spectrum (100.6 MHz, D_2O, sodium 4,4-dimethyl-4-silapentanesulfonate (DSS)) this result is supported by satellite doublets (isotope-induced β and γ shifts)[10] upfield for C-1 (δ = 72.917, ^1J(P,C) = 155.0 Hz, $\Delta\delta$ = 0.04) and C-2 (δ = 53.314, ^2J(P,C) = 4.5 Hz, $\Delta\delta$ = 0.16) for the labeled compound. The presence of a mono- or a dideuteriated species must be ruled out, as in the ^{1}H NMR spectrum these would give rise to additional doublets for 3-H, which would be considerably broadened through coupling with either one or two deuterium atoms. Additional satellite doublets for C-2 in the ^{13}C NMR spectrum would also be expected. Thus, the methyl group is transferred intact.

In order to determine whether phosphonoacetaldehyde (**3**) itself or another, as yet unknown, compound serves as the acceptor for the methyl group, 2-[hydroxy-^{18}O]hydroxyethylphosphonic acid (**9**) was synthesized from acetal **7** and added to the growth medium (470 mg L^{-1}). **9** is dehydrogenated by a dehydrogenase to give the aldehyde and is then taken up into the biosynthetic pathway. The ease with which oxygen exchanges in aldehydes appears to render [formyl-^{18}O]phosphonoacetaldehyde (cf. **3**) an unsuitable substrate. The half-life for the exchange of oxygen

[**] Biosynthesis of Natural Products with a P–C Bond, Part 11. This work was supported by the Fonds zur Förderung der wissenschaftlichen Forschung (Projects 8671 and 6537C). – Part 10: F. Hammerschmidt, H. Kählig, *Liebigs Ann. Chem.* **1992**, 1201–1203.

in acetaldehyde is approximately 1 min in neutral aqueous solution.[11] In the cell the [formyl-^{18}O]phosphonoacetaldehyde generated in situ should be methylated quickly before ^{18}O is completely exchanged. For the synthesis of **9**, diethyl 2,2-diethoxyethylphosphonate (**7**)[12] was hydrolyzed in $H_2{}^{18}O$ (95% ^{18}O) with HCl formed by addition of chlorotrimethylsilane. After three days the mixture (molar ratio of aldehyde **3**/acetal **7** = 1:1 after two days; ^{1}H NMR) was reduced with sodium borohydride in anhydrous ethanol. The ^{18}O-labeled hydroxyphosphonate **8** corresponded to the unlabeled compound (thin-layer chromatography (TLC), boiling point, ^{1}H NMR and IR spectra) which was obtained by the same procedure, except that H_2O was employed for the hydrolysis of **7** instead of $H_2{}^{18}O$. The electron impact (EI) mass spectrum of **7** showed that ^{16}O of the P=O bond had not been exchanged for ^{18}O.

According to the field desorption (FD) mass spectrum, the extent of labeling was at least 92%. The $^{13}C\{^1H\}$ NMR spectrum (100.6 Hz, $CDCl_3$) of the labeled compound **8** shows the C-2 doublet to be upfield (δ = 56.417, ^2J(C,P) = 4.6 Hz, $\Delta\delta$ = 0.018). **8** was treated with bromotrimethylsilane/allytrimethylsilane[9, 13] and finally hydrolyzed to give the free phosphonic acid **9**, which was added to the growth medium (470 mg L^{-1}). The labeled fosfomycin that formed (10 mg L^{-1}) was once again transformed into 2-amino-1-hydroxypropylphosphonic acid and isolated. The ^{1}H NMR spectrum (400.1 MHz, D_2O) of this material is identical to that of the unlabeled compound **6**. The $^{13}C\{^1H\}$ spectrum obtained after the addition of NaOD (30%) in D_2O[9] showed that adjacent to the doublet (δ = 78.885, ^1J(P,C = 144.7 Hz) for C-1 is a satellite doublet with the same intensity as for ^{18}O-labeled **6** which is shifted upfield by $\Delta\delta$ = 0.025. This corresponds to 50% labeling. It is evident, therefore, that the labeled phosphonoacetaldehyde has a short lifetime in the cell. According to these two experiments the methyl group is probably transferred formally as CH_3^- which, however, rules out L-methionine and (*S*)-adenosylmethionine (which deliver the methyl group formally as CH_3^+ in biological systems) as direct donors for the CH_3^- unit.[14] It is, however, assumed that the methyl group of L-methionine is transferred possibly with a corrin as an intermediate carrier (reverse formation[15] of L-methionine from methylcobalamin and homocysteine?) and from there as CH_3^- to phosphonoacetaldehyde (**3**). Seto et al. showed that the methyl group of [^{14}C-methyl]methylcobalamin is incorporated into fosfomycin by a growing culture of *Streptomyces wedmorensis*.[5] It is, however, in no way shown that this is the direct donor for the methyl group.

The two experiments described add further support to the assumption that in the biosynthesis of fosfomycin a methyl group originating from L-methionine adds to the carbonyl group of phosphonoacetaldehyde as CH_3^- by means of an umpolung step which has, until recently, been unknown. Experiments are currently underway to ascertain whether a chiral methyl group is transferred with retention or inversion of configuration.

Experimental Procedure

8: To a solution of 7 (5.08 g, 20 mmol) in $H_2{}^{18}O$ (95% ^{18}O; 1.0 g, 50 mol) was added chlorotrimethylsilane (0.51 mL, 4 mmol), and the solution was stirred for 72 h at room temperature. The mixture was then taken up in 40 mL anhydrous ethanol (pretreated with sodium) to which $NaBH_4$ (0.756 g, 20 mmol) was added in portions (exothermic reaction). After one hour glacial acetic acid (0.57 mL, 10 mmol) was added. The solution was concentrated and the residue dissolved in 30 mL water. Mannitol (4.0 g) was added and the solution was continuously extracted with ethyl acetate for 2 h. Purification by flash chromatography (eluting first with ethyl acetate, then ethyl acetate/ethanol 10/1; R_f **8** = 0.49 (in ethyl acetate/ethanol 10/1), visualized with I_2) and Kugelrohr distillation (90–100 °C/8 Torr) gave 2.0 g (54% yield) of **8** as a colorless oil. IR (film) [cm^{-1}]: ν = 3374 (OH); ^{1}H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 4.12 (m, 4H; 2 × $POCH_2$), 3.88 (dt, ^3J(P,H) = 18.7 Hz, ^3J(H,H) = 6.4 Hz, 2H; CH_2OH), 3.48 (br. s, 1H, OH), 2.07 (dd, ^2J(P,H) = 17.7 Hz, ^3J(H,H) = 6.4 Hz, 2H; PCH_2), 1.34 (t, ^3J(H,H) = 6.9 Hz, 6H; 2 × CH_3); $^{13}C\{^1H\}$ NMR (100.6 MHz, $CDCl_3$): δ = 61.694 (d, ^2J(P,C) = 6.5 Hz; $POCH_2$), 56.435 (d, ^2J(P,C) = 4.6 Hz, C-^{16}O; d for C-^{18}O shifted upfield by $\Delta\delta$ = 0.018), 29.069 (d, ^1J(P,C) = 138.0 Hz; PCH_2), 16.259 (d, ^3J(P,C) = 3.0 Hz; CH_3).

9: A solution of **8** (1.83 g, 10 mmol), bromotrimethylsilane (5.2 mL, 40 mmol), and allyltrimethylsilane (3.2 mL, 20 mmol) in anhydrous CCl_4 (20 mL) was heated for 3 h at 50 °C with exclusion of moisture. Volatile components were removed in vacuo (0.2 Torr, up to 40 °C). The residue was dissolved in 15 mL ethanol and 15 mL water and concentrated after 10 min. Water was added again twice and the solution concentrated. Finally the residue was dissolved in 30 mL water and lyophilized; 1.2 g (94% yield). The viscous oil was used directly for the feeding experiments. ^{1}H NMR (400.1 MHz, D_2O): δ = 3.95 (dt, ^3J(P,H) = 12.3 Hz, ^3J(H,H) = 7.4 Hz, 2H; CH_2OH), 2.20 (dt, ^3J(P,H) = 18.2 Hz, ^3J(P,H) = 7.4 Hz, 2H; PCH_2).

The feeding experiment with L-[methyl-$^2H_3$]methionine (300 mg L^{-1}, 99% D) and the isolation of labeled **6** were carried out according to literature procedures [9]. Six 1 L Erlenmeyer flasks, each with 220 mL medium were used. **6** was isolated by ion-exchange chromatography (Dowex 50, H^+; Dowex 50, H^+; Dowex 1, OAc; Dowex 50 H^+, 1 N HCO_2H). Yield after crystallization: 5.5 mg.

Feeding experiment with **9**: The free acid was added to the main culture before autoclaving (470 mg L^{-1}); 2 × 6 Erlenmeyer flasks. The eluates of the first Dowex-50 H^+ column were combined for further workup. Yield: 8 mg labeled **6**.

Selective Measurement of the Time-Dependence of Transient Overhauser Effects in Magnetic Resonance: Applications to Oligonucleotides**

Sébastien J. F. Vincent, Catherine Zwahlen, and Geoffrey Bodenhausen*

Ever since Anil Kumar, Wagner, Ernst, and Wüthrich[1] recorded "build-up plots" by two-dimensional nuclear Overhauser effect spectroscopy (NOESY)[2] to monitor cross-peak amplitudes a_{AX} as a function of the mixing time τ_m, it has been known that cross relaxation in macromolecules can be misleading and that the correct interpretation of NOESY experiments must take spin-diffusion effects into account.[3-6] Spin diffusion can be avoided for very short mixing times τ_m, but in this case the long-range Overhauser effects—which are crucial in order to derive structural information—are too weak to be observed. If the mixing time is increased to reveal weaker interactions, the strongest dipole–dipole couplings become so dominant that the magnetization is immediately transmitted to near neighbors through spin diffusion. A correct interpretation is possible if one considers the simultaneous effect of all cross-relaxation rates σ_{ij}, so that all transfer processes of longitudinal magnetization, both direct and indirect, are properly accounted for. This approach has come to be known as the "full relaxation matrix" method.[7] Although some authors[8-10] believe that a single high-quality NOESY spectrum obtained with a suitably chosen mixing time is sufficient, the majority of researchers appear to be convinced that extensive build-up plots hold the key to meaningful comparisons between molecular models and experiment. With the help of linear prediction and singular value decomposition methods,[11] it is possible to analyze a build-up curve corresponding to a single cross peak and decompose the envelope into its constituent exponential components.[12] This promising approach requires a good signal-to-noise ratio and a large number of τ_m increments. Unfortunately, extensive series of two-dimensional NOESY experiments are very time consuming and set stringent demands on the stability of both sample and instrument. The recording of extensive build-up curves may also tend to be neglected because various other forms of 3D spectroscopy[13] seem to be more attractive. This is why we propose to use 1D methods that can supplement the information provided by 2D NOESY spectra and give insight into the build-up behavior of a few strategically chosen cross peaks.

Figure 1 shows the pulse sequence of a one-dimensional experiment that is designed for the selective measurement of the time dependence of transient Overhauser effects, which can be adapted for the selective measurement of the decay of longitudinal magnetization (see below). The pulse sequence starts with a selective inversion of the longitudinal magnetization of a chosen source spin A, that is, $\langle I_z^A \rangle \rightarrow -\langle I_z^A \rangle$. This inversion can be achieved by using a Gaussian Q^3 cascade,[14] which must be applied at the chemical shift Ω_A of spin A. The longitudinal magnetization of A (more accurately, its deviation from thermal equilibrium) is allowed to migrate freely through cross relaxation during the interval τ_m. The cross-relaxation behavior

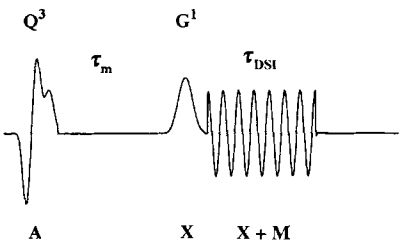

Fig. 1. Pulse sequence for selective build-up measurements of transient Overhauser effects. For details, see text. The method can be readily adapted for measuring the τ_m dependence of the amplitude a_{AA} of a diagonal peak by applying the G^1 pulse to A and transferring the magnetization from A to M′ with $\tau_{DSI} \approx 1/J_{AM'}$.

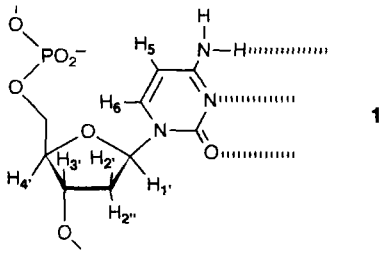
observed by our method is *exactly the same* as in a NOESY experiments.[2] A fraction of the magnetization migrates from the source spin A to a target spin X, that is, $\langle I_z^A \rangle \rightsquigarrow \langle I_z^X \rangle$. In principle, if there is no overlap between cross peaks in the NOESY spectrum, it should be possible to observe the magnetization of the X spin directly. In practice, however, limitations in the accuracy of difference spectroscopy make this difficult. Therefore, we resort to a more sophisticated scheme that is related to three-dimensional spectroscopy in the sense that there are two consecutive mixing events. At the end of the mixing period, the longitudinal component $\langle I_z^X \rangle$ of the target spin X is converted into $\langle I_x^X \rangle$ by a selective 270° Gaussian G^1 pulse,[15] and then transferred to a scalar-coupled "spy" nucleus M, that is, $\langle I_x^X \rangle \rightarrow \langle I_x^M \rangle$. This transfer can be achieved through a doubly selective homonuclear Hartmann–Hahn effect[16] during a *d*oubly *s*elective *i*rradiation period τ_{DSI}. The audio modulation of the radiofrequency field required for the transfer can be readily set up,[17] and the duration of the double irradiation can be optimized empirically in the vicinity of $\tau_{DSI} \approx 1/J_{MX}$ (shorter values of τ_{DSI} are advisable if relaxation is rapid). If the transfer efficiency is less than 100%, only the sensitivity of the experiments is affected, but not the accuracy of the build-up and decay curves. Two complementary experiments are performed, one with and one without the initial inversion pulse, and the difference spectrum is calculated. For longer τ_m values, the signals therefore tend to decay to zero like in NOESY, but in contrast to the selective inversion–recovery method[18] in which the signals asymptotically approach a nonvanishing equilibrium value. Unlike the usual NOESY technique, this method does not suffer from artifacts due to zero-quantum coherences (so-called *J* cross peaks),[19] nor can it be affected by longitudinal two-spin order.[20]

Many commentators of exchange and relaxation effects in multi-dimensional NMR spectroscopy have emphasized the fact that it would be useful to monitor the amplitudes of diagonal peaks.[5, 9, 21] In particular, Mirau[9] has pointed out that it would be possible to normalize the amplitudes of all cross peaks in a spectrum if the decay of one or several diagonal peaks could be measured accurately. Unfortunately, in most NOESY and other 2D spectra it is difficult to measure the amplitudes of crowded diagonal peaks quantitatively.[22] Although 3D spectroscopy[13] can be helpful in principle, limited digital resolution makes integration of peak volumes hazardous. Our 1D techniques can help to overcome this restriction. It is sufficient to apply, at the end of the τ_m interval, the 270° Gaussian G^1 pulse to the A spin, and then to transfer the A magnetization to a spy spin M′ through a scalar coupling $J_{AM'}$, that is, $\langle I_x^A \rangle \rightarrow \langle I_x^{M'} \rangle$. A difference spectrum is again obtained by subtracting a signal recorded without initial inversion.



We have tested our methods on oligonucleotides, because spin-diffusion effects are known to be severe in these systems,[4]

and build-up curves are therefore of particular interest.[23] Here we report measurements on the cytosine-9 residue (**1**) in the dimer of the self-complementary palindromic DNA dodecamer d(CGCGAATTCGCG). This system, which is often referred to as Dickerson's dodecamer, has been the object of extensive X-ray diffraction[24] and NMR[25, 26] studies, and has been investigated in detail by molecular dynamics.[10, 26–28]

1

Figure 2 shows build-up measurements for selected pairs of protons in **1**. The spins of C9-H1′ and C9-H3′ of the deoxyribose ring of the cytosine-9 residue **1**, as well as the proton C9-H5 of the corresponding pyrimidine base were inverted in turn. Each

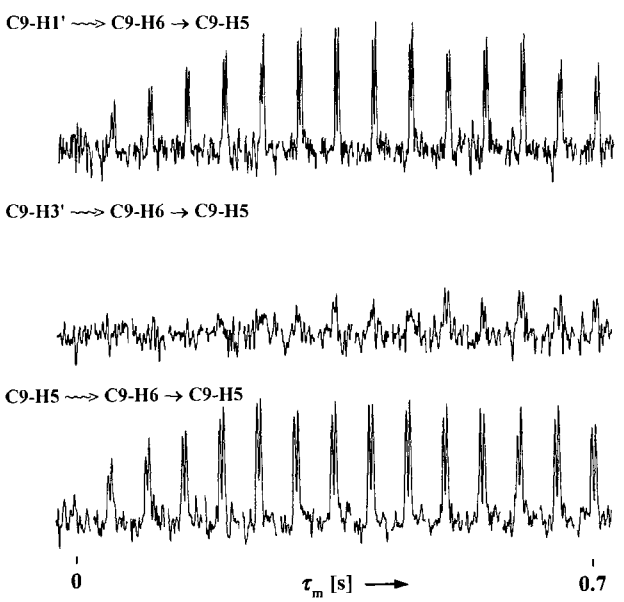

Fig. 2. Examples of selective build-up measurements of NOEs in d(CGCGAATTCGCG)$_2$, dissolved in D_2O. Conditions: $T = 303$ K, pH = 7.0, 3 mM d(CGCGAATTCGCG) monomer, 100 mM sodium chloride and 10 mM phosphate buffer, $\tau_{DSI} = 131.7$ ms. The mixing time τ_m was incremented in 50 ms steps from 0 to 0.7 s. The experiments were performed on a Bruker MSL 300 spectrometer equipped with an Oxford Research Systems selective excitation unit. For further details, see text.

of these three protons thus fulfilled the role of source spin. We then monitored cross-relaxation processes (NOE's) to the C9-H6 proton of the pyrimidine base of the same cytosine-9; the spin of this proton was the target in each case. The magnetization of the C9-H6 proton was transferred for observation through a doubly selective homonuclear Hartmann–Hahn effect to the C9-H5 proton; this pyrimidine proton acted as spy in these experiments. This latter transfer can only be used for cytosine, which has two scalar-coupled aromatic protons. Purine and thymine residues containing only one aromatic proton cannot be handled in the same manner. In these cases the same information can be obtained by observing cross relaxation in the reverse direction, that is, from the aromatic base to the deoxyribose.

It is known that symmetrically related cross peaks in NOESY spectra should have equal amplitudes.[29] This rule applies to 2D experiments that begin with a nonselective excitation pulse and involve a mixing period that is symmetrical with respect to time- and phase-reversal. At first sight, it would appear that our selective one-dimensional experiments, which are inherently asymmetrical in the time domain, need not necessarily obey this symmetry rule. In fact, the symmetry is preserved, because the physical processes taking place during the mixing period are the same as in conventional NOESY. Figure 3 shows two build-up curves resulting from cross relaxation between C9-H2′ and C9-H6 in **1**, which represent transfer processes in opposite directions. Since

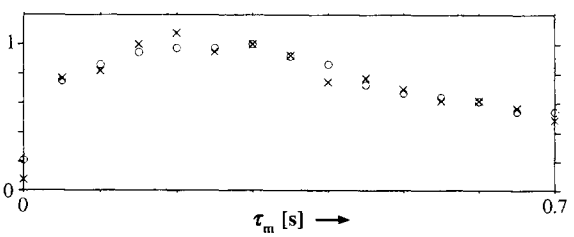

Fig. 3. Selective measurements of symmetrically related transient Overhauser effects between the C9-H6 and C9-H2′ protons of **1** in duplex d(CGCGAATTCGCG)$_2$. Circles: NOE from C9-H2′ to C9-H6 with a magnetization transfer to C9-H5 ($\tau_{DSI} = 131.7$ ms). Crosses: NOE from C9-H6 to C9-H2′ with transfer to C9-H1′ ($\tau_{DSI} = 64.8$ ms). The two series of experiments yield similar build-up curves after normalization of the vertical scale ($I_{rel} = 1$ for $\tau_m = 300$ ms). All other experimental parameters were as for Figure 2.

we observed two different protons with different multiplet structures, and since the Hartmann–Hahn transfer processes may have unequal efficiencies, the vertical scales of the two build-up curves were normalized to illustrate the equivalence of the two symmetrically related cross-relaxation processes.

It is also possible to measure NOEs between protons belonging to the same sugar residue. Figure 4 shows a build-up measurement revealing the cross-relaxation process between two geminal protons of the deoxyribose ring of **1**. The C9-H2″ proton

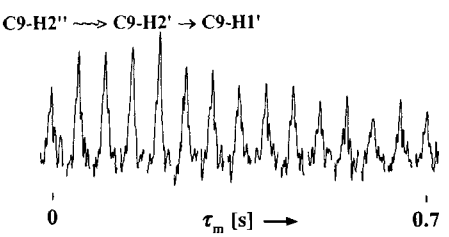

Fig. 4. Selective measurement of a transient Overhauser effect similar to Figure 2. The spin of the source proton C9-H2″ of **1** was selectively inverted, and the NOE to the neighboring target C9-H2′ proton was monitored by transferring the magnetization to the spy spin C9-H1′ ($\tau_{DSI} = 64.8$ ms). All other parameters were as for Figure 2.

played the role of source spin, while the C9-H2′ proton was the target spin, and the C9-H1′ proton the spy. The success of these procedures depends on the spread in chemical shifts of the protons under investigation. Barring near-degeneracies, we have found that it is not particularly difficult to use protons in the

same deoxyribose ring. Figure 5 shows two examples of "diagonal peak measurements" in duplex d(CGCGAATTCGCG)$_2$, obtained with the modified pulse sequence of Figure 1, described above. The magnetization was transferred from the aromatic C9-H6 proton to C9-H5 in Figure 5a, and from the C9-H2′ proton of deoxyribose to C9-H1′ in Figure 5b.

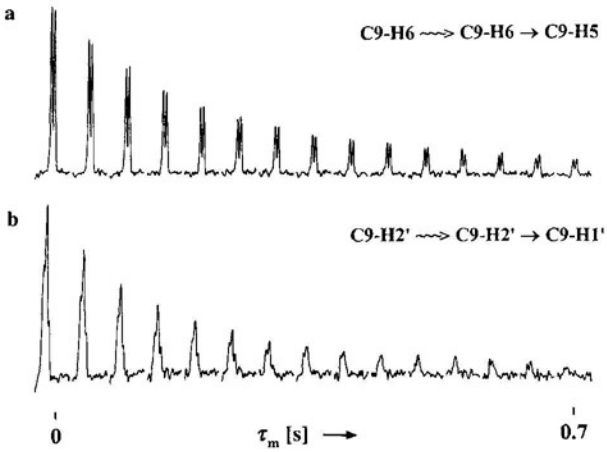

Fig. 5. Selective measurements of the τ_m dependence of the diagonal peak intensity of a) C9-H6 and b) C9-H2′ in duplex d(CGCGAATTCGCG)$_2$. The magnetization was transferred for observation in a) from C9-H6 to C9-H5 (τ_{DSI} = 131.7 ms) and in b) from C9-H2′ to C9-H1′ (τ_{DSI} = 64.8 ms). All other parameters were as for Figure 2.

The amplitudes of build-up plots such as those in Figure 2 can be compared directly with those of the molecular dynamics (MD) simulations of Withka et al.[28] The build-up curves of Figure 6a allowed us to rank the six proposed models. The "electrostatic simulation" based on the standard potential energy function of GROMOS86[30] is not satisfactory. A much better agreement can be obtained by adding harmonic constraints for the hydrogen bonds involved in Watson–Crick pairing.[28] The hypothesis of isotropic tumbling with a single correlation time τ_c of 6 ns can also be discarded on the grounds of our experiments. However, it remains difficult to distinguish between the two models of Withka et al.[28] that both consider the overall motion to be anisotropic, but in which internal motion is either excluded or included. The build-up curves for the most sophisticated model of Withka et al.[28] are reproduced in Figure 6b. With respect to our experimental observations (Fig. 6a), one significant divergence remains for the process C9-H1′ ⇝ C9-H6, which though predicted to be nearly as weak as the C9-H3′ ⇝ C9-H6 conversion, appears to be much stronger in our experiments.

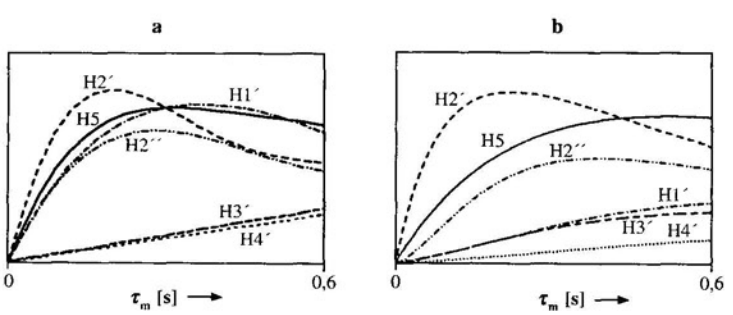

Fig. 6. a) Selective build-up measurements of NOEs to the C9-H6 proton of **1** in duplex d(CGCGAATTCGCG)$_2$. The source protons C9-H1′, C9-H2′, C9-H2″, C9-H3′, and C9-H5 of **1** were inverted in turn. Experimental conditions as for Figure 2. b) Corresponding curves, reproduced from Withka et al. [28], and obtained for the most sophisticated MD model, which includes overall anisotropy and internal motion as described in the text.

As shown in the last example of Figure 2, it is possible to set up experiments where the source and spy spins are identical. At first sight, this may appear paradoxical, but, thanks to the combination of difference spectroscopy and phase alternation, there is in fact no contradiction in this dual function. The absence of zero-quantum interference makes it possible to use nominal values of zero for τ_m. If cross relaxation is very rapid, however, (as between the geminal protons illustrated in Figure 4), and if the spectrum is so crowded that the inversion pulse must be fairly long to be selective enough, some cross relaxation will occur *during* this inversion pulse. In this case one observes a nonvanishing signal at $\tau_m = 0$. In order to ensure that even the weakest Overhauser effects emerge from the noise, all signals shown were obtained with 512 transients at 1.5 s intervals; thus, each multiplet required 13 minutes, and each of the complete build-up curves, which consist of 15 increments extending from $\tau_m = 0$ to 0.7 s, required 3.2 h. To extract similar information from conventional two-dimensional exchange NOESY experiments, one would have to run a series of 15 high-resolution NOESY spectra, taking suitable precautions to suppress J cross peaks, which would require about a week of spectrometer time. In the same time, one could record more than 50 build-up plots of the type shown in Figure 3. Of course, our one-dimensional methods are in essence selective, and only provide information on the interaction between one particular pair of protons, while a set of NOESY spectra provides information on all pairs. Yet we believe that a few strategically chosen pairs of resonances would provide sufficient evidence to test some crucial predictions made by molecular dynamics calculations.[10, 26–28]

The one-dimensional techniques presented in this paper allow one to measure the build-up and decay curves corresponding to selected peaks in NOESY. The methods can be used to refine measurements obtained by the standard 2D NOESY method and have a resolving power that is similar to 3D techniques. It is possible to monitor the build-up of Overhauser effects under conditions that are identical to those prevailing in 2D NOESY, but without the inconvenience of J cross peaks and longitudinal two-spin order. In general, one can choose the nuclei at will, subject only to the conditions that the coupling J_{MX} between the target X and the spy M should be nonvanishing, and that these two spins should have nondegenerate chemical shifts. The time-efficient manner in which the amplitudes of individual cross peaks in a NOESY survey spectrum can be quantitated lead us to dub our experiment *q*uantitative *u*nraveling of *i*ntensities for *c*orroborating *k*nowledge in *n*uclear *O*verhauser *e*ffect *s*pectroscop*y* (QUICK-NOESY). The experiment is equally applicable to proteins and other macromolecular systems including protein/DNA complexes, and to small molecules, either in isolation or bound to large receptors.

Fast Amide Cleavage under Mild Conditions: An Evolutionary Approach to Bioorganic Catalysis**

Fredric M. Menger* and Zheng X. Fei

F. Monod has written that "Nature is a tinkerer".[1] This statement might be amended to read, "Nature is a tinkerer with no time constraints." Thus, Nature has had 4.5 billion years in which to synthesize and examine, unhurredly, innumerable compounds while progressively selecting the most serviceable ones. This random search for improvement has led to a family of catalytic proteins called enzymes. Chemists attempting to imitate enzymes face, unfortunately, a seemingly unsolvable problem: the finite lifetime of human beings. Synthesizing complicated molecules with potential enzyme-like activity is a time-consuming business and, through no personal fault, chemists can survey only a limited number in the years allowed them. The evolutionary approach that has served Nature so well seems hopeless in the organic laboratory.

It occurred to us that the problem facing mortal chemists could, in small measure, be alleviated by avoidance of the covalent bond. Formation of covalent bonds is, after all, the major consumer of time when enzyme mimics are constructed. If, alternatively, mimics were assembled through noncovalent bonds, then one could test large numbers of them because noncovalent bonds establish themselves, to all intents and purposes, instantaneously.

The original idea was, therefore, to mix in water various proportions of long-chained compounds bearing at their termini an imidazole, carboxylic acid, hydroxyl, or amine functionality. Owing to hydrophobic association, the compounds would assemble into species we call "clumps". A clump is defined as a multicomponent mixture of weakly associated species, each possessing a potentially catalytic group that can function in concert with its neighbors. Literally hundreds of clumps have recently been screened, in two-minute spectrophotometric assays, for their ability to accelerate the hydrolysis of ester **1**. In this manner, we discovered systems that catalyze the hydrolysis of **1** at rates too fast to measure conventionally. Among these systems, the fastest turned out to be, to our surprise, pure hexadecanoate. Although multicomponent clumps might likely be more effective for various other reaction types (a point being tested),[2] we were so intrigued by the fast hexadecanoate-induced hydrolyses that we continued their study using a less reactive substrate, amide **2**. Before the kinetic details are given, a word should be said about amide hydrolyses.

1 **2**

Amide hydrolysis is widespread in biological systems, but that is not the only reason the reaction has, over the years, attracted the attention of bioorganic chemists.[3–8] Amides are resonance-stabilized entities and difficult to hydrolyze. For example, a typical chemical procedure for hydrolyzing aliphatic amides calls for heating in 8 N HCl at reflux for ten hours.[9] Thus, amides present a special challenge to those interested in catalyzing reactions of recalcitrant functionalities. Until now the challenge has been met mainly by intramolecular catalysis[3–8] including an example of our own (i.e. an amide of Kemp's triacid that hydrolyzes with a $\geq 10^{12}$ acceleration).[10] But these enzyme mimics rely on the juxaposition between amide and catalytic group that is enforced by covalent bonds and is imparted to the molecule during its synthesis.[11] Enzymes, of course, do not have this advantage; they must operate by means of noncovalent association at their active sites. Thus, it would be desirable to find an enzyme mimic that splits amides under biological conditions in the absence of "covalent assistance". The hydrophobic clumping of **2** with hexadecanoate, and the subsequent fast reaction, provides an example of such enzyme-like behavior.

[**] This work was supported by the National Science Foundation.

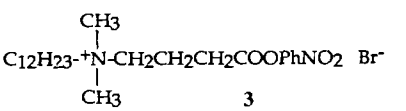
Hydrophobic association of a substrate to a catalyst, leading to enhanced rates, has been known for a long time. Three old but classical studies can be mentioned as examples. Wagner et al.[12] reported that a long-chained *p*-nitrophenyl carbonate ester is hydrolyzed by *N*-stearoylhistidine about 2000 times faster than by *N*-acetylhistidine. Gitler and Ochoa-Solano[13] found that micellar *N*-myristoylhistidine hydrolyzes *p*-nitrophenyl hexanoate about 20 times faster than *p*-nitrophenyl acetate. And Moss et al.[14] observed that a long-chained imidazole derivative is a 200-fold better catalyst than imidazole in the hydrolysis of *p*-nitrophenyl hexanoate. It is now known that *p*-nitrophenyl esters are not realistic surrogates for amides.[15]

Lerner et al.,[16] in an effort to "develop catalytic antibodies that can catalyze reactions that are energetically more demanding", studied, as we did, the hydrolysis of a *p*-nitrophenyl amide. The success of their biological screening as compared to our chemical screening will be discussed momentarily.

Amide **2** is an inherently stable molecule. It was unchanged after 27 days at pH 8.0 and 25.0 °C (as indicated by a flat curve in a plot of absorbance (at 390 nm) vs. time). If a finite rate was created by deliberately imparting a small slope to the plot, then a reaction half-life of about a year could be obtained (Table 1). In reality, of course, the half-life must be even longer. When amide **2** (2×10^{-5} M) was dissolved in a buffer solution at pH 8 and 25.0 °C containing 0.2 M sodium acetate, no reaction was observed after 45 h. Acetate is worthless as a catalyst even at high concentrations.

Table 1. Kinetic data[a] on the amide cleavage of amide **2** (2×10^{-5} M) in water at 25.0 °C.

Catalyst	[Catalyst] [M]	pH [b]	k_{obs} [min^{-1}]	Half-life
–		8.0		> 1 year
acetate	0.20	7.0		> 450 h
hexadecanoate	2×10^{-5}	8.0	0.22	3.1 min
hexadecanoate	1×10^{-5}	8.0	0.12	5.8 min
hexadecanoate	5×10^{-6}	8.0	0.067	10 min
hexadecanoate	2×10^{-5}	5.0	0.11	6.3 min
hexadecanoate	2×10^{-5}	9.0	0.22	3.1 min
dodecanoate	2×10^{-5}	8.0	0.00082	840 min



[a] Rate constants represent the average of at least two runs and are accurate to ±6%. The kinetics were cleanly first order for two half-lives, indicative of "pseudo-intramolecular" reactivity within the clumps to which the reactants remain totally bound. [b] System is insoluble at pH 4.0. Solutions at pH 7.0 and 8.0 were prepared with 0.05 M phosphate. Solutions at pH 5.0 and 9.0 were prepared with 0.05 M phthalate and 0.1 M borate, respectively.

When 2×10^{-5} M amide **2** was mixed with 2×10^{-5} M hexadecanoate (pH 8.0, 25.0 °C), the observed rate constant k_{obs} was found to equal 0.22 min^{-1}, corresponding to a half-life of 3 min (Table 1). In order to estimate the acceleration induced by hexadecanoate, we assumed (conservatively) that the half-life of the 0.2 M acetate system is 450 h. Thus, when concentration differences are taken into consideration, hexadecanoate is seen to be at least 10^8 times more effective than acetate (a number obtained from $[450 \times 60]/3$ multiplied by $0.2/2 \times 10^{-5}$). The acceleration by hexadecanoate relative to acetate-free buffer is an incalculably large number. Clearly, hexadecanoate catalysis at enzyme-like concentrations rivals or exceeds that found in many of the better covalently enforced intramolecular catalysts.[11]

A pH–rate profile of amide **2** and hexadecanoate (2×10^{-5} M of each) (not shown) revealed only a twofold variation between pH 5 and 9. Hexadecanoic acid must function primarily in the carboxylate form. Importantly, the rate constant diminished to 8.2×10^{-4} min^{-1} (a 256-fold decrease) when 2×10^{-5} M dodecanoate was used in place of 2×10^{-5} M hexadecanoate (Table 1). The simplest explanation is that catalysis proceeds in hexadecanoate clumps induced, very likely, by the presence of cationic **2**. Dodecanoate has, presumably, too short a chain to aggregate at the extremely low concentration used in the experiments. Mixed clumps of **2** and hexadecanoate were undetectable by dynamic light scattering under kinetic conditions owing to the low concentrations of the components. It is known, however, that mixtures of oppositely charged amphiphiles form tight complexes that often develop into vesicles[17] or coacervates[18] at higher concentrations.

A precipitate forms when 2×10^{-5} M amide **2** is mixed with $> 3 \times 10^{-5}$ M hexadecanoate, reaffirming our contention that catalysis arises from complex formation. Although solubility problems prevented an examination of reaction molecularity and kinetics over a wide concentration range, we were able to ascertain that the rate constants decrease proportionally to the concentration of hexadecanoate as the latter is reduced from 2×10^{-5} to 5×10^{-6} M (Table 1). The infinity absorbance also decreased proportionally, indicating that the reaction between amide **2** and hexadecanoate is stoichiometric. Apparently, formation of a mixed anhydride intermediate prevents turnover. In other words, amide cleavage is so fast within the clump that anhydride hydrolysis is actually rate-limiting in the overall amide hydrolysis.[19]

The hexadecanoate catalyst also possesses a degree of substrate specificity. Thus, no amide cleavage was observed with amide **3**, a close analogue of amide **2**. Lack of reaction could arise from a diminished inductive activation of the carbonyl group in **3** as well as from improper positioning of the amide group, relative to the carboxylate function, within the clump.

3

How does our system compare with an antibody-catalyzed hydrolysis of a *p*-nitrophenyl amide?[16] The k_{cat} for the antibody reaction is 0.05 min^{-1}, decidedly smaller that our k_{obs} of 0.2 min^{-1}. Moreover, the antibody experiments were carried out under more severe conditions (pH 9.0, 37 °C) than ours (pH 7–8, 25 °C). On the other hand, amide **2** is activated by an ammonium group, unlike the substrate used in the antibody work. On balance, one might tentatively conclude that the two rates are comparable, and that a "hopeful search" through a random collection of clumps is no less profitable than a "hopeful search" through a random collection of antibodies.

In summary, a peptidase "model" has been developed in which low concentrations of catalyst (ca. 10^{-5} M) induce large rate enhancements (ca. 10^8) in an amide substrate. Reaction rates are highly sensitive to the structure of both the substrate and catalyst. We surmise that hydrophobic binding, in cooperation with electrostatic attraction between the carboxylate group and cationic nitrogen center, enforces an intimate contact between the carboxylate function and the amide's carbonyl group prior to actual reaction. This is totally consistent with the observed first-order kinetics (Table 1), the structural specificity, and the known tendency for oppositely charged amphiphiles to complex tightly with each other.[17, 18] Note that we have al-

ready expressed our view that prolonged contact at close distances holds the key to the reactivity of both enzymes and enzyme models.[20, 21]

Multicomponent clumps are being investigated as catalysts for diverse organic reactions by using the same screening procedure that uncovered the fast amide hydrolysis.[2] There is an amusing parallel here to biological evolution: The randomly created clumps correspond to random mutations; our selecting clumps with the fastest rates corresponds to natural selection of the fittest; and (to push the analogy to its limits) the publishing of our best clumps corresponds to the passing on of the most advantageous traits to future generations.

Experimental Procedure

Amide **2** was synthesized following the reaction $C_{12}H_{25}N(CH_3)_2 + BrCH_2COOCH_3 \rightarrow C_{12}H_{25}\overset{+}{N}(CH_3)_2CH_2COOCH_3Br^- = RCOOCH_3 \rightarrow RCOOH \rightarrow RCOBr \rightarrow RCONHPhNO_2$ (*para* isomer). After three recrystallizations amide **2** had a m.p. of 213–214 °C; the spectroscopic data (^1H NMR, FAB-MS, IR) and elemental analysis were consistent with the given structure. Reactions were monitored at 390 nm by using a Varian DMS 200 spectrophotometer with a cell chamber thermostated at 25.0 ± 0.1 °C. The solvent consisted of 3% CH_3CN in an aqueous phosphate buffer.

Conformational Effects on the Redox Potentials of Tetraarylporphyrins Halogenated at the β-Pyrrole Positions**

Philippe Ochsenbein, Khadija Ayougou, Dominique Mandon, Jean Fischer, Raymond Weiss,* Rachel N. Austin, Karupiah Jayaraj, Avram Gold, James Terner, and Jack Fajer

Porphyrins with alkyl substituents in the β-positions of the pyrroles are easier to oxidize and harder to reduce than porphyrins bearing phenyl substituents at the *meso* positions.[1] Nickel(II) and zinc(II) derivatives of β-alkyl-substituted tetraphenylporphyrins, which are hybrids of these two major types, adopt saddle conformations and are more easily oxidized than the corresponding octaethyl- or tetraphenylporphyrins, in accord with the theoretically predicted destabilization of the π system resulting from the saddle distortion.[2, 3] In contrast, tetraphenylporphyrins that are partially halogenated at the pyrrole β-positions are easier to reduce and harder to oxidize than the nonhalogenated parent macrocycle.[4] To gain insights into the relationship between the redox potentials of tetraarylporphyrins halogenated at the β-positions of the pyrroles and substituent-induced changes in macrocycle conformation, we have investigated the electrochemical properties and crystal structures of 5,10,15,20-tetramesitylporphyrin **1**,[5] derivatives **2** and **3**[6] halogenated at antipodal pyrrole β-positions (7,8,17,18), and derivatives **4** and **5**[7] halogenated at *all* β-pyrrole positions (2,3,7,8,12,13,17,18). The observation that the octahalogenated macrocycles are easier to oxidize than the te-

trahalogenated derivatives is rationalized by the effects of distortion of the porphyrin framework.

The crystal structures of **2** and **3** have a center of symmetry and hence at least C_i symmetry.[8] As a consequence, they are not saddle-shaped but show a slightly distorted chairlike conformation (Fig. 1). The two opposite halogenated pyrrole rings are tilted up and down with respect to the mean plane of the porphyrin framework and are also twisted around their median lines, whereas the nonhalogenated rings are only twisted. Both β-carbon atoms of the halogenated pyrrole rings lie above or below the porphyrin mean plane; their average displacements are 0.03(1) Å in **2** and 0.105(6) Å in **3**. The β-carbon atoms of the nonhalogenated rings have corresponding average displacements of 0.02(2) Å in **2** and 0.050(6) Å in **3**. Difference electron density maps of **3** and ^{1}H NMR studies of **2** and **3** in CD_2Cl_2 show that the two NH protons are located on the nonhalogenated pyrrole rings, in agreement with a previous study of β-tetrabrominated tetraarylporphyrins.[6]

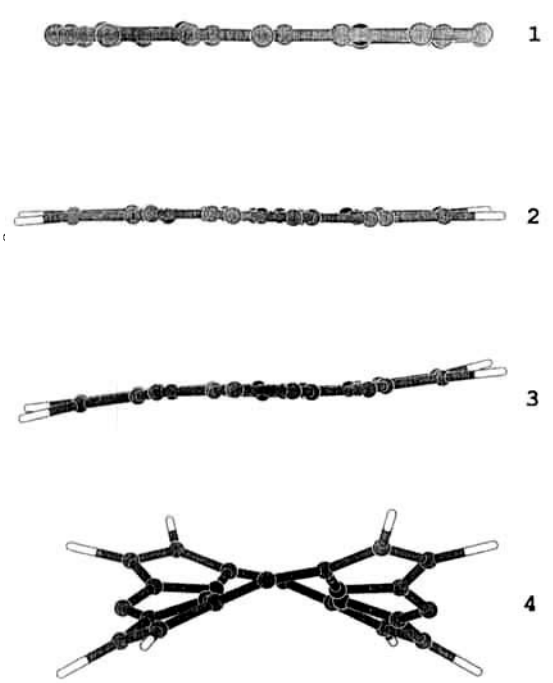

Fig. 1. Edge-on views of the skeletons of tetramesitylporphyrin **1**, the antipodal tetrasubstituted derivatives **2** and **3**, and the octachloro derivative **4** (the *meso*-mesityl groups are omitted for clarity).

As in the crystal structure of **5**,[7] the macrocycle **4** lies on a crystallographic fourfold inversion axis and hence has S_4 symmetry.[8] Since the two NH groups preclude symmetry higher than C_2, two tautomeric forms must be disordered around the S_4 axis. Porphyrin **4** is also clearly saddle-shaped;[8] alternate pyrrole rings are tilted severely up or down relative to the porphyrin mean plane and are also twisted about their median lines (Fig. 1). The average displacement of the β-carbon atoms of one pyrrole ring relative to the porphyrin mean plane is 0.905(5) Å in **4**, compared to 0.95(2) Å in **5**.[7] The mesityl rings are twisted into the porphyrin mean plane to minimize unfavorable contacts with the β-pyrrole substituents. The average dihedral angle between the two planes is 58.1(1)° in **4** and 58.6(6)° in **5**. The corresponding values of 83.6(3)° in **2** and 84.9(1)° in **3** are close to the angle of 83.6(1)° found in **1**. Unfavorable contacts are minimized in the tetrahalogenated macrocycles by increasing the $(X\text{-}C_\beta)C_z\text{-}C_m\text{-}C_{Ph}$ angle relative to the $(H\text{-}C_\beta)C_z\text{-}C_m\text{-}C_{Ph}$ complement. The mean values of these angles are 120.8(4)° and 113.9(4)° in **2** and 122.2(2)° and 112.4(2)° in **3**, respectively.

The smallest ruffling of the porphyrin ring occurs in **1**, where the average displacement of the C_m carbon atoms with respect to the porphyrin mean plane is only 0.015(4) Å (Fig. 1).[8] The tetrahalogenated tetramesitylporphyrins are slightly more ruffled; the *meso*-carbon atoms lie 0.04(1) Å above (and below) the porphyrin mean plane in **2** and 0.087(6) Å in **3**. Ruffling is most pronounced in the octahalogenated porphyrins **4** and **5**, where the displacement of the *meso*-carbon atoms relative to the porphyrin mean plane is 0.322(5) Å and 0.30(2) Å, respectively.

The experimental one-electron redox potentials $E_{ox}^{1/2}$ and $E_{red}^{1/2}$ were determined by cyclic voltammetry for **1**–**5** (Table 1). Substitution at the pyrrole β-positions with electron-withdrawing groups makes the porphyrins easier to reduce and harder to oxidize than the parent tetramesitylporphyrin. The differences in the reduction potentials $\Delta E_{red}^{1/2}$ for **1**/**2**, **1**/**3**, **2**/**4**, and **3**/**5** range from +0.25 to +0.32 V. While the difference in the oxidation potentials $\Delta E_{ox}^{1/2}$ for **1**/**2** and **1**/**3** are positive (though somewhat smaller than the values of $\Delta E_{red}^{1/2}$), the $\Delta E_{ox}^{1/2}$ values are negative for **2**/**4** (−0.10 V) and **3**/**5** (−0.13 V) indicating that the octahalogenated porphyrins **4** and **5** are easier to oxidize than the tetrahalogenated derivatives **2** and **3**, in spite of the additional β-halogen substituents.

Table 1. Redox potentials determined by cyclic voltammetry [a].

Porphyrin	Halogen substituents	$E_{red}^{1/2}$	$\Delta E_{red}^{1/2}$	$E_{ox}^{1/2}$	$\Delta E_{ox}^{1/2}$
1	–	−1.41		+0.91	
			+0.29		+0.24
2	4 Cl	−1.12		+1.15

[a] $E^{1/2}$ in V; solvent CH_2Cl_2, electrolyte NBu_4PF_6 (0.1 mol L^{-1}) vs. SCE, scan rate 200 mV s^{-1}, T = 25 °C.

The one-electron redox potentials of porphyrins reflect the energy levels of their HOMOs and LUMOs.[3] INDO calculations on tetraphenylporphyrins octaalkyl-substituted at the pyrrole β-positions have shown that saddle distortions of the macrocycle decrease the energy gap between the HOMOs and LUMOs by raising the energy of the HOMOs.[2] Thus, β-alkyl substitution decreases $E_{ox}^{1/2}$, while $E_{red}^{1/2}$ is almost unchanged.[3] The data in Table 1 shows that the electron-withdrawing β-halogen substituents stabilize the LUMOs and, to a slightly lesser degree, the HOMOs. The negative values of $\Delta E_{ox}^{1/2}$ for **2**/**4** and **3**/**5** can be explained if the energy decrease in the HOMOs of **4** and **5** expected from substitution with additional electron-withdrawing halogens is offset by the saddle distortion. That the saddle distortions observed in the solid state are maintained in solution is evidenced by the strongly red-shifted Soret and Q absorption bands of **4** and **5** and shifts of the ν_2 marker bands in the resonance Raman spectra of the molecules.[9, 10]

Experimental Procedure

1 was prepared according to a published procedure [5]. Single crystals of **1** · $2CHCl_3$ were obtained by slow diffusion of hexane into a solution of the porphyrin in

chloroform. Crystal data (−100 °C, dark blue crystal of dimensions $0.30 \times 0.30 \times 0.22$ mm): $C_{58}H_{36}N_4Cl_6$, $M = 1021.8$, tetragonal, space group $I4_1/a$, $a = 27.093(8)$, $c = 14.876(6)$ Å, $V = 10919.4$ Å^3, $Z = 8$, $\varrho_{calcd} = 1.246$ g cm^{-3}, $\lambda(CuK_\alpha) = 1.5418$ Å, 4269 reflections ($3° < \theta < 52°$) were collected; empirical absorption corrections were applied, 2337 reflections with $I > 3\,\sigma(I)$ were used in the refinements; number of parameters 337, $R = 0.064$, $R_w = 0.089$, GOF = 1.45, final residual electron density = 0.21 e Å^{-3}.

2: **1** (100 mg) was treated with 5.4 equiv of *N*-chlorosuccinimide in boiling 1,1,2,2-tetrachloroethane (30 mL) for 60 h. The crude reaction product was purified twice by chromatography on a SiO_2 column, first eluting with toluene and then with toluene/hexane (1:1). The product was recrystallized by slow addition of methanol to solution of the compound in chloroform. Yield: 59%. UV/VIS (CH_2Cl_2, 25 °C): λ_{max} (ε [mol^{-1} L cm^{-1}]) = 426 (231), 522 (19.5), 598.5 (6.8), 654.5 nm (8.0). Single crystals of **2** · $4CHCl_3$ were obtained by slow diffusion of methanol into a solution of the porphyrin in chloroform. Crystal data (−100 °C, red-purple crystal of dimensions $0.15 \times 0.20 \times 0.32$ mm): $C_{60}H_{54}N_4Cl_{16}$, $M = 1398.4$, triclinic, space group $P\bar{1}$, $a = 11.182(3)$, $b = 12.078(3)$, $c = 13.501(4)$ Å, $\alpha = 74.57(2)$, $\beta = 67.59(2)$, $\gamma = 87.87(2)$, $V = 1620.8$ Å^3, $Z = 1$, $\varrho_{calcd} = 1.433$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.7107$ Å, 4475 reflections ($2° < \theta < 23°$) were collected; empirical absorption corrections were applied, 1712 reflections with $I > 3\,\sigma(I)$ were used in the refinements; number of parameters 266, $R = 0.093$, $R_w = 0.116$, GOF = 2.02, final residual electron density = 0.81 e Å^{-3}.

3 was obtained according to a published procedure for tetraarylporphyrins [6]. UV/VIS (CH_2Cl_2, 25 °C): λ_{max} (ε [mol^{-1} L cm^{-1}]) = 430 (214), 525.5 (20.3), 604 (8.0), 660.5 nm (9.0). Single crystals of [**3** · $2Cl_2CH_2$] were obtained by slow diffusion of pentane into solution of the porphyrin in dichloromethane. Crystal data (−100 °C, black crystal of dimensions $0.13 \times 0.20 \times 0.38$ mm): $C_{58}H_{54}N_4Br_4Cl_4$, $M = 1268.5$, monoclinic, space group $P2_1/n$, $a = 11.413(3)$, $b = 17.856(5)$, $c = 13.736(4)$ Å, $\beta = 102.40(2)$°, $V = 2731.1$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.436$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.7107$ Å; 5189 reflections ($2° < \theta < 25°$) were collected; empirical absorption corrections were applied, 3030 reflections with $I > 3\,\sigma(I)$ were used in the refinements; number of parameters 319, $R = 0.052$, $R_w = 0.075$, GOF = 1.58, final residual electron density = 0.31 e Å^{-3}.

4: The zinc salt of **1** (200 mg) was treated with 70 equiv of *N*-chlorosuccinimide in refluxing tetrachloroethylene (200 mL) for 17 h. The crude product was purified by chromatography on a SiO_2 column eluting with dichloromethane/hexane (1:1). The complex was demetalated by stirring in 10% v/v trifluoroacetic acid in dichloromethane for 23 h. Yield: 34%. Single crystals of **4** · $2CH_3OH$ were obtained by slow diffusion of hexane into a solution of the porphyrin in dichloromethane/methanol. Crystal data (−100 °C, black crystal of dimensions $0.15 \times 0.25 \times 0.40$ mm): $C_{58}H_{54}N_4Cl_8O_2$, $M = 1122.7$, tetragonal, space group $P\bar{4}2_1c$, $a = 15.011(4)$, $c = 13.289(3)$ Å, $V = 2994.4$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.206$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.7107$ Å, 4851 reflections ($2° < \theta < 29°$) were collected; empirical absorption corrections were applied, 1257 reflections with $I > 3\,\sigma(I)$ were used in the refinements; number of parameters 172, $R = 0.044$, $R_w = 0.058$, GOF = 1.12, final residual electron density = 0.43 e Å^{-3}.

The Effect of Chiral Bilayers: Wax Tubes Made of (*S*)-Nonacosan-10-ol**

Jürgen-Hinrich Fuhrhop,* Thomas Bedurke, Airan Hahn, Siegfried Grund, Jürgen Gatzmann, and Markus Riederer

The CO_2/O_2 gaseous exchange in pine needles and similar lipophilic leaf structures occurs through stomata which are covered by a dense mesh of lipid tubes.[1] These tubes have internal diameters of 0.1–0.5 μm and consist of hydrophobic wax with an extremely high content of hydrocarbon units.[2, 3] The function of these tubes is presumably to filter off suspended particles from the air, which —if they have accumulated despite this— may be washed off the smooth, hydrophobic surface by rain. Whereas pine needles from healthy trees keep their tube system intact for six years, the tube system of diseased trees breaks down within months.[4] The stomata become blocked by the lipids of the tubes. We are interested in whether the curvature of the tubes is related to the chirality of their constituents.[5]

The main component of the lipid tubes that are pressed out through the wax cuticle (Fig. 1a) is the secondary alcohol nona-

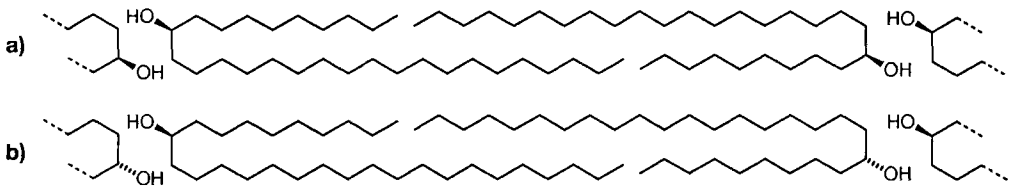

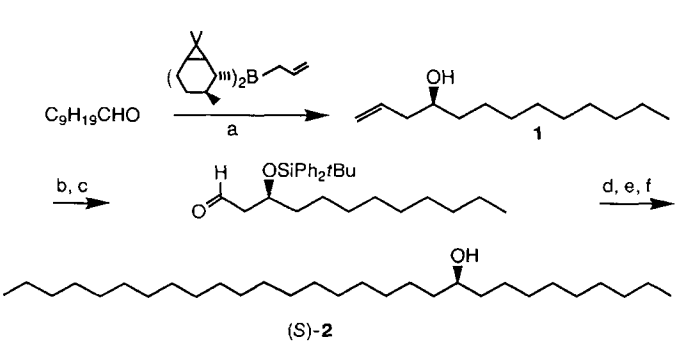

Fig. 2. Model of the molecular bilayer made of (*S*)-nonacosan-10-ol (a) and racemic (*R,S*)-nonacosan-10-ol (b). Curved bilayers are formed from (*S*)-**2** and planar bilayers from *rac*-**2**.

cosan-10-ol (**2**).[6] It is not known whether the natural substance nonacosanol is a pure enantiomer.[7] Attempts to separate a synthesized racemate chromatographically by means of diastereomeric derivatives such as (1-naphthylethyl)carbamate failed, as did attempts at differentiation by NMR spectroscopy. The carbon chains at the asymmetric center, of **2** with nine and nineteen neighboring methylene groups are too similar to be able to be differentiated chemically or spectroscopically.[7] We could repeat the experiment already described[8] to produce thin lipid tubes from the natural product nonacosanol by evaporating solutions of the natural material in chloroform (Fig. 1 b). However, use of the racemate obtained by a Grignard reaction (Fig. 1 c) produced only interlocked platelets without curvature. The same result was obtained with many other racemic alcohols of different chain lengths.

In order to provide evidence that the curvature of the tubes depends on the chirality of the alcohol component we finally carried out a moderately stereoselective synthesis of **2** by an allylboration as described by Brown (Scheme 1).[9] The enantiomeric excess of 76% could not be increased despite many attempts because the long chain starting material did not react at the low reaction temperatures (3 h at $-78\,^{\circ}C$) in the original procedure. Within 17 hours the desired tridecanol **1** formed with a yield of only 22% at $-50\,^{\circ}C$ with an enantiomeric excess of 76% (S:R = 8:1). The impure (*S*)-nonacosan-10-ol (*S*)-**2** that was finally obtained was, however, completely sufficient for our purposes.[7, 10] This was then "crystallized" from chloroform under identical conditions to the racemate, and tubes did in fact form (Fig. 1 d).

How does the curvature of the tubes of this extremely simple chiral compound arise and why is it not found in the crystallized racemate *rac*-**2**? As the structure of **2** is so simple, the explanation of these questions may also be readily deduced despite the lack of knowledge of diffraction data which can not be obtained from the wax: The hydroxy groups and the short and long chains of **2** will, of course, be located together (Fig. 2). The resulting bilayer of (*S*)-**2** has all OH groups on one side, and methine protons on the other. The bilayer curves in this case because of unsymmetrical molecular interactions. In the racemate of **2** one hydroxy group is located on each side of the bilayer in a uniform molecular arrangement.

To our knowledge, this case is the simplest curvature-producing effect of chiral bilayers for amphiphiles.[5] It is characteristic that it is produced by the interaction of hydroxy groups in an apolar medium in which the intermolecular association at the center of chirality is less influenced by solvation than it is in water. This case is similar to the helices of 11-hydroxystearates produced by Tachibana et al. in toluene.[11] Kunitake et al. have converted glutamate ester with cationic head groups into helical fibers in water,[12] and we could prepare not only helices from gluconamides in aqueous media[5, 13] but also tubes in xylene.[14] In all four cases the racemates formed crystalline platelets under identical conditions. The spontaneous curvature of molecular bilayers and the chirality of their amphilic building blocks are therefore closely related to each other. There is incidentally also a quantitative physical description of this in the form of an equation for the energy of curvature.[15] The case described here is particularly noteworthy because, firstly, the tube structure occurs in nature, and secondly, it may be attributed to a molecular asymmetry which only becomes effective at a great distance from the center of chirality. In solution it is hardly detectable; however, it determines the structure in the case of molecular assemblies.

Scheme 1. a) Et_2O, 17 h, $-50\,^{\circ}C$ (instead of $-78\,^{\circ}C$), 22% yields based on decanal; b) THF, imidazole, *t*BuPh$_2$SiCl, 48 h, 40 °C (73%); c) 1. [7] Tris[3-(2,2,2-trifluoro-1-hydroxyethylidene)-D-camphorato]europium was used as shift reagent in chloroform. The signals for the terminal allyl alcohol reproduced in Scheme 1 occurred at $\delta = 5.5-6.0$ and split into four doublets of equal intensities in the racemate. In the synthesized *S* isomer we found two similar signal groups in a ratio of 8:1. Racemic (*S,R*)-**2**, on the other hand, produced no such splitting of the signals.

[10] The *S* configuration was established by comparison of the angles of optical rotation ($[\alpha]_D^{25} = -8.5$ (benzene)) with a corresponding literature value (H. Riediker, R. D. Duthaler, *Angew. Chem.* **1989**, *101*, 488–490; *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 494–495) and following predictions of H. C. Brown [9]. For natural 10-nonacosanol and $[\alpha]_D^{25}$ (chloroform) values of 1.9 and 2.2 were reported (S. Beckmann, H. Schinkle, *Z. Naturforsch. B* **1968**, *23*, 471). We found values of 0.33 and 0.30 for the synthetic (*S*)-nonacosanol. The common positive sign of the rotation angles for the natural and synthetic alcohols suggest an *S* configuration also for the natural compound. Since the angle of rotation is so small, the conclusion is uncertain. Attempts to crystallize diastereomeric derivatives failed. Only a molecular structure determination of such a diastereomer could establish the chirality of the natural product.

The Biosynthesis of Nitro Compounds: The Enzymatic Oxidation to Pyrrolnitrin of Its Amino-Substituted Precursor**

Sabine Kirner and Karl-Heinz van Pée*

Several of the naturally occurring nitro compounds are biologically active, and the nitro group plays an important role in their activity. In the biosynthesis of the antibiotics chloramphenicol[1] and pyrrolnitrin **5**,[2] the nitro group is formed in the final step, by oxidation of an amino group, but till now nothing has been reported about the enzymes that catalyze this oxidation. Here we describe the oxidation of the precursor **4** to pyrrolnitrin **5** by chloroperoxidase (CPO-P) from *Pseudomonas pyrrocinia*.[3]

Compound **5** is an antifungal agent which is produced by several species of soil bacteria. The biosynthesis of **5** has not yet been fully elucidated (Fig. 1), but contains two chlorination steps and the oxidation of an amino group to a nitro group.

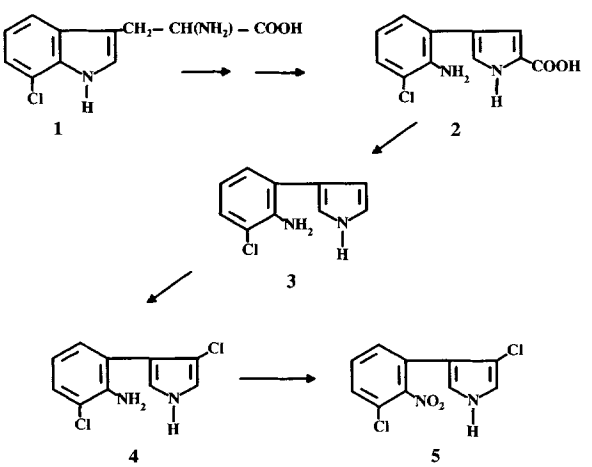

Fig. 1. Hypothetical biosynthetic pathway according to van Pée et al. [2]. **1**, 7-chlorotryptophan; **2**, 4-(2-amino-3-chlorophenyl)pyrrole-2-carboxylic acid; **3**, 3-(2-amino-3-chlorophenyl)pyrrole; **4**, 3-(2-amino-3-chlorophenyl)-4-chloropyrrole; **5**, pyrrolnitrin.

Investigations by the research group of Itoh[4] on a partially purified bromoperoxidase from a *Pseudomonas putida* strain have demonstrated that this enzyme can oxidize aniline to nitrobenzene. Attempts to use the enriched extract to transform other arylamines, such as *o*-chloroaniline, *p*-toluidine and **4**, to their nitro derivatives were unsuccessful.

A chloroperoxidase (CPO-P) which could perform the chlorination reaction **3** → **4** was isolated from the pyrrolnitrin producer *Pseudomonas pyrrocinia*.[3] It seemed logical to test whether this enzyme, in contrast to that studied by Itoh et al.,[4] can catalyze the oxidation of **4** to **5**. Since the chloroperoxidase gene has been cloned and overexpressed,[5] large amounts and high concentrations of the highly purified enzyme were available (340 Units g^{-1} cell material). The enzyme could therefore be added at higher concentrations (1.8 Units mL^{-1}) than in the experiments of Itoh et al. (3 mUnits mL^{-1}).[4]

In analogy to the halogenation reaction with CPO-P, we chose a tenfold higher acetate concentration and a lower pH value for the oxidation than were used by Itoh et al. The reaction product was isolated by preparative TLC and compared with authentic **5** by GC and HPLC. The retention times of the isolated product, and its mass spectrum, were identical to those of **5**. In the absence of the enzyme, no disappearance of **4** was observed.

In contrast to the halogenation reaction catalyzed by this metal- and cofactor-free haloperoxidase, nothing is known about the mechanism of the oxidation reaction.[6] No intermediates have yet been identified in the oxidation of **4**.

The fact that two separate steps in the biosynthesis of pyrrolnitrin are catalyzed in vitro by the same enzyme makes it very probable that the CPO-P of *Pseudomonas pyrrocinia* also participates in the biosynthetic pathway in vivo. This will be further investigated at the genetic level by inactivation of the gene.

H_2O_2 also presumably serves as cosubstrate in vivo, although the intracellular concentration is certainly much lower than that used here. The role of acetate, which is absolutely required for the reaction, is still unclear. It is possible that another substance assumes its function in vivo, since the concentrations required for optimum activity in vitro are too high to be considered physiological.

It remains to be seen whether similar enzymes participate in the biosynthesis of other nitro compounds such as chloramphenicol, and whether other bacterial haloperoxidases, either of heme or non-heme type, can also catalyze the described reaction.

Experimental Procedure

4 was synthesized from **5** by reduction with sodium dithionite [7]. Experiments on the in vitro oxidation of **4** were carried out in 1 M sodium acetate buffer, pH 4.5, 40 mM H_2O_2, and 1 mM **4** (500 μL total volume). The reaction was started by the addition of 300 mUnits CPO-P (100 Units mL^{-1} in 5 mM ammonium acetate, pH 6.8; specific activity 63 Units mg^{-1}). The mixture was incubated at 30 °C with shaking, and additional enzyme (300 mUnits) was added after 2 and 4 h. Control experiments contained no enzyme. After a total of 6 h incubation, the samples were extracted with 800 μL ethyl acetate and dried under vacuum. The residue was dissolved in ethanol and chromatographed over silica gel (with fluorescence indicator), with toluene as eluent. **4** and **5** have R_f values of 0.29 and 0.62. The compounds were located by spraying with van Urks reagent [8], which leads to a characteristic purple color in the presence of **5**. The reaction product was purified for HPLC and MS by preparative TLC. The region which fluoresced under UV (254 nm) was scraped off the plate, extracted with ethyl acetate, and dried under vacuum. The residue was dissolved in a suitable solvent and compared directly with authentic **5**, using HPLC [9], GC [10], and MS.

Phosphindolyl Anions by Elimination from 1-Phosphoallyllithium Complexes–η^5 and η^3 Coordination of a Phospholyl Fragment**

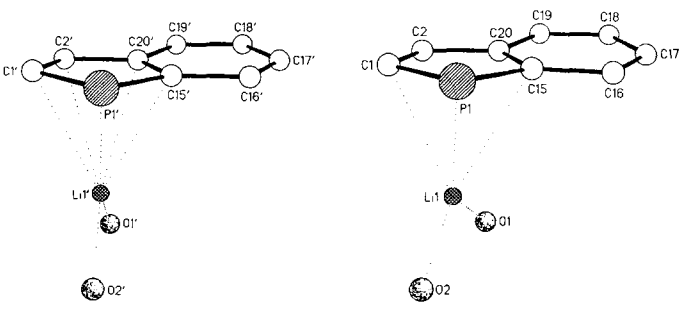
Edgar Niecke,* Martin Nieger, and Peter Wenderoth

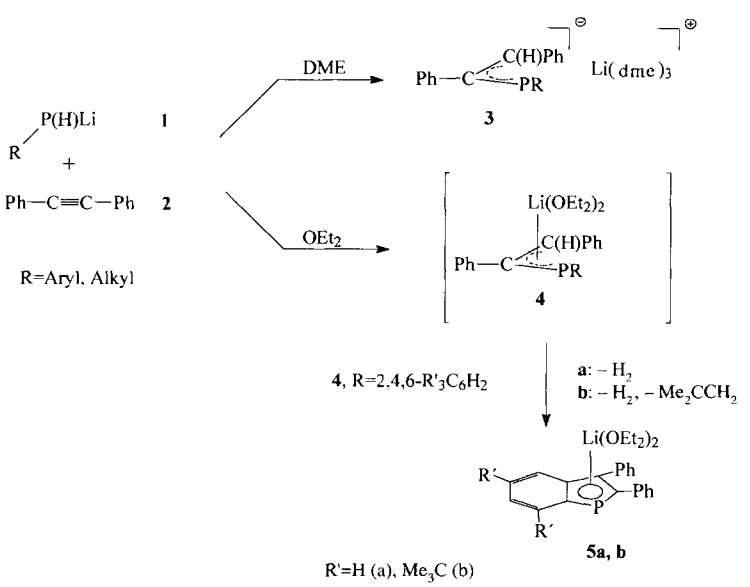
Lithium complexes of hydrocarbons with delocalized π bonding systems are a major research area in organoelement chemistry because of their synthetic potential and their unique bonding.[1] It is therefore not surprising that recently similar anionic P/C-pπ bonding systems have also aroused increasing interest. One priority in this research is the phospholyl system, and many transition metal complexes with this system in the coordination sphere have been synthesized.[2] However, knowledge about the phospholyl anions is rare and has until now been limited to NMR studies[3] and to the crystal structure of the phospholyl derivative [Li(tmeda)PC_4Me_4] **I**.[4] Here we report on a simple route to phoshindolyl lithium complexes of type **II** and their structure in the solid state.

I **II**

As we could show recently, lithium alkyl- and arylphosphides (**1**) react with tolane (**2**) in the presence of the strong donor dimethoxyethane (DME) to form isolated 1-phosphoallyl anions **3**.[6, 7] The attempt in the presence of a weak donor (ether) to realize π coordination between lithium and the phosphoallyl system, as in **4**, led surprisingly in the case of lithium arylphosphides **1a** (R = C_6H_5) and **1b** (R = 2,4,6-tBu$_3$-C_6H_2) to the formation of the phosphindolyl lithium complexes **5a** and **5b**[10] through elimination of hydrogen (**a**) or hydrogen and 2-methylpropene (**b**),[8] respectively.

Crystals suitable for an X-ray structural analysis[11] could be obtained from **5b**. The unit cell contains two independent molecules (**A** and **B**), which differ essentially in the coordination of the lithium (Fig. 1). Thus lithium is η^5-coordinated with respect





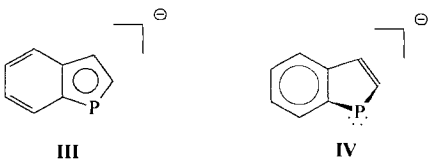


Fig. 1. Reduced representation of the two independent molecules of **5b**. Selected distances [Å] and angles [°] (molecules **A** and [**B**]): P1-C1 177.4(2) [177.0(2)], P1-C15 178.5(3) [178.9(3)], C1-C2 140.4(4) [139.4(4)], C2-C20 143.5(4) [144.3(4)], C15-C20 143.5(3) [143.1(3)], C15-C16 144.0(4) [143.4(4)], C16-C17 136.1(4) [137.1(4)], C17-C18 141.6(3) [142.2(3)], C18-C19 137.3(4) [137.9(4)], P1-Li1 258.4(5) [252.1(5)], Li1-C1 262.9(6) [261.9(6)], Li1-C15 260.1(6) [270.8(6)], Li1-C2 276.6(5) [291.9(6)], Li1-C20 276.2(6) [298.2(6)], Li1-O1 197.0(6) [189.6(7)], Li1-O2 199.2(6) [195.4(7)]; C1-P1-C15 90.6(1) [90.4(1)], O1-Li1-O2 100.8(2) [110.1(3)].

to the planar PC_4 fragment in molecule **A**, as is also observed for the phospholyl lithium complex [Li(tmeda)$P(CMe)_4$] (type **I**).[4] Longer Li-C distances are observed, however, for the fused benzene (Li1'–C1'[C15', C2',C20'] 260–277 pm) than are found for the monocycle (about 240 pm).

In molecule **B** two Li–C distances (Li1–C1[C15] 262, 271 pm) are comparable to those found in **A**, whilst two (Li1–C2[C20] 292, 298 pm) are significantly longer. This corresponds to a η^3 coordination of the metal to the ring fragment C1-P1-C15. Even though the P–C[C'] (177–179 pm) and C–C[C'] distances (139–144 pm) in the five-membered ring of both molecules can be taken as evidence for a delocalized π system as in **III**, a preferential localization of the negative charge on the hetero atom as in **IV** is already indicated in the observed structure change in the transition from **A** to **B**. Thus the PC_4 fragment in **B** is significantly distorted toward an envelope conformation (deviation of the P1 atom of the ring plane C15-C20-C2-C1 = 5 pm), and the Li–P1 distance is reduced to 252 pm (258 pm in **A**). The slight shortening of the C1–C2 bond to 139.4 pm (140.4 pm in **A**) is in agreement with these findings. The O1-P1-O2 plane in **5** is orthogonal to the PC_4 ring plane; the Li···O distances (190–199 pm) correspond to typical values for ether-coordinated lithium salts.

III **IV**

The ^{7}Li NMR spectrum of **5b** (–75 °C, Et_2O; LiBr/H_2O ext.) shows a signal at δ = –4.6 (W = 40 Hz), whose high-field position at least indicates a contribution from a π complex in solution. The determination of the constitution of **5a** was achieved by interpretation of the NMR spectra. The ^{7}Li NMR spectrum of **5a** resembles that of **5b**; whereas the ^{31}P NMR spectrum shows a resonance shifted upfield (δ = 19.7(d), $^3J_{PP}$ = 6.0 Hz) compared to that of **5b** (δ = 30.0(s)). The ^{13}C NMR spectrum of **5a** shows the expected number of signals for a 2,3-diphenylphosphindolyl system.[13]

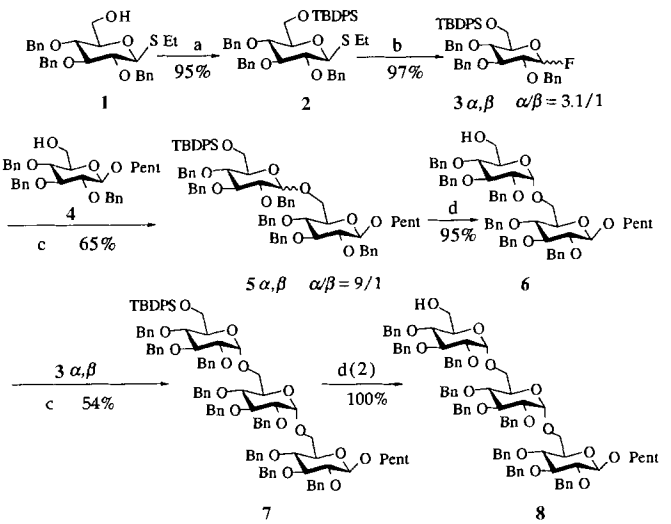
Synthesis of Benzylated Cycloisomaltotri- and -hexaoside**



Stéphan Houdier and Philippe J. A. Vottéro*

Cyclomaltooligosaccharides known as α-, β- and γ-cyclodextrins are obtained in large quantities by enzymic synthesis with cyclodextrin glycosyl transferase.[1] The well-known ability of cyclodextrins to include apolar molecules and their solubility in water can be improved by chemical modifications.[2] Very promising modifications are the per-3,6-anhydro-α- and -β-cyclodextrins,[3] and the per-2,3-anhydro-β-cyclodextrins[4] previously synthesized.

Besides these "derivatizations" of natural cyclodextrins, a parallel route based on chemical synthesis was developed by Ogawa et al.[5] and Vignon et al.[6] The strategy centers around the preparation of a linear precursor with the suitable number of sugar residues activated in such a way that the cyclization may be achieved. Beyond the inherent difficulties of glycosylation, chemical synthesis of cyclooligosaccharides as hosts for predefined guests is a challenge.[7]

It is in this context that we synthesized cyclooligosaccharides in the isomaltose series that may have new or optimized inclusion properties with respect to natural or modified cyclodextrins. The α-1,6-glucosidic linkage can be considered as a highly flexible bridge between two D-glucopyranosyl residues. Starting from this idea we designed the synthesis of oligocycloisomaltosides consisting of two, three, four, and six monomer units. We recently reported the first synthesis of benzylated cycloisomaltotetraoside[8] using a modification of the Mukaiyama method for the cycloglycosylation step.[9]

We report here on the synthesis of benzylated cycloisomaltotrioside **9** and benzylated cycloisomaltohexaoside **10**. The glycosylation method proposed by Fraser-Reid based on activation of pentenyl glycosides with I^+[10] was used for the cyclization of the linear precursor **8** (Scheme 1). Along with the cyclic trimer **9** a small amount of the hexamer **10** and a nonsymmetric trimer **11** were also obtained (Scheme 2). These new compounds were characterized by NMR spectroscopy and mass spectrometry. Because of the symmetry of **9** and **10**, their NMR spectra, which exhibit the signals of a benzylated α-D-glucopyranoside, give no information about the number of monomers. The FAB$^+$ and DCI mass spectra clearly show molecular peaks consistent with the proposed structures of **9** and **10**. The NMR spectrum of **11** indicates three anomeric protons, two of which are α-configurated and one β-configurated according to the coupling constants. The molecular peak in the mass spectrum con-

firmed the trimeric structure of **11**. Studies of conformational and inclusion properties of **9**–**11** are in progress.

Scheme 2 outlines the cycloglycosylation of the linear precursor **8**. The cyclization was carried out unter high-dilution conditions to favor the intramolecular glycosylation over intermolecular reaction; the yield is quite good (83%). A compromise was found

Scheme 2. Cycloglycosylation of the linear precursor **8** by the Fraser-Reid method giving the title compounds **9**, **10**, and **11**. **a**: iodonium dicollidine perchlorate (2 equiv), 1,2-dichloroethane/Et_2O (1:1).

between rate and stereoselectivity by using a 1:1 mixture of 1,2-dichloroethane and diethyl ether as solvent for the reaction. Our experience has shown that a higher proportion of the α-configurated product (1,2-*cis*-glycosylation) is obtained with this solvent system, but the rate is generally slowed dramatically.[10] In the typical experiment described here, all traces of the linear precursor **8** disappeared within approximately 30 minutes. As a result of the solvent system, but probably also because of the strained molecular structure of **9**, a significant amount (24%) of the nonsymmetric benzylated cycloisomaltotrioside **11** with one β-1,6- and two α-1,6-linkages was produced by 1,2-*trans*-glycosylation. It is very interesting to note that no trace of nonsymmetric cycloisomaltohexaoside (one β-1,6- and five α-1,6-glucosidic linkages) was detected. This is probably due to the fact that practically no strain develops during the cyclization step leading to **10**, in contrast to the formation of **9** which is stereoselective. A molecular mechanics simulation will be undertaken to confirm or reject this hypothesis. NMR data are given in Tables 1 and 2 for compounds **9**–**11**.

Experimental Procedure

General: Thin-layer chromatograms (Riedel de Haen 37332) developed by charring. Column chromatography (SiO_2 Merck 7734). NMR spectroscopy (Bruker AM400 or Varian Unity-400). Mass spectrometry (ZAB-SEQ(VG) for FAB^- or DCI modes; NERMAG R10-10 for DCI).

Compound **1** was prepared from the 6-*O*-trityl compound [8] by detritylation [11] (BF_3, Et_2O). Subsequent treatment with *tert*-butyldiphenylsilyl chloride [12] afforded **2**, which was fluorinated following the method of Nicolaou et al. [13] to give **3**. Compound **4** was prepared from the 6-*O*-trityl compound previously described [11].

5: **4** and **3**α, β (1.46 equiv) were dissolved in diethyl ether, and molecular sieves 4 Å were added. A mixture of silver perchlorate (3 equiv) and molecular sieves 4 Å in diethyl ether/THF (2:1) was prepared separately. The two solutions were stirred for 24 h before mixing. Tin(II) chloride (3 equiv) was finally added. After 4 d at room temperature the reaction mixture was diluted with dichloromethane, filtered on celite, and washed (saturated NaCl solution). The crude product was directly purified by HPLC (Merck L-6200 pump; IOTA refractometer; commercial column: Si-60/5 μm, LiChroCART 250-4; toluene/ethyl acetate 98:2). **5**α 59%, R_f 0.51 (toluene/ethyl acetate 95:5); **5**β 6%, R_f 0.41 (same solvent). MS (FAB^-) *m/z* (%): 1321.8(43) [$(M+Cs)^+$]. **5**α ^1H NMR ($CDCl_3$, 400 MHz): δ = 4.40 (d, 1H, H-1, $J_{1,2}$ = 7.82 Hz), 5.08 (d, 1H, H-1′, $J_{1',2'}$ = 3.51 Hz). ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 26.70 (*t*Bu), 28.88(2), 30.13(3), 62.82 (C-6′), 65.13 (C-6), 68.95(1), 96.62 (C-1′), 103.28 (C-1), 114.76(5), 137.91(4), 127.32–138.86 (C arom.). **5**β ^1H NMR ($CDCl_3$, 400 MHz): δ = 4.42 (d, 1H, H-1, $J_{1,2}$ = 7.98 Hz), 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 7.77 Hz). ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 26.96 (*t*Bu), 29.06(2), 30.32(3), 62.83 (C-6′), 66.50 (C-6), 69.61(1), 74.78, 75.30, 75.80, 76.06 (6 × CH_2Ph), 103.80 (C-1 or C-1′), 104.16 (C-1 or C-1′), 115.01(5), 127.9–136.06 (C arom.), 138.15(4).

6: To a solution of **5**α in THF was added a 1 M solution (2 equiv) of tetrabutylammonium fluoride in THF. After 2 d the reaction mixture was diluted with 1,2-dichloroethane, washed with saturated NaCl solution, concentrated, and purified by column chromatography (SiO_2, petroleum ether/ether 4:1) to give **6** in 95% yield. R_f 0.36 (hexane/ethyl acetate, 7:3). ^1H NMR ($CDCl_3$, 400 MHz): δ = 4.36 (d, 1H, H-1, $J_{1,2}$ = 7.83 Hz), 4.96 (d, 1H, H-1′, $J_{1',2'}$ = 3.39 Hz); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 28.91(2), 30.13(3), 61.79 (C-6′), 96.87 (C-1′), 103.39 (C-1), 114.81(5), 127.44–128.31 (C arom.).

7 was prepared in analogy to **5**, except 2.3 equiv 3α, β (3.1/1) were employed. Yield: 54%; R_f 0.75 (hexane/ethyl acetate 7:3). MS (FAB^+): *m/z* (%): 1754.7 (63) [$(M+Cs)^+$]. ^1H NMR ($CDCl_3$, 400 MHz): δ = 4.42 (d, 1H, H-1, $J_{1,2}$ = 7.84 Hz), 5.04 (d, 1H, H-1″, $J_{1'',2''}$ = 3.51 Hz), 5.10 (d, 1H, H-1′, $J_{1',2'}$ = 3.51 Hz). ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 26.68 (*t*Bu), 28.87(2), 30.10(3), 62.62 (C-6″), 65.36, 65.49 (C-6 or C-6′), 68.98(1), 72.01, 72.20, 74.73, 74.85, 75.42, 75.59 (9 × CH_2Ph), 80.20 (C-2″), 81.68 (C-3′), 82.24 (C-2), 96.82 (C-1′, C-1″), 103.30 (C-1), 114.78(5), 127.3–135.7 (C arom.), 137.85(4).

8 was prepared in analogy to **6**. Yield: 100%; R_f 0.46 (hexane/ethyl acetate 6:4). MS (FAB^-): *m/z* (%): 1515.6 (65.5) [$(M+Cs)^+$].

9–**11**: **13**, **14**, **15**: After dissolution of **8** (26 mg, 1.85×10^{-2} mmol) in 1,2-dichloroethane/diethyl ether (3 mL, 1:1) iodonium dicollidine perchlorate (2 equiv) was added. Although **8** disappeared totally within 30 minutes, the reaction mixture was left under stirring for another 12 h. The reaction mixture was then diluted with dichloromethane, washed (saturated $Na_2S_2O_3$ solution), and dried (Na_2SO_4). The crude product mixture was separated in two steps by HPLC (Merck L-6200 pump; IOTA refractometer; commercial Si-60/5 mm, LiChroCART 250-4); first step:

(hexane/ethyl acetate 83:17; flow rate: 2 mL min^{-1}), **9**: 47%; t_r (retention time) 24.17 min; R_f 0.6 (hexane/ethyl acetate 7:3), MS (FAB$^+$): *m/z* (%): 865(62) [(2*M*/3+H)$^+$], 1297(42) [(*M*+H)$^+$], 1319(100) [(*M*+Na)$^+$], 2616(5) [(2*M*+Na)$^+$]; MS (DCI): *m/z* (%): 1313.6(100), [(*M*+NH$_3$)$^+$], and (**10**+**11**) t_r 42.42 min; second step: (toluene/ethyl acetate 75:25; flow rate: 2 mL min^{-1}), **10**: 12%; t_r 5.58 min; R_f 0.48 (toluene/ethyl acetate 9:1), MS (FAB$^+$): *m/z* (%): 431.2(100) [*M*/6+H)$^+$], 865.3(10) [(*M*/3+H)$^+$], 2727.5(80) [(*M*+Cs)$^+$], MS (DCI): *m/z* (%): 2610.4(100) [(*M*+NH$_3$)$^+$], **11**: 24%; t_r 8.49 min; R_f 0.26 (toluene/ethyl acetate 9:1), MS (FAB$^+$): *m/z* (%): 865(12) [(2*M*/3+H)$^+$], 1429.3(100) [(*M*+Cs)$^+$], MS (DCI): *m/z* (%): 1314.6(100) [(*M*+NH$_3$)$^+$].

Synthesis and Structure of the Magnesium Imide [(thf)MgNPh]$_6$**

Tony Hascall, Karin Ruhlandt-Senge, and Philip P. Power*

Metal imides[1] may, most simply, be represented by the monomeric formula MNR (M = divalent metal, R = H, alkyl, or aryl group). In reality, however, monomeric structures are not observed in condensed phases owing to the tendency of the MNR units to associate strongly. In main group chemistry this behavior is exemplified by the polyiminoalanes (R'AlNR)$_n$[2] and compounds of the composition (MNR)$_n$ (where M is a main group 4 metal (Ge, Sn, or Pb) in a lower oxidation state).[3–5] Usually, association numbers of $n \geq 4$, are observed for these compounds, and the resulting structures are three-dimensional cages. At present, however, no well-characterized homometallic imido derivatives of the neighboring main group 2 elements have been reported.[6] In this paper, the first X-ray crystal structure of such a species is now described.

The title compound **1** · THF was synthesized as a colorless

[(thf)MgNPh]$_6$ **1**

crystalline material by the straightforward reaction of Et_2Mg with H_2NPh in ether and crystallization from hexane/THF. The ^1H and ^{13}C NMR spectra are consistent with a 1:1 stoichiometry of THF and Ph ligands in **1**. The X-ray crystal structure analysis of **1**[7] reveals a slightly distorted hexagonal-prismatic framework of magnesium and nitrogen atoms arranged in an alternating manner at the apices (Fig. 1). Each nitrogen atom

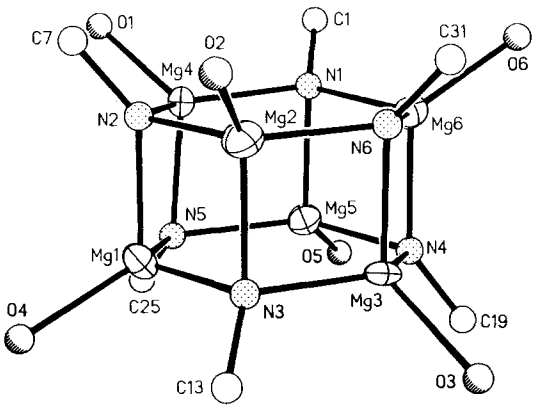

Fig. 1. Molecular structure of **1** (computer-generated). For clarity, only the oxygen atoms of the THF molecules, *ipso*-carbon atoms of the Ph substituents, and the Mg_6N_6 framework are shown.

bears a phenyl substituent, whereas the magnesium atoms are each solvated by a single THF donor molecule. The N and Mg atoms are thus tetracoordinated in a distorted-tetrahedral fashion. The average Mg–N distance between the six-membered rings (2.08 Å) is slightly longer than the average Mg–N bond length (2.05 Å) within the six-membered rings. In addition, the parallel, hexagonal Mg_3N_3 arrays are almost planar with a slight distortion toward chair configurations. The maximum deviation of Mg or N atoms from the best-fit plane is no greater than 0.08 Å. The average internal angle at the Mg atoms (122.7°) in the six-membered ring is greater than that at the N atoms (116.5°). The average Mg–O bond length is 2.04 Å and the average N–C distance is 1.37 Å.

The structure observed for **1** closely resembles those found for the related iminoalanes (R'AlNR')$_6$,[8, 9] which also possess hexagonal prismatic frameworks with slightly puckered Al_3N_3 ring planes. As in **1** the Al–N distances between the six-membered rings are longer (e.g. 1.956 vs. 1.898 Å in [HAlN(*i*Pr)]$_6$[8]) than those within the rings. The Mg–N bonds in **1** are, of course, longer than these distances owing to the larger radius of magnesium (1.45[10] vs. 1.3 Å[10] for Al). The Mg–N bond lengths in **1** are, in fact, very close to those observed (Mg–N = 2.09 Å) in the cubane species **2**[11] in which one of the Al–H corners is

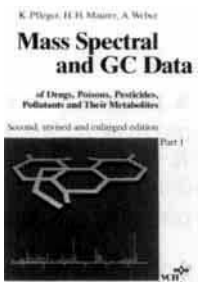
[(HAlN*t*Bu)$_3${MgN*t*Bu(thf)}] **2**

replaced by a Mg(thf) moiety. Compound **2** appears to be the only other instance of the involvement of a magnesium atom in a metal-imide cage structure.[6, 12] The Mg–N distances in cage species **1** and **2** can be regarded as being relatively short, since they involve λ^4-Mg-λ^4-N type bonds (cf. 2.055 for λ^4-Mg-λ^3-N connectivity in [(thf)$_2$Mg(N*t*Bu)$_2$(SiMeN*t*Bu)$_2$],[13] 2.118 Å for

λ^3-Mg-λ^4-N bonds in $[\{s\text{BuMgN(SiMe}_3)_2\}_2]$,[14] 2.082 Å for λ^4-Mg-λ^4-N bonds in $[\{(Et_2O)Mg(NSiMe_3)_2C_6H_4\}_2]$[15]). The average Mg–O distances in **1** and **2** are also very similar (2.04 and 2.002 Å, respectively).[11]

In summary, it has been shown that a magnesium imide $[(thf)MgNPh]_6$ (**1**) can be readily synthesized and crystallized in a facile manner. Its structure is similar to that observed for the related $(R'AlNR)_6$ hexamers. It remains to be seen whether the reactivity pattern of **1** will have widespread synthetic applicability. An investigation of the chemistry and the potential structural diversity of these novel species is now in progress.

Experimental Procedure



All manipulations were carried out under anaerobic and anhydrous conditions. Diethyl magnesium was prepared by the dioxane precipitation method [16] from the corresponding Grignard reagent. After evaporating the solvent, coordinated ethers were removed by heating at 170 °C under high vacuum for 2 h [17].

Freshly distilled (over $LiAlH_4$) aniline (0.66 g, 7.1 mmol) was dissolved in diethyl ether (30 mL) and added with cannula to a solution of Et_2Mg (0.71 g, 8.7 mmol) in Et_2O (30 mL). This resulted in a slight warming of the mixture and gas evolution. The solution was stirred for a further 1 h whereupon the volume of Et_2O was reduced to 30 mL. Addition of hexane (5 mL) afforded a white precipitate which was dissolved in THF (45 mL). Filtration over a bed of Celite followed by cooling the solution in a −20 °C freezer gave white crystals of **1** · THF. Yield 0.50 g, 38%. The crystals rapidly turned brown on exposure to air and did not melt on heating to 320 °C but showed evidence of desolvation. The IR spectrum (nujol mull) displays several bands in the metal–ligand region (< 600 cm^{-1}) that are presumably due to Mg–O and Mg–N stretching bands: 580, 550, 510, 480, 320 cm^{-1}; ^1H NMR: (300 MHz, C_7D_8) δ = 1.203 (s, 4H, THF), 3.58 (m, 4H, THF), 6.45 (m, 1H, *p*-H), 6.83 (m, 2H, *m*-H), 7.013 (m, 2H, *o*-H). $^{13}C\{^1H\}$ NMR: (75.47 MHz, C_7D_8) δ = 24.64 (s, THF), 69.38 (s, THF) 109.76 (s, *o*-C), 128.96 (s, *m*-C), 167.82 (s, *ipso*-C).

[1] There appears to be some controversy with regard to the nomenclature of these species in the literature. This arises from the fact that the description "metal imide" has also been applied to species of formula $M(N{=}CR_2)_n$.

Mass Spectral and GC Data of Drugs, Poisons, Pesticides, Pollutants and Their Metabolites. Volumes 1–3. 2nd edition. By *K. Pfleger, H. H. Maurer* and *A. Weber*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XXIX, 4224 pp., hardcover DM 1290.00.—ISBN 3-527-26989-4/0-89573-855-4

In clinical toxicology the diagnosis of toxic symptoms requires that a poison must be definitely identified from the various possibilities in a very short time, so that remedial treatment can begin as soon as possible. Mass spectrometry in combination with gas chromatography (GC–MS) has become established as the analytical method of choice for this application. The mass spectra obtained by electron impact ionization in the full scan mode yield detailed structural information which can be verified by comparing with reference spectra. For this purpose, in 1985 the authors of this work published the first (two-volume) version, a compilation of over 1500 mass spectra of drugs, poisons, and their metabolites. In this second, three-volume edition the collection has been enlarged to include data from further toxicological studies. Of the 4370 spectra about 1500 are of drugs and poisons, 800 of pesticides and environmental pollutants, and 2000 of metabolites.

In addition to giving mass spectra (measured in their own laboratory) of all these biologically active substances and metabolites, with details of artefacts resulting from the sample preparation or from the gas chromatographic separation, the authors also relate these directly to the corresponding sample matrix (e.g., plasma, intestine contents, urine, or the pure compound). Volume 1 describes the analytical procedures used, including extraction, derivatization, concentration, and measurement of retention time (RT) index. Computer monitoring programs for rapid detection of individual suspected compounds are also given; with these one searches for specific substances in defined retention time windows using the ion-specific mass chromatogram. To complete this volume there are tables in which the substances are indexed according to compound name (or common name), active groups, RT index, exact molar mass, and CAS Registry number.

All this information, coded by means of a set of abbreviations, as well as molecular and structural formulas, is given along with the individual mass spectra. One is also told whether or not background subtraction has been applied to the spectrum shown, since this can affect the intensity ratios of the ions. Also important are the indications given in cases where the analysis of standard solutions is essential for unambiguous identification, and especially for quantification.

With electron impact ionization the molecular ion peak, whose mass is the most important piece of structural information, is not always strong enough to be measured satisfactorily. Consequently the arrangement of the mass spectra in Volume 2 ($m/z = 4$ to 221 amu) and Volume 3 ($m/z = 222$ to 777 amu) is not wholly consistent, being in order of increasing mass of a characteristic fragment ion or of the molecular ion itself. Thus, for example, in the mass spectra of the morpholine fungicides one finds tridemorph (p. 491) listed under the base peak $m/z = 128$, whereas fenpropimorph (p. 1502) appears under the molecular ion $m/z = 303$, despite the fact that the base peak is at $m/z = 128$. Consequently, when searching for compounds according to their molar mass one must first refer to Table 4 in Volume 1 to find the page numbers of the corresponding spectra in Volumes 2 or 3. In cases where there are two further ion peaks with intensities greater than 80% of the base peak, variations in measurement conditions affecting the intensities can result in the mass spectrum appearing twice. Thus, the metabolites of the neuroleptic agent promethazine-M (Nor-sulfoxide) after acetylation give as the strongest ion peaks $m/z = 58$ and $m/z = 212$ (base peak). However, following the entry under $m/z = 58$ (p. 104), the second entry appears not under the base peak but under the molecular ion $m/z = 328$ (p. 1634). The system whereby an individual mass spectrum can appear twice therefore seems to be rather unhelpful, especially since in this example only the mass spectrum on page 1634 is listed in the volume containing the tables (Vol. 1).

The data systems of modern mass spectrometers include commercially available libraries of spectra such as the NIST or Wiley collections, containing as many as 130000 entries, which can be augmented by users' own spectra libraries. One therefore has to question the justification for producing this present spectra collection in book form. However, a comparison of the spectra entries reveals that the standard collections only partly cover the range of compounds included in this Pfleger/Maurer/Weber library, which is expressly intended for use in systematic clinical and toxicological analysis, and is also an important resource for toxicological work in the fields of legal medicine, the workplace, food analysis, and the environment, as well as the control of doping. Whereas computerized spectra libraries often consist only of reduced mass spectra, those reproduced in these volumes are complete spectra with much useful additional information.

On-line library searching allows one to apply different search criteria and thus offers greater flexibility, and therefore for routine analysis it is desirable to be able to use the Pfleger/Maurer/Weber library in computerized form. However, it is not available from all mass spectrometer manufacturers, as licensing arrangements do not exist in all cases. Moreover, for some mass spectrometers, especially older ones, compatible data storage media are not available, and thus the three-volume work should prove a valuable resource in these cases.

Relationships between Structure and Function of Cytochrome P-450—Experiments, Calculations, Models. (Series: Frontiers in Biotransformation, Vol. 7.) Edited by *K. Ruckpaul* and *H. Rein*. Akademie-Verlag, Berlin, 1992. VIII, 370 pp., hardcover DM 224.00. —ISBN 3-05-501 329-8

Researchers in the field of cytochrome P-450 are currently investigating possible ways around the unsolved problem of the three-dimensional structure of the isoforms of membrane-bound eukaryontic P-450. Of the three prokaryontic soluble forms of cytochrome P-450 that have so far been crystallized, a detailed structural characterization has up to now been achieved for only one of these (P-450-cam). Therefore, in order to get the information about structure–function relationships that is so essential for understanding the many reactions of biosynthesis, toxicity, and

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

detoxification that are catalyzed by P-450, there is no alternative to the approaches based on modeling of proteins, directed mutagenesis, matching of ligands, comparisons with analogous (or supposedly analogous) model systems, more sophisticated methods of spectroscopic analysis, etc. This volume collects together some of the results obtained by such strategies.

The editors have recruited a team of competent authors to prepare the ten chapters. The book begins with a chapter on that same P-450-cam (one is tempted to add, in accordance with tradition), in which Raag and Poulos emphasize the importance of matching the substrate to the enzyme used for the catalysis. This is followed by a shorter contribution by Strobel summarizing current ideas about the likely topology of eukaryontic cytochrome P-450 variants in membranes of the endoplasmic reticulum. An excellent review by Woggon and Matile provides an introduction to the 'P-450 mimics', metalloporphyrin models that can simulate the bonding to and activation of substrates, the role of the thiolate group, and the embedding of cytochrome P-450 in lipid membranes. Lewis discusses, with an appropriate degree of reserve and critical caution, the possibilities of using computer modeling as an aid to rationalization in making predictions about carcinogenicity, in the context of known metabolic reactions and known structural characteristics of P-450 variants. In another highly informative contribution Loew and Collins give an impressive account of the interesting results (predictions of regio- and stereoselectivities) that can be obtained by integrating together a number of different experimental and modeling strategies. Hildebrandt contributes an article on studies of P-450 by resonance Raman spectroscopy.

The articles that follow are concerned with the characterization of enzyme systems, which one can expect to lead indirectly to further insights into the structure and function of P-450. Hawkins and Dawson discuss the only monooxygenase that is not a P-450 (which catalyzes the oxidative *N*-dealkylation of secondary amines in certain bacteria), mainly from the viewpoint of the iron–oxygen interaction, while Veitch and Williams give a general overview of electron transfer systems, including cytochromes c and b_5 and iron–sulfur clusters. After this digression the two concluding chapters revert to concentrating solely on P-450. Gray summarizes current knowledge regarding electron transfer in P-450 monooxygenase systems, and discusses the importance of each individual component, which involves some overlapping with the subject matter of the preceding chapter. In the final article Lu gives a lucid introduction to the interpretation of the deuterium isotope effect and the contribution that this brings to understanding the P-450 catalyzed cleavage of C–H bonds.

This book appears at a rather turbulent time in the progress of such research. In the first place, work is proceeding on the three-dimensional structure of bacterial $P\text{-}450_{BM-3}$, which shows promise as a model for most eukaryontic cytochrome P-450 variants, but it has not been possible to include that work in this volume. Secondly, there is active competition in books on this theme: the past year saw the appearance of Volume 206, *Cytochrome P-450*, in the *Methods in Enzymology* series, which contains not only detailed procedures for the analysis of P-450 enzymic activities, for purification, and for heterologous expression, but also some limited information about P-450 structures. And now Volume 105 of the *Handbook of Experimental Pharmacology*, also entitled *Cytochrome P-450*, has been published, containing a greater number of individual contributions which make up a survey that is nearly exhaustive, although orientated mainly towards P-450 function.

In this area of research the volume reviewed here suffers from the disadvantage that, although the chosen topics are certainly interesting and are competently reviewed (covering publications up to mid-1991 in most cases), such a selection does not provide a consistent overview of the current state of knowledge on P-450 structural characteristics, nor is it claimed by the editors to do so. It seems to this reviewer that the work could have been improved if the editors had exercised firmer control to impose some order; in particular it would have made life easier for the reader seeking information if the contents of the individual volumes of the series were more clearly coordinated with each other, at least by cross-referencing and perhaps also by a cumulative index. For example, important information relating to the structure of P-450-cam (corresponding to Ch. 1 of this volume) also appears in Volume 4 of the series (*Microbial and Plant Cytochromes P-450*), information on P-450 insertion into membranes (corresponding to Ch. 2) also appears in Volume 5 (*Membrane Organization and Phospholipid Interaction of Cytochrome P-450*), and information on metalloporphyrin models (corresponding to Ch. 3) can also be found in Volume 1 (*Basis and Mechanisms of Regulation of Cytochrome P-450*).

Nevertheless, this volume forms an appropriate extension to and advance on the earlier volumes that appeared in the *Frontiers in Biotransformation* series from 1989 onwards. As a comprehensive work on this field the series is almost unrivalled, and it should be in the departmental library of every laboratory with ambitions in this area, whether concerned primarily with biochemistry, microbiology, pharmacology, endocrinology, or protein structure.

A Dictionary of Concepts in NMR. (Biophysical Techniques Series. Series editor: *R. A. Dwek.*) By *S. W. Homans.* Clarendon Press, Oxford, 1992. VI, 372 pp., paperback £ 17.50.—ISBN 0-19-854765-X

This book is an introduction to the basic concepts of NMR spectroscopy. The theoretical fundamentals are explained under subject headings arranged alphabetically, together with a brief mathematical appendix on the properties of cartesian product operators, trigonometric identities, matrix algebra, and rotation operators. As the author explains in his preface, the book is intended to help the reader with a basic knowledge of NMR spectroscopy to deal with the confusing plethora of acronyms and technical jargon. He believes that this form of presentation enables the reader to get a quick overview of a particular topic in NMR spectroscopy without a laborious study of the original literature. The book is intended especially for chemists and biochemists concerned with applications, so that they can remedy gaps in their understanding of the methods that they are using to an ever greater extent.

The subject headings have been well chosen. There is a definite emphasis on the description of multidimensional NMR experiments on solutions, and nearly all the applications described are taken from the armory of methods used for determining the structures of biochemical macromolecules. At least of equal importance to this is the quality of the information given. In this respect we find that there are peaks and troughs. Apart from a few small errors the most important standard procedures such as COSY and NOESY (each occupying about ten pages) are explained clearly and in considerable detail, with the help of the product operator formalism. The liberal use of the latter concept for describing NMR experiments, combined with a good introduction under the relevant subject heading, is undoubtedly an important

positive aspect of the book. Based on this foundation the book provides clear explanations of even those methods that have been most recently adopted into biological NMR spectroscopy, the 3D and 4D techniques (HCACO, HCA[CO]N, HNCA, and HNCO). The pulse sequences shown here have already been superseded by new ones, but this can hardly be avoided in a field that is undergoing such rapid development. The descriptions of the basic principles of NMR spectroscopy also leave one with a positive impression. This applies to the quantum-mechanical aspects as well as to the terminology of Fourier analysis. Regrettably, however, there is no quantum-mechanical discussion of relaxation phenomena, despite their great importance in structure determination. One searches in vain for the heading "heteronuclear T_1 values", even though these are essential parameters for describing internal mobilities in systems such as proteins. The absence of a more thorough introduction to relaxation theory is all the more surprising when one notes that the author does not shrink elsewhere from explaining relationships that are more difficult than these. The explanations under the headings "Average Hamiltonian theory" and "Dyson time ordering parameter" could easily have been omitted in favor of relaxation, especially since one is none the wiser after reading them.

In the descriptions of the NOESY and ROESY procedures it is always assumed that one is dealing with large molecules for which the extreme narrowing condition does not apply, which is perhaps reasonable from a biochemical standpoint. However, this leads the author to the erroneous conclusion that one can never distinguish between exchange effects and nuclear Overhauser effects in NOESY spectra. The discussion of the ROESY experiment is also not very satisfactory. The statements regarding the possibility of integrating ROESY cross-peaks, and in particular the view that the transmitter frequency should be positioned on the low-field side of the spectrum to avoid TOCSY peaks, do not reflect the state of the art in 1992 when the book was published. Also the description of the *z*-filter technique as one whose use is restricted to generating pure phases in 2D spectra does not convey the true importance of the device.

In our view one of the book's most serious shortcomings is that the literature references given at the ends of the articles are often not up-to-date and not very relevant. This is especially obvious under the important heading "Cross relaxation". The references begin (correctly) with the historically important paper by I. Solomon in *Physical Reviews* (1955), but then there is only one reference to the special problems of cross-relaxation in proteins from a 1976 paper! On following up the cross-references (e.g., to "Spin-lattice relaxation" and "Nuclear Overhauser effect") one at last finds the classical 1971 book on the nuclear Overhauser effect by Noggle and Schirmer. The modern treatment of the subject in the excellent monograph by Williamson and Neuhaus (1989) is, unfortunately, not listed. A more extensive and up-to-date listing of carefully chosen literature references would have made this a valuable resource for the reader!
