It also seems quite incomprehensible that the author has failed to include methods for determining coupling constants. The important E.COSY experiments for this purpose are not mentioned. The book seriously undervalues the importance of this NMR parameter, which is so relevant to conformation, especially in biopolymers. The treatment of the Karplus relationship is very short on detail, which is consistent with the above undervaluation. The uninitiated reader would get the impression that coupling constants are of a similar nature to house numbers, with little relevance to structure. Here, as also in the descriptions of the NOESY and ROESY experiments, the reader interested specifically in obtaining structural information is offered no help whatsoever.

In addition to these shortcomings in the contents, it also becomes apparent that this paperback version is not very successful in its external appearance and in the author's lack of care in adopting illustrations from the original papers. Figures and legends that do not belong together have been copied uncritically from the original literature (see HMQC, HMBC). On page 189 (at least in this reviewer's copy), the reader encounters total chaos, for which the author is, of course, not responsible. Here, in order to follow the discussion, one needs to make a tremendous mental leap, since the explanation of "Magnetogyric ratio" begins at the foot of this page, whereas the top of the next page unexpectedly continues in the middle of "Multiple quantum filter", followed by an equally abrupt switch to an explanation of "Matrix representation". The beginning of the latter and the equations M4 to M16 that belong with it are missing altogether. Instead one finds on pages 203 and 204 a repeat of pages 190 and 191! A survey of the findings of colleagues who also possessed copies of Homan's book showed that anyone buying it has about a 50% chance of enjoying this "random reading".

However, although this review has up to now emphasized the negative aspects of the book, it must be said in conclusion that it affords the interested user of modern NMR methods quick access to basic information on many important topics. Despite its faults it can be recommended for the readership mentioned in the preface (biologists and chemists with biological interests), especially in view of the affordable price. But it certainly does not live up to the author's claim of eliminating the need to study more advanced texts, nor of giving easy access to relevant literature.

Fourier Transform Raman Spectroscopy. Instrumentation and Chemical Applications. By *P. Hendra, C. Jones* and *G. Warnes*. Ellis Horwood, Chichester, 1991. 311 pp., hardcover $ 90.50.—ISBN 0-13-327032-7

To state the most important fact first: this book is a must for anybody considering the purchase of a Raman spectrometer for almost any conceivable application or contemplating the addition of Raman spectroscopy to an analytical laboratory already operating a Fourier Transform infrared spectrometer. It is a recommended text for researchers and students alike interested in an up-to-date introduction to vibrational spectroscopy focussing on instrumentation and applications.

After a brief historical background of Raman spectroscopy in the first section, the second chapter outlines the vibrational behavior of molecules and their absorption and scattering of electromagnetic radiation. Conventional Raman spectrometers and their components are discussed in the third chapter; this section contains much information that is difficult to get from manufacturers' instructions supplied with some conventional instruments. Vibrational Fourier transform (FT) spectroscopy is discussed next; after dealing with technical aspects the authors clearly explain the principal advantages of interferometry (the Jacquinot, Fellgett, and Connes advantages). The development of practical FT Raman spectroscopy, sampling, safety, and criteria for instrument purchasing are discussed in Chapter 6.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0303-0361 $ 10.00+.25/0

The determination of Raman intensities for quantitative measurements is discussed in the next section. Advantages compared with dispersive spectrometers, where these calculations are rather difficult, are clearly indicated. The remaining chapters are devoted to a broad survey of applications of FT Raman spectroscopy in organic, inorganic, surface, and polymer chemistry, and biology. Numerous examples illustrating the advantages are provided. The lack of fluorescence that results from sample excitation with near-infrared laser light in a region of the spectrum where few absorptions occur is the most obvious argument in favor of FT Raman spectroscopy. In addition the ease of data manipulation and the capability for quantitative analysis even of complicated samples indicate a bright future for FT Raman spectroscopy. A brief outlook to further instrumental developments and an appendix explaining data processing in FT spectrometers in a very lucid and understandable manner are presented in the last chapters. The index is brief, but it seems to contain enough keywords to facilitate using the book.

There are only a few minor weak points and errors. The trace for the ideal output function of a monochromator in Figure 3.8 has been omitted, and presumably trace d is meant when reference is made in the text to trace b. When discussing the advantages of charge-coupled devices as detectors, a word about the smaller dynamic range of these devices as compared to photomultipliers might have been appropriate. The authors use the term "Jacquinot stops" for the interferometer components usually referred to by instrument manufacturers as apertures; unfortunately this is not explained anywhere in the book. The width of vibrational bands is generally described by giving the full width at half maximum, commonly abbreviated as FWHM; in this book it is called FWHH (H = height). In the chapter on surface enhanced Raman spectroscopy (SERS) the enhancement mechanism discussed is confined to electromagnetic contributions; considering the wealth of review papers a more balanced view including other explanations should have been possible.

Anybody wondering about the plastic duck on the book's front cover will find on page 179 the experimental arrangement used in measuring the FT Raman spectrum of the plastic material whose spectrum is also displayed on the cover. Better than any words this illustrates the ease of using FT Raman spectroscopy to study real world samples.

All the chapters contain short lists of references and an additional bibliography of pertinent books, enabling the reader to easily locate the original papers discussed and to find additional literature for further reading. The many figures and photographs are carefully reproduced, and they support the text in a very eye-opening way. Considering the size and quality of the book the price seems to be appropriate both for libraries operating on a tight budget and for interested researchers.

Electron Paramagnetic Resonance of d Transition Metal Compounds. (Series: Studies in Inorganic Chemistry, Vol. 16.) By *F. E. Mabbs* and *D. Collison*. Elsevier, Amsterdam, 1992. XX, 1326 pp., hardcover HFl 995.00, $ 622.00.—ISBN 0-444-89852-2

This book of 18 chapters and 13 appendices gives a very comprehensive and detailed description of the application of continuous-wave (CW) EPR spectroscopy to transition metal complexes. It is intended mainly for all chemistry undergraduate and graduate students, as well as interested readers from neighboring disciplines. Beginners are recommended to start by reading Chapters 1, 2, and 4.

Eight of the chapters are devoted to a description of the EPR of systems with spin $S = 1/2$ and of complex molecules with $S > 1/2$, which is well-balanced and of gradually advancing difficulty. The authors explain thoroughly all the relevant magnetic interactions ($\boldsymbol{B}_0.\boldsymbol{S}$, $\boldsymbol{S}.\boldsymbol{I}$, $\boldsymbol{S}.\boldsymbol{S}$, $\boldsymbol{B}_0.\boldsymbol{I}$) and electric (quadrupole) interactions, and the effects of symmetry on these interactions (based on ligand field theory), extending even to cases of non-coincident tensor principal axes in ligand hyperfine structure interactions. However, although the material is skillfully presented, CW-EPR is not the most appropriate experimental technique for studying the last-named interactions, nor for the majority of small quadrupolar effects, and even simulations are not very helpful.

In contrast to most treatments by other authors, the mathematical derivations of the relationships that make up the essential 'toolkit' of formulas for EPR spectroscopy are here given in full and explicit detail. One's first reaction is that this will probably cause the uninitiated reader just as much 'pain' as it would to read up these matters in the more usual compact form of presentation. On second thought, however, the reader will come to appreciate the value of this approach, as it clearly explains the intermediate steps leading to the final result. Moreover, there are practically no errors in the equations and formulas! The explanations presented are especially valuable for users who rely exclusively on standard EPR software (Ch. 16), as they will learn the basic principles on which their work depends. Equally useful are the many simulated spectra, which occupy more than 500 pages distributed throughout the chapters; these show very clearly the effects of altering the various spectral parameters for paramagnetic species with different symmetry properties. These enable even a chemist with only a basic knowledge of EPR to become aware of the more detailed aspects of the problem in hand and to assess their relative importance.

It is unfortunate that in such a detailed treatment of the EPR of transition metal complexes there is little or no discussion of ligand exchange reactions in complexes and their thermodynamics and kinetics, nor of short-lived complexes. Dynamic effects have been excluded so far as possible, and the Jahn–Teller effect receives only a bare mention. Relaxation effects are briefly discussed in Chapter 18. However, the authors explain in the preface that they make no claim to completeness.

To summarize, the book offers a very comprehensive description of CW-EPR, treating in particular detail the mathematical armory needed, with simulated spectra to illustrate the discussion, and useful additional information in the appendices. Newcomers to EPR spectroscopy need not be deterred, but must have a sound mathematical background knowledge; Chapters 1, 2, and 4 are recommended for beginners, and can be read in a short time. However, the price is very high for newcomers to the field. On the other hand, the book will prove indispensable for departments that have already installed equipment for EPR spectroscopy.

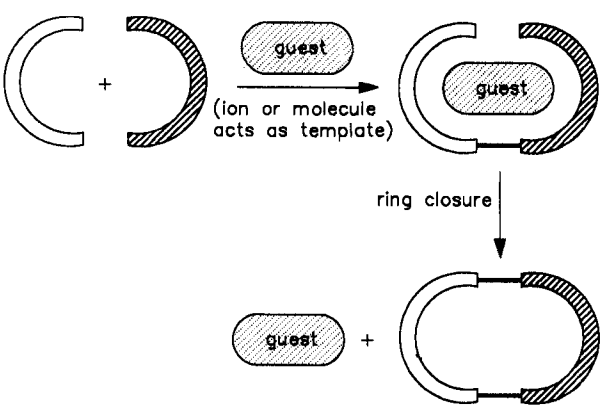
Template Syntheses



Ralf Hoss and Fritz Vögtle*

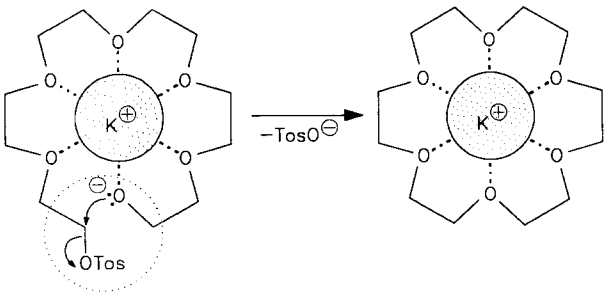
Although the principle of template synthesis has been known since the sixties, surprising discoveries and new applications in the field of supramolecular chemistry over the last decade have provoked a boom in the subject. The synthesis of supramolecular species has been made much more efficient, or even in some cases possible, by the introduction of template ions or molecules. It is not just metal ions that can act as templates. Neutral molecules, electrostatic interactions, and hydrogen bonds also support the formation of binary and tertiary complexes. Energetically favorable conformations then lead to the formation of a specific desired product in high yield. In addition to the discussion of metal ions and neutral molecules as templates, covalent, positive, and negative templates are differentiated. Kinetic and thermodynamic aspects will also be considered in this review, together with the influence of templates on the phenomenon of self-organization. Further developments and applications include the synthesis of oligonucleotides, peptide blocks capable of forming secondary structure, and template polymers. Template synthesis of defined molecular cavities ultimately leads to "inclusion chemistry on a nanometer scale."

1. Introduction

That metal ions can affect the course of "organic" reactions has been known for decades.[1] In the preparation of large ring compounds containing donor atoms by condensation reactions, such an effect is used intentionally by the addition of suitable cations and has achieved considerable importance.[2] As guest the metal ion or—as first found in the 1980s (see Section 3)—the neutral molecule as guest "coordinates" a ligand or host molecule, which is thereby generally brought into a suitable conformation for the formation of a specific (most often cyclic) product. This phenomenon is generally described as the "template effect" (Scheme 1). In this and the following schemes the template is marked by shading. In later Schemes, in addition, the strategic bond formed in the template synthesis is indicated by a dotted circle.

The term template effect was first used and defined at the beginning of the sixties.[3] (In this review the term matrix is used as a synonym for template.) Generally, all intermolecular forces that play a role in host–guest complexes effect a stabilization of the necessary binary or tertiary complexes. The countless examples found in the literature cover the relevance of the template effect under the heading of rational synthesis on the one hand, and on the other differentiate the individual template effects necessary. A selection has necessarily been made, and the latest examples have been given prominence here.

Scheme 1. Principle of the template effect: The guest (ion or molecule, indicated by shading) acts as a template, favoring connection of the decisive ("strategic") bond.



2. Template Syntheses with Metal Cations

The longest known and most frequently employed template syntheses are those based on metal ion chelates—either temporary or permanent.[4] The formation of copper phthalocyanines[5] and crown ethers,[6] now textbook examples, were among the first ligand syntheses in which metal ions acted as templates and ensured good yields: The ligand building blocks wrap themselves around the metal ion (Scheme 2), thereby favoring ring closure to the macrocycle.

The synthesis of catenanes,[7] among the highlights of supramolecular chemistry, is based (for example, for those of Sauvage et al.[8]) on the tetrahedral coordination of Cu^{I} ions by functional-

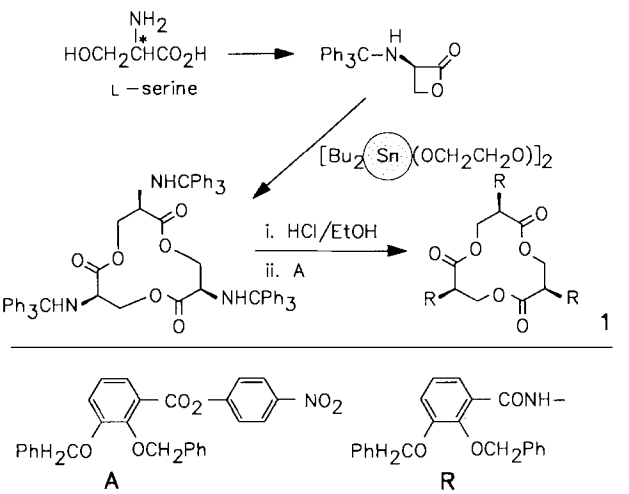
Scheme 2. Template synthesis of [18]crown-6. The potassium ion acts as a convex template.

ized phenanthroline ligands. In the synthesis these ligands become rigidly but reversibly and orthogonally arranged (Scheme 3).



Scheme 3. Synthesis of [2]catenanes with Cu^{I} as convex template (from Sauvage [8]). DMF = dimethylformamide.

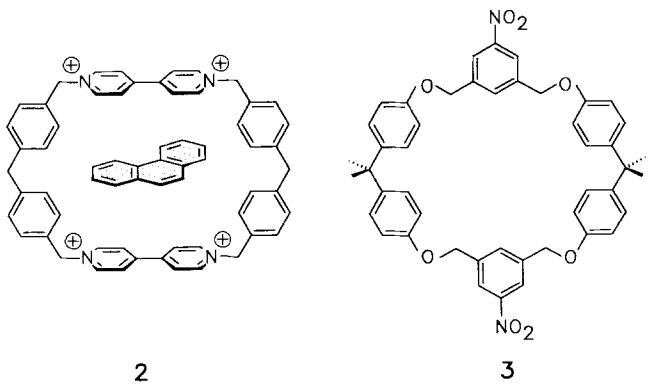
The total synthesis of protected enterobactin **1**, developed by Shanzer and Libman,[9a] involves the use of tin compounds as templates in the cyclooligomerization of β-lactones to macrocyclic polylactones (Scheme 4).[9b]

3. Neutral Molecules as (Supramolecular) Templates

An example of π-stacking as the driving force in a template synthesis is that by Hünig et al.[10] of the cationic host molecule **2**. The latter displays π-acceptor properties. In this case an increase in yield from 3–5% to 16% was observed when an excess

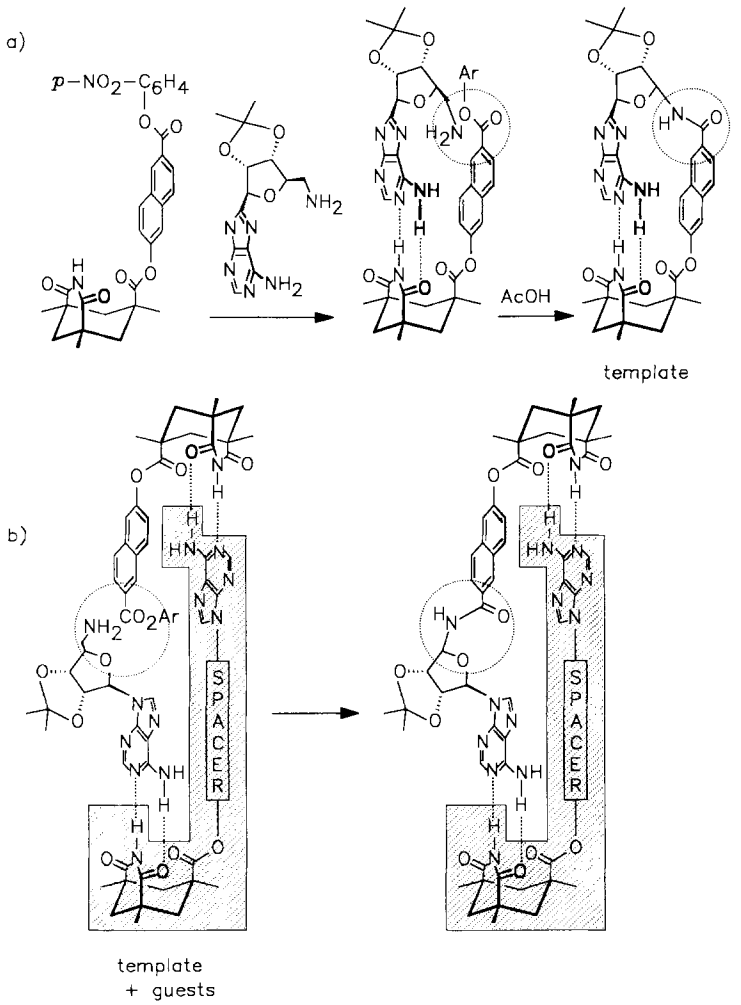
Scheme 4. The template-controlled total synthesis of the protected enterobactin **1**, which makes use of the potential of optically active natural products (L-serine).

of phenanthrene (as π-donor guest) was added to the reaction mixture. This example could even be considered as the first template effect of a hydrocarbon guest. Simultaneously the authors cast doubt on an earlier[11] template effect postulated as a result



F. Vögtle

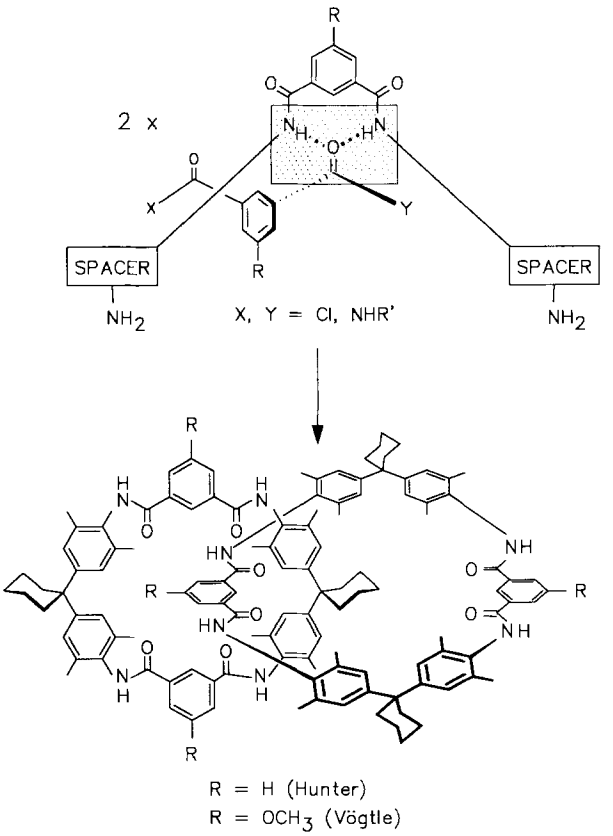
R. Hoss



Fritz Vögtle, born in 1939 in Ehingen/Donau, studied chemistry in Freiburg as well as chemistry and medicine in Heidelberg. There he received his Ph.D. for research with H. A. Staab on the valence isomerization of double Schiff bases. After his habilitation on steric interactions inside cyclic compounds, he was H2/H3 professor in Würzburg from 1969 to 1975. He then accepted a position as full professor and director of the Institut für Organische Chemie und Biochemie in Bonn. He is interested in the fields of supramolecular chemistry and molecular recognition, and after working on topics concerning crown ethers, podands, and siderophores, he has concentrated on compounds with large intramolecular cavities, ligands for supramolecular photochemistry, concave dyes, molecular tweezers, and spherical and tubular molecules. His further areas of research are deformed, strained and helical molecules, cyclophanes, and compounds with appealing architecture.

Ralf Hoss was born in 1963 in Mechernich/Eifel and studied in Bonn from 1983–1989. In 1993 he completed his Ph.D. under the supervision of F. Vögtle on macromonocyclic hosts to complex organic guest molecules. Currently he holds a postdoctoral position at the University of Bern in the group of J. Hulliger, working in the field of crystal growth and solid state properties of inorganic and organic materials.

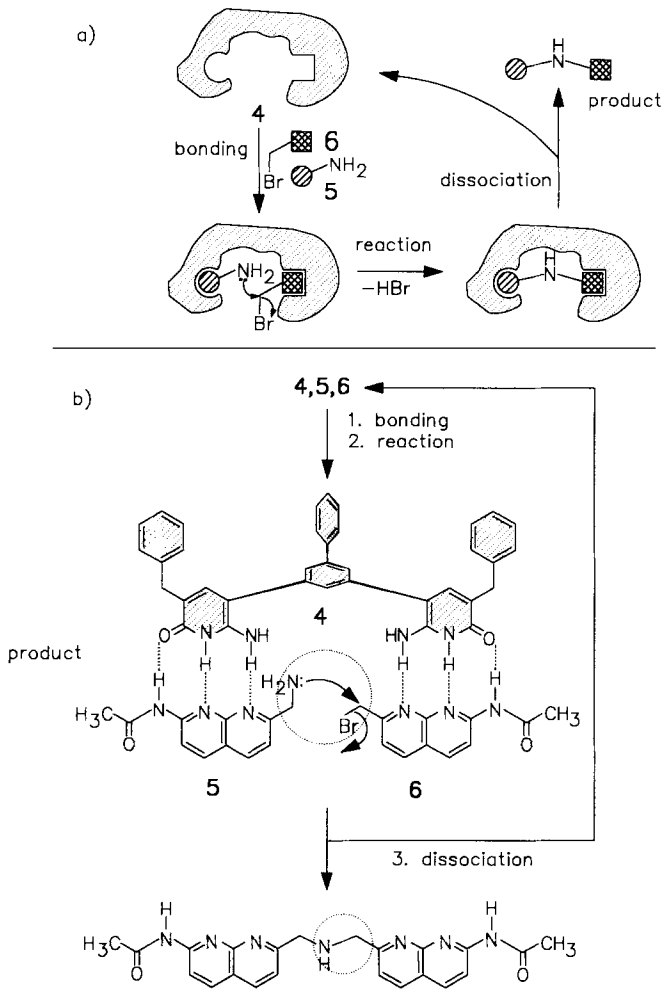
2 3



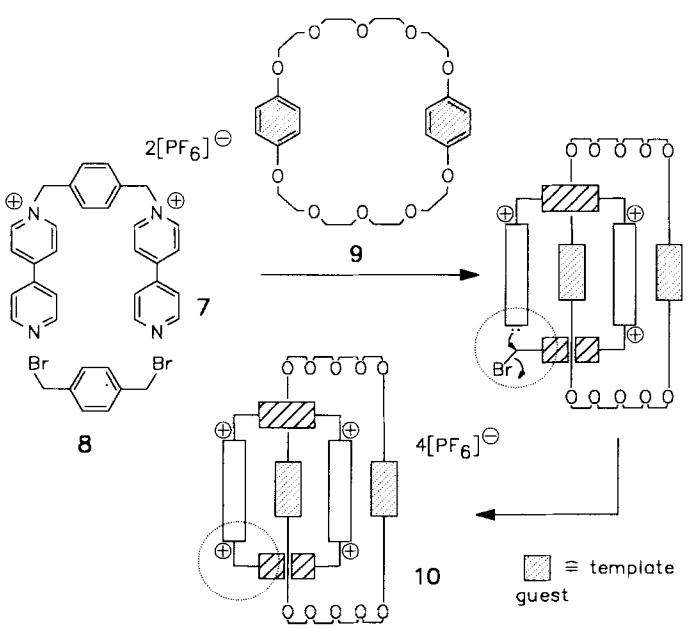
Scheme 5. Template synthesis of the cationic host molecule **2**, governed by π-stacking interactions. Addition of phenanthrene increases the yield from 4% to 16% [10]. In the synthesis of **3** [11], there is probably no template effect operative (see text).

Scheme 6. Replication experiment of Rebek et al. a) π-Stacking and hydrogen bonding support formation of the concave template molecule; b) the supramolecular (tertiary) complex promotes reaction between the amine and the carboxylic acid ester guest. The overall process is autocatalytic.

of an increased yield, because the macrocycle **3** binds benzene as guest only in the crystal lattice, not in solution (Scheme 5).



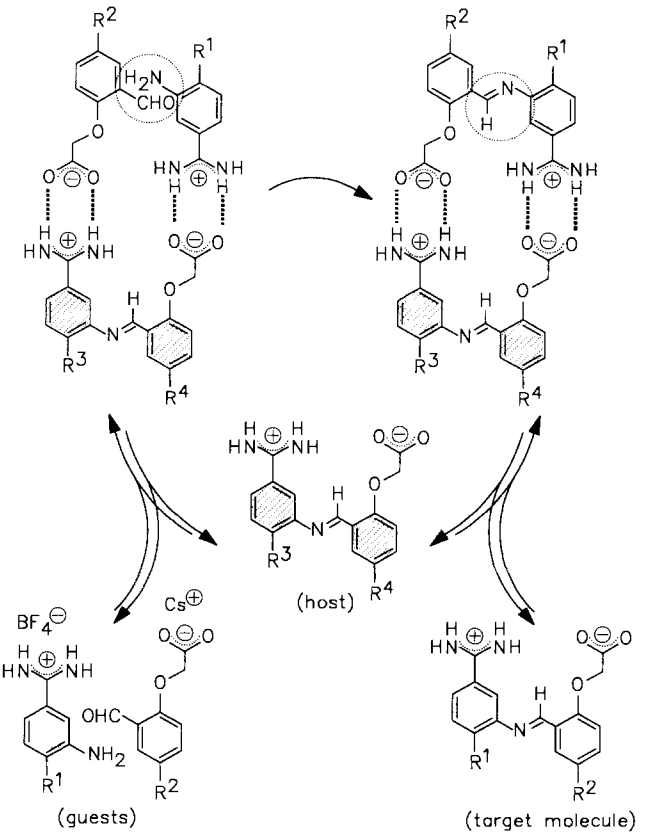
The phenomenon of π-stacking, supported by additional hydrogen bonds, leads in Rebek et al.'s replication experiments to aggregation (Scheme 6),[12] and in the productive two- and one-step catenane syntheses of Hunter (34% yield)[13] and Vögtle et al. (8.4% yield),[14] respectively, to orthogonalization of the intertwined macrocyclic molecular chains (Scheme 7).



Scheme 7. [2]Catenane syntheses by Hunter and by Vögtle et al. with a concave template.

In 1989 Kelly et al. carried out a template-promoted reaction between two substrates (Scheme 8).[15] As a result of its architecture the completely synthetic molecule **4** possesses two binding centers and is able to temporarily bind two organic substrates at the same time. Analogously to natural enzymes it is thereby able to convert an intermolecular reaction into an "intramolecular" process. Kinetic measurements show that **4** accelerates the S_N2 reaction between the amine **5** and the bromide **6**. Results of molecular calculations and kinetic experiments are in agreement with the assumption of a ternary complex (**4**···**5**···**6**) as intermediate.

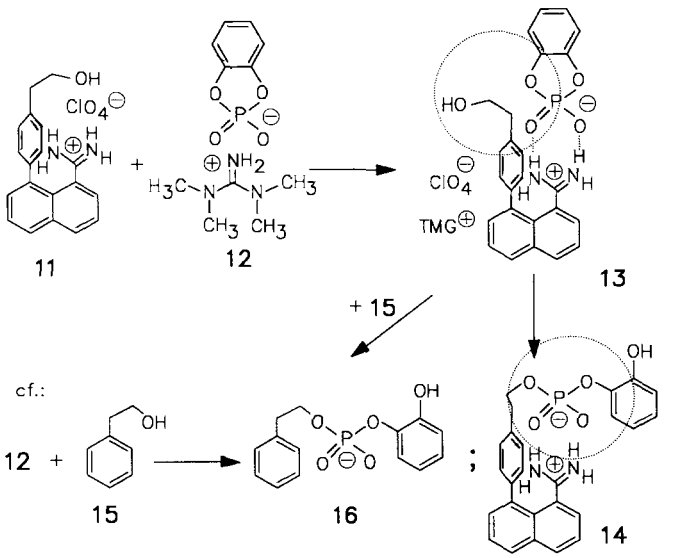
Stoddart et al. developed the efficient template-directed one-pot synthesis of the [2]catenane **10** from the bispyridinium salt **7**·2PF_6^-, the bis(bromomethyl)benzene **8**, and the paracyclophane crown ether **9** (Scheme 9).[16] The dominant, noncovalent interactions involved are based on electrostatic and dispersive forces—brought about by the reciprocal formation of a sandwich a) of a hydroquinone ether unit (guest) between parallel bipyridinium units (host) and b) of a bipyridinium unit (guest) between parallel hydroquinone ether units. The π-donor–π-acceptor stacking of the electron-rich and electron-poor arene groups leads to an orthogonal arrangement of the building blocks, the logical consequence of which is the formation of [2]catenanes in yields that were previously not held to be possible.



Scheme 8. Reaction between **5** and **6** in $CDCl_3$ in the presence of the concave template **4**. a) Schematic representation, b) specific template synthesis. Concentrations: **4**, **5**, **6** 4×10^{-3} M. The addition of the template accelerates the reaction by a factor of 6.

Scheme 9. Template-supported macrocyclization to give [2]catenane **10**, according to Stoddart et al. The unexpectedly high yield of **10** is 70% based on **7** [16], whereas without template support the macrocycle from **7** and **8** is formed with a yield of only 12% (ambient pressure) [16].

An interesting aspect of the template effect also dependent on electrostatic interactions is the parabolic self-multiplication-replication—with the aid of amidinium carboxylate bridges (Scheme 10).[17a] Replication generally takes place by way of



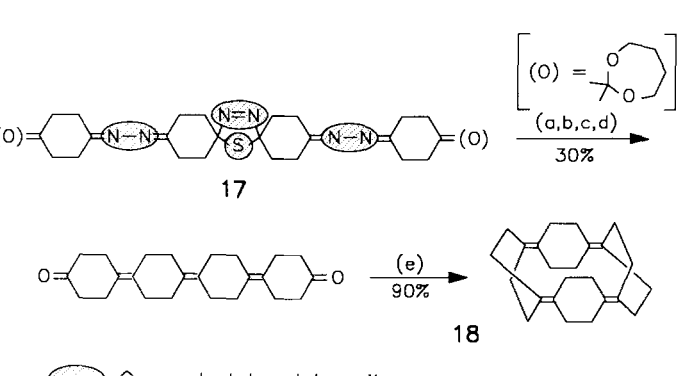
Scheme 10. Formation of the target molecule (R^1 = Me, R^2 = NO_2) in [D_6]dimethylsulfoxide ([D_6]DMSO). The reaction was monitored at 27 °C to a conversion of 25% with ^{1}H NMR spectroscopy. In the presence of the (host) template molecule (R^3 = *t*Bu, R^4 = H), the synthesis of the target molecule, a Schiff's base, is accelerated by a factor of about 370 M^{-1}.

(+)- or (−)-strands: The (+)-strand, as matrix, catalyzes formation of the (−)-strand and vice versa. In the self-complementary (palindromic) sequences the (+)- and (−)-strands are not distinguishable. A chemical "ligature" with a palindromic matrix is potentially a self-replicating system, or, in other words, the simplest model of self-replication is the autocatalytic synthesis of a self-complementary template molecule.[17b]

Göbel et al.[18] attempted to devise simple synthetic phosphordiesterases based on the strategy of formation of amidinium phosphate ion pairs. The rate of reaction of the amidinium alcohol **11** with **12** to give **14**, via the ion pair **13**, was considerably higher than that of the control reaction of **12** with **15** (Scheme 11). The phosphorylation of **11** took place as a supramolecular (quasi-intramolecular) process within the ion pair **13** rather than as an intermolecular process.

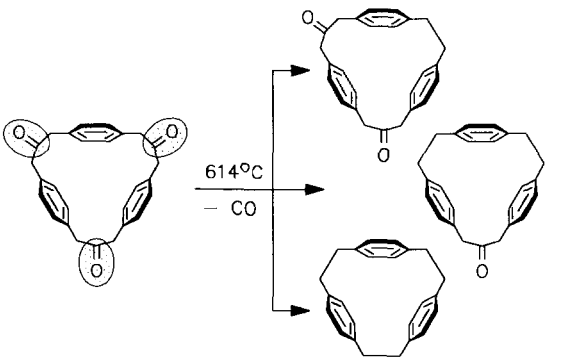
4. Template Syntheses with Covalent Molecules

Apart from the cyclization around a metal ion, specific atoms or molecular groups can be construed as temporary, covalently



Scheme 11. Condensation of the alcohol **11** that functions as template with the tetramethylguanidinium (TMG) salt **12**. The conversion takes place 9000 times faster than the reaction of **12** with the neutral phenylethanol **15**.

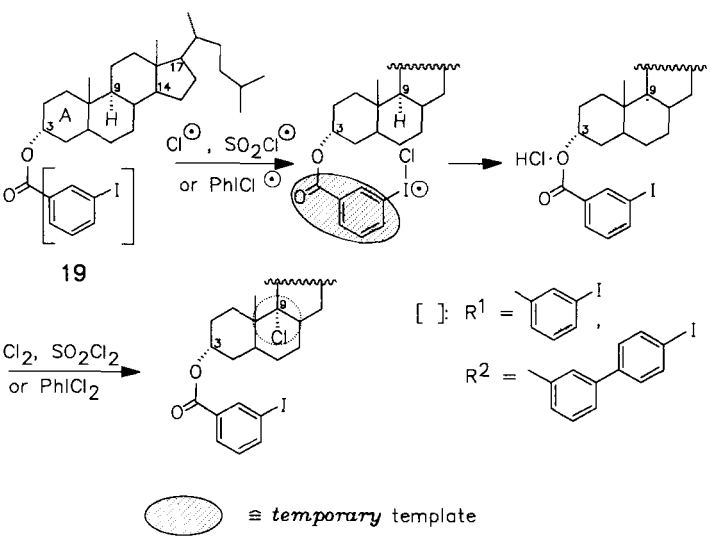
bound templates. There is a fundamental difference between these and supramolecular host–guest systems, in that molecular recognition is not necessary, rather "host" and "guest" (here, of course, not functioning as such) are joined together by one or more covalent bonds from the outset.



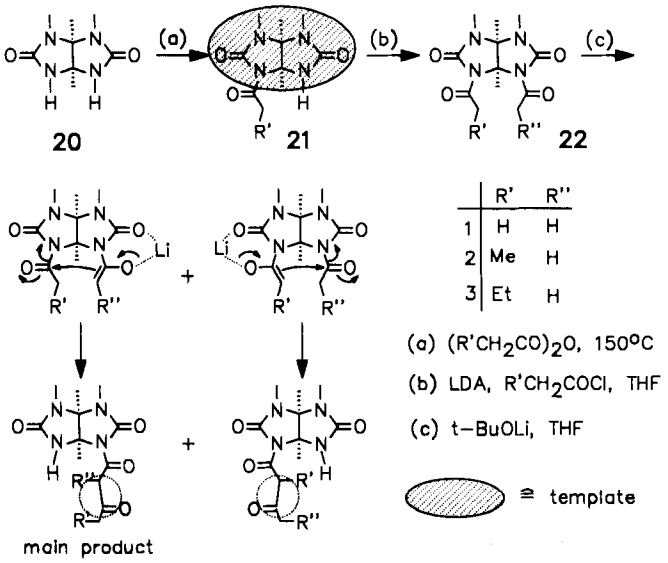
4.1. Temporary, Covalently Bound ("External") Templates

A template is described as temporary or external if it is eliminated at the end of a synthesis and is therefore not incorporated into the end product.[19] Sulfur or nitrogen, which can be eliminated by pyrolysis from the product after a successful reaction, can be regarded as the best known *exo*-templates. For example, McMurry et al.[20] used extrusion of N_2 and S (Barton method) from the thiadiazolines **17** in the preparation of the 16-membered hydrocarbon macrocycle **18** (Scheme 12).

The stereoselective synthesis of sterically unhindered alkenes takes place according to this principle.[21] Similarly, the carbocyclic [2.2]cyclophanes are easily accessible by extrusion of sulfur from dithia[3.3]metacyclophanes.[22] The synthesis of unsymmetrical [*m.n*]paracyclophanes (*m* and *n* are the number of bridging atoms) was hitherto only possible by multistep reactions. Selective ketone pyrolysis—the carbonyl group was introduced as temporary template by reaction of the corresponding benzyl halides with tosylmethyl isocyanide—allowed a new entry to hydrocarbon structures of this type (Scheme 13).[23, 24]



Scheme 12. Use of a covalently bound template for bond formation. a) H_2S, H_3CCN; b) $Pb(OAc)_4$, H_2CCl_2; c) HCl, H_2O, H_2CCl_2; d) toluene, Δ; e) $TiCl_3/Zn/Cu$, dimethoxyethane, 48 h, Δ.

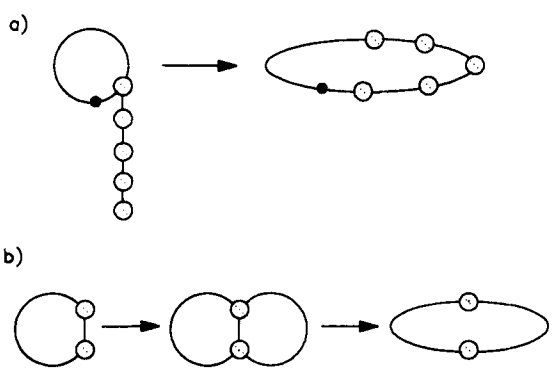


Scheme 13. Carbonyl groups as temporary covalently bound templates in the preparation of [*m.n*]paracyclophanes.

Radical chlorination of the steroid backbone was achieved by R. Breslow et al.[25] by introduction of a *m*-iodobenzoate template (see **19**, Scheme 14); the latter is easily removed by hydrolysis. With chlorinating agents such as $PhICl_2$, SO_2Cl_2, or Cl_2, attack of the free radical takes place not directly at the steroid H-atom as expected, but preferentially at the iodine atom. As a consequence, even such unselective radicals as Cl· or SO_2Cl· can be controlled and spatially directed by means of a template. The remarkable advantage of this process is that functional groups attached to the A ring are unaffected, and the unactivated position at C9 is attacked selectively (remote control of reactions).

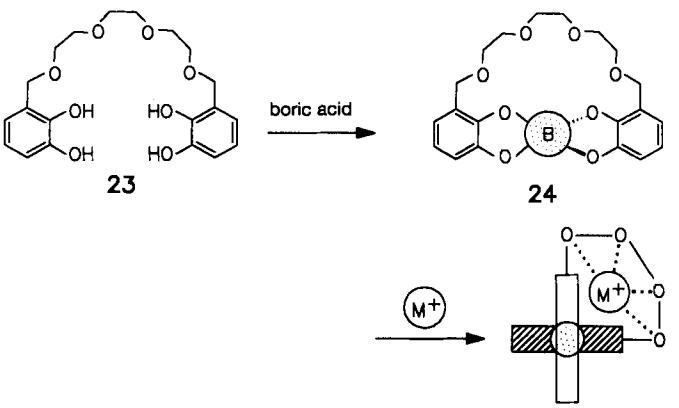
Scheme 14. The selectivity of biochemical reactions can be traced back to the geometry of the enzyme/substrate complex. Breslow et al. attempted to obtain such geometric control by using the reagent/substrate complex [25]. The reagent (e.g., Cl·) is attached to a covalently bound template and thereby permits regioselective attack on the substrate at C9.

Acylation of the 3,4,7,8-tetramethylglycoluril (**20**) by the method of Sun and Harrison[26] leads to the monoacyl derivative **21**, which can be further selectively acylated with lithium diisopropylamide (LDA) and acyl chlorides. The resulting symmetrical or asymmetrical diacyl compounds **22** undergo a base-catalyzed acyl transfer reaction (Scheme 15). Consequently, **20** acts



Scheme 15. The tetramethylglycoluril **20** acts as a temporary, covalently bound template in a base-catalyzed acyl transfer. R' = H, Me, Et; R'' = H. a) $(R'CH_2CO)_2O$, 150 °C; b) LDA, $R''CH_2COCl$, THF; c) *t*BuOLi, THF.

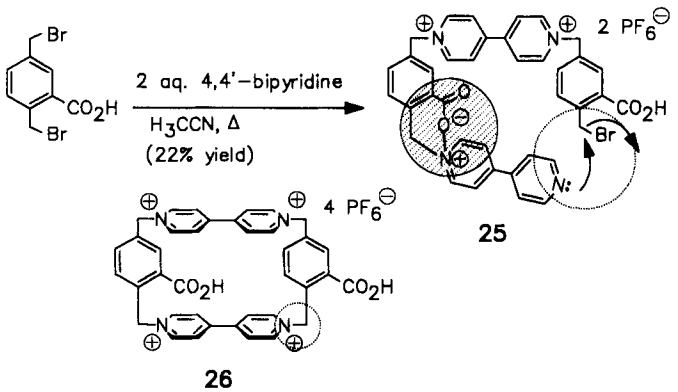
as a temporary template that facilitates a simple condensation between acyl units. The absence of O-acylation products is explained by chelation of the lithium by the intermediate enolate.



4.2. Permanent, Covalently Bound ("Internal") Templates

If the formation of a macrocycle is effected, for example, by expansion of a smaller ring by the insertion of a side chain already present, the smaller ring is designated as a permanent template or *endo*-template, because all the molecular components originally present are also found in the end product (Scheme 16a). The most common example is probably the "zip" reaction (transamidation).[27] In addition, selected bond cleavage (C–N,[28] N–N,[29] C–C,[30] or C=C bonds[31]) of an initially synthesized bicyclic molecule can lead to macrocycles that contain all the original atoms. Thus, this method of ring formation can also be regarded as involving a permanent template (Scheme 16b).

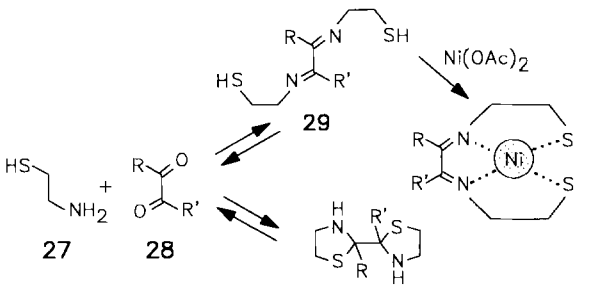
Scheme 16. Template syntheses with permanently bound templates. a) Ring extension by insertion and b) ring expansion by selected bond cleavage.



Kobuke et al.[32] demonstrated that the podand **23** only forms weak complexes with alkali metal ions. However, when a chiral macrocyclic crown ether structure is formed by complexation with boric acid, alkali metal ions are bound much more strongly (Scheme 17). A certain amount of stiffening, provided by a covalent B–O bond, improves the preorganization of the ligands that is required for the complexation of metal ions.

Scheme 17. The podand **23** displays more marked concave preorganization on esterification with boric acid (conversion to the crown **24**).

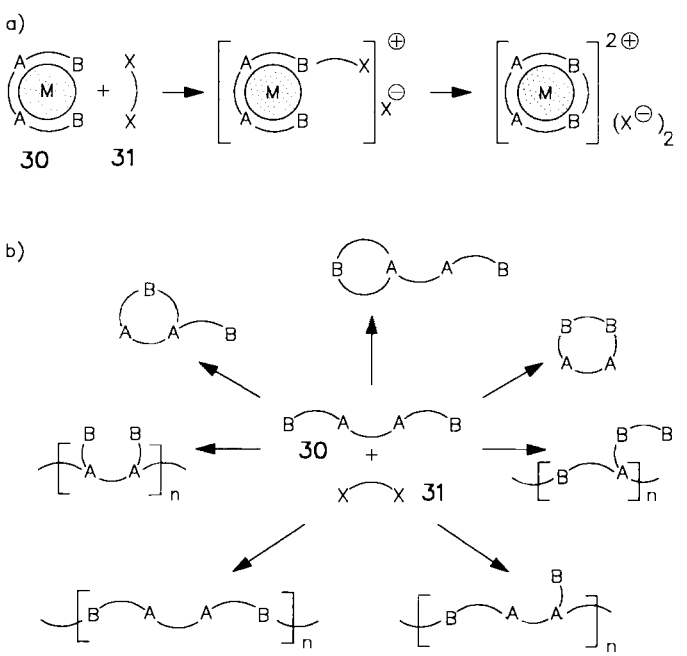
The functionalized cyclophane **26** was synthesized by Harriman et al.[33] in a one-step cyclization (Scheme 18). The crucial step in this synthesis is the postulated formation of the zwitterionic open-chain intermediate **25**, in which the degree of rotational freedom is restricted by interaction between the carboxylate group and the pyridinium nitrogen atom, thereby leading to the correct geometry for the formation of the macrocycle. The zwitterionic structure element in **25** can be regarded as both an internal and a permanent, ionic template.



From the last two examples it can be seen that the distinction between covalent and noncovalent (supramolecular, weakly bound) templates is not rigid.

Scheme 18. The carboxylate group in **25** provides an "internal template effect" by ion association and facilitates the intramolecular ring closure to **26**.

5. Kinetic and Thermodynamic Template Effects

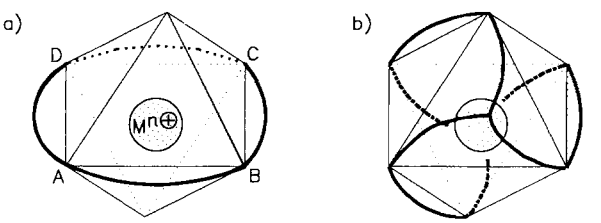


The thermodynamic or "equilibrium" template effect is based on the fact that in the absence of the template the desired product is indeed formed, but with one or more (undesired) compounds that are in equilibrium with each other.[34] A marked tendency of the product to form chelates enables a template to displace the product equilibrium in the desired direction. The first example of an equilibrium template effect was the formation of a nickel(II) complex of the Schiff base **29** formed from β-aminoethanethiol (**27**) and the α-diketone **28** (Scheme 19).[35]

Scheme 19. Example of a thermodynamic template effect.

As the equilibria are frequently complex, it is often difficult to recognize a thermodynamic template effect unequivocally. Not infrequently, the best indication is the formation of an unexpected product in high yield. The principle of complementarity must be emphasized here: if a ligand (host) in a product mixture is complementary to an available metal ion or neutral (guest) molecule, then this will be bound selectively, and the equilibrium shifted in its favor.

The kinetic template effect exploits the advantage of molecular organization ("self-organization") of ligands around a template.

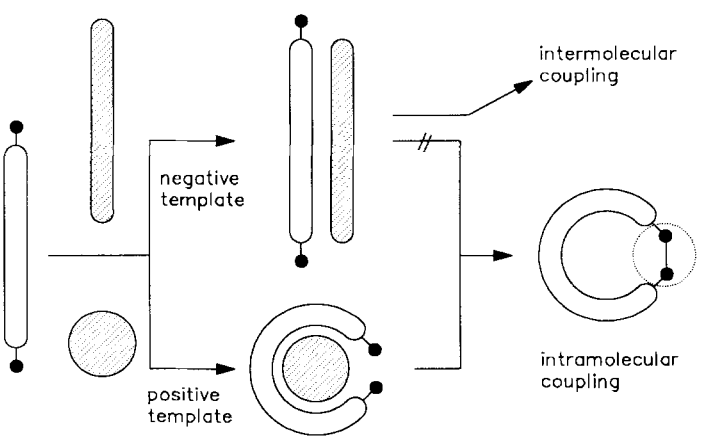


Scheme 20. Kinetic template effects. a) Function of a template molecule M as coordination center; b) in the absence of M numerous equilibria often occur.

The formation of oligo- or polycondensation products is largely suppressed by the action of the template as a coordination center. A simplification of the possible reactions between a linear ligand **30** and a bifunctional, electrophilic reagent **31** in the presence and absence of a template species is shown in Scheme 20.

If no guest molecule is present then the two reagents can react to give a series of polymeric and cyclic products (Scheme 20b). The presence of a template M can steer the reaction. If the template binds the linear ligand selectively in a planar arrangement, the two terminal functional groups (B) will be held adjacent to each other within the "coordination sphere" of the template (Scheme 20a). Then the terminal donor atoms (B), if still able to react as nucleophiles in spite of interaction with the template (M), are correctly positioned to react with the bifunctional electrophile.

A metal ion in a template reaction usually organizes two or three reactive centers (A, B, C) at the corners or faces of its idealized coordination polyhedron. If one of the corners is included (e.g. with Ni^{2+}), a chelate ring is formed, and the product is usually a large monocyclic ligand (Scheme 21a). If a face is involved (e.g.



Scheme 21. The corners or faces of an idealized coordination polyhedron act as reactive centers in a template reaction.

with Co^{3+}), then the product can be a cage compound (Scheme 21b). This synthetic strategy has been used successfully for the construction of numerous polydentate ligands.[36–38]

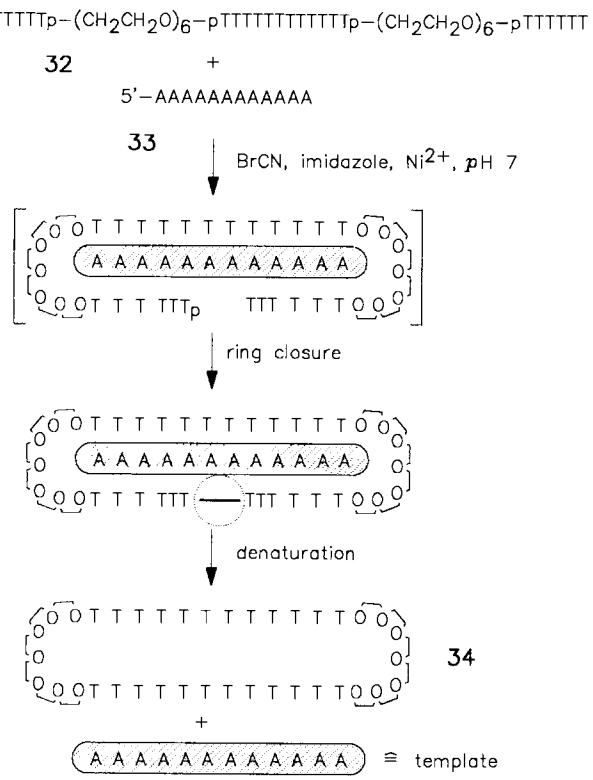
6. Positive and Negative Templates

In the use of templates, Sanders et al.[39] differentiate between two modes of action that are complementary (Scheme 22): A

Scheme 22. Only the positive template leads by intramolecular ring closure to the desired result (discrete target molecule). In contrast, the negative template leads to less uniform, higher molecular mass products, most of which cannot be aspired to. Both cases involve convex templates.

"positive" template directs the approach of two reactive end groups in a molecule, thereby generally supporting the desired intramolecular cyclization. In contrast, a "negative" template effect holds the reactive groups apart, thereby suppressing the intramolecular cyclization and leading preferentially to the—undesired—intermolecular reaction.

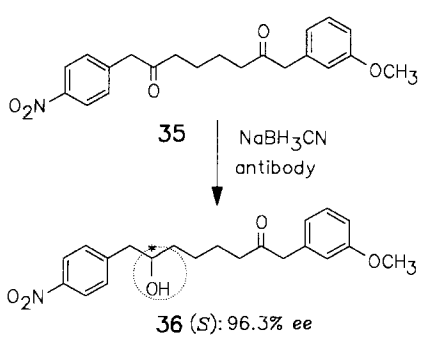
7. Self-Organization



From template effect to self-organization (self-assembly) is only a small jump, if even that. It follows from the view that an arbitrary number of subunits with corresponding molecular recognition properties can not only congregate by self-recognition to form a superstructure, but that substrate–template recognition can also lead to the organization of a defined supramolecule and that the features of natural self-assembling systems, classified by Stoddart et al.,[40] can be transfered to the supramolecular template-substrate complex. If subunits have corresponding molecular recognition properties, the template effect will underly the self-examination prior to assembly. On the grounds of exact recognition characteristics, specific for every subunit, it is improbable that defective subunits would be used in the construction of a superstructure. Defective subunits would be rejected by the growing supramolecular structure. Thus, absolute accuracy in the construction of a subunit is not necessary, as mistakes will be removed in the aggregating step. The high synthetic efficiency, a direct result of self-examination, is convincing. The use of specially synthesized templates is becoming more common, for example in the synthesis of polypeptides.[41–44]

8. Further Developments and Applications

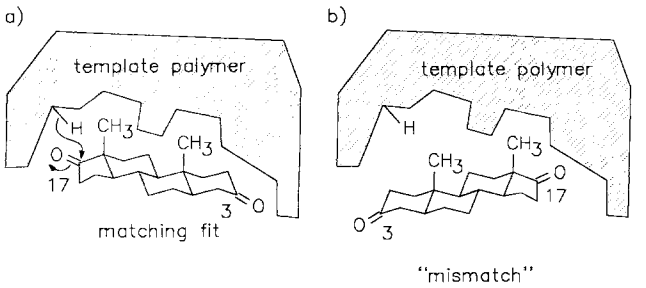
Kool et al.[45] have reported on the construction of the cyclic hybrid molecule **34**, which contains two oligonucleotide sections bridged by two oligo(ethylene glycol) chains (Scheme 23). The oligomer **33** is employed as (guest) template in the cyclization, in order to bring the reactive phosphate and hydroxy end groups into the appropriate orientation for intramolecular esterification in the presence of BrCN, imidazole, and $NiCl_2$.



The sequence-specific binding of synthetic oligonucleotides and analogs to RNA and DNA is being studied intensively in the examination of natural polynucleotides and for the development of potential therapeutics.[46]

Natural proteins undergo a folding process that leads to a spatially defined tertiary structure. With synthetic polypeptides folding to a globular structure is not a matter of course. The situation in vivo is not always comparable with that in a test tube. A concept introduced by Mutter et al.[47] represents a step toward achieving the folding of artificial proteins. According to this concept, peptide blocks leading to formation of secondary structure are covalently attached to a topologically tailor-made template. The template serves to direct the peptide chains into a characteristic three-dimensional structure, as in proteins. The resulting macromolecules are described by Mutter et al., in accord with the method used in their formation, as template-associated synthetic proteins (TASPs). In contrast to the other template molecules discussed here, in this case the template results in the stabilization of a specific conformation rather than in supporting the formation of a covalent link.

Scheme 23. Preparation of the cyclic hybrid molecule **34** with the aid of oligonucleotide **33** as (guest) template. T = thymidine, A = adenosine.



The remarkable specificity of a monoclonal antibody has been used by P. G. Schultz et al.[48] to control the selective reduction of the carbonyl compound **35** with $NaBH_3CN$ (Scheme 24). The observed enantiomeric excess of 96% (*S*)-**36** cannot be obtained with conventional chemical methods.

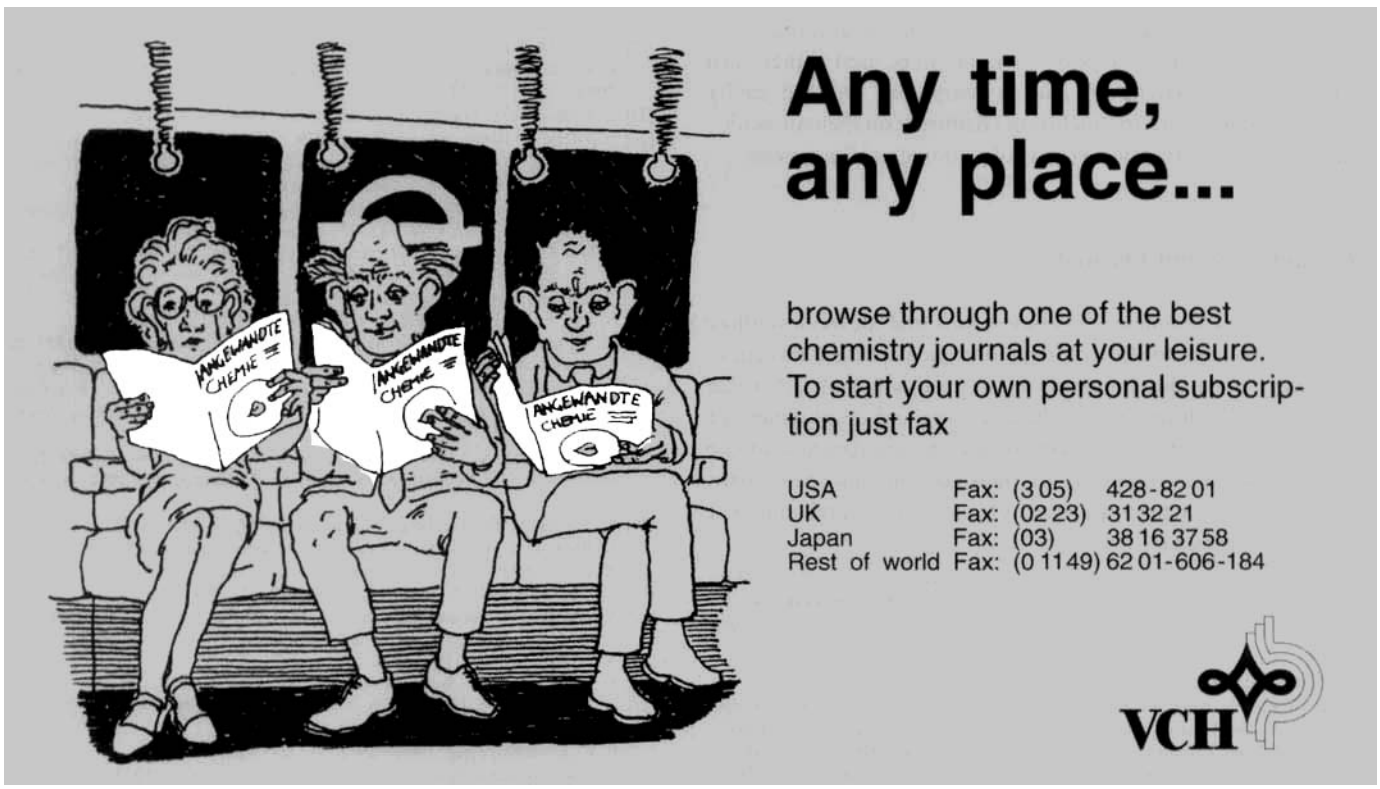
Scheme 24. Stereoselective reduction of diketone **35** with $NaBH_3CN$ in the presence of a monoclonal antibody (*ee* = 96%) [48].

Use of polymers in place of discrete metal ions or neutral molecules gave rise to the template polymers[49] of Byström et al. If the term "template" is taken in its original meaning borrowed from photography, the template polymers are actually templates in the true sense. In a process similar to that used in photography, impressions (macromolecular niches) are initially generated on

the surface (or in the interior) of the polymer by so-called "imprint molecules". If the molecular imprint contains appropriate functional groups, molecules can be adsorbed and chemically converted with regio- and stereoselectivity (Scheme 25). The selective reduction of steroid ketones by means of $LiAlH_4$-activated template polymers can be carried out following the principle of an ion exchanger. Although the application of polymers in template syntheses is currently limited, and the reactions do not always run satisfactorily, this method appears to be a landmark for future rational syntheses.

Scheme 25. Niches, which allow regio- and stereoselective conversion of the substrate, are produced on the surface of the polymer by "imprint" molecules. For the steroidal ketone selected here only a specific polymer/substrate binding leads to optical transfer of the hydride from the concave template to the carbonyl group of the guest (a). All other polymer/substrate bindings are unsuitable on steric grounds (b) and do not lead to the desired reaction (at the carbonyl group).

Microporous phases with three-dimensional lattice networks and defined pore structures and sizes can be obtained by the use of molecules or hydrated ions of alkali metals or alkaline earth metals as templates.[50] A concept developed by the Mobil Oil Company for the synthesis of porous materials employs a regular arrangement of molecules formed by self-assembly rather than a single, solvated, organic molecule or metal ion as template. Three-dimensional porous media can be used in their turn for molecular recognition and as templates. Defined cavity structures could lead to "inclusion chemistry on the nanoscale" and are termed "reaction vessels of nanometer dimensions".



9. Summary and Outlook

Tailor-made template units (guest ions and molecules) allow acceleration and control of reactions in a defined direction, frequently even the preparation of products that otherwise would be difficult to obtain. The discovery and development of new template-controlled reactions and the clarification of the basic mechanisms involved in intermediate and permanent host–guest interactions are worthy targets of research aimed at effective syntheses.

Organic and Organometallic Molecular Magnetic Materials—Designer Magnets

Joel S. Miller* and Arthur J. Epstein*

Magnets composed of molecular species or polymers and prepared by relatively low-temperature organic synthetic methodologies are a focus of contemporary materials science research. The anticipated properties of such molecular-species-based magnetic materials, particularly in combination with other properties associated with molecules and polymers, may enable their use in future generations of electronic, magnetic, and/or photonic/photronic devices ranging from information storage and magnetic imaging to static and low-frequency magnetic shielding. A tutorial of typical magnetic behavior of molecular materials is presented. The three distinct models (intramolecular spin coupling through orthogonal orbitals in the same spatial region within a molecule/ion, intermolecular spin coupling through pairwise "configuration interaction" between spin-containing moieties, and dipole–dipole, through-space interactions) which enable the design of new molecular-based magnetic materials are discussed. To achieve the required spin couplings for bulk ferro- or ferrimagnetic behavior it is crucial to prepare materials with the necessary primary, secondary, and tertiary structures akin to proteins. Selected results from the worldwide effort aimed at preparing molecular-based magnetic materials by these mechanisms are described. Some organometallic solids comprised of linear chains of alternating metallocenium donors (D) and cyanocarbon acceptors (A) that is, $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$, exhibit cooperative magnetic phenomena. Bulk ferromagnetic behavior was first observed below the critical (Curie) temperature T_c of 4.8 K for $[Fe^{III}(C_5Me_5)_2]^{\bullet+}[TCNE]^{\bullet-}$ (Me = methyl; TCNE = tetracyanoethylene). Replacement of Fe^{III} with Mn^{III} leads to a ferromagnet with a T_c of 8.8 K in agreement with mean-field models developed for this class of materials. Replacement with Cr^{III}, however, leads to a ferromagnet with a T_c lowered to 3.65 K which is at variance with this model. Extension to the reaction of a vanadium(0) complex with TCNE leads to the isolation of a magnet with a $T_c \approx 400$ K, which exceeds the thermal decomposition temperature of the material. This demonstrates that a magnetic material with a T_c substantially above room temperature is achievable in a molecule/organic/polymeric material. Finally, a new class of one-dimensional ferrimagnetic materials based on metalloporphins is discussed.

1. Introduction

Magnets have captivated mankind from time immemorial and have played a prominent role in the development of both science and technology as well as in the evolution of society.[1] In perhaps the earliest example of technology transfer involving condensed matter science, Chinese workers exploited the fundamental observation of magnetic behavior that had been discovered by ancient Grecians by invention of the "south-pointing" compass.[1b] The development of present day experimental[1c] and theoretical condensed matter physics as well as quantum mechanics and molecular chemistry are also deeply indebted to magnetism. Magnets have become ubiquitously woven into the fabric of everyday life and are indispensable in our present world. This is reflected by the annual sales of magnets in the western-world which reached $\$2 \times 10^9$[2] in 1990. Applications of magnets span from magneto-mechanical machines (frictionless bearings, medical implants, magnetic separators, etc.) to magnetic shielding and electromagnetic radiation absorption (deflection of static and low-frequency magnetic fields), to acoustic devices (loudspeakers, microphones, etc.), to telecommunication/information technology (switches, sensors, magnetic resonance imaging, as well as magnetic and optical disks, etc.), and to motors and generators.[3] Futuristic "smart" materials and systems will rely upon "smart" switches, sensors, and transducers that undoubtedly will be comprised in part by mag-

netic materials. Magnets consequently are an important focus of modern materials research programs, with emphasis on improvement of their technologically useful properties.

Current magnetic materials share the generic attributes of a) being atom-based, b) having d or f orbital transition- or lanthanide-metal-based spin sites, and c) possessing extended network bonding in at least two dimensions. Furthermore, they d) are prepared by high-temperature metallurgical methodologies. Metamorphosis from such atom-based inorganic materials to molecule-based organic/polymeric materials should enable the a) specific alteration of the magnetic properties by established organic chemistry methodologies, b) combination of magnetic properties with other mechanical, electrical, and/or optical properties, and c) simplicity of fabrication often enjoyed by organic materials, that is, low-temperature synthesis as opposed to the high-temperature metallurgical methods currently utilized. These qualities may herald the use of organic materials in future generations of electronic, magnetic, photonic and/or photronic devices. The discovery of molecule-based magnets parallels the discovery of cooperative electrical phenomena in organic/molecular superconductors with the advent of cooperative magnetic phenomena in organic/molecular materials.

The issue of what constitutes a molecule-based magnet frequently arises. As noted previously classical magnets are comprised solely of a high density of d or f orbital metal spin sites and are prepared by metallurgy. An organic magnetic material, in contrast, must possess at least one type of spin site that is based on s and p orbitals and be prepared by organic chemistry methodology; that is, an organic component of the material plays an active role in the resultant magnetic behavior. Intermediate between these extremes lie solely metal-spin-site-based magnetic materials prepared and modified by organic chemistry methodologies (i.e., an organic component of the material plays a passive role in the resultant magnetic behavior). In principle, organic-based materials prepared by metallurgy (i.e., high-temperature pyrolysis of organic compounds[7]) lie between these extremes. Although various specific criteria for a molecule/organic magnetic material have been applied, we define organic/polymeric magnetic materials as those materials prepared through the established low-temperature synthetic procedure of organic, organometallic, and coordination metal synthetic chemistry. We use the term "molecular species" to refer to any of the above be it a molecule, ion, or polymer. This feature is common to all the materials studied by the majority of the scientists that have participated at conferences on this topic.[4] It should be noted that the ferromagnetic Zintl phase $Ca_{14}MnBi_{11}$ composed of isolated ions,[5] the ferromagnet Rb_2CrCl_4 composed of a covalently bonded two-dimensional

Joel S. Miller was born in Detroit, Michigan and received his Bachelor of Science in Chemistry from Wayne State University (1967) and Ph. D. from UCLA (1971). After a postdoctoral fellowship at Stanford University he joined the Xerox Webster Research Center in 1972 and later he joined the late Occidental Research Corporation (1978). He was Visiting Professor of Chemistry at the University of California, Irvine, CA and Chairman of the Southern California Section of the American Chemical Society (1981). He joined the Central Research & Development Department at the Du Pont Company in 1983 where he was a Research Supervisor for solid-state science. He has been a Visiting Scientist at the Weizmann Institute (1985) and a Visiting Professor of Chemistry at the University of Pennsylvania (1988). Recently he joined the faculty of department of chemistry at the University of Utah. He is on the advisory board of Advanced Materials, Chemistry of Materials, and Journal of Materials Chemistry, and a member of the Inorganic Synthesis Corporation. His research interests focus on the solid-state magnetic, electrical, and optical properties of molecular (organic, organometallic, and inorganic coordination) compounds and electron transfer complexes as well as the surface modification of solids. Currently he is actively involved in synthesis and characterization of molecular/organic-based ferromagnets. In addition to patents he has edited eight monographs and published over 240 papers in these and other areas.

Arthur J. Epstein was born in Brooklyn, New York and received his B. S. in Physics from the Polytechnic Institute of Brooklyn in 1966 and his Ph. D. in Physics from the University of Pennsylvania in 1971. After thirteen years at the Xerox Webster Research Center, where he was Principal Scientist, he joined The Ohio State University in 1985 as Professor of Physics and Professor of Chemistry. He has been The Director of the Ohio State University Center for Materials Research since 1989. He also has been adjunct Professor of Physics at the University of Florida and was a Visiting Professor at Université Paris-Sud and The Technion-Israel Institute of Technology. He is a Regional Editor for Synthetic Metals. His current research interests include experimental and theoretical study of magnetic, electronic/optical, and transport phenomena of synthetic magnets (molecular, organic and polymeric magnets) and synthetic metals (conducting polymers, organic and molecular materials), including the study of excitations and their dynamics. He also is active in the exploration of potential applications of unconventional magnetic, electronic, and optical materials for which he consults with several companies. In addition to having originated twenty patents and editing three conference proceedings, he has published over 350 papers in these and other areas.

network structure,[6] as well as several examples of magnetic materials prepared by the pyrolysis of organic molecules[7] are typically prepared at high temperatures and as such are not within the direct focus of this review.

Molecular-species-based ferromagnetic compounds although postulated in the 1960s have been realized only within the past decade.[4, 8, 9] In this review we will briefly summarize the essence of the magnetic behavior important for understanding the physical properties of this class of materials[9, 10] and review some of the research results achieved worldwide in this rapidly developing area of contemporary inquiry.

2. Magnetic Behavior—A Tutorial

Magnetic behavior is typically detected by a material's attraction (or repulsion) to a magnet. It arises from the intrinsic spin of an electron and how the electron spins on adjacent atoms (or molecules) couple with each other. Every electron has a minute magnetic moment associated with the quantum-mechanical "spin". The electrons reside in orbitals and each orbital may have two electrons—one "spin-up", that is, spin aligned with an applied magnetic field (↑), and one "spin-down", that is, spin aligned opposing an applied magnetic field (↓)—such that the spins cancel. A radical is an atom, ion, or molecule with an odd number of electrons (or an even number of electrons n in more than $n/2$ orbitals. Thus, a radical must have at least one orbital with an unpaired electron and hence have a net spin.

The unpaired electron has a spatial distribution, termed spin density, which can be distinct from the charge and electron densities of a molecular species. For a radical anion such as the tetracyanoethenide radical, $[TCNE]^{\cdot -}$, the additional electron is added to the lowest unoccupied molecular orbital (LUMO) of the closed shell TCNE. The original LUMO of TCNE is now a partially occupied molecular orbital (POMO), if we follow a restricted open-shell Hartree–Fock (ROHF) formalism in which all of the orbitals are doubly occupied except for the POMO. (Note that POMO refers to orbital occupancies that may lead to states that can be different.) For $[TCNE]^{\cdot -}$ the POMO is a π^* orbital of b_{2g} symmetry,[11] and there are several nodes in this orbital which are dominated by a large node between the central carbon atoms participating in the TCNE double bond (Fig. 1 top). In the ROHF formalism, the spin density of the POMO represents the excess spin density in the molecular species, and this spin density must be in one direction (positive) and is termed α spin. Furthermore, for $[TCNE]^{\cdot -}$ this excess spin density can only reside in the p orbitals, and it should not have EPR hyperfine splittings because there is no mechanism for the spin to interact with the s orbitals which have the proper symmetry to interact with the nuclear spins. The simplest way to couple all of the orbitals is to use the unrestricted Hartree–Fock (UHF) model in which the restriction of double occupancy in an orbital is relaxed. In the UHF model each orbital is singly occupied and one thus solves for positive (α) or negative (β) spin densities.[13a] (By convention for a radical, the positive spin density (α spin) is greater than the negative spin density (β spin)). Because the α- and β-spin densities are calculated individually, coupling of all of the orbitals is possible so that regions exist with excess α and β spins. The amount of unpaired spin density on an atom within the molecular species need not, however, correspond to the atom contributions in the POMO (Fig. 1 middle). Furthermore, the regions of excess spin are now no longer determined by the ROHF POMO; thus mixing with s orbitals leads to the observation of EPR hyperfine splittings.

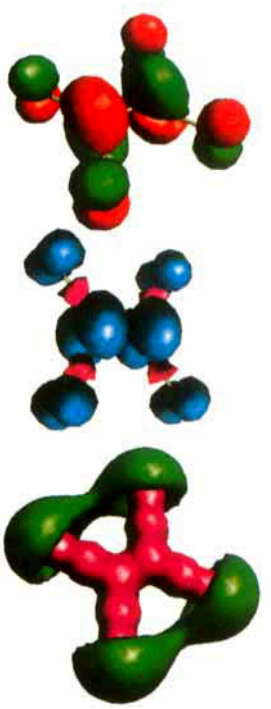

Fig. 1. Electron structure information for $[TCNE]^{\cdot -}$. All calculations were done on $[TCNE]^{\cdot -}$ with the local density functional method using the optimum calculated geometry [11] and the unrestricted spin formalism with the program DGauss and visualizations with UniChem [14a]. Highest occupied α-spin orbital (top); spin density (middle); electrostatic potential (ESP) energy surface at ± 90 kcal mol^{-1} (3.9 eV) (bottom). ESP surface was obtained by the interaction of a particle of 1+ charge with the unrelaxed molecular electron density. Positive regions (violet) correspond to repulsive interactions and negative regions (green) correspond to attractive regions (from ref. [14b]). (Figures kindly provided by D. A. Dixon and S. C. Walker).

Spin polarization can be described by either valence bond (Fig. 2) or molecular orbital approaches. Spin polarization arises because there are different exchange interactions between the unpaired α-spin electrons in the POMO and the other α-spin electrons as compared to no exchange with the β-spin electrons. For example, for the Li atom the 2s electron polarizes the 1s electrons because there are different effective potentials for the α- and β-spin 1s electrons. Relaxing the double occupancy for the 1s orbital will lead to a lower energy. Another way to consider such spin polarizations, which has been used to explain the spin density in the $CH_3^{\bullet}$ radical[13b] (positive (α) spin density on C and negative (β) spin density on H), is the use of two simple rules: 1) an intraatomic Hund's rule in which electrons on an atom tend to have parallel spins and 2) electrons that form a chemical bond tend to have antiparallel spins. Because the α- and β-spin densities can interact, spin polarization can occur, by which an unpaired electron can polarize the paired spins in an adjacent σ or π bond in such a way that one of the paired electrons in the bond is closer to one atom than another (Fig. 2).

A way to view the charge distribution in a molecular species, in addition to the use of Mulliken charges,[13c] is to calculate the electrostatic surface potential (ESP). The interaction energy (attractive or repulsive) of a test charge (in this case 1+) with the unrelaxed electron density is thus calculated as illustrated for $[TCNE]^{\cdot -}$ in Figure 1 bottom. The ESP surface shows that there is significant negative charge on the nitrogen atoms even though one formally would place most of the negative charge on the two carbon atoms of the double bond.

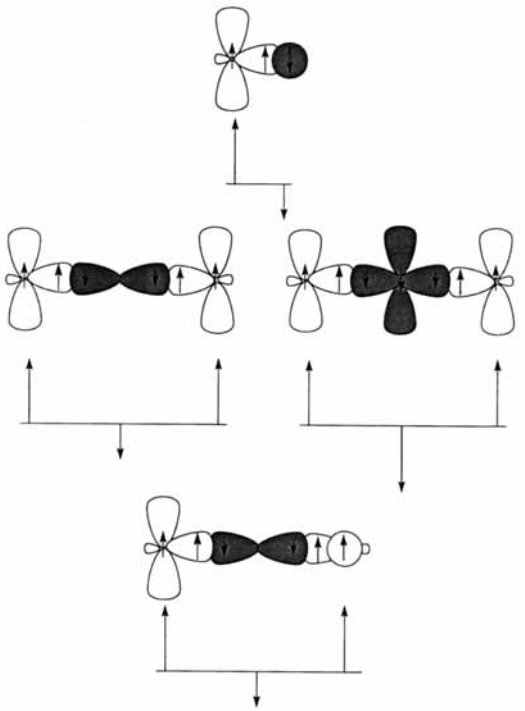

Fig. 2. Illustration of the orbital interactions for spin polarization in a σ bond (top), between π orbitals through two σ bonds (center left), between π orbitals through σ bonds and π orbitals (center right), and between π orbitals rotated by 90° through σ bonds (bottom).

The net $S = 1/2$ spin density (positive or negative) on each atomic site of a molecular species is determined by adding up separately the contribution to each atomic site of every "up-spin" and "down-spin" filled electron orbital, that is, the sum of all α-spin electron densities minus the sum of all β-spin electron densities. The POMO electron and spin densities differ from the molecular/ion charge densities. The total charge density is a sum of the charge density associated with each occupied energy level (both α and β spin) at each atomic site less the positive nuclear charge, and is illustrated by the electrostatic surface generated when a point charge is brought toward a molecular species (Fig. 1 bottom). The POMO electron density, the unpaired spin density, and the total charge density of a molecule will therefore differ from each other as shown in Figure 1 for $[TCNE]^{\cdot -}$.

The wavefunction and therefore the POMO valence-electron density is determined computationally, however, electron and spin densities can be determined experimentally by diffraction methods. The valence-electron density can be determined from the low-angle scattering in a high-resolution single-crystal structural determination[12e] or preferably from the difference between results obtained by using single-crystal X-ray and neutron diffraction studies at the same temperature. The absolute spin density can be directly determined from single-crystal polarized-neutron diffraction studies at low temperature. Absolute spin densities may also be obtained experimentally from analysis of either the NMR contact shifts[12b] or detailed analysis of the EPR hyperfine couplings constants;[15] however, the relaxation time of the species must be amenable for these resonance measurements to be applicable.

Radicals are usually far enough apart that their magnetic coupling energy is small compared to the coupling-breaking thermal energy. Such spins do not couple (that is, align cooperatively), instead they form a weak magnet (paramagnet Fig. 3a). When the radicals come sufficiently close to each other, the coupling energies increase, ultimately influencing the alignment of the neighboring spins. If this alignment occurs in such a manner that the spins oppose each other, this leads to antiferromagnetic behavior (Fig. 3b). Bulk ferromagnetic behavior, albeit rare, occurs when the spins in a solid align in the same direction (Fig. 3c), resulting in a net magnetic moment. Thus, ferromagnetism requires that the individual unpaired spins interact collectively with each other aligning themselves. Ferrimagnets can occur when there are different moments (essentially a different number of spins) on neighboring sites which align antiferromagnetically but do not cancel; this leads to a net moment for the solid (Fig. 3d). It is vital to note that this commercially useful highly magnetic behavior is not a property of a molecular species; it is a cooperative solid-state (bulk) property. Three-dimensional (3D) interactions are typically necessary to achieve long-range magnetic order and bulk ferromagnetic behavior; however, two-dimensional (2D) interactions in some circumstances suffice, as is probably the situation for Rb_2CrCl_4[6a] in which interlayer spacings can be increased by replacing Rb^+ with bulky alkylammonium counterions (vide infra), but the T_c is not significantly altered. For strictly one-dimensional (1D) nearest neighbor interactions, long-range order can only occur at 0 K. However, for the special case when a chain has anisotropic interactions with randomness in the anisotropy, hysteretic effects mimicking three-dimensional order may occur (vide infra). For ferrigmagnets (e.g., chain systems comprised of alternating quantum ($S = 1/2$) and classical ($S > 1/2$) spins) the net magnetization may reverse direction as a function of increasing temperature (i.e., compensation may occur).

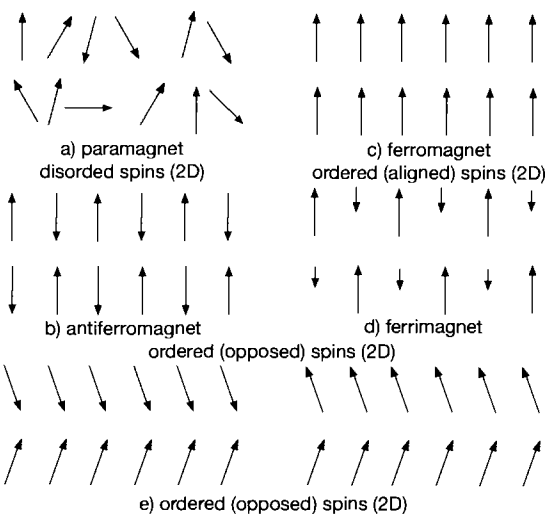

Fig. 3. Two-dimensional spin alignment for a) paramagnet, b) antiferromagnet, c) ferromagnet, d) ferrimagnet, and e) canted ferromagnet behavior.

As noted previously, magnets are characterized by their response to a nearby magnet, or more specifically to an applied magnetic field, H. For ideal, noninteracting spins a net magnetic moment or magnetization, M, is induced in the solid when ex-

posed to an applied magnetic field, H; where M is proportional to H [Eq. (1)]. The proportionality constant is termed the molar

$$M = \chi H \tag{1}$$

magnetic susceptibility χ, and it has a temperature dependence that is characterized by the Curie expression [Eq. (2)]. The Curie

$$\chi = \frac{C}{T} \tag{2}$$

constant C in emu K mol^{-1}, is defined according to [Eq. (3)], in

$$C = \frac{Ng^2\mu_B^2 S(S+1)}{3k_B} \tag{3}$$

which S is the spin quantum number (one-half of the number of unpaired electrons per radical), N is Avogadro's number, g is the Lande factor, μ_B is the Bohr Magneton, and k_B is the Boltzmann constant. Sometimes the spins experience an effective parallel (or antiparallel) exchange field due to cooperative interactions with the neighboring spins which increases (or decreases) the measured susceptibility from that predicted for independent spins by the Curie law. The high-temperature susceptibility data often can be fit to the Curie–Weiss law [Eq. (4)]; where for

$$\chi = \frac{C}{T-\theta} \tag{4}$$

parallel (ferromagnetic) and antiparallel (antiferromagnetic) interactions, θ is greater or less than zero, respectively. The value of θ can be determined from the $\chi^{-1} = 0$ intercept obtained in the linear extrapolation of the plot of χ^{-1} versus T at high temperature; note the value of χ is temperature-dependent. Chemists frequently report the effective moment μ_{eff} or sometimes simply χT. The effective moment is defined in Equation (5).[16a]

$$\mu_{eff} = \sqrt{\frac{3\chi k_B T}{N}} = 2.83\sqrt{\chi T} \tag{5}$$

For a simple system comprising one mole of noninteracting spins (i.e., $\theta = 0$), and where S is a valid spin quantum number, μ_{eff} is temperature-independent [Eq. (6)].

$$\mu_{eff} = \mu_B\sqrt{g^2 S(S+1)} \tag{6}$$

The magnetization M also has a characteristic applied magnetic field dependency that enables the rapid qualitative determination of the magnetic behavior. At low temperatures and high magnetic fields (conditions under which the magnetic energy ($gS\mu_B H$)[16b] is comparable in magnitude to the thermal energy ($k_B T$)), the magnetization no longer obeys Equation (1), but approaches the limiting value or saturation magnetization M_s [Eq. (7)]. M_s has the units of emuG mol^{-1}, though it sometimes

$$M_s = \mu_B NSg \tag{7}$$

is reported in units of μ_B molecule^{-1}. For independent spins the temperature dependence of M is described by the Brillouin function [Eq. (8)]

$$M = \mu_B NSgB \tag{8}$$

where

$$B = \frac{2S+1}{2S}\coth\left(\frac{2S+1}{2S}x\right) - \frac{1}{2S}\coth\left(\frac{x}{2S}\right)$$

and

$$x = \frac{gS\mu_B B}{k_B T}.$$

The Brillouin function no longer applies when there are significant ferromagnetic or antiferromagnetic interactions among the spins. However, for $T \gg \theta$ an effective temperature given by $T_{eff} = T - \theta$ may be used in the argument of the Brillouin function to obtain a "fitting" of the data.[38] Table 1 summarizes typical expected values for χT, μ_{eff}, and M_s as a function of S.

Table 1. Representative values of χT, μ_{eff}, and M_s as a function of S and the Lande g value.

S	g	χT [emu K mol^{-1}]	μ_{eff} [μ_B mol^{-1}]	μ_{eff}^2 [μ_B^2 mol^{-2}]	M_s [emuG mol^{-1}]	gS [μ_B per molecule]

1/2 + 3/2	2	2.250	4.24	18	22340	4
1/2 + 2	2	3.375	5.20	27	27925	5

The temperature dependencies of χ, χ^{-1}, and μ_{eff} are illustrated for independent spins (Curie), and spins with ferro-, and antiferromagnetic interactions in Figure 4. A schematic illustration of a number of field-dependent magnetization behaviors is shown in Figure 5.

At sufficiently low temperature the spins may order. This temperature is the critical temperature T_c. If the spins align parallel to each other (ferromagnet, Fig. 3c), a macroscopic spontaneous magnetization in zero applied field (i.e., $M(H_{applied} = 0) > 0$) is present, and the critical temperature in this case is sometimes referred to as the Curie temperature T_C. If neighboring spins are aligned antiparallel (antiferromagnet, Fig. 3b), there is no net macroscopic moment and the susceptibility is anisotropic. Here the critical temperature is sometimes referred to as the Néel temperature T_N. As noted earlier, ferrimagnetism can occur when the antiferromagnetically aligned spins have differing local moments, resulting in the incomplete cancellation of the parallel and antiparallel spin sublattices which leads to a reduced, but nonzero, moment (Fig. 3d). In this case the critical temperature is also sometimes referred to as the Néel temperature T_N.

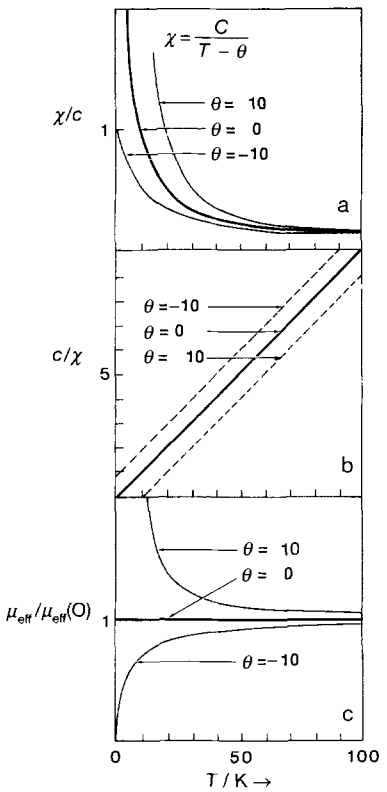

Fig. 4. The susceptibility χ (a), the reciprocal susceptibility χ^{-1} extrapolated from the high-temperature region (b), and the effective moment μ_{eff} (c) as a function of temperature for independent $g = 2$, $S = 1/2$ spins as well as ferromagnetically coupled ($\theta = 10$ K) and antiferromagnetically coupled ($\theta = -10$ K) spins. The Curie–Weiss law. (Taken from ref. [9]).

For ferro- and ferrimagnets well below the critical temperature, the atomic or molecular magnetic moments are essentially all aligned on a microscopic scale. Actual samples, however, are composed of small regions termed domains, within which the local magnetization is essentially saturated. The relative direction of the magnetic moment in adjacent domains is not parallel. This phenomenon has its origin in the lowering of the total energy of the magnet by transformation from a configuration of all parallel moments (resulting in a high energy stored in the magnetic field generated by these moments) to an array of domains that point in various directions (resulting in little energy stored in magnetic fields but at an energy cost of forming "domain walls" between the domains). The coercive field H_c is the reverse magnetic field necessary to reduce the magnetization of a sample to zero starting in a saturation condition magnetization. "Hard" magnets have large values of H_c (>100 Oe), whereas "soft" magnets have low, sometimes unobservable values of H_c (<10 Oe). Large values (hundreds of Gauss) of H_c are necessary for magnetic storage of data, while low values (milliGauss) are necessary for ac motors. An example of a molecular-species-based soft ferromagnet is the complex $[Fe^{III}(S_2CNEt_2)_2]Cl$, which has been characterized by magnetic susceptibility, heat capacity, and ^{57}Fe Mössbauer spectroscopy. It exhibits a T_c of 2.46 K, but does not exhibit hysteretic effects.[17] Magnetic materials that are subdomain in size exhibit superparamagnetic (high-spin) behavior, for example, naturally occurring ferritin.[18a] The magnetization and coercivity are important parameters in ascertaining the commercial utility of a magnet. Table 2 summarizes values for some of the more common magnetic materials and new molecular-species-based magnets.

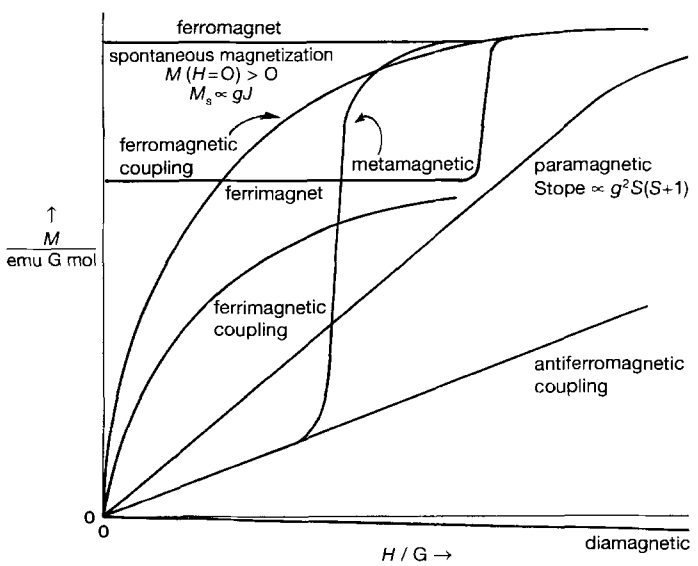

Fig. 5. Schematic illustration of the magnetization M as a function of applied magnetic field H for several types of commonly observed magnetic behavior (from ref. [9]).

It is interesting to ponder the limiting size of a molecule beyond which its spins will no longer remain aligned within a single magnetic domain. Calculations of the size of a single magnetic domain are very complex due to dependencies on the geometry, magnetic anisotropy etc.,[18b,d] and to the best of our knowledge this question has not been experimentally or theoretically addressed for a molecular-species-based system. As a preliminary model one may consider typical spin magnitudes in a known single-domain magnetic material. The single domain of magnetite, Fe_3O_4, which is present in magnetotactic bacteria,[19] has a volume of about 1×10^8 Å^3,[19] and thus contains 1.2×10^6 Fe_3O_4 units with four net spins each or about 5×10^6 total spins (i.e., 0.05 spin per Å^3). For iron, if one assumes an effective critical domain radius of 75 Å for a spherical single domain,[18e] each single-domain particle has 1.5×10^4 iron atoms and about 3.3×10^4 spins (0.2 spin per Å^3). Likewise, for $Nd_2Fe_{14}B$, if one assumes a conservative single-domain radius of 150 Å,[18f] 2×10^6 spins (0.1 spin per Å^3) are present per domain. Assuming that the single domain contains at least 10^6 spins, it is feasible that a molecular-species-based material, containing a single spin per repeat unit with an equivalent weight of 100 daltons, and with about 10^6 repeat units (thus a molecular weight of 10^8 daltons), might also be a single domain. The spatial dimensions of such a domain would be quite large and its spin density would be relatively low. Note that the domain size also depends strongly on the shape of the particle; for example, altering the shape of an iron particle from a sphere to a prolate ellipsoid with an aspect ratio of ten increases the domain size from 1.5×10^5 to 9.6×10^7 Fe atoms.[18e] Thus, materials with a high aspect ratio such as linear and minimally branched polymers may have a substantially greater number of spins and larger dimensions and still remain single magnetic domains.

If the relatively large single-domain molecular species remain far apart from each other so that the interaction among these molecules is very weak, the temperature and magnetic field dependence of the measured magnetization would reflect the behavior of single-domain particles. In this case, the magnetization of the single-domain molecule follows the direction of the applied magnetic field by rotation of the magnetic moment. If an uniaxial anisotropy is present, there will be a barrier to the rotation of the magnetic moment in response to the changes in the magnetic field. The "supermagnetic" behavior of single-domain magnets differs in time dynamics from that of the reversal of magnetization within a multimagnetic domain particle due to domain wall motion.[10, 20]

orientation at neighboring sites in the ordered state may be canted with respect to each other.

Metamagnetism is a magnetic-field-dependent transformation from an antiferromagnetic state to a high-moment ferromagnetic state; that is, the spin alignment depicted in Figure 3b is transformed to that depicted in Figure 3c by application of an applied magnetic field. Decamethylferrocenium 7,7,8,8-tetracyano-*p*-quinodimethanide, $[Fe(C_5Me_5)_2][TCNQ]$, is a molecular-species-based metamagnet (see Section 5). A spin glass occurs when there are local spatial correlations in the directions of neighboring spins, but no long-range order. For a spin glass the spin alignment is as described for a paramagnet (Fig. 3a). However, unlike a paramagnet where the directions of the spins vary

[a] FO = ferromagnetic, FI = ferrimagnet, MM = metamagnet, C/W = canted/weak ferromagnet. [b] D = disordered, P = powder diffraction, Pn = neutron powder diffraction, SC = single crystal, SCn = neutron single crystal, UC = unit cell, H_{cr} = metamagnet critical field. [c] Abbreviations H_2Pc = phthalocyanine.

Many other magnetic phenomena are possible. Canted ferromagnetism, metamagnetism, and spin-glass behaviors are examples. A canted ferromagnet can result from the relative tilting of ferromagnetically coupled chains such that, though the material is ferromagnetic, there is a reduction of the moment (see Fig. 3e). Sometimes a canted ferromagnet is referred to as a weak ferromagnet. A molecular-species-based example is phthalocyaninatomanganese(II) (MnPc). This complex has a T_c of 8.3 K, but a saturation magnetization corresponding to only 72% of the fully aligned spins due to the canting arising from the herringbone structural motif.[21] In other cases, the spin with time, the spins remain fixed in their orientations for a spin glass. A correlated spin glass has spins pointing in similar directions for short distances, but no long-range order. $[V(TCNE)_x] \cdot y(MeCN)$ at low temperature is an example of a correlated spin glass (see Section 9).

Like the familiar gas/liquid critical behavior, critical behavior occurs at the onset of cooperative magnetic ordering near the critical temperature T_c. The critical exponents can be compared to theoretical expectations to elucidate the dimensionality and anisotropy of the spin interactions which dominate the formation of the ordered spin state.

3. Origin of Cooperative Magnetic Behavior in Molecular-Based Magnetic Materials

Creating a magnetic molecular material demands the alignment of the spins in all three directions of the solid material.[22] The "exchange interaction" J describes the type (ferro- or antiferromagnetic) and degree of coupling between pairs of spins and is to first order a two-body interaction. It is thus essential to have magnetic exchange interactions in all three directions and any de novo design of new materials must include an exchange interaction between neighboring spins in all directions.[22] In order to accomplish this, it is, of course, necessary to examine the sign and magnitude of the exchange between pairs of molecular-species-based spins.

The magnetic exchange interaction is a direct consequence of quantum mechanics. The total electronic wavefunction can be factored into spatial and spin terms. Because electrons are fermions, the total electronic wavefunction must be antisymmetric. The spin (magnetic) exchange has its origin in the requirement that the total electronic wavefunction must change sign under the interchange of two electrons. For example, consider bringing two H atoms together to form H_2. If the two electron spins are antiparallel ($\uparrow\downarrow$: $S_1 + S_2 = 0$), the real-space wavefunction is symmetric or bonding. On the other hand if the two electron spins are parallel ($\uparrow\uparrow$: $S_1 + S_2 = 1$), the real-space wavefunction is antisymmetric or antibonding. The difference in energy of the symmetric and antisymmetric wavefunctions is related to the exchange energy. The lower energy of the real-space bonding wavefunction for H_2 results in an antiferromagnetic exchange, since the pair of electron spins are antiparallel.

The close approach of two spin-containing molecular species ($\boldsymbol{A}$ and $\boldsymbol{B}$) leads to a similar interaction. The new total wavefunction is often calculated in a configuration interaction (CI) (i.e., perturbation theory) approach. That is, the total wavefunction for the combined pair of molecules is approximated by admixing the ground state with an excited state arising from the promotion of an electron from the partly filled (spin-containing) orbital of $\boldsymbol{A}$ to a virtual (empty) orbital of $\boldsymbol{B}$ as well as the opposite case for partially occupied orbitals of $\boldsymbol{B}$ and virtual orbitals of $\boldsymbol{A}$. This leads to a new set of energies for each spin-symmetry state. The spin state of the lowest energy configuration determines whether the pair of molecular species are coupled antiferromagnetically (antiparallel spins on the adjacent molecules) or ferromagnetically (parallel spins on the adjacent molecules). The difference in energy between this lowest energy configuration and the lowest energy configuration of the opposite spin state is related to the exchange energy.[23, 24] The relative energies of the differing configurations depend strongly upon the charge transfer integrals between the selected orbitals of $\boldsymbol{A}$ and $\boldsymbol{B}$ (i.e., i and j, respectively) ($\beta^{ij}_{\boldsymbol{AB}}$), and also upon the difference in energy between the ground state of isolated **A** and **B** and the various excited state configurations ($\Delta E^{ij}_{\boldsymbol{AB}}$). The magnitude of each contribution to the total pairwise-exchange interaction is proportional to $(\beta^{ij}_{\boldsymbol{AB}})^2/\Delta E^{ij}_{\boldsymbol{AB}}$; the sign is determined by the total spin of the excited state.[25, 26] (The formation of this "incipient" chemical bond is sometimes termed "kinetic" exchange.) If the charge transfer integral between $\boldsymbol{A}$ and $\boldsymbol{B}$ is zero (i.e., orthogonal orbitals), the antisymmetrized real-space total wavefunction and symmetrized spin-space wavefunction (high-spin state) is lower in energy than the symmetrized real-space total wavefunction and antisymmetrized spin-space total (low-spin state), that is, Hund's rule applies. (Of course, if $\boldsymbol{A}$ and $\boldsymbol{B}$ approach close enough to form a covalent bond, the perturbation approach of CI must be replaced by calculating the full wavefunction of the new molecule derived from $\boldsymbol{A}$ and $\boldsymbol{B}$.)

It is not possible to calculate accurately the total energies and transfer integrals for pairs of molecular species each containing hundreds of electrons. Therefore a number of simplifying special cases of the configuration interaction concept have been emphasized by several research groups as a practical guide to enable the synthetic design of molecular-species-based magnets. These simplifying approximations differ in complexity and in their usefulness to the synthetic chemist. The simplest intramolecular approach is to consider molecular species with spins in orthogonal orbitals. The next simplest would involve spin polarization through bridging groups with filled orbitals connecting two spin-containing species. The next level of interaction involves the partial transfer of electrons between different molecular species. The simplest intermolecular approach utilizes the CI of the spin-containing molecular species, each considered as a whole unit, and where only interactions between the POMO of one molecular species and the POMO of its neighbor are examined. Other still more complex cases include the CI between the next highest HOMO (NHOMO) and/or the next lowest LUMO (NLUMO) of a pair of molecular species. An even more complex variant is to consider the excitations of occupied $\boldsymbol{A}$ orbitals to virtual orbitals on $\boldsymbol{A}$ as well as to virtual orbitals of $\boldsymbol{B}$. Again, it is important to emphasize that the CI models give two-body (pairwise coupling) terms. This is insufficient to account for three-dimensional magnetic behavior, for which configuration interactions in all three directions are crucial.

Increasing the complexity of CI calculations more accurately describes the system, however, it makes the model less useful to the practicing synthetic chemist. As a practical guide to the synthetic chemist we have classified the three distinct mechanisms for spin coupling (Scheme 1).

1. Ferromagnetic exchange resulting from orthogonal orbitals (no CI)—Hund's rule (intramolecular spin coupling)
2. Configuration interaction (CI) to determine dominant ferro- or antiferromagnetic exchange
   - 2.1. Intramolecular species excitations (spin polarization)
   - 2.2. Intermolecular species excitations
     - 2.2.1. Involving only the POMOs on adjacent molecular species
       - 2.2.1.1. Without spatial constraints
       - 2.2.1.2. With spatial constraints
     - 2.2.2. Involving NHOMOs and/or NLUMOs on adjacent molecular species
       - 2.2.2.1. Intermolecular species excitations
       - 2.2.2.2. Intramolecular species excitations
     - 2.2.3. Excitations between localized and delocalized (metallic) states (intramolecular spin coupling)
3. Dipole–dipole (through-space) exchange (intermolecular spin coupling)

Scheme 1. Classification of three mechanisms of spin coupling.

Often in discussions of the exchange mechanisms emphasis is given to the chemical stabilization of a spin state capable of exchange. This leads to identification of exchange mechanisms by their chemical or physical nomenclature. An example of this

is ferromagnetic exchange between polarons created in conjugated segments of block copolymers. In this case, polarons are the means of creating spin-containing units. The exchange between these polarons comes from CI through the intervening moieties (vide infra). The above is a classification of operative spin-exchange mechanisms, not the means to achieve spins.

Frequently it is unclear which mechanism is the primary exchange mechanism in a particular chemical system. Particularly for molecular-species-based systems with complex compositions and structures, it is probable that more than one mechanism plays a significant role (e.g., ferromagnetic coupling of spins within a one-dimensional chain due to orthogonal orbitals (mechanism 1) and ferromagnetic or antiferromagnetic coupling between chains due to configuration interaction (mechanism 2) or possibly dipole–dipole interactions between chains (mechanism 3)). Furthermore, since there are many levels of complexity of the CI model (mechanism 2), there are many ways to describe this exchange mechanism and properly truncated exhaustive calculations are required to provide a detailed understanding.

Examples of these models elaborated in terms of their chemical embodiments are described below. Note that the suggested mechanisms may not stand the test of time, but evolve with increased understanding of the structures and properties. Each of the mechanisms given in Scheme 1 is discussed below.

3.1. Intramolecular Ferromagnetic Exchange Resulting from Orthogonal Orbitals (No CI)—Hund's Rule

The essence of achieving high-spin behavior by using this approach is the presence of unpaired electrons in orthogonal orbitals (zero quantum mechanical overlap), which, however, reside in the same spatial region. The greater the latter condition is fulfilled, the stronger the ferromagnetic exchange. In this case the antibonding real-space total electron wavefunction is lower in energy than the bonding real-space total electron wavefunction so that the high-spin state is stabilized. This has been demonstrated for orthogonal orbitals on the same site, for example, carbene, $:CH_2$ ($S = 1$) and Mn^{II} ($S = 5/2$), and multiple sites in the same spatial region, for example, trimethylenemethane, $:C(CH_2)_3$ ($S = 1$) and O_2 ($S = 1$). This essence of Hund's rule is schematically illustrated in Figure 6.

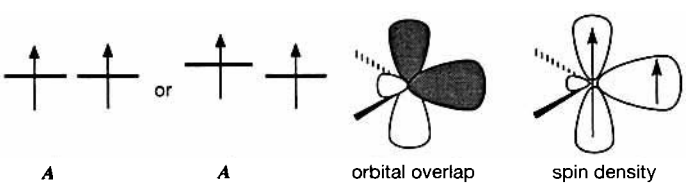

Fig. 6. Schematic illustration of the relative energy, orbital overlap, and spin density for orthogonal POMOs on *A*.

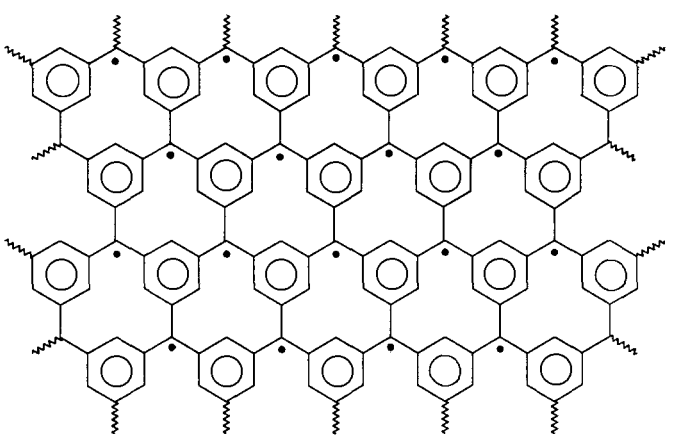
The concept of having a large number of unpaired electrons residing in orthogonal orbitals that are ferromagnetically coupled by CI through-bond coupling or superexchange (vide infra) through a spinless bridging halide has been exploited by P. Day et al. in their studies of Rb_2CrCl_4 and related materials which have an extended-network structure in two dimensions.[6a] These materials are not normally attributed to molecular-species-based chemistry and thus might be considered by some to be inappropriate to be discussed in this review. Nonetheless, ferromagnetic materials can be also prepared by substitution of the alkali metal cation with a quaternary ammonium ion, $[RNH_3]^+$ (R = Me, Et, $PhCH_2$ etc.). These fascinating ferromagnets have relatively high T_c values (> 50 K) which are essentially independent of interlayer separation and are reasonably transparent.[6] These layered compounds, in principle, lend themselves to form Langmuir–Blodgett-like monolayer films which would be suitable to test concepts of two-dimensional magnetic behavior.

The general idea of designing a material with spins residing in orthogonal orbitals on adjacent sites has also been pursued by O. Kahn et al. as well as others; however, only intriguing high-spin small molecules have been reported.[27] Recently extended-network solids of $[Bu_4N][MCr(ox)_3]$ (ox = oxalato; M = Fe, Co, Ni, Mn, Cu) have been reported to exhibit ferromagnetic behavior.[28]

It is important to reemphasize that highly magnetic behavior is not a property of a molecular species; it is a cooperative solid-state (bulk) property. Thus, to achieve bulk ferromagnetic behavior in the context of the aforementioned high-spin molecular species, intermolecular interactions, perhaps as described below, must be operative or the molecular species need to be sufficiently large to be considered a magnetic domain (vide supra).

3.2. Configuration Interaction to Determine Dominant Ferro- or Antiferromagnetic Exchange

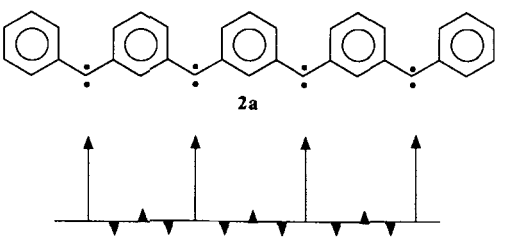
The orthogonal-orbital mechanism (see Section 3.1) provides a means to achieve a high-spin ferromagnetically coupled molecular species in which the spins reside in the same spatial region. In order to magnetically couple spins residing in distant spatial regions within a molecular species, the total wavefunction of the system must be considered, and it is typically evaluated by configurational interactions. Additionally, the CI can be applied between molecular species within a solid to achieve the ferromagnetic coupling between these species needed to induce bulk ferromagnetic behavior. These are complex, time-consuming computations that are often simplified by limiting the number of CIs considered. The details of the CI, of course, depend on how the problem is formulated, that is, what is given for the ground state and excited state wavefunctions. The simplest approximation employs only the POMOs on adjacent molecular species.



3.2.1. Intramolecular Excitations (Spin Polarization)

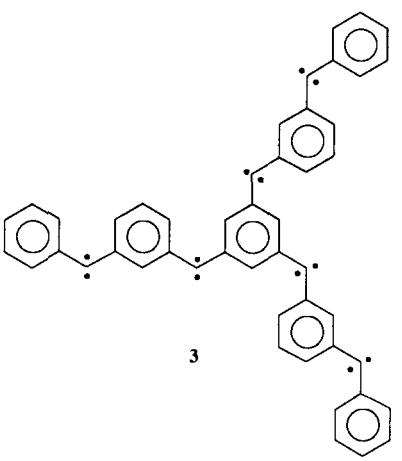
As discussed above, an unpaired electron spin in a POMO can polarize the paired electron spins in an orthogonal bond connecting it to another moiety with a POMO. This polarization is illustrated by the coupling between a carbon π electron and a proton nucleus through the hyperfine interactions. Although a valence bond-like picture is usually utilized (see Fig. 2 top), a full molecular orbital calculations reveals that the proper description of the spin polarization requires the admixture (config-

uration interaction) of a small amount of an antibonding excited state into the ground state to obtain the spin polarization.[12a] Hence the spin polarization mechanism is an intramolecular configuration interaction mechanism.



Spin polarization is an intramolecular effect that is used extensively to interpret EPR hyperfine coupling constants.[12, 30, 31] Hyperfine splittings are observed for unpaired electrons in proximity to ring hydrogens in aromatic compounds, and although unpaired spin density is not delocalized directly onto the hydrogen atom, unpaired spin density is induced at the hydrogen nucleus and observed (through the hyperfine splitting) by spin polarization (i.e., an unpaired electron in a C-based p orbital polarizes the paired spins in an orthogonal C–H σ bond so that one of the paired electrons is more in the vicinity of the C atom than another, even though there is no unpaired spin density delocalized onto it; Fig. 2 top).[12c, d]

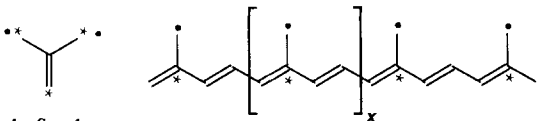
With the knowledge of the spin-polarization mechanism and that the ground states of dioxygen and some carbenes were high-spin triplets due to spins residing in orthogonal orbitals, K. Itoh and N. Mataga in 1968 suggested[29] that large planar alternate hydrocarbons comprised of *meta*-substituted triplet diphenylcarbene moieties would have a high-spin (ferromagnetically coupled) ground state in accord with Hund's rule and spin polarization. Proposed examples of high-spin multiplicity polymers[29b] include **1**.



1

H. Iwamura et al.[32] have prepared several high-spin polycarbene radicals including **2a** ($S = 4$). The largest compounds characterized, albeit in situ, are the hexacarbene **3** ($S = 6$)[32b] and a nonacarbene ($S = 9$).[32c] The magnetization of **3** confirms the $S = 6$ ground state, however, the temperature dependence of the susceptibility demonstrates only antiferromagnetic coupling between the $S = 6$ radicals.[32b] The high-spin ($S = 4$) ground state in **2** has been attributed to four $S = 1$ carbene sites (arising from spins in orthogonal orbitals in the same spatial region, Fig. 6 right) (vide supra) coupled by spin polarization as illustrated in **2a** with arrows denoting the direction of the polarized spins.[33] (Note that for *ortho*- or *para*-substituted analogues spin polarization results in antiferromagnetic coupling and diamagnetic behavior.) The spin polarization in an idealized poly(*m*-diphenylcarbene) was evaluated by K. Nasu by using a CI approach (tight-binding calculation of energy bands) that includes the effects of on-site Coulomb repulsions (Hubbard model) to describe the antiferromagnetic coupling between adjacent π electrons within the C_6 ring and the bridging carbene moieties, resulting in a net ferromagnetic coupling. Nasu accounts for the ferromagnetic coupling between the nonbonding and π electrons of the carbene by using a periodic Kondo model (i.e., Hund's rule for orthogonal orbitals).[34a] K. Tanaka et al. similarly calculated spin polarization by which long-range magnetic coupling is possible in poly(phenylnitrenes) using a tight-binding calculation of energy bands (CI).[34b] The efficacy of the polyene bridges in pairs of spins has been recently demonstrated by using bipyridylpolyene-bridged bimetallic complexes.[34c]

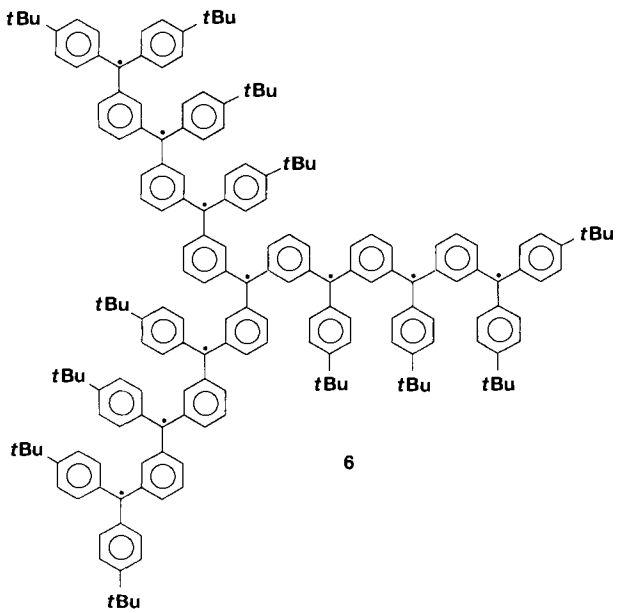
2a



3

A. A. Ovchinnikov[35] has developed a simple approach to account for the CI between spins on arrays of adjacent carbon atoms each with a single p_z electron. He noted that the net S for planar alternate hydrocarbons (e.g., **2**–**6**) can be calculated by Equation (9), where n is the number of nonstarred atoms and n^*

$$S = \frac{|n^* - n|}{2} \tag{9}$$

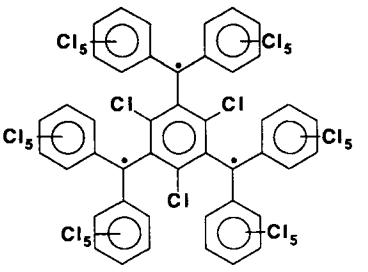


is the number of starred atoms (adjacent atoms are alternately starred (*) and nonstarred and identically denoted atoms are not adjacent to each other). For example, trimethylenemethane (**4**) has an $S = 1$ ground state, and larger molecules could have large values of S. Polymers such as **5** are predicted to have a large value for S ($S = x/2$, where x is the number of repeat units within the polymer).[35, 36] Chemical reactivity arising from the strong tendency of unpaired electrons to form covalent bonds suggests that stable high-spin materials are difficult to prepare following this methodology. Bond distortions as well as inter-

4 $S = 1$ 5 $S = x/2$

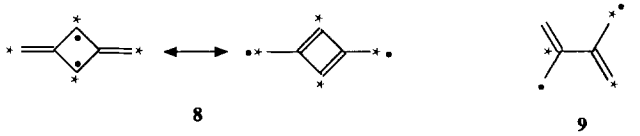
molecular coupling which pair-up electrons must also be avoided.

High-spin radicals based upon several triarylmethyl radical sites are under investigation by several research groups worldwide. An $S = 5$ radical, **6**, has been prepared.[37] Perchloropoly-



6

triarylmethyl radicals have also been studied; the largest example characterized is **7** ($S = 3/2$), which has been isolated in two stereoisomeric forms.[38] Polymers based on triarylmethyl radicals have been reported to exhibit saturation magnetizations of the order of 1 % of bulk.[7, 39] These materials are poorly characterized.



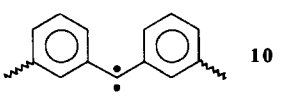
Another example of a high-spin moiety sought as a building block for an s/p orbital-based magnet is 1,3-cyclobutanediyl (**8**), which has spins residing in different regions within the radical and, like trimethylenemethane (**4**) has a strong triplet preference.[40]

Equation (9) is not sacrosanct and may fail for the prediction of $S = 0$ compounds; thus it may not reliably guide the synthetic chemist toward high-spin molecules. This is clear as tetramethyleneethane (**9**) is an unsolved puzzle. Equation (9) as well as more sophisticated molecular orbital calculations lead to the expectation that **9** has a singlet ground state; however, a triplet ground state has been reported for **9** in its twisted as well as its planar analogues.[41] Thus, Equation (9) appears valid for $n^* \neq n$, but may not properly describe a system for $n = n^*$, if they are non-Kekulé or cross-conjugated.[43b]

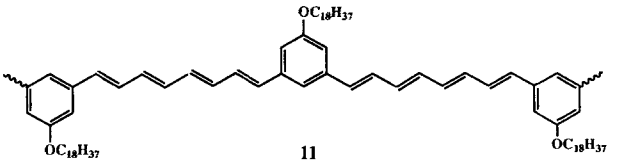
H. Fukutome et al. suggested that block copolymers comprised of conjugated conducting oligomers and ferromagnetic spin-coupling segments (for configuration interaction, e.g., *meta*-substituted benzene unit) will upon doping have ferromag-

7

8 9



netically coupled polarons.[42a] Conducting oligomers based upon poly(*trans*-acetylene), poly(pyrrole) or similar polymers were identified as candidates to test this approach. Upon, for example, p-"doping", a cation radical (positive polaron) segment is formed, which may be schematically represented as shown in Scheme 2. Ferromagnetic coupling of these radicals is



Scheme 2.

proposed[34, 42] to be stabilized by a *meta*-substituted diphenylcarbene moiety such as **10** (vide supra).

Synthetic chemists have just started to prepare suitable examples of these block copolymers to test this model. D. A. Dougherty et al. reported[43a] that partial oxidation of **11** with either I_2 or AsF_5 leads to a material for which the magnetization is best described by the presence of spins with an $S > 2$ behavior, not an independent spin ($S = 1/2$) behavior; however, antiferromagnetic coupling among these spins and the low density of spins need to be circumvented.[43b]

10

11

3.2.2. *Intermolecular Species Excitations*

Configuration interaction can be applied between molecular species within a solid to provide a means for magnetic coupling among these species that is needed to achieve bulk magnetic behavior. In the simplest case this can be done by considering only the POMOs. It can also be done by considering the next highest occupied (NHOMO) and/or next lowest unoccupied molecular orbitals (NLUMO) or between a localized state and a delocalized (metallic) state.

3.2.2.1. Involving the POMOs on Adjacent Molecular Species

Dominant ferromagnetic or antiferromagnetic exchange determined by configuration interaction (CI) between POMOs on adjacent molecular species can be enhanced by the spatial relationship of the atoms on adjacent molecules and their pairwise contribution to the total exchange (i.e., Heisenberg exchange).

3.2.2.1.1. Without Spatial Constraints

The application of configuration mixing of a virtual triplet charge-transfer excited state of a whole molecular species with the ground state, in order to stabilize ferromagnetic exchange coupling (kinetic exchange) for $\cdots[A]^{\bullet+}[B]^{\bullet-}[A]^{\bullet+}[B]^{\bullet-}\cdots$ (A = donor, B = acceptor) chains, was introduced by H. M. McConnell.[44a] The large separations and energy differences between ions on adjacent sites lead to small overlaps of the frontier orbitals ("incipient" bonding) and prevent the formation of metallic energy bands for mixed-stack electron-transfer salts.[26a, 45] In contrast, the spins of the $[A]^{\bullet+}[B]^{\bullet-}$ repeat units with half-occupied nondegenerate POMOs can couple antiferromagnetically (Fig. 7a). Admixture of the higher energy charge-transfer states (Fig. 7a, right) with the ground state (Fig. 7a, left) lowers the total electronic energy and stabilizes antiferromagnetic coupling ($\uparrow\downarrow$) which, if the number of spins on the two moieties are different, leads to ferrimagnetic behavior.

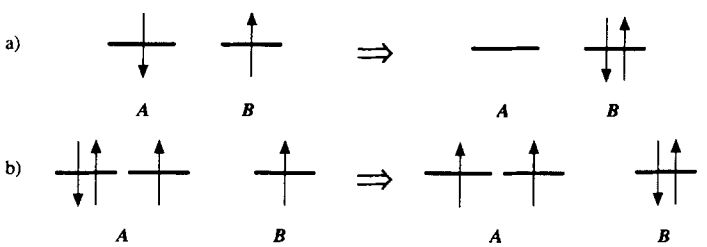


Fig. 7. Schematic illustration of the stabilization of ferro- or antiferromagnetic coupling by configurational interaction (CI) only involving POMOs on adjacent sites (A and B). If both A and B have a half-filled nondegenerate POMO (s^1), the $B \leftarrow A$ (or $A \leftarrow B$) virtual charge-transfer excited state stabilizes antiferromagnetic coupling (a). If B (or A) has a nonhalf-filled degenerate POMO (e.g., d^3, assumed here to be A), the $B \leftarrow A$ charge-transfer excited state formed (b) will stabilize ferromagnetic coupling (or $A \leftarrow B$ charge-transfer excited states formed through excitation of a "spin-up" B electron will stabilize antiferromagnetic coupling).

This energy reduction and spin delocalization does not occur when the two electron spins are parallel ($\uparrow\uparrow$; ferromagnetically aligned) in accord with the Pauli exclusion principle. Thus, antiferromagnetic coupling ($\theta = -18$ K) has been reported for the salt $[TTF]^{\bullet+}[Ni\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$ (TTF = tetrathiafuvalene)[46a] which has the $\cdots[A]^{\bullet+}[B]^{\bullet-}[A]^{\bullet+}[B]^{\bullet-}\cdots$ structure in all three directions.[46b] (Note, however, ferromagnetic coupling ($\theta = +16$ K) has been reported (vide infra) for the isoelectronic $[TTF]^{\bullet+}[Pt\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$ salt[46a, c] which has a similar structure, but is not isomorphous.[46d])

For other electron configurations involving partially occupied degenerate orbitals pairwise (AB) ferromagnetic coupling may be achieved (see Fig. 7b). Magnetic couplings predicted by this model for representative electronic configurations are summarized in Table 3. To achieve ferromagnetic coupling with this model requires that at least A or B possesses a degenerate (accidental or intrinsic) orbital that is not half-filled, empty, or filled. The magnetic properties of several electron-transfer salts based on metallocenes and cyanohydrocarbons have been discussed within this model.[8i, 9, 44b] The configurational interaction model for the degenerate (d, t ...) and nondegenerate (s) cases (see Table 3 for abbreviations) can be represented by using forms for the nearest neighbor Hubbard model.[25, 26]

Table 3. Representative magnetic couplings for homo- and heterospin systems with singly, doubly, and triply degenerate POMOs [a].

[a] AF = antiferromagnetic coupling; FI = ferrimagnetic coupling; FO = ferromagnetic coupling. Intrinsic or accidental orbital degeneracies: s = singly (a or b), d = doubly (e), t = triply (t).

Configurational mixing of a virtual singlet excited state with the ground state for $[A]^+[B]^-$ systems, which stabilizes antiferromagnetic coupling when the spin on the donor and that on the acceptor are unequal and produces ferrimagnetic order,[44b] has been applied[8j, 47-51] to the high-temperature molecular-species-based magnet $[V(TCNE)_x] \cdot y$ (solvent) (t^3/s^1) (vide infra). Application of the model to $[Cr^{III}Cp_2^*]^{\bullet+}[TCNQ]^{\bullet-}$ or $[Cr^{III}Cp_2^*]^{\bullet+}[TCNE]^{\bullet-}$ (t^3/s^1) leads to the expectation of antiferromagnetic coupling leading to ferrimagnetic behavior; however, ferromagnetic order is observed (vide infra). Other subsets of this model have been the specific research focus of several groups.[52]

Key to achieving pairwise bulk magnetic ordering is the extension of the model beyond pairwise (AB) interactions in one-dimension. Figure 8 illustrates how the energy of the ferromagnetically coupled system depicted in Figure 7b is lowered upon the admixture of the ground state of energy E_{gs} with one or two intrachain (a and a, b, respectively) virtual charge-transfer excited states of energy E_{es} and additionally with a second interchain excited state (a, b, c).[8g-i, 9]

3.2.2.1.2. With Spatial Constraints

In 1963 McConnell suggested a mechanism for ferromagnetic exchange that involved a spatial arrangement of neighboring

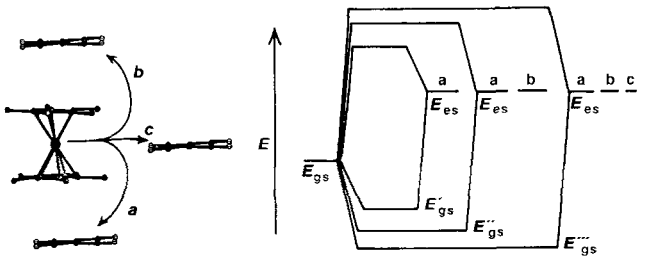

Fig. 8. Schematic state diagram depicting the relative energy of the ground E_{gs} and excited states E_{es} before and after admixing (virtual $[A]^{+}[B]^{-}$ charge transfer) with a single excited state a), an intrachain pair of excited states a) and b), and with a third interchain excited state arising from admixture with an out-of-registry acceptor to stabilize ferromagnetic coupling (from ref. [8g]).

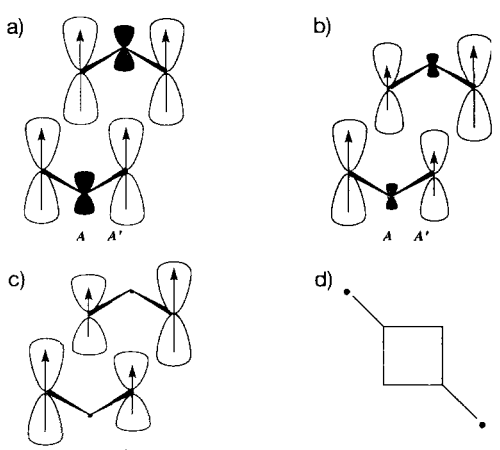
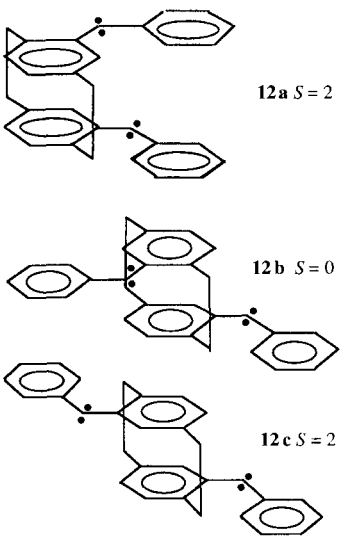
radicals, which possessed both positive and negative spin densities.[53] He claimed that radicals with "... large positive and negative atomic π-spin densities... [that] pancake... so that atoms of positive spin density are exchanged coupled... to atoms of negative spin density in neighboring molecules... gives a ferromagnetic exchange interaction." This is illustrated in Figure 9 for a pair of identical allyl radicals, *A* and *A'* which have positive spin densities on the terminal carbon atoms and negative spin density on the central carbon atom.[12b] For large separations between *A* and *A'* spin interactions do not occur (Fig. 9a). As *A* and *A'* approach each other in such a way that regions of positive and negative atomic π-spin densities can "pancake", net ferromagnetic exchange resulting from the incomplete cancellation of antiferromagnetic coupled spin components arising from pairwise (CI-like) interactions of atomic components of the radicals increasingly occurs (Figs. 9b, c). To achieve ferromagnetic exchange by this mechanism, routes to spin pairing, for example bond formation, arising from the close approach of the *A* and *A'*, (see Fig. 9d) must be avoided. (Note that the molecule in Fig. 9d may be a triplet.) Like the mechanism 2.2.1.1 in Scheme 1, this is a mechanism for ferromagnetic exchange between adjacent radicals, not bulk ferromagnetism. Ferromagnetic exchange in three dimensions is necessary for bulk ferromagnetic behavior.





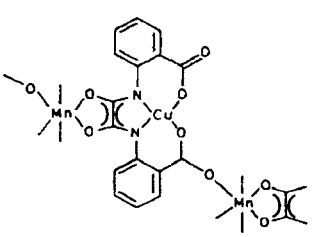


Fig. 9. Schematic illustration using the spin density of a pair of allyl radicals (*A* and *A'*) for the stabilization of ferromagnetic coupling by configurational interaction (CI) involving spin-exchange which results from regions of positive spin density (not of the entire POMOs) of *A* interacting with regions of negative spin density on *A'* as these exemplary $S = 1/2$ radicals as they are brought closer together. Minimal interactions occur at large separations (a), which increase as the separation decreases (b) and (c), until bonding occurs at short separations (d).

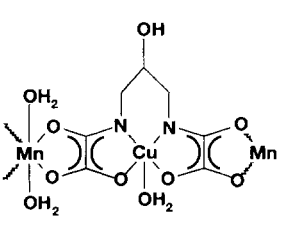
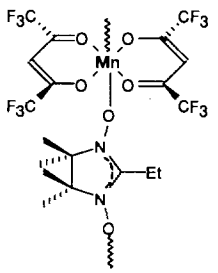


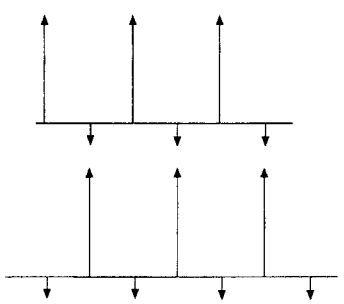
Cleverly designed stable radicals were sought to test this model. The spin multiplicity of dicarbenes incorporated into rigid [2.2]cyclophanes have been shown to be controlled by the overlapping of the spin-containing orbitals in the aromatic C_6 rings.[54] McConnell's model[53] suggests that the pseudo-*meta* isomer **12b** should possess a singlet ground state. This is in contrast to the behavior of the pseudo-*ortho* **12a** and pseudo-*para* **12c** isomers of the bis(phenylmethylenyl)[2.2]cyclophanes, which both have a quintet ground state. ESR data on this system are consistent with these results, suggesting that ferromagnetic exchange can be achieved by this McConnell model.[54] Note that the ground state spin multiplicity of these isomers has been described by CI by K. Yamaguchi et al.[55a] Tanaka et al. used CI incorporating the spatial distribution of the spin to calculate the favorable orientations for ferromagnetic exchange between diphenylcarbenes as a function of relative rotation and tilt angles of the molecules.[55b] Achievement of bulk ferromagnetic behavior in these materials has yet to be reported.

Similar to this McConnell approach using molecules with registered spin distributions, the antiferromagnetic coupling of alternating spin sites with different metal atoms with a different number of spins per site leading to ferrimagnetic behavior has been promoted by O. Kahn.[8b] Likewise, D. Gatteschi and P. Rey[8c] have focused on the same paradigm by utilizing extended network structures comprised of metal ions and nitroxide radicals. Due to configuration interaction, adjacent spin sites couple antiferromagnetically (↑↓), whereas next-adjacent spin sites couple ferromagnetically (↑↓↑). Thus, through alternating sites with a larger number of spins (e.g., 5 for ($S = 5/2$) Mn^{II}) with sites with fewer spins (e.g., 1 for ($S = 1/2$) Cu^{II} or nitroxide ligands) (i.e., ↑↓), the *S*s cannot cancel, thereby leading to a ferrimagnetic system (see Fig. 3d). Kahn et al. have reported several examples of highly magnetic systems developed by this strategy using Mn^{II}/Cu^{II}; for example, $[Cu^{II}Mn^{II}$ (obbz)] · H_2O[56a] (**13**) (obbz = *N,N'*-bis(2-carboxyphenyl)oxamidato) has a T_c of 14 K. This group also reported that the



13

14



structurally characterized $[Mn^{II}Cu^{II}(pbaOH)] \cdot 3H_2O$ (**14**) (pbaOH = 2-hydroxy-1,3-propanediylbis(oxamato)) has a T_c of 4.6 K,[56b] and upon dehydration and concomitant structural alteration to $[Mn^{II}Cu^{II}(pbaOH)] \cdot 2H_2O$ the T_c is increased to 30 K.[56c]

The Gatteschi and Rey collaboration has focused on Mn^{II}/nitroxide systems, such as the ferrimagnetic complex **15** with a T_c of 8.1 K.[57a] They have also reported on a nonstructurally characterized $[\{Mn(O_2CC_6F_5)_2\}_2$-NITEt] (NITEt = ethyl nitronyl nitroxide) compound with a θ-value of about 25 K and a T_c of 20.5 K.[57b] The rare-earth-containing analogue $[\{Dy^{III}$-$(hfac)_3NITEt\}]$ (hfac = hexafluoroacetylacetonate), in contrast, exhibits antiferromagnetic ordering at 4.4 K ($\theta = -6.1$ K).[57c]

15

For **13**–**15** the interchain interactions may well involve the spin-exchange mechanism illustrated in Scheme 3; here each horizontal line depicts a chain of alternating $S = 5/2$ (↑) and antiferromagnetically coupled $S = 1/2$ (↓) spins, and the adjacent out-of-registry chains are arranged so that the $S = 5/2$ spins (↑) are close to the antiferromagnetically coupled $S = 1/2$ (↓) spins, which leads to ferromagnetic coupling of antiferromagnetically coupled spins.

Scheme 3.

Note that these ferrimagnetic systems possess a few common features; namely, they do not obey the Curie–Weiss expression, as $\chi^{-1}(T)$ is not linear, but a fit to the higher temperature susceptibility has $\theta < 0$. Also plots of χT and moment vs. temperature have a minimum value. A mathematical model describing isolated linear chains of alternating $S = 1/2$ quantum spins and $S > 1/2$ classical spins has been derived by J. Seiden and has been used for some of the aforementioned ferrimagnetic systems.[57d]

3.2.2.2. Excitations Involving NHOMO and/or NLUMO

Configuration interactions can be more complex by inclusion of either the NHOMO and/or NLUMO in addition to the POMO on one or more of the molecular species. In this case the CI can be considered within each molecular species (e.g., excitations from occupied *A* orbitals to virtual orbitals on *A*) as well as between species (e.g., excitations from occupied orbitals on *A* to virtual orbitals of *B*).

3.2.2.2.1. Intermolecular Species Excitations

Configuration interactions involving intermolecular excitations from a POMO to NLUMO or NHOMO to POMO are illustrated in Figure 10. As pointed out in the discussion of mechanism 2.2.1.1 (Section 3.2.2.1.1), the simplest application of the CI model between partially occupied molecular orbitals on adjacent molecules does not produce the correct sign of the exchange interaction for $[CrCp_2^*][TCNE]$[58a, b] (t^3/s^1) ($Cp^* = C_5Me_5$) as well as for $[CrCp_2^*][TCNQ]$ (t^3/s^1),[59] $[Cr(C_6Me_xH_{6-x})_2]^{\cdot+}[TCNE]^{\cdot-}$ ($x = 3,6$) ($\theta > 10$ K) (s^1/s^1),[58c] and $[TTF]^{\cdot+}[Pt\{S_2C_2(CF_3)_2\}_2]^{\cdot-}$ ($\theta = 18$ K) (s^1/s^1).[46c, 58c] For these materials the CI between POMOs predicts antiferromagnetic exchange (resulting in ferrimagnetism for the former pair of examples), yet ferromagnetic exchange and, for the former pair of compounds, ferromagnetic order was observed. Instead

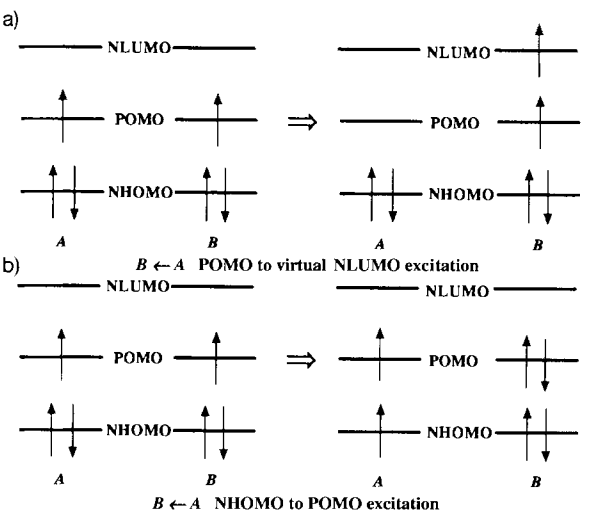


Fig. 10. Schematic illustration of the stabilization of ferromagnetic coupling by configurational interaction (CI), involving only virtual excitation from a POMO on *A* to a virtual NLUMO on *B* (a) or NHOMO on *A* to a POMO on *B* (b).

of considering an excitation between POMOs, an excitation from the POMO of $[CrCp_2^*]^{\cdot+}$ to the NLUMO of $[TCNE]^{\cdot-}$ (or alternatively an excitation from the POMO of $[TCNE]^{\cdot-}$ to the NLUMO of $[CrCp_2^*]^{\cdot+}$) results in the expectation of ferromagnetic exchange. (Similarly, an excitation from the NHOMO of $[CrCp_2^*]^{\cdot+}$ to the POMO of $[TCNE]^{\cdot-}$ as well as the reverse from the NHOMO of $[TCNE]^{\cdot-}$ to the POMO of $[CrCp_2^*]^{\cdot+}$ results in the expectation of ferromagnetic exchange.) The importance of "subjacent" orbitals has also been invoked to explain the observation of reactions forbidden by the Woodward–Hoffmann rules.[60] Thus, the extended configurational admixing model can account for the ferromagnetic coupling observed for a pair of $[CrCp_2^*]^{\cdot+}$ salts. Because of the large number of electrons involved, an ab initio calculation to determine the primary exchange mechanism is beyond current computational capabilities. The necessity to invoke NHOMO → POMO excitation to stabilize ferromagnetic coupling was originally used to explain the ferromagnetic coupling ($\theta > 10$ K) observed for $[Cr(C_6Me_xH_{6-x})_2]^{\cdot+}[TCNE]^{\cdot-}$ ($x = 3,6$).[58c]

3.2.2.2.2. Intramolecular Species Excitations

As discussed previously one may consider CI by intramolecular excitations as well as intermolecular excitations. This special

case is sometimes described as spin polarization (or spin delocalization) or superexchange.[122, 123] It depends upon which energy levels are admixed with the chosen ground state wavefunction and it is closely related to the previous discussion. For example, Figure 11 a illustrates an intramolecular species virtual excitation from the POMO to the NLUMO on *A* followed by a virtual excitation from the POMO on ***B*** to the NLUMO on *A* and is referred to as spin delocalization, while Figure 11 b illustrates intramolecular species virtual excitation from the NHOMO to the POMO on *A* followed by a virtual excitation from the POMO on ***B*** to the NLUMO on *A* and is referred to as superexchange. It is important to note that these mechanisms can give rise to either ferromagnetic or antiferromagnetic coupling.

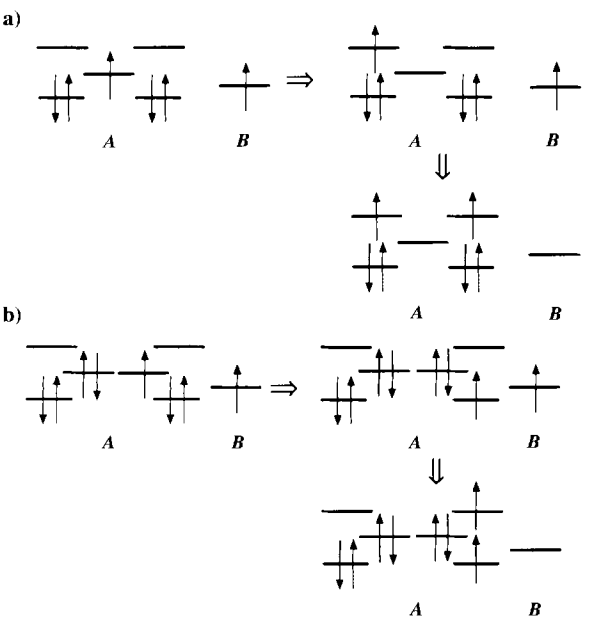

Fig. 11. Schematic illustration of the stabilization of ferromagnetic coupling by configurational interaction (CI), involving the virtual excitation of an electron from a POMO to a NLUMO on *A* followed by a virtual excitation from the POMO on ***B*** to the NLUMO on *A* (spin delocalization) (a), or from a NHOMO to the POMO on *A* followed by a virtual excitation of an electron from the POMO on ***B*** to the NLUMO on *A* (superexchange) (b).

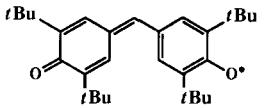
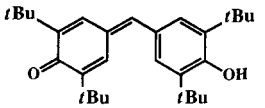


Intramolecular species spin polarization was discussed under mechanism 2.1 (Section 3.2.1) and can also be considered as an intramolecular species effect. For $[FeCp_2^*]^{\bullet+}[TCNE]^{\bullet-}$ A. L. Buchachenko suggested that intramolecular spin polarization of the Cp* five-membered rings by the spin(s) of the transition metal ions (e.g., Fe^{III}) should induce a small negative spin on Cp* ring carbon atoms and result in net ferromagnetic coupling to the adjacent $[TCNE]^{\bullet-}$.[33] This was later quantified by Kahn et al.[61a, b] They suggest a polarization (by CI arising from an intra-ion excitation of electrons from the Cp* ligand to the metal-ion) of the bonds between the ring C atoms of the Cp* ligand, leading to a negative spin density on the carbon atoms of the Cp* five-membered ring, the magnitude of which increases with the spin on the metal ($S = 1/2$, 1, and 3/2 for $[FeCp_2^*]^{\bullet+}$, $[MnCp_2^*]^{+}$, and $[CrCp_2^*]^{\bullet+}$, respectively). In contrast, for $[NiCp_2^*]^{+}$, a direct delocalization of spin density from the Ni^{III} to the Cp* ring, resulting in positive spin density on the ring carbon atoms is suggested. The ferromagnetic (for $[FeCp_2^*]^{\bullet+}$, $[MnCp_2^*]^{+}$, and $[CrCp_2^*]^{\bullet+}$) or antiferromagnetic (for $[NiCp_2^*]^{\bullet+}$) exchange with $[TCNE]^{\bullet-}$ or $[TCNQ]^{\bullet-}$ then results from interaction of the spin on the Cp* ring carbon atoms with that of the anion radical.[61a, b] Recent NMR studies of $[M(C_5EtMe_4)_2]^{+}$ support the presence of negative spin densities on the carbon atoms of the five-membered ring for M = Fe, Mn, and Cr and positive spin density on the carbon atoms of the five-membered ring for M = Ni, consistent with the hypothesis.[62] Polarized single-crystal neutron diffraction studies are in progress to directly determine the spin density of the $[FeCp_2^*]^{\bullet+}$ cation. Configuration interaction involving excitation from the POMO of the nitroxyl radical to the higher occupied Cu^{II}-based orbitals has been suggested as the origin of the ferromagnetic exchange for bischelated Cu^{II} complexes with axially coordinated nitroxyl ligands. In contrast the CI between the POMO of the nitroxyl ligand and the Cu^{II} POMO gives rise to antiferromagnetic exchange for similar complexes with equatorially coordinated nitroxyl ligands.[63]

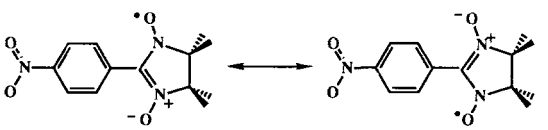
Soos and McWilliams,[61d] as well as more recently Kollmar and Kahn[61c] pointed out that many additional competing excitations need to be considered by CI than those described under mechanism 2.2.1.1. Furthermore, due to the almost-orthogonal nature of the POMOs on the donor and acceptor for $[FeCp_2^*][TCNE]$, the simplest POMO/POMO-based CI is less likely than the many competing excitations; thus, the Cp* ligand can provide a pathway for superexchange or spin delocalization. Yamaguchi et al.[64] describes an intramolecular spin polarization of the Cp* ring by the spin(s) of the transition metal ions as partial charge transfer from the Cp* of an electron (with spin parallel to that of the metal) to the metal atom followed by the CI between the Cp* and the acceptor ($[TCNE]^{\bullet-}$). The net effect is usually ferromagnetic: $M^{+}(\uparrow)Cp^{*}(\downarrow)A(\uparrow)$. The sign of the net exchange then depends upon the sign of the exchange between Cp* and $[TCNE]^{\bullet-}$.



It is noted, however, that the T_c values increase as $[MnCp_2^*]^{+} > [FeCp_2^*]^{\bullet+} > [CrCp_2^*]^{\bullet+}$, and do not increase monotonically with S as expected (see Section 6). This suggests that for the $[CrCp_2^*]^{\bullet+}$ salts, which are predicted to have antiferromagnetic coupling by the simplest POMO/POMO-based CI model, the POMO/POMO CI does not dominate, and ferromagnetic coupling by the more complex POMO/NHOMO/NLUMO-based CI model or an intramolecular CI spin polarization model may be more appropriate.[58a, 59, 61c] Thus, further studies are necessary to firmly establish which specific exchange mechanisms dominate in this series of electron-transfer salts.

The combination of CI using POMO/NHOMO/NLUMOs as well as spin polarization have been used to explain the ferromagnetic coupling reported for galvinoxyl (**16a**). Galvinoxyl has received substantial attention because it exhibits relatively strong ferromagnetic coupling ($\theta = 19$ K) in the solid state. The θ value is too large for dipole interactions (vide infra) alone to be operative. Below 85 K it undergoes a first-order phase transition to a weakly magnetic state.[65a] The details of this structural transformation are unknown. A solid solution of **16a** and hydroxygalvinoxyl (**16b**) has been reported to exhibit ferromagnetic coupling ($10 < \theta < 19$ K), since the high-temperature

structure is maintained.[65b] Hysteresis curves characteristic of a bulk ferromagnet were not observed for either of these materials.[65a]



16a

16b

More recently, the ferromagnetic ordering reported for β-*p*-$O_2NC_6H_4NIT$ (NIT = nitronyl nitroxide) (**17**) has been ascribed to a CI between the POMO on one site and a NHOMO on another site.[66] It, however, is plausible that nonbonding,

17

through-space dipole–dipole interactions may be important, and this system is described in greater detail under mechanism 3 (see Section 3.3).

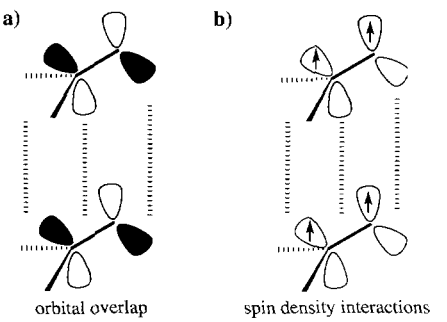
3.2.2.3. Excitations between Localized and Delocalized (Metallic) States (Intramolecular Spin Coupling)

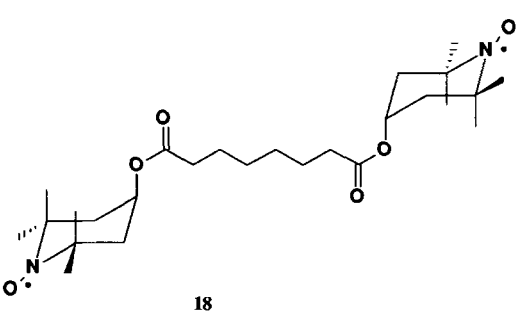
A model of antiferromagnetic exchange (by configuration interaction) between localized d electron spins of the organometallic radicals and a proposed band of delocalized organic moiety based π electrons has been proposed by Tchougreeff and Misurkin and applied to [$FeCp_2^*$][TCNE].[67] This picture resembles those which arise in the Kondo problem[68] and in the Ruderman, Kittel, Kasuda, and Yoshida (RKKY) model for the interaction of magnetic impurities in metals.[23f] They proposed that the POMO b_{2g} $[TCNE]^{\cdot -}$ π^* orbital hybridizes with the delocalized π orbitals of the Cp* ligands and the overlapping 4s and 4p orbitals of Fe^{III} to form a partially filled band of states. They showed that antiferromagnetic exchange between the localized d electrons of $[FeCp_2^*]^{\cdot +}$ and the delocalized π electrons of the organic system could lead to ferromagnetic order in the system of localized Fe d-orbital-based spins. This does not, however, produce the correct saturation magnetization for [$FeCp_2^*$][TCNE], because the delocalized π electrons would have a reduced net spin, part of which would order antiferromagnetically with respect to the Fe d-orbital-based spins. Furthermore, the insulating nature of [$FeCp_2^*$][TCNE] indicates that a delocalized π electron band model is inappropriate. However, a similar approach of interaction of localized metal-based spins with delocalized π electrons was used to account for phenomena in selected phthalocyanine-based salts.[69]

Recent work on the ferromagnetic Zintl phase $A_{14}MnBi_{11}$ (A = Ca and Sr) with critical temperatures of 55 and 33 K, respectively, attributes the magnetic properties to the ferromagnetic coupling of spins between the localized Mn^{III} centers by the conduction electrons (the RKKY model).[5]

3.3. Dipole–Dipole (Through-Space) Exchange

Dipole–dipole, through-space spin-spin interactions not involving the overlap of orbitals have not been formally discussed as a mechanism to achieve bulk ferromagnetic behavior; however, the results of several studies show that through-space spin-spin interactions can lead to cooperative magnetic behavior below about 1 K.[70] This weak magnetic interaction is due to magnetic fields generated by the magnetic moment associated with each spin. It does not involve overlap of orbitals or spin density as illustrated in Figure 12.





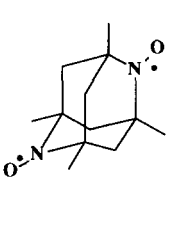


Fig. 12. Schematic illustration of the orbitals (a) and spin densities (b) for nonbonding dipole–dipole, through-space interactions involving a POMO on *A*.

Tanol suberate (**18**), which has a sheetlike crystal structure, and exhibits Curie–Weiss behavior at higher temperature (θ = 0.7 K) and metamagnetic behavior below a T_c of 0.38 K, is a candidate for this mechanism. Below the critical field (H_{cr}) of 100 G **18** is an antiferromagnet, while above 100 G **18** has a high-moment state.[71] Polarized-neutron studies were utilized to determine that the spin density is solely located on the NO moiety, equally between the O and N.[72a] Neutron scattering has also determined that the NO groups couple ferromagnetically within layers separated by 5.9, 6.4, and 6.9 Å, and couple antiferromagnetically between the layers separated by 10.8 Å. Very recently 1,3,5,7-tetramethyl-2,6-diazaadamantane-2,6-dioxyl (**19**) was reported to exhibit ferromagnetic interactions in the solid as evidenced by a θ of 10 K and a fit of the $M(H)$ data to $S = 6$.[73a] The relatively large value of θ suggests that through-space dipole–dipole interaction is not the only mechanism operative. Compound **19** recently has been reported to order at 1.48 K.[73b]

18

19

Crystals of **17** fit the Curie–Weiss expression ($\theta \approx 1$ K) at higher temperatures and have been reported to have a ferromag-

netic state for a T_c at 0.60 K.[66] In contrast γ-p-$O_2NC_6H_4NIT$ is an antiferromagnet.[66b] The origin of the exchange has been ascribed to a CI between the POMO on one site and a NHOMO on another site (vide supra).[66d] However, due to the nonbonding interactions, dipole–dipole interactions may be important. Under hydrostatic pressure the ferromagnetic coupling, as evidenced by an increase of θ, is increased by 40% at 9 kbar pressure.[66c] The large pressure-dependence suggests that through-space dipole–dipole interaction is insufficient to account for the three-dimensional ordering. Zero-field muon spin resonance, which detects the spontaneous static local magnetic fields in ordered states, clearly shows a precession signal comparable to that expected from a three-dimensional Heisenberg model and a T_c of about 0.67 K.[74] Antiferromagnetic coupling has been observed for several other nitronyl nitroxides.[75]

4. Progress in the Discovery of Magnetic Materials Based on Molecular Species

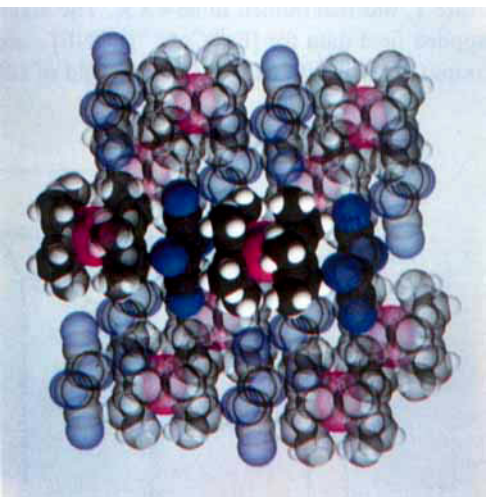
Worldwide interest in molecular-species-based ferromagnets is growing at the present time.[4] Experimental evidence for bulk ferromagnetic behavior in molecular-species-based compounds has been limited to the electron-transfer salts comprised of decamethylmetallocenes and tetracyanoethylene (TCNE) and/or 7,7,8,8-tetracyano-p-quinodimethane (TCNQ), and β-p-$NO_2C_6H_4NIT$ (**17**). Ferromagnetic coupling has been reported for $[(Me_2N)_2CC(NMe_2)_2](C_{60})$, though no hysteresis curves were reported below a transition temperature of $\approx$16 K, and the saturation moment at 5 K corresponds to about 10% of the expected value for only one spin per C_{60}.[76] Recent studies ascribe the high-temperature antiferromagnetic behavior ($\theta = -58$ K) to a superparamagnetic state above $\approx$16 K.[76c] Preliminary zero-field muon spin resonance, however, does not show a change in the spectra as the temperature is reduced to below T_c.[74] There is a rapid suppression of the T_c with pressure by about 10 K per kbar.[76d] The unusually strong pressure-dependence combined with the relatively high conductivity ($\approx 10^{-2}$ S cm^{-1}) of $[(Me_2N)_2CC(NMe_2)_2](C_{60})$ led to the suggestion[76d] that the transition at 16.1 K may be due to an itinerant ferromagnetic state. In contrast, ESR studies suggested[76b,c] that the radical spins in the magnetically ordered state localize on the C_{60} moiety and are ferromagnetically correlated. Further study is necessary to establish the low-temperature magnetic state of this system and determine the origin of the exchange interaction. Cooperative magnetic behavior is not observed for $[(Me_2N)_2CC(NMe_2)_2](C_{70})$.[76b,c]

Evidence for ferrimagnetic ordering has been demonstrated for several $Mn^{II}Cu^{II}$ and Mn^{II} (nitroxide) extended chain structures discussed previously as well as the room-temperature magnet $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ and the recently reported manganese(III) prophyrin-TCNE electron-transfer salt (vide infra).

Numerous attempts to prepare ferromagnetic polymers by the topochemical polymerization of a dinitroxyldiacetylene, oxidation of 1,3,5-triaminobenzene or an indigo polymer, thermolysis of numerous hydrocarbons and polymers, hydrogen abstraction from polymers based upon triphenylmethyl fragments, and electrodeposited polyaniline have been reported. The stated magnetizations correspond to only a few percent of the maximum theoretical magnetization. The poor chemical characterization, low values of the saturation magnetization, and marked variation between samples suggest that the ferromagnetic behavior in these infusible, intractable polymers may not be intrinsic. This area has been recently reviewed.[7] In the remainder of this review we focus on research primarily, but not exclusively, carried out in our laboratories which was initiated with the discovery of cooperative magnetic behavior in a metallocene-based electron-transfer salt.

5. Structure and Magnetic Properties of Electron-Transfer Donor/Acceptor Salts

In 1979 $[Fe^{III}Cp^*_2]^{\bullet+}[TCNQ]^{\bullet-}$ was shown to exhibit a high-moment ferromagnetic state above 1600 Oe (i.e., cooperative metamagnetic properties).[77a] The linear chain structure was established for the kinetic phase of $[Fe^{III}Cp^*_2]^{\bullet+}[TCNQ]^{\bullet-}$[77b] (Fig. 13). The moment μ significantly deviates to positive values



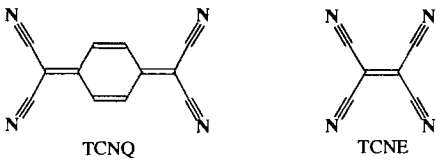


Fig. 13. Alternating donor/acceptor $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ linear chain structure of $[Fe^{III}Cp^*_2]^{\bullet+}[A]^{\bullet-}$ [A = TCNQ, TCNE, $DDQCl_2$, $C_4(CN)_6$], $[Fe^{II}Cp_2][TCNE]$, and $[Fe^{III}Cp^*_2]^{\bullet+}[C_3(CN)_5]^-$. The structure shows views of adjacent in-registry and out-of-registry chains for A = TCNE.

at low temperature from the temperature-independent Curie behavior characteristic of ferrocenium salts with spinless anions.[9, 77a] The field-dependent magnetization $M(H)$ reveals metamagnetic behavior, that is, for an applied field of less than 1600 Oe the magnetization is characteristic of an antiferromagnet; whereas above 1600 Oe a sharp rise and approach to magnetization saturation characteristic of a ferromagnet is observed (cf. Fig. 5).[77a] While several metamagnets, for example, $FeCl_2$, had been characterized,[78] this was the initial example in which neither a one-, two- nor a three-dimensional covalently bonded network structure is present. Subsequently, we sought to elucidate the structure–function relationship by the systematic modification of the acceptor A, the substituents on the C_5Me_5 ring, and the metal ion to identify the steric/electronic features necessary to stabilize ferromagnetism and ultimately design a molecular-species-based ferromagnet.

On the supposition that a smaller radical anion would have a greater spin density which could lead to increased spin-spin interactions, we sought to identify stable radical anions smaller than $[TCNQ]^{\bullet -}$, and thus selected $[TCNE]^{\bullet -}$. $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$ was prepared and found to possess the same $\cdots D^{\bullet +}A^{\bullet -}D^{\bullet +}A^{\bullet -}\cdots$ motif (Fig. 13).[79] With application of only the Earth's magnetic field a spontaneous magnetization is observed.[25] The saturation magnetization for single

crystals aligned parallel to the $\cdots D^{\bullet +}A^{\bullet -}D^{\bullet +}A^{\bullet -}\cdots$ stacking axis is 36% greater than iron on a g-atom basis, and agrees with the calculated saturation moment for ferromagnetic alignment of the donor and the acceptor.[8g-j] The critical (Curie) temperature T_c was determined to be 4.8 K. The magnetization versus applied field data for $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$ exhibits hysteresis loops (Fig. 14) with a large coercive field of 1000 Oe at 2 K.[25]

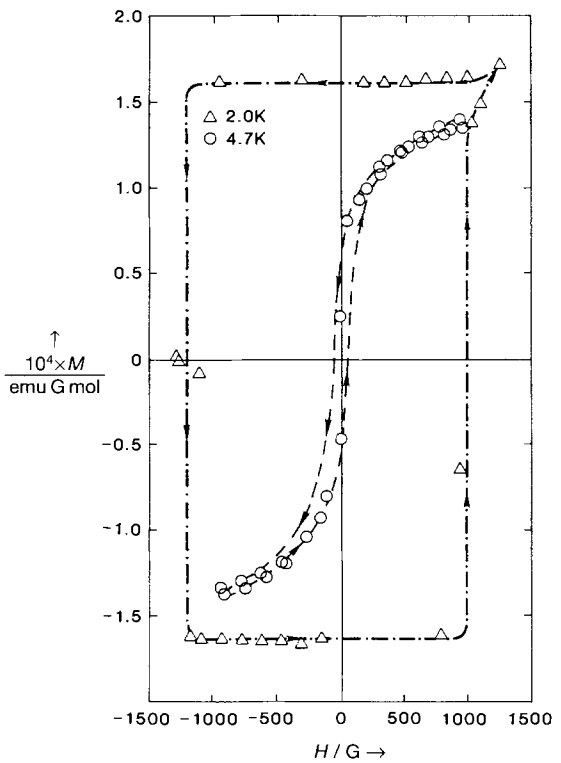

Fig. 14. The magnetization M as a function of applied field H for $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$ shows hysteresis loops at 2 K.

It is sufficiently magnetic at low temperatures to be attracted to a Co_5Sm magnet (Fig. 15).

Fitting the single-crystal magnetic susceptibility data taken for the applied magnetic field parallel to the C_5 axis of the donor

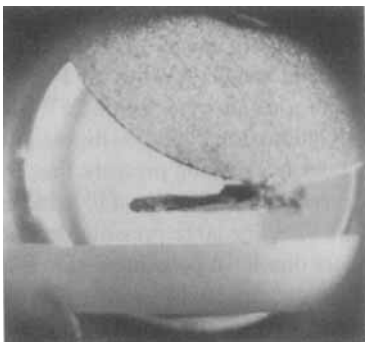

Fig. 15. Photograph of a compacted powder sample of $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$ being attracted to a Co_5Sm magnet at low temperature in a liquid helium dewar. (Photograph by J. V. Caspar and R. S. McLean.)

to different physical models aids in the understanding of the microscopic spin interactions. Above 16 K interactions among the nearest neighbor spins within individual one-dimensional chains are sufficient to understand the magnetic behavior. The Curie–Weiss Law is sufficient to model the higher temperature ($T > 130$ K) data with $\theta = 30$ K.[25, 79] A one-dimensional Heisenberg model with a ferromagnetic exchange coupling (J) of 19 cm^{-1} (27 K), however, better accounts for the data down to 16 K.[25] These models are insufficient to account for the magnetic behavior below 16 K as long-range spin correlations and three-dimensional spin interactions become increasingly important. This continues until permanent long-range (three-dimensional) ferromagnetic order occurs at 4.8 K. Preliminary studies of the pressure dependence of T_c reveals that T_c increases with applied pressure by 0.21 K $kbar^{-1}$ and reaches 7.8 K at 14 kbar applied pressure.[80a] (This is in marked contrast to decreasing T_c with increasing pressure of the organic superconductors.[80b]) Variation of the low-field magnetic susceptibility with temperature above T_c, magnetization with temperature below T_c, and the magnetization with magnetic field at T_c enabled a measurement of three critical exponents (Table 4) for the magnetic field parallel to the chain axis. The observed values are in accord with a transition to a three-dimensional ordered magnetic state.

The configuration admixing of a virtual-triplet excited state with the ground state model (mechanism 2.2.1.1 in Scheme 1) provides a mechanism to stabilize ferromagnetic interactions within donor/acceptor (D/A) complexes and a simple, preliminary framework to view this class of materials and make some predictions as to the magnetic coupling of new materials. The paradigm of this model is realized by this series of electron-transfer salts possessing a linear chain (one-dimensional) structure comprised of alternating cation donors (D) and anion acceptors (A) that is, $\cdots D^{\bullet +}A^{\bullet -}D^{\bullet +}A^{\bullet -}\cdots$ (Fig. 13).[8g, 9] This model is described in further detail under the mechanism 2.2.1.1 (Scheme 1; Section 3.2.2.1.1). More complex models have been invoked to describe this system and are described under the mechanism 2.2.2 (Scheme 1; Section 3.2.2.2).

To identify the structure–function relationship with the goal of preparing a molecular-species-based ferromagnet with a higher critical temperature, the properties of $\cdots$DADA$\cdots$ structured compounds based on $[M(C_5R_5)_2]^+$ were studied. Three modifiable entities are: replacement of the Me groups with H and Et, use of alternate open and closed-shell anions, and replacement of Fe^{III} with other metal ions.

Table 4. Summary of the critical temperatures T_c and data for the coercive fields of compunds of the $[MCp^*_2]$ [A].

Compound $[MCp^*_2]$	[A]	S_D	S_A	T_c [K]	θ [K] [d]	H_c [G] (T [K])	α [h]	β [h]	γ [h]	δ [h]	Ref.
$[FeCp^*_2]^{+\cdot}$	$[TCNE]^{-\cdot}$	1/2	1/2	4.8	+16.9 [e]	1000(2)	0.09	≈ 0.5	1.21	4.42	[25, 79]
$[MnCp^*_2]^{+\cdot}$	$[TCNE]^{-\cdot}$	1	1/2	8.8	+22.6	1200(4.2)					[81]
$[CrCp^*_2]^{+\cdot}$	$[TCNE]^{-\cdot}$	3/2	1/2	3.65 [j]	+22.2	[g]		0.5	1.1		[58]
$[FeCp^*_2]^{+\cdot}$	$[TCNQ]^{-\cdot}$	1/2	1/2	2.55 [a]	+12.3						[77a]
$[MnCp^*_2]^{+\cdot}$	$[TCNQ]^{-\cdot}$	1	1/2	6.3 [b]	+10.5 [i]	3600(3)					[82]
$[CrCp^*_2]^{+\cdot}$	$[TCNQ]^{-\cdot}$	3/2	1/2	3.3 [c]	+11.6 [f]	[k]					[59]

[a] Metamagnetic with a 1600 G critical field. [b] 50 G, T_c from the maximum slope of dM/dT is reported as 6.2 K. [c] 15 G, T_c from the maximum slope of dM/dT is reported as 3.1 K. [d] For polycrystalline samples. [e] For crystals aligned parallel and perpendicular to the applied magnetic field: $\theta_{\parallel} = 30$ K and $\theta_{\perp} = 10$ K [25]. [f] 12.8 K (R. S. McLean, J. S. Miller unpublished results). [g] Not observed. [h] Critical constants. [i] 9.0 K (R. S. McLean, J. S. Miller unpublished results). [j] 0.15 G. [k] Not observed; <0.15 Oe.

Substituted C_5 rings may maintain the fivefold symmetry necessary to form a cation with degenerate partially occupied molecular orbitals and a Kramers doublet (^2E) ground state as reported for decamethylferrocenium. Three other such ferrocenes have been studied: ferrocene, 1,2,3,4,5-pentamethylferrocene, and decaethylferrocene. Ferrocene is significantly more difficult to oxidize than decamethylferrocene, and is not oxidized by TCNE.[83] Nonetheles, $[Fe^{II}Cp_2][TCNE]$ forms and belongs to the same structure type[84] (Fig. 13) and is diamagnetic.[84b] [FeCpCp*] (Cp = cyclopentadienide, C_5H_5) is a sufficiently strong donor to reduce TCNE, and the simple (1:1) one-dimensional salt as well as three other phases were prepared.[85] This 1:1 phase exhibits weak ferromagnetic coupling as evidenced from the fit of its susceptibility to the Curie–Weiss expression with $\theta = 3.2$ K, but cooperative three-dimensional magnetic ordering is not observed to the lowest temperature studied (≈2 K).[85] A linear chain structure is proposed for $[Fe^{III}(C_5Et_5)_2]^{+\cdot}[TCNE]^{-\cdot}$, which also exhibits ferromagnetic coupling as evidenced from the fit of its susceptibility to the Curie–Weiss expression with $\theta = 7.5$ K. It also did not exhibit cooperative three-dimensional magnetic ordering.[86]

To test the necessity of a ^2E ground state, the TCNE electron-transfer salt with the lower symmetry $[Fe(C_5Me_4H)_2]$ donor was prepared.[87] The magnetic susceptibility can be fit by the Curie–Weiss expression with $\theta \approx 0$ K. The absence of either three-dimensional ferro- or antiferromagnetic ordering above 2.2 K in $[Fe(C_5Me_4H)_2]^{+\cdot}[TCNE]^{-\cdot}$ contrasts with the behavior of $[FeCp^*_2]^{+\cdot}[TCNE]^{-\cdot}$. The ^{57}Fe Mössbauer data are in accord with the absence of significant magnetic coupling among the radical ions, and show only nuclear quadrupole splitting for the $[Fe(C_5Me_4H)_2]^{+\cdot}$ salts and not the zero-field Zeeman splitting observed for $[FeCp^*_2]^{+\cdot}[TCNE]^{-\cdot}$,[79] $[FeCp^*_2]^{+\cdot}[TCNQ]^{-\cdot}$,[77b] $[FeCp^*_2]^{+\cdot}[C_4(CN)_6]^{-\cdot}$,[88] and $[FeCp^*_2]^{+\cdot}[DDQCl_2]^{-\cdot}$ ($DDQCl_2$ = 2,3-dichloro-5,6-dicyanobenzoquinone).[89] The lack of magnetic ordering apparently arises from poorer intra- and intermolecular overlap within and between the chains leading to substantially weaker magnetic coupling for $[Fe(C_5Me_5H)_2]^{+\cdot}[TCNE]^{-\cdot}$. This suppresses the spin-ordering temperature. Alternatively, due to the overall C_{2v} symmetry the $[Fe(C_5Me_4H)_2]^{2+}$ charge-transfer excited state may be a singlet, not a triplet as expected for $[FeCp^*_2]^{2+}$, and the admixture of a singlet, not a triplet charge-transfer excited state should lead to antiferromagnetic, not ferromagnetic, coupling.[8g, 87] Since significant antiferromagnetic coupling was also absent for $[Fe(C_5Me_4H)_2]^{+\cdot}[TCNE]^{-\cdot}$, perhaps a reduced overlap with neighboring radicals is the more important effect of modification of the cation.

Substitution of TCNE with either TCNQ,[90] $C_4(CN)_6$,[88] $TCNQI_2$,[91] ($TCNQI_2$ = 2,5-diiodo-TCNQ), $DDQCl_2$,[89] or $[M\{S_2C_2(CF_3)_2\}_n]^{-\cdot}$ {$n = 2$, M = Ni,[92a] Pt[92b]; $n = 3$, M = Mo[92c]} acceptors leads to $\cdots D^{+\cdot}A^{-\cdot}D^{+\cdot}A^{-\cdot}\cdots$ structured complexes with dominant ferromagnetic coupling (see Tables 5 and 6).

Replacement of $[TCNE]^{-\cdot}$ with diamagnetic $[C_3(CN)_5]^-$ also leads to the formation of a $\cdots D^{+\cdot}A^{-}D^{+\cdot}A^{-}\cdots$ structured phase; it exhibits only Curie susceptibility ($\theta = -1$ K).[79] The $[Co^{III}Cp^*_2]^+[TCNE]^{-\cdot}$ complex with a diamagnetic donor has been prepared and exhibits essentially the Curie susceptibility anticipated for $[TCNE]^{-\cdot}$.[79] This demonstrates the necessity of having both the D and A radicals for stabilizing ferromagnetic coupling in the linear chain alternating $\cdots D^{+\cdot}A^{-\cdot}D^{+\cdot}A^{-\cdot}\cdots$ motif.

Attempts to prepare $[M^{III}Cp^*_2]^+$ (M = Ru, Os) salts of $[TCNE]^{-\cdot}$ have yet to lead to compounds suitable for comparison with the highly magnetic Fe^{III} phase.[93] Replacement of Fe^{III} in $[Fe^{III}Cp^*_2]^{+\cdot}[A]^{-\cdot}$ (A = TCNE, TCNQ, $C_4(CN)_6$) with doublet Ni^{III}, triplet Mn^{III}, and quartet Cr^{III} leads to compounds exhibiting antiferro-, ferro-, and ferromagnetic coupling, respectively (see Tables 4 and 5). This series enables the direct testing of several models. The simplest POMO/POMO-based CI model predicts antiferro-, ferro-, and antiferromagnetic coupling, respectively; whereas invoking the more complex NHOMO/NLUMO excitation CI model predicts the observed antiferro-, ferro-, and ferromagnetic coupling, respectively. More importantly, the anomalous behavior of $[Cr^{III}Cp^*_2]^{+\cdot}[TCNE]^{-\cdot}$ is striking since its T_c is less than that observed for $[Fe^{III}Cp^*_2]^{+\cdot}[TCNE]^{-\cdot}$ and $[Mn^{III}Cp^*_2]^{+\cdot}[TCNE]^{-\cdot}$, and fails to follow $T_c \propto S(S+1)$, which suggests the competition of more than one mechanism (vide infra).

Magnetic ordering is not observed for bis(dithiolato)metallate salts of decamethylferrocenium; however, ferromagnetic coupling as evidenced by Curie–Weiss θ constants which range from 0 to 27 K is observed (Table 6). This provides an insight into a structure–function relationship. Of the compounds studied only $[MCp^*_2][M'\{S_2C_2(CF_3)_2\}_2]$ (M' = Ni, Pt; M = Fe,[92b] Mn[97]) and $[FeCp^*_2][Mo\{S_2C_2(CF_3)_2\}_3]$[92c] have a one-dimensional chain structure. The M = Fe complexes have the largest θ values, the largest effective moments, and the most pronounced magnetic field dependencies of the susceptibility. The Pt analogue ($\theta = 27$ K) possesses one-dimensional

Table 6. Summary of the Curie–Weiss θ values and μ_{eff} values for $[FeCp_2^*][M\{S_2C_2(CN)_2\}_n]$.

Anion	Structural arrrangement	Spin repeat unit	Susceptibility θ [K]	μ_{eff} [μ_B]
$[Ni\{S_2C_2(CN)_2\}_2]^{\bullet-}$	$D^{\bullet+}[A]_2^{2-}D^{\bullet+}$ dimer [a]	$D^{\bullet+}$	0	2.83
α-$[Pt\{S_2C_2(CN)_2\}_2]^{\bullet-}$	$\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}\cdots$ sheets $1D\cdots D^{\bullet+}[A]_2^{2-}\cdots$ chains [a]	$D^{\bullet+}$ +1/3 $A^{\bullet-}$	6.6	3.05
β-$[Pt\{S_2C_2(CN)_2\}_2]^{\bullet-}$	$1D\cdots D^{\bullet+}A^{\bullet-}\cdots$ chains $D^{\bullet+}[A]_2^{2-}D^{\bullet+}$ dimer [a]	$D^{\bullet+}$ +1/3 $A^{\bullet-}$	9.8	3.10
$[Ni\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$	$1D\cdots D^{\bullet+}A^{\bullet-}\cdots$ [b]	$D^{\bullet+}$ + $A^{\bullet-}$	15	3.73
$[Pt\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$	$1D\cdots D^{\bullet+}A^{\bullet-}\cdots$ chains	$D^{\bullet+}$ + $A^{\bullet-}$	27	3.76
$[Mo\{S_2C_2(CF_3)_2\}_3]^{\bullet-}$	$1D\cdots D^{\bullet+}A^{\bullet-}\cdots$ chains	$D^{\bullet+}$ + $A^{\bullet-}$	8.4	3.85

[a] $[A]_2^{2-}$ = isolated $S = 0$ $[M\{S_2C_2(CN)_2\}_2]_2^{2-}$ dimer. [b] Zigzag chains.

$\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ chains, whereas the Ni analogue (θ = 15 K) possesses zigzag one-dimensional $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ chains and longer M···M separations (11.19 Å vs. 10.94 Å for the Pt analogue). Thus, the enhanced magnetic coupling the Pt compound compared with that of the Ni compound presumably arises from the stronger intrachain coupling. In contrast, for $[MnCp_2^*][M'\{S_2C_2(CF_3)_2\}_2]$ (M′ = Ni, Pd, Pt) weak ferromagnetic coupling is observed ($\theta = 2.8 \pm 0.8$ K), and metamagnetic behavior with a T_c of 2.5 ± 0.3 K was reported.[97] This is comparable to the T_c reported for metamagnetic $[FeCp_2^*]^{\bullet+}[TCNQ]^{\bullet-}$.[77a]

It is curious to note that, whereas replacement of $[FeCp_2^*]^{\bullet+}$ ($S = 1/2$) in $[FeCp_2^*]^{\bullet+}[TCNE]^{\bullet-}$ with $[MnCp_2^*]^{+}$ ($S = 1$) increases T_c nominally in accord with theory (i.e., $T_c \propto S(S+1)$, vide infra),[81] and replacement of $[FeCp_2^*]^{\bullet+}$ in $[FeCp_2^*]^{\bullet+}[TCNQ]^{\bullet-}$ with $[MnCp_2^*]^{+}$ destabilizes the metamagnetic behavior and stabilizes ferromagnetic ordering, however, replacement of $[FeCp_2^*]^{\bullet+}$ in $[FeCp_2^*][M'\{S_2C_2(CF_3)_2\}_2]$ with $[MnCp_2^*]^{+}$ stabilizes metamagnetic behavior.[97] The absence of simple trends emphasizes the important role of interchain as well as intrachain interactions (vide infra).

In the opposite extreme $[FeCp_2^*][Ni\{S_2C_2(CN)_2\}_2]$ possesses isolated $D^{\bullet+}A_2^{2-}D^{\bullet+}$ dimers and has a zero θ, the lowest μ_{eff}, and has no field dependence of the susceptibility.[92a] The observed high moment is consistent with one spin possessing a highly anisotropic *g* value per repeat unit. Intermediate between the one-dimensional chain and dimerized chains structures are the α- and β-phases of $[FeCp_2^*][Pt\{S_2C_2(CN)_2\}_2]$ which have one-dimensional $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ strands in one direction and $\cdots$ DAAD $\cdots$ dimer units in another direction. Their θ and μ_{eff} are intermediate in value (Table 6). This is consistent with one-third of the anions having a singlet ground state. Thus a correlation exists between the presence of one-dimensional $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ chains and the presence and magnitude of ferromagnetic coupling as evidenced by a positive θ value.

Insight into the effect of increasing the intrachain separation was obtained through the study of a tris(dithiolato)metallate salt of $[FeCp_2^*]^{\bullet+}$, namely $[FeCp_2^*]^{\bullet+}[Mo\{S_2C_2(CF_3)_2\}_3]^{\bullet-}$.[92c] The salt possesses only parallel out-of-registry one-dimensional $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ chains with intrachain Mo···Mo separations of 14.24 Å. The θ value is only 8.4 K, which probably reflects the enhanced shielding of the spin and reducing of the spin-spin interactions due to the bulky CF_3 groups. $[FeCp_2^*]^{\bullet+}[Mo\{S_2C_2(CF_3)_2\}_3]^{\bullet-}$ and $[TTF]^{\bullet+}[Mn\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$ (M = Ni, Pt) are the sole structures reported to date that only possess out-of-registry parallel chains and do not have parallel chains in-registry. Thus, the antiferromagnetic s^1/s^1 $A^{\bullet-}/A^{\bullet-}$ interchain interactions are eliminated; however, for the latter pair of electron-transfer salts antiferromagnetic s^1/s^1 $D^{\bullet+}/A^{\bullet-}$ interchain interactions are present.

These results support the utility of one-dimensional $\cdots D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ chain structures for achieving significant ferromagnetic coupling and ultimately bulk ferromagnetic behavior as observed for $[FeCp_2^*]^{\bullet+}[TCNE]^{\bullet-}$.[79] With the wide variation of bis- and tris-dithiolates available other salts may exhibit stronger ferromagnetic coupling and possibly bulk ferromagnetic behavior. Furthermore, many polymorphs with differing physical properties can easily, albeit sometimes irreproducibly, be prepared and the specific design of structure types,

for example, one-dimensional $\cdots$ DADA $\cdots$ chains, continues to be an art.

6. Calculation of the Critical (Curie) Temperature T_c

Heisenberg along with Dirac[99] solved expressions that relate T_c to the exchange integral (J) between sites i and j for the general spin case assuming that only the number of equivalent nearest neighbor sites (z) is important. This simplest mean-field model leads to Equation (10).[23]

$$T_c = \frac{2JzS(S+1)}{3k_B} \tag{10}$$

Equation (10) is constrained to have only one spin site S and a unique J. These are poor assumptions for the $[MCp_2^*]^+[TCNE]^{\bullet -}$ system since the distinct spin sites may have different values of S, and the crystal structure implies four distinctly different nearest neighbor exchange integrals, that is, J_z, J_{AA}, J_{DD}, and J_{OR}^{DA} (Fig. 16). A more appropriate mean-field expression for T_c was therefore developed.[24] In the simplest form, since the values for the four exchange integrals are unknown, a single effective J, J_{eff}, is utilized. In this simplified description, which may be inadequate for highly anisotropic materials, there are two distinct spin averages (S_D and S_A corresponding to the D^+ and $A^{\bullet -}$ sites, respectively). The Hamiltonian per molecule ($\mathscr{H}$) takes the form of Equation (11): The directions of the vectors $\langle \boldsymbol{S}_A \rangle$ and $\langle \boldsymbol{S}_D \rangle$ are along their respective effective magnetic fields. A state of spontaneous spin polarization in the absence of an external field exists in the mean-field model whenever the Equations (12) have nonzero solutions. The transition temperature T_c is the highest temperature for which this is valid. Near the T_c the self-consistent spin averages are small and a Taylor series expansion of the equations reduces them to the coupled linear Equations (12a and 12b).

$$\mathscr{H} \approx -\mu_B H \cdot g_A S_A - \mu_B H \cdot g_D S_D - 4\{S_A \cdot [J_{eff}\langle \boldsymbol{S}_A \rangle + 3J_{eff}\langle \boldsymbol{S}_D \rangle] - S_D \cdot [J_{eff}\langle \boldsymbol{S}_D \rangle + 3J_{eff}\langle \boldsymbol{S}_A \rangle]\} \tag{11}$$

$$\langle \boldsymbol{S}_A \rangle = \frac{2S_A(S_A+1)[2J_{eff}\langle \boldsymbol{S}_A \rangle + 6J_{eff}\langle \boldsymbol{S}_D \rangle]}{3k_BT} \tag{12a}$$

$$\langle \boldsymbol{S}_D \rangle = \frac{2S_D(S_D+1)[2J_{eff}\langle \boldsymbol{S}_D \rangle + 6J_{eff}\langle \boldsymbol{S}_A \rangle]}{3k_BT} \tag{12b}$$

Equations (12) have a solution only if the determinant of the coefficients vanishes; a condition which leads to a quadratic equation for $1/T = 1/T_c$, and only one of the roots gives a positive T_c. This formalism breaks down as J in one direction becomes large compared to the other interactions because a one-dimensional system is formed in this limit and T_c must approach zero Kelvin. The prediction of a finite transition temperature for a one-dimensional system is a well-known fundamental deficiency of mean-field models, and a more sophisticated method is probably required to fully treat the strongly anisotropic case. Nonetheless, the general solution for a single effective J, J_{eff}, for Equation (12) is Equation (13).

$$T_c = \frac{64J_{eff}(S_AS_D + S_A^2S_D + S_AS_D^2 + S_A^2S_D^2)}{3\left[\sqrt{S_A^2 + 2S_D^3 + S_A^4 + S_D^2 + 2S_D^3 + D_D^4 + 34(S_AS_D + S_A^2S_D + S_AS_D^2 + S_A^2S_D^2)} - (S_A + S_A^2 + S_D + S_D^2)\right]} \tag{13}$$

Assuming that the intra- and interchain interactions remain unchanged as the donor is varied, J_{eff} will remain constant and consequently the relative T_c can be calculated for different values of S_A and S_D (Table 7). For $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$, T_c is $4J_{eff}$ within this mean-field model. Since the observed T_c is 4.8 K, J_{eff} is 1.2 K (0.83 cm^{-1}, 0.1 meV). This result points out that though the value of J_{eff} is indeed small, it is sufficient to enable a T_c at experimentally accessible temperatures due to the large number of nearest neighbors.

The major advantage of the above equation is that T_c can be scaled for different S_D values (Table 7). Thus, T_c for a donor ($S_D = 1$) (with an $S_A = 1/2$ acceptor) is 6.8 J or 1.7 times greater than that for a $S_D = 1/2$ donor (with an $S_A = 1/2$ acceptor) system. Hence, since T_c is 4.8 K for $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$, and all else being equal, T_c would be expected to be 8.2 K for the isostructural $[Mn^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$. This is in good agreement with the reported value of 8.8 K for $[Mn^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$.[81] (More complex equations utilizing four different J values lead to

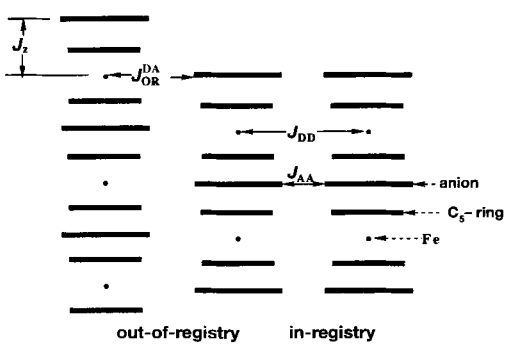

Fig. 16. Schematic illustration of the structure of orthorhombic $[Fe^{III}Cp_2^*]^{\bullet +}[TCNE]^{\bullet -}$ showing intrachain, pairwise out-of-registry and in-registry interactions.

Table 7. Calculated mean-field T_c as a function of S_D for $S_A = 1/2$ systems.

S_D	T_c	scaled T_c [a]
1/2	4 J	1.00
1	6.8 J	1.70
3/2	10 J	2.50

[a] Scaled: $T_c = T_c/T_c$ ($S_D = 1/2$).

an improved scaling of T_c as a function of S_D.[24, 81]) Thus, the observed T_c is in excellent agreement with the experimental values and suggests that if this mean-field model is correct, similar exchange interactions operate for both $[Fe^{III}Cp_2^*]^{\cdot+}[TCNE]^{\cdot-}$ and $[Mn^{III}Cp_2^*]^{+}[TCNE]^{\cdot-}$.[100]

The $S_D = 3/2/S_A = 1/2$ case (i.e., $[Cr^{III}Cp_2^*]^{\cdot+}[TCNE]^{\cdot-}$) was also theoretically treated and a predicted scaled value for the T_c of 12 K was obtained. Experimental study of the magnetic susceptibility of $[Cr^{III}Cp_2^*]^{\cdot+}[TCNE]^{\cdot-}$ shows a ferromagnetic transition at 3.65 K substantially lower than that of either $[Fe^{III}Cp_2^*]^{\cdot+}[TCNE]^{\cdot-}$ or $[Mn^{III}Cp_2^*]^{+}[TCNE]^{\cdot-}$.[58] This trend is also observed for $[Mn^{III}Cp_2^*]^{+}[TCNQ]^{\cdot-}$ ($T_c = 6.2$ K)[82] and $[Cr^{III}Cp_2^*]^{\cdot+}[TCNQ]^{\cdot-}$ ($T_c = 3.1$ K)[59] and may arise from the Cr^{III} salts having significantly lower values of J than the Mn^{III} and Fe^{III} salts.[101] The anomalously low value of T_c is further compounded by the observed ferromagnetic exchange, in contrast to the prediction of antiferromagnetic exchange and a ferrimagnetic ground state for the configuration mixing model described previously. (This model successfully yields the sign of the magnetic exchange of all other linear chain metallocene cases studied so far.) Experimental study of $[CrCp_2^*][TCNE]$ is complicated by its extreme sensitivity to the presence of oxygen which modifies the observed exchange interactions.[58]

7. Dimensionality of the Electron-Transfer Donor/Acceptor Salt System

The mean-field models described previously emphasize a three-dimensional approach to magnetic ordering. The low value of the three-dimensional ordering temperature ($T_c = 4.8$ K) compared to the one-dimensional exchange interaction (as indicated by $J = 19$ cm^{-1} (27 K)) for $[FeCp_2^*]^{\cdot+}[TCNE]^{\cdot-}$, suggests the applicability of quasi-one-dimensional models for the onset of three-dimensional cooperative ordering. For example, for a tetragonal lattice with interacting nearest neighbor chains [(Eq. (14)].[102]

$$T_c = \frac{1.556\sqrt{J_{intra}J_{inter}}}{k_B} \qquad (14)$$

Using a value of $J = 27$ K for the intrachain exchange and the experimental value of T_c, a ratio of $J_{intra}/J_{inter} = 77$ is obtained. Thus, $[FeCp_2^*]^{\cdot+}[TCNE]^{\cdot-}$ and most of the other metallocene electron-transfer salts are in the one-dimensional limit.

To test the critical importance of the one-dimensionality, spinless $S = 0$ $[CoCp_2^*]^{+}$ cations were randomly substituted for the cation in the $[FeCp_2^*]^{\cdot+}[TCNE]^{\cdot-}$ structure. This resulted in the formation of random finite magnetic chain segments embedded into the linear chains.[95] The dramatic, precipitous reduction of T_c with increasing $[CoCp_2^*]^{+}$ content is in excellent agreement with theoretical concepts[103] (Fig. 17, Table 5) for highly anisotropic systems. With a 14.5% replacement of Co^{III} for Fe^{III}, T_c dropped from 4.8 to 0.75 K. The extreme sensitivity of the three-dimensional ordering temperature T_c stands as a cautionary note in attempts to observe a high T_c for solids comprised of high-spin oligomers. For such systems the ratio of the intra- to the interoligomer exchange may be very large. Given the finite length of oligomers, the results of the aforementioned doping

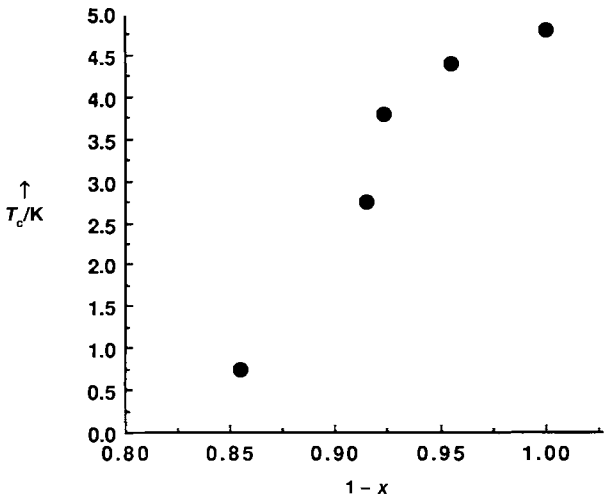

Fig. 17. Variation of T_c with the amount of $[CoCp_2^*]^{+}$ introduced into the structure of $[FeCp_2^*]^{\cdot+}[TCNE]^{\cdot-}$, $[\{FeCp_2^*\}^{\cdot+}]_{1-x}[\{CoCp_2^*\}^{+}]_x[TCNE]^{\cdot-}$.

experiments suggest a significant suppression of three-dimensional ordering.

8. Unusual Magnetic Properties of $[MnCp_2^*]^{+}[DDQCl_2]^{\cdot-}$

With the goal of preparing additional molecular-species-based ferromagnets, the ferromagnetically coupled $[FeCp_2^*]^{\cdot+}[DDQCl_2]^{\cdot-}$ electron-transfer salt was characterized ($\theta = 10$ K).[89] As T_c is proportional to the spin magnitude (Eqs. (10) and (13)), $[MnCp_2^*]^{+}[DDQ]^{\cdot-}$ was prepared anticipating that T_c might occur at temperatures accessible in our laboratories.[94] The high-temperature magnetic susceptibility of $[MnCp_2^*]^{+}[DDQCl_2]^{\cdot-}$ can be fit by the Curie–Weiss expression with a θ value of 26.8 K, which suggests that the strongest exchange interactions (the interactions within individual chains) are ferromagnetic. Hysteretic magnetic field dependent behavior, albeit complex, was observed below ≈ 7 K. The 150 to 2000 G magnetic field dependencies of the magnetization for a sample previously aligned in zero field or in high field (19.5 kG) is presented in Figure 18 for increasing and decreasing magnetic fields. Above ≈ 3.8 K the magnetization exceeds the expected value calculated from the Brillouin function [Eq. (8)] for fully aligned $S = 1$ and $S = 1/2$ spins, whereas dramatically different behavior is observed below this temperature. Thus, the data imply a complex magnetic phase diagram at low temperature (Fig. 19). If one assumes complete alignment of the crystals with magnetic field parallel to the C_5 molecular axis, a sample-history dependent saturation magnetization (M_s) is observed with values up to 24200 emuG mol^{-1}. The data are consistent with strong ferromagnetic coupling between adjacent radicals within each chain and a net weak antiferromagnetic coupling between the chains.[104] This leads to metamagnetic behavior. Thus, when an applied magnetic field is large enough, it becomes energetically favorable for the spins in all the chains to align ferromagnetically. Below ≈ 4 K there is an anomalous behavior with large hysteresis and remnant magnetization.[104] For example, at ≈ 4 K the magnetization abruptly drops by

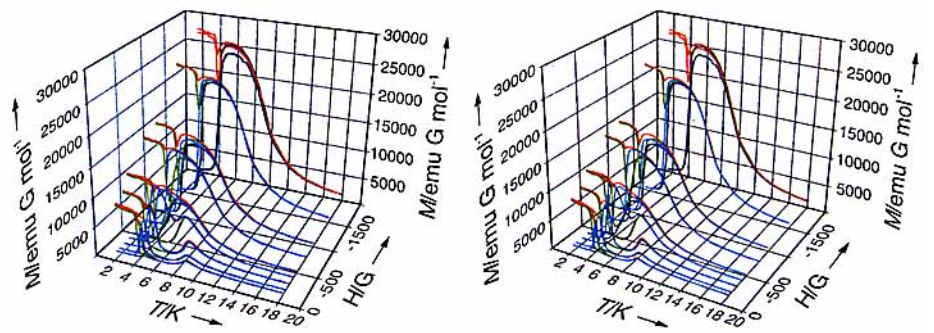

Fig. 18. Stereoview of the molar magnetization M as a function of temperature for a zero-field (blue and cyan) and high-field (red and green) cooled (previously aligned in 19.5 kG) polycrystalline sample of $[MnCp_2^*]^+[DDQCl_2]^-$. The cyan and green data were taken from decreasing applied fields, while the red and blue data were taken from increasing applied fields. (The actual field application sequence was 150, 300, 500, 1000, 2000, 1500, 750, 400, and 200 G prior to annealing at 25 K in zero field for 30 min and then applying 200, 400, 750, 1500, 2000, 1000, 500, 300, and 150 G fields.) The pair of similar curves at 2000 G arises from the two independent times the data was acquired.

more than an order of magnitude depending on the applied field to a value lower than that calculated from the Brillouin function. At high temperature there is a field-dependent crossover from a low-magnetization to a high-magnetization state. This is suggestive of the presence of perhaps both metamagnetic and possible lattice distortion (spin-Peierls-like) transitions. However, since spin-Peierls transitions occur only in antiferromagnetic states, complex magnetic behaviors must be operative in the material. Simple metamagnetic behavior has been reported for $[FeCp_2^*]^{\bullet+}[TCNQ]^{\bullet-}$[77a] and $[MnCp_2^*]^+[M\{S_2C_2(CF_3)_2\}_2]^{\bullet-}$ (M = Ni, Pd, Pt).[97]

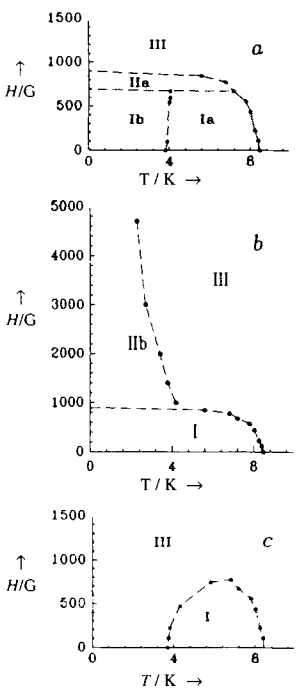

Fig. 19. Magnetic phase diagram (see text) for $[MnCp_2^*]^+[DDQCl_2]^-$ (from ref. [104]).

On the basis of the experimental results three phase diagrams were derived to describe the various transitions. The equilibrium phase diagram for decreasing and increasing temperatures in which the value of applied magnetic field is changed above a three-dimensional antiferromagnetic ordering temperature of 8.5 K and is kept constant during the temperature scan is presented in Figure 19a. There are three distinct regions: antiferromagnetic phase I, mixed phase II, and the coexisting ferromagnetic-paramagnetic phase III. A nonequilibrium phase diagram was derived by cooling the sample in a zero applied field above 8 K, followed by increasing the applied magnetic fields at constant temperatures (Fig. 19b). This diagram shows the first-order boundary separating the different phases: the antiferromagnetic phase I, the intermediate phase IIb, and the ferromagnetic–paramagnetic phase III. A nonequilibrium phase diagram can be generated for the metastable ferromagnetic state, which appears after the system is cooled from 10 K (in an applied field exceeding 1500 Oe) to the desired temperature and the field is decreased to the selected value and the temperature is subsequently reduced. This phase diagram is also achieved if a zero-field cooled sample is exposed to a sufficiently large external field (Fig. 19c). The field is then decreased to the desired value and the temperatureis subsequently raised. The ferromagnetic state is stabilized at low fields (<650 G) below 4 K by using this procedure.[104]

9. Room Temperature Polymeric Magnet $[V(TCNE)_x] \cdot y(CH_2Cl_2)$

Following the observation of bulk ferromagnetic behavior for $[MnCp_2^*]^+[TCNE]^-$ we targeted the preparation of the electron-transfer salt of $[V(C_6H_6)_2]^{\bullet}$ and TCNE.[47–50] $[V^I(C_6H_6)_2]^+$, like $[Mn^{III}Cp_2^*]^+$, is an $S = 1$ cation possessing a $^3E_{2g}$ ground state $[a_{1g}^1 e_{2g}^3 (\approx d_{z^2}^1 d_{xy}^2 d_{x^2-y^2}^1)]$ (Fig. 20).[105] The addition of $[V(C_6H_6)_2]^{\bullet}$ to an excess of TCNE in dichloromethane results in an immediate black precipitate. The empirical composition of this material is $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ ($x \approx 2$; $y \approx 1/2$).[106] However, due to the extreme insolubility of the precipitate, reactivity of the solvent, and extreme air and water sensi-

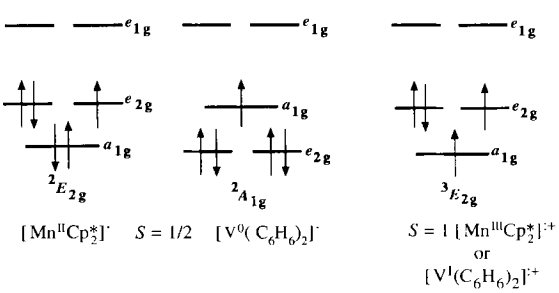

Fig. 20. Schematic illustration of the electronic configurations of $[Mn^{II}Cp_2^*]^{\bullet}$, $[Mn^{III}Cp_2^*]^+$, $[V^0(C_6H_6)_2]^{\bullet}$, and $[V^I(C_6H_6)_2]^+$.

tivities, variations in composition as a function of preparation conditions have been observed. The first step in the reaction is electron transfer from $[V(C_6H_6)_2]^*$ to TCNE followed, unexpectedly, by loss of the benzene ligands, as is evident from the IR spectra which lack ν_{C-H} absorption bands in the 3060 to 3100 cm^{-1} region.[47, 49, 50] The mass spectrum of the magnetic material has peaks assignable to CH_2Cl_2 and TCNE; however, a peak at m/z 78 assignable to $C_6H_6^+$ was not observed. All of the materials exhibit strong, broad absorption bands at 2099 and 2188 cm^{-1} which can be assigned to $\nu_{C\equiv N}$ or perhaps $\nu_{N=C=C}$. The breadth of the $\nu_{C\equiv N}$ absorption bands and their relatively low energy are consistent with the presence of reduced TCNE, with its nitrogen atoms coordinated to vanadium. The oxidation state of the vanadium or TCNE (Table 8) has yet to be determined.[47, 49, 50]

Table 8. Charge and spin states for V and TCNE as a function of oxidation states.

Species	Oxidation state	Charge z	Spin State S
V^0	0	0	1/2
V^I	I	1+	1
V^{II}	II	2+	3/2
V^{III}	III	3+	1
V^{IV}	IV	4+	1/2
V^V	V	5+	0
$[TCNE]^0$	0	0	0
$[TCNE]^{\cdot -}$	−I	1−	1/2
$[TCNE]^{2-}$	−II	2−	0

$[V(TCNE)_x] \cdot y(CH_2Cl_2)$ has a field-dependent magnetization (M) between 1.4 and 350 K (Fig. 21). The nearly linear increase

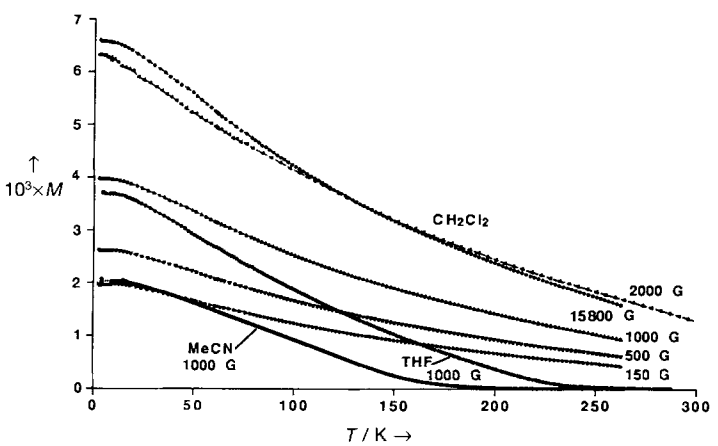

Fig. 21. Typical magnetization (M) [emuG mol^{-1}] as a function of temperature (T) at 15.8 (◂), 2.0 (♦), 1.0 (▲), 0.5 (▾), and 0.15 (▸) kG for $[V(TCNE)_x] \cdot y(CH_2Cl_2)$, 1.0 kG (●) for $[V(TCNE)_x] \cdot y(MeCN)$, and 1.0 kG (○) for $[V(TCNE)_x] \cdot y(THF)$.

of M with decreasing temperature is unusual and may reflect the contribution of the two spin sublattices (V and TCNE) and/or the effects of disorder. Hysteresis with a coercive field of 60 G is observed at room temperature (Fig. 22). The strong magnetic behavior of this material is readily observed by its attraction to a permanent magnet at room temperature (Fig. 23). Thus, this system is the first and only example to date of a molecular/organic-based material with a critical temperature above room temperature. The critical temperature exceeds 350 K, the thermal decomposition temperature of the sample. A linear extrapolation of the magnetization to a temperature at which it would vanish leads to an estimate of a $T_c \approx 400$ K. An independent estimate to T_c was obtained[48] by using the empirical correlation between the spin-wave coefficient and T_c for amorphous magnets.[107] From spin-wave theory and data taken below 60 K a spin-wave dispersion coefficient has been estimated for the V-based magnet,[8j, 48, 108] and T_c is estimated to be ≈ 400 K in agreement with the linear extrapolation of $M(T)$.

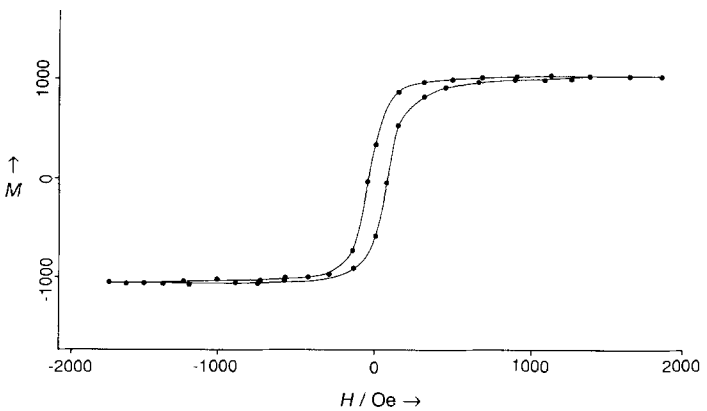

Fig. 22. Hysteresis ($M(H)$) of $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ at room temperature. (The data was taken on a vibrating sample magnetometer: $T = 300$ K, $H_c = 60$ G (From ref. [47]).

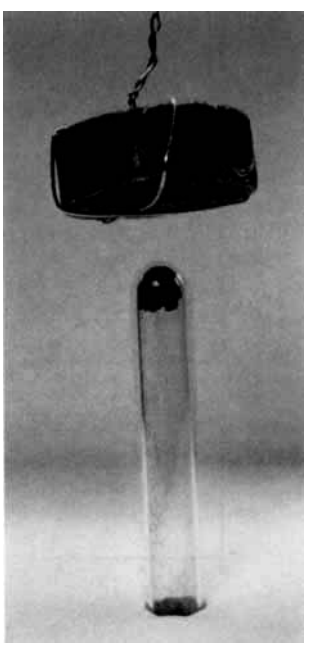

Fig. 23. Photograph of a powdered sample of the $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ magnet being attracted to a Co_5Sm magnet.

$[V(TCNE)_x] \cdot y$(solvent) has been prepared with a variety of $S = 0$ solvents including THF, acetonitrile (MeCN), diethyl ether, benzene, 1,2-dichloroethane, and hexane; CH_2Cl_2, THF, and MeCN have been most extensively studied. The magnetization varies dramatically with the choice of solvent, and T_c sys-

tematically decreases with the ability of the solvent to coordinate with the vanadium center (vide infra).

Due to the structural disorder and variable composition of the magnetic material, the detailed structure has yet to be elucidated (vide infra). TCNE may bond to metals in many ways. For early transition metals linear or bent V–N σ bonds are anticipated. Presently we formulate each vanadium center as being surrounded by up to six ligands which are primarily nitrogen atoms from different TCNE moieties. Chlorine atoms from the weak CH_2Cl_2 ligand or from oxidative addition of CH_2Cl_2 may also coordinate (Fig. 24). Any trace oxygen that is present will strongly bond to the vanadium. The TCNE ligands may bind up to four different vanadium centers through σ N bonds. This fragment may be planar or twisted (Fig. 24). Nonetheless, its ability to bind to more than one vanadium atom enables the construction of a three-dimensional network structure that supports the strong three-dimensional spin-spin coupling necessary for a T_c of 400 K. By using THF or MeCN as alternative solvents, materials with a $T_c < 350$ K can be isolated and characterized. Given the geometrical constraints imposed by the coordination of TCNE to a metal, an open structure with unfilled vanadium coordination sites is unexpected, and thus would be consistent with the observed high surface area of $\approx 100\ m^2\,g^{-1}$, which suggests internal porosity on the molecular level.

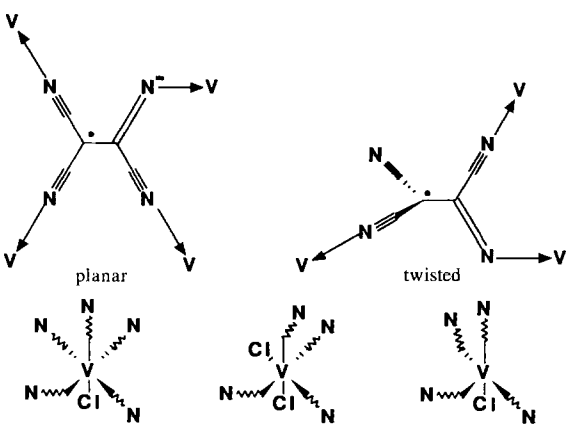

Fig. 24. Proposed local bonding about each TCNE and V center in $[V(TCNE)_x] \cdot y(CH_2Cl_2)$.

Attempts to prepare magnetic materials from the reaction of $[V^0(C_5H_5)(C_7H_7)]$[109] or $[V^{II}(C_5H_5)_2]$ and TCNE or with $[V^0(C_6H_6)_2]$ and other acceptors such as perfluoro-TCNQ ($TCNQF_4$), $C_4(CN)_6$, $C_3[C(CN)_2]_3$, 2,3,5,6-tetrachlorobenzoquinone (chloranil), $DDQCl_2$, and 2,3,5,6-tetracyanobenzoquinone (cyanil)[98] lead to the isolation of insoluble precipitates of unknown composition. These materials do not exhibit field-dependent magnetic susceptibilities and their high-temperature susceptibilities can be fit to the Curie–Weiss expression with $\theta \approx -1$ K characteristic of weak antiferromagnetic coupling between spins. Likewise, in an attempt to prepare the Nb analogue of the V-based magnet, TCNE was allowed to react with $[Nb(C_6H_3Me_3)_2]$; the rapidly formed precipitate exhibited weak antiferromagnetic coupling.

Although the structure is as yet unknown, it is interesting to speculate as to the type of magnetic coupling present in this system. Based upon the IR data and elemental analysis, the composition of the precipitate is presently best formulated as $[V^{II}(TCNE)_2] \cdot 1/2(CH_2Cl_2)$ with $S = 3/2$ V^{II} and two $S = 1/2$ $[TCNE]^{\bullet -}$ ligands. Ferromagnetic coupling gives a total spin S_{total} of 5/2, and if one assumes that g is 2, the saturation magnetization (M_s) is expected to be 28×10^3 emuG mol^{-1}. For antiferromagnetic coupling between V^{II} and the two $[TCNE]^{\bullet -}$ ligands, and hence ferrimagnetic behavior, the S_{total} is 1/2 and M_s is expected to be 5.6×10^3 emuG mol^{-1}; the latter is in good agreement with the value of 6×10^3 emuG mol^{-1} observed at 2 K and 19.5 kG.[47]

The origin of the antiferromagnetic exchange between the spins is important for the design of future high-temperature molecular-based magnets. A variation of the CI mixing of virtual triplet excited states with the ground state to produce a ferromagnetic coupling model (mechanism 2.2.1.1 (Scheme 1; Section 3.2.2.1.1), proposed to account for the ferromagnetic exchange in $[FeCp_2^*][TCNE]$,[44b] can account for the antiferromagnetic exchange of $[V(TCNE)_x] \cdot y$(solvent) and the resulting ferrimagnetic state with a high T_c. The configurational mixing suggested is that of a virtual singlet excited state with the ground state for the $V[TCNE]_2$ system, in which the spin on the V^{II} center ($S = 3/2$) and that on the acceptor ($S = 1/2$) are unequal and produce ferrimagnetic order.[8j, 47, 51] The proposed bonding of the TCNE nitrogen atoms to the vanadium center leads to a sizable orbital overlap; thus, this mechanism should produce a sizable exchange.

The degree of randomness in $[V(TCNE)_x] \cdot y$(solvent) appears to increase for the CH_2Cl_2 < THF < MeCN prepared materials, respectively.[110] This is probably due to the increasing ability of the solvents to coordinate with the vanadium center which in turn displaces some of the TCNE-based radicals and limits the connectivity between vanadium sites. The random anisotropy then leads to the formation of a wandering axis ferrimagnet or even a correlated spin-glass (vide infra).[111] These types of local order are shown schematically in Figure 25 and may be contrasted with the more rigid ordering indicated in

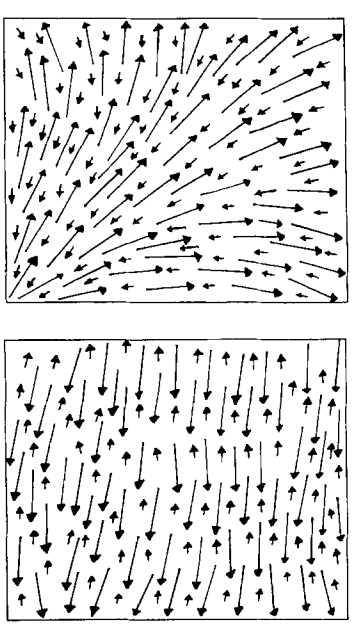

Fig. 25. Schematic illustration of wandering axis ferrimagnet (top) and correlated (ferrimagnetic) spin-glass (bottom).

Figure 3d for a classical ferrimagnet. For the case where the randomness is small compared to the uniaxial anisotropy, a wandering axis ferrimagnet is obtained. This differs from the usual ferrimagnet as the spins do not completely align even at relatively large applied fields. However, when the random anisotropy is larger than the uniaxial anisotropy the average direction the spins point in varies over a spatial correlation length.

Extensive physical studies have now been carried out on the $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ system as well as on similar materials prepared from THF and MeCN solvents. The results of temperature- and magnetic-field-dependent magnetization,[108, 112] ac susceptibility,[113] electron paramagnetic resonance,[112b, 114] dc and audio frequency (10^1 through 10^5 Hz) conductivity and dielectric constant,[115] and microwave frequency conductivity, dielectric constant, and permeability[115, 116] lead to a self-consistent picture of the $[V(TCNE)_x] \cdot y$(solvent) systems as being dominated by the presence of weak random anisotropy.[111a] That is, the magnetic phenomena are dominated by the effects of variation of magnetic interactions from site to site due to the solvent and disorder in the system.

Extensive $M(H,T)$ studies of $[V(TCNE)_x] \cdot y$(THF) and $[V(TCNE)_x] \cdot y$(MeCN), in addition to studies of $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ provide strong support for the key role of random anisotropy. The $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ system has a T_c in excess of room temperature. The T_c for the materials prepared in THF and MeCN are ≈ 200 and ≈ 140 K, respectively (Fig. 21), although this transition temperature is sample-dependent and varies with solvent content and structural order. The ac susceptibility studies suggest that the most disordered of these materials $[V(TCNE)_x] \cdot y$(MeCN) is a reentrant spin-glass with a spin-glass freezing temperature (T_f) of ≈ 10 K (again the transition temperature varies with solvent content and structural order). The materials prepared in THF and MeCN have only weak or absent coercive fields in accord with the greater randomness.

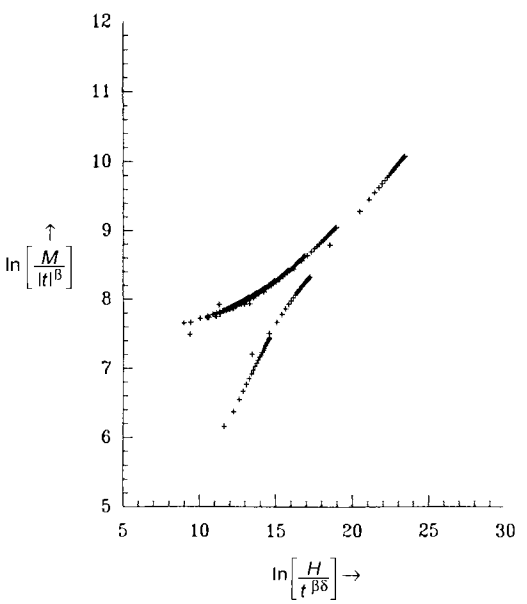

Fig. 26. Scaling plot of $M(T,H)$ for $[V(TCNE)_x] \cdot y$(MeCN). The ordinate is the natural log of M divided by the reduced temperature $t\,[\equiv (|t| = |(T - T_c)/T_c|]$ raised to the β power; the abscissa is H divided by $t^{\beta\delta}$, where β and δ are critical exponents. Note that the data collapse onto the universal curves, the upper one for $T < T_c$ and the lower one of $T > T_c$ (ref. [112a]).

The results of an equation-of-state analysis for the materials prepared in MeCN in the vicinity of the three-dimensional ordering temperature $T_c \approx 138$ K are shown in Figure 26. Here the magnetization data for all H and T studied in the vicinity of T_c collapses to universal curves for $T > T_c$ and $T < T_c$. The values of the effective critical exponents are in accord with the random anisotropy model.[112]

The EPR spectra of $[V(TCNE)_x] \cdot y$(solvent) have been recorded for CH_2Cl_2, THF, and MeCN solvents.[114] The rich set of temperature-dependent spectra obtained provide an insight into the magnetism. A typical derivative spectrum at room temperature for $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ is shown in Figure 27.

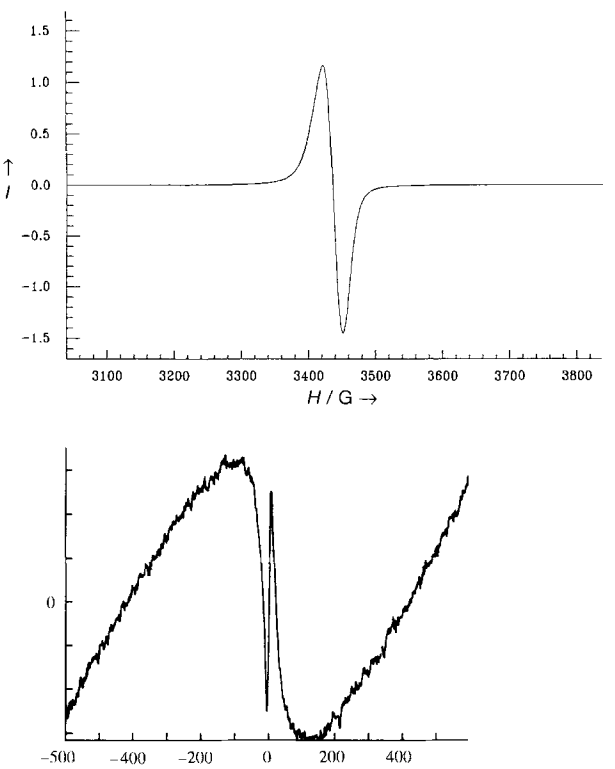

Fig. 27. Top: Derivative EPR signal vs. H for $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ at 295 K. I = intensity (arbitrary units). Bottom: Near zero-field EPR signal of $[V(TCNE)_x] \cdot y(CH_2Cl_2)$ at 200 K (from ref. [114]). Note the greatly expanded vertical scale. The abcissa is in units of Gauss; the ordinate is the derivative of EPR intensity in arbitrary units.

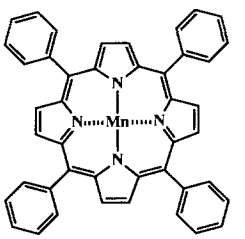
Four distinct resonance signals are observed: 1) the main resonance with $g \approx 1.92$, 2) an approximately half-field resonance, 3) a broad near-zero-field resonance, and 4) a narrow zero-field antiresonance.[114] These resonance signals vary systematically with the composition of the sample (including differing solvents) and the temperature. The latter two signals at 200 K are more clearly shown in Figure 27b. The integrated intensity of the main resonance for each of the compositions studied is proportional to the measured temperature-dependent dc magnetization, hence it is associated with the ferrimagnetic resonance. Contrary to the usual magnetic systems, the linewidth reaches a minimum at T_c, with a critical behavior mimicking the critical behavior of $M(T)$, as expected for a material with "sloppy" waves (spin waves with wavevector $q > \zeta$, where ζ is the correla-

tion length).[117] The shift of the g value of the main resonance correlates with the magnetization and agrees in magnitude with the expected values for demagnetization effects.

The broader low-field signal is largest in the materials prepared in CH_2Cl_2, weak in the systems prepared in THF, and virtually nonexistent in the materials prepared in MeCN. The peak-to-peak width and its sample variation suggest that this low-field signal is similar to that observed for a domain wall like resonance. The sharp zero-field signal is unusual. It is present in each of the compositions below T_c, though for the samples prepared in MeCN it evolves into a resonance signal from an antiresonance below ≈ 15 K, a temperature associated with freezing out of the spins into a spin-glass phase.[113] Based on this temperature dependence, this antiresonance may be caused by a low-field magnetoresistance which makes it more difficult for electrons to hop among charge carrier sites (presumably TCNE), thereby reducing the sample absorbance of microwaves at higher magnetic fields.



The $[V(TCNE)_x] \cdot y$(solvent) materials are semiconductors which have moderate conductivities of the order 10^{-5} to 10^{-3} S cm^{-1} at room temperature depending upon the solvent.[115, 116] In general, the dc conductivity varies as $\exp[-(T_0/T)^{1/4}]$, which is reminiscent of Mott variable-range hopping.[118] However, the strongly temperature-dependent frequency dependence suggests that the behavior is more complex. This effect was suggested to be a ramification of the correlated spin-glass behavior of the $[V(TCNE)_x] \cdot y$(solvent) materials.[115, 116] The charge transport probably involves charge hopping among anionic $[TCNE]^{\bullet -}$ sites.

The results of the physical studies reinforce the importance of three-dimensional coupling in the $[V(TCNE)_x] \cdot y$(solvent) system. Because of the three-dimensional network structure present, Equation (10) (Table 7) may be used to provide an estimate of the effective exchange interaction J_{eff} operative in the room temperature magnet system (solvent = CH_2Cl_2). If one assumes a T_c of 400 K, an average of five nearest neighbors, and for $S(S+1)$ the root-mean square of $S_A = 1/2$, and $S_D = 3/2$ (i.e., $[(1/2)(1/2+1)(3/2)(3/2+1)]^{1/2}$), a value of J_{eff} of 70 K (50 cm^{-1}) is obtained. This is less than a factor of three larger than the intrachain exchange (Section 5) in $[FeCp_2^*][TCNE]$ for which $T_c = 4.8$ K; yet T_c is nearly one hundred times larger. The differences in transition temperatures do not correlate with the difference in J_{eff} alone, but also with the change in dimensionality from a quasi one-dimensional (for which Equation (14) is operative) to essentially a three-dimensional system (for which Equation (13) is operative). Hence, we conclude that to achieve a high T_c in a molecular-species-based system it is a significant advantage to increase the dimensionality and connectivity of the spin network as well as J.

The solvents are suggested to effect the magnetic state through several mechanisms. These mechanisms include 1) reducing the number of nearest neighbor spins surrounding the vanadium ion, 2) reducing the connectiveness among the vanadium ions by the multicoordinating molecular unit (thereby effectively reducing the dimensionality of the magnetic state), and 3) effecting the degree of crystalline order around each of the vanadium ion sites (thus introducing random anisotropy and also random exchange).

10. Metalloporphyrin-Based Magnets

We recently reported[119] that $[MnTPP]^{\bullet +}[TCNE]^{\bullet -} \cdot 2PhMe$ (TPP = *meso*-tetraphenylporphinato) represents a new structural class of molecular magnets. $[MnTPP]^{\bullet +}[TCNE]^{\bullet -} \cdot 2PhMe$ crystallizes as parallel one-dimensional $\cdots [D]^{\bullet +}[A]^{\bullet -}[D]^{\bullet +}[A]^{\bullet -} \cdots$ chains in which the $[TCNE]^{\bullet -}$ binds identically to two $[MnTPP]^{\bullet +}$ (**20**) moieties in a *trans*-μ_2-N-σ-bound fashion (Fig. 28a). The solid-state motif is distinctly different than that for the $[MCp_2^*]^+[A]^{\bullet -}$ electron-transfer salts (Fig. 13), since $[A]^{\bullet -}$ does not coordinate to the M in the latter system. Thus, the bonding of reduced TCNE to Mn is a model for the bonding of reduced TCNE to V in the $[V(TCNE)_x] \cdot y$(solvent) magnet.

20 MnTPP

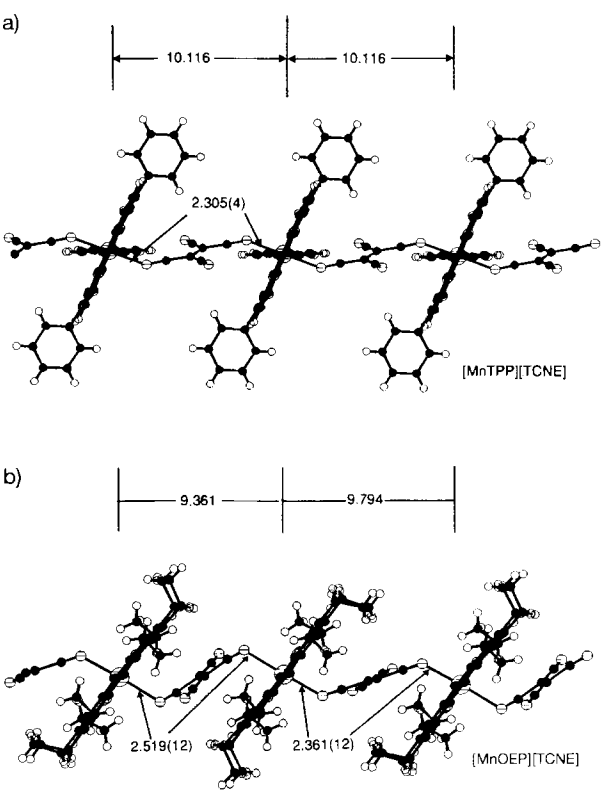


Fig. 28. Segment of a one-dimensional $\cdots D^{\bullet +}A^{\bullet -}D^{\bullet +}A^{\bullet -} \cdots$ chain showing $[TCNE]^{\bullet -}$ *trans*-μ_2-N-σ-bonding to (a) $[MnTPP]^{\bullet +}$ (the toluene molecules of solvation are not shown for clarity) and (b) $[MnOEP]^{\bullet +}$. Distances in Å.

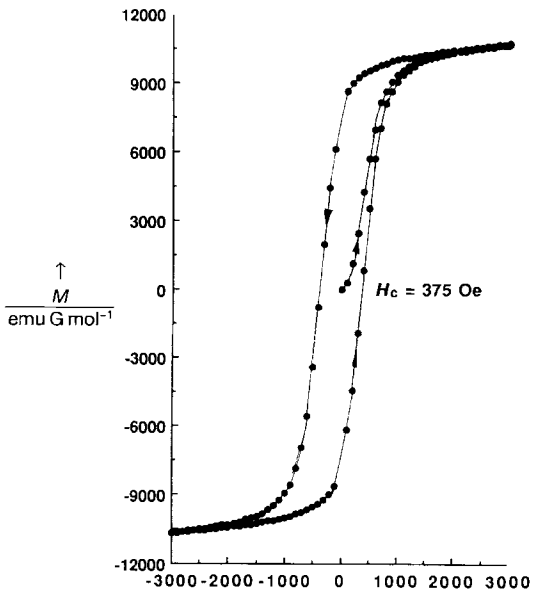
The susceptibility for $[MnTPP]^{\bullet +}[TCNE]^{\bullet -} \cdot 2PhMe$ can be fit by the Curie–Weiss expression between 115 and 250 K ($\theta = 61$ K) and above 280 K ($\theta \approx -15$ K). A minimum in the value of χT characteristic of one-dimensional ferrimagnetic behavior (vide supra)[27a, 120] is observed at ≈ 310 K, and field-dependent susceptibility is observed below 50 K. The saturation magnetization M_s of 30 000 emu G mol^{-1} is in good agreement with the expected saturation magnetization of

29900 emuG mol^{-1} if one assumes ferromagnetic ordering of the $S = 1/2$ [TCNE]$^{\bullet -}$ spin and $S = 2$ [MnTPP]$^{\bullet +}$ spins. A hysteresis curve with a coercive field of 375 G was obtained at 5 K (Fig. 29), which demonstrates that [MnTPP][TCNE] is a magnet at low temperature. Extrapolation of the steepest slope of



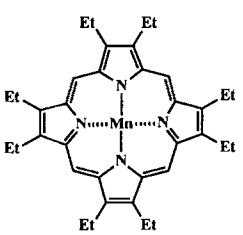


Fig. 29. Hysteresis data at 5 K for polycrystalline [Mn^{III}TPP]$^{+}$[TCNE]$^{\bullet -}$ · 2 MePh. (Recorded with a SQUID magnetometer; SQUID = superconducting quantum interference device).

the 3 G $M(T)$ data to zero yields an estimate of a magnetic ordering temperature of 18 K. A much weaker second transition is observed at 40 K which may reflect ordering to a canted spin state or other complex magnetic behavior. Thus, [MnTPP][TCNE] with the *trans*-μ_2-N-σ-bonded [TCNE]$^{\bullet -}$ is an example of a new structure type of molecular-species-based magnetic material. The presence of magnetic hysteresis and a relatively high T_c value for such a structurally (and probably magnetically) one-dimensional material suggests the possible role of random anisotropy or other disorder in the production of these "ordering" effects.[121a]

As a consequence of the alternating $S = 2$ and $S = 1/2$ chain structure, the [MnTPP]$^{\bullet +}$[TCNE]$^{\bullet -}$ · 2 PhMe one-dimensional chain is an excellent model system for studying a number of unusual magnetic phenomena, for example, the magnetic behavior of mixed quantum/classical spin systems.[122] Thus, for example, [MnTPP]$^{\bullet +}$[TCNE]$^{\bullet -}$ · 2 PhMe may reveal a compensation phenomenon upon further study.[123]

21 MnOEP

To extend this system the analogous TCNE electron-transfer complex was prepared with the easier to oxidize MnOEP (OEP = octaethylporphine), **21**. [MnOEP]$^{\bullet +}$[TCNE]$^{\bullet -}$ exhibits weak ferromagnetic coupling as evidenced by the fit of the susceptibility to the Curie–Weiss expression with a θ of 7 K. However, this material does not exhibit any evidence for cooperative magnetic ordering down to 2 K. The differences in the magnetic properties lie in the structural differences. Although both [MnTPP]$^{\bullet +}$[TCNE]$^{\bullet -}$ and [MnOEP]$^{\bullet +}$[TCNE]$^{\bullet -}$ form parallel one-dimensional $\cdots$[D]$^{\bullet +}$[A]$^{\bullet -}$[D]$^{\bullet +}$[A]$^{\bullet -}\cdots$ chains as noted in Figure 28, they are dimeric instead of uniform for [MnOEP]$^{\bullet +}$[TCNE]$^{\bullet -}$. Also the π^*[TCNE]$^{\bullet -}$ orbitals interact differently with the Mn^{III} centers. Thus, uniform chains appear to be important to achieve long-range magnetic order. This necessity has also been identified to achieve high, metallike dc electrical conductivity for one-dimensional molecule-based metals such as those based on TCNQ.[45]

11. Epilogue

Since the initial reports of three-dimensional cooperative metamagnetism in [FeCp$_2^*$][TCNQ][77a] and ferromagnetism in [FeCp$_2^*$][TCNE],[124] there has been very rapid progress in the development of materials, models for the origin and control of the spin-exchange interaction, theories for the origin, and details of the observed magnetic behavior such as T_c and saturation magnetization (M_s). The chronology of increases in T_c is compared to that of the organic and ceramic superconductors in Figure 30. From these first examples of materials exhibiting

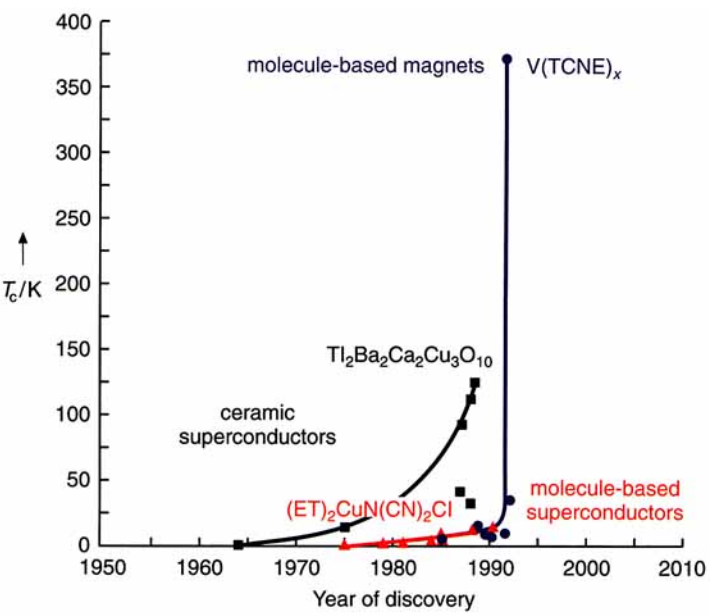

Fig. 30. Time evolution of the discovery of increasing critical temperatures, T_c, for molecular-based magnetic materials as well as organic and oxide superconductors. ET = bis(ethylenedithio)tetrathiafulvalene.

cooperative magnetic ordering, the field of molecular-species-based magnets has evolved. It now includes a wide range of phenomena such as magnetism in molecular-species-based materials at temperatures significantly in excess of room temperature. As this research area has evolved, based upon the models of spins in orthogonal orbitals in the same spatial region within a molecular species in order to achieve intramolecular spin coupling and high-spin behavior, the pairwise configuration inter-

action between molecular species and/or dipole–dipole, through-space interactions to achieve intermolecular spin coupling, several chemical features have emerged as important considerations in designing new magnetic materials. Clearly, to prepare a molecular-species-based magnet, both the donor and acceptor, if present, must be radicals. Such radicals need only have one spin per site; however, a greater number of spins per site is expected to lead to materials with a higher T_c. For donor/acceptor-based systems the competition between ferromagnetic and antiferromagnetic interactions arises from D···D, D···A, as well as A···A interactions. Subtle changes in the orbital overlaps presumably lead to substantial changes in magnetic coupling. Thus, as is the case with proteins, the primary, secondary, and tertiary structures are crucial for achieving the desired cooperative magnetic properties. Currently the discovery of new molecular-species-based magnets is limited by the rational design of solid-state structures which remains an art. This is due to the formation of numerous polymorphs, complex and solvated compositions, as well as undesired structure types. The growth of crystals enabling the study of the single-crystal structure and magnetic properties is also an important limitation. New radicals, donors, and acceptors as well as new structure types are necessary for this area of research to develop further. Finally, one needs to understand the frontier orbital overlaps as they contribute to the interchain and intrachain coupling. Given the present rapid growth in this field it is clear that major advances will be occurring over the next decade in this new multidisciplinary branch of solid-state science.

We have benefited greatly from the stimulating interactions and continued collaborations with our colleagues, postdoctoral fellows, and students for they have made important contributions enabling the rapid progress of the work reported herein. Special thanks are extended to L. Abrams, A. Böhm, M. J. Burk, J. C. Calabrese, F. Chen (Houston), C. W. Chu (Houston), K. R. Cromack, D. A. Dixon, G. Du, A. Grand (Grenoble), R. Hoffmann (Cornell), Z. J. Huang (Houston), G. A. Jones, J. Joo, N. J. Jones, M. Laridjani (Orsay), L. Lardear, S. Long, W. Marshall, R. S. McLean, B. G. Morin, K. S. Narayan, Z. Oblakowski, J. P. Pouget (Orsay), Y. T. Ren (Houston), E. Ressouche (Grenoble), J. Schweizer (Grenoble), A. Suna, A. L. Tchougreeff (Cornell), C. Vazquez, Y. Y. Xue (Houston), S. Zane (Miami), A. Zheludev (Grenoble), P. Zhou, and F. Zuo (Miami) for allowing us to report work in progress. The authors furthermore gratefully acknowledge the support that the Department of Energy, Division of Materials Sciences (Grant Nos. DE-FG02-86BR45271 and DE-FG03-93ER45504) has given for these studies.

[100] Though the observed T_c is in excellent agreement with this mean-field model prediction, and suggests similar exchange interactions are operating for both the $[MCp^*_2]^+[TCNE]^{\cdot-}$ M = Fe, Mn) systems, the Curie–Weiss θ value of 22.6 K observed for the $[MnCp^*_2]^{\cdot+}[TCNE]^{\cdot-}$ in the high-temperature regime does not scale with the increased magnitude of the spin (S) on the metallocene. Instead it is slightly less than the value of θ recorded for $[FeCp^*_2]^{\cdot+}[TCNE]^{\cdot-}$; hence these mean-field scaling models must be used with caution.

[101] Since as described earlier $J \propto 1/\Delta E^2_{AB}$ and since instead of the POMOs being involved in the charge-transfer excitation, the excitation involves the NHOMO and/or NLUMO; thus, the ΔE will be greater and J will be smaller.

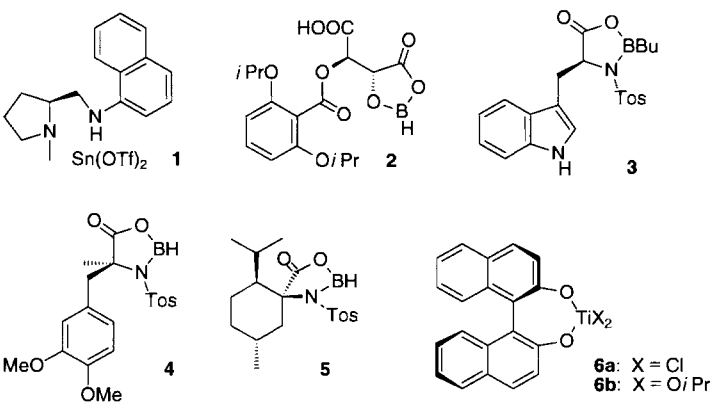
Catalytic Enantioselective C–C Coupling— Allyl Transfer and Mukaiyama Aldol Reaction

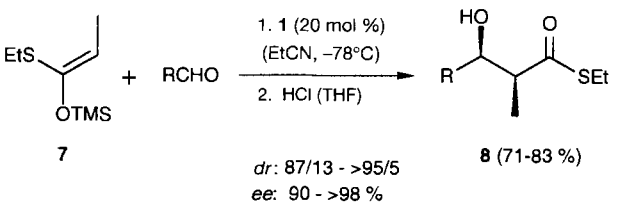


Thorsten Bach*

The search for a synthetic access to enantiomerically pure, naturally occurring products derived from polyketides has in the past years repeatedly pushed back the frontiers of organic chemistry. The allyl transfer[1] and aldol reaction[2] have been developed from these endeavors as the most elegant methods of extending the carbon framework. By now the relative and absolute configuration of the target molecule can be skillfully controlled in almost every case. Nevertheless, for enantioselective reaction courses, the stoichiometric use of chiral reagents can hardly be relinquished. A catalytic modification should remove this drawback. The strategy would be to employ a reagent that under normal conditions does not react with the substrate, but that undergoes a selective reaction under the influence of catalytic amounts of a chiral substance.

Certain metal compounds like silyl enol ethers[3] (Y = O, M = SiR_3), allyl silanes[1,4] (Y = CH_2, M = SiR_3), and allyl stannanes[1,4,5] (Y = CH_2, M = SnR_3) can indeed react specifically with carbonyl compounds in the presence of Lewis acids $M'X_n$, that is, they offer a catalytic alternative to conventional allyl transfer and aldol reactions (Scheme 1). The tiresome snag to this method is the choice of the suitable chiral Lewis acid catalyst. The demands made on such a miracle reagent are considerable. Under no circumstances may the catalyst react irreversibly with the products and substrates, because then it would be anchored to the oxygen atom of alcoholate **B** and would have to be used in stoichiometric amounts. During the reaction either an even stronger oxophile (MX) must form to procure the cleavage of the catalyst, or ideally, $M'X_n$ must activate only the carbonyl component. In the latter scenario, the metal transfer must proceed rapidly after the formation of a cationic intermediate **A**. Moreover, the catalytic activation of other nonchiral species like MX must be excluded. An additional requirement, and most often a more difficult task to solve, is the distinction between the two faces of the carbonyl compound, which must be as close to perfect as possible to guarantee high *ee* values; that is, one side of the prochiral carbonyl compound must be efficiently shielded. In fact, almost all the procedures with Lewis acids employed today (Scheme 2) fulfill the last demand; a lower priority was assigned to the attempt to introduce suitable modifications so that a catalytic enantioselective method may be developed. For this reason the often relatively large amounts of catalyst required reflect a compromise that is justifiably eyed critically, and that is dominated by the desire for a sufficiently fast, enantioselective reaction.

Scheme 1. Catalysis of the allyl transfer and the Mukaiyama aldol reaction by a Lewis acid $M'X_n$.



Scheme 2. Common chiral catalysts for enantioselective C–C coupling (Tos: toluenesulfonate; Tf: trifluoromethanesulfonate).

For a long time the enantiomeric excesses achieved with Mukaiyama aldol reactions were not particularly high. At the beginning of the 90s, however, two communications simultaneously heralded good news. Mukaiyama et al. had succeeded in

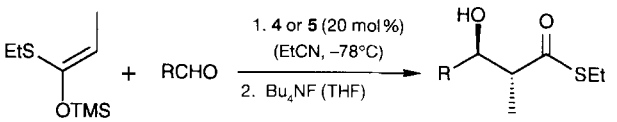
achieving the catalytic Sn^{II}-initiated transformation of the thioketal **7** (TMS = Me_3Si) by the use of propionitrile as solvent and slow addition of the electrophile.[6] The choice of solvent seems to be crucial for a successful catalytic cycle. In the reaction **7** → **8**, an intermediate analogous to **B** is probably formed, which reacts with TMSOTf (MX) to regenerate the Lewis acid **1**. Propionitrile appears to influence this process positively and prevents—together with the dosage of the reagent—too high a concentration of the likewise catalytic TMSOTf. This solvent was used in almost all subsequent investigations. The control of the simple diastereoselectivity is good, and after desilylation the corresponding *syn* products **8** are furnished in excellent enantiomeric excesses. The ketene acetal stereoisomeric to **7** yields poorer results.

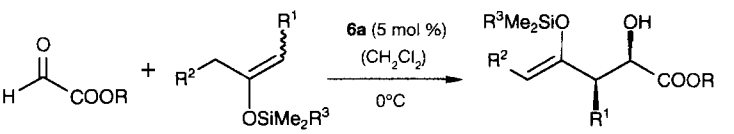
7 *dr*: 87/13 - >95/5 *ee*: 90 - >98 % **8** (71-83 %)



A little later H. Yamamoto et al. reported the reaction of silyl enol ethers with aldehydes in the presence of the previously known chiral acyloxyborane complex **2** (CAB).[7] The β-hydroxy-α-methylcarbonyl compounds are also obtained predominantly in the *syn* configuration (diastereomeric ratio *dr*: 80/20–95/5; *ee*: 80–96%). The *E*/*Z* configuration of the olefin is immaterial for the relative configuration of the products, and this stereoconvergent course of reaction probably proceeds via open-chain transition states. Unsubstituted silyl enol ethers and ketene acetals were tested with slightly smaller success (*ee*: 80–85%). The methyl-substituted ketene acetal prepared from phenyl propionate afforded the best results with α,β-unsaturated aldehydes (*dr*: >95/5; *ee* 94–97%).

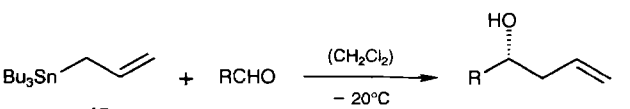
A series of recent papers make use of chiral oxazaborolidine catalysts.[8, 9] The stoichiometric conversions of Kiyooka et al.[10] were followed by the first substoichiometric process of Masamune et al.[11] and other catalytic variants of Corey et al.[12] and Kiyooka et al.[13] Corey et al.[12] used mainly unsubstituted silyl enol ethers **9** and from them they obtained **10** in good enantiomeric excesses.[12a]

9 *ee*: 89–93 % **10** (67–100 %)



Ketene acetals are too reactive and afford only unsatisfactory *ee* values. In accord with results of prior studies on the asymmetric Diels–Alder reaction, the electrophile attacks from the *re* side.[12b] Masamune et al. achieved good results with **5** as catalyst also for unsubstituted ketene acetals (81–93% *ee*).[11b] Interestingly, from ketene acetals with the (*O*)-*E* configuration predominantly *anti* products like **11** are isolated, which, however, arise in only average enantiomeric excesses.[11, 13] Nevertheless, for the first time this system offers an acceptable enan-

7 *dr*: 66/33 - 91/9 *ee*: 60 - 89 % **11** (78-94 %)



tioselective solution of the *anti* configuration problem, whereas—as we have seen—a few synthesis paths had already been opened up for *syn*-β-hydroxy-α-methylcarbonyl compounds and their α-unsubstituted counterparts. With respect to the direction of the asymmetric induction, the surprising reversal of the side differentiation on use of **4** and **5** as opposed to **3** may be explained by a rotation of the aldehyde about the coordinate O–B bond.[12b, 14] Other transition states were also discussed in this context.[13]

A reaction path that is different from a mechanistic point of view can also lead to β-hydroxycarbonyl compounds, as Mikami et al. recently reported.[15] The reaction of glyoxylate **12** with the silyl enol ethers **13** yields, in the presence of **6a**, aldol products that can be isolated on careful workup as silyl enol ethers **14**. The reaction is stereoconvergent and yields *syn* adducts. The absolute configurations of **14** are the same as those of the products of conventional ene reactions catalyzed with **6a**.[16] An alternative mechanistic interpretation to a pericyclic process is an intramolecular proton abstraction from the intermediate **A**.[17]

12 R = Me, Bu **13** R^1 = H, Me R^3 = Me, *t*Bu *dr*: 73/27 - 99/1 *ee*: 77 - >99 % **14** (54-73 %)

A crucial breakthrough in the area of allyl transfer was achieved with catalyst **6**. After the CAB complex **2** developed by Yamamoto et al. already had given respectable enantiomeric excesses for some transformations of allyl silanes and stannanes,[18] Keck et al.[19] and Tagliavini, Umani-Ronchi et al.[20] discovered almost simultaneously that the allyl stannane **15** undergoes highly selective reactions with diverse aldehydes. Keck et al.'s catalyst was the diisopropoxide **6b**, whereas the Italian group employed the dichloride **6a**.

15 **16**

6b (10 mol%): *ee*: 77 - 96 % **16** (78-99 %)
ent-**6a** (20 mol%): *ee*: 80 - 98 % *ent*-**16** (75-96 %)

Interestingly, the direction of the asymmetric induction is in accord with results of Mikami et al.[15,16] In contrast to the ene reaction, the 4 Å molecular sieve used in the preparation of the catalyst has some significance for the selectivity and rate of this reaction.[20] This new process appears to be suitable for many applications because of the really broad range of substrates that it can convert, and it is likely to stimulate several new impulses both in methodology and in synthesis.

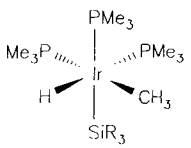
Making and Breaking of Si–E (E = C, Si) Bonds by Oxidative Addition and Reductive Elimination Reactions

Ulrich Schubert*

The making and breaking of silicon–element bonds in the coordination sphere of transition metals is a preparative tool which is becoming increasingly interesting for transformations of organosilicon compounds. While metal-catalyzed addition of Si–H bonds to unsaturated organic groups ("hydrosilylation") is well established, other metal-mediated stoichiometric or catalytic reactions of organosilicon compounds are becoming more and more important. This is particularly true for reactions involving Si–E bonds, where E is a group IV element (mainly C or Si), because of the growing interest in making or modifying polymers containing Si–E bonds.



There are mainly two ways in which silicon–element bonds can be formed or broken in catalytic reactions: σ-bond metathesis[1] and oxidative addition/reductive elimination. The latter type of reaction has received much attention for C–C, C–H, and C–halogen bonds in organometallic chemistry, because it constitutes a key step in many catalytic reactions. In comparison, surprisingly little is known about the oxidative addition and reductive elimination of silicon–element bonds, with the exception of Si–H bonds.

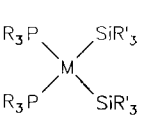
There are very few examples for the reductive elimination of Si–C or Si–Si bonds from isolated complexes. A very recent article by Milstein et al.[2] and prior results on a related system[3] provide new evidence for answering the still unresolved question: What conditions are required to make these elimination reactions occur in a particular complex? The complexes **1** are a particularly interesting class of compounds, because, in principle, H–CH_3, H–SiR_3, or H_3C–SiR_3 could be eliminated. The elimination behavior was found to depend very much on the electronic properties of the SiR_3 ligand. While both the $Si(OEt)_3$ and the $SiPh_3$ derivatives exclusively liberate CH_4 on heating, the $SiEt_3$ derivative gives CH_4 *and* $MeSiEt_3$ in a 4:1 ratio.[2] The Rh analogue (only formed as an intermediate) behaves similarly.[3] The different behavior of the SiR_3 complexes was attributed to the different M–Si bond (M = metal) strengths. Electron-donating groups at the silicon atom weaken the M–Si bond and make Si–C elimination competitive with C–H elimination. It should be noted that no H–SiR_3 elimination is observed.

A related problem was encountered when the reductive elimination of R_3E–SiR'_3 from the complexes **2** (E = C, Si, Sn; L = CO, PPh_3) was studied.[4] The ER_3 groups had a pronounced influence on the kind of products formed. Reductive elimination was only observed for the alkyl(silyl) derivatives

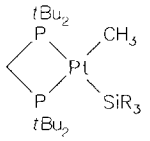
mer-$[(CO)_3LFe(CH_3)ER_3]$ (E = Si). The reactivity of the corresponding bis(silyl) (E = Si) or silyl(stannyl) complexes (E = Sn) is much more complicated. Depending on the substituents at the silicon atom and the ligand L, a variety of products was formed; however, reductive elimination was never observed. Disiloxanes or siloxystannanes were the only organosilicon products formed besides various metal complexes; the oxygen atom stems from one of the CO ligands.



1

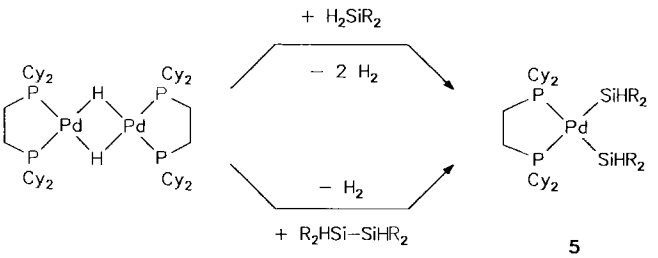
2

A recent ab initio MO study, in which the oxidative addition reactions (the reversal of the reductive eliminations) of C–H, C–C, and Si–E bonds (E = H, C, Si) to $Pt(PH_3)_2$ were compared,[5] sheds light on the energetics of such reactions and may lead to an understanding of some of these observations. The exothermicity, which can be predicted from the bond energies, decreases in the order Si–Si > Si–H > Si–C > C–C > C–H (for the hydrogen-substituted compounds), while the activation barrier was found to increase in the order Si–H < Si–Si < C–H ≈ Si–C ≪ C–C. In the Si–H oxidative addition the Pt–H bond can be formed without having to completely break the Si–H bond, due to the spherical valence orbital of the H atom. The reaction therefore proceeds with a small activation barrier. Although the Si–Si oxidative addition is much more exothermic, the activation barrier is much higher; this mainly results from the distortion of $H_3Si–SiH_3$ at the transition state. The SiH_3 group must shift the direction of the highly directional sp^3 valence orbital of SiH_3 to form the bond with the metal atom.



From these results it is clear that to get disilane eliminations, alternative reactions with lower activation barriers or thermodynamically more favorable products must be avoided. It is apparent that the reaction channel leading to oxygen-containing products can be switched off if complexes without CO ligands are used. Reductive elimination of disilanes was indeed observed for a few CO-free complexes. In complexes of the type **3** (M = Pd, Pt) the kind of metal center and ligands influenced the elimination reactions as predicted: more electron-donating and/or less sterically demanding ligands in *cis*-$[(R_3P)_2Pt(SiMe_2Ph)_2]$ resulted in thermally more stable bis(silyl) complexes, that is, complexes less prone to the reductive elimination of the disilane.[6] The corresponding palladium complexes, for example, *cis*-$[(MePh_2P)_2Pd(SiHPh_2)_2]$ were much more labile than the platinum complexes, as expected, and readily decomposed by elimination of the disilane $HPh_2Si–SiPh_2H$.[7] The elimination of $MeSiPh_2H$ from $[(MePh_2P)_2Pd(Me)SiHPh_2]$ was also observed.[7]

3



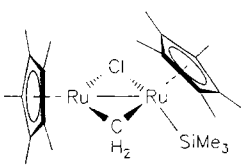
There are only a few examples in which the oxidative addition of Si–C or Si–Si bonds has resulted in stable metal complexes. The preparation of bis(silyl) or alkyl(silyl) complexes by such reactions is not only a question of bond activation, but also of stabilizing the obtained complexes with regard to reductive elimination. Electronic and steric factors favoring reductive eliminations disfavor oxidative additions, and vice versa. Oxidative additions are facilitated by heavy transition metals (which are easier to oxidize), by a high electron density at the metal center, and by small ancillary ligands. Furthermore, oxidative additions of organosilicon compounds are also promoted by electronegative substituents at the silicon atom. It is therefore not surprising that halogenated disilanes were employed in nearly all examples for the formation of stable bis(silyl) complexes by oxidative addition of disilanes.[8]

However, there are additional possibilities to make oxidative additions of Si–E bonds easier. Hofmann et al. generated the 14-electron species [(dtbpm)Pt] (dtbpm = $tBu_2PCH_2PtBu_2$), in which the small P-Pt-P angle both raises the total energy and changes the frontier orbitals relative to the corresponding complexes with linear phosphane ligands $[(R_3P)_2Pt]$. With the "hot" (dtbpm)Pt species the activation of Si–C bonds is possible under mild conditions. The complexes **4** (SiR_3 = $SiMe_3$, Si_2Me_5, $SiMe_2OSiMe_3$) were obtained at room temperature from the corresponding methylsilanes.[9] In the light of the above-mentioned energetics, it is rather surprising that in the reaction with Si_2Me_6 the Si–C bond was exclusively added to the metal, but not the Si–Si bond.

4

Distortion of the structure of the metal fragment also stabilized the bis(silyl) palladium complexes with regard to reductive elimination. Unlike the $[(MePh_2P)_2Pd(SiHPh_2)_2]$ complexes with nonchelating phosphane ligands, the bis(silyl) complexes $[(dcpe)Pd(SiHR_2)_2]$ (**5**) (dcpe = $Cy_2PCH_2CH_2PCy_2$) were very stable and could even be prepared by oxidative addition of $HR_2Si–SiR_2H$ to $[\{(dcpe)Pd\}_2(\mu\text{-}H)_2]$.[10]

5



In the 1970s Lappert et al.[11] and Sakurai et al.[12] obtained 1-sila-2-ferracyclopentanes and 1,3-disila-2-ferracyclopentenes, respectively, by insertion of $[Fe(CO)_4]$ into the Si–C bond of silacyclobutanes or the Si–Si bond of 1,2-disilacyclobutenes, respectively. C. S. Liu et al. developed a rich chemistry by reacting 1,1,2,2-tetrafluoro-3-*tert*-butyl-1,2-disilacyclobutene with a variety of transition metal complexes.[13] Oxidative addition of the Si–Si bond is often the primary step in these reactions. The reactivity of the Si–C or Si–Si bond in the four-membered rings is increased by the ring strain, and the stability of the oxidative addition products is high, because reductive elimination is very unfavorable.

A final possibility to promote oxidative addition is to use the chelate effect (chelate-assistance). For example, oxidative addition of the Si–H bond of $Ph_2PCH_2CH_2SiR_2H$ results in com-

plexes with the chelating phosphinoalkylsilyl ligands, in which the reductive elimination of the R_3Si-H bond is not favored by entropy, as in the corresponding nonchelated complexes.[14] "Chelate-assistance" could certainly also make the oxidative addition of other bonds to transition metal center easier. This was recently demonstrated for Sn–C bonds;[15] however, there is no example for Si–C or Si–Si bonds yet.

The tools to tune the ability of a metal complex fragment to undergo oxidative addition reactions with Si–E bonds (or to influence the stability of metal complexes with regard to reductive elimination, respectively) are in principle known. However, most of these parameters also influence the oxidative addition behavior of other groups present in the reactants (for instance, C–C or C–H bonds). The challenge ahead is to control the selectivity and thus make oxidative addition (reductive elimination) of Si–E bonds more predictable. In most of the known examples the reaction proceeds in only one direction, that is, oxidative addition *or* reductive elimination of the Si–E unit. For the better understanding of Si–H oxidative additions and reductive eliminations the investigation of reversible reactions was very beneficial. It might be also helpful in finding such reactions for Si–E bonds.

In this context the recent observation of a reversible C–Si bond cleavage in a dinuclear complex is remarkable. Treatment of $[\{Cp^*RuCl\}_4]$ ($Cp^* = C_5Me_5$) with $Mg(CH_2SiMe_3)_2$ resulted in the complex **6**. There was NMR spectroscopic evidence for a reversible migration of the $SiMe_3$ group to the methylene carbon atom, leading to the reformation of the Si–C bond. Reformation of the Si–C bond was also achieved by reaction with PMe_3, CO, or F_3CCOOH.[16]

6

Intramolecular activation of Si–E bonds in metal complexes is still an underdeveloped area. Rapid progress is predicted for the near future, because the known examples spectacularly show that these reactions may be very relevant to catalytic processes. While the above example is the only one for an intramolecular Si–C activation, there is now convincing evidence that Si–Si bonds both in α and β positions with respect to the metal center are activated. Several groups have shown that disilanyl complexes $[L_nM-SiR_2SiR_3]$ may rearrange via intermediate silyl(silylene) complexes $[L_nM(=SiR_2)SiR_3]$, if L_nM is an electron-deficient fragment.[17] The cleavage of the β-Si–Si bond was similarly postulated for the rearrangement of complexes of the type $[L_nM\text{-}CH_2SiR_2SiR_3]$.[18] It is assumed that intermediate silyl(silene) complexes $[L_nM(SiR_3)(\eta^2\text{-}SiR_2CH_2)]$ are formed by SiR_3 migration. From the available evidence, α-Si–Si bonds seem to be more active than β-Si–Si bonds and β-Si–Si bonds more active than α-Si–C bonds.

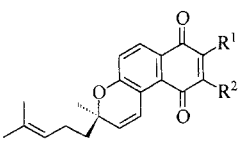
Conocurvone—Prototype of a New Class of Anti-HIV Active Compounds?**

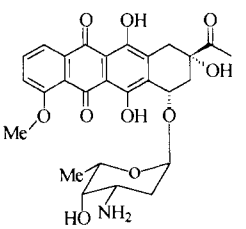
Hartmut Laatsch*



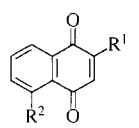
Workers at the National Cancer Institute recently achieved a remarkable success in their search for active plant metabolites. During routine screening, extracts of a shrub indigenous to Australia were noted for their exceptionally high, and, more importantly, selective anti-HIV activity in a variety of cellular in vitro tests. The substance responsible for this effect was the naphthoquinone conocurvone **1a**, which was isolated after an elaborate purification procedure in a yield of 22 mg per kg plant material (*Conospermum sp. Proteaceae*).[1]

As fluorescence tests with BCECF (2',7'-bis-2(2-carboxyethyl)-4(5)-carboxyfluorescein), the XTT–tetrazolium test, and a test with the intercalating dye DAPI (4',6-diamidino-2-phenylindole dihydrochloride) showed, the presence of conocurvone **1a** at a concentration of $EC_{50} \leq 0.02$ μM completely averted the death of HIV1-infected human lymphoblastoid cells (CEM–SS). Measurements of viral reverse transcriptase, the viral P24 antigen, and the syncytium forming units (SFU) revealed that virus replication came to a standstill at the same time. Since conocurvone **1a** is cytotoxic and inhibits growth only at or above a concentration of 50 μM, the therapeutic index has the unusually high value for a virostatic of 2500. Whether this value also holds for other viruses, or is limited to HIV-1 viruses, was not reported.

1a



1b: Hydrogen instead of ring A



2a: R^1 = OH, R^2 = H
2b: $R^1 = R^2$ = H
2c: R^1 = H, R^2 = *p*-$O_2CC_6H_4Br$
2d: $R^1 = R^2 = SC_6H_5$

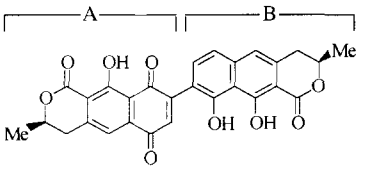
Conocurvone **1a** is a deoxy-trimer of teretifolion B (**2a**), a compound that has been known for longer and was first isolated from *Conospermum teretifolium*. The fast atom bombardment (FAB) mass spectrum of the trimeric quinone revealed a molecular ion corresponding to the formula $C_{60}H_{56}O_{11}$, but the structure of **1a** was in the end only fully elucidated by synthesis. The reason for this was that atropoisomeric equilibria were formed and led to more or less complex ^1H NMR spectra that varied with solvent and with temperature. The compound therefore appeared to be a complex mixture. However, the synthetic product was identical to the natural material, even in its chiroptical parameters, thus confirming the structure and also the low rotation barrier around the quinone–quinone axis, a property which has also been found for other quinonoid-quinonoid-coupled oligomers.

Quinones constitute an extremely important group of natural products. They are one of the oldest known classes of compounds, have achieved importance as dyestuffs, and in addition possess many different biological activities: many quinones are active as antibiotics, are cytotoxic (like daunomycin (**3**), or are (weakly) antiviral. Even simple compounds such as plumbagin (**4a**) prove to be highly effective and selective as enzyme inhibitors. For other quinones the activity derives from interaction with physiological redox systems, or—at least for unsubstituted quinonoid double bonds—from the reaction with nucleophiles.[2]

3

4a: R^1 = Me, R^2 = OH
4b: R^1 = H, R^2 = OH
4c: R^1 = OH, R^2 = H

In the case of conocurvone (**1a**) a physiological effect has once again been found for an oligomeric quinone, which is completely absent for the monomer **2a**. This must therefore be a new property that arises from the *oligomerization*, and should thus stimulate renewed interest in oligonaphthoquinone synthesis. A brief outline of the current state of knowledge about this class of substances is hence justified.



In all but a few cases (one of which is **1a**), the over seventy naturally occurring dimeric, trimeric, *cyclo*-trimeric, and higher oligomers are all constructed of identical units derived from juglone (**4b**, 5-hydroxynaphthoquinone). These units are linked together in various ways, symmetrically or asymmetrically with respect to the C–C framework. With the exception of crisamicin A, all these compounds have an oxygen atom in the *ortho* position to the linkage site.

The reason for this variety lies in the mechanism of formation of dimeric quinones, which may be regarded as a phenol oxidation. The synthesis starts from substituted naphthols, such as **5b**, and leads, depending on the initial substrate and the enzymes of the organism concerned, not only to the monomeric quinone but via binaphthols (e.g. vioxanthin (**5c**)) also to dimeric (e.g. xanthomegnin (**5d**)) or oligomeric quinones. It also yields the polymeric, black allomelanin, which gives ebony, for instance, its characteristic color. This pathway is confirmed by the presence—often in the same organism—of dimers with lower oxidation states, which are formal intermediates in diquinone

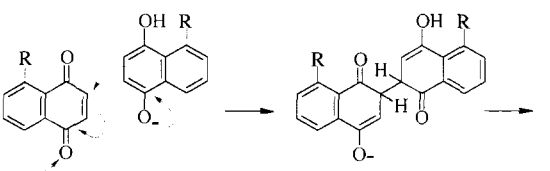
6

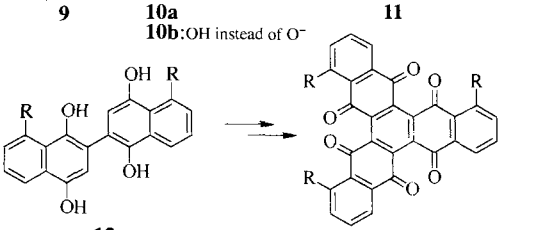
In nature, the oxidative dimerization of phenols is controlled by enzymes, as is demonstrated by the axial chirality of the 6,8′-coupled juglone derivative isodiospyrin. In synthesis, however, phenol oxidation only proceeds in high yields when the enzymatic reaction control is replaced by substituent control, that is, if all but one of the positions with high spin density in the radical (*ortho* and *para* positions) are blocked.

The synthetic usefulness of this principle is well documented by numerous examples, even under biomimetic conditions.[3] In this way, using a similar synthetic sequence by co-oxidation of **7a** and **7b**, we have obtained not only the dimers, but also quinones **8a** and **8b**. These are related to conocurvone **1a**, but their antiviral properties have not yet been studied.

7a
7b: only component A



8a
8b: trimer instead of tetramer



Unlike in the case of phenols, direct oxidative dimerization of quinones only takes place under drastic conditions and requires a hydroxy or amino group on the quinonoid double bond, as in Lawson **4c**, the dye in Arabian henna. Since the work of Pummerer (1937), however, it has been known that monomeric 1,4-quinones can be oligomerized much more easily under acidic or basic conditions.[5] In pyridine/ethanol, or by warming in glacial acetic acid, we have converted naphthoquinone, 1,4-anthraquinone, and numerous derivatives—though not benzoquinones—smoothly into dimers and *cyclo*-trimers. In this highly regioselective reaction, juglone (**4b**) and several of its derivatives afford exclusively the symmetrical 3,3′-linked dimers, several of which were already known as natural products.[6] It was only recently discovered that *o*-quinones may also be dimerized by this principle.[7]

According to Brockmann, this process is an autocatalytic one, in which traces of hydroquinone, which are always present, undergo a Michael addition to the excess of quinone to form a biaryltetrol (**12**),[8] an intermediate which also occurs during phenol oxidation. Dehydrogenation of this intermediate by the monomeric quinone yields the biaryldiquinone and further hydroquinone, until all the monomeric quinone has been transformed ($3\,\mathbf{9} + x\,\mathbf{10c} \rightarrow \mathbf{12c} + \mathbf{10b}$). When air is excluded, conversions of naphthoquinone reach 90%; when air is present, or when nitrobenzene is used as solvent, the yield of dimer can be increased even more through reoxidation of the hydroquinone.

Under suitable reaction conditions, the dimer that is initially formed can react further to yield trimers of type **8b**. It has not yet been possible to isolate these compounds, since they are always converted into the trimeric cyclic quinones **13a**. Indeed, **8b** is also converted into **13a** by phenol oxidation under weakly basic conditions. The stability of conocurvone **1a** is therefore due to the presence of hydroxy groups at position 2 of the monomer, which prevent cyclization. This cyclization via a symmetrical dimer of type **12b** explains why none of the known hydroxylated *cyclo*-trimers (e.g. *cyclo*-trijuglone **13b**) display C_3-symmetry with respect to the *peri*-hydroxy groups.

12b: R = OH
12c: R = H, quinone instead of hydroquinone

13a: R = H
13b: R = OH

The synthesis of conocurvone (**1a**) also makes use of the well established principle of phenol/quinone addition, even though the term was inspired by the reaction of quinones with hydroxy-2*H*-1-benzopyran-2-ones, a reaction that was discovered later but proceeds in a similar manner. Brief warming of two equivalents of teretifolion B (**2a**) with naphthoquinone in glacial acetic acid afforded the predicted **1b** in 9% yield. For the synthesis of conocurvone (**1a**), 2-deoxyteretifolione (**2b**) was warmed with two equivalents of **2a** in pyridine, analogously to the synthesis of 2,2′-binaphthyldiquinone. All the spectroscopic and pharmacological properties of the synthetic material agreed with those of the natural product.

The main difficulty in the synthesis of **1a** lay in the deoxygenation of **2a** to **2b**. This was eventually carried out by transforming

the *p*-bromobenzoate **2c** to **2d** with thiophenol, with subsequent catalytic reduction with Raney nickel.

Nothing is yet known about the site of action or structure–function relationships for derivatives of **1a** (as, for example, **1b**), and any discussion is therefore very speculative in nature. However, it is conceivable that **1a** assumes a helical conformation which winds into the groove of the DNA strand. Similar conformations are also expected for **8a**, and in particular for **8b** and higher oligomers. As we have shown, partial reduction of these compounds leads to deep blue, intramolecular quinhydrones, which are also stable in solution and can be shown by molecular modeling to be stabilized in a helical conformation. For **1a**, additional interactions may be expected between the quinonoid hydroxy groups and petides, like those that play a role in coloring hair and skin with henna (**4c**). It will be fascinating to see whether these hypotheses are confirmed.

Bond-Stretch Isomers: Fact not Fiction

Philipp Gütlich,* Harold A. Goodwin, and David N. Hendrickson

The concept of bond-stretch isomerism was introduced by Stohrer and Hoffmann in 1972.[1] In the simplest terms, two molecules are bond-stretch isomers if they differ only in the length of one or more bonds. During the last two decades several transition metal complexes have been reported to exhibit bond-stretch isomerism.[2–11] Interest in this new form of isomerism has recently been revived,[12] and a lively debate on its actual existence has ensued.[13]

We wish to draw attention to the long known and now well-characterized phenomenon of thermal spin-crossover, which indeed leads to genuine bond-stretch isomers. In certain transition metal complexes with thermal spin-crossover the energy difference between the high-spin (HS) and low-spin (LS) states is on the order of thermal energy kT, such that the two spin states may coexist in thermal equilibrium. The most thoroughly studied spin-crossover systems are Fe^{II} complexes in which the Fe center is coordinated to six nitrogen atoms.[14]

The criteria for thermal spin-crossover leading to coexisting bond-stretch isomers can best be illustrated by means of the one-dimensional potential energy diagram shown in Figure 1. If a molecule exists in two bond-stretch isomeric forms, then, as pointed out previously,[1] there must be two electronic states that are close in energy and separated by a potential energy barrier ΔE_{pot}. In Figure 1 the potential energy of an Fe^{II} complex is plotted as a function of some nuclear coordinate, for example, the totally symmetric Fe–ligand stretch. The two minima correspond to the LS($^1A_{1g}$) and HS($^5T_{2g}$) electronic states of an octahedral Fe^{II} complex, which arise from the t_{2g}^6 and the $t_{2g}^4e_g^2$ electronic configurations, respectively. The two states coexist in thermal equilibrium if $\Delta E_{HL}^{o} \approx kT$. These two isomeric forms have long been known as spin-state isomers (in other words, isomers that differ only in their total spin), and there is no doubt that they can also be considered bond-stretch isomers for the following reason: In the conversion from the LS state to the HS state, two electrons are moved from the bonding t_{2g} orbitals to the antibonding e_g orbitals. As a consequence, the length of the Fe–ligand bond Δr_{HL} is roughly 10% greater in the HS state than in the LS state.[15] The potential energy minima shift further apart by Δr_{HL}, and the increased energy barrier leads to a stabilization of the two electronic states. For example, in single-crystal X-ray structure determinations of the spin-crossover complex $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (2-pic = 2-picolylamine)[16] it was found that the Fe–N(amine) bond length changes from 2.199 Å in the HS state (227 K) to 2.032 Å in the LS state (115 K); the Fe–N(pyridine) bond length changes from 2.197 to 2.000 Å in the same temperature range.

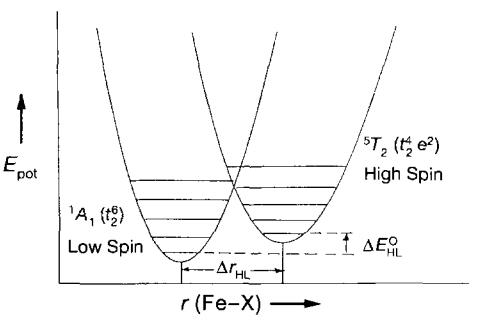

Fig. 1. One-dimensional potential energy diagram for an octahedral Fe^{II} spin-crossover complex. The potential energy E_{pot} is plotted as a function of distance between the iron center and the coordinating ligand atom X. The low-spin ($^1A_{1g}$) and high-spin ($^5T_{2g}$) electronic states are separated in energy by ΔE_{HL}^{o}.

The distance between the metal center and the coordinating ligand atom is always greater in the HS bond-stretch isomer than in the LS isomer.[15] The largest value of Δr_{HL} is 0.28 Å for the average Fe–P distance in $[Fe(dppen)_2Cl_2] \cdot 2(CH_3)_2CO$[17] (dppen = $Ph_2PCH{=}CHPPh_2$), and the smallest value is 0.04 to 0.05 Å for the Co–N bonds in $[Co(terpy)_2]I_2 \cdot 2H_2O$[18] (terpy = 2,2′,2″-terpyridine). The inescapable conclusion is that each complex exhibiting thermal spin-crossover has two bond-stretch isomers that coexist if $\Delta E \approx kT$. The magnitude of the potential energy barrier between them dictates the rate at which the two bond-stretch isomers interconvert.

The difference in the Gibbs free energy of the HS and LS states ($\Delta G_{HL} = \Delta H_{HL} - T\Delta S_{HL}$) is a measure of the thermodynamic energy difference between the two isomers; $\Delta H_{HL} = H_{HS} - H_{LS}$ and $\Delta S_{HS} = S_{HS} - S_{LS}$ are the differences in enthalpy and entropy, respectively. Since ΔH_{HL} (enthalpy difference of the electronic states) is rather small (between 5 and 10 kJ mol^{-1}), the entropy change, which is on the order of 50 to 80 J K mol^{-1}, is the essential driving force for thermal spin-crossover.[19] Con-

tributions to ΔS_{HL} arise from differences in the numbers of unpaired electrons, in other words spin multiplicities, as well as from differences in the vibrational degrees of freedom between the two isomeric forms.

Bond-stretch isomers are conveniently detected by their different magnetic properties, optical spectra, vibrational spectra, Mössbauer spectra, and by their crystal structures.[14] ^{57}Fe Mössbauer spectroscopy is particularly sensitive for the detection of bond-stretch isomers in Fe^{II} spin-crossover complexes. As an example, Figure 2 shows Mössbauer spectra of $[Fe(mtz)_6](BF_4)_2$ (mtz = 1-methyltetrazole) recorded at 120, 75, and 20 K.[20] The

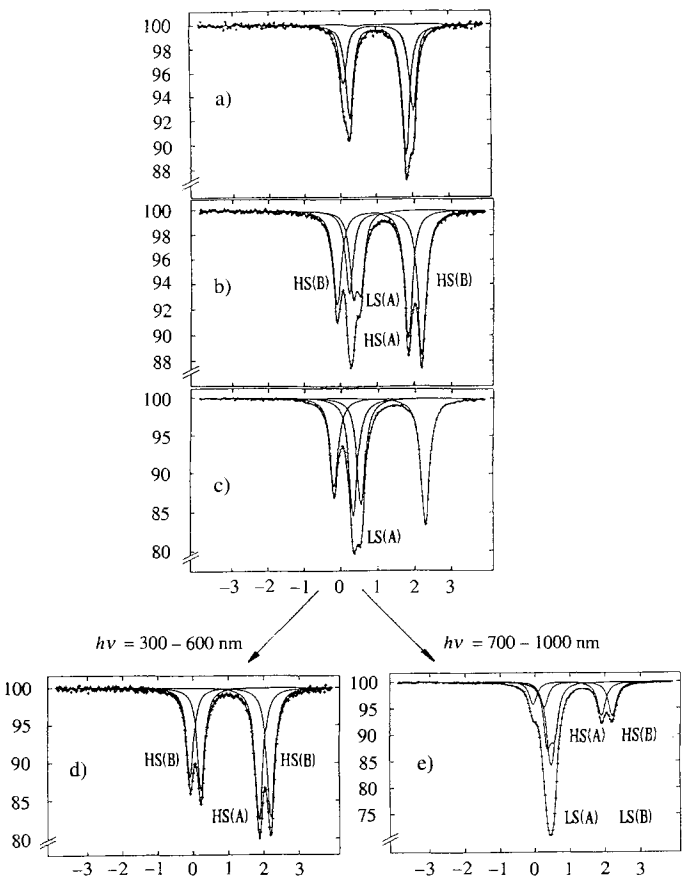

Fig. 2. The ^{57}Fe Mössbauer spectra of $[Fe(mtz)_6](BF_4)_2$ a) at 120 K, b) at 75 K, c) at 20 K, d) at 20 K after irradiation with green light, e) after irradiation with red light. The relative velocity between the Mössbauer source and the absorber v [mm s^{-1}] is plotted on the x axis, the relative transmission [%] on the y axis.

spectrum at 120 K is composed of two quadrupole-split doublets characteristic of Fe^{II} ions in the HS state. This result is consistent with the two crystallographically nonequivalent cation sites (A and B in Fig. 2) seen in the X-ray structure at room temperature.[21] As the temperature is decreased below 120 K, the doublet HS(A) disappears gradually in favor of a new doublet (LS(A)), which has a smaller splitting characteristic of a LS Fe^{II} complex. At 20 K the spectrum shows clearly that the cations in site A have converted totally to the LS state, whereas those in site B remain in the HS state at all temperatures. Thus, at this temperature the bond-stretch isomers A and B coexist.

At 75 K equal amounts of the LS and HS complexes are found in crystal site A,[20] and the Gibbs free energy difference ΔG is 0. The Mössbauer spectrum recorded at this temperature (Fig. 2b) reveals the coexistence of three bond-stretch isomers, LS(A), HS(A), and HS(B). Admittedly, the differences in the bond lengths of HS(A) and HS(B) are small.[21]

In 1984 the remarkable observation was made that the spin-crossover complex $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole) can be converted at low temperatures from the LS state to the HS state by irradiation with green light.[22] The crystalline sample remains in the HS state practically indefinitely. This phenomenon, the mechanism of which has been elucidated,[23] is called the LIESST effect (light-induced excited spin state trapping) and has since been observed in many other Fe^{II} spin-crossover compounds. Furthermore, the metastable HS state can be converted back to the stable LS state by irradiation with red light (reverse LIESST effect).[24] The LIESST effect in $[Fe(ptz)_6](BF_4)_2$ is illustrated in Figure 2; at 20 K green light ($300 \leq \lambda \leq 600$ nm) converts the stable LS(A) state to the metastable HS(A) state. The back-conversion with red light has also been demonstrated for this complex.[20] Since the lifetime of the metastable HS(A) state is at least a few days, we may consider HS(A) and its precursor LS(A) to be two bond-stretch isomers that are interconvertible by light. It is interesting to note that spectrum d confirms the coexistence of HS(A) and HS(B) at 20 K, which is also seen at higher temperatures, for example at 120 K (spectrum a), for two stable HS states.

Finally, upon irradiation of a sample of the mtz complex at 20 K with red light ($700 \leq \lambda \leq 1000$ nm) the intensity of the HS(B) signal is reduced considerably in favor of a new signal arising from a metastable LS(B) state (spectrum e). Since the light-induced conversion in this experiment was not complete (owing to broad-band irradiation), the Mössbauer spectrum shows the presence of four isomers, actually two pairs of bond-stretch isomers, one pair for each lattice site.

In conclusion, we are not responsible for the birth of the concept of bond-stretch isomerism[1] or its apparent demise;[13] however, we have definitively shown that bond-stretch isomerism is a reality in spin-crossover complexes.

Crystal Structure of a Supramolecular Dimer Formed by $\pi-\pi$ Interactions between Two Interlocked Cyclic Zinc Porphyrin Trimers**

Harry L. Anderson, Alan Bashall, Kim Henrick, Mary McPartlin,* and Jeremy K. M. Sanders*

One of the key features of many natural enzymes is the ability to bind two substrate molecules in a close and well-defined spatial relationship; model systems that are intended to mimic this property will therefore need to possess two or more convergent binding sites for organic guest molecules.[1, 2] Previously, as part of a project to design catalytic systems, the synthesis[2, 3] and some binding properties[3, 4] of the zinc porphyrin trimer **1** were reported, and very recent results show that **1** can stereoselectively accelerate the Diels–Alder reaction between appropriate ligands.[5] Successful molecular design in this system has so far been based on the structures deduced from space-filling models and molecular mechanics calculations. We now report the details of a full single-crystal analysis[6] of **1**·py_3, a tris(pyridine) adduct of **1**, which provides an insight into the sources of flexibility and distortion within the porphyrin trimer and will facilitate further progress in planned molecular assembly. Furthermore, we present evidence that $\pi-\pi$ interactions between guest pyridines and between pyridines and porphyrins provide the driving force for the formation of a remarkable interlocking dimer of trimers.

1

pyridine

quinuclidine

The molecular structure of **1**·py_3 shown in Figure 1 provides proof that the host can indeed accommodate three independent ligands, as had been deduced previously.[2] The mean distances from the zinc atom to the porphyrin and pyridine nitrogen atoms, 2.05 and 2.16 Å, respectively, are similar to those observed in other zinc porphyrins (2.06–2.08 and 2.15–2.20 Å, respectively).[7] The nitrogen atoms of each porphyrin ring are nearly coplanar [maximum deviations 0.01 (ring a), 0.07 (b), and 0.05 Å (c)]; the zinc atoms lie at a mean distance of 0.32 Å above the N_4 planes towards the pyridine group [Zn(1a) 0.32, Zn(1b) 0.33, Zn(1c) 0.30 Å], which is within the range observed for this displacement in mononuclear zinc porphyrins (0.31–0.37 Å).[7]

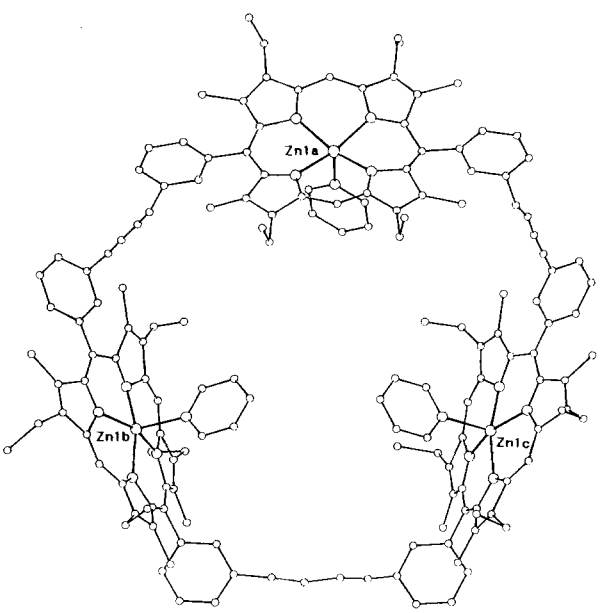

Fig. 1. The molecular structure of the pyridine adduct **1**·py_3 of the zinc porphyrin trimer **1**.

The trimer does not have an idealized D_{3h}-symmetric structure in which all aryl and butadiyne groups lie in a plane perpendicular to the porphyrin rings, as might have been expected from the known geometric properties of aryl and alkyne groups. Inspection of models and molecular mechanics calculations on the isolated molecule show that the zinc atoms form an approximately equilateral triangle with three Zn···Zn separations of

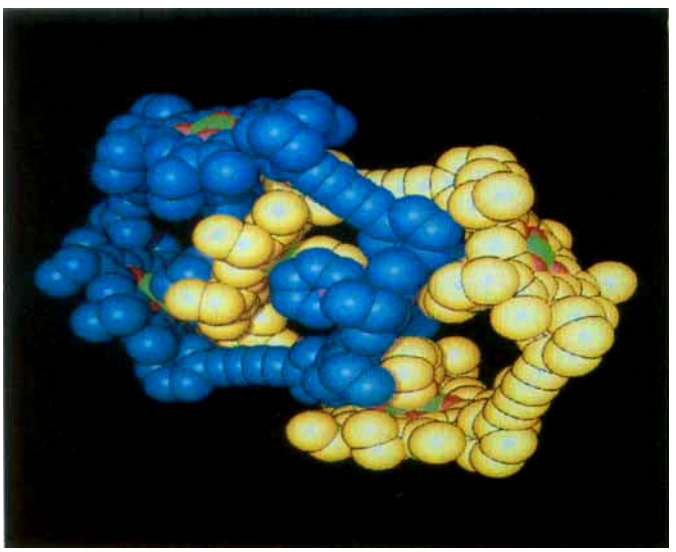

Fig. 2. Top: A stereoview showing the dimer of trimers formed by interpenetration of two centrosymmetrically related molecules of $1 \cdot py_3$. Left: A computed space-filling model of the dimeric supramolecule showing the interpenetration of two trimers.

around 16 Å. However, in the crystal there is considerable molecular distortion such that only two Zn $\cdots$ Zn separations are of about this length [Zn(1a)–Zn(1b) 15.899, and Zn(1a)–Zn(1c) 15.255 Å), whereas the third is considerably shorter [Zn(1b)–Zn(1c) 13.941 Å]. Overall the molecule has only virtual C_s symmetry; the approximate mirror plane passes through Zn(1a), N(5a), and the *para* carbon atom C(52a) of the pyridine ring, bisecting porphyrin ring a and its associated pyridine ring and lying between the two remaining porphyrins.

The flexibility of the framework, demonstrated by the marked deviation from threefold symmetry, is clearly seen in the different orientations of the porphyrin planes in Figure 1: none are perpendicular to the Zn_3 plane. Two porphyrin planes (b and c) tilt towards each other (dihedral angle between N_4 and Zn_3, 104 and 101°, respectively], and porphyrin a tilts in the opposite direction (dihedral angle 76°). The molecular distortion results from a remarkable interpenetration of pairs of the trimer molecules giving a strongly interlocked centrosymmetric "dimers of trimers" in the solid state, in which one porphyrin of each trimer is a guest in the cavity of the second. One side of porphyrin ring a of the first trimer is tightly wedged between the three pyridine rings of the second trimer and vice versa to give the supramolecular dimeric unit shown in Figure 2. The pyridine ligand of Zn(1a) of the first trimer lies parallel to that of the second trimer, at a separation (3.8 Å) slightly larger than the sum of the van der Waals distances. The remaining two pyridine ligands (b anc c) of the first trimer are right round on the opposite side of the unique porphyrin ring a of the second trimer with closest contact distances of 3.4 (Zn(1a)–H(52b′) and 3.3 Å (Zn(1a)–H(52c′). Thus the unique porphyrin a of each trimer is effectively trapped in the central cavity of the other.

The overall crystal structure is composed of layers of interlocked dimers of trimers parallel to a plane defined by the *b* axis and the *ac* diagonal of the unit cell. Large channels run between the layers throughout the crystal parallel to the *b* axis (Fig. 3), which accommodate the many solvent molecules trapped in the lattice. There is a marked resemblance to the structure of many

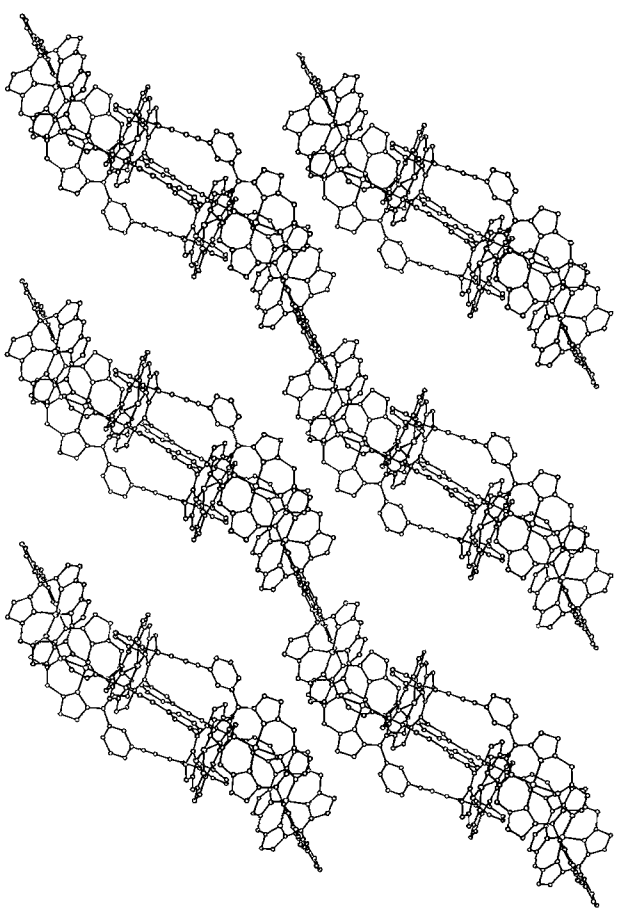

Fig. 3. The crystal structure of the porphyrin trimer $1 \cdot py_3$ viewed down the *b* axis showing the large diamond-shaped channels that run right through the crystal parallel to *b* (pyridine ligands and alkyl substituents removed for clarity).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0430 $ 10.00+.25/0

tetraarylporphyrins, which have been described as "porphyrin sponges" because they contain many solvent molecules trapped in the cavities in their solid-state structures. These channels are known to persist even in the absence of the solvent.[8] The crystal of **1**·py_3 has a similar spongelike structure giving a clathrate with eleven molecules of solvent per dimer unit.

Remarkably, the adduct of **1** with quinuclidine, **1**·qn_3, has quite a different structure even when crystallized from precisely the same solvent mixture as the pyridine adduct. Preliminary X-ray structural studies show that the trimeric molecule of **1**·qn_3 forms discrete monomeric units and has significantly less molecular distortion than in **1**·py_3; the Zn···Zn distances are nearly equal (14.2–14.8 Å).[9] Given the very similar size of pyridine and quinuclidine we must find another cause of the different structure, and the most likely is the pyridine π-system. Inspection of the crystal structure of the pyridine adduct reveals at least three sets of arrangements favorable for π–π interactions:[10, 11] 1) the pyridine ligands of the two unique a porphyrins are in near van der Waals contact, parallel and offset by 1.1 Å in the now-classic arrangement identified by Hunter and Sanders.[10] 2) The b and c pyridines are each in van der Waals contact with a pyrrole unit of porphyrin a of the other trimer unit; the angle between each pyridine and pyrrole is approximately 34°. This favorable arrangement is often found in hydrophobic protein cores[11] (four of these interactions are found in each dimer of trimers). 3) Protons of the aryl linking groups attached to porphyrin a point directly at pyridines b and c to give the T-shaped arrangement found in the crystal structures of many arenes (again four of these interactions are found in each dimer of trimers). It is difficult to assess the energies of these π–π interactions, but each could be as large as 4–6 kJ mol^{-1}.[11] This gives a maximum of less than 60 kJ mol^{-1} of stability to the dimer, which corresponds roughly to the entropy required to bring the two ligated trimer arrays together in solution. The equilibrium constant for dimerization will therefore be too small to observe experimentally in solution at accessible concentrations but is more than large enough to control the mode of crystallization.

The results presented here show that trimer **1** is rather flexible and able to respond to weak interactions and differing substrates by distorting the porphyrin framework and by torsion around the bond connecting the porphyrin to its aryl linker. Whether this flexibility confers the disadvantage of dissipating catalytic potential, or the advantage of allowing it to reach an optimum binding geometry, remains to be tested by synthesis of both less flexible and more flexible analogues.

[6] Crystal data for **1**·py_3·(4.5C_6H_{12})·C_6H_5Cl: $C_{195}H_{200}ClN_{15}Zn_3$, M_r = 2985.45, triclinic, space group $P\bar{1}$ (No. 2) a = 21.883(6), b = 22.325(6), c = 20.746(5) Å, α = 99.40(3), β = 98.84(4), γ = 82.32(3)°, Z = 2, V = 9818.90 Å^3, ρ_{calc} = 1.010 g cm^{-3}, $F(000)$ = 3116, $\mu(Mo_{K\alpha})$ = 4.1 cm^{-1}, R = 0.1087 for 4550 reflections with $I \geq 3.0\sigma(I)$. Crystals of **1**·py_3 were extremely fragile and lost solvent rapidly in air, so X-ray data were collected, with considerable difficulty, using a crystal sealed with mother liquor in a Lindemann tube. 13437 Data were scanned in the σ-range 2–18° using a Phillips PW1100 diffractometer. The three metal atoms were located by direct methods, and all non-hydrogen atoms of **1**·py_3 were located from very many subsequent difference-Fourier syntheses. No recognizable solvent fragments could be identified, but nine separate rings of extended electron density were apparent in difference-Fourier syntheses. Satisfactory refinement was achieved by including all peaks greater than ca. 1.5 e Å^{-3} as partial atoms in structure factor calculations (population parameters of these atoms were adjusted to correspond to the total of ca. 1.0 chlorobenzene and 4.5 cyclohexane molecules indicated from analysis of the ^{1}H NMR spectrum), but only their thermal parameters were refined. The phenylene and pyridine rings were treated as rigid groups in blocked full-matrix refinement. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB12 1EZ (UK), on quoting the full journal citation.

Schiff Base Complexes with Five-Coordinate Cobalt as Dioxygen Activating Sites in Zeolites**

Dirk E. De Vos, Frédéric Thibault-Starzyk, and Peter A. Jacobs*

Metal complexes have been heterogenized on microporous inorganic materials like zeolites in view of applications in photochemistry, the separation of gases, and catalysis. Several classes of dioxygen-binding Co^{2+} compounds, such as the polyamine and cyanide complexes, were prepared in the intracrystalline cages of zeolite Y and characterized.[1] The synthesis of [Co(salen)] (**1**) (H_2salen = bis(salicylidene)ethylenediamine) in zeolite Y has also been claimed, but the spectroscopic and electrochemical features of the resulting material deviate from those of **1** in the solid state or in solution.[2] Schiff base complexes like **1** and the related [Co(smdpt)] (**2**) (H_2smdpt = bis[3-(salicylidenamino)propyl]methylamine) catalyze homogeneous oxidations with dioxygen.[3] In view of heterogenization of these catalysts, we have

1 **2**

reexamined the synthesis of Co^{2+} Schiff base complexes in faujasite-type zeolites. The newly proposed use of the smdpt ligand in a zeolitic environment leads to a much simplified synthesis method and results in the formation of many sites for the reversible binding of dioxygen, whereas with salen only small

amounts of atypical species can be detected; no reversible oxygen binding is observed in salen-loaded zeolites.

Herron first proposed the use of salen on zeolite Y exchanged with Co^{2+} to mimic the oxygen-binding function of hemoglobin.[2] However, since the material was EPR-inactive even after the adsorption of pyridine, it is doubtful that square-planar **1** or its square-pyramidal pyridine adduct were indeed formed.[4] The pyridine adduct of **1** may even be too large to fit in a NaY supercage, and the role of pyridine in the observed oxygen sorption is hence unclear. In order to enhance the interaction between Co^{2+}, salen, and the axial base, Putyera et al. used an isonicotinate-exchanged hydrotalcite as a support.[5]

We now propose the use of the pentadentate ligand smdpt as an alternative for the tetradentate salen; in this case the supplementary axial base ligand is no longer needed. Though it is generally accepted that square-planar **1** can be accommodated easily inside the supercage of a cubic faujasite (FAU), it is less clear whether the more voluminous, trigonal-bipyramidal **2** can be placed in a NaY supercage. Therefore the steric interactions of the guest complex **2** with the host structures were simulated with a molecular graphics program.[6] This simulation indicated that the fit of **2** in a supercage of NaY is tight (Fig. 1): the aromatic moieties pass through the twelve-membered rings of the zeolite cage and almost inhibit motion of the complex.

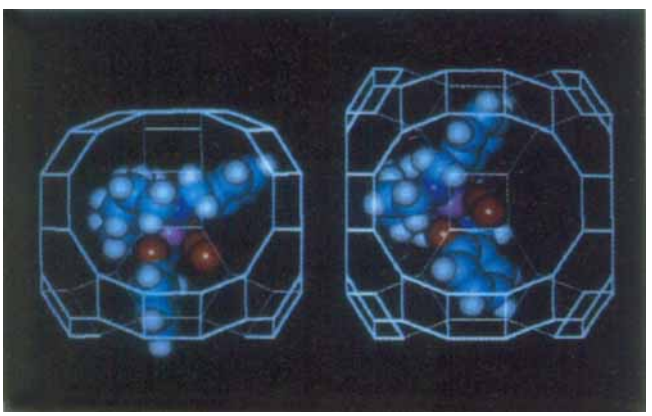

Fig. 1. Computer-generated model (Hyperchem) of [Co(smdpt)] (**2**) in the hypercage of EMT (right) and in the smaller supercage of FAU (left).

Therefore the new, hexagonal polymorph of faujasite, a zeolite with EMT topology, was also used.[7] As in the case of NaY, the cages of EMT are accessible through twelve-membered rings with an inner diameter of about 0.74 nm; some cages in EMT, however, the so-called hypercages, have five of these windows instead of four and are thus considerably more spacious than the FAU supercages of NaY, which are limited by just four windows. A new calculation revealed that **2** can assume a variety of positions in an EMT hypercage but is too large to pass through the twelve-membered rings of the cage; hence, the complex should be truly entrapped (Fig. 1).

The EPR spectrum of [salen]-CoNaY (i.e. CoNaY loaded with salen, see Experimental Procedure) recorded at room temperature shows only the background signal of the NaY zeolite,[2] which is due to Fe impurities in the zeolite. Upon cooling, however, spectral features appear which indicate that some of the Co^{2+} ions experience a higher ligand field through interaction with salen; the typical spectra of low-spin **1** (with an unpaired electron in the $d_{x^2-y^2}$ or the d_{z^2} orbital) are not observed (Fig. 2).[4]

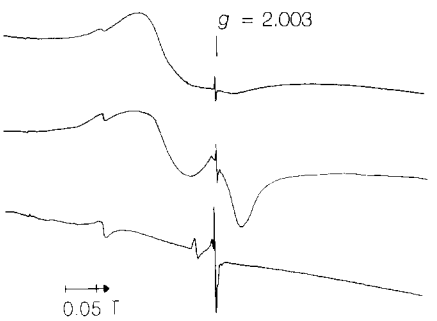

Fig. 2. EPR spectra of [salen]-CoNaY (X-band, gain 10^5) before soxhlet extraction at 293 K (top) and at 130 K (middle), and after pyridine extraction, 130 K (bottom).

The synthesis product [salen]-CoNaY was extracted not only to remove the excess ligand and thus restore the diffusion in the material, but also to bring a solvent molecule as a fifth ligand onto the complex. Extractions drastically changed the [salen]-CoNaY EPR spectra. Both strongly and weakly coordinating solvents (pyridine, dimethylformamide, and CH_2Cl_2) were employed. After extraction the signals possibly arising from square-planar Co^{2+} or from superoxo adducts (around $g = 2$) were still very weak (Fig. 2). The signals observed at $g = 2.20$ and $g = 1.94$ may arise from low-spin Co^{2+}, but the values do not correspond to those of low-spin **1**, and the typical hyperfine structure on the parallel component is lacking.[4] Apparently, formation of square-planar **1** by simple adsorption of salen on CoNaY is very limited. All extraction solvents yielded similar results, which proves that the simple liquid-phase technique for the axial coordination of a base on **1** cannot be used in this zeolitic environment because of steric interactions or adsorption effects.

In contrast, **2** is a high-spin Co^{2+} complex and should hence be EPR-inactive.[8] A strong EPR signal is observed, however, even before extraction of the [smdpt]-CoNaY and [smdpt]-CoNaEMT samples (Fig. 3). In the spectrum of NaY, in particular, the

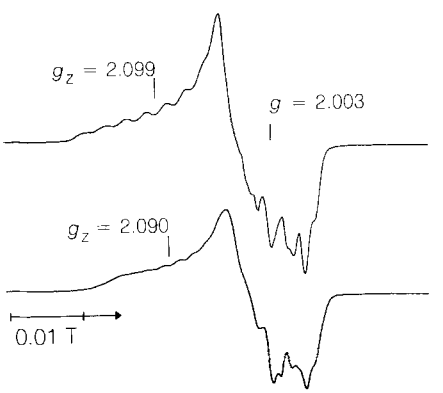

Fig. 3. EPR spectra of Co^{2+} faujasite loaded with smdpt (X-band, 130 K): FAU before soxhlet extraction (top), $g_z = 2.099$, $A_z = 27$ G (gain 2.5×10^4); EMT extracted with CH_2Cl_2 (bottom), $g_z = 2.090$, $A_z = 20$ G (gain 3.2×10^3).

eight-line hyperfine structure of the signal is clearly resolved. Due to the immobilization of the guest complex in the zeolite, the signal is anisotropic even at room temperature. An estimation of the EPR parameters by spectral simulation yielded $g_z = 2.099 \pm 0.003$, $A_z = 27.0 \pm 0.5$ G, $g_y = 2.00 \pm 0.01$, $A_y = 15 \pm 2$ G, $g_x = 2.00 \pm 0.01$, $A_x = 15 \pm 2$ G, a parameter set typical for

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0432 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 4

Co^{2+} superoxo adducts. The binding of dioxygen to this complex requires a roughly square-pyramidal disposition of the five ligand donor atoms around the Co^{2+} ion; hence, at least some of the Co^{2+} cations can no longer be coordinated by the zeolite. The EPR parameters (especially the rather large A_z value) do not exactly match those of [Co(smdpt) · O_2] in frozen solution. Nevertheless, they are reminiscent of those of some related Schiff base chelates in which the tertiary nitrogen base is replaced by a noncoordinating sulfur or oxygen linkage.[9] An imposed distortion of the complex and a weakened ligand field around Co^{2+} may thus result in a smaller electron transfer to O_2 and a larger A_z value. The occurrence of isomers with a different stereochemistry at the Co^{2+} ion may be an alternative explanation for the anomalous EPR parameters. A similar superoxo species is observed on the NaEMT zeolite, though the spectral resolution is somewhat less than on NaY. In both cases the molar ratio (bound O_2: total Co^{2+}) is less than 0.05 before soxhlet extraction.

The extraction with CH_2Cl_2 weakened the signal for [Co(smdpt) · O_2] in NaY, but increased its intensity in NaEMT. More strikingly, the EPR parameters were unaffected in the case of NaY but assumed new values ($g_z = 2.090$, $A_z = 20$ G) in the case of NaEMT (see Fig. 3). Since the new parameters are quite close to those observed for the frozen solution,[9] it can be safely stated that the electronic structures of the EMT and the solution species are very similar. The reorganization of the first type of [Co(smdpt) · O_2] (most clearly observed in NaY before extraction) into the second, more common type (observed in NaEMT after extraction) is apparently impossible in NaY; the only reasonable explanation for this is a distortion of the complex imposed by the NaY supercage. The larger NaEMT hypercage allows a more relaxed and normal complex conformation.

Evacuation of CH_2Cl_2-extracted [Co(smdpt)]-NaEMT and subsequent reexposure to oxygen results in removal and reappearance of the superoxo signal; the evacuation and oxygenation cycle can be repeated at room temperature several times without a noticeable loss in signal intensity. This proves that the dispersion of the complexes over the zeolite cages effectively protects the active sites against dimerization and irreversible oxidation. The maximal amount of [Co(smdpt) · O_2] in NaEMT, which was measured at 130 K and determined by double integration of the EPR spectrum, corresponds to about 25% of the total Co^{2+} content.

The present results demonstrate that formation of the square-planar complex **1** with four-coordinate cobalt is very difficult in faujasite, while complex **2** with five-coordinate cobalt is easily formed. This strongly suggests that the additional tertiary nitrogen in the ligand provides the donor strength required to remove Co^{2+} from the zeolite coordination environment, while the softer salen donor atoms are not capable of this. Simultaneously, the problem of the addition of an axial base is circumvented by use of pentadentate smdpt: the consecutive coordination by four equatorial donors (of the tetradentate salen ligand) and one axial base ligand (pyridine), which is hardly controllable in heterogeneous media, is replaced by a concerted equatorial and axial coordination by smdpt. This system provides one of the first examples of chelation by a multidentate ligand inside a zeolite cavity and the first example of a single coordination compound that displays structural differences when encaged in two different zeolite cages.

Experimental Procedure

FAU was obtained as a commercial NaY zeolite from the PQ Corporation. EMT was synthesized by using [18]crown-6 (Janssen Chimica) as a template, according to the procedure of Delprato et al. [7]. The X-ray powder diffraction pattern of the calcined sample was consistent with a purely hexagonal phase. The salen ligand was from Strem, smdpt was crystallized by condensation of 2 equiv of salicylaldehyde (Merck) with 1 equiv of bis(3-aminopropyl)methylamine (Aldrich) in the absence of a solvent. The Na^+ ions of both zeolites were exchanged for Co^{2+} (up to 0.9 wt.% Co). The samples were dried under an oxygen flow at 473 K, flushed with nitrogen, and mixed with an excess of crystalline ligand (ligand: Co ratio 2:1). The synthesis mixture was heated in a dry atmosphere at 373 K (smdpt) or 413 K (salen) for 10 h; soxhlet extractions were performed with pyridine, dimethylformamide, or dichloromethane (salen), or with dichloromethane (smdpt). After 10 h the extraction solvent was colorless.

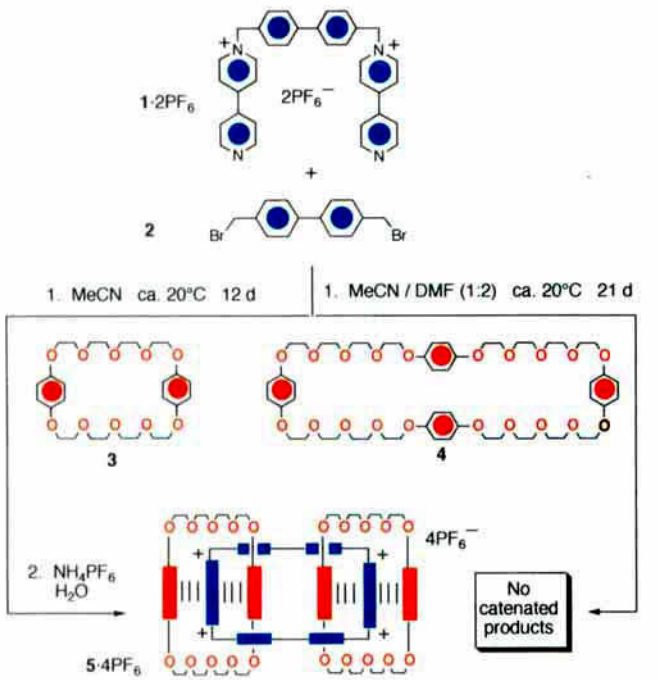
The Two-Step Self-Assembly of [4]- and [5]Catenanes**

David B. Amabilino, Peter R. Ashton, Anatoli S. Reder, Neil Spencer, and J. Fraser Stoddart*

Although polyrotaxanes[1] have already received considerable attention,[2] no convincing strategy for the synthesis of polycatenanes[3] has yet been proposed. Polycatenanes embody one of the ultimate goals of polymer chemists—namely, the construction of polymer chains in which the components are a series of interlinked rings, reminiscent of our familiar mechanical chains.



Our recent demonstrations[4, 5] that [3]catenanes, such as **5** · $4PF_6$, can be self-assembled[6, 7] from appropriate building blocks (**1** · $2PF_6$, **2**, and **3** in Scheme 1) with remarkable efficiencies appeared, at first sight, to open up the possibility of a template-directed approach to the synthesis of polycatenanes. However, even although **4** serves readily[5] as a template around which to construct either one or two cyclobis(paraquat-*p*-phenylene) macrocycles, all our numerous attempts to catenate **4** with cyclobis(paraquat-4,4'-biphenylene) rings—starting

[*] Prof. J. F. Stoddart, Dr. D. B. Amabilino, P. R. Ashton, A. S. Reder, Dr. N. Spencer
School of Chemistry, The University of Birmingham

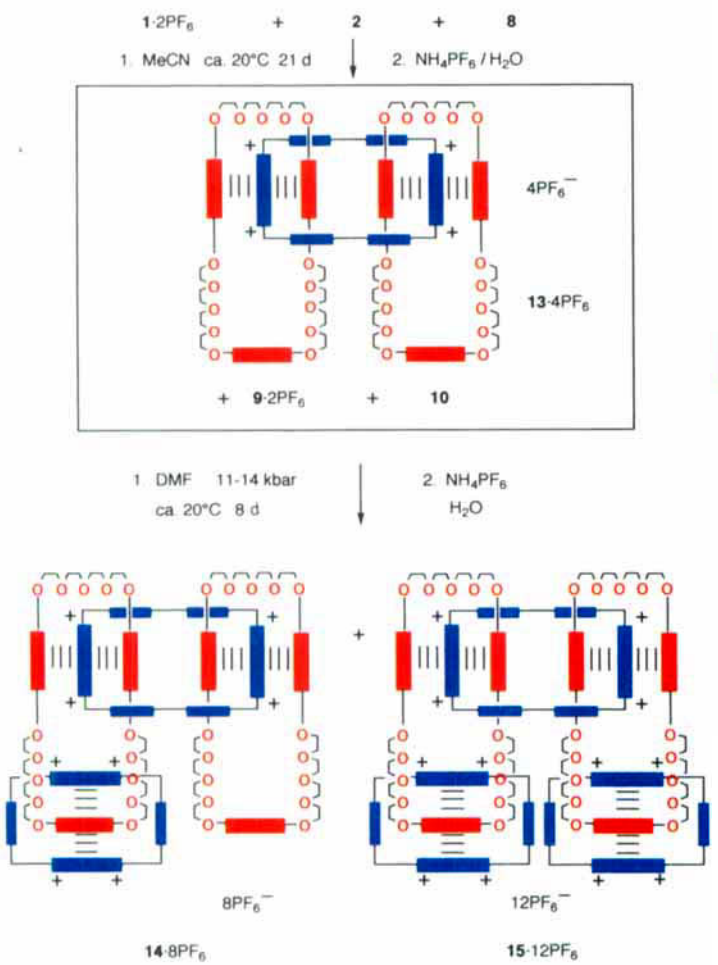
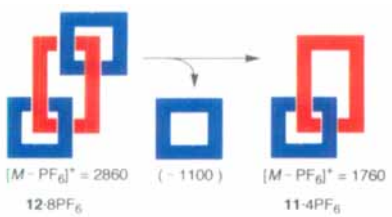
[**] This work was supported by the Science and Engineering Research Council.

from, for example, $1 \cdot 2PF_6$ and **2**—have so far met with no success. We attribute these failures to the large dimensions of the two macrocycles involved and to the flexibility of **4**. Presumably, the molecular recognition between intermediates formed when $1 \cdot 2PF_6$, **2**, and **4** are mixed together in solution in the required molar proportions does not attain that critical level which is essential to sustain an efficient self-assembly process. With these thoughts in mind, we decided to find out whether tris-*p*-phenylene-[51]crown-15 (**8**)—intermediate in constitution between the successful building block bis-*p*-phenylene-[34]crown-10 (**3**) and the failed unit, tetrakis-*para*-phenylene-[68]crown-20 (**4**)—would participate in the template-directed syntheses of catenanes. The answer is that it does! Here we report: 1) the one-step self-assembly (Scheme 2) of the [2]catenane $\mathbf{11} \cdot 4PF_6$ and the [3]catenane $\mathbf{12} \cdot 8PF_6$ and 2) the two-step self-assembly (Scheme 3) of the [4]catenane $\mathbf{14} \cdot 8PF_6$ and the [5]catenane $\mathbf{15} \cdot 12PF_6$ via the intermediate [3]catenane $\mathbf{13} \cdot 4PF_6$, following 3) the cesium-ion-promoted, phase-transfer-catalyzed synthesis (Scheme 2) of tris-*p*-phenylene-[51]crown-15 (**8**) from its immediate precursors, the diphenol **6** and the ditosylate **7**. We describe 4) the characterization of these new catenanes by FAB-MS (FAB-MS = Fast Atom Bombardment Mass Spectrometry),[8] LSI-MS (LSI-MS = Liquid Secondary Ion Mass Spectrometry),[9] and NMR spectroscopy[10] and draw attention to 5) the temperature dependences of the ^1H NMR spectra of $\mathbf{11} \cdot 4PF_6$, $\mathbf{12} \cdot 8PF_6$, $\mathbf{13} \cdot 4PF_6$, $\mathbf{14} \cdot 8PF_6$, and $\mathbf{15} \cdot 12PF_6$.

The macrocyclic polyether **8** was obtained (Scheme 2) in 14% yield from the readily available starting materials **6** and **7** by using a procedure similar to that described[5] for the preparation of tetrakis-*p*-phenylene-[68]crown-20. In the knowledge that it was possible with this macrocyclic polyether to isolate a [2]catenane on reaction of $\mathbf{9} \cdot 2PF_6$ with **10** at normal pressure and a [3]catenane when the same 'clipping' reaction was carried out at ultrahigh pressure, we employed a similar approach to the catenation of **8**. As anticipated, the [2]catenane $\mathbf{11} \cdot 4PF_6$ can be assembled from $\mathbf{9} \cdot 2PF_6$ and **10** in the presence of an excess of **8** in 48% yield at normal pressure. The [3]catenane $\mathbf{12} \cdot 8PF_6$ can be isolated (in 15% yield) *only* under ultrahigh pressure conditions (10 kbar) when $\mathbf{9} \cdot 2PF_6$ and **10** are employed in excess relative to **8**. Encouraged by this result, we carried out a reaction at normal pressure and room temperature in acetonitrile between $\mathbf{1} \cdot 2PF_6$, **2**, and an excess of **8** (Scheme 3), and managed to isolate,[11] albeit in low yield, the [3]catenane $\mathbf{13} \cdot 4PF_6$, a key intermediate in the construction of the [4]catenane $\mathbf{14} \cdot 8PF_6$ and the [5]catenane $\mathbf{15} \cdot 12PF_6$: a subsequent ultrahigh pressure reaction in the range 11–14 kbar between $\mathbf{13} \cdot 4PF_6$ and an excess of $\mathbf{9} \cdot 2PF_6$ and **10** in DMF at room temperature for 8 days afforded $\mathbf{14} \cdot 8PF_6$ in 22% yield and a trace[12] of $\mathbf{15} \cdot 12PF_6$.

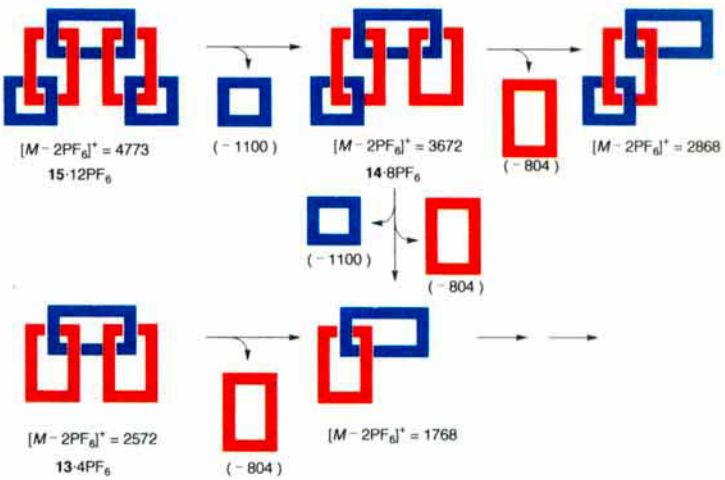


Scheme 1. The template-directed synthesis of the [3]catenane $\mathbf{5} \cdot 4PF_6$ [5] and the failure to catenate **4**. The chemical cartoons are defined as follows: *para*-phenylene rings ≡ small blue rectangles, bipyridinium units ≡ large blue rectangles, hydroquinol rings ≡ red rectangles.



Scheme 2. The cesium template-directed synthesis of **8** from the diphenol **6** and ditosylate **7**, and the subsequent template-directed synthesis of the [2]catenane $\mathbf{11} \cdot 4PF_6$ and the [3]catenane $\mathbf{12} \cdot 8PF_6$ from **8**, $\mathbf{9} \cdot 2PF_6$, and **10**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0434 $ 10.00+.25/0



Scheme 3. The two-step template-directed synthesis in which the [3]catenane $\mathbf{13} \cdot 4PF_6$ is prepared first at normal pressure from $\mathbf{1} \cdot 2PF_6$, **2**, and **8**, and then used with $\mathbf{9} \cdot 2PF_6$ and **10** to form the [4]catenane $\mathbf{14} \cdot 8PF_6$ and the [5]catenane $\mathbf{15} \cdot 12PF_6$.

The techniques of FAB-MS and LSI-MS allowed us to identify and interrelate $\mathbf{11} \cdot 4PF_6$ and $\mathbf{12} \cdot 8PF_6$, and $\mathbf{13} \cdot 4PF_6$, $\mathbf{14} \cdot 8PF_6$, and $\mathbf{15} \cdot 12PF_6$. The combined mass spectrometry data is summarized in Table 1: comparisons of m/z values are made in the horizontal direction. The relationships between the various catenanes in terms of the stepwise losses of rings during FAB-MS and LSI-MS are highlighted in Schemes 4 and 5. The fragmentation patterns listed in Table 1 are highly characteristic[13, 14] of catenanes and establish the identities of all the [2]-, [3]-, [4]-, and [5]catenanes beyond any doubt.

Scheme 4. The initial fragmentation experienced by $\mathbf{12} \cdot 8PF_6$ to afford $\mathbf{11} \cdot 4PF_6$ (see Scheme 2). The large red rectangle represents tris-*p*-phenylene-[51]crown-5 (**8**), and the small blue rectangle cyclobis(paraquat-*p*-phenylene) tetrakis(hexafluorophosphate).

All the catenanes of Table 1 exhibit multiple temperature dependencies in their ^1H NMR spectra above and below room temperature that are commensurate with site exchange processes involving different kinds of movements (for example, circumrotation and pirouetting, as well as rocking and rattling)[15] of the interlocked rings relative to each other.

Scheme 5. The sequence of fragmentations in FAB and LSI mass spectra experienced by $\mathbf{13} \cdot 4PF_6$, $\mathbf{14} \cdot 8PF_6$, and $\mathbf{15} \cdot 12PF_6$. The large blue rectangle represents cyclobis(paraquat-4,4′-biphenylene) tetrakis(hexafluorophosphate). The nature of the other rectangles is defined in the caption to Scheme 4. The values for $[M - 2PF_6]^+$ are calculated ones. Any arithmetic anomaly reflects the fact that no more than four significant figures are quoted.

We have demonstrated that, by subtle and appropriate modification of 'intelligent' components, the efficient molecular recognition and assembly processes that have spawned [2]- and [3]catenanes incorporating hydroquinol rings as π-donors and bipyridinium units as π-acceptors[4–7, 15] can be applied successfully to the construction of more highly catenated molecules. We trust that constitutional amendments that increase the information[16] content of the compounds are both possible and practical; this confidence leads us to believe that polycatenanes will soon be commonplace.

Experimental Procedure

8: A solution of the diphenol **6** [15] (1.9 g, 5.0 mmol) in dry DMF (70 mL) was added to a stirred suspension of Cs_2CO_3 (16.3 g, 50 mmol) in dry DMF (50 mL) under nitrogen, and the mixture was heated to 60 °C. After an additional 30 min, CsOTs (3.0 g, 10.0 mmol) and Bu_4NI (0.2 g, 0.5 mmol) were added as solids. A solution of the ditosylate **7** [5] (3.9 g, 5.0 mmol) in dry DMF (80 mL) was added over 2 h, and the temperature was then raised to 80 °C. Stirring and heating at 80 °C were continued for 3 days. The reaction mixture was then filtered, and the precipitate washed with DMF (30 mL). The solvent was removed under vacuum, and the residue was partitioned between toluene (250 mL) and water (50 mL). The toluene fraction was dried and concentrated under vacuum to afford a residue that was purified by column chromatography [SiO_2, Me_2CO/C_6H_{14} (2.5:3)] to yield **8** as a white solid (0.55 g, 14%, m.p. 49–51 °C); positive-ion FAB-MS: m/z 804 (M^+); ^1H NMR ($CDCl_3$): δ = 3.64–3.72 (m, 24H), 3.78–3.84 (m, 12H), 4.02–4.09 (m, 12H), 6.82 (s, 12H); ^{13}C NMR ($CDCl_3$): δ = 68.2, 69.8, 70.7, 70.8, 115.7, 153.1. Subsequently, when the same reaction procedure was repeated with 1,4-bis[2-[2-[2-[2-(4-hydroxyphenoxy)ethoxy]ethoxy]ethoxy]ethoxy]benzene [5] and tetraethyleneglycol bistosylate as starting materials, a 30% yield of **8** was obtained.

$\mathbf{11} \cdot 4PF_6$: **10** (38 mg, 0.14 mmol) in dry MeCN (2 mL) was added to a solution of $\mathbf{9} \cdot 2PF_6$ (88 mg, 0.12 mmol) and **8** (200 mg, 0.25 mmol) in dry MeCN (5 mL). After the reaction mixture had been stirred at room temperature for 5 days, the solvent was removed under vacuum to afford a red solid which was subjected to column chromatography [SiO_2, MeOH:2 N aqueous NH_4Cl:$MeNO_2$ (7:2:1)]. The solvents were evaporated off under vacuum from the crude product, which was dissolved in

[a] The fragmentation patterns for the catenanes should be compared with the diagrams of Schemes 4 and 5. [b] See ref. [8] for details of how the FAB-MS were obtained. [c] See ref. [9] for details of how the LSI-MS were obtained. [d] Peaks indicating the generation of the [2]catenane **11** · $4PF_6$ by loss of the cyclobis(paraquat-*p*-phenylene) macrocycle from the [3]catenane **12** · $8PF_6$. [e] Peaks indicating the generation of a [2]catenane by loss of **8** from the [3]catenane **13** · $4PF_6$. This [2]catenane has indeed been isolated and characterized. The positive-ion FAB-MS of this catenane yields a very similar series of peaks. The peaks reported represent the ion corresponding to this fragment, followed by the loss of one, two, and three PF_6 ions. See ref. [11]. [f] Peaks indicating the generation of a [3]catenane by loss of **8** from the [4]catenane **14** · $8PF_6$. The peaks reported correspond to the loss of two, three, and four PF_6 ions from the fragment. [g] Peaks indicating the generation of a [2]catenane by loss of **8** and the cyclobis(paraquat-*p*-phenylene) macrocycle from the [4]catenane **14** · $8PF_6$. This [2]catenane has indeed been isolated and characterized. The positive-ion FAB-MS of this catenane yields a very similar series of peaks. The peaks reported correspond to the loss of one, two, and three PF_6^- ions from the fragment. See ref. [11]. [h] Peaks indicating the generation of the [4]catenane **14** · $8PF_6$ by loss of the cyclobis(paraquat-*p*-phenylene) macrocycle from the [5]catenane **15** · $12PF_6$. The peaks reported correspond to the loss of one, two, and three PF_6^- ions from the fragment. [i] Peaks indicating the generation of a [3]catenane by loss of **8** and the cyclobis(paraquat-*p*-phenylene) macrocycle from the [5]catenane **15** · $12PF_6$. The peaks reported correspond to the loss of one, two, three, and four PF_6^- ions from the fragment.

water (10 mL). A saturated aqueous NH_4PF_6 solution was added to this solution until precipitation was complete. The precipitate was filtered off, washed with H_2O (10 mL), and dried under vacuum to give **11** · $4PF_6$ as a red solid (110 mg, 48%, m.p. >250 °C); positive-ion FAB-MS: *m/z* 1904 (M^+), 1759 ([M − PF_6]$^+$), 1613 ([$M - 2PF_6$]$^+$), 1469 ([$M - 3PF_6$]$^+$); ^{1}H NMR (CD_3COCD_3): δ = 3.50–4.10 (m, 52H), 6.01 (s, 8H), 6.60 (br s, 8H), 7.96 (s, 8H), 8.15 (d, J = 7 Hz, 8H), 9.30 (d, J = 7 Hz, 8H); ^{13}C NMR (CD_3COCD_3): δ = 65.7, 70.6, 71.3, 115.9, 126.6, 128.5, 128.6, 130.5, 130.7, 131.3, 131.8, 137.7, 145.7, 147.2, 151.5.

12 · $8PF_6$: **10** (300 mg, 1.16 mmol), **9** · $2PF_6$ (750 mg, 1.06 mmol), and **8** (170 mg, 0.21 mmol) were dissolved in dry DMF (10 mL), and the solution was subjected to pressure (10 kbar) for 20 h at room temperature. After evaporation of the solvent, the residue was purified by column chromatography [SiO_2, MeOH:2 N aqueous NH_4Cl:DMF (4:5:2)]. After counterion exchange, as described for **11** · $4PF_6$, pure **12** · $8PF_6$ was isolated as a red solid (92 mg, 15%, m.p. >250 °C); positive-ion FAB-MS: *m/z* 2860 ([$M - PF_6$]$^+$), 2715 ([$M - 2PF_6$]$^+$), 2570 ([$M - 3PF_6$]$^+$), 2425 ([$M - 4PF_6$]$^+$); ^{1}H NMR (CD_3COCD_3, 53 °C): δ = 3.64–4.03 (m, 48H), 4.74 (br s, 12H), 6.05 (s, 16H), 8.03 (s, 16H), 8.22 (d, J = 7 Hz, 16H), 9.32 (d, J = 7 Hz, 16H); ^{13}C NMR (CD_3COCD_3): δ = 65.8, 67.9, 70.7, 71.2, 71.5, 114.5, 126.9, 131.9, 137.8, 145.8, 147.7, 152.1.

13 · $4PF_6$: **2** (0.31 g, 0.91 mmol) in dry MeCN (5 mL) was added to a solution of **1** · $2PF_6$ (0.65 g, 0.83 mmol) and **8** (2.0 g, 2.5 mmol) in dry MeCN (20 mL). Following a procedure identical to that described for the preparation of **11** · $4PF_6$, apart from the reaction time (in this case, 21 days), **13** · $4PF_6$ was isolated as a red solid (83 mg, 3.5%, m.p. <250 °C); positive-ion FAB-MS: *m/z* = 2861 (M^+), 2716 ([$M - PF_6$]$^+$), 2571 ([$M - 2PF_6$]$^+$), 2425 ([$M - 3PF_6$]$^+$); ^{1}H NMR (CD_3COCD_3): δ = 3.57–3.78 (m, 96H), 5.99 (s, 24H), 6.02 (s, 8H), 7.83–7.90 (AB system, J_{AB} = 8 Hz, 16H), 8.13 (d, J = 7 Hz, 8H), 9.31 (d, J = 7 Hz, 8H); ^{13}C NMR (CD_3COCD_3): δ = 65.8, 68.5, 70.5, 71.3, 71.3, 115.7, 127.3, 128.8, 131.1, 135.3, 141.6, 146.0, 148.1, 153.2. See also ref. [11].

14 · $8PF_6$: **10** (21.1 mg, 0.080 mmol), **9** · $2PF_6$ (51.2 mg, 0.073 mmol), and **13** · $4PF_6$ (41.5 mg, 0.015 mmol) were dissolved in dry DMF (7 mL), and the solution was subjected to 11 kbar for 5 days at room temperature. Then further quantities of **10** (21.1 mg, 0.080 mmol) and **9** · $2PF_6$ (51.2 mg, 0.073 mmol) were added, and the reaction was continued under pressure (14 kbar) for 3 days. The reaction was worked up as described for **12** · $8PF_6$. Pure **14** · $8PF_6$ was isolated as a red solid (12.9 mg, 22%, m.p. >250 C); LSI-MS: *m/z* 3818 ([$M - PF_6$]$^+$), 3672 ([$M - 2PF_6$]$^+$), 3527 ([$M - 3PF_6$]$^+$), 3382 ([$M - 4PF_6$]$^+$); ^{1}H NMR (CD_3COCD_3): δ = 3.50–3.95 (m, 100H), 5.97 (s, 20H), 5.99 (s, 8H), 6.07 (s, 8H), 7.82–7.88 (m, 16H), 8.07, (s, 8H), 8.10 (d, J = 7 Hz, 8H), 8.29 (d, J = 7 Hz, 8H), 9.28 (d, J = 7 Hz, 8H), 9.39 (d, J = 7 Hz, 8H); ^{13}C NMR (CD_3COCD_3): δ = 65.7, 67.8, 68.4, 70.5, 71.1, 71.3, 71.4, 114.9, 115.7, 127.0, 127.4, 128.7, 131.0, 132.0, 135.4, 137.9, 141.6, 146.0, 147.8, 148.2, 153.2. [8] FAB-MS for samples **11** · $4PF_6$, **12** · $8PF_6$, and **13** · $4PF_6$ was carried out on a Kratos MS80RF mass spectrometer (accelerating voltage, 3 kV; resolution, 1000) coupled to a DS90 data system and off-line Sun Workstation for processing the raw data experiments. The atom gun was an adapted saddle field source (Ion Tech Ltd.) operated at about 8 keV and a tube current of about 2 mA. Krypton was used to provide a primary beam of atoms, and the samples were dissolved in a small volume of 3-nitrobenzyl alcohol that had previously been coated onto a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 30 seconds per decade.

[9] For samples **14** · $8PF_6$ and **15** · $12PF_6$, LSI-MS was carried out on a Kratos Concept 1H mass spectrometer (accelerating voltage, 8 kV; resolution, 1000) coupled to a Sun Sparc Station with Mach3 Software. The samples were dissolved in acetone, and a small volume (1–2 μL) was added to the 3-nitrobenzyl alcohol matrix. Spectra were recorded in the positive-ion mode at a scan speed of 5 seconds per decade. We gratefully acknowledge the assistance of Kratos

Analytical, and in particular Dr. M. Kimber, Dr. H. Wight, and Dr. J. Moncur, in the collection of the mass spectra for these compounds.

[10] The ^1H and ^{13}C NMR spectra were recorded on a Bruker AMX400 spectrometer operating at 400.13 MHz and at 100.63 MHz, respectively. All chemical shifts are referenced by means of the residual CHD_2COCHD_2 or CHD_2CN signals to Me_4Si.

[11] A minor product of this reaction was the [2]catenane comprising a cyclobis(paraquat-4,4'-biphenylene) macrocycle and a tris-*p*-phenylene-[51]crown-15 ring. It was isolated as a red solid (0.7%, m.p. > 250°C); positive-ion FAB-MS: *m/z* 2056 (M^+), 1911 ($[M - PF_6]^+$), 1766 ($[M - 2PF_6]^+$), 1621 ($[M - 3PF_6]^+$), 1476 ($[M - 4PF_6]^+$); ^1H NMR (CD_3COCD_3): δ = 3.68–3.79 (m, 48H), 6.05 (s, 12H), 6.10 (s, 8H), 7.70–7.80 (AA'BB' system, J_{AB} = 8.5 Hz, 16H), 8.49 (d, J = 6 Hz, 8H), 9.49 (d, J = 6 Hz, 8H); ^{13}C NMR (CD_3COCD_3): δ = 65.8, 68.6, 70.4, 71.2, 71.3, 115.9, 127.9, 128.7, 130.8, 135.3, 141.5, 146.2, 149.2, 153.4.

[12] A very small quantity (< 1 mg) of the [5]catenane **15** · $12PF_6$ was isolated from the reaction yielding the [4]catenane **14** · $8PF_6$. The identification of **15** · $12PF_6$ rests solely on its LSI-MS (Table 1) at present. The sluggishness of the [4]catenane to go on and afford the [5]catenane perplexes us. We speculate that a negative allosteric effect is operating in so far as the first catenation of **13** · $4PF_6$ by a cyclobis(paraquat-*p*-phenylene) macrocycle to give **14** · $4PF_6$ inhibits the second catenation to give **15** · $12PF_6$.

Fullerene Chemistry in Three Dimensions: Isolation of Seven Regioisomeric Bisadducts and Chiral Trisadducts of C_{60} and Di(ethoxycarbonyl)methylene**

Andreas Hirsch,* Iris Lamparth, and Heinrich R. Karfunkel

The exohedral chemistry of C_{60} has been dominated thus far by investigations of its reactivity and the isolation and characterization of monoaddition products.[1] Up to this point the regiochemistry of polyadducts has hardly been examined systematically.[2] The synthesis of polyadducts with defined three-dimensional structure is also topical in view of fullerene derivatives with interesting biological[3] or material properties.[4] We describe here the systematic investigation of the regiochemistry of C_{60} derivatives with two and three methano bridges; of the eight possible products, the seven stable regioisomeric bisadducts and chiral trisadducts formed in a stepwise fashion and were isolated.

The cyclopropanation of C_{60} with diethyl bromomalonate was chosen as a model reaction.[5] This reaction proceeds very uniformly, and only the bonds common to two six-membered rings in the fullerene framework (6-6 bonds) are attacked. We first isolated the monoaddition product $C_{61}(COOEt)_2$ **1** by chromatography, and subjected it to the same reaction conditions to synthesize $C_{62}(COOEt)_4$ **2**.

1 **2**

For a description of the spatial arrangement of the added groups, the C_{60} molecule is divided into three sections with regard to the location of the second attack (Fig. 1). This second addition can take place on the same hemisphere (*cis*), at the equator (*e*), or on the opposite hemisphere (*trans*). Three different sets of double bonds can be attacked within the same hemisphere (*cis*-1, *cis*-2, *cis*-3), and four different sets of double bonds are available on the opposite hemisphere (*trans*-1, *trans*-2, *trans*-3).[6]

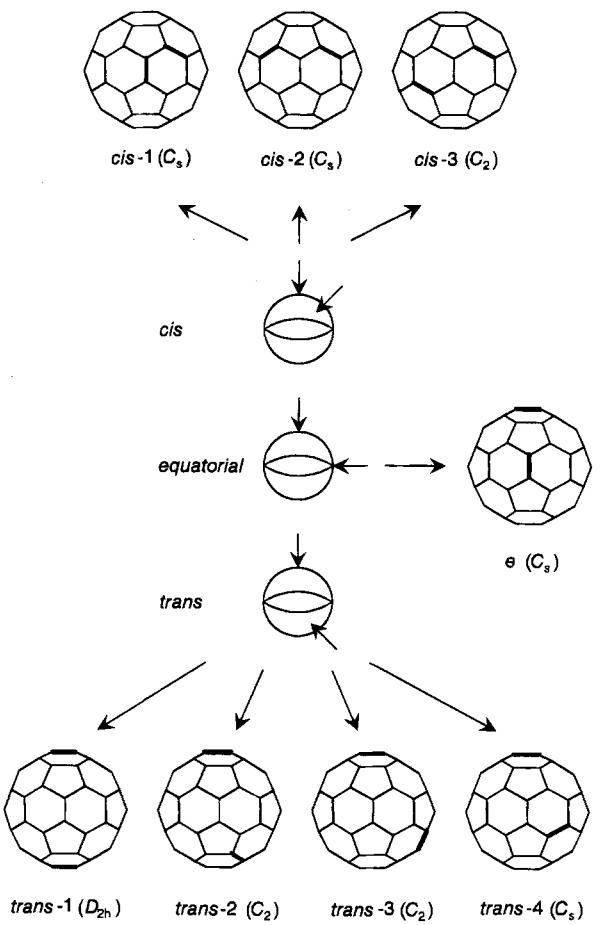

Fig. 1. Positional relationships between the 6-6 bonds in C_{60} and the symmetry of the corresponding bisadducts.

Chromatographic separation of the reaction mixture gave (in order of elution following **1**) a fraction of five different bisadducts **2a–e** and a mixed fraction consisting of two further bisadducts **2f, g** (Table 1) as well as trisadducts **3**. Further separation with preparative HPLC provided the bisadducts **2a–e** (on SiO_2) and **2f, g** (on a nitrophenyl phase with toluene as eluent). Compounds **2a–g** were characterized by UV/VIS, IR, ^1H NMR, and ^{13}C NMR spectroscopy (Table 2) as well as by mass spectrometry.[7]

Table 1. Order of elution (Elution no.), symmetry, number of the possible modes of construction (No.), yield [%], and assignment of the isolated bisadducts **2a–g**, along with the calculated relative AM1 heats of formation ($AM1_F$) in kcal mol^{-1} and AM1 dipole moments ($AM1_D$) in Debye for all eight regioisomers (the *cis*-1 isomer was not isolated).

Elution no.	Cmpd.	Sym. [a]	No.	Yield	Assign. [b]	$AM1_F$ [c]	$AM1_D$ [c]
1	**2a**	D_{2h}	1	0.8	*trans*-1*	0.2	0.1
2	**2b**	C_2	4	5.3	*trans*-2* (*cis*-3)	0.2	1.2
3	**2c**	C_2	4	12.0	*trans*-3*	0.1	2.0
4	**2d**	C_s	4	3.7	*trans*-4* (*cis*-2) (*cis*-1)	0.0	2.3
5	**2e**	C_s	4	15.5	*e** (*trans*-2)	0.0	2.6
6	**2f**	C_2	4	2.5	*cis*-3* (*trans*-4)	1.3 [d]	3.0 [d]
7	**2g**	C_s	4	0.9	*cis*-2* (*cis*-1)	1.8	3.5
–	–	C_s	4	0.0	*cis*-1	17.7 [e]	3.8 [e]

[a] Determined from the ^{1}H and ^{13}C NMR spectra. [b] The assignments marked with * are based on the order of elution. The isomers with the same symmetry are listed in parentheses. [c] To simplify the calculation the methyl esters $C_{62}(COOMe)_4$ were examined. [d] Value for one of the two optimized conformers. [e] Value for one of the three optimized conformers.

The symmetry of **2a–g** is evident from their NMR spectra (Table 1). The least polar isomer **2a** could thus be assigned as the *trans*-1 product with D_{2h} symmetry and **2e** as the *e* isomer with C_s symmetry.[8] The order of elution of these isomers corresponds to the calculated polarities (Table 1). The other isomers are either C_s-symmetric with 32 NMR sigals for the fullerene C atoms, of which four are half as intense as the others, or they are chiral and C_2-symmetric giving rise to 30 NMR signals for the fullerene C atoms. The red to copper-colored compounds **2b–g** are readily soluble in toluene and $CHCl_3$, whereas the least polar orange isomer **2a** (*trans*-1) is only marginally soluble. Compound **2a** can arise from **1** by attack at only a single double bond; in the formation of the other isomers four bonds are available in each case. These relations are reflected in the low yield of **2a** especially relative to the yields of **2b**,**e** (see Table 1). The uncertainty in the structure assignments can be further reduced by comparison of the order of elution, the yields, and the symmetries of the regioisomers of **2** with their calculated stabilities and dipole moments (Table 1). The calculations also show that the formation of a *cis*-1 isomer is considerably disfavored. Indeed, a yet more polar eighth regioisomer of **2** could not be detected in the reaction mixture.

The isomerically pure compounds **2b–e** were cyclopropanated to give the trisadducts **3**. Each crude product was separated into at least three fractions of trisadducts **3** by preparative HPLC. Remarkably, the bisadduct **2e** with the methano bridge in position *e* gave the intensely orange-red trisadduct **3a** preferentially; **2c** gave primarily the red trisadduct **3b**. In each case the yield

3a **3b**

was 40%. Both regioisomers are chiral; the ^{1}H and ^{13}C NMR spectra (Table 2) demonstrate unequivocally that **3a** has C_3 symmetry and **3b** D_3 symmetry. In **3a** all methano bridges are in *e* positions relative to each other (*e*,*e*,*e*) and in **3b** in *trans*-3 positions (*trans*-3,*trans*-3,*trans*-3). In **3b** the methano bridges lie on a belt along the equator about the threefold axis of the C_{60} framework. For each enantiomer the 6-6 bonds point either up or down. The spectroscopic characterization of **3b** also indicates that **2c** can be conclusively assigned as the *trans*-3 isomer (see Table 2). The apparently preferred formation of **3a** and **3b** (additions in *trans*-3 and *e* positions) can be correlated with the relatively high yields of **2c** and **2e** (see Table 1). In the cyclopropanation of **2b** and **2d** the main reactions are *trans*-3 and *e* additions.

The regioselective assembly of tetra- and hexaadducts with higher symmetry by *e* additions to **2a** and **2e** is a topic of further investigations.

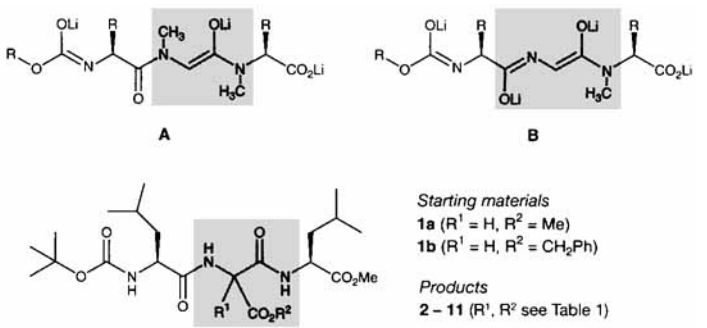
[6] The individual derivatives can be named according to the nomenclature suggested by Chemical Abstracts in which all C atoms are numbered in a spiral pattern starting from a five-membered ring; however, this does not provide a clear description of the spatial relationships (like *ortho*, *meta*, and *para* in benzene chemistry) necessary for a discussion of the regiochemistry of fullerene derivatives.

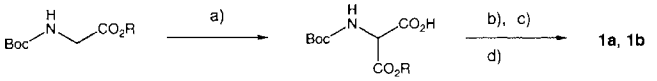


[7] The FD mass spectra of **2a–g** display an M^+ peak at $m/z = 1036$ as the only peak. The UV/VIS spectra (CH_2Cl_2) resemble that of **1** [5], although significant differences are observed in the region between 400 and 600 nm. The FT-IR spectra (KBr) show typical C_{60} bands at 1427 and 580–514 cm^{-1} in addition to ester bands.

[8] Two sp^3 C_{60} atoms lie in the mirror plane in **2e**. Thus three signals are observed for sp^3 C_{60} C atoms, two signals for the C atoms of the methylene bridge and three signals each for the ester groups.

Preparation and C-Alkylation of Peptides with Aminomalonate Building Blocks**

Hans G. Bossler, Pius Waldmeier, and Dieter Seebach*

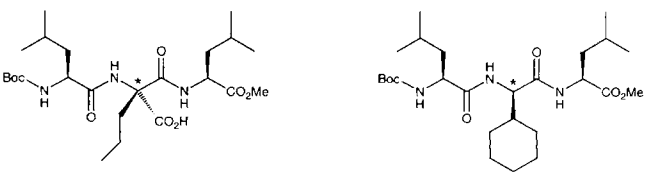


As was shown in previous papers,[1, 2] oligopeptides that may contain more than ten amino acids can be alkylated at sarcosine or glycine residues through polylithiated derivatives. This method is suitable for the preparation of numerous analogous peptides with various side chains from a single precursor. Yet this procedure can be used only if an N-methylated amino acid is incorporated next to the peptide enolate unit in the direction of the C terminus. The method is based upon the following principle: all relatively acidic HX protons are first removed and then the CH_2 group can be deprotonated to form an enolate (see Li_3[1] and Li_4 derivatives[2] **A** and **B** in Scheme 1). In order to alkylate oligopeptides that are not N-alkylated we have now reversed this principle so that the position to be substituted is the most acidic one of the molecule.[3]

Scheme 1. Polylithiated peptides **A** and **B** (geometry of C=C and C=N double bonds drawn arbitrarily), containing enolate moieties, and C-alkoxycarbonylated tripeptides **1** – **11**.

As a first example the aminomalonate-containing tripeptides **1a** and **1b** have been prepared (with Boc and methyl ester protecting groups at the *N* and C termini, respectively). In these peptides the hydrogen atom in the R^1 position can be removed with an alkoxide base. The synthesis of the methyl and benzyl esters **1a** and **1b**, respectively, is straightforward: The Boc-protected glycine esters were doubly deprotonated and carboxylated with CO_2 to the aminomalonic acid mono esters.[4] These were then coupled with the appropriate leucine derivative at the acid and amino groups, following standard procedures (see specifications in Scheme 2). To the best of our knowledge, only a diketopiperazine,[5a] a tripeptide,[5b] and some peptide isosteres[5c] containing one or two aminomalonic acid building blocks have been reported.

For the reaction of the new Boc-tripeptide diester **1** with electrophiles we chose MeONa or *t*BuOK as bases. They were employed stoichiometrically (1.3 equiv) in tetrahydrofuran for alkylations with halides, and catalytically (0.3 equiv) in methanol for Michael additions to acrylic acid derivatives and nitrostyrene. The yields of products **2**–**11** consisting of mixtures of diastereo-



Scheme 2. Preparation of tripeptide derivatives **1**. a) LDA and TMEDA, each 2 equiv, THF, −75 °C, then CO_2 bubbled in; workup with dilute H_2SO_4; quantitative yields. b) Leucine methyl ester · HOTos, DCC, HOBt, NMM, THF, 0 °C to 20 °C; yields 50–70%, 10 g starting material. c) Et_2O saturated with HCl, about 95% yield. d) Boc-Leu-OH, conditions as in b), yields for **1a** 66%, for **1b** 83%; both compounds are powders and are produced as 1:1 mixtures of products epimeric at the amino acid residue in the middle.

isomers (ca. 1:1) range from 70 to 90% (see Table 1). So far, we have not been able to saponify and decarboxylate the malonate group of the dimethyl esters **2**–**7**, whereas the benzyl ester groups of the benzyl methyl esters **8**–**11** could be smoothly cleaved by hydrogenolysis (H_2/Pd-C/MeOH). Depending on

Table 1. Products **2** – **7** and **8** – **11** from the reaction of **1a** and **1b**, respectively, with alkyl halides and with Michael acceptors. Solvent THF (for **2** – **4** and **8** – **11**) or methanol (for **5**–**7**), base (quantity see text) MeONa (for **3** – **7**) or *t*BuOK (for **2**, **8**–**11**), temperature 0 °C, reaction times 10 min to 4 h. Yield of **2** with MeONa only 74%. The yields given are those of chromatographically purified products. The epimers were not separated. The structures of **2** – **11** follow unequivocally from ^1H, ^{13}C NMR, and FAB mass spectra.

Starting material no.	Electrophile	Product no.	R^1	R^2	yield [%]
1a	methyl iodide	**2**	Me	Me	91
1a	allyl bromide	**3**	CH_2–CH=CH_2	Me	58
1a	benzyl bromide	**4**	CH_2Ph	Me	87
1a	methyl acrylate	**5**	CH_2–CH_2–CO_2Me	Me	93
1a	acrylonitrile	**6**	CH_2–CH_2–CN	Me	80
1a	*β*-nitrostyrene	**7**	CH(Ph)CH_2NO_2	Me	67
1b	methyl iodide	**8**	Me	CH_2Ph	88
1b	allyl bromide	**9**	CH_2–CH=CH_2	CH_2Ph	72
1b	cyclohex-2-enyl bromide	**10**	2-cyclohexene-1-yl	CH_2Ph	73
1b	benzyl bromide	**11**	CH_2Ph	CH_2Ph	75

the reaction times, the free acids or the decarboxylated products were isolated. The double bond of the allyl and of the cyclohexenyl derivatives **9** and **10** was simultaneously hydrogenated (see examples in Scheme 3). The diastereoisomeric acids (e.g. **12** from **9**) as well as the decarboxylated products (e.g. **13** from **10**) were separated by chromatography (Scheme 3).

Boc-Leu-(2-HO_2C)Nva-Leu-OMe (**12** + *epi*-**12**) Boc-Leu-(2-cyclohexyl)Gly-Leu-OMe (**13** + *epi*-**13**)

Scheme 3. Two products **12** and **13** from the debenzylation and decarboxylation of the malonate units in **9** and **10**, respectively. The allylic substituents in **9** and **10** were hydrogenated under the debenzylation conditions (H_2/Pd-C/MeOH). Yields of carboxylic acids 74 and 89% from **9** and **11**, of Boc-tripeptide methyl ester quantitative (from **8** and **10**), see also text. The pairs of diastereoisomers at the stage of the carboxylic acids and of the decarboxylated products were separated by chromatography (thick layer, SiO_2, H_2O-sat. EtOAc or – for the products from **11** – EtOAc/MeOH 9:1). The tripeptide derivates from the debenzylation were cleaved as usual for peptides (HCl/H_2O) and derivatized following the method of Bayer [6] [a) *i*PrOH/HCl, b) $(C_2F_5CO)_2O$] and analyzed on a Chirasil-Val GC column. Hereby the racemic amino acids H-Ala-OH, H-Phe-OH, H-Nva-OH, and cyclohexylglycine were identified, as well as the non-racemic H-Leu-OH.

Nothing can be said about the diastereoselectivities of the three steps (enolate formation, alkylation, and decarboxylation), since all reactions have so far been carried out only with 1:1 mixtures of diastereoisomers (to obtain both separable epimers may be an advantage rather than a disadvantage for medicinal chemists!). It appears certain that this way of modifying peptides[7] is more suitable for larger oligopeptides than is polylithiation. Corresponding experiments are in progress, and these might lead to an attractive general method of preparing entire series of peptides from a single precursor, a process of much current interest in connection with establishing peptide libraries.[8]

Chiral Dendrimers from Tris(hydroxymethyl)-methane Derivatives**

Dieter Seebach,* Jean-Marc Lapierre, Konstantinos Skobridis, and Guy Greiveldinger

Dendrimers are molecules in the no-man's land between the conventional target molecules of organic synthesis and those of polymer chemistry,[1] which may have interesting properties and applications.[1, 2] As far as we know, there is only one report[3] on chiral starburst[1–4] dendrimers which were obtained by attaching tryptophan units to the end groups of a second generation dendrimer with a four-branch center piece or core. We report here on the first synthesis of starburst dendrimers with chiral core units and, in one case, also chiral branch units. We hope that this work will provide information about questions such as: a) Will a chiral core in a dendrimer with otherwise achiral building blocks cause the dendrimer to have a chiral shape or to be optically active? b) Will there be enantioselective clathration or host–guest interaction near the core of such a dendrimer? c) Will a dendrimer containing chiral, unsymmetrical branching units really have the predicted surface with fractal dimensions[5] and thus a pronounced capability for chiral recognition?

Our trifunctional chiral building blocks were prepared, as described previously,[6] from the dioxanone **1**, which is accessible from poly (*R*)-3-hydroxybutanoate (PHB).[7] The aldol adducts of the dioxanone **1** to aldehydes can be reduced to the chiral tris(hydroxymethyl)methane derivatives **2**–**4a**. By using the Fréchet

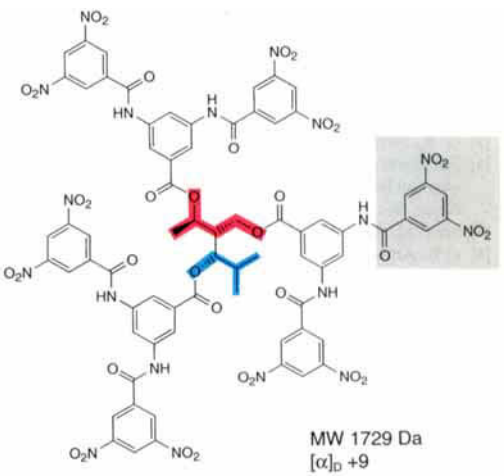
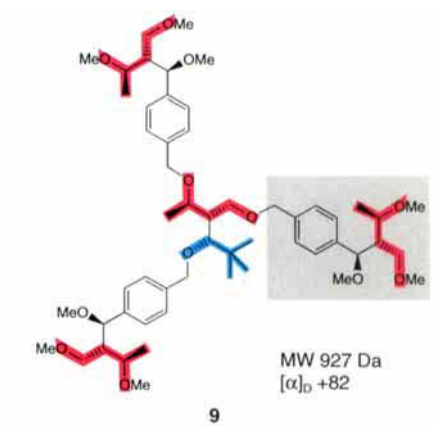
[**] J.-M. L. was recipient of a fellowship from the Natural Sciences and Engineering Research Council of Canada (1991–1993), K. S. from the Deutsche Forschungsgemeinschaft (1992/1993); part of the Diplomarbeit of G. G., ETH Zürich, 1993.



6

dine (>95%). The six nitro groups of the product were reduced to amino groups (>95%), which were acylated with the same acid cloride (83%). The dendrimer **9** (generation 1), in which both the core and the branches are chiral, was prepared from the triols **3** and **4a**.[9] After the triol **4a** was O-methylated (→ **4b**), the *tert*-butyldiphenylsilyl (OTBDPS) group was cleaved (→ **4c**), and the benzylic alcohol was converted into a benzyl bromide (→ **4d**, overall yield of 70%). This in turn was used for etherification of the triol **3**. Compound **9** is *one* out of 4096 possible stereoisomers!



7

After the etherification step with the corresponding benzylic bromides, the dendrimers **5**, **6**, **7**, and **9** were isolated in yields of between 55 and 75% from reactions carried out on a 0.5–1.0 g scale. The dendrimers were purified by flash chromatography and fully characterized by IR, ^{1}H, and ^{13}C NMR spectroscopy, FAB mass spectrometry, and elemental analysis. In the ^{1}H NMR spectra of the dendrimers **5**–**7** we noticed that nonequivalent benzylic and aromatic protons gave rise to complex signals when they are found near the core and to singlets when they are found near the periphery of the dendrimer molecule. In the formulae shown the molecular weights and the specific rotations[10] of the compounds **5**–**9** are also given. It turns out that

8

the optical activity decreases as the dendrimers of type **5**, **6** and **7** increase in size;[11] in contrast, for the "fully chiral" dendrimer **9**, the rotation is approximatively the same as that of the building block ([α]$_D$ of **4c** and **4d**: +88 and +78). The transition

9

from the first to the second generation of the nitro-substituted dendrimers leads to a change of sign for the optical activity (dendrimer of first generation with six NO_2 groups: $[\alpha]_D = -17$; Dendrimer **8** with twelve NO_2 groups: $[\alpha]_D = +9$).

With several of the starburst dendrimers we observed the formation of very stable clathrates. Thus, compound **5** could be freed from CCl_4 only by heating at 100 °C/0.5 Torr for several hours. Moreover, the dodecanitro derivative **8** was isolated and characterized as a complex of composition [(2 · **8**) · EtOAc · (8 H_2O)], and for its hexaamine precursor we have identified 1:1, 2:1, and 6:1 complexes with 1,4-dioxane.[6c]

The preliminary results obtained so far lead us to believe that the synthesis of higher generation chiral dendrimers[12] will provide answers to the questions posed in the introduction and

thus deepen our understanding of organized complex molecules and their interactions with small molecules.[13]

[9] Compound **4a** was obtained as the minor diastereomeric product from **1** and 4-(*tert*-butyldiphenylsiloxymethyl)benzaldehyde, see [6c]. The epimer at the benzylic position of **4a** was also used for preparing the corresponding diastereomer of **9**.

[10] **5**, **6**, **7**, **9** in $CHCl_3$ ($c = 1$ 2 g/100 mL), **8** in dioxane ($c = 1.05$ g/100 mL).

[11] The $[\alpha]_D$ values in generation 1 (three peripheral OBn), 2 (six OBn), and 3 (twelve OBn) of the dendrimer without spacer (type **5**), with aliphatic spacer (type **6**), and with aromatic spacer (type **7**) are: $+15/+8/+4$, $-1/-2/-0.2$, and $+12/+7/+4$, respectively; for simple presentation of the generations of such Fréchet dendrimers, see [1c].

[12] There are five principle methods of assembling chiral dendritic structures: 1) chiral core with achiral branch units, 2) achiral core with chiral branch units, 3) both the core and the building blocks for the branches are chiral, 4) constitutionally different branches attached to an achiral core (see discussion in: J. Ehrler, D. Seebach, *Liebigs Ann. Chem.* **1990**, 379; G. Guanti, L. Banfi, E. Narisano, *J. Org. Chem.* **1992**, *57*, 1540), and 5) constitutionally different branches attached to a chiral core.

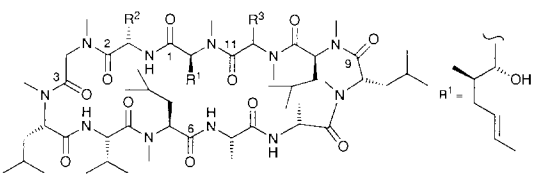
Cyclosporin: A Li- and Ca-Specific Ionophore!**

H. Michael Bürger and Dieter Seebach*



The cyclic undecapeptide cyclosporin A (**1**) is an immunosuppressive agent that has revolutionized the field of organ transplantation.[1] Although its biological activity is subject to intensive research, the detailed mode of interaction in the complex immune reaction of mammals is far from being completely understood.[2, 3] It has been established that an initial step of the immunosuppressive action of cyclosporin and FK 506 (another, although nonpeptidic immunosuppressive agent) is the inhibition of Ca^{2+}-dependent signaling pathways in T and mast cells.

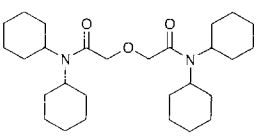
[**] Part of the Ph.D. Thesis of H. M. Bürger, dissertation no. 10436, ETH, Zürich, **1993**.

The structure of cyclosporin in organic solvents,[4] in the solid state,[5] and in a complex with its cytoplasmatic binding protein cyclophilin[6, 7] is well known from NMR spectroscopy[4, 6] and X-ray structure determinations,[5, 7] but its structure in an aqueous environment is still uncertain. Interactions of cyclosporin with metal ions are known;[8, 9] it was shown by thermoanalytical methods that surprisingly high enthalpies result when Li salts are added to cyclosporin solutions in tetrahydrofuran (up to 125 kJ mol^{-1}).[9] Similar conformational changes[10] as in the complexation with cyclophilin[6, 7] (e.g. the isomerization of a 9,10-*cis* to a 9,10-*trans* peptide bond) occur when cyclosporin complexes metal ions. Inspired by the pronounced interaction of cyclosporin with metal ions we set out to look for possible ionophoric activity of cyclosporin.



We investigated the migration of alkali and alkaline-earth metal ions across an organic solvent phase under the influence of cyclosporin A (**1**), C (**2**), and H (**3**) as well as of ascomycin (**4**) and the Ca-ionophore ETH 129 (**5**), by using the U-tube technique we recently employed for studying ion transport by derivatives of 3-hydroxybutanoic acid.[11, 12]

1 Cyclosporin A (CS), R^2 = Et, R^3 = (*S*)-*i* Pr
2 Cyclosporin C ([Thr^2]CS), R^2 = CH(OH)CH_3, R^3 = (*S*)-*i* Pr
3 Cyclosporin H ([D-MeVal^{11}]CS), R^2 = Et, R^3 = (*R*)-*i* Pr

4 Ascomycin
(21-Dihydro-*nor*-FK506)

5 ETH 129

To determine the ionophoric properties of compounds **1**–**5** we overlayered their dichloromethane solutions in a U tube with two buffered (pH 8.1) aqueous phases, one containing the metal chloride and its picrate. The extent of migration was monitored by UV spectrometry (356 nm; see *Experimental Procedure*). The transport rates for the alkali and alkaline-earth metal salts shown in Figures 1a and b were measured with a 0.005 M solution of cyclosporin A (**1**). The rates follow the Hofmeister or lyotropic sequence (increasing ionic radius – decreasing heat of hydration – increasing transport rate)[13] in both series – with two remarkable exceptions: first Li^+ migrates faster than Na^+, K^+, and Rb^+ and second Ca^{2+} migrates faster than the other alkaline-earth metal ions, even significantly faster than Ba^{2+}! The Ca^{2+} transport is strongly dependent on the cyclosporin A concentration,[14] as evident from the data collected in Table 1.

Like the physiological activity,[15] the Ca^{2+} migration through the organic phase depends upon the substituents on the cyclosporin skeleton: a comparison of compounds **1**–**5** shows (Fig. 1c) that cyclosporin H (**3**) is slightly more and cyclosporin C (**2**) distinctly less efficient[16] than cyclosporin A (**1**)

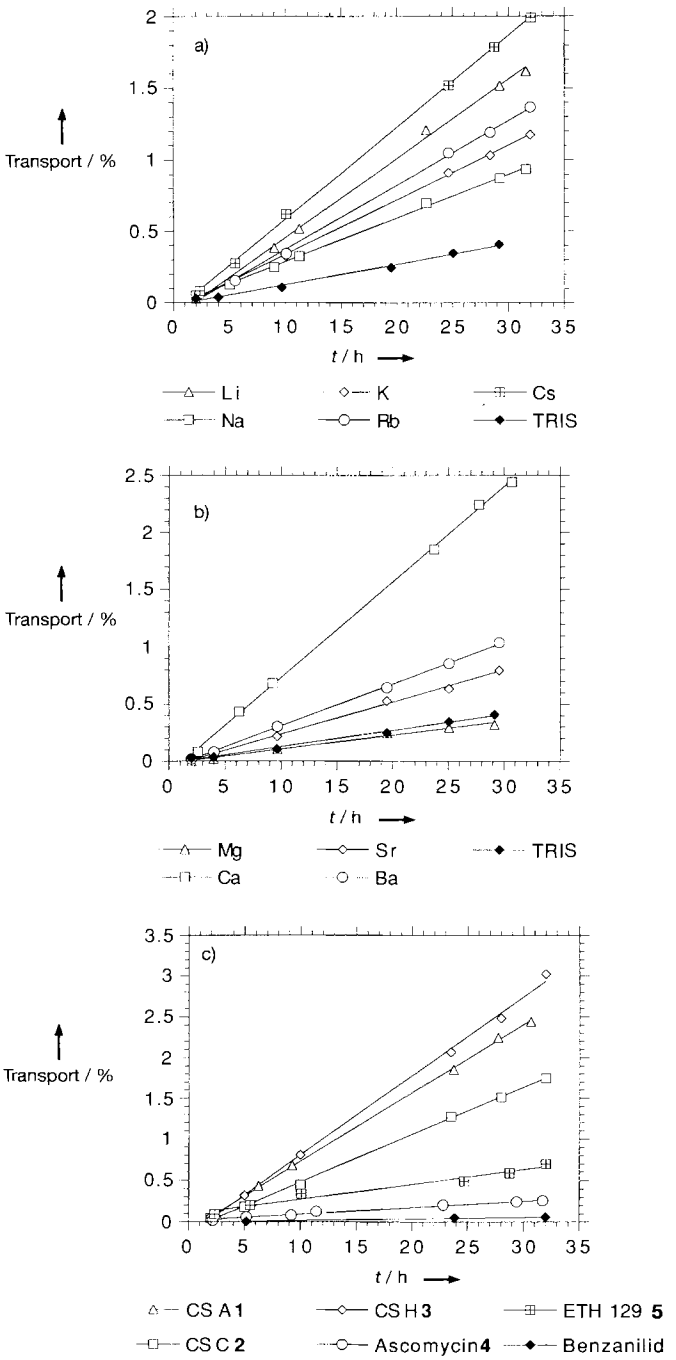


Fig. 1. Transport rates of the alkali and alkaline-earth metal picrates across a bulk liquid CH_2Cl_2 membrane. No metal ions were added to the donating solution in the control experiment (TRIS). a) Transport of the alkali metal ions with cyclosporin A (**1**) as ionophore. b) Transport of the alkaline-earth metal ions with cyclosporin A (**1**) as ionophore. c) Transport of calcium ions with the cyclosporins (CS) A (**1**), C (**2**), H (**3**), as well as ascomycin (**5**), and the ETH ligand **5** as ionophores. An experiment with benzanilid, employing the same amount of amide groups as in the cyclosporin experiments, was done as a reference.

(the order of immunosuppressive activity is: **1** ≥ **2** ≫ **3**).[15] Furthermore, ascomycin (**4**) and the ETH ligand **5**[17] are much poorer Ca^{2+} ionophores under these conditions.

The following comments concerning the preferred transport of Li^+ and Ca^{2+} ions by cyclosporin appear appropriate to us: a) Although the immunosuppressive agents **1**–**4** change intracellular Ca^{2+} levels in T cells,[12] only the cyclosporins **1**–**3** show pronounced ionophoric activity in our experiments. b) The Ca^{2+}-binding serin-threonin-phosphatase calcineurin and the ubiquitous Ca^{2+}-modulator calmodulin are involved in the cascade of the immune response.[1–3, 18] c) The results described herein shed new light on the role of cyclosporin in immunosuppression and should encourage new biochemical, physiological, and medical investigations.[19]

Table 1. Comparison of the transport rates of the alkali and alkaline-earth metal picrates with cyclosporin A (**1**) as ionophore. The error in the transport rates is aproximately ±10%.

Metal ion	Concentration [mM]	Transport rate [% transported in 100 h]
Li^+	5	5.5
Na^+	5	3.1
K^+	5	3.8
Rb^+	5	4.5
Cs^+	5	6.4
Mg^{2+}	5	1.2
Ca^{2+}	1	2.5
	5	8.4
	50	39.4
Sr^{2+}	5	2.8
Ba^{2+}	5	3.7
(TRIS)	5	1.4

Experimental Procedure

The transport experiments were done in a similar way as described for the derivatives of 3-hydroxybutanoic acid [12] (see also [11]). The ion-donating solutions were 0.101 M alkali metal chloride and 1 mM picric acid or 0.101 M alkaline-earth metal chloride and 2 mM picric acid in 0.1 M tris-(hydroxymethyl)-aminomethane (TRIS)/HCl buffer (final pH 8.1). The pure buffer solution served as acceptor solution. For the determination of the ionophoric behavior, 15 mL of a CH_2Cl_2 solution of the compounds **1**–**5** (0.005 M) was placed in a U-shaped tube (internal diameter 15 mm) made of quartz glass and overlayered with 7.5 mL of the donor and 7.5 mL of the acceptor solutions in the two legs. The organic phase was stirred magnetically (ca. 200 rpm) at room temperature, and the extent of transport was measured UV spectrometrically by recording the migration of picrate (λ_{max} 356 mm).

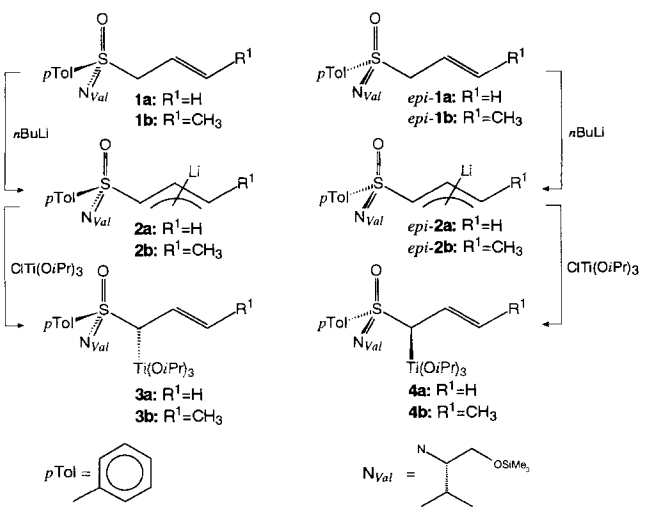
[16] Quite surprisingly **2**, despite having an additional hydroxy group in the side chain of amino acid no. 2, transports less efficiently than the more lipophilic **1**.
[17] The Ca-ionophore ETH 129 **5** forms strong complexes with Ca^{2+} (E. Bakker, M. Willer, M. Lerchi, K. Seiler, E. Pretsch, *Anal. Chem.* **1994**, *66*, (4), in press). Strong complexing agents are not well suited for transport experiments, since the release of ions into the receiving solution is slow and may determine the overall transport rate (M. Kirch, J.-M. Lehn, *Angew. Chem.* **1975**, *87*, 542; *Angew. Chem. Int. Ed. Engl.* **1975**, *14*, 555). In a separate extraction experiment with equal volumes of the described donor and organic solutions the picrate extraction by **5** into the organic layer was almost complete, an effect not observed with the immunosuppressive compounds **1**–**4**.
[18] With regard to the Li^+ selectivity in the interaction [9] between alkali metal ions and cyclosporin **1** it should be noted that the physiological activity of Li^+ as an antidepressive drug is related to the inhibition of a Mg^{2+}-dependent inositol phosphatase in the neurotransmitter system: A. J. Wood, G. M. Goodwin, *Psychological Medicine* **1987**, *17*, 579.
[19] The use of cyclosporin as an ionophore in ion-sensitive electrodes is currently being investigated by Prof. E. Pretsch, Laboratorium für Organische Chemie, ETH Zürich. Quite some time ago the Mg^{2+} selectivity of several cyclic octa- and dodecapeptides was described: F. Behm, D. Ammann, W. Simon, K. Brunfeldt, J. Halstrøm, *Helv. Chim. Acta* **1985**, *68*, 110. Synthetic Li-selective ionophores for application in ion-sensitive electrodes have been investigated by the same group (E. Metzger, D. Ammann, R. Asper, W. Simon, *Anal. Chem.* **1986**, *58*, 132; E. Metzger, R. Aeschimann, M. Egli, G. Suter, R. Dohner, D. Ammann, M. Dobler, W. Simon, *Helv. Chim. Acta* **1986**, *69*, 1821) and by other groups as well (R. Kataky, P. E. Nicholson, D. Parker, *J. Chem. Soc. Perkin Trans. II* **1990**, 321; R. Kataky, P. E. Nicholson, D. Parker, A. K. Covington, *Analyst* **1991**, *116*, 135; M. Bocheńska, J. E. Biernat, J. S. Bradshaw, *J. Inclusion Phenom. Mol. Recognit. Chem.* **1991**, *10*, 19).

Diastereoselective Hydroxyalkylation of Enantiomerically Pure 2-Alkenylsulfoximides**



Michael Reggelin* and Heinz Weinberger

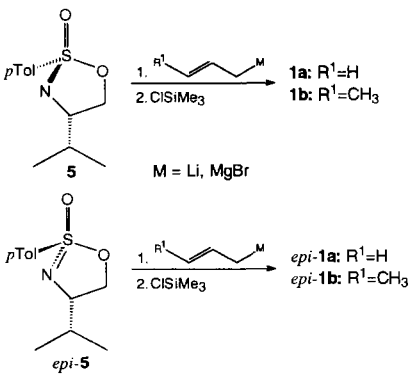
For a new asymmetric reaction the direction and extent of the attainable asymmetric induction must be predictable. In addition the reagent should be invariant with respect to stereogenic elements already present in the substrate. For the practical implementation of such reagent-controlled asymmetric conversions electrophilic substitutions, enantiomerically pure and configurationally stable organometallic compounds are available. In these reactions the stereocontrol achieved is usually directly correlated with the specificity associated with electrophilic substitution. Prime examples of this strategy are the chiral, dipole-stabilized[1] α-oxyalkanides introduced by D. Hoppe et al.[2] and an analogous pyrrolidine derivative prepared by P. Beak et al.[3] For the synthesis of such uniformly configurated, enantiomerically pure organometallic compounds, which are usually lithium compounds, three general methods are available:

1) tin–lithium exchange in uniformly configurated stannanes, which are in turn obtained from the resolution of racemates,[4, 5]
2) diastereotopos-differentiating[*] deprotonation,[6]
3) enantiotopos-differentiating[*] deprotonation with chiral, nonracemic base systems.[2, 3]

The diastereotopos-differentiating bromine–lithium exchange on substituted α-dibromoalkanes introduced by R. W. Hoffmann, which is stereochemically related to 2), also leads to configurationally uniform, though till now only racemic, organometallic compounds.[7]

Most important for the success of the reaction is the configurational stability of the organometallic compound under the conditions required for its generation. This requirement necessarily restricts the choice of possible reagents, since resonance-stabilized "carbanions" are configurationally stable only to a certain extent[8] and α-acceptor-substituted, polar organometallic compounds with uniform absolute configuration at the metalated carbon are, as yet, not available in enantiomerically pure form.[9] We describe here one solution, the diastereoface-differentiating transmetalation of configurationally labile, enantiomerically pure, lithiated 2-alkenylsulfoximides **2** to give the enantiomerically pure, configurationally stable (?) 2-alkenyltitanium compounds **3** and **4** (Scheme 1).

Scheme 1. Deprotonation and transmetalation of 2-alkenylsulfoximides.



The required starting material, enantiomerically pure allylsulfoximides **1**, can be prepared in high yield from 4,5-dihydro-1,2λ⁶,3-oxathiazol-2-oxides **5** and *epi*-**5** recently described by us, which itself is available in 70% yield from *O*-trimethylsilylvalinol and *p*-toluenesulfinic chloride (Scheme 2).[10]

Deprotonation of sulfoximides **1** at −78 °C with *n*BuLi generates the configurationally labile lithium compounds **2**, which react with high diastereoselectivity at 0 °C with chlorotris(isopropoxy)titanium[11] to form **3** and **4**. Reaction of **3** and **4** with aldehydes yield the diastereomerically pure γ-hydroxyvinylsulfoximides **6** and **7**, respectively (Scheme 3, Table 1). Workup of the titanium-containing reaction mixture with saturated ammonium carbonate as indicated in Scheme 3 is essential for the successful termination of the reaction. This workup protocol is superior to the alternative method with potassium fluoride solution[12] and is the method of choice for cases in which the usual acidic workup cannot be used because of insufficient product

[a] Determined from the ^{1}H NMR spectrum of the crude product. When no other diastereoisomers could be detected a detection limit of 3% was assumed and the diastereoselectivity *ds* is given as ≥97%. [b] After chromatography on silica gel; pure by ^{1}H NMR spectroscopy.

In order to verify our working hypothesis that the configuration of the products is controlled by diastereoface-differentiating transmetalation of a configurationally labile organolithium compound, the epimeric 1-methallylsulfoximides **8** and *epi*-**8** were prepared as a 50:50 epimeric mixture (determined by ^{1}H NMR spectroscopy) (Scheme 4).

Scheme 4. Allylation and C-methylation of *epi*-**5**.

Remarkably, the opening and C-methylation of the sulfonimidate *epi*-**5** occurs in one step. The lithium compound generated after deprotonation of the allyl derivative reacts exclusively at C1. O-methylated products could not be detected. If the Li compounds generated from **8** or *epi*-**8** are configurationally labile, a stereoconvergent course for the γ-hydroxyalkylation is expected, since after deprotonation the stereogenic center at C1 is destroyed and the same anion is formed from both epimers (Scheme 5).

Scheme 5. Stereoconvergent γ-hydroxyalkylation of methallylsulfoximides **8**/*epi*-**8**.

In accord with this configurational behavior, the expected product **11** was isolated as a single enantiomerically pure diastereoisomer. This result is important not only for our investigations but is also instructive, since quantitative studies of metalated secondary sulfones (i.e. the oxa analogues of the sulfoximides) verify their configurational stability.[9]

Conclusive experimental confirmation of our working hypothesis with respect to the configurational stability of the titanated intermediate is not yet available. However, we assume a configurationally stable titanium compound, since the observed substrate independence of the γ-hydroxyalkylation (see Table 1) is characteristic for a 1,3-chirality transfer. Here the degree of stereocontrol achieved correlates directly with the absolute configuration at C1. If configurational lability were present, then both the imides **1a** and **1b** and their S epimers must be assumed to have an equally high induction for all the chosen aldehydes. This seems hardly likely, as in this case (substrate control) a combination of the C and S chiral centers should determine the stereochemical result of the reaction, and the existence of a "matched" and a "mismatched" combination of these two stereogenic elements would be expected. This, in turn, should lead to higher induction for one series of diastereo-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0445 $ 10.00+.25/0

isomers and lower induction for the other series; however, this is not observed.

On account of the combination of properties of the sulfoximides **1** which at first sight seem incompatible – acidification of protons in the α position by means of an electron acceptor and stereocontrol by electrophilic substitution at a metalated carbon atom of stable configuration – 1,3-chirality transfer to homoallylic alcohols with acceptor-substituted double bonds can be achieved. A series of subsequent reactions are then possible which rely on the one hand on the electron deficiency of the acceptor-substituted double bond (e.g. Diels–Alder reactions) and on the other hand on the carbanion-stabilizing effect of the sulfoximide group (e.g. "Michael" additions at C2).

The titanated sulfoximides **3** and **4** may serve as asymmetric allyl transfer agents which, on account of their structure, allow functionalizations of the initial product of their addition to aldehydes, which are not necessarily possible with alternative allyl transfer agents.[14]

We are conducting NMR experiments to obtain detailed information about the structure and dynamics of the metalated intermediates.[15] We are interested most of all in the configurational behavior of the organometallic compounds so that the stereochemical course of the reaction can be explained even without a model of the transition state. Preliminary results of the NMR determination of relative configurations, which were made without prior assumptions about the conformational preferences of the system under study, will be reported in one of the next issues of this journal.

Experimental Procedure

A solution of 0.267 g (0.755 mmol) *epi*-**1a** in 3 mL of dry THF was cooled to −78 °C under argon and allowed to react with 1.1 equiv *n*BuLi (1.6 M in hexane). After 15 min, 1.2 equiv $ClTi(OiPr)_3$ was added. After 5 min the mixture was warmed to 0 °C, stirred for 55 min, and finally cooled again to −78 °C at which point 2.0 equiv of 2-methylpropanal was added dropwise over 15 min. The reaction mixture was then poured, with vigorous stirring, into a saturated solution of $(NH_4)_2CO_3$ (20 mL). After 30 min the mixture was extracted with ether, and the organic phase was dried over $MgSO_4$. The crude product was dissolved in 4 mL of THF, and 1.2 equiv of nBu_4NF (1.1 M in THF) was added dropwise at 0 °C. After 15 min the mixture was poured onto ice and extracted with ethyl acetate. The organic phase was dried over $MgSO_4$, and flash chromatographed on silica gel (eluent: ethyl acetate/hexane) to provide 0.299 g (0.648 mmol, 86%) **7b** as a colorless oil.

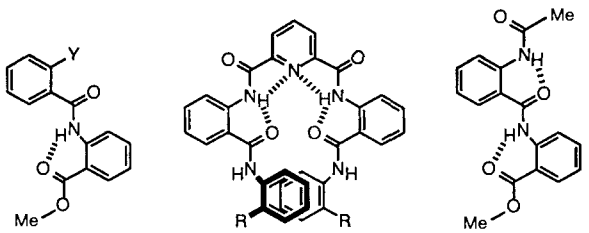
Novel Molecular Scaffolds: Formation of Helical Secondary Structure in a Family of Oligoanthranilamides**

Yoshitomo Hamuro, Steven J. Geib, and Andrew D. Hamilton*

The two most important secondary structural features in polypeptides are α helices and β sheets.[1] These form the ordered molecular scaffolding in proteins to which less repetitive catalytic or recognition elements are linked. A critical role in stabilizing both α helices and β sheets is played by intramolecular hydrogen bonds from one amide group to others further along the chain. As part of our work on molecular recognition, we wondered if a biomimetic approach might be applied to the design of novel scaffolds with well-defined and compact conformations.[2, 3] In this paper we report that a simple combination of anthranilamide[4] and 2,6-pyridinedicarboxamide derivatives (shown in **1** and **2**, respectively) can lead to molecules that take up a helical secondary structure stabilized, in part, by hydrogen bonding between the components.[5]

1



2, X = N, $N^- — O^+$

These individual subunits can be readily linked by a series of simple synthetic transformations. Treatment of 2-nitrobenzoyl chloride with methyl anthranilate gave **3**, which was converted by catalytic hydrogenation to aminoamide **4** and then treated with 2,6-bis(chloroformyl)pyridine to give **5a**.[6] Our expectation was that **5a** would take up a helical structure, as depicted in **5a** and **7** (≡ **5a**), in which the terminal anthranilamide rings overlap each other in a face-to-face arrangement.[7, 8] This struc-

ture should be stabilized by intramolecular hydrogen bonding[9] and $\pi-\pi$ stacking between the subunits as well as the normal preference for secondary benzamides to take up a *trans* conformation with only a small deviation from planarity.[11]

7, R = CO_2Me (≡ **5a**)

8, R = CO_2Me

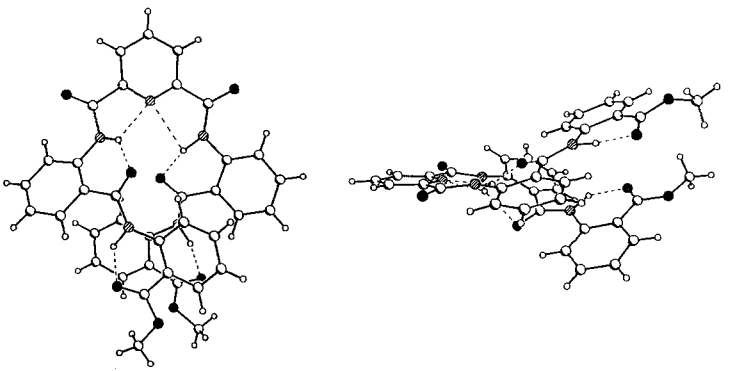
The ^1H NMR of **5a** in $CDCl_3$ shows several features consistent with a helical structure in solution, and these are collected in Table 1 together with data from model compounds **6** and **8**.

Table 1. Selected ^1H NMR chemical shifts [δ] of oligoanthranilamides **5a**, **6**, **8**, and **9** in $CDCl_3$ (all spectra measured for 2 mM solutions except that of **8** which reached saturation at <1 mM). Ph_a and NH_a refer to those groups adjacent to the pyridine, and Ph_b and NH_b to the terminal anthranilamides.

Cmpd.	NH_a	NH_b	Ph_a6H	Ph_a5H	Ph_a4H	Ph_a3H	Ph_b6H	Ph_b5H	Ph_b4H	Ph_b3H
5a	13.08	11.60	7.58	7.22	7.63	8.88	7.90	6.89	6.70	8.50
6	11.17	12.05	7.87	7.24	7.54	8.67	8.11	7.18	7.64	8.78
8	9.72	12.12	8.18	8.18	8.00	8.00	8.11	7.14	7.63	8.95
9	13.80	11.78	7.86	7.35	7.58	8.60	7.91	6.92	7.27	8.88

The large downfield shift of the pyridinecarboxamide proton NH_a in **5a** compared to the equivalent resonances in **6** and **8** indicates bifurcated intramolecular hydrogen bonds involving both pyridine N and carbonyl O atoms as acceptors. In contrast, the signal for NH_b as well as those for the protons in the 6-, 5-, 4-, and 3-positions of the terminal anthranilamides are shifted upfield ($\Delta\delta$ = 0.45, 0.21, 0.29, 0.94, and 0.28, respectively) compared to the corresponding signals in **6**, consistent with their position above the ring current of the opposing anthranilamides in a helical conformation (see **5a**/**7**).[12] Further support for the role of intramolecular hydrogen bonds in stabilizing this conformation comes from the temperature dependence of the amide NH resonances in 20% [D_6]DMSO/$CDCl_3$ (DMSO = dimethyl sulfoxide). Both the NH_a and the NH_b signals in **5a** show a small variation with temperature (3.0×10^{-3} and 1.5×10^{-3} ppm K^{-1}, respectively), as expected for amide NH groups forming intramolecular H bonds in a polar solvent.[13] As a comparison, the signal for the anilide NH proton in **5b**, which is incapable of intramolecular hydrogen bonding, shows a large upfield shift with increasing temperature (7.1×10^{-3} ppm K^{-1}), while the NH_a resonance undergoes little change (2.1×10^{-3} ppm K^{-1}).

Tetraamide **5a** maintains its helical conformation in the solid state. X-ray analysis of a crystal of **5a** (grown from $CHCl_3$/hexane) shows a distinct helical arrangement of the five rings stabilized by six intramolecular hydrogen bonds (Fig. 1; $NH_a\cdots N$, 2.20 and 2.22 Å;[9] $NH_a\cdots OC$, 2.00 and 1.62 Å; $NH_b\cdots OC$, 1.64 and 1.67 Å). The pitch of the helix is narrow with close contact between the terminal anthranilamide rings and a distance of only 3.69 Å from Ph_bC2 to $Ph_b'C2$. As a result Ph_b4H is positioned above the first anthranilamide ring (Ph_a), suggesting an explanation for the large upfield shift of its ^1H NMR resonance in solution (Table 1).[14] Figure 1 shows the right-handed helix; however, the crystal is racemic with both right- and left-handed forms present in the unit cell.



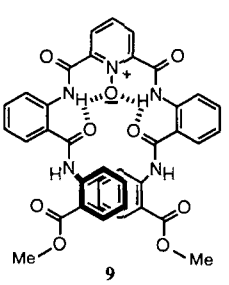


Fig. 1. X-ray structure of the helical oligoanthranilamide **5**. Left: front view; right: side view.

Subtle modifications can be made to the secondary structure by converting pyridinedicarboxamide (**5a**) to its *N*-oxide derivative as in **9**.[15] This leads to strong intramolecular hydrogen bonds completing six-membered rings in the turn region with a resultant expansion of the helix. Figure 2 shows the X-ray structure of **9** and confirms the persistence of the intramolecular hydrogen bonding motif despite changes in the components. Two short ($NH_a\cdots ON$, both 1.83 Å) and two long ($NH_a\cdots OC$, both 2.13 Å) hydrogen bonds enforce the helical conformation in the turn region, with two additional interactions ($NH_b\cdots OC$, both 1.81 Å) in the terminal rings. However, the increased steric bulk of the pyridine *N*-oxide unit relative to that of the simple pyridine in **5a** leads to a wider separation of the two terminal anthranilamide rings (Ph_bC2 to $Ph_b'C2$ distance 9.24 Å in **9**) and an increase in the pitch of the helix.[14] The expanded helical structure of **9** is also reflected in its ^1H NMR spectrum in $CDCl_3$ which shows (Table 1) large downfield shifts of the NH_a and NH_b resonances, similar to **5a** and consistent

9

with strong intramolecular hydrogen bonding, but much smaller upfield shifts of Ph_b4H and Ph_b5H due to reduced ring current effects.

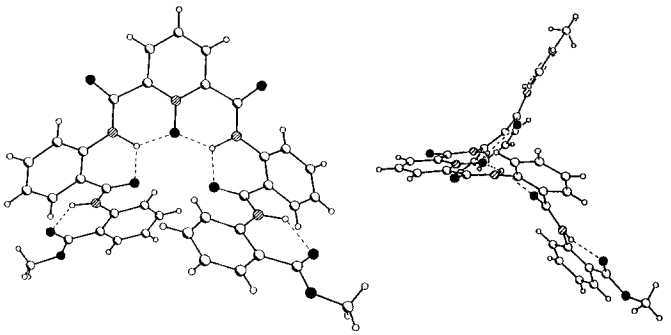

Fig. 2. X-ray structure of **9**. Left: front view; right: side view.

In summary, we have shown that a very simple series of anthranilic acid based subunits can be induced to take up, in both the solution and solid state, a helical secondary structure stabilized in part by intramolecular hydrogen bonding. We are currently preparing extended and substituted versions of these scaffolds to test the generality of the approach.

[9] The intramolecular hydrogen bonds of the simple 2,6-pyridinedicarboxamide forming five-membered rings are expected to be weak due to the reduced basicity of the pyridine [10]. However, the conformation shown in **5a** is still expected to be favored, since the alternative (nearly planar) conformations, involving $\approx 180^\circ$ rotation about one or both pyridine–CO bonds, should be destabilized by electrostatic repulsion between the pyridine N and carbonyl O atoms.

Generation of the Parent Allyl Cation in a Superacid Cryogenic Matrix**

Peter Buzek, Paul von R. Schleyer,* Hrvoj Vančik, Zlatko Mihalic, and Jürgen Gauss

Although many substituted allyl cations have been observed as persistent species in superacid media,[1] the parent allyl cation (**1**) has remained elusive. The putative ^{1}H NMR spectrum was reported in the early days of superacid chemistry,[2] but this observation has not been cofirmed. Numerous subsequent attempts to obtain ^{1}H and ^{13}C spectra of **1** failed.[3] Evidently, the allyl precursors polymerized instead.

The direct observation of **1** in condensed phases is quite challenging, as this allyl cation is about 6 kcal mol^{-1} less stable thermodynamically[5] than the isopropyl cation, 2-$C_3H_7^+$, the smallest carbocation persistent in superacid media (Scheme 1).

1

Scheme 1.

While there were earlier indications of the formation of allyl cation intermediates in zeolites,[6] the first direct CP-MAS NMR spectroscopic observation (CP-MAS = *c*ross *p*olarization *m*agic *a*ngle *s*pinning) of **1** adsorbed on H-ZSM-5 zeolite has only just been claimed by Biaglow, Gorte, and White (BGW).[7] They employed allyl alcohol enriched at the hydroxylated carbon with ^{13}C as the precursor and low surface coverage to minimize polymerization. Upon heating, a ^{13}C NMR

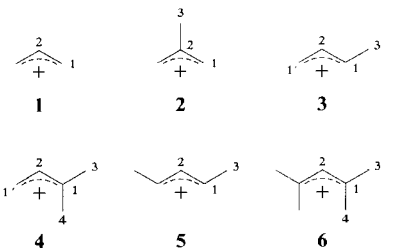
[**] The work at Erlangen was supported by the Fonds der Chemischen Industrie, the Stiftung Volkswagenwerk, the Deutsche Forschungsgemeinschaft, and the Convex Computer Corporation, at Zagreb by the Research Council of Croatia (project: 1-07-226), and at Karlsruhe by the Fonds der Chemischen Industrie. We appreciate the special efforts of Prof. H.-U. Siehl, Martin Fuss, and Bernhard Müller to observe the allyl cation by NMR. Bernd Reindl performed the geometry optimizations for several of the allyl cations in Table 1. In addition, J. G. thanks Prof. Ahlrichs for his generosity and encouragement.

signal at $\delta = 218$ appeared; this was assigned to C1 and C3 in **1**, although other possibilities were discussed. However, this chemical shift does not agree with $\delta(^{13}C) = 245.7$ predicted by Schindler from IGLO chemical shift computations (Basis III level) for carbocations.[8] The chemical shift of $\delta = 218$ is also lower than a rough estimate ($\delta = 236$) based on an extrapolation of the experimental ^{13}C data for the methylene carbons in the 1,1-dimethylallyl ($\delta = 274.3$) and 1-methylallyl ($\delta = 255.1$) cations.[1]

This paper has several objectives. We first analyze BGW's data in light of new theoretical results for the ^{13}C chemical shifts obtained with the recently developed GIAO–MP2[9] method for calculating chemical shifts as a correlated level. These calculations, which are more accurate and reliable than the previous SCF based calculations (IGLO[8] or GIAO–SCF[10]), cast some doubt on BGW's suggestion that the zeolite species was a free allyl cation. We then report our own direct observation of the allyl cation (**1**) by infrared spectroscopy in a cryogenic superacid matrix.



Schindler's IGLO ^{13}C shifts for alkyl-substituted allyl cations[8] deviated significantly from the available experimental values. (The IGLO data in Table 1 have been refined by using the MP2/6-31G* geometries, but do not differ appreciably from Schindler's.) Similar errors in ^{13}C chemical shifts calculated at

[a] All allyl cations were optimized at MP2(FULL)/6-31G*: **4**, **5**, **6** by Bernd Reindl; for numbering of C atoms, see Scheme 2. [b] **1**: [7], **3**: [1g]; **4**: [1f], **5**: [1c]; **6**: [1b]. [c] Averaged values for C1 and C1′ (C_s symmetry).

SCF levels (e.g., IGLO or GIAO) for unsaturated organic compounds are corrected at GIAO–MP2,[9] which includes electron correlation in a practical method for the computation of magnetic properties for the first time. Our recent application to the benzenonium and the phenonium ions demonstrates the decisive improvements that are possible in unsaturated carbocations.[11] The agreement with the experimental data for the set of four methyl-substituted allyl cations included in Table 1 is improved similarly. The ^{13}C chemical shifts at the IGLO–SCF and GIAO–SCF levels differ by an average of $\Delta\delta = 9.2$, and the largest discrepancy is $\Delta\delta = 24$. The GIAO–MP2 performance is superior. With the larger tzp/dz basis set (tzp = triple zeta + polarization, dz = double zeta), the average deviation is reduced to $\Delta\delta = 2.7$, and the largest discrepancy drops to $\Delta\delta = 6$.

Scheme 2. Structures of the allyl cations in Table 1, showing the numbering of the C atoms.

At the higher tzp/dz level, GIAO–MP2 predicts $\delta = 227.4$ for C1 and C3 of the allyl cation. BGW observed a signal at $\delta = 218$ in their solid-state zeolite NMR spectrum.[7] While the difference is not large it is outside the error range found for the other cations in Table 1. The experimental signal may be due to another species, or it may be displaced in the solid state, for example, by complexation of the allyl cation with the zeolite (cf. ref. [15d] for a more extreme example of the effects of complexation on NMR spectra).

The recent development of cryogenic techniques for the determination of the vibrational spectra of carbocations under matrix conditions[12] prompted our reexamination of the problem. Allyl cation formation, rather than polymerization, might be favored under the codeposition conditions, which ensure lower concentrations, and the controlled gradual increase in temperature.

Moreover, computed ab initio IR spectra[13] (see, for example, Table 2 and the simulation in Figure 1 for **1** at CISD/6-31G**) provide a reliable basis for interpreting experimental results. Such theoretical spectra predict that allyl cations have a

characteristic feature: an intense IR absorption near 1580 cm^{-1} attributable to the asymmetric allyl C-C-C stretching vibration. We have reported an intense peak at 1581 cm^{-1} for the *trans*-1-methylallyl cation generated from crotyl chloride under cryogenic conditions.[14a] The MP2/6-31G* computed frequency,[14b] when scaled by 0.94, was 1604 cm^{-1}. Since the harmonic approximation is employed,[13] ab initio frequencies are systematically too high and are scaled to correspond with the anharmonic experimental values (see Table 2). The asymmetric C-C-C stretching vibration of **1** is predicted to be 1592 cm^{-1} (MP2/6-31G*, scaled by 0.94) and 1558 cm^{-1} (CISD/6-31G**, scaled by 0.92).

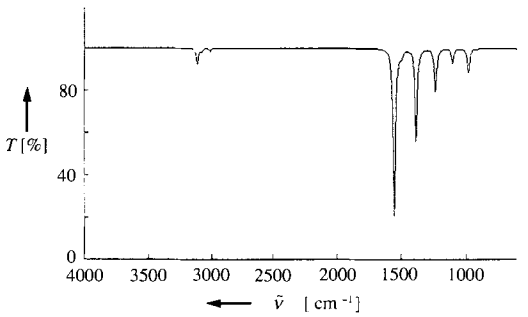

Fig. 1. Simulated IR spectrum of the allyl cation (CISD/6-31G** level).

Different procedures and precursors were employed in attempts to prepare the parent allyl cation (**1**). The most obvious way is to ionize allyl halides directly. In Erlangen, allyl chloride was codeposited with SbF_5 in vacuo on a sodium chloride window at 130 K. Even at that temperature, new signals accompanied the allyl chloride spectrum, which was characterized by the C=C stretching vibration at 1641 cm^{-1}. Further changes occurred on warming to 170 K (Fig. 2a). In particular, two signals at 1577 (the more intense signal) and 1547 cm^{-1} became stronger as the 1641 cm^{-1} peak first diminished and then disappeared. Other changes in the spectrum occurred on further warming, and at 230 K both the 1547 cm^{-1} and the 1577 cm^{-1} peaks are prominent (Fig. 2b). This suggests that the allyl cation formed first (1577 cm^{-1} peak) but then converted to undefined products (1547 cm^{-1}; perhaps polymer) at the higher temperatures. However, since the observed spectra (Fig. 2) have many more peaks than are computed for the allyl cation (Fig. 1), oligomerization or other side reactions must have occurred even at the low temperatures.

Allyl bromide gave analogous results in Zagreb. There was also some evidence for the formation of the allyl cation indirectly from trimethylsilyl propyne codeposited with a HBr/SbF_5 protonation medium. The initial IR spectrum at 77 K (displaying the C≡C stretching frequency of the precursor at 2184 cm^{-1}), underwent a number of changes on warming (details will be reported elsewhere). A transient signal at 2017 cm^{-1} was assigned to the Si–C hyperconjugatively stabilized[15] vinyl cation, $(CH_3)_3SiCH{=}C^+CH_3$. Above 180 K this peak disappeared, but the spectrum, while still indicating some starting material, resembled Figure 2b rather closely. Evidently, β-elimination of the $SiMe_3$ group (presumably as $FSiMe_3$) from the starting material gave propyne, which, at least in part, was protonated immediately in situ, and rearranged to the allyl cation **1**. Nevertheless, attempts to prepare **1** directly by protonating propyne failed to give any promising IR spectra.

In contrast to all these experiments, clean spectra were obtained in Erlangen by using cyclopropyl bromide as a precursor for **1**. Schleyer et al. had shown in 1969 that 1,3-dimethylallyl cations could be generated stereospecifically from the 2,3-dimethylcyclopropyl chloride isomers.[16] Codeposition with SbF_5 at 110 K results in an IR spectrum (Fig. 3a) completely different from the starting material. The prominant signal at 1578 cm^{-1} already had been observed (at 1577 cm^{-1}, Fig. 2) from the reaction of allyl chloride (and allyl bromide) with SbF_5. The intensity of the signals at 1578, 1418, and 1267 cm^{-1} increased when warmed to 140 K (cf. Fig. 3b), but additional peaks at 966 and 901 cm^{-1}, due to some side product also arise. At 250 K, the peak attributable to the asymmetric C-C-C stretching vibration of **1** (1578 cm^{-1}) is almost completely replaced by a peak at 1535 cm^{-1}.

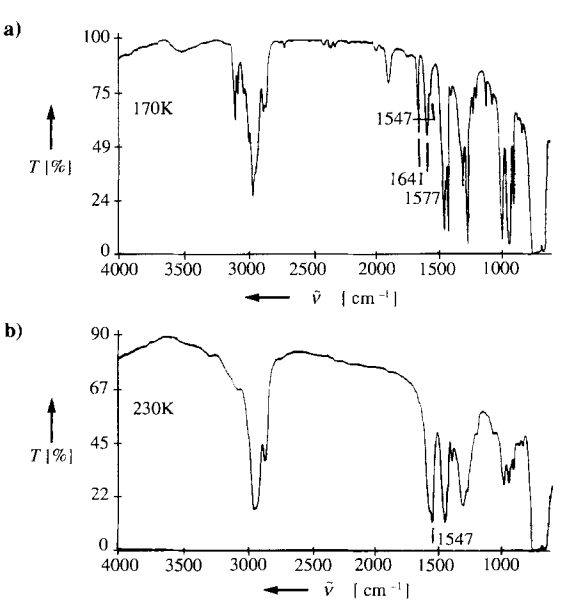

Fig. 2. a) Experimental IR spectrum from allyl chloride in an SbF_5 matrix at 170 K. Note the peak for the allyl cation (**1**) at 1577 cm^{-1}. Some "polymer" is present (e.g. band at 1547 cm^{-1}). b) Final spectrum at 230 K, attributed to "polymer".

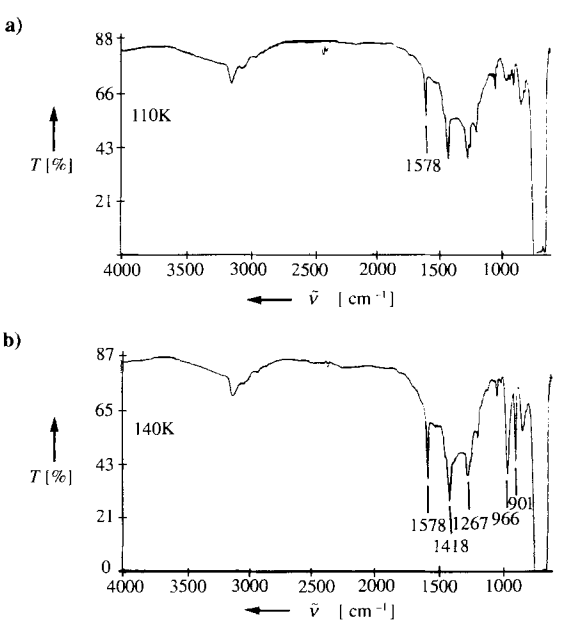

Fig. 3. a) Experimental IR spectrum of the allyl cation (**1**) generated from cyclopropyl bromide in SbF_5 matrix at 110 K. b) The spectrum at 140 K; the new signals at 966 and 901 cm^{-1} are due to side products.

Very good agreement is found between the calculated and experimental frequencies for **1** (Table 2). The graphical comparison (Fig. 4) demonstrates that the experimental frequencies correspond excellently to the calculated values.

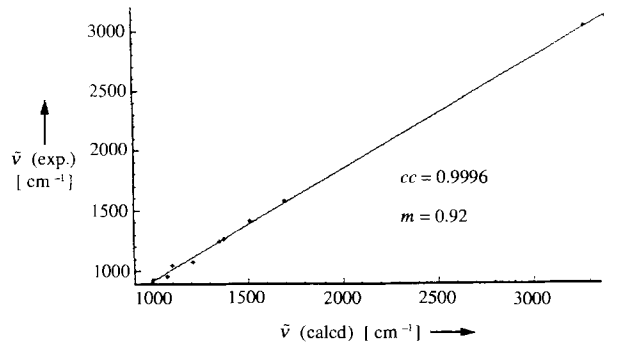

Fig. 4. Correlation of the experimental and calculated (CISD/6-31G**) IR frequencies of the allyl cation **1**. *cc* = correlation coefficient, *m* = slope.

The allyl cation **1** is now the smallest long-lived carbocation observable in a solid SbF_5 matrix. Our findings provide solid evidence that the allyl cation was formed under cryogenic conditions by ionizing cyclopropyl bromide. Unlike the unsaturated precursors of **1**, cyclopropyl bromide evidently does not react with **1** during generation. The IR asymmetic stretching vibration at about 1575 cm^{-1} characterizes **1** as well as allyl cations in general. Although accompanied by side reactions, **1** apparently also formed from allyl chloride and bromide, and possibly from trimethylsilylpropyne as well.[17] BGW's NMR evidence for **1** is equivocal. In light of the difference of $\Delta\delta \approx 10$ in the ^{13}C chemical shifts of the zeolite and the GIAO–MP2 ^{13}C chemical shifts, confirmation is desirable.

[17] It has not been possible to observe the allyl cation by NMR starting with cyclopropyl bromide. New experiments carried out at Tübingen by Prof. H.-U. Siehl, Martin Fuss, and Bernhard Müller using the matrix cocondensation technique (ref. [1g] p. 31) only gave the broad, featureless spectra characteristic of polymers. The ^1H NMR spectra were not clean enough to allow identification of signals expected for the allyl cation. No peak near $\delta = 227$ in the ^{13}C NMR spectrum, as predicted from GIAO-MP2 calculations for **1**, could be detected.

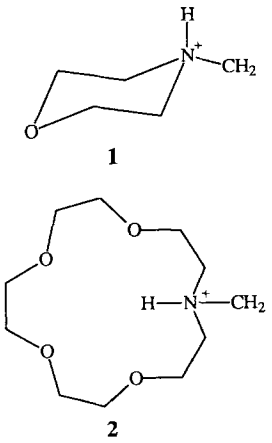
Novel Conjunction of Hetero(macro)cycles and a Pentamolybdodiphosphonate Cage**

Mark P. Lowe, Joyce C. Lockhart,* William Clegg, and Kelly A. Fraser

Macrocycles having separate additional functionality are much sought after for the development of supramolecular chemistry.[1] Polyoxometalates with separate, additional functionality are also in demand in materials sciences for the development of difunctional catalysts[2] and a whole gamut of other applications.[3] The conjunction of these two major areas of current research has been achieved with the synthesis of the first examples of polyoxomolybdate cages derivatized with hetero(macro)cycles. The potential of these novel conjugates for a variety of applications from catalysis to nuclear medicine is under investigation.

Incorporation of the heterocycles as their methylphosphonates was achieved by mixing phosphonate (**1** or **2**) and molybdate according to Equation (a) at pH 2–5. The mixture was

$$2\,[C(NH_2)_3]^+ + 2\,ZPO_3H + 5\,MoO_4^{2-} + 8\,H^+ \rightleftharpoons [C(NH_2)_3]_2[Mo_5(ZP)_2O_{21}] + 5\,H_2O \quad \text{(a)}$$



$Z^+ = \mathbf{1}, \mathbf{2}$

heated to nearly boiling and allowed to cool slowly to give colorless crystals suitable for X-ray crystallography.[4]

Since heterocycle Z has a protonated nitrogen atom, ZPO_3H is a zwitterion. The structure of $[C(NH_2)_3]_2$[**3**] · 3 H_2O consists

of guanidinium cations, water molecules of crystallization and $[(ZP)_2Mo_5O_{21}]^{2-}$ anions **3** (the protonated nitrogen atoms of Z provide two additional internal counterions). Anion **3** lies on a crystallographic C_2 axis passing through Mo3 and O7. Its structure (Fig. 1 and Table 1) is similar to that well known for the $[P_2Mo_5O_{23}]^{6-}$ anion[5] in that it consists of a ring of five distorted MoO_6 octahedra. Four of the octahedra are joined by edge-

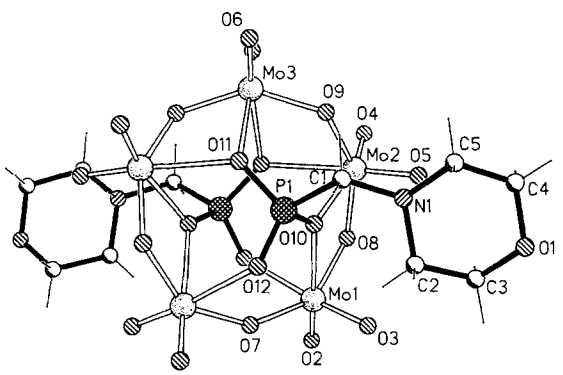

Fig. 1. Structure of the anion **3** in a crystal of $[C(NH_2)_3]_2$[**3**] · 3 H_2O.

sharing oxygen atoms; the ring is completed and the symmetry broken by one corner-sharing oxygen atom between two molybdenum atoms. Two ZPO_3 tetrahedra cap the top and bottom of the ring; one oxygen atom is shared with only one MoO_6 octahedron (the corner-sharing one) and the other two shared with two MoO_6 octahedra each. As a result the ten-membered $(Mo-O)_5$ ring has an envelope-type conformation, whereby one molybdenum atom is bent out of the plane formed by the other four. This is reflected in the Mo-O-Mo bond angles. The angles at the four edge-sharing linkages are roughly 123°, whereas the angle at the shared corner is 148°. Extensive intra- and intermolecular hydrogen bonding is evident throughout the crystal. The morpholine ring bends over the molybdenum cage and its protonated nitrogen atom forms an intramolecular hydrogen bond to a terminal molybdenum oxygen atom (N–H···O = 2.043 Å, angle = 106.4°). This is reflected in the terminal Mo=O bond lengths: Mo–O groups not involved in hydrogen bonding have a Mo=O bond length of 1.700 Å; however, the

[a] Symmetry transformation for primed atoms: $-x+1, y, -z+3/2$.

group forming a hydrogen bond has one of 1.715 Å. Although this difference is hardly significant, the overall pattern of bond lengths for terminal Mo=O bonds in the anion (see below) does show a real correlation with the hydrogen bonding.

The C–H protons of the morpholine ring and of the NCH_2P group are extremely close to the terminal (Mo=O) and bridging (Mo–O–P) oxygen atoms on the adjacent molecule. The O···H–C distances are in the range 2.3–2.5 Å. The guanidinium counterions form hydrogen bonds to the oxygen atoms in the molybdenum cage, the morpholine oxygen atoms, and the water molecules with O···H–N distances of 2.2–2.3 Å. The water molecule, as well as being involved in hydrogen bonding with the previously mentioned guanidinium ions, is also hydrogen bonded to just one terminal molybdenum oxygen atom (Mo3-O6) with O–H···O distances of approximately 2.3 Å. The combination of two water molecules forming hydrogen bonds to this oxygen atom results in an increase in the Mo=O bond length from roughly 1.700 Å to 1.723 Å.

The cage anions were characterized in solution by ^{31}P NMR spectroscopy. Individual species have been assigned in systems of pentamolybdodiphosphonates (and other systems) by Pettersson et al.[6] by using electromotive force (EMF) and spectroscopic methods including ^{31}P NMR. These studies indicate that at defined ratios of P:Mo in defined pH ranges, signals maximize in sequence according with species postulated based on the results of EMF and crystallographic studies.

A selection of ^{31}P NMR spectra at a P:Mo ratio of 2:5 and pH 1–6 (for phosphonates **1** and **2**) is shown in Figure 2. In

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0452 $ 10.00+.25/0

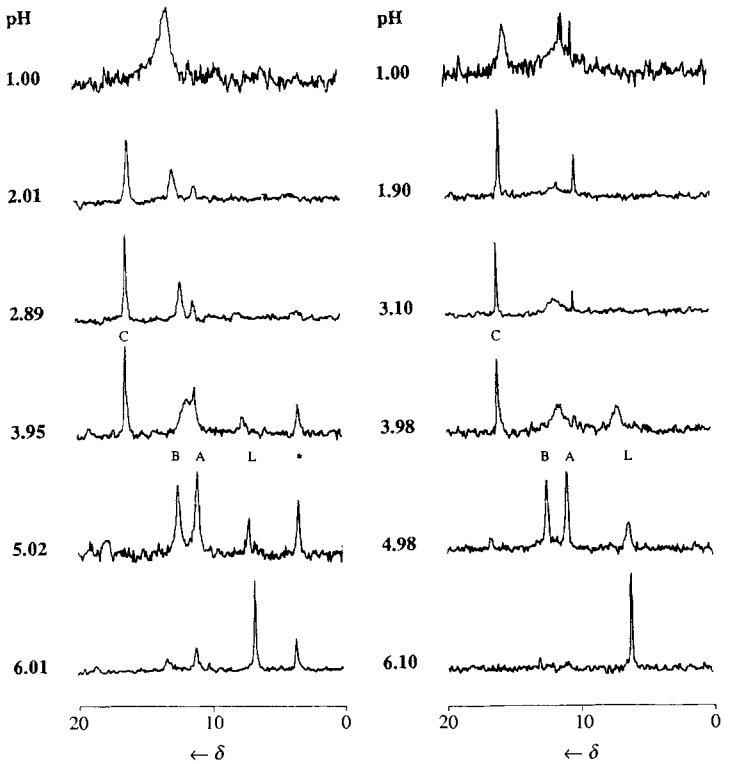

Fig. 2. Change in the ^{31}P NMR signals with pH in mixtures of [**2**] and $[MoO_4]^{2-}$ (left), and [**1**] and $[MoO_4]^{2-}$ (right), in both cases at a ratio of 2:5. Chemical shifts: free ligand L: $\delta = 6.50-7.60$, A: $\delta = 10.95-11.10$, B: $\delta = 11.80-12.80$, C: $\delta = 15.60-17.70$, H_3PO_3 (impurity marked with *): $\delta = 3.30-3.50$.

addition to signal L of the phosphonate reagent, which disappeared around pH 3, three prominent signals marked A, B, and C were observed for both phosphonates in the range $\delta = 10.9-11.1$ (A), 11.8–12.8 (B) and 15.6–17.7 (C) within the pH range 1.5–4.5. That signal C pertains to the cage is confirmed for phosphonate **1**: upon addition of guanidinium chloride the salt of anion **3** precipitates and concomitantly signal C disappears

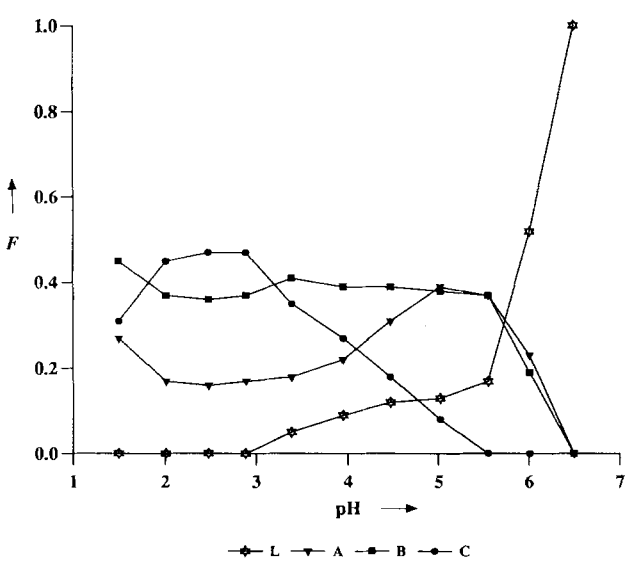

Fig. 3. Mole fraction of phosphorus F (derived from the ^{31}P NMR spectra of ligand **2** by using the relation F = (integral of one P signal)/(total integral of all P signals) for each of the species A, B, C, and L for L = **2** at different pH values.

from the spectrum of the filtrate; however, no attempt was made to observe the reestablishment of the equilibrium. The signals broadened at lower pH values indicating fast exchange processes not quite at the fast-exchange limit on the NMR timescale. Cage rearrangements are a recognized phenomenon in polyoxometalate chemistry and have been studied in much detail by NMR spectroscopic methods.[7]

The plot of signal intensities in Figure 3 indicates that the concentration of the $[(ZP)_2Mo_5O_{21}]^{2-}$ anion should be maximized at pH = 2–3. The plot also indicates (as noted by other workers[8]) that the most abundant species in solution is not necessarily the one that precipitates. Indeed the 2:5 compound is never the most abundant species here. Also clear from the plot is the total incorporation of the macrocycle into some form of molybdenum cluster at pH < 3.

Intramolecular hydrogen bonding between the protonated nitrogen atom of the hetero(macro)cycle and the terminal Mo–O oxygen atom of the MoO_6 octahedra is an integral part of these structures, and the bending of the hetero(macro)cycle to form this hydrogen bond can clearly bring an attached macrocyclic ring and associated metal ions into close proximity to the MoOP cage. Since analogous phosphonomolybdates with rings containing N, S, and O donors have been successfully synthesized in this work, an entire range of metal ions from hard alkali metals to soft thiophiles could be incorporated. In view of the great potential of these conjugates at the interface of two burgeoning fields, we are seeking to extend the range of cages and macrocycles that may be joined, especially by using organic solvents.

Experimental Procedure

All chemicals were obtained from Aldrich except the phosphonic acids, which were synthesized by using modifications to the Moedritzer–Irani reaction [9].

$[C(NH_2)_3]_2$[**3**] · 3 H_2O: $Na_2MoO_4 \cdot 2\ H_2O$ (3.00 g, 12.40 mmol) and the hydrate of ligand **1** (1.00 g, 5.02 mmol) were dissolved with stirring in H_2O (50 mL). Guanidine carbonate (0.70 g, 3.89 mmol) was neutralized with HCl (11.34 M) and added dropwise to the stirred solution. The pH was lowered to 3.5 with HCl (3 M). The white precipitate that formed was redissolved by heating the solution to 90 °C. On slow cooling large colorless crystals formed (yield: 1.1 g, 35%); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 925, 897 [Mo-O(terminal)]; 690 [Mo-O(bridging)], 1151, 1067, 978 (P–O); 1296, 1263 (P–C); correct C,H,N analysis.

NMR Titration of ligand **2** with the molybdate anion: A solution containing $Na_2MoO_4 \cdot 2\ H_2O$ (0.095 g, 0.39 mmol) and the sodium salt of ligand **2** (0.054 g, 0.16 mmol) in H_2O (1 mL) was titrated with HCl (11.34 M). No correction was made for the 7% volume increase during the titration. The ^{31}P NMR spectra of samples were recorded at regular intervals of pH [10]. The resultant spectra are shown in Figure 2, and a plot of the relative intensities of the signals is shown in Figure 3. Corresponding spectra for ligand **1**, shown in Figure 2 for comparison, were obtained similarly by using a solution in H_2O (10 mL) containing $Na_2MoO_4 \cdot 2\ H_2O$ (0.45 g, 1.88 mmol) and the hydrate of ligand **1** (0.15 g, 0.75 mmol).

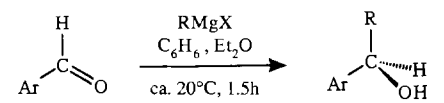
Enantioselective Reactions in a Static Magnetic Field

Guido Zadel, Catia Eisenbraun, Gerd-Joachim Wolff, and Eberhard Breitmaier*



Absolute asymmetric synthesis (AAS)[1] denotes an enantioselective synthesis from achiral starting materials without the help of chiral reagents. An example is the synthesis of hepta- and octahelicenes in circular polarized light with enantiomeric excesses up to 7.3%.[2, 3] Absolute asymmetric synthesis has been discussed as the origin of optical activity in evolution.[4–11]

In 1975 P. Gerike introduced a new absolute asymmetric synthesis.[12] He carried out reactions in electric fields (15–8100 Vcm^{-1}) to which parallel, antiparallel, or orthogonal constant or alternating magnetic fields (8×10^3–1.17×10^5 Am^{-1}, 0–50 Hz) were superimposed. The formation of oxiranes, the addition of bromine to C–C double bonds, and the alkylation of prochiral ketones with Grignard reagents to form secondary alcohols were studied. The enantiomeric excesses amounted to at most 0.94% without preference for either (*R*) or (*S*) isomer. However, the level of enantiomeric excesses contradicts the theoretical prediction of W. Rhodes and R. C. Dougherty[13] that enantiomeric excesses of no more than 3×10^{-5}% should be achievable with magnetic flux densities of up to 1 T. R. C. Dougherty et al. later studied the formation of oxiranes and cyclopropanes at flux densities of "about 1.1 T"[14, 15] without, however, the simultaneous application of an electric field. Instead, they spun the reaction vessel at high speeds (6000–14000 rpm) in order to achieve the desired selectivity with the additional gravitational field.[14] As Gerike had reported, they found an irregular preference for the (*R*) or (*S*) enantiomer (*ee* < 1%), which they traced back to photochemical side-effects (daylight, artificial light), after the influence of the earth's magnetic field had been eliminated by aligning the apparatus with the compass.

Before we were aware of this work we investigated two preparatively versatile reactions in static magnetic fields of varying flux densities. These were the alkylation of aldehydes **1** with alkyl magnesium halides and the reduction of prochiral ketones **2** with complex metal hydrides. The dependence of the enantioselectivity of these reactions on the magnetic flux density was studied.

It was found that a static magnetic field of flux density 0.2–2.1 T was sufficient to achieve considerable enantiomeric excesses in these reactions.[16] Thus the addition of dimethylmagnesium, methyl magnesium iodide, or ethylmagnesium *t*-butylalcoholate to benzaldehyde (**1a**) or naphthalene-2-carbaldehyde (**1b**) in a static magnetic field of flux density 1.2 T leads to (*R*)- or (*S*)-1-phenylethanol (**3a**), -1-(2-naphthyl)ethanol (**3b**), or -1-phenylpropanol (**3c**), respectively, with enantiomeric excesses of 65, 98, and 57%, respectively. The reduction of phenones **2a–c** with lithium aluminum hydride at 1.2 T yielded the (*R*)- or (*S*)-1-arylethanols **3a–c** with similar selectivity (55–98% *ee*). Significantly lower enantiomeric excesses (11%, 2.1 T) were achieved in the reduction of butanone **2d** to give (*R*)- or (*S*)-2-butanol **3d**.

1 **3**

	R	Ar	X	B_0 [T]	*ee* [%]
3a	Me	Ph	I/Me	1.2	65
3b	Me	2-naphthyl	I	1.2	98
3c	Et	Ph	O*t*Bu	1.2	57

2 **3**

	R	R'	B_0 [T]	*ee* [%]
3a	Ph	Me	1.2	67
3b	2-naphthyl	Me	0.4	68
3c	Ph	Et	2.1	55
3d	Et	Me	2.1	11

When the reactions were repeated under the same flux density the enantiomeric excesses were always reproducible, although which enantiomer dominated was unpredictable. However, in the case of the crystalline 1-(2-naphthyl)ethanol (**3b**), we could repeatably demonstrate that by seeding the reaction mixture of **2b** in the magnetic field with the desired isomer of **3b** before the start of the reaction, it was possible to produce the desired isomer. Without the magnetic field the observed enantiomeric excess corresponded to the amount of seed crystals added.[16]

The enantiomeric excesses were determined by specific rotation and also by ^1H and ^{13}C NMR measurements in the presence of tris(3-heptafluoropropylhydroxymethylene)-D-camphoratoeuropium(III) or -praseodymium(III) as chiral shift reagent (Fig. 1). The absolute configurations of the products were determined by comparison with the known, published directions of rotation. As shown in Figure 2 the enantiomeric excess increases steadily with the magnetic flux density B_0 within the field range investigated so far.

No Enantioselective Reactions in a Static Magnetic Field

Based on part of the PhD thesis by G. Zadel (completed 1993) and parallel investigations by Catja Eisenbraun the communication "Enantioselective Reactions in a Static Magnetic Field" appeared under my auspices together with G. Zadel, C. Eisenbraun, and G. J. Wolff in this journal (*Angew. Chem.* **1994**, *106*, 460; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 454). Several independent research groups have informed me since that the experiments reported (1,2-addition of Grignard compounds to aldehydes; reduction of prochiral ketones with lithium aluminum hydride), contrary to the results published by us gave no enantiomeric excesses. In light of this I instructed three experienced co-workers from my research group (F. Keller, K. Berlin, and T. Marx) to repeat the most important experiments [reduction of 2-acetylnaphthalene with lithium aluminum hydride to (*R*)- or (*S*)-1-(2-naphthyl)ethanol; 1,2-addition of methylmagnesium iodide to benzaldehyde to give (*R*)- or (*S*)-1-phenylethanol] completely independently from the chief experimentalist (G. Zadel). These co-workers carried out several experiments in Bonn and Karlsruhe, some in my presence but all in the absence of G. Zadel, and could detect no measureable enantiomeric excesses (NMR with $[Eu(hfc)_3]$, GC with β-cyclodextrin, polarimetry). In one case, we were able to prove quite clearly (GC-MS, polarimetry) that the starting solution prepared by G. Zadel for the reduction of propiophenone with lithium aluminum hydride also contained considerable amounts of (+)-1-phenylpropanol in addition to propiophenone. G. Zadel admitted this deception and two other manipulations in front of witnesses. Therefore we must assume that the data in the publication as well as "successful" attempts at reproducing the results by other co-workers in my research group and guest scientists in the presence of G. Zadel came about because of consistent and particularly cleverly disguised manipulations. I therefore wish to disassociate myself and the coauthors C. Eisenbraun and G. J. Wolff from all the experimental results in this publication.

When the reactions were repeated under the same flux density the enantiomeric excesses were always reproducible, although which enantiomer dominated was unpredictable. However, in the case of the crystalline 1-(2-naphthyl)ethanol (**3b**), we could repeatably demonstrate that by seeding the reaction mixture of **2b** in the magnetic field with the desired isomer of **3b** before the start of the reaction, it was possible to produce the desired isomer. Without the magnetic field the observed enantiomeric excess corresponded to the amount of seed crystals added.[16]

The enantiomeric excesses were determined by specific rotation and also by ^1H and ^{13}C NMR measurements in the presence of tris(3-heptafluoropropylhydroxymethylene)-D-camphoratoeuropium(III) or -praseodymium(III) as chiral shift reagent (Fig. 1). The absolute configurations of the products were determined by comparison with the known, published directions of rotation. As shown in Figure 2 the enantiomeric excess increases steadily with the magnetic flux density B_0 within the field range investigated so far.

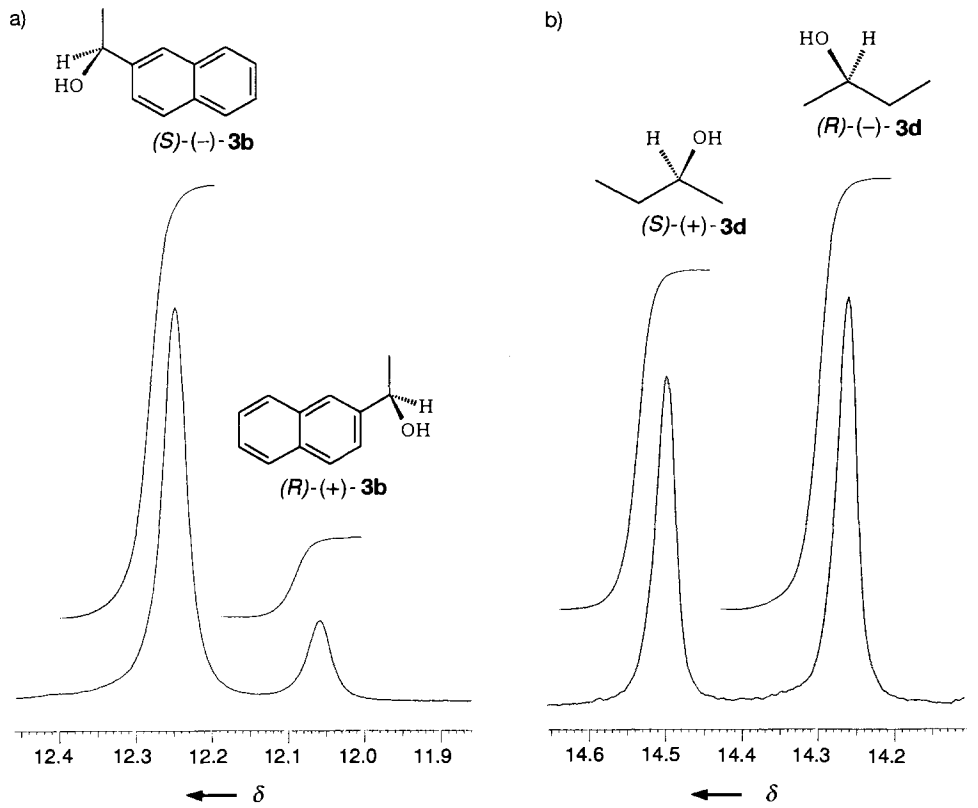

Fig. 1. *ee* Determination with $[Eu(hfc)_3]$. Extreme cases: a) (*R*)- and (*S*)-**3b** from **1b** and methylmagnesium iodide at 0.4 T; ^{1}H NMR signal for the methyl protons (400 MHz): 68% *ee*. b) (*R*)- and (*S*)-**3d** from reduction of **2d** with lithium aluminum hydride at 2.1 T; ^{1}H NMR signal for the C-1 methyl protons (400 MHz): 11% *ee*.

The enantiomeric excesses obtained for 1-arylethanols **3a–c** in the magnetic fields available to us (flux density up to 2.1 T) are comparable to those achieved with other methods of enantioselective synthesis, such as the use of chiral auxiliaries.[17] Substantially less preparative effort, good reproducibility, low cost, and minimal environmental impact make enantioselective reactions in static magnetic fields rather attractive within the preparative scales limited by the size of commercial electro- and cryomagnets.

From the study of further reactions[16] it appears that particularly those reactions between compounds with prochiral polar double bonds and organometallic reagents can proceed enantioselectively in a static magnetic field. On the other hand, the addition of *m*-chloroperbenzoic acid to the nonpolar C–C double bond of styrene (which contains a prochiral C atom) in a magnetic field (up to 2.1 T) yields racemic styrene oxide; similarly the [4 + 2] cycloaddition of methyl acrylate to cyclopentadiene in a magnetic field gives racemic *endo* and *exo* isomers.[16]

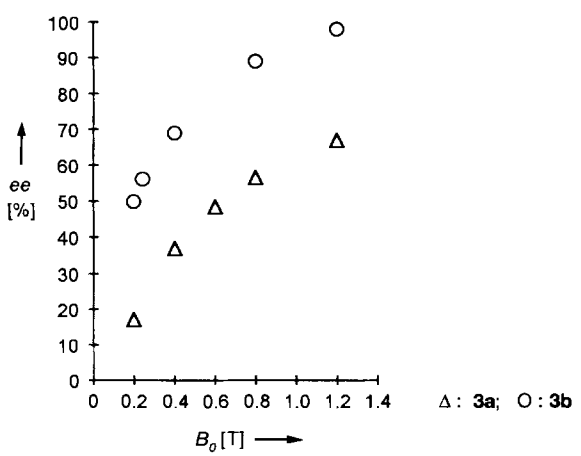

Fig. 2. Enantiomeric excess of **3a** by reduction of **2a** with $LiAlH_4$ and of **3b** by Grignard methylation of **1b** as a function of the magnetic flux density B_0 of the static magnetic field.

The limits of applicability and the elucidation of the mechanism of this asymmetric induction by a static magnetic field requires numerous further experiments. It is unlikely that the precession of polar, prochiral double bonds in a static magnetic field is the (sole) source of the enantioselectivity. The somewhat greater population of the lower energy (and therefore preferred) direction of dipole precession (along and not opposed to the B_0 direction) could indeed cause the *Re–Si* face differentiation necessary for the observed enantioselectivity (accessible side outside, protected side inside the precession cone); however, the difference in populations would fall far short of that required to explain the enantiomeric excesses obtained.[13] Particularly striking are the high enantiomeric excesses of the 1-arylalkanols. The constant dependence of the enantiomeric excesses on the magnetic flux density (Fig. 2) suggests a regularity; understanding this should further promote the development of the method.

Experimental Procedure

1. Arylethanols by addition of organometallic compounds to prochiral carbonyl compounds

A solution of the aromatic aldehyde (**1a,b,c**, 1 mmol) in benzene (0.2 mL) was diluted to a total volume of 4 mL with isoamyl ether at room temperature and transferred to a 50 mL three-neck flask fitted with an inert gas inlet (glass capillary) and reflux condenser. The reaction flask was held in position in the homogeneous region of a regulated electromagnet (7 cm bore). After 5 min a solution of methylmagnesium iodide (1.27 M) in isoamyl ether (1 mL ampule, Merck, was added dropwise over 1 h (for the formation of **3a** and **3b**). For the preparation of **3a** a solution of dimethylmagnesium (1 M) in 1,4-dioxane:tetrahydrofuran (1:1, 1.27 mL) was

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0455 $ 10.00+.25/0

also used. The preparation of **3c** was carried out in the same manner with 1.27 mL of a solution of ethylmagnesium *tert*-butylalcoholate in 1,4-dioxane (1 M). To ensure mixing a slow stream of nitrogen was bubbled through the solution. The reaction was quenched by addition of water (5 mL) and worked up by pouring the resulting mixture into saturated ammonium chloride solution (10 mL). After separation of the organic phase, the aqueous phase was extracted with diethyl ether (3 × 10 mL). The combined organic phases were washed with saturated aqueous sodium bisulfite solution (5 mL) and dried with magnesium sulfate; the solvent was removed under vacuum (18 hPa, 13 Torr).

1-Phenylethanol (**3a**): Yield 56%; b.p. 83 °C (18 hPa); 65% *ee* (NMR) at 1.2 T; $[\alpha]_D^{20} = +29.9$ ($c = 1.08$ in toluene); pure enantiomer: $[\alpha]_D^{20} = \pm 46.3$ ($c = 1$ in toluene).

1-(2-Naphthyl)ethanol (**3b**): Yield 40%; m.p. 68–70 °C; 98% *ee* (NMR) at 1.2 T; $[\alpha]_D^{20} = -36.8$ ($c = 1.24$ in methanol); pure enantiomer: $[\alpha]_D^{20} = \pm 38$ (± 0.5) ($c = 1$ in methanol); for further ee/B_0 pairs see Figure 2.

1-Phenylpropanol (**3c**): Yield 60%; b.p. 96 °C (18 hPa); 57% *ee* (NMR) at 1.2 T; $[\alpha]_D^{20} = +26.8$ ($c = 1.8$ in hexane): pure enantiomer: $[\alpha]_D^{20} = \pm 46$–48 ($c = 2.2$ in hexane).

2. Secondary alcohols by reduction of prochiral carbonyl compounds with complex metal hydrides

Lithium aluminium hydride (0.08 g, 2 mmol) was covered with anhydrous THF (ca. 2 mL). Anhydrous benzene was then added to give a total volume of 6 mL. The apparatus was inserted in the magnetic field; 5 min later the carbonyl compound (**2a–d**, 1.7 mmol in the same volume of benzene) was added dropwise over 1 h. After an additional 15–30 min the reaction mixture was removed from the magnetic field and carefully quenched with water (5 mL). The workup consisted of pouring the reaction mixture into saturated ammonium chloride solution (10 mL), extracting the alcohol with diethyl ether, and drying the solution over $MgSO_4$, and removing the solvent by distillation. For the production of a particular enantiomer of **3b** the reaction mixture was seeded in the magnetic field with 0.04 mmol (7 mg) of the desired isomer before the addition of the carbonyl compound **2b**[16].

3a: Yield 98%; b.p. 83 °C (18 hPa); 67% *ee* (NMR) at 1.2 T; $[\alpha]_D^{20} = +31.4$ ($c = 1.3$ in toluene); pure enantiomer $[\alpha]_D^{20} = \pm 46.3$ ($c = 1$ in toluene); for further ee/B_0 pairs see Figure 2.

3b: Yield 98%; m.p. 68–70 °C; 68% *ee* (NMR) at 0.4 T; $[\alpha]_D^{20} = -25.8$ ($c = 1.3$ in methanol); 52% *ee* at 0.25 T (average of 5 seeding experiments); $[\alpha]_D^{20} = -19.3$ ($c = 1.3$ in methanol); pure enantiomer: $[\alpha]_D^{20} = \pm 38$ (± 0.5) ($c = 1$ in methanol).

3c: Yield 88%; b.p. 96 °C (18 hPa), 55% *ee* (NMR) at 2.1 T $[\alpha]_D^{20} = +25.4$ ($c = 2.1$ in hexane); pure enantiomer $[\alpha]_D^{20} = \pm 46$–48 ($c = 2.2$ in hexane).

3d: Yield 98% (GC); b.p. 99–100 °C, 11% *ee* (NMR) at 2.1 T (average of nine experiments); $[\alpha]_D^{20} = -1.09$ (neat); pure enantiomer $[\alpha]_D^{20} = \pm 10$–12.5 (neat).

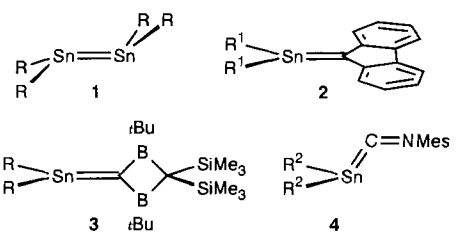
A Stannanediyl with a Tin–Carbon Multiple Bond**



Hansjörg Grützmacher,* Werner Deck, Hans Pritzkow, and Michael Sander

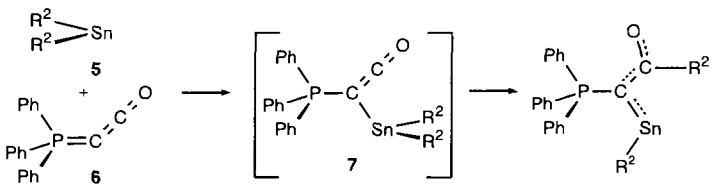
Dedicated to Professor Wolfgang Sundermeyer on the occasion of his 65th birthday

According to a model from Trinquier and Malrieu, the structures of compounds with the formula $R_2X{=}YR_2$ can be correlated with the singlet–triplet excitation energy $\Delta E_{(S\rightarrow T)}$ of diylene, R_2X: (X, Y = C, Si, Ge, Sn).[1] When the relationship $\Sigma\Delta E_{(S\rightarrow T)} < 1/2\,E_{\sigma+\pi}$ ($E_{\sigma+\pi}$ = total bond energy) is fulfilled, "classical" planar molecular structures, such as ethylene, are formed ($\Sigma\Delta E_{(S\rightarrow T)} \approx -20$ kcal mol^{-1}; $1/2\,E_{\sigma+\pi} = 86.6$ kcal mol^{-1}). If, on the other hand, $\Sigma\Delta E_{(S\rightarrow T)} > 1/2\,E_{\sigma+\pi}$, "non-classical" double bond systems are predicted, with the molecular fragments occupying *trans* positions being bent with respect to the plane of the X=Y double bond.[2] The best known example is the distannene **1**, which was investigated by Lappert et al. The R_2Sn molecular fragments in this molecule are bent to the extent of 41°[3] ($\Sigma\Delta E_{(S\rightarrow T)} \approx 45$ kcal mol^{-1}; $1/2\,E_{\sigma+\pi} < 35$ kcal mol^{-1}, calculated values for $H_2Sn{=}SnH_2$[1]).

Investigations on borderline cases, such as compounds with tin–carbon multiple bonds, are particularly interesting. Depending on the substituents, these compounds can belong to either the one double bond type, or the other, due to the weak nature of the tin–carbon bond in stannaethenes, $R_2Sn{=}CR'_2$ (ca. $E_{\sigma+\pi} < 70$ kcal mol^{-1}). These compounds may also, therefore, be considered as carbene-fragment transfer reagents.

The intermediate behavior of stannaethenes has been discussed;[4] however, only a few compounds, such as **2** and **3**, have been isolated, of which the latter was structurally characterized.[4e] The tin–carbon bond in **3** is short, in spite of the severe twisting of the molecular fragments, and has essentially been attributed to electrostatic interactions. We recently described the stannaketenimine **4**, with its considerably bent Sn–C–N arrangement, as being a weakly bonded adduct formed from an isonitrile and a stannanediyl.[5] Both fragments have singlet

R = $CH(SiMe_3)_2$ R^1 = 2,4,6-$iPr_3C_6H_2$ R^2 = 2,4,6-$CF_3C_6H_2$



ground states, so the relationship $\Sigma\Delta E_{(S\rightarrow T)} > 1/2\,E_{\sigma+\pi}$ is satisfied. We have now investigated the reaction of the stannanediyl **5**[6] with the ketene ylide **6**,[7] and are able to report on a new

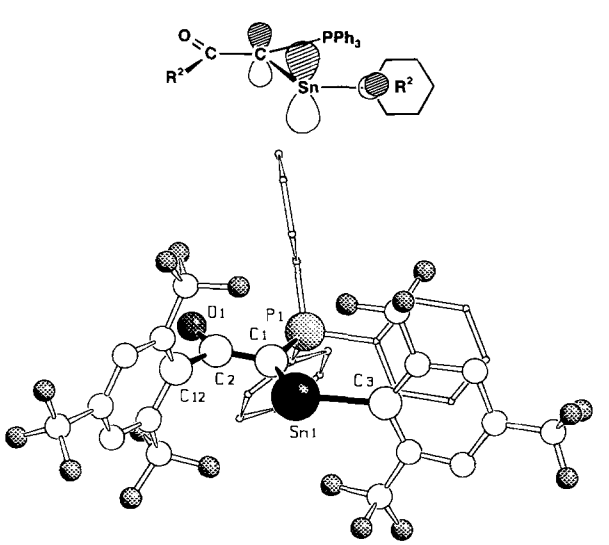
reaction, leading to a product in which a tin–carbon multiple bond can be discussed.

In the reaction of the stannanediyl **5** with the cumulene **6** in toluene, the adduct **7** is formed, in which the ylidic α-carbon atom in **6** is coordinated to the low-coordinate tin atom in **5** (cf. [4b]). In addition, a further product can be detected by NMR spectroscopy, which, after reaction at 25 °C for about 6 h, becomes the main product together with small amounts of various hydrolysis products.[8] In contrast to **7** [$\delta(^{119}Sn) = 121$], **8** is characterized by a ^{119}Sn resonance signal which is strongly shifted down field to $\delta = 932$. This signal is shifted approxi-

mately 250 ppm down field from the signal of the stannanediyl **5**. The molecular peak for *m/z* (**5** + **6**) in the field-desorption (FD) mass spectrum is observed with the correct isotopic distribution. Attempts to crystallize the products were difficult, as very small amounts of impurities, such as those arising from hydrolysis due to the water contained in the glass walls of the reaction vessels,[9] prevented the formation of crystals suitable for X-ray structure analysis. Only after the glass vessels had been treated with hexamethyldisilazane, $HN(SiMe_3)_2$,[10] was it possible to grow crystals of suitable quality. The data set for the determination of the molecular structure of **8** was collected at 173 K in an attempt to limit the disorder of the *para* CF_3 groups.[11] The molecular structure of one of the two crystallographically independent molecules in the unit cell of **8** is shown in Figure 1, and confirms the structure previously assumed. Compound **8** contains a tin atom with coordination number 2 and is formed by a new type of ligand coupling reaction on a tin atom with coordination number 3, in which an aryl substituent, R^2, on the tin atom is transferred to the activated CO group of the ketene **7**.



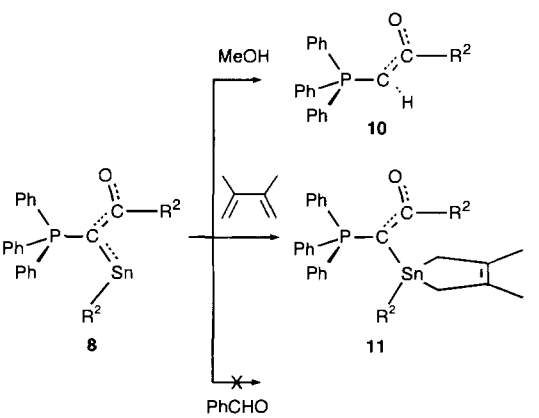


Fig. 1. Molecular structure of one of the independent molecules in **8** (SCHAKAL). Selected distances [Å] and angles [°]: Sn1-C1 2.12(2), Sn1-C3 2.25(2), P1-C1 1.76(2), C1-C2 1.41(2), C2-O1 1.29(2), C2-C12 1.54(2), P1-*ipso*-C(Ph) 1.796–1.835(9), R^2 to Sn1 (C3-C8) 1.37–1.42(3), R^2 to C2 (C12-C17) 1.38–1.45(2); C1-Sn1-C3 108.4(5), P1-C1-Sn1 135.2(8), P1-C1-C2 110.7(11), C2-C1-Sn1 113.3(10), O1-C2-C1 125.3(14), O1-C2-C12 111.5(13), C12-C2-C1 123.1(14).

The tin center in **8** is bonded to two sp^2-hybridized carbon atoms, each of which is part of a conjugated multiple bond system. The atoms C3, Sn1, C1, C2, and P1 all lie approximately in a plane (max. deviations: C3 0.010, Sn1 0.007, C1 −0.068, C2 0.033, P1 −0.010 Å), so that the p orbital functions on Sn1 and C1 have maximum overlap. The aryl ring containing C3 as a ring member, in contrast, is arranged almost perpendicular (96.5°) to this plane. The Sn1–C3 distance [2.25(2) Å] is somewhat shorter than the corresponding distance in the stannanediyl **5** [2.278(5) Å] and lies within the range that we determined for ($R^2_2Sn^{IV}$ compounds [R^2 = 2,4,6-$(CF_3)_3C_6H_2$].[12] The Sn1–C1 bond is only 2.12(2) Å long, however. For the undisturbed Sn=C bond in $H_2Sn{=}CH_2$, a bond length of 1.982 Å was calculated [experimentally determined in **3**: 2.025(4) Å]. The value found in **8** therefore lies between that of a single bond (ca. 2.23 Å) and a double bond. Compound **8** can be compared with the isosteric phosphonio-substituted methylenephosphane **9**, the P–C double bond character of which has been proven.[13] As is the case in **9**, an elongated P1–C1 bond, as compared to that in phosphorus ylides, is also observed in **8** [**9**: 1.788(14); **8**: 1.76(2); ylide: 1.65–1.70 Å[14]]. The P1–C1 bond in **8** is, however, only insignificantly longer than the corresponding distances in stabilized ylides such as **10** (1.73–1.76 Å),[15] and is in this case, therefore, not a suitable indicator for the presence of a Sn=C bond in **8**.

Admittedly, the ^{31}P NMR signal in **8** (22.3 ppm) is observed in a resonance area typical for triphenylphosphonium salts and is clearly shifted down field in comparison to the signal in **10** (δ = 13.9). The C1–C2 distance [1.41(2) Å] and distances within the aryl rings [1.35–1.41 Å] all correspond with the expected values. The C2–O1 bond length [1.29(2) Å] of the carbonyl group is, as expected, significantly longer than the C=O distance found in $H_2C{=}O$ [1.209 Å] and also somewhat longer than that found in stabilized ylides (1.23–1.25 Å).[15] The frequency ν(C=O) in **8** (1525 cm^{-1}) is shifted 30 cm^{-1} to lower wavenumbers than in **10** [ν(C=O) = 1555 cm^{-1}].[16] This observation is in agreement with the formulation of a Sn=C–C=O bonding system, but can also be simply explained, however, by the σ-donor effect of the electropositive tin atom.

The reactivity of compound **8** is similar to that of the stannanediyl **5**: reaction with MeOH leads to cleavage of the

tin–carbon bond, formation of $Sn(OMe)_2$, R^2H, and the ylide **10** in almost quantitative yield.[16] The reaction with 2,3-dimethylbutadiene (DMB) occurs by [1 + 4]cycloaddition to give **11**; a [2 + 4]cycloaddition does not occur (cf. [5]). Compound **8** does not react with aldehydes even at elevated temperatures. Our assumption that there is a tin–carbon multiple bond in the *planar* molecular framework of **8** (P1, C1, C2, Sn1, C12) is largely based on the significant shortening of the Sn1–C1 bond. A shortening of about 0.1 Å for a Sn=N bond in the stannanimine $[(Me_3Si)_2N]_2Sn{=}N(2,6\text{-}iPr_2C_6H_3)$ (**12**) was recently reported by Meller et al, the tin atom having a trigonal-planar coordination.[17] Together with the observations on **3** and **12**, this would seem to indicate that planar multiple bonding systems between the main group *metal* elements of the higher periods and the *nonmetal* elements of the second period may be accessible. In addition, an interesting ligand coupling reaction on a low-coordinate tin atom was observed, which extends still further the synthetic potential of organotin compounds.

Experimental Procedure

8: **5** (2.25 g, 3.3 mmol) and **6** (1 g, 3.3 mmol) were placed in an apparatus consisting of two 100 mL round-bottomed flasks fitted with taps, and connected to each other by a glass frit (GIII). The apparatus was treated with hot $HN(SiMe_3)_2$ prior to use. Subsequently, toluene (20 mL) was condensed into the apparatus and the solution stirred for about 24 h at 25 °C. All volatile components were then removed under vacuum, and *n*-hexane (20 mL) was condensed on to the oily yellow residue. A homogeneous solution resulted temporarily on stirring. Compound **8** precipitated as a finely crystalline product after a short period of time. Further product could be crystallized from the mother liquor at 0 °C. Yield 70–85 %; m.p. 99–103 °C.

10: **8** (1 g, 1 mmol) in toluene (5 mL) was treated with a few drops of MeOH. The reaction solution immediately became colorless and a colorless, finely crystalline precipitate was formed. All volatile components were removed under vacuum and the residue partially redissolved in a small amount of toluene. Insoluble components were filtered off and the filtrate concentrated by evaporation of solvent under reduced pressure. The ensuing oil crystallized over a period of several hours to give beige colored crystals. Yield 85–92%; m.p. 148–150 °C.

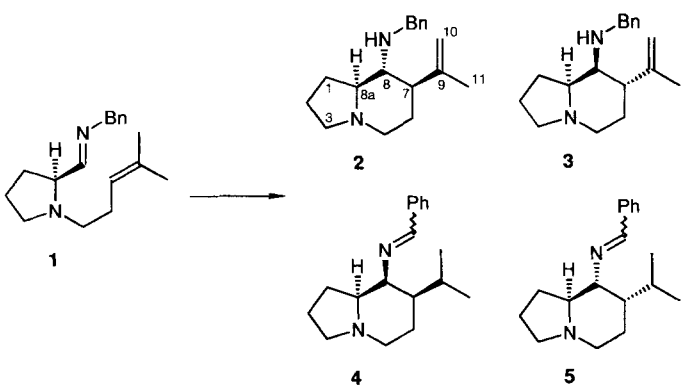
Diastereoselective Synthesis of Amino-Substituted Indolizidines and Quinolizidines by the Intramolecular Hetero-Ene Reaction of Prolinal Imine and 2-Piperidine Carbaldimine**



Sabine Laschat* and Matthias Grehl

Despite its great synthetic potential the hetero-ene reaction of unactivated imines[1–3] has remained relatively unexplored in comparison to the carbonyl–ene reaction[4] which has been investigated intensively for years. In addition, the intramolecular type I imino–ene reaction [5] seems particularly suitable for the synthesis of alkaloids, since in this reaction a ring is formed in one step stereoselectively, and simultaneously two neighboring stereocenters are constructed, to one of which an N atom is bound. We have thus concerned ourselves with the question of the extent to which diastereoselectively substituted indolizidines and quinolizi-

[**] This work was supported by the Alfried-Krupp-von-Bohlen-und-Halbach-Stiftung and the Wissenschaftsministerium Nordrhein-Westfalen (Lise-Meitner-Stipendium for S. L). We thank Dr. Andreas Ruchmann and Karin Busse for their help with the NMR spectroscopic structure investigation.

dines can be constructed with such hetero-ene reactions[6] particularly in view of the fact that a range of these alkaloid derivatives are effective glucosidase inhibitors[7] and are thus of increasing interest because of their Anti-HIV activity.[8] In the following we report on a new intramolecular Lewis acid catalyzed imino–ene reaction for the diastereoselective construction of 7-alkenyl-8-amino-substituted indolizidines and 2-alkyl-1-amino-substituted quinolizidines. In this reaction the relative configuration of the two newly formed stereocenters can be controlled by the choice of Lewis acid. The reaction of (−)-(*S*)-*N*-[*N*-(4-methyl-3-pentenyl)pyrrolidine-2-methylidene]benzylamine (**1**) with $FeCl_3$ affords three stereoisomeric indolizidines in a ratio of 90.3:7.0:2.7 (Scheme 1, Table 1). After chromatographic purification the main

Scheme 1. Cyclization of **1**. Reaction conditions: 2.5 equiv Lewis acid, CH_2Cl_2, room temperature.

Table 1. Reaction of **1** with Lewis acids [a,b].

Lewis acid	*t*[h]	Product ratio [c] 2	3	4	5	Yield [%]
$FeCl_3$	48	90.3	7.0	2.7	–	62 (**2**)
$TiCl_4$	21.5	1.2	3.7	94.7	0.3	45 (**4**)

[a] The reactions were carried out with 2.5 equiv Lewis acid in CH_2Cl_2 at room temperature. [b] Enantiomeric purity of the isolated products **2** and **4**: > 98% *ee*. For the determination of the *ee* values see ref. [9]. [c] Isomeric ratios were determined from the crude products by capillary GC.

product **2** was isolated with an enantiomeric excess of > 98 %.[9] If, however, $TiCl_4$ is used as Lewis acid, the isomeric ratio was altered completely (Table 1), and an additional indolizidine **5** was also formed.[10] As a result of the X-ray structure analysis,[11] product **2** can be assigned unambiguously to the all-*trans* configuration shown in Scheme 1. NMR spectroscopic investigations showed that one benzylideneamino group is bound to the indolizidine framework of **4** at position 8 and one isopropyl group at position 7; however, the unequivocal stereochemical assignment of **4** was only achieved after its transformation into the *N*-acetyl derivative **6** (Scheme 2). For this, first a hydrogenolysis in the presence of $PdCl_2$ was carried out on the imine **4**,[12] the resulting product was then acetylated with acetic anhydride. The vicinal coupling constants for H-8 obtained from the ^1H NMR spectrum of **6** (Table 2) clearly show the all-*cis* arrangement of H-8a, H-8, and H-7. This arrangement was confirmed by a NOESY experiment, in which a nuclear Overhauser effect (NOE) was observed between H-8a and H-8 and also between H-8 and H-7. The application of the same hydrogenation/hydrogenolysis/acetylation sequence on **2** yielded the diastereomeric *N*-acetyl product **7**, whose vicinal coupling constants of H-8 confirm the all-*trans* configuration of **4**. Although, the stereochemical configuration of the two by-products **3** and **5** could not be elucidated unambiguously, the assignment made according to Scheme 1 is supported by the mass spectra of **3** and **5**. The mass spectrum of **3** shows an almost identical fragmentation pattern and comparable intensities to that of **2**; accordingly, the spectrum of **5** is extremely similar to that of **4**. The formation of the products **2** and **3** can

Table 2. Selected spectroscopic and analytical data of the indolizidines.

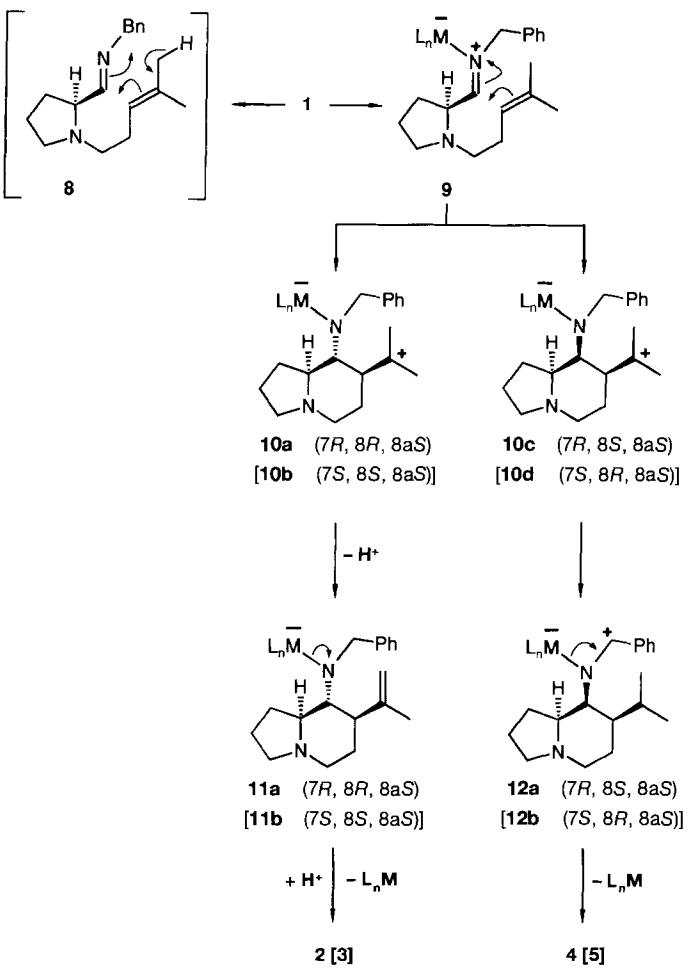
Scheme 2. Synthesis of *N*-acetylindolizidines **6** and **7**. Reaction conditions: a) 1 equiv $PdCl_2$, MeOH, 1 atm H_2, 20 °C, 4 h; b) 1.1 equiv Ac_2O, 3 equiv NEt_3, CH_2Cl_2, reflux, 12 h.

be explained by an intramolecular type I hetero-ene reaction (Scheme 3). An alternative multistep mechanism is also conceivable, in which at first the alkene attacks the initially formed iminium ion **9** leading to the formation of the carbenium ions **10**.[14, 15] Starting from **10** either a reprotonation via **11**, leading to the benzylamines **2** and **3**, or a hydride shift takes place to give the benzyl cation **12**, from which the imines **4** and **5** are formed after the elimination of the Lewis acid. The stereochemistry of the cyclization products **2**–**5** indicates that the competing pathways of reprotonation or hydride shift depend on the relative configuration at C-7/C-8 of the carbenium ion **10**, that is, a hydride shift is only favored when the benzyl and the isopropyl group (C-7/C-8-*cis*) lie in close proximity to each other. However, so far we have not found a reasonable explanation for why the two Lewis acids $FeCl_3$ and $TiCl_4$ react so differently with regard to the stereochemistry of the ring closure. The different coordination geometry of the two Lewis acids cannot be the reason, since other Lewis acids, for example $SnCl_4$, show isomeric ratios comparable to the $FeCl_3$ case. A similar dependence of the diastereoselectivity on the Lewis acid used is also observed for the analogous reaction of racemic piperidine carbaldimine **13** to give the quinolizidines **14**–**16** (Scheme 4). Other products were not observed, and the diastereoselectivities are significantly lower than those for the corresponding indolizidines (Table 3).

Scheme 4. Cyclization of *rac*-**13**. For clarity only one enantiomer of **14**–**16** is shown in each case. Reaction conditions: 2.5 equiv Lewis acid, CH_2Cl_2, room temperature.

Table 3. Reaction of **13** with Lewis acids [a].



Lewis-acid	*t* [h]	Product ratio [b]			Yield [%]
		14	**15**	**16**	
$FeCl_3$	48	71.6	14.8	13.6	68 (**14**)
$TiCl_4$	48	2.0	1.4	96.6	50 (**16**)

[a] Reaction conditions see Table 1, footnote [a]. [b] Compare Table 1, footnote [c].

Regardless of the mechanisms discussed above, the hetero-ene reactions of **1** and **13** described here provide a simple and diastereoselective access to α-amino-functionalized indolizidines and quinolizidines, respectively, which opens new perspectives in natural product chemistry.

Experimental Procedure

To an ice-cooled solution of imine **1** or **13** (1.00 mmol) in dry CH_2Cl_2 (28 mL), Lewis acid (2.5 mmol; $FeCl_3$: 1.0 M solution in Et_2O; $TiCl_4$: 1.0 M solution in CH_2Cl_2) was added dropwise over 30 min, and the resulting mixture was stirred at room temperature. Following complete conversion (GC control) the mixture was hydrolyzed by addition of 2 N NaOH and extracted three times with CH_2Cl_2 (100 mL). After the organic phase had been dried over $MgSO_4$ and concentrated, the crude product was purified by flash chromatography (silica gel, hexane/ethyl acetate/triethylamine 79:16:5).

Scheme 3. Possible reaction mechanisms for the formation of the products **2**–**5**.

Structural Principles in Seven-Coordinate Subgroup Compounds: The Complex Anions MoF_7^-, WF_7^-, and $ReOF_6^-$ **

Steffi Giese and Konrad Seppelt*

It was recently shown that main group molecules or molecular anions like IF_7, TeF_7^-, $ROTeF_6^-$, $(RO)_2TeF_5^-$, and IOF_6^- always form as pentagonal bipyramids.[1–6] This is remarkable considering that the interligand repulsions that result from this special geometry are greater, albeit only slightly, than those arising from the competing capped octahedral and capped trigonal-prismatic geometries.[7] It thus appears that as long as lattice forces or special electronic effects do not influence the structure in some other way, molecules of this type having the coordination numbers (CN) five, seven, and eight will always form the highest symmetry coordination polyhedra of the possible structural alternatives (trigonal bipyramid vs. square pyramid; pentagonal bipyramid vs. capped octahedron; square antiprism vs. trigonal dodecahedron).[8] The highest symmetry may be defined as that which requires the smallest number of parameters for its complete description. In the case of CN = 7 this principle of the highest possible symmetry clearly dominates, and the greater ligand–ligand repulsions of this coordination polyhedron are alleviated through small systematic deviations from the ideal D_{5h} structure ("ring puckering"). As yet, there has been no attempt to transcribe this principle of highest possible symmetry into a unified bonding model.

Is this structure principle also valid for subgroup compounds? Ideally, an accurate structural investigation of a homoleptic neutral compound should be used to approach this problem; the only molecule that comes into consideration here is ReF_7. However, just as with IF_7,[2, 9] the structure of ReF_7 is very difficult to determine experimentally. Electron diffraction investigations suggest a distorted D_{5h} structure.[10] Since the thermal fluctuations of the ligands in molecules with CN = 7 are expected to cause large-amplitude vibrations, no definitive structural information is possible with electron diffraction alone.[9] Because of the existence of several solid phases, including one that is plastic, the crystal structure of ReF_7 has not yet been determined with certainty.[11]

To clarify this problem we have investigated the structures of the anions MoF_7^- and WF_7^-. The influence of the lattice energy on the structures of these anions should be precluded by variation of the countercations. MoF_6 and WF_6 are known to form complexes with fluorides which, according to their elemental analyses, have the compositions MF_7^- and MF_8^{2-} (M = Mo, W).[12] Reliable structure information on these, however, does not exist.

The complexes $Cs^+MoF_7^-$ and $Cs^+WF_7^-$ are formed from the reaction of CsF with an excess of MoF_6 and WF_6, respectively. The colorless salts recrystallize well from acetonitrile. Crystal structure analyses showed that both salts have isotypic structures in which the anions take the form of capped octahedra (Fig. 1). Each anion lies on a threefold axis of the cubic crystal

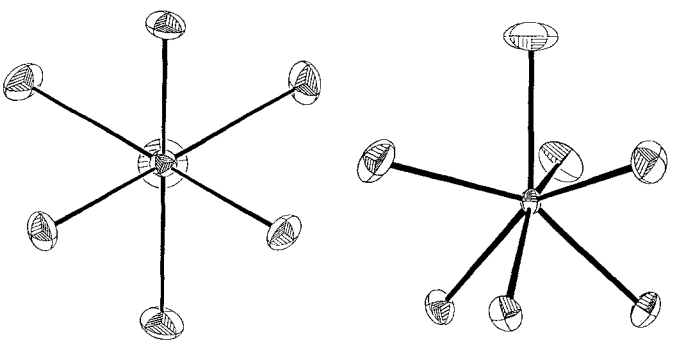

Fig. 1. The structure of the MoF_7^- ion in $Cs^+MoF_7^-$. Left: view along the threefold axis; right: view perpendicular to the C_3 axis (ORTEP representation with thermal ellipsoids at the 50% probability level). The structure of the anions in $Cs^+WF_7^-$ and in the other hexafluoromolybdates(IV) are qualitatively the same.

system which coincides with the symmetry axis of the anion. Thus, the structure of the anion could be dictated by the crystal system itself. To clarify this we synthesized $NO_2^+MoF_7^-$ from the reaction between NO_2F and MoF_6, obtained single crystals, and examined the salt by X-ray crystallography.[13] The compound crystallizes as $NO_2^+MoF_7^- \cdot CH_3CN$. The MoF_7^- ion has

a capped octahedral structure here as well as in $C_{11}H_{24}N^+MoF_7^-$ ($C_{11}H_{24}N^+$ = 1,1,3,3,5,5-hexamethylpiperidinium).[14] Finally, $(CH_3)_4N^+MoF_7^-$ was prepared from $(CH_3)_4N^+F^-$[15] and MoF_6, and its crystal structure determined. Its anion also exhibits a capped octahedral structure, but, as a result of the tetragonal crystal symmetry, a fourfold disorder is observed for the anion. This result is meaningful, since both $(CH_3)_4N^+TeF_7^-$[1] and $(CH_3)_4N^+MoF_7^-$ crystallize in the same space group (*P4/nmm*). The coordinates of the atoms of the cations as well as those of the Te and Mo atoms are identical, but the coordinates of the fluorine atoms differ such that different types of disorder are exhibited; TeF_7^- forms a pentagonal bipyramid and MoF_7^- a capped octahedron. It can therefore be concluded here that neither the lattice type nor the crystal packing have an influence on the different structures of the anions.

Three types of bonds can be distinguished in the capped octahedron: one apical, three equatorial, and three basal bonds. The bonds from the metal center to the equatorial fluorine atoms are always observed to be shorter than those to the other four fluorine atoms (Table 1). If the valence shell electron pair repulsion model is used, the larger ligands in capped octahedral complexes containing different types of ligands in ratios of 3:4 or 1:3:3 should occupy equatorial sites preferentially. Two of the few known examples are the compounds $[MoCl_4\{(CH_3)_2C_6H_5P\}_3]$[16] and $[WBr_3(CO)_4]^-$,[17] assuming that the phosphane and carbonyl ligands require more space owing to the π-bonding part of their M–P and M–CO bonds.

Table 1. Interatomic M–F distances (M = Mo, W) [pm] and F-M-F bond angles [°] in the capped octahedral structures of the MoF_7^- and WF_7^- anions (ap = apical, eq = equatorial, ba = basal).

Cmpd.	M-F_{ap}	M-F_{eq}	M-F_{ba}	F_{ap}-M-F_{eq}	F_{ap}-M-F_{ba}
$Cs^+MoF_7^-$	189.4(9)	185.3(5)	189.8(5)	75.5(2)	131.8(2)
$NO_2^+MoF_7^-$	185.2(2)	183.5(2) [a]	187.3(2) [a]	76.8(1) [a]	132.4(1) [a]
$C_{11}H_{24}N^+MoF_7^-$	184.4(3)	183.3(3) [a]	184.4(4) [a]	75.7(2) [a]	130.0(2) [a]
$Cs^+WF_7^-$	191.0(10)	186.4(5)	189.8(5)	75.5(2)	131.8(2)

[a] Averaged value.

Of course the capped octahedral coordination polyhedron is not rigid. In both compounds the MoF_7^- and WF_7^- anions show a sharp singlet in their solution ^{19}F NMR spectra.

Already when just one bulkier ligand is introduced, the structure principle of a capped octahedron no longer holds; the pentagonal-bipyramidal structure results, since the larger ligand(s) can now coordinate at one (or two) of the axial positions. Exactly this is found in the anion $ReOF_6^-$, as first prepared by us with the complexes $Cs^+ReOF_6^-$ and $NO_2^+ReOF_6^-$. In these salts the anions have a pentagonal-bipyramidal structure, in which the oxygen atom occupies an axial position (Fig. 2). In principle these complexes are similar to the recently prepared IOF_6^- anion; however, the two pentagonal-bipyramidal structures differ upon closer examination. Whereas the axial Re–O bond is considerably shorter in $ReOF_6^-$, the axial and equatorial Re–F bonds are almost of equal length. In addition, the equatorial fluorine atoms are coplanar, in other words the "ring puckering" observed for the pentagonal bipyramids of the main group compounds is not found here (Table 2). These differences can be explained by the size of the rhenium atom. Owing to the longer Re–F bonds, the repulsive forces between the fluorine atoms are so small that an undistorted structure forms in which all the bonds are equivalent. Both IOF_6^- and $ReOF_6^-$ are rigid molecules; a well-resolved AB_6 system is observed in their ^{19}F NMR spectra (Fig. 3), which provides additional qualitative evidence for the correctness of the structure model. The space requirements of the oxygen atom is apparently so large that intramolecular exchange processes are suppressed. The Raman spectrum of the $ReOF_6^-$ anion can also be interpreted based on C_{5v} symmetry in analogy to the spectrum of IOF_6^-.[5]

Table 2. Interatomic distances [pm] and bond angles [°] in the pentagonal-bipyramidal $ReOF_6^-$ anions of the complexes $Cs^+ReOF_6^-$ and $NO_2^+ReOF_6^-$. Two crystallographically distinct anions I and II are found in the latter (ax = axial, eq = equatorial).

	Re-O	Re-F_{ax}	Re-F_{eq}	O-Re-F_{ax}	O-Re-F_{eq}
$Cs^+ReOF_6^-$	167.1(7)	192.3(6)	186.6–190.8(7)	178.0(3)	93.2–94.7(3)
$NO_2^+ReOF_6^-$(I)	165.9(13)	192.7(10)	189.9–191.4(7)	178.0(3)	91.7–94.6(4)
$NO_2^+ReOF_6^-$(II)	162.9(14)	189.4(11)	186.2–191.7(7)	178.4(4)	91.5–95.7(5)

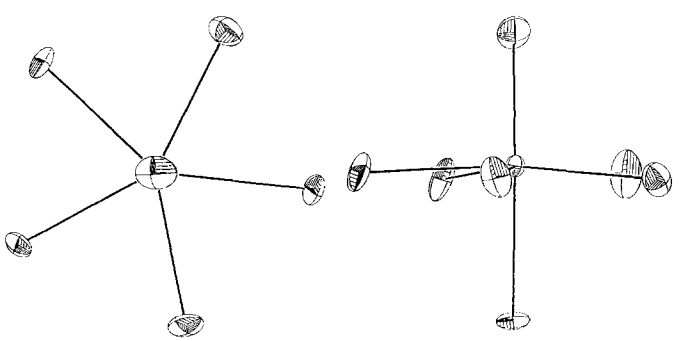

Fig. 2. The structure of the crystallographically distinct $ReOF_6^-$ anion II in $NO_2^+ReOF_6^-$. Left: view along the fivefold axis; right: view perpendicular to the C_5 axis (ORTEP representation with thermal ellipsoids at the 50% probability level). The structure of the $ReOF_6^-$ anion I and that of the anion in $Cs^+ReOF_6^-$ are qualitatively the same.

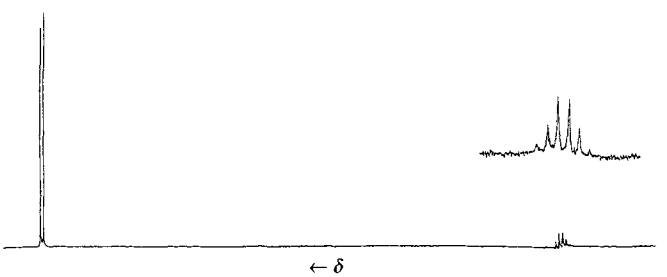

Fig. 3. ^{19}F NMR spectrum of $NO_2^+ReOF_6^-$ in CH_3CN. The signals for the axial and equatorial ligands are observed at δ = 68.44 and δ = −53.35 (J_{FF} = 65.9 Hz), respectively.

Surprisingly, if one introduces a more weakly binding ligand in addition to the six fluorine atoms, as in 2-fluoropyridine·WF_6, a capped trigonal prism is formed in which the nitrogen atom occupies the capping position.[18] This structure is also found in K_2NbF_7 and K_2TaF_7, but strong interionic interactions dominate in these structures.[19]

Experimental Procedure

$Cs^+MoF_7^-$: Powdered anhydrous CsF was treated with a fivefold excess of MoF_6 at 50–60 °C in a perfluoropoly(ethylene propylene) (FEP) reaction tube to give a colorless microcrystalline solid. Unreacted hexafluoride was sublimed off under

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0462 $ 10.00+.25/0

vacuum. Cubic crystals of $Cs^+MoF_7^-$ were obtained from CH_3CN at -40 °C. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 1020.5 (s), 976 (m), 915 (m), 841.5 (s), 682.5 (sst), 427.5 (s, br), 317.5 (s, br). ^{19}F NMR (CH_3CN): δ = 193.1. Correct Cs, Mo, F analyses. Here, and in all further cases, a single crystal was mounted with a special apparatus under nitrogen atmosphere on a CAD-4 diffractometer ($Mo_{K\alpha}$, graphite monochromator) and measured at -145 °C. Crystal structure: a = 102.8(2) pm, $Pa3$ (No. 205), $V = 1167.4(4) \times 10^6$ pm^3, 524 independent reflections with $F \geq 3\sigma(F)$, 29 parameters, R = 0.037, Rw = 0.037.

$Cs^+WF_7^-$ was prepared in analogy to $Cs^+MoF_7^-$. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 984.5 (m), 712 (sst), 439 (s, br), 323 (s, br). ^{19}F NMR (CH_3CN): δ = 143.9. Correct Cs, W, F analyses. Crystal structure: a = 1056.5(4) pm, $Pa3$ (No. 205), $V = 1179(1) \times 10^6$ pm^3, 458 independent reflections with $F \geq 3\sigma(F)$, 29 parameters, R = 0.027, Rw = 0.022.

$NO_2^+MoF_7^- \cdot CH_3CN$: MoF_6 and NO_2F were allowed to react in a 1:1 stoichiometric ratio at -78 °C to yield a colorless crystalline solid. Colorless needle-shaped single crystals were obtained from CH_3CN. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 1022, 686.5 (sst), 662 (ss), 630.5 (s), 514.5 (s), 422.5 (m), 335.5 (s). ^{19}F NMR (CH_3CN): δ = 269.67. Crystal structure $C2/c$: a = 2592.1(3), b = 521.6(2), c = 1420.4(2) pm, β = 116.79(5)°, $V = 1714.4 \times 10^6$ pm^3, 2112 independent reflections with $F \geq 3\sigma(F)$, 136 parameters, R = 0.025, Rw = 0.021.

$(CH_3)_4N^+MoF_7^-$: MoF_6 was condensed into a FEP tube containing a partially dissolved mixture of $(CH_3)_4N^+F^-$ [13] in acetonitrile. After the reaction mixture was allowed to warm to room temperature and the excess unreacted MoF_6 was removed by vacuum sublimation, colorless needle-shaped crystals were obtained by slowly cooling the solution to -18 °C. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 949 (m), 753.5 (m), 679 (sst), 459.5 (s), 429.5 (s), 320 (s, br). ^{19}F NMR (CH_3CN): δ = 204.1. Correct C,H,N,Mo,F analyses. Crystal structure: a = 831.3(2), c = 704.8(2) pm, $P4/mmn$ (No. 129), $V = 487.1(3) \times 10^6$ pm^3, 524 independent reflections with $F \geq 3\sigma(F)$, 33 parameters, R = 0.049, Rw = 0.044.

$(CH_3)_4N^+WF_7^-$ was prepared in analogy to $(CH_3)_4N^+MoF_7^-$. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 983.5(s), 948.5 (m), 753.5 (m), 707.5 (sst), 683.5 (s), 459.5 (s), 322 (s, br). ^{19}F NMR (CH_3CN): δ = 147.6. Correct C,H,N,W,F analyses. Crystal structure: a = 835.1(5), c = 703.6(5) pm, $V = 490.8(4) \times 10^6$ pm^3, $P4/nmm$ (No. 129).

$C_{11}H_{24}N^+MoF_7^-$: 1,1,3,3,5,5-hexamethylpiperidinium fluoride[14] was treated with a twofold excess of MoF_6 in acetonitrile at room temperature. Unreacted hexafluoride was sublimed off under vacuum. The colorless salt crystallized out at -40 °C. ^{19}F NMR (CH_3CN): δ = 272.05. Raman (solid): $\tilde{\nu}$ = 427.5 (s), 570 (m), 676.5 (sst), 785 (m), 902 (m), 964 (m), 1253.5 (s), 1294 (s), 1377.8 (s), 1466 (s). Correct C,H,N,Mo,F analyses. Crystal structure: a = 764.5(3), b = 878.4(2), c = 1234.1(3) pm, α = 89.47(2), β = 75.27(2), γ = 79.83(2)°, $V = 791.0(4) \times 10^6$ pm^3, $P\bar{1}$, 2552 independent reflections with $F \geq 3\sigma(F)$, 253 parameters, R = 0.044, Rw = 0.034.

$Cs^+ReOF_6^-$: $ReOF_5$ (obtained according to the reaction $2ReF_7 + SiO_2 \rightarrow 2ReOF_5 + SiF_4$) was allowed to react with CsF in a 1:1 stoichiometric ratio over 20 h in a FEP tube at 60 °C. Recrystallization from acetonitrile at -40 °C gave pale yellow, single crystals. $Cs^+ReOF_6^-$ also crystallized out of an acetonitrile solution of $Cs^+ReF_8^-$; traces of moisture account for the slow hydrolysis. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 999.5 (m, ν_{ReO}), 697 (m), 683 (sst), 659 (m), 445 (m), 341.5 (s, br). ^{19}F NMR (CH_3CN): δ = 68.80 (d), -53 (st, J_{FF} = 68.4 Hz). Correct Cs,F analyses. Crystal structure: a = 797.1(1), b = 702.2(2), c = 1063.9(3) pm, β = 93.04(2)°, $V = 594.6(3) \times 10^6$ pm^3, $P2_1/c$, 2220 independent reflections with $F \geq 3\sigma(F)$, 82 parameters, R = 0.041, Rw = 0.038.

$NO_2^+ReOF_6^-$: ReF$_5$ was treated with a 2.5-fold excess of NO_2F at -78 °C to give a light yellow salt. After the excess NO_2F was removed under vacuum, the salt was dissolved in a minimal amount of CH_3CN. The solution was cooled to -40 °C, and slow hydrolysis produced single crystals. Raman (solid): $\tilde{\nu}$[cm^{-1}] = 1001 (m), 988 (s, ν_{ReO}), 702.5 (s), 688 (st), 659.5 (m), 644.5 (m), 450 (m), 419 (s), 342 (s, br). ^{19}F NMR (CH_3CN): δ = 68.44 (d), -53.35 (st, J_{FF} = 65.9 Hz). Crystal structure: a = 1210.8(1), b = 1007.9(1), c = 1045.9(1) pm, β = 115.56 (6)°, $V = 1152.7(3) \times 10^6$ pm^3, $P2_1/c$, 2220 independent reflections with $F \geq 3\sigma(F)$, 202 parameters, R = 0.035, Rw = 0.036. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57737.

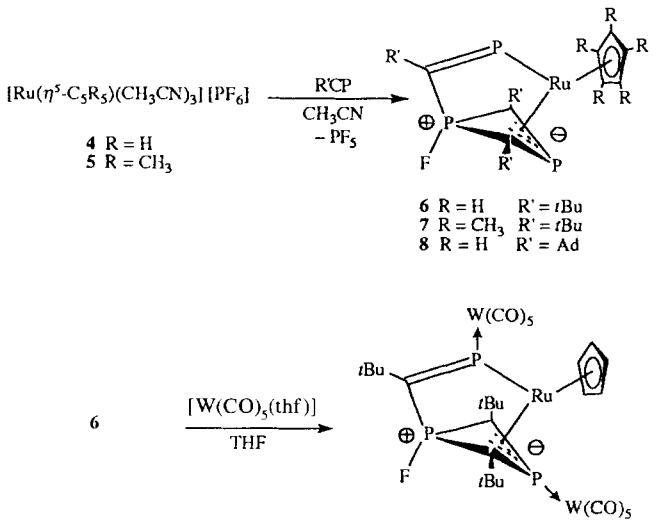
Novel Trimerization of Phosphaalkynes in the Coordination Sphere of Ruthenium Complexes**

Peter B. Hitchcock, Cameron Jones, and John F. Nixon*

Despite the current interest in the oligomerization of phosphaalkynes at transition metal centers,[1] only a few complexes possessing a coordinated trimeric phosphaalkyne unit have been reported. These include the molybdenum complex **1**, which contains a 1,3,5-triphosphabenzene ligand,[2] the vanadium complex **2** with a bound Dewar triphosphabenzene,[3] and the unusual tantalum complex **3**.[4] It should be noted that the proposed

1 **2** **3**



structure of **1** could not be confirmed by independent investigators and therefore must remain tentative. Herein we report a new structural type for trimers of phosphaalkynes, which incorporates the first example of a 2-phosphaallyl fragment that can coordinate η^3 and η^1 to two different metal centers.

Treatment of the ionic ruthenium complexes **4** and **5**[5] with $R'C{\equiv}P$[6] [R' = *t*Bu or adamantyl (Ad)] afforded the neutral

yellow complexes **6**–**8** (Scheme 1) which were purified by recrystallization, or by sublimation (10^{-3} mbar) in the case of **6** and **7** (100 and 130 °C, respectively). At room temperature **6** readily reacts with two equivalents of $[W(CO)_5(thf)]$ yielding **9** as orange crystals.

Scheme 1. Synthesis of compounds **6**–**9**.

From the results of the X-ray crystal structure analysis[7] (Fig. 1), compound **6** can be formulated as possessing a metallophosphaalkene fragment (Ru-P3-C11) which is bound through a fluoro-substituted phosphonium center (P2) to a four-membered P_2C_2 ring. The positive charge on the phosphonium center is balanced by the negative charge delocalized over the atoms C1-P1-C2. This novel 2-phosphaallylic unit can be considered to act as a four-electron donor to the ruthenium(II) center.

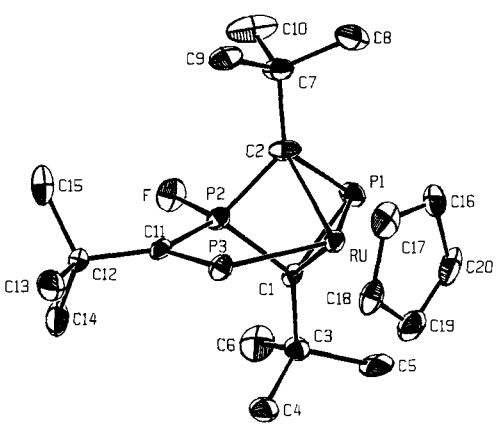

Fig. 1. Molecular structure (ORTEP, 50% thermal ellipsoids) of **6**. Important bond lengths [Å] and angles [°]: Ru-P1 2.323(2), Ru-P3 2.348(2), Ru-C1 2.170(8), Ru-C2 2.187(8), P2-F 1.601(5), P1-C1 1.816(9), P1-C2 1.811(8), P2-C2 1.758(9), P2-C11 1.716(8), P2-C1 1.753(8), P3-C11 1.692(8); P1-Ru-P3 125.0(1), C2-P1-C1 82.1(4), C2-P2-C1 85.5(4), Ru-P3-C11 104.4(3), P2-C1-P1 92.6(4), P2-C2-P1 92.6(4), P2-C11-P3 100.1(4).

Although **6** crystallizes with five independent molecules in the asymmetric unit, there are no significant geometric differences found between them. As a result of the allylic nature of the C1-P1-C2 unit, the four-membered ring is considerably bent, forming a dihedral angle of 25.7(7)° between the two PC_2 planes. This angle compares well with that between the corresponding planes in $[Mo(\eta^5\text{-}C_9H_7)(CO)_2(\eta^3\text{-}t\text{BuCPC}t\text{BuPFBF}_3)]$ (**10**),[8] the only other example of a complex containing a 2-phosphaallylic unit within a P_2C_2 ring. It is noteworthy that uncomplexed 2-phosphaallyl anions are unknown, however, a related 1-phosphaallyl anion was reported very recently.[9] The P3–C11 double bond length in **6** (1.692(8) Å) is close to those in related metallophosphaalkenes.[10] Both Ru–P bonds (Fig. 1) are slightly shorter than the mean Ru–P distance (2.44 Å) in the sandwich complex $[Ru(\eta^5\text{-}C_2t\text{Bu}_2P_3)_2]$.[11]

The solid-state molecular structure of **9**[7] (Fig. 2) retains the same structural features as that of **6**. A crystallographic mirror

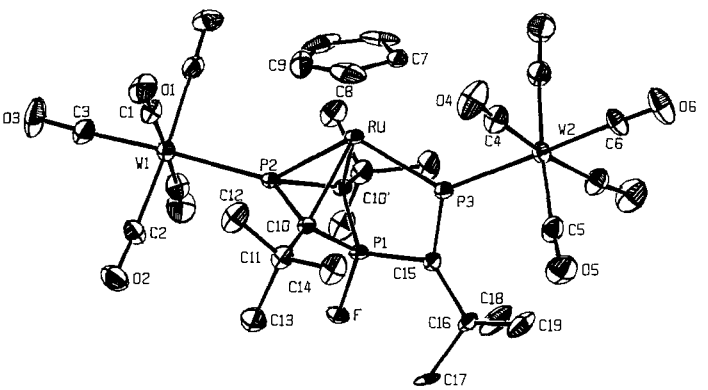

Fig. 2. Molecular structure (ORTEP, 20% thermal ellipsoids) of **9**. Important bond lengths [Å] and angles [°]: Ru-P2 2.310(1), Ru-P3 2.388(4), Ru-C10 2.20(1), W1-P2 2.502(2), W2-P3 2.587(1), F-P1 1.582(5), P1-C15 1.77(2), P1-C10 1.76(2), P2-C10 1.81(2), P3-C15 1.70(1); P2-Ru-P3 123.1(1), P2-Ru-C10 47.3(3), C10-P1-C10' 87(1), C10-P2-C10' 84.0(8), Ru-P3-C15 105.7(8), P2-C10-P1 90.5(4).

plane containing all three phosphorus atoms bisects the molecule. The P3–W2 distance (2.587(1) Å) is significantly longer than the P2–W1 distance (2.502(2) Å), and lies close to the P–W distance known for $[W(CO)_5]$ fragments η^2-bonded to P=C double bonds.[12] The lengthening of the P3–W2 bond probably results from the steric constraints imposed by the proximity of the *t*Bu group at C10′ and the cyclopentadienyl ring.

The results of NMR spectroscopic studies of **6**–**8** are consistent with each having a similar structure in solution as **6** in the solid state. Three inequivalent phosphorus signals are observed in the ^{31}P NMR spectrum of **6** (Table 1). The signal of P3 lies at low field (δ = 559.3) in the region characteristic of metallophosphaalkenes.[10] Similarly, the signal for the P1 atom occurs, as expected, at high-field (δ = −72.6), in the chemical shift range known for η^3-1-phosphaallyls.[13] The multiplet centered at δ = − 50.4 (P2) is, however, upfield of usual monofluorophosphonium ion δ values.[14]

The ^{31}P and ^{19}F NMR spectra provide supporting evidence for the proposed charge-separated structure of **6**. Surprisingly, the $^1J(P,F)$ coupling (1250 Hz) is considerably greater than the expected value (900–1000 Hz) for ions of the type $(R_3PF)^+$ (R = alkyl, aryl).[14] However, the high value in **6** can be explained by the proximity of the electron-withdrawing allylic group to the phosphonium center. Indeed, this coupling constant is nearer to that normally found for halogeno-substituted phosphonium ions (e.g. $[Cl_3PF]^+$ $^1J(P,F)$ = 1296 Hz).[14] Also, the eight line pattern in the ^{19}F NMR spectrum is centered at δ = 0.4, downfield from that normally seen for $[R_3PF]^+$ but close to the region of its halo-analogues (e.g. $[Cl_3PF]^+$ δ = 8.8).[14]

Several changes are seen in the ^{31}P NMR spectral pattern when **6** is complexed to two $[W(CO)_5]$ fragments to yield complex **9**. Significant differences occur in the chemical shifts of all three phosphorus centers, most notably a 115 ppm upfield shift for the metallophosphaalkene phosphorus atom (P3). In addi-

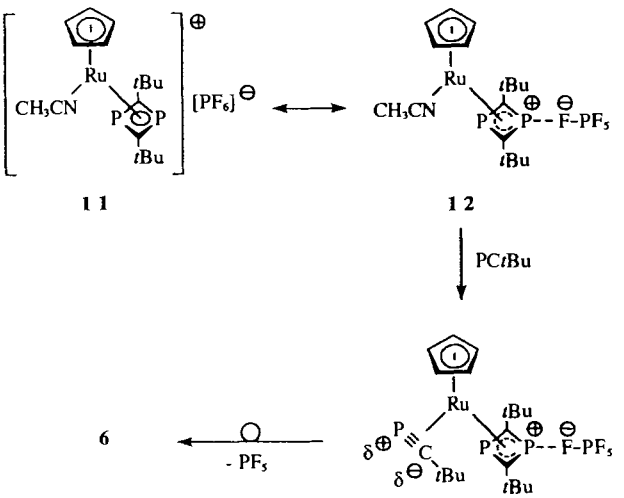
7: ^{1}H NMR: $\delta = 0.63$ (s, 18H, *t*Bu), 1.36 (s, 9H, *t*Bu), 1.92 (s, 15H, CH_3); ^{31}P NMR: $\delta = 52.1$ (ddd, ^1J(P,F) = 1238 Hz, ^2J(P,P) 46, 7 Hz, P2), −49.9 (pseudo-t, ^2J(P,P) = 7 Hz, ^3J(P,F) = 6 Hz, P1), 597.0 (dd, ^2J(P,P) = 46 Hz, ^3J(P,F) = 34 Hz, P3); ^{19}F NMR: $\delta = 0.7$ (ddd, PF).



8: ^{1}H NMR: $\delta = 0.9$–2.4 (m, 45H, Ad), 5.11 (s, 5H, C_5H_5); ^{31}P NMR: $\delta = -76.4$ (dd, ^2J(P,P) = 6 Hz, ^3J(P,F) = 8 Hz, P1), −49.7 (ddd, ^1J(P,F) = 1251 Hz, ^2J(P,P) = 42, 6 Hz, P2), 567.2 (dd, ^2J(P,P) = 42 Hz, ^3J(P,F) = 40 Hz, P3); ^{19}F NMR: $\delta = 4.8$ (ddd, PF).

9: ^{1}H NMR: $\delta = 0.95$ (s, 18H, *t*Bu), 1.50 (s, 9H, *t*Bu), 5.47 (s, 5H, C_5H_5); ^{31}P NMR: $\delta = -39.9$ (ddd, ^2J(P,P) = 5, 14 Hz, ^3J(P,F) = 8 Hz, ^1J(P,W) = 248 Hz, P2), −15.4 (ddd, ^1J(P,F) = 1242 Hz, ^2J(P,P) = 122, 5 Hz, P1), 445.6 (ddd, ^2J(P,P) = 122, 14 Hz, ^3J(P,F) = 22 Hz, ^1J(P,W) = 195 Hz, P3); ^{19}F NMR: $\delta = -15.7$ (ddd, PF); IR(nujol): $\tilde{\nu} = 2078$, 2066, 1952, 1915 cm^{-1} (CO).

[a] ^{1}H (250 MHz, TMS), ^{31}P (101.3 MHz, 85% H_3PO_4) and ^{19}F NMR spectra (75.4 MHz, $CFCl_3$) in $CDCl_3$. The numbering of the atoms corresponds to that in Fig 1 for **6**–**8** and to that in Fig. 2 for **9**.

tion, the P3 center displays a ^2J(P,P) coupling to the allylic phosphorus atom of 14 Hz, whereas the same coupling was not detected in **6**. Both ^1J(W,P) couplings in **9** are unexceptional.

At present we have little evidence to propose a mechanism of formation of **6**. However, it seems likely[15] that in the initial stages of the reaction two molecules of acetonitrile are displaced from **4** followed by a head-to-tail coupling of the coordinated phosphaalkyne molecules to give the cationic η^4-diphosphacyclobutadiene complex **11** (Scheme 2). It is conceivable that a

Scheme 2. Proposed mechanism for the formation of **6**.

shift in the positive charge from the metal center to one phosphorus atom in the C_2P_2 ring would give rise to **12**, which can be considered as containing a phosphenium ion in contact with a $[PF_6]^-$ ion. Precedent for this structure lies with the recently crystallographically characterized complex **10**.[8] Displacement of the remaining acetonitrile ligand from **12** could then promote an attack on the electrophilic phosphenium center by the nucleophilic phosphaalkyne carbon atom, subsequently yielding **6** by abstraction of F^- from the $[PF_6]^-$ ion.

Experimental Procedure

6: To a solution of **4** (0.26 g, 0.6 mmol) in acetonitrile (25 mL) at 0 °C was added *tert*-butylphosphaacetylene (0.5 g, 5 mmol). After 10 h at 20 °C the yellow solution was concentrated under vacuum (10^{-3} mbar) to about 6 mL. Cooling to −30 °C overnight yielded **6** as yellow crystals. Yield: 0.14 g (48%); m.p. 95 °C. Compounds **7** and **8** were prepared by similar procedures; **7**: M.p. 126 °C; **8**: M.p. 143 °C.

9: To a solution of [W(CO)$_5$(thf)] (0.28 g, 0.7 mmol) in THF (50 mL) was added **6** (0.10 g, 0.2 mmol) in THF (8 mL). After 10 h volatiles were removed under vacuum 25 °C/10^{-3} mbar and the brown residue was eluted on a silica gel column (hexane). Concentration of the yellow band under vacuum 25 °C/10^{-3} mbar to about 10 mL gave orange crystals of **9** overnight at −30 °C. Yield: 0.17 g (74%); m.p. 168 °C (decomp).

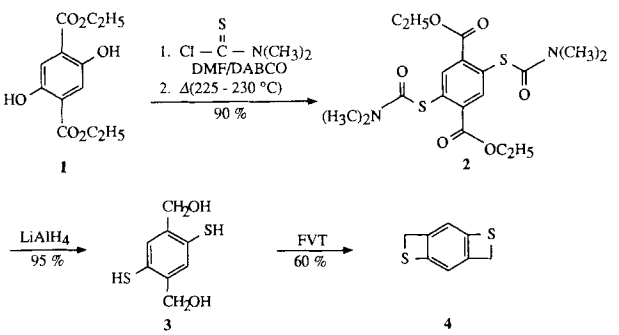
2*H*,5*H*-Benzo[1,2-*b*:4,5-*b'*]bisthiete—A Highly Reactive Bisdiene System**

Herbert Meier* and Axel Mayer

Rigid molecules with two or more 1,3-diene units are of particular interest for the construction of molecular band- and starlike structures by repetitive cycloadditions.[1] The selection of suitable compounds for these reactions, however, is small and is limited still further because of unsatisfactory yields of the pure compounds or because of their low reactivity.



Encouraged by the high reactivity of 2*H*-benzo[*b*]thiete towards a large number of dienophiles and heterodienophiles,[2] we

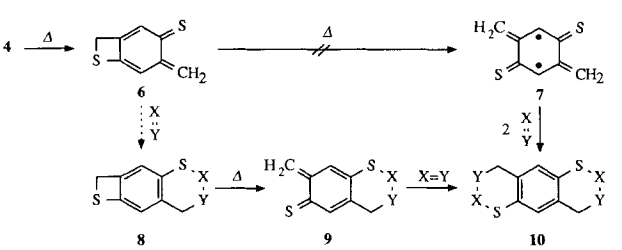
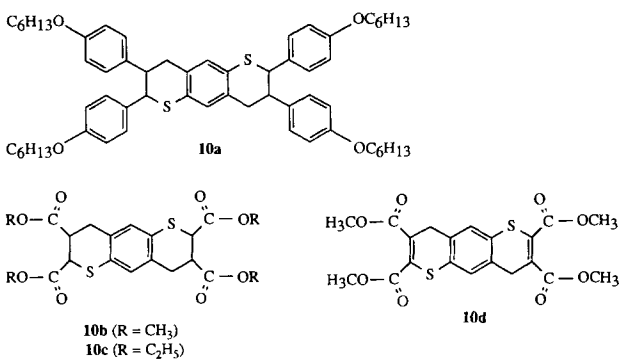
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

set about the synthesis of 2*H*,5*H*-benzo[1,2-*b*:4,5-*b*']bisthiete(4,9-dithiatricyclo[6.2.0.0^{3,6}]deca-1,3(6),7-triene) (**4**).



Diethyl 2,5-dihydroxyterephthalate (**1**) was treated with *N*,*N*-dimethylthiocarbamoyl chloride in the presence of DMF/DABCO at room temperature.[3,4] The resulting double *O*-thiocarbamate was formed in quantitative yield and rearranges by way of a Newman–Kwart reaction[5] into the double *S*-thiocarbamate **2** on heating in diphenyl ether. The reduction of **2** with $LiAlH_4$ affects all four functional groups, and 2,5-dimercapto-1,4-phenylenedimethanol (**3**) is obtained in 95% yield. The desired compound **4** is obtained from this by flash vacuum thermolysis (FVT);[6] **4** is a colorless solid that decomposes above 160 °C with deflagration.[7]



The four-membered ring of the 2*H*-benzo[*b*]thiete can be readily opened thermally or photochemically. This leads to a highly reactive 8π-electron system. In the absence of reaction partners the thermal reaction results in a dimerization ([8π + 8π] cycloaddition) to give 6*H*,12*H*-dibenzo[*b*,*f*][1,5]dithiocin.[2] Under these circumstances a polymer is formed from **4** which has the band structure **5**. Disulfide bridges can be excluded. The IR spectrum (in KBr) reveals a saturation of the chain ends by the trace amounts of water present. Small quantities of higher cyclooligomers can also form from benzo[*b*]thiete[2]—a variant which will be investigated for **4** in more detail.

With 2π components X=Y compound **4** undergoes the reaction sequence **4** → **6** → **8** → **9** → **10** which is composed of alternating ring-openings and [8π + 2π] cycloadditions. A double ring opening **4** → **6** → **7** can be excluded for the thermal reaction (toluene, 90 °C). (However, the high-energy diradical **7** or the corresponding bicycle 3,6-dimethylenebicyclo[2.2.0]hexane-2,5-dithione might be realizable by photochemical ring-opening with intensive laser light).

Even fairly unreactive components X=Y such as (*E*)-stilbenes add smoothly to **6** and **9**. The 2:1 adduct **10a**[8] is formed from **4** and (*E*)-1,2-bis(4-hexyloxyphenyl)ethene in 40% yield. Similar reactions of **4** with dimethyl fumarate and diethyl maleate lead to **10b**[9] (≥ 90%) and **10c**[10] (68%), respectively. The investigation of the stereochemistry of **10a–c** always reveals a *trans* position of the substituents on the thiopyran rings; that is, cycloadducts with *trans* configuration are formed from the (*E*)-configurated olefins as expected; however, from the (Z)-configurated dimaleate, the di-*trans* adduct with high stereoselectivity is formed in addition.[11] The stereogenic centers of **10a–c** do not show any observable interaction over the benzene ring, that is, the di-*trans* products are composed of 1:1 distributions of one chiral C_2 and one achiral C_i configuration each.[12]

The 2:1 adduct **10d**[13] (68%) is isolated with dimethyl acetylenedicarboxylate. Furthermore, the crude product of this reaction contains cycloadducts, whose compositions correspond to alkyne:benzobisthiete ratios of 2:2, 2:3, and 3:3, which confirms the construction of band structures.

Moreover, as a result of the extremely high reactivity of benzothiete with almost all double bond systems (C=C, C=N, C=O, N=N, N=O, etc.),[2] the bisthiete **4** is of interest for thermal and photochemical cross-linking of polymers.

The carbocyclic system analogous to **4**, tricyclo[6.2.0.0^{3,6}]deca-1,3(6),7-triene, synthesized for the first time by Cava et al.,[14] has a very much higher activation energy for opening the four-membered ring and is hardly suitable for repetitive cycloadditions. From the pyrolysis under optimized conditions[15] it forms "belt structures", whose occurrence has so far not been confirmed for **4**.

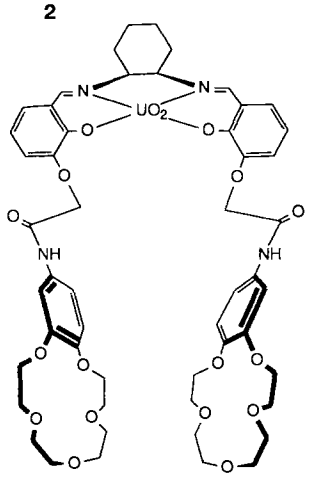
A Difunctional Receptor for the Simultaneous Complexation of Anions and Cations; Recognition of KH_2PO_4

Dmitry M. Rudkevich, Zbigniew Brzozka, Marcin Palys, Herman C. Visser, Willem Verboom, and David N. Reinhoudt*



The design and synthesis of neutral macrocyclic receptors that selectively complex cations in apolar solvents rests on their ability to arrange their nucleophilic binding sites (Lewis-basic oxygen atoms of crown ethers etc.) in an array complementary to the cation.[1] Similarly macrocyclic and acyclic ligands that contain Lewis-acidic binding sites like boron, silicon, tin, and mercury centers complex anions, but the selectivity is not simply introduced.[2] Recently Reetz et al.[3] reported on a heterotopic receptor which, in addition to a crown ether moiety for complexation of K^+ ions, contains a σ-bonded Lewis-acidic boron center that is able to form a tetracoordinated adduct with anions and binds F^- ions selectively.

Recently we showed that neutral metalloclefts and metallomacrocycles containing both immobilized Lewis-acidic UO_2^+ centers and amido units as additional binding sites are excellent receptors for anions with a high selectivity for dihydrogen phosphate $H_2PO_4^-$.[4] We now describe the synthesis and complexation properties of a difunctional neutral receptor which contains binding sites for both *cations* and *anions* is therefore able to complex both species simultaneously in apolar solvents.[5]

The synthesis of the difunctional receptor **3** is summarized in Scheme 1. Reaction of (4-aminobenzo)[15]crown-5[6] with chloroacetyl chloride and K_2CO_3 in EtOAc/H_2O gave the corresponding [4-(chloroacetamido)benzo][15]crown-5 (**1**) in 85% yield. Aldehyde **2** was obtained by alkylation of 2-(2-allyloxy)-3-hydroxybenzaldehyde[7] with **1**, followed by palladium-catalyzed deallylation in 69% overall yield. Subsequent reaction of **2** with *cis*-1,2-diaminocyclohexane and $UO_2(OAc)_2 \cdot 2H_2O$ afforded the difunctional receptor **3** in 76% yield.

1 **2**

3

Scheme 1. All = allyl.

The complexation of the difunctional receptor **3** with cations and with anions was investigated by ^1H NMR spectroscopy, cyclic voltammetry, fast atom bombardment mass spectrometry (FAB-MS), and liquid–liquid extraction experiments. We first studied the complexation of tetrabutylammonium dihydrogen phosphate and potassium picrate, because UO_2-containing clefts complex $H_2PO_4^-$ [4] and bis(benzo[15]crown-5) ethers bind K^+ with a high degree of selectivity.[8]

In dilution experiments[9] with solutions of **3** and $Bu_4N^+H_2PO_4^-$ in [D_6]DMSO the ^1H NMR signals of the HC=N groups of both the free and complexed ligand were observed at δ = 9.51 and 9.46, respectively. From this experiment an association constant K_{ass} of $1.1 \times 10^3\ M^{-1}$ was calculated. The contribution of the C(O)NH $\cdots$ $H_2PO_4^-$ hydrogen bond to the overall anion complexation can clearly be observed in the

^{1}H NMR spectrum even in [D$_6$]DMSO as a solvent, since the N–H signals of the free and complexed **3** appear at $\delta = 10.47$ and 11.21, respectively.

Complexation of K^+ ions by receptor **3** was studied by picrate (Pic) extraction[8] experiments. For the 1:1 complex **3** · K^+Pic^- a value of lg $K_{ex} = 5.3$ was obtained in chloroform.[10]

The complexation of K^+ and $H_2PO_4^-$ ions by **3** was also investigated by cyclic voltammetry in DMSO with 2% H_2O and with tetrabutylammonium tetraphenylborate as a supporting electrolyte. Addition of Bu_4N^+ $H_2PO_4^-$ to a solution of **3** causes a clear shift of both cathodic and anodic peaks toward more negative potentials. This effect is accompanied by a systematic increase in the peak separation, from 85 to 100 mV, and by a decrease of the normalized peak heights. These results suggest that a labile, redox-inactive complex is formed with $H_2PO_4^-$. Assuming the formation of a 1:1 complex, a K_{ass} value of 1.3×10^3 M^{-1} for $H_2PO_4^-$ is obtained, which is in a good agreement with the ^{1}H NMR measurements.

Upon addition of potassium tetraphenylborate to a solution of receptor **3** in DMSO the electrochemical behavior did not change, probably since the crown ether moieties in **3** are situated rather far from the redox-active UO_2 center. However, an indirect procedure for the determination of complexation constants[11] based on competition between Tl^+ and K^+ ions gave a K_{ass} value of 1.0×10^2 M^{-1} for K^+.

Finally, we used FAB-MS, an established technique for investigation of complexes in which cations[12] and anions are bound noncovalently.[4, 13] In the FAB$^+$ mass spectrum (*m*-nitrobenzyl alcohol as matrix) of the 1:1 complex[14] of receptor **3** and KH_2PO_4, prepared by mixing the host and guest in acetonitrile with 10% water and evaporating the solvent, an intense peak corresponding to $[\mathbf{3} + K^+]^+$ was observed. The corresponding FAB$^-$ mass spectrum of the same sample yielded an intense peak for $[\mathbf{3} + H_2PO_4^-]^-$, while a signal for $[\mathbf{3} + H_2PO_4^- + K^+]^-$ is also present, which clearly proves the complexation of the salt.

Previously in our laboratory cation carrier assisted transport of *lipophilic* potassium salts was studied.[15] Now preliminary investigations have shown a significant transport of KH_2PO_4 as a *hydrophilic* potassium salt through a supported liquid membrane with receptor **3**.

In conclusion, we have demonstrated that the combination of binding sites for both cations and anions in a neutral receptor molecule leads to hosts with unique, multifunctional complexation behavior.

Experimental Procedure

A solution of aldehyde **2** (1.3 mmol) and *cis*-1,2-cyclohexanediamine [16] (0.65 mmol) in MeOH (100 mL) was refluxed for 1 h. Subsequently a solution of $UO_2(OAc)_2 \cdot 2H_2O$ (0.65 mmol) in MeOH (10 mL) was added and refluxing was continued for 1 h. After cooling, the precipitate that formed was filtered off and washed with MeOH (2 × 10 mL) to give **3** as a red solid in 76% yield. M.p. 185–187 °C; IR (KBr) $\tilde{\nu} = 1685$, 1617, 904 cm^{-1}; ^{1}H NMR ([D$_6$]DMSO): $\delta = 10.47$ (s, 2H, NH), 9.51 (s, 2H, HC=N), 7.47, 7.31 (2 d, $^3J_{HH} = 7.8$ Hz, 4H, arom.), 7.20–6.70 (m, 8H, arom.), 4.95 (s, 4H, $CH_2C(O)$), 4.75–4.65 (m, 2H, cyclohexylene), 4.70–4.00 (m, 32H, OCH_2), 2.40–1.70 (m, 8H, cyclohexylene); ^{13}C NMR ([D$_6$]DMSO): $\delta = 167.8$ (d, HC=N), 167.3 (s, C=O), 159.7, 149.5, 148.4, 144.7, 132.1 (5 s, arom.), 128.6 (d, arom.), 124.5 (s, arom.), 122.0, 116.2, 114.0, 112.0, 106.3 (5 d, arom.), 71.0 (t, $CH_2C(O)$), 70.5 (d, cyclohexylene), 69.8, 69.6, 68.7, 68.1 (4 t, OCH_2), 27.3, 21.5 (2 t, cyclohexylene); FAB-MS (NBA matrix): *m/z* 947.0 [(*M* + H)$^+$, calcd. 947.3]; correct C,H,N analysis.

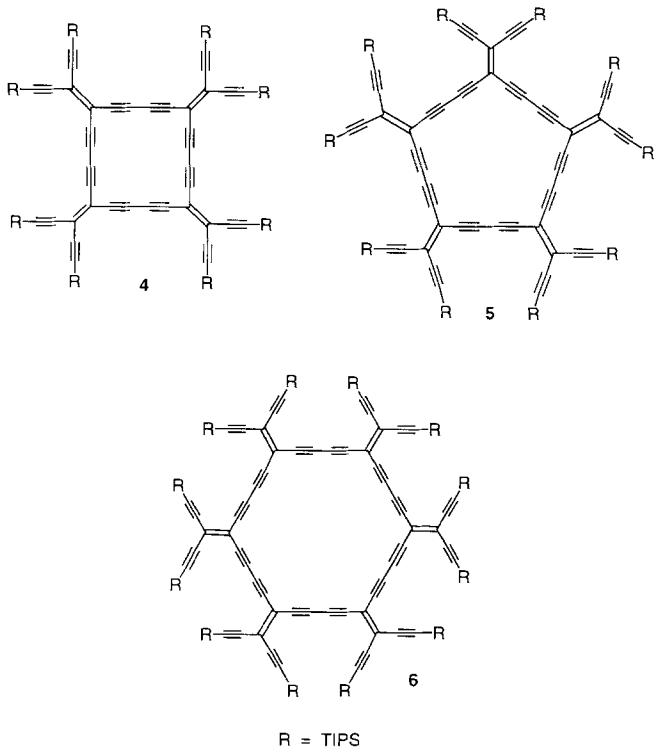
Expanded Radialenes: A Novel Class of Cross-Conjugated Macrocycles**

Armen M. Boldi and François Diederich*

Dedicated to Professor Donald J. Cram on the occasion of his 75th birthday



Radialenes (**1**) are a homologous series of all-*exo*-methylenecycloalkanes of molecular formula C_nH_n (for a recent review see ref. [1]). Upon insertion of acetylene or diacetylene moieties between each pair of vicinal *exo*-methylene units in the cyclic framework, the carbon-rich, hitherto unknown homologous se-

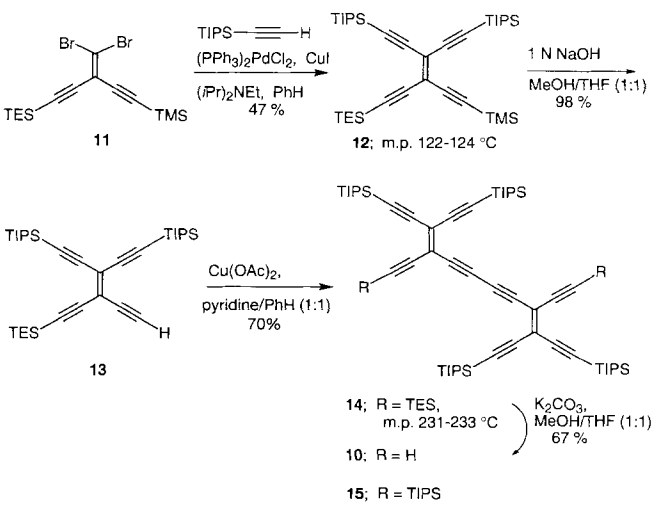
[**] This work was supported by the Schweizerischen Nationalfonds zur Förderung der wissenschaftlichen Forschung. We thank ETH Zürich for the purchase of the MALDI-TOF mass spectrometer.

ries of *expanded radialenes* **2** and **3** with the molecular formulae $C_{2n}H_n$ and $C_{3n}H_n$, respectively, are obtained. Here we report on the synthesis and electronic properties of the perethynylated derivatives **4**–**6**, the first representatives of the expanded radialenes, which can also be viewed as persilylated C_{40} (**4**), C_{50} (**5**), and C_{60} (**6**) isomers. With their extended π-electron perimeters, these compounds could potentially show interesting conducting and nonlinear optical properties.[2]



Initial attempts to prepare **4**–**6** by means of Eglinton–Glaser cyclization of **7**[3] did not afford any isolable quantities of the macrocycles but led to acyclic oligomeric material. To favor the cyclization providing **4**–**6** over competing polymerization reactions, the dimeric compound **10** was prepared as the cyclization component.[4, 5]

	R^1	R^2	R^3

8	TIPS	TIPS	H
9	H	TIPS	H

Sequential, kinetically controlled deprotection of trimethylsilyl (TMS)- and triethylsilyl (TES)-protected acetylenes in the presence of the analogous triisopropylsilyl (TIPS)-protected groups was the key to the successful preparation of **10**.[6] We removed the TMS group in **12** selectively in 98% yield by stirring the compound for 2–5 min in MeOH/THF (1:1) containing a few drops of 1 N NaOH. Stirring the mixture for longer periods of time also led to the cleavage of the TES group to give **7**. Removal of the TES groups in **14** with K_2CO_3 in MeOH/THF (1:1) gave **10** as an unstable oil in 67% yield.

When **10** (0.02 mmol) was added under N_2 dropwise by syringe over several hours to a solution of anhydrous $Cu(OAc)_2$

(0.19 mmol) in pyridine/benzene (3:2, 10 mL), the expanded radialenes **4** and **6** were formed in 15% and 20% yield, respectively.[7] For the synthesis of the pentagonal macrocycle **5**, the cyclization component **17** was prepared by coupling **7** with **13** (2 equiv) [$Cu(OAc)_2$, pyridine/benzene (1:1), 9%] to give **16** followed by deprotection of the TES-alkynyl residues [K_2CO_3, MeOH/THF (1:1), 60%]. Oxidative cyclization of **17** (0.003 mmol) with **10** (0.003 mmol) in pyridine/benzene (3:2, 10 mL) in the presence of $Cu(OAc)_2$ (0.055 mmol) afforded **5** (15%) as the major product besides very small amounts of **4** and **6**.

All three expanded radialenes **4**–**6** are readily soluble, highly stable compounds with melting points above 260 °C. The remarkable stability indicates the absence of free terminal alkyne groups which generally destabilize polyacetylenic chromophores. The proposed cyclic structures are also supported by the absence of signals for terminal acetylenic protons in the ^1H NMR spectra (Table 1). Similarly, the IR spectra did not show any ≡C–H stretches; only weak C≡C stretches at 2125 (**4**), 2122 (**5**), and 2124 cm^{-1} (**6**) were visible. No C=C stretching

bands were observed, which is in agreement with the IR spectra of other weakly polar tetraethynylethene derivatives. In the ^{13}C NMR spectra four acetylenic and two characteristic olefinic carbon resonances are observed (Table 1). The molecular weight

19: Orange microcrystals. M.p. 257–258 °C. FT-IR (film): $\nu = 2155$, 2116 (C≡C) cm^{-1}. ^1H NMR (300 MHz): $\delta = 1.09$ (s, 24H), 1.10 (s, 144H). ^{13}C NMR (75.5 MHz): $\delta = 11.17$, 11.24, 18.55, 18.60, 82.21, 82.66, 84.51, 84.70, 101.32, 101.51, 103.34, 103.65 (2 ×), 103.70, 104.81, 105.47, 115.71, 119.89, 121.31. UV/VIS (hexane): λ_{max} [nm] = 207 sh (ε 91500), 225 (58000), 235 sh (54700), 308 sh (41000), 328 sh (37100), 344 sh (34100), 368 (30500), 390 sh (26900), 417 sh (40100), 431 sh (46900), 455 sh (56900), 475 (42400), 479 (39600). LD-TOF-MS: m/z 1619 (M^-); $C_{102}H_{168}Si_8$ (1619.16).

[a] All NMR spectra were recorded in $CDCl_3$. [b] All new compounds were fully characterized by ^1H and ^{13}C NMR, FT-IR, and UV/VIS spectroscopy, EI or LD-TOF mass spectrometry, and correct elemental analysis. [c] C18 reversed-phase.

of the three macrocyles was confirmed by laser desorption time-of-flight (LD-TOF) mass spectrometry in the negative ion mode. The spectra, obtained without matrix assistance, showed strong molecular ions in the expected m/z range as well as a complete absence of any fragmentation or impurity peaks (Fig. 1). LD-TOF mass spectrometric techniques, which previously had been successfully applied to the analysis of fullerenes and their covalent derivatives,[8] clearly provide a powerful analytical tool for the detection and characterization of all-carbon and carbon-rich materials.[9] The formation and detection of anions in the gas phase suggests that the expanded radialenes can be electrochemically reduced, and an examination of the redox properties of **4**–**6** is under way.

Despite their high degree of unsaturation, **4**–**6** are yellow colored, which indicates the existence of only a weak macrocyclic π-electron conjugation. This assumption is clearly supported by a comparison between the electronic absorption spectra of **4**–**6** and **15** (Fig. 2). Compound **15** contains the 3,4,9,10-tetraalkynyl-substituted dodeca-3,9-diene-1,5,7,11-tetrayne chromophore[4] in a preferred *anti* array; in the enforced *syn* array this is also the longest linearly conjugated π-electron fragment in the macrocycles. The spectral end absorption does not change much between **15** and **4**–**6** and, within the macrocyclic sequence, it even remains almost constant. Hence, π-electron delocalization in **4**–**6** seems to extend efficiently only through the longest linearly conjugated fragment, and the measured linear increase in the extinction coefficient of the strongest absorption band with increasing ring size presumably results from the increasing number of such fragments in the macrocycles. The low extent of π-electron delocalization in **4**–**6** could be due to inefficient macrocyclic cross-conjugation[10] and/or the nonplanarity of the rings.[11] Preliminary AM1 calculations[12] show that the steric repulsion between the bulky peripheral TIPS groups distorts all three expanded radialenes significantly

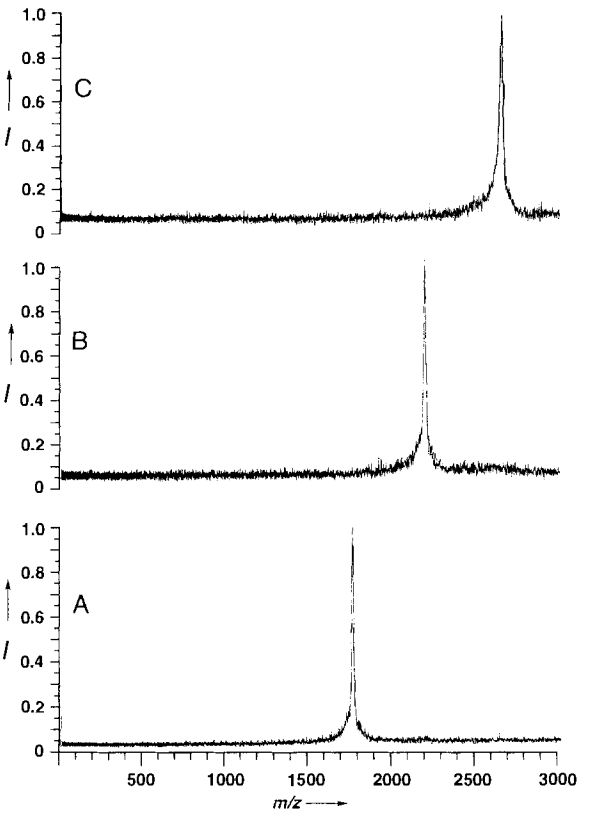

Fig. 1. Laser desorption time-of-flight mass spectra of **4** (A), **5** (B), and **6** (C) recorded in the linear mode at −15 kV.

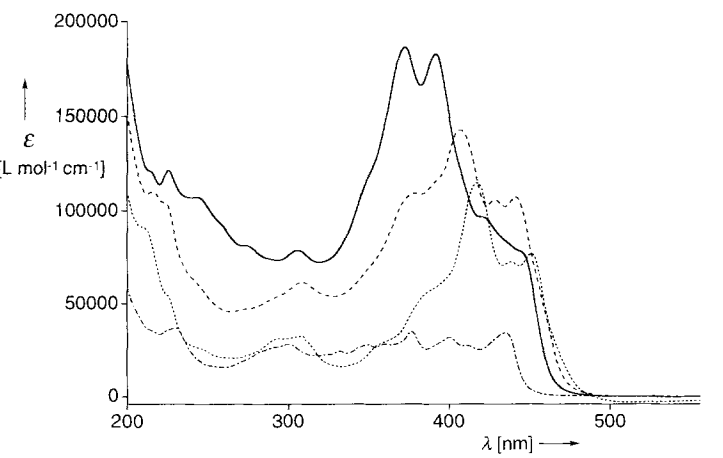

Fig. 2. Electronic absorption spectra of **15** (— · · —), **4** (· · ·), **5** (— — —), and **6** (— · —) recorded in hexane. $T = 298$ K.

out of planarity. However, the pronounced vibrational fine structure of the electronic absorption spectra also suggests that the macrocycles have strong conformational preferences and are not very flexible.

We compared these electronic properties to those of the acyclic isomeric chromophores **18** and **19**. The dendralene-type[13] isomer **18** was prepared in 6% yield by mixed coupling [$Cu(OAc)_2$, pyridine/benzene (1:1)] of **7** with **8** (2 equiv), and the linear isomer **19** of the poly(enebutadiyne) type[14] was obtained in 5% yield by coupling **9** with **8** (2 equiv). The UV/VIS spectra show that the extension of the linear π-electron conjugation in **19** leads to a significant bathochromic shift ($\approx$ 30 nm) in the end absorption as compared to **15** (Fig. 3). In sharp contrast, isomer **18** does not give a significant red shift but rather shows a spectrum nearly identical to that of the smaller π system **15**. Since **18** contains twice the chromophore of **15**, the extinction coefficients of its absorption bands are nearly doubled. Similar to the macrocycles **4**–**6**, π-electron delocalization in **18** is limited to the longest linearly conjugated fragment. The origin of this limited π-electron delocalization, owing to inefficient cross-conjugation or nonplanarity because of TIPS group repulsion, as well as the chemical reactivity of the new π systems are now under further investigation.

Selective Catalysis on Silicon Dioxide with Substrate-Specific Cavities**

Jens Heilmann and Wilhelm F. Maier*

Many properties (thermal, chemical and mechanical stability, activity, space–time yields, regenerability, long term stability, applicability) make technically important heterogeneous catalysts superior to biocatalysts. As yet unattainable, however, is the selectivity of enzymes, which is attributable to the substrate-specific clefts at the binding site of the enzyme. The limited availability of enzymes recently led to the preparation of antibodies that can bind transition state analogues of reactions for which no natural enzymes are known. These antibodies show an enzyme-like, highly selective catalytic activity.[1, 2] The cavity in enzymes and antibodies is not rigid, but during the interaction with the substrate it is complementary to the structure of the transition state (lock-and-key principle).

Substrate-selective cavities can also be generated in nonbiological systems, for example, in organic polymers, which can then be employed for selective chromatographic separation[3] and molecular recognition.[4] A desired goal for heterogeneous catalysis is the combination of the particular catalytic properties of two systems: the high activity and stability of the technical catalysts and the high selectivity of enzymes. Such a combination could be achieved if it were possible to fix a rigid cavity complementary to a transition state in an inorganic matrix.

Morihara et al.[5] reported in 1988 on the first generation of specific imprints of transition state analogues in the surface of alumina-containing silica gels. Such catalysts were used in the butanolysis of benzoic anhydride and showed substrate inhibition as well as a reduced Michaelis constant k_M, but a reduced rate of reaction relative to control catalysts containing no imprint. Chemoselective and enantioselective effects have also

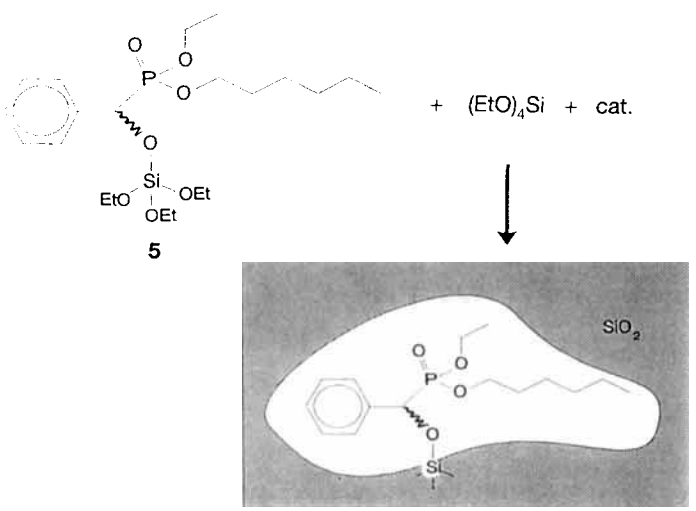
[**] We thank H. Grondey for the solid-state NMR investigations.

been shown.[6] We report here on the preparation of catalytically selective, amorphous silicon dioxide catalysts by a modified sol–gel process[7] involving a transition state analogue. The transesterification of ethyl phenylacetate (**1**) with *n*-hexanol to form hexyl phenylacetate (**2**) served as the reaction to be catalyzed.

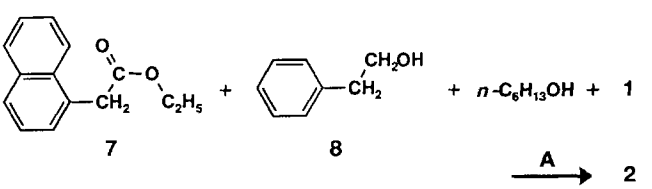


This transesterification of **1** proceeds at measurable rates only with acid or base catalysis; the transition state **3** with a C atom in a tetrahedral environment can be formulated for the acid catalyzed reaction. As transition state analogue, the phosphonate **4** with tetrahedrally surrounded phosphorus atom was synthesized, and coupled to a triethoxysilyloxy group as monomer unit to form **5**. The synthesis of **4** started with commercially

3 **4**

available diethyl phosphite that was transformed into the monosodium salt with NaOH.[8] Exchange of the Na^+ ion for the tetrabutylammonium ion and treatment with *n*-hexyl iodide, analogous to the method of Kluba and Zwierzak[9] afforded the mixed ethyl hexyl phosphite, which was coupled with benzaldehyde according to the method of Texier-Boullet and Foucaud in the presence of CsF to form ethyl hexyl 1-hydroxyphenylmethanephosphonate (**4**).[10] This transition state analogue was coupled to chlorotriethoxysilane with pyridine to give the copolymerizable **5**. Compound **5** was subjected to the HCl catalyzed sol–gel process together with a 100-fold molar excess of $Si(OEt)_4$ (Scheme 1).

The finished gel was dried for several days at room temperature and crushed finely in a mortar. With the aim of creating cavities, the powder was slowly heated to 250 °C, maintained at this temperature for 5 h, and then cooled. The container was evacuated and refilled with Ar for storage (selective catalyst **A**). In the mass spectrum of this heat-treated material, none of the transition state analogue **4** was detected. To confirm that before the heat treatment there was still **4** in the pulverized silicon dioxide, the powder was examined by mass spectrometry. In the mass spectrum the characteristic mass of **4** could be clearly

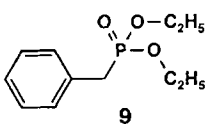


5 **6**

Scheme 1.

detected as major decomposition product at temperatures above 200 °C, which shows that at least a part of the transition state analogue **4** leaves the solid without decomposition. Thus, cavities possibly complementary to **4** might be left behind. Parallel to this procedure, silicon dioxide was prepared under identical conditions but without addition of **5** to act as control catalyst **B**. A comparison by means of ^1H and ^{29}Si solid state NMR spectroscopy and crossover polarization experiments of **A** before heat treatment with **B** and with **B** containing physically adsorbed **5** confirms the chemical incorporation of **5** in the SiO_2 matrix of the untreated **A**, as formulated in **6**. N_2 and Ar adsorption isotherms of all synthesized materials were recorded routinely. The silica gels **A** and **B** were shown to be not only highly porous but also entirely microporous; they do not differ significantly in either the pore distribution or in the BET overall surface (800–900 m^2g^{-1}). Interpretation of the isotherms by the method of Horvath–Kawazoe gave a pore distribution with a maximum at a pore diameter of 10 Å. The anticipated cavities in **A** cannot be recognized in the adsorption isotherms, which is probably due to the small proportion of cavities relative to the total porosity of 0.2 cm^3g^{-1}. Studies on **A** with transmission electron microscopy revealed that the silica gel is completely amorphous. The elemental distribution in dried, but not heat-treated **A** (which still contained **6**) determined with nm resolution by X-ray back-scattering analysis (EDX) showed, however, that the proportion of carbon in the material varied over a wide range, which suggests a partial association of the transition state analogue in the gel process and refutes the desired uniform molecular distribution of **6** in the glass.

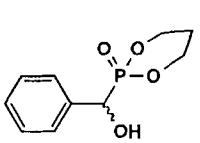
The transesterification of **1** was performed under argon at 130–140 °C. The catalyst was pulverized, and the rate of stirring was increased until the reaction rate no longer increased. A mixture, free of traces of acid or base, containing 10 mmol of **1**, 100 mmol of *n*-hexanol, 100 mmol of *n*-octanol, and 100 mmol of phenylethanol (**8**), to which no catalyst had been added, underwent no detectable reaction within 2 h; after 2 h incipient autocatalysis was detectable. In the presence of the control catalyst **B** no reaction was detectable within 48 h. With catalyst **A** an immediate turnover to a 1:1 mixture of hexyl and octyl phenylacetate at a rate of 7 $mmol\,h^{-1}\,g^{-1}$ was observed. At the beginning of the reaction the formation of phenylethyl ester could not be detected. This showed that the reaction which does not take place in the presence of control SiO_2 **B** under these conditions is catalyzed by **A**. To monitor the selectivity, **1** was subjected to the analogous reaction in the presence of sulfuric acid. The rate of transesterification was the same for all three alcohols in the mixture. This experiment, repeated without sulfuric acid with the control material **B**, showed no conversion within 24 h. Addition of **A** immediately initiated the reaction,



7 **8**

but the reaction with phenylethanol **8** was distinctly delayed. Repetition and long-time experiments demonstrated that the two alkyl esters formed 8–10 times faster than the phenylethyl ester. The extent to which the formation of the undesired phenylethyl ester, detectable after 2 h, is caused by unavoidable autocatalysis or is an indication of the intrinsic selectivity of **A** could not be clarified. These experiments confirmed the high

substrate selectivity of the catalyst **A**. A further pointer to the high selectivity of the catalyst was obtained with **7** and **8**, whose transesterification was not measurably catalyzed by **A** within 12 h. Addition of **1** and *n*-hexanol to this mixture again yielded **2** immediately and selectively.



Kinetic investigations showed that the reaction is first order with respect to ester, alcohol, and catalyst. Michaelis-Menten kinetics with $V_{max} = 3.75$ μmol and $k_M = 3.6$ mmol was observed for the conversion of **1** with hexanol and 400 mg of **A** from 0 to 30% conversion. At higher conversions, however, the reaction begins to deviate slightly from this model, which suggests deactivation. In fact, in further experiments and also on reuse of the catalyst, a distinct, irreversible deactivation affecting not only the loss of activity, but also the selectivity was observed. This decrease in selectivity was also noticeable at higher conversion (> 50%). The long reaction time of several days at 130 °C presumably causes a slow, but irreversible sintering of the original cavity structure.

It remained to be proved whether the observed activity and selectivity of **A** was perhaps attributable to a combination of adsorption and diffusion effects or to some acidic decomposition product of **4** deposited on the inner SiO_2 surface. Half a gram of **B** was impregnated with 30 mg of phosphorous acid, tempered at 100 °C, and used as catalyst in the transesterification with the mixture of three alcohols. The material was catalytically active, but the selectivity of the alkyl ester formation over the phenylethyl ester formation of a factor of 1.5 was distinctly less than that of **A**. The presence of catalytic amounts of Brønsted acid centers in **A** was demonstrated by the selective formation of *tert*-butyl ethers catalyzed by **A** in the absence of phenylacetate from a mixture of *tert*-butanol, *n*-hexanol, *n*-octanol, and 2-phenylethanol (140 °C in a closed vessel). It must therefore be assumed that phosphoric acid centers arise during the calcination of **A** at 250 °C, and that these are probably responsible for the catalytic activity of **A**. This assumption was also supported by the observation that neither **4** (decomposes at higher temperatures in benzaldehyde and hexyl ethyl phosphite) nor the thermally stable, specifically synthesized compound **9** could influence the catalytic transesterification (no inibition). Extraction of **A** in a Soxhlet apparatus with THF, acetic acid, and water resulted in complete deactivation.

9

Because of the high porosity of these silica gels, it must be determined whether the observed selectivity is caused by transport phenomena (different diffusion rates, different adsorption) of the alcohols through the micropores. If transport phenomena are responsible for the selectivity, an increase in the particle size should not only decrease the reaction rate, but also increase the catalytic selectivity, or at least change it. Although an experiment with very large catalyst particles (> 500 μ) gave the expected reduction in the reaction rate of a factor of 10, the selectivity (alkyl ester formation 8–9 times faster than phenylethyl ester formation) remained of the same order as that with the finely pulverized catalyst. In the meanwhile, a catalyst, analogous to **A** but containing another transition state analogue (**10**) for a lactonization reaction, was prepared in the same way.[11] This catalyst, which is just as microporous as **A** (pore distribution maximum 10 Å), was tested in the transesterification reaction. Its activity is comparable with that of **A**, but the attained selectivity of a factor of 1.5 lay in the same range as that of **B** impregnated with phosphoric acid. Apparently the observed selectivity of the transesterification reaction is only achievable with a silica gel with cavities, structure-complementary to **4**.

10

The investigations indicate that we have prepared a selective silicon dioxide catalyst that in its action—combination of active Brønsted acid centers and discriminating cavities ("footprint")—resembles the catalysts of Morihara, but shows a higher selectivity. We have thereby shown that this type of catalyst is not unique, but can be prepared by other routes. How the cavities in silicon dioxide responsible for the selectivity are constructed, where the active centers are, where the limits of applicability, selectivity, activity, and maximum capacity lie, and what can be improved in these materials must still be studied. The thermal and long-term stability of these cavities must be significantly improved for practical applications. It is remarkable that even in such a simple compound like silicon dioxide the spatial requirements of an organic molecule can be so precisely imprinted on it that the material can distinguish between phenyl and naphthyl, or octyl and phenylethyl groups, and that this imprint is retained also at temperatures up to 250 °C. This demonstrates that glassy cavity structures can be generated with molecular resolution.

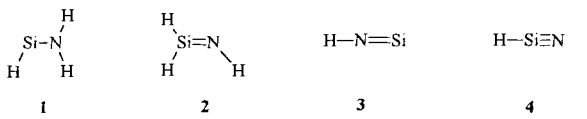
Silane Nitrile: Matrix Isolation, Adduct with Hydrogen**



Günther Maier* and Jörg Glatthaar

Divalent silicon compounds (silylenes, silanediyls)[1] and compounds with Si–element multiple bonds[2] are still of great interest to theoreticians and preparative chemists. Our attention has been directed particularly toward the unsubstituted parent compounds. Of the nitrogen-containing derivatives **1**–**4**, aminosilylene (**1**)[3] and iminosilylene (silaisonitrile) (**3**)[4] were previously trapped in an argon matrix and identified. We report here on the identification of the two compounds still missing, **2** and

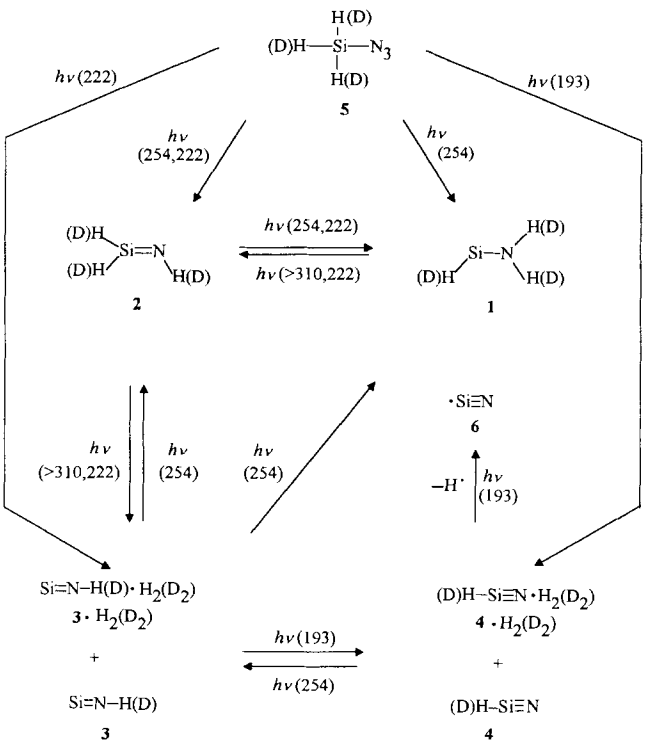
[**] Hetero π Systems, Part 19; lecture (G. M.) given at the Silicon conference (August 3, 1992) in München. This work was supported by the Fonds der Chemischen Industrie. Part 18: G. Maier, H.-J. Wolf, R. Boese, *Chem. Ber.* **1990**, *123*, 505-511.



4. Silane nitrile (**4**) is of particular interest since, whereas in the equilibrium RCN⇌RNC[5] the nitrile form is preferred, the opposite is expected in the sila series. According to ab initio calculations[6] silane nitrile (**4**) is—depending of the basis set used—50–100 kcal mol^{-1} higher in energy than the isomer **3**.

The ideal experimental access to the H_3SiN and HSiN hypersurface is offered by silyl azide (**5**).[3,4] As previously described by us,[3] after irradiation of **5** in argon at 10 K with light of wavelength 254 nm, aminosilylene (**1**) is detected [UV: λ_{max} = 348, 220, 208 nm; IR: $\tilde{\nu}$ = 866(ν_{Si-N}) cm^{-1}; calcd[7]: 948 cm^{-1}]. If light of shorter wavelength (222 nm; KrCl excimer laser) is applied, the main product is iminosilylene (**3**) [UV: λ_{max} = 250 nm (weak); IR: $\tilde{\nu}$ = 3585, 3580(ν_{N-H}), 1202, 1200($\nu_{Si=N}$), 522(δ_{N-H}) cm^{-1}; calcd[8]: 3613, 1216.5, 518.4 cm^{-1}]. Aminosilylene (**1**) is not directly transformed into the iminosilylene (**3**). In accordance with theory[7] it can be assumed that initially a H shift **1** → **2** (calculated barrier: 74 kcal mol^{-1}) occurs followed by a dehydrogenation of **2** to give **3**.[9a] Indeed, an intermediate can be detected along the pathway **1** → **3**, which can be interpreted as the unsubstituted silane imine (**2**) [UV: λ_{max} = 240 nm; calcd[9b]: 238 nm; IR: $\tilde{\nu}$ = 2253, 2175 (ν_{Si-H}), 1097 ($\nu_{Si=N}$) cm^{-1}; calcd[7]: 1247 cm^{-1}].

The reaction proceeds differently for the matrix irradiation of silyl azide (**5**) with an ArF excimer laser (193 nm). The IR spectrum of a new species is recorded, which according to the spectral data must be silane nitrile (**4**) [UV: λ_{max} = 238, 258, 266, 350 nm; IR: $\tilde{\nu}$ = 2151, 2149 (ν_{Si-H}); 1163, 1161 ($\nu_{Si\equiv N}$) cm^{-1}]. Thus, to our knowledge, this is the first compound with a formal Si≡N triple bond of the nitrile type to be identified spectroscopically.[10] Additional structural evidence for **4** is derived from the fact that it loses its hydrogen atom on prolonged irradiation at 193 nm, and is transferred into the well-known[11] SiN radical **6** [UV: particularly strong band at 410 nm; IR: $\tilde{\nu}$ = 1144 ($\nu_{Si\equiv N}$) cm^{-1}].

The genetic relationships between the species **1**–**6** are given in Scheme 1. They result from the increase or decrease of the corresponding bands when different light sources are applied. The crucial intermediate is silane imine (**2**). This is formed from silyl azide (**5**) via the silyl nitrene H_3SiN:, which cannot be trapped.[3] Silane imine (**2**) forms a photoequilibrium with aminosilylene (**1**), but yields mainly iminosilylene (**3**) by H_2 elimination. The eliminated hydrogen remains in the matrix cage. This is not only supported by the fact that the hydrogen elimination is reversible (!), at least as long as the hydrogen occurs in the same matrix cage as **3**, but there is also spectroscopic evidence: First the stretching vibrational bands of **3** are doubled. This is probably the result of the occurrence of a mixture of free **3** (ca. 10%; $\tilde{\nu}$ = 3585, 1202 cm^{-1}) and a H_2 adduct **3**·H_2 (ca. 90%; $\tilde{\nu}$ = 3580, 1200 cm^{-1}). Second, and this finding is particularly informative, the hydrogen molecule associated with **3** can be observed directly. Because of its proximity to **3** the H_2 molecule eliminated from **2** becomes IR "active", and a band is registered at 4178 cm^{-1}.[12] This absorption band disappears together with the bands of **3**·H_2 on thawing of the matrix to 30 K. Simultaneously, an increase in pressure is noted, which indicates that the hydrogen eliminated does not remain in the matrix but escapes under these conditions into the gas phase. The absorption bands of free **3** (higher wavenumbers) increase in intensity. At

Scheme 1.

the same time the possibility of retrapping the hydrogen by irradiation (254 nm) of iminosilylene (**3**) and reforming the aminosilylene (**1**) via silane imine (**2**) disappears. The phenomenon of adduct formation with hydrogen is also observed for silane nitrile (**4**). As mentioned previously, irradiation of **5** at 193 nm affords double bands with two almost equally intensive peaks. This means that a mixture of fortuitously equal fractions of H_2 adduct **4**·H_2 ($\tilde{\nu}$ = 2149, 1161 cm^{-1}) and free **4** ($\tilde{\nu}$ = 2151, 1163 cm^{-1}) can be assumed. The hydrogen stretch for **4**·H_2 appears at 4164 cm^{-1}. Again, on thawing to 30 K the band for free **4** becomes more intensive, that for **4**·H_2 weaker.

As long as the H_2 adduct **4**·H_2 occurs, irradiation at 254 nm leads back to aminosilylene (**1**) via **3**·H_2 and **2**. This reaction is

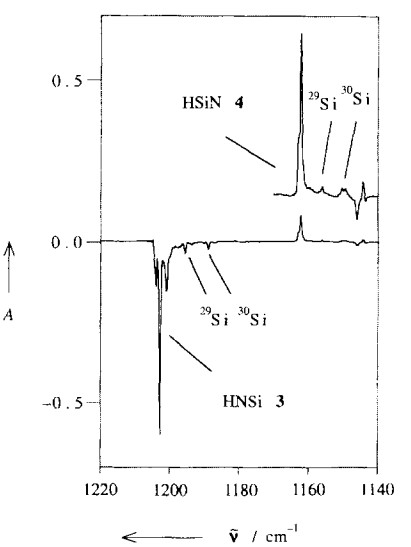


Fig. 1. IR spectra (difference spectrum of the photoreaction **3** → **4** at 193 nm) of HSiN (**4**) and HNSi (**3**) in argon at 10 K. A = absorbance.

no longer possible after annealing at 30 K when only free silane nitrile (**4**) is still present. In this case only the rearrangement **4** → **3** is observed on irradiation at 254 nm. By changing to 193 nm light the corresponding backreaction **3** → **4** occurs (Fig. 1). These mutual relationships are additional proof that the two participating species **3** and **4** must be isomers.

The complete reaction process can be confirmed from the corresponding spectra of the deuterated isotopomers ([D_3]**2**: $\tilde{\nu}$ = 1638, 1585 (ν_{Si-D}); 1063 ($\nu_{Si=N}$) cm^{-1}; calcd 1754, 1704, 1200 cm^{-1}; [D]**4**: $\tilde{\nu}$ = 1580, 1578 (ν_{Si-D}), 1145, 1144 ($\nu_{Si\equiv N}$) cm^{-1}. The absorption band of the "associated" deuterium for [D]**3**·D_2 appears at 2994, that of [D]**4**·D_2 at 3010/3005 cm^{-1}.[12]

The structure of silane nitrile (**4**) is derived from the analysis of the IR spectra; the isotopic shifts provide additional proof. Three fundamental vibrations are expected for **4**. The two valence stretches can be proven experimentally, but not the bending mode. The latter is either very weak or lies outside the range possible for us to measure (up to 220 cm^{-1}). The calculations (Table 1)[13] show an unusually strong deviation of the band positions for the SiN valence stretches (ν_3) depending on the basis set used. Contrary to our expectations, calculation at the MP2 level gives a lower value than that observed. Our experience indicates that this result is typical for systems containing SiN multiple bonds. Nonetheless, the calculated isotopic shifts are consistent with those obtained from the experiment. The following force constants are calculated from the four IR bands measured (see Table 1): f_{SiH} = 2.59, f_{SiN} = 7.08, $f_{SiH/SiN}$ = − 0.45 N cm^{-1}. According to Siebert[14] this results in a bond order of 2.0. An analogous analysis for HNSi (**3**) (f_{SiN} = 8.85) gives a value of 2.3.

Table 1. Observed (Ar matrix) and calculated IR spectra of HSiN (**4**) and DSiN [D]**4**; wavenumbers in cm^{-1}. Integrated intensities (relative to the strongest band) in parentheses.

Band			exp.	MP2/6-31G*	MP2/D95**
ν_1	σ	ν_{SiH}	2152.2 (0.59)	2249.1 (0.76)	2261.8 (0.45)

[a] HSiN **4**. [b] DSiN [D]**4**.

Conclusion: Matrix isolation spectroscopy not only provides proof of silane nitrile (**4**) (and silane imine (**2**)), even the photochemically eliminated hydrogen can be directly detected spectroscopically. Furthermore, experiment and theory[6] agree perfectly in at least five points: 1. The stability within the series of H_3NSi isomers increases in the series silyl nitrene/silane imine (**2**)/aminosilylene (**1**). Thus, it is not surprising that silyl nitrene cannot be observed. 2. A considerable barrier exists between **1** and **2**, which can be overcome by photoexcitation. 3. The predicted small barrier (calcd 4–13[6e] or 7.8 kcal mol^{-1}[6i]) for the isomerization **4** → **3** is sufficient for the spectroscopic detection of **4** in an argon matrix. 4. α-Elimination of two hydrogen atoms at one silicon atom is preferred over β-elimination, for which the second H atom is situated at a neighboring C or N atom. 5. HSiN (**4**) is a better source of the SiN radical **6** than HNSi (**3**).

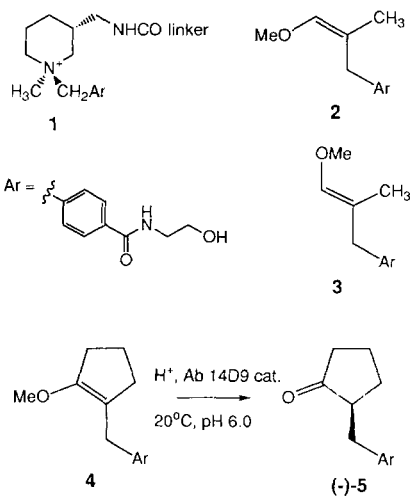
Enantioselective, Multigram-Scale Synthesis with a Catalytic Antibody**

Jean-Louis Reymond,* Jean-Louis Reber, and Richard A. Lerner*



The scope of antibody catalysis now encompasses many reactions of interest to synthetic chemists including enantioselective and disfavored processes.[1] These reactions can be carried out under very mild aqueous conditions, which would make them

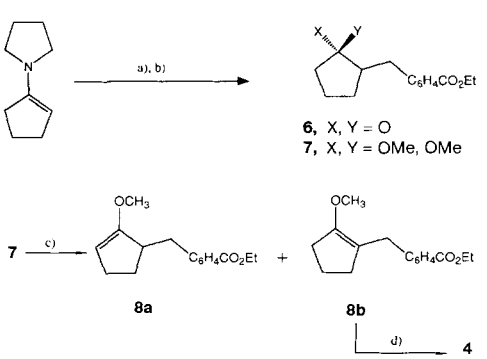
[**] We would like to thank Prof. L. Ghosez, Belgium, for pointing out the importance of a preparative-scale experiment with a catalytic antibody. We thank Sandoz, Basel, for sabbatical support to J.-L. Reber.



very attractive for preparative chemistry provided that they can be carried out on a large scale. We now report the preparation of gram quantities of product using a catalytic antibody and a very simple laboratory procedure. This demonstrates that catalytic antibodies should be considered as practical tools for organic synthesis in the laboratory.

We recently reported that antibodies raised against hapten **1** catalyzed the hydrolysis of enol ethers **2** and **3** (Scheme 1) with very high enantioselectivity for proton delivery.[2] In the course of our investigation into alternative substrates, we discovered that antibody 14D9 was particularly effective for the hydrolysis of the cyclic enol ether **4** to produce enantiomerically pure ketone (−)-**5** with a turnover $k_{cat.}$ of 0.4 s^{-1} at pH 6.0 and a rate enhancement $k_{cat.}/k_{uncat.}$ of 10^4.[3] Furthermore, when a 1 mM solution of substrate **4** was incubated at pH 7.0 and 20 °C with a 10 μM solution of antibody 14D9, complete conversion to product was observed within one hour with no apparent product inhibition. Without antibody less than 5% of the substrate was converted to product. Encouraged by these preliminary results, we set out to scale up this reaction.

Scheme 1. Hapten, substrates, and catalytic reaction of antibody 14D9.

Substrate **4** was synthesized as follows (Scheme 2): alkylation of pyrrolidino-1-cyclopentene with ethyl (4-chloromethyl)benzoate and ketalization of the resulting ketone **6** gave **7**. Ketal **7** was converted in high yield to a 1:1 mixture of enol ethers **8a** and **8b** upon heating in trimethylorthoformate with ammonium camphorsulfonate (NH_4^+CSA) catalyst.[4] Isomer **8b** was purified by column chromatography and converted into **4** by treatment with ethanolamine.[5]

Scheme 2. Synthesis of **4**: a) $ClCH_2C_6H_4CO_2Et$ (0.5 equiv.), CH_3CN, reflux, 10 min, 58%; b) $(MeO)_3CH$, MeOH, CSA cat., room temperature, 15 min, 100%; c) $(MeO)_3CH$, NH_4^+CSA cat., reflux, 30 min, 85%; d) ethanolamine, ethanol, K_2CO_3, 50 °C, 17 h, 94%.

Monoclonal antibody 14D9 was prepared and purified as previously described.[6] For the antibody-catalyzed reaction we wanted a procedure that required only conventional laboratory glassware and allowed efficient recovery of the antibody catalyst. Our procedure[7] is based on the use of dialysis for the separation of product and unreacted substrate from the catalyst and relies on the significant solubility of both **4** and **5** in water. Thus, a solution of substrate **4** (500 mg, 1.83 mmol) in 1 mL of methanol is added to a solution of antibody (57 mL, 7 mg mL^{-1}, 400 mg) in buffer[8] and magnetically stirred at room temperature in a 250 mL glass round-bottom flask. The reaction proceeds to 80% conversion in 5 h giving **5** with 89–91% *ee*.[9] The solution is then transferred to a dialysis bag and dialyzed into 1 L of the same buffer at pH 7, which effectively separates 95% of the products from the antibody catalyst by dilution.[10] Unreacted starting material and product are recovered from the dialysis buffer by extraction.[11] The pure ketone (−)-**5**[12] is obtained by recrystallization[13] in 60–65% yield (based on starting material) and with an optical purity of 86% *ee*.[14] The antibody contained in the dialysis bag is dialyzed again with 1 L of buffer at pH 6, which returns it to the original conditions while removing the remaining product by dilution. The antibody solution is then returned to the original flask for another reaction cycle.

The procedure was repeated five times to consume a total of 2.55 g of substrate **4**. The total yield of (−)-**5** was 1.50 g (62% based on invested substrate) with 86% *ee* after recrystallization. The activity of the antibody sample dropped by 5% after each run, which probably reflects loss upon transfer of the solutions. Each catalytic site invested in this experiment carried out 4700 turnovers (940 in each run).[15]

Although we used purified antibody in the experiment described above, all preliminary experiments were carried out with the crude ammonium sulfate precipitate. In both cases all the catalytic activity observed for the hydrolysis of **4** was completely inhibited by the hapten and was thus specific to the antibody combining site. In fact, the catalytic activity of the purified antibody per weight unit turned out to be lower than for the ammonium sulfate precipitate, which suggests that purification was accompanied by partial, irreversible denaturation of the protein. In both cases the activity corresponds to 20–40% of the activity expected for a pure protein. The use of the crude antibody preparation provides significant labor and cost advantages, as subsequent prufications consume time and material.

In summary, we have shown that antibody-catalyzed reactions can be carried out on a gram scale with conventional laboratory techniques. The antibody catalyst is recovered and can be reused. The reaction chosen in this study is examplary, as it cannot be carried out enantioselectively by any other known catalytic system, and it illustrates the contribution that antibodies can make as catalysts in synthetic organic chemistry.

[4] This procedure is simpler than other published procedures. Its generality is under current investigation.

[5] Selected physical properties of **4**. Colorless crystals, m.p. 74–75 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.67, 7.22 (2 m, 2 × 2 H), 6.69 (br. t, 1 H), 3.82 (td, 2 H, J = 5, 4.5), 3.61 (dt, 2 H, J = 8, 4), 3.40 (br. s, 2 H), 2.48 (m, 2 H), 2.10 (m, 2 H), 1.81 (m, 2 H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 168.7, 152.3, 145.1, 131.4, 128.8, 126.9, 112.9, 62.5, 56.8, 42.8, 32.4, 31.0, 28.8, 19.5; IR (KBr): $\tilde{\nu}$ = 3287, 2937, 2850, 1689, 1639, 1546, 1339, 1292, 1163, 1108, 1060, 1033, 860, 704 cm^{-1}.

[6] 14D9 is a murine hybridoma cell line obtained by fusion of a 129G1X$^+$ spleen cell (from a mouse immunized with hapten **1**) with a balb/c myeloma cell, and it produces a $\kappa\gamma_1$ antibody. Antibody 14D9 was produced by growing ascites from this cell line. Purification of the ascites fluid involved ammonium sulfate precipitation, anion exchange, and protein G chromatography. a) G. Köhler, C. Milstein, *Nature* **1975**, *256*, 495; b) E. Enguall, *Methods Enzymol.* **1980**, *70*, 419.

[7] All reactions were monitored by HPLC (Chiralpak AS column, 0.45 × 22 cm; hexane/isopropanol 7:3; 1 mL min^{-1}): t_R(**4**) = 5.3 min, t_R((+)-**5**) = 9.2 min, t_R((−)-**5**) = 12.5 min. Detection by UV at 240 nm.

[8] The buffer is 50 mM bistris (*N,N*-bis(hydroxyethyl)tris(hydroxymethyl)aminomethane), 100 mM NaCl, pH 6.0.

[9] The antibody-catalyzed reaction is 100% enantioselective. Under the present conditions, 10% of the product is formed by the hydrolysis of **4** catalyzed by H_3O^+ to give racemic **5**.

[10] We used cellulose dialysis tubes that allow the diffusion of proteins up to 12–14 kDa. The antibody has a molecular weight of 150 kDa and is retained inside the bags, while molecules smaller than 12–14 kDa diffuse through the membrane. Equilibration was reached after 17 h at 20 °C. Dialysis bags are also used with enzymes. See C.-H. Wong, *Science* **1989**, *244*, 1145.

[11] Extraction with toluene (4 × 50 mL) selectively removes the unreacted **4**. The buffer is then saturated with NaCl, and **5** extracted with ethyl acetate (4 × 200 mL).

[12] The absolute configuration of (−)-**5** was shown as (*S*) by comparison with (+)-(*R*)-2-benzylcyclopentanone. K. Matsumoto, H. Ohta, *Tetrahedron Lett.* **1991**, *32*, 4729.

[13] The crude product (370 mg) was dissolved in 2 mL of hot ethyl acetate and recrystallized by dropwise addition of 1.5 mL hexane, yielding 310 mg (65%) of (−)-**5**. Colorless crystals, m.p. 88–90 °C. $[\alpha]_D^{25} = -134$ (c = 0.9 in EtOH); ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.69, 7.21 (2 m, 2 × 2 H), 6.78 (br. t, 1 H), 3.81 (br. m, 2 H), 3.61 (q, 2 H, J = 5), 3.15 (dd, 1 H, J = 14, 4), 3.04 (br. m, 1 H), 2.60 (dd, 1 H, J = 14, 9), 2.36 (m, 2 H), 2.08 (m, 2 H), 1.96 (m, 1 H), 1.81 (br. s, 1 H), 1.74 (m, 1 H), 1.53 (ddd, 1 H, J = 23, 11, 7); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 220.0, 168.4, 144.0, 132.1, 129.1, 127.2, 62.1, 50.7, 42.8, 38.1, 35.3, 29.0, 20.5; IR (KBr): $\tilde{\nu}$ = 3296, 2936, 2874, 1731, 1637, 1557, 1503, 1441, 1404, 1055, 805, 682 cm^{-1}.

[14] The drop in optical purity is due to partial hydrolysis of the remaining enol ether **4** during dialysis. When dialysis was attempted at pH 8, hydrolysis of **4** was stopped but racemization of **5** was then observed.

[15] The concentration of catalytic sites before and after each run was measured by quantitative titration of the catalytic activity with the hapten as described before (see ref. [3]). The total amount of active catalyst in the experiment was 1.3 μm at the start and gradually dropped to 0.97 μm after five runs. Thus, only approximately 0.06 mol% catalyst was present in each run.

How do they fit so much in?

VCH

Inorganic Structural Chemistry. By *U. Müller*. Wiley, Chichester, 1993. 246 pp., paperback £ 14.95.—ISBN 0-471-93717-7

The significance of this book is well summed up by the following extract: "Chemical and physical properties of a substance can only be understood when its structure is known." Thus, an integrated course on *structural chemistry* which extends beyond organic stereochemistry is a highly appropriate topic for any college chemistry curriculum. This text has been developed from a lecture course given by H. Bärnighausen at the University of Karlsruhe, Germany. With respect to the United States, the level of this book would probably be suitable for advanced undergraduates, or perhaps as a starting graduate text. In Britain, it might well serve as a second-year or third-year coursebook. As in any good teaching text, there are exercise problems, both numerical and descriptive, at the end of each chapter; answers are also provided to many of these. Basic knowledge of atomic theory and bonding are a prerequisite, and some background knowledge of structure determination techniques will be useful. Some familiarity with calculus is helpful, although the mathematics in the text is largely descriptive.

The subject is developed over 19 well-illustrated chapters, which fall into two broad categories. Firstly, there are several general sections which range from *how to describe structures* (either empirically or by a more formal symmetry/crystallographic description), to *what factors are responsible for particular structures* (thermodynamics, atomic/ionic sizes, ligand field theory, simple molecular orbital theory). These are nicely set out, and concepts such as Pauling's rules, VSEPR theory, the Jahn–Teller effect, and simple band theory are covered.

Secondly, there are several chapters detailing the actual structures of non-metals (nice treatment of S, Se, P, As, etc.), continuous structures (diamond-like, etc.), clusters, metals (sphere packing), and polyhedral networks. Some of the more complex structures discussed include zintl phases, chevrel phases, perovskites, and silicate networks. The treatment is up-to-date and well referenced with some 65 primary literature citations: the ubiquitous $YBa_2Cu_3O_{7-\delta}$ high-T_c superconductor phase and C_{60} "buckyballs" are described in the appropriate sections. The treatment of structure in these chapters is descriptive rather than crystallographic.

There is a tantalizingly brief section on the physical properties of solids, which provides an overview of bulk mechanical, electrical, and magnetic properties and their relationship to the structures of solid materials. However, the reader is referred elsewhere for more detailed treatments. It would have useful to include some more examples of real materials here.

There are no details provided on structure determination in this volume, and the two sections on crystallographic descriptions are brief: the first describes the basis of symmetry in three dimensions, and the second largely discusses crystallographic group–subgroup relationships, which may prove to be heavy going for some. I would have liked to see some straightforward descriptions of the crystallographic representation of real structures, perhaps akin to the treatment provided in H. D. Megaw's classic *Crystal Structures: A Working Approach*.

Overall, this book reminded me somewhat of *Structural Inorganic Chemistry* by A. F. Wells, but at a somewhat simplified level, and at a greatly reduced price. It is nicely produced and well set out with the TEX typesetting system, and largely illustrated by means of the ATOMS molecular graphics program. I recommend this book for courses teaching structural chemistry and also for those who wish to obtain a clear and up-to-date overview of this important area of solid-state science.

Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Gaseous Molecular Ions. An Introduction to Elementary Processes Induced by Ionization. (Series: Topics in Physical Chemistry, Vol. 2. Series editor: Deutsche Bunsen-Gesellschaft für Physikalische Chemie.) By *E. Illenberger* and *J. Momigny*. Steinkopf, Darmstadt/Springer, New York, 1992. XIV, 344 pp., hardcover DM 64.00.—ISBN 3-7985-0870-4/0-387-91401-3

This book is concerned with elementary processes in the ionization of molecular systems. As the title of the series indicates, the emphasis expected from the authors is not so much on giving a comprehensive treatment of the subject as on introducing the reader to a topical area of research from a chemical perspective. Here the authors have sensibly limited their treatment to research topics with which the chemist is likely to be already familiar from a number of aspects, and have reported on the latest state of progress in these areas. The book is of outstanding interest for the chemist, providing not only a survey of well-established experimental techniques such as photoelectron spectroscopy and electron capture but also an up-to-date description of the dynamics of unimolecular breakdown, which is also of interest for teaching purposes. The latest high-resolution laser techniques such as resonance-enhanced multiphoton ionization (REMPI), ZEKE (zero kinetic energy) photoelectron spectroscopy, and photodetachment receive only marginal coverage—these topics could have been treated more effectively in a separate volume.

The book is divided into three parts. The first part deals with experimental techniques for generating molecular ions, the second with the breakdown of electronically excited molecular ions, and the third with electron capture by molecules and clusters. The book certainly lives up to the claim of providing a survey of a large part of this rapidly developing field. The literature coverage is extensive and up-to-date, even including most of the work published in 1991.

In the experimental part, methods such as photoelectron spectroscopy and photoionization mass spectrometry for studying molecular ions are described in detail. Light sources, analyzers, and the important coincidence techniques are described in such a way that the reader will gain a good understanding of the experimental aspects without needing to consult the original literature. Here the authors concentrate on results obtained by single-photon ionization using vacuum-UV sources;

they describe examples of different types of mass spectrometric systems, as well as the most important types of photoelectron analyzers and detectors. This survey is quite comprehensive and reasonably up-to-date, although it would have been useful to draw attention to the laser ionization methods that have recently become so important, by including references to relevant review articles. Also the book does not cover methods for studying free radicals, such as the important photoelectron spectroscopic techniques reported during the last ten years, and the use of photodetachment spectroscopy for studying negative ions is only treated sketchily. Despite these reservations (concerning topics that could only be treated properly in a separate volume), this review of experimental aspects is very useful, as it provides a degree of detail and up-to-dateness that was hitherto only accessible by reading the original literature.

The second part of the book deals with unimolecular breakdown processes in electronically excited molecular ions. As well as describing the most important ionization processes and showing how these can be understood on the basis of molecular orbital theory, the authors give special attention to the energetic aspects (breakdown curves) that are so important to the chemist, and to ionization mechanisms. A digression to consider the possible types of transitions between electronic states of molecular ions is followed by a discussion of the energy distribution in dissociation. Here the authors include a chapter on the application of statistical theories of breakdown (RRKM and QET). Although these methods are also described in other books and in the original literature, this chapter is very useful, even for advanced students. In it the authors discuss the most important points that must be considered when using the RRKM theory, including the choice of the transition state, effects of nonadiabatic interactions, and numerical methods for performing the calculations. However, the effects of rotation and angular momentum on the reaction rate are only treated marginally. Altogether this chapter gives the reader a good introduction to the complexities of the theoretical approaches that are currently available, such as the use of potential surfaces derived by ab initio methods to support RRKM calculations.

The third part of the book is concerned with the 'classical' experimental methods of electron capture in thermal gases. The difficulty with these methods is the poor resolution due to the broad thermal energy distribution, which prevents one from obtaining state-selective information. Here it would have been useful to give a survey of modern techniques, such as the generation of very low temperature negative ions using an ultrasonic beam. The authors also neglect to include the important recent work on the photodetachment of molecular and cluster anions, which yields much more detailed information than the classical electron capture methods. Nevertheless, this part of the book summarizes the most important mechanisms of the formation, stabilization, and energetics of negative ions in a form that will make it much easier for the chemist to get a grasp of this subject.

In this book the authors have succeeded in presenting the subject of molecular ions, which is extremely important to chemists, in such a way that not only physical chemists but also inorganic and organic chemists should have sufficient background knowledge to understand it. The reader is given a very good introduction to the problems of this very active field of research. The book belongs in the library of every chemist who is concerned with matters such as the formation, reactivity, energetics, and kinetics of ions. It is also attractively priced.

The Organic Chemistry of β-Lactams. Edited by *G. I. Georg*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XI, 381 pp., hardcover DM 189.00.—ISBN 3-527-38188-6/1-56081-083-1

Although it is 65 years since Fleming's momentous discovery of penicillin, research on the chemistry of the 'enchanted ring' (J. C. Sheehan) is still active and flourishing. It is therefore difficult to get a comprehensive overview of all the recent developments in the chemistry of β-lactams. This book aims to remedy that situation by collecting together all the most important results achieved during the 1980s, with a few references to work published up to 1991. Instead of treating individual types of antibiotics in turn, as in similar books on the subject, the authors discuss methods that are of general importance.

The first chapter, "Protective Groups in β-Lactam Chemistry" (H. Wild, 48 pp.) goes straight into practical matters with a survey of the special protecting group methods used, supported by numerous tables. The next chapter, "Introduction and Transformation of Functional Groups in β-Lactam Chemistry" (H. Wild, 71 pp.), well illustrates the extent to which the lability often encountered with the four-membered ring forces one to adapt the reactions and methods to suit special situations. In "Strategies for the Synthesis of Bicyclic β-Lactams" (76 pp.) J. Kant and D. G. Walker describe methods for anellating an additional ring on to the existing β-lactam system. In the chapter entitled "β-Lactam Synthon Method: Enantiomerically Pure β-Lactams as Synthetic Intermediates" (I. Ojima, 59 pp.), we are taken outside the usual area of antibiotics for a description of the use of β-lactams as intermediates for the synthesis of aminoacids, especially optically active products, and of oligopeptides. In "Novel Methods for the Construction of the β-Lactam Ring" (37 pp.) R. J. Ternansky and J. M. Morin Jr. collect together various ring closure reactions for synthesizing β-lactams; however, the information content of this chapter falls well short of that in other treatments of β-lactam antibiotics. Lastly, the editor and V. T. Ravikumar together report on "Stereocontrolled Ketene–Imine Cycloaddition Reactions" as applied to the synthesis of β-lactams (74 pp.). Two topics not covered in the book are syntheses of β-lactams by cyclocondensation of ester-enolates with imines, and reactions of imines with carbene complexes.

The chapters are well furnished with literature references and appear to have been carefully checked; one error that has slipped through appears in the formula of Dane's salt (p. 346). The formula diagrams have evidently been drawn by the individual authors, and consequently they differ in style from chapter to chapter; however, this does not detract from the very good visual impression given by the book. Altogether this is a work which contains much interesting and valuable information for β-lactam chemists, and it can be recommended unreservedly to everyone working in this field.

Multiple Bonds Between Metal Atoms. 2nd edition. By *F. A. Cotton* and *R. A. Walton*. Oxford University Press, Oxford, 1993. 787 pp., hardcover £ 70.00.—ISBN 0-19-855649-7

In 1994 it will be thirty years since the crystal structure of $K_2Re_2Cl_8 \cdot 2H_2O$ was

determined, and the term quadruple bond was introduced into the literature, together with the recognition that multiple bonds between metals were experimentally accessible. In retrospect it is clear that the occurrence of multiple bonds between metal atoms was discovered in the most favorable circumstances. The previous decade had seen great advances in the understanding of the electronic structure of transition metal compounds, the physical methods necessary for the characterization and study of inorganic materials had largely been developed, and finally, the quadruple bond was first established in the laboratory of one of the most dynamic of modern inorganic chemists, Professor F. A. Cotton. The model of the bonding that was proposed in the very first publications served as a guide for further synthetic efforts, and the increasing availability of X-ray crystal structure determination as a routine tool allowed rapid and unambiguous characterization of the compounds. The subject has developed rapidly, but coherently, to become a paradigm of modern descriptive chemistry. Many high yield syntheses of these multiply bonded compounds are now available, and the bonding exotica of twenty-five years ago have become the readily available starting materials of today. There have, of course, been many surprises in this development, not least in the number of multiply bonded species that may be prepared for a wide variety of transition metals. The extraordinary reactivity of the metal–metal multiple bond (shown for example by the rapid breaking of the carbon–carbon triple bond on reaction of alkynes with $W_2(OR)_6$, or the dissociation of the chromium–chromium quadrupole bond of $[Cr_2(O_2CCH_3)_4]$ in aqueous solution) was hardly predictable.

The continuing interest in this remarkable chemistry has led the authors to produce a second edition of the book they originally published in 1982. The activity during the ten years following its publication was such that the second edition is 70% longer than the first. It comprehensively covers the literature up to 1990, with most of 1991 and some papers of early 1992. After a brief historical introduction, the greater part of the book discusses the compounds according to the metals involved: dirhenium and ditechnetium compounds (111 pp.), dimolybdenum and ditungsten compounds (119 pp.), excluding the $L_3M{\equiv}ML_3$ compounds which are treated in a separate chapter (96 pp.), dichromium compounds (45 pp.), diruthenium and diosmium compounds (32 pp.), dirhodium compounds (71 pp.), other dimetal compounds (31 pp.), and metal–metal multiple bonds in other contexts (97 pp.). Each chapter is logically subdivided according to metal type, metal oxidation state, and ligand type. The text is extremely well presented, with abundant use of tables, figures, and structural formulas. In contrast to this element by element approach, Chapter 10 discusses physical, spectroscopic, and theoretical results for all compounds, and thereby gives a more comparative view. It shows not only the power of modern physical methods, but also the limitations and difficulties of interpretation associated with the methods, be they experimental or theoretical. It is piquant to note that it is easier to measure the metal–metal vibrational frequencies in the first excited state than to make a reasonably accurate ($\pm 10\%$) estimate of the metal–metal bond energy. Finally, Chapter 11 gives a brief coverage of the literature of late 1991 and early 1992. The chapter lengths given above show clearly how metals of Groups 6 and 7 still occupy a dominating position in this field, quite logically since they are most easily obtained in the d^3 and d^4 configurations so well suited for metal–metal multiple bonding. This reviewer was, however, struck by the relative paucity of mechanistic studies involving the classical L_4MML_4 systems in comparison with the abundance of reactivity studies for $L_3M{\equiv}ML_3$ compounds.

The authors are to be thanked for undertaking the arduous task of assembling the data from over 2000 research papers into a critical and comprehensive book, and should be congratulated on their success. As in the case of the first edition, this book will become the standard reference and an essential tool for anyone working in the field. However, this book is too good to leave to specialists alone. The introductory chapter could be read with pleasure and profit by any advanced undergraduate, and the chapter on physical, spectroscopic, and theoretical results, while it may require some cross-references to earlier chapters, is a model of clear exposition and critical examination of results which should interest all inorganic chemists. This book gives a masterly description of one of the most active areas of modern inorganic chemistry, and will serve not only as a reference, but as a stimulus for further research.

Kinetic Theory and Irreversible Thermodynamics. By *B. C. Eu.* Wiley, Chichester, 1992. 732 pp., hardcover £ 67.00. ISBN 0-471-61 524-2

The thermodynamics of irreversible processes close to equilibrium is now a well-established area of physics and physical chemistry. In order to calculate the increase in entropy resulting from an irreversible process, one assumes that a local thermodynamic equilibrium is established. The flows and the thermodynamic forces driving them are related by appropriately chosen linear equations, in which the reciprocity condition of Onsager and the Curie principle play an important role. The range over which the linear equations are valid must be determined experimentally.

However, irreversible processes also take place under conditions such that the system under observation is far removed from equilibrium and the linear equations are no longer applicable. The theoretical treatment of such processes raises a number of fundamental questions which must be answered before one can attempt to formulate a consistent theory of irreversible processes remote from equilibrium. This monograph is a contribution towards the development of an appropriately extended form of irreversible thermodynamics. The author considers irreversible kinetic equations such as the Boltzmann equation as fundamental relationships that are based on the microscopic equations of motion of particles. The irreversible kinetic equations are used to describe the behavior of macroscopic systems (gases, liquids, etc.). Based on the theory of irreversible processes, methods of solution are developed which are consistent with the laws of thermodynamics.

The book is divided into fifteen chapters. The continuum theory and the thermodynamics of irreversible processes (including a chapter on irreversible processes in electromagnetic fields) are treated in Chapters 2 to 9, then the kinetic theory and the statistical-mechanical basis of irreversible thermodynamics remote from equilibrium are treated in Chapters 10 to 15.

The book is intended for physicists and chemists with interests in this area of theory, and can be recommended for reading by everyone who wishes to learn about the current situation in the development of an extended thermodynamic theory of irreversible processes.

Dietrich Woermann
Institut für Physikalische Chemie der Universität Köln (FRG)

Super-Acids and Acidic Melts as Inorganic Chemical Reaction Media. By *T. A. O'Donnell*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XI, 243 pp., hardcover DM 184.00.—ISBN 3-527-28092-8/1-56081-035-1

There have been a number of monographs on this subject area, most recently the book *Superacids*, by Olah, Surga Prakash, and Sommer, which appeared in 1985 and dealt mainly with the protonation of organic molecules. The latter topic is therefore not treated in the book reviewed here.

After giving the essential definitions of acids and bases and an introduction to the chemistry of aqueous solvent media, the author compares different methods for investigating dissociation in superacids and establishing a scale of acidity. This is followed by a description of the most commonly used acidic solvents, H_2SO_4, CF_3SO_3H, and FSO_3H; in accordance with their importance, considerable space is devoted to hydrogen fluoride and its mixtures with Lewis acids. The part on specific substances covers a wide range, extending from the homonuclear cations of halogens, chalcogens, and metals, through transition element cations in both normal and lower oxidation states, to zintl, polychalcogen, and polyhalogen anions.

The author points out that the various ions described have certain common properties, insofar as polycations can only exist in superacids and acidic melts, whereas polyanions can be formed in basic solvents. This general ordering principle accounts for various observations. Since Br_2^+ and Br_3^+ are only formed in extremely strong superacids with H_0 values of about -19 and -15 respectively, the still significantly electrophilic species Cl_2^+ cannot be isolated as a substance. The example of I_3^+ discussed on pages 109 and 219 provides impressive confirmation that, in addition to the absolute acidity, the individual properties of the solvent play an important role in stabilization. The fact that bases catalyze the disproportionation of polycations is regarded as highly significant. The author cites many examples of this behavior, which is observed both in superacids and in chloroaluminate melts when their basicity is increased. Aspects of the chemistry in salt melts are also discussed at length, with special attention to the similarities and differences compared with superacids.

This book is well worth reading, not only for its systematic treatment but also for the valuable practical hints on working with these very difficult solvents. For example, how many chemists already know all the factors that must be observed in order to achieve the record value $H_0 = -21$ in HF/SbF_5?

The subject matter is clearly arranged, and the individual chapters can be read independently of each other. Many cross-references are given, so that one can work through the material quite rapidly. A less satisfactory aspect is that, apart from his own publications, the author relies mainly on the reviews by Gillespie, Passmore, Corbett, Mamantov, and others, while neglecting the primary literature, especially the most recent work. Consequently the book is not very up-to-date. However, despite some shortcomings in matters of detail it can be recommended unreservedly for advanced students.

Icons and Symmetries. By *S. L. Altmann*. Oxford University Press, Oxford, 1992. VIII, 104 pp., hardcover £ 14.95.—ISBN 0-19-855 599-7

The subject of symmetries and their mathematical description using group theory is a popular one for book authors. It has become difficult even to keep track of the number of textbooks written specifically for chemists. Simon Altmann has already published several monographs and textbooks on the subject, all of which introduce novel aspects, both in content and form of presentation.

Thus, one opens this slim book with great curiosity, and is not disappointed. Treating the subject at a mathematical level accessible to most readers, Altmann uses three case studies, taken from his lectures in the Science Faculty of the Catholic University of Leuven, to explore the relationships between physical objects, models, and symbols ("icons"). Although he cites Hermann Weyl's well-known book *Symmetry* as the model for these lectures, Altmann wisely decides on a different, quite original, approach. He discusses the formulation of the physical problem hand-in-hand with the historical and philosophical aspects, with the aim of showing how ideas of symmetry have entered into our scientific thinking. Thus, the book is concerned with discussing symmetry in a general way rather than with formally describing it by group theory, and accordingly the term "group" is not even mentioned.

The three examples can be roughly classified as belonging respectively to physics, mathematics, and chemistry. In the first the author discusses the concept of symmetry from the standpoint of Oersted's paradox concerning the interaction between a compass needle and an electric current. This involves mirror image symmetry—to be more precise, the transformation properties of vectors on reflection. Altmann compares different formulations of the symmetry principle by Archimedes, Thomas Aquinas, and Pierre Curie ("Lorsque certaines causes produisent certains effets, les éléments de symmetrie doivent se retrouver dans les effets produits"). [Since definite causes produce definite effects, the elements of symmetry must be deduced from the effects that they produce.] He shows very convincingly the sort of confusion that can arise if one applies symmetry uncritically to analyze a physical problem and equates the properties of a symbol such as a vector arrow with those of the physical entity that it represents. Nowadays we are all familiar with the need to distinguish between polar and axial vectors.

In the second example Altmann discusses the relationship between quaternions and rotations, which he treated in detail a few years ago in a monograph devoted to the topic. He relates the fascinating history of quaternions as an example of how even such a clever intellect as that of Hamilton, the inventor of quaternions, could be led astray through a wrong choice of an "εικών". In a conclusive analysis Altmann shows how this error, which influenced later developments over a long period, was related to Hamilton's particular philosophical view of nature. Hamilton arrived at the idea of quaternions by an algebraic route while attempting to further generalize complex numbers. Altmann contrasts Hamilton's approach with that of Rodrigues, who, independently and at almost the same time, developed a theory of rotations from a geometrical standpoint. The chapter ends with a rigorous and detailed consideration of the transformation properties of vectors, with a look also at tensors and spinors and their symmetry properties.

In the third chapter the author discusses the use of symmetry considerations to classify the energy levels of atoms and solids. He bases the latter on a version of the band structure theory of solids reduced to its minimum essentials, that of a linear chain. Next he discusses the problem of symmetry breaking, taking as an example the Peierls instability of polyacetylene. Here again a paradox only arises if one too hastily equates the symmetry of the model with that of the real physical situation. However, as the author himself

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0482 $ 10.00+.25/0

points out, the reader needs to be more adept at formal reasoning here than in the rest of the book, in order to follow the proof given here for the degeneracy of states at the boundaries of the Brillouin zone in a quasilinear chain as a consequence of the presence of a glide plane. Nevertheless, it is difficult to see why the author, despite his insistence on care in the choice of symbols, does not use two orbital representations of the corresponding Bloch functions, which would have immediately convinced any chemist that a degeneracy exists.

This book contains many ideas to stimulate the reader to think about symmetry and its effects as they relate to describing nature. The historical perspectives undoubtedly help here, although occasionally these are presented in a way that the reader may find trying. Sometimes one has the impression that extra details are included not so much to illuminate the problem as to show off the author's historical knowledge. At one point (p. 44) it seems that he is conscious of this himself: "...and thus you will feel like closing the book. If this is so, please listen to my entirely disinterested advice (my royalties are paid to me even if you burn this book) and go on reading...". This style is perhaps not to everyone's taste. It also seems a little surprising when the author, in the preface, expresses a wish that young people might read this book before coming to university. Despite these comments, the book can be thoroughly recommended to everyone who wishes to become involved with symmetry and its role in science.

Charge Transfer Photochemistry of Coordination Compounds. By *O. Horváth* and *K. L. Stevenson*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1993. XVIII, 380 pp., hardcover $ 98.00, DM 238.00.—ISBN 1-56081-564-7/3-527-89564-7

It is now almost a quarter of a century since Balzani and Carassiti, in their classic work *Photochemistry of Coordination Compounds* (Academic Press, 1970), presented the last comprehensive picture of the subject. In the monograph reviewed here, O. Horváth and K. L. Stevenson set out to bridge this gap in time for an important part of that subject, namely charge transfer photochemistry. Their treatment is mainly concerned with photoreactions in which the primary step is a charge transfer process involving light excitation of a Werner type metal complex in homogeneous solution. The book also briefly covers some photoredox reactions of such complexes in the solid state or in microheterogeneous systems. The restriction of the coverage of the photochemistry of organometallic compounds, which is stated in the preface, is only departed from significantly in the treatment of rhenium complexes.

The book is divided into two parts, with thirteen chapters altogether. The first part consists of three chapters which deal, mainly in a condensed form, with the basic principles of the spectroscopy, photochemistry, and photophysics of coordination compounds. The second part covers in detail the results published up to the beginning of 1991 on the charge transfer photochemistry of the complexes, arranged according to the group of the Periodic Table to which the central atom belongs. Here the authors have sensibly devoted most attention to the photochemistry of the Main Group metals, previously only rather scantily covered in monographs, while presenting in condensed form the photochemistry of ruthenium(II)-polypyridyl complexes, which has already been very adequately reviewed elsewhere. To make the work as up-to-date as possible there is a bibliographic appendix listing publications that appeared in the period 1990–1992 and could not be reviewed in the individual chapters. A further appendix explains the abbreviations and symbols used, and the volume is completed by formula and keyword indexes.

The exhaustive coverage of experimental results makes this book a mine of information for the professional photochemist. On the other hand, it is doubtful whether the authors have succeeded in their declared aim of presenting the subject in an attractive way to many potential newcomers. There are three main reasons for this. Firstly, the concentration on experimental results has meant that many fascinating applications of charge transfer photochemistry, such as solar energy conversion, information processing, or the generation of catalytically active species for organic synthesis, have had to be virtually ignored. Secondly, the arrangement of the complexes according to which group of the Periodic Table the central atom belongs to creates a problem, as it means that generalizations within individual chapters are rarely possible, since the direction of the photoinduced charge transfer, and therefore the subsequent reaction steps, are greatly dependent on the oxidation state of the central atom and the nature of the ligands. The authors have tried to take this into account by dividing the chapters into subsections for different oxidation states of the central atom and by including many cross-references. However, it is hard to understand why the further subdivision according to coordination pattern that has been used in the text is not indicated in the list of contents. Thirdly, it would have been desirable to have a summary classifying the reactions according to broad types.

Regrettably, the reader is often confused by the inconsistent use of terms and symbols, and by the many printing errors which in some cases alter the meaning. For example, the quantum yield is represented by the symbol Π in the introduction and in the list of abbreviations and symbols, whereas in the main text the more usual symbol Φ is used. The neutral complex $[Co(gly)_3]$ is shown in the formula index, and sometimes also in the text, with a triple positive charge. The acetate ion in Equation 9.123 is shown as retaining its negative charge even after oxidation. In the text accompanying Equation 12.29 reference is made to a ring-opening with cleavage of a Co–C bond, whereas the formula diagram shows cleavage of the Co–N bond. In the classification of charge transfer transitions in Chapter 3 the expression 'ion pair charge transfer' (IPCT) is not mentioned, despite the fact that it is used frequently, even incorrectly in a few cases (pp. 94, 163). Lastly a word about the presentation: in the illustrations to the chapters of the second part the authors have gone to the trouble of converting the formula diagrams and spectra copied from the original papers into a uniform style; however, the result is not altogether convincing when compared with the quality of the figures in the first part.

Notwithstanding these critical comments, the book is likely to be very well received by both coordination chemists and photochemists. The former will learn how light can serve as a reagent by interacting with their compounds in ways that may be new to them, while the latter will appreciate having easy access to a large collection of factual material. Therefore, despite the high price it deserves a place in every chemical library.

Organic Photochemistry: A Visual Approach. By *J. Kopecký*. VCH Publishers, New York/VCH Verlagsgesellschaft,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0404-0483 $ 10.00+.25/0

Weinheim, 1992. IX, 285 pp., hardcover DM 98.00.—ISBN 0-89573-296-3/3-527-26952-6

This book is an introduction to organic photochemistry for students who have already assimilated "regular" organic chemistry, and for mature synthetic organic chemists. Nothing new there, one might think. Not so, because the book is based on a brilliant teaching concept. Many chemists would rather listen to lectures than read books, as the former are illustrated by slides which present scientific information in a remarkably concentrated and striking form which is well suited to the strongly visual nature of the scientist's thinking, especially that of the organic chemist. Thus one should write a book in the style of a slide presentation, with the "slides" arranged one after another on the left-hand side and the explanations on the right. The book consists of 16 such "slide talks": an introduction; electronically excited states; photophysical processes; theoretical concepts; eight chapters on individual compound classes; photochemical oxidations and singlet oxygen; preparative techniques; factors influencing the progress of photochemical reactions; applications (including a last example from outside the research laboratory, concerning what happens to beer in sunlight and why it is better kept in brown bottles than green ones). The book is illustrated by 597 "slides", representing an enormous amount of work by the author and his colleagues. These are intended to be mainly self-explanatory, so that the accompanying text should be almost superfluous. This works very well in the chapters dealing with the photochemical behavior of the individual compound classes, but is less well suited for the first four chapters which are more theoretical. For the novice meeting these ideas for the first time, much of the content of these first four chapters will probably remain enigmatic, despite the explanatory text, which needs to be expanded in some parts to remedy this; space for this could be made by eliminating some of the repetitions. However, for the reader who has failed to understand some points, the many literature references on particular matters in the theoretical chapters and the detailed lists of material for further reading should help considerably. Throughout the book generally, the original literature is thoroughly covered; for example, there are 776 references just in the chapters on photochemical reactions. It is unfortunate, though, that the CIEEL (chemically induced electron excitation luminescence) mechanism receives only one brief mention (in 13.26), with neither an explanation nor a literature reference. The chapter on applications is excellent, not only describing industrial and analytical applications but also emphasizing the importance of photochemical reactions in biology, medicine, and the environment.

In a work of this kind one inevitably finds that a few errors have crept in. The incidence of errors in the physical and theoretical sections is somewhat higher than elsewhere. This begins with Figure 1.3, where the vibrational energy in the electromagnetic spectrum should correspond approximately to the range 2500–15000 nm rather than 700–1100 nm, and the values of the λ(cm)-scale should be reduced by about a factor of ten. The symmetry symbols contain a number of errors: for example, in 2.30 (explanatory text) the subscripts 2 and 1 relate not to σ_v but to C_2' (through the atoms). Similarly in 2.29 (the figure), it should be mentioned that, depending on symmetry group, these same two subscripts may relate not to σ_v but to C_2'. Also, in the same figure, the symbols A, B do not have the absolute significance for certain groups (D_{nd} and S_n) that is given here. The direct product $E_{1g} \times E_{2u}$ is incorrectly written in 2.31 (figure) and in 2.33 (text) on the left-hand side of each equation. In 2.31 (figure), where the point group is given as $D_{6\infty}$ instead of $D_{\infty h}$, the error is innocuous and immediately obvious, but a more serious error appears in 5.3 (figure), where the T_1 and T_2 states of the planar ethylene molecule are wrongly denoted as $^3B_{2g}$ and $^3B_{2u}$ (instead of $^3B_{1u}$ and $^3B_{3u}$). In 3.11 (text) it appears that the first two arrows should be reversed. In the equations given in 3.44 and 3.45 $\Sigma_i k_1$ should be replaced by $\Sigma_i k_i$, $1/k_i$ by $1/\Sigma_i k_i$, and $k_q + k_q$ [Q] by $k_d + k_q$ [Q]. In 4.13 (figure) under (c), "adiabatic" should be "nonadiabatic". In 4.23 (figure) the "bonding interactions" for $A^{\bullet +}$ are wrongly stated to be always weakened compared with those for A; if the outermost electron of A is in an antibonding molecular orbital (MO), the bonding interactions are instead increased ($N_2H_4 \rightarrow (N_2H_4)^{\bullet +}$, $O_2 \rightarrow (O_2)^{\bullet +}$). The entire analysis in Figure 13.9 is incorrect, since both the highest occupied MO and the lowest unoccupied MO of $^1\Delta_g - O_2$ are not symmetric but antisymmetric with regard to a reflection through the plane perpendicular to the axis of the molecule. The "organic" chapters contain a number of incorrect formula diagrams (in 5.29, 6.31, 6.42, 9.11, 15.3, two in 15.30, and 15.43); these are innocuous, since even the novice reader will notice that something is wrong and can look it up if necessary. In 5.17 cyclohexene is a badly chosen example to illustrate the text, since in this particular case dimerization occurs via *cis–trans* isomerization. In 5.18 the value of E_T for acetone should be 79–82 instead of 75. In 6.10 the middle arrow should be a two-way one (mesomerism, not reaction). In 2.86 (text) the descriptions "in the plane of the molecule" and "perpendicular to the molecular plane" should be interchanged, as also should "electron deficient" and "electron rich" in 8.27 (text). In 13.43 (figure) CP$^\bullet$ should be CP$^{\bullet +}$ in both cases.

There are also some explanations that could be misunderstood. In 2.10 (text, fifth sentence) the impression is given that no molecular π-orbitals are present in molecules such as O_2, N_2, and acetylene. (Although these molecules have no low-lying Π-states they do have π-MOs.) In 2.23 (fourth sentence), 2.38 (first sentence), and 6.40 (first sentence) some readers may have difficulty in understanding the author's meaning, even though the facts themselves are simple. In 3.7 the reasoning would be much clearer if the words "thermally equilibrated" appeared before S_1 and T_1 in the statement of Kasha's rule. In any case, Ermolaev's rule is not a consequence of Kasha's rule, and to emphasize it in 3.7 is misleading, as it is so seldom valid for solutions. In 4.3 (figure), the explanation could be expressed more simply as follows: "The total number of electrons involved, divided by two, plus the total number of antarafacial interactions is even." In 8.28, the *cis–trans* isomerization of 1,2-dicyanoethylene is, of course, not "stereospecific", as is stated in the text and suggested by the figure; instead it always yields a *cis–trans* mixture.

However, these shortcomings (and others that have no doubt passed unnoticed) can be remedied, though the reader should be aware of them. They are of relatively little importance compared with the great service to organic photochemistry that is achieved in this book. It is a great pity that Professor Kopecký is no longer here to witness the favorable reception of his book. One certainly wishes it great success!

Mülheim an der Ruhr (FRG)

Nitrogen Donors in Organometallic Chemistry and Homogeneous Catalysis

Antonio Togni* and Luigi M. Venanzi

Homogeneous catalysis has been responsible for many major recent developments in synthetic organic chemistry. The combined use of organometallic and coordination chemistry has produced a number of new and powerful synthetic methods for important classes of compounds in general and for optically active substances in particular. For this purpose, complexes with optically active ligands have been used, most of them coordinating through phosphorus. More recent developments have highlighted the use of "nitrogen-donors", particularly as they are easily obtained from the "chiral pool". However, the remarkable achievements in this area have been based on an empirical approach. This article attempts to bridge the gap between the synthetic and the coordination chemist. The first section discusses the rates of formation and dissociation of complexes with nitrogen donors, their relationship to the rates of product formation, and presents the factors which induce homolytic cleavage of M–C bonds. It also provides a summary of the main types of organometallic complexes formed by metal centers coordinated to nitrogen donors and their reactivity patterns. The second section highlights the most significant, homogeneously catalyzed reactions involving complexes with nitrogen ligands. Foremost among them are the asymmetric aspects of hydrogenation (particularly those involving boranes as reducing agents), hydrosilylation, cyclopropanations, Diels–Alder reactions, aldol condensations, alkylation of aldehydes, conjugate addition reactions, Grignard cross-coupling reactions, allylic alkylations, oxidation reactions, olefin epoxidations, and dihydroxylation of olefins.

1. Introductory Remarks

The development of organometallic chemistry and homogeneous catalysis during the last forty years, and particularly that involving transition metals, has been closely associated with the realization that their formation, stability, and reactivity are governed by the fundamental rules of coordination chemistry.[1] Thus, an awareness of these rules is essential for any rational discussion of organometallic reactions.

When applying these rules to carbon donors one must take into account the fact that the great majority of compounds containing M–C bonds also contain coligands (often referred to as "spectator ligands", although their real role is far from that of being mere spectators) which have donor atoms other than carbon. Foremost among these are the P-donors. Two other essential coligands in organometallic chemistry are the hydride ion and CO, itself a C-donor. Indeed these two ligands played a central role in the early developments of the synthetic applications of organometallic chemistry, particularly because of their dual role as "reagents" and coligands.

Textbooks of organometallic chemistry and homogeneous catalysis[2] make sporadic reference to the use of N-donors, but hitherto no attempt has been made to systematize their role, as has been done for P-donors. Furthermore, although phosphorus donors and their higher homologues have received much attention, and numerous books and reviews describing their coordination chemistry have been published,[3] nothing of the kind has occurred for the organic nitrogen donors, possibly because their complexes have not been extensively used for synthetic organic applications. Therefore, this article will discuss the role of the N-donors in the above areas, often by comparing and contrasting them mainly with P-donors.

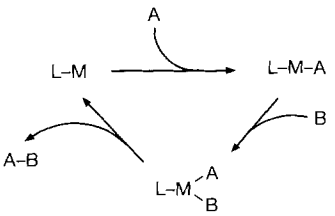
2. Fundamental Concepts of Organometallic Chemistry

The organometallic chemistry discussed here is concerned with the formation, transformation, and rupture of M–C bonds. Nevertheless, as this review emphasizes the role of complexes with nitrogen donors in organic synthesis, reactions that are not organometallic in the sense defined above will also be included in the section dealing with catalytic processes.

The metal centers which will feature prominently are those of the transition and post-transition series, although the organometallic chemistry of the lanthanides and actinides is being actively investigated.[4] Organometallic compounds of some of the alkali and alkaline earth elements, as well as those of boron



and aluminum, are frequently used as reagents or catalysts in the reactions described later. Furthermore, there is no fundamental difference between their chemistry and that of the transition and post-transition elements: They share an essential and common feature in their "coordination behavior", even though boron and aluminum frequently form compounds having three-center, two-electron bonds.[5]

As its title implies, this review will be mainly concerned with compounds containing nitrogen donors as coligands and their organometallic chemistry. For this purpose it will be useful to summarize briefly the main features of coordination behavior, of the carbon donors and their properties, and of the nitrogen donors.

2.1. Coordination Behavior

Any atom, generally referred to as the "central atom", which possesses low energy orbitals containing fewer electrons than required for the formation of the maximum possible number of conventional, two-electron covalent bonds, can easily form more bonds than its "classical" covalency implies. In other words, a molecule containing such a central atom is a Lewis acid. Conversely, a Lewis acid is a molecule containing such a central atom and is said to be "coordinatively unsaturated". This is a major feature in the context of this article, as many Lewis acidic complexes containing nitrogen donors play a role in catalytic processes (see, for example, Sections 5.6 and 5.7).

As will become apparent later, the most prominent application of complexes containing nitrogen donors is the synthesis of optically active organic molecules. For most organometallic reactions of interest here, one can envisage a pathway of the type shown in Scheme 1.

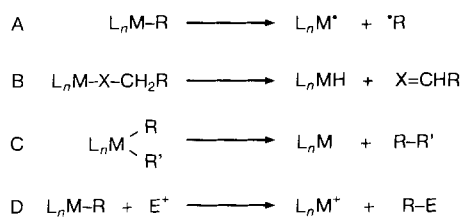
Scheme 1. A general description of organometallic or related reactions. L = coligand or ligands; M = central atom; A, B = organometallic or other reagent.

The ligand or ligands denoted by L in this Scheme may fulfill a variety of functions:

1. modulation of the electron density at the central atom M and, therefore, its reactivity;
2. blocking of a number of coordination sites at M and, consequently, control of the multiplicity and symmetry of the valence orbitals available for the organometallic reaction;
3. provision of the environment within which the organometallic reaction will take place.

Furthermore, the dynamics of the M–L interactions play a crucial role in successful organometallic reactions. This is obviously connected with the dissociation rate of the M–L fragment: if it is much faster than the rate-determining step for the formation of A–B, the ligand L will not exert a significant influence on the organometallic reaction. Important exceptions to this simplified behavior are those catalytic systems in which ligand-induced acceleration is observed (see Section 5.12.2). It follows that, when considering the role of a coligand L (a nitrogen donor in our case), not only the thermodynamics[6] but also the kinetics of complex formation between M and L must be considered.

Before discussing these factors it is appropriate to say a few words about the organometallic steps of a reaction sequence. An essential feature of a catalytic reaction is that it includes one step that is either irreversible or virtually irreversible. Most frequent-

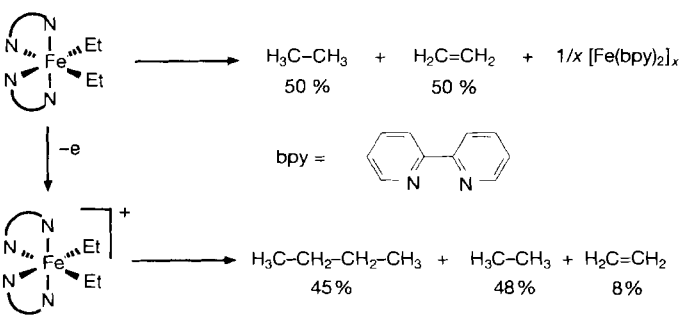


Antonio Togni, born in 1956 in Roveredo, Switzerland, studied chemistry at the Eidgenössische Technische Hochschule (ETH) Zurich, where he completed his Diploma in 1979, and his Ph.D. in 1983, working with Luigi M. Venanzi. After a postdoctoral year at the California Institute of Technology in John E. Bercaw's group and a short stay with Alberto Albinati at the University of Milan, he returned to the ETH as a research associate. In 1985 he joined the Central Research Laboratories of CIBA-GEIGY Ltd., where he spent seven years as a research scientist in the field of asymmetric catalysis. He is currently Assistant Professor of Organometallic Chemistry at the Laboratory of Inorganic Chemistry at ETH. His research interests are in the field of homogeneous catalysis and molecular materials.

Luigi M. Venanzi was born in Rome in 1927 and received his Diplom in Chemistry at the University of Kiel in 1952. He then joined the Butterwick Research Laboratories of ICI Ltd., working in the group of J. Chatt. In 1956 he was appointed ICI Research Fellow at the University of Oxford. After attaining the degree of D. Phil. in 1958, he became a Lecturer at the Inorganic Chemistry Laboratory and a Fellow of Magdalen College, Oxford, positions he held until 1968 when he joined the State University of New York at Albany as Professor of Chemistry. In 1971 he became E.I. du Pont Professor and Chairman of the Chemistry Department at the University of Delaware. He has been Professor of Inorganic Chemistry at the ETH in Zürich since 1973. His research interests range from homogeneous catalysistro cluster chemistry, with a strong bias for the coordination chemistry of the platinum-group metals and polydentate phosphanes.

ly, this is a reductive elimination reaction,[2] as shown in the last step of Scheme 1, where either a C–H or a C–C bond is formed. Furthermore, in principle, one can envision the same organometallic reaction with a variety of coligands coordinating through different donor atoms; their electronic nature and geometry will favor, or disfavor, one or more steps of the same reaction. Thus for the same metal, a given catalytic cycle may be more or less disfavored by the use of a particular ligand, or, for the same ligand, by a suitable choice of metal.

At this point it is necessary to discuss *undesirable* organometallic reactions. Foremost among them are those leading to the homolytic cleavage of M–C bonds and, consequently, to loss of regiochemical or stereochemical selectivity (Scheme 2).



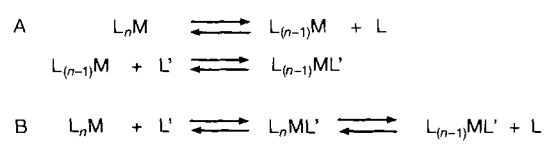
Scheme 2. Processes leading to the cleavage of an M–C bond: A) homolytic cleavage [7]; B) β-hydrogen abstraction [8]; C) reductive elimination [9]; D) electrophilic attack at a coordinated carbon atom [10].

Nucleophilic displacement of a coordinated C-σ-donor is generally associated with its transformation into a π-donor and will not be considered here.

While reactions B–D in Scheme 2 can constitute integral parts of desirable catalytic cycles, reaction A is generally to be suppressed, and therefore metal complexes in which homolytic cleavage can easily take place should be avoided.

The ease of cleavage A is related to the stability of the resulting fragments $L_mM^{\bullet}$ and $^{\bullet}$R. However, the role of the metal-containing fragment is the more complex given the variety of metal centers, their spin states, and the number and nature of the accompanying ligands. The foremost consideration is that the unpaired electron, associated with the metal fragment produced after the homolytic cleavage, will be localized on the metal center, thereby lowering its oxidation state by one unit.

A good example of this effect is shown in Scheme 3.[11] The "normal" mode of Fe–C cleavage of the d^6 Fe^{II} compound, a β-H abstraction reaction, changes to a radical decomposition



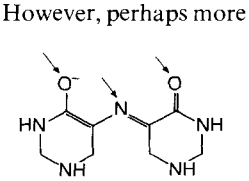
Scheme 3. Different decomposition pathways of dialkyl Fe^{II} and Fe^{III} complexes (β-hydrogen elimination vs. homolytic cleavage) [11].

after the corresponding d^5 Fe^{III} complex is formed. In general, whenever the metal complex can give another stable species with the metal center in an oxidation state one unit lower, homolytic cleavage will be favored. Complexes of the metal centers d^7 Co^{II} and d^9 Cu^{II} provide good illustration of this behavior. On the other hand, homolytic cleavage in d^8 Ni^{II} complexes is uncommon.[12]

Thus the *preferred* metal centers for organometallic reactions should have even-numbered electron configurations, particularly d^0, d^6 (low spin), d^8 (low spin), and d^{10}. However, numerous exceptions are known (e.g., d^7 Rh^{II} in Section 5.5.3, or d^5 Fe^{III} in Section 5.6).

These redox reactions do not prevent the use of catalyst precursors containing metal centers with electron configurations such as d^7 and d^9, as, upon addition of an organometallic reagent, reduction will take place, and the metal center of the resulting complex will be in the oxidation state best suited for catalysis (see, for example, the cobalt catalyst in Section 5.2.2). However, the use of a catalyst precursor containing the metal center in the appropriate oxidation state is usually preferable, as fewer side-reactions are then likely.

Any discussion of ligand exchange processes must be approached from their reaction mechanisms. These can be conveniently described in terms of the two extreme models illustrated in Scheme 4.[13] In the absence of specific information about a



Scheme 4. The limiting models for the mechanism of a ligand exchange process. A: dissociative, B: associative.

given ligand-exchange reaction in organometallic chemistry, one can judiciously use the following generalizations:

1. Coordinatively saturated complexes, particularly those in which the central atom has either an effective atomic number (EAN) of 18, or a half-filled d shell, are likely to undergo ligand exchange by a dissociative process.
2. Coordinatively unsaturated complexes, that is, those with EAN < 18, *may* undergo ligand exchange by an associative mechanism.

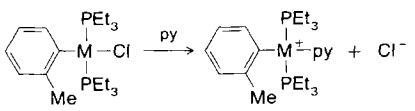
It is apparent from these generalizations that one cannot always expect a direct correlation between velocity of a ligand exchange and thermodynamic stability of a given ML_n complex. However, for dissociative ligand-exchange processes their rates are presumably closely related to the strengths of the M–L interactions in the ML_n complexes.

Before discussing the factors influencing ligand exchange rates, it is useful to have an idea of their range. The most complete set of data relates to water exchange in most metal cations, which extends from 10^{-7} to 10^9 s^{-1}.[14] However, perhaps more relevant to the chemistry discussed here are the dissociation rates in complexes with polydentate ligands. Some data for murexide [valid for reaction (a)], which, under the experi-

1

mental conditions used, acts as a uninegative, terdentate ligand coordinating through the donor atoms indicated by the arrows in the structure sketched below, are listed in Table 1.[15]

Table 1. Some rate constants for reaction (a) in 0.1 M KNO_3 at pH 4.0 and 10 °C.



M^{z+}	k_1 [$M^{-1}s^{-1}$]	k_{-1} [s^{-1}]	M^{z+}	k_1 [$M^{-1}s^{-1}$]	k_{-1} [s^{-1}]
Ca^{2+}	$\geq 6\times10^7$	$\geq 1.6\times10^5$	In^{3+}	2.0×10^6	50
Sr^{2+}	$>6\times10^7$	$>6\times10^5$	Sc^{3+} [a]	4.8×10^7	1.5×10^3
Mn^{2+}	ca. 9×10^6	ca. 7.5×10^4	Y^{3+} [b]	1.7×10^7	5.5×10^3
Co^{2+}	1.5×10^5	5.1×10^2	La^{3+} [b]	8.6×10^7	3.2×10^4
Ni^{2+}	1.0×10^3	0.41	Gd^{3+} [b]	5.2×10^7	4.3×10^3
Cu^{2+}	1.2×10^8	5.2×10^3	Tb^{3+} [b]	3.0×10^7	3.3×10^3
Zn^{2+}	2.0×10^7	2.0×10^4	Lu^{3+} [b]	1.3×10^7	4.5×10^3
Cd^{2+}	1.1×10^8	7.8×10^3			

[a] At pH 3.0 and 12 °C. [b] At 12 °C.

$$M^{z+}_{aq} + \mathbf{1} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [M(\mathbf{1})]^{(z-1)+} \qquad \text{(a)}$$

As can be seen, even these rates span a very wide range, which is comparable to that of water exchange if the same metal ion is used. Several factors influence these rates. Foremost among them are the electron configuration, ionic charge, size, spin-state, coordination number, and geometry of the metal center, the ionic charge of the complex, the nature of the coligands, and the nature of the chemical reaction.

One further general point is that the kinetics of substitution reactions for transition metal complexes with the same outer electron configuration are faster for metal centers of the first transition series than for the corresponding centers of the second and third transition series, as can be seen for the examples shown in Scheme 5.[16]

M	T [°C]	k_{obs} [s^{-1}]
Pt	25	1.7×10^{-5}
Pd	−40	5.8×10^{-3}
Ni	−65	1.6×10^{-2}

Scheme 5. Ligand exchange reactions for Ni^{II}, Pd^{II}, and Pt^{II} complexes with pyridine ([py] = 6.2×10^3 M) [16].

Another consideration should be kept in mind: ligand-disproportionation reactions [Eq. (b)] can easily occur. Obviously,

$$2MLX \rightleftharpoons MX_2 + ML_2 \qquad \text{(b)}$$

processes of this type are to be avoided as, in such cases, the organometallic reaction at one center is not influenced by the nitrogen ligand, while the second center, being strongly coordinated to two L moieties, may not be available for the organometallic reactions. This disproportionation can be prevented by the use of nitrogen ligands with bulky substituents.

Useful reactivity is likely to be found for metal ions that show intermediate exchange rates (10^{-2} to 10^2 s^{-1}). The lower boundary is fixed by the need to have a reasonably fast catalytic reaction, while the higher boundary is coupled to the speed of the organometallic transformation leading to the product, as this must clearly be faster than the ligand-exchange rate. This is merely a guideline, and significant deviations can be found in practice as the intrinsic lability of a given metal center can be decreased or increased in a variety of ways. Therefore, the range of "useful" metal centers can be considerably extended.

When nitrogen donors are used as coligands one has to solve a problem which does not arise with Lewis bases coordinating through phosphorus atoms. As has been pointed out when discussing Scheme 1, the influence of the ligand L will be felt if the M–L exchange rate is significantly slower than the rate of the organometallic reaction, as is the case of a phosphorus donor, which has the great advantage of labilizing the ligand *trans* to it. The labilizing effect of a given ligand upon the rates of substitution of other ligands present in the same complex has been extensively studied. In the present context one only needs to consider the *trans* effect, that is, the labilizing effect of one ligand upon another situated in *trans* position.[17] Some data on this effect are summarized in Table 2.

Table 2. The more common donors arranged in order of decreasing *trans* effect, and approximate values of the exchange rates of the *trans* ligands in a Pt^{II} complex [13a].

trans effect	Donor ligand	$k_{rel.}$
very large	CO, CH^-, C_2H_4, $PR_3 \approx H$	ca. 10^5
large	$SC(NH_2)_2$, NO_2^-, I^-, SCN^-, CH_3^-, $C_6H_5^-$	ca. 10^2
moderate	Br^-, Cl^-	ca. 1
weak	py, NH_3, OH^-	ca. 10^{-1}

As can be seen, in a given complex one can have a substitutionally inert, coordinated phosphane ligand and *trans* to this P-donor, a kinetically very labile ligand. This, unfortunately, is not the case for nitrogen donors, because they are among the ligands that exert the weakest *trans* effect. Nevertheless, coordinated amines do impart a smaller labilizing effect on the residual ligands, as can be seen from the data shown in Table 3.[14] However, generally, in order to have reasonable reaction rates in the case of complexes containing nitrogen coligands one must choose labile metal centers and find a way of reducing the lability of the metal–nitrogen bond(s).

Table 3. The labilizing effect on M-OH_2 bonds of coordinated aliphatic amines, as expressed by the water exchange reaction.

$$[Ni(H_2O)_{6-n}L_n]^{2+} + H_2O \overset{k_{H_2O}}{\rightleftharpoons} [Ni(H_2O)_{6-n-1}L_n]^{2+} + H_2O$$

Complex [a]	k_{H_2O} [b]
$[Ni(H_2O)_6]^{2+}$	3×10^4
$[Ni(H_2O)_5(NH_3)]^{2+}$	2.5×10^5
$[Ni(H_2O)_4(NH_3)_2]^{2+}$	6.1×10^5
$[Ni(H_2O)_4(en)]^{2+}$	4.4×10^5
$[Ni(H_2O)_3(dien)]^{2+}$	1.2×10^6
$[Ni(H_2O)_2(trien)]^{2+}$	2.9×10^6
$[Ni(H_2O)_3(tach)]^{2+}$	3.8×10^6

[a] en = ethylenediamine, dien = diethylenetriamine, trien = triethylenetetramine, tach = 1,3,5-triaminocyclohexane. [b] At 25 °C; k_{H_2O} is defined as $k_f(6)/k_{obs}(6-n)$, where n is the number of bound nitrogen ligands; k_f = rate constant for the formation reaction.

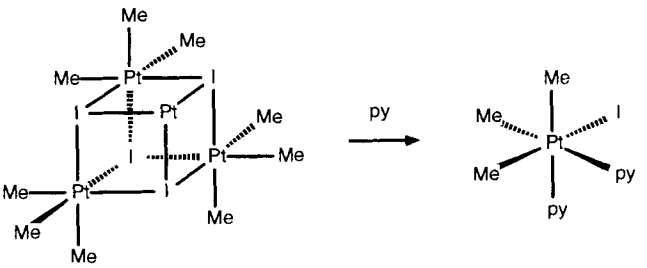
This can be achieved by the use of polydentate or anionic ligands of rigid structure optimally designed to fit the size of the metal center (see, for example, the polydentate ligands in Section 5.12.1). The lower lability of chelating systems has been amply demonstrated in classical coordination compounds. As can be seen from Table 4,[18] monodentate ligands are much

Table 4. Rate constants [s^{-1}] for the dissociation of mono- and bidentate nitrogen heterocycles [s^{-1}] from Ni^{II} and Co^{II} complexes: $T = 25\,^{\circ}C$, pH ≈ 6.0.

Complex [a]	M = Ni	M = Co
$[M(H_2O)_5(py)]^{2+}$	40	8×10^{-2}
$[M(H_2O)_4(bpy)]^{2+}$	5×10^{-5}	6×10^{-2}
$[M(H_2O)(phen)]^{2+}$	1×10^{-5}	1×10^{-2}

[a] py = pyridine, bpy = bipyridine, phen = phenanthroline.

more labile than the corresponding bidentate ligands. Indeed, with ter- and tetradentate ligands measurable dissociation rates can only be measured in acidic solution.[14] However, as acidic media are only used for workup of organometallic reactions, it is useful to have an idea of the inertness of a chelating nitrogen ligand in neutral solution. Thus, the bpy dissociation rate constant for the complex $[Ni(H_2O)_4(bpy)]^{2+}$ is $5 \times 10^{-5}\ s^{-1}$, in contrast to $40\ s^{-1}$ for the corresponding monopyridine complex.[18]



Particularly relevant for the transfer of chiral information from a metal complex to a product is the rigidity of the coligand(s). Thus, as can be seen in the data of Table 4, the rigid phenanthroline exchanges at a slower rate than the more flexible 2,2′-bipyridine ligand.

Finally, ligand-exchange rates in polydentate ligands do not necessarily give a complete picture as far as transfer of chirality is concerned, as a facile process involving the opening and closing of one arm of a polydentate ligand could lead to a decrease in transfer of chirality without complete detachment of the ligand from the metal. Thus, macrocyclic and related ligands prove to be particularly valuable as "spectator" ligands.

2.2. Characteristics of Coordination Compounds with M–C Bonds

Because there are many types of C-donors it should be noted that even those classified as "one-carbon centers" may bind to more than one metal center and, if available, may use more than one electron pair for bonding; furthermore, while most C-donor ligands also act as reagents in organometallic reactions, some of them, particularly six-electron donors such as the cyclopentadienyl anion and benzene, mainly function as coligands ("protecting groups"), that is, they block a number of coordination sites at a metal center, leaving available for further reaction a given number of free coordination sites in well-defined spatial relationships. Furthermore, they can direct incoming reagents and leaving groups along specific pathways and also strongly influence the electronic properties of the reacting fragment, L_nM.

The most stable organometallic compounds of a given metal center are those in which all low-energy orbitals are involved in bonding (preferably two-electron bonding). For instance, $PtIMe_3$ is tetrameric with the structure shown in Scheme 6, but

Scheme 6. The reaction of $[PtIMe_3]_4$ with pyridine (the methyl groups at one Pt atom are omitted for clarity) [19].

mononuclear complexes are readily obtained by reaction with additional ligands, for example pyridine, which gives the complex $[PtIMe_3(py)_2]$.[19] The platinum centers in both complexes are 18-electron systems with octahedral coordination geometry. Catalyst precursors are often di- or oligomeric and can become monomeric under the reaction conditions used (see, for example, the aluminum Lewis acid in Scheme 36, Section 5.6).

The absence of unpaired electrons on a metal centers of coordination compounds implies first that the metal center should have an even number of electrons and second that the complex should be of the low-spin type, that is, one where there is maximum pairing of all the available metal d electrons. This second requirement dictates the choice of the metal center and of its ligands. Thus, all metal centers of the second and third transition series give virtually only low-spin complexes. Furthermore, their metal centers in oxidation states having an odd number of electrons (generally only one) are relatively unstable and easily reduced. As C-donors are good reducing agents, paramagnetic organometallic compounds of these elements are rare.

Mention has been made earlier that the complexes of metal centers of the second and third transition series, in their stable oxidation states, are intrinsically kinetically inert (see Scheme 5). Thus, their use as catalysts generally requires coligands other than nitrogen (*trans* effect). An important exception is the $[Os^{II}(NH_3)_5]$ system discussed in Section 5.13.

A metal center from the first transition series can be chosen by taking into account that the tendency of a given metal ion to form low-spin complexes is generally expressed in terms of two parameters. The first, the spin-pairing energy P_T, expresses the metal-based, unfavorable energy change upon spin-pairing, while the second, the ligand field stabilization energy Δ, expresses the ligand-based, favorable energy change upon spin-pairing. Values for these parameters for some metal centers and ligands are listed in Table 5.[20]

The data confirm that the metal ions of the first transition series show a lower tendency to give low-spin complexes and thus require coligands such as phosphanes to be formed.

However, all the d^6 low-spin complexes, particularly if in an octahedral coordination environment, give slow substitution rates. Thus their complexes with nitrogen donors are seldom useful in homogeneous catalysis. This leaves the important class of low-spin complexes with coordination numbers four and a square-planar structure, or five and structures which can range from square-pyramidal to trigonal-bipyramidal.

Another group of metal centers deserves special mention, namely those with a d^5 electron configuration such as Mn^{II}. This

Table 5. Spin-pairing (P_r) and ligand field (Δ or f) parameters for some metal ions in hexaaqua complexes, and for various ligands [a].

M^{z+}	Electron config.	P_r [kJ mol^{-1}]	Δ (H_2O) [kJ mol^{-1}] [a]	X or L [b]	f
Cr^{2+}	d^4	244.3	100.3	Br	0.72
Mn^{3+}		301.6	150.1	Cl	0.78
Mn^{2+}	d^5	285.0	0	F	0.9
Fe^{3+}		357.4	0	dmf	0.98
Fe^{2+}	d^6	229.1	47.6	H_2O	1.00
Co^{3+}		282.6	188	$MeNH_2$	1.17
Co^{2+}	d^7	250	71.5	MeCN	1.22
				NH_3	1.25
				bipy	1.33
				phen	1.34
				CN	ca. 1.7

[a] $\Delta = f$ (ligands) $\cdot g$ (central ion); g: see ref. [20]. [b] X = anionic ligand, L = neutral ligand.

electron configuration is particularly stable and, although very labile, the complexes of these metal centers exibit useful reactivity for homogeneously catalyzed reactions.

Finally, another group of metal centers particularly useful for organometallic reactions is that with d^{10} electron configuration: Cu^{I}, Ag^{I}, Au^{I}; Zn^{II}, Cd^{II}, Hg^{II}; Ga^{III}, In^{III}, Tl^{III}; Sn^{IV}.

Summing up, complexes with nitrogen donors displaying useful reactivity for organometallic reactions will be found mainly among low-spin complexes of transition elements having coordination numbers four and five or having metal centers with d^5 configuration, or even among complexes of the post-transition elements. The considerably oxophilic character of the early transition elements will severely restrict their use.

3. Characteristics of Nitrogen-Donors

Before discussing in detail the coordination chemistry of nitrogen donors it is appropriate to mention the relative strength of M–C, M–N, and M–O bonds. (The M–O bond is included, because many of the ligands used for the reactions to be discussed later also contain this atom as donor.)

Some representative values of the M–Y bond energies are listed in Table 6.[121] The M–C bonds are weaker than the M–N

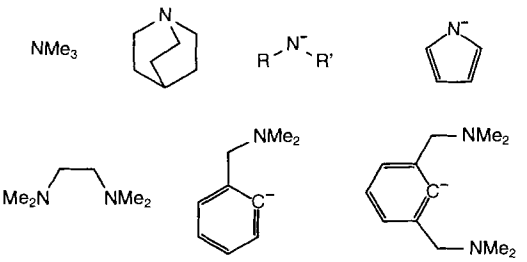


Table 6. Mean M–L bond dissociation enthalpies $\bar{D}$ [kJ mol^{-1}] for homoleptic metal compounds ML_4 as well as M–X bond dissociation enthalpies for X = H, C, N [kcal mol^{-1}].

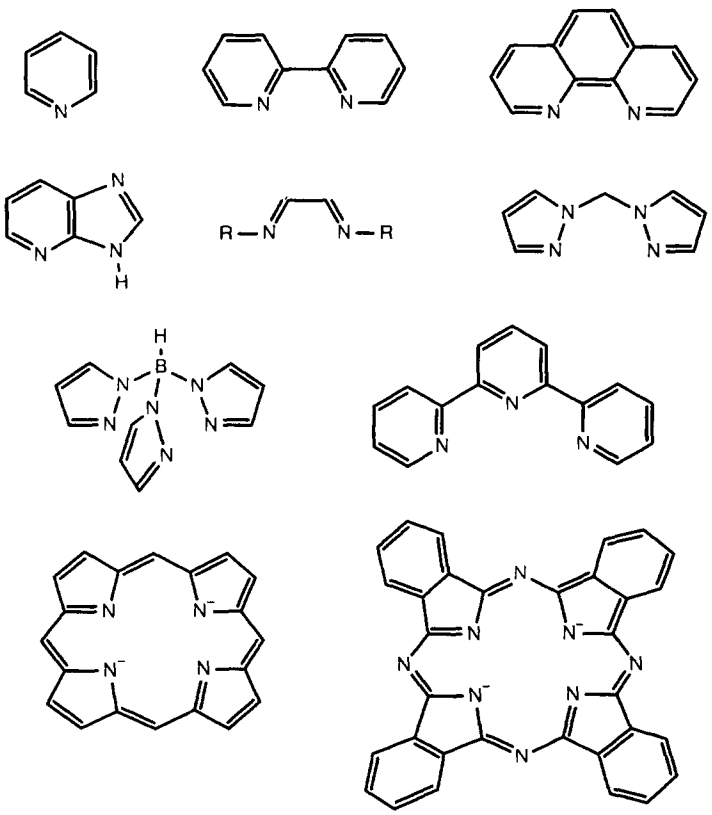
	ML_4			$X-M^+$			
L	Ti	Zr	Hf	M	H	CH_3	NH_2
CH_2tBu	188	227	224	Sc	57(2)	59(3)	85(2)
NEt_2	309	340	367	Ti	54(3)	54(2)	85(3)
O*i*Pr	444	518	534	V	48(2)	50(2)	73(2)
F	586	648	665	Fe	50(2)	58(2)	67(12)
				Co	47(2)	49(4)	62(2)
				Ni	40(2)	45(2)	56(5)

bonds, which in turn are weaker than the M–O bonds.[122] Although different types of complexes may show significant deviations from the data in Table 6, the values quoted can be taken as a guideline.

The range of nitrogen donors is more extensive than that of any other atom: It is enough to recall how varied the organic chemistry of nitrogen is and that most of these compounds are potential donors. By comparison, in inorganic chemistry only very few molecules or ions bind to metals through a nitrogen atom. Thus, only ligands of the former group will be discussed here.

An appropriate classification of nitrogen donors can be based on the hybridization of this atom, sp^3, sp^2, and sp. The types of compounds containing sp^3-hybridized nitrogen atoms are summarized in Scheme 7. Complexes with nitrogen donors containing N–H bonds are generally not suitable for most organometallic reactions as the H atom (or atoms) on coordinated nitrogen are sufficiently acidic to react with a nucleophile. Therefore, the common nitrogen donors having N–H bonds have not been included in Scheme 7. Furthermore, coordinated nitrogen atoms containing nonbonding pairs of electrons are susceptible to electrophilic attack by suitable reagents. However, coordinated "nitrogen anions", also listed in Scheme 7, show an extensive and useful coordination chemistry, particularly when associated with sp^2-hybridized carbon atoms.

Scheme 7. Some nitrogen-donors with tertiary sp^3-hybridized N atoms.



Of special interest in the present context are many natural products containing ternary nitrogen atoms, for example the alkaloids. A number of them have been successfully used for the enantioselective synthesis of organic compounds (see, for example, Sections 5.11 and 5.12.2).

Ligands containing sp^2-hybridized nitrogen atoms, particularly when the N-atom is part of an aromatic system (see, for example, Scheme 8), have a very extensive coordination chemistry. Also for donors of this type, a much more extensive and useful coordination chemistry is possible when they are bi- or terdentate ligands. However, the use of such ligands in asymmetric catalysis requires the presence of a stereogenic substituent.

The presence of C–N and C–C double bonds in these molecules renders them susceptible to further reactions, such as nucleophilic attack or, under appropriate conditions, hydrogenation. This is particularly true of Schiff's bases.

The only class of organic nitrogen donors with sp hybridization are the nitriles. Their main function is as labile ligands that are replaced by appropriate reagents. Furthermore, once coordinated, nitriles are quite susceptible towards nucleophilic attack.

As might be expected, the donor properties of nitrogen ligands differ significantly from those of phosphorus. However, an accurate assessment of their relative donor properties and of

Scheme 8. Some nitrogen-donors with sp^2-hybridized N atoms.

related ligands with other donor atoms is difficult. The most commonly used criterion to compare donor properties of nitrogen compounds is their pK value. However, these values refer to aqueous solutions and meaningful comparisons are seldom possible, because solvation effects may mask true electronic contributions. Furthermore, for compounds sparingly soluble in water, the pK values are not available.

Another useful criterion for the comparison of the donor ability of various ligands is the first ionization potential of the donor atoms. Also in this case the values can only be used qualitatively, as removal of an electron to infinity is conceptually and quantitatively different from the formation of a dative bond, particularly as the former process is not influenced by steric effects whereas the latter is. Therefore, any consideration of relative stability of metal–ligand bonds in general and metal–nitrogen bonds in particular must take into account steric interactions. These have been successfully parametrized for the phosphorus donors by means of Tolman's "cone-angle" values, θ_P. Some of these values are shown in Table 7.[23] The corresponding values for nitrogen donors, θ_N, have only been reported, recently.[23b] They are in general larger than for the corresponding P-donors, the difference being greater for the larger ligands.

Table 7. Tolman's cone angle values for phosphorus-donors (θ_P [23a]) and the corresponding values θ_N for nitrogen-donors [23b].

Ligand	θ_P [°]	θ_N [°]
EH_3	87	94
EMe_3	118	132
EEt_3	132	150
EPh_3	145	166

Tolman has also obtained a set of values for an "electronic parameter", v_p, which expresses the relative donor capacity of a phosphane ligand in the absence of distortions caused by steric effects.[23] Once again, a similar set of data does not appear to have been obtained for nitrogen ligands. However, in this case the corresponding nitrogen values cannot be estimated from the phosphorus data because the nature of the M–L bonds in the two cases are different. M–N bonds are mainly of σ type and M–P bonds of σ and π type.

Finally, H. C. Brown et al. obtained data useful in the context of the stability of metal–nitrogen bonds and their relation to steric effects (relevant in the context of reactions catalyzed by oxazaborolidines; see Sections 5.2.2, 5.6, and 5.7).[24] This is summarized in Table 8.

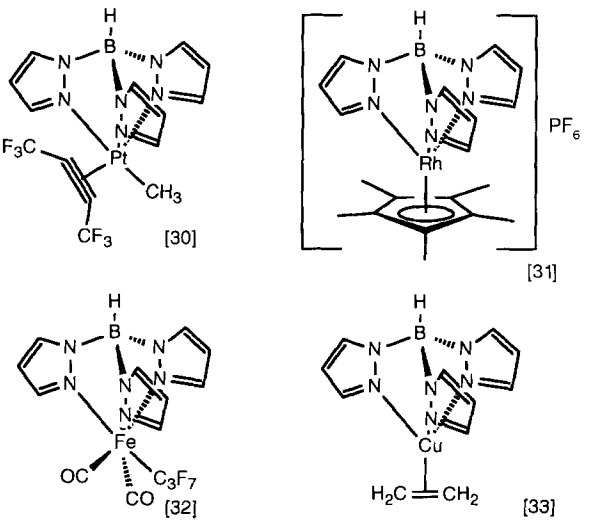
Table 8. Bond dissociation energies [kcal mol^{-1}] for trimethylborane adducts of amines at 100 °C.

Compound	ΔG	ΔH	ΔS
Me_3B-NH_3	−1.134	13.75	0.040
Me_3B-NH_2Me	2.472	17.64	0.041
$Me_3B-NHMe_2$	2.885	19.26	0.044
Me_3B-NMe_3	0.557	17.62	0.046
Me_3B-NEt_3		ca. 10.0	
Me_3B–quinuclidine	2.916	19.94	0.046

In conclusion, if one considers only the nitrogen ligands relevant for organometallic chemistry, one reaches the conclusion that nitrogen atoms in donor molecules in coordination chemistry, as well as in other branches of chemistry, can form strong bonds to metal centers; the strength of the bonds depends largely on their σ covalency with a potentially significant contribution from the ionic character of the bond itself.

Nevertheless, π interactions are possible with ligands containing sp^2-hybridized nitrogen donors, and π back-bonding effects, particularly between nitrogen heterocycles and metal centers, have been frequently invoked to explain a variety of observations. However, while their occurrence may be beyond dispute, the extent to which they determine the chemical properties of any given compound is controversial, because ground-state effects are likely to be small.

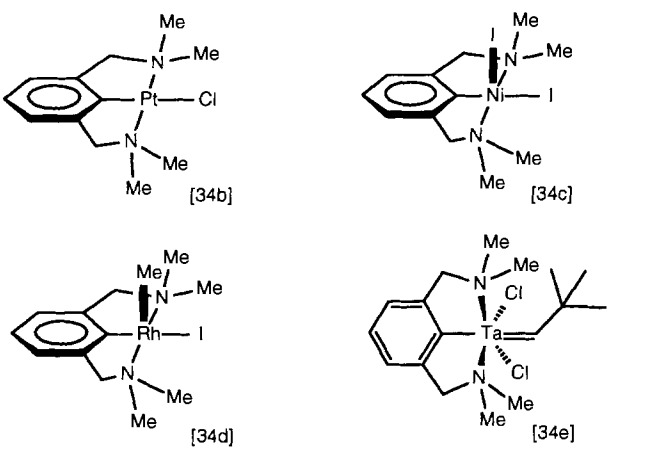
Thus the following gneralizations, which typically must be used in this case probably with a rather large grain of salt(!), can be made:



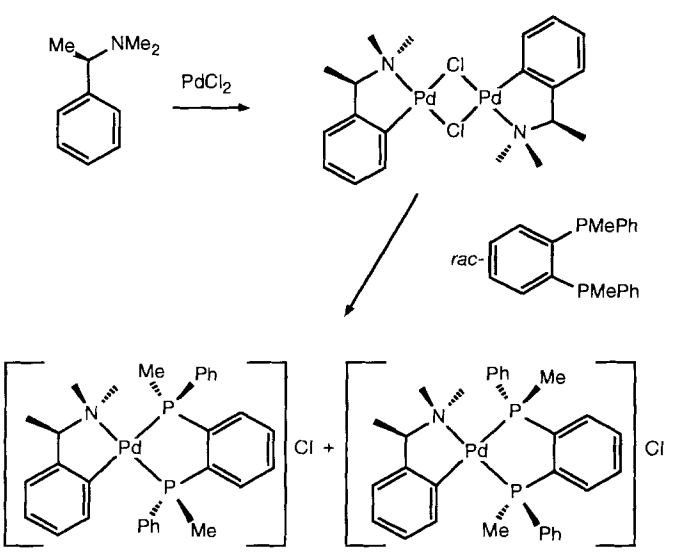
1. Donor–acceptor bonds formed by nitrogen donors are generally fairly strong and, in contrast to those formed by phosphorus donors, their strength is unlikely to show drastic changes if the metal center, but not the ionic charge, is changed. As a consequence, bonds of nitrogen donors to the transition elements of the first transition series and the inner transition series as well as some of the post-transition metals will be stronger than those of the related phosphorus donors ("A" vs. "B" character, "hard" vs. "soft" donors).
2. The strength of the M–N bonds will be affected much more by steric effects than that of the corresponding M–P bonds.
3. The nitrogen donors, generally, will not be as effective in producing low-spin complexes with the consequence that the species produced are less thermodynamically stable and more kinetically labile than their low-spin analogues with P-donors.

The consequences of these "boundary conditions" are that nitrogen-donor ligands forming robust complexes are, in general, di-, ter-, or multidentate ligands, often macrocyclic, and contain ligands with sp^2-hybridized N-atoms. Thus, the organometallic complexes with nitrogen donors as coligands described in the next section are likely to contain the above-mentioned types of compounds.

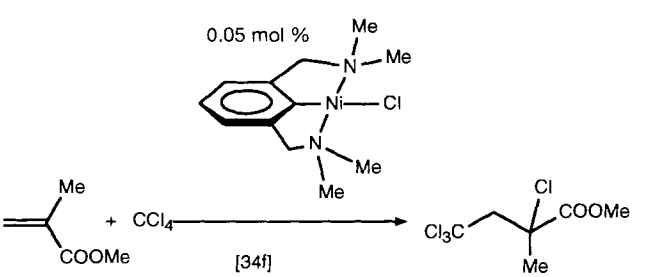
4. Organometallic Complexes Containing Nitrogen-Donors



Many ligands of organometallic complexes contain double (C=X) or triple (C≡Y) bonds (X and Y are atoms other than nitrogen), and it is now well established that a significant contribution to their total M–L bond strength is provided by the formation of π back bonds. However, nitrogen donors do not form π bonds to any significant extent, and thus, the strength of the M–C bonds in the presence of these ligands is directly related to the electron density at the metal center. Thus the isolated occurrence of organometallic compounds containing nitrogen coligands is not surprising. There is, however, an increasing body of evidence showing that organometallic complexes of the type $[MR_n(L^N)_m]$ (L^N = nitrogen donor ligand) are readily formed and, in many cases, can be isolated, even if the metal center belongs to the second or third transition series. Particularly instructive examples are provided by the complex $[PdX(Me)_3(NN)]$ (X = halide; NN = *N,N,N′,N′*-tetramethylethylenediamine, or 2,2′-bipyridine),[25] and by the $[Os^{II}(NH_3)_5]$ system described in Section 5.13. Furthermore, nitrogen donors are frequently used as part of chelating systems together with phosphorus- or carbon-donors. The organometallic chemistry of the P,N-donors does not significantly differ from that of the P,P-ligands, but several interesting differences in organometallic reactivity, including catalysis, have been reported.[26] On the other hand the C,N-donors have played a significant role in organometallic chemistry because of their ready formation through a cyclometalation reaction,[27] and because an optically active cyclometalated compound is useful for the separation of racemic mixtures, generally of phosphanes (see Scheme 9).[28]



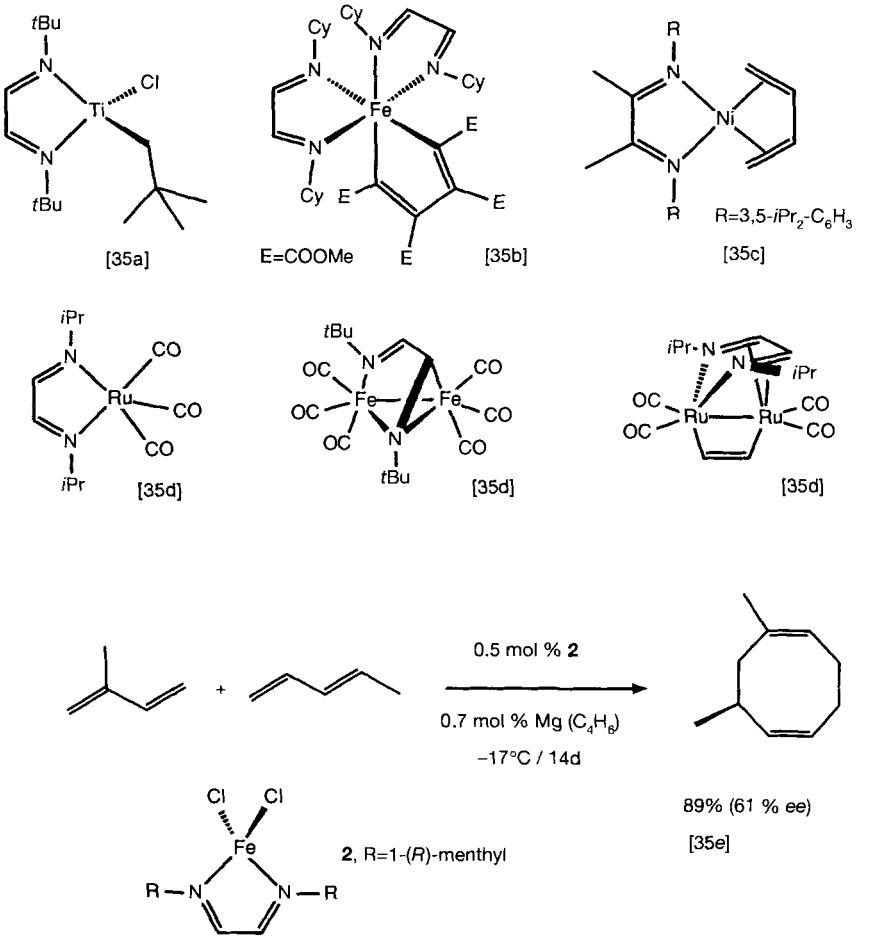
Many organometallic compounds containing nitrogen donors have been obtained by using polypyrazolylborate ligands.[29] A representative selection of compounds of this type is shown in Scheme 10.[30–33]



Scheme 10. Examples of organometallic complexes containing the tris(pyrazolyl)borato ligand [30–33].

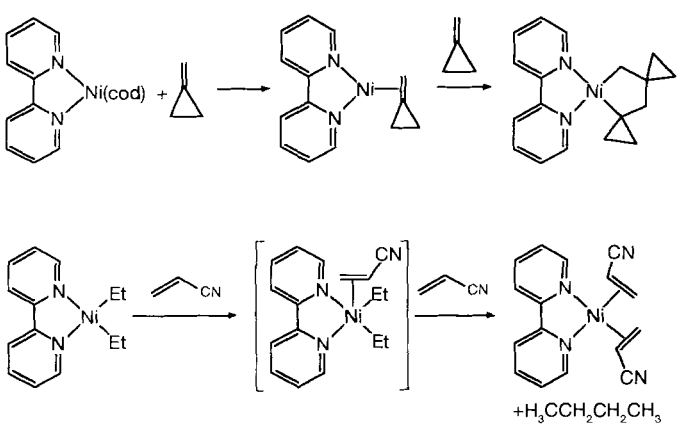
Noteworthy is also the organometallic chemistry based on complexes of the N,C,N-terdentate ligand shown in Scheme 11,[34] and that of complexes containing 1,4-diaza-1,3-dienes, some of which are given in Scheme 12.[35]

Scheme 9. The formation of optically active Pd^{II} complexes with C,N-donors and their use in the separation of racemic mixtures via diasteromeric complexes [28a].



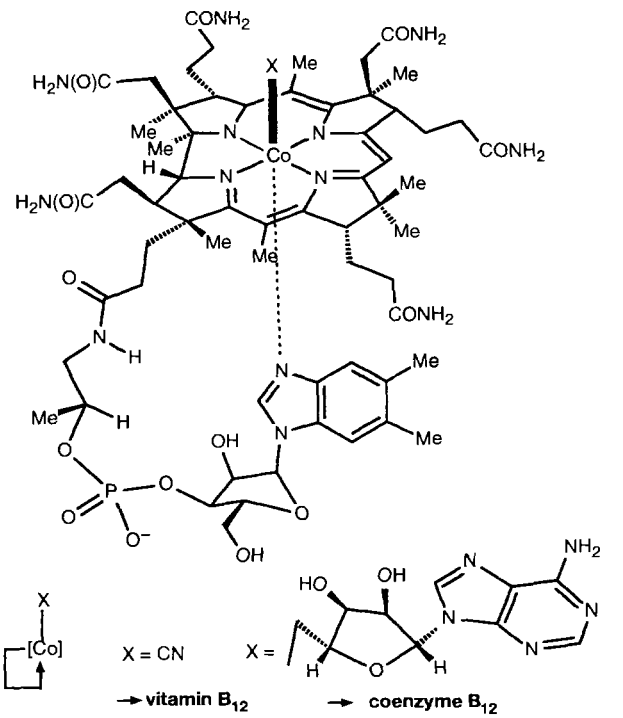
Scheme 11. Some complexes with van Koten's "pincer" ligand, and a reaction catalyzed by it [34].

However, a common feature of organometallic compounds containing nitrogen ligands is apparent: they usually exhibit high reactivity. Examples of this type of behavior are shown in Scheme 13.[36]



The electron-withdrawing effect of coordinated alkenes is well illustrated by the reaction of the complex $[Ni(Et)_2(bpy)]$. Upon addition of acrylonitrile, this complex gives a relatively stable adduct with pentacoordinated Ni atoms, but exposure to excess acrylonitrile leads to clean reductive elimination of butane to afford the corresponding bis(olefin)-Ni^0 complex.[36b]

Finally, even a very brief survey of the organometallic chemistry with nitrogen-donors would be grossly incomplete without a mention of the extensive and fascinating chemistry of Vitamin B_{12}, its coenzyme (Scheme 14), and the cobalamines. While reference to more specialized reviews[37a] will give for a deeper understanding of the chemistry of systems of this type, two general points of coordination chemistry emerge from published work, which may be relevant in some catalytic systems used for organic synthesis.[37b] The first of them concerns the mode of cleavage of Co-R bonds in compounds of this type (Scheme 15).[38] All the cleavage modes described in Section 2.1 are found to occur with comparable activation energies in the presence of the appropriate reagents. The second point concerns the oxidation state at the cobalt atom. A summary of the electron-transfer processes are shown in Scheme 16.[38]



Given the complex chemical nature of vitamin B_{12} and its coenzyme, coordination chemists have invested much time in developing and studying model systems. The simplest (and not the least effective) models for B_{12} systems are the cobalamines, shown schematically in Scheme 17.[38]

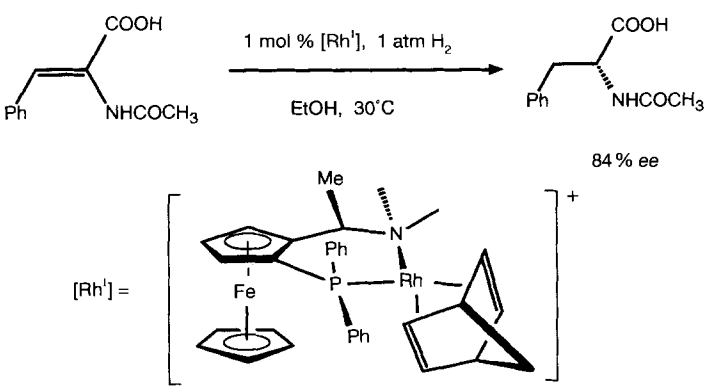
5. Homogeneous Catalysis with Nitrogen Ligands



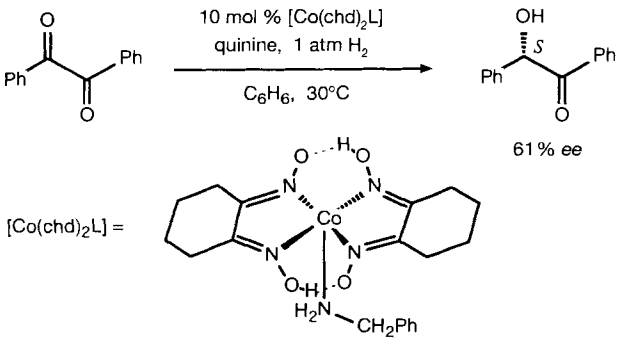
5.1. Introductory Note

Nitrogen ligands in homogeneous catalysis have received increasing attention in recent years. In particular, the use of optically active, chelating, nitrogen-containing ligands made many significant contributions to the field of asymmetric catalysis. Very often in such cases the N-ligands are derivatives of amino acids and thus obtainable from the chiral pool.[39] The following discussion will focus on the type of reaction that is catalyzed by complexes containing N-ligands, because a reaction-oriented section should enable comparisons (for example, with phosphane ligands used in the same reaction), as well as the identification of new possibilities and trends. Since systematic studies of the significance of N-ligands, for example, as opposed to P-ligands, for a given reaction do not exist, and coordination-chemical rationalizations for the choice of such ligands have not been reported, the N-ligands have been used on an ad hoc basis. Studies concerning the influence of basicity, steric hindrance, and electronic properties of a certain class of nitrogen ligands on the catalytic properties of the corresponding complexes do not exist either. Such theoretical viewpoints are well established for phosphane ligands (for example, the concept of cone-angle,[23] or the well-defined electronic influence of the substituents on the phosphorus atoms upon reactivity) and are often applied in the discussion of catalytic effects. Despite the relative infancy of nitrogen ligands in homogeneous catalysis, the amount of published work is considerable. Therefore, this review cannot present a comprehensive account, and only the most significant or recent examples will be discussed.

5.2. Asymmetric Hydrogenation and Reduction

5.2.1. Hydrogen as Reducing Agent

Asymmetric hydrogenation reactions, catalyzed by rhodium complexes containing chiral chelating diphosphanes, have been very successful and constitute classic examples of well-established catalytic methodologies.[40] Probably for this reason nitrogen ligands have been rather neglected. However, mixed P,N-ferrocenyl ligands have been shown by Cullen et al. to give enantioselectivities as high as 84% in the rhodium-catalyzed hydrogenation of acetamidocinnamic acid[41] (Scheme 18). An

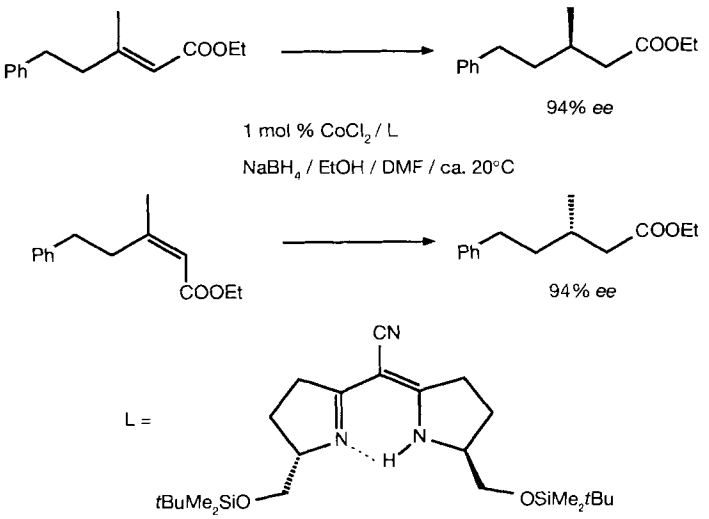


Scheme 18. Asymmetric hydrogenation catalyzed by a Rh^I complex [41].

X-ray crystal structure determination of the catalyst precursor $[Rh^I]$ as PF_6 salt shows that the ligand coordinates as a chelate to the rhodium atom.[41a] However, selectivity and activity seem to be dominated by the phosphorus ligand. Thus, replacement of the PPh_2 group by a $P(t\text{Bu})_2$ fragment leads to a more active

catalyst, which gives products of the opposite absolute configuration.[41b] These catalysts are less active than those containing chelating diphosphanes.

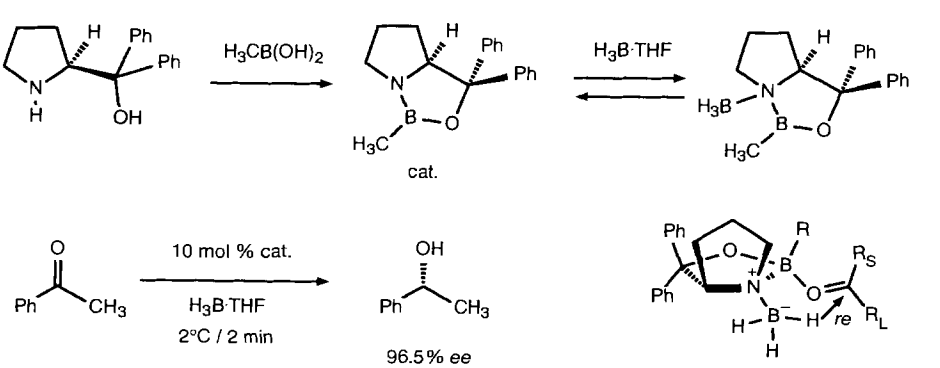
A completely different catalyst system for the hydrogenation of benzil to benzoin has been reported by Ohgo, Takeuchi et al.[42] Chiral bis(glyoximato)Co^{II} complexes in the presence of an optically active amino alcohol as cocatalyst (e.g., quinine) were found to afford enantioselectivities up to 61% *ee* (Scheme 19). The same system also hydrogenates acetamido



Scheme 19. Asymmetric hydrogenation catalyzed by bis(glyoximato) Co^{II} complexes, with quinine as cocatalyst [42].

acrylic acid derivatives, but with a much lower enantioselectivity (up to 20% *ee*). The axial ligand in the catalyst precursor (typically an amine or a tertiary phosphane) has only a minor influence on the efficiency of the catalyst, but increasing the hydrogen pressure had a beneficial effect on the reaction rate. Although its details still remain obscure, this reaction raises several interesting mechanistic aspects: The chiral cocatalyst quinine does not appear to be directly bonded to cobalt; a second-sphere interaction between the chiral amino alcohol and the coordinated substrate has been invoked in the stereodifferentiating step; an electron-transfer step seems to be involved in the course of substrate hydrogenation.[42a] The possibility that the actual catalyst is a Co^{I} complex does not appear to have been considered.

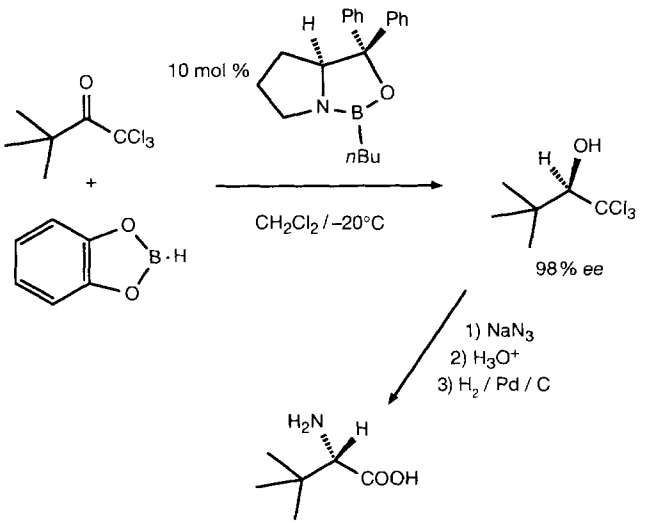
5.2.2. *Boranes as Reducing Agents*



In recent years, Pfaltz et al.[43] have developed chiral chelating semicorrin ligands and used them for several asymmetric, homogeneously catalyzed reactions (see also Sections 5.5 and 5.11). Such monoanionic ligands are easily prepared from pyroglutamic acid and form six-membered conjugated chelate rings which are C_2-symmetric.[43] The reduction of α,β-unsaturated esters with $NaBH_4$ in ethanol/dimethylformamide (DMF) is efficiently catalyzed by Co^{II} salts in the presence of the ligand shown in Scheme 20. The enantioselectivities reach 94%. Iso-

Scheme 20. (Semicorrinato)Co^{I}-catalyzed asymmetric reduction of α,β-unsaturated esters with $NaBH_4$ [44].

meric configurations at the double bonds yield products of opposite absolute configurations, and nonactivated olefins are not reduced.[44] The active catalyst, formed in situ from $CoCl_2$ and the ligand, is thought to be a Co^{I} species.

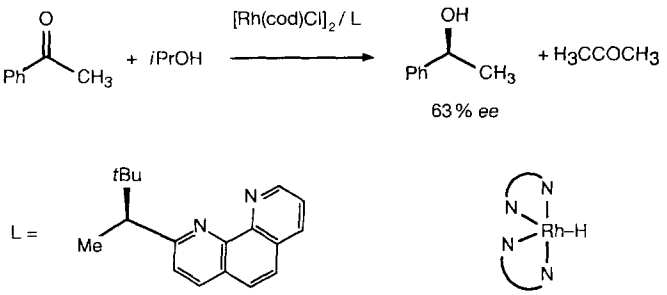


Chiral β-amino alcohols, mainly derived from α-amino acids, react with BH_3 (mostly used as its THF adduct) to form 1,3,2-oxazaborolidines.[45] These compounds are also efficient and highly selective catalysts for the reduction of ketones with $H_3B \cdot L$ (L = THF, or $S(CH_3)_2$). Itsuno et al. were the first to report, in 1981,[46] the use of such borolidines as stoichiometric reductants. Catalytic applications of oxazaborolidines were also initiated by the Itsuno group,[47] and the methodology has been exploited more recently by several other groups.[48–53] Scheme 21 shows one specific example; a more detailed collection of data is found in a recent review by Wallbaum and Martens.[45]

Scheme 21. Formation of a 1,3,2-oxazaborolidine and its use as catalyst for the enantioselective reduction of ketones with $BH_3 \cdot THF$ [54]. Bottom right: result of the X-ray structure analysis.

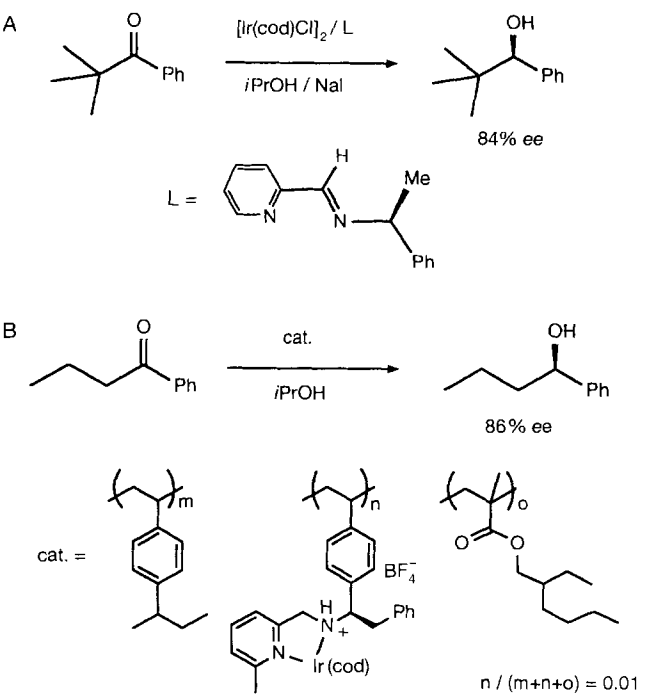
Oxazaborolidines are unique in that they contain a Lewis acidic and a Lewis basic center next to each other, and, according to the model developed by Corey,[54] are able to activate both the carbonyl functionality of the substrate and the borane. This model, which allows a prediction of the absolute configuration of the secondary alcohol formed, has recently been corroborated by the X-ray crystal structure of the BH_3 adduct shown in Scheme 21,[54] as well as by quantum mechanical calculations.[55]

The reduction of trichloromethyl ketones with catecholborane offers a general and highly selective method for the synthesis of α-amino acids[56] (Scheme 22). Finally, the oxazaborolidine methodology has recently been extended to the reduction of ketimines.[57] The optical yields are generally lower than those obtained for the reduction of ketones and also lower than those of the corresponding stoichiometric reactions.



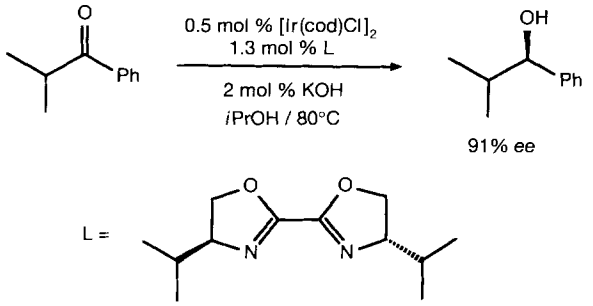
Scheme 22. Synthesis of α-amino acids by asymmetric reduction of trichloromethyl ketones [56].

5.3. Asymmetric Transfer Hydrogenation



Chiral nitrogen ligands have been used in the asymmetric hydrogen transfer more frequently and more successfully[58] than in hydrogenation reactions with H_2. This reflects the compatibility of nitrogen donor atoms with the mechanistic peculiarities of this reaction. In the typical hydrogen-transfer reaction, the coordination sphere of the metal comprises hard donor ligands (e.g., nitrogen and alkoxy), and no change in the formal metal oxidation state need be invoked.[58]

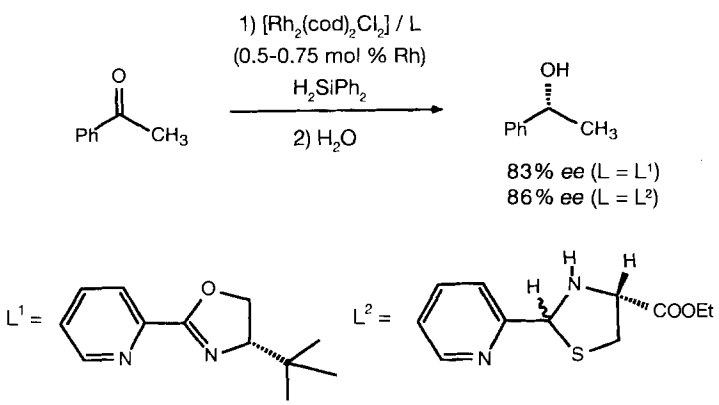
Rhodium catalysts containing chiral bipyridine or phenanthroline derivatives have been used by Mestroni et al.[59] Because such ligands are planar, stereogenic groups can only be introduced in peripheral regions of the molecule, where their influence is rather modest. Accordingly, the selectivities obtained are rather low. The nature of the rhodium-containing catalyst precursors ([Rh_2(1,5-cyclooctadiene)$_2Cl_2$] or [Rh_2(1,3-cylohexadiene)$_2Cl_2$]), as well as the rhodium-to-ligand ratio, seem to influence the selectivity significantly. A pentacoordinated hydridorhodium complex is postulated as an intermediate in the catalytic cycle[60] (Scheme 23).



Scheme 23. Rh-catalyzed asymmetric transfer hydrogenation of acetophenone in the presence of a chiral phenanthroline derivative [59] and the postulated Rh-hydrido intermediate [60].

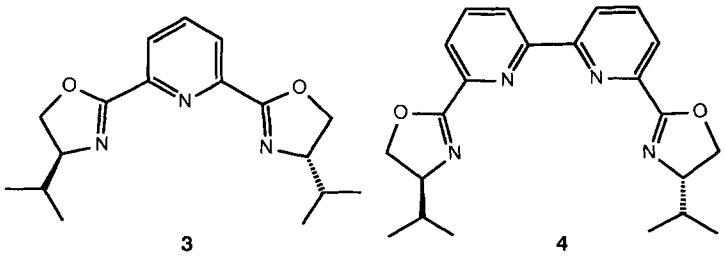
Alkylaminomethyl- and alkyliminomethylpyridines have been used as ligands in the Ir-catalyzed hydrogenation reaction. Selectivities are generally low, and only the bulky *tert*-butyl phenyl ketone can be reduced according to Scheme 24 A in 84% *ee*.[61] The same type of ligand in a polymer-bound form yields enantioselectivities up to 86% (Scheme 24 B).[62]

Scheme 24. Ir-catalyzed transfer hydrogenation in the presence of an alkyliminopyridine (A) [61] and an immobilized alkylaminomethylpyridine (B) [62] as ligands. For B the composition of the polymer is also given.



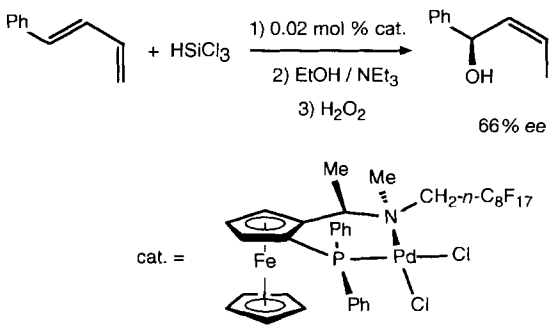
Pfaltz et al. have recently shown that C_2-symmetric tetrahydrobioxazoles are effective ligands for this type of reaction and reported that enantiomeric excesses reach 91% (Scheme 25).[63]

Scheme 25. Tetrahydrobisoxazole–Ir complexes in the asymmetric transfer hydrogenation of alkyl aryl ketones [63].



5.4. Asymmetric Hydrosilylation

Brunner et al. have demonstrated that chelating nitrogen ligands containing a stereogenic fragment in a peripheral region of the molecule are superior to conventional C_2-symmetric chiral diphosphanes in the Rh-catalyzed asymmetric hydrosilylation of ketones.[64] The diphosphanes are characterized by the rather rigid chiral array of the phenyl substituents on the phosphorus atoms. This feature is one of the dominant selectivity-determining factors and was already recognized in the early days of asymmetric Rh-catalyzed hydrogenation.[65] However, for hydrosilylation the key factor appears to be a stereogenic group close to the free coordination sites at the metal center. This is achieved by using pyridine derivatives such as those shown in Scheme 26. The hydrosilylation of acetophenone with diphenylsilane affords 1-phenylethanol with a maximum enantiomeric excess of 86%.[66]

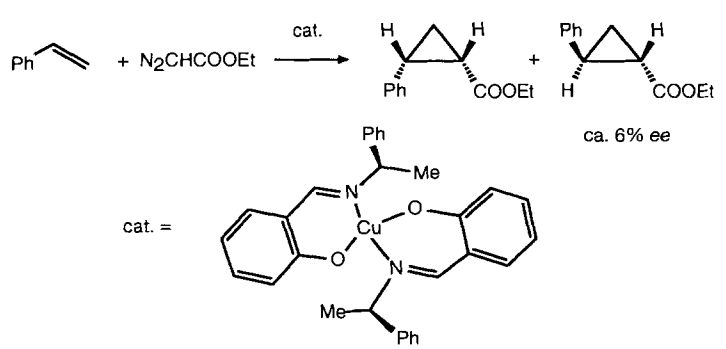


Scheme 26. Asymmetric hydrosilylation of acetophenone with diphenylsilane catalyzed by Rh in the presence of pyridyldihydrooxazoles and pyridylthiazolidines [66].

Much higher enantioselectivities for the same reaction (up to 94%) have been reported by Nishiyama et al., who used terdentate ligands like **3**.[67] The corresponding trichlororhodium complex, characterized by X-ray diffraction,[67b] was used as a catalyst precursor. For the catalytic reaction to take place, the addition of a Ag^I salt was required. This led to the formation of a Rh^{III} cationic complex, which was then reduced by the silane to the catalytically active Rh^I species. A tetraaza ligand (**4**), related to **3**, which was recently reported by the same group, gave slightly lower enantioselectivities.[67d]

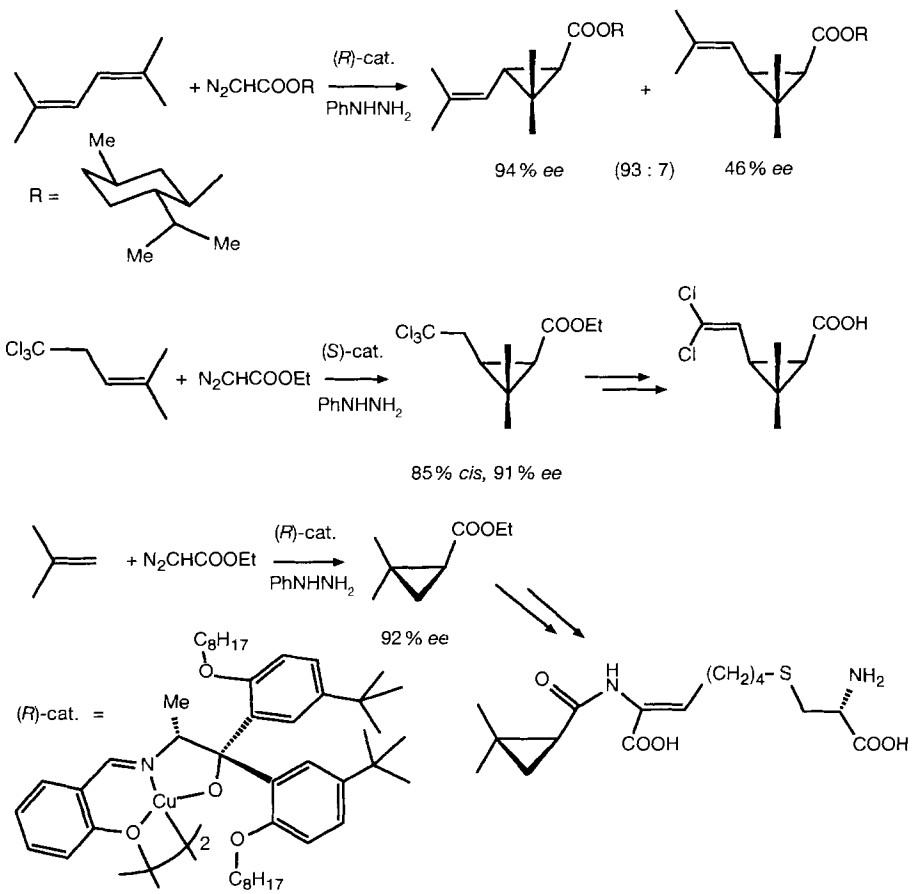
A completely different system for the hydrosilylation of 1,3-dienes with $HSiCl_3$ was reported by Hayashi et al.[68] (Scheme 27). The catalyst precursor was a $PdCl_2$ complex containing a chiral P,N-ferrocenyl ligand. Good regioselectivities

Scheme 27. Pd-catalyzed asymmetric hydrosilylation of a 1,3-diene [68].



(up to 93%) as well as moderate enantioselectivities (up to 66% *ee*) were obtained. The ligand contains a perfluorinated alkyl substituent on the nitrogen atom, which ensures catalyst solubility in the solvent-free mixture of reactants.

5.5. Asymmetric Cyclopropanation



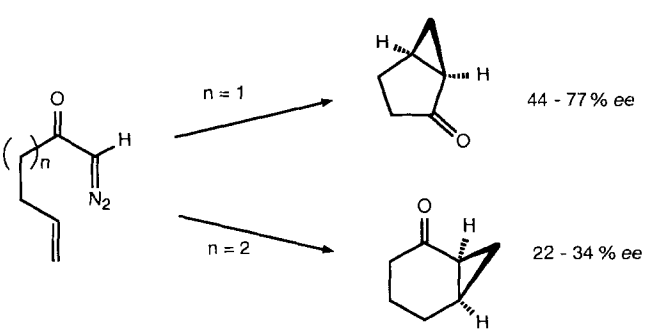
5.5.1. Copper Catalysts

The synthesis of optically active cyclopropane derivatives[69] by the stereoselective addition of a carbenoid reagent to an olefin is a most important reaction from both a historical as well as from a practical point of view.[70] The vast majority of the known and successful catalysts for this reaction are complexes of the late transition metals (Cu, Co, Rh) with nitrogen ligands.

Apparently the very first example of asymmetric catalysis by a soluble metal complex is a cyclopropanation reaction reported by Nozaki et al. in 1966. The Cu^{II} complex shown in Scheme 28

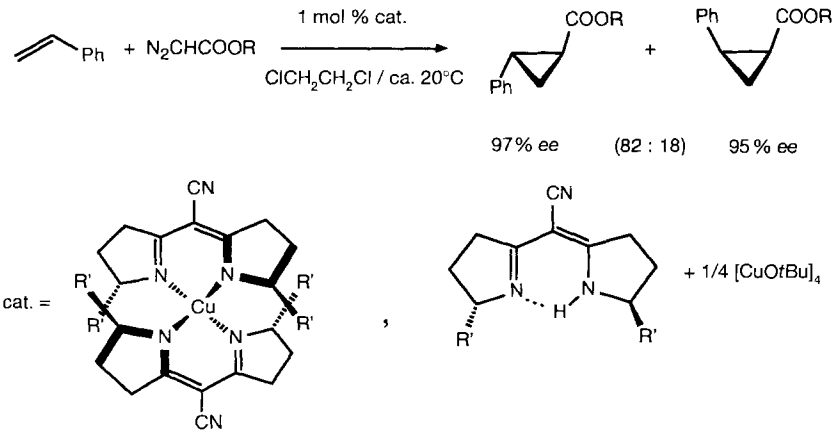
Scheme 28. The first asymmetric reaction catalyzed by a soluble transition metal complex [71a].

Scheme 29. Industrially important applications of the Cu-catalyzed asymmetric cyclopropanation. Synthesis of chrysanthemic acid esters (R = D-menthyl), permethrinic acid, and cilastatin [72]. Bottom left: the catalyst precursor in its *R* configuration.



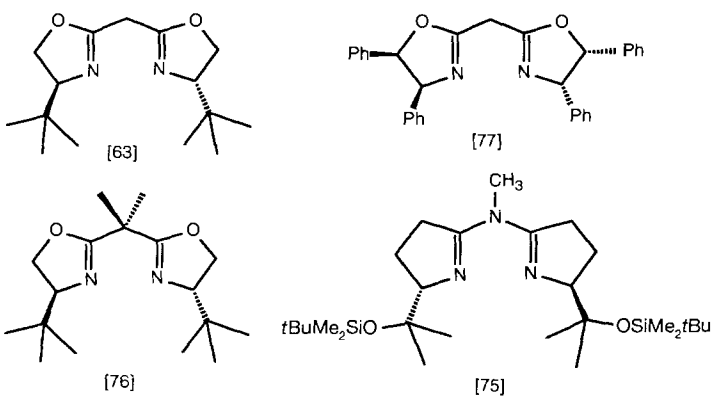
contains a Schiff base ligand derived from salicylaldehyde and optically pure 1-phenylethylamine and served as catalyst precursor for the "decomposition of diazoacetates in the presence of olefins".[71] The stereoselectivities were rather modest, but intensive screening and improvement of the ligand system by the Aratani group finally led to the commercialization of the copper-catalyzed cyclopropanation.[72] Industrially important applications of this reaction are the synthesis of intermediates of pyrethroid insecticides and cilastatin. Some relevant examples with *ee*'s higher than 90% are summarized in Scheme 29. The best ligands are terdentate dihydroxyl Schiff bases with two hydroxyl groups (O,N,O) derived from amino alcohols bearing bulky *ortho*-alkoxyphenyl substituents. The dimeric, μ-O-Cu^{II} complexes formed by such ligands are used as catalyst precursors. The catalytically active Cu^{I} species is generated in situ with phenylhydrazine as a reducing agent.

Dauben et al. have shown the Aratani catalyst to be effective in the intramolecular version of the cyclopropanation reactions too, although the resulting enantioselectivities were only moderate (up to 77% *ee*)[73] (Scheme 30).



Whereas nowadays high enantioselectivities can be obtained with several catalysts (see Sections 5.5.2–5.5.4), relatively modest diastereoselectivities (*cis*/*trans* cyclopropane derivatives) still constitute the major stereochemical problem of catalytic cyclopropanation. This problem has not been completely solved as yet, even by using catalysts bearing C_2-symmetric semicorrinato ligands propanation. This problem has not been completely solved as yet, even by using catalysts bearing C_2-symmetric semicorrinato ligands, first reported by Pfaltz et al. in 1986,[74] or by employing bis(dihydrooxazole) ligands, described in more recent years (Scheme 31).

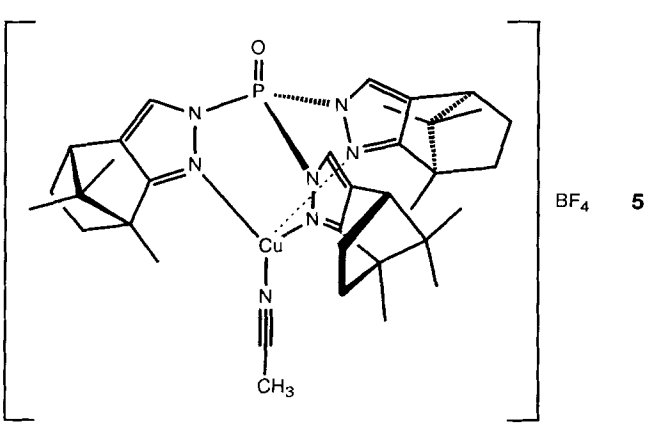
Enantioselectivities up to 97% are obtained in the cyclopropanation of styrene with methyl diazoacetate (Scheme 31). A slight effect of double stereodifferentiation is observed by using the two enantiomeric menthyl esters. Selectivity does not depend upon the method of generation of the catalyst. Thus, either the bis(semicorrinato)Cu^{II} complex as catalyst precursor, or the catalyst generated in situ from equivalent amounts of the ligand and $[CuO\mathit{t}Bu]_4$ give identical stereochemical results.



More recently the Pfaltz group showed that very high enantioselectivities can be obtained by using the conceptually similar (from a stereochemical and electronic point of view), but synthetically more easily accessible bis(dihydrooxazole)[63] and 5-azasemicorrins.[75] Both the Evans and Masamune groups have developed analogous systems.[76, 77] Representative bis(dihydrooxazole) ligands are shown in Scheme 32. With these ligands extremely high optical yields (up to 99% *ee*) can be obtained in the reaction of styrene with ethyl diazoacetate.[76] However, high *trans*/*cis* ratios of the diastereomeric cyclopropanes are achieved only when the diazo ester bears a very bulky group (e.g., 2,6 di-*tert*-butyl-4-tolyl). The catalysts are best generated in situ from soluble Cu^{I} salts containing weakly coordinating anions (triflate, ClO_4^-); $[CuO\mathit{t}Bu]_4$ seems to give erratic results.[75] Evans et al. have shown that the catalyst formed from the CMe_2-bridged bis(dihydrooxazole) of Scheme 32 and CuOTf is polymeric in the solid state.[76b] An interesting helical structure results from the nearly linear coordination of two oxazole nitrogen atoms to

Scheme 30. Intramolecular cyclopropanation of diazoketones catalyzed by Aratani's complex (see Scheme 29) [73].

Scheme 31. Pfaltz's semicorrinato ligands in the Cu-catalyzed cyclopropanation [74]. R = D-menthyl, R' = CMe_2OH.

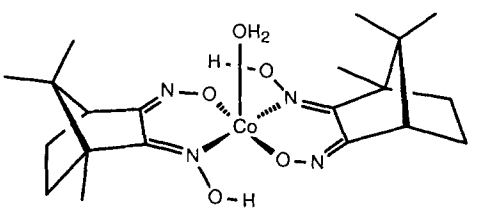


Scheme 32. The novel methylenebis(dihydrooxazole) and 5-aza-semicorrin ligands used in the Cu^I-catalyzed asymmetric cyclopropanation.

each Cu^I center, in which the ligands act as bridging units. The triflate anions are not coordinated.

The CMe_2-bridged bis(dihydrooxazole)s and the 5-azasemicorrins behave strictly as neutral ligands, whereas their methylene-bridged counterparts, like the semicorrins, can be deprotonated, thus forming anionic ligands. This is an interesting feature which shows the flexibility of the copper catalysts, because all classical ligands are anionic.

Finally, a C_3-symmetric optically active ligand containing stereogenic pyrazolyl units, recently described by Tolman et al.,[78] was found to bind in a terdentate manner to Cu^I to form complexes like **5**. This complex is a cyclopropanation catalyst, but the reported enantioselectivities are modest to moderate (up to 60% *ee*).

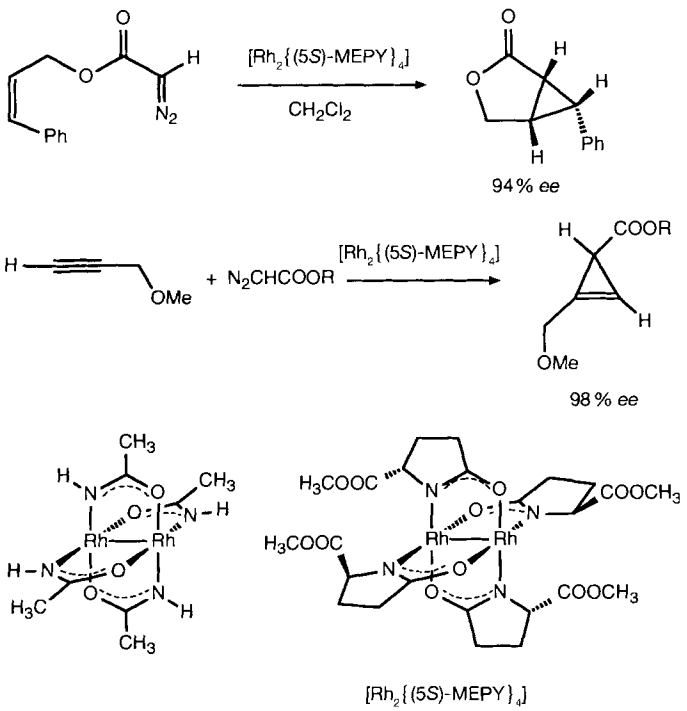


5

5.5.2. Cobalt Catalysts

Parallel to the development of efficient copper catalysts by Aratani et al., the Nakamura and Otsuka groups reported in the seventies the use of Co^{II} complexes of type **6** bearing α-camphorquinonedioximato ligands.[79]

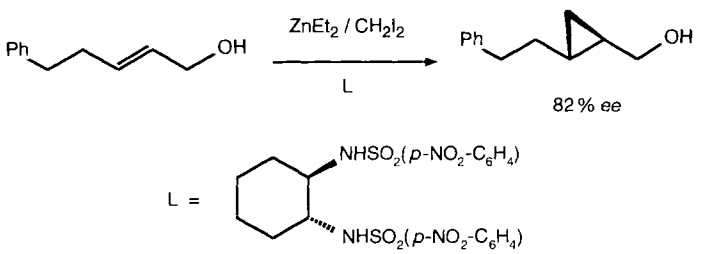
These catalysts are somewhat unusual in that they show good activity only for the conversion of conjugated olefins. Enantiomeric excesses up to 88% were obtained in the reaction of styrene with neopentyl diazoacetate. Despite the relatively high selectivity reported, no further development of these catalysts has appeared in the literature.



6

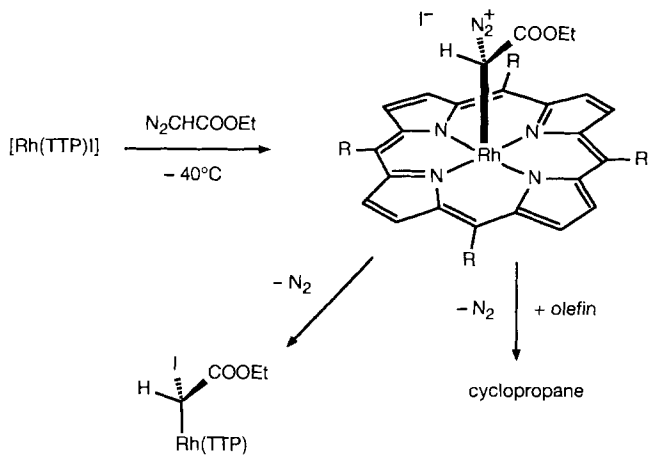
5.5.3. Rhodium Catalysts

The prototype of a catalyst for carbenoid reactions of diazocarbonyl compounds is $[Rh_2(OAc)_4]$. Not only cyclopropanations, but also insertions into C–H and N–H bonds are effectively catalyzed by a number of tetracarboxylato dirhodium complexes.[80] Attempts to achieve stereoselectivity by using optically active amino acids in such complexes were not very successful.[81] Doyle et al. used carboxamido complexes of the type shown in Scheme 33[82] after it was reported that acetamide can displace acetate in $[Rh_2(OAc)_4]$.[83] This discovery was the underlying idea for the development of, in part, highly enantioselective Rh^{II} cyclopropanation catalysts, containing optically active, bidentate N,O ligands of this type. The most efficient of them appears to be methyl 2-pyrrolidone-5-carboxylate (5-HMEPY). Its Rh^{II} complex gives up to 86% *ee* in the cyclopropanation of styrene with menthyl diazoacetate,[84a] and up to 94% *ee* in the intramolecular reaction of allylic diazoacetates.[84b,c] Furthermore, $[Rh_2(5\text{-MEPY})_4]$ is a very effective catalyst for the cyclopropenation of alkynes[85] (see Scheme 33).



5.5.4. Miscellaneous

A procedure that does not employ diazo reagents for the synthesis of cyclopropane derivatives from olefins is the Simmons–Smith cyclopropanation.[86] The carbene is typically generated from CH_2I_2 and mediated by a Zn–Cu couple. Kobayashi et al. recently reported the first catalytic, enantioselective Simmons–Smith cyclopropanation of disubstituted allylic alcohols by a $ZnEt_2/CH_2I_2$ system. Chiral disulfonamide

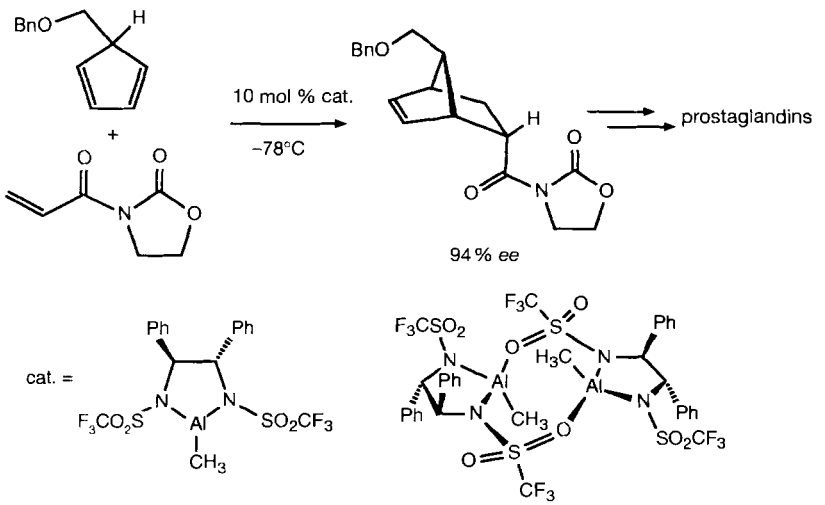


Scheme 33. Asymmetric intramolecular cyclopropanation of an allylic diazoacetate [84b, c] and cyclopropenation of an acetylene (R = D-menthyl) [85] catalyzed by a carboxamidato-Rh^{II} complex.

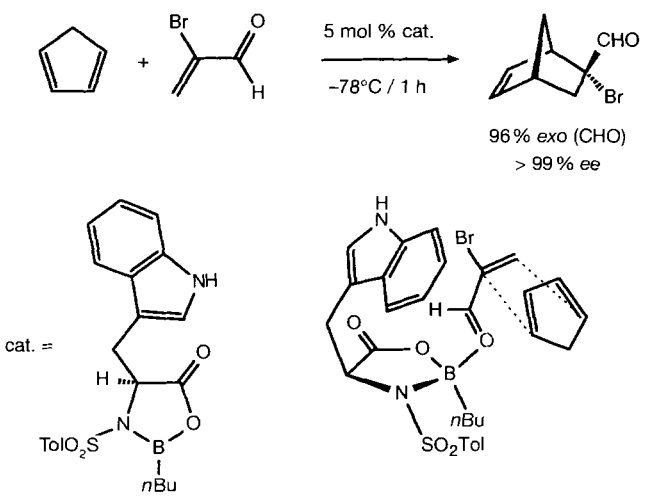
ligands were used as catalysts, and optical yields up to 82% were obtained.[87] An example is given in Scheme 34.

Scheme 34. The first example of asymmetric Simmons–Smith cyclopropanation with a catalyst containing a chiral disulfonamide ligand [87].

For the vast majority of the known cyclopropanation reactions no reliable experimental details on the mechanism are available. The formation of carbene complexes is obviously the most probable route, but such complexes have never been observed in catalytic systems. The formation of the cyclopropane ring can occur either by a concerted addition of the olefin, or via a metallacyclobutane intermediate.[88] A recent spectroscopic study addressed these questions for the iodo(tetra-*p*-tolylporphyrin)-rhodium system.[89] The 1-diazoalkyl complex resulting from the addition of ethyl diazoacetate to the catalyst could be detected at low temperatures (Scheme 35). At temperatures higher than $-20\,^{\circ}C$ this complex decomposed in the presence of olefins to afford cyclopropanes. If no olefins were added, the corresponding 1-iodoalkyl complex formed. Both reactions are taken as indicative of the generation of a highly reactive carbene intermediate.



Scheme 35. Identification of intermediates in the addition of ethyl diazoacetate to a Rh–porphyrin cyclopropanation catalyst [89]. TTP = tetra-*p*-tolylporphyrin, i.e. R = *p*-tolyl.

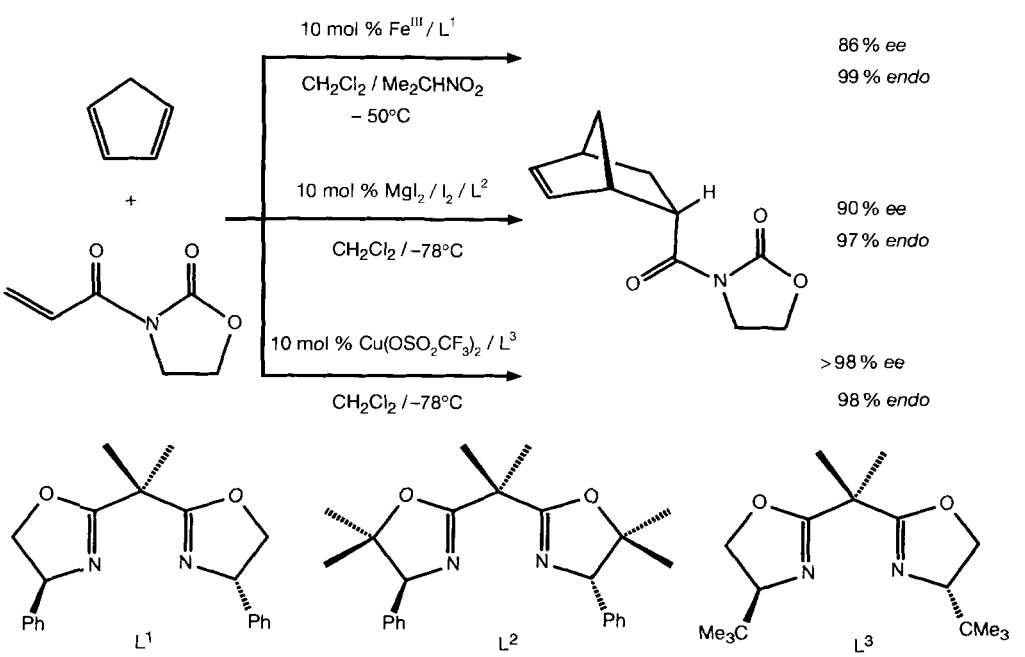


5.6. Asymmetric Diels–Alder Reactions

Chiral Lewis acids effectively catalyze [4 + 2] cycloaddition reactions of various dienes and dienophiles.[90] In recent years several boron and aluminum catalysts bearing optically active nitrogen ligands have been shown to impart very high enantioselectivities to Diels–Alder reactions. Whereas the vast majority of the successful catalysts contain chelating oxygen ligands, recent developments have shown that optically active nitrogen-ligands can give superior results. In particular, with the nitrogen-ligands, fine-tuning the electronic and steric properties seems to be much more flexible. Corey et al. have demonstrated that the diazaaluminolidine represented in Scheme 36 is an effective catalyst for the cycloaddition of cyclopentadiene derivatives to activated dienophiles.[91] The specific product shown in the example was used as an intermediate for the synthesis of prostaglandins. The ligand is a C_2-symmetric bis(sulfonamide), derived from 1,2-diamino-1,2-diphenylethane. The catalyst, which is easily formed in situ from the bis(sulfonamide) and, for example, $AlMe_3$, displays an interesting dimeric structure in the solid state (Scheme 36, bottom right).[91c] One of the two sulfonyl groups of each monomeric unit acts as a bridge through one oxygen atom, to give a tetrahedral coordination environment at the aluminum centers.

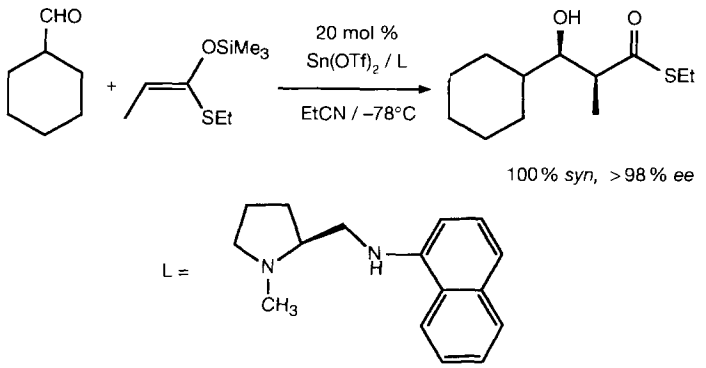
An oxazaborolidine derived from tryptophane has recently been shown by Corey et al. to impart extremely high enantioselectivity (>99% *ee* according to NMR) to the cycloaddition of 2-bromoacrolein and cyclopentadiene (see Scheme 37).[92] The high stereoselectivity is ascribed to an attractive interaction between the π-acidic dienophile and the π-basic indole moiety in the transition state, which leads to a highly preferential exposure of one enantioface of the dienophile to the attack by the diene. Such an attractive interaction is similar in concept to secondary interactions between ligands and substrates, which were postulated, for example, for several reactions catalyzed by functionalized ferrocenylphosphane complexes.[93] Very similar oxazaborolidines, also derived from amino acids but not able to display such crucial interactions, were found to afford lower optical yields (up to 86% *ee*).[94]

Scheme 36. Al-catalyzed asymmetric Diels–Alder reaction of a functionalized cyclopentadiene and (bottom right) a schematic representation of the dimeric structure of the catalyst in the solid state [91].



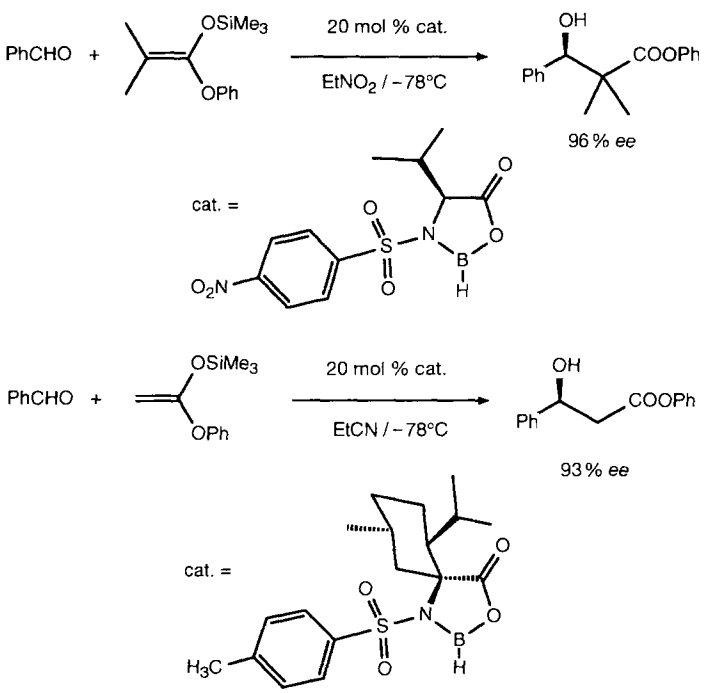
Scheme 37. Asymmetric Diels–Alder reaction of 2-bromoacrolein with cyclopentadiene catalyzed by an oxazaborolidine derived from tryptophan, and the proposed transition-state assembly [92].

Bis(dihydrooxazole) complexes of Fe^{III}, Mg^{II}, and Cu^{II} have also been successfully employed as catalysts for the Diels–Alder reaction.[95] The exact nature of the iron catalyst, which is generated in situ from the ligand L^1 in Scheme 38 and $FeCl_2$, FeI_2, or Fe powder and I_2, is rather obscure. This catalyst affords enantiomeric excesses of up to 86% in the Diels–Alder condensation illustrated in Scheme 38. It is also one of the still rare examples of non-d^0 transition metal Lewis acids used as catalysts in asymmetric cycloaddition reactions.[96] Slightly higher optical yields (90% *ee*) were reported for the same reaction when MgI_2 and the more bulky ligand L^2 formed the catalyst, whereas enantiomeric excesses of exceeding 98% were obtained in the case of the Cu catalyst in combination with ligand L^3, which demonstrates that the choice of metal *and* ligand plays a very important role.[95c] In all systems, cationic or dicationic complexes are assumed to be the catalytically active species.



5.7. Asymmetric Aldol Condensations

The addition of silyl enol ethers to carbonyl compounds, the Mukaiyama aldol reaction,[97] is promoted by several Lewis acids. Studies by Mukaiyama et al. have in recent years shown that the combination of Sn^{II} triflate and a chiral diamine impart very high stereoselectivities to this reaction.[98] This system is commonly best used in a stoichiometric fashion with addition of tributyltin fluoride or dibutyltin diacetate as promoters. However, a judicious choice of solvent and reaction conditions turns this reaction into a catalytic process, albeit with modest turnover numbers. Thus, slow addition of the reactants to a solution of the catalyst (20 mol%) in propionitrile at low tem-

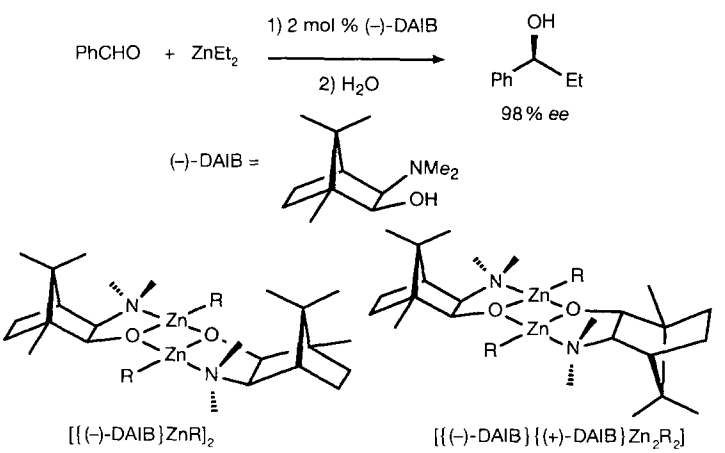


Scheme 38. Asymmetric Diels–Alder reactions catalyzed by Fe^{III} and Mg^{II} halide as well as by Cu^{II} triflate complexes containing bis(dihydrooxazole) ligands [95].

perature affords the aldol products in good yields and high stereoselectivities. The condensation of cyclohexylcarbaldehyde with (*Z*)-1-trimethylsilyloxy-1-(ethylthio)propene is shown in Scheme 39. The *syn*-configurated aldol product is exclusively formed with an optical yield that is higher than 98% *ee*.

Scheme 39. Asymmetric Mukaiyama aldol condensation catalyzed by a Sn^{II} complex containing a chiral chelating diamine [98].

More recently, the Kiyooka[99] and Masamune[100] groups have shown that chiral oxazaborolidines similar to those described in Section 5.6 (Diels–Alder reactions) are very effective catalysts for the Mukaiyama reaction. Optical yields up to 99% *ee* were reported. The catalysts are formed in situ from $BH_3 \cdot THF$ and an arenesulfonamide of an α-amino acid. Two examples are illustrated in Scheme 40. As was the case for the Sn-catalyzed reactions, the choice of solvent and reaction conditions plays a crucial role; best results are obtained in nitroethane, or propionitrile, and by slow addition of the aldehyde compound to the reaction mixture.

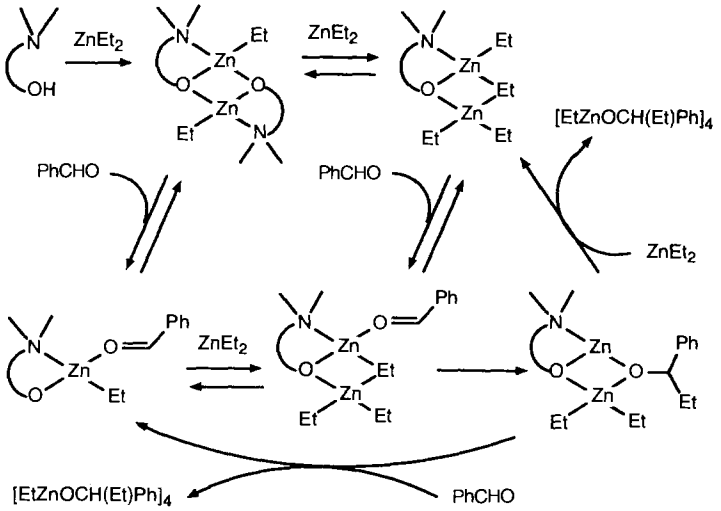


Scheme 40. Asymmetric Mukaiyama aldol condensations catalyzed by chiral oxazaborolidinones derived from *N*-sulfonylamino acids [99, 100].

Future developments of this important reaction will probably focus on the improvement of the catalytic activity of the already successful systems described above.

5.8. Asymmetric Alkylation of Aldehydes

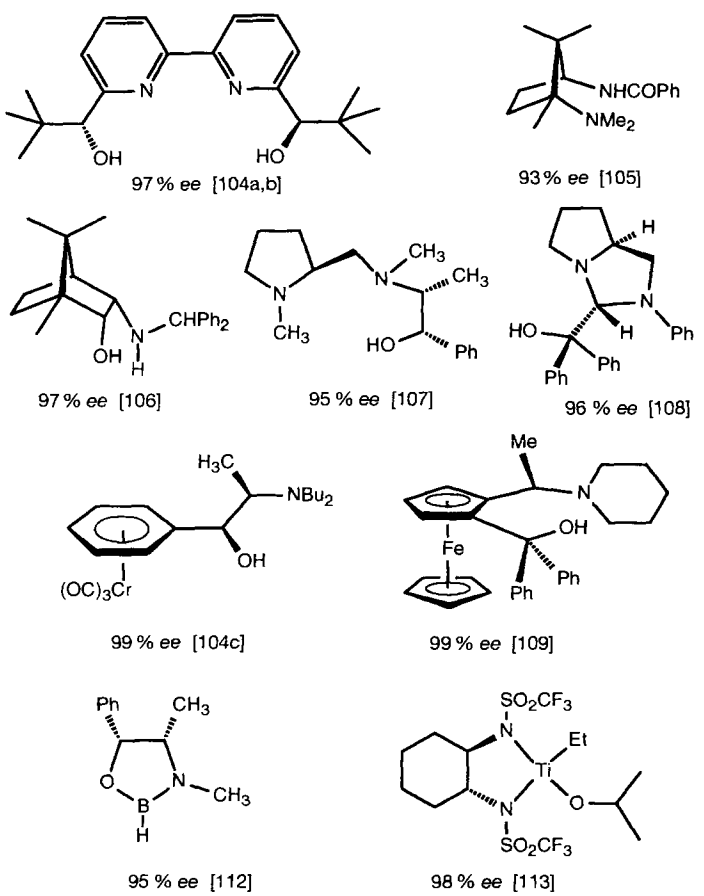
The enantioselective nucleophilic addition of dialkylzinc reagents to aldehydes, in the presence of catalytic amounts of a chiral ligand (typically an amino alcohol), has been extensively studied by several groups. Excellent review articles on this topic have appeared in recent years.[101]



Oguni and Omi first showed that the reaction of $ZnEt_2$ with benzaldehyde is effectively catalyzed by chiral 2-amino-1-alcohols derived from simple amino acids.[102] Since then, this reaction has served as a standard test reaction in the development of new catalysts. One of the best understood systems has been described by Noyori et al.[103] The main conclusions from that study will be briefly discussed here, as they can be applied to other systems. There, 3-*exo*-(dimethylamino)isoborneol (DAIB) is used as catalyst in 1–5 mol% (to aldehyde). A virtually quantitative yield of the secondary alcohol is obtained if one equivalent of the $ZnEt_2$ reagent is employed (Scheme 41). Only one

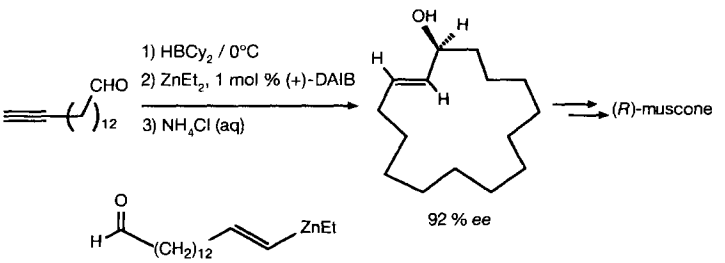
Scheme 41. The DAIB-catalyzed asymmetric addition of $ZnEt_2$ to benzaldehyde and the two diastereomeric dimers $[(DAIB)ZnR]_2$, involved in chiral amplification (characterized by X-ray crystallography for R = Me): The less stable and more reactive homochiral form, and the more stable and less reactive *meso* form [103].

ethyl group is transferred to the electrophile, and the actual alkylation takes place via a dinuclear zinc species as illustrated in Scheme 42.



One of the most interesting features of this reaction are the nonlinear effects in the enantioselectivity. Thus, maximum enantioface discriminations (95–98% *ee*) in the ethylation of benzaldehyde are still obtained when scalemic mixtures of DAIB, for instance, in an optical purity as low as 15%, are used. This has been explained by the formation of two diastereomeric dimeric complexes (both characterized by X-ray diffraction), one of them a homochiral and the other a centrosymmetric *meso* form (see Scheme 41). The former is both thermodynamically and kinetically less stable and therefore exhibits much higher turnover frequencies than the achiral counterpart. The possibil-

Scheme 42. The mechanism of the DAIB-catalyzed addition of $ZnEt_2$ to benzaldehyde [103].

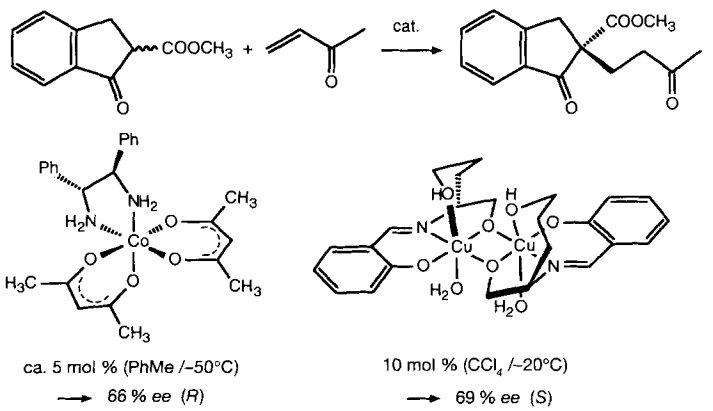


ity of obtaining high enantioselectivities despite the relatively low optical purity of the inducing ligand has been named *asymmetric amplification*, and was first observed by Kagan et al.,[104d] as well as by other groups more recently.[104a-c]

Several other N,O-ligands catalyze the addition of dialkylzinc to aldehydes in high optical yields. Scheme 43 illustrates the structural variety of such ligands.[105-109]

Scheme 43. A selection of ligands and complexes used as catalysts in the addition of $ZnEt_2$ to benzaldehyde (the *ee* values of the product 1-phenylpropanol are indicated).

In recent years efforts have been made to extend the range of zinc reagents from simple to functionalized alkyls.[110] Progress in this area is exemplified by the work of Knochel et al.[110a] and Oppolzer et al.[110b-d] For example, alkenylzinc reagents are generated in situ by transmetalation from ZnR_2 (R = Me, Et) and a vinylborane, the latter being obtained by hydroboration of the corresponding terminal alkyne. The addition of such nucleophiles is catalyzed, for example, by DAIB, which gives excellent enantioselectivities. This methodology was very recently applied, in an intramolecular variation, to the total synthesis of (*R*)-muscone[110d] (Scheme 44). Finally, dialkynylzinc and alkynylbromozinc reagents can also be used in this type of reaction (catalyzed by, for instance, ephedrine derivatives) and give moderate to good stereoselectivities.[111]

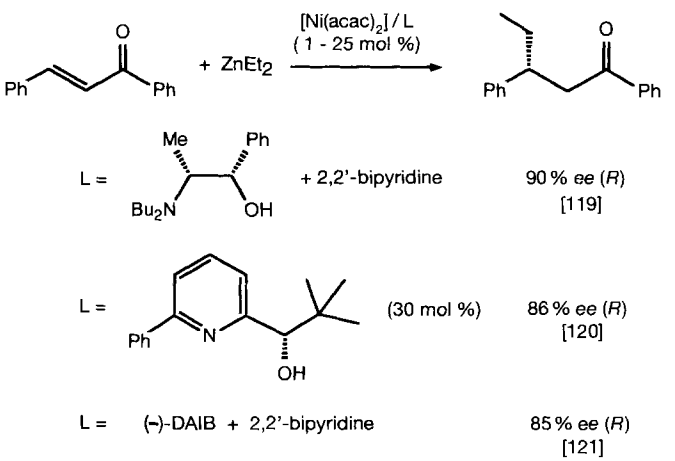


Scheme 44. Oppolzer's synthesis of muscone by the intramolecular reaction of the alkenylzinc reagent (shown at the bottom) that arises in situ from $ZnEt_2$ and the hydroborated ω-pentadecinal [110d].

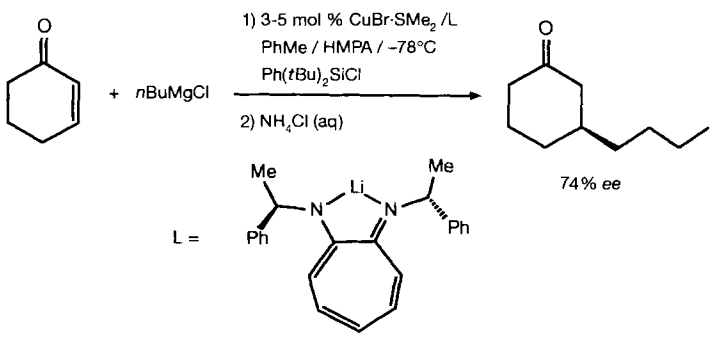
Scattered reports have appeared on the use of boron and titanium catalysts containing nitrogen-ligands. Thus, the oxazaborolidine, formed in situ from (−)-ephedrine and $H_3B \cdot S(CH_3)_2$, catalyzes the standard formation of 1-phenylpropanol with an enantiomeric excess of 95%.[112] The same reaction is very efficiently catalyzed by the bistrifluoromethanesulfonamide of *trans*-1,2-diaminocyclohexane in the presence of equivalent amounts of titanium tetraisopropoxide, and affords the product in 98% *ee*.[113] The actual catalyst is considered to be the ethyltitanium complex shown in Scheme 43.

5.9. Asymmetric Conjugate Addition Reactions

The conjugate addition reaction (this term includes any nucleophilic 1,4-addition to an α,β-unsaturated system) is an extremely important transformation which finds wide application in organic synthesis.[114] The number of recent publications dealing with the asymmetric version of this reaction testifies to the worldwide interest.[115] However, asymmetric catalysis still plays a minor role in conjugate addition, since most studies have employed chiral ligands (or complexes) in stoichiometric amounts.[116] One of the first studies, carried out by Brunner et al.,[117] was the cobalt-catalyzed 1,4 addition of methyl 1-oxo-2-indanate to vinyl methyl ketone. By using 1,2-diphenyl-1,2-ethanediamine as the chiral ligand, optical yields up to 66% *ee* were obtained (Scheme 45). The catalyst precursor is the octahedral Co^{II} complex $[Co(acac)_2(diamine)]$, formed in situ from $[Co(acac)_2]$. The same reaction is also catalyzed by a



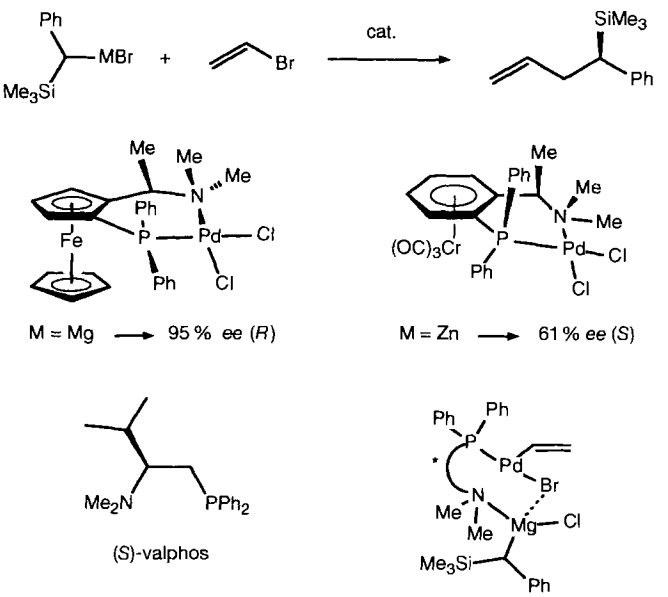
Scheme 45. Asymmetric Michael addition catalyzed by Co^{II} [117] and Cu^{II} complexes [118].



dimeric Cu^{II} complex bearing a tetradentate Schiff base as ligand) (Scheme 45). A slightly higher enantioselectivity (69% *ee*) was observed by Desimoni et al. with this complex.[118]

The use of $[Ni(acac)_2]$ as a catalyst precursor in the addition of diethylzinc to chalcone in the presence of various chelating, optically active N,O-ligands has been reported by Soai et al.,[119] Bolm et al.,[120] and Feringa et al.[121] Simple ephedrine derivatives, novel pyridyl (or 2,2'-bipyridyl) alcohols, or the well-known DAIB afforded enantiomeric excesses of up to 90%. Relevant examples are shown in Scheme 46. An interesting aspect of this reaction is the beneficial effect that the presence of a second, achiral nitrogen ligand has on the enantioselectivity. Thus, a variety of chelating diamines such as 2,2'-bipyridine, 1,10-phenanthroline, and 2,2'-biquinoline were found to improve selectivity significantly.[119, 121]

Finally, Lippard et al. have shown that chiral aminotropone imidates are effective ligands in the Cu-catalyzed conjugate addition of Grignard reagents to cylohexenone.[122] This virtually unique ligand system afforded enantiomeric excesses as high as 74% (Scheme 47).



Scheme 46. Enantioselective 1,4 addition of $ZnEt_2$ to chalcone catalyzed by Ni^{II} in the presence of chelating N,O-ligands [119–121].

Scheme 47. A chiral *N,N'*-dialkylaminotropone imidate ligand in the Cu^{I}-catalyzed 1,4 addition of Grignard reagents to cyclohexenone [122].

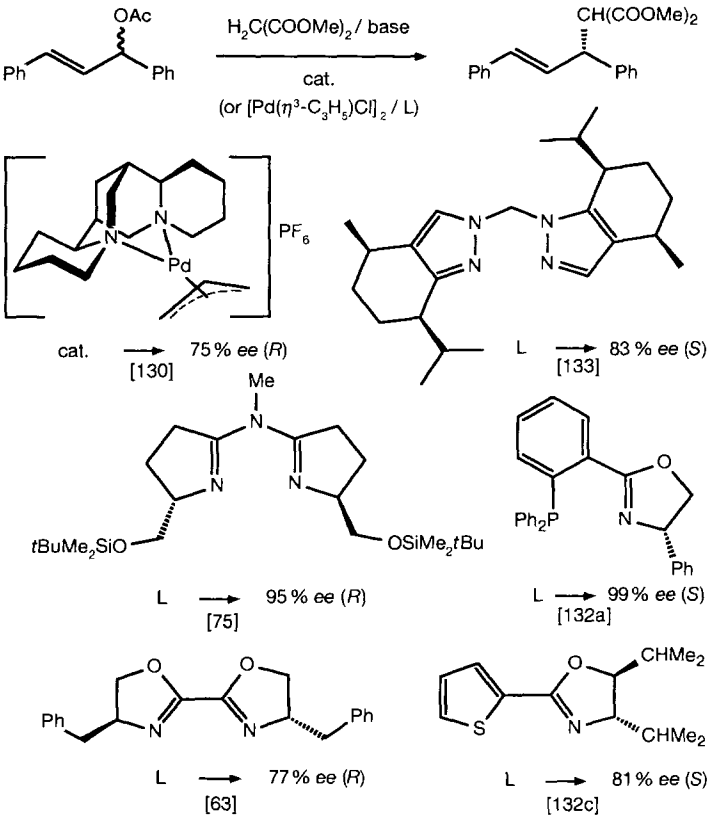
5.10. Asymmetric Grignard Coupling

The use of nitrogen-containing ligands in the Ni- and Pd-catalyzed coupling of secondary Grignard reagents with alkenyl halides has been pioneered by Hayashi and Kumada.[123] The most successful ligands used for this reaction are chelating P,N-systems, derived either from amino acids[124] or from chiral ferrocenyl systems.[125] The best characterized catalysts are the $NiCl_2$, or $PdCl_2$ complexes with ppfa ((*S**)-*N,N*-dimethyl-1-[(*R**)-2-diphenylphosphino)ferrocenyl]ethylamine). Enantiomeric excesses exceeding 90% were obtained in the reaction of [α-(trimethylsilyl)benzyl]magnesium bromide with vinyl bromide, which afforded an optically active allylsilane (Scheme 48). It

Scheme 48. Synthesis of β,γ-unsaturated allylsilanes by asymmetric Pd-catalyzed Grignard coupling. Examples of catalysts with ferrocenyl [125], (η^6-arene)Cr [126], and amino acid derived P,N-ligands [124], and the postulated transition-state assembly.

has been proposed that the dimethylamino group on the ligands fulfills an important role in the transition state of the reaction. Its dissociation from palladium (or nickel) and temporary coordination to magnesium enables one of the enantiomers of the Grignard reagent to be selected, which leads to the formation of the preferred diastereomeric transition-state assembly, as illustrated in Scheme 48.[125c] Such an assembly immediately

precedes the key transmetalation step of the alkyl fragment from magnesium to palladium (or nickel). However, this model postulates a coordinatively unsaturated palladium (or nickel) center, which seems rather unlikely.



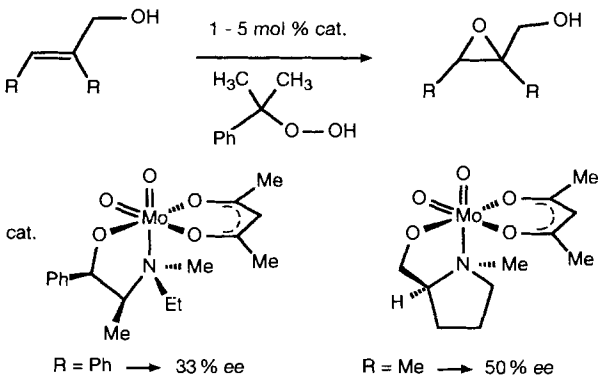
Of the two elements of chirality contained in ferrocenyl ligands of the ppfa type, the planar chirality due to the 1,2-disubstitution of the ferrocene moiety plays the dominant role in determining stereoselectivity in Grignard cross-coupling reactions.[125c] Hayashi and Uemura recently reported the synthesis of a chromium complex containing an analogous P,N-ligand system in which the planar-chirality is part of a η^6-coordinated arene.[126] The novel ligand provided enantioselectivities up to 61% *ee* (Scheme 48).

5.11. Asymmetric Allylic Alkylation

The allylic alkylation reaction consists of the substitution of a suitable leaving group in allylic position by a carbon nucleophile.[127] This transformation is typically catalyzed by phosphane–Pd complexes, and high degrees of enantioselection have been obtained by using a variety of chiral chelating diphosphanes.[128] Reports on the use of optically active nitrogen-ligands did not appear until 1990 and are still very rare.[129] In fact, it is commonly accepted that Pd(0) species that are stabilized by phosphane ligands are involved in the catalytic cycle.[127] It is also well-known that nitrogen-donors are generally rather poor ligands for the stabilization of low oxidation states of late transition metals. A combination of these factors may have generated a prejudice against nitrogen-ligands as alternatives to phosphorus-ligands.

One of us has recently shown that the alkaloid (−)-sparteine is an effective inducing ligand for aymmetric allylic alkylation.[130, 131] Optical yields of up to 85% *ee* were obtained in the alkylation of simple 1,3-disubstituted allylic acetates with the anion of dimethyl malonate as a nucleophile. The Pd^{II} complex $[Pd(\eta^3\text{-}C_3H_5)(\text{sparteine})]PF_6$ was used as catalyst precursor (Scheme 49). The corresponding η^3-cyclohexenyl and η^3-1,1,3-triphenylallyl complexes, postulated as intermediates in the catalytic alkylation of cyclohexenyl acetate and 1,1,3-triphenylallylacetate, respectively, were prepared and characterized by X-ray crystallography.[130b] The catalytic activity of such sparteine–Pd complexes was qualitatively estimated to be one to two orders of magnitude lower than that of phosphane–Pd systems[130a] (this rule of thumb seems to apply to other nitrogen-containing systems; see below).

Highly enantioselective catalysts containing bis(dihydrooxazole), or 5-azasemicorrin ligands were used by Pfaltz et al.[63, 75] Under conditions where the nucleophile is generated in situ from dimethylmalonate, *N,O*-bis(trimethylsilyl)acetamide, and a cocatalytic amount of KOAc in CH_2Cl_2, alkylation products were obtained in very high optical yields (up to 95% *ee*). Recently Pfaltz and von Matt[132a] and Helmchen and Sprinz,[132b] independently, developed (phosphinoaryl)dihydrooxazoles as P,N-ligands, which were shown to give more active and highly selective catalysts in this reaction. Thienyl dihydrooxazoline ligands were used by Frost and Williams,[132c] but were inferior, both in terms of activity and selectivity, when compared to the abovementioned P,N-systems (Scheme 49).



Scheme 49. Asymmetric allylic alkylation catalyzed by Pd complexes containing chelating nitrogen-ligands.

A novel asymmetric bis(pyrazolyl)methane ligand derived from menthone was recently prepared in these laboratories.[133] Good enantioselectivities (up to 83% *ee*) were obtained in the standard alkylation reaction of 1,3-diphenylallylacetate (Scheme 49). It was found that one equivalent of chloride, for example, present in solution when the catalyst was prepared in situ from the binuclear complex $[Pd_2(\eta^3\text{-}C_3H_5)_2Cl_2]$ and the ligand, had a beneficial effect on stereoselectivity. A halide effect of this type, which possibly also plays an important role in the systems of Pfaltz et al., is not yet understood, and holds out the hope that future mechanistic studies may lead to further improvements of this "old" reaction.

5.12. Asymmetric Oxidation Reactions

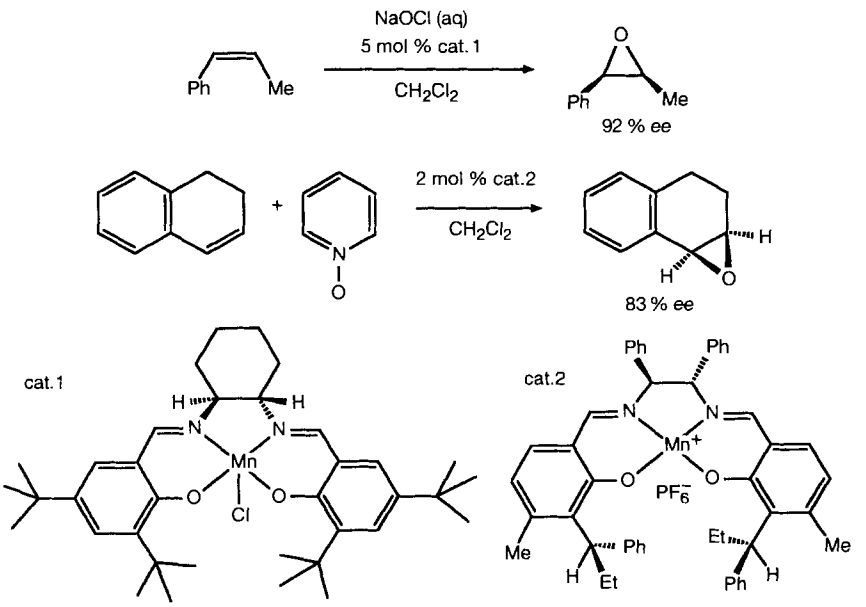
Before the advent of the Sharpless epoxidation of allylic alcohols with *tert*-butylhydroperoxide (TBHP) catalyzed by titanium tartrate systems,[134] several reports of molybdenum[135] and vanadium[136] catalysts had appeared. These systems contain chiral auxiliaries such as ephedrine and proline derivatives. The cases where the nitrogen-donors interact directly with the metal are illustrated in Scheme 50. Modest to good enantioselectivities were obtained (up to 50% *ee*). It should be noted that the dioxomolybdenum complexes shown there can give rise to diastereomeric mixtures, because the metal atom becomes a stereogenic center.

After the spectacular success of the Sharpless epoxidation reaction, progress in this field followed very slowly, and effec-

Scheme 50. Early example of asymmetric epoxidation of an allylic alcohol with cumene hydroperoxide catalyzed by Mo^{VI} complexes [135].

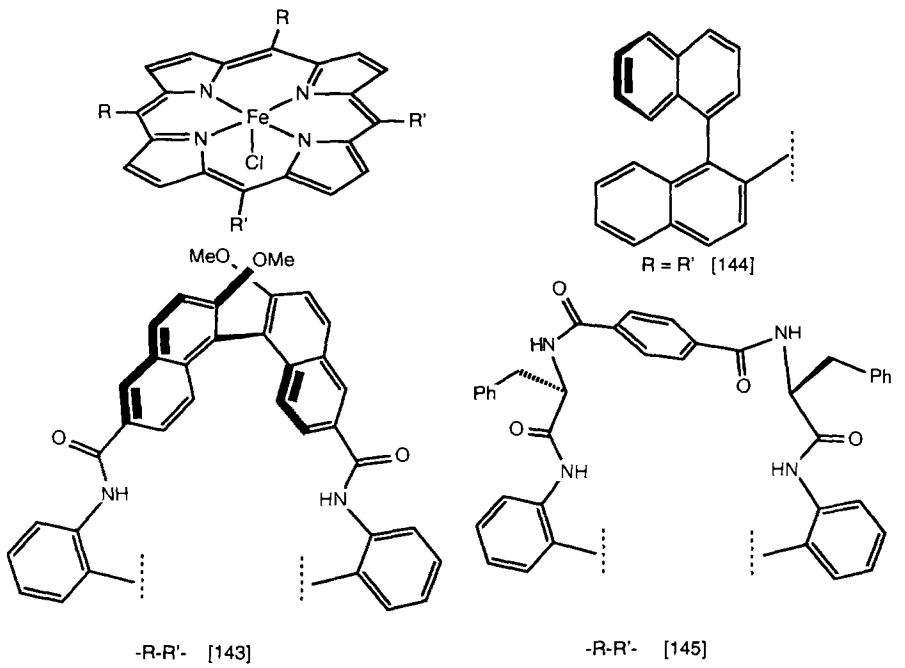
tive chiral catalysts capable of epoxidizing nonfunctionalized olefins have been discovered only in recent years.

5.12.1. Asymmetric Expoxidation of Simple Olefins



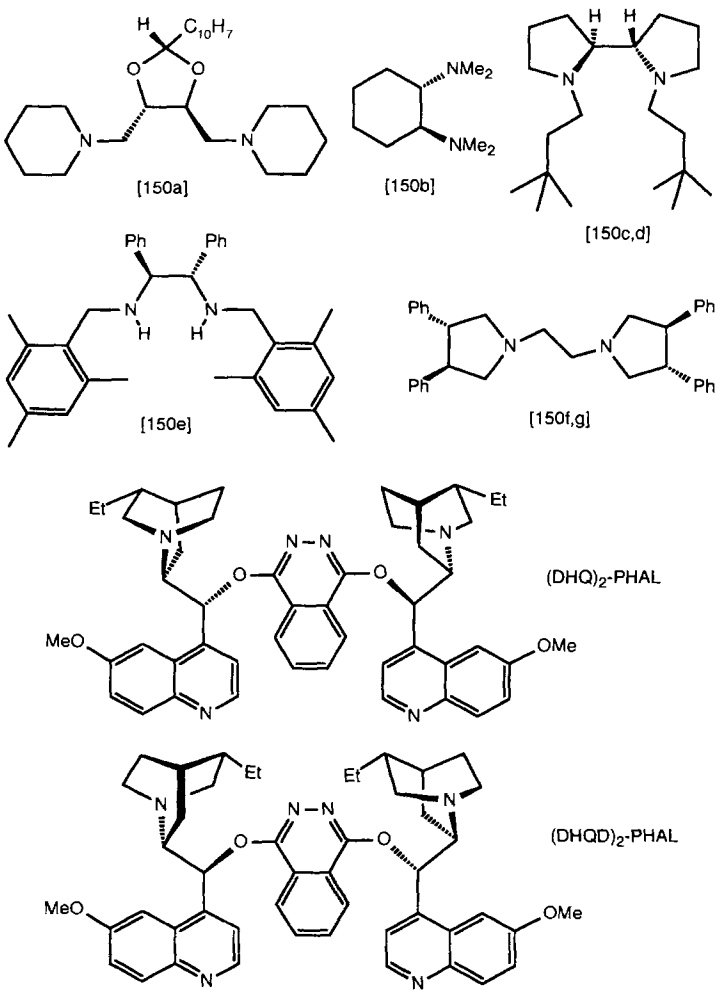
Kochi et al. have shown that achiral Mn^{III} and Cr^{III} complexes containing salen type ligands (salen = *N*,*N*′-bis(salicylidene)-ethylenediamine) are active catalysts for the epoxidation of nonfunctionalized olefins with, for example, iodosylbenzene as oxidant.[137] In the case of chromium, an oxochromium(v) species is an intermediate in the catalytic cycle. An analogous oxomanganese(v) could not be isolated and characterized, but sound indirect evidence for its existence has been reported.[137a] The formation of such oxo species implies the successive oxygen atom transfer from the oxidant to the metal and hence to the substrate, the "oxygen rebound".[138] This mechanism is fundamentally different from that operating with Sharpless's titanium catalysts.

Following up Kochi's pioneering work, Jacobsen et al.[139] and, independently, Katsuki et al.[140] prepared chiral derivatives of the $[Mn(salen)]^+$ complexes and, using oxidants such as PhIO, or more elegantly, aqueous NaOCl (commercial bleach) under phase-transfer conditions, achieved the catalytic epoxidation of simple olefins with enantiomeric excesses exceeding 90%. Some examples are shown in Scheme 51. Chirality is introduced in the essentially planar salen–manganese system by replacing the ethylenediamine backbone by optically active 1,2-diphenylethylene diamine or *trans*-1,2-diaminocylohexane. Furthermore, it is crucial that the ligand bears bulky substituents adjacent to the phenoxy oxygen atoms. Whereas Jacobsen et al. showed that a *tert*-butyl group is sufficient to achieve high selectivities in the phase-transfer process (using NaOCl as oxidant), Katsuki et al. obtained better results (with PhIO as oxidant) by introducing a stereogenic 1-phenylprop-1-yl group. These systems seem to be particularly well suited for the epoxidation of *Z*-configurated, 1,2-disubstituted and cyclic olefins. Thus, enantioface discriminations of up to 98% *ee* were obtained with chromene derivatives as substrates.[139c,d] Mukaiyama et al. recently demonstrated that chiral salen–manganese complexes are also suitable catalysts for the epoxidation of nonfunctionalized olefins with molecular oxygen.[141] Since the system additionally requires pivalaldehyde as reductant, the actual oxidant is possibly a hydroperoxide (peroxopivalic acid). These findings show the versatility of the manganese catalysts and their potential for future developments and applications.



Moderate enantioselectivities (up to 62% *ee*) were recently reported by Thornton et al. for the oxidation of silyl enol ethers to α-hydroxy ketones with PhIO, catalyzed by another salen–manganese complex.[142] Finally, efforts to develop chirally modified porphyrin ligands are worth mentioning. The groups of Groves,[143] Kodadek,[144] Mansuy,[145] and Collman[146] prepared peripherally functionalized porphyrins bearing stereogenic binaphthyl, amino acid, or threitol units, as illustrated in Scheme 52. Fe^{III} as well as Mn^{III} complexes of porphyrins of the above type were shown to be efficient catalysts for the epoxidation of simple olefins in combination with either NaOCl or PhIO as oxidants, and afforded enantioselectivities in the range of 15–88% *ee*. The strategy common to the different approaches is apparent: Introduction of stereogenic substituents onto the porphyrin moiety, either with bulky and conformationally rigid groups or by bridging the *meso* positions, generates a "chiral pocket" around the metal. The results obtained so far are encouraging and show scope for further developments.

5.12.2. Osmium-Catalyzed Dihydroxylations

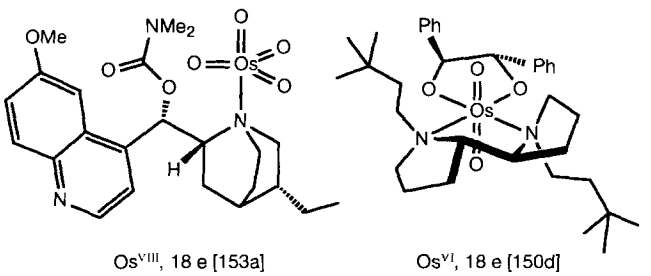


The development of the asymmetric Os-catalyzed dihydroxylation of olefins by Sharpless et al. is recognized to be one of the most significant advances in homogeneous catalysis in recent years. Scope, applications, and mechanistic aspects of this reaction have been studied in detail and excellent reviews have ap-

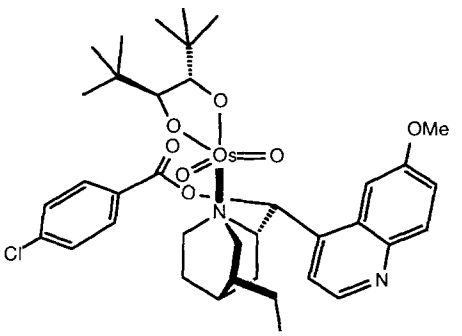
Scheme 51. Asymmetric epoxidation of unfunctionalized olefins catalyzed by Mn^{III}–salen complexes [139, 140].

Scheme 52. Partial structures of some chiral porphyrins that in Fe^{III} complexes are used as catalysts in asymmetric tion of simple olefins [143–145].

Scheme 53. A selection of chiral chelating diamines used in the stoichiometric osmylation of olefins [150] and the state-of-the-art dihydroquinine and dihydroquinidine ligands for the catalytic dihydroxylation [152]. $C_{10}H_7$ = naphthyl.



peared.[147] Therefore, just the relevant aspects related to the use of chiral nitrogen ligands will be highlighted.

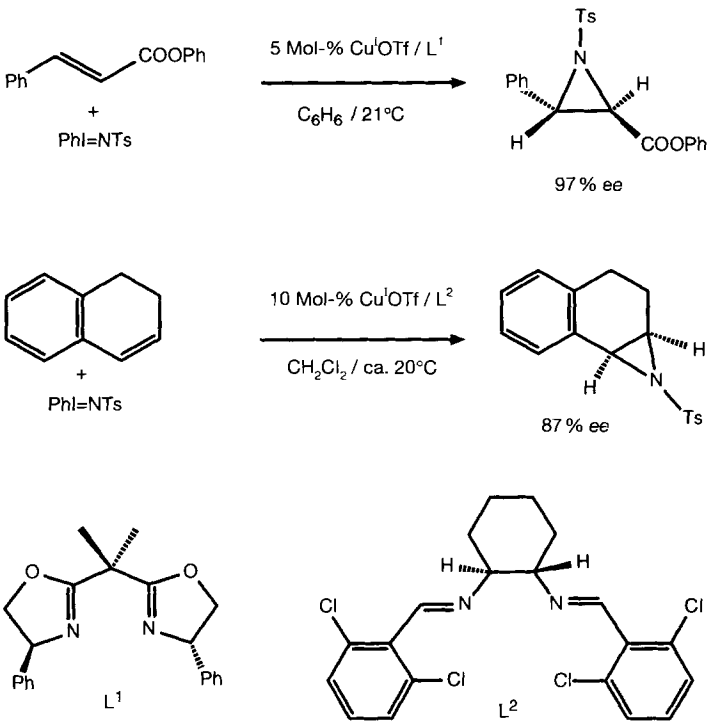


It has been known for decades that pyridines or tertiary amines accelerate the addition of OsO_4 to olefins.[148] Sharpless et al. introduced cinchona alkaloids as inducing agents in the stoichiometric osmylation of olefins in 1980.[149] In succeeding years several authors reported the use of chelating diamines as chiral auxiliares in this reaction.[150] Some are shown in Scheme 53. Enantiomeric excesses approaching 100% were obtained, but none of these diamine systems could be turned into a catalytic process. The fundamental breakthrough came in 1988 when Sharpless reported the catalytic version of the dihydroxylation with the OsO_4/cinchona system and *N*-methylmorpholine-*N*-oxide as a cooxidant.[151] During the following years, they further developed and optimized the process.[152] In particular, the use of $K_3[Fe(CN)_6]$ as a co-oxidant in a biphasic system and a broad screening of cinchona alkaloid derivatives impressively extended the scope of the catalytic reaction. Thus, for a wide variety of olefins, excellent enantioselectivities were obtained (>95% *ee*). The new class of phthalazine ligands, $(DHQD)_2$-PHAL and $(DHQ)_2$-PHAL, incorporating two alkaloid units into the same molecule, are derivatives of dihydroquinidine (DHQD) and dihydroquinine (DHQ). As DHQD and DHQ are a pseudoenantiomeric pair, both optical isomers of the dihydroxylation products are accessible in remarkably similar stereoselectivities.[152a]

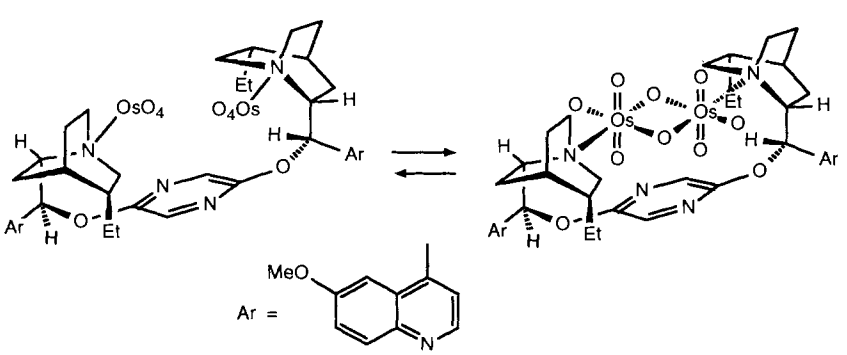
A very important aspect of cinchona alkaloid derivatives (with respect to catalysis) is that they behave as monodentate ligands, that is, only the quinuclidine nitrogen atom coordinates to the metal. The complexes characterized by X-ray diffraction are shown in Scheme 54 (top left).[153]

The dioxoosmium(VI)diolato complexes (osmate esters), resulting from the reaction of [OsO_4 · amine] with an olefin during the catalytic cycle are coordinatively unsaturated species (16 e) only when monodentate amine ligands are used (Scheme 54, bottom). As pointed out by Sharpless et al.,[154] coordinative unsaturation at this stage is required to achieve reoxidation of the osmate ester and its hydrolysis. A coordinatively saturated system (for example, when a chelating diamine is used) or one formed in the presence of an excess of amine, is not susceptible to fast reoxidation/hydrolysis. This offers an explanation why chelating diamines, despite the excellent stereochemical results obtained in stoichiometric reactions, cannot be employed in catalytic processes.

A speculative, postulated mechanism for the Os-catalyzed dihydroxylation has been reported by Corey et al.[155a,b] They suggested that the cinchona ligands, which contain two alkaloid moieties, are able to accommodate two OsO_4 units coordinated to the quinuclidine nitrogen atoms. These complexes can exist as an equilibrium mixture (Scheme 55). Whereas the open form in which the OsO_4 fragments do not interact with each other was



Scheme 54. Schematic representation of results of X-ray structural analyses of oxo-osmium complexes with dihydroquinine derivatives as monodentate ligands [153] and with a chelating diamine [150d].

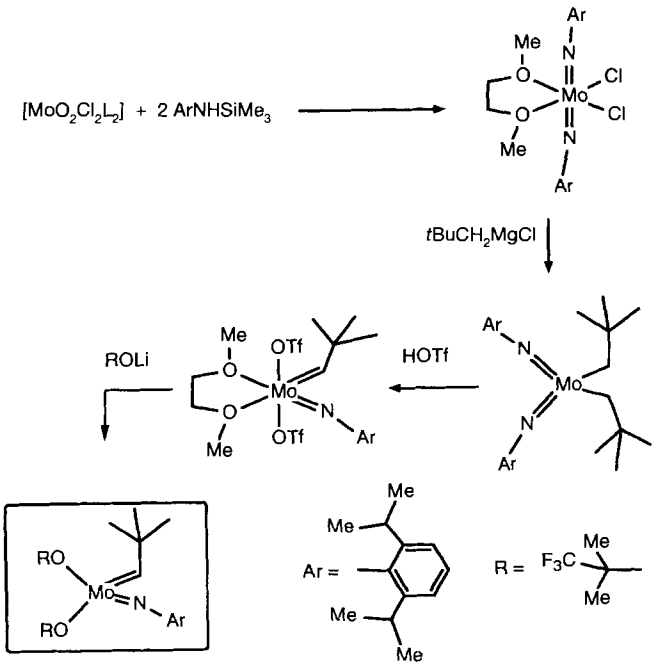


isolated and characterized by X-ray diffraction, the more reactive oxo-bridged form is proposed to be involved in the catalytic cycle. Recently, however, Sharpless et al.[155c] have shown that the kinetics of catalytic dehydroxylation is first order in osmium. This throuws doubt on the relevance of Corey's postulate.

5.12.3. *Asymmetric Aziridination*

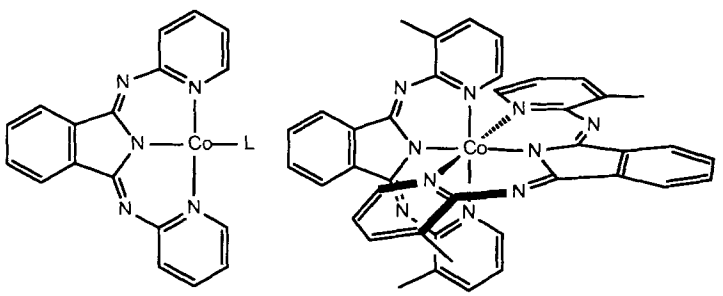
A topic closely related to epoxidation is aziridination (the formation of an aziridine from an olefin and a suitable nitrene-delivering reagent).[156] An important discovery was made by the Evans group in 1991,[157a] when the catalytic activity of Cu^I salts was demonstrated. The simple compound $[Cu(NCMe)_4]ClO_4$ effectively catalyzed the aziridination of various olefins with (*N*-(*p*-toluenesulfonyl)imino)phenyliodinane (PhI=NTs). More recently, other groups have shown that several salen–metal complexes are able to catalyze this reaction,[158] but only very recently were highly enantioselective Cu^I catalysts disclosed. Using CuOTf with bis(dihydrooxazole) ligands (these catalysts are also very successful in cyclopropanation reactions; see Section 5.5.1), Evans et al. obtained optical yields of up to 97% *ee* for the aziridination of α,β-unsaturated esters (Scheme 56). The aziridines themselves are suitable precursors for the synthesis of α-amino acid derivatives.[157b] A further, remarkably simple, chiral, bidentate ligand has been reported by Jacobsen et al. (L^2 in Scheme 56).[159] A common feature of these first two successful approaches is the use of neutral, C_2-symmetric N,N-ligands. In analogy to cyclopropanation and to Mn-catalyzed epoxidation, the transfer of the nitrene fragment could occur via intermediate imido–metal complexes. Although such complexes are known for several transition metals,[160] and play an important role in ROMP catalysis (see Section 5.13), whether they are involved in catalytic aziridination remains the subject of speculation.

Scheme 56. Asymmetric aziridination of olefins catalyzed by Cu^I complexes [157b, 159].



Scheme 55. Structure of a binuclear oxoosmium complex (characterized by X-ray analysis) and its postulated more reactive, dioxo-bridged form [155].

5.13. Miscellanous Reactions



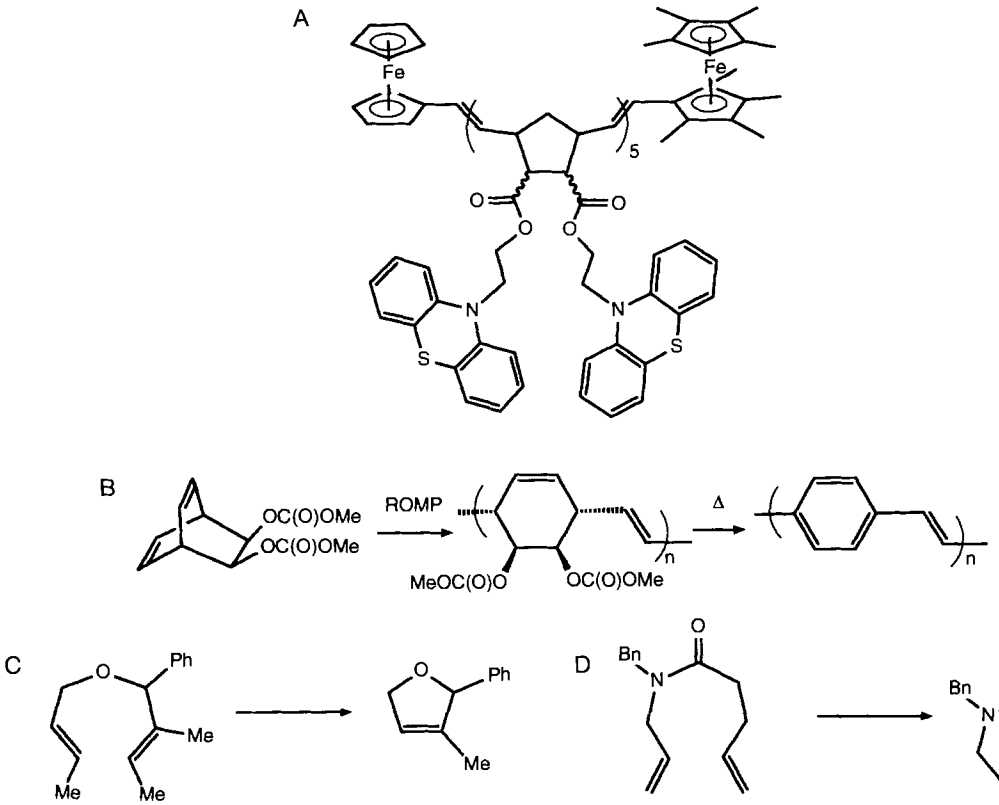
The oxidation of cyclohexane by air, which gives a mixture of cyclohexanol and cyclohexanone, is a fundamentally important industrial process.[161] The reaction, in which cyclohexyl hydroperoxide is an intermediate, is catalyzed by a hydrocarbon-soluble Co^{II} carboxylate, whose role is to decompose the hydroperoxide. Tolman, Ittel, et al. reported in 1988 that bis(2-pyridylimino)dihydroindolatocobalt complexes (Scheme 57) are very active and long-lived catalysts for this

oxidation process.[162] The advantage of such complexes is that they are active at lower temperatures and higher peroxide concentrations (higher conversions) than conventional catalysts. Cobalt porphyrins and phthalocyanins were also found to be efficient catalysts.[162]

In recent years well-defined catalysts for the ring-opening metathesis polymerization (ROMP) reaction have been developed. Starting from (usually) strained cyclic olefins and using ROMP it is now possible to prepare homopolymers and block copolymers with a very narrow molecular weight distribution.[163] The best catalysts are pseudo-tetrahedral alkylidene complexes of molybdenum and tungsten in the formal oxidation state +VI. The coordination sphere of the metal in these complexes contains two bulky alkoxide ligands and one sterically demanding imido ligand. This combination of ligands ensures sufficient stability of the alkylidene complex by preventing, for example, intermolecular ligand scrambling or other decomposition reactions. At the same time it still allows the coordination of the substrate with formation of a five-coordinate complex, and thus its transformation into the intermediate metallacyclobutane complex.[164a] One of two imido ligands also plays the role of a protecting group in a precursor of the catalyst, allowing the selective introduction of two alkyl ligands.[164] The synthesis and reactivity of such imido complexes are illustrated in Scheme 58. Several of these complexes have been characterized by X-ray diffraction and show the peculiarity of the NAr ligand: Because of the relative electron-deficiency of the metal center, a strong donation of the nitrogen lone pair takes place. This causes an apparent sp hybridization at the nitrogen atom, resulting in an M-N-C angle approaching 180°. Correspondingly, the M–N distance in the range of 1.70–1.75 Å is very short—indeed shorter than the M–C distance of the alkylidene ligands (1.85–1.95 Å).[164]

Scheme 58. Synthesis of a Mo ROMP catalyst containing imido ligands [164a]. L = thf.

Scheme 57. Cobalt catalysts containing bis(pyridylimino)dihydroisoindolato ligands for cyclohexane oxidation (L = $RCOO^-$ or second ligand) [162].



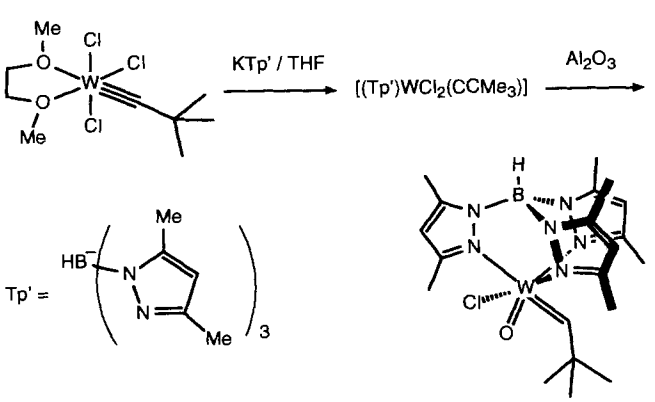
With ROMP catalysts the synthesis of, for example, small block copolymers containing redox-active groups was recently achieved (Scheme 59A). The well-behaved solution electrochemistry of such copolymers has been reported by Schrock, Wrighton, et al.[165]

Grubbs et al. have shown that the interesting polymer poly(1,4-phenylenevinylene) is readily accessible by ROMP (Scheme 59B)[166] and that the catalysts shown in Scheme 57 can be employed in the ring-*closing* olefin metathesis of diolefins for the synthesis of oxygen- and nitrogen-heterocycles (Scheme 59C and D).[167]

An alkylideneoxotungsten(VI) complex containing a tris(pyrazolyl)borato ligand has been reported by Boncella et al.[168] as an exceptionally stable ROMP catalyst. Its synthesis is achieved from an alkylidynetrichloro complex by ligand exchange and treatment with neutral alumina, as shown in Scheme 60. It is found to be a very active ROMP catalyst, in the presence of $AlCl_3$ as a cocatalyst, for example, for cyclooctene and norbornene polymerization. The role of the Lewis acid $AlCl_3$ is thought to involve abstraction of the chloride ligand, thus generating a coordinatively unsaturated cationic alkylidene species which acts as the actual catalyst.[168]

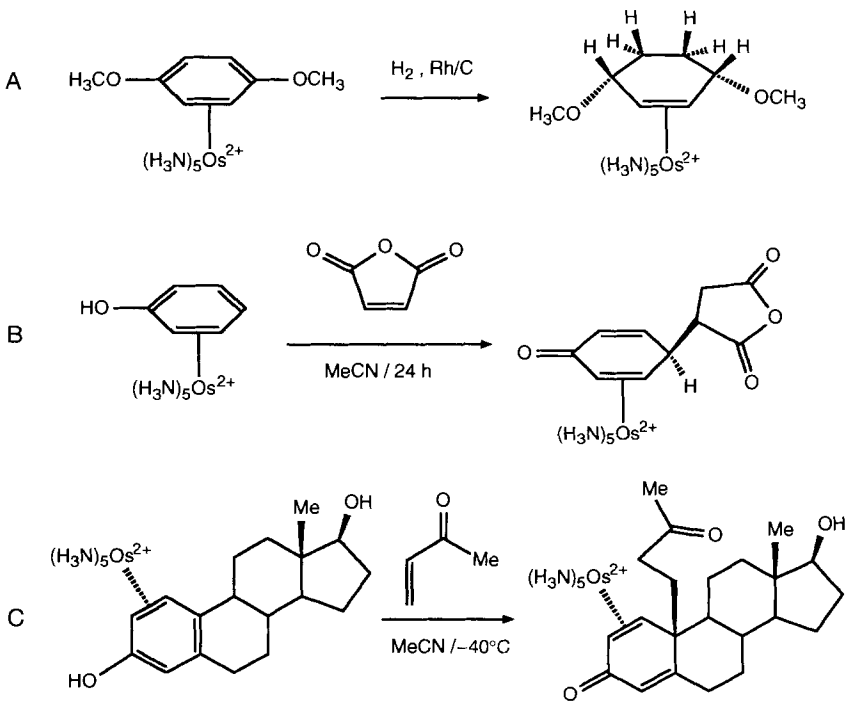
Although not directly relevant to homogeneous catalysis, the unique reactivity patterns imparted to arenes by the fragment $[Os(NH_3)_5]^{n+}$, $n = 2, 3$, discovered by Harman and Taube[169] should be mentioned. When Os^{III} but also Ru^{III} pentaammine salts are reduced in the presence of benzene, exceptionally stable $[M^{II}(NH_3)_5(\eta^2\text{-}C_6H_6)]^{2+}$ complexes are formed. This behavior is unprecedented in the coordination chemistry of such ammine complexes. The arene derivatives undergo smooth arene substitution reactions, but most important, they are susceptible to selective hydrogenation reactions and electrophilic substitution processes. Thus, a coordinated, substituted arene can be stereospecifically hydrogenated (for example, in the presence of a heterogeneous catalyst) to the corresponding η^2-cyclohexene derivative (Scheme 61A). Furthermore, the electrophilic substitution at a coordinated phenol derivative by, for example, maleic anhydride (a potentially acylating reagent) can be mechanistically viewed as a 1,4 addition (Scheme 61B). This reaction has been shown to be useful in the dearomatization of β-estradiol by direct stereospecific 1,4 alkylation (Scheme 61C).

Finally, to return to asymmetric reactions, a recent report by Inoue et al.[170] about the Ti-catalyzed formation of cyanohy-



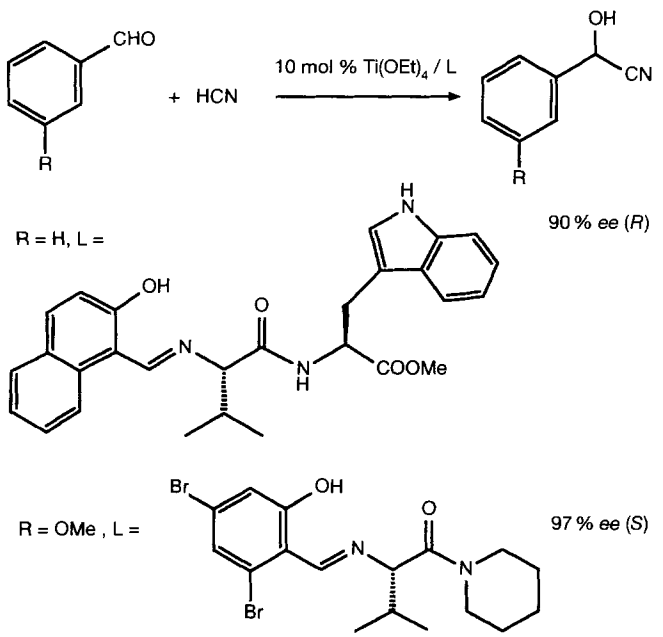
Scheme 59. Examples of recent applications of the imidomolybdenum ROMP catalysts.

drins is worth mentioning. Enantiomeric excesses up to 97% have been obtained for the addition of HCN to aldehydes in the presence of 10 mol% of ethyl or isopropyl orthotitanate and a Schiff base of a peptide as chiral ligand (Scheme 62). MM2 calculations indicate that such compounds behave as terdentate O,N,O ligands; the oxygen atom of the peptide linkage coordinates to the metal. A judicious construction of the ligand system utilizing only natural amino acids allows the preparation of both enantiomers of the products in high *ee*'s.



6. Conclusions

Nitrogen-ligands play an important role in modern organometallic chemistry and homogeneous catalysis. The properties and reactivities of the many complexes reported in the literature that contain such donors can be understood if one takes into consideration the general rules of coordination chemistry. Thus, in terms of their coordination behavior, it is fundamental to recognize the most important differences between nitrogen- and phosphorus-ligands: 1. the π backbonding ability of N-donors is insignificant, thus making them generally unsuited for the stabilization of low oxidation states of the transition metal center. 2. The *trans* effect exerted by N-donors is negligible, when compared to that of most other ligands encountered in organometallic chemistry, and thus their own rates of substitution reactions are usually high. 3. The reactivity of, for example, alkyl complexes of transition metals containing N-donors is usually high.



Scheme 60. Synthesis of an exceptionally stable W–alkylidene complex for applications as a ROMP catalyst [168].

For the vast majority of the reported cases nitrogen-ligands have been used as part of a chelating system that also involves other donor atoms such as C, O, P, and S. This is particularly true for the many applications in homogeneous catalysis described in Section 5, where nitrogen-ligands are responsible for various important developments in the field of asymmetric synthesis. Progress in this field in recent years has been achieved in a very empirical manner, mainly by synthetically oriented research groups, because chiral nitrogen ligands are often easily accessible from the "chiral pool". Thus, one is tempted to attribute the success of such ligands to organic chemists. At the same time, the wealth of applications of nitrogen-ligands in a variety of catalytic homogeneous reactions should be an incentive for systematic studies from the point of view of coordination chemistry in the near future.

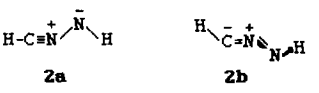
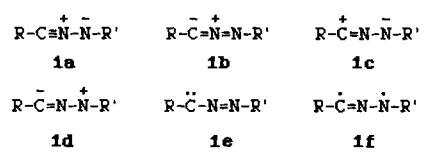
Nitrile Imines: From Matrix Characterization to Stable Compounds



Guy Bertrand* and Curt Wentrup*

The concept of 1,3-dipolar cycloaddition was developed, starting in the late 1950s, largely by Rolf Huisgen and his students in Munich, and it has led to one of the most versatile methods for the construction of five-membered ring heterocycles. Although first known only as transient intermediates, nitrile imines have been at the heart of mechanistic studies of this type of cycloaddition reactions. Hundreds of mechanistic papers appeared in 1960s and 1970s; reliable spectroscopic observations were achieved in the early 1980s both at low temperatures and in the gas phase; finally, the first crystalline nitrile imine was reported in 1988. The unusual structures found by X-ray analyses as well as the facile rearrangements observed experimentally have fostered a new interplay between experiment and theory. The story of nitrile imines, from matrix characterization to stable compounds, nicely illustrates the role that main group elements can play in organic chemistry.



1. Introduction

Until recently, nitrile imines **1**,[1-6] like several other 1,3-dipoles, were considered reactive intermediates. Since their discovery by Huisgen at al. in 1959,[1a] nitrile imines have been generated in situ and used in numerous 1,3-dipolar cycloaddition reactions leading to pyrazoles, pyrazolines, and other heterocyclic compounds.[6, 7] Furthermore, nitrile imines have been at the heart of mechanistic studies of the 1,3-dipolar cycloaddition reaction and of the controversy over Firestone's diradical pathway.[8]

Nevertheless, because of their character as reactive intermediates, there has been very little direct experimental evidence on the structures of nitrile imines. The most important canonical structures[6] are indicated in formulas **1a**–**f** (Scheme 1). These do not say anything about the actual structures, not even whether the nitrile imines are linear or bent. Ab initio calculations by Houk et al.[9, 10] reveal that the parent compound formonitrile imine **2n**[**] may exist in either a planar (propargylic, **2a**) or a nonplanar, bent (allenic, **2b**) form; **2b** is favored by 2.2 kcal mol^{-1} when the STO-3G basic set is employed, but the progargylic form **2a** is favored by 3.9 kcal mol^{-1} at the 4-31G level. Thus, the unsubstituted nitrile imine is described as a "floppy" molecule,[9] which may be able to adapt its geometry easily in response to substituents. Similar calculations[9] for nitrile ylides ($R-C\equiv\overset{+}{N}-\overset{-}{C}R_2$) indicate that these prefer bent, nonplanar structures, whereas in nitrile oxides ($R-C\equiv\overset{+}{N}-O^-$) the linear form is theoretically favored, in agreement with experiment. For both nitrile imines and nitrile ylides, electron-withdrawing substituents, particularly at the N or CR_2 termini, are expected to promote the planar, propargylic forms.[9, 11]

Scheme 1. Canonical structures of nitrile imines.

The situation has changed recently. Nitrile imines have become accessible as stable, sometimes crystalline solids or distillable liquids. Accordingly, their structures and properties can now be probed in a much more direct manner. It has been found, as described in Section 5.1, that all stable nitrile imines examined by X-ray crystallography to date definitely possess bent, helical backbones, more of the "allenic" type **2b**. Furthermore, high-level calculations[11,2] also predict that the bent, helical structure represents the lowest energy form of nitrile imines (see Section 5.1).

Another problem concerns the rearrangements of nitrile imines and of 1,3-dipoles in general. Rearrangements to diazo compounds ($R_2C=\overset{+}{N}=N^-$) have been postulated several times

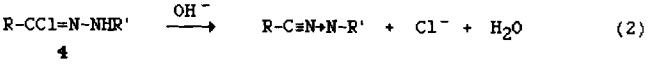
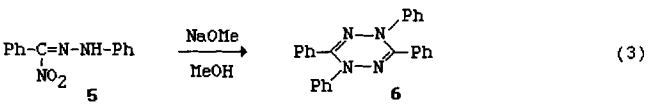
(see Section 7). If this is a concerted process, it constitutes a highly interesting and formally "forbidden" 1,3-shift. Likewise, both thermal and photochemical rearrangements to carbodiimides (RN=C=NR) have been reported (Section 7). With the emergence of stable, isolable nitrile imines, it has become possible to probe such rearrangements directly.



2. History

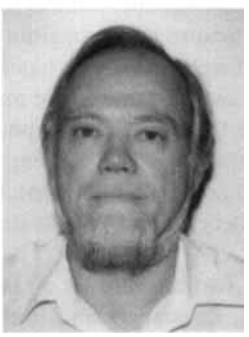
The parent formonitrile imine **2n** is still unknown. It was once thought to be formed on deprotonation of diazomethane with methyllithium at room temperature, followed by hydrolysis [Eq. (1)].[13] However, 34 years later, it was established, largely



on the basis of the NMR and infrared spectra, that this "isodiazomethane" was in fact isocyanoamine **3**.[14–16] It is not known whether nitrile imine **2n** is actually an intermediate in this reaction.[17] Isocyanoamine **3** is rapidly converted to diazomethane under the influence of alkali metal hydroxides. It is interesting to note that E. Müller called **3** "Knallsäureamid", that is, fulminic acid amide. However, W. Beck later established that fulminic acid has the structure HCNO, not HONC as had been believed until then.[18] H_2N-NC (**3**) may thus be considered as an amide of HONC (isofulminic acid) but not of fulminic acid.

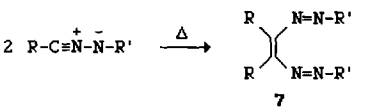
In the 1930s and 1940s Fusco and his students in Italy carried out work on hydrazonoyl chlorides **4**.[19] It is now known that these compounds generate nitrile imines, which undergo cycloaddition reactions to furnish pyrazoles. The possibility of formation of disubstituted isodiazomethanes ("isodiazometani bisostituiti") was mentioned in 1946 and 1948 by Fusco and Romani, who also considered other isomers of diazomethane [Eq. (2)].[20]

Even earlier, a compound had been postulated which would nowadays be called diphenylnitrile imine. In 1901 Bamberger and Grob treated α-nitrobenzylidenephenylhydrazine (**5**) with sodium methoxide in methanol and obtained tetraphenyldihydrotetrazine (**6**) in 39% yield [Eq. (3)].[21, 22] This was explained



with the words: "Das Natriumsalz des Isonitrokörpers zerfällt in Nitrit und den Molekularrest $C_6H_5-\ddot{C}-N=N-C_6H_5$, welcher sofort zum Tetrazolinderivat polymerisiert".[21b] As Huisgen et al. later pointed out,[22] this "molecular residue" corresponds to the canonical structure **1e** of a nitrile imine.

Nitro compounds such as **5** are versatile precursors of nitrile imines, in particular in cases where the corresponding hydrazonoyl halides are inaccessible. It is also known that the "nitrohydrazone route" gives particularly high yields of dihydrotetrazines; this cannot be due to direct dimerization of the nitrile imines but rather to a reaction between one molecule of nitrile

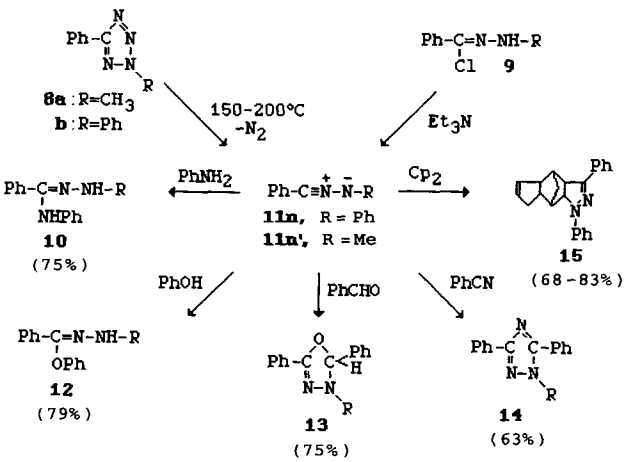


Guy Bertrand was born in Limoges, France, on July 17, 1952. He graduated (ingénieur ENSCM) from the University of Montpellier and moved to Toulouse as an "Attaché de Recherche CNRS" in 1975. He defended his "Thèse d'Etat" at the University of Toulouse in 1979. After one year at Sanofi Recherche Company, he came back to the University Paul Sabatier as a "Chargé de Recherche". In 1988 he went to the Laboratoire de Chimie de Coordination du CNRS where he is now "Directeur de Recherche CNRS". By employing main group elements, his group is trying to isolate at room temperature species hitherto believed to be only transient intermediates. They use these species in organic synthesis, as ligands for transition metal complexes, and as precursors for new materials.

Curt Wentrup was born in Holtug, Denmark, on July 11, 1942. He received his "Diplom (cand. scient.)" in chemistry in 1966 from the University of Copenhagen for work with K. A. Jensen on alkyl cyanates, his Ph.D. in 1969 from the Australian National University, Canberra, and his Dr. scient. in 1977 from the University of Copenhagen for work on carbene and nitrene rearrangements. After a period as a postdoctoral associate and later "Privatdozent" with Hans Dahn at the University of Lausanne, Switzerland (1969–1976), he joined the chemistry faculty at the University of Marburg, Germany (1976–1985). In 1985 he returned to Australia as professor of organic chemistry and head of the Organic Chemistry Section, Department of Chemistry, University of Queensland, Brisbane. His research interests include reactive intermediates and unusual molecules often generated by flash vacuum pyrolysis and studied by matrix isolation techniques.

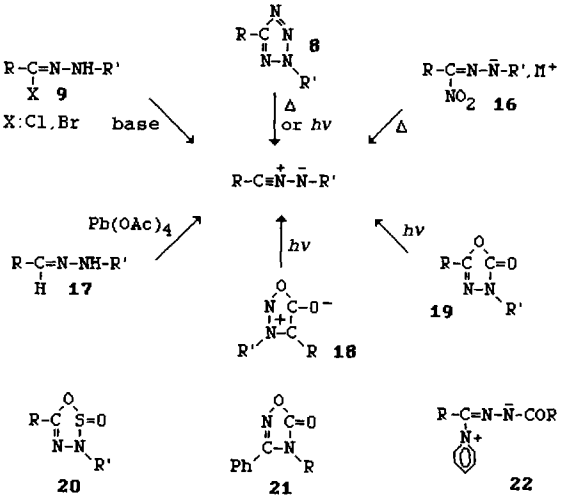
imine with the long-lived anion of the starting material **5**.[22] In general, it appears that the formation of dihydrotetrazines in substantial yields is indicative of reaction between the nitrile imine and its precursor.[22-25]

The true dimerization of nitrile imines in the absence of other reaction partners leads to bis(azo)ethylenes of the type **7**, which can be isolated in certain cases[26-28] [Eq. (4)] (see also Section 3.2).



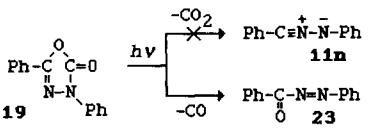
(4)

3. Nitrile Imines as Reactive Intermediates



3.1. Generation

Since very authoritative reviews of the classical chemistry of nitrile imines and other 1,3-dipoles exist,[2-7] only a brief sketch will be provided here. In the first deliberate generation and trapping of nitrile imines in 1959,[1a] both the thermal decomposition of 2,5-disubstituted tetrazoles **8** at 150–200 °C and the base-induced dehydrochlorination of the hydrazonoyl chloride **9** were examined. Diphenylnitrile imine **11n** was trapped in situ in nucleophilic additions of aniline and phenol (giving compounds **10** and **12**, respectively) and in 1,3-dipolar cycloaddition reactions with benzaldehyde, benzonitrile, and dicyclopentadiene to produce **13**, **14** and **15**, respectively (Scheme 2).

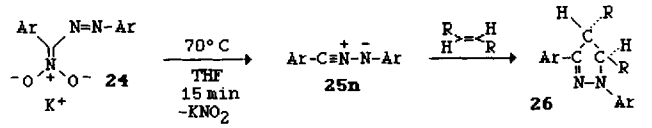


Scheme 2. First generation and trapping of a transient nitrile imine. Here and in subsequent schemes the percentages in parentheses refer to the yields.

The generation of nitrile imines by photolytic decomposition of tetrazoles **8** was reported soon afterwards.[1b] These methods, as well as the use of salts of *aci*-nitro-azo compounds (α-nitrohydrazones) **16**,[22,29] have become standard procedures for nitrile imine production. In addition, the oxidation of hydrazones **17** with lead tetraacetate,[30] the photolysis of sydnones **18**,[26,31] and the photolysis of 1,3,4-oxadiazol-5(4*H*)-ones **19**[32] also provide nitrile imines (Scheme 3). Whether the latter reaction,

Scheme 3. Methods used for the generation of transient nitrile imines.

photolysis of **19**, actually generates nitrile imines is disputed.[26] Although the same products and the same orientations of cycloaddition are obtained with **19** (R = R′ = Ph) as with diphenylnitrile imine (**11n**) generated from 2,5-diphenyltetrazole (**8b**),[32a] the photolysis of **19** in the absence of a dipolarophile was found to be extremely sluggish, and it was postulated that CO and benzoylazobenzene **23** formed rather than the nitrile imine (Scheme 4).[26]

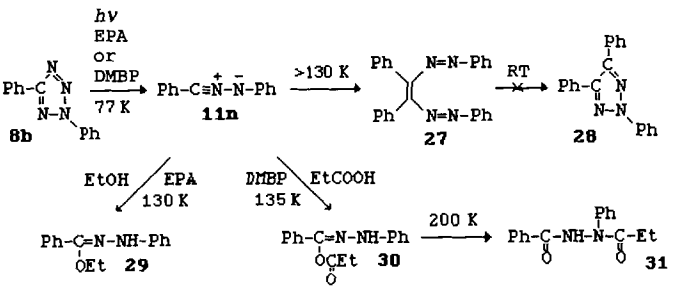


Scheme 4. Photolysis of 1,3,4-oxadiazol-5(4*H*)-ones **19**.

Thus, the cycloadditions starting with **19**, which mimic nitrile imine cycloadditions, may involve direct reaction between an excited state of **19** and the dipolarophile. Interestingly, it was reported that no nitrile imine dimers were formed in the photolysis of **19**.[32a] Although the yields of dimers are often low, their total absence may be a telltale sign that no nitrile imine was formed.

Less common precursors for nitrile imines are 1,2,3,4-oxathiadiazole-2-oxides **20**,[33] 1,2,4-oxadiazol-5(4*H*)-ones **21**,[34] and pyridinium betaines **22**.[35]

3.2. Methods for the Direct Observation of Transient Nitrile Imines

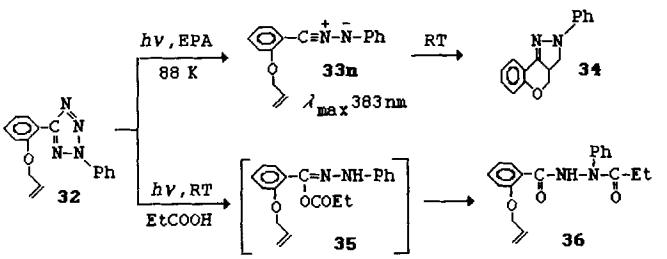


Surprisingly, before 1988, there was only one report on the direct observation of a nitrile imine in solution. Grundmann and Flory[29] used the thermal decomposition of the *aci*-nitro-azo compound **24** to prepare dimesitylnitrile imine **25n** in solvents such as THF and benzene (Scheme 5). Potassium nitrite formed quantitatively in 10–20 minutes, and the solution turned orange, presumably because of the formation of **25n**. When the reaction was carried out in the presence of dimethyl fumarate, cycloadduct **26** was formed in over 90% yield. When

Scheme 5. Generation and trapping of dimesitylnitrile imine **25n**. Ar = 2,4,6-trimethylphenyl (mesityl); R = CO_2Me.

the reaction was repeated in the absence of the trapping agent and the solution filtered to remove KNO_2 before dimethyl fumarate was added, **26** was still isolated in 18% yield. The IR spectrum of the orange solution featured a band at 2200 cm^{-1}, which disappeared in the course of 24 h. In the spectra of reaction mixtures containing dimethyl fumarate, the same band disappeared in 1–2 h (surprisingly slowly). This experiment constitutes the first direct observation of a nitrile imine.

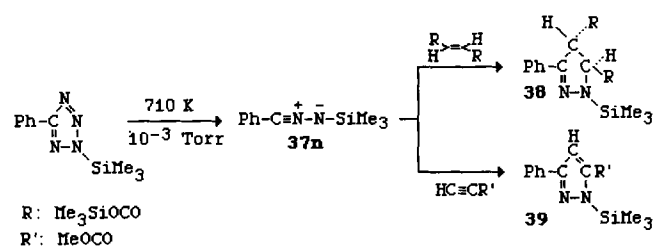
2,5-Disubstituted tetrazoles **8** have been used to generate nitrile imines both photochemically and thermally (flash vacuum pyrolysis) for direct UV and IR spectroscopic observation. Heimgartner et al.[36] photolyzed 2,5-diphenyltetrazole (**8b**) at 77 K in organic glasses (ether/pentane/ethanol (EPA), 2-methylpentane (2MP), or 2,3-dimethylbutane-pentane (DMBP)). Upon irradiation with light of wavelength 280–290 nm, a new species was observed (λ_{max} = 378 nm) which, on the basis of its behavior, was identified as diphenylnitrile imine **11n** (Scheme 6).



Scheme 6. Synthesis and characterization of diphenylnitrile imine **11n**. RT = room temperature.

Toubro and Holm[37] carried out similar photolyses (λ = 250 nm) of **8b** in EPA or poly(vinyl chloride) (PVC) at 85 K and observed the UV spectrum of **11n** at 377 nm. Moreover, they observed a major IR band at 2228 cm^{-1} (PVC, 85 K), which was ascribed to the C≡N stretch in **11n**. This assignment was corroborated by generation of ^{15}N isotopomers by photolysis of suitably labeled tetrazoles. Nitrile imine **11n** is stable in the glass at temperatures below roughly 130 K. In the absence of trapping agents, it dimerizes above 130 K, in all likelihood forming bis(azo)ethylene **27**. The latter compound decomposes at room temperature, but 1,2,3-triazole **28** is not formed in the process (**28** is formed on room-temperature photolysis of **8b**).[36]

Nitrile imine **11n** is trapped by ethanol above the softening point of the EPA matrix, giving hydrazone **29** at 130 K.[28] With propionic acid in DMBP glass at 135 K, **11n** was trapped to give initially **30**, which on warming to 200 K isomerized to hydrazide **31** (Scheme 6). The reaction **30** → **31** was monitored by UV spectroscopy.[28]



Nitrile imine **33n** was generated analogously by photolysis of tetrazole **32** and observed by UV spectroscopy (Scheme 7).[28]

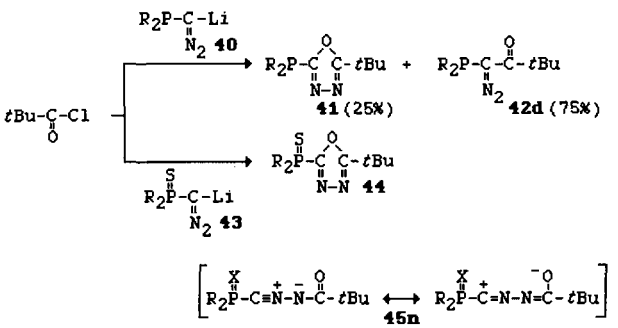
Scheme 7. Photolysis of tetrazole **32**.

Warming nitrile imine **33n** to room temperature resulted in an intramolecular[38] 1,3-dipolar cycloaddition reaction giving **34**. This compound was also obtained in 84% yield in the preparative photolysis of **32** at room temperature. Preparative photolysis in the presence of a 1000-fold excess of propionic acid gave hydrazide **36** in 83% isolated yield, presumably via an initial adduct **35**. Thus, carboxylic acids were found to be extremely efficient traps for nitrile imines, and the corresponding reactions compete with the intramolecular 1,3-dipolar cycloaddition reaction (Scheme 7).[28]

The direct detection of thermally generated nitrile imines is more difficult because of rapid rearrangement reactions[39–42] (see Section 7). However, *N*-trimethylsilyl-*C*-phenylnitrile imine (**37n**) turned out to be quite stable under flash vacuum pyrolysis (FVP) conditions (Scheme 8). It was directly observed

Scheme 8. Thermal generation and trapping of nitrile imine **37n**.

in the gas phase by mass spectrometry and distinguished from the isomeric carbodiimide and diazo compound by collisional activation mass spectrometry.[43] Deposition of **37n** at 77 K permitted the recording of the IR spectrum, which featured a strong absorption at 2230 cm^{-1}. The IR spectrum was also distinct from those of the isomeric diazo compound and carbodiimide.

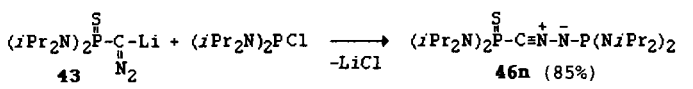


Nitrile imine **37n** was trapped in high yields in 1,3-dipolar cycloadditions in the gas phase. More importantly, it could also be cocondensed with the trapping reagent at 77 K and observed by IR spectroscopy (absorption band at 2230 cm^{-1}). Warming to 170 K resulted in cycloaddition reaction, giving the products **38** and **39** (Scheme 8) in almost quantitative yields. Trapping **37n** with methyl propiolate gave **39** regiospecifically; the product was identical to the compound obtained on silylation of methyl 5-phenylpyrazole-3-carboxylate, and the latter compound was also obtained on hydrolysis of **39** in 90% ethanol.

This work made it possible also to obtain the first photoelectron spectra of nitrile imines by directly monitoring the FVP reactions. The first ionization potential was 7.85 eV for $Ph-C\equiv\overset{+}{N}-\overset{-}{N}-SiMe_3$ (**37n**), and 8.14 eV for $CH_3-C\equiv\overset{+}{N}-\overset{-}{N}SiMe_3$.[44]

4. Synthesis of Stable Nitrile Imines

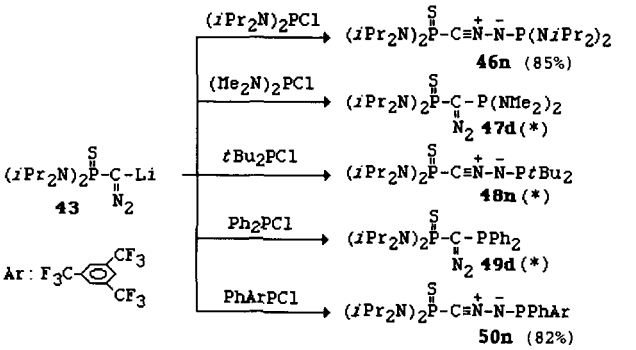
4.1. Starting from Lithium Salts of Diazo Compounds



As often happens, the discovery of the synthetic route later used to prepare most of the stable nitrile imines was unexpected. In one attempt to synthesize *C*-acylated phosphinodiazomethane **42d** by reacting pivaloyl chloride with the lithium salt **40** of bis(diisopropylamino)phosphinodiazomethane, the formation of 1,3,4-oxadiazole **41** was observed in addition to the expected diazoketone **42d**.[45] Moreover, the reaction of pivaloyl chloride and the thiophosphinoyldiazo analogue **43** quantitatively afforded the five-membered ring heterocycle **44**.[46] These results strongly suggested that *N*-acylation could compete with *C*-acylation in the case of phosphorus-substituted diazo lithium salts, since the simplest explanation for the formation of oxadiazoles **41** and **44** was a 1,5-electrocyclization[47] of the initially formed carbonylnitrile imine **45n** (Scheme 9).

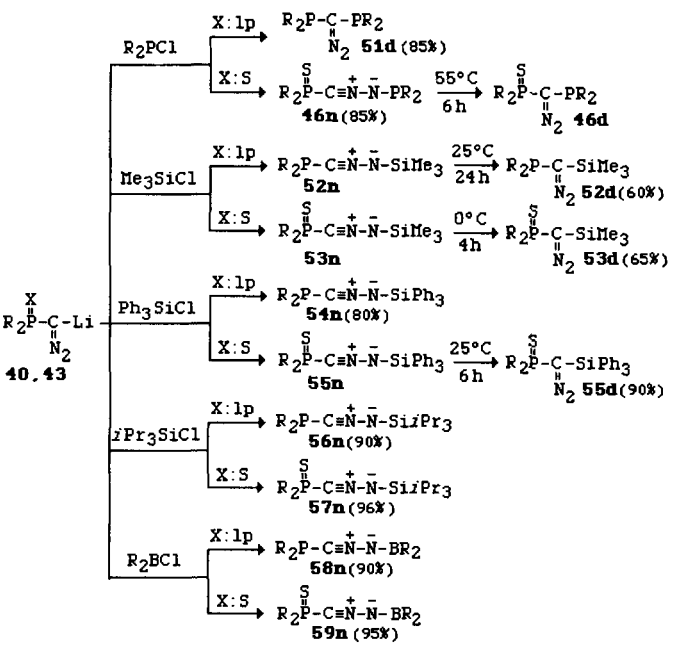
Scheme 9. *N*- and *C*-acylations of phosphorus-substituted diazo lithium salts. R = iPr_2N; X = lone pair or S.

However, although salts of diazo compounds possess two nucleophilic centers, it was generally believed that electrophiles only react at carbon giving the corresponding substituted diazo compound.[48] Since diazo compounds and nitrile imines both react with dipolarophiles,[6] the best way to prove the hypothesis was to try to prepare a stable nitrile imine. A good approach to forcing the attack of the electrophiles at the nitrogen nucleophilic center is to try to prevent the attack at carbon: the use of sterically hindered salts of diazo compounds and electrophiles was the obvious answer. Moreover, push–pull substituents could decrease the polarity of the nitrile imine skeleton and therefore increase its kinetic stability.



The first stable nitrile imine **46n** was obtained in 85% yield from the reaction of the lithium salt **43** of bis(diisopropylamino)thiophosphinoyldiazomethane with chlorobis(diisopropylamino)phosphane (Scheme 10).[46,49] Nitrile imine **46n**, which was fully characterized (including an X-ray crystal study

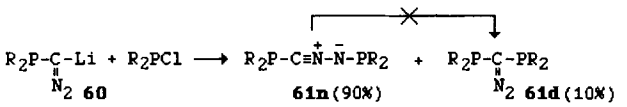
Scheme 10. Synthesis of the first stable nitrile imine **46n**.



(see Fig. 2)), is not air sensitive, and since it melts at 100 °C without decomposition, the compound is quite stable thermally.

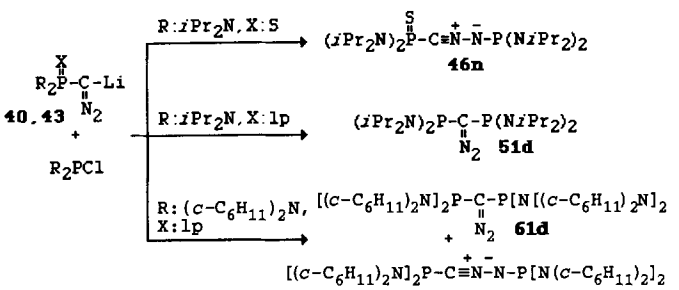
The influence of both the lithium salt and the electrophile on the reaction has been studied. The reactions of the thiophosphinoyl diazo lithium salt **43** with chlorophosphanes as electrophiles were unequivocal.[46,49–53] When electronic factors are constant, reactions with bulky and less hindered chlorophosphanes lead to nitrile imines and diazo compounds, respectively (Scheme 11).

Scheme 11. Influence of the chlorophosphanes in the reactions with thiophosphinoyl diazo lithium salt **43**. (*): High yield according to ^{31}P NMR spectrum; the compound was not isolated.



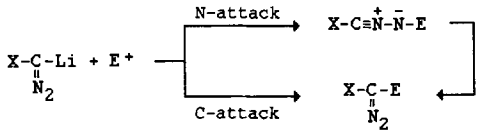
Comparison of the results of the reaction of diazo lithium salts **40** and **43** with various electrophiles (Scheme 12) poses a second problem. The nitrile imines resulting from the N-attack of the electrophiles can isomerize into the thermodynamically favored diazo compounds. Scheme 12 gives four examples of

Scheme 12. Reactivity of diazo lithium salts **40** and **43** with various electrophiles. R = iPr_2N; lp = lone pair.



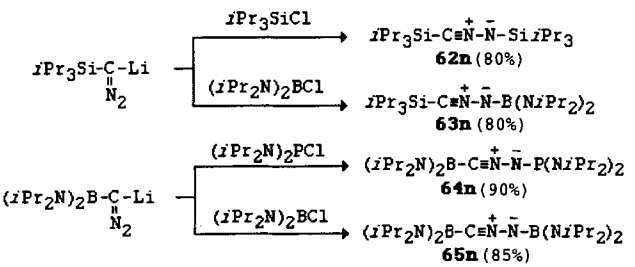
this rearrangement, which takes place, depending on the substituents, between 0 and 55 °C.[49, 50, 54] Therefore, one possible way to rationalize the formation of diazo compounds in cases in which no nitrile imines were observed was to postulate that the nitrile imines were always the kinetic products of the electrophilic attack on the diazo lithium salts, but that they rearranged into the thermodynamically favored diazo compounds (see Section 7). This hypothesis was reinforced by the formation of diazo compound **51d**[45, 55] in the reaction of the phosphinoyldiazo lithium salt **40** with chlorobis(diisopropylamino)-phosphane, and the formation of nitrile imine **46n** in the analogous reaction of the thiophosphinonyl analogue **43**.[46, 49] Indeed, since lithium salts **40** and **43** are sterically quite similar, the opposite regioselectivity of the reactions was difficult to explain. The results observed are apparently best attributed to electronic factors: the presence of two electron-donating groups destabilizes nitrile imine **51n** ($R_2P-CNN-PR_2$, $R = iPr_2N$) thus favoring the rearrangement to the thermodynamically preferred isomer **51d**.

Finally, the concomitant formation of both isomers **61n** and **61d** in the reaction of the lithium salt **60** of bis(dicyclohexylamino)phosphinoyldiazomethane and chlorobis(dicyclohexylamino)phosphane, and the absence of isomerization of **61n** into **61d**, demonstrated that the C- and N-attacks of electrophiles on salts of phosphorus-substituted diazo compounds are competitive processes (Scheme 13).[56]



Scheme 13. Concomitant formation of diazo derivative **61d** and nitrile imine **61n**.

A very small change in the steric factors, such as replacing a lone pair by a sulfur atom, or exchanging diisopropylamino by dicyclohexylamino groups, can totally reverse the ratio of nitrile imine to diazo compound (Scheme 14).

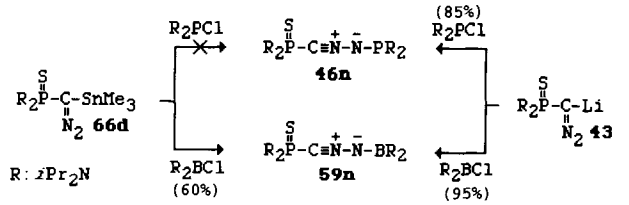


Scheme 14. Influence of the diazo lithium salt on the formation of the nitrile imine and diazo derivative.

Although electronic factors are not totally negligible, steric factors are of primary importance for the kinetic stabilization of nitrile imines that can isomerize into the thermodynamically preferred diazo compounds. Thus, the formation of diazo compounds can result either from C-attack of the electrophile or from N-attack followed by rearrangement of the initially formed nitrile imine (Scheme 15).

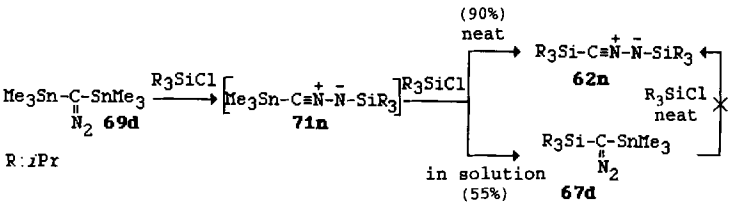
Scheme 15. The two pathways for the formation of diazo compounds.

In any case, the route employing diazo lithium salts appeared to be a very general method for synthesizing stable nitrile imines, as two further examples demonstrate. The two *C*-silylated nitrile imines **62n**[54, 57] and **63n**[58] were prepared, and more recently the two *C*-borylated nitrile imines **64n** and **65n** were synthesized from the first stable boryldiazomethane (Scheme 16).[58, 59]



Scheme 16. Synthesis of *C*-silyl- and *C*-borylnitrile imines.

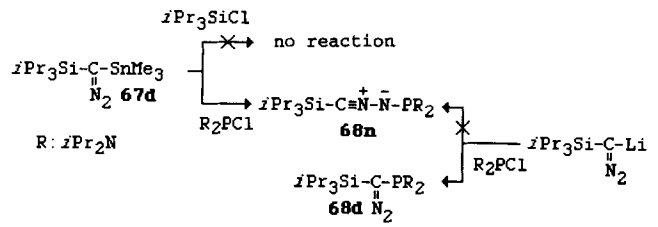
Phosphorus–carbon bonds are not easily cleaved, thereby limiting application of the *C*-phosphorus-substituted nitrile imines in organic synthesis. In contrast, silicon–carbon and boron–carbon bonds are easily cleaved. Thus, nitrile imines **62n**–**65n** are not only laboratory curiosities but potential building blocks for the facile synthesis of a variety of heterocycles.



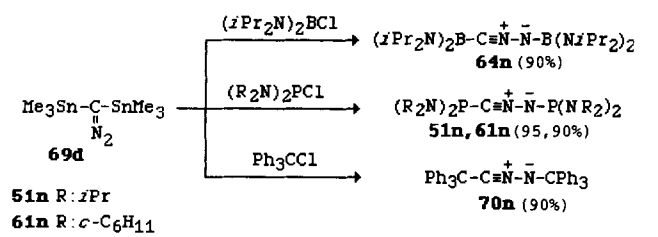
4.2. Starting from Stannyldiazo Compounds

Since the regioselectivity of the attack of electrophiles on the lithium salts of diazo compounds depends almost entirely on steric factors, it was logical to think that the use of diazo precursors bearing a metal atom larger than lithium would favor the formation of nitrile imines over diazo compounds; stannyl diazo compounds were potentially good candidates. In contrast to lithium diazo compounds, their structures are well established;[60] the tin atom is bound to carbon. The reaction of stannyl(thiophosphinoyl)diazomethane **66d** with chlorobis(diisopropylamino)borane was examined first. Indeed, the corresponding nitrile imine **59n**, already prepared by the diazolithium salt method, was obtained.[56] However, no reaction occurs between stannyldiazomethane **66d** and chlorobis(diisopropylamino)phosphane, thus proving that **66d** is less reactive than its lithium analogue **43** (Scheme 17).[56]

In the same way, triisopropylsilyl(trimethylstannyl)diazomethane (**67d**) does not react with triisopropylchlorosilane, but a clean reaction occurs with chlorobis(diisopropylamino)-



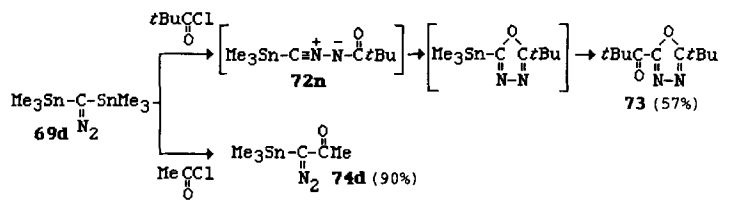
Scheme 17. Comparison of the reactivity of stannyl- and lithiodiazo compounds **66d** and **43**.



Scheme 20. Reactivity of **69d** with chlorotriisopropylsilane.

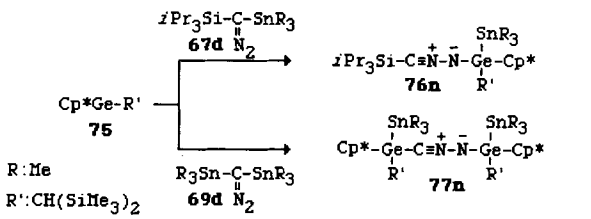
phosphane leading to nitrile imine **68n**.[56] This result is of special interest since nitrile imine **68n** was not available by the diazolithium salt method, which instead gave the diazo isomer **68d**[54] (Scheme 18).

Scheme 18. Comparison of the reactivity of stannyldiazo derivative **67d** with that of its lithio analogue.



The question then arises whether bis(trimethylstannyl)-diazomethane (**69d**)[61] would act as a CNN^{2-} transfer agent and thus allow the one-step synthesis of nitrile imines, especially those not accessible by the diazo lithium salt method. The results summarized in Scheme 19 clearly demonstrate that this is possible. The formation of the bis(boryl)nitrile imine **64n** in high yield shows the efficiency of the method.[56] By the diazo lithium salt method, diphosphinonitrile imine **51n** was not available,[45] while **61n** was obtained as a mixture with its diazo isomer **61d**.[56] The stannyldiazomethane starting material unequivocally leads to nitrile imines **51n** and **61n**, demonstrating the high selectivity of the method.[56] The most striking result is certainly the preparation of the first stable, purely organic nitrile imine **70n**[56, 62] (Scheme 19).

Scheme 19. Synthesis of nitrile imines from bis(stannyl)diazomethane **69d**.



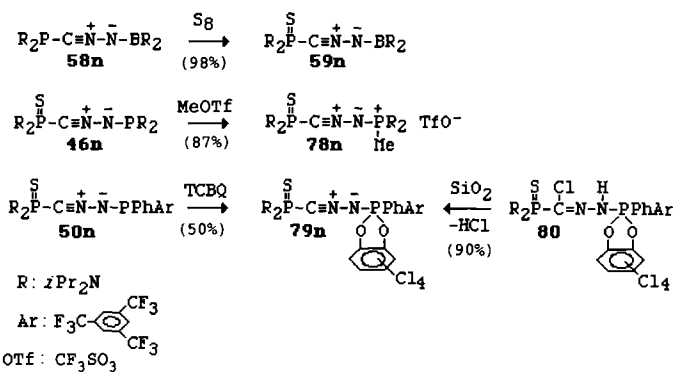
The dramatic differences observed in the reaction of **69d** with triisopropylchlorosilane, with and without solvent, are of primary interest (Scheme 20).[56] Since silyl(stannyl)diazomethane **67d** does not react with chlorotriisopropylsilane, it is obvious that **67d** is not the intermediate leading to nitrile imine **62n**. Thus, under both sets of experimental conditions the first step is certainly *N*-silylation giving rise to the *N*-silyl-*C*-stannylnitrile imine **71n**. In the absence of solvent, **71n** undergoes a substitution reaction by another molecule of chlorosilane affording bis-(silyl)nitrile imine **62n**, whereas in the presence of a solvent, the nitrile imine isomerizes to the diazo compound **67d** (Scheme 20).

These results seemed to show that, in contrast to lithiodiazomethanes, stannyldiazomethanes always react with electrophiles at the nitrogen terminus. However, it has been proven that they also undergo substitution at the carbon atom. Diazo compound **69d** reacts with the bulky pivaloyl chloride giving oxadiazole **73**, thus implying the primary formation of *N*-acyl-*C*-stannylnitrile imine **72n**; in contrast, with the sterically less demanding acetyl chloride, acyl(stannyl)diazomethane **74d** is formed (Scheme 21).[56]

Scheme 21. Reactivity of **69d** with acyl chlorides.

Stannyldiazo compounds **67d** and **69d** have also been treated with germanediyl **75** to prepare germyl-substituted nitrile imines **76n** and **77n**.[63] However, these reactions proceed by a completely different mechanism, since no trimethylchlorostannane is eliminated; so far this mechanism has not been investigated in more detail (Scheme 22).

Scheme 22. Synthesis of nitrile imines starting from germanediyl **75**. Cp* = C_5Me_5.

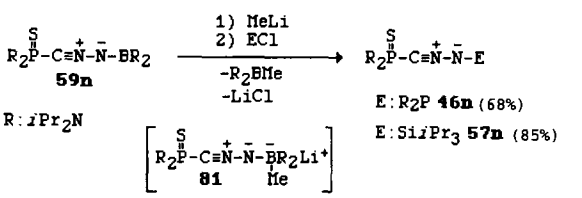


Stannyldiazo compounds allow the straightforward synthesis of a variety of symmetrically and unsymmetrically substituted nitrile imines. The experimental conditions are very mild, and the trimethylstannyl chloride formed is easily removed by sublimation (10^{-2} mm Hg, room temperature). Moreover,

bis(trimethylstannyl)diazomethane (**69d**) can be easily prepared in multigram quantities and acts as a safe CNN^{2-} transfer reagent, in contrast to analogues such as the dimercury, disilver, and dilithium diazomethane salts, which are explosive.[48]

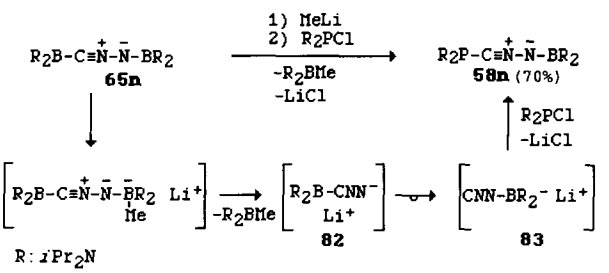
4.3. Starting from Stable Nitrile Imines

Since stable nitrile imines were available, the question arose as to whether it was possible to use the heteroatom bound to the 1,3-dipole as a second center of functionality in the molecule. In other words, was it possible to do chemistry at the periphery of the nitrile imine without destruction of the CNN skeleton?



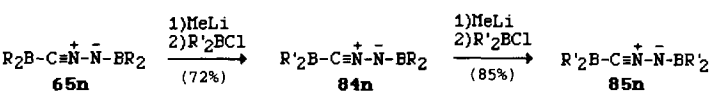
Three examples have been reported with phosphinonitrile imines. Addition of elemental sulfur to the *N*-boryl-*C*-phosphinonitrile imine **58n** led quantitatively to the *C*-thiophosphinoyl analogue **59n**,[58] already obtained by the lithiodiazomethane and the stannyldiazomethane methods (Scheme 23). More interestingly, addition of methyl trifluoromethanesulfonate to the *N*-phosphinoylnitrile imine **46n** afforded the corresponding *N*-phosphonio-substituted nitrilium betaine **78n**.[64] Since it is rather difficult to imagine another route to compound **78n**, this approach is of real synthetic interest. Lastly, *N*-phosphinonitrile imine **50n**, which has a phenyl and a 2,4,6-trifluoromethylphenyl group at phosphorus, reacted with tetrachloro-*o*-benzoquinone (TCBQ) to afford the only known $\lambda^5\sigma^5$-phosphorus-substituted nitrile imine **79n**.[65] However, this reaction is not general (see Section 7).

Scheme 23. Synthesis of stable nitrile imines starting from nitrile imines.



Surprisingly, **79n** can also be obtained by simply filtering a solution of the corresponding hydrazonoyl chloride **80** on silica gel. The ready elimination of HCl has been explained by the structure of compound **80** and the fact that the proton and the chlorine atom are only 2.45 Å apart (according to a single-crystal X-ray analysis).[65] So far, **79n** is the only example of a stable nitrile imine prepared by this classical method.

The high reactivity of boron–nitrogen bonds has been exploited in substitution reactions of boryl-substituted nitrile imines.[66] Addition of methyllithium to *N*-boryl-*C*-thiophosphononitrile imine **59n**, followed by addition of chlorobis(diisopropylamino)phosphane (or chlorotriisopropylsilane) led to the corresponding *N*-phosphinoylnitrile imine **46n** (or *N*-silylnitrile imine **57n**) in reasonable yields (Scheme 24). The first step of the reaction must be electrophilic attack by the boron atom, leading to a transient borate **81**, which after elimination of bis(diisopropylamino)methylborane gives rise to diazo lithium salt **43** (cf. Scheme 9).



Scheme 24. N-substitutions on a nitrile imine.

Interestingly, formal C-substitution can also be performed with C,N-disubstituted nitrile imines.[66] Indeed, addition of methyllithium to a THF solution of *C,N*-[bis(diisopropylamino)boryl]nitrile imine (**65n**), followed by addition of chlorophosphane, afforded *C*-phosphinoylnitrile imine **58n** in 70% yield. It has been shown that **58n** does not result from substitution at the carbon end of the nitrile imine but from rearrangement of the first-formed boryllithiodiazomethane **82** into the isomeric "boryllithioisodiazomethane" **83**[59] (Scheme 25).

Scheme 25. Formal C-substitutions on a nitrile imine.

By using these properties, it has been possible to substitute nitrile imines at both carbon and nitrogen in a two-step sequence. *C,N*-[Bis(diisopropylamino)boryl]nitrile imine (**65n**) was first treated with methyllithium and then with chlorobis(dicyclohexylamino)borane. This led to *C*-[bis(dicyclohexylamino)boryl]-*N*-[bis(diisopropylamino)boryl]nitrile imine (**84n**). The reaction sequence was repeated with **84n** to give *C,N*-[bis(dicyclohexylamino)boryl]nitrile imine (**85n**) in fair yield (Scheme 26).[66] This method could be of special interest when the diazo compounds are not stable, since preparation of the corresponding lithium salts would not be required. In summary, a large variety of stable nitrile imines is now available (Table 1). Their stability is essentially due to steric factors.

Scheme 26. Formal C- and N-substitutions on a nitrile imine.

5. Characterization of Nitrile Imines

5.1. X-ray Data and Ab Initio Calculations

The key angles and bond lengths in those nitrile imines for which X-ray crystallographic structures have been determined are listed in Table 2. Selected X-ray structures are shown in Figures 1–3. Inspection of the data immediately reveals the large variability of structures, which range from close to propargylic (cf. **2a**) to allenic (cf. **2b**).

The X-ray data in Table 2 may be compared with the results of high-level ab initio calculations[12] on model compounds (Table 3). On the basis of STO-3G and HF/4-31G calculations Houk et al.[9, 11] found two minima for the unsubstituted nitrile imine HCNNH **2n** at the STO-3G level. These correspond to **2a** and **2b**. However, at the MP2/6-31G* level, there is only one stable form, which is bent and nonplanar and thus resembles the allenic structure **2b** more than the propargylic **2a**. This preference for the allenic form is further supported by higher level geometry optimization at the MP2/6-311 + G(2df,2p) and QCISD/6-311G** levels (Table 4).[12]

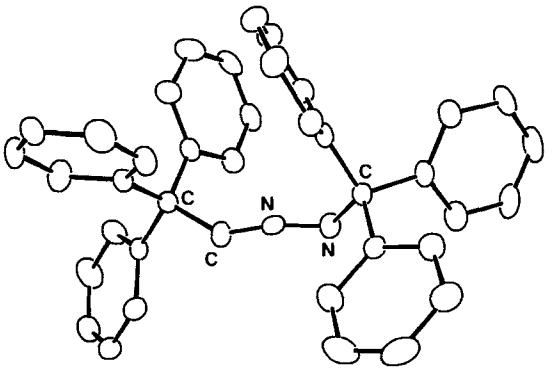

Fig. 1. Crystal structure of **70n** [62].

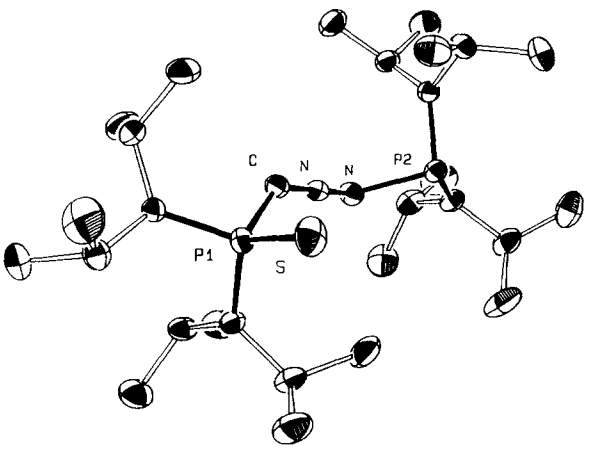

Fig. 2. Crystal structure of **46n** [49].

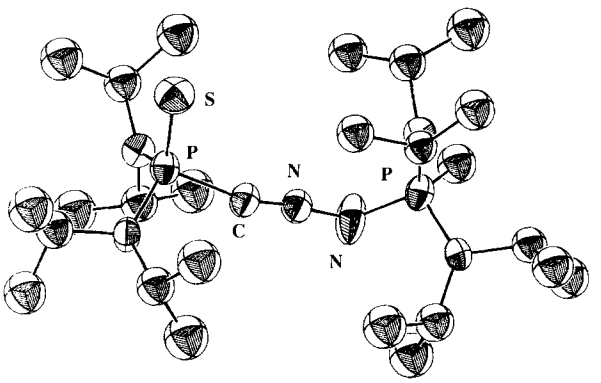

Fig. 3. Structure of the cation of **78n** in the crystal [64b].

The MP2/6-311G**(2df,2p)-level geometry of HCNNH (Tables 3 and 4) is in excellent agreement with the experimental data for bis(triphenylmethyl)nitrile imine (**70n**) given in Table 2 and Figure 1. Thus, this compound may be considered typically allenic and perturbed minimally by steric or electronic effects.

The *N*-phosphino-*C*-thiophosphinoylnitrile imine **46n** (Fig. 2) also has an allenic structure very similar to that of **70n**; however, the structure of the phosphonio-substituted compound **78n** is dramatically different (Fig. 3). The P-C-N angle is much flatter (163.5°); the C–N bond is particularly short (1.14 Å), and the N–N bond correspondingly long (1.285 Å). This change in geometry is nicely corroborated by the results of calculations for $HCNNPH_3^+$ (Table 3), which was shown to be a planar and "propargylic" compound with a linear HCN moiety, a short C–N bond, and a long N–N bond. The main difference between the actual structure of **78n** and that calculated for the model compound is the dihedral angle of 84° between the PCN and CNN planes in the former. However, the CNNP moiety in **78n** is nearly planar, and the CNN backbone nearly linear, so that the deviation from the calculated structure is not so dramatic, and it may well be caused by steric and/or crystal lattice effects.

According to calculations the boryl compound $H_2B-CNN-H$ also tends toward linearity and planarity, although the C–N bond is not quite so short and the compound thus less "propargylic" (Table 3). The bis(boryl) compound $H_2B-CNN-BH_2$ has a similar structure.[12] These trends are

in accord with the X-ray structure of **85n**, which is similar to that of the phosphonio compound **78n** but not quite as clearly propargylic as judged by the lengths of the C–N and N–N bonds (Table 2). The BCNN skeleton is close to linear (BCN = 165.1°), and the B–C bond is quite short (1.559 Å).

In the propargylic forms of these molecules with partial C≡N triple bonds the negative charge on the terminal nitrogen atom is increased as in **2a**, and the electronegative *N*-phosphonio and *N*-boryl substituents are thus stabilized. Accordingly, the N–P bond in **78n** is rather short (1.623 Å in **78n** vs 1.777 Å in **46n**).[64b] The calculations indicate, however, that a BH_2 group on carbon has a greater "linearizing" effect than one on nitrogen (Table 3).[12]

5.2. Infrared Spectra

The frequencies of the asymmetric CNN stretching vibrations of all the stable nitrile imines are given in Table 1, and the calculated IR spectrum of HCNNH is in Table 5. By applying the usual correction factor[68] of 0.93 to the calculated frequency, it is seen that the absorption band of the still unknown[17] parent formonitrile imine may be expected in the range 2100–2200 cm^{-1}.

Table 5. Calculated harmonic vibrational frequencies and IR intensities for formonitrile imine **2n** (MP2/6-311G (2df, 2p)) [12].

No.	$\tilde{\nu}$[cm^{-1}]	Int. [km mol^{-1}]	Assignment

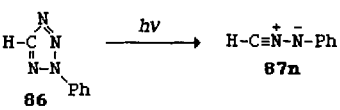
ω_7	2228	194	CNN symmetric stretch
ω_8	3236	95	CH stretch
ω_9	3296	34	NH stretch

The experimental data in Table 1 indicates that stabilized nitrile imines fall in two classes: 1) those absorbing in the range 2010–2100 cm^{-1}, and 2) those absorbing from 2140 to 2170 cm^{-1}. According to a valence bond description, the propargylic structure -C≡N–N- is expected to have a high C≡N stretching frequency approaching the nitrile region (≥2200 cm^{-1}), whereas the frequency for the allenic structure -C=N=N- should be lower. The data agrees with the results of the X-ray determinations described previously. Thus, the compounds listed as entries 3–5, 11, 14, 19, and 22–25 in Table 1 may be described as partially propargylic. For compounds **78n** and **85n** (entries 5 and 25) this has been discussed already. The electron-withdrawing tris(trifluoromethyl)phenyl substituent on phosphorus in **50n** (entry 3) is seen to have a large effect and increases the CNN stretching frequency into the "propargylic" range. Even phenyl groups on silicon have this effect in compounds **55n** and **54n** (entries 7 and 14). Boron has a large effect in the same direction both in *C*-boryl (**64n**, entry 22) and *C,N*-bis(boryl) compounds (**65n**, **84n**, **85n**, entries 23–25). The diaminoboryl substituent on nitrogen alone has little effect (**59n**, entry 9), but the more electrophilic dimesitylboryl substituent in entry 10 has a large effect.



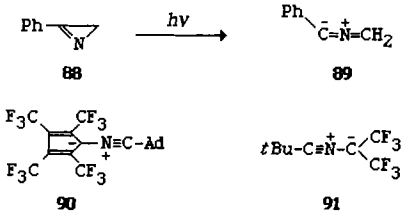
None of the stable nitrile imines for which X-ray structures have been determined so far are truly "propargylic": none have a linear X–C≡N- backbone, and none absorb in the actual nitrile region of the IR spectrum. It appears that the *C*-arylnitrile imines examined in low-temperature matrices constitute a separate class with nitrile-like Ar–C≡N- moieties, which absorb above 2200 cm^{-1} in the IR spectrum.

Diphenylnitrile imine (**11n**) absorbs at 2228 cm^{-1} in PVC matrix[37] and at 2242 in Ar matrix.[69] ^{15}N labeling of the central nitrogen atom causes, as expected, a large isotopic shift (to 2195 cm^{-1}), whereas labeling of the terminal nitrogen atom has a miniscule effect (2227 cm^{-1} in PVC matrix).[37] This is in line with the nitrile-type Ar–C≡$\overset{+}{N}$–$\overset{-}{N}$–Ar structure. The corresponding ^{15}N isotope shift in benzonitrile itself is 27 cm^{-1} (PhC≡N 2228 cm^{-1}; PhC≡^{15}N 2201 cm^{-1} in PVC).[37] Evidence that the compound observed was in fact diphenylnitrile imine was given by its photochemical rearrangement to diphenylcarbodiimide and cleavage to benzonitrile and phenylnitrene (see Section 7).[37]

Similarly, *C*-phenyl-*N*-trimethylsilylnitrile imine absorbs at 2230 cm^{-1} (film, 77 K), and its structure was confirmed by mass spectrometry, photoelectron spectroscopy, and trapping reactions,[43, 44] as well as by its photochemical rearrangement to *N*-phenyl-*N'*-trimethylsilylcarbodiimide.[69]

Dimesitylnitrile imine (**25n**) (Scheme 5) absorbs in solution at 2200 cm^{-1}, as Grundmann and Flory observed.[29]. However, *N*-methyl-*C*-phenylnitrile imine, generated by Ar matrix photolysis of 2-methyl-5-phenyltetrazole at 12 K, absorbs at 2032 and 1361 cm^{-1} and is photochemically converted to *N*-phenyl-*N'*-methyl-carbodiimide.[69] It would be highly interesting to synthesize a stable *C,N*-diarylnitrile imine to further investigate the structure.

N-Phenylnitrile imine (**87n**), generated in PVC matrix by photolysis of 2-phenyltetrazole (**86**) [Eq. (5)], was reported to



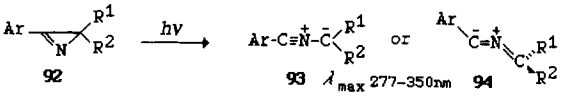
(5)

absorb at the low frequency of 2014 cm^{-1}.[37] This compound is a derivative of HCN, which absorbs near 2100 cm^{-1}.[70] Nitrile imine **87n**, which lacks a *C*-aryl substituent, may be more of the allenic type. ^{15}N labeling could give more information, but at any rate a low-frequency absorption band for **87n** is not unexpected. The nitrile oxides R–C≡$\overset{+}{N}$–$\overset{-}{O}$, which are linear or nearly linear,[71] absorb at very high frequencies near 2300 cm^{-1}, except for the parent member, fulminic acid, H–C≡$\overset{+}{N}$–$\overset{-}{O}$, which has a strong band at 2198 cm^{-1} (gas)[18] or 2193 cm^{-1} (Ar matrix).[72]

It is instructive to note that the C≡N–C absorption frequencies of nitrile ylides span almost 400 cm^{-1}. Benzonitrile methylide **89**, generated in Ar matrix by photolysis of 2*H*-azirine **88**, was reported to absorb strongly at a relatively low frequency, 1930 cm^{-1}.[73] The only stable nitrile ylide known was prepared and characterized by Arduengo et al.:[74] in com-

pound **90** an essentially linear C–N≡C- moiety was established by X-ray crystallography. The IR spectrum of this compound features a C–N stretching vibration at extremely high frequencies: a doublet at 2210, 2323 cm^{-1}.[75] Electron-withdrawing substituents on the ylidic carbon atom are expected[11] to stabilize the linear structure as in **90** and **91**. Ylide **91** has been isolated in matrix and absorbs in the nitrile region at 2250 cm^{-1}[76] (Scheme 27).

Scheme 27. Nitrile ylides characterized by IR spectroscopy. Ad = adamantyl.



The span of approximately 200 cm^{-1} in the symmetric stretching vibration ν_{CNN} in nitrile imines is thus perhaps not so surprising. Unfortunately, the calculated IR frequencies (Table 3) cannot be compared directly with experimental values for differently substituted compounds, because the ν_{CNN} vibrations in the monosubstituted nitrile imines are found computationally to be strongly coupled with either the C–H or N–H stretching modes. The existence of coupled vibrations could explain all the variations observed in the IR spectra. More work is needed to understand the relationship between structure and vibrational frequencies in nitrile imines.

5.3. UV Spectra

Selected UV spectral data for nitrile imines are given in Table 6. While less structural information can be gleaned from these data, it is instructive to compare the UV spectrum of diphenylnitrile imine (**11n**; λ_{max} = 378 nm) with that of the corresponding benzonitrile benzylide PhC≡$\overset{+}{N}$–$\overset{-}{C}$HPh.[77] In their discussion whether nitrile ylide **93** or **94** is generated by photolysis of 2*H*-azirines **92** in 2MP or DMBP glasses at 77 K (Scheme 28), Hansen and Heimgartner[77] argue in favor of the bent allene-type structure **94**, because the changes in the UV spectra are more in line with those observed for benzylideneamines than for benzonitriles. In the same vein, one can argue that diphenylnitrile imine is linear because of the bathochromic shift of the UV absorption maximum relative to that of benzonitrile benzylide (PhC≡$\overset{+}{N}$–$\overset{-}{C}$HPh; λ_{max} = 344 nm). If **11n** were bent like **94**, a hypsochromic shift would be expected. Nevertheless, the high-level ab initio calculations given in Table 3 predict that nitrile imines with aromatic substituents will be nonlinear and allenic.

Table 6. UV spectroscopic data of nitrile imines.

5.4. NMR Spectra

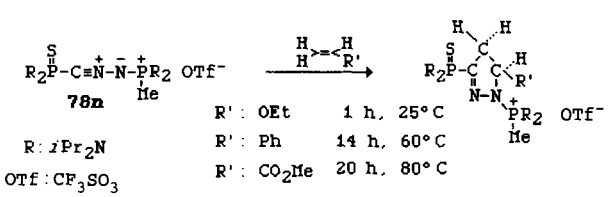
In contrast to X-ray analyses and IR spectroscopy, NMR spectroscopy does not really allow a differentiation between the allenic and propargylic structures. For illustration, we can compare the NMR data for the best representative of each structure type, namely the allenic *N*-phosphino-*C*-thiophosphinoylnitrile imine **46n** and the propargylic *N*-phosphonio-*C*-thiophosphinoylnitrile imine **78n**. The ^{13}C NMR signal for the quaternary carbon atom of **46n** and **78n** appears at δ = 61.04 and 69.83, respectively; the difference is not significant. The ^{14}N NMR signals of **46n** and **76n**, δ = −173.6 and −215, respectively, are possibly more informative. It is, however, surprising to find a δ value of only −191.0 for the *C*,*N*-bis(boryl)nitrile imine **85n**.

However, NMR spectroscopy is a very valuable tool for the identification of nitrile imines. In studies of reactions in which a nitrile imine and/or a diazo compound can be formed, a rapid and reliable method is needed for distinguishing these two structural isomers. The IR absorptions for both types of compounds are very similar.

The ^{13}C NMR chemical shift of the quaternary carbon atom of nitrile imines is generally in the range δ = 45–70; ditritylnitrile imine with a signal for the corresponding carbon atom at δ = 85.5 is an exception. This chemical shift range can serve as a criterion for differentiation of nitrile imines and diazo compounds, since the signal of the diazo carbon atom appears at higher field (δ < 40). However, observation of these ^{13}C NMR resonances is hampered owing to the fairly long longitudinal relaxation time T_1 (^{13}C). In addition, the transverse relaxation time T_2 (^{13}C) is considerably shortened by second-order scalar relaxation caused by the adjacent ^{14}N nucleus. Further difficulties arise when nuclei such as ^{11}B or ^{31}P are attached to the carbon atom, giving rise to additional broadening or splitting, respectively.

So far, all attempts to obtain a ^{15}N NMR spectrum of nitrile imines have failed. In contrast, ^{14}N NMR spectroscopy provides a simple and quick way to identify nitrile imines and differentiate them from diazo isomers.[78] The $^{14}N_\alpha$ nuclei ($CN_\alpha N_\beta$) give rise to comparatively narrow ^{14}N NMR signals, which are easily observed at room temperature. The chemical shifts of the N_α atoms of nitrile imines are between δ = −170 and −215, while for diazo compounds the analogous signals are between δ = −110 and −130; this difference is sufficient for a definitive structure assignment. Note that, as expected, the $^{14}N_\alpha$ chemical

shifts for the nitrile imines are found in a range similar to those of nitrile oxides.[79] The $^{14}N_\beta$ resonance has never been observed even at high temperature (80 °C), probably because the electric field gradient at the site of the $^{14}N_\beta$ nucleus is very large, thus causing the $^{14}N_\beta$ relaxation time T_Q to be very short.

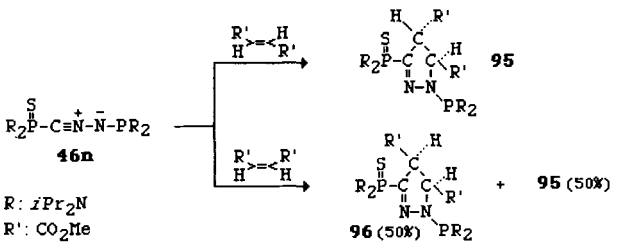


Since many of the known, stable nitrile imines have heteroatom substitutents, NMR data from heteronuclei have been widely used for structure determination. In the case of *C*-phosphorus-substituted nitrile imines, the ^{31}P chemical shift was always at higher field than that of the diazo isomer; this is particularly dramatic with thiophosphinoyl substituents ($\Delta\delta = 27-43$) but also evident with phosphino substituents ($\Delta\delta = 9-12$). Moreover, the presence of a phosphorus atom at the carbon terminus induces couplings with the nitrile imine carbon ($^1J_{PC} = 48-133$ Hz) and also sometimes with the *N*-nitrile imine substituent ($^4J_{PP} = 0-9$ Hz; $^4J_{PSi} = 0-4$ Hz). The ^{29}Si NMR signals are somewhat difficult to observe and are not indicative of the structure. In the same way, ^{11}B NMR spectra are not very helpful, since the signals are very broad and the range very narrow. For instance, in the case of *C,N*-bis(boryl)nitrile imine **65n**, the boron atoms can only be differentiated at 348 K ($\delta = +23$ and $+28$).[58]

6. Reactivity of Nitrile Imines

6.1. 1,3-Dipolar Cycloaddition Reactions

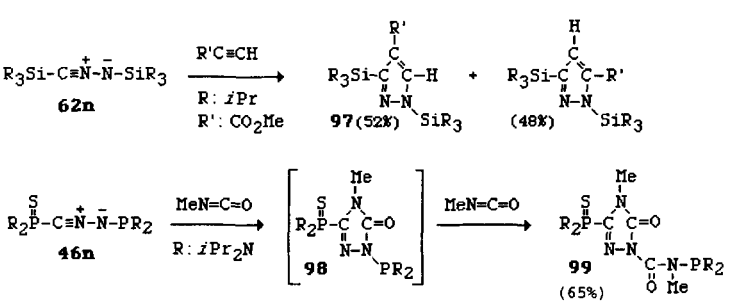
The general features of 1,3-dipolar cycloaddition reactions are well known.[2-6, 11, 38c, 77] In this section we briefly compare the results obtained with transient and stable nitrile imines, emphasizing the differences between these to types of compounds.



Nitrile imines are Class II dipoles in the classification of Sustmann;[80] in other words, HOMO(dipole)/LUMO(dipolarophile) and HOMO(dipolarophile)/LUMO(dipole) interactions are about equally important. Consequently, nitrile imines can behave as both nucleophiles and electrophiles toward the dipolarophile; that is, the nitrile imines are ambiphilic. This statement fits well with the experimental results for transient nitrile imines. Most of the known stable nitrile imines do not react with styrene, butadiene, or phenylacetylene but react with electron-poor dipolarophiles (note that even the transient diphenylnitrile imine adds to dimethyl fumarate 177 times faster than to styrene).[81] The only real exception is the *N*-phosphonio-substituted nitrile imine **78n**, which is strongly electrophilic.[64b] It reacts with electron-rich olefins such as ethyl vinyl ether at room temperature, whereas the reaction with styrene requires 14 h at 60 °C. Reaction with the electron-poor olefin methyl acrylate needs 20 h at 80 °C (Scheme 29). This order of reactivity of **78n** with dipolarophiles was confirmed by competition experiments.

Scheme 29. Reactivity of nitrile imine **78n** to dipolarophiles.

Lastly, it should be noted that the reactivity of the *N*-borylnitrile imines (**58n**, **59n**, **63n**) is quite usual but, surprisingly, the *C*-borylnitrile imines (**64n**, **65n**, **84n**, **85n**) are rather unreactive.[58]

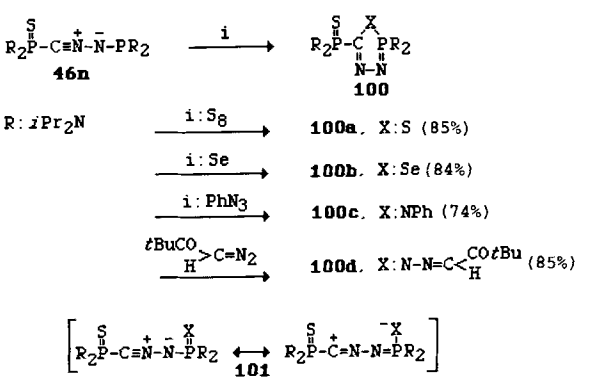


1,3-Dipolar cycloaddition reactions are usually stereospecific, and it was long assumed that any exception was due to prior isomerization of the dipolarophile or subsequent isomerization of the product.[4, 5] Surprisingly, nitrile imine **46n** reacted stereospecifically with dimethyl fumarate affording the *trans* adduct **95**, while with dimethyl maleate a mixture of *cis*-**96** and *trans* adducts **95** was obtained. Since attempted epimerization of **96** failed, and NMR spectroscopy revealed that the unconsumed dipolarophile was not isomerized when the reaction was run with 1.2 equivalent of maleic ester, it was concluded that the lack of stereoselectivity observed was due to a "nonconcerted addition" process[49] (Scheme 30). Two previous examples of

Scheme 30. An example of nonstereoselectivity in [2 + 3] cycloaddition reactions.

nonconcerted [2 + 3] cycloaddition reactions have been reported; the first was described by Huisgen et al. for the reaction of strongly nucleophilic thiocarbonyl ylides with particularly electrophilic alkenes,[82] and the second by Quast et al. for the reaction of electrophilic azides with 5-alkylidenedihydrotetrazoles.[83]

The regiochemistry of the cycloaddition reactions has also been rationalized in terms of frontier molecular orbital (FMO) theory.[4, 5, 11, 84] As predicted, addition of unsymmetrically substituted olefins or alkynes usually yields the 5-substituted pyrazolines or pyrazoles as the major product. However, in the case of *C,N*-bis(silyl)nitrile imine **62n**, the 4-substituted pyrazole **97** becomes the major isomer;[54] this finding is also in agreement with theory, since the silyl groups raise the FMO energies. Nitrile imine **46n** reacts with methyl isocyanate only with the C=N and not with the C=O double bond, as expected for a HOMO(dipole)-controlled cycloaddition and in contrast to the results observed with transient nitrile imines.[5, 6] (The isolated product **99** results from the insertion of a second molecule of isocyanate into the P–N bond of the primary product **98**)[49] (Scheme 31). To summarize, both transient and stable

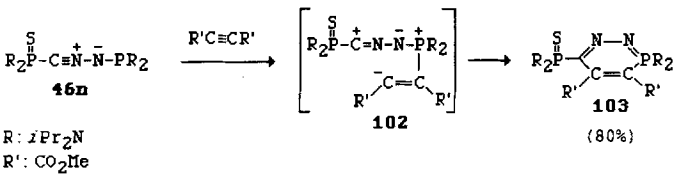


Scheme 31. Examples of the regioselectivity of [2 + 3] cycloaddition reactions of nitrile imines **62n** and **46n**.

nitrile imines have similar reactivities with 1,3-dipoles, although, not surprisingly, the stable nitrile imines are somewhat less reactive.

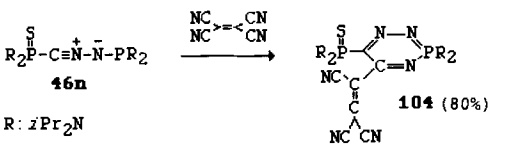
6.2. Reactions Involving the CNN Skeleton and a Heteroatom Substituent

As described in Section 5, the structure of nitrile imines is not strongly perturbed by heteroatom substituents. However, one of the important questions was whether the heteroatom bonded to the CNN moiety could extend the scope of nitrile imine reactions.



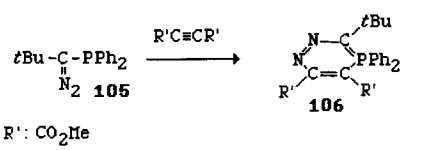
Indeed, reactions involving both the CNN unit and a λ^3-phosphorus atom bound to the nitrogen terminus have been reported.[52, 64a] Nitrile imine **46n** reacts with sulfur, selenium, phenyl azide, and pivaloyldiazomethane at room temperature to afford 1,3,4,2λ^5-thiadiazaphosphole **100a**, 1,3,4,2λ^5-selenadiazaphosphole **100b**, and 1,2,4,3λ^5-triazaphospholes **100c** and **100d**, respectively, in good yields. Adducts **100** formally result from a [4 + 1] cycloaddition. But actually a two-step mechanism is most likely involved: electrophilic attack of sulfur, selenium, phenyl azide, or diazo compound on the phosphorus lone pair, which is activated by the electron-rich nitrile imine moiety, leads to intermediates **101**, which undergo 1,5-electrocyclization[47] (Scheme 32). These reactions can be compared with the formation of 1,3,4-thiadiazoles and 1,3,4-triazoles from unstable *N*-thiocarbonyl-[85] and *N*-iminonitrile imines,[86] respectively.

Scheme 32. Formal [1 + 4] cycloaddition reactions of nitrile imine **46n**.



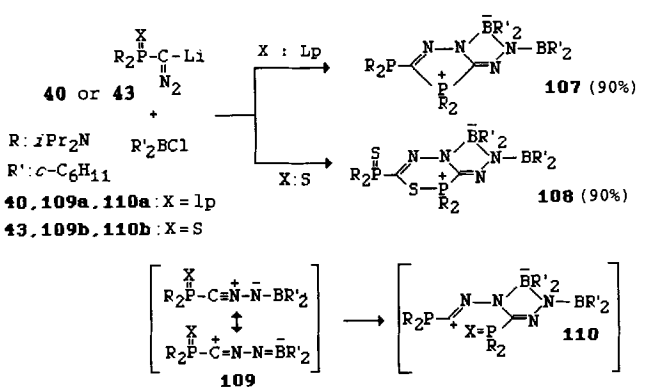
The four reagents used in the above reactions are known to react with the phosphorus lone pair and not with the nitrile imine moiety. In contrast, a dipolarophile such as dimethyl acetylenedicarboxylate could react both with the lone pair[87] and with the 1,3-dipole. In fact, the reaction of **46n** with this electron-poor alkyne affords the 1,2,3λ^5-diazaphosphinine **103** (Scheme 33).[52, 64a] Although heterocycle **103** formally results from a [4 + 2] cycloaddition process, it is likely that the first mechanistic step is the electrophilic attack of the alkyne on the phosphorus lone pair of **46n**, followed by the 1,6 ring closure of **102**. This is the first example of 1,6-electrocyclization involving nitrile imines.

A similar reaction has been observed between nitrile imine **46n** and tetracyanoethylene giving rise to **104**.[52, 64a] Although



Scheme 33. Formal [2 + 4] cycloaddition reaction of nitrile imine **46n** with dimethyl acetylenedicarboxylate.

addition and cycloaddition reactions of tetracyanoethylene usually proceed with high selectivity at the C–C double bond,[88] in this case the reaction involves the nitrile group[89] (Scheme 34).



Scheme 34. Formal [2 + 4] cycloaddition reaction of nitrile imine **46n** with tetracyanoethylene.

Recently Regitz et al. reported a formal [2 + 4] cycloaddition reaction involving phosphinodiazomethane **105** (Scheme 35).[90] All these reactions are of synthetic interest, since the resulting heterocycles **100**, **103**, **104**, and **106** are hardly available by classical routes.

Scheme 35. Formal [2 + 4] cycloaddition reaction of phosphanyldiazomethane **105**.

An atypical dimerization of nitrile imines involving the *N*-heteroatom substituent is noteworthy.[91] The reactions of the lithium salts of phosphinodiazomethane and thiophosphinoyldiazomethane, **40** and **43**, respectively, with chlorodicyclohexylborane lead to bicyclic compounds **107** and **108**, respectively (Scheme 36). It is quite likely that the first step of these

Scheme 36. Atypical dimerization of nitrile imines **109**.

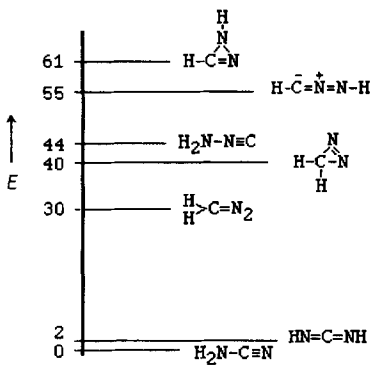
reactions is the formation of nitrile imines **109a** and **109b**, which possess a formal boron–nitrogen double bond. Thus, the CNN unit of one molecule can react as a 1,3-dipole with the boron–nitrogen double bond of a second molecule giving intermediates **110a** and **110b** having a carbocation center, which react with the phosphorus or sulfur atoms to give the observed products.

Lastly, as already mentioned Section 4.3, the heteroatom substituents can be employed in the preparation of other stable nitrile imines.

7. Rearrangements of Nitrile Imines

In this review only the rearrangements of the nitrile imine skeleton, and not those involving the substituents bonded to the carbon or nitrogen termini, will be discussed.

Theoretical studies on the relative stabilities of the various possible ground state isomers of CH_2N_2 have been published.[92] Interestingly, 1*H*-diazirine is found to be of only slightly higher energy than the parent formonitrile imine **2n**: +14.2 kcal mol^{-1} at the HF/6-31G level,[92c] +8.4 kcal mol^{-1} at the HF/3-21G* level (with electron correlation),[92b] and +1.1 kcal mol^{-1} at the G2(MP2) level[92d]. Diazomethane is significantly more stable, and carbodiimide is the most stable of these isomers (cyanamide is the global minimum) (Fig. 4).



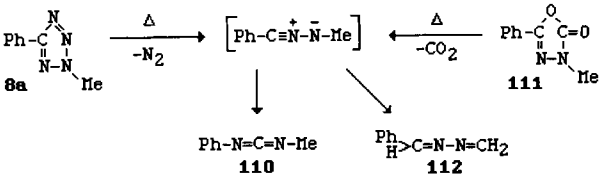


Fig. 4. Calculated relative energies [kcal mol^{-1}] of H_2CN_2 isomers (G2(MP2) level [92d]).

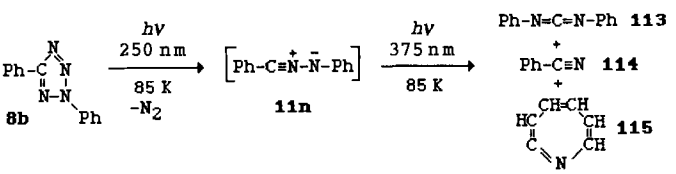
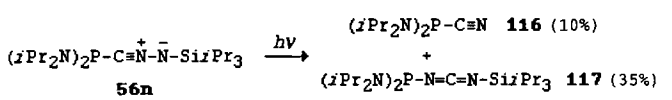
Therefore, considering the thermodynamics, it is not surprising that nitrile imines rearrange to diazo compounds and carbodiimides. The nitrile imine → carbodiimide rearrangement was postulated to proceed through a 1*H*-diazirine intermediate, which by ring-opening would lead to an imidoylnitrene;[42] the Wolff-type rearrangement of imidoylnitrenes to carbodiimides is well known.[42, 93] Ab initio calculations indicate high energy barriers for the ring closure of nitrile imine to 1*H*-diazirine and for the 1,3-hydrogen shift leading to diazomethane (Fig. 4).[92b, d] Nevertheless, there is some experimental evidence for such rearrangements.



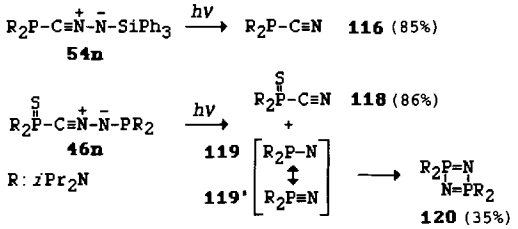
7.1. Rearrangements of Nitrile Imines to Carbodiimides and N–N Bond Cleavage

The thermal rearrangement of nitrile imines to carbodiimides (both systems are isoelectronic to those in the nitrile oxide → isocyanate rearrangement)[93] has been postulated to explain the formation of methylphenylcarbodiimide (**110**) on flash vacuum thermolysis of 2-methyl-5-phenyltetrazole (**8a**) or 3-methyl-5-phenyl-1,3,4-oxadiazol-2(3*H*)-one (**111**) (Scheme 37).[42] The yield of this reaction is rather low (1–8%) but can be increased when the reaction is conducted photochemically.[69] In the thermal reaction, azine **112**, which results from a 1,4-hydrogen shift, was also obtained in 10% yield.[42]



Scheme 37. Thermal rearrangement of transient *N*-methyl-*C*-phenylnitrile imine.

In a very elegant paper[37] Holm et al. demonstrated the photochemical rearrangement of a nitrile imine to a carbodiimide. Diphenylnitrile imine (**11n**) was generated in PVC matrix at 85 K by photolysis of 2,5-diphenyltetrazole (**8b**) at 250 nm. **11n** was characterized by IR and UV spectroscopy (ν = 2228 cm^{-1}; λ_{max} = 378 nm). Continued irradiation (λ = 370 nm) of nitrile imine **11n** led to diphenylcarbodiimide (**113**), along with benzonitrile (**114**) and 1-aza-1,2,4,6-cycloheptatetraene (**115**) (Scheme 38). The structures **11n** and **113**–**115** were confirmed by ^{15}N-labeling experiments. Compound **115** originates from rearrangement of the initially formed phenyl nitrene.[73] Thus, the rearrangement of the nitrile imine to carbodiimide competes with nitrogen–nitrogen bond cleavage.



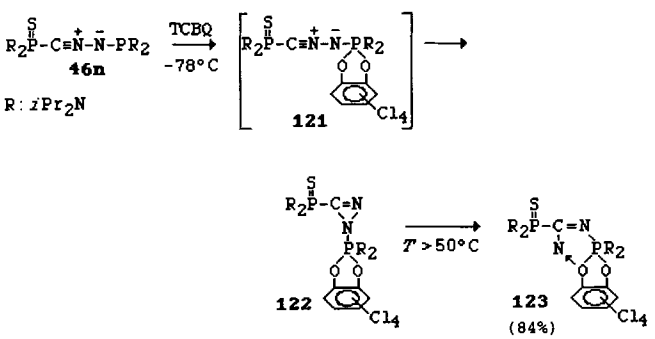
Scheme 38. Photochemical rearrangement of diphenylnitrile imine **11n**.

For nitrile imines that are stable at room temperature, competing reactions of this type have only been observed on irradiation of *C*-[bis(diisopropylamino)phosphino]-*N*-triisopropylsilylnitrile imine (**56n**), which led to phosphinonitrile **116** and carbodiimide **117** (Scheme 39).[54]

Scheme 39. Photochemical rearrangement of nitrile imine **56n**.

All the other photolyses reported with stable nitrile imines unequivocally led to carbodiimides, except in the cases of *C*-phosphino-*N*-triphenylsilylnitrile imine **54n**[54] and *N*-phosphino-*C*-thiophosphinoylnitrile imine **46n**[49] which underwent nitrogen–nitrogen bond cleavage. The photolysis of nitrile imine **54n** gave phosphinonitrile **116** in 85% yield along with several

Scheme 40. Photochemical rearrangement of nitrile imines **54n** and **46n**.



silylated products which were not isolated (Scheme 40). Irradiation of **46n** at 300 nm led to thiophosphinoylnitrile **118** and to phosphinonitrene **119** which dimerizes into the cyclodiphosphazene **120**. It has already been shown that **119**, generated by photolysis of bis(diisopropylamino)phosphanyl-azide, behaves as "phosphonitrile" **119'**,[94] and dimerizes to give the four-membered ring compound **120**[95] (Scheme 40).

The photochemical rearrangement of nitrile imines to carbodiimides seems to be rather general. As indicated in Scheme 41, the reaction is possible for compounds with a wide variety of substituents at the carbon and nitrogen termini.[54, 58, 63, 69]

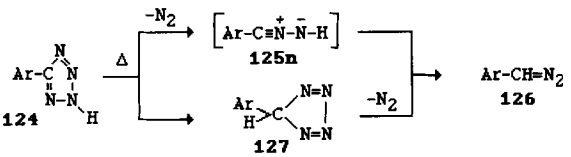
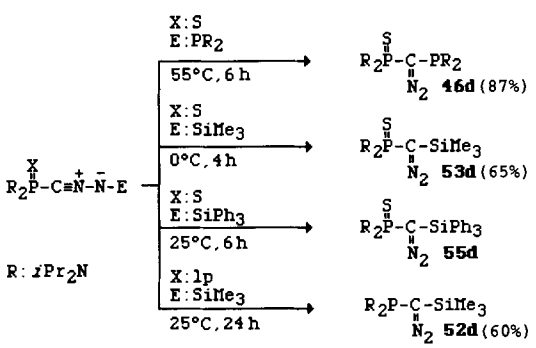
Scheme 41. Photochemical rearrangement of nitrile imines into carbodiimides. Wavenumbers of IR absorption bands of the carbodiimides are given in the right column.

As mentioned above, the nitrile imine → carbodiimide rearrangement was postulated to proceed through an 1*H*-diazirine intermediate which leads to an imidoylnitrene by ring opening.[42] Interestingly, one piece of evidence for this mechanism has been reported.[96] Addition of tetrachloro-*o*-benzoquinone to nitrile imine **46n** led to compound **123**, which was isolated after workup (Scheme 42). This compound can be regarded as an imidoylnitrene stabilized by donor–acceptor interaction with an oxygen atom (the stabilization of nitrenes by



Scheme 42. Evidence for the rearrangement nitrile imine → isodiazirine → imidoylnitrene.

coordination at nitrogen is known).[97] Moreover, when the reaction was monitored by NMR spectroscopy at −50 °C, an intermediate tentatively assigned as isodiazirine **122** was detected. Many questions remain concerning the factors influencing the photochemical reactions of nitrile imines.

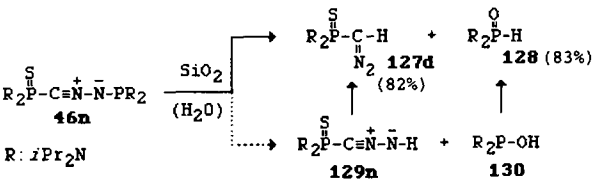


7.2. Rearrangement of Nitrile Imines to Diazo Compounds

The possible existence of a diazomethane–nitrile imine equilibrium was described in Section 2 [Eq. (1)]. Nitrile imine → diazoalkane rearrangements have been postulated to explain the products obtained in the thermolysis of potential nitrile imine precursors.[98, 99] However, the nitrile imines were never observed, and apart from one case[98] the resulting diazo compounds were also not stable under the experimental conditions. Moreover, even the thermolysis of 5-aryltetrazole **124**[98] leading to the isolable diazo compound **126** may proceed by an alternative mechanism that bypasses nitrile imine **125n** and involves instead the tautomeric 5*H*-tetrazole **127** (Scheme 43). Recent ab initio calculations support the latter mechanism.[100]

Scheme 43. Formation of diazo derivatives from 5-aryltetrazoles.

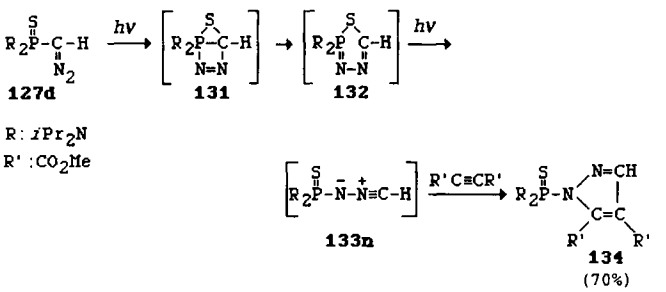
The first definitive proof for the nitrile imine → diazoalkane rearrangement was reported in 1988.[50] Indeed, nitrile imine **46n**, which was fully characterized (including single-crystal X-ray diffraction), rearranged on heating in chloroform (55 °C, 6 h) to the stable phosphino(thiophosphinoyl)diazomethane **46d** (Scheme 44). However, this rearrangement does not appear



Scheme 44. Rearrangement of stable nitrile imines into diazo compounds.

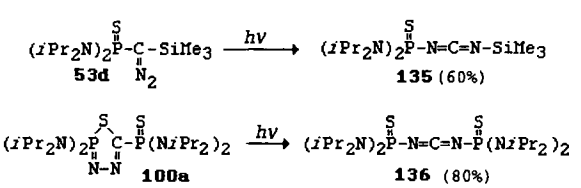
to be general. So far, only three other examples have been published, and all of them involve *C*-phosphorus-*N*-silyl-substituted nitrile imines.[54]

For the sake of comprehensiveness, the formation of bis(diisopropylamino)thiophosphinoyldiazomethane (**127d**) and phosphane oxide **128** from hydrolysis of nitrile imine **46n** should



be mentioned. This reaction takes place on silica gel and has been rationalized in terms of a nitrile imine → diazoalkane rearrangement.[50] The first step could be the hydrolysis of the phosphorus–nitrogen bond leading to the *N*-unsubstituted nitrile imine **129n** and the hydroxyphosphane **130**, followed by isomerization to **127d** and **128**, respectively (Scheme 45).

Scheme 45. Hydrolysis of nitrile imine **46n**.



The factors governing the rearrangement of nitrile imines to diazo compounds are not understood. At the most, it seems that the larger the substitutent on the nitrogen atom, the slower the rearrangement.

The reverse rearrangement of diazo compounds to nitrile imines has been postulated to explain the formation of *N*-(thiophosphinoyl)pyrazole **134** from the photolysis of thiophosphinoyldiazomethane **127d** in the presence of dimethyl acetylenedicarboxylate.[101] Pyrazole **134** is the expected product of the [2 + 3] cycloaddition of nitrile imine **133n** and the alkyne, and it could well be that the diazo → nitrile imine rearrangement proceeds via **131** and **132** (Scheme 46). In other words, this rearrangement would be assisted by the presence of the phosphorus–sulfur double bond.

Scheme 46. Example of a diazo compound → nitrile imine rearrangement.

This mechanistic hypothesis is corroborated by the formation of carbodiimides **135** and **136** on photolysis of (trimethylsilyl)(thiophosphinoyl)diazomethane **53d** and 1,3,4,2λ⁵-thiadiazaphosphole **100a**, respectively.[101] In fact, these reactions could be examples of the rearrangement of a diazoalkane to a nitrile imine to a carbodiimide (Scheme 47).

Scheme 47. Rearrangements of diazo compound **53d** and thiadiazaphosphole **100a** to carbodiimides.

Numerous questions remain concerning mechanisms of the rearrangements of the various isomers of nitrile imine. One of the most fundamental ones is whether they are intra- or intermolecular. Future work in our laboratories will address such questions.

8. Conclusion and Outlook

Nitrile imines were only accessible as reactive intermediates until a few years ago, and since then many stable compounds of this type have been prepared. Some of them are solids, others distillable liquids. Most of the stable nitrile imines have been prepared by nonclassical routes, and these compounds are now available in multigram quantities. Their stabilization is determined largely by steric interactions. For this reason, the isolable nitrile imines tend to be less reactive. They are also less ambiphilic than their transient counterparts; that is, they are usually nucleophilic, with the exception of the positively charged *N*-phosphonionitrile imine **78n**, which is strongly electrophilic.

The question of concertedness in 1,3-dipolar cycloaddition reactions was previously much debated. The addition of the stable nitrile imine **46n** to dimethyl maleate has been shown to be nonconcerted. Examples of nonconcerted cycloaddition of other 1,3-dipoles have been reported previously.

A striking feature of stable nitrile imines is the possibility of reactions at the periphery of the CNN skeleton, which allow the synthesis of other nitrile imines. Reactions involving the nitrile imine moiety and a heteroatom substituent are also noteworthy.

X-ray crystal structures have now been obtained for several stable nitrile imines. While all of these compounds possess nonplanar, allenic structures, electron-withdrawing substituents promote a partial linearization in the direction of the propargylic structure. This is the case of the *C,N*-bis(boryl) compound **85n** and the *N*-phosphonio derivative **78n**. These unusual structures have generated a renewed interest in high-level ab initio calculations of nitrile imines. While calculations at the Hartree–Fock level indicate that the allenic and the propargylic forms can coexist as discrete minima, incorporation of electron correlation with Møller–Plesset perturbation theory leads to the prediction that only the allenic form should be stable. However, substituents on the CNN framework can strongly modify the geometry. The agreement between experimentally determined structures and those calculated for model compounds is excellent. These results will prompt further high-level calculations of structures and energies for nitrile imines.

The variability of structure between the allenic and propargylic extremes makes a rigorous interpretation of the infrared spectra difficult. Both theoretical and experimental work is needed here, in particular regarding the hitherto elusive *C*-arylnitrile imines.

Another area of interplay theory and experiment concerns the rearrangement of nitrile imines to diazo compounds and to carbodiimides. Theory predicts a very high activation energy both for the 1,3-hydrogen shift (by either concerted or homolytic pathways) and for the ring closure to the 1 *H*-diazirine intermediate. However, there are several examples of such rearrangements taking place under mild conditions. Further studies of their mechanisms are highly desirable.

The story of nitrile imines clearly illustrates that heteroatoms are wonderful tools for stabilizing highly reactive species. The variety of easily available heteroatom substituents with disparate electronic effects allows a ready understanding of the factors that influence the stability of the compounds. This simplifies the choice of the right organic substituents required for the synthesis of purely organic, stable species.

It is now clear that nitrile imines are no longer laboratory curiosities; they are easily available and storable, and their use as building blocks for organic synthesis or for polymeric materials is anticipated.

We would like to thank the Centre National de la Recherche Scientifique (CNRS) for a Visitor's Fellowship (to C. W.) which made this collaboration possible. Thanks are due also to our coworkers A. Baceiredo, R. Réau, G. Sicard, M. Granier, F. Castan, M. P. Arthur, K. Horchler von Locquenghien, M. Soleilhavoup, and G. Veneziani in Toulouse, and G. G. Qiao, R. Leung-Toung, and M. W. Wong in Brisbane, without whom this work would never have come to fruition. The financial support of the experimental work in Toulouse by the CNRS and Pierre Fabre Médicaments is greatfully acknowledged.

Just what does a referee system achieve?

Regular readers of "Angewandte" are well aware that Dr. Hans-Dieter Daniel has researched this question using *Angewandte Chemie* as example. The preliminary results were presented in a communication on this topic (Issue 2/93). Now the complete analysis by Daniel is available in book form: "The Guardians of Science: Fairness and Reliability in Peer Review" by H.-D. Daniel, foreword by H. Nöth (VCH, Weinheim, 1993, ISBN 3-527-29041-9, DM 78.—).

Novel Carbon Compounds with "Naked" C_n Units

Heinrich Lang*

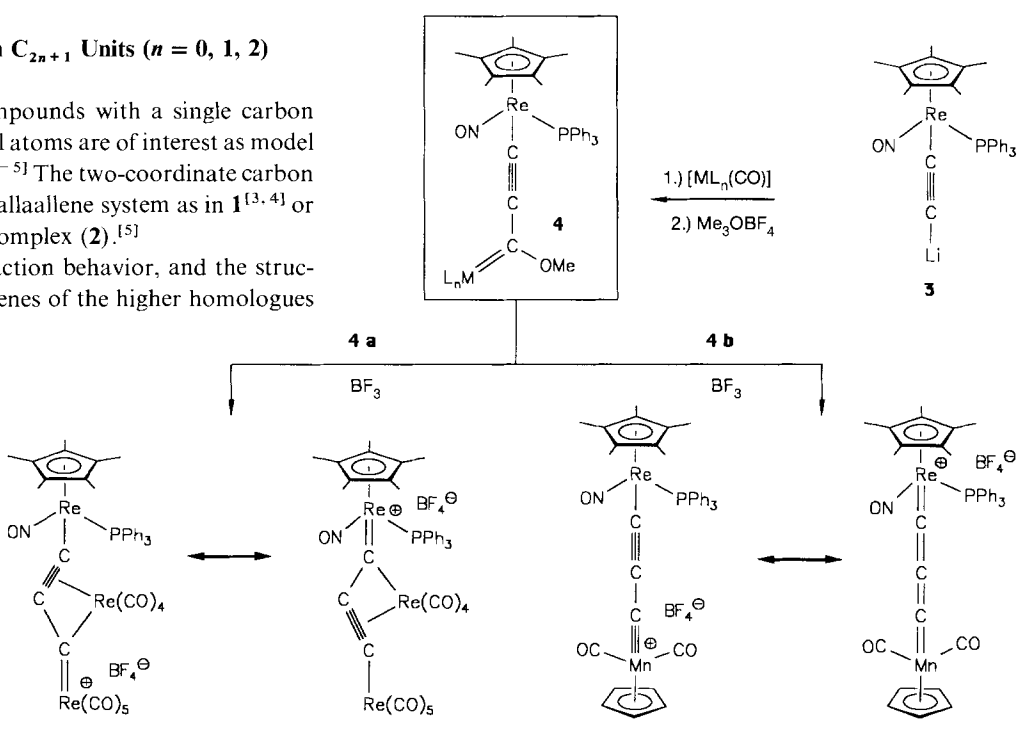
A new class of compounds interesting in view of their new material properties[1] and as model systems for surface carbides in heterogeneous catalysis[2, 3] has become significant: compounds in which linear carbon chains C_n ($n = 1-5$) bridge different organometallic building blocks. Whereas compounds with "naked" C_n units ($n = 1, 2, 4$) and identical terminal metal complex fragments have already been well studied,[3] complexes with C_n bridges ($n = 1-5$) which link different transition metal complex building blocks have only recently become accessible.[1e, 3-18]

With regard to the synthesis of complexes with C_n bridges a formal classification of these compounds into those with an even number of C_{2n} ($n = 1, 2, \ldots$) bridges and those with an odd number of C_{2n+1} ($n = 0, 1, 2, \ldots$) bridges is possible.

Transition Metal Complexes with C_{2n+1} Units ($n = 0, 1, 2$)

C_1 Bridges: Organometallic compounds with a single carbon atom between two different metal atoms are of interest as model systems for surface carbides.[1e, 2-5] The two-coordinate carbon atom may be part of a 1,3-dimetallaallene system as in **1**[3, 4] or part of a C-metalated carbyne complex (**2**).[5]

Whereas the synthesis, the reaction behavior, and the structural features of 1,3-dimetallaallenes of the higher homologues of carbon have been well-studied,[19-22] only few examples of isolated and structurally characterized carbon compounds such as **1** are known.[3, 4] One of these compounds is the 1,3-dimetallaallene **1a** synthesized by W. Beck et al., which contains the shortest metal–carbon bond (Fe–C: 161 pm) known so far.[4] Compound **1a** was obtained by the reaction of the dichlorocarbene complex $[(tpp)Fe{=}CCl_2]$ (tpp = tetraphenylporphyrinate) with $[Re(CO)_5]^-$. The extension of



$[(tpp)Fe{=}C{=}ML_n]$ $[L_nM{\equiv}C{-}M'L_n]$

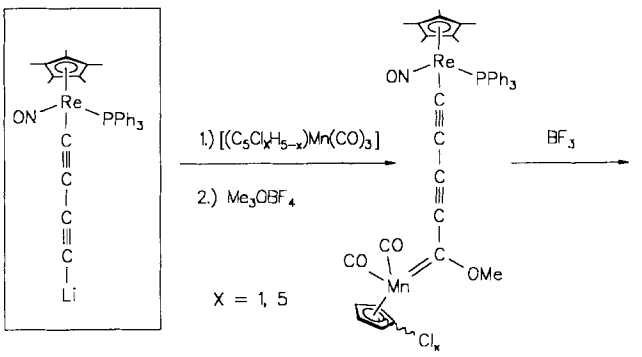
1 **2**

1a: $ML_n = Re_2(CO)_9$ [4]
1b: $ML_n = Mn_2(CO)_9$ [3]
1c: $ML_n = Cr(CO)_5$ [3]
1d: $ML_n = Fe(CO)_4$ [3]
2a: $ML_n = HB(pz)_3(CO)_2Mo$; $M'L_n = FeCp(CO)_2$ [5a]
2b: $ML_n = HB(pz)_3(CO)_2Mo$; $M'L_n = PtBr(PPh_3)_2$ [5b]
2c: $ML_n = (Me_3CO)_3W$; $M'L_n = RuCp(CO)_2$ [5c]

this synthetic method to the carbonyl metalates $[Mn(CO)_5]^-$, $[Cr(CO)_5]^{2-}$, and $[Fe(CO)_4]^{2-}$ leads to the compounds **1b–d**.[3]

The complex **2a** can be prepared by nucleophilic substitution of $[\{HB(pz)_3\}(CO)_2Mo{\equiv}CCl]$ (pz = 3,5-dimethylpyrazolyl) with $K[FeCp(CO)_2]$;[5a] **2b** is formed by the reaction of the analogous bromocarbyne with "$Pt(PPh_3)_2$".[3, 5b] A particularly elegant synthetic method makes use of the alkyne-analogous reactivity of $[(Me_3CO)_3W{\equiv}CEt]$ which in the metathesis with the alkyne complex $[Cp(CO)_2Ru{-}C{\equiv}CMe]$ affords the C-metalated carbyne complex **2c**.[5c]

5a **5b** **6a** **6b**



Scheme 1. **4a**: $ML_n = Re(CO)_4Re(CO)_5$; **4b**: $ML_n = CpMn(CO)_2$; **4c**: $ML_n = W(CO)_5$; **4d**: $ML_n = Fe(CO)_4$.

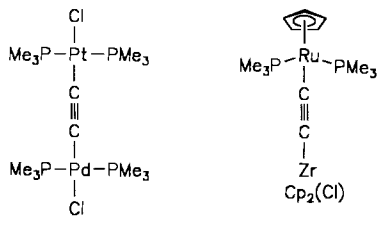
C_3 and C_5 Bridges: By using the classic Fischer–carbene and -carbyne synthesis,[6] J. A. Gladysz et al. were able to prepare complex **5** in a two-step reaction sequence; this compound exhibits a novel nonlinear form of a C_3 bridge (Scheme 1).[7] The synthesis of this compound is achieved by treating the acetylide complex **3** first with $[Re_2(CO)_{10}]/Me_3OBF_4$ and subsequently with BF_3. If the mononuclear carbonyl complexes $[CpMn(CO)_3]$, $[Fe(CO)_5]$, or $[W(CO)_6]$ are used instead of $[Re_2(CO)_{10}]$, initially compounds **4b–d** are formed by an analogous reaction pathway; subsequent reaction of **4b** with BF_3 leads to the cationic complex **6**,[7a] which, in contrast to **5**, has a linear, terminally bound C_3 chain.

The structures of compounds **5** and **6** have been confirmed by X-ray structure analyses.[7] Thus, the structure of compound **6** can best be described by the "cumulene formula" **6b**.[7] The Re–C and C–C distances in **5** correspond best to the limiting structure **5b**,[7b] which is consistent with the stronger donor properties of the Ph_3P- and Cp*-substituted rhenium atom.

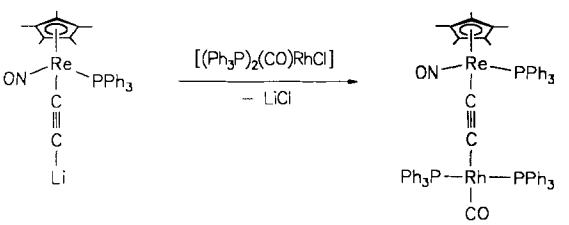
The successful strategy for the preparation of complexes **5** and **6** could be extended to the synthesis of compound **9** containing a C_5 chain.[8] A decision as to which of the two given limiting formulae is more important for **9** may only be reached by a structure analysis.[8]

7 8



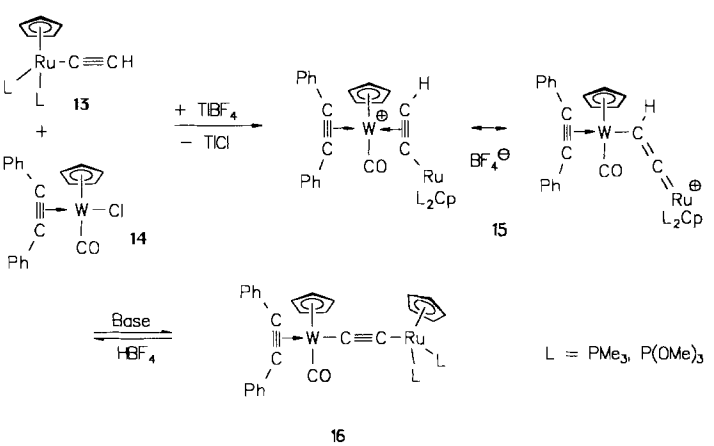
9

Transition Metal Complexes with C_{2n} Units ($n = 1, 2$)



C_2 Bridges: Complexes with a C_2 bridge are a rapidly developing class of compounds.[3] The C_2 building blocks can be readily obtained from acetylene derivatives. Thus, compounds are usually formed in which two identical organometallic substituents are bound to the C_2 unit, such as in $[(CO)_5Re-C\equiv C-Re(CO)_5]$.[9]

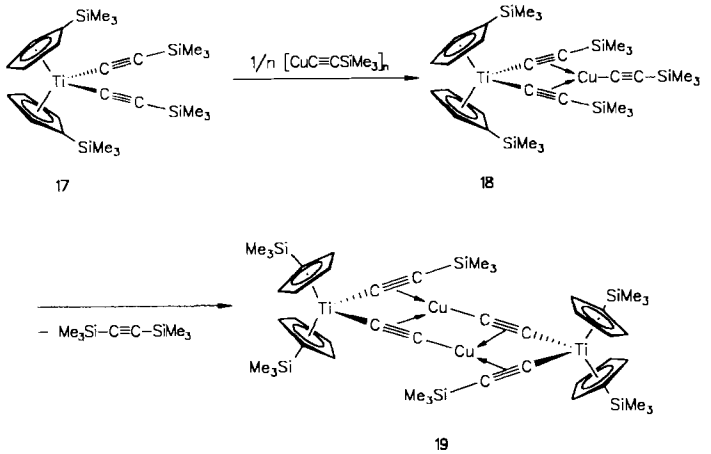
In general, the synthesis of compounds with two different metal complex fragments at the C_2 building block requires first the preparation of the organometallic-substituted alkyne. Compound **10** is formed in this way by the reaction of $[(Me_3P)_2(Cl)Pt-C\equiv CH]$ with $[(Me_3P)_2PdCl_2]$ in the presence of Cu^ICl and $HNEt_2$;[10] compound **11** forms from $[Cp(Me_3P)_2Ru-C\equiv CH]$ and $[Cp_2Zr(Cl)(NMe_2)]$ with the elimination of $HNMe_2$.[11]



10 11

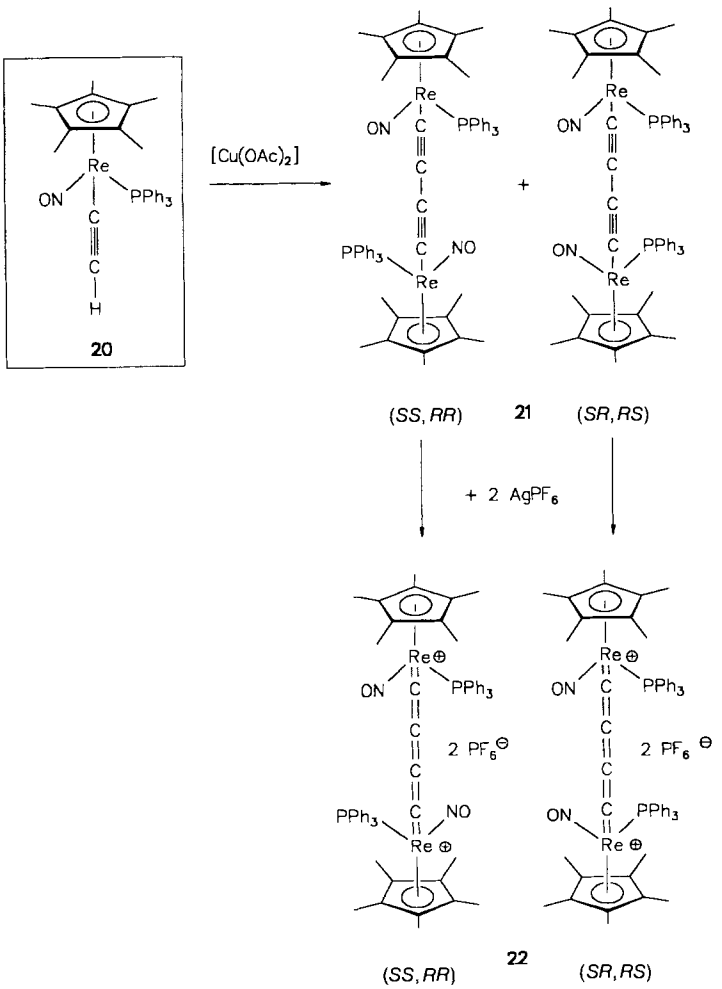
The reaction of the rhenium complex **3** with $[(Ph_3P)_2(CO)RhCl]$ to give **12** is an example of the reaction of terminal lithiated alkynyl building blocks.[12]

3 12



An interesting reaction sequence, which finally leads to complex **16** containing a linear C_2 bridge, was recently developed by J. P. Selegue et al.[13]

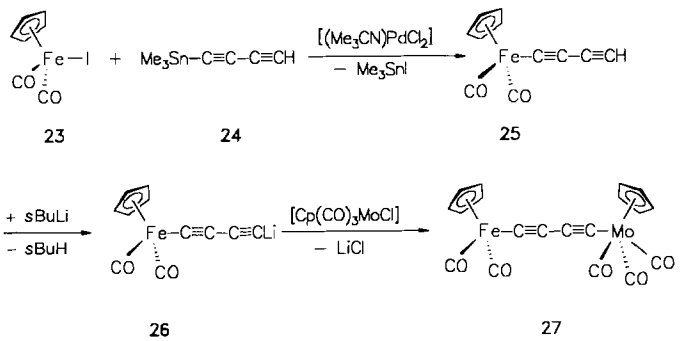
13 14 15 16



The reaction of the titanium complex **17** with $[CuC\equiv CSiMe_3]_n$ illustrates that compounds with different metal complex fragments attached to the C_2 building block can also be prepared from (silylalkynyl) complexes.[14]

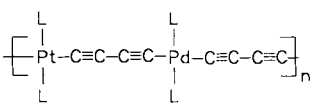
C_4 Bridges: The elegant synthesis of compound **21** shows that metal-bound alkynyl groups can be coupled in a way very sim-

17 18 19



ilar to that of free alkynes. Since **20** is chiral, two diastereomers are formed, which can be separated by crystallization.[1e, 15] The bond lengths in **21** are appropriate for the given formulation of the complex with two alkyne functions. The dications **22** are obtained by oxidation of **21**; the Re–C and C–C distances in **22** can be assigned to a cumulene system.[15]

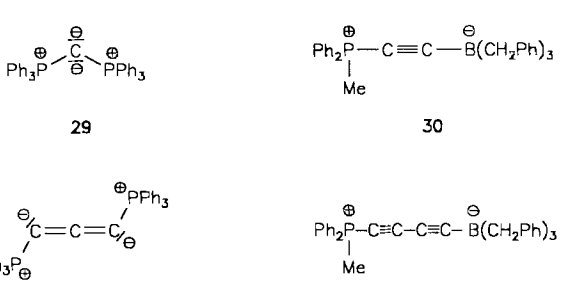
20 (SS,RR) 21 (SR,RS) (SS,RR) 22 (SR,RS)



Compounds of the type **21** are also known with a range of other organometallic terminal groups.[3] Emphasis here should also be placed on complexes with different terminal transition metal fragments at the 1,3-butadiyne-1,4-diyl bridging ligands.[13, 16, 17]

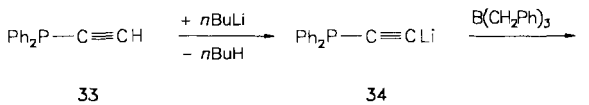
For the preparation of compounds similar to **27**, usually building blocks are employed which already contain a C_4 chain. In this way the coordination of different organometallic terminal groups can be achieved.[16]

23 24 25 26 27



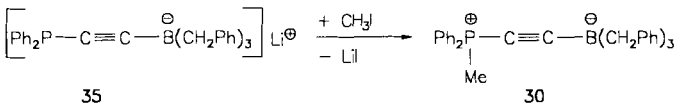
The preparation of polymers in which the C_4 building blocks are linked in a continuous chain as *trans* ligands by ML_2 building blocks is of great interest with regard to new materials.[1, 18] The square-planar coordination exhibited by the d^8 metals (M^{II} ions) makes them suitable for such linkages. An elegant synthesis for such compounds was described previously by N. Hagihara et al., who showed that $[L_2Pt(C{\equiv}C{-}C{\equiv}CH)_2]$ reacts with $[L_2PdCl_2]$ (L = PBu_3) to give the polymer **28**.[18] In this way an ordered series of different metal bridges can be built into the polymer.

28



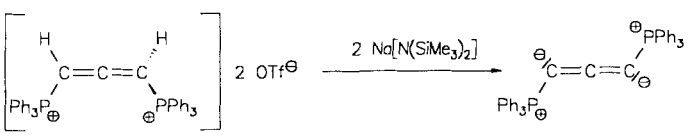
C_n Chains ($n = 1-4$) with Terminal Main Group Element Units

Polyalkyne derivatives X-C_n-Y whose terminal groups X and Y are main group element units can be prepared by numerous, in some cases well-developed, procedures.[1c] The compounds **29**–**32** are particularly interesting examples in phosphorus chemistry.[23–25] The chemistry of these compounds has been intensively studied by the groups of H. J. Bestmann and H. Schmidbaur.



29 30 31 32

The compounds with C_1 or C_3 building blocks can be considered as bis-ylides. The compounds with C_2 or C_4 building blocks are zwitterions with charge centers more widely separated from one another. The preparation of such compounds is exemplified by the synthesis of **30**.[24] The structures of **30** and **32** determined by X-ray analysis support the formulation of the given valence formulae.[24, 25]



33 34

35 30

Whereas the preparation of **30** and **32** is relatively simple, the synthesis of **31** is more difficult. Compound **31** is obtained by the reaction of the allene-1,3-diylbisphosphonium salt **36** with two equivalents of sodium [bis(trimethylsilyl)amide].[25]

36 31

Outlook

The isolation of the compounds described reveals that the highly reactive carbon units C_n ($n = 1-5$) can be stabilized by suitable terminal building groups. The synthesis of these new compounds particularly for those containing organometallic substituents is often surprisingly simple.

The synthesized alkyne complexes offer a fascinating perspective for the preparation of novel organic compounds. In a wider sense it is also conceivable that alkyne-containing metal complexes with conjugated carbon bridges between different terminal groups could be used as signal transformers in nonlinear optical materials (NLO) and perhaps even as molecular wires. Finally, applications in the field of material science may also be possible in which the inherent mechanical stability of the C_n chains plays an essential role.

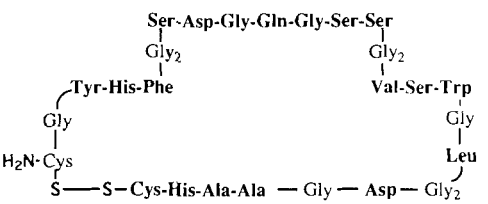
Enzyme Mimics

Anthony J. Kirby*

One of the great intellectual challenges presented to Science by Nature is a proper understanding of how enzymes work. At one level we can "explain" enzyme catalysis—what an enzyme does is bind, and thus stabilize selectively, the transition state for a particular reaction.[1] But our current level of understanding fails the more severe, practical test—that of designing and making artificial enzyme systems with catalytic efficiencies which rival those of natural enzymes.

Enzyme mimics have long been high-profile targets for bioorganic chemists. The picture to date has been the familiar one of steady progress, with occasional flashes of inspiration, and a heightening awareness of just how complex the problem is. But two recent reports[2, 3]—approaching the problem from completely different directions—claim catalytic efficiencies in artificial systems which are extraordinary in terms of conventional wisdom. First we should set the scene.

The "conventional wisdom" is based on the one hand on mechanistic work on enzymes, and on the other hand on (mostly separate) studies of binding and catalysis in simpler, artificial systems. Enzymes are of course more than just highly evolved catalysts: they also recognize and respond to molecules other than their specific substrate and product, as part of the control mechanisms of the cell. But the evolution of enzyme mimics is at a stage where the efficient combination of binding and catalysis is the main objective. A starting point may be a system which shows efficient binding; or the mechanism of the reaction concerned, since it is the rate-determining transition state which is the most important target for the binding process. Eventually the two approaches must converge if a genuine enzyme mimic is to emerge. This sort of work holds out the promise of artificial catalysts, which may be more robust than proteins, for unnatural reactions of interest. On the other hand, the most natural basis for an enzyme mimic is inevitably a real enzyme. All these approaches are currently producing interesting results.



Enzyme-Based Mimics

It is possible to modify a natural enzyme, chemically or more commonly by the methods of protein engineering, in such a way that its specificity is altered, even to the point that the modified system will catalyze a new reaction. Such systems are modified enzymes rather than enzyme mimics, which to qualify in this context should have been constructed artificially.

When it became possible to identify the functional groups in enzyme active sites it was natural to look at small peptides containing active-site sequences of amino acids as possible catalysts. The results of this sort of work were uniformly negative. We know now that a working enzyme active site has its functional groups disposed in a specific, dynamic three-dimensional array, with significant interactions with the rest of the protein; this cannot successfully be modeled in two dimensions.

A true enzyme-based mimic might try to reproduce the three-dimensional arrangement of the functional groups of the active site in a synthetic framework. The reasoning is simple; turning the idea into real molecules less so. However, what appears to be a major success for this approach is the report of Atassi and Manshouri[2] on the preparation of two so-called "pepzymes", modeled from the active site structures of trypsin and chymotrypsin by "surface-simulation". This involved the design and synthesis of a series of relatively small (29 residue) peptides containing the key catalytic and binding amino acid sequences of the enzymes. These were connected by glycine spacers so as to model the three-dimensional arrangement known from the X-ray structures of the enzyme and its complexes with substrate analogues. An early version which showed some trypsin-like binding activity was modified systematically to the point where the peptide (native active site residues indicated in bold) shows extraordinary catalytic activity, specifically in the cyclic (disulfide) form **A**.

A

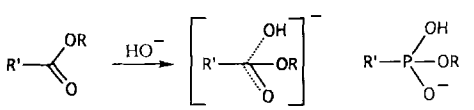
Not only does this molecule hydrolyze the simple trypsin "substrate" *N*-tosyl-L-arginine methyl ester with k_{cat} and K_m comparable to those of the native enzyme, but it also hydrolyzes test proteins to give similar peptide profiles. A peptide closely related to **A** based on the chymotrypsin active site had similar activity and the expected, different specificity.

It must be said that this level of activity is surprising, especially against amide bonds, and intensive efforts to repeat the results are under way. If confirmed this work will be seen as an important advance: the design stage may be complex, but with modern synthetic methods peptides of this sort of size are quite reasonable synthetic targets. A practical limitation, as always with enzyme-based mimics, is that—at this stage of development at least—complete success simply means doing a reaction as well as an available natural catalyst.

Mechanism-Based Mimics

At the other extreme, it is possible to achieve enormous rate accelerations in quite simple systems by by-passing the binding process and making reactions intramolecular, that is, by bringing the functional groups concerned together on the same molecule.[4] Typically, making the reaction of interest part of a thermodynamically favorable cyclization can produce systems in which the extraordinarily stable groups of structural biology (amides, glycosides, and phosphate esters have half-lives of many years under physiological conditions near pH 7) can be

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0551 $ 10.00+.25/0

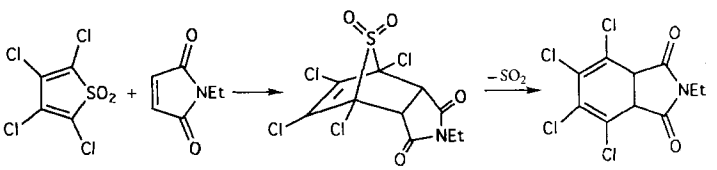


cleaved in a fraction of a second. Detailed chemical mechanisms of catalysis can then be worked out for specific reactions, studied under the same conditions and proceeding at similar rates as the same reactions between the same two (or more) functional groups in enzyme active sites. Two measures of catalytic efficiency are relevant: the effective molarity (EM), that is the effective concentration of the catalytic group, that would be needed to make an intermolecular reaction go at the rate of the intramolecular one,[4] and, of course, the absolute rate of the reaction. Because reactions in enzyme active sites are very fast: fast enough for many enzymes to have reached evolutionary perfection, defined by Albery and Knowles[5] as catalytic efficiency so high that the rate-determining step of the reaction concerned is diffusion away of the products.

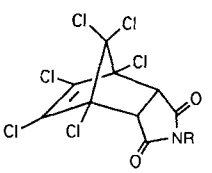
EM values as high as $10^{13}-10^{14}$ M—meaning half-lives of the order of a second—can be attained in systems where on ordinary aliphatic amide is forced into close proximity with a COOH group,[5, 6] or a phosphate diester unit with a neighboring OH,[7] and it is possible to define detailed mechanisms for such model reactions. These serve as an essential basis for the discussion of the mechanisms of the same reactions in enzyme active sites, or for the design of enzyme mimics. It is not possible– so far at least—to attain rate-enhancements of anything like this magnitude when the reacting groups are brought together by noncovalent binding.

Binding-Step Based Mimics

A minimum requirement for a true enzyme mimic is a binding interaction between two molecules prior to the catalytic reaction, indicated by Michaelis–Menten kinetics. Intramolecular systems can support very rapid reactions because we can use synthesis to bring groups together into close and unavoidable proximity. But an enzyme must select and bind its substrate noncovalently in a dynamic equilibrium. The chemistry of the molecular recognition processes involved is one of the most active areas of current research, and a popular topic for meetings,[8, 9] highlights,[10] and reviews.[11] As with chemical catalysis, much of our understanding of noncovalent interactions comes from studies of simple systems designed to answer specific questions about the basic processes. More directly relevant to the development of enzyme mimics are systems designed to achieve catalysis by binding, that is without specific catalytic groups built in. These fall into two important classes: synthetic hosts designed to bring two reactants into close and productive proximity, and most catalytic antibodies.



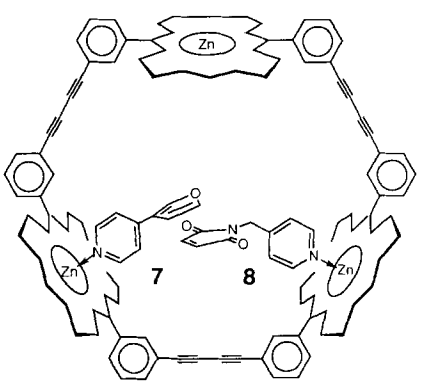
The majority of catalytic antibodies[12, 13] so far known have been designed to catalyze the hydrolysis of carboxylic acid derivatives, and have been raised against phosphonate haptens **2**, which model the structure of the tetrahedral transition states involved (**1**). Catalysis of ester hydrolysis is rather reliably obtained with suitable haptens (and substrates), with the nucleophile coming from the solvent. More ambitious systems with catalytic groups built-in can, in principle, be obtained by careful



1 **2**

hapten design (coupled with a large slice of luck); or from an existing catalytic antibody by protein engineering. This is an area of definite promise, and much current activity.

Careful hapten design also allowed the preparation of an antibody that catalyzed the Diels–Alder reaction of tetrachlorothiophene dioxide **3** and *N*-ethylmaleimide.[14] Again, catalysis results simply from productive binding (an EM of >110 M is estimated): turnover depends on the instability of the initial adduct **4**, which loses SO_2 very rapidly to give the product **5**. This avoids product inhibition, which is a common problem with such potential catalytic systems: the hapten **6** ($R=(CH_2)_5CO_2H$) is a reasonable transition state analogue, but geometrically very different from the final product.

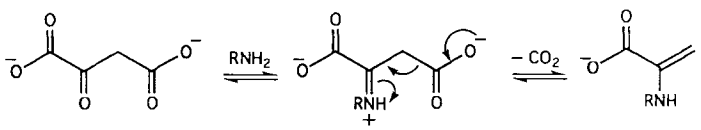


3 **4** **5**

6

The Diels–Alder reaction can also be catalyzed by simple artificial systems. A recent example is the reversible reaction between **7** and **8**, which is accelerated by (stoichiometric amounts of) a cyclic zinc-porphyrin trimer host which binds pyridine derivatives inside the cavity.[16] The product is the *exo*

7 **8**

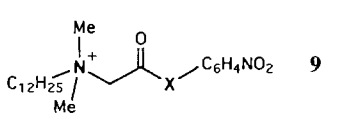


adduct, produced up to 1000 times faster than the corresponding *endo* isomer (which is obtained as the kinetic product in the absence of the macrocycle). This corresponds to an EM of about 20 M. The system is not catalytic because of product inhibition (as was an early example using the cavity of a cyclodextrin as host[17]).

Enzyme Mimics Showing Binding and Catalysis

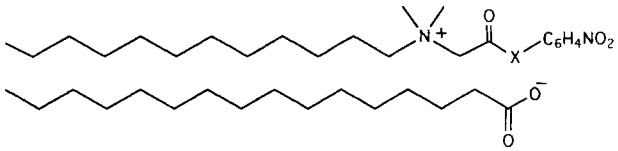
Many of the most successful enzyme mimics have involved functionalized cyclodextrins, and the work of Breslow et al., in

particular, is familiar to anyone who has followed the field.[18] These hosts bind aromatic rings within a hydrophobic cavity. In another seminal contribution Lehn et al.[19, 20] used polyammonium macrocycles to catalyze phosphate transfer reactions of ATP, demonstrating that multiple hydrogen bonds can also be an effective source of binding between flexible systems in aqueous solution.



A different approach has been reported by Benner et al.,[20] who based the design of a synthetic decarboxylase on the known properties of proteins and the mechanism of amine-catalyzed decarboxylation of β-ketoacids. Their enzyme mimics are 14-residue peptides (called oxaldie 1 and 2) based on leucine and lysine, in a sequence known to favor α-helix formation, and thus expected to adopt protein-like conformations, with a hydrophobic core and a hydrophilic exterior. They catalyze the decarboxylation of oxalylacetate by the expected mechanism (see Scheme 1), with the cationic lysine side chains presumably involved in binding the two carboxylates of both substrate and transition state (acetoacetate, with a single carboxylate group, is not a substrate). Michaelis–Menten kinetics are observed and

Scheme 1. Decarboxylation of oxalylacetate catalyzed by an enzyme mimic. R = lysine side chain.



imine formation is 10^3–10^4 times faster than with simple amine catalysts. Also the activity does indeed seem to depend on the degree of α-helix formation.

The simplest, and one of the most remarkable, new enzyme mimics has emerged from a piece of "lateral thinking" by Menger and Fei.[3] No synthesis is involved. These authors simply mixed long-chain carboxylic acids, amines, alcohols, and alkylimidazoles, of the sort known to form aggregates, and eventually micelles, in aqueous solution: then screened large numbers of such mixtures for catalytic activity. The test reaction was the hydrolysis of the reactive ester **9** (X = O), which is easily followed above pH 7 by the release of the *p*-nitrophenolate chromophore. Some of the mixtures used effected the hydrolysis of **9** (X = O) at rates too fast to measure manually. Remarkably this was also true in the presence of a single component when this was the hexadecanoate anion, and this system also effects the hydrolysis of the *p*-nitroanilide (**9**, X = NH). This is an activated amide, but one that is not hydrolyzed detectably in the presence of 0.2 M acetate at pH 7 (25 °C). But under similar conditions, in the presence of just 2×10^{-5} M hexadecanoate its half-life is only three minutes.

9

Only nucleophilic catalysis can account for such an efficient process.[4] No EM can be calculated as no data are available for a suitable comparison, but hexadecanoate is at least 10^8 times more effective than acetate. Interestingly the reaction is stoichiometric: though a mixed anhydride is almost certainly an intermediate, its hydrolysis must be rate-determining in the overall hydrolysis of the anilide. The authors suggest that the reaction takes place in submicellar aggregates or "clumps", in which hydrophobic association of the long alkyl chains brings anilide carbonyl and hexadecanoate carboxylate groups into close and remarkably productive proximity (see Scheme 2). (Simply adding three methylene groups to the substrate [**9**, X = $(CH_2)_3NH$] eliminates the observed reaction.)

Scheme 2. Hydrophobic association between **9** and hexadecanoate.

Two points are of special interest here: the high reactivity, which is much greater than previously observed for such apparently loosely-associated systems: and the principle of screening large numbers of simple systems, rather than actually synthesizing complex, carefully designed ones. The newer approach supplements existing ways of thinking, and practical applications may result.

Molecular Solids as Ligands in Organometallic Chemistry: $[Cp^*_6Ti_6Na_7F_{19}\cdot 2.5thf]$ ($Cp^* = C_5Me_5$) and $[Cp^*_4Ti_4Mg_2F_{12}\cdot 7thf]$, Links Between Ionic Solids and Organometallic Compounds**

Feng-Quan Liu, Annja Kuhn, Regine Herbst-Irmer, Dietmar Stalke, and Herbert W. Roesky*

We previously reported the isolation of inclusion complexes from the reaction of $[Cp^*TiF_3]$ (**1**) ($Cp^* = C_5Me_5$) with NaF in acetonitrile. These complexes can be considered as analogues of crown ethers;[1] encapsulation of the Na^+ ion by two $[(Cp^*TiF_3)_2F]^-$ fragments corresponds to that in $[Na([12]crown\text{-}4)_2]^+$. Here, the nucleophilic host has a fluoride surface which surrounds the sodium ion. The reaction of $[Cp^*TiF_3]$ with sodium metal in THF in a 1:1 molar ratio results in the formation of NaF and the expected reduction of Ti^{IV} to Ti^{III}. Surprisingly, no NaF precipitates out during this synthesis. If the solution is left to stand for an extended period of time, green crystals of composition $[Cp^*_6Ti_6Na_7F_{19}\cdot 2.5thf]$ (**2**) are formed.

The structure of **2** has been determined by a single-crystal X-ray analysis,[2] and its central inorganic structural unit is depicted in Figure 1. The structure has a noncrystallographic two-fold axis which runs through Na1 and F19. The six Cp^*TiF_2 groups almost completely enclose seven NaF molecules such that a "molecular NaF structure" is formed within the aggregate. Here, however, a different coordination is found than that in crystalline NaF. Only F19 is octahedrally coordinated; all other fluorine atoms exhibit lower coordination. Thus, F9 and F15 have the coordination number five, F3 and F6 the coordination number four, and the remaining fluorides exhibit a coordination number of three. Although Na1, Na6, and Na7 are six-coordinate, their coordination polyhedra are distorted in such a way as to prohibit their description as octahedra. While Na2 and Na3 are seven-coordinate, the peripherally "naked" atoms Na4 and Na5 are each coordinated to four fluorine atoms and one oxygen atom (from a THF molecule). The average Na–F bond length (234.9 pm) is similar to that in solid NaF (231 pm),[3] but significantly shorter than that in $[tBu_2SiFNaNtBu]_2$ (243.4 pm and 332.5 pm),[4] $[2,4,6\text{-}(CF_3)_3C_6H_2ONa\cdot 2thf]_2$ (266.4 and 272.0 pm),[5] or $[2,4,6\text{-}(CF_3)_3C_6H_2SNa\cdot 2thf]_x$ (243.4 to 257.1 pm).[5] The Ti–F distances in **2** (204.6 pm) are similar to those in $[(Cp_2TiF_2)_3Ti]$ (209.4 pm; $Cp = C_5H_5$).[6] In the crystal of **2**, a THF molecule is trapped between two $[Cp^*_6Ti_6Na_7F_{19}\cdot 2thf]$ units in such a way that the molecule is disordered with its oxygen atom directed towards one of the sodium atoms (Fig. 2). The Na–O bond to this molecule is about 30 pm longer than those to the rigidly coordinated THF molecules.

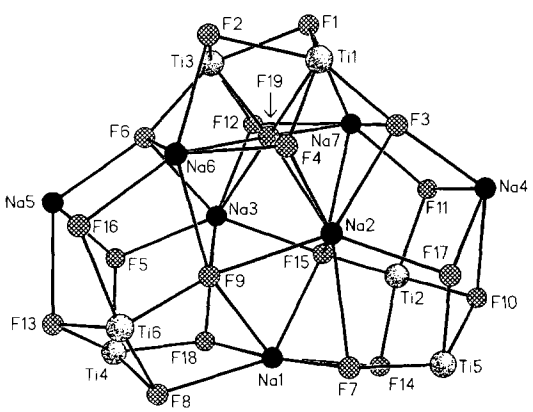

Fig. 1. Structure of the central inorganic unit of **2** in the crystal. Selected bond lengths [pm]: Ti–F 204.6* (194.7–215.2), $Ti\text{–}Cp^*_{(center)}$ 203.2*, Na–F 234.9* (215.3–275.1), Na4–O1 229.1(4), Na5–O2 231.9(4), Na7–O9 263(2). The values marked with a * are average values.

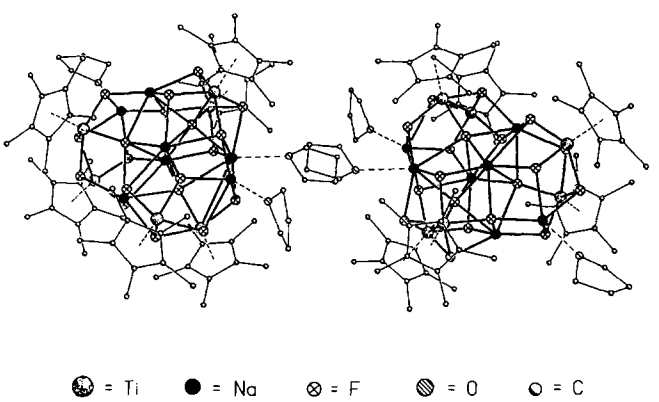

Fig. 2. Arrangement of two molecules of **2** about a trapped THF molecule.

We then investigated whether the coordination pattern found in **2** would also be exhibited by Group 2 elements. $[Cp^*TiF_3]$ (**1**) reacted with magnesium metal in THF to form **3** [Eq. a]. In this

$$4\,[Cp^*TiF_3] + 2\,Mg \xrightarrow{thf} [Cp^*_4Ti_4Mg_2F_{12}\cdot 7thf] \qquad (a)$$

1 → **3**

reaction, two magnesium atoms are incorporated between four $[Cp^*TiF_3]$ units. The single-crystal X-ray structure analysis of **3**[2] (Fig. 3) revealed a six-coordinate magnesium atom similar to that in solid MgF_2.[3] Two of the six coordination sites in **3**, however, are occupied by THF molecules. Whereas the THF molecules containing O1 and O2 are each bound to one magnesium atom as terminal ligands, the O3-containing THF molecule bridges the two Mg atoms. To our knowledge, such μ_2-

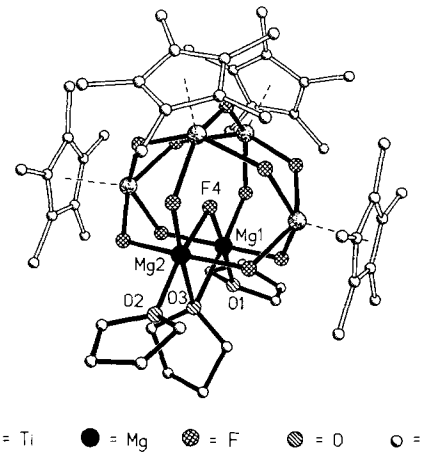

Fig. 3. Structure of **3** in the crystal. Selected bond lengths [pm]: Ti–F 202.5* (200.4–203.6). Ti–$Cp^*_{(centerr)}$ 204.6*. Mg–O(1,2) 206.0*, Mg1–O3 226.8(3), Mg2–O3 235.8(4), Mg1–F4 202.6(3), Mg2–F4 201.8(3), Mg–F 190.5* (190.0–190.9). The values marked with a * are average values.

bridging THF molecules in alkaline earth metal compounds are unknown to date. Although the Mg–F distances to the Mg bridging fluorine atom F4 (202.2 pm) correspond to the distances in the rutile lattice of MgF_2 (205 pm),[7] the remaining Mg–F bond lengths in **3** (mean 190.5 pm) are significantly shorter. The central $Ti_4Mg_2F_{12}$ inorganic core is outwardly shielded by both the Cp* groups and the coordinated THF molecules. Four Ti, two Mg, and twelve F atoms build a cage-like framework whose cavity has a μ_2-bridging fluorine atom (Mg1–F4–Mg2) projecting into it.

With these examples, we have shown for the first time that molecular solids can function as ligands in organometallic chemistry. Continuing investigations are aimed at determining how the size of the aggregates can be influenced by, for example, changes in the ligands, the solvent, or through template effects as well as whether corresponding oxide systems can be prepared.

Experimental Procedure

2: A solution of **1** (0.72 g, 3 mmol) in THF (40 mL) was added dropwise to a suspension of Na (0.07 g, 3 mmol) and mercury (10 g) in THF (20 mL) at 0 °C. The reaction must be carried out under careful exclusion of water and oxygen. The mixture was stirred for 12 h, filtered, and the solvent was then removed in vacuum. Crystalline **2** (0.52 g, 65% yield) was obtained by recrystallizing the green residue from THF/hexane (20 mL/40 mL). M.p. 204 °C (decomp). The decomposition temperature refers to the solvent-free compound, which is obtained by evacuation of **2** (10^{-2} mbar, 25 °C, 12 h). Correct elemental analyses. IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1497(m), 1260(m), 1061(s), 1027(s), 815(s), 545(s), 507(s), 494(s), 471(s).

3: A solution of **1** (0.72 g, 3 mmol) in THF (40 mL) was added dropwise to Mg (0.35 g, 14 mmol) in THF (20 mL) under an inert atmosphere. The magnesium was first activated with $HgCl_2$ (5 mg). The mixture was stirred for 12 h at room temperature, filtered, and the solvent was then removed in vacuum. The residue was recrystallized from THF/hexane (40 mL/20 mL) which yielded 0.5 g of **3** (75%). M.p. 240 °C. Correct elemental analyses from the solvent-free compound (10^{-2} mbar, 25 °C, 12 h). IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1498(m), 1260(m), 1031(s), 801(s), 519(s); MS(El) *m/z*: 873 (M–Cp*, 1.2%), 135 (Cp*, 100%).

[2] Crystal data for **2**: $C_{68}H_{100}F_{19}Na_7O_2Ti_6 + 1/2$ thf, $M_r = 1800.91$, triclinic, space group $P\bar{1}$, $a = 1195.0(2)$, $b = 1407.7(2)$, $c = 2670.9(5)$ pm, $\alpha = 80.99(1)$, $\beta = 77.67(1)$, $\gamma = 72.46(1)°$, $V = 4.165(1)$ nm^3, $Z = 2$, $\rho_{calcd} = 1.436$ $g\,cm^{-3}$, F(000) = 1860, $\lambda = 71.073$ pm, $\mu(Mo_{K\alpha}) = 0.668$ mm^{-1}. The data were collected on a Stoe-Siemens-Huber four-circle diffractometer. The intensities were determined at −120 °C from a rapidly cooled crystal in a drop of oil [8] having dimensions of $0.4 \times 0.3 \times 0.2$ mm by the $2\theta/\omega$ method over the range $8° \leq 2\theta \leq 45°$. A semiempirical absorption correction method was applied to the 10922 independent reflections from the 18706 collected. 10920 of the independent reflections and 5683 restraints were used in the refinement of 1143 parameters. Largest minimum and maximum in the final difference-Fourier synthesis: 460 and −480 $e\,nm^{-3}$, respectively. $R1(F > 4\sigma(F)) = 0.046$ and $wR2 = 0.128$ (for all data). **3**: $C_{52}H_{84}F_{12}Mg_2O_3Ti_4 + 4$ thf, $M_r = 1513.83$, monoclinic, space group $P2_1/m$, $a = 1470.9(1)$, $b = 1679.8(2)$, $c = 1539.5(2)$ pm, $\beta = 105.53(1)°$, $V = 3.6649(7)$ nm^3, $Z = 2$, $\rho_{calcd} = 1.372$ $g\,cm^{-3}$, F(000) = 1600, $\lambda = 71.073$ pm, $\mu(Mo_{K\alpha}) = 0.517$ mm^{-1}. The data were collected on a Stoe-Siemens-AED four-circle diffractometer. The intensities were determined at −120 °C from a drop of oil [8] having dimensions of $0.2 \times 0.2 \times 0.1$ mm by the $2\theta/\omega$ method over the range $8° \leq 2\theta \leq 50°$. From the 6666 independent reflections out of the 8199 collected, 6663 were used together with 1416 restraints in the refinement of 696 parameters. Largest minimum and maximum in the final difference-Fourier synthesis: 600 and −380 $e\,nm^{-3}$, respectively. $R1(F > 4\sigma(F)) = 0.048$ and $wR2 = 0.140$ (for all data). The values for $R1$ and $wR2$ were defined as $R1 = \Sigma||F_o| - |F_c||/[\Sigma|F_o|]$; $wR2 = \{[\Sigma w(F_o^2 - F_c^2)^2/[\Sigma w(F_o^2)^2]\}^{1/2}$. The structures were solved by direct methods (SHELXS-90) [9] and refined by least-squares methods (SHELXS-93) [10]. The hydrogen positions were refined by a riding model in which CH_3 groups can rotate about their local threefold axes. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ on quoting the complete literature citation.

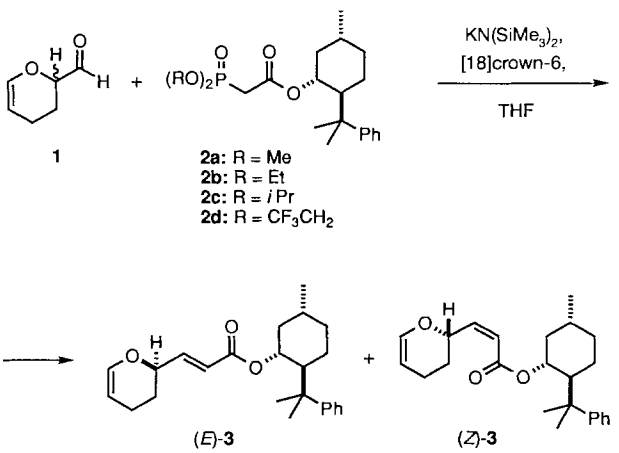
Kinetic Resolution of the Acrolein Dimer by Asymmetric Horner–Wadsworth–Emmons Reactions**

Tobias Rein,* Nina Kann, Reinhard Kreuder, Benoit Gangloff, and Oliver Reiser*



Dedicated to Professor Björn Åkermark on the occasion of his 60th birthday

The Diels–Alder dimer of acrolein **1**[1] is available in bulk quantities and has great potential as a synthetic building block[2] because of its aldehyde and enolether functionality.

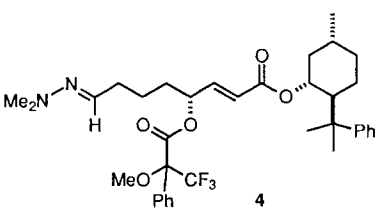
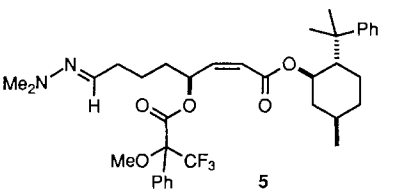
[**] We thank the Swedish Natural Sciences Research Council, the Deutsche Forschungsgemeinschaft (Re 948/1-2), Carl Tryggers Foundation for Scientific Research, the Foundation Bengt Lundqvists Minne, Helge Axson Johnsons Foundation, and the Royal Institute of Technology for financial support. Dr. D. Yu, Degussa AG, Germany, is acknowledged for a generous sample of aldehyde **1**. Travel grants from the Erasmus program for student exchange (B. G.) and the Bundesamt für Ausbildungsförderung Flensburg (R. K.) are gratefully acknowledged. We also thank Professors B. Åkermark, Royal Institute of Technology, Stockholm, A. de Meijere, Göttingen, and P. Helquist, University of Notre Dame IN, USA, for their continued interest and support, and Ms. Gurli Hammarberg for assistance with spectroscopic analyses.



However, **1** has not yet found wide application since it is not available in optically pure form. As part of our ongoing studies regarding asymmetric alkene synthesis[3] and the utilization of vinyl-substituted dihydropyrans as homoaldol equivalents,[4] we have studied kinetic resolutions of racemic **1** by reactions with chiral phosphonate reagents. In all previously reported cases of kinetic resolution by asymmetric alkene synthesis,[5] the substrates used have been ketones. In this paper, we report that kinetic resolutions of the aldehyde **1** can give high diastereoselectivities, and furthermore that either (*E*)-**3** or (*Z*)-**3** can be obtained as the main product.



Initial studies were performed by using the chiral phosphonate **2a**[6] which has previously been used[7] in asymmetric alkene synthesis with ketone substrates, and has also given good results in our studies of reactions with *meso* dialdehydes.[3] The reaction of **1** with **2a** gave high diastereoselectivities for both (*E*)-**3** and (*Z*)-**3** (Table 1, entry 1), however, the (*E*)/(*Z*) ratio was only modest (39:61).[8, 9] To study the influence of variations in the phosphonate structure on the selectivity,[10] the new phosphonate **2b**[11] and the previously known reagent **2c**[6] were synthesized in the same manner as **2a**. Use of **2b** favored formation of the (*E*) isomer (entry 2), and performing the reaction at lower temperature (entry 3) gave a good yield of (*E*)-**3**[11] with high diastereomeric purity (88% *de*) after chromatography. Reactions with phosphonate **2c** (entries 4 and 5) gave even higher (*E*)/(*Z*) selectivity, but the diastereoselectivities were lower.[12]

It is known that the formation of (*Z*) alkenes in Horner–Wadsworth–Emmons reactions is favored by using trifluoroethoxy substituents on phosphorus.[13] In order to enable selective preparation of the (*Z*) product, we thus synthesized the new phosphonate reagent **2d**[11] by the same method as used for the other reagents **2**. To our delight, **2d** gave high diastereoselectivity for the (*Z*) product, together with useful double bond selectivity (entries 6 and 7). After chromatography, high yields of (*Z*)-**3**[11] with excellent diastereomeric purity (96–98% *de*) were obtained.

Our assignments of the absolute configurations of the condensation products are based on the NMR analysis[14] of the Mosher ester derivatives **4** and **5** obtained from (*E*)-**3** and (*Z*)-**3**, respectively, by straightforward transformations. This analysis shows that the (*E*) and (*Z*) products are formed from different enantiomers of the starting material **1**. Further support for this conclusion comes from the reaction in entry 8, in which only one equivalent of **1** was used, also indicating that the (*E*) and (*Z*) isomers are formed from different enantiomers of the starting aldehyde. The alternative explanation of a fast racemization of the aldehyde in the course of the reaction is unlikely since similar (*E*)/(*Z*) selectivites and yields would be expected in entries 6 and 8 if racemization was faster than the condensation process.

Concerning the mechanistic reasons behind the observed selectivities, there are several points that need to be investigated further before any well-founded rationalizations can be made.[10] It is not clear which reaction step is the rate-determining one for a given combination of reactants, the initial addition of the phosphonate anion to the aldehyde or the subsequent elimination step. Also, the analysis is complicated by the fact that each alkene isomer might in theory have been formed from either of two different diastereomeric β-alkoxy anion precursors.

We are presently studying the possibility of using other types of aldehydes as substrates in these reactions, as well as synthetic applications. We believe that kinetic resolutions of this type should have considerable synthetic potential.

Experimental Procedure

To a solution of the phosphonate reagent **2** (1.1 equiv, 0.01–0.02 M) and [18]crown-6 (5 equiv) in THF at −78 C under argon was added 1.0 equiv of $KN(SiMe_3)_2$ (0.5 M in toluene). After 30 min, the resulting solution/slurry was added by cannula to a precooled (−78 or −100 C) solution of **1** (2.1–3.0 equiv) in THF. The reaction mixture was stirred for 2–4 h at −78 or −100 C and then quenched with 1 M acetic acid in MeOH followed by pH 7 phosphate buffer. Extractive workup (ethyl acetate), drying ($MgSO_4$), and concentration gave the crude condensation product which was purified by flash chromatography on silica gel by using 2% EtOAc in hexanes. Selected ^{1}H NMR data (400 MHz, $CDCl_3$): (*E*)-**3**: δ = 6.57 (dd, J = 15.8, 4.4 Hz, 1 H, C*H*=CHC(O), major diastereomer), 6.37 (dd, J_1 = 5 Hz, J_2 not measurable (overlapping signals), 1 H, C*H*=CHC(O), minor diastereomer), 6.35 (dt, J = 6.2, 1.9 Hz, 1 H), 5.50 (dd, J = 15.7, 1.8 Hz, 1 H), 4.84 (td, J = 10.7, 4.4 Hz, 1 H), 4.70 4.66 (m, 1 H), 4.40–4.34 (m, 1 H); (*Z*)-**3**: δ = 6.33 (dd, J = 6.2, 1.7 Hz, 1 H), 6.11 (dd, J = 11.7, 7.3 Hz, 1 H), 5.22 (tm, J = 8.1 Hz, 1 H), 5.16 (dd, J = 11, 2 Hz, 1 H, CH=C*H*C(O), minor diastereomer), 5.09 (dd, J = 11.8, 2.0 Hz, 1 H, CH=C*H*C(O), major diastereomer), 4.78 (td, J = 10.7, 4.4 Hz, 1 H), 4.73 4.68 (m, 1 H).

[8] Since the aldehyde **1** is quite sensitive towards decomposition, a slight excess (2.1 3 equivalents) was used. We have not determined the *ee* of remaining unreacted aldehyde in any case.
[9] Only the major diastereomers of (*E*)-**3** and (*Z*)-**3** [i.e. (*R*,*E*)-**3** and (*S*,*Z*)-**3**, respectively] have been illustrated. The (*E*)/(*Z*) ratio for the crude product refers to the total amounts of (*E*) and (*Z*) products. Strictly speaking, all four isomeric products are diastereomers; for clarity, however, we have only given diastereomeric ratios between products with the same alkene geometry [that is the comparison of (*R*,*E*)-**3** with (*S*,*E*)-**3** and of (*S*,*Z*)-**3** with (*R*,*Z*)-**3**].
[10] For recent reviews covering the Horner–Wadsworth–Emmons reaction, including mechanistic aspects, see: a) B. E. Maryanoff, A. B. Reitz, *Chem. Rev.* **1989**, *89*, 863–927; b) S. E. Kelly in *Comprehensive Organic Synthesis*; *Vol. 1* (Eds.: B. M. Trost, I. Fleming), Pergamon Press, Oxford, **1991**, pp 761–773.
[11] Spectroscopic and analytical data (^{1}H and ^{13}C NMR, IR, MS, elemental analysis) in accordance with the structure were obtained for this compound.
[12] An initial attempt to increase the (*E*) selectivity further by using phosphonate **2b** in combination with *n*-butyllithium as base, instead of potassium hexamethyl disilazide (KHMDS)/[18]crown-6, gave a much lower diastereomeric ratio for the (*E*) product.

Ring Opening of Cyclopropane at 10 K**

Günther Maier* and Stefan Senger

We recently reported the irradiation of methylenecyclopropane in a halogen-doped xenon matrix, which surprisingly leads to trimethylenemethane.[1, 2] To explore the potential of this unusual C–C bond cleavage, we have subjected cyclopropane **1** to the same conditions. This molecule does not absorb light in the UV region and has a considerable energy barrier to thermally induced ring opening.[3] Nonetheless, even at 10 K a C–C bond was easily broken with this new fragmentation method.

Cyclopropane (**1**) is inert at 10 K with respect to irradiation with 254 nm light in a xenon matrix. This changes drastically when bromine is mixed into the xenon matrix (ratio bromine:cyclopropane:xenon ≈ 1:1.5:1000), and subsequently bromine atoms are generated by irradiating with light (254 nm) from a mercury-vapor lamp. After only 30 min, bands corresponding to propene (**3**) and allyl radical (**5**)[4] are visible in the IR spectrum. After 24 h irradiation, the cyclopropane is completely consumed. Alongside the bands for **3** and **5**, those from allene (**6**), propyne (**9**), and small amounts of acetylene and methane can be seen in the IR spectrum.[5] Interestingly, irradiation of **1** in a xenon matrix doped with Cl$^\bullet$, Br$^\bullet$ or I$^\bullet$ at wavelengths greater than 270 nm (mercury-vapor lamp with cutoff filter) produces propene (**3**) exclusively. The other products are only formed if the irradiation is changed to a shorter wavelength (254 nm). Control experiments (dependence of the appearance and disappearance of the relevant signals on wavelength and irradiation time) show that the first observable product is always propene (**3**). The allyl radical (**5**) is formed from this product by loss of a hydrogen atom. Radical **5** splits off a second H atom in forming allene (**6**), which then isomerizes to propyne (**9**, Scheme 1). A C–C bond cleavage can also occur in **5**, which leads eventually to acetylene and methane (probably via a methyl radical).

Scheme 1.

If the allyl radical (**5**) is generated by pyrolysis of a mixture of allyl iodide and xenon gas at 850 °C and immediately cooled to 10 K, then the product mixture subsequently formed in the I$^\bullet$-doped xenon matrix by irradiation is dependent on the wavelength of light used. Irradiation at 254 nm gives, as in the presence of Br$^\bullet$ atoms, allene (**6**), propyne (**9**), acetylene, methane, and, contrary to expectations, traces of propene (**3**) by trapping of an H atom.

The initial step in the transformation of cyclopropane (**1**) should be a C–C bond cleavage. The dissociation energy of the C–H bond is roughly 30 kcal mol^{-1} higher than for the C–C bond, so formation of the cyclopropyl radical (**4**) is unlikely. In spite of this, we examined the behavior of **4** in a halogen-doped matrix. The cyclopropyl radical **4**[6] was produced by irradiation into the long wavelength band of the allyl radical **5** at

(λ_{max} = 408.5 nm[4a]). This isomerization also occurs relatively quickly (1 h) when **5** is irradiated at >320 nm (mercury-vapor lamp with cutoff filter) in an I$^{\bullet}$-doped xenon matrix. A rapid reverse reaction of **4** to **5** is observed if the wavelength is subsequently changed to 254 nm. However, it cannot be concluded that propene (**3**) formation from irradiating cyclopropane (**1**) occurs by the pathway **1** → **4** → **5** → **3**, because the quantity of propene produced by the irradiation of cyclopropane is much greater than that produced in the irradiation of allyl radical **5**, carried out in a control experiment.

In addition to cyclopropane, cyclopropene (**7**) was also irradiated under the same conditions (Scheme 1). In the gas phase, **7** shows an UV absorption maximum at 190 nm[7] and also a noticeable end absorption above 200 nm. As a consequence, **7** is not stable with respect to 254 nm light in an argon matrix and affords allene (**6**) and propyne (**9**).[8] This photoisomerization proceeds much more easily in a xenon matrix. However, **7** is stable if the irradiating wavelength is 313 nm. In a Br$^{\bullet}$-doped xenon matrix, **7** is efficiently isomerized to **6** and **9** at both wavelengths, but faster at the shorter wavelength. Use of light of 254 nm leads to almost complete conversion after 2.5 hours.

What is the mechanism for the ring-opening of cyclopropane (**1**) and cyclopropene (**7**)? Our working hypothesis is the following: initially, exciplexes of type **10** are formed by excitation of the available halogen atoms (Scheme 2). This species is a hole/

Scheme 2.

anion pair in which the hole is delocalized in the valence band of the xenon and the anion is fixed. When no other partner is available, **10** relaxes to the more stable exciplex **11** in which the hole is also localized (by self-capture) in the form Xe_2^{+} (as partner to the ion X^-). The formation of **11** is confirmed by observation of the appropriate emissions.[1, 9a, b] The opportunity to perform chemistry with the delocalized hole **10** is new. If a suitable substrate molecule, like **1**, is available as a donor molecule, the delocalized hole in the xenon valence band can perform a capture reaction with it. The localized charge-transfer complex $(Xe_n \leftarrow \mathbf{1})^{\bullet +}$ is well away from the fixed X^- ion. Nonetheless, neutralization between the complex $(Xe_n \leftarrow \mathbf{1})^{\bullet +}$ and X^- can take place, because electron transfer can occur over large distances.[10] The energy stored in the charge separation of the cation radical and anion is thereby released. The energy contained in **12**, which is released instantaneously on neutralization, is sufficient to bring the substrate molecule to such a high vibrational state that bond cleavage results. For **1**, the barrier to be overcome is 65.0 kcal mol^{-1}.[3] This reaction probably proceeds via the diradical **2**,[11] or, starting from cyclopropene **7**, diradical **8** (vinylcarbene)[11] (activation energies E_A (**7** → **9**) = 34.7, E_A (**7** → **6**) = 43.4 kcal mol^{-1}[12]). In this manner the seemingly paradoxical result arises in which, in a thermal reaction at 10 K, **1** and **7** overcome a considerable energy barrier to break a C–C bond. The higher the excitation energy, the further apart the hole **10** and the halogen ion are separated from each other and the greater the stored energy. The following findings support this hypothesis: the formation of the exciplex **10** is indicated by a characteristic absorption maximum (Xe/I$^{\bullet}$: λ_{max} = 280 nm; Xe/Br$^{\bullet}$: λ_{max} = 310 nm; Xe/Cl$^{\bullet}$: λ_{max} = 354 nm). In principle, irradiation with light of this wavelength should be the most efficient for opening cyclopropane (**1**). Strangely, this is not the case. Photoexcitation of **1** with 313 nm light (mercury-vapor lamp, monochromator) in a Br$^{\bullet}$-doped xenon matrix gave absolutely no reaction, even though the wavelength employed corresponds to the absorption optimum. Only after changing to light of higher energy (254 nm) is the opening of **1** to **2** induced.

[2] Doping of the xenon matrix with halogen atoms was carried out either by irradiation of the halogen molecules in the xenon matrix (bromine and chlorine) or by pyrolytic generation of BX$^{\bullet}$ and immediate cooling to 10 K (bromine and iodine). Since then we have discovered that the halogen-doping necessary for converting methylenecyclopropane into trimethylenemethane can also be achieved by irradiation of hydrogen bromide in the xenon matrix. The simultaneously generated H atom forms a Xe_2H^+ type ion with xenon (H. Kunttu, J. Seetula, M. Räsänen, V. A. Apkarian, *J. Chem. Phys.* **1992**, *96*, 5630–5635). These ions as well as the simultaneously formed hydrogen dibromide ion HBr_2^- (M. Räsänen, J. Seetula, H. Kunttu, *ibid* **1993**, *98*, 3914–3918) can be identified by using IR spectroscopy: G. Maier, D. Jürgen, unpublished results.

Buckminsterfullerene Adducts from *Ortho*-Quinodimethanes**

Andreas Gügel, Alexander Kraus,
Jochen Spickermann, Pavel Belik, and Klaus Müllen*

Covalent-bonded fullerene adducts can be synthesized by the reaction of the fullerene C_{60} (**1**) with arynes,[1] carbenes,[2] or

[**] This work was supported by the Bundesministerium für Forschung und Technologie (grant no. 13N6076).

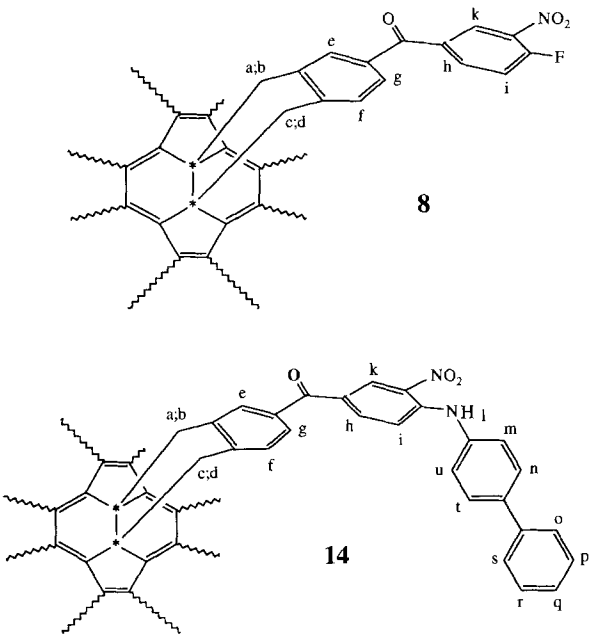
organometallic reagents.[3] The Diels–Alder reaction of **1** with *o*-quinodimethane described by us, leads to thermally stable and soluble cycloadducts **3**,[6] **4**,[6] and **5** in high yields. It has now become apparent that modified fullerenes can be obtained from functionalized *o*-quinodimethanes. The former provide access to a broad spectrum of stable fullerene adducts by subsequent nucleophilic aromatic substitution. Thus it becomes possible to link C_{60} (**1**) in a simple way through bridging groups with chromophoric, electrophoric, or ionophoric units.

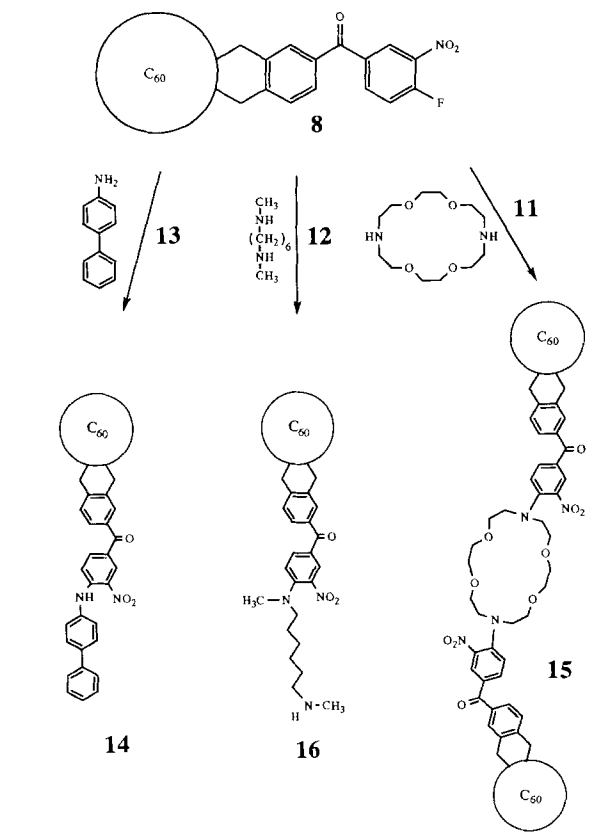
Functionalized derivatives of *o*-quinodimethane[4] can be obtained (under reaction conditions which are tolerated by **1**) by thermolysis of the corresponding derivatives of 3-isochromanone,[5] 1,2-dihydrocyclobutabenzene **2**, or 1,3-dihydrobenzo[*c*]thiophene-2,2-dioxide.[5] The thermolysis is thus an alternative to iodide-induced bromine elimination from 1,2-bis(bromomethyl)benzene derivatives.[6]

If C_{60} (**1**) is treated with 1.5 equivalents of unsubstituted **2** (accessible by flash vacuum pyrolysis of 2-methylbenzyl chloride[7]) in boiling 1,2,4-trichlorobenzene for 8 h, the monoadduct **3** (70%), the bisadduct **4** (27%; each based on converted C_{60}), and traces of the trisadduct **5** are formed. About 10% of unconverted C_{60} was recovered. The separation of the Buckminsterfullerene adducts **3**–**5** was achieved by chromatography on polystyrene gel by using toluene or chloroform as eluents.[5] The regioisomers of **4** and **5**, however, cannot be separated in this way.

Compound **2** can be transformed into **7** by a Friedel–Crafts reaction with the readily accessible carboxylic acid chloride **6**[8] (tin tetrachloride as catalyst *and* solvent). The reaction of **7** with **1** affords in quantitative yield (based on converted C_{60}) a mixture of the mono- (**8**) and bisadduct (**9**) as well as traces of the trisadduct **10**. The [4 + 2]cycloaddition involves exclusively the 6-6 bonds without the occurrence of subsequent ring openings (Fig. 1). The products were separated by chromatography on polystyrene gel with chloroform as the mobile phase. The very good solubility of the adducts in chloroform (ca. 20 mg mL^{-1}) as well as the good peak separation allowed the separation of up to 30 g crude material on a 20 × 600 mm 100 Å polystyrene gel column per day. All adducts **8**–**10** are thermally very stable, as supported by the thermogravimetric analysis of **9**; decomposition takes place first above 400 °C. Compound **8** can be detected in an almost unfragmented form by field desorption mass spectrometry.

The high activation of the fluorine-substituted phenyl ring by the nitro and keto group allows nucleophilic aromatic substitution of adducts **8**–**10** in almost quantitative yields.[9] The highly nucleophilic aliphatic amines such as 7,16-diaza[18]crown-6 (**11**)





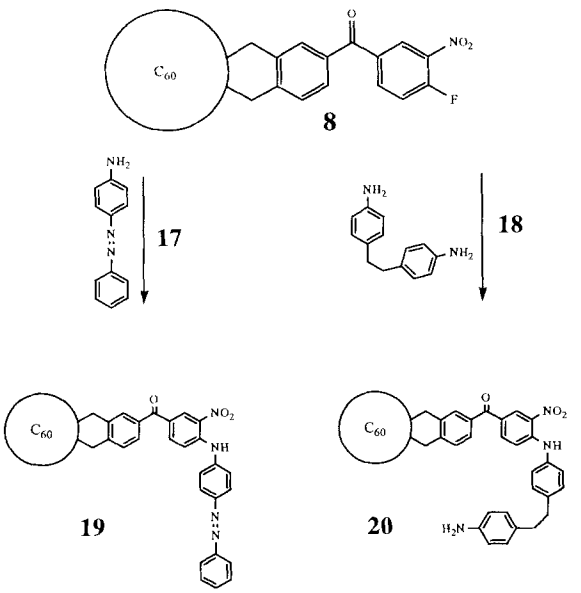


Fig. 1. Sections of **8** and **14** with the protons a–k and a–u, respectively.

or 1,6-bis(methylamino)hexane (**12**) react at room temperature within only a few minutes with **8**, whereas the less nucleophilic aromatic amines such as 4-aminobiphenyl (**13**) require significantly longer reaction times. The resulting mono- or bisfullerene adducts **14** and **16** and **15**, respectively are stable like the starting material **8**. They can also be separated readily from the starting materials by chromatography on polystyrene gel. The reaction of **8** with **11** occurs kinetically in a very unusual way. In contrast

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0560 $ 10.00+.25/0

to the reaction of **12** with **8**, the bis-substitution product **15** forms almost exclusively even when the diamine **11** is present in a 100-fold excess and **8** is added very slowly. On the other hand, the monosubstitution product of **11** is always formed in only trace amounts. Besides the compounds described, a large number of other aromatic amines such as 4-aminoazobenzene (**17**) and 4,4'-diaminobibenzyl (**18**) were treated with **8**, leading to the formation of the adducts **19** and **20**, respectively.

The functionalization method chosen by us is limited by the electronic properties of C_{60} (**1**). Thus, the reaction of **8** with 1,3-benzenedithiol does not give the expected substitution product but leads to oligophenylenedisulfides by oxidative coupling (C_{60} and its derivatives are weak oxidizing agents). Likewise the reaction of 4-*tert*-butylphenol with potassium carbonate and **8** at 70 °C does not afford the expected adduct but a fragmentation of the C_{60} framework takes place. By the nucleophilic aromatic substitution of **8** and **9** it is now possible to bind primary and secondary amines covalently to Buckminsterfullerenes. From an electronic standpoint it is important to link the electron acceptor C_{60} with electron donors, since this provides substrates for the study of electron- and energy-transfer processes. In **15** two C_{60} units are bound by an ionophore. Furthermore, as a result of their functionalization, the mono- and bisadducts **8** and **9** are suitable for the incorporation of C_{60} as an active unit in side and main chain polymers.

Experimental Procedure

Reaction of 1 with 7: C_{60} (**1**) and **7** (1.5 equiv) were heated under reflux in 1,2,4-trichlorobenzene (1 mL per 6 mg **1**) for 8 h. The solution turned dark brown. The batch was concentrated to dryness at 100 °C/10^{-2} Torr, the brown solid taken up in chloroform, and the brown solution filtered through an 0.25 μm Teflon membrane filter. After chromatography on polystyrene gel the fractions were precipitated with methanol and the brown solid was dried for 4 h at 100 °C/10^{-2} Torr. The adducts **8**–**10** were usually prepared in 1–2 g quantities. The yield of **8** was 65% and of **9** 31% (each based on converted C_{60}). About 10% C_{60} (based on the C_{60} used) could be recovered. Compound **10** was formed in traces.

UV/VIS: The UV/VIS spectra of all the compounds described are similar to that of C_{60}. All monoadducts show an absorption band at 435 nm; for the higher adducts this band is missing. Compound **15** shows an additional weak absorption band at 701 nm.

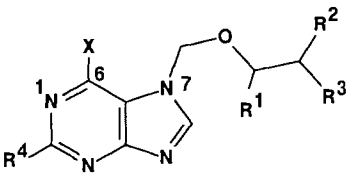
Regioselective Synthesis and Antiviral Activity of Purine Nucleoside Analogues with Acyclic Substituents at N7**

Gerhard Jähne,* Herbert Kroha, Armin Müller, Matthias Helsberg, Irvin Winkler, Gerhard Gross, and Thomas Scholl

Classic antiviral purine nucleosides such as 9-[(2-hydroxyethoxy)methyl]guanine (Aciclovir, ACV, **1a**),[1] 9-[(1,3-dihydroxy-2-propoxy)methyl]guanine (Ganciclovir, GCV, **1b**),[2] and 9-[(2,3-dihydroxy-1-propoxy)methyl]guanine (**1c**)[3] have an acyclic side chain linked to the N9 position of the natural heterocycle guanine instead of the D-ribofuranose residue of guanosine; in **1a** this substituent is a C1′-O-C4′-C5′ chain,[***] in **1b** a branched C1′-O-C4′-(C5′,C3′) chain.[***] The guanine derivatives **1a,b** are important in the treatment of viral diseases caused by herpes viruses including the herpes simplex virus 1 (HSV-1), herpes simplex virus 2 (HSV-2), varicella zoster virus (VZV), and the human cytomegalovirus.[4]



Since the discovery of the selective antiherpes action of **1a**[5] a multitude of purine and pyrimidine nucleoside analogues have been described.[6] In the synthesis of these purine nucleosides with acyclic substituents the N9 regioselectivity of the coupling of the heterocycle with the acyclic residue was considered essential, as natural purine nucleosides are substituted at N9. It was simply assumed that the analogous N7 regioisomers would not display antiviral activity. Indeed, this assumption was found to hold for the few hitherto isolated and characterized N7-substituted purines.[7] We report here on a regioselective route to purine nucleoside analogues having acyclic substituents at N7 and on the antiviral activity of one compound in this new class of drugs.

Guanine derivatives having carboacyclic substituents, in which the oxygen atom of the C1′-O-C4′-C5′ chain at N7 is replaced by a methylene group, can be prepared with moderate regioselectivity.[8] However, the synthetic route cannot be applied to the synthesis of purine nucleosides with acyclic substituents at N7. In contrast, the regioselective preparation of the N7 isomer of guanosine is known: a solution of persilylated N^2-acetylguanine and tetra-*O*-acetyl-β-D-ribofuranose in acetonitrile at room temperature is treated with a fivefold excess of tin tetrachloride.[9]

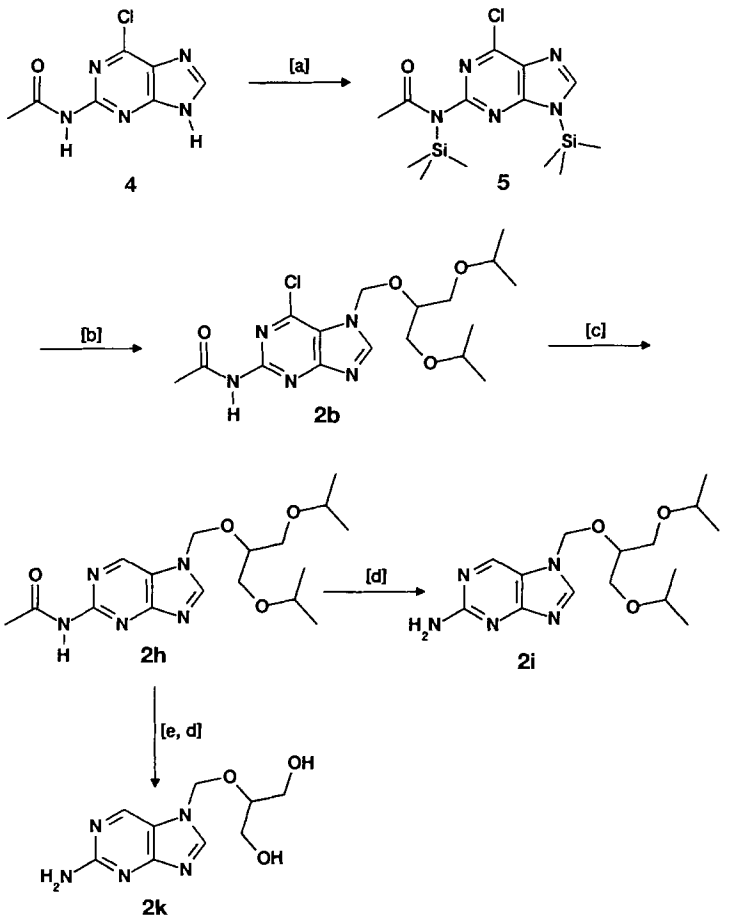
We first examined the analogous reaction of persilylated N^2-acetylguanine with 1,3-diisopropoxy-2-methylthiomethoxypropane or 2-acetoxymethoxy-1,3-diisopropoxypropane (**3**)[10] under the same reaction conditions. A 1:1 mixture of the N9 isomer **1d** and the N7 isomer **2a** was obtained in good overall yield (80%). By modification of the starting materials, reagents, and conditions a regioselectivity of 9:1 could be obtained for the N7/N9 substitution. Persilylated N^2-acetylguanine was replaced with persilylated 2-acetamido-6-chloropurine (**4**), instead of a fivefold excess of tin tetrachloride 1–1.2 equivalents of trimethylsilyl trifluoromethanesulfonate (TMSOTf) was employed as the Lewis acid, 1,2-dichloroethane (DCE) served as the solvent rather than acetonitrile, and the reaction temperature was reduced to −30 °C. Under these conditions the N7 regioisomer **2b** was isolated as the kinetic reaction product in 65% yield (Scheme 1).[11] Following this procedure, compounds with related activated side chain components could be prepared regioselectively. Derivatives with other 1,3-dialkoxy-2-propoxymethyl side chains (**2c–2e**), the isomeric 2,3-dialkoxy-1-propoxymethyl side chain (**2f**), and a simple 2-alkoxyethoxymethyl side chain (**2g**) were synthesized.[11] A further advantage in the application of **4** instead of of N^2-acetylguanine is that the chloro substituent of **4** is conducive to a large number of modifications of the purine system. For example, **2b** can be converted into **2h** by hydrogenolysis and then into **2i** by subsequent aminolysis (Scheme 1). Diol **2k**, an isoster of the N9-substituted adenine derivative **1f**, which has only weak antiviral activity,[7b] is obtained by ether cleavage of **2h** with boron trichloride followed by removal of the *N*-acetyl protective group.



The N7- and N9-substituted products **2i** and **1e** (HOE 602), respectively, can be distinguished by their ^1H and ^{13}C NMR spectra.[12a] The spectroscopic data are in accord with those of other purine derivatives.[12b]

The antiviral activity of these compounds was measured in vitro with Vero cells infected with HSV-1 and HSV-2. We found that the N7-substituted purine derivative **2k** has a minimal inhibitory concentration (MIC) of 3.99 μM for HSV-1 and 6.9 μM for HSV-2. (The MIC is the concentration at which half of the

[**] We thank Dr. H.-W. Fehlhaber, Dr. H. Kogler, and M. Weber, Hoechst AG, Allgemeine Pharma Forschung, Analytisches Labor, for measuring the ^1H and ^{13}C NMR and mass spectra of the new compounds.

[***] The numbers refer to positions in the ribofuranose residue.

Scheme 1. Regioselective synthesis of 2-amino-7-[(1,3-dihydroxy-2-propoxy)-methyl]purine (**2k**). [a] $NH(SiMe_3)_2$, xylene, $(NH_4)_2SO_4$ cat., N_2, reflux, quantitative; [b] 2-acetoxymethoxy-1,3-diisopropoxypropane (**3**), TMSOTf, −30 °C, DCE, 65%; **2b**: m.p. 70–71 °C; [c] Pd/C (10%), H_2, MeOH, NEt_3, 91%; **2h**: m.p. 94 °C; [d] H_2NCH_3/H_2O, MeOH, reflux, 80%; **2i**: m.p. 154 °C; [e] BCl_3 in CH_2Cl_2, −40 °C, 78%; **2k**: m.p. 180 °C.

infected cells no longer show the cytopathogenetic effects caused by the virus.) The analogous inhibition values for **1a** are 2.42 and 1.7 μM, those for **1b** are 0.7 and 7.56 μM, respectively. N9-substituted purines like **1g** and **1e** are known to function in vivo as prodrugs of the corresponding guanine derivatives **1a** and **1b**, respectively. Xanthine oxidase converts **1g** into **1a**,[13] whereas in the bioconversions acting on **1e** this first anabolic step is followed by the cleavage of two isopropyl ether groups by enzymes of the P_{450} system.[14] Thus the excellent antiherpes action of **2k** might possibly be explained by its in vivo oxidation to **2m**, the N7 regioisomer of **1b**, or by the in vivo rearrangement of **2m** to give **1b** or of **2k** to provide **1h** followed by oxidation with xanthine oxidase yielding **1b**. The first hypothesis does not explain the antiviral action, as the antiherpes activity of **2m** has an MIC of ≥1.57 mM for HSV-1 and HSV-2. Preliminary studies of the metabolism of compound **2k** in vitro and in vivo do not indicate that the other possible processes occur.[15]

Thus we have developed a new regioselective synthesis of 2-aminopurine nucleoside analogues. One of these, **2k**, which displays promising antiviral activity (possibly after intracellular phosphorylation to the triphosphate ester), was shown not to be converted into a N9-substituted isomer. We are now examining the suitability of **2k** and its derivatives as new orally active antiviral drugs.

The Influence of Charge Distribution on Bond Lengths in the P_4O_6 Framework in Compounds of the Type P_4O_6X**

Max Mühlhäuser, Bernd Engels, Christel M. Marian, Sigrid D. Peyerimhoff,* Pablo J. Bruna, and Martin Jansen

The occupation of orbitals in a molecule is a determining factor for the geometry of the nuclear framework. For this reason, electronic excitations often lead to significant changes in the molecular structure. Continuous changes in the charge distribution through various substituents can also cause noticeable

alterations in the nuclear framework. These alterations need not necessarily be effected in the immediate vicinity of the disturbance. A marked example for this is the cage structure of phosphorus oxides and phosphorus oxide sulfides with the general formula $P_4O_6X_n$ (X = O, S; n = 0–4). The structures of these compounds can be derived from the adamantane-like P_4O_6 central framework, which has taken up oxygen or sulfur atoms at terminal positions on phosphorus.

The highly symmetrical P_4O_6 structure (T_d symmetry) is characteristically distorted in the monosubstituted compounds P_4O_6X, as can be seen in Figure 1. Both the first and second coordination spheres of the attacked phosphorus atom are changed upon transition from $P^{III} \rightarrow P^V$. The bonds between P^V and the nearest oxygen neighbours (P–O bonds) are now shorter, whereas the bonds between the bordering oxygen centers and the remaining phosphorus atoms (O–P bonds) are longer than in P_4O_6 (Table 1). Rather surprisingly, the alterations effected by the sulfur and oxygen substituents are of almost equal size. The small differences in the bond lengths found in phosphorus oxides and phosphorus oxide sulfides are in agreement with the situation found in numerous phosphoryl and thiophosphoryl compounds[4] and in P_4O and P_4S.[5]

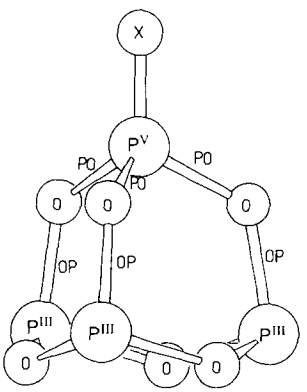

Fig. 1. Structure of P_4O_6X.

We have now carried out quantum chemical calculations which should help elucidate by which mechanisms the shortening of the P–O bond and lengthening of the O–P bond are effected, and whether the changes are directly connected, as had been assumed.[6] The deviations of the calculated structural data from the experimentally determined data are small, as can be seen in Table 1. This means that our Hartree–Fock calculations in a DZP (double zeta plus polarization) basis [7] are of sufficient accuracy to correctly describe the geometrical distortions in a qualitative manner.

Table 1. Comparison of the equilibrium geometries of P_4O_6, P_4O_7, and P_4O_6S as determined experimentally by X-ray structure investigations [1–3] and calculated theoretically (bond lengths in pm, bond angles in degrees).

In order to clarify whether the size of the distortion of the central P_4O_6 framework is directly related with the electron-attracting capability of the substituent X, geometry optimizations for P_4O_6X were performed by using a series of substituents, X, whose electronegativities stretched over a wide range. These included strongly electron-attracting substituents such as F^+ and H^+, and the electron-repelling N^-. As can be seen in Figure 2, there is a relationship between the charge density on the P^V center and the change in the P–O bond length. The shifts of the 1s orbital energies of P^V in P_4O_6X, as compared to its 1s orbital energy in the undisturbed P_4O_6 molecule, were used as a measure for the extent of the changes in the charge distribution. Population analyses that we carried out (Mulliken and Roby–Davidson) did not deliver reliable results due to the high polarity of the compounds involved. The 1s orbital energy of phosphorus can be expressed as in Equation (1);[10] where $\varepsilon_{1s}(P^{13+})$

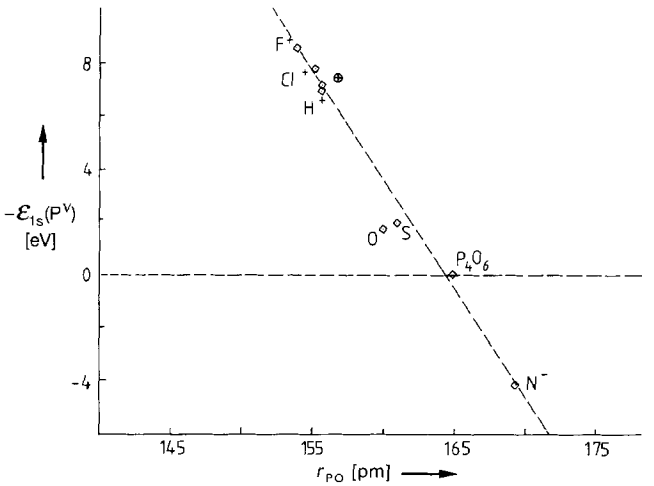

Fig. 2. Relationship between the 1s orbital energy $-\varepsilon_{1s}$ of the P^V center and the shortening of the P–O bond. The 1s orbital energies of the P^V center in P_4O_6X are plotted relative to its 1s orbital energy in the undisturbed P_4O_6 molecule. The sign has been chosen so that positive energy differences correspond to a more positive P^V center relative to P_4O_6. The individual compounds are denoted by the terminal substituent, the cation $P_4O_6^+$ by the symbol ⊕.

$$-\varepsilon_{1s}(P) = -\{\varepsilon_{1s}(P^{13+}) + V_{val} + V_{ext}\} \quad (1)$$

is the energy of the 1s electron of atomic phosphorus after removal of all outer electrons. V_{val} is the potential energy of the 1s electron in the mean field of the valence electrons on phosphorus, and V_{ext} the potential energy in the field of the electrons and nuclei of the other atoms. The last two terms are directly dependent on the electronic environment of the phosphorus; the 1s orbital energy is proportionally lower according to the increase in the positive partial charge on the phosphorus. The change in the 1s orbital energy of a particular center can, therefore, be regarded as a theoretical analogue to the chemical shift in ESCA (electron spectroscopy for chemical analysis) spectroscopy.[11, 12, 13] As can be seen in Figure 2, the P–O bond lengths vary considerably (> 15 pm), and this variation bears a direct correlation with the change in the electron density on the P^V center caused by the substituents. Particularly noteworthy is the observation that the reduction in P–O bond lengths, as found for the electron-attracting substituents, turns into an elongation for the electron-repelling N^-.

P_4O_6S and P_4O_7 deviate slightly from the correlation lines. As a result of the high electronegativity of oxygen, one would at first expect a significantly stronger electron-attracting effect and therefore a larger shift of the 1s orbital energy. According to Equation (1), however, the high electron density on the terminal P=O bond works to counteract this. In the case of P_4O_6S, the greater polarizability of sulfur allows the electrons to be distributed over a greater spatial volume, thus causing the effective charge densities to be approximately equal in both compounds. For this reason, sulfur has to be assigned the same effective electronegativity as oxygen in phosphorus-containing compounds. The relationship between the electron density in the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0564 $ 10.00+.25/0

terminal bond and the shift in the 1s orbital energy becomes particularly apparent when the atoms involved in a P–O bond are displaced (artificially) from their equilibrium positions. If the P–X distance is held constant and the P–O bond length is varied, the following picture (Fig. 3) ensues: The electron density on the phosphorus center is small for large P–O bond lengths ($r_{PO} > 165$ pm), and one obtains, as expected, a greater shift in the 1s orbital energy of P_4O_7 than in P_4O_6S; shorter PO bond lengths (< 165 pm), corresponding to higher electron densities on phosphorus, reverses this trend, as the electrons can be more easily shifted towards sulfur.

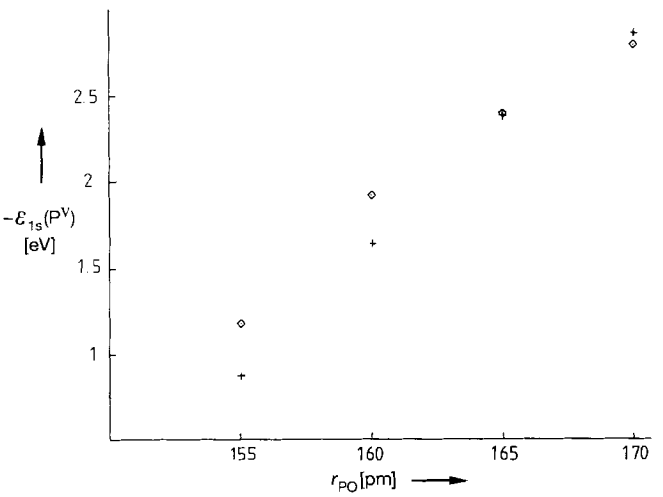

Fig. 3. Change of the 1s orbital energy of the P^V center in P_4O_6S (◇) and P_4O_7 (+) caused by an artificial distortion of the P–O bond. The sum of the P–O and the O···P bond lengths were held constant.

A correlation between the shortening of the P–O bond lengths and the elongation of the O···P bonds can be clearly seen in Figure 4. Whereas both bond lengths vary considerably in the series investigated, their sums remain virtually constant. This relationship, which is often employed in solid-state chemistry,[6] can be confirmed quite impressively here. The propagation of the disturbance arising on the P^V center into the P_4O_6 framework manifests itself in that the withdrawal of charge from P^V results in a more positive partial charge (with respect to P_4O_6) on the other phosphorus centers (Fig. 5). This shift in charge is

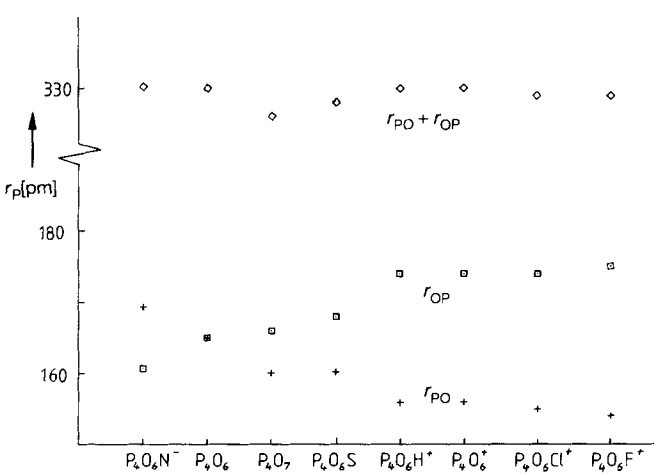

Fig. 4. Relationship between the shortening of the P–O bond and the elongation of the O···P bond. The individual bond lengths PO (+), OP (⊡) and their sums (◇) are plotted according to the substituents X.

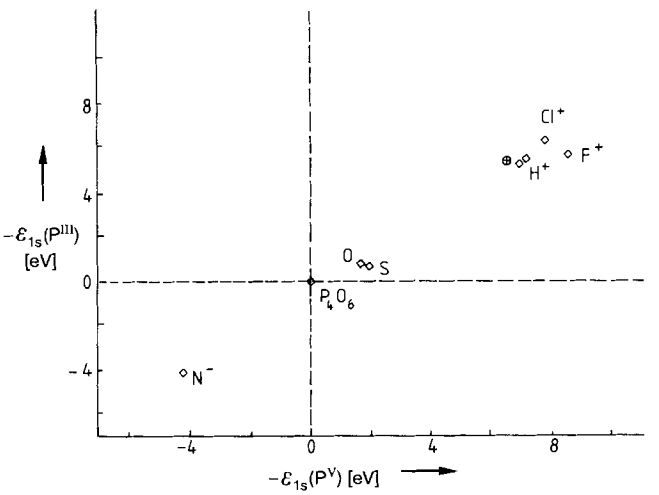

Fig. 5. Relationship between the charge density on P^V and the other phosphorus centers. The dimensions are defined in Figure 2.

more readily propagated for $X = Cl^+$ than for $X = F^+$, which indicates that both inductive and mesomeric effects play a role. The oxygen atoms which connect the P^V center with the remaining phosphorus centers take the role of a mediator such that no net charge displacement can be observed on them.

The comprehension of the individual form of a chemical bond in a defined environment, in such a way as to enable the construction of cause–effect relationships, has only been partially successful as yet. Our quantum chemical analyses on the phosphorus oxides and phosphorus oxide sulfides, which are particularly suited for this treatment, have shown that: 1) The change in bond lengths can be described in terms of the amount of charge transferred on substitution, which is documented by the 1s orbital energies, and 2) a strongly electron-repelling substituent, $X = N^-$, causes an elongation of the P–O bonds of the substituted P atom.

The synthesis and structural characterization of $P_4O_6N^-$ is therefore a great challenge for the preparative chemist, while at the same time being an acid test for the models proposed in this article.

The First Water-Dependent Liquid Clathrate: X-Ray Evidence in the Solid for a C–H···π(Heteroarene)···H–C Interaction**

Roger Hunter*, Renate H. Haueisen, and Anne Irving

In spite of the explosion in supramolecular chemistry in recent years, few examples of boron host compounds[1] have emerged in the literature, presumably because of the air sensitivity of many of the boron-containing functionalities. In this regard, boronic acid derivatives[2] have found favor because of their relative air stability. To our knowledge the only host compound with borate units known to date has been reported by Nassimbeni et al.[3] They showed that certain tetraalkylammonium tetraalkylborates form liquid clathrates with a variety of hydrocarbons. However, the borate derivatives were difficult to purify and no satisfactory X-ray analysis could be obtained. Here we report on the synthesis of the first air- and water-stable cyanoborate[4] clathrand **1** which forms both a liquid and solid clathrate with furan depending on water content. An X-ray analysis[5] of the solid clathrate of **1** with furan has revealed an interesting C–H···π(heteroarene)···H–C interaction.

Bis-hydroboration of 1,5-hexadiene with 9-borabicyclo-[3.3.1]nonane (9-BBN) followed by cyanidation with sodium cyanide in *N,N*-dimethylformamide (DMF) and cation exchange with methyltriphenylphosphonium bromide furnished the air-stable clathrand bis(methyltriphenylphosphonium) *B,B'*-dicyano-*B,B'*-hexamethylenebis(9-boratabicyclo[3.3.1]nonane) **1** in 76% overall yield (Scheme 1). The ^1H and ^{13}C NMR spectra were in agreement with the proposed formula and compound **1** analyzed as **1** · H_2O.[6] The complete removal of water was followed by thermal gravimetric analysis (TGA) and required heating **1** in vacuo (0.5 mm Hg) at 70 °C for 16 h.

1

Scheme 1. a) 9-BBN (2 equiv), THF, 0 °C to 25 °C; b) NaCN (2 equiv), DMF; c) $PMePh_3Br$ (2 equiv), MeOH.

A study of the clathrate behavior of **1** with furan revealed it to be highly dependent on the water content in the sample of **1** · nH_2O. Samples of **1** with different n values were obtained by varying the drying temperature and n was determined by TGA. A completely anhydrous sample did not dissolve in furan, whereas warming of a sample with $n = 1$ with furan resulted in rapid formation of a slightly yellow-colored liquid clathrate beneath a colorless furan layer. The ^1H NMR spectrum indicated that the liquid clathrate contained about eight furan units per borate host, and IR and ^1H NMR spectroscopic investigations of the two layers indicated that the water resided in the liquid clathrate layer. The cut-off point for formation of a liquid clathrate was around $n = 0.8$, while much higher values of n than 1 promoted the formation of three layers, one being water.

[**] This work was supported by Dynamic Power Systems Anglo American and the Foundation for Research and Development Pretoria. We thank L. Barbour for the data collection and Prof. L. R. Nassimbeni for helpful discussions.

This result is striking since, although a number of groups[7] have discovered liquid clathrate sustaining salts which are considerably more air- and water-stable than those of Atwood's original alkylaluminates[8], **1** constitutes the first example of a salt forming a water-dependent liquid clathrate. A further important aspect is that over a period of time (at least two days) beautiful transparent crystals of a solid clathrate appeared from the liquid clathrate layer; the crystallization time decreases with diminishing n. By ^1H NMR spectroscopy and TGA, the host–guest ratio in the solid clathrate was established as 1:2. Furthermore, water, although necessary for the formation of the liquid clathrate, was absent in the solid clathrate structure according to TGA, IR, and ^1H NMR. The result of an X-ray structure analysis of the solid clathrate is shown in Figure 1.

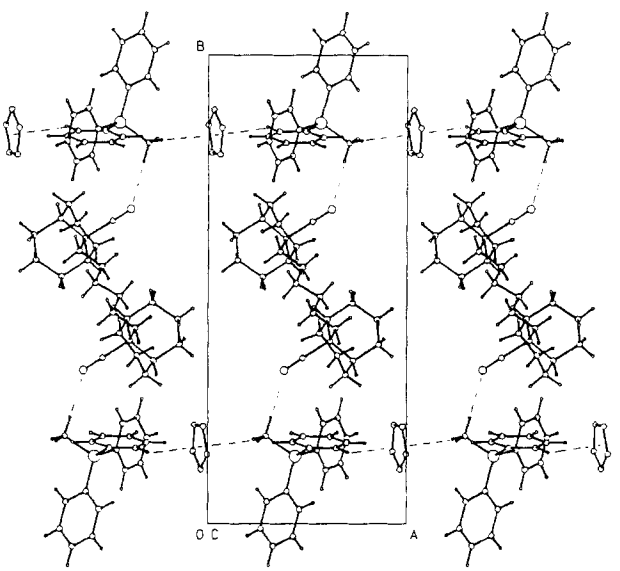

Fig. 1. Packing of **1** · $2C_4H_4O$ in the crystal. The view down Z0 showing the C–H···π···H–C and C–H···N hydrogen bonding scheme of the centrosymmetric ions solvated with furan.

Several features of the X-ray structure deserve mentioning. In contrast to aromatic compounds, very few structure analyses have been carried out on compounds involving furan as either a π ligand or as a guest in a solvate.[9] The cyanoborate clathrate is an example of a coordinatoclathrate[10] in a coordination-assisted host–lattice. The latter is provided by hydrogen bonding between a nitrogen atom[11] of a cyano group and a hydrogen atom of a phosphonium methyl group. The furan unit interacts with two hydrogen atoms from opposite faces of the plane of the heteroarene ring (see Fig. 1).[12] The hydrogen atoms involved in this C–H···π(heteroarene)···H–C interaction originate from the methyl group and the *ortho* position of a phenyl group of different phosphonium ions. Thus, the phosphonium ion plays a pivotal structural role in this clathrate and lends itself to future design characteristics.

C–H···π(arene) interactions have been of much interest recently[13] and are encountered when there is a deficiency of hydrogen bond acceptors.[14] Such interactions have been frequently reported for calixarene cavitates[15] involving π-electron-rich phenolic rings. We believe this to be the first example of a C–H···π(arene)···H–C interaction[16] and this may be due primarily to the π-excessive nature of the heteroaromatic guest. This interaction, however, is spatially analogous, although not electronically so, to a C–H···π(arene)···Cl–C interaction recently reported.[17]

In summary, this work extends the important contributions on the clathrate chemistry of organic onium compounds made by Vögtle et al.[18] Furthermore, clathrate activity is not just restricted to furan. Compound **1** also forms water-dependent liquid clathrates with benzene and thiophene, and normal solid clathrates with a range of aromatic compounds. The average guest:host (G:H) ratios of some examples were as follows benzene (0.8), *o*-, *m*-, and *p*-xylene (all ≈ 0.3), mesitylene (0.2), anisole (0.5), and *N*,*N*-dimethylaniline (1.0). Changing the cation of **1** to benzyltriphenylphosphonium extended the solid clathrate activity towards the recognition of more polar guests with higher G:H ratios compared to **1**. For instance, ether was included from the extraction procedure in a 0.4–0.8 G:H ratio and only released at 80–100 °C according to TGA. Some examples of other guests included were anisole (G:H ratio 2), benzothiazole (2.5), DMF (1.2). Hence, these phosphonium cyanoborates constitute a new family of clathrands whose activity (solid/liquid and selectivity) may be controlled by appropriate functional group changes. In our case the borate anion plays an important structural role and phosphonium is preferred over the ammonium cation. Further results on these interesting cyanoborates as novel clathrands will be communicated in due course.

Experimental Procedure

1: To a solution of 9-BBN (0.5 M in THF, 60 mL, 30 mmol) cooled to 0 °C was added 1,5-hexadiene (1.8 mL, 15 mmol) with a syringe. The mixture was stirred overnight at room temperature before the THF was removed by distillation at atmospheric pressure followed by pumping in vacuo. To the resulting liquid was added dry, deoxygenated DMF (1.5 mL) and dry NaCN (1.8 g, 36.7 mmol), and the mixture stirred until the reaction had cooled to room temperature. Na^+ ion exchange was carried out by adding methyltriphenylphosphonium bromide (10.72 g, 30.0 mmol) dissolved in MeOH (25 mL) to the borate mixture and stirring until a homogeneous mixture had formed. MeOH was removed under vacuum and ether and water were added resulting in the formation of three layers. Addition of solid NaCl (0.1 g) assisted in salting out the borate. The lower aqueous layer was separated and extracted twice with ether (2×30 mL). The combined ether extracts together with the oily middle layer from the first extraction were then washed three times with water (3×30 mL). This usually resulted in the formation of crystals from the middle layer. The combined ether extracts together with the oily middle layer and the crystals were kept at room temperature for all the precipitate to form. If solid did not form, all the aqueous and organic extracts were combined and left at 0 °C to precipitate out. The solid was filtered, washed with ether and water twice and vacuum dried to afford **1** · H_2O (10.56 g, 76%; m.p. 110–113 °C) as clear crystals. The included H_2O was removed under vacuum (0.5 mm Hg) at 70 °C for 16 h to afford anhydrous **1**. Correct C,H,N elemental analyses. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 0.14$ (m, 4H), 0.35 (br.s, 4H), 0.95–2.12 (m, 32H), 2.89 (d, ^2J(P,H) = 13.3 Hz, 6H), 7.48–7.87 (m, 30H); ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C): $\delta = 9.9$ (^1J(C,P) = 58 Hz), 24.6, 25.6, 26.5, 28.7, 30.7, 34.6, 35.9, 118.6 (^1J(C,P) = 88 Hz), 130.5 (^2J(C,P) = 12.9 Hz), 132.9 (^3J(C,P) = 10.8 Hz), 135.2, 150.0 (CN); IR (THF): $\tilde{\nu}$[cm^{-1}] = 2906, 2826, 2146 (CN), 1437, 1114.

[12] The position of the *ortho* phenyl proton H(O) and of the methyl proton H(M) from two different phosphonium ions with respect to the furan ring suggests that C–H···π interactions are possible here, since the hydrogen atoms are vertically above and below the plane of the ring and, at a distance from it less than the sum of the van der Waals distances for a π bond and a hydrogen atom (1.77 + 1.17) Å. Geometric parameters for H(M) and H(O) are respectively: perpendicular distance from the plane of the furan ring 2.67, 2.79 Å; H···ring-centroid 2.79, 2.80 Å; angle between the C–H bond and the perpendicular from the hydrogen atom to the ring plane 148, 144°; C–H···ring-centroid 132, 140°; range of distances from the furan ring atoms 2.73 to 3.32, 2.96 to 3.10 Å. The H···ring-centroid···H angle is 165°. The C–H···π interaction of chloroform with benzene has been known for a long time [13b]. Accordingly, the generality of the $(Cl_3C)H\cdots\pi$(arene) interaction was probed with the 1992 version of the Cambridge Structural Database [19] (102 103 entries). 153 error-free, non-disordered structures, $R < 0.100$, were used. Intermolecular contacts were evaluated from normalized hydrogen positions with GSTAT90. The angle between the C–H bond and the perpendicular from the H atom to the plane of the aromatic ring was constrained to lie between 100 and 180°. The distances of the hydrogen atom to each of the six ring carbon atoms were restricted to the range 2.0 to 4.0 Å to ensure that the H atom was vertically over the inside of the periphery of the ring. Three hits (refcodes: DAJLOP, FECTAI, DUYXEA) were obtained and these were scrutinized manually. The results in Table 1 show that the parameters for the C–H···π(heteroarene)···H–C interaction fit very neatly into the pattern for $(Cl_3)C$–H···π(arene) interactions.

Table 1. Some geometric parameters for C–H···π interactions.

	H···π [a] [Å]	Angle [b] [°]	Range of H···C(π) [Å]
DAJLOP	2.35	170	2.57–4.03
FECTAI	2.42	173	2.59–3.08
Ref. [17]	2.60	158	2.76–3.16
DUYXEA	2.65	143	2.68–3.61
H(M)	2.67	148	2.73–3.32
H(O)	2.79	144	2.96–3.10

[a] Perpendicular distance of the hydrogen atom to the ring. [b] Angle between the C–H bond and the perpendicular from the hydrogen atom to the ring plane.

Further support for the C–H···π(heteroarene)···H–C interaction is given from work reported on the geometry of interactions of X–H (X = O, N) with π-electron systems [20]. A second hydrogen atom of the phosphonium methyl group forms a hydrogen bond to the cyano nitrogen atom; C(H)···N 3.425(3), H···N 2.46 Å, C–H···N 177°.

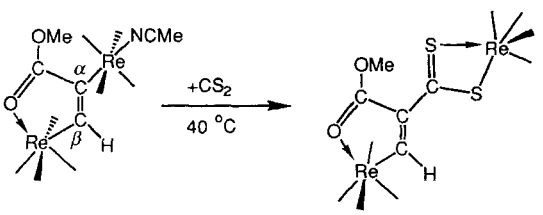
Reactions at Both Ends of a Dimetalated Olefin: CS_2 Insertion into and Atom Transfer Reactions of $[Re(CO)_4\{trans\text{-}\mu\text{-}HC{=}C(CO_2Me)\}Re(CO)_4(NCMe)]$**



Richard D. Adams,* Linfeng Chen, and Wengan Wu

Polynuclear metal complexes with bridging alkyne ligands are of great interest in organic synthesis.[1-3] Dimetalated olefins **A** and **B** are a special class of di-σ-coordinated alkyne complexes whose organic chemistry has not yet been widely studied.[4, 5]

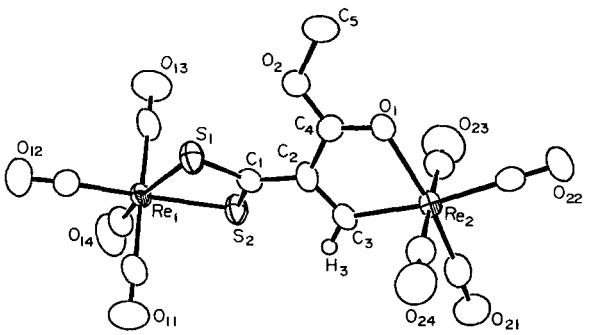
A B

We have now found an interesting combination of reagents that permits the functionalization of a dimetalated olefin at both ends of the ligand. Complex **1**[5a] reacts readily with carbon disulfide to yield the new complex **2** (78% yield) by insertion of the CS_2 molecule exclusively into the Re–C_α bond of **1**.

1 2

Compound **2** has been structurally characterized by X-ray diffraction methods (Fig. 1).[6] The structures of **2** and the related complex $[Re(CO)_4\{(E)\text{-}HC{=}C(CO_2Me)C{=}N(C_6H_4\text{-}p\text{-}Me)S\}Re(CO)_4]$ formed by the reaction of *p*-tolylisothiocyanate with **1** are very similar.[5b] The two $Re(CO)_4$ groups in **2** are linked by an (*E*)-methylcarboxylate-substituted dithiocarboxylatovinyl unit. The dithiocarboxylate group is chelated to the Re1 center (Re1–S1 2.496(2) and Re1–S2 2.495(2) Å). The C–C distances indicate that the C2–C3 bond is a double bond (1.35(1) Å) and that the C1–C2 bond is a single bond (1.47(1) Å). The methylcarboxylate group is coordinated by its ketonic oxygen atom to Re2 as in **1** (Re2–O1 2.201(5) Å).

Most interestingly, compound **2** subsequently reacts with the atom transfer reagents, pyridine-*N*-oxide and ethylenesulfide, to



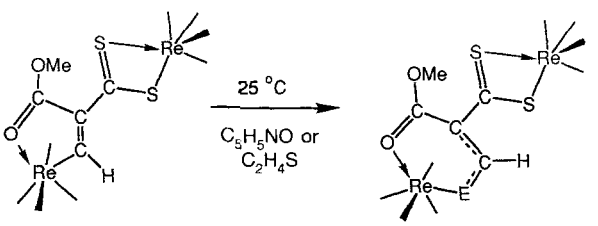


Fig. 1. Molecular structure of **2** (ORTEP, 50% probability thermal ellipsoids). Selected interatomic distances [Å]: Re1–S1 2.496(2), Re1–S2 2.495(2), Re2–C3 2.125(9), Re2–O1 2.201(5), C1–C2 1.47(1), C2–C3 1.35(1), C1–S1 1.686(8), C1–S2 1.696(9), C2–C4 1.45(1).

insert a heteroatom into the Re–C_β bond. Treatment of **2** with pyridine-*N*-oxide at 25 °C afforded the new complex **3a** in 97% yield, the reaction with ethylenesulfide at 25 °C gave compound **3b** in 50% yield. Both compounds were characterized by IR and ^{1}H NMR spectroscopy and elemental analyses. Compound **3b**

2 **3a,b:** E = O, S

was further characterized by a single-crystal X-ray diffraction analysis (Fig. 2).[6] The structures of **2** and **3b** have many common structural features; the most noticeable difference is that in **3b** a sulfur atom S3 has been inserted into the Re2–C3 bond

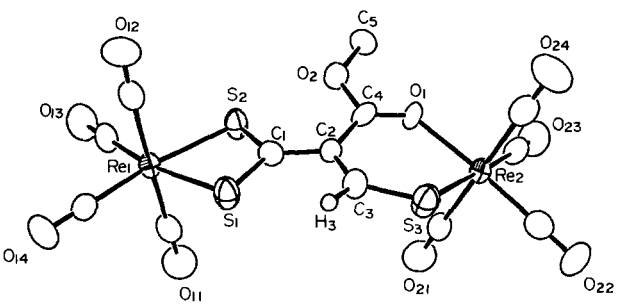

Fig. 2. Molecular structure of **3b** (ORTEP, 50% probability thermal ellipsoids). Selected interatomic distances [Å]: Re1–S1 2.495(2), Re1–S2 2.481(2), Re2–S3 2.452(2), Re2–O1 2.163(5), C1–C2 1.46(1), C2–C3 1.38(1), C1–S1 1.713(7), C1–S2 1.702(7), C3–S3 1.676(8), C2–C4 1.47(1).

(Re2–S3 2.452(2) Å). The C2–C3 distance in **3b** is short (1.38(1) Å), likewise the C3–S3 distance is also short (1.676(8) Å), and is even shorter than the C–S distances in the dithiocarboxylate group (1.713(7) and 1.702(7) Å). Thus, this C–S bond may also contain some multiple bond character.

An increasing number of studies have focused on the oxygenation of organic ligands in metal complexes by atom transfer.[7] We are unaware of any previous studies that demonstrate

both oxygen and sulfur atom insertions occurring at the same transition metal–carbon bond.

Experimental Procedure

2: **1** (100.0 mg, 0.139 mmol) and CS_2 (100.0 μL, 1.660 mmol) were dissolved in CH_2Cl_2 (200 mL) and heated to reflux for 4 h. The product was separated by TLC on silica gel to give 82.8 mg **2** (orange, 78%). IR (hexane): $\tilde{\nu}$(C=O) [cm^{-1}] = 2098(w), 2008(s), 1995(m), 1959(s), 1582(w); ^1H NMR ($CDCl_3$): δ = 11.65 (s, 1H, C*H*), 4.09 (s, 3H, O*Me*); MS: *m/z* = 758 (M^+, ^{187}Re) and ions corresponding to the loss of eight carbonyl ligands; correct elemental analysis.

3a: **2** (20.0 mg, 0.026 mmol) in CH_2Cl_2 (30 mL) was allowed to react with C_5H_5NO (3.0 mg, 0.032 mmol) at 25 °C for 20 min. The product was separated by TLC on silica gel to give 19.8 mg **3a** (yellow, 97% yield). IR (hexane): $\tilde{\nu}$(C=O) [cm^{-1}] = 2120(vw), 2101(w), 2018(s), 2002(s), 1991(s), 1958(s), 1605(m). ^1H NMR ($CDCl_3$): δ = 9.64 (s, 1H, C*H*), 3.92 (s, 3H, O*Me*); MS: *m/z* = 774 (M^+, ^{187}Re) and ions corresponding to the loss of six carbonyl ligands; correct elemental analysis.

3b: **2** (20.0 mg, 0.026 mmol) in hexane (20 mL) was allowed to react with C_2H_4S (20.0 μL, 0.336 mmol) at 25 °C for 3 h. The product was separated by TLC on silica gel to give 10.2 mg **3b** (orange, 50% yield). IR (hexane): $\tilde{\nu}$(C=O) [cm^{-1}] = 2114(vw), 2101(w), 2019(s), 2004(s), 1993(m), 1963(s), 1958(m), 1585(w). ^1H NMR (C_6D_6) **3b**: δ = 10.17 (s, 1H, C*H*), 2.82 (s, 3H, O*Me*); correct elemental analysis.

$[SbN(SbCl)_3(NSbCl_2)(NSiMe_3)_2 \cdot SbCl_3]$, an Unusual Nitridoantimony Complex with a Heterocubane Structure

Markus Rhiel, Frank Weller, Jürgen Pebler, and Kurt Dehnicke*

Nitrido complexes of main group elements in their highest oxidation states, in particular of the heavy elements, are rare,[1] in contrast to the many such examples of complexes of transition metals.[2] One of the reasons is considered to be the instability of the element's bond to nitrogen—these complexes are energetically favored only by a lowering of the basicity of the nitrogen atoms by electron-withdrawing groups or through mesomeric effects.[1] One example is the imidoantimony(v) complex **1**, which has an Sb_4N_4-heterocubane structure.[3] This

$[(CH_3NSbCl_3)_4]$ **1**

tendency also seems to be present in the nitrides of main group elements in lower oxidation states, as the comparison of explosive Se_4N_4 with the distinctly more stable chloronitride Se_2NCl_3 shows.[4]

This concept was confirmed in the first nitrido–antimony(III) complex, which we have now synthesized, whose nitride moiety is apparently stabilized by the other units of the heterocubane structure. Compound **2** is formed almost quantitatively from antimony trichloride and tris(trimethylsilyl)amine in dichloromethane as sparingly soluble, white, moisture-sensitive precipitate [Eq. (a)]. In spite of the complexity of this reaction, the

$$6\,SbCl_3 + 4\,N(SiMe_3)_3 \longrightarrow [SbN(SbCl)_3(NSbCl_2)(NSiMe_3)_2 \cdot SbCl_3] + 10\,ClSiMe_3 \quad (a)$$

2

same product arises irrespective of the relative amounts of the starting materials. Single crystals of **2** were obtained from dilute solution by mixing the reactants at −60 °C and subsequent very slow warming to 20 °C.

According to the results of the crystal structure analysis,[5] **2** has the heterocubane structure reproduced in Figure 1. Each

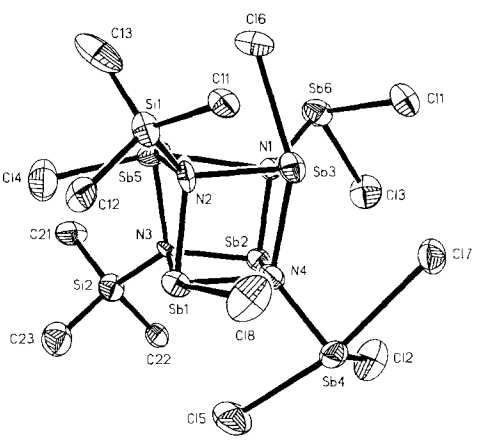

Fig. 1. Molecular structure of **2** in the crystal. Ellipsoids of thermal vibration represent 50% probability at 19 °C. individual molecule is chiral; the symmetry constraints, however, require that a racemate is present in the unit cell. Of the four nitrogen atoms of the heterocubane framework, only the N4 atom has nitride character (N^{3-}); the other three N atoms have imide character. To each of N2 and N3 is bound a trimethylsilyl group ($NSiMe_3^{2-}$), whereas N1 bears a dichloro-

antimony substituent ($NSbCl_3^{2-}$). In the nitride unit, N4 achieves the coordination number 4 by addition of an $SbCl_3$ molecule, but displays a strikingly short Sb–N bond of 208 pm for this bond type. Typical Sb–N distances in donor–acceptor complexes of $SbCl_3$ are 253 pm in [$SbCl_3$·aniline[6]] and 224.5 and 231.7 pm in [$SbCl_3$(2,2′–bpy)] (**3**, bpy = bipyridine[7]). The T-shaped arrangement of the chlorine atoms of the $SbCl_3$ molecule bound to N4 is surprising. Such a geometry was also observed in the chelate complex **3**,[7] but monofunctional donor molecules bound to $SbCl_3$ give rise, in general, to pyramidal structures.[6, 8] With the exception of the Sb–N bonds of the heterocubane framework (Sb1–N3, Sb3–N4 and Sb5–N1), in which the bond lengths are 235, 234, and 258 pm, respectively, the Sb–N bond lengths of between 200 and 217 pm hardly differ from one another. They correspond well with the

[$SbCl_3$(2,2′-bpy)] **3** [{$SbCl_2(NSMe_2NSiMe_3)$}$_2$] **4**

distances observed for the folded Sb_2N_2 four-membered ring in **4** (206.4 and 223.2 pm).[9] Similar Sb–N distances are also displayed by the heterocubane **1** (215–219 pm),[3] in which the antimony atoms are in a distorted octahedral environment.

In **2** all six antimony atoms are in a distorted pseudo-trigonal-bipyramidal environment; the antimony atoms Sb2 and Sb6 achieve this coordination through strong intermolecular interactions with the chlorine atom Cl7, to which Sb···Cl contacts of 315.6 and 315.5 pm are formed along the lattice vector [101]. These contacts are far shorter than the sum of the van der Waals radii of 400 pm.[10] The polymeric association coupled with this phenomenon also explains the low solubility of **2** in organic solvents. However, **2** dissolves extremely well in dichloromethane on addition of only the equimolar amount of tetraphenylphosphonium chloride, and the salt PPh_4^+[**2**·Cl^-] is formed. In the process the cubane framework in the chloro complex [**2**·Cl^-] is retained.[11] Presumably the chloride ion adds to the Sb2 atom; thus, all antimony atoms of the heterocubane become equivalent. As a consequence of the intermolecular bridging function of the Cl7 atom in **2**, the Sb4–Cl7 distance is stretched to 279.0 pm, the longest direct Sb–Cl bond in **2**.

The ^{121}Sb Mössbauer spectrum of **2**[12] reflects the pseudo-trigonal-bipyramidal surroundings of all six nonequivalent antimony atoms (Fig. 2). The Lorentz fit (solid curve) provides an average value for the isomeric shift of $\delta_{IS} = -13.4(4)$ mm s^{-1} and for the quadrupole splitting of $\Delta E^Q = 18.4(4)$ mm s^{-1}, which has a positive sign for all Sb atoms. The size of the isomeric shift fits well with those measured for **4** (13.5(1) mm s^{-1}[9]) and for **5**

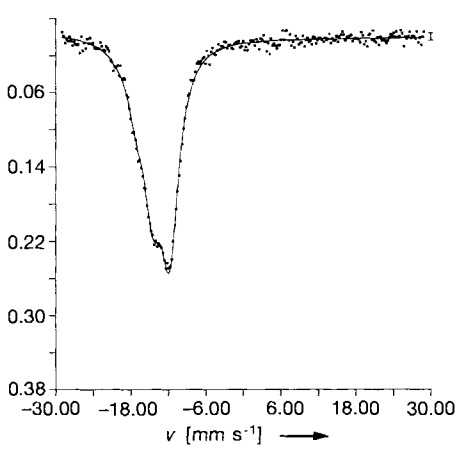

Fig. 2. ^{121}Sb Mössbauer spectrum of **2** at 4.2 K. The x axis represents the relative speed of the source relative to the absorber, and the y axis the absorption.

[Ph–C(NSiMe$_3$)$_2$SbCl$_2$] **5**

(−13.2(1) mm s^{-1}[13]). In both complexes the antimony atoms are surrounded by a pseudo-trigonal-pyramid of Cl and N atoms, as in **2**. The large quadrupole splitting in the Mössbauer spectrum of **2** upon coordination of the Sb atoms by N and Cl atoms is, because of the only slight difference in electronegativity, in essence attributable to the steric requirements of the lone pairs on the antimony atoms, according to all experience.[9, 13–15] Similarly large values for the quadrupole splitting are found in the Mössbauer spectra of amidinatoantimony(III) complexes in which the coordination environment at the antimony atoms resembles that of **2**[16] (for example, $\Delta E^Q = 15.5$ mm s^{-1} in **5**[13]).

Experimental Procedure

2·CH_2Cl_2: A solution of $N(SiMe_3)_3$ (3.53 g, 15.1 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a stirred solution of $SbCl_3$ (5.18 g, 22.7 mmol) in CH_2Cl_2 (30 mL). The initially clear solution was slowly allowed to warm to 20 °C without stirring and was then filtered under a dry nitrogen atmosphere, washed with CH_2Cl_2, and dried under vacuum. Yield 4.43 g (90%). Correct elemental analysis for C, H, N, Cl, Si.

Continuous Enzymatic Synthesis of 2′-Deoxythymidine-5′-(α-D-glucopyranosyl)diphosphate**

Astrid Zervosen, Lothar Elling, and Maria-Regina Kula*

2′-Deoxythymidine-5′-(α-D-glucopyranosyl)diphosphate (dTDP-Glucose) **3d** belongs to the primary nucleotide sugars whose existence and importance in the biosynthesis of glycosylated compounds was recognized in 1950 by Leloir et al.[1] In current basic research the role of complex glycoconjugates in intercellular and immunological recognition events in biological systems is being closely studied.[2] In the course of this development enzymatic synthesis of oligosaccharide structures with glycosyl transferases[3] and glycosidases[4] have assumed ever greater importance in comparison with labor-intensive chemical syntheses with their extensive use of protective groups.[5] The use of a glycosyl transferase depends on the availability of a suitable nucleosidediphosphate sugar. In recent years several activated sugars have been synthesized in preparative amounts by means of pyrophosphorylases.[6]

We have, for the first time, used sucrose synthase (EC 2.4.1.13), which catalyzes both the synthesis and the cleavage of a disaccharide, for the preparation of dTDP-glucose. Starting from dTDP-glucose a series of activated deoxy sugars (e.g. dTDP-dihydrostreptose, dTDP-L-rhamnose) are obtainable, which are components of particular antibiotics[7] or of lipopolysaccharides of enterobacteria.[2] The purified sucrose synthase, isolated from rice grains, cleaves sucrose in the presence of uridine-5′-(UDP) (**2a**), 2′-deoxythymidine-5′(dTDP) (**2d**), adenosine-5′-(ADP) (**2b**), cytidine-5′-(CDP) (**2e**), and guanosine-5′-(GDP) diphosphate (**2c**) (Scheme 1) and is, thereby, a candidate for the synthesis of primary nucleotide sugars.[8] The enzyme can be used in glycosyl transferase catalyzed reactions for the in situ regeneration of dTDP-glucose. In contrast, dTDP-glucose pyrophosphorylase,[9] which catalyzes the reaction of dTDP with glucose-1-phosphate, cannot be used for coupled reactions because of the as yet unsolved problem of the enzymatic regeneration of dTTP from dTDP.

The first continuous enzymatic synthesis of a nucleosidediphosphate sugar in preparative amounts was realized with an enzyme membrane reactor (EMR). The sucrose synthase was purified from rice with the elimination of contaminating phosphatases and invertases.[10] Under the conditions for synthesis (200 mM 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonic acid (Hepes)–NaOH buffer, pH 7.0, 30 °C), the measured half-life for the activity of the enzyme was 119 h. Under these conditions dTDP-glucose is stable whereas 1% of the substrate dTDP is hydrolysed to 2′-deoxythymidine-5′-monophosphate (dTMP) during the synthesis in the EMR. The conversion of 5 mM dTDP (**2d**) and 350 mM sucrose (**1**) gave a maximum yield of 89.6% dTDP-glucose **3d** in the EMR (Fig. 1). This corresponds to a space–time yield of 98.1 $g L^{-1} d^{-1}$ (about 1 $g d^{-1}$ dTDP-glucose in the reactor used). In comparison with syntheses carried out in parallel in a batch reactor, the enzyme consumption can

Scheme 1. Synthesis of nucleoside diphosphate sugars with sucrose synthase from rice.

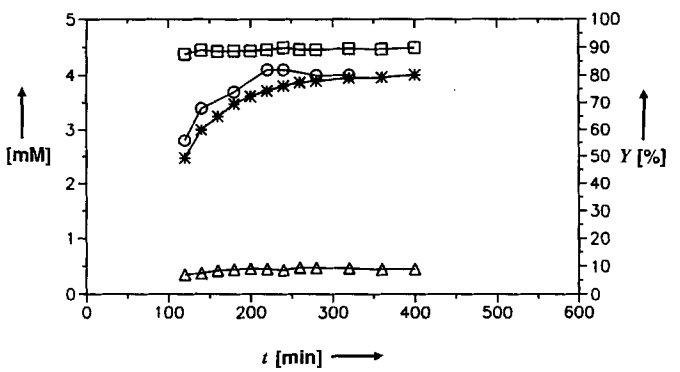

Fig. 1. Concentration/time curves for the continuous synthesis of dTDP-glucose **3d** (*) in an enzyme membrane reactor; starting concentrations: 5 mM dTDP **2d** (△), 350 mM sucrose **1**, 200 mM Hepes–NaOH; pH 7.0; 30 °C; 990 mU sucrose synthase; residence time: 0.67 h. D-fructose (○); **Y**: Yield (□).

be lowered from 3.9 $U g^{-1}$ dTDP-glucose to 1 $U g^{-1}$. Aliquots of the dTDP-glucose **3d** synthesized in the EMR were worked up by two different purification methods. dTDP-Glucose was isolated by ion exchange chromatography. In the subsequent lyophilization, the amount of decomposition of the dTDP-glucose was decreased by maintaining a pH of 7.0. As an alternative to the desalting of the lyophilizate by gel filtration precipitation with ethanol/acetone was carried out, which has the advantage of an easy scale-up. Both purification procedures can still be improved. On account of the high yield of almost 90% dTDP-glucose, the product can be used without prior purification for further enzymatic conversions. The enzymatically prepared dTDP-glucose (purification method 2) was characterized by means of ^1H and $^{13}C\{^1H\}$ NMR spectroscopy (Table 1).

Table 1. NMR data of dTDP-glucose **3d** in D_2O. ^1H NMR: 400 MHz; $^{13}C\{^1H\}$ NMR: 100 MHz; [11].

^1H NMR (400 MHz, D_2O): $\delta = 7.80$ (s, 1H; H-6'), 6.40 (dd, $^3J(1,2a) \approx {}^3J(1,2b) \approx 7.0$ Hz, 1H; H-1), 5.65 (dd, $^3J(1'',2'') \approx 3.6$ Hz, $^3J(1'',P) = 7.1$ Hz, 1H; H-1''), 4.80 (HDO), 4.66 (m, 1H; H-4), 4.25 (m, 2H; H-5a, 5b), 4.02–3.86 (m, $^2J(6_a'',6_b'') = 12.7$ Hz, 2H; H-5'', H-$6_a''$), 3.86–3.79 (m, $^3J(3'',4'') = 9.2$ Hz, $^3J(4'',5'') = 8.7$ Hz, $^3J(5'',6_b'') \approx 4.6$ Hz, $^2J(6_a'',6_b'') = 12.7$ Hz, 2H; H-4'', H-$6_b''$), 3.58 (ddd, $^3J(1'',2'') = 3.6$ Hz, $^3J(2'',3'') = 9.7$ Hz, $^4J(2'',P) = 3.4$ Hz, 1H; H-2''), 3.51 (dd, $^3J(2'',3'') = 9.7$ Hz, $^3J(3'',4'') = 9.2$ Hz, 1H; H-3''), 2.43 (m, 2H; H-2a, b), 1.98 (s, 3H; 5'-CH_3)

$^{13}C\{^1H\}$ NMR (100 MHz, D_2O): $\delta = 156.1$ (C-5'), 137.6 (C-6'), 95.8 (d, $^3J(C\text{-}1'', P) = 6.5$ Hz, C-1''), 85.5 (C-1), 73.1 (C-5''), 71.8 (d, $^4J(C\text{-}2'',P) = 8.5$ Hz, C-2''), 71.4 (C-3), 71.2 (C-4), 69.5 (C-3''), 65.7 (d, $^3J(C\text{-}5,P) = 6.5$ Hz, C-5), 60.6 (C-6'') 38.8 (C-2), 11.9 (5'-CH3)

Experimental Procedure

The reaction was carried out in Hepes-NaOH buffer (200 mM, pH 7.0) at 30 °C. At the start 990 mU of purified sucrose synthase [10] and 10 mg bovine serum albumin were injected through a sterile filter (0.2 μm, Sartorius, Göttingen) into the sterile EMR filled with buffer solution (volume 10 mL; Bioengineering, Wald, Switzerland). Subsequently the substrate solution (100 mL) with dTDP (**2d**, Na^+ salt, 230 mg, Sigma) and sucrose (**1**, 11.98 g, 350 mM) was pumped continuously through the reactor in which the enzyme was retained by means of an ultrafiltration membrane (YM 10, Amicon, Witten), with a flow rate of 15 mL h^{-1}. The synthesis was monitored for 400 min (ten residence times) by means of regular sampling. The nucleoside phosphates and nucleotide sugar were separated and quantitatively analyzed by ion-pair HPLC [10]. Aliquots of the dTDP-glucose were worked up with different procedures. Method 1 (84.4 mg crude product): First dTDP, the sugar, and the buffer were separated by ion exchange chromatography on Sepharose Q in the Cl^- form (1.8 × 30 cm, gradient: 55–200 mM LiCl at pH 5.0). The separation of dTMP was achieved with Dowex 1 × 2 in the Cl^- form (100–200 mesh, 2.6 × 7.0 cm, gradient: 55–350 mM LiCl with 3 mM HCl). After lyophilization the product was desalted by gel filtration chromatography (G-10, 1.6 × 30 cm). (Yield of purified product: 39.1 mg, 46.4%).

Method 2 (57.8 mg, crude product): After ion exchange chromatography on Sepharose Q, dTMP was removed with Dowex 1 × 2 in the Cl^- form (100–200 mesh, 2.6 × 7.0, 0–500 mM LiCl). After lyophilization the lyophilizate was dissolved in ethanol. The dTDP-glucose was precipitated by the addition of 2.5 times the amount of acetone, filtered off, and dried. (Yield of purified product: 24.5 mg, 42.4%) $[\alpha]_d^{22.5} = 48.1$ (c = 4.6 mM in H_2O). The product contained 6.5% dTMP according to HPLC analysis [10].

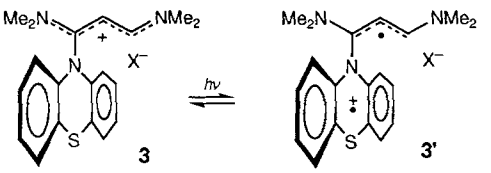
Phenothiazinyl-Substituted Cyanines: Model Compounds for Molecular Switches**

Agnes Ehmann, Rudolf Gompper,* Horst Hartmann, Thomas J. J. Müller, Kurt Polborn, and Reiner Schütz

Conjugated π-electron systems such as polyacetylene, polypyrrole, polythiophene, polyaniline, and polyphenylenevinylene,[1] which are electrically conducting in either their doped or undoped state, have paved the way to molecule-based electronic devices.[2] Molecular switches are one of the essential components of molecular electronics, and proposals for such systems have been made.[3–6] (The term switch is defined in ref. [5].) One of these model systems is polyacetylene **1** with donor and acceptor substituents. The conjugation in the "molecular wire" can be



interrupted by the interaction of light with the β-nitroenamine chromophore.[2b, 3] This model has been criticized[3] in part because of anticipated difficulties in its synthesis (cf. solid-state polymerization of a push–pull diacetylene[7]). But it is also doubtful, for example, whether the donor–acceptor portion of the molecule can be excited selectively and whether the radical cation or cationic center generated at the terminus of the polyene would be sufficiently localized for the migration of a soliton through the system (resonance delocalization of the soliton is more likely). Thus we propose system **2**; the electric conductivity of this molecule is controlled by photoinduced electron transfer (PET) from a donor group not involved in π-conjugation to the "molecular wire" of the polymethinecyanine framework (**2** → **2***).

Reaction of (2-substituted) vinamidinium salts with, for example, *p*-phenylenediamine, provides polyvinamidines, which have high electrical conductivities[8] (undoped 10^{-5} to 0.15 S cm^{-1}, doped 0.03 to 50 S cm^{-1}). For this reason we used the vinamidinium salts **3** as model systems for **2**. Instead of the porphyrin group frequently employed in π-σ-π electron systems,[9–12] we chose the phenothiazinyl group. Phenothiazines are known to give rise to stable radical cations and dications[13–17] as well as charge transfer complexes.[18, 19] Phenothiazinyl-substituted ligands in metal complexes have served as probes in UV/VIS studies of electron transfer processes.[20, 21]

[**] This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. T. J. J. M. thanks the State of Bavaria for a Stipendium zur Förderung des künstlerischen und wissenschaftlichen Nachwuchses. We thank Dr. A. Lerf, Hahn-Meitner-Institut, Garching (FRG), for conducting the conductivity measurements.

In contrast to most of the systems used in studies of charge separation in PET processes, the phenothiazinyl group in **3** is coupled directly to the vinamidinium system. Selective oxidation of the phenothiazinyl group should be possible owing to the stability of the phenothiazinyl radical cation, especially if the phenothiazine and vinamidinium systems are not coplanar. We report here on the synthesis of **3** and on our findings that the π-electron systems are mutually orthogonal and that photoinduced electron transfer most likely gives **3'**.

Reaction of 10-acetylphenothiazine with *N*,*N*-dimethylformamide chloride at room temperature in chloroform and subsequent workup with aqueous tetrafluoroboric acid or perchloric acid furnished the 3-chloro-3-phenothiazinylpropeniminium salts **4** in good to excellent yields (cf. chloroformylation of *N*,*N*-disubstituted acetamides[22] and the analogous reaction of *N*-acetylphenoxazine[23]). The 1-phenothiazinylvinamidinium salts **3a**, **b** were obtained by treatment of **4** with ethanolic dimethylamine at room temperature. When hot ethanolic solutions of **3a** and lithium tetracyanoquinodimethane (Li^+TCNQ^-) were combined and cooled, salt **3c** formed as blue-black crystals.

In the X-ray structure analysis of **4b**[24] (Fig. 1) the W form typical for vinamidinium salts[25] is evident, and the phenothiazinyl unit is almost coplanar with the allyl cation moiety. Since the C1–N1 bond is considerably longer than the C3–N2 bond (134.8 vs 129.4 pm), the phenothiazinyl group rotates about the C1–N1 bond more readily than the dimethylamino group about the C3–N2 bond. Consequently only one set of signals is seen for the phenothiazine C atoms in the room-temperature ^{13}C NMR spectrum, whereas the dimethylamino C atoms give rise to two signals. The phenothiazinyl group is thus conjugated with the trimethine system, but the dimethylamino group is more so.

The crystal structure of **3b**[26] (Figs. 2–4) shows that the phenothiazine and cyanine unit are almost orthogonal. The cyanine system (plane 1: N2, C13, C14, C15, N3) is planar and the CC and CN bond lengths (136.9, 137.5 and 131.0, 132.4 pm, respectively) are characteristic of a trimethinecyanine (139, 132 pm).

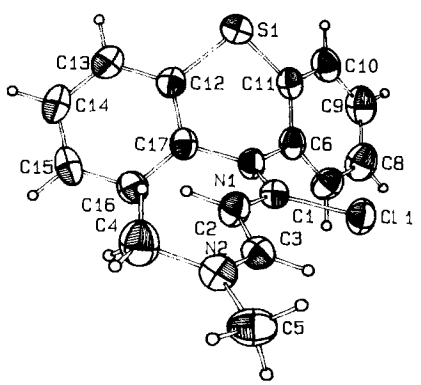

Fig. 1. X-ray structure of the cation of **4b** (ORTEP); selected bond lengths [pm] and angles [°]: C1-N1 134.8(5), C3-N2 129.4(5), C1-C2 135.9(5), C2-C3 138.9(5), C1-Cl1 172.3(4); N1-C1-C2 124.9(4), C1-C2-C3 123.7(4), C2-C3-N2 126.1(4).

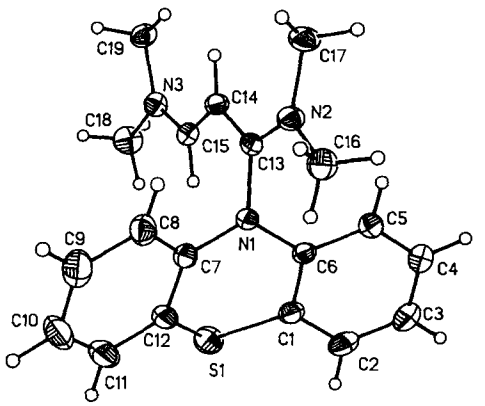

Fig. 2. X-ray structure of the cation of **3b** (ORTEP); selected bond lengths [pm] and angles [°]: N1-C13 142.4(5), N2-C13 132.4(6), N3-C15 131.0(6), C13-C14 136.9(6), C14-C15 137.5(7); N2-C13-C14 124.6(4), C13-C14-C15 120.2(4), C14-C15-N3 126.4(4).

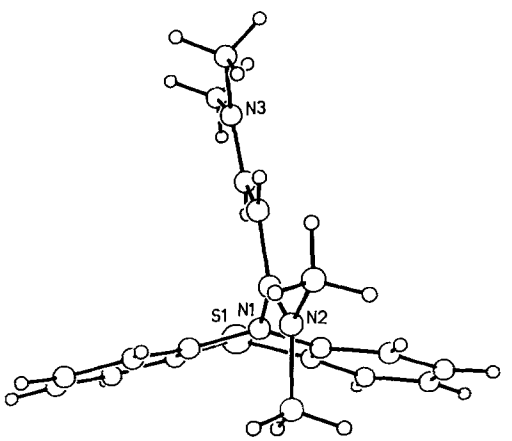

Fig. 3. ORTEP representation of the cation of **3b**; view along the N2–C13 bond.

The angle between plane 2 (S1, N1, C1, C2, C3, C4, C5, C6; maximum deviation 6.24 pm) and plane 3 (S1, N1, C7, C8, C9, C10, C11, C12; maximum deviation 3.20 pm) is 151.7°, close to that in monoclinic phenothiazine[28] (153.3°). The S and N atoms of the butterfly-shaped phenothiazinyl unit (cf. ref.[29]) do not quite lie in the plane of the central six-membered ring, which is found in a tub conformation.

Planes 1 and 2 form an angle of 82.6°. The distance between N1 and C13 (142.4 pm) is significantly larger than the corresponding distance in **4b** (134.8 pm) and lies in the range of $C(sp^2)$–$N(sp^2)$ single bonds.[30] Thus, the phenothiazine unit in **3b**, in contrast to **4b**, is not in conjugation with the cyanine system. It should therefore be possible to oxidize **3** to the radical dication without the unpaired electron being delocalized in the cyanine system.

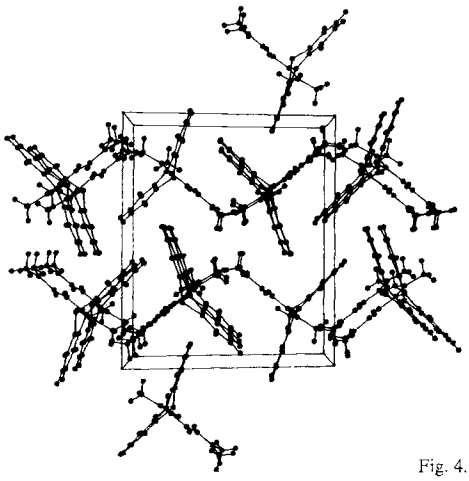

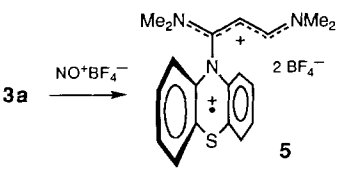

Fig. 4. X-ray structure of **3b**.

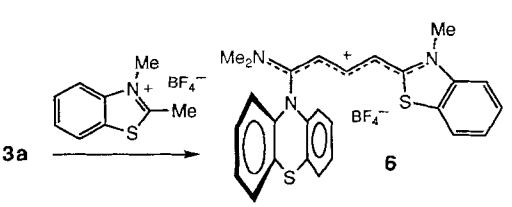
The head-to-tail arrangement of the cations is evident in Figure 4; the direction of this arrangement alternates in adjacent chains.

Oxidation of **3a** at −30 °C in dichloromethane with nitrosyl tetrafluoroborate provided the black-violet salt **5** of the radical cation, which is stable under exclusion of air and moisture.



The radical structure is supported by the ESR spectrum of a solution of **5** in acetonitrile, which shows a broad triplet (a_N = 5.13 G; g = 2.0724). Although a high-resolution ESR spectrum could not be obtained even in degassed acetonitrile, the distribution of the bands indicates that **5** is a typical phenothiazine radical cation.[17]

In the UV/VIS spectrum of **5** bands characteristic of the phenothiazine radical cation[17, 31] occur at 276, 522, and 815 nm. The band with the greatest extinction coefficient is that of the cyanine system at 330 nm. Bands that would indicate the interaction of the radical cation with the cyanine system are not evident. Apparently the phenothiazine radical cation unit and the cyanine moiety in **5** are orthogonal as in **3a**.

Structural derivatives of salts **3a, b** can also be prepared. When, for example, **3a** was heated with dimethylbenzothiazolium tetrafluoroborate in ethanol in the presence of triethylamine, the cyanine salt **6** was obtained as fine red needles with a metallic green shimmer (λ_{max} (lgε) [DMSO] = 512 nm (4.592), 558 (S, 3.799)). Other spectroscopic data indicate that the structure of **6** is similar to that of **3**.

The electron spectrum of **3c** has bands at 376, 392, 417, 432, and 663, 679, 726, 742, 760 nm, which are typical for TCNQ and

TCNQ$^{\cdot-}$. The cyanine band of **3a** occurs at 331 nm, which rules out the interaction of the cyanine system in **3a** with TCNQ or TCNQ$^{\cdot-}$. Since the phenothiazinyl radical cation absorbs at 522 nm, the phenothiazinyl group and TCNQ apparently do not interact either.

The single-crystal conductivity of **3c** is 10^{-7} Scm^{-1}, which is relatively low compared to the conductivities of salts with TCNQ anions.[32]

The cyclic voltammograms of **3a** and **6** display reversible one-electron waves at 0.84 and 0.79 V, respectively. A quasireversible transition at 1.32 V is observed for **3a**; an irreversible transition at 1.11 V is evident for **6**. In the reduction range **3a** gives rise to a quasireversible transition at −1.32 v, **6** an irreversible transition at −0.96 V.

As the potentials for the oxidation of **3a** (0.84 V) and **6** (0.79 V) to the respective radical ions are in the same range, the phenothiazine unit in both **6** and **3** must be orthogonal to the cyanine moiety. The oxidation potentials of **3a** and **6** are anodically shifted relative to those of phenothiazine[14] (0.27 V) and *N*-methylphenothiazine;[14] in other words, oxidation to the radical cations is hampered by the cationic cyanine substituent.

The reduction potentials of **3a** (−1.32 V) and 3-chloro-3-dimethylamino-*N*,*N*-dimethylpropenium perchlorate[33] (−1.37 V) are very similar. This finding along with the NMR and electron spectra indicate that the phenothiazinyl group exerts the same electronic effect on the cyanine system as a chlorine atom; put simply, the negative induction effect of the phenothiazine N atom dominates in **3a**.

Salt **4a** (E_2 = 1.19 V) is considerably more difficult to oxidize than **3a** (E_2 = 0.84 V). The phenothiazine N atom in **4a** is involved with the conjugated π-electron system of the trimethine unit, and the radical cation is thus less stable than that of **3a** (**4a** could not be oxidized with nitrosyl tetrafluoroborate).

Time-resolved spectroscopy: The phenothiazine radical cation also forms upon irradiation of a solution of phenothiazine in chloroform.[31] The radical cation is evident by its intense orange-red color, and like the radical cations of its derivatives, can be recognized by time-resolved spectroscopy. The kinetics of its decomposition can be obtained from the decay rates.[20d]

A solution of **3a** in acetonitrile was examined at room temperature under argon by time-resolved spectroscopy. A weak transient absorption with a maximum at about 500 nm was observed, which is assigned to a T–T process because of the lifetime and sensitivity to oxygen. The decay follows strict first-order kinetics and is assigned to an intersystem crossing (ISC) process $T_1 \rightarrow S_0$, which has a surprisingly small rate constant $k_1 = 36\ s^{-1}$. The corresponding lifetime for the T_1 state, which probably corresponds to structure **3′**, is 28 ± 2 ms. The S_1 lifetime of **3a** could not be determined because of the lack of fluorescence.

The transient absorption of **3a** in 1,2-dibromoethane occurs at the same wavelength, is stronger than in acetonitrile, and can be detected even in dilute solution and in the presence of oxygen. The decay follows strict second-order kinetics. Owing to technical problems only the product of the corresponding rate constant k_2 and the extinction E_m of the sample could be determined ($k_2 E_m = (5.1 \pm 1.5) \times 10^3$). Apparently this decay is related to an $S_1 \rightarrow T_n$ process initiated by the heavy atoms in the solvent, which leads to the efficient population of the corresponding T_1 state. This state is deactivated by means of a triplet–triplet annihilation process.

PPP-π-SCF calculations were carried out based on force field calculations, in which a twisted structure analogous to the X-ray structure was used for the starting geometry. In these calculations the two lowest lying S_1 and T_1 states are characterized as

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0574 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 5

charge transfer states, in which one electron from the HOMO, which is localized primarily in the phenothiazine unit, is transferred to the LUMO, which is localized predominantly in the trimethine unit. Thus, the electronic properties of both units change during the relatively long lifetime of the T_1 state. If it were possible to produce polyvinamidines[8] from **3**, then this change in the electronic properties should be apparent, for example, as a change in the electric conductivity.

Thus the 1-phenothiazinylvinamidinium salt **3a** can be considered to be a model of a molecular switch; flash excitation induces the transfer of an electron from the phenothiazine moiety to the cyanine unit, whereby the properties of both units change reversibly.

Experimental Procedure

4b: *N,N*-dimethylformamide (9.3 mL, 25 mmol) in anhydrous chloroform (10 mL) was mixed with oxalyl chloride (2.2 mL, 25 mmol) in chloroform (10 mL) at 0 °C. To this solution was added dropwise a solution of 10-acetylphenothiazine (2.11 g, 10 mmol) in anhydrous chloroform (10 mL). After 12 h the solvent was removed under vacuum at room temperature, and the residue was treated with ice water and 70% aqueous perchloric acid (2 mL). Yield: 2.18 g (52%); yellow crystals, m.p. 205 °C (acetonitrile/ether). ^{1}H NMR (CD_3CN): δ = 3.06 (s, 3H, NCH_3), 3.48 (s, 3H, NCH_3), 5.73 (d, J = 11.2 Hz, 1HJ, CCHC), 7.49–7.71 (m 8H, benzo-H), 8.19 (d, J = 11.2 Hz, 1H, NCHC).

3b: A suspension of **4b** (0.83 g, 2 mmol) in ethanol (5 mL) was treated with 33% ethanolic dimethylamine (5 mL). After 12 h the precipitate was removed by vacuum filtration. Yield: 0.50 g (70%); yellow crystals, m.p. 187–188 °C (methanol). ^{1}H NMR ($CDCl_3$): δ = 3.29 (s, 9H, NCH_3), 3.40 (s, 3H, NCH_3), 5.68 (d, J = 12 Hz, 1H, CCHC), 6.45–7.18 (m, 8H, benzo-H), 7.73 (d, J = 12 Hz, 1H, NCHC).

5: A suspension of **3a** (0.41 g, 1 mmol) in anhydrous dichloromethane (20 mL) was cooled to −30 °C and stirred while nitrosyl tetrafluoroborate (0.12 g, 1.1 mmol) was added in portions. The reaction mixture was allowed to warm to room temperature over 30 min. The precipitate was removed by vacuum filtration after 6 h. Yield 0.09 g (18%); black-violet needles (acetonitrile/ether), m.p. 185–186 °C (decomp). UV/VIS (MeCN): λ_{max} (lg ε) = 211 (4.473), 256 (4.427), 276 (4.438), 330 (4.619), 522 (3.978), 815 (2.903) nm.

Correct elemental analyses were obtained for all compounds.

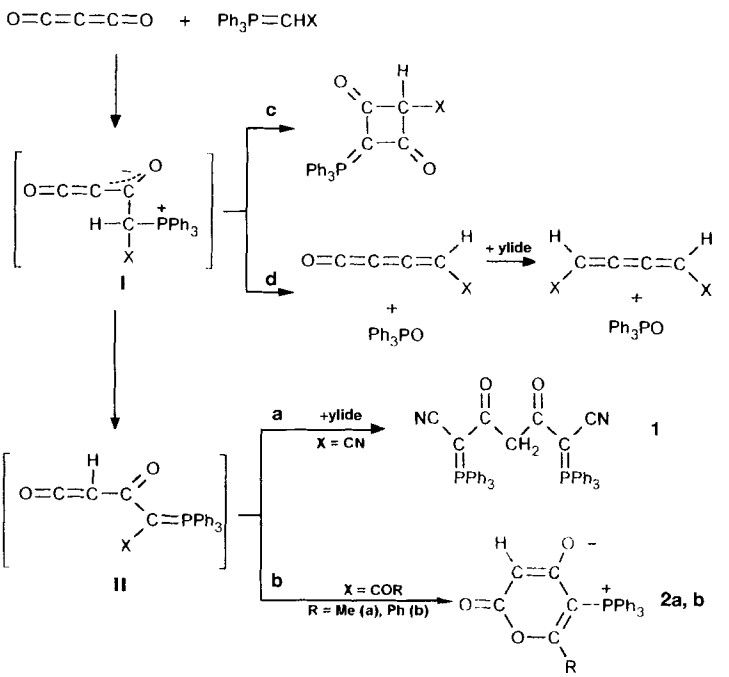
Reactions of C_3O_2 with Stabilized Triphenylphosphoranes $Ph_3P{=}CHX$ (X = CN, COMe, COPh)**

Luciano Pandolfo,* Giacomo Facchin,* Roberta Bertani, Paolo Ganis, and Giovanni Valle

Dedicated to Professor Gastone Paiaro on the occasion of his 65th birthday



Carbon suboxide, C_3O_2, ist an extremely reactive "clean" compound, suitable for various organic and organometallic syntheses.[1] By reaction with nucleophiles a great variety of either open chain malonic acid derivatives, or heterocycles can be obtained depending on the reagents and reaction conditions used.[1]

Phosphorus ylides are quite versatile nucleophiles, whose electronic and steric properties can be modulated by changing the substituents on the ylidic carbon atom.[2]

A few reactions between C_3O_2 and ylides have been published;[3] however, the results of these are not completely in agreement with each other. Excluding the earlier report,[3a] in which the formation of a cyclobutanedione derivative was postulated, the reaction of C_3O_2 with ylides has been applied to prepare pentatetraenic systems (C_5 compounds with four double bonds) through the Wittig reaction. However, well-defined cumulenic products were obtained only in the case of ylides without hydrogen substituents on the ylidic carbon atom.[3b, c]

Here we report the reactions between C_3O_2 and the stabilized ylides $Ph_3P{=}CHX$ (X = CN, COMe, COPh). The reactions, performed in toluene at room temperature or at 80 °C or in 1,2-dichloroethane, give, depending on the ylide used, linear (**1**) or cyclic (**2**) compounds in nearly quantitative yields. Several routes are possible for this reaction and these are summarized in Scheme 1. Very likely the first step consists of a nucleophilic attack of the ylidic carbon atom on one carbonyl group of C_3O_2,[1] forming the intermediate **I**. This is followed by different reactions or rearrangements. There is no evidence of the Wittig reaction as a main process and high yields of stable linear malonic acid derivatives or zwitterionic pyrone-like compounds are obtained.

Cyanomethylenetriphenylphosphorane ($Ph_3P{=}CHCN$) reacts with C_3O_2 to give exclusively the malonic acid derivative **1** (route a of Scheme 1). The reaction proceeds at room temperature in 1:2 ratio (C_3O_2/ylide) and is complete within a few minutes. The molecular structure of **1**[4] is depicted in Figure 1. The molecule shows virtual C_2 symmetry, with the twofold axis passing through the C4 atom. The bond lengths P1–C1 and P2–C6, both of about 1.75 Å, are indicative of some double

Scheme 1. Possible pathways for the reaction between C_3O_2 and ylides.

bond character. The bond lengths C1–C3 (1.434(8) Å) and C5–C6 (1.421(8) Å) indicate partial double bond character as expected in the presence of adjacent CO groups.[5] The C–O bond

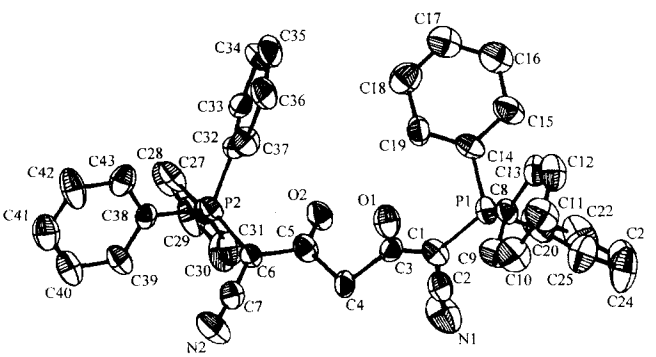


Fig. 1. Molecular structure of **1** (thermal ellipsoids at 30% probability level) with atom numbering. Selected distances [Å] and angles [°] with standard deviations in parentheses: P1-C1 1.754(8), P1-C8 1.787(6), P1-C14 1.783(7), P1-C20 1.775(7), P2-C6 1.746(8), P2-C26 1.795(5), P2-C32 1.787(6), P2-C38 1.793(7), C1-C2 1.403(8), C1-C3 1.434(8), C2-N1 1.152(7), C3-O1 1.226(7), C3-C4 1.528(9), C5-C4 1.543(8), C5-O2 1.231(7), C5-C6 1.421(8), C6-C7 1.416(9), C7-N2 1.156(8); P1-C1-C3 118.4(7), P1-C1-C2 118.4(9), C2-C1-C3 122.9(7), P2-C6-C5 115.0(9), P2-C6-C7 121.1(8), C7-C6-C5 123.4(7), C6-C5-O2 119.4(7), C6-C5-C4 120.5(7), O2-C5-C4 120.0(7), C1-C3-O1 123.4(8), C1-C3-C4 116.9(7), O1-C3-C4 119.6(8), C3-C4-C5 107.9(8).

lengths are almost normal for keto groups; these are oriented in such a way as to bisect the bond angles C8-P1-C14 and C26-P2-C32, probably in order to favor a positive interaction between $P^{\delta+}$ and $O^{\delta-}$. The resulting "eclipsed" conformation of the cyano groups with respect to the bonds P1–C20 and P2–C38 gives rise to nonbonding distances C2···C20 and C7···C38 of about 3.05 Å. The crystal structure contains 1.5 molecules of toluene per molecule of **1**.

The ^{31}P NMR spectrum of **1** shows a singlet at $\delta = 20.37$, which is high-field shifted with respect to the ylide signal at $\delta = 23.18$, and is in the range expected for a phosphonium

system. This is in agreement with the relatively long P–C bonds, as found in the X-ray determination. In the ^{1}H NMR spectrum of **1**, recorded in CD_2Cl_2 or in $CDCl_3$, signals originating from a possible keto–enol equilibrium are not detected.

By reacting C_3O_2 with $Ph_3P{=}CHCOR$ (R = Me, Ph) in toluene, the cyclic derivatives **2a** and **2b** are obtained in high yields. The reactions proceed in a stoichiometric ratio 1:1, resulting in the formation of the heterocyclic systems after a nucleophilic intramolecular attack of the ylidic carbonyl group (COR) on the ketene moiety in **II** (route b, Scheme 1). Closely related behavior was previously reported in the reaction of C_3O_2 with 1,3-dicarbonilyl compounds.[6]

The molecular structure[4] of **2a** is shown in Figure 2. The six-membered ring is almost planar and the same plane also contains the atoms P1 and C7. The bond lengths C2–O1

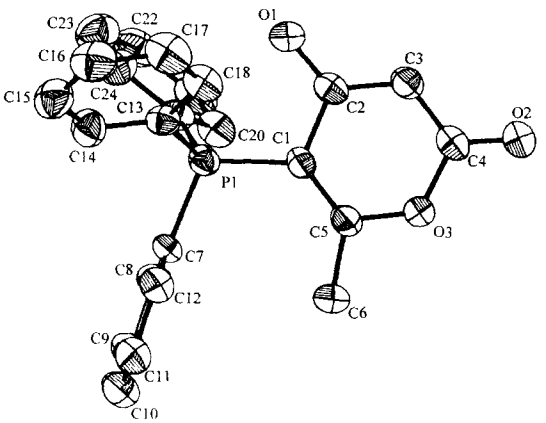

Fig. 2. Molecular structure of **2a** (thermal ellipsoids at 30% probability level) with atom numbering. Selected distances [Å] and angles [°] with standard deviations in parentheses: P1-C1 1.787(3), P1-C7 1.800(4), P1-C13 1.796(4), P1-C19 1.804(4), C1-C2 1.492(5), C2-C3 1.354(4), C2-O1 1.251(4), C3-C4 1.404(5), C4-O2 1.218(4), C4-O3 1.380(4), C5-O3 1.387(4), C5-C6 1.494(6), C5-C1 1.349(4); P1-C1-C5 128.4(4), P1-C1-C2 111.1(2), C1-C5-C6 131.7(4), C1-C5-O3 118.9(4), C6-C5-O3 109.5(3), C5-O3-C4 124.0(3), C3-C4-O3 116.2(4), C3-C4-O2 123.9(5), O3-C4-O2 119.8(3), C2-C3-C4 124.0(4), C1-C2-O1 118.2(4), C1-C2-C3 116.4(3), O1-C2-C3 125.3(4).

[1.251(4) Å] and C4–O2 [1.218(4) Å] support the zwitterionic character of the molecule, confirmed also by the P1–C1 distance of 1.787(3) Å which falls in the range of bond lengths reported for phosphonium ions.[7] Noteworthy is the eclipsed conformation of the bonds P1–C7 and C1–C5, as found for **1**, and the relatively short intramolecular nonbonding distance between C7 and C6 (ca. 3.13 Å). The conformation, such as obtained through a rotation of 180° about the P1–C1 bond and with analogous distortions of the angles C1-C2-O1 and P1-C1-C2, would be certainly preferred on the basis of mere intramolecular van der Waals interactions, but it would probably oppose the stabilizing ionic interaction between $P1^+$ and $O1^-$, which in **2a** are 2.78 Å apart. The crystal structure contains two solvent molecules of CH_2Cl_2 per molecule of **2a**.

^{31}P NMR spectra of **2a** and **2b** show a singlet at $\delta = 16.16$ and 17.31, respectively, characteristic for phosphonium systems.[2]

We have tried to force the Wittig reaction (route d) by heating compounds **1** and **2** under reflux in 1,2-dichloroethane for three days. The solution of **1** remains unchanged, whereas solutions of **2a, b** become red, slowly releasing CO_2 (evidenced by IR spectra) which possibly originates from the decomposition of the α-pyronic ring. TLC of the resulting solutions show the presence of several compounds, which were not further characterized.

The present work shows that the reactions of C_3O_2 with ylides bearing a hydrogen atom on the ylidic carbon atom follow alternative routes with respect to those previously reported for different ylides without H substituents.[3] A fundamental role seems to be played by the easily displaceable hydrogen atom. It migrates to the carbanionic carbon atom in the intermediate **I** forming the ylide **II**. This process is similar to that reported for the reaction of ylides with electron-poor olefins.[8] For X = CN intermediate **II** reacts with a second molecule of cyanomethylenetriphenylphosphorane to yield **1** (route a, Scheme 1). For X = COR an intramolecular nucleophilic attack of the carbonyl oxygen atom of the ylide moiety on the carbonyl carbon atom of the ketene occurs, (route b) leading to the pyrone derivatives **2**. In all cases, we have not found any evidence for a Wittig reaction (route d), or for the formation of cyclobutanedione derivatives (route c).

Experimental Procedure

1: The ylide $Ph_3P{=}CHCN$ (0.550 g, 1.82 mmol) was dissolved in 50 mL of a toluene/CH_2Cl_2 solution (5/1) and a solution of C_3O_2 in toluene (3.2×10^{-2} M, 28.5 mL, 0.91 mmol) was added at room temperature under stirring. The solution became light yellow and the IR spectra revealed the disappearance of C_3O_2. The solution was concentrated under vacuum at room temperature to 40 mL, the white solid obtained was filtered off, washed with toluene, and dried under vacuum. Yield 0.450 g (73%). Compound **1** was also obtained when the reaction was performed in 1,2-dichloroethane, yield 85%. M.p. 243–244 °C (decomp). Correct C,H,N analysis. IR(nujol) [cm^{-1}]: 2175 (CN), 1565 (CO); ^{1}H NMR (200 MHz, CD_2Cl_2, 25 °C): $\delta = 4.01$ (s, CH_2), 7.72–7.46 (m, C_6H_5), ^{13}C NMR (CD_2Cl_2, 25 °C): $\delta = 49.63$ (d, ^1J(CP) = 126.70 Hz, CP), 51.30 (t, ^3J(CP) = 7.04 Hz, CH_2), 191.04 (dt, ^2J(CP) = 5.84, ^2J(CH) = 5.39 Hz, CO), CN (signal too weak to be observed). ^{31}P NMR ($CDCl_3$, 25 °C) $\delta = +20.37$(s). FAB MS in glycerol: *m/z* (%): 671 (13.7) [$M - H^+$], 670 (0.1) [M^+].

2: The ylide ($Ph_3P{=}CHCOMe$ (**a**) or $Ph_3P{=}CHCOPh$ (**b**)) was dissolved in anhydrous toluene, an equimolecular amount of C_3O_2 [9] dissolved in toluene was added at room temperature and the solution was stirred for 3 h. The solvent was partially removed under vacuum, and pale yellow crystals were obtained which were filtered, washed with toluene at 0 °C, and dried under vacuum. Yield: **2a**: 91%, **2b**: 96%. **2a** and **2b** were obtained, with similar yields, also when the reactions were performed in 1,2-dichloroethane at room temperature or in toluene at 80 °C.

2a: M.p. 213–215 °C (decomp). Correct C, H analysis. IR(nujol) [cm^{-1}]: 1693 (CO). ^{1}H NMR (200 MHz, CD_2Cl_2, 25 °C): $\delta = 1.52$ (d, ^4J(HP) = 1.42 Hz, CH_3), 5.00 (d, ^4J(HP) = 3.59 Hz, CH), 7.69–7.16 (m, C_6H_5). ^{13}C NMR (CD_2Cl_2, 25 °C): $\delta = 20.05$ (q, ^1J(CH) = 130.25 Hz, CH_3), 84.32 (dd, ^1J(CH) = 165.15 Hz, ^3J(CP) = 3.59 Hz, CH), 100.76 (d, ^1J(CP) = 116.70 Hz, =CP), 165.18 (d, ^2J(CH) = 3.80 Hz, CO^-), 172.63 (dq, ^2J(CP) = 28.68 Hz, ^2J(CH) = 5.38 Hz, Me-C-O-), 177.13 (d, ^2J(CH) = 3.59 Hz, C=O). ^{31}P NMR ($CDCl_3$, 25 °C): $\delta = +16.16$(s). FAB MS in glycerol *m/z* (%): 387 (0.3) [$M - H^+$], 386 (0.4) [M^+].

2b: M.p. 216–218 °C (decomp). Correct C, H analysis. IR(nujol) [cm^{-1}]: 1706 (CO). ^{1}H NMR (200 MHz, CD_2Cl_2, 25 °C): $\delta = 5.13$ (d, ^4J(HP) = 3.59 Hz, CH), 7.57–6.89 (m, C_6H_5). ^{13}C NMR (CD_2Cl_2, 25 °C): $\delta = 85.78$ (dd, ^1J(CH) = 165.16, ^3J(CP) = 4.20 Hz, CH), 100.35 (dd, ^1J(CP) = 113.58, ^3J(CH) = 4.25 Hz, =CP), 165.08 (d, ^2J(CH) = 3.52 Hz, CO^-), 173.39 (dt, ^2J(C,P) = 17.97, ^3J(CH) = 8.43 Hz, Ph-C-O-), 177.35 (d, ^2J(CH) = 3.20 Hz, C=O). ^{31}P NMR ($CDCl_3$, 25 °C): $\delta = +17.31$(s). FAB MS in glycerol *m/z* (%): 449 (0.1) [$M - H^+$], 448 (0.05) [M^+].

Reactivity of a Phosphanylcarbene (λ^5-Phosphaacetylene) with Lewis Acids: X-Ray Crystal Structures of the First Carbene–Gallane Complex and *C*-Gallyl-Substituted Phosphorus Ylide**

Alan H. Cowley,* François P. Gabbaï, Carl J. Carrano, Ladd M. Mokry, Marcus R. Bond, and Guy Bertrand*

So far, only two types of stable carbene are known.[1, 2] Although both of them are heteroatom-substituted, their structures, as shown by molecular orbital calculations[3, 4] and reactivity studies, are significantly different. Arduengo et al.[5] have recently reported the synthesis of an alane-imidazol-2-ylidene complex, which is in fact the only structurally characterized carbene–Lewis acid adduct. In contrast, phosphanylcarbene–borane complexes are unstable and undergo a variety of rearrangements.[6] Herein, we report that phosphanylcarbenes exhibit a remarkably diverse reactivity depending on the nature of the Lewis acid employed, and of particular interest, we describe the synthesis of a stable phosphanylcarbene–Lewis acid complex.

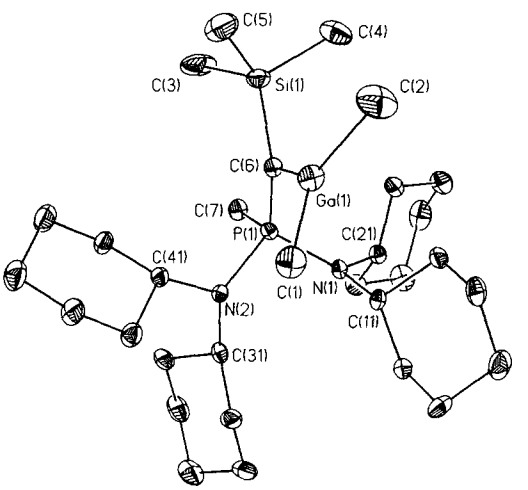
[Bis(dicyclohexylamino)phosphanyl](trimethylsilyl)carbene (**1**) reacts cleanly with $AlMe_3$, $GaMe_3$, and $InMe_3$ in Et_2O at −78 °C to afford the corresponding 1:1 adducts **2**, **3**, and **4**, respectively (Scheme 1). The similarity of the NMR data[7] for

Scheme 1. R = *cyclo*-C_6H_{11}; M = Al (**2**), Ga (**3**), In (**4**).

2, **3**, and **4** suggests that they possess comparable structures. For compound **3**, the presence of a doublet at $\delta = 1.61$ ($J_{PH} = 11.7$ Hz) in the ^{1}H NMR spectrum and a doublet at $\delta = 22.37$ ($J_{PC} = 84.4$ Hz) in the ^{13}C NMR spectrum indicated the presence of a methyl group directly bonded to phosphorus. The X-ray structure analysis[8] of the gallium compound **3** confirmed that formal Me–$GaMe_2$ addition across the phosphorus–carbon bond had taken place (Fig. 1). A number of



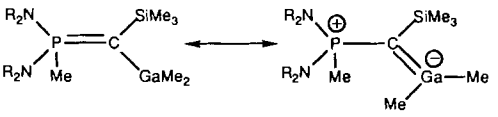


Fig. 1. View (ORTEP) of **3** showing the atom labeling scheme. Important bond lengths [Å] and angles [°]: P-C6 1.658(7), P-C7 1.808(6), P-N1 1.693(5), P-N2 1.690(5), C6-Si1 1.829(7), C6-Ga1 1.935(6), Ga1-C1 1.994(8), Ga1-C2 1.988(10); C6-P1-C7 113.4(3), C6-P1-N1 118.1(3), C6-P1-N2 112.6(3), C7-P1-N1 103.8(3), C7-P1-N2 105.3(3), N1-P1-N2 102.2(3), Ga1-C6-P1 120.0(4), Ga1-C6-Si1 110.3(3), Si1-C6-P1 129.1(4), C1-Ga1-C2 112.1(4), C1-Ga1-C6 125.4(3), C2-Ga1-C6 122.5(3).

structural aspects merit comment. The Ga1–C6 distance (1.935(6) Å) is appreciably shorter than those of the Ga1–C1 and the Ga1–C2 bonds (av. 1.991(10) Å), C6 and Ga1 both adopt a trigonal planar geometry (sums of angles = 359.4(4)° and 360.0(4)°, respectively) and the dihedral angle between the C1-Ga1-C2 and P1-C6-Si1 planes is small (36.7°). Taken collectively, this suggests a modicum of π-type interaction between C6 and Ga1 (canonical form **3B**; Scheme 2). However, the P1–C6 distance (1.658(7) Å) is shorter than that observed in the analogous boron system (1.696(2) Å), where such a π-type interaction has been demonstrated[9] thus favoring canonical form **3A**. In variable-temperature ^{1}H NMR experiments, we have found that the methyl groups of the $GaMe_2$ moiety become nonequivalent only below −85 °C.

3 A 3 B

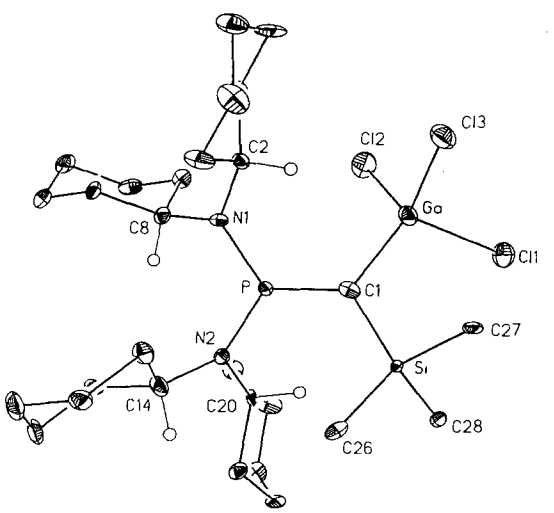
Scheme 2. Possible canonical formulae of **3**.

The reactions of **1** with the analogous chlorinated Lewis acids $AlCl_3$, $GaCl_3$, and $InCl_3$ in Et_2O solution at 25 °C likewise afford 1:1 adducts, namely **5**, **6**, and **7**, respectively (Scheme 3).

5-7

Scheme 3. M = Al (**5**), Ga (**6**), In (**7**).

However, the ^{31}P chemical shifts[7] of the products are distinctly different from those of the carbene–MMe_3 adducts. The X-ray structure analysis of **6**[8] indicated that **6** is the first carbene–gallane adduct (Fig. 2). Examination of the molecular structure



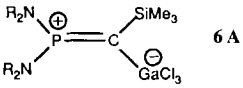


Fig. 2. View (ORTEP) of **6**·CH_2Cl_2 showing the atom labeling scheme. Important bond lengths [Å] and angles [°]: P-C1 1.601(9), P-N1 1.622(7), P-N2 1.619(8), C1-Si 1.886(8), C1-Ga 1.978(10), Ga-Cl1 2.210(3), Ga-Cl2 2.179(3), Ga-Cl3 2.198(3); N1-P-N2 113.4(4), N1-P-C1 125.1(5), N2-P-C1 121.4(4), P-C1-Si 121.8(6), P-C1-Ga 122.6(5), Si-C1-Ga 115.7(5), C1-Ga-Cl1 111.4(3), C1-Ga-Cl2 113.9(3), C1-Ga-Cl3 112.8(3), Cl1-Ga-Cl2 105.49(11), Cl1-Ga-Cl3 104.35(12), Cl2-Ga-Cl3 108.19(12).

of **6** reveals the following salient points: 1) the phosphorus and carbon atoms both adopt a trigonal planar geometry (sums of the angles = 359.8(8) and 360.0(8)°, respectively), 2) the phosphorus–carbon bond length of 1.610(15) Å, together with a rather small torsional angle of 34.1°, are indicative of a bond order of two, 3) the geometry at gallium is tetrahedral, thus implying that **6** is best described by a zwitterionic methylenephosphonium canonical form **6A** (Scheme 4).[10] Evidently, a similar structure persists in solution; the deshielded ^{31}P chemical shift of $\delta = 130$ is consistent with the presence of a double bond and positive charge development at phosphorus. Moreover, since the ^{31}P chemical shift and $^3J_{PH}$ coupling con-

6 A

Scheme 4. Predominant canonical formula of **6**.

stants for **5** and **7** are virtually identical to those of **6**, similar structures can be proposed for these adducts.[7] Compounds **5**–**7** are evidently the first examples of neutral zwitterionic methylenephosphonium compounds. However, an uneven charge distribution has been implied previously in the cation $[(iPr_2N)_2P{=}C(SiMe_3)_2]^+$.[10]

Overall, the present results demonstrate that the reactions of phosphanylcarbenes with Lewis acids are highly versatile and that the outcomes are based on subtle interplays of thermodynamic and steric effects.

Experimental Procedure

3: An excess of neat trimethylgallium (0.50 mL, 5.0 mmol) was added to a solution of **1** (1.0 mmol) in Et_2O (15 mL) at −78 °C. The reaction mixture was allowed to warm to 25 °C. The solvent and volatiles were then evaporated yielding a microcrystalline residue which was washed with pentane (5 mL) to afford 0.38 g (65% yield) of pale yellow microcrystalline **3** (m.p. 146–148 °C). X-ray quality crystals were grown by cooling a saturated toluene solution of **3** to −20 °C for two weeks. Compounds **2** and **4** were prepared by a similar procedure.

6: A solution of gallium trichloride (0.176 g, 1.0 mmol) in toluene (3 mL) was added to a solution of **1** (1.0 mmol) in Et_2O (15 mL) at 25 °C. The reaction mixture was stirred for 20 minutes during which time a precipitate was formed. The solution was removed with a cannula and the precipitate was washed with Et_2O (5 mL) affording 0.52 g (79% yield) of pale yellow solid **6** (m.p. 110 °C, decomp). X-ray quality crystals of **6**·CH_2Cl_2 were grown from a dichloromethane solution by slow evaporation of the solvent. Compounds **5** and **7** were prepared by a similar procedure.

[2 + 2]Cycloaddition of Norbornenes with Alkynes Catalyzed by Ruthenium Complexes**

Take-aki Mitsudo,* Hiroshi Naruse, Teruyuki Kondo, Yoshihiko Ozaki, and Yoshihisa Watanabe*

The [2 + 2]cycloaddition of olefins and/or alkynes is a versatile method for preparation of cyclobutane derivatives, and the cycloaddition has been achieved by thermal reactions via biradical intermediates,[1] photoreactions,[2] and transition-metal-catalyzed reactions.[3] Among them, ruthenium-complex-catalyzed cycloaddition of norborn*enes* (bicyclo-[2.2.1]heptene derivatives) with ethynedicarboxylates is a unique reaction.[3] The catalyst was $[RuH_2(CO)(PPh_3)_3]$ or [Ru(cod)(cot)] (cod = 1,5-cyclooctadiene, cot = 1,3,5-cyclooctatriene)]/PR_3), and the reaction was applied to the preparation of pseudo-ladder compounds.[4, 5] However, the reaction had a severe limitation: only ethynedicarboxylates could be used. We now report that [Cp*RuCl(cod)][6] (**1**, Cp* = pentamethylcyclopentadienyl) is an excellent catalyst for the [2 + 2]cycloaddition of norbornenes with various alkynes. Further, the analogous reaction of terminal alkynes with norborn*adiene* (nbd, bicyclo[2.2.1]hepta-2,5-diene) gives 1,3-disubstituted benzene as well as the [2 + 2] adducts.

Both aliphatic and aromatic internal alkynes readily reacted with norbornene in the presence of a catalytic amount of **1** at 80 °C to give the corresponding [2 + 2]cycloadducts, *exo*-3,4-disubstituted tricyclo[4.2.1.0.^{2,5}]non-3-enes in high yields (Scheme 1, **A**/**B**). The *exo* structure of the adducts was confirmed by ^{1}H NMR spectroscopy; no coupling of the 2,5-protons with those at the bridgehead was observed.[7] Unsymmetrical internal alkynes as well as symmetric ones reacted successfully. Furthermore, a double cross-adduct was also prepared by a stepwise reaction (run 7).

Complex, **1** also catalyzed the reaction of internal alkynes with norborn*adiene* (Scheme 1, **C**) to give the corresponding [2 + 2]cycloadducts, and the complex was completely converted into [Cp*RuCl(nbd)] in the reaction. Since the formed [Cp*RuCl(nbd)] is more stable than **1**, the rate of [2 + 2]cycloaddition of diphenylethyne with norbornadiene (run 11) was slower than that in the reaction with norbornene (run 1). However, alkynes with electron-withdrawing groups such as methyl 2-butynoate (run 9), and ethyl 3-phenylprop-2-ynolate (run 10) readily reacted to give the corresponding adducts in high yields.

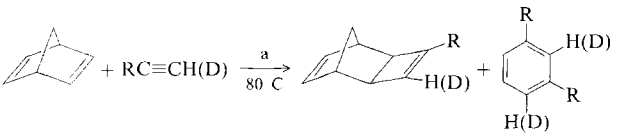
Scheme 1. [Cp*RuCl(cod)]-catalyzed [2 + 2]cycloaddition of norbornenes and norbornadiene with alkynes. The reactions were performed in an argon atmosphere. a) 4.0 mmol norbornene, 2.0 mmol ethyne, 0.1 mmol [Cp*RuCl(cod)] (**1**); b) 1.5 mL NEE_3 as solvent; c) 1 mL benzene as solvent; d) 10.0 mmol norbornadiene, 2.0 mmol alkyne, 0.1 mmol **1**, no solvent. The yields are based on the alkyne concentration. The yield in parentheses was determined by gas chromatography.



Effects of solvents and additives on the [2 + 2]cycloaddition reaction of diphenylethyne with norbornene (run 1) catalyzed by **1** were examined. The reaction proceeded smoothly at 80 °C for 15 h in *n*-hexane (85% yield determined by gas chromatography), benzene (83%), triethylamine (91%), and THF (85%), but when pyridine (2%) or DMSO (0%) was employed as a solvent, the reaction was suppressed. Although phosphane ligands had been quite effectively employed in the reaction of dimethyl ethynedicarboxylate with norbornenes catalyzed by [Ru(cod)(cot)]/P*n*Bu$_3$ or $[RuH_2(CO)(PPh_3)]$ etc.,[3] in the present reaction addition of PPh_3 to the benzene solution resulted in the decease of the yield to 51% for PPh_3/Ru = 1.0 mol/mol and to 26% for PPh_3/Ru = 2.0 mol/mol. Cyclopentadienyl–phosphane complexes such as $[CpRuCl(PPh_3)_2]$ were inactive. Treating catalyst **1** with $AgOSO_2CF_3$ in triethylamine to generate a cationic $[Cp^*Ru]^+$ species[8] also decreased the catalytic activity (26% yield). These results strongly suggest that an active species of this reaction is a *neutral* "[Cp*RuCl]" moiety.

Both aromatic and aliphatic substituted terminal alkynes also reacted readily with norborn*adiene* in the presence of a catalytic amount of **1** at 80 °C to give the corresponding [2 + 2]cycloadducts accompanied by the formation of unexpected 1,3-disubstituted benzene derivatives (Scheme 2). Neither the 1,4- nor 1,2-disubstituted isomer was detected at all.

If the alkyne used in this reaction is [D_1]phenylethyne, in the [2 + 2]cycloadduct the expected position was labeled by deuterium, and in the 1,3-disubstituted benzene, *m*-terphenyl, the 2- and 4-positions were selectively labeled. Furthermore, dicyclopentadiene formed by Diels–Alder reaction of cyclopentadiene was detected in the reaction mixture. These results demonstrate that the source of the carbon atoms C5 and C6 in *m*-terphenyl is norbornadiene (olefinic carbons) and that C1 to C4 originate from two alkyne molecules.

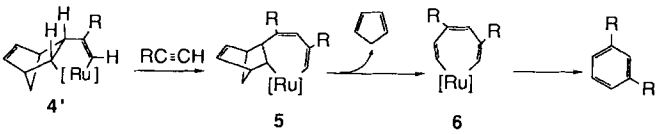
No.	R	t [h]	Yield (add.)	Yield (arene)
12	Ph	16	44	26
13	n-C_8H_{17}	40	23	20
14	n-$C_{10}H_{21}$	40	23	12

Scheme 2. [Cp*RuCl(cod)]-catalyzed reaction of norbornadiene with terminal alkynes. The yields were determined by gas chromatography. a) 10 mmol norbornadiene, 2 mmol alkyne, 0.10 mmol **1**. add. = [2 + 2]cycloaddition product, arene = 1,3-disubstituted benzene product.



Although mechanism of the [2 + 2]cycloaddition has not yet been clarified, one of plausible possibilities is illustrated in Scheme 3. At first an unsaturated complex, [Cp*RuCl] (**2**), is formed by dissociation of cod from **1**; then norbornene and the alkyne coordinate at the unsaturated sites to form **3**. The coordination of norbornenes was invariably *exo* because π-electron density of the *exo* face of norbornenes is higher than that of the *endo* face.[9] A ruthenacyclopentene complex **4** is formed by oxidative cyclization. By successive reductive elimination, the *exo*[2 + 2]cycloadduct is formed, and unsaturated **2** is regenerated. The related reaction intermediates to the ruthenacyclopentene intermediate **4** in dimerization of norbornadiene with Ir[10] or Ni[11] catalyst have been isolated.

Scheme 3. Possible mechanism for the [2 + 2]cycloaddition. [Ru] = Cp*RuCl.

With an excess amount of norbornadiene, after the alkyne was completely consumed, [Cp*RuCl(nbd)], in which norbornadiene replaced 1,5-cyclooctadiene, was formed and recovered; therefore no deactivation of the catalyst was observed. However, with an excess of norbor*nene*, neither [Cp*RuCl(norbornene)$_2$] nor [Cp*RuCl(cod)] was detected after the reaction at all. The catalytic activity of [Cp*RuCl(cod)] was so high that ruthenacyclopentene complex **4** could not be detected. Furthermore, when the stoichiometric reaction of [Cp*RuCl(nbd)] with diphenylethyne was monitored by ^{1}H NMR at 100 °C, only the signals for the substrates, [Cp*RuCl(nbd)], and the product were observed. The complexes **3** and **4** could not be detected, which suggests that the rate-determining step of this reaction is the simultaneous coordination of the norbornadiene and the alkyne to **3**.

The formation of 1,3-disbustituted benzene is rationalized by the route shown in Scheme 4 via the ruthenacyclopentene com-

Scheme 4. Possible mechanism for the formation of 1,3-disubstituted benzenes. [Ru] = Cp*RuCl.

plex **4'**. The second alkyne molecule inserts into **4'** to form **5**, then cyclopentadiene is eliminated from **5** by a retro-Diels–Alder reaction,[12] followed by reductive elimination to produce 1,3-disustituted benzene. These reactions are, to our knowledge, the first examples of carbon–carbon bond-forming reactions efficiently catalyzed by a neutral Cp*–ruthenium complex.

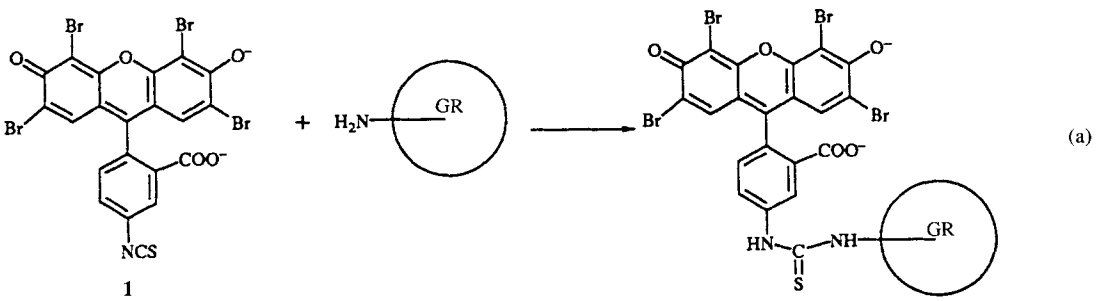
[12] The possibility of a retro-Diels–Alder reaction after the reductive elimination of **5** should be mentioned. No cyclohexadiene derivative derived from the reductive elimination of complex **5** was detected at all. Details will be discussed in a full paper.

Activation of Glutathione Reductase by Light: A Novel Approach to Design Redox Photo-Enzymes**

Itamar Willner* and Eran Zahavy

Dedicated to Professor Mordecai Rabinovitz on the occasion of his 60th birthday



Photoactivation of proteins has been the subject of extensive research efforts.[1] Reversible "ON–OFF" activation of enzymes[2] and other proteins[3] has recently been achieved by covalent linkage of photoisomerizable (photochromic) units to

the proteins. The participation of redox enzymes in light-induced electron transfer processes was accomplished by chemical modification of the protein in electron relay units.[4] In these studies protein-anchored electron acceptors acted as quenchers for the excited state of a diffusional photosensitizer and as electron mediators for transporting the electron to the enzyme active site. Here we report on the conversion of the enzyme glutathione reductase (GR) to a photoactive biocatalyst by covalent attachment of eosin to the protein. This modified enzyme is activated (switched "ON") by light. The light-induced redox process is followed by an electron transfer within the protein, and this leads to a biotransformation of the biocatalyzed reduction of oxidized glutathione (GSSG). Till now proteins with light-sensitive components have been modified to study electron transfer pathways in proteins.[5, 6] Our results highlight the possibility of coupling light-induced electron transfer with chemical transformations.

GR (from bakers yeast, EC 1.6.4.2, Sigma) was allowed to react with eosin isothiocyanate (**1**) to form the xanthene-dye-modified protein [Eq. (a)]. The loading of the enzyme corresponds to two units of eosin per protein. The eosin-modified enzyme Eo^{2-}-GR retains 50% of the activity of the native GR protein.[7] Illumination ($\lambda > 475$ nm) of our photosystem that includes Eo^{2-}-GR in a phosphate buffer solution (pH = 7.5) as well as Na_2EDTA (EDTA = ethylenediaminetetraacetic acid) as sacrificial electron donor and oxidized glutathione (GSSG), results in the formation of reduced glutathione GSH. The rate of GSH[8] formation as a function of illumination time is shown in Figure 1a. No GSH formation is observed in the dark or when Na_2EDTA is excluded from the system. These results indicate that GSH is formed by a photoinduced electron transfer. Indeed, stepwise illumination of the photosystem (Fig. 1b) reveals that GSH is formed upon exposure of the system to light and that the process is switched-off in the dark. Based on the amount of GSH formed after 200 minutes of illumination, we estimate 75 cycles of the enzyme active site (the molecular weight of GR used for this calculation was MW = 118000 g mole^{-1}[7]). Thus, Eo^{2-}-GR acts as a photocatalyst in this light-induced transformation.

Illumination of a photosystem ($\lambda > 475$ nm) that includes the native enzyme GR and eosin as a diffusional photosensitizer in the presence of Na_2EDTA and GSSG results in only trace amounts of GSH (Fig. 1c). The rate of GSH formation with the xanthene-dye-modified protein is about fivefold enhanced as compared to the diffusional biocatalyst–dye assembly. This improved yield with the covalently modified Eo^{2-}-GR is attributed to facilitated electron transfer communication within the protein. It should be noted, however, that the photosystem with Eo^{2-}-GR is about 1000-fold less active towards reduction of GSSG than the activity of the native enzyme that utilizes NADPH as electron donor.

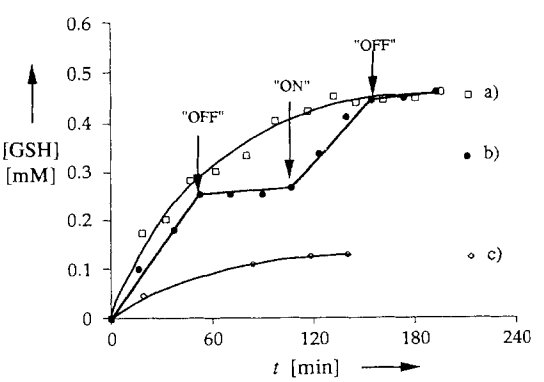

Fig. 1. Rates of GSH formation as a function of illumination time ($\lambda > 475$ nm): a) Photosystem consists of Eo^{2-}-GR (1 mg mL^{-1}), Na_2EDTA (1×10^{-2} M), and GSSG (1×10^{-2} M). b) The photosystem includes similar components as in (a). Arrows indicate the times when the light is switched "ON" or "OFF". c) Photosystem consists of GR, Eo^{2-} (1.7×10^{-5} M), Na_2EDTA (1×10^{-2} M), and GSSG (1×10^{-2} M). Phosphate buffer solutions (pH = 7.5) are used in all photosystems. All experiments were performed under an inert argon atmosphere.

A detailed flash photolysis study has allowed us to elucidate the electron transfer mechanism. The triplet lifetime of Eo^{2-}-GR is 36 μS. The primary process involves the intra-protein electron transfer quenching of the excited Eo^{2-}-GR state to generate the xanthene dye ion pair $Eo^{\bullet-}$ and $Eo^{3\bullet-}$ [Eq. (b)].[9] In the absence of the sacrificial electron donor Na_2EDTA, and GSSG, back electron transfer of the photogenerated products occurs [Eq. (c); $k_b = 2 \times 10^3\ s^{-1}$].[10] In the presence of added Na_2EDTA, oxidation of the sacrificial electron donor, [Eq. (d)] competes with the back reaction, and $Eo^{3\bullet-}$ is accumulated,

$$(^{T}Eo^{2-} + Eo^{2-}) - GR_{ox} \rightarrow (Eo^{\bullet-} + Eo^{3\bullet-}) - GR_{ox} \quad \text{(b)}$$

$$(Eo^{\bullet-} + Eo^{3\bullet-}) - GR_{ox} \xrightarrow{k_b} (Eo^{2-} + Eo^{2-}) - GR_{ox} \quad \text{(c)}$$

$$(Eo^{\bullet-} + Eo^{3\bullet-}) - GR_{ox} + Na_2EDTA \xrightarrow{k_{ox}} (Eo^{2-} + Eo^{3\bullet-}) - GR_{ox} + Na_2EDTA_{ox} \quad \text{(d)}$$

$$\downarrow$$

decomposition products

$$(Eo^{2-} + Eo^{3\bullet-}) - GR_{ox} \xrightarrow{k_{et}} (Eo^{2-} + Eo^{2-}) - GR_{red} \quad \text{(e)}$$

$$(Eo^{2-} + Eo^{2-}) - GR_{red} + GSSG + 2H^{+} \longrightarrow (Eo^{2-} + Eo^{2-}) - GR_{ox} + GSH \quad \text{(f)}$$

$k_{ox} = 3.8 \times 10^4\ s^{-1}$. In the presence of GSSG and Na_2EDTA, the photogenerated reduced product $Eo^{3\bullet-}$ decays. This process corresponds to electron transfer from the ion pair to the enzyme redox site, [Eq. (e); $k_{et} = 1.7 \times 10^2\ s^{-1}$] where reduction of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0582 $ 10.00+.25/0

GSSG occurs [Eq. (f)]. The electron transfer rate constant from $Eo^{3\bullet-}$ to the protein active site is small in comparison to previously reported values.[11]

It should be noted that the active site of GR is composed of an isoalloxazine unit, which is a part of the flavine adenine dinucleotide (FAD) cofactor, and a disulfide bond between Cys58 and Cys63.[12] We assume that electron transfer from $Eo^{3\bullet-}$ to the disulfide bond is mediated by the isoalloxazine unit.

This postulated kinetic scheme for electron transfer [Eq. (b)–(f)] was further supported by modification of α-chymotrypsin with eosin isothiocyanate. The α-chymotrypsin acts as hydrolytic protein and lacks an active redox center. Accordingly, the electron transfer reactions in this xanthene-dye-modified protein follow Equations (b)–(d). Nonetheless, since this enzyme lacks the active site, $Eo^{3\bullet-}$ (λ_{max} = 400 nm) is accumulated upon flash photolysis of the system in the presence of Na_2EDTA without noticeable decay.

We thus conclude that modification of GR with the photoactive eosin units converts the biocatalyst into a photostimulated protein. The covalently associated dye functions by two complementary pathways: It initiates the photoinduced electron transfer and acts as a relay unit within the protein backbone that facilitates electrical communication with the enzyme redox center. Nonetheless, the biocatalytic performance of Eo^{2-}-GR is substantially lower than that of the native enzyme and its NADPH cofactor. Linkage of chromophores to the protein exhibiting longer tethers may improve the electrical communication within the protein and also the activity of the photoenzyme. We suggest that such chromophore-modified proteins could provide a basic principle for designing novel photosynthetic devices.[13] By coupling two redox enzymes (an oxidative and a reductive protein) and their modification with appropriate light-active compounds, cyclic photosynthetic systems can be envisaged.

From Inorganic Materials to Carbohydrates

Inorganic Materials. Edited by *D. W. Bruce* and *D. O'Hare*. Wiley, Chichester, 1992. XIV, 543 pp., hardcover £ 55.00.– ISBN 0-471-92889-5

This book is another attempt to meet the need, which has become much more pressing in the last few years, for a modern presentation of inorganic chemistry and its close interaction with materials science. However, the title is to some extent misleading, as the nine chapters are concerned not so much with individual compounds as with areas of inorganic chemistry where there is activity in research and applications developments. Thus the book is in direct competition, both in its general subject area and detailed contents, with "Compounds", edited by A. K. Cheetham and P. Day, the recently published second volume in the series "Solid State Chemistry" (see *Angew. Chem.* **1993**, *105*, 472; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1396). In their choice of authors the editors have concentrated mainly on younger scientists, giving them the opportunity to present their specialist areas from their individual viewpoints. The result is a collection of articles that are concise, free from unnecessary verbiage, and sometimes unconventional but nevertheless highly competent. Often the individual chapters begin with a brief review of the historical development of the area under discussion, including definitions of the main terms used and an explanation of the necessary limitations on the choice of subject matter. This is followed by a more detailed treatment of a class of compounds, usually molecular.

Thus P. Cassoux and L. Valade, in their chapter entitled "Molecular Inorganic Superconductors" (58 pp.), place the main emphasis on $M(dmit_2)$ complexes (dmit = 4,5-dimercapto-1,3-dithiole-2-thionato), while O. Kahn, Y. Pei, and Y. Journaux in "Molecular Inorganic Magnetic Materials" (56 pp.) are concerned mainly with the ferri- and ferromagnetic properties of one-dimensional and discrete transition metal complexes. In "Metal-Containing Materials for Nonlinear Optics" (50 pp.), S. R. Marder first lays the foundation with an excellent introduction to the theory then deals mainly with second- and third-order nonlinear optical effects in organometallic compounds. D. O'Hare's survey of "Inorganic Intercalation Compounds" (71 pp.) is virtually all-embracing, though with a clear emphasis on intercalation phenomena in two-dimensional host lattices. In the chapter on "Biogenic Inorganic Materials" (58 pp.) S. Mann deals mainly with purely inorganic materials such as gypsum, magnetite, and calcite; in particular he discusses the different types and functions of these materials and their biological control mechanisms. In the chapter entitled "Clay Chemistry" (57 pp.) R. W. McCabe first describes the structures of these materials then discusses organic reactions that take place at their surfaces. The contribution by G. E. Kellogg and J. Gaudiello on "Polymeric Coordination Complexes" (52 pp.) is subtitled "Bridging Molecular Metals and Conductive Polymers", and takes up the theme of the metallophthalocyanines already mentioned in an earlier chapter, going into greater detail with regard to their synthesis and physical characterization. In the chapter on "Metal-Containing Liquid Crystals" (86 pp.) by D. W. Bruce the main focus is on mesomorphic coordination complexes with divalent ligands, while in "Precursors for Electronic Materials" (45 pp.) P. O'Brian is concerned mainly with small single-source molecules for the production of II/VI and III/V semiconductors.

In view of the limited length of the individual chapters it is understandable that an exhaustive treatment of all the interesting and important details has not been possible. On the other hand, there are some apparently inexplicable editorial failings which greatly detract from the effective use of the book. One such concerns the scanty index of only slightly more than six pages, which is also very superficial and unevenly compiled. Some important terms and substances are missing, and in other cases not all the relevant passages are listed. It would have been preferable to have two separate indexes for keywords and substances. Another deficiency is undoubtedly the abbreviations used for journals, which often do not follow international conventions and even differ within a single chapter. Abbreviations in the names of authors and journals are invariably given without periods (full stops), which may be the recommended practice nowadays, but takes a little getting used to and also sacrifices clarity. Yet another problem is the inconsistent treatment of abbreviations in the names of substances, so that whereas some of these are never explained, others are explained each time they appear. Here it would have been useful to include a separate list of such abbreviations, either with each chapter or for the book as a whole. Again, whereas one normally expects the figures to clarify points in the text, in this book they do not always succeed in doing so, as the figure captions are often too brief and superficial. Moreover, the device of distinguishing the different types of atoms in a compound by different filling colors has not been applied consistently, and sometimes degenerates into a chemical puzzle because the color codes are not explained. Also each figure or table needs to be mentioned in the text. The typeface is unnecessarily large. A more compact presentation would have significantly reduced the number of pages and also the price.

Notwithstanding these criticisms regarding the editorial and production aspects of the book, it must be said that the authors have devoted much effort to providing a thorough treatment not only of the physical properties of the materials but also of the chemical and preparatve aspects.

To summarize, the individual chapters give brief but mainly excellent introductions to important areas of research in inorganic chemistry, providing newcomers and non-specialists with an initial over-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

view and some insights. To that extent the book fulfills the aims set out by the editors in the preface. Those wishing to study the subject in greater depth will need to extend their reading to advanced monographs and more detailed texts, helped by the numerous literature references given (nearly 1500). Although not suitable as a student textbook, the work certainly offers students with sufficient previous knowledge an excellent resource for stimulating an interest in inorganic chemistry with regard both to materials and applications.

Thermal Analysis—Techniques and Applications. Edited by *E. L. Charsley* and *S. B. Warrington*. Royal Society of Chemistry, Cambridge, 1992. VIII, 296 pp., hardcover £ 45.00.—ISBN 0-85186-375-2

This multiauthor work is based on a course held in 1992 by the Thermal Analysis Consulting Service. It aims to provide an overview of the most important methods used in thermal analysis (TA) and to acquaint the reader with some recent advances and applications.

A brief (and superficial) introduction to TA methods is followed by chapters on differential thermal analysis and dynamic difference calorimetry (too brief and too qualitative), thermogravimetry, supplementary methods (not exhaustive, but up-to-date), evolved gas analysis, thermomechanical analysis and dynamic mechanical analysis (not enough relevant literature references), controlled rate TA (an important and valuable introduction to this new technique), applications of TA to polymers (informative, but lacking enough references to more advanced and detailed literature), TA in pharmacy (superficial and does not give an up-to-date review), applications of TA in metallurgy and materials science (very specialized), applications to minerals and fossil fuels, applications of TA to catalysts (does not remotely live up to what the title of the chapter promises), and quality control by TA (a first introduction to this important area, though it does not treat it in much depth).

Unfortunately the chapters concerned with fundamentals are not by themselves adequate in either their breadth of coverage or depth of treatment to enable the reader to apply TA methods. On the other hand, the chapters on applications are very uneven in quality. In some cases the authors are content to merely list examples of applications, and in others only a few examples are discussed in detail (as in the case of magnetic resonance TA, a technique which has probably scarcely been used by anyone other than the inventor and author of the article). There has evidently been insufficient discussion between the authors of the individual chapters, resulting in much unnecessary repetition and a lack of consistency in nomenclature. The quality of printing is good, despite the fact that the manuscripts have been reproduced in ordinary typescript characters (surprising in view of modern text-processing technology), with some of the chapters in justified style and others with an irregular right-hand margin. Some of the equations have been very carelessly typed.

Thus we have here a review volume which is of rather uneven quality (though inexpensive). It can serve as an introduction to this field, though not in much depth.

Determination of Thermodynamic Properties. 2nd Edition. (Series: Physical Methods of Chemistry, Vol. 6) Edited by *B. W. Rossiter* and *R. C. Baetzold*. Wiley, Chichester, 1992. XI, 743 pp., hardcover £ 157.00.—ISBN 0-471-57087-7

At a time when the primary literature is expanding at a near-explosive rate, whereas library budgets are suffering deep cuts, handbooks have become even more important than they were, say, 20 years ago. Such classics as the *Physical Methods of Chemistry* series aim to provide scientists involved in research and applications with a comprehensive, accurate, and concise introduction to the theory, methodology, and applications of measurement techniques, thus enabling them to select the most suitable ones for particular problems, and to consult the specialist literature before applying them.

Volume 6 of this 12-volume handbook is concerned with the determination of thermodynamic properties (although, regrettably, it does not cover the subject anywhere near exhaustively). In the chapter on "Mass and Density Determinations" R. S. Davies and W. F. Koch give a thoroughly adequate description of the most important methods of determining mass, together with their fundamental basis, including secondary effects on the weighing operation. However, in some places they might have brought out more clearly the advantages and disadvantages of the different weighing principles. The use of weighing methods in applications such as density measurement, and the measurement of partial molar volumes, moisture contents, and specific surface areas, are treated in appropriate detail. However, for many other applications, such as the determination of surface tension and contact angle, not even literature references are given. In the chapter "Pressure and Vacuum Measurements" C. R. Tilford treats the physical aspects of the measurement methods thoroughly, but includes almost nothing on applications, nor on the suitability of the methods for particular measurement tasks, aspects that the chemist wishing to determine properties would expect to find included. For example, there is not a word about vapor pressure measurements! P. J. Dunlop, K. R. Harris, and D. J. Young, in their chapter "Methods for Studying Diffusion in Gases, Liquids, and Solids", give a lucid introduction to the theory of diffusion (including ternary systems) and describe in great detail the experimental methods for gases, liquids, and solids. D. K. Wyatt and L. T. Grady contribute a chapter on "Determination of Solubility" (regrettably with some printing errors that should have been corrected) in which they review the classical methods. Here the authors could have shortened some of the material included in the previous edition and instead given more detail on, for example, gas-chromatographic and optical methods, the currently important topic of determining solubilities in liquified and supercritical gases, and continuous methods. Appropriate space is devoted to the determination of the rate of dissolution of solids in liquids. In the chapter on "Viscosity and its Measurement" J. Greener gives a good and detailed (perhaps even too detailed) theoretical treatment of the viscous behavior of fluids, and devotes special attention to the various sources of error in viscosity measurements. Unfortunately, though, measurements on gases are generally not discussed in enough detail. In the chapter on "Temperature Measurement with Application to Phase Equilibria Studies" J. B. Ott and J. R. Goates give a good introduction to this subject of great practical importance, with a wealth of important literature references, and their account of the application of temperature measurements to investigating phase equilibria is lucidly presented. However, it is unfortunate that in deriving thermodynamic relationships for mixed

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0505-0586 $ 10.00+.25/0

systems they have mainly limited their treatment to the ideal cases that so seldom occur in practice. J. L. Oscarson and R. M. Izatt, in their contribution on "Calorimetry", give most emphasis to descriptions of types of calorimeters, with less attention to the principles and applications of calorimetry, with the result that the chapter is more a list of publications than an aid to the user. The chapter "Differential Thermal Methods", by J. Boerio-Goates and J. E. Callenan, is of very uneven quality, with numerous printing errors (including some in equations), an inadequately researched literature coverage, and not enough references to up-to-date monographs and reviews dealing with new techniques and their applications.

These eight contributions together make up a volume in which much of the material is of excellent quality but some is in need of improvement. The editors ought to have paid attention to achieving better coordination between the contributions (and less repetition), ensuring that the same symbols were used for the same quantities throughout, eliminating obsolete units, and above all ensuring appropriate coverage of published work from outside the USA (especially when highly relevant). However, although the volume leaves much to be desired, it and the series to which it belongs should be in every library.

Solid Supports and Catalysts in Organic Synthesis. (Organic Chemistry Series.) Edited by *K. Smith*. Ellis Horwood/Prentice Hall, New York, 1992. XIV, 338 pp., hardcover $ 85.00. ISBN 0-13-639998-3

As K. Smith explains in the preface to this book on solid phase reagents and catalysts, it has been written especially with the needs of organic chemists in mind. It can be said at the outset that this aim has been very well fulfilled. The twelve chapters by eminent authors provide the reader with information on almost every aspect of solid phase reagents in organic and bioorganic synthesis. The individual contributions together make up a well rounded work, a praiseworthy achievement by the editor.

The first part (61 pp.) describes the most commonly used solid phases. The discussion is divided into inorganic phases (P. Diddams) and organic phases (J. M. Maud), affording an insight into the structures and properties of silica gels, aluminas, graphites, clays, and zeolites, as well as a variety of polymers, mostly polystyrene-based. The tables detailing and comparing the different phases are an especially pleasing feature; the wealth of useful information provided includes structural type, pore size, specific surface area, acidity, manufacturers (!), and names of commercial products (!).

The second part (130 pp.) describes "conventional" organic reactions using solid state reagents. These are discussed according to the types of support materials, namely amorphous inorganic supports (M. Butters), clays and graphites (J. A. Ballantine), zeolites (M. Butters), and polymers (J. M. Maud), rather than under reaction types. This arrangement gives a good overview of the areas of application of each type of solid phase, but for the user wishing to carry out a particular transformation it is undeniably rather inconvenient. This would not be a serious shortcoming if there were a good index enabling one to find particular reaction types. Here, however, one of the book's few weaknesses becomes apparent, as the subject index is much too sparse and does not even enable one to find relevant sections. For example, if one is seeking information about the oxidation of alcohols, under this heading the index refers one only to Section 3.10.1 (oxidation of alcohols on SiO_2), failing to mention Sections 5.12.1 (oxidation of alcohols on zeolites) or 9.6 (oxidation of alcohols using biocatalysts). Under "Alcohols" one finds no entry at all on this topic. Regrettably, any number of such examples could be given, and this diminishes the value of the book.

The third part (80 pp.) is devoted to biological applications, consisting of detailed treatments of solid phase peptide syntheses (J. S. Davies), oligonucleotide syntheses (H. A. White), and immobilized biocatalysts (J. M. Woodley). Nonspecialists too will benefit from reading these clear and readily understandable chapters.

Last but not least, the fourth part (52 pp.) describes special applications. It begins with a chapter by M. E. Fakley and F. King on hydrogenations, which is unfortunately rather too brief. In the report on microreactors by P. Laszlo which follows, one would again have liked some more detailed information on the types and applications of such systems. The book ends with an excellent chapter on the use of microwave radiation to activate reactions on solid phases (G. Bram, A. Loupy, and D. Villemin), including many examples illustrating the considerable potential of this method, which has so far been little exploited.

Despite some weaknesses (notably the subject index), a few printing errors, and minor inelegancies (floating substituents in some of the structure diagrams), the organic chemist will find in this book a wealth of useful examples of reactions on solid phases. The numerous literature references will be an additional aid to readers seeking to become involved in the world of supported reagents and catalysts.

Institut für Organische Chemie
der Universität Göttingen (FRG)

Solid State Chemistry. An Introduction. By *L. Smart* and *E. Moore*. Chapman and Hall, London, 1992. XII, 292 pp., paperback £ 15.95. ISBN 0-412-40040-5

L. Smart and E. Moore have set themselves the task of writing an *introductory* textbook on solid state chemistry specially for students following a basic chemistry course. It can be said at the outset that they have succeeded very well. Each of the eight chapters introduces its subject matter at a basic level, assuming very little previous knowledge.

Chapter 1 is concerned with simple crystal structures, which are described in terms of the occupancy of the holes in a close-packed arrangement of spheres. The two-color illustrations (in green and gray) are clear and self-explanatory. The only structure diagram that I would criticize is that for quartz, in which the helical connection of the tetrahedra is not obvious. Chapter 2 treats bonding in solids on the basis of the band structure model, then Chapter 3 discusses lattice defects and nonstoichiometric compounds. The authors constantly seek to relate the subject to modern technological applications; in this chapter, for example, they describe oxygen ion conductors and the sodium–sulfur accumulator. Chapter 4 deals with low-dimensional solids such as polyacetylene and the tetracyanoplatinates, and discusses their anisotropic physical properties. Chapter 5 introduces the structural chemistry of zeolites, including also modern techniques for the elucidation of zeolite structures such as solid-state ^{29}Si NMR spectroscopy. Applications of zeolites are discussed, with the main emphasis on their catalytic properties. Chapter 6 is concerned with the optical properties of solids, and again these

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0505-0587 $ 10.00+.25/0*

are related to modern technological applications, with lucid explanations of the mechanisms of light-emitting diodes (LEDs) and diode lasers. Chapter 7 deals with the magnetic properties of solids. A short introduction to the different types of magnetic materials is followed by a discussion of some applications, for example, data storage using ferromagnetic materials such as CrO_2 or ferrimagnetic materials as the basis for magnetic bubble data stores. The book ends with Chapter 8 on superconductivity. The treatment of this highly topical subject consists of a historical survey of the discovery and development of superconducting materials, followed by a lucid but rather superficial account of the Bardeen–Cooper–Schrieffer (BCS) theory, and a detailed discussion of the structures of oxide superconductors. Each chapter ends with a list of references for further reading, with comments, and a set of carefully chosen questions that can be used to test one's knowledge, together with answers.

In a book of fewer than 300 pages it is inevitable that there are some gaps. For example, the ligand field theory is not discussed, nor are preparative aspects of solid state chemistry such as chemical transport reactions. However, the authors have not aimed to write a comprehensive work on solid state chemistry; instead they have accomplished the rare trick of producing a textbook that is a pleasure to read and is capable of arousing in students an interest in the supposedly "dry" but highly topical subject of solid state chemistry.

Analytische Chemie
der Universität Gießen (FRG)

Carbohydrates—Synthetic Methods and Applications in Medicinal Chemistry. Edited by *H. Ogura, A. Hasegawa* and *T. Suami*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York/Kodansha, Tokyo, 1992. XIII, 406 pp., hardcover DM 208.00.—ISBN 3-527-29012-5/1-56081-701-1/4-06-205807-3

This book is a summary of twenty essays presented at "Fuji 90", a post-symposium of the 15th International Carbohydrate Symposium. It is intended mainly for scientists in synthetic and medicinal chemistry. Without claiming completeness, the authors discuss some highly topical aspects of the latest state of knowledge on the synthetic applications and biological functions of carbohydrates. While research on carbohydrates was in the past directed mainly towards their utilization in agriculture, manufacturing, and construction, present day research focusses on the use of carbohydrates as cheap enantiomerically pure raw materials for stereocontrolled syntheses of complex biologically active molecules. Recent developments in carbohydrate structural analysis and synthetic methodology benefit biochemists and medicinal chemists in their studies on cell–cell interactions at the molecular level in the search for new therapeutic agents.

The book is organized in four general topics: Synthetic Methods for Chemical Modification of Carbohydrates; Synthetic Methods for Enzymatic Modification of Carbohydrates; Synthetic and Biological Studies of Sialic Acid; Functional and Biological Studies on Glyco-Conjugates.

The first topic includes nine articles related to the conversion of mono- and disaccharides into suitably functionalized enantiopure building blocks for the synthesis of various non-sugar target molecules or different types of carbohydrate analogs. Since there is an enormous amount of literature on natural products synthesized via this approach, the authors focus on selected examples including marine natural products, macrolides, antibiotics, and alkaloids. Special attention is paid to transformations of carbohydrates involving their anomeric center, such as glycosylation reactions, C-glycosyl bond formation, and radical spirocyclization. The examples given demonstrate the efficient application of modern preparative organic methodology, thus reflecting the state of the art in the subject.

As a logical continuation of the first topic, articles contained in the second topic deal with combined synthetic and enzymatic methods for construction of oligosaccharides by glycosylation of monosaccharides or degradation of polysaccharides. Following the biochemical pathways of carbohydrate metabolism, the practical use of enzymes such as glycohydrolases and glycosyltransferases is discussed. Heterooligosaccharides such as glycoproteins and glycolipids are chosen as synthetic targets due to their significant role in processes of intercellular recognition, cell differentiation, and growth.

A third main theme of the book is the chemistry and biology of the cell surface located sialic acids as the most important terminal units of glycolipids and glycoproteins. Sialic acids are involved in a series of important regulatory processes such as membrane permeability, intercellular interactions, suppression of immune reactions, and protection of glycoproteins such as enzymes against too rapid proteolysis. On the other hand, pathological disorders of sialic acid metabolism are connected with many diseases caused by viruses, bacteria, and toxins. Therefore, the extensively described up-to-date synthetic and biological studies on various analogs and derivatives of sialic acids offer possibilities for a better understanding of their structural and functional role in cell biology and for the development of novel medicinal therapeutic strategies.

In the last three chapters the biological significance of cell surface carbohydrates in cell adhesion and binding is reviewed. Interaction of cell surface carbohydrates with biologically active proteins, such as immunoglobulins, triggers lymphocyte differentiation resulting in an immune response. Different oligosaccharide ligands are synthesized and their bindings with homologous monoclonal antibodies are studied in order to determine the bonding and nonbonding interactions between the antigen and the combining region of the immunoglobulin. The final chapter of this book is devoted to chemical and enzymatic methods for depolymerization and modification of heparin for the preparation of structurally well-defined low molecular weight heparins with new or improved chemical and biological properties.

Leaving aside some printing errors and inaccurate numbering of a few molecules in the text and the illustrations, the book has an excellent layout. A pleasing feature is the standard format of each article consisting of an introduction, main text, conclusion, and extensive bibliography. Usually the references include articles pertaining to the author's own research as well as the most relevant papers by others, thus directing the reader to suitable background reading on topics that may be unfamiliar.

The choice and variety of the topics and the quality of the presentations make this book a valuable source of information and new ideas for synthetic and medicinal chemists involved in the expanding field of research on carbohydrates and glycobiology.

Chiral Aziridines—Their Synthesis and Use in Stereoselective Transformations

David Tanner*

The preparation of enantiomerically pure compounds is one of the major areas of organic chemistry. Much emphasis is placed on the elaboration of naturally occurring starting materials and on the development of techniques for enantioselective transformations of achiral substrates. In this field, chiral aziridines form an attractive class of compounds, since they are available in enantiomerically pure (or highly enriched) form by a variety of procedures and can be used for asymmetric synthesis in a number of different ways. The chemistry of aziridines is dominated by ring-opening reactions, the driving force for which is relief of ring strain. By suitable choice of substituents on the carbon and nitrogen atoms, excellent stereo- and regiocontrol can be attained in ring-opening reactions with a wide variety of nucleophiles, including organometallic reagents; this makes chiral aziridines useful as *substrates* for the synthesis of important biologically active species including alkaloids, amino acids, and β-lactam antibiotics. Substrate-controlled diastereoselective synthesis is also possible by use of aziridines as removable chiral *auxiliaries*, while metalation at a ring carbon atom allows aziridines to be used as chiral *reagents* for asymmetric synthesis. Chiral bisaziridines can act as *ligands* for transition metals, and applications in the challenging field of enantioselective catalysis can be envisioned. *Today, the exclusion of three-membered carbo- and heterocycles from the arsenal of the organic chemist is inconceivable.*[1]

1. Introduction

Aziridines **1** are saturated three-membered heterocycles containing one nitrogen atom. This class of compounds dates back to 1888, when Gabriel (unwittingly) synthesized the parent member.[2] Like other three-membered rings such as cyclopropanes and epoxides, aziridines are highly strained.[3] Ring strain renders aziridines susceptible to the ring-opening reactions that dominate their chemistry and, as shown below, makes them useful synthetic intermediates that fully deserve a prominent place in the arsenal of the organic chemist.

1

In view of the long history of aziridine chemistry, it is not surprising that the literature on the subject is very extensive. For the interested reader requiring a general introduction, several excellent discussions are available.[4] The present review of chiral aziridines is thus intended to be representative rather than comprehensive, and the selection of material inevitably reflects the author's own interests and/or prejudices. The discussion will deal mainly (but not exclusively) with nonracemic aziridines, and an attempt will be made to illustrate their great potential and versatility as chiral *substrates, auxiliaries, reagents,* and *ligands* in the field of stereoselective synthesis.

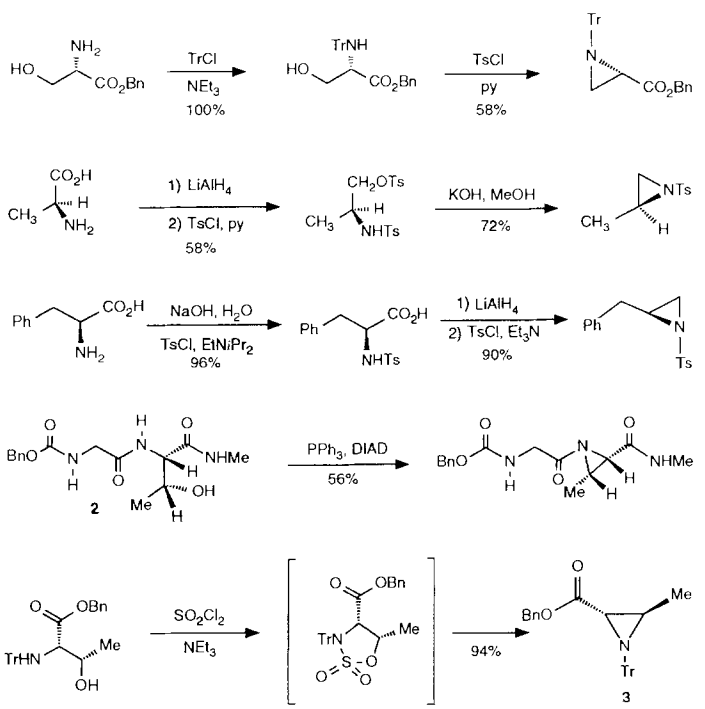
2. Synthesis of Chiral Nonracemic Aziridines



A variety of routes[5] to chiral nonracemic aziridines is available, most of which rely either on the availability of enantiomerically pure starting materials from natural sources (amino acids, carbohydrates, hydroxy acids) or on asymmetric transformations of C–C or C–N double bonds. These two general approaches are discussed below, together with some recent methods for efficient enantiomer separation and enzymatic transformations.

2.1. Synthesis from Amino Acids

Since the ring closure of 1,2-amino alcohols or suitable derivatives thereof[6] provides a convenient and usually efficient synthesis of aziridines, it is not surprising that amino acids are widely used as chiral starting materials. Some representative examples are shown in Scheme 1.

The first three sequences[7–9] can be conducted easily on a multigram scale with good overall yields. The conditions used by Wipf and Miller[10] to cyclize the threonine moiety of the peptide **2** provided some insight on the factors governing the steric course of such Mitsunobu-type[11] reactions (see also Scheme 4). The "one-pot" method developed by the Dutch group[12] for the synthesis of **3** is noteworthy for its simplicity and efficiency.

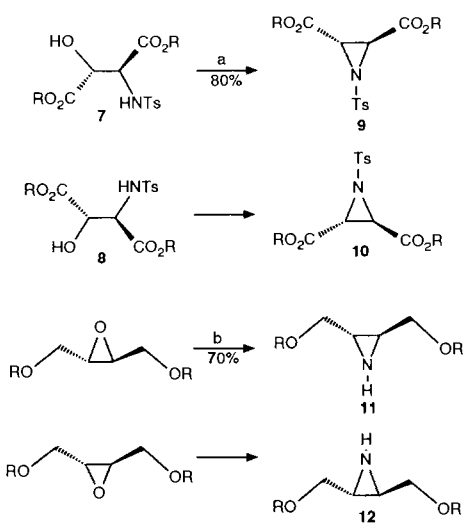
Scheme 1. Synthesis of enantiomerically pure aziridines from amino acids. Bn = CH_2Ph, Ts = SO_2Tol, DIAD = diisopropyl azidocarboxylate, Tr = CPh_3, py = pyridine.

2.2. Synthesis from Carbohydrates

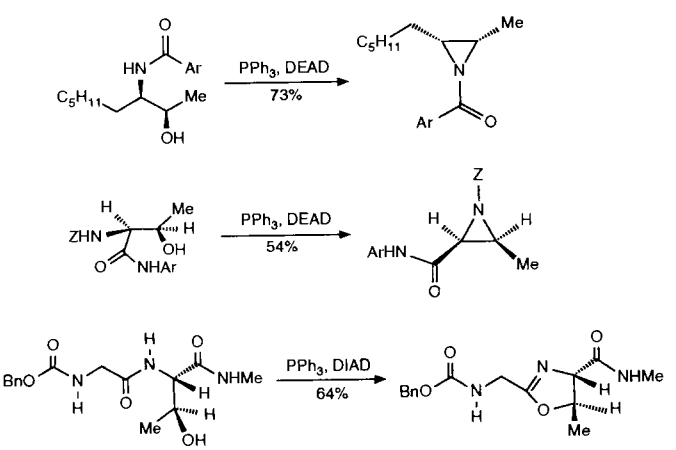
By taking advantage of steric, stereoelectronic, and conformational effects, the regio- and stereoselective manipulation of the various hydroxyl groups in carbohydrates is possible.[13] Sugar derivatives are thus attractive chiral starting materials for a wide variety of synthetic purposes, including the preparation of aziridines; Scheme 2 shows just a few[14–18] of the many possibilities. As is the case for the amino acids, the major drawback to the use of carbohydrates as starting materials is that usually only one of a given pair of enantiomeric starting compounds is easily or cheaply available. The unusual regiochemistry of the subsequent ring opening[14] of aziridine **4** will be discussed in Section 4.2. Spiroaziridines such as **5**[15] are very useful intermediates in the synthesis of important branched-chain amino sugars (Section 5.2), and the chiral bisaziridines **6**[18] provide an elegant route to α-amino acids and aldehydes

Scheme 2. Synthesis of enantiomerically pure aziridines from carbohydrates. Ms = SO_2Me.



(Section 5.3). Further references to the ring closure of azido alcohols to aziridines by use of organophosphorus reagents can be found in references [19–21].

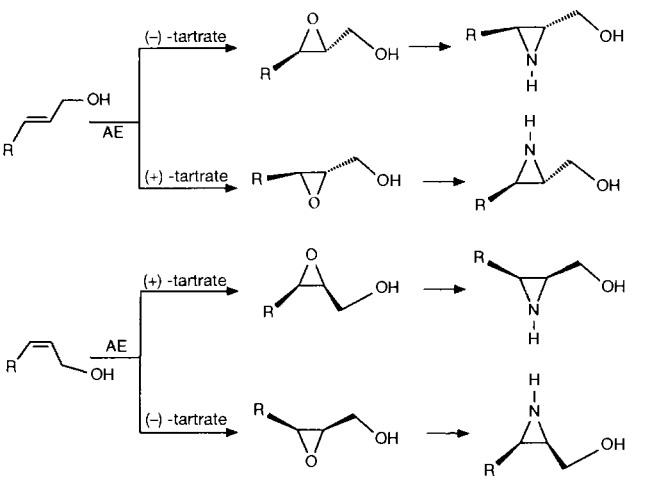
David Tanner was born in 1955 in Inverness, Scotland, and studied chemistry at the University of Edinburgh (B. Sc. 1977). He then moved to Göteborg, Sweden, where he obtained his doctorate in 1981 under the supervision of O. Wennerström. After a one-year postdoctoral stay with K. C. Nicolaou at the University of Pennsylvania, he returned to Göteborg in 1983 to pursue independent research; he received the title of "Docent" from Chalmers University of Technology in 1986. In 1988 he was appointed to a lectureship at the University of Uppsala, where he also currently holds a personal research position in organic synthesis awarded by the Swedish Natural Science Research Council.



2.3. Synthesis from Hydroxy Acids

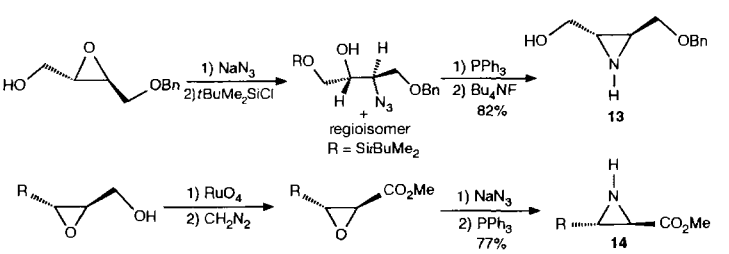
The hydroxy acid most familiar to organic chemists is no doubt tartaric acid, derivatives of which are not only of great historical importance[22] but also allow access to an impressive variety of enantiomerically pure "building blocks" for synthesis.[23] Tartaric acid is also used to provide the chiral environment for the Sharpless asymmetric epoxidation reaction discussed in the next section. Both enantiomers of tartaric acid are readily available and can be converted to the enantiomerically pure pairs of aziridines **9** and **10**,[24] and **11** and **12**[25] shown in Scheme 3. Some applications of these C_2-symmetric compounds in asymmetric synthesis will be demonstrated in Sections 4.4 and 6.

Scheme 3. Synthesis of C_2-symmetric aziridines from tartaric acid. a) PPh_3, diethyl azodicarboxylate (DEAD); b) 1. NaN_3, 2. MsCl, 3. $LiAlH_4$. R = Et, CH_2Ph. Compound **7** and the precursor of **11** were obtained from (+)-tartaric acid, compound **8** and the precursor of **12** from (−)-tartaric acid.



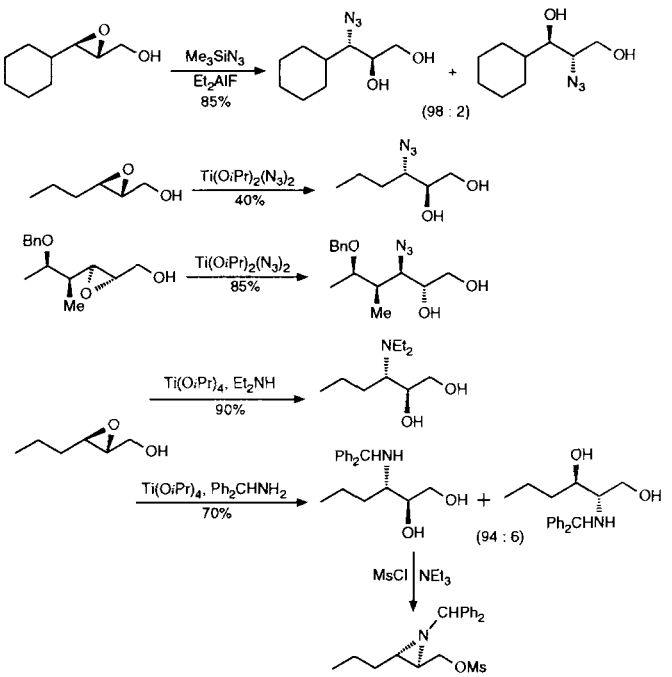
The Mitsunobu-type reactions used for the ring closure[26] of the hydroxy sulfonamides **7** and **8** are stereospecific and occur with inversion at the carbon center bearing the OH group. The results of the related reactions shown in Scheme 4 can be compared[27, 28] and contrasted[10] with that shown for cyclization of **2** in Scheme 1.

Scheme 4. Some stereospecific intramolecular Mitsunobo reactions. Ar = aryl, Z = benzyloxycarbonyl.



2.4. Synthesis from Alkenes via Chiral Epoxides and 1,2-Diols

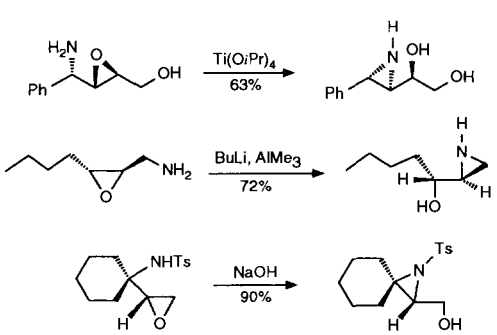
As emphasized in Schemes 2 and 3, ring opening of epoxides by nitrogen nucleophiles followed by ring closure of the resultant 1,2-amino alcohol derivatives is an attractive route to aziridines. Although epoxides had long been regarded as versatile intermediates and had been used extensively in synthesis,[29] their potential was increased enormously in the 1980s by the discovery of the asymmetric epoxidation (AE) reaction of allylic alcohols by Sharpless et al.[30]. This epoxidation is mediated by a titanium(IV) alkoxide and *tert*-butyl hydroperoxide in the presence of a tartrate ester. As outlined in Scheme 5, this catalytic asymmetric synthesis provides a general route to all possible stereoisomers of a given hydroxymethylaziridine ("2,3-aziridino alcohol").



Scheme 5. A general route to chiral 2,3-aziridino alcohols by the Sharpless asymmetric epoxidation (AE).

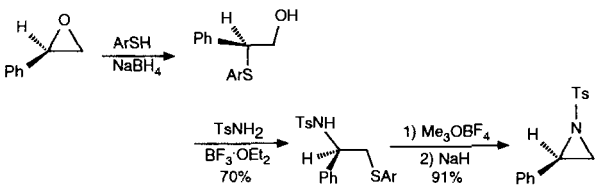
One of the many advantages associated with the Sharpless AE reaction is that both enantiomers of the product are available equally easily from a common starting material. As pointed out above, azide ion is often an excellent nucleophile for the ring opening of epoxides, and azido alcohols can then be converted to aziridines; the overall epoxide → aziridine transformation is thus stereospecific (inversion at both carbon atoms of the original epoxide). Some examples[31, 32] are shown in Scheme 6. Aziridino alcohols and esters such as **13** and **14** are very useful chiral intermediates (see Sections 4.3 and 4.4).

Scheme 6. Synthesis of chiral, nonracemic aziridino alcohols and esters via epoxides available by the Sharpless AE reaction.



It is usually of little consequence that the ring-opening reactions shown in Scheme 6 are not regioselective, since both regioisomers of a given azido alcohol eventually yield the same aziridine. However, in the case of epoxy alcohols, the sequence does entail temporary protection of the primary hydroxyl group. Regioselectivity in the ring opening by azide[33–35] and secondary[36] or primary[37] amines is possible if the reaction is mediated by aluminum or titanium complexes. The products from the primary amines have been converted[38] to aziridines (Scheme 7). Good to excellent regioselectivity in the C-3 ring

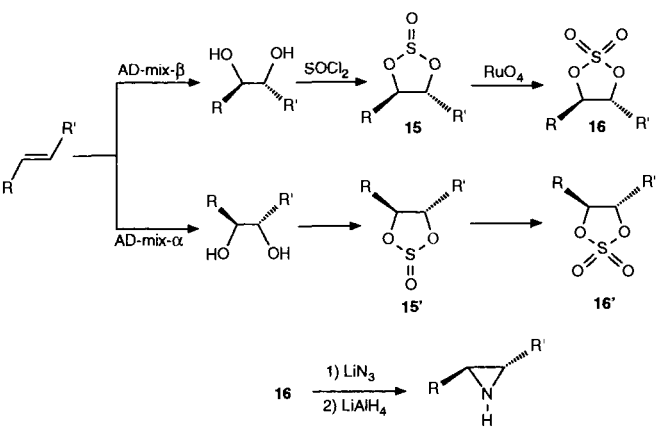
Scheme 7. Regioselective ring opening of epoxy alcohols.



opening of 2,3-epoxy acids and amides by amines[39] and the C-2 ring opening of 2,3-epoxy esters by azide[40] has also been demonstrated.

A useful tactic in epoxy alcohol chemistry is use of the Payne rearrangement.[41] As shown in Scheme 8, amino epoxides can perform in an analogous fashion in the presence of complexes of titanium[42] or aluminum.[43] *N*-Tosylamino epoxides undergo the same type of rearrangement simply upon treatment with base (Scheme 8).[44]

Scheme 8. Chiral aziridines by Payne-type rearrangement of amino epoxides.



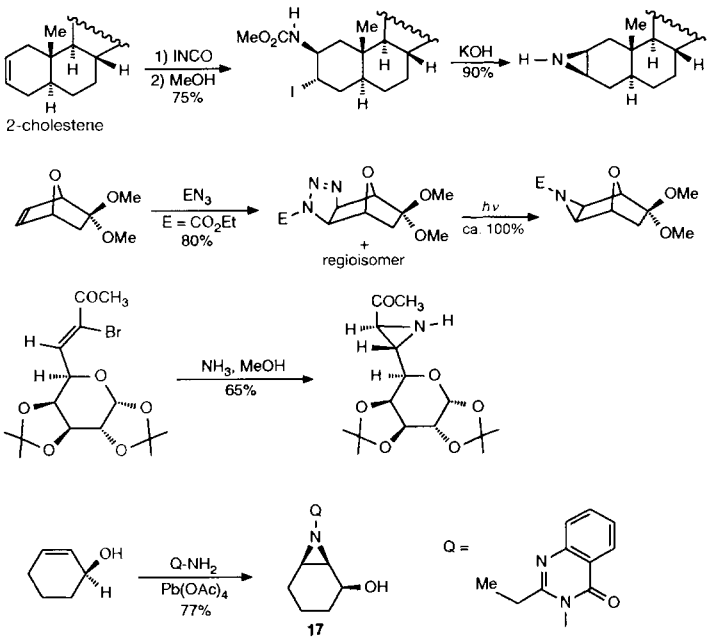
The epoxide → aziridine transformations outlined in Schemes 6–8 involve overall inversion of configuration. However, an interesting method for conversion of a terminal epoxide to the corresponding *N*-tosyl aziridine with overall retention[45] was introduced recently (Scheme 9). This use of sulfur chemistry

Scheme 9. Conversion of a terminal epoxide to an *N*-tosyl aziridine with retention of configuration.

nicely complements the methods that proceed with overall inversion and thus allows the synthesis of both enantiomers of a given terminal aziridine from a single chiral epoxide.

While the Sharpless AE reaction is a beautiful example of catalytic asymmetric synthesis, its major limitation is that the substrate must contain a "handle" in the form of an allylic hydroxyl goup. Chiral terminal epoxides such as those shown in Scheme 9 are thus not available directly by the AE method, and indeed the direct asymmetric epoxidation of "nonfunctionalized" olefins remains a major challenge.[46] However, Sharpless et al. have provided a very attractive indirect solution to this problem which relies on cyclic sulfates of chiral 1,2-diols. These compounds are now easily available in enantiomerically pure (or highly enriched) form by the osmium-catalyzed asymmetric dihydroxylation (AD) reaction[47] shown in Scheme 10; the chiral ligands

Scheme 10. Sharpless asymmetric dihydroxylation (AD) as a route to chiral, nonracemic aziridines. The mixtures of reagents used here are denoted AD-mix-α and AD-mix-β.

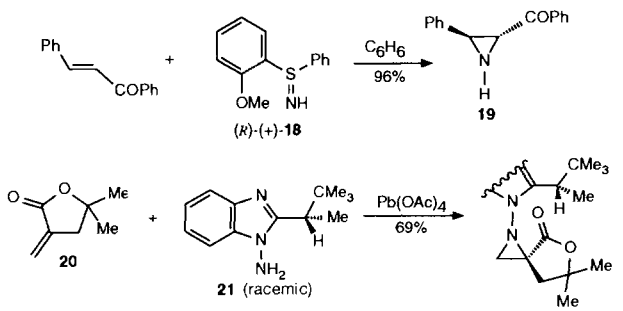


in the AD-mix reagents are based on hydroquinidine and hydroquinine. The cyclic sulfates **16** in many ways surpass the corresponding epoxides in terms of reactivity ("like epoxides only more reactive"[48]), and aziridines are readily available[49] from these intermediates. The cyclic sulfites **15** can also be used for aziridine formation.[50]

Although the two types of ligands employed in the AD-mix formulations[47] are not enantiomers, they actually behave as if they were, and the process provides equally easy access to both enantiomers of a given 1,2-diol from the same olefin. In connection with the AD reaction, it may be mentioned here that osmium also mediates the stereospecific oxyamination of olefins and thus provides another stereospecific synthesis of aziridines.[51] However, no enantioselective version of this reaction has yet been reported.

2.5. Other Asymmetric Transformations of C–C Double Bonds

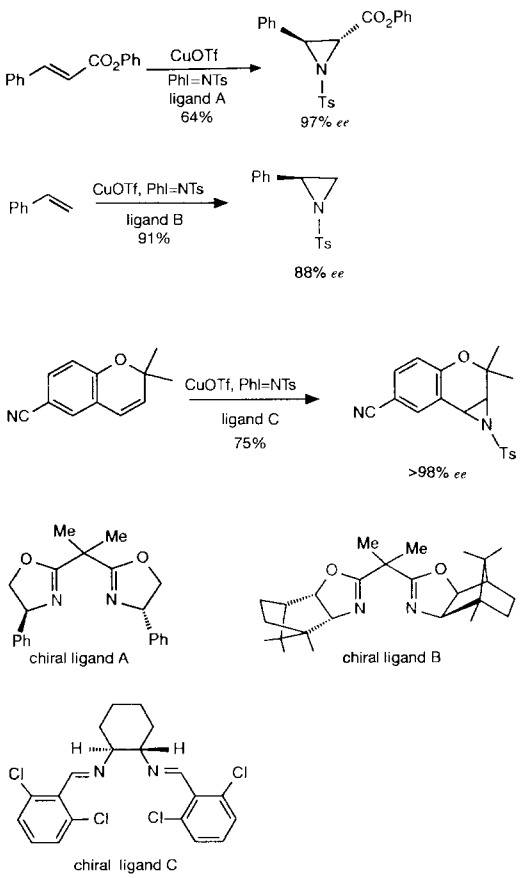
Some of the well-established methods[5] for the synthesis of aziridines from olefins are: 1) addition of IN_3 or INCO followed by reductive or hydrolytic ring closure; 2) 1,3-dipolar cycloaddition of azides followed by decomposition of the intermediate triazoles; 3) addition of a primary amine to a suitably 2-substituted acrylic acid derivative or Michael addition of a nitrogen nucleophile followed by expulsion of a leaving group at nitrogen; and 4) direct addition of nitrene species. These general methods for aziridine formation can be used to exemplify the "hierarchy" of asymmetric synthesis, which ranges from substrate control, through reagent control, to enantioselective catalysis.



Some examples[52–55] of substrate control are presented in Scheme 11. Although the starting material for the synthesis of

Scheme 11. Asymmetric synthesis of aziridines by substrate control.

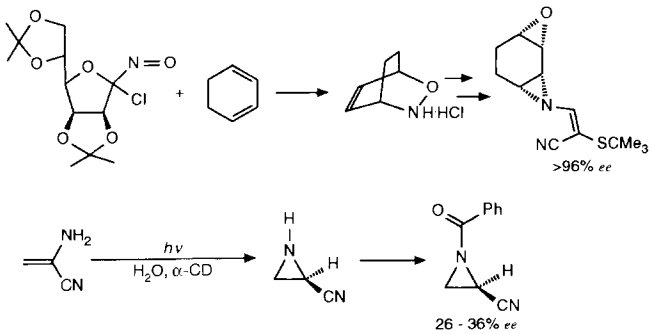
17[55] was racemic, optically pure 2-cyclohexen-1-ol is available.[56] Good to excellent diastereoselectivity in the addition of nitrenes to chiral enoates has been described by the Dreiding group.[57]



Two examples of reagent control are given in Scheme 12. The chiral sulfimide reagent **18**[58] yields aziridine **19** with only modest enantioselectivity (30% *ee*), whereas asymmetric induction is

Scheme 12. Asymmetric synthesis of aziridines by reagent control.

complete in the nitrene reaction[59, 60] of alkene **20**. Reagent **21** has not yet been prepared in enantiomerically pure form, but some asymmetric induction has been claimed[61] for an interesting variant of this reaction, in which an optically active oxidant (lead tetra-(*S*)-2-methylbutanoate) was used.

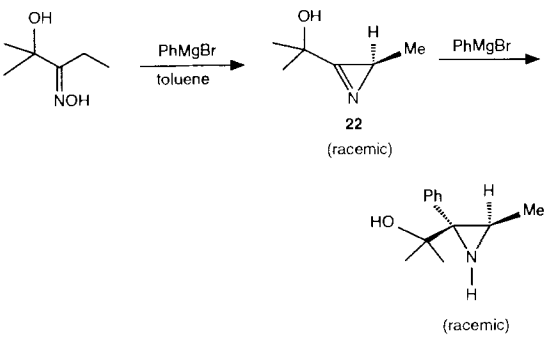


In the previously mentioned "hierarchy" of asymmetric synthesis, enantioselective catalysis is at the very top. Two examples (the Sharpless AE and AD reactions, Section 2.4) have already been discussed, and three very exciting developments in catalytic asymmetric aziridination[62–64] are shown in Scheme 13. For

Scheme 13. Asymmetric synthesis of aziridines by enantioselective catalysis.

related work on the direct (nonenantioselective) aziridination of alkenes, including catalysis by metalated porphyrins, see references [65–70].

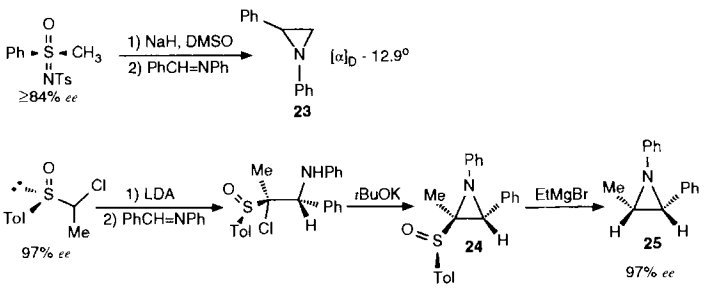
This section concludes with the two interesting aziridination reactions depicted in Scheme 14. The highly diastereo- and enantioselective functionalization[71] of all four carbon atoms in



Scheme 14. Chiral aziridines by asymmetric cycloaddition with a chiral auxiliary (top) and by enantioselective photocyclization (bottom).

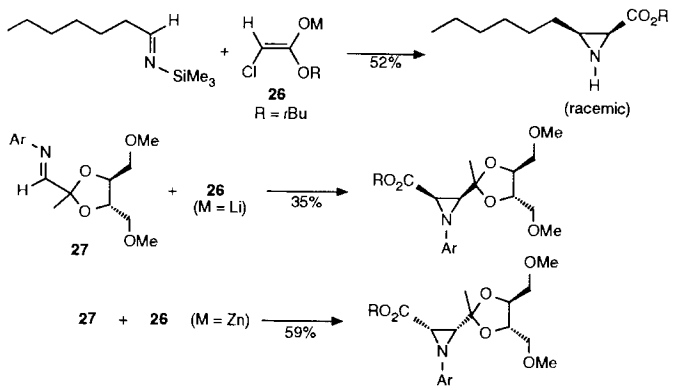
the diene unit of cyclohexadiene relied on the use of a chiral auxiliary derived from a carbohydrate.[72] The enantioselective photocyclization reaction in the presence of α-cyclodextrin (α-CD)[73] was performed in connection with studies of compounds of potential interest to prebiotic chemistry.

2.6. Asymmetric Transformations of C–N Double Bonds



Aziridines are available by reaction of α-hydroxy oximes with Grignard reagents via azirine intermediates (Scheme 15). The

Scheme 15. Diastereofacial selectivity in the conversion of an azirine to an aziridine.

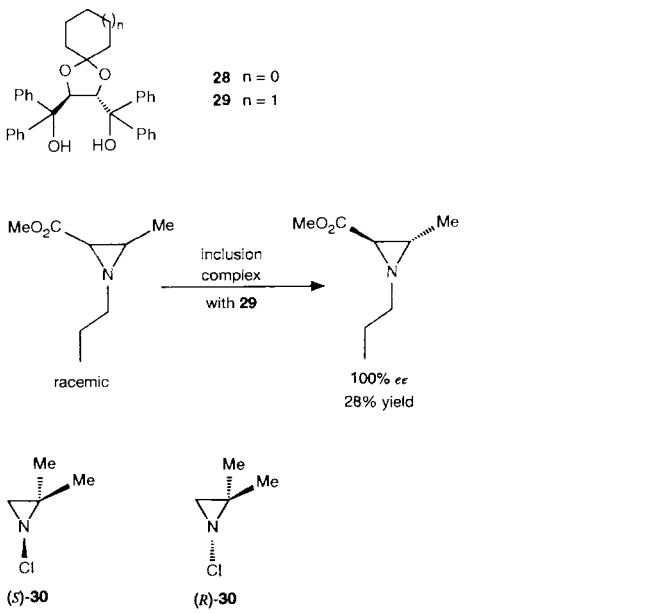


results of an interesting study[74] on the diastereofacial selectivity of this reaction were interpreted in terms of complexation of the Grignard reagent to the alcohol function of **22** followed by intramolecular delivery of the nucleophile to the less hindered face of the C–N double bond.

Two examples of reagent control are presented in Scheme 16. In the first, an *N*-tosylsulfoximine[75] was used as a chiral nucleophilic alkylidene transfer reagent; unfortunately, the enantiomeric purity of aziridine **23** was not determined. The second example[76] shows a very efficient asymmetric synthesis based on the chemistry of chiral sulfoxides in which a stereospecific desulfinylation reaction of **24** gives aziridine **25**. The proposed intermediate is a chiral metalated aziridine, an interesting type of nucleophilic species which is discussed in more detail in Section 7.

Scheme 16. Reagent control in the asymmetric transformation of a C–N double bond. DMSO = dimethyl sulfoxide. LDA = lithium diisopropylamide.

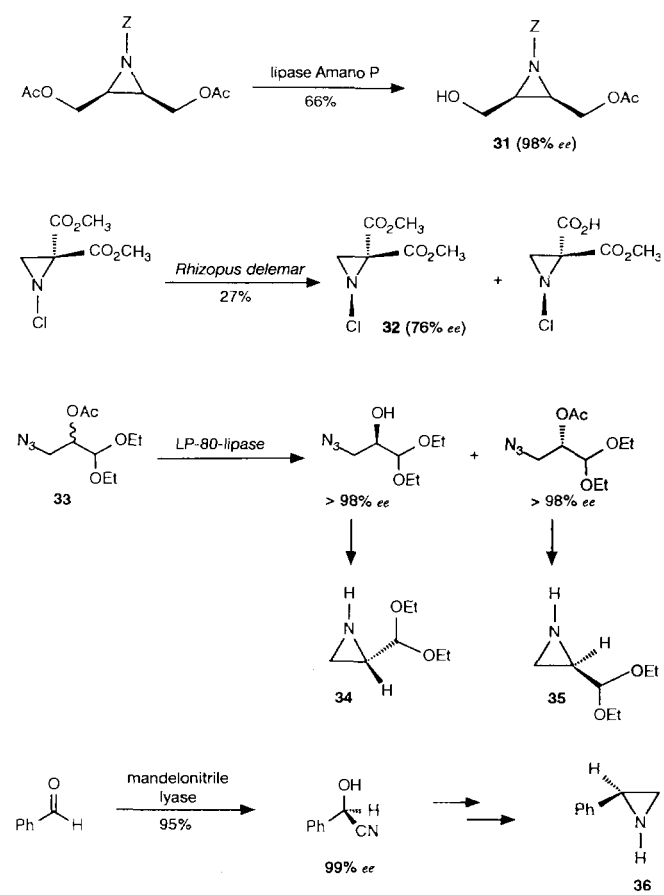
Scheme 17 shows two analogues of the Darzens reaction.[77] For the first,[78] which is highly diastereoselective, the authors suggested a cyclic transition state to explain the observed *cis* selectivity. They also pointed out that this type of reaction should be amenable to the preparation of nonracemic aziridines. The second example,[79] in which a chiral auxiliary is used, shows that this is indeed the case. It is remarkable that complete "stereodivergence" is possible here simply by switching the metal counterion of the enolate from lithium to zinc!



Scheme 17. Synthesis of chiral aziridines by Darzens-type reactions. M in **26**: Li.

2.7. Chiral Aziridines by Resolution of Racemates

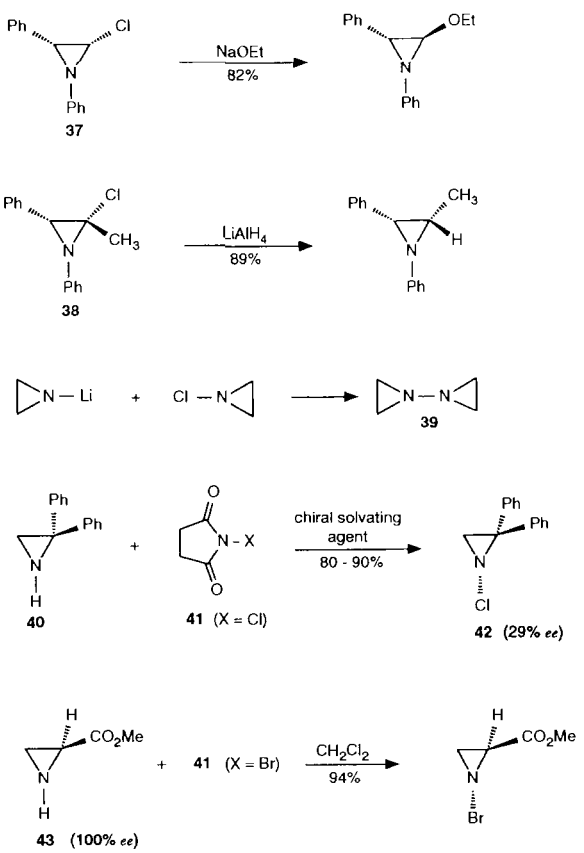
Early attempts[80] at direct optical resolution of chiral aziridines were not promising. But recently Mori and Toda[81] reported an efficient method based on the formation of inclusion complexes between certain aziridines and the optically active host compounds **28** and **29**, which are derived from tartaric acid. Enantiomeric purities up to 100% were obtained (Scheme 18).



An important structural feature of aziridines is the high barrier[82] to pyramidal inversion at the ring nitrogen atom when it is bonded to alkyl or aryl groups or, especially, to heteroatomic moieties such as Cl, OR, or NH_2. This has allowed the separation[83] of the enantiomers (invertomers) of, for example, 1-chloro-2,2-dimethylaziridine (**30**, Scheme 18) by complexation gas chromatography. This elegant study also allowed accurate determination of the inversion barrier, which earlier had been estimated[84] from ^{1}H NMR spectroscopic data.

Scheme 18. Two methods for the resolution of racemic aziridines.

2.8. Enzymatic Routes to Chiral Aziridines

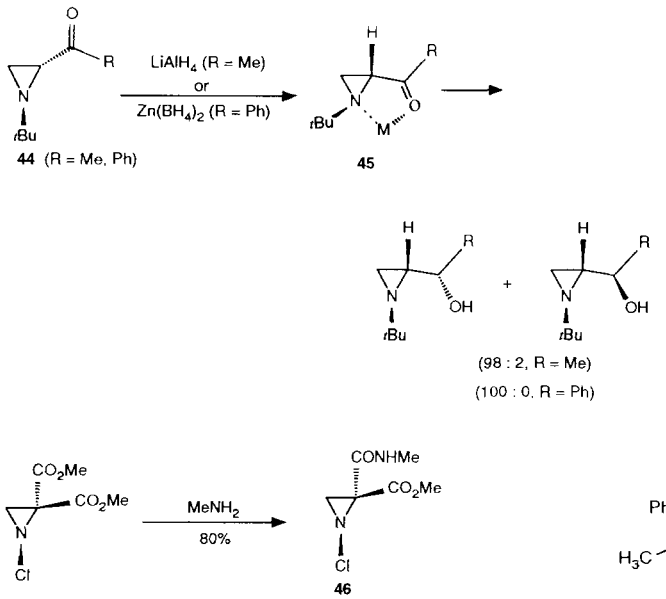


In recent years the use of enzymes in synthetic organic chemistry has increased steadily.[85] A popular technique is the enantioselective hydrolysis of *meso* diesters, exemplified[86] by the reaction yielding aziridine **31** in Scheme 19. Enzymes were also employed[87] in the preparation (by selective hydrolysis) of aziridine **32**, which is chiral solely because of slow nitrogen inversion. Wong et al.[88] prepared the enantiomerically pure aziridines **34** and **35** by enantioselective hydrolysis of **33**, and Effenberger et al.[89, 90] have reported the synthesis of enantiomerically pure aziridine **36** by a sequence involving enzyme-catalyzed cyanohydrin formation.

Scheme 19. The use of enzymes in the synthesis of enantiomerically pure aziridines.

3. Stereoselective Transformations at Ring Atoms and in Side Chains without Ring Opening

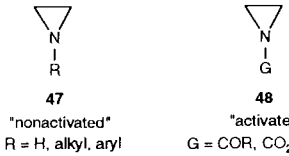
As will be discussed in Section 4, ring opening occurs in many of the reactions of aziridines. However, for "nonactivated" aziridines (see Section 4) it is possible to perform stereoselective transformations either at ring atoms (carbon or nitrogen) or in side chains without disrupting the ring. Some examples are shown in Schemes 20 and 21.



Scheme 20. Stereoselective transformations at ring atoms of aziridines.

The first examples of facile nucleophilic displacements at the carbon atoms in three-membered rings were provided by Deyrup and Greenwald,[91] who showed that the products of displacement reactions on **37** and **38** were formed with clean inversion. As far as the present author is aware, no nonracemic derivatives of the interesting 1,1'-diaziridine **39**[92] have been reported. Attempted asymmetric chlorination at the nitrogen atom in **40** in the presence of a chiral solvating agent gave **42** with only modest

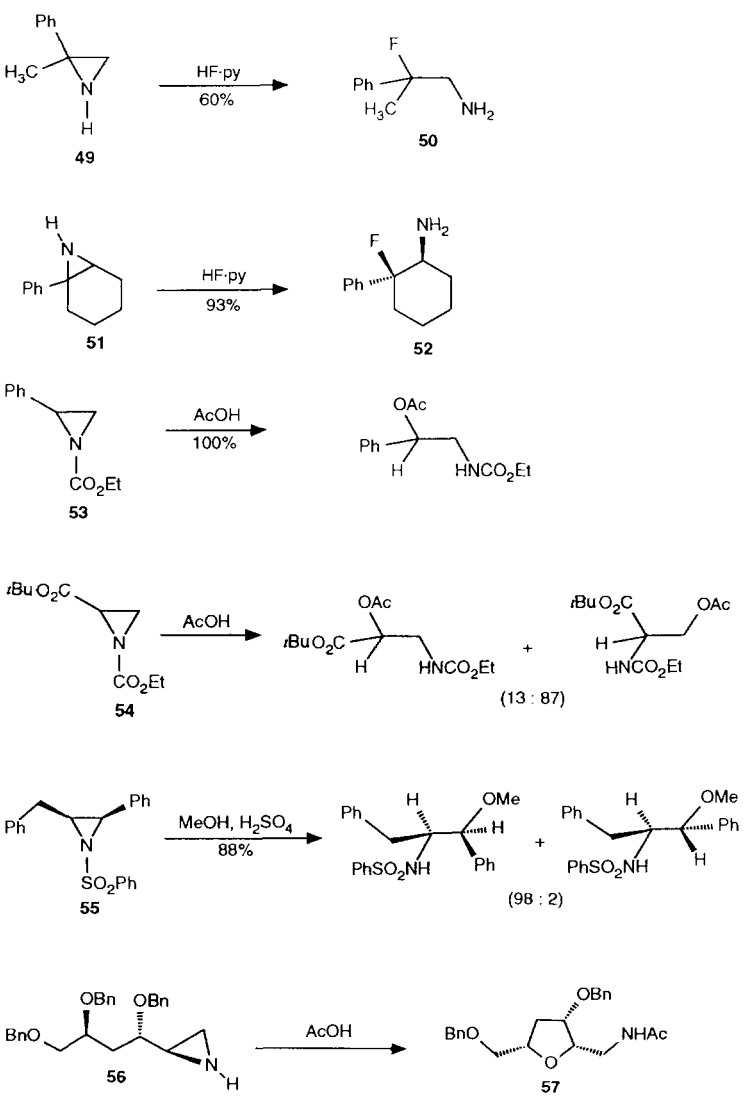
enantioselectivity.[93] However, *N*-bromination[94] of optically pure **43** was completely stereoselective (Scheme 20).



The reactions depicted in Scheme 21 show that aziridines with suitable substituents on the nitrogen atom may react with powerful nucleophiles such as metal hydrides[95, 96] without ring opening. Pierre et al.[97] and Laurent et al.[98] both explained the results of reduction of **44** by $LiAlH_4$ or $Zn(BH_4)_2$ by the intermediacy of chelate **45**. Modest diastereoselectivity was also observed in the reaction of aziridino aldehydes with Grignard reagents.[99] The aminolysis that yields **46** is completely diastereoselective.[100]

Scheme 21. Stereoselective transformations in side chains of aziridines.

4. Ring-Opening Reactions

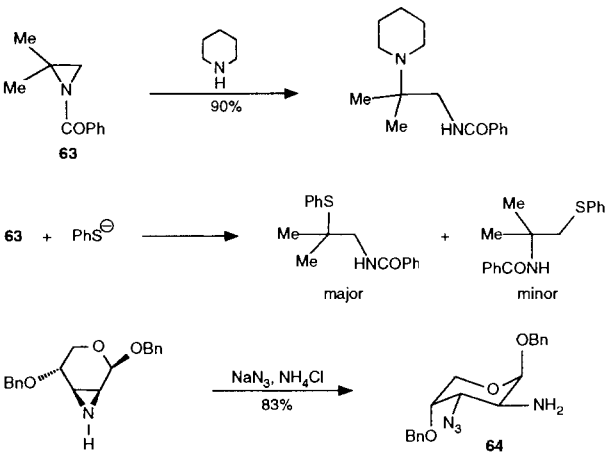


As a consequence of the ring strain present in aziridines and related three-membered rings, ring-opening reactions are a dominant feature of their chemistry. In this respect, aziridines can be divided into two main groups,[101] according to the nature of the substituent on nitrogen. The first group, "nonactivated" aziridines, **47**, contain a basic nitrogen atom, and ring-opening reactions usually occur only after protonation, quaternization, or formation of a Lewis acid adduct. The second group, "activated" aziridines, **48**, contain a substituent which can conjugatively stabilize the negative charge that develops on the nitrogen atom in the transition state for ring opening by a nucleophile. (It may also be noted here that the nitrogen lone pair in aziridines has increased s character as compared to other aliphatic secondary amines, which results in lower basicity and reduced π-donor ability.[102])

If aziridines, whether activated or not, are to be of use in synthesis, it is of prime importance to be able to control the stereochemistry and the regiochemistry of the ring-opening process. The issues of stereo- and regioselectivity will be emphasized in the following discussion, which will deal mainly with activated aziridines.

4.1. Acid-Catalyzed Ring Opening

The detailed mechanism of acid-catalyzed ring-opening reactions of aziridines has been the subject of much debate.[103] Some examples for both nonactivated and activated aziridines are shown in Scheme 22. Wade[104] interpreted the formation of **50** and **52** from **49** and **51**, respectively, in terms of an S_N1 mechanism (see, however, ref. [105]). Acetolysis of **53** and **54** was proposed[106] to occur by an A-2 pathway, in which the acetoxy group preferentially attacks the carbon atom best able to ac-



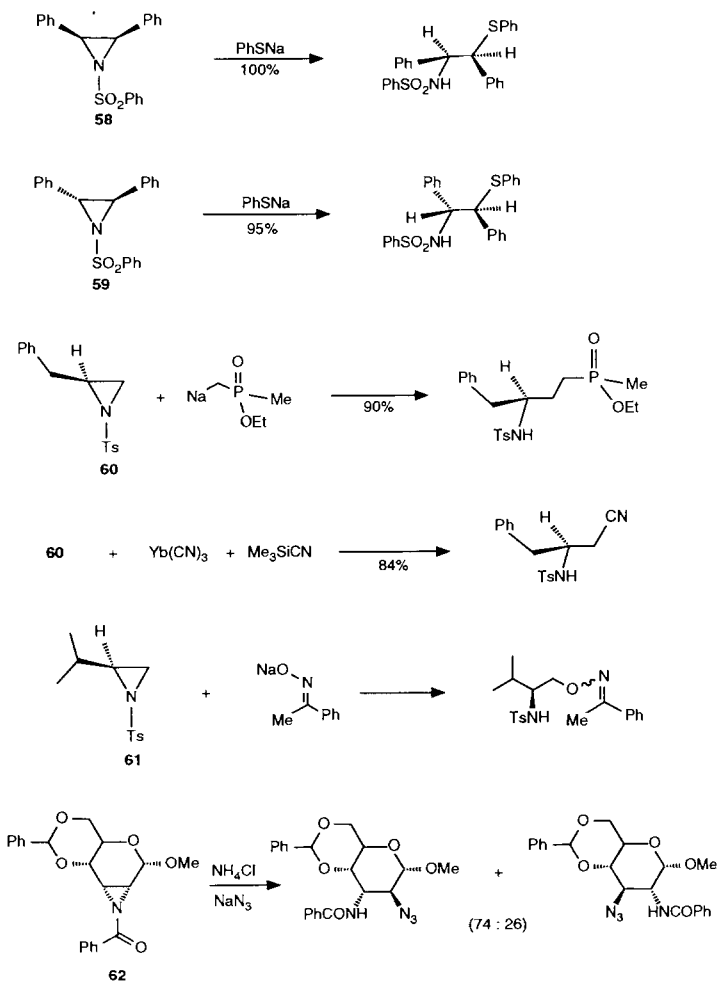
Scheme 22. Acid-catalyzed ring opening of aziridines.

commodate some carbenium ion character. Borderline behavior was observed[107] for the alcoholysis of *cis*-aziridine **55**, which was cleaved completely regioselectively with nearly complete inversion (98:2 ratio of diastereoisomers). Finally, the completely stereo- and regioselective conversion of **56** to **57** provides an interesting and unusual example of neighboring group participation of benzyl ethers.[108]

4.2. Nucleophilic Ring Opening of Activated Aziridines

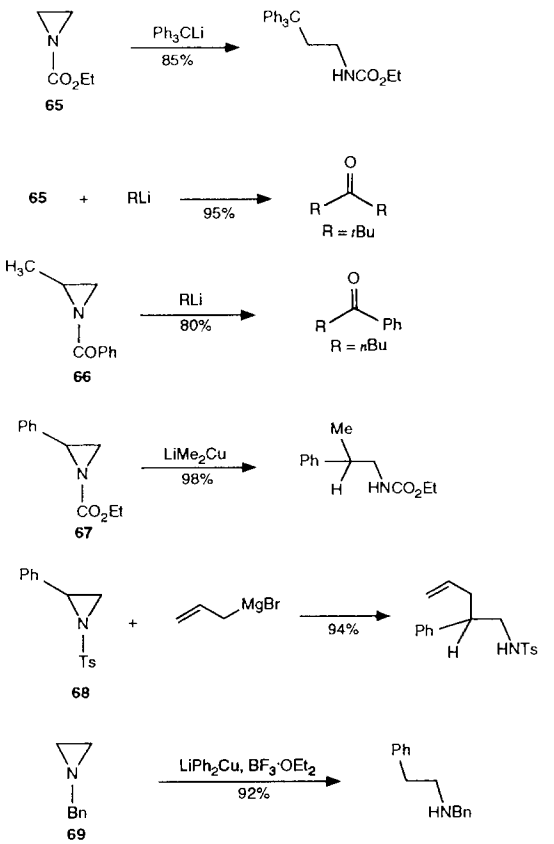
The reaction mechanism for the nucleophilic ring opening[109] of activated aziridines is more clear-cut than that for nonactivated species, and some generalizations can be made. For monocyclic aziridines, nucleophilic attack is expected to occur by an S_N2-like mechanism with inversion. Monosubstituted aziridines are expected to be attacked predominantly or exclusively at the methylene carbon atom. In analogy with epoxides, fused bicyclic aziridines may be expected to obey the Fürst–Plattner rule[110] for *trans*-diaxial ring opening. Scheme 23 shows some examples of "normal" nucleophilic ring-opening reactions. The *cis*/*trans* isomers **58** and **59** underwent a clean S_N2 reaction[111] with complete Walden inversion; the monosubstituted aziridines **60** and **61** were attacked exclusively[112–114] at the less hindered site; and the sugar aziridine **62** gave predominantly the product of diaxial ring opening.[115]

Some "abnormal" nucleophilic ring openings are presented in Scheme 24. Stamm et al.[116,117] have explained the unusual ring opening of **63** both as a single electron transfer process and also as a borderline S_N2 reaction, depending on the nucleophile used. The anti-Fürst–Plattner ring opening that yields **64**[14] is more difficult to explain.[118,119]



Scheme 24. Some "abnormal" nucleophilic ring-opening reactions.

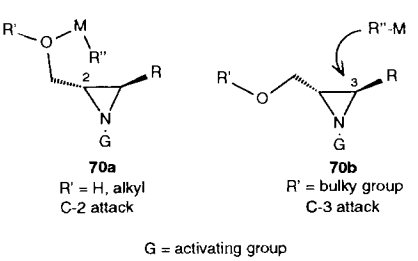
Since organometallic reagents offer a host of possibilities for selective carbon–carbon bond formation, often under mild reaction conditions, the ring opening of chiral three-membered heterocycles by organometallic compounds should be an attractive tactic in stereoselective synthesis. While such reactions of epoxides were quite well explored at a relatively early stage,[120] the corresponding aziridine chemistry developed more slowly. The difficulties associated with the use of aziridines stem mainly from the inherently low reactivity of the unactivated heterocycles and the ambident nature of activated species such as aziridinecarbamates and *N*-acylaziridines. Some of the problems and solutions are depicted in Scheme 25.



The work of Hassner and Kascheres[121] on aziridinecarbamate **65** clearly demonstrates the ambident electrophilic nature of the substrate. In addition to the convenient synthesis of ketones shown, *N*-acylaziridines such as **66**[122] provide a route to aldehydes.[123] The study conducted by Kozikowski et al.[124] on the ring opening of **67** and **68** underscores the chemoselectivity of cuprate reagents and also the greater activating power of the sulfonyl group relative to the acyl and alkoxycarbonyl groups. The compatability of cuprates with certain Lewis acids allows smooth ring opening of the unactivated aziridine **69** under very mild conditions.[125] Reactions of more elaborate aziridines with organometallic reagents are discussed in Sections 4.3–4.5 and 5.4.

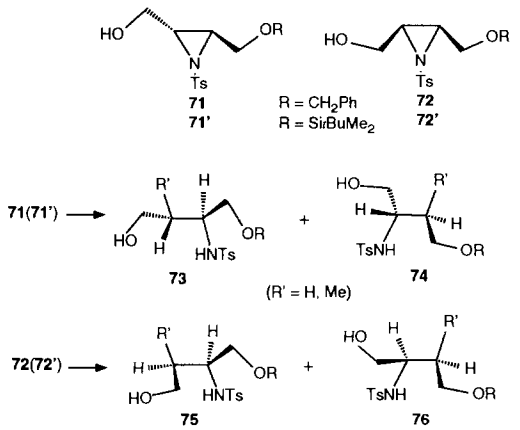
4.3. Ring Opening of Aziridino Alcohols

Thanks to the experimental simplicity and excellent enantioselectivity of the Sharpless asymmetric epoxidation, 2,3-epoxy alcohols have rapidly gained importance in stereoselective synthesis.



Scheme 23. Nucleophilic ring opening of activated aziridines.

Scheme 25. Reaction of aziridines with some organometallic reagents.



hols have rapidly gained importance in stereoselective synthesis. Much of their chemistry is based on regioselective ring-opening reactions,[126] and in this section it will be demonstrated that their aziridine counterparts, readily available in enantiomerically pure form (see Scheme 6), are also attractive as chiral building blocks.

The basic concept is illustrated by structure **70**, in which G is a strongly activating group which can control *stereochemistry*

by promoting clean S_N2-type attack under as mild conditions as possible; *regiochemistry* is controlled by the substituent on the oxygen atom, which can be used to direct the incoming nucleophile to C-2 (by complexation to the attacking species) or to C-3 (by exerting steric effects).

The substrates chosen[31, 127] were the two *trans*/*cis*-pairs **71**/**72** and **71'**/**72'**; the reagents were either complex hydrides, organocuprates, or organoaluminum compounds (Scheme 26). The results of the ring opening of **71** and **72** by the complex hydrides Red-Al (sodium bis(2-methoxyethoxy)aluminum hydride), $LiAlH_4$, and DIBAL (diisobutylaluminum hydride) are shown in Table 1. Excellent C-2 regioselectivity was observed in the reactions with Red-Al (entries 1 and 2); none of the products of ring opening at C-3 could be detected by high-field ^1H NMR spectroscopy. Since the corresponding epoxy alcohols[128–130] behave in the same way, it seems reasonable to suggest that the free hydroxyl group first coordinates to the reagent, which thus allows intramolecular delivery of the hydride to the proximal carbon atom via a five-membered cyclic transition state.

Scheme 26. Possible regioisomers from the ring opening of *trans* and *cis* aziridino alcohols.

Table 1. Ring opening of **71** and **72** by hydride reagents (R' = H).

Entry	Substrate	Reagent/Conditions	73:74	75:76	Yield [%]
1	**71**	Red-Al, THF, −78 °C	>99:1		86
2	**72**	Red-Al, THF, −78 °C		>99:1	81
3	**71**	$LiAlH_4$, THF, −20 °C	>99:1		80
4	**72**	$LiAlH_4$, THF, −20 °C		>99:1	70
5	**71**	DIBAL, THF, −78 °C → RT [a]	>99:1		30 [b]
6	**72**	DIBAL, THF, −78 °C → RT [a]		58:42	19 [b]
7	**71**	DIBAL, C_6H_6, 0 °C → RT [a]	50:50		20 [b]
8	**72**	DIBAL, C_6H_6, 0 °C → RT [a]		70:30	53 [b]

[a] RT = room temperature. [b] Incomplete reaction.

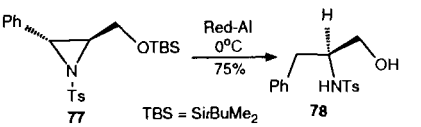
The same high levels of regioselectivity were obtained in the reactions with $LiAlH_4$ (entries 3 and 4). This also parallels the behavior of the corresponding epoxy alcohols[128] and can be explained in the same way as the Red-Al results. Interestingly, the regioselectivity is much better for the reactions of aziridines, which can be conducted at lower temperatures thanks to the strongly activating *N*-tosyl group. Epoxy alcohols usually undergo selective C-3 attack by DIBAL,[129] but aziridines **71** and **72** do not mimic this behavior, for reasons which are not yet clear (entries 5–8). However, in the case of epoxides, regioselectivity is probably determined to some extent by complexation of Lewis acidic reagents such as DIBAL to the epoxide oxygen atom. Such complexation is less likely for the *N*-tosyl groups of **71** and **72**.

Reactions with alkyl nucleophiles are synthetically more interesting, since the products of ring opening retain two contiguous stereocenters. The reagents chosen were the Gilman cuprate $LiMe_2Cu$,[131] the Lipshutz "higher order" cyanocuprate Li_2Me_2CuCN,[132] and trimethylaluminum. The results for the *trans*-aziridines **71** and **71'** are collected in Table 2. Both types of

Table 2. Ring opening of **71** and **71′** by methylation reagents (R′ = Me).

Entry	Substrate	Reagent/Conditions	**73**:**74**	Yield [%]
1	**71**	$LiMe_2Cu$, Et_2O, −20 °C	>99:1	80
2	**71′**	$LiMe_2Cu$, Et_2O, −20 °C	>99:1	98
3	**71**	Li_2Me_2CuCN, THF, −20 °C	92:8	81
4	**71′**	Li_2Me_2CuCN, THF, −20 °C	>99:1	92
5	**71**	$AlMe_3$, toluene, 75 °C	<1:99	71
6	**71′**	$AlMe_3$, toluene, 75 °C	15:85	82

cuprate reagents gave very satisfactory C-2 regioselectivity (entries 1–4) irrespective of the substituent on C-4. Once again, it seems plausible to suggest that initial complexation of the reagent to the C-1 hydroxyl group is followed by intramolecular attack at C-2. The corresponding epoxy alcohols behave similarly. It is noteworthy, however, that in the reaction with $LiMe_2Cu$ aziridine **71** shows much higher regioselectivity than its epoxide counterpart.[133, 134] On the other hand, trimethylaluminum gave good to excellent C-3 selectivity (entries 5 and 6). Thus, for the ring opening of aziridine **71** complete regiocontrol can be exercised (cf. entries 1 and 5). Presumably the first equivalent of the reagent forms an aluminum alcoholate by removal of the OH proton. This alcoholate is expected to transfer a methyl group more slowly than a trialkylaluminum species.[135, 136] A second equivalent of the reagent then forms a Lewis acid–base complex with the benzyloxy group on C-4, which is followed by intramolecular delivery of a methyl group to the proximal (C-3) carbon. Entry 6 is in line with this reasoning, since the *tert*-butyldimethylsiloxy group in **71′** should be a poorer Lewis base than the benzyloxy group.[137] As for the reaction with $LiMe_2Cu$, the ring opening of **71** by $AlMe_3$ proceeds with much better regioselectivity than that of the corresponding epoxy alcohol.[134]



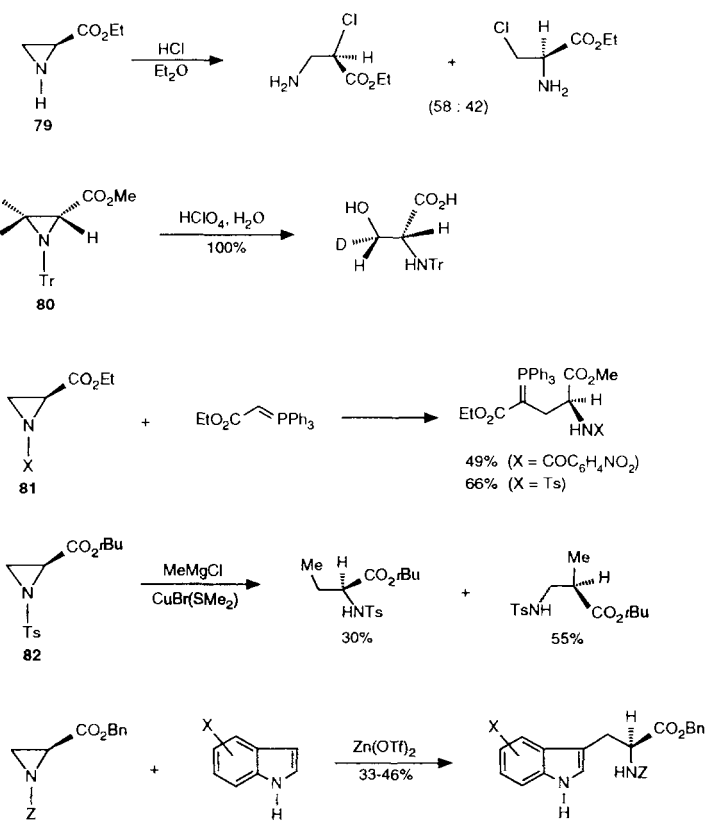
The results of the ring-opening reactions of the *cis*-aziridines **72** and **72′** are shown in Table 3. Inspection of entries 1–4 shows

Table 3. Ring opening of **72** and **72′** by methylation reagents (R′ = Me).

Entry	Substrate	Reagent/Conditions	**75**:**76**	Yield [%]
1	**72**	$LiMe_2Cu$, Et_2O, −20 °C	– [a]	–
2	**72′**	$LiMe_2Cu$, Et_2O, −20 °C	78:22	87
3	**72**	Li_2Me_2CuCN, THF, −20 °C	79:21	73
4	**72′**	Li_2Me_2CuCN, THF, −20 °C	88:12	68
5	**72**	$AlMe_3$, toluene, 75 °C	<1:99	92
6	**72′**	$AlMe_3$, toluene, 75 °C	33:66	60

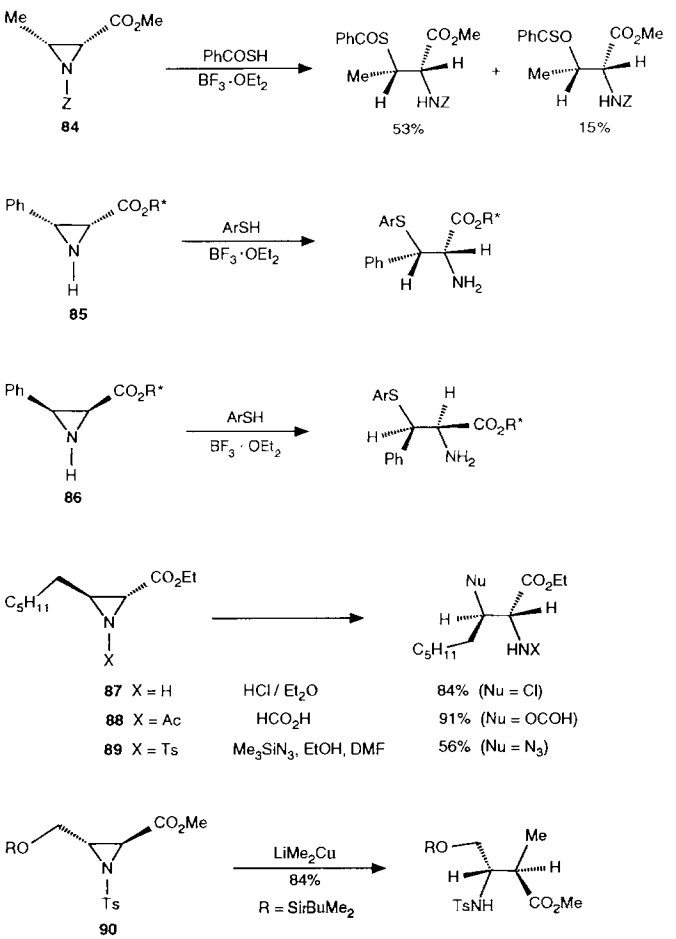
[a] No reaction.

the general trend of poorer regioselectivity (and lower reactivity, entry 1) for the reactions of **72** and **72′** as compared to the *trans* isomers **71** and **71′**. Presumably if complexation of the organometallic reagent to the free hydroxyl group is important for the regiochemistry of the ring scission, the poorer performance of the *cis* isomers is mainly due to steric effects. However, ring opening of **72** with trimethylaluminum gave the same excellent C-3 selectivity as observed for the *trans* isomer **71**; the importance of having a good Lewis base at the C-4 position is again underlined by comparison of entries 5 and 6. Applications of this ring-opening methodology to the enantioselectivity synthesis of some natural products are described in Section 5.4.



Scheme 27. Regioselective ring opening of **77** accompanied by cleavage of a silyl ether. TBS = *tert*-butyldimethylsilyl.

The transformation[138] shown in Scheme 27 illustrates complete selectivity for ring opening at the benzylic position of **77** and also the sometimes surprising lability[139] of silyl ethers towards complex hydrides.

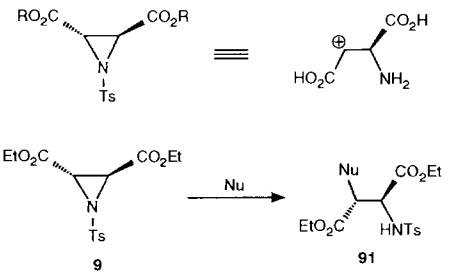


4.4. Ring Opening of Aziridine-2-carboxylates

Aziridino esters (aziridine-2-carboxylates) are potentially very useful synthetic intermediates, since enantioselective routes to unusual amino acids (by regioselective ring-opening reactions) can be envisaged. Leading references can be found in the recent paper by Zwanenburg et al.,[140] who have developed a convenient route to enantiomerically pure aziridino esters (see Scheme 6). Some representative examples of the ring opening of both activated and nonactivated substrates are shown in Schemes 28 and 29.

As discussed in Sections 4 and 4.1, the mechanism and regioselectivity of the acid-catalyzed ring opening of nonactivated aziridines may vary, depending on the exact conditions used. This is

Scheme 28. Regioselective ring opening of aziridine-2-carboxylates. DMF = dimethylformamide.



Scheme 29. Regioselective ring opening of 3-substituted aziridine-2-carboxylates. In **85** and **86** R* = (−)-menthyl.

nicely demonstrated by the reactions of aziridines **79**[141] and **80** (Scheme 28).[142] The latter reaction provides convenient access to stereospecifically labeled amino acids. Baldwin et al. have described the ring opening of the activated species **81** with Wittig reagents[143] (see also Section 5.3) and the copper-catalyzed reaction of **82** with Grignard reagents.[144] Unfortunately, the nonactivated *N*-benzyl analogue of **82** was not a good substrate for organometallic reagents, even in the presence of Lewis acids.[125] In studies directed toward the synthesis of biologically active natural products, Sato and Kozikowski[145] showed that the reaction of **83** with a variety of substituted indoles was highly dependent on the nature of the Lewis acid used to promote the reaction.

The ring opening of disubstituted aziridino ester **84**[146] (Scheme 29) was completely regioselective but illustrates the complications associated with ambident nucleophiles. Interestingly, a peptide analogue of **84** gave a single regioisomer with sole formation of the *S*-acyl derivative, without the need for Lewis acid catalysis.[146] In the nonactivated series, Marquet et al.[147] observed complete stereo- and regioselectivity in the ring opening of **85** and **86** by a thiol; the corresponding *trans* isomers behaved similarly. (For the ring opening of nonactivated aziridinecarboxylic acids with thiols under mild conditions, see ref. [148]). Zwanenburg et al.[140] have published an extensive study of 3-alkylaziridine-2-carboxylic esters such as **87**–**89**. Scheme 29 shows some examples of the excellent stereo- and regioselectivity obtained in the ring-opening reactions of both nonactivated and activated substrates. Complete C-2 regioselectivity was observed[149] for the ring opening of **90** by a cuprate reagent, a result that may be compared to those listed in Tables 2 and 3.

In Section 2.3 the synthesis of the C_2-symmetric aziridine **9** (Scheme 30) from tartaric acid was described. The C_2 symmetry

Scheme 30. The C_2-symmetric aziridine **9** is a synthetic equivalent for the β cation of L-aspartic acid; *ent*-**9**, the synthetic equivalent of the β cation of D-aspartic acid, can be used analogously.

removes the question of regioselectivity as far as ring opening is concerned, and the three electron-withdrawing groups in **9** make this substrate highly susceptible to attack by nucleophiles.[24] Some results are shown in Table 4. In each case, ring opening occurred with inversion under very mild conditions, which reflects the combined activating effects of the three substituents. As sketched in Scheme 30, the diester **9** and its enantiomer can be considered as synthetic equivalents for the β-cation of L- and D-aspartic acid, respectively. This approach to stereospecifically substituted aspartic acid derivatives complements the work of Baldwin et al.[150] and Hanessian et al.,[151] who independently developed synthetic equivalents of the corresponding anionic synthons.

4.5. Ring Opening Promoted by Transition Metal Complexes

The development of organo transition metal chemistry[152] has brought new dimensions to organic synthesis and greatly expanded the repertoire of techniques available for chemo-, regio-, and stereoselective transformations. Some reactions of aziridines mediated by transition metal complexes are depicted in Schemes 31 and 32; particularly attractive are the *catalytic* procedures shown in Scheme 32.

Scheme 31. Reactions of aziridines with transition metal complexes. SEM = trimethylsilylethoxymethyl.

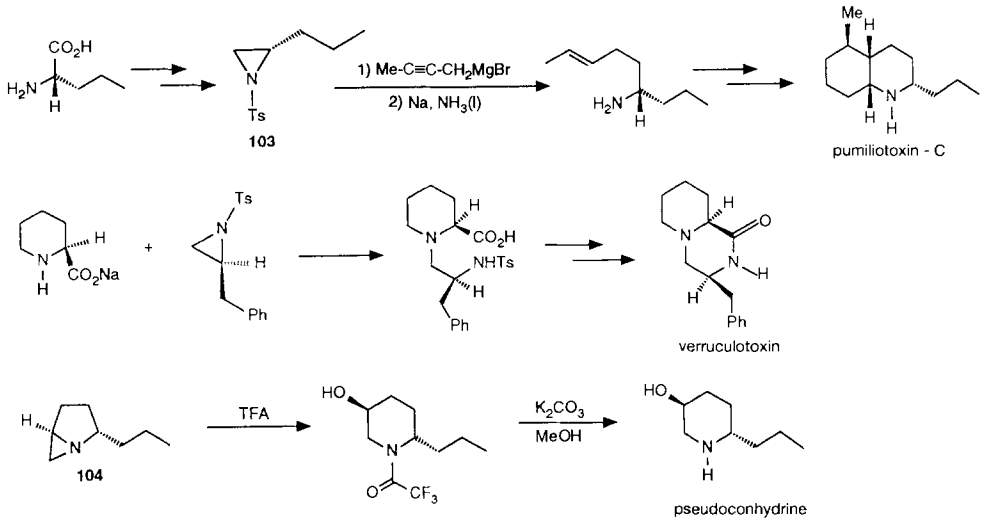
The ring expansion of aziridine **92** to give bicyclic compound **93** can be regarded as an "organometallic analogue" of the Stevens rearrangement of ammonium ylides.[153] The process involves the insertion of two molecules of diphenylacetylene and a single molecule of carbon monoxide. The reaction of **94** with $[Fe(CO)_5]$ was one of the first applications of vinylaziridines.[154] The pathway proposed[155] for the remarkable transformation of aziridinium ion **95** into **96** provides a good demonstration of the mechanistic diversity exhibited by organometallic complexes. The type of nickel-mediated ring expansion used to transform aziridine **97** into β-lactam **98** was shown to be both regio- and stereoselective.[156]

Scheme 32. Regio- and stereoselective transformations of aziridines catalyzed by transition metals.

In the catalytic procedures shown in Scheme 32, the rhodium-mediated ring expansion developed by Alper et al.[157] was shown to be both stereo- and enantiospecific, and occurred with retention of configuration. This reaction could also be used for kinetic resolution of aziridines, when menthol was added as chiral ligand. In a similar type of reaction, palladium was used[158] to catalyze the formation of α-methylene-β-lactams **99**. Palladium was also employed by Oshima et al.[159] in an excellent synthesis of vinylpyrrolines such as **100** from dienylaziridines. Vinylaziridines[160] are also substrates of interest, and the palladium-catalyzed reaction[161] of **101** was regio- and stereoselective, yielding an azetidinone (**102**) of considerable synthetic potential. A related reaction conducted with diastereo- and enantiomerically pure material is discussed in Section 5.4.

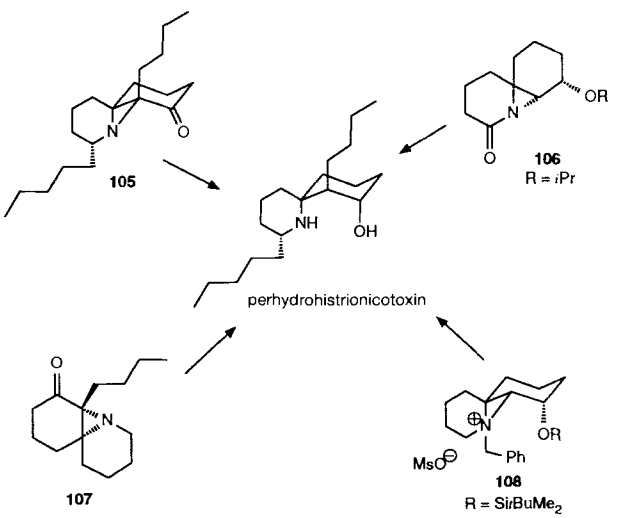
5. Chiral Aziridines and Aziridinium Ions in Total Synthesis

It should be clear from the foregoing sections that chiral aziridines are attractive building blocks for organic synthesis. In the following discussion, representative applications of chiral aziridines and aziridinium ions in the total synthesis of some natural products and their analogues will be presented. In most of these syntheses nonracemic materials were employed. This section is subdivided according to the types of target molecules.



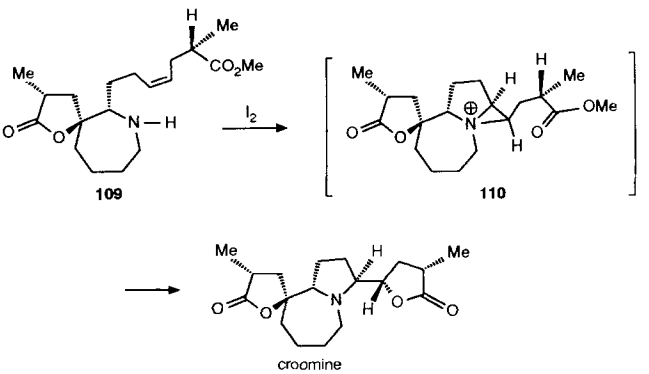
5.1. Alkaloids

Oppolzer and Flaskamp[162] used the chiral aziridine **103** (Scheme 33) in an enantioselective total synthesis of pumiliotoxin-C. This elegant piece of work allowed unambiguous assignment of the absolute configuration of the natural product and was also one of the first applications of an organometallic reagent for the ring opening of an activated aziridine. Scheme 33 also shows a convenient enantiospecific synhesis of verruculotoxin[163] as well as a route to racemic pseudoconhydrine,[164] which made use of the thermodynamic control of the ring opening of bicyclic aziridine **104**.

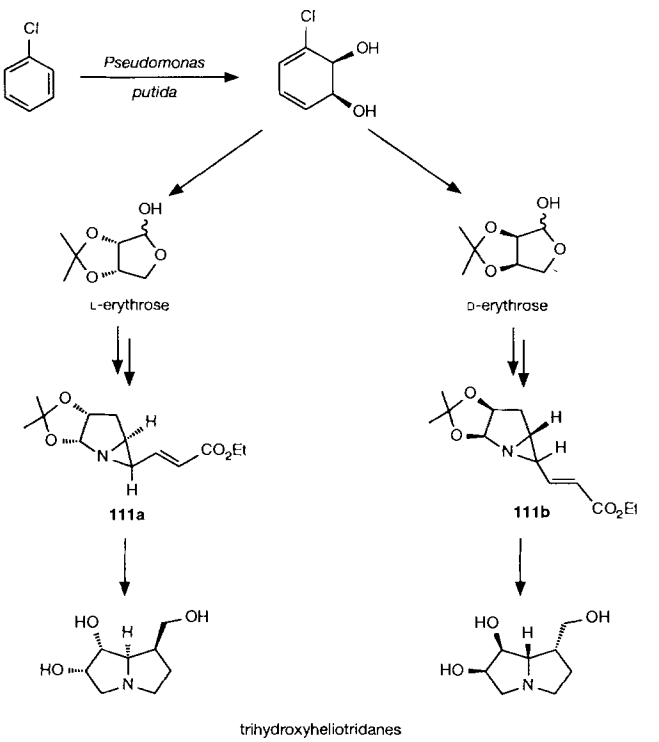


Tricyclic aziridines **105**,[165] **106**,[166] and **107**[167] and aziridinium ion **108**[168] have all featured in routes to the synthetically challenging histrionicotoxin family of spirocyclic alkaloids (Scheme 34).

The synthesis of (+)-croomine[169] shown in Scheme 35 involved the one-pot conversion of **109** into the target molecule by intramolecular capture of the aziridinium species **110**.

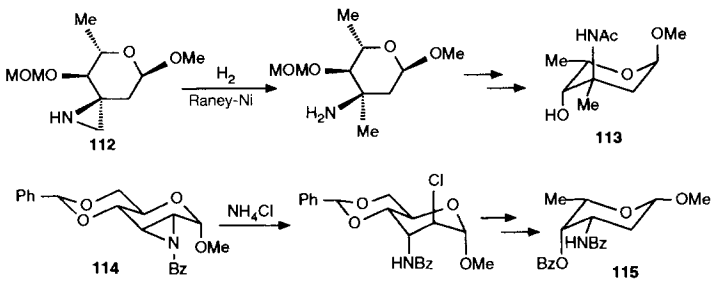


Hudlicky et al.[170] have developed an ingenious and efficient enantiodivergent route to the pyrrolizidine alkaloid trihydroxyheliotridane (Scheme 36). Starting from chlorobenzene, which was subjected to enantioselective microbial oxidation, the synthesis diverged to give protected derivatives of both L- and D-erythrose. Elaboration of both enantiomers of bicyclic vinylaziridine **111** was followed by thermal rearrangement to provide the desired bicyclic ring systems.



Scheme 33. Stereoselective synthesis of some alkaloids from chiral aziridines. TFA = trifluoroacetic acid.

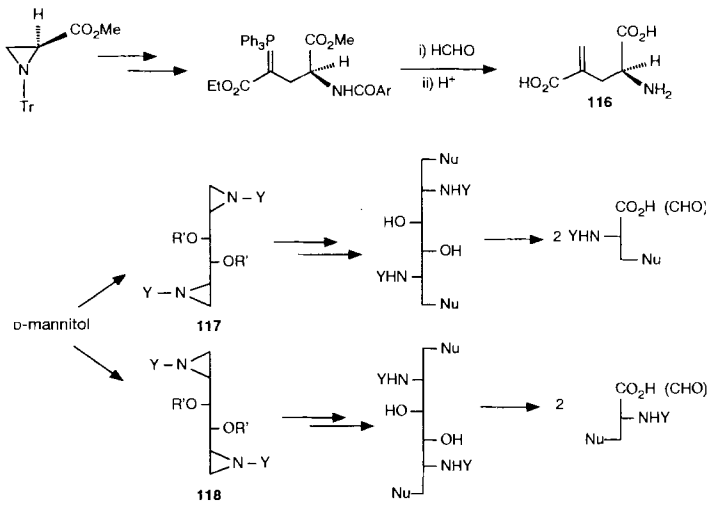
Scheme 34. Aziridine-based routes to the alkaloid perhydrohistrionicotoxin.



Scheme 35. An aziridinium ion as a key intermediate in the enantioselective total synthesis of the alkaloid croomine.

Scheme 36. Synthesis of trihydroxyheliotridanes via enantiomeric vinylaziridines.

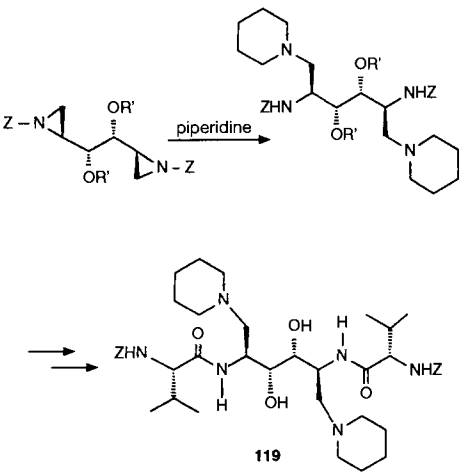
5.2. Amino Sugars



Sugar aziridines (cf. Scheme 2) often provide convenient access to the amino sugars found in many naturally occurring antibiotics. Two examples, in which the ring opening of both spiro and fused bicyclic aziridines are utilized, are shown in Scheme 37. The synthesis[171] of the branched-chain amino sugar **113** included hydrogenolysis of aziridine **112** over Raney nickel; the route[172] to the daunosamine deriative **115** proceeded via the Fürst–Plattner regioisomer (cf. Section 4.2) from the ring opening of fused aziridine **114**.

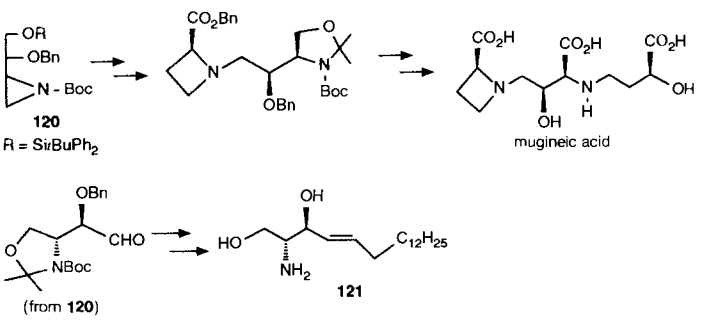
Scheme 37. Chiral aziridines in the synthesis of enantiomerically pure amino sugars. MOM = methoxymethyl, Bz = benzoyl.

5.3. Amino Acids and Derivatives



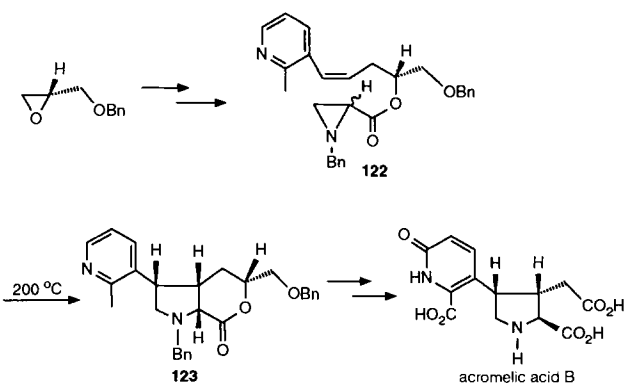
Baldwin et al.[143] have used the ring opening of aziridine-2-carboxylates by Wittig reagents (Section 4.4) as a key step in the synthesis of naturally occurring unsaturated amino acids (synthesis of **116**, Scheme 38). In Section 2.2, a general synthesis of chiral

Scheme 38. Chiral aziridines in the synthesis of amino acids and their derivatives. Nu = alkyl, halide, N_3^-, PhS^-.



bisaziridines from mannitol was presented (cf. **117** and **118**, Scheme 38). These form the basis of the elegant and convenient route[173] to α-amino acids and aldehydes shown in Scheme 38. The best activating groups (Y) were tosyl and benzyloxycarbonyl, and a very thorough study of twofold ring-opening reactions with a wide range of nucleophiles was performed. Oxidative cleavage of the central 1,2-diol moiety finally provided two molecules of chiral product per molecule of substrate. The same mannitol derivatives could be used for the synthesis[174] of C_2-symmetric inhibitors of HIV-1 protease (**119**, Scheme 39, cf. [175]).

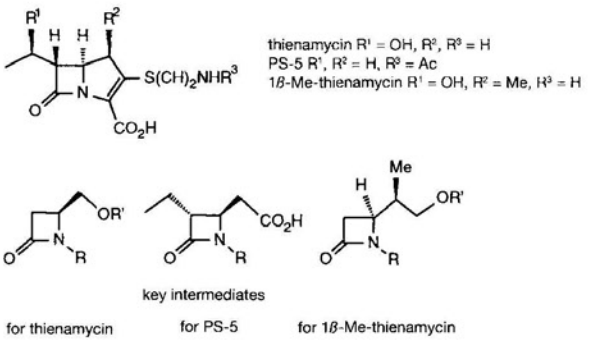
The Paris group[176] has also reported an enantioselective approach toward mugineic acid. The chiral aziridine **120** (Scheme 40) was synthesized from 2-*O*-benzyl-L-threitol and could be converted in a few steps (including regioselective ring opening by phenylthiolate) to an advanced key intermediate. Aziridine **120** is also a possible precuror to optically active *erythro*-sphingosine (**121**).[177]



Scheme 39. Synthesis of an inhibitor of HIV-1 protease (**119**) via a chiral bisaziridine. Z = benzyloxycarbonyl.

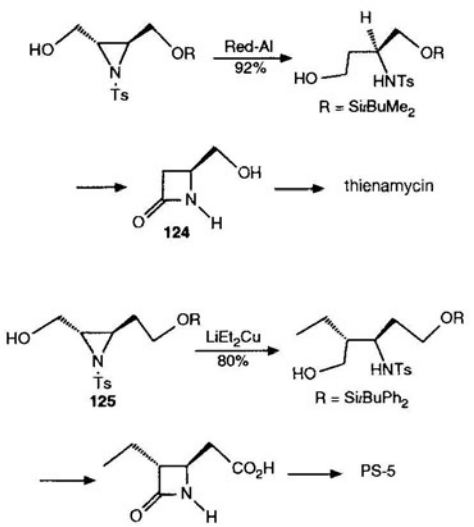
The 1,3-dipolar cycloaddition reactions of azomethine ylides produced by thermolysis of aziridines have been studied very thoroughly by Huisgen et al.[178] An interesting intramolecular version of this reaction was used by Takano et al.[179] as a key step in the enantioselective total synthesis of acromelic acid B

Scheme 40. Enantioselective routes to mugineic acid and *erythro*-sphingosine (**121**) via chiral aziridine **120**.



from (*S*)-*O*-benzylglycidol (Scheme 41). Thermolysis of a 50:50 mixture of aziridine epimers **122** gave a single stereoisomer of pyrrolidine **123**, which was then elaborated to the target molecule by a sequence involving epimerization at C-2.

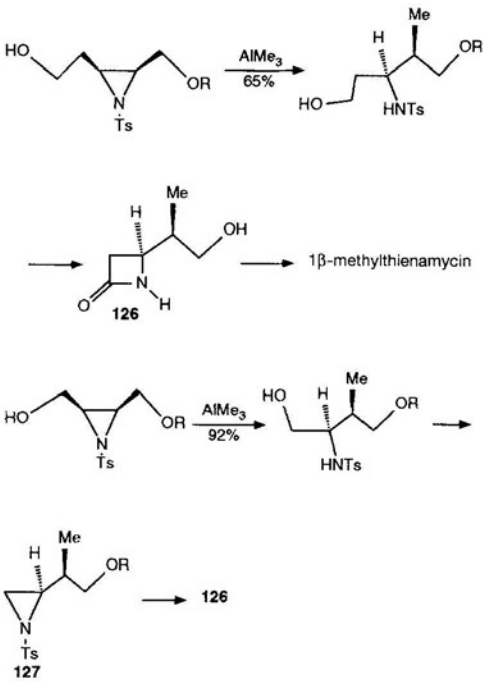
Scheme 41. Aziridine **122** as a key intermediate in the enantioselective total synthesis of acromelic acid B.



5.4. β-Lactam Antibiotics

In Sections 2.4 and 4.3 the synthesis and ring-opening reactions of enantiomerically pure 2,3-aziridino alcohols were described. It will now be demonstrated how this methodology can be applied to the enantioselective synthesis of some members of the important class of carbapenem antibiotics. The target molecules and the types of key intermediates for their total synthesis are shown in Scheme 42.

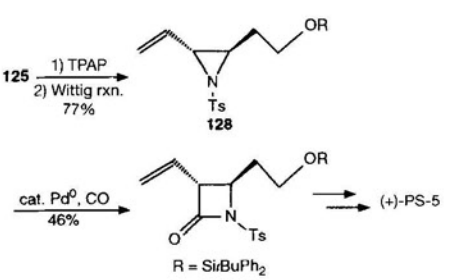
Scheme 42. Key intermediates for the enantioselective synthesis of some carbapenem antibiotics.



The synthesis of these three key intermediates relies on the regio- and stereoselective ring opening of suitable aziridino alcohols by Red-Al, $LiEt_2Cu$, and $AlMe_3$, respectively. *trans*-Aziridines were used in the routes to thienamycin, via **124**,[31] and PS-5, from **125**[180] (Scheme 43). The C-2 regioselectivity was

Scheme 43. Enantiomerically pure *trans* aziridino alcohols provide a route to the carbapenem antibiotics thienamycin and PS-5.

excellent in both cases, presumably owing to the directing effects of the free hydroxyl group (cf. Section 4.3).

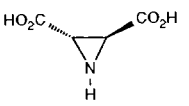


cis-Aziridines were used in two approaches[181] to 1β-methylthienamycin (via key intermediate **126**); the second route involved chiral aziridines at two different stages (Scheme 44). The regioselectivity of the ring opening, now dictated by the benzyl moiety (Section 4.3), is complete in both cases. The route via **127** is particularly efficient in terms of overall yield.[181]

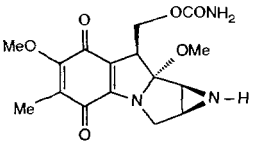
Scheme 44. Use of *cis* aziridino alcohols in the synthesis of 1β-methylthienamycin. R = $PhCH_2$.

All four of the required aziridino alcohols can be obtained in >90% *ee* from the corresponding epoxides. The tosyl group not only activates the ring toward nucleophilic attack but also is important for efficient closure of the azetidinone ring under mild conditions.[182] Non-natural analogues of these antibiotics are equally easily available by this route simply by suitable permutations of the *cis* or *trans* geometry of the allylic alcohol used in the Sharpless AE reaction, the (+) or (−) enantiomer of the tartrate ester serving as a ligand in the AE reaction, and the nature of the nucleophile used in the ring opening of the activated aziridine.

A complementary method[183] for the synthesis of PS-5 is shown in Scheme 45. Key steps in this stereoselective route are

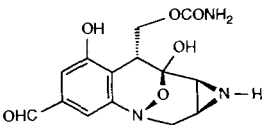


Scheme 45. A stereoselective palladium-catalyzed transformation of a vinylaziridine to an enantiomerically pure β-lactam. TPAP = tetra-*n*-propylammonium perruthenate, R = Si^tBuPh_2.

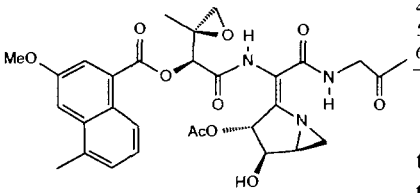


the palladium-catalyzed ring opening of vinylaziridine **128**, followed by insertion of CO and ring closure to the β-lactam (cf. Section 4.5).

5.5. Some Natural Products Containing Aziridine Units



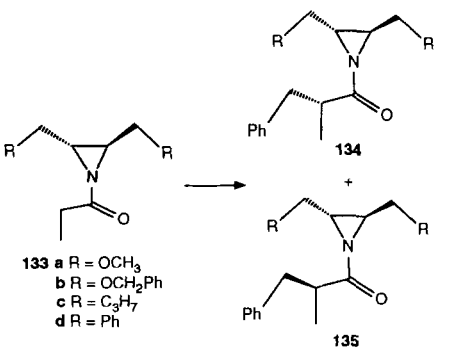
The C_2-symmetric aziridine **129** can be synthesized[184] in a few steps from (+)-tartaric acid (cf. Scheme 3). Not surprisingly, the other much more intricate structures have prompted much synthetic activity; the most effort[185] has been devoted to the



129

130 mitomycin A

131 FR-900482



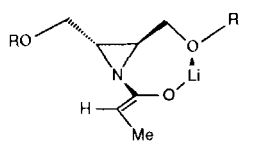
132 azinomycin A

mitomycins. (The first total synthesis of racemic mitomycin A was accomplished by Kishi et al.[186] as early as 1977.) Racemic FR-900482 was synthesized very recently by Fukuyama et al.,[187] and an enantiospecific approach from L-methionine (via an aziridine closely related to compound **31** in Scheme 19) has also been reported.[188] Coleman and Carpenter[189] have disclosed a stereoselective route from D-glucosamine to the aziridine substructure of the azinomycins.

6. Aziridines as Chiral Auxiliaries for Asymmetric Synthesis

As shown in Section 2.3, tartaric acid provides convenient access to C_2-symmetric chiral aziridines. Scheme 46 shows how these materials can be used as chiral auxiliaries[25] for diastereoselective alkylation. The enolates of amides **133a–d** were formed at low temperature and allowed to react with various electrophiles. Results from the alkylations with benzyl bromide (Table 5) illustrate some of the interesting features of the reaction. The lithium enolates of aziridines **133a** and **133b**, which have ether side chains, reacted with complete diastereoselectivity to give the alkylated products with the absolute configuration shown for **134** (Table 5, entries 1 and 2). For **133b** the effect of varying the counterion of the enolate was studied; lithium was found to be far superior to sodium or potassium (entries 2–4). The importance of the nature of the cation and insensitivity of the steric bulk of the alkoxy group suggests that a chelate is formed between the metal ion and an oxygen atom in the enolate and one in the side chain. This hypothesis was tested by studying

133 a R = OCH_3
b R = OCH_2Ph
c R = C_3H_7
d R = Ph



134 + **135**

Scheme 46. Use of C_2-symmetric aziridines as chiral auxiliaries for diastereoselective alkylation with alkali metal bis(trimethylsilyl)amides and benzylbromide.

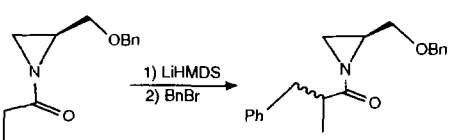


Table 5. Diastereoselective alkylation of **133** with $MN(SiMe_3)_2$ and $PhCH_2Br$.

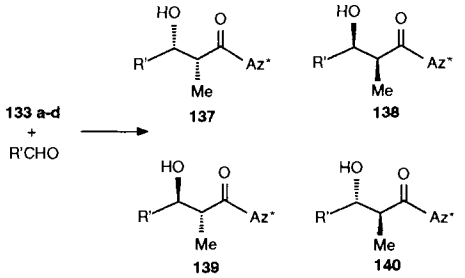
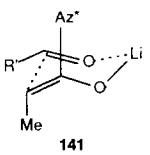
Entry	Substrate	$M^{\oplus}$	**134**:**135**
1	**133a**	Li	>99:1
2	**133b**	Li	>99:1
3	**133b**	Na	75:25
4	**133b**	K	67:33
5	**133c**	Li	80:20
6	**133d**	Li	75:25

the reaction of aziridines **133c** and **133d** (available in enantiomerically pure form by the Sharpless asymmetric dihydroxylation procedure),[190] which have two relatively bulky side chains with no donor atoms for chelate formation (entries 5 and 6). A simple model[25] to explain the results is provided by structure **136**. Under the reaction conditions used, the (*Z*) enolate is formed,[191] and the enolate species is presumed[192] to have a pyramidalized nitrogen atom. Chelation of the metal ion (expected to be most favorable for lithium) then directs the incoming electrophile to the opposite face of the enolate, which results in the absolute configuration observed in the products. Since the substrate has C_2 symmetry, it makes no difference on which face of the aziridine ring the chelate is formed. The importance of the symmetry element[193] is emphasized by the results of the reaction shown in Scheme 47.



136



Scheme 47. Poor diastereoselectivity (75:25) in the alkylation of a non-C_2-symmetric substrate. LiHMDS = lithium hexamethyl disilazide.

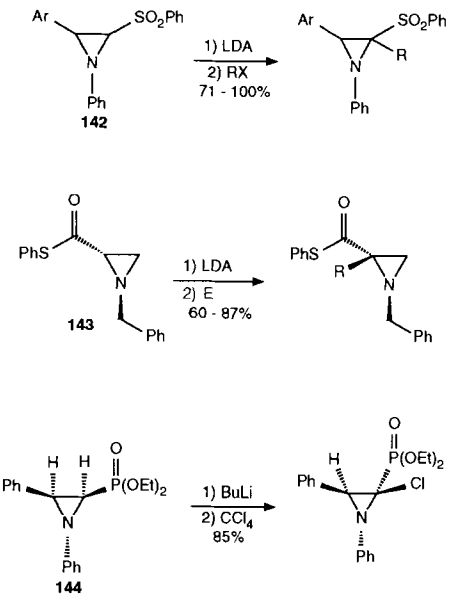
Much effort has been expended on the development of asymmetric versions of the aldol reaction.[191] Since many of the most successful approaches are based on the use of chiral auxiliaries, it was of interest to test the performance of the C_2-symmetric aziridines. Four diastereomeric products are possible for the aldol reactions (Scheme 48).

Scheme 48. Four possible diastereomers may result from an aldol reaction in which a chiral aziridine auxiliary (Az*) is used.

One important stereochemical factor is the enolate geometry. (*Z*) Enolates of the type used here tend to give *syn*-aldol products under conditions of kinetic control. The Zimmerman–Traxler model of the transition state (**141**) has gained widespread use for explaining the stereochemical outcome.[191] A selection of results[25, 190] is shown in Table 6.

141

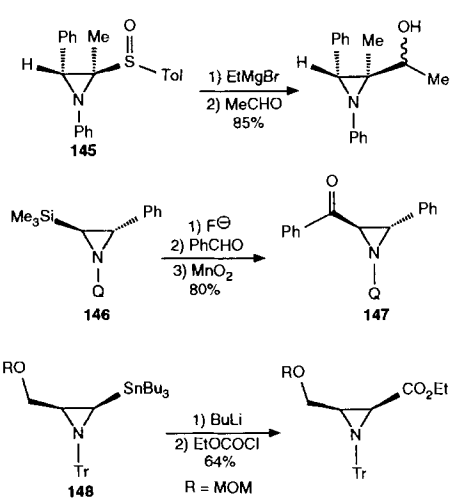
Table 6. Diastereoselective aldol reactions of **133** and R'CHO.



Entry	Substrate	R'	**137**:**138**:**139**:**140**
1	**133a**	Ph	87:13:<1:<1
2	**133b**	Ph	99:1:<1:<1
3	**133c**	Ph	>99:<1:<1:<1
4	**133d**	Ph	91:9:<1:<1
5	**133b**	Et	40:40:10:10
6	**133c**	Et	87:13:<1:<1
7	**133d**	Et	85:15:<1:<1

Bis(benzyloxymethyl)aziridine **133b** gave excellent results only with relatively bulky aldehydes (cf. entries 2 and 5), while the bis(methoxymethyl) species **133a** was even less selective (entry 1). This behavior does not parallel that observed for the alkylation reactions (cf. Table 5). Another significant difference is the much improved performance of auxiliaries having side chains not containing oxygen atoms (entries 3, 4, 6, 7). For the Zimmerman–Traxler mechanism to be operative, the metal ion must be able to coordinate simultaneously to both the enolate and the aldehyde oxygen atoms. This is not possible if the metal ion is already coordinated to the side chain of the auxiliary. In the special case of the reaction between **133b** and benzaldehyde (entry 2) the diastereoselectivity appears to be entirely due to steric effects on the approach of the aldehyde to the enolate. For the reactions involving auxiliaries without oxygen atoms in their side chains, the Zimmerman–Traxler transition structure (**141**) is assumed.

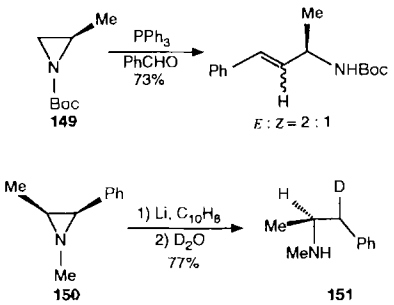
The C_2-symmetric aziridines discussed here thus fulfill the usual requirements for a good chiral auxiliary: both enantiomeric forms are readily available; they give good to excellent *de* in subsequent reactions; and they can be removed easily[194] in a nondestructive manner.



7. Aziridines as Chiral Reagents

The reaction of chiral metalated aziridines with electrophiles has obvious potential for stereoselective synthesis. However, as summarized by Seebach and Häner,[195] the generation and handling of "carbanionic" three-membered heterocycles can be problematic. Some successful solutions to this problem are discussed below (Schemes 49 and 50).

Scheme 49. Stereoselective reactions with metalated aziridines as chiral intermediates. Top: R = CH_3, $C_6H_5CH_2$, CH_2=$CHCH_2$; middle: E = MeI, $C_6H_5CH_2Br$, C_6H_5CHO, β-nitrostyrene.

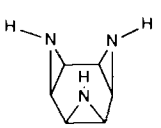


The 2-phenylsulfonylaziridine **142** could be metalated and then alkylated with reactive alkyl halides in excellent yield (Scheme 49).[196] Racemic compounds were used and, unfortunately, no stereochemical information was provided. Seebach et al. have published the results of a careful study of the lithiation and subsequent reactions of both racemic[195] and enantiomerically pure[197] (*S*)-phenyl aziridinecarbothiates **143**; electrophilic substitution was shown to occur with retention of configuration. Lithiated (racemic) aziridinylphosphonate **144** could not be alkylated or trapped by aldehydes but did react with carbon tetrachloride; in this case, inversion of configuration was suggested.[198]

Scheme 50. Further examples of the use of configurationally stable "carbanionic" aziridine species. Q is given in Scheme 11.

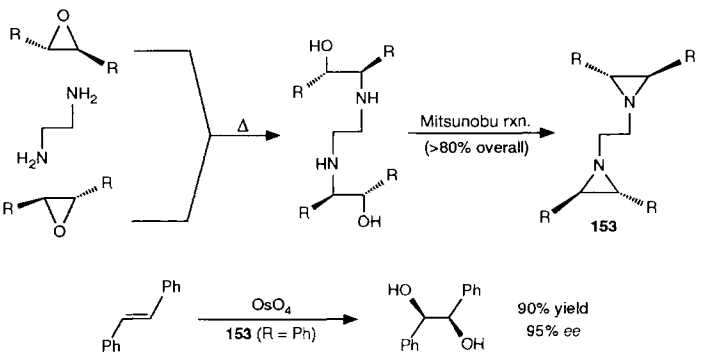
The sulfinylaziridine **145** (which can be obtained in enantiomerically pure form, see Section 2.6) was transformed to the corresponding Grignard reagent, which could be trapped by acetaldehyde but not with alkyl halides (Scheme 50).[76] An aziridinyl carbanion was implicated in the efficient sequence[199] leading from **146** to **147**. Vedejs and Moss[200] have described the preparation of configurationally stable (racemic) aziridinyllithium reagents by tin–lithium exchange[201] on aziridines such as **148**; the lithiated species could be trapped efficiently by a range of electrophiles, and an interesting anionic Stevens rearrangement was also observed.

Two interesting examples of chiral reagents formed from ring-opening reactions of aziridines are shown in Scheme 51. A chiral



Scheme 51. Formation and reaction of chiral reagents from the ring opening of aziridines.

Wittig reagent was prepared from the enantiomerically pure aziridine **149** and used for the synthesis of optically active allylic amines.[202] Yus et al. obtained a single diastereomer of **151** from the naphthalene–lithium catalyzed ring opening[203] of (racemic) aziridine **150** followed by quenching with D_2O.



8. Aziridines as Chiral Ligands. Toward Enantioselective Catalysis

Many of the most exciting recent developments in stereoselective organic synthesis are based on transition metal catalyzed processes, and the rational design of chiral ligands for enantioselective catalysis presents a formidable challenge.[204] Aziridines can be employed not only in the preparation of such chiral species[205, 206] but should also be useful ligands in their own right. Trisaziridine **152** is an (achiral) ligand and just one of a series of fascinating compounds prepared and studied by Prinzbach et al.[207]

152

A general approach[208] to C_2-symmetric bisaziridine ligands is shown in Scheme 52. Two equivalents of a *trans*-epoxide are ring-opened by one equivalent of a diamine, and the resultant species is subjected to a double Mitsunobu ring closure. In a stoichiometric reaction ligand **153** mediates the enantioselective *syn*-dihydroxylation of *trans*-stilbene in excellent chemical yield and with 95% *ee*. Current work focuses on the development of catalytic procedures for this and other reactions, for example enantioselective cyclopropanation and aziridination.

Scheme 52. Synthesis of C_2-symmetric bisaziridine ligands and their use in enantioselective synthesis.

9. Summary and Outlook

Chiral aziridines are readily available in enantiomerically pure form by a variety of procedures, and the reactivity of these three-membered heterocycles can be modified by suitable choice of the substituent on the nitrogen atom. Regio- and stereoselective ring-opening reactions with many types of nucleophiles provide access to a great number of useful synthetic intermediates. In addition to being attractive substrates or "building blocks" for the organic chemist, aziridines can also function as chiral auxiliaries, chiral reagents, and chiral ligands for asymmetric synthesis.

The utility of chiral aziridines in organic synthesis will be further enhanced by the development of improved general procedures for the catalytic enantioselective aziridination of olefins. But it seems appropriate even now to close this review by paraphrasing the title of an article by Sharpless et al.[48]: *Chiral aziridines—like epoxides only even more versatile.*

It is a pleasure to acknowledge the experimental and intellectual contributions of the following co-workers: Dr. Peter Somfai (Lund Institute of Technology), Dr. Hua Ming He, Dr. Carin Birgersson, Adrian Harden, and Hardip K. Dhaliwal. Prof. K. B. Sharpless and Prof. E. N. Jacobsen very kindly provided copies of manuscripts prior to publication. I also thank Prof. Tomas Trnka for an extensive list of references to sugar aziridines, Ms. Anita Meurling for the literature search, and Mr. Olle Eriksson for the drawings. Generous financial support was provided by the University of Uppsala and the Swedish Natural Science Research Council.

Theoretical Definition of a Functional Group and the Molecular Orbital Paradigm

Richard Frederick William Bader,* Paul Lode Albert Popelier, and Todd Alan Keith

It is the purpose of this review to demonstrate that the empirical classification of the observations of chemistry in terms of the properties assigned to functional groups is a consequence of and is predicted by physics. This is accomplished by showing that the atoms and functional groups of chemistry can be identified with bounded space-filling objects whose properties are defined by quantum mechanics. The quantum mechanical definition of a group is combined with a new pictorial representation of its form to obtain a unified picture which should make it eminently recognizable to chemists. This picture, when combined with the demonstrated ability of these groups to recover the measured properties of atoms in molecules, is offered as one which meets the expectations a chemist associates with the concept of a functional group. The manner in which this physical definition of a group differs fundamentally from models of functional groups based upon molecular orbital theory is discussed.

1. Introduction

1.1. Does Chemistry Have a Basis in Physics?

It is reasonable to ask why it has taken considerable time to arrive at a possible quantum mechanical definition of a functional group, and why there has evolved instead a prevailing opinion that this fundamental operational concept of chemistry, while unquestionably useful, would find no firm basis in physics. First, it has taken a reformulation of physics, as afforded by the work of Feynman[1] and Schwinger,[2] to provide us with the necessary quantum mechanical framework for asking the question "are there atoms in molecules?" Second, as so eloquently expressed and illustrated by Kuhn[3] with examples from all branches of science, is the phenomenon of the resistance accorded a new theory because of the conceptual bias exerted by existing paradigms. The paradigm of molecular orbital theory effectively filters out the hope of establishing a quantum mechanical basis for functional groups.

This review summarizes the evidence in favor of the identification of quantum subsystems with the functional groups of chemistry. Quantum subsystems are defined as regions of real space. A new pictorial representation of a quantum subsystem is presented to complement the demonstration of their equality with a chemist's mental and physical model of a group. This summary is prefaced with a discussion of why molecular orbital theory, whose components are rooted in the mathematical Hilbert space, appears to be at variance with this identification. It is shown that this conflict is a result of insisting that all chemical concepts be cast in the orbital mold, thereby requiring that the orbital model be applied beyond its intended scope.

1.2. Classification as a Definition of Science

A scientific discipline begins with the empirical classification of observations. It becomes exact in a predictive sense, when these observations are classified in such a way as to reflect the physics governing its behavior. In this limiting situation, prediction and classification are synonymous and the classification is based upon what physics predicts can be observed. This situation is exemplified in quantum mechanics by the classification of a given state in terms of the eigenvalues of the maximal commuting set of observables which constitute the measurable properties specific to that state.[4] In this sense, science is classification.

1.3. Classification in Chemistry

The observations of chemistry are classified empirically in terms of the properties exhibited by functional groups. In chemistry we recognize the presence of a group in a given system and predict its effect upon the static and dynamic properties of the system in terms of the characteristic set of properties assigned to that group. The functional group is the central concept in the working hypothesis of chemistry, the molecular structure hypothesis. According to this hypothesis, which rests upon the accumulated observations of experimental chemistry, the properties of matter are a consequence of the atoms it contains and of the network of bonds that link them. It is the purpose of this

article to demonstrate that the classification based upon the properties of functional groups is a consequence of and is predicted by physics, and that the classification is therefore, fundamental.[5]

2. The Molecular Orbital Paradigm

The molecular orbital point of view and its associated paradigm that is used to argue against the possibility of establishing a physical basis for functional groups, is illustrated by a quotation from a paper by Libit and Hoffmann.[6] It follows a paragraph in which they stress that it is the logic of substituent effects that has made possible the great strides in synthetic and mechanistic organic and inorganic chemistry: "Nothing like this logic comes out of molecular orbital calculations. Every molecule is treated as a whole and no set of transferable properties associated with a functional group emerges." This statement appears as true or false depending upon the role one assigns to the molecular orbitals (MOs) used in the calculation. If the orbitals are used not only to calculate the state function, but are in addition used in the search for properties to be assigned to an individual atom or group which forms a part of the real space of the molecule, the statement is true, since the orbitals, like the state function they are used to approximate, are necessarily delocalized over the whole system. If, however, the role of the molecular orbitals is confined to the determination of the state function and the electronic structure of the system, the statement is false. A state function contains the necessary information for the exhaustive partitioning of the real space of a molecule into separate regions whose properties reflect the very transferability associated with functional groups.[5, 7] It is the demonstration of this fact that will relieve chemists of the dilemma of having to contend with the coexistence in their minds of two apparently mutually exclusive models: one experimentally based, which provides the framework for the ordering of their observations and another, mathematically based, which when improperly applied, suggests that this framework has no basis in theory.

2.1. Molecular Orbital Theory as a Model of Electronic Structure

Mulliken[8] and Hund[9] developed molecular orbital theory to obtain a classification and understanding of band spectra. Molecular orbitals provide the basis for a model of the electronic structure of molecules. The molecular orbital model provides an excellent example of a classification scheme which parallels the predictions of theory. This model, when applied to the oxygen diatomic molecule for example, enables one to predict without the necessity of calculation that this sixteen-electron system will possess a ground state of $^3\Sigma_g^-$ symmetry followed by $^1\Delta_g$ and $^1\Sigma_g^+$ excited states. This classification is precisely what quantum mechanics predicts can be observed experimentally, the spin and orbital angular momentum operators, along with the symmetry operations, forming a maximal commuting set with the Hamiltonian operator.[10]

The use of orbital theory for the calculation of approximate state functions was initiated by Hartree[11] who introduced the concept of the self-consistent field (SCF) in the numerical determination of atomic orbitals. The incorporation of exchange was accomplished by Fock[12] and by Slater,[13] the latter through the specific variation of the spin orbitals in a determinantal wave function. The possibility of applying the Hartree–Fock method to the calculation of molecular orbitals was accomplished by Roothaan[14] and Hall,[15] by showing how the orbitals could be expanded in a set of basis functions. Their work and its extension by others, has made it practicable to calculate state functions for molecules to any desired degree of accuracy within the extended framework of orbital theory.

Molecular orbitals are used for purposes other than as a basis for the classification and calculation of electronic states. The orbitals themselves can be classified as bonding or antibonding, a classification which correlates with observed changes in bond lengths and dissociation energies of new states generated by changes in occupation of a particular orbital.[16] Because of their delocalized nature, there was an original reluctance on the part of chemists to embrace the molecular orbital model and use it in place of the valence bond approach which provided a quantum mechanical basis for the Lewis model of the electron pair and its directed properties.[17, 18] This reluctance was overcome in part by the introduction of equivalent orbitals by Lennard-Jones[19] and their subsequent evolution into localized orbitals. Lennard-Jones emphasized that any unitary transformation amongst a set of orbitals leaves all properties, including the total charge density, unchanged and that such transformations must be interpreted with caution.[20]

Wigner and Witmer introduced the use of group theory into chemistry in 1928 by deriving a set of rules for determining what types of states for diatomic molecules result from given states

Dr. Richard F. W. Bader was born in Kitchener, Ontario in 1931. He received his B.Sc. and M.Sc. from McMaster University and his Ph.D. in 1957 from the Massachusetts Institute of Technology (MIT) working with Professor C. G. Swain. He did post doctoral work at MIT from 1957 to 1958 and at Cambridge University from 1958 to 1959 in the Laboratory of Professor H. C. Longuet-Higgins. He began his scientific career as a physical organic chemist. He was at the University of Ottawa from 1960 to 1963 and then moved to McMaster University, where he remains today. His research interests are centered on the continued development of the theory of atoms in molecules and its application to chemistry.

of the separate atoms.[21] The first symmetry rule for molecular reactions appeared in 1962.[22] It predicts the reaction coordinate in terms of the symmetry of the transition density obtained by mixing in the first excited electronic state in a second-order perturbation expansion of the energy, expressed in terms of the nuclear displacements. This model likens the instability of a system for motion along a reaction coordinate to a pseudo Jahn–Teller effect. It is the nature of the first excited state of proper symmetry which determines the course of a chemical reaction.[22] Molecular orbital theory in combination with group theory is indispensable in predicting the ordering and symmetries of electronic states, as first demonstrated by Mulliken,[23] and the transition density itself can be usefully approximated in terms of the product of relevant orbitals which in many cases corresponds to the HOMO–LUMO product. In this manner the symmetry rule justifies the assumptions of frontier molecular orbital theory.[24] The same phase information of molecular orbitals provides the basis for the success of the concept of the conservation of orbital or state symmetry in the prediction of the course of a chemical reaction.[25] In these and other related approaches to reactivity and discussions of bonding, the orbitals are properly used in their capacity to provide information regarding the electronic structure of a system.

2.2. Looking for Atoms in Molecular Orbitals

A significant breach of the model occurs when physical significance is ascribed to particular choices of nuclear-centered basis functions used in the expansion of the molecular orbitals. An orbital describes the motion of a single electron in the field of all the nuclei and in the self-consistently determined average field of the remaining electrons. It is obtained by solving a set of coupled integral–differential equations whose solutions for an atom are called atomic orbitals and for a molecule, molecular orbitals.[26] The solutions to these equations are independent of the method used to obtain them, whether it be numerical or expressed in terms of an expansion.

The acronym LCAO-MO (linear combination of atomic orbitals for molecular orbitals) grew naturally out of early attempts to gain some understanding of the form of an MO in terms of its correlated one-electron states at infinite separation,[26] an idea first introduced by Lennard-Jones in 1929.[27] The pioneer workers, however, very much appreciated that this manner of representing a molecular orbital was meant to provide no more than a crude model of its form and that it did not imply the presence of an atomic component in a molecular orbital. Mulliken described how atomic orbitals (AOs) to be used as basis functions in the expansion of a molecular orbital, should be suitably modified for the molecule and not identified with the atomic case. He then continued with the statement,[28] "However, it should be kept in mind that the concept of an SCF MO is an independent one, and thus the use of a linear combination of AO's or STO's (Slater type orbitals) as building blocks to construct an MO is merely a convenience." In this same paper Mulliken presents an explanation as to why no physical significance should be ascribed to an atomic population based on an LCAO expansion. This acronym, for the sake of clarity of thought, should be changed to LCBF (linear combination of basis functions). In a later paper[29] Mulliken et al. completely disowned the concept of a population analysis upon the demonstration that it bore no relation to the form of the total charge distribution, as evidenced by the statement "It should be possible to avoid such inconsistent and unsatisfactory results by computing atomic charges directly from the molecular charge distribution." It is more than a question of semantics to understand that basis functions are not atomic orbitals. There are no atomic orbitals in a molecule, nor is there any overlap of atomic components.

It is perhaps asking too much of some that they give up the notion that a molecular orbital is a linear combination of atomic orbitals and indeed it is not necessary that they do so. It is only necessary that they not insist that the only chemical concepts capable of definition are those which survive the filtering through the successive levels of approximation within the molecular orbital model, as outlined above. The delocalized nature of molecular orbitals and of the basis functions employed in their expansion, which are associated with truncated portions of the mathematical Hilbert space, should not be used to exclude the possibility of identifying atoms or functional groups with bounded regions of real space. There is no question concerning the possibility of obtaining a quantum mechanical definition of uniquely defined regions of real space.[5, 30] The answer to the question of whether or not these regions correspond to the atoms of chemistry should not to be prejudiced by any existing orbital-based paradigm, but rather be determined solely by comparison of their predicted properties with the observed properties of matter.

3. Observational Constraints on the Definition of a Functional Group

Before proceeding with the quantum mechanical development, it is imperative to state what are the essential requirements imposed upon the definition of an atom in a molecule by the observations of chemistry. The first stems from the necessity that two identical pieces of matter exhibit identical properties. Since the form of matter is determined by the distribution of charge throughout real space, two objects are identical only if they possess identical charge distributions. This parallelism of properties with form exists not only at the macroscopic level, but as originally postulated by Dalton, is assumed to exist at the atomic level as well. It demands that an atom be a function of its form in real space, requiring that it be defined in terms of the charge distribution. It follows that if an atom exhibits the same form in the real space of two systems, or at two different sites within a crystal, it contributes identical amounts to the total value of every property in each case. This requirement demands in turn that the atomic contributions sum to yield the total value for the system, that is, the atomic contributions to a property must be additive. Only atoms meeting these two requirements can account for the observation of so-called additivity schemes wherein the atomic properties appear to be transferable as well as additive. Finally, the boundary defining an atom or functional group must be such as to maximally preserve its form and thereby maximize the transfer of chemical information from one system to another.

These are the there requirements that must be satisfied if one is to predict that atoms and functional groupings of atoms contribute characteristic and measurable sets of properties to every system in which they occur. It is because of the direct relationship between the spatial form of a group and its properties that we are able to identify it in different systems. Since the purpose of quantum mechanics is to predict the measurable properties of a system, it is reasonable to suppose that these observational constraints will be met by the quantum definition of an atom.

4. From Dirac's Theory to the Theory of Atoms in Molecules

Our goal here is not to review the mathematical foundation of the theory of a quantum subsystem. This has been done previously in a number of references.[5, 31] Here we wish to concentrate on its underlying ideas. We preface this discussion with a brief synopsis of this discussion for readers who wish to proceed directly to Section 4.3. Central to the new approach to physics developed by Feynman[1] and Schwinger[2] is the principle of least action, the idea that there exists a quantity called the action whose minimization yields the equation describing the motion of a system. The action itself is a quantity which is determined by the evolution in time of a system in real space and it thus defines a space–time volume. Schwinger showed how one can obtain all the laws of physics by extremizing this space–time volume in a general way. If one desires a definition of an atom based on physics, the atom must generate its own space–time volume and its boundaries must therefore, be defined in real space. This is the reasoning underlying the basic tenet of the theory of atoms in molecules, which is that atoms be defined as pieces of real space.[5]

4.1. From Dirac's to Schwinger's Theory

The historical development of the ideas that led to Schwinger's formulation of physics began with Dirac. Dirac demonstrated the equivalence of Schrödinger's wave mechanics and Heisenberg's matrix mechanics, both of which are firmly rooted in classical Hamiltonian dynamics.[32] Dirac's work went beyond this demonstration of equivalence, and in particular he introduced the theory of unitary transformations to parallel the canonical transformations of classical theory. Unitary or canonical transformations enable one to obtain equivalent descriptions of a system by passing from one representation to another.

In 1933, in what was to be a paper of singular importance,[33] Dirac posed and answered the question of what would correspond in the quantum theory to the Lagrangian method of classical mechanics and its associated action integral, a formulation of mechanics he considered to be more fundamental than that based on Hamiltonian theory. The answer to this question is provided by the so-called multiplicative law. This law provides the possibility of expressing a probability amplitude connecting two states as a product of contributions connecting intermediate states. As a consequence of this theorem, the associated action can be expressed as a sum of corresponding contributions. It is upon these ideas that both Feynman[1] and Schwinger[2] based their new formulations of quantum mechanics.[34a] These approaches are equivalent in that Schwinger's "fundamental dynamical principle" is a differential statement of Feynman's "path integral", but Schwinger's approach is specifically formulated to enable one to ask new questions of physics. It is this aspect of Schwinger's work that is not fully appreciated. One cannot find atoms in pre-Schwinger quantum mechanics. If one tries, one is simply led to his formulation.

4.2. From Schwinger's Theory to the Theory of Atoms in Molecules

Central to the Lagrangian approach is the principle of least action described above. Within quantum mechanics, the extremization of the action can be accomplished by varying the state function in the action integral. In extending the principle to a subsystem of a total system, one must necessarily retain these variations on the surface of the subsystem. But, retaining the variations on the boundary of the system is the very step which Schwinger purposefully makes in his generalization of the action principle. He does this to introduce Dirac's transformation theory, a step he accomplishes by identifying the variations with the generators of unitary transformations. Such generators describe all possible transformations, and hence all physical changes a system can possibly undergo. With their introduction, Schwinger generalizes the action principle to obtain quantum mechanics from a single dynamical principle.[34b] In particular, the extended action principle defines the observables of quantum mechanics, their equations of motion and their expectation values, in addition to the commutation relations. These are precisely the properties which must be established and defined for a subsystem if one wishes to obtain a quantum prescription for an atom in a molecule.

The possibility of defining the action for a subsystem is a consequence of its fundamental additive nature. The variation of the action for a subsystem leads one down the same road traversed by Schwinger, but one does not arrive at the same destination and recover his principle unless the subsystem satisfies a particular boundary condition. This condition is imposed as a constraint on the variation of the action and it requires that the subsystem be bounded by a surface through which there is a zero flux in the gradient vector field of the electron density $\varrho(\boldsymbol{r})$ [Eq. (a)], where $\boldsymbol{n}$ is the unit vector normal to the surface.

$$\nabla\varrho(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r}) = 0 \text{ at every point on the surface} \qquad \text{(a)}$$

Because the boundary condition is stated in terms of the electron density, a quantum subsystem is defined in real space, as it must be if its properties are to be defined as quantum mechanical expectation values. Indeed there is no such thing as an isolated system, and all systems are subsystems with varying degrees of interaction through their shared zero-flux surfaces.

4.3. Defining a Group by Applying the Quantum Boundary Condition

The application of the boundary condition defining a quantum subsystem, the zero-flux requirement in Equation (a), leads to a disjoint partitioning of the space of a molecule into a set of atomic basins.[5, 35] This is a consequence of the principal topological property exhibited by the electron density; that is, it exhibits local maxima at the positions of the nuclei. A nucleus thus serves as an attractor in the $\nabla\varrho$ field, and the region of space traversed by the trajectories of $\nabla\varrho$ that terminate at a nuclear maximum defines the basin of the atom. The basin is necessarily bounded by a zero-flux surface.[5, 35]

A representation of a group as a space-filling object with zero-flux surfaces separating it from the remainder of the molecule, is shown in Figures 1a and 1b. The group is the central

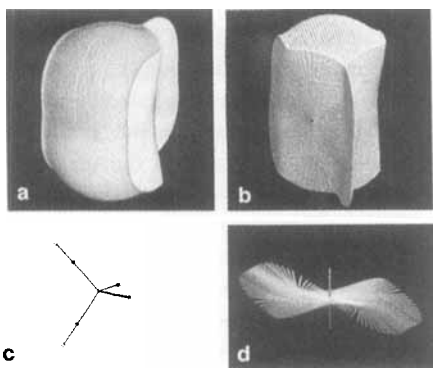

Fig. 1. A view of the transferable methylene group of the hydrocarbons with a) the van der Waals surface of the two hydrogen atoms, and b) the two C|C surfaces displayed in the foreground. The bond critical point is denoted by a dot for one C|C surface. c) The portion of the molecular graph that defines the methylene group up to the two bond critical points (denoted by dots) in the C|C interatomic surfaces. d) A display of the individual trajectories of $\nabla\varrho$ which terminate at a bond critical point and define a C|C interatomic surface. Also illustrated is the unique pair of trajectories which originate at the critical point and define the bond path. The shape of this surface is characteristic of surfaces between saturated carbon atoms, including that found in the diamond lattice.

methylene in pentane. It is obtained by separating the basins of the two neighboring carbon atoms in the hydrocarbon chain at their common interatomic surfaces. The group is represented symbolically by $|C(H_2)|$, the vertical bars denoting the C|C interatomic surfaces, and graphically (see Fig. 1a, b) by showing the two interatomic surfaces and their intersection with a surface on which the electron density attains a prescribed value, in this case 0.001 au. This envelope of electron density determines the van der Waals shape of the group[36] and is used to replace those portions of the atomic surfaces which occur infinitely far from the nuclei.

Illustrated in Figure 1d is the manner in which a C|C interatomic surface is defined by the set of trajectories of $\nabla\varrho$ which terminate at a bond or (3,−1) critical point of the electron density (a point where $\nabla\varrho = 0$), as well as the unique pair of trajectories which originate at this point and terminate at each of the neighboring nuclei. They define the bond path, the line of maximum charge density linking the carbon nucleus to its bonded C neighbors. The network of bond paths determines the molecular graph which in turn defines the molecular structure.[5, 35] That portion of the molecular graph which defines the methylene group up to its interatomic surfaces is shown in Figure 1c. In agreement with the chemical definition, a functional group is a linked set of atoms, bounded by a zero-flux surface.

Aside from the interatomic surfaces being curved rather than flat, this representation of the methylene group is similar in all respects to the space-filling models of atoms that chemists link together to represent a group or molecule. The boundaries between the atoms in the van der Waals envelope defined by the electron density are in general, less pronounced than when they are approximated by using van der Waals atomic spheres.[36] A group identical to that in Figure 1, bound only to other methylenes, is found in all *n*-hydrocarbons following and including pentane. In terms to its spatial representation and its other properties, it fulfills the chemist's expectations of the transferable methylene group of the hydrocarbons; it possesses a zero net charge, as it must if it is to be the repeating building block of the *n*-hydrocarbons. It makes a constant contribution to the molar volume as anticipated by the experiments of Kopp in 1855. Its energy equals the energy increment between successive pairs of hydrocarbons in agreement with the heats of formation of the hydrocarbons measured by Rossini et al.[37] Its polarizability and magnetic susceptibility reproduce the measured values of these field-induced properties for the methylene group.[38, 39]

This group serves as an example of the groups that are defined by theory and demonstrates their ability to reproduce the quantitative as well as the qualitative properties of the groups of chemistry. The classification and identification of a group in terms of its properties is the central idea in the application of quantum mechanics to the study of functional groups. Thus, the quantum mechanical concepts underlying the definition of the measurable properties of a system deserve careful consideration.

5. Definition of Group Properties

5.1. Observables and Expectation Values

Associated with every measurable property of a system is a linear Hermitian operator, an observable. An oft repeated statement concerns the impossibility of defining an atom or its properties, an atomic population for example, because they are not "quantum observables".[40] Part of the problem with such statements arises from their misuse of the language of quantum mechanics, and one again turns to Dirac for a clear statement of the principles involved. Dirac defines an *observable* to be a real dynamical variable, that is, a linear Hermitian operator, whose eigenstates form a complete set.[32] The *measurable* value of a property is one of the eigenvalues of the corresponding observable, an expectation value being the average value obtained by repeated measurement.[32]

Properly stated, the electron density is the measurable *expectation value* of the density operator, a quantum mechanical *observable*.[41] Thus an atom is defined in terms of the expectation value of a quantum observable. To state, as some do, that "an atom or its population is not a quantum observable" is to say

that neither is a linear Hermitian operator, which while true, is not a meaningful statement. The quantum boundary condition defining an atom [Eq. (a)] can be stated in terms of the density operator and thus an atom can be defined directly in terms of the action of a quantum observable.[30] Similarly, an electron population is defined as the expectation value of the number operator, the integral form of the density operator, and again a quantum observable.[41] It will yield an atomic population if one can obtain a quantum definition of its expectation value for atoms in molecules.

5.2. Atomic Expectation Values

As discussed above, Schwinger's formulation of quantum mechanics[2] does indeed enable one to define expectation values for a subsystem which satisfies the boundary conditions [Eq. (a)]. The required statement obtained from the generalized variation of the action integral is given in Equation (b).[5, 30, 31] In this equation the symbol $\mathscr{L}[\Psi,\Omega,t]$ denotes the Lagrange integral for a system Ω bounded by a zero-flux surface, the quantity whose integral over time yields the action. The Hamiltonian operator is denoted by $\hat{H}$, and $\hat{G}$ denotes any quantum observable. The important point to note about Equation (b) is that the commutator $[\hat{H},\hat{G}]$, when multiplied by i/h, gives the time rate-of-change of $\hat{G}$, the Heisenberg equation of motion. Thus, Equation (b) is a variational derivation of the equation of motion for the average value of an observable.

$$\delta\mathscr{L}[\Psi,\Omega,t] = (\varepsilon/2)\{i/h)\langle\Psi|[\hat{H},\hat{G}]|\Psi\rangle_\Omega + \text{complex conjugate}\} \quad \text{(b)}$$

The equation applies to any region of space bounded by a surface of zero-flux in the gradient vector field of ϱ [Eq. (a)]. It applies equally to the total system and to every atom within the system. Thus an atomic expectation value is defined on an equal footing with the expectation value of the same property for the total system. An important consequence of the averaging implied in Equation (b) is that the expectation value of any observable $\hat{M}$ for the total system is given by the sum of the corresponding atomic values $M(\Omega$ [Eq. (c)].

$$\langle\hat{M}\rangle = \sum_{\Omega} M(\Omega) \quad \text{(c)}$$

6. Atomic Theorems

6.1. Atomic Populations

Setting the observable $\hat{G}$ in Equation (b) equal to the number operator yields not only a definition of an atomic population, as the integral of the electron density over the atomic basin, but also an equation for its time rate-of-change, the integrated equation of continuity.[5, 41] It is a general result that a single variation principle [Eq. (b)] defines an observable's expectation value and yields a theorem governing its behavior, for both the total system and for its constituent atoms.[5, 42]

6.2. Atomic Force Theorem

The time rate-of-change of the momentum is force, and setting the generator $\hat{G}$ equal to $\hat{p}$, the momentum operator for an electron, yields the atomic force theorem. This is the Ehrenfest force,[43] the average force exerted on the electron density. In a stationary state this theorem establishes that the force acting on an atomic basin is determined by the flux in the force through its atomic surface, and is equal and opposite to that exerted by its bonded neighbors. Thus an atom and its properties respond only to changes in the total Ehrenfest force acting on each element of its surface, and hence only to changes in its surface. By preserving the interatomic surface characteristic of a given interaction, the properties of the group are preserved whether or not the bonded neighbor is considered to be present.

Using this property it is not necessary to "cap" a group when only a fragment of a larger system is to be studied, as exemplified by the isolation of the single peptide group from a polypeptide shown in Figure 2b. The alanyl group is obtained by separating the basins of neighboring N and C atoms at their common interatomic surfaces in the two amide bonds which link the group to a polypeptide chain. The alanyl group, like the other peptide groups investigated so far, possesses a zero net charge,[44, 45] and a peptide unit can serve as a building block of a polypeptide chain. The C|N interatomic surface of the amide bond undergoes only minor change, primarily in its outer reaches far from the bond critical point, as the substituent R is changed and different peptide units can be linked together to form a polypeptide with only minor modifications in their form and properties.[44, 45]

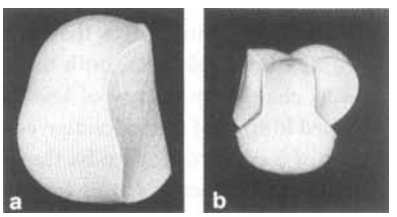

Fig. 2. a) A representation of the transferable methyl group of saturated hydrocarbons with its single interatomic surface. This group and its properties is found in all *n*-hydrocarbons following and including propane. b) A representation of the alanyl group, |NHCHRC(=O)|. R = CH_3. The -C(=O)| surface is on the right, the -HN| surface on the left, and the CHR group is in the foreground with the methyl group pointing down. Figure 2b is drawn to half scale relative to Figure 2a.

The sensitivity of an interatomic surface to changes in neighboring atomic basins acts as probe for spatially isolating changes within a system. Thus a rotation about the C–N bond of formamide causes only minor changes to the C|O and C|H surfaces, but results in a substantial shift in the C|N surface towards the N nucleus. As anticipated on the basis of these findings, the properties of the carbonyl oxygen and hydrogen atoms, their charges, energies, and associated bond lengths, are largely unaffected by the rotation, the major changes occurring within the basins of the C and N atoms and primarily in the region of their interatomic surface.[46]

6.3. Atomic Virial Theorem

Setting the generator equal to the operator $\hat{r} \cdot \hat{p}$, where $\hat{r}$ is an electronic position coordinate, yields the atomic statement of the virial theorem. Since this generator has the dimensions of action, its time derivative is energy. Thus this theorem defines the atomic averages of the electronic kinetic and potential energies. The potential energy, which is determined by the interactions between all the particles in a system, is defined to be the virial of the Ehrenfest force, a local property. Thus the total energy, like all properties, is given by a sum of atomic contributions.

An atomic energy exhibits the necessary property of being as transferable as is the electron density itself. As discussed above, when the physical form of any object, including an atom, is the same in two situations, observation requires that all of its properties, including its energy, must remain unchanged.[47] This requirement is fulfilled by the energies of the transferable methyl and methylene groups depicted in Figures 1 and 2a.[48–51] While there is no known functional relation between the electron density and the total energy, the properties of the quantum atom speak for its existence and ultimate discovery. The total energies of the methyl and methylene groups are in the tens of thousands of $kJ\,mol^{-1}$, yet they are transferable amongst the *n*-hydrocarbon molecules, both theoretically and experimentally, with changes in energy of less than four $kJ\,mol^{-1}$. This is observed in spite of the individual contributions to the potential energy of a group changing by thousands of $kJ\,mol^{-1}$ between succeeding members of the homologous series. The glycyl group, with an energy of approximately 524000 $kJ\,mol^{-1}$, can be transferred from formylglycylamine to triglycyl with a change of only $24\,kJ\,mol^{-1}$.[45]

By reason of their definition in terms of the zero-flux surface[5] and by demonstration,[7, 36, 44, 45, 48–51] the atoms and groups of theory are the most transferable pieces of a system definable in an exhaustive partitioning of real space. If perturbations are relatively small, groups respond so as to minimize the total change resulting from their interaction. Thus, the methyl group of ethane necessarily withdraws a small amount of electronic charge from the methylene group when transferred to propane, but not only is charge conserved, so is the energy. The energy lost by the methylene group equals the energy gained by each methyl group, and a similar conservation of charge and energy occurs for methylene groups bonded to a single methyl group in succeeding members of the homologous series. Thus additivity of energy is preserved in spite of the methyl group in ethane necessarily being unique.[48–51]

6.4. Atomic Current Theorem

The time rate-of-change of position is velocity and setting the generator in Equation (b) equal to $\hat{r}$ yields the theorem governing the average velocity of the electrons in the basin of an atom. In the presence of a constant uniform applied magnetic field, this velocity corresponds to the average of the electronic current induced over the basin of the atom. Equation (b) shows this atomic average of the electronic velocity to be equal to the flux in the position-weighted current through the surface of the atom.[42] The contribution of this flux to the mean atomic magnetic susceptibility $\bar{\chi}(\Omega)$, becomes vanishingly small when the current flow, like the charge density, is localized within the atomic basins, as illustrated for the ionic system LiH in Figure 3a. It becomes appreciable and comparable in magnitude to the basin contribution to $\bar{\chi}(\Omega)$ in systems with shared atomic interactions, as found in methane (Fig. 3b). The flux in the current flow across the interatomic surfaces for a linked ring of atoms dominates $\bar{\chi}$ in molecules such as benzene.[52, 53] Equation (b) also demonstrates that in a steady magnetic field there is local conservation of the current over each atomic basin.

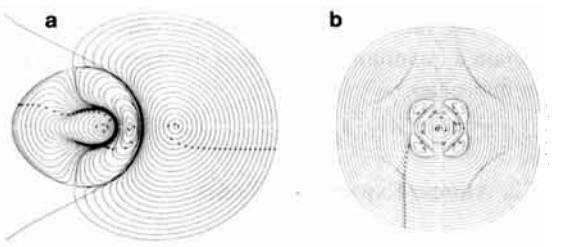

Fig. 3. a) The current density induced by an externally applied magnetic field for a symmetry plane containing the nuclei in LiH; the Li nucleus is on the left. The direction of flow within a current loop, for a field applied perpendicular to and into the plane, is indicated by an arrow. The positively charged Li atom has both diamagnetic and paramagnetic currents induced in its basin, the paramagnetic loops being isolated from the diamagnetic flow in the basin of the negatively charged H atom by the interatomic surface. This localized atomic behavior of the current flows and the presence of a paramagnetic component in the basin of the electropositive atom is typical of molecules with closed-shell (ionic) or intermediate (polar) interactions [5] and reflects the corresponding localization of the electron density. b) The current flow in an alternating plane of symmetry containing the carbon nucleus in the methane molecule, showing the intersection of the C|H interatomic surfaces. In this molecule with shared (covalent) atomic interactions [5] there is a substantial flow of current across the interatomic surfaces.

The electronic current density and its derived properties induced by a magnetic field for an atom in a molecule exhibit the same degree of transferability as does the charge density itself. Thus the methyl and methylene groups of Figures 1a, b and 2a contribute constant amounts to the magnetic susceptibilities of the members of the homologous series of hydrocarbons, confirming Pascal's values[39] for the group susceptibilities.[53] The same constancy in group contributions is found for the mean polarizability when the molecules are in the presence of an applied electric field.[50] Thus even in the presence of external fields, the atoms of theory behave as required by observation; their field-induced properties reflecting the form of the atom in the field-free case.

6.5. Atoms in Crystals

The idea of individual atoms being the source of the scattering of X-rays in a crystal dates back to Laue and Bragg.[54] A carbon atom in the face-centered cubic structure of diamond is shown in Figure 4.[55] It is completely bounded by its four interatomic surfaces, each of which is curved in the form of a chaise-longue. This atom, of T_d symmetry, linked to a mirror-image neighbor at one of its interatomic surfaces, defines a Wigner–Seitz cell of D_{3d} symmetry for the crystal. This cell is the smallest connected set of atomic basins which preserves the translational

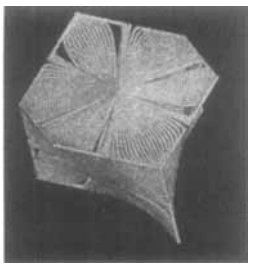

Fig. 4. A representation of a carbon atom of T_d symmetry in the diamond lattice. It is linked by bond paths to four other atoms, each bond path originating at the critical point defining the associated interatomic surface.

invariance of the lattice. The *single* atom depicted in Figure 4 determines all of the bulk properties of the lattice in terms of its quantum mechanical expectation values, including the scattering of X-rays and the appearance of the "forbidden" 222 reflection.

Any and all expectation values and their associated theorems are defined by Equation (b) for an atom, a linked grouping of atoms, or for the complete molecule or crystal. The above examples illustrate how the theory of atoms in molecules enables one to apply the theorems and principles governing the behavior of quantum mechanical observables to the functional groups of chemistry, and do so in precisely the same manner as is done for the total system. In what follows a survey of the form and properties of some atoms and common functional groups is presented to demonstrate how they recover and expand upon our understanding of this basic chemical concept.

7. Form and Properties of Functional Groups

The periodic variations in the form of the A and H atoms in the second-row hydrides AH_n are displayed in Figure 5 and selected properties are given in Table 1. The properties of the atoms in LiH, BeH_2, and BH_3 reflect the hydridic nature of these compounds. There is an abrupt change in the form of the H atom at methane, reflecting a change to a nonpolar interaction that is characterized by a nearly equal sharing of the valence charge density. The decreasing size of the H atom in NH_3, H_2O, and HF reflects the increasing polarity of the atomic interactions and the resultant acidity in these latter members. The atomic first moment $\boldsymbol{M}(\Omega)$ measures the dipolar polarization of an atomic density relative to its nucleus. The directions of $\boldsymbol{M}$(H) reflect the interatomic charge transfers, the H atoms being polarized towards the positively charged A atoms preceeding carbon and away from those bearing a negative charge following it. The atomic susceptibilities also parallel the characteristics of the atomic charge distributions. The currents localized in the basins of the A atoms in the hydridic molecules correspond to opposing paramagnetic and diamagnetic flows, as illustrated for LiH in the Figure 3a. The resulting cancellation leads to a small negative value of $\bar{\chi}$(A) for Li and positive or paramagnetic contributions for Be and B.

The boron and hydrogen atoms in B_2H_6, and the apical H-B| group in $B_6H_6^{2-}$ are displayed in Figure 6. The stability of these electron-deficient compounds is a consequence of the delocalization of electronic charge over the surfaces of the three- and four-membered rings of atoms.[56] A boron atom in B_2H_6 is a member of a single four-membered ring. The apical boron atom in B_5H_9 shares in four four-membered rings, possesses 0.90 more electrons on average, and is more stable by

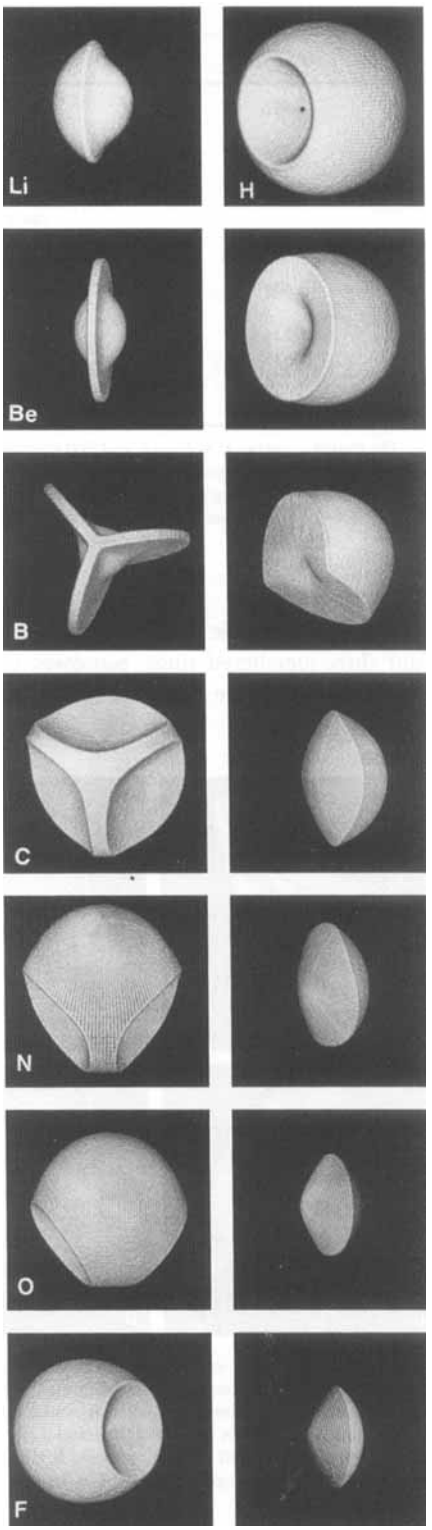

Fig. 5. Representations of the atoms in the second-row hydrides AH_n. In the hydridic members, LiH, BeH_2, and BH_3, the A atom consists primarily of a core of decreasing radius, dressed with some residual valence density. The form and properties of the atoms undergo a marked change at methane, a nonpolar molecule: no core is visible on the C atom, and the H atoms, considerably reduced in size and population, now lie on the convex side of the interatomic surface. The increasing polarity of the remaining members is reflected in the decreasing size of the H atom and the increasing convexity of its interatomic surface.

[a] The charge q, energy E, volume v, and first moment M are in atomic units (au), the magnetic susceptibility $\bar{\chi}$ is in 10^{-29} J (Tesla)$^{-2}$. [b] Volume is determined by the 0.001 au density envelope. The number in parentheses is the fraction of the atomic population contained within this envelope. [c] A negative sign denotes a polarization of the electron density of A along the principal symmetry axis in a direction away from the protons, a positive sign the reverse. [d] A negative sign denotes a polarization of the electron density of H towards A along the A–H bond direction, a positive sign the reverse.

1070 kJ mol^{-1}, while a boron atom in $B_6H_6^{2-}$ participates in four three-membered rings, possesses 1.66 more electrons on average, and is more stable by 1730 kJ mol^{-1}.

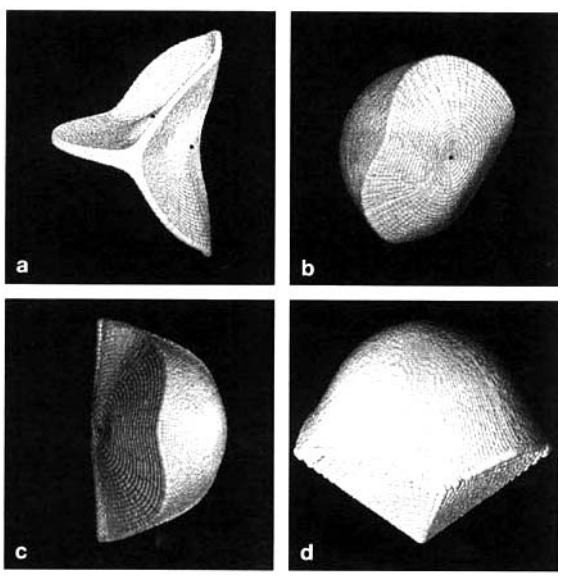

Fig. 6. a) The boron atom in diborane. The two terminal hydrogen atoms lie in the plane of the diagram and one such B|H interatomic surface is shown on the left. An interatomic surface for a bridging hydrogen, which will project out of the plane of the diagram, is also shown. b) and c) A terminal and a bridging hydrogen atom, respectively, in diborane. d) A H–B| group of $B_6H_6^{2-}$ showing two of its four B|B interatomic surfaces. A cage critical point is located at the apex where the four surfaces intersect.

The carbon and hydrogen atoms of ethane, benzene, ethene, and ethyne are displayed in Figure 7 and properties are given in Table 2. The value of ϱ at the C|C bond critical point, the quantity ϱ_b, increases throughout this series and yields bond orders of 1.0, 1.6, 2.0, and 3.0, respectively. The decreasing extent of charge transfer from C to H evidenced in the atomic charges q(H), reflects the increase in the electronegativity of the carbon atom with change in hybridization from sp^3 to sp. The sp^2 carbon atom in benzene is more stable than that in ethene.

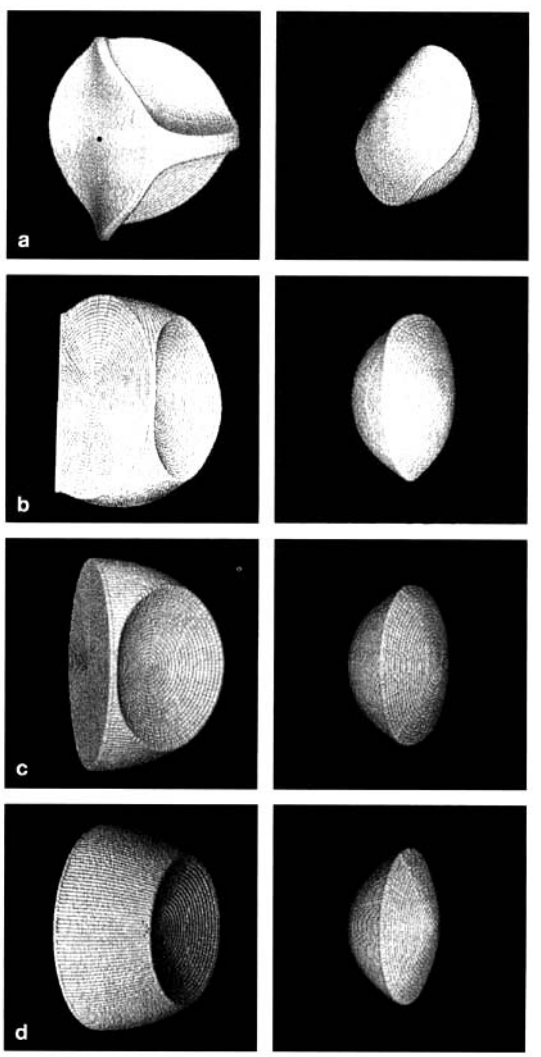

Fig. 7. The C and H atoms in ethane (a), benzene (b), ethene (c), and ethyne (d), respectively. The C|C surface in ethane is similar in shape to that found in methyl or methylene groups and diamond (Figs. 2a, 1a, b, 4). The C|C surfaces in the remaining molecules are planar as a consequence of symmetry. Note that the H atom is largest in ethane and smallest in ethyne.

Bridgehead carbon atoms in [1.1.1]bicyclopentane and [1.1.1]propellane are shown in Figure 8a and c. In addition to the C|H surface, the carbon atom in the bicyclic compound has

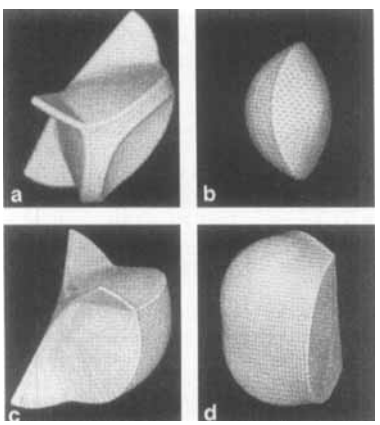

Fig. 8. a) A bridging C atom and b) its H atom in [1.1.1]bicyclopentane, c) a bridging C atom in [1.1.1]propellane, and d) a methylene group in cyclopropane. For details see text. The carbon atom in (a) is capped by electron density bound to a proton in the basin of a hydrogen atom (b). The carbon atom in (c) exhibits a bulge of nonbonded density, which the Laplacian of the charge density shows to be a nonbonded charge concentration, a site of electrophilic attack [5].

three C|C interatomic surfaces with the methylene carbon atoms. Their common point is a cage critical point where the electronic charge density attains a local minimum value of 0.098 au.[57] The carbon atom in the propellane molecule, in addition to three similar C|C surfaces with methylene carbon atoms, shares a fourth surface with the second brighehead carbon atom. This surface, the flat inner triangle bounded by three ring critical points, while of rather limited spatial extent, represents a significant accumulation of electronic charge. The value of ϱ at the ring critical points is only 0.004 au less than its value of 0.203 au at the central bond critical point, of bond order 0.7 (0.6 with a GVB wave function[57]), where ϱ attains its maximum value in the interatomic surface. The result is a *triangular* accumulation of electronic charge linking the bridgehead carbon atoms, in place of the usual *line* of maximum of charge density. Note the significant accumulation of electronic charge in the nonbonded region of the propellane carbon atom[57] whose presence accounts for its susceptibility to electrophilic attack.[58]

In Figure 8d a methylene group from cyclopropane is shown. It differs from the standard transferable methylene groups displayed in Figure 1 by having planar C|C interatomic surfaces. Subjecting the standard group to the geometrical constraints of a three-membered ring results in a strain-induced transfer of charge from H to C within the CH_2 group. This leads to an increase of 38.7 kJ mol^{-1} in its total energy relative to the standard group and to a total strain energy three times this, or 116.1 kJ mol^{-1},[48, 50] in agreement with the experimental value of 115.1 kJ mol^{-1}.[59] This is another example of an experimentally measured property being recovered in terms of a group defined as a quantum subsystem. Figure 9 gives representations of the carbon atom in the methyl cation, the methyl radical, and the methyl anion. Atomic properties are given in Table 2. The atomic forms provide a vivid display of the growth of the nonbonded charge on the carbon atom.

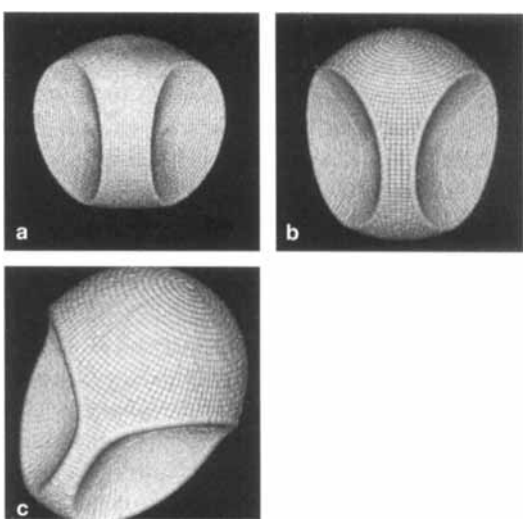

Fig. 9. The carbon atoms in the methyl cation (a), radical (b), and anion (c), respectively. A comparison of (a) with (c) adds to the understanding of the differing properties of cationic nd anionic carbon atoms.

8. Summary and Outlook

This article has presented the quantum mechanical definition of a subsystem and its properties made possible by Schwinger's reformulation of physics. It has shown that the properties of these subsystems meet the constraints imposed on the definition of atoms in molecules by the observations of chemistry. Their properties and physical forms are compatible with a chemist's expectations regarding the behavior of a functional group. In particular, the subsystem expectation values for the historically important additive and transferable properties of volume, energy, polarizability, and magnetic susceptibility, agree with the experimental values obtained for the homologous series of *n*-hydrocarbons. Agreement with experiment is the ultimate test of any theory.

It has been demonstrated that the classification and prediction of chemical behavior afforded by the concept of a functional group is contained within the quantum mechanical framework of observables and their equations of motion. This extension of the predictions of quantum mechanics to include the atoms that make up a total system increases the input of physics into chemistry and complements the information obtained from theories and models of electronic structure. The literature now contains many examples of how the properties of atoms in molecules can be used to increase our understanding of chemistry.

Perhaps because of its use of a new and unfamiliar principle of physics, there is a tendency to ignore the quantum basis of the theory as exemplified in reference [40], or to overlook this basis and instead refer to it as an "electron density analysis".[60] The theory is a generalization of quantum mechanics to a subsystem, enabling one to apply physics to the total molecule or to its constituent atoms on an equal footing. The electron density enters through the statement of the boundary condition,[61] a condition necessarily expressed in terms of the density if the theory is to apply to real physical systems. The boundary condition is identical to that used by Wigner and Seitz[62] in the definition of an atomic cell in their historic quantum investigation of the properties of metallic sodium within the one-electron model. The boundary condition is of profound physical importance. It not only defines atoms in molecules, but further study of the gradient vector field of the electron density leads to a complete theory of structure and structural stability.[5] The resulting unified theory of molecular structure is obtained because the definition of an atom given in Equation (a) is a consequence of the fundamental form exhibited by matter at the atomic level.

In outlook, one can anticipate an increase in the effectiveness of the functional group concept, through the replacement of the present qualitative and largely empirically derived knowledge of group properties by the predictions of quantum mechanics. Since theory predicts what can be observed, one should eventually be able to do everything with the functional groups of theory that one does with them in the laboratory, including their use[44, 45] as synthons.[63] It is perhaps our ability to design the synthesis of a desired molecule in terms of the successive linking of chemical transformations, each step depending upon the particular characteristics of a given functional group, that represents the crowning achievement of the functional group concept. The synthesis of a given molecule from a bank of theoretically defined groups will require further advances in subsystem quantum mechanics in the form of a variation or perturbation theory to predict the changes undergone by a group when it is placed in a new environment,[64] as required in the synthesis. It is to be hoped that the recognition of the theory of atoms in molecules as an extension of quantum mechanics to the atomic domain[65] will spur workers entering the field to further explore and develop subsystem quantum mechanics, enabling physics to be put to its fullest use in chemistry, in the design and synthesis of new molecules.

The authors wish to acknowledge helpful discussions with Dr. Richard G. A. Bone. One of us (R. F. W. B.) would like to thank Mr. G. Reading for restimulating his interest in Kuhn's thesis regarding the influence of existing paradigms on new developments in science.

[20] J. E. Lennard-Jones, *J. Chem. Phys.* **1952**, *20*, 1024–1029. Lennard-Jones pointed out that the degree to which electrons are localized in pairs is determined by the pair density. The physical localization determined in this manner demands a corresponding localization of the Fermi correlation hole, a condition which within the orbital model, requires that the orbitals be localized to separate regions of space [5]; R. F. W. Bader, M. E. Stephens, *J. Am. Chem. Soc.* **1975**, *97*, 7391–7399. This condition is, in general, not satisfied by localized valence moleular orbitals because they exhibit significant absolute overlap and such orbitals do not represent spatially localized pairs of electrons [5].

[34] a) To quote from Feynman [1]: "We shall see that it is the possibility of expressing S (the action) as a sum, and hence Φ (the probability amplitude for a single path) as a product of contributions from successive sections of the path, which leads to the possibility of defining a quantity having the properties of a wave function." b) To quote from Schwinger [2]: "Quantum mechanics involves two distinct sets of hypotheses – the general mathematical scheme of linear operators and state vectors with its associated probability interpretation and the commutation relations and equations of motion for specific dynamical systems. It is the latter aspect that we wish to develop, by substituting a single quantum dynamical principle for the conventional array of assumptions based on classical Hamiltonian dynamics and the correspondence principle." The fundamental dynamical principle is stated as a variational equation for the transformation function connecting eigenvectors associated with different spacelike surfaces, which describe the temporal development of the system.

In this review of the book listed in reference [5] the theory is referred to as "der Bader-Analyse der Elektronendichte". No mention is made of the theory being based upon a generalization of Schwinger's action principle to a subsystem, nor is any mention made of the development of the quantum mechanical description of atoms in molecules. The essence of the theory, as stated in the title of the book, is not discussed.

[61] Every variational result is obtained subject to boundary conditions. The derivation of Schrödinger's equation from the restricted variation of the action integral for the total system, requires the vanishing of $\boldsymbol{V}_i\psi \cdot \boldsymbol{n}\delta\psi$ on the infinite boundary of the system, as obtained by requiring that $\boldsymbol{V}_i\psi \cdot \boldsymbol{n} = 0$ for all particles. These terms are retained in Schwinger's generalization of the action principle, see Equations 2.17 and 2.19 of reference [2]. Their retention and combination with the terms derived from the boundary condition Equation (a), that $\boldsymbol{V}\varrho \cdot \boldsymbol{n}$ vanish on the surface of the atom, leads to the extension of the generalized action principle to an atom in a molecule. It is this marriage of surface terms which yields the fundamental relation between the variation in the energy or action, and the infinitesimal flux in the current density through the surface of the subsystem.

[62] E. Wigner, F. Seitz, *Phys. Rev.* **1933**, *43*, 804–810.

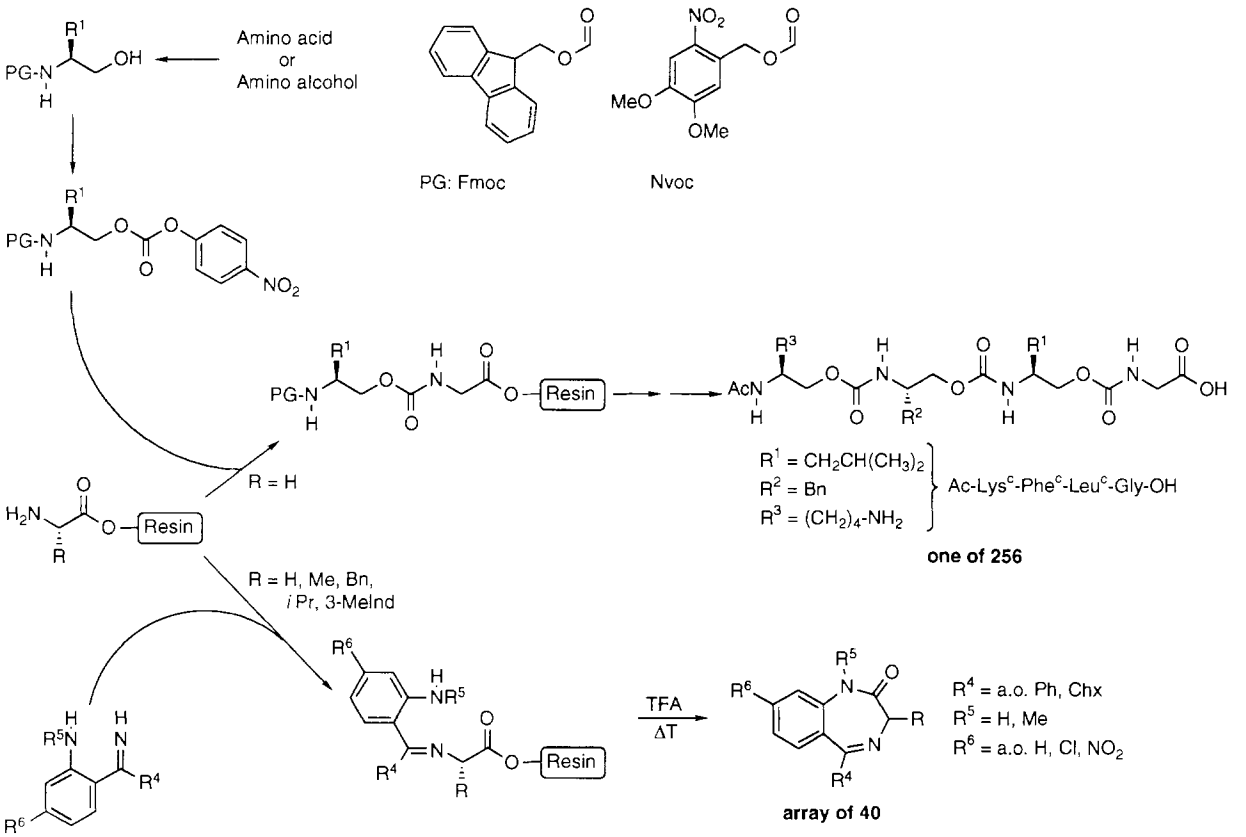
[65] An essential part of physics is the possibility it provides of proving a proposed theory or conjecture wrong. Either the generalization of the quantum action principle, subject to the boundary condition given in Equation (a) to yield Equation (b), the atomic generalization of Schwinger's variation principle, is correct, or it can be disproven.

Opportunities for New Chemical Libraries: Unnatural Biopolymers and Diversomers

Rob M. J. Liskamp*

The solid-phase methodology for the synthesis of biopolymers is nowadays indispensable in chemistry, pharmacology, immunology, physiology, biology, and biophysics. Using this fantastic tool,[1] it is not only possible to prepare (large) peptides in a (semi)automatic manner in which amino acids and other reagents are added, and excess of reagents and waste are removed (without the tedious purification of intermediates), but this methodology has also been successfully applied to the synthesis of nucleic acids and recently carbohydrates.[2, 3] Once developed the next logical step was the adaptation of the efficient solid-phase methodology to the *simultaneous* synthesis of *several* peptides. This led to the development of several multiple peptide synthesis strategies with a large range of applications.[4] A significant step further are the peptide libraries, for example, aimed at the systematic synthesis of many –if not all– possible peptides of a certain length. When each amino acid residue is one of the 20 proteinogenic L-amino acids, there are 400 possible dipeptides, 8000 possible tripeptides etc. in a library: with each amino acid increment the number of peptides increases 20-fold. However, there will be intrinsic difficulties in preparing and handling such large libraries,[4] in addition to difficulties in identification, selection, and enrichment of promising compounds from a library. In order to facilitate identification and enrichment, encoded libraries might be very interesting. In one particular promising type of these libraries a chemically synthesized entity, for example a peptide, is linked to a particular oligonucleotide sequence. It is proposed that the use of the encoding genetic tag should serve to identify and to enrich the promising compounds from the library.[5, 6] Peptide libraries are undeniably useful in the discovery of chemical lead compounds. However, the chemical lead discoveries from these libraries still require extensive modifications before suitable drug candidates are produced. This is due to the disadvantages of peptides, such as their water solubility and in many cases their facile degradation by proteases, which limit their use in biological systems. Therefore the results described by Cho et al. and Hobbs DeWitt et al. are the next significant steps on the way to new libraries,[7, 8] which first may—to a certain extent—circumvent these disadvantages, second provide lead compounds, possibly requiring less extensive modifications, and third may provide new frameworks for generating macromolecules with novel properties.



Cho et al. described the principles of the solid-phase synthesis of an oligocarbamate as well as the generation of an oligocarbamate library.[7] This oligocarbamate was referred to as "an unnatural biopolymer",[9] "unnatural" because it is obviously not found in nature and "biopolymer" to hint at the origin of the monomers which were derived from proteinogenic amino acids. The term "biopolymer mimetic" is perhaps a better alternative, as "unnatural biopolymer" is a contradiction in itself. The monomeric, *N*-protected aminoalkylcarbonates were conveniently prepared from the corresponding *N*-protected amino acids or from amino alcohols derived from amino acids (Scheme 1). By using the base-labile Fmoc-protecting group, an oligocarbamate was synthesized by standard solid-phase methods; the coupling yields were greater than 99% per step. Even more interesting was the use of the photolabile nitroveratryloxycarbonyl (Nvoc) amino-protecting group (Scheme 1). This enabled the authors to prepare a library containing 256 oligocarbamates, by employing a binary masking strategy as was described by Fodor et al. in their light-directed parallel synthesis of libraries of oligopeptides and oligonucleotides.[10] The library contains all of the compounds that can be formed by deleting one or more carbamate units from the parent sequence Ac-Tyr^c-Phe^c-Ala^c-Ser^c-Lys^c-Ile^c-Phe^c-Leu^c (the superscript "c" indicates the presence of a carbamate linkage). The library was attached to a glass surface of approximately 1.3 cm by 1.3 cm and screened for its ability to bind a monoclonal antibody against Ac-Tyr^c-Lys^c-Phe^c-Leu^c. It was found that the oligocarbamates Ac-Lys^c-Phe^c-Leu^c-Gly-OH (Gly is the linker in the keyhole limpet hemocyanin conjugate of this oligocarbamate), Ac-Phe^c-Lys^c-Phe^c-Leu^c-Gly-OH, Ac-Tyr^c-Lys^c-Phe^c-Leu^c-Gly-OH, Ac-Ala^c-Lys^c-Phe^c-Leu^c-Gly-OH, and Ac-Ile^c-Phe^c-Leu^c-Gly-OH were among the ten highest affinity ligands based on fluorescence intensities. Competitive enzyme-linked immunosorbent assay experiments in solution using the free oligocarbamates resulted in IC_{50} values between 60 and 180 nM. It was therefore suggested that the dominant epitope of the antibody was Phe^c-Leu^c. Although, Ac-Tyr^c-Phe^c-Leu^c-Gly-OH containing this epitope did bind in solution with an IC_{50} value of about 160 nM, the fluorescence signal associated with this oligocarbamate on the solid support, that is the glass surface in the library,

[*] Dr. R. M. J. Liskamp

ranked in the bottom 30%. This suggests that the conformation of the oligocarbamate on the solid support may be different from that in solution. This problem certainly has to be addressed in the future before a general application of the use of libraries can be recommended for affinity studies.[11]

compounds (comparable to an in-house sample collection of a pharmaceutical company), which can be offered to the often automated, fast high throughput biological screening assays.

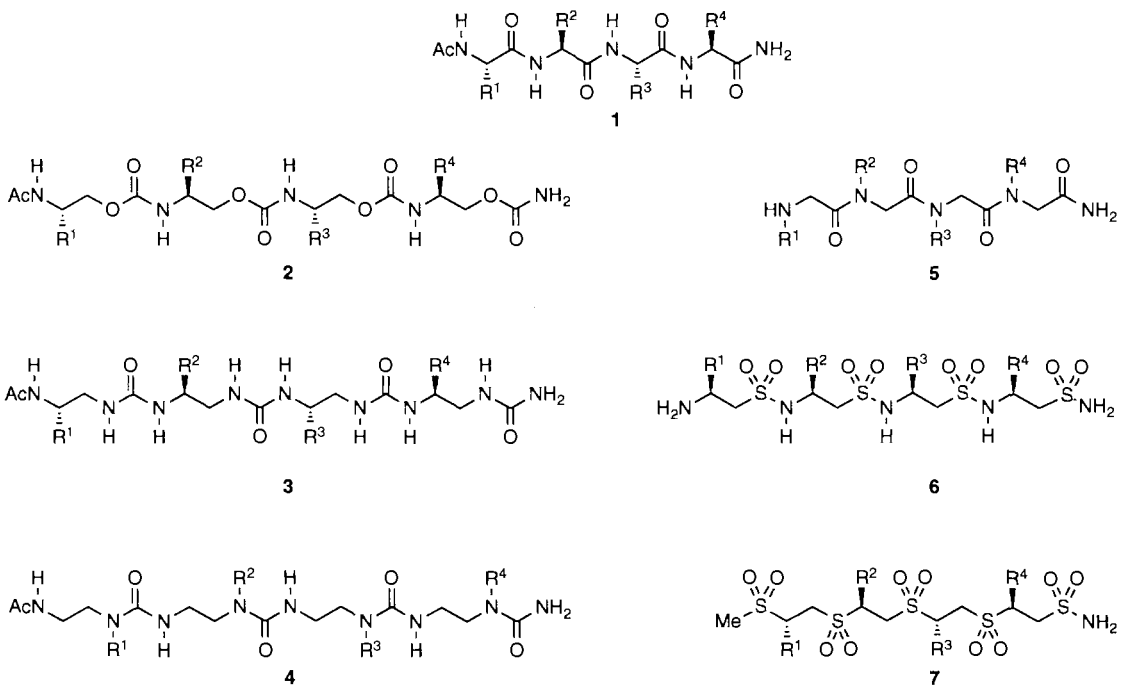
In contrast to the well-known procedure in which polyethylene rods or pins were used as a solid support for mul-

Scheme 1. Solid-phase synthesis of oligocarbamates and benzodiazepines starting with a resin-bound amino acid. The Fmoc-protected 4-nitrophenyl carbonate monomers derived from amino acids or amino alcohols were used in a normal solid-phase synthesis of an oligocarbamate, whereas the corresponding Nvoc-protected monomers were used in the generation of a library of 256 oligocarbamates of which one representative (Ac-Lysᶜ-Pheᶜ-Leuᶜ-Gly-OH) is shown. An array of 40 diazepines was synthesized by reacting the resin-bound amino acid with eight different 2-aminobenzophenone imines followed by cyclization. Ind = indolyl. Chx = cyclohexyl.

Although the oligocarbamate differs significantly from the corresponding polypeptide, for example, it is more extended (that is there are four atoms located between the side chains instead of two atoms as in a peptide), some inherent disadvantages of peptides seem to be less pronounced in oligocarbamates: a) the oligocarbamates are significantly more hydrophobic, as was determined from a comparison of the water/octanol partitioning coefficients; b) the oligocarbamates are resistant to degradation by trypsin and pepsin.

Contrary to the Berkeley and Affymax report, the diversomer paper by Hobbs De Witt et al. placed no emphasis on the preparation of an oligomer library but focussed entirely on the generation of a library of diverse, albeit related, organic compounds called "diversomers".[8] An important reason for the creation of these libraries is to discover lead compounds, which will be structurally more related to the ultimate drug, since lead compounds discovered from peptide or nucleotide libraries still require extensive modifications (vide supra). Another equally important reason is to rapidly obtain a large library of organic

tiple peptide synthesis in the "PEPSCAN" method,[4, 12] hollow pins, ending in a glass frit were used, each containing approximately 100 mg resin to which a Fmoc amino acid was attached by a linker. The removal of the Fmoc-group from eight amino acid resins and treatment of each resin with five different isocyanates followed by cyclization led to 39 of the 40 desired hydantoins in 4–81% yield. Similarly, by starting from Boc-protected amino acid Merrifield resins (five), 40 different benzodiazepines were synthesized by reacting with eight different 2-aminobenzophenone imines followed by cyclization (Scheme 1). The 40 products were obtained in 9–63% yield and their purity was typically >90% (determined by ^{1}H NMR spectroscopy). These compounds were then used in an assay for inhibition of fluoronitrazepam. A report by Bunin and Ellman had earlier described the solid-phase synthesis of ten benzodiazepine derivatives using an alternative approach.[13]



An important message from the reports is that the authors are able by carrying out synthesis on a solid support—to prepare an array of unnatural compounds, which can be used for screen-

ing purposes to discover new lead compounds. These lead compounds may then be closer to ultimate drugs, because they are obtained from an array of compounds further removed from natural systems such as peptides and nucleotides.

Using the solid-phase strategy also libraries of other biopolymer mimetics may become accessible, for example, oligoureas, oligosulfones, peptidosulfonamides,[14] peptidophosphoramidates, and peptoids (Scheme 2).[15] These compounds will undoubtedly provide new biologically active compounds and also opportunities for the construction of biopolymers with novel properties.

tance of creating library compounds with defined conformations that are similar if not identical in different environments.

The scientist has an innate desire to be able to *rationally* design a compound with a predicted (biological) activity. Computer-assisted molecular modeling techniques, X-ray crystallographic analysis, and NMR methods have intensified this desire and the belief that this should ultimately be possible for all drugs. Nevertheless, many of the current drugs or at least the lead compounds which initiated their development have been obtained by screening approaches, that is, by an "*irrational*" approach. Although it is expected that the rational design of

Scheme 2. A peptide (**1**), the corresponding oligocarbamate (**2**), oligoureas (**3** and **4**), peptoid (**5**), peptidosulfonamide (**6**), and oligosulfone (**7**).

The diversomer library shows that an array of organic compounds can be synthesized, and, although the number is much smaller than that which can be achieved by most of the current methods for generating peptide libraries, a significant number of structural analogues can be obtained in a faster way than is the case when each of the compounds is synthesized separately. Furthermore, it should be possible to adapt the method to many more organic reactions, so that it is likely that a number of diversomer libraries will be appear in the near future.

Another challenge is the development of "conformationally restricted" libraries in which the conformation of an oligomer is more accurately defined, for example, by introducing rigid monomers at different locations in an oligomer. This is noteworthy, since there is ample evidence in the literature that in many cases merely the presence of functional groups delivered, for example, by an amino acid sequence is not sufficient for an optimal biological activity, but that a proper orientation of functional groups is essential too.[16] In addition, the conformation on the solid support of the library may be different from that in solution (vide supra), which may diminish the reliability of a library for the selection process. This underlines the importance of drugs will become increasingly important, screening approaches will gain more momentum too, since they will contribute to a faster and more direct access to information. Therefore the rational design of irrational screening procedures holds promises for the future, and as a result there will be plenty of opportunities for the creation and applications of new libraries.[17]

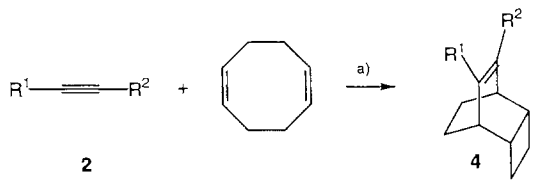
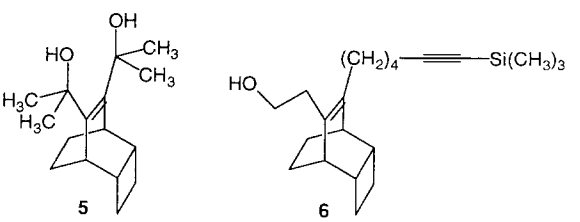
Construction of Carbon Frameworks with the Help of Ruthenium Complexes: 1,5-Cyclooctadiene as a Reagent in Transition Metal Catalyzed Reactions



Holger Butenschön*

A communication by B. M. Trost et al.[1] which appeared last year is one of several important papers that have been published recently from the rapidly developing area of ruthenium–organic chemistry. 1,5-Cyclooctadiene (COD) is frequently used in transition metal complexes as a bidentate, neutral ligand, which can be removed again often under mild conditions with the formation of free coordination sites. The perfect example of this is bis(1,5-cyclooctadiene)nickel(0) as a precursor of "naked nickel", with which G. Wilke et al. carried out a large number of important reactions and thus emphasized the special value of organometallic chemistry for the synthesis of organic compounds at a very early stage.[2] It is noteworthy that there have been very few reports on the reactions of COD at the metal center despite its frequent use as a ligand. One such example is the formation of the bicyclo[3.3.0]octadienylcobalt complex **1** from the reaction of cobalt reagents with COD, as reported by Lehmkuhl et al. as well as Otsuka et al.[3–5]

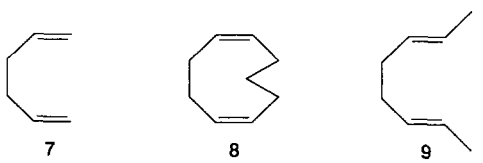


1

The relatively narrow spectrum of the organic chemistry of COD has been considerably extended by B. M. Trost et al.[1] who discovered that COD can formally function as a bis-homodiene in metal-catalyzed [4 + 2]cycloadditions. A 0.1 M solution of the alkyne **2** reacts with 1.1 equivalents of COD in the presence of 5 mol% chloro(η^4-cyclooctadiene)(η^5-cyclopentadienyl)ruthenium(II) [CpRu(COD)Cl] (**3**)[6] in boiling methanol to give derivatives **4** of tricyclo[4.2.2.$0^{2,5}$]dec-7-ene (Scheme 1). Yields of between 78 and 100% are achieved in seven out of eight examples, in the other case the yield is only 22% (however, as the authors note, this is in fact "65% yield brsm", where brsm stands for "based on recovered starting material"). Electron-deficient alkynes react particularly slowly and no reaction takes place with dimethyl butynedioate. Steric hindrance slows down the reaction; **5** is obtained only in 51% (98% brsm) after 80 h at reflux. This can, however, be used for the differentiation of triple bonds in alkynes with several triple bonds, as shown by the selective formation of **6** in 63% (72% brsm, Scheme 2).

2 **4**

Scheme 1. a) 5% [CpRu(COD)Cl] (**3**), MeOH; R^1 = Me, Et, $CH_2OSi(iPr)_3$, *p*-$CH_2C_6H_4OCH_3$, H; R^2 = CH_2OH, $CH_2OSi(iPr)_3$, CH_2CH_2OH, *p*-$CH_2C_6H_4OCH_3$, CO_2Me, $CH_2CH_2CH_2CO_2Me$; 78–100% (see text).



5 **6**

The catalytic cycle proposed by the authors starts from a cationic cyclopentadienylruthenium complex, bearing one COD ligand and one solvent molecule. The latter is displaced by the alkyne, which subsequently reacts with a double bond of the COD ligand to give a metallacyclopentene. An intramolecular carbometalation of the remaining double bond of the eight-membered ring with successive reductive elimination leads to the elimination of the products **4**; renewed complexation of a COD molecule regenerates the catalytically active species. The authors point out that the reaction is also catalyzed by other coordinatively highly unsaturated ruthenium complexes and fi-

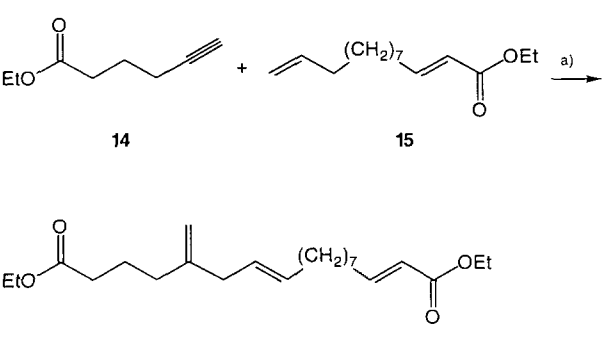
nally make the important remark that the ease of the reactions observed by them suggests that a range of other ruthenium-catalyzed reactions of COD may well be possible. They assume that the coordination properties of COD cannot only be derived from the entropic effect of the spatial arrangement of the two double bonds in COD. Possibly electronic effects similar to those in norbornadiene exist in an attenuated form in COD. This is in agreement with the fact that the dienes **7**–**9** do not undergo the reaction found with COD.[7]

7 **8** **9**

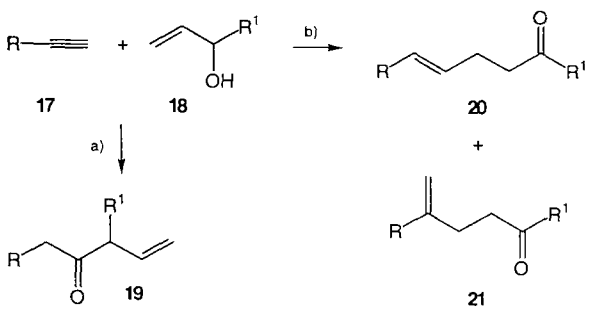


The ruthenium catalyst **3** was recently used by B. M. Trost et al. also for coupling reactions of alkenes **10** with alkynes **11**.[8] These reactions lead to the branched coupling products **12** as well as the linear isomers **13** (Scheme 2). The yields lie between

10 **11** **12** **13**

Scheme 2. a) 5% **3**, dimethylformamide (DMF)/H_2O 3:1, 100 °C, 2 h; R = Bu, CH_2CH_2OH, COMe, $(CH_2)_3CO_2Me$; R′ = Pr, $CH_2OTBDMS$, CO_2Et; 60–90%.

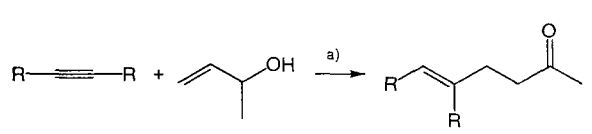
60 and 90%, and in most cases the branched isomer **12** is formed preferentially (**12**:**13** up to 6:1). Substituents at the propargyl position of **11** reduce the regioselectivity, and the presence of propargylic oxygen substituents even leads to an inversion of the selectivity in favor of the linear coupling products. The chemoselectivity of the reaction is impressively underlined by the reaction of **14** with the $\alpha\beta$-unsaturated ester **15** to give exclusively **16** in 70% yield (Scheme 3).



14 **15** **16**

Scheme 3. a) 5% **3**, DMF/H_2O 3:1, 100 °C, 2 h, 70%.

Also in these reactions the authors assume that a cationic cyclopentadienylruthenium complex is the catalytically active species, the only difference here being that in addition to the chloro ligand also the COD ligand is decomplexed and all three free coordination sites are filled by readily displaceable solvent molecules. After the complexation of the alkene component, the latter is transformed into an allyl ligand and the hydrogen atom released is bound to the metal as a hydrido ligand. After coordination, the alkyne is either intramolecularly hydrometalated or carbometalated starting from the allyl ligand. From both intermediates the reaction product, still coordinated to ruthenium, can be easily formed, which is then released with the regeneration of the above-mentioned catalytically active species.

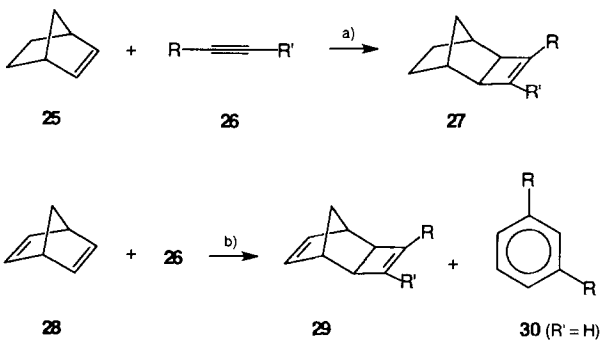


Several years ago B. M. Trost et al.[9] reported on the coupling of terminal alkynes **17** with allyl alcohols **18** in the presence of NH_4PF_6. This reaction is catalyzed by $[(PPh_3)_2CpRuCl]$ and leads to the formation of $\beta\gamma$-unsaturated ketones **19** (Scheme 4). A mechanistic study reveals that vinylidene complexes are formed as intermediates from the terminal alkynes.[10] Also allyl alcohols can be isomerized with $[(PPh_3)_2CpRuCl]$ directly to give saturated ketones.[11] Interestingly, compound **3**, which is different from $[(PPh_3)_2CpRuCl]$ only in that instead of the two phosphane ligands a COD ligand is present, catalyzes the coupling of alkynes **17** and allyl alcohols **18** in 51–85% yields to give $\gamma\delta$-unsaturated ketones **20** and **21** (Scheme 4).[12]

17 **18** **19** **20** **21**

Scheme 4. a) 6% $[(PPh_3)_2CpRuCl]$, 10% NH_4PF_6, 100 °C, 10 h, 44–74%; b) 10% **3**, 10–20%, NH_4PF_6, 100 °C, 1–2 h; R = $C_{10}H_{21}$, C_6H_{13}, $CH(OH)C_5H_{11}$, $C(C_2H_5)(OH)C_5H_{11}$; R^1 = Me, *i*Pr, cyclohexyl, $C_{11}H_{23}$; 51–85%.

From the fact that in the reaction catalyzed by **3** also internal alkynes **22** can react to give ketones **23** (Scheme 5), the authors conclude that in this case no vinylidene complex acts as an intermediate. Apparently, its formation is favored by the presence of phosphane ligands, and in their absence other reaction paths are followed. The regioselectivity of the reaction as well as its yield can be increased if a mixture of water and DMF is used as solvent. The reaction functions also with alkynes whose triple bond is conjugated to an ester group. The chemoselectivity of the reaction was demonstrated by the coupling of a steroid side



22 **18** ($R^1 = CH_3$) **23**

Scheme 5. a) 10% **3**, 10–20% NH_4PF_6, 100 °C, 1–2 h, R = Bu (45%), Ph (50%).

chain with an allyl alcohol; one $\alpha\beta$-unsaturated carbonyl functionality present in the steroid part remained unaltered.

The significance of ruthenium-catalyzed reactions is also emphasized by a very recent publication by T. Mitsudo et al.,[13] who achieved [2 + 2]cycloadditions of norbornene **25** and norbornadiene **28** with a range of alkynes **26**. These reactions are catalyzed by chloro(η^4-cyclooctadiene)(η^5-pentamethylcyclopentadienyl)ruthenium(II) [Cp*Ru(COD)Cl] (**24**)[14] and give **27** and **29**, respectively in good yields (Scheme 6). Ru-catalyzed

Scheme 6. a) 5% [Cp*Ru(COD)Cl] **24**, 80 °C, 15–20 h, NEt_3, R, R′ = Me, Et, Ph, C_5H_{11}, $CH(OEt)_2$, CO_2Me, CO_2Et, 40–88%; b) 5% **24**, 100 °C, 24–120 h, R, R′ = H, Me, Ph, CO_2Me, CO_2Et, C_8H_{17}, $C_{10}H_{21}$, 23–87% **29**, 12–26% **30** (R′ = H).

[2 + 2]cycloadditions of norbornene with butynedioates have been known for a long time.[15, 16] However, what is new is that the reaction, which was successful with other ruthenium catalysts only with butynedioates, now functions with a whole series of different alkynes, and that not only norbornene **25**, but also norbornadiene **28** can be used. In this way in the course of the reaction [Cp*RuCl(nbd)] (nbd = norbornadiene) is formed, which is more stable than **3**. Thus, slightly higher reaction temperatures are required for reactions with norbornadiene. In addition to the adducts **29** to norbornadiene, *meta*-disubstituted arenes **30** are also formed. The use of phenylethyne which is deuterated at the terminal alkyne position reveals that the additional C_2 building block present in **30** stems from norbornadiene. In agreement with a retro-Diels–Alder reaction, di(cyclopentadiene) was detected in the reaction mixtures.

As a possible mechanism for the reaction the authors propose that **24** releases the COD ligand with the formation of the catalytically active species and the two free coordination sites are then filled by norbornadiene and the alkyne. From this a metallacyclopentene is formed, which either reacts by reductive elimination to give the [2 + 2]cycloadduct or by insertion of a further alkyne molecule forms a metallacycloheptadiene. The latter then releases cyclopentadiene in a retro-Diels–Alder reaction and is thus transformed into the metallacycloheptatriene, the direct precursor of **30**.

Interestingly, the only difference between the catalysts used by B. M. Trost et al. (**3**) and T. Mitsudo et al. (**24**) is that an unsubstituted cyclopentadienyl ligand is present in **3** and a pentamethylcyclopentadienyl ligand in **24**. The electronic and steric differences of the two ligands are well known; in light of the papers presented here the question arises as to how the spectrum of ruthenium-catalyzed reactions may be extended by the use of a new ligand recently described by P. Gassman et al.;[17] the title of the work read as follows: "1,2,3,4-Tetramethyl-5-(trifluoromethyl)cyclopentadienide: A Unique Ligand with the Steric Properties of Pentamethylcyclopentadienide and the Electronic Properties of Cyclopentadienide".

That the Cp*Ru fragment can also be used to break down carbon frameworks was shown at the beginning of 1993 by B. Chaudret et al.[18], who, using an example from steroid chemistry, achieved the elimination of methane from a methyl-substituted cyclohexadiene with consequent aromatization.

A Novel Open-Framework Cobalt Phosphate Containing a Tetrahedrally Coordinated Cobalt(II) Center: $CoPO_4 \cdot 0.5\ C_2H_{10}N_2$ **

Jiesheng Chen, Richard H. Jones, Srinivasan Natarajan, Michael B. Hursthouse, and John Meurig Thomas*

The ever-growing family of microporous aluminophosphates, first synthesized in 1982,[1] continues to stimulate synthesis of other novel compounds with open-framework structures comparable to the naturally occurring zeolites. Among the so-called ALPO family ($AlPO_4$-*n*, where *n* signifies a distinct framework structure) some members have structures exactly analogous to those of zeolites (for example, $AlPO_4$-17 has the erionite structure[2] and $AlPO_4$-20 is isostructural with sodalite[1]), whereas others (such as VPI-5[3] and JDF-20[4]) have no naturally occurring counterparts. Notable examples of newly synthesized open-framework structures containing elements other than Si and Al are the gallophosphate cloverite, which has 20-membered rings as openings,[5] and $Zn_7[P_{12}N_{24}]Cl_2$ (which consists of sodalite units constructed with P–N linkages),[6] germanium dioxides,[7] and several beryllium and zinc phosphates.[8–11] The formation of open-framework structures with transition metal phosphates was first demonstrated for iron.[12] Recent work by Haushalter and co-workers has opened up a rich chemistry with molybdenum compounds.[13–15] It has also proved possible to introduce relatively low concentrations of transition metals into various members of the $AlPO_4$-*n* family,[16, 17] and there are structures in which the transition metal is found in a quite high concentration.[18] To our knowledge, however, there are no reported examples of an open framework constructed from transition metal phosphate in which the transition metal is exclusively in a tetrahedral environment and is present in a metal/P ratio of unity. Here we report the first framework structure based on cobalt, phosphorus, and oxygen only, which is, additionally, the first cobalt phosphate of any type that has the metal exclusively in a tetrahedral environment. The compound is designated DAF-2 (Davy Faraday number 2; DAF-1 is a magnesium aluminum phosphate[19] with a framework composition of $Mg_{0.22}Al_{0.78}PO_4$).

The deep blue DAF-2 crystallizes in the monoclinic space group *I*2/*b* (nonstandard setting) with $a = 14.719(6)$, $b = 14.734(5)$, $c = 17.891(6)$ Å, $\gamma = 90.02(2)°$. The structure is based on a network of strictly alternating CoO_4 and PO_4 tetrahedra in which all the vertices are shared (Fig. 1). It thus differs markedly from other transition metal phosphates or arsenates with an open-framework structure[12–15, 20] where there is octahedral coordination of the metal. DAF-2 is similar to microporous phosphates with other divalent nontransition metals, such as beryllium, and zinc.[8–11] The formula of the anionic structure is $[CoO_2PO_2]^-$, and its stoichiometry is similar to that found in the zinc and beryllophosphates. This composition results in the same anionic charge as found for Lowenstein-limited zeolites with an Al:Si ratio of 1:1, $[AlO_2SiO_2]^-$.[11] The charge neutrality for DAF-2 is achieved by incorporation of the template in its protonated form: there are 0.5 $[H_2en]^{2+}$ ions per framework formula unit (en = ethylenediamine).

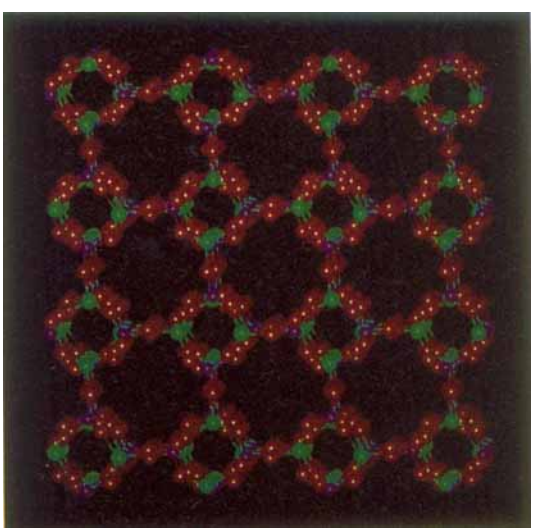

Fig. 1. The framework structure of DAF-2 viewed along the [001] axis. Red: oxygen; green: cobalt; violet: phosphorus. For clarity, the template molecules occluded in the framework channels are omitted. The channel window contains eight T atoms (T = Co and P) which are strictly alternated.

The framework structure consists of three systems of channels with windows containing eight T-atoms (T = Co and P) parallel to each of the crystallographic axes. The channels which are in the [001] direction have fairly regular windows with O–O distances which lie between 3.9 and 4.7 Å. The structure is pseudotetragonal; the channels in the [100] and [010] directions have similar characteristics (Fig. 2). The windows of these latter channels which do not intersect with each other, are irregular in shape with O–O contacts which vary between 1.9 and 4.8 Å. These channels do, however, intersect with those parallel to [001] giving rise to a three-dimensional open network, at the junctions of which the diprotonated ethylenediamine cations are preferentially accommodated. The organic cations are hydrogen-bonded to the oxygen atoms of the framework. The structure can be related to a previously predicted 4.8.8 net[21] in the (001) plane. These net layers are linked through the four-mem-

bered rings arranged in an "untwisted" manner with respect to the layer below. Structures based upon the idealised 4.8.8 net have also been found for both naturally occurring and synthetic compounds[11, 22–24]

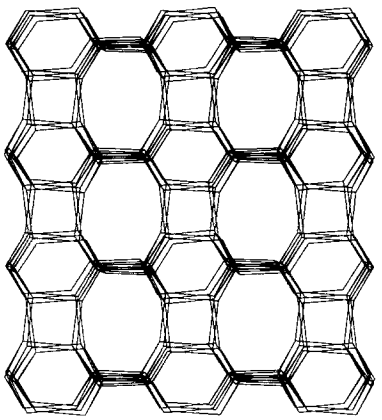

Fig. 2. The framework structure of DAF-2 depicting only (Co P) atoms viewed along either the [100] or the [010] direction.

In previously synthesized cobalt phosphates, the Co^{II} centers were coordinated to five or six oxygen atoms.[25, 26] And although it is possible to introduce Co^{II} into three-dimensional open-framework structures where the Co atom resides in a tetrahedral environment,[16–18] in none of these compounds does the Co/P ratio approach unity. Thus DAF-2 is the first cobalt(II) phosphate in which Co is found exclusively in a tetrahedral site and there is a Co/P ratio of unity. The Co–O distances vary from 1.906 to 1.992 Å, and the average (1.95 Å) is in good agreement with those for Co tetrahedrally coordinated to four oxygen atoms, for example, 1.947 Å in Co_3O_4.[27] The P–O distances are within the range 1.480–1.576 Å, and the average (1.53 Å) is quite similar to that seen in cobalt phosphates (for example, 1.538 Å in $Co_3(PO_4)_2$) and comparable to that in berlinite (1.516 Å), which is the aluminum phosphate analogue of quartz.[28]

Differential thermal analysis and thermal gravimetric analysis shows that the template ethylenediamine occluded in DAF-2 structure decomposes endothermically at 400–500 °C, which gives rise to a marked weight loss. At 600–700 °C, the compound undergoes recrystallization, as indicated by an intense exothermic effect without significant weight loss. After the template decomposes, DAF-2 becomes X-ray amorphous; thus, as expected, the thermal stability of DAF-2 is inferior to that of most members of the $AlPO_4$-*n* family and the newly synthesized magnesium aluminum phosphate[19] DAF-1. When held for prolonged periods at the recrystallization temperature, DAF-2 converts via an amorphous phase into a crystalline phase of composition $Co_2P_2O_7$ and known structure.[29]

Whilst it has not yet proved possible to remove the template of this solid thermally to obtain a microporous material, we are currently investigating chemical routes to achieve this goal, which would open up many intriguing possibilities in materials chemistry. Preliminary magnetic measurements with a SQUID magnetometer under an applied field of 100 G, down to 1 K, reveal that the solid exhibits classic Curie–Weiss paramagnetism down to about 5 K. At 2 K, the solid orders antiferromagnetically.

Experimental procedure

DAF-2 was synthesized hydrothermally from a cobalt phosphate gel containing ethylenediamine as a structure-directing template. Thus, cobalt carbonate hydrate, phosphoric acid (85%), ethylenediamine (en), and water in the ratio $CoO:0.9P_2O_5:1.0en:1.0H_2CO_3:25H_2O$ were mixed and stirred until homogeneous. The mixture was sealed in a PTFE-lined stainless steel autoclave and heated at 190 °C for 3 days. Pure deep blue crystals suitable for X-ray analysis were recovered by filtering off the solid products. The blue colour is indicative of the presence of tetrahedrally coordinated cobalt(II) centers. Chemical analysis yields an empirical formula of $CoHPO_4 \cdot 0.5en$ for the compound. Single crystal diffraction data were collected with an Enraf-Nonius FAST diffractometer with Mo(Kα) radiation ($\lambda = 0.71069$ Å). A total of 15310 reflections were collected of which 8992 satisfied the criterion for measurement. These were merged to give 4960 unique data of which 1730 were considered to be observed with $I > 3\sigma(I)$. The structure was refined by full-matrix least squares to $R = 0.073$ and $R_w = 0.057$ with a total of 170 parameters. During the final stages of refinement a total of 8 reflections with $F_o \ll F_c$ were omitted. A nonstandard setting of *I*2/*b* was chosen because of the pseudotetragonal nature of the structure. Whilst the structure can be refined in space group $I4_1/a$, the *R* values at all corresponding stages of the refinement were much higher, and the model required a disordered arrangement of the template molecule. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ on quoting the full literature citation.

Ionization and Delocalization in Potassium Zeolite L: A Combined Neutron Diffraction and Electron Spin Resonance Study**

Paul A. Anderson,* A. Robert Armstrong, and Peter P. Edwards*

On account of their regular intracrystalline channels and cavities, and consequent large internal surface area, zeolites – powerful catalysts in their own right – have found increasing use as supports for dispersed metal catalysts.[1] Since alkali metals are paramagnetic in states of aggregation ranging from the free atom to bulk metal itself, electron spin resonance (ESR) spectroscopy is particularly suited to the study of dispersions of these metals in zeolites.[2–5] Although single-line ESR spectra for such materials have been widely attributed to the presence of metal clusters or particles within the zeolite pores,[2–4] some recent work has questioned this interpretation.[5,6] Here we present the results of the first combined structural and spectroscopic study of an alkali metal dispersed in a zeolite support. The interaction of potassium vapor with zeolite L leads to spontaneous ionization of the guest metal atoms and delocalization of the resulting electrons among the potassium cations that line the one-dimensional channels of the zeolite host.

The pale blue solid K_1/K_9-L was prepared through the controlled reaction of dehydrated potassium LTL (K_9-L) with a calibrated amount of potassium vapor equivalent to one potassium atom per unit cell. Rietveld refinement of neutron diffraction data from unloaded K_9-L and from K_1/K_9-L converged to yield the final parameters given in Tables 1 and 2, respectively; calculated diffractograms and the corresponding difference profiles of both materials are shown in Figure 1. In both dehydrated K_9-L and K_1/K_9-L potassium was located in only three sites, K(2), K(3), and K(4), which correspond to cation positions B, C, and D, respectively[7] (Fig. 2). The conversion of K_9-L to K_1/K_9-L through the inclusion of potassium metal resulted in a small decrease in both lattice parameters a and c, but the most significant structural change was an increase in the partial occupancy of the K(4) site in the large channels from 0.72(7) to 0.92(6), which accounts neatly for the extra potassium atom incorporated from the vapor phase.

Table 1. Structural parameters for K_9-L (space group $P6/mmm$, $a = 18.483(1)$, $c = 7.4938(4)$ Å).

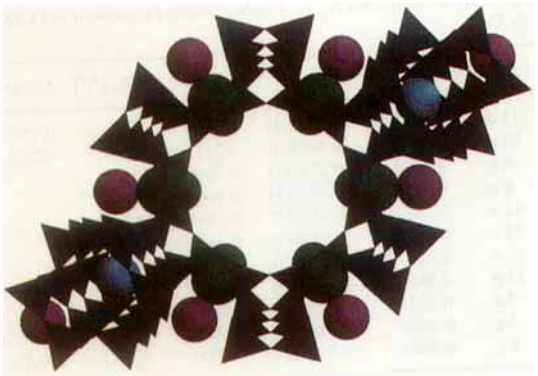

Fig. 2. The structure of zeolite L viewed along the c axis, showing the three potassium sites K(2), K(3), and K(4) in pale blue, purple, and green, respectively.

Observation of the included potassium in K_1/K_9-L in a conventional ionic site on the zeolite framework is convincing proof that ionization of the incoming potassium atoms has occurred. Presumably in return for a framework coordination site, the guest atoms give up their valence electrons, which then interact with the framework cations. This process has been proposed in other sodium and potassium zeolites, where it leads to the creation of paramagnetic centers of the form $(M^+)_n e^-$ consisting of an electron delocalized over a well-defined number of cations.[2, 8, 9] In the case of K_1/K_9-L, however, ESR measurements were unable to detect centers of this kind. Moreover, although the ESR spectrum of K_1/K_9-L (Fig. 3) was consistent ($g = 1.9995 \pm 0.0003$, $\Delta H_{pp} = 2.65 \pm 0.05$ mT) with those of metallic clusters or small particles of potassium located within zeolite pores,[2, 4] the diffraction data provided no evidence for clustering or particle formation.

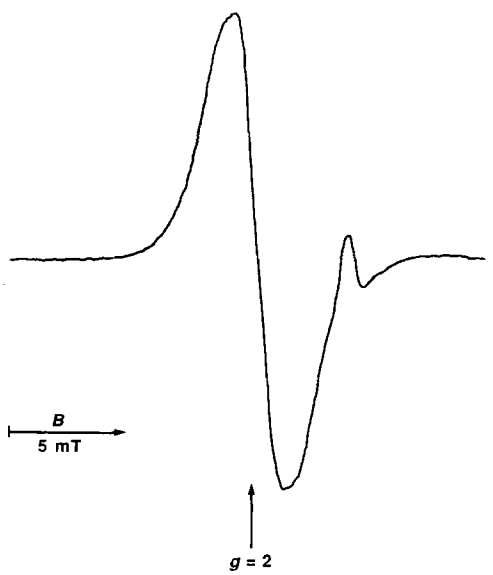

Fig. 3. The ESR spectrum of K_1/K_9-L at 77 K.

Using linewidth and hyperfine splitting parameters measured from the K_4^{3+} center ($n = 4$),[2] we have simulated (see Fig. 4) ESR spectra for a zeolite in which an electron interacts with different numbers of potassium ions. We conclude that the observed spectrum results from electron spins delocalized over a sufficiently large number of cations such that individual hyperfine splittings cannot be resolved. In such cases Anderson et al.[5] showed how the number of ions involved may be estimated from the observed ESR linewidth; a figure of $n \approx 30$–40 is estimated for K_1/K_9-L. In this case the ESR spectrum also exhibits a secondary feature at high field ($g = 1.9739 \pm 0.0005$), which is probably indicative of anisotropy in the sample (Fig. 3). Although this phenomenon has not to our knowledge been observed before in alkali metal zeolites, it is consistent with the one-dimensional channel structure of zeolite L (Fig. 2). As diffraction data clearly locates the included potassium ions in the large channels of zeolite L, for reasons of charge balance it is likely that released valence electrons interact primarily with the potassium cations at K(4) positions there. In order to interact

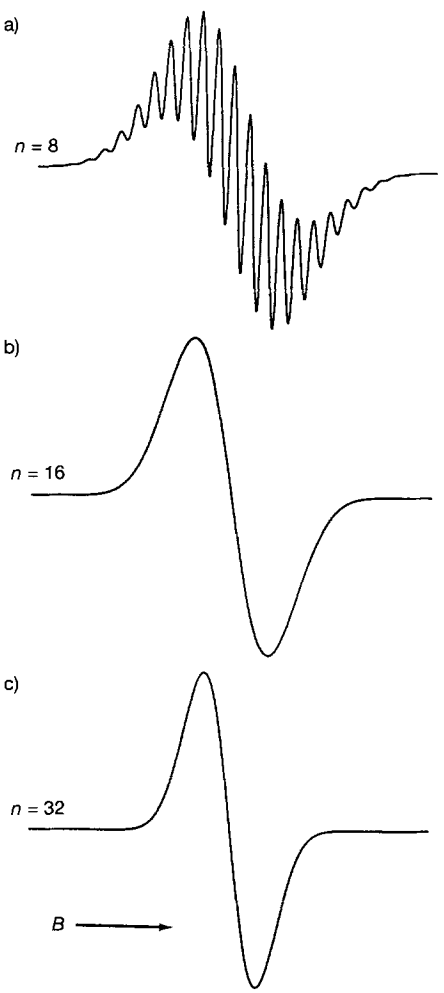

Fig. 4. Simulated ESR spectra ($\Delta H_{pp} = 0.8$ mT, $a = 1.71 \times 4/n$ mT) for $(K^+)_n e^-$. a) $n = 8$, b) $n = 16$, and c) $n = 32$.

with 30–40 such cations, each electron if confined to a single channel would have to be effectively delocalized over a distance of 6–8 unit cells or 4.5–6.0 nm. Through careful fine-tuning of the concentration of electrons in the one-dimensional channels of zeolite L it may be possible to engineer charge transport along the channels and produce a unique compound comprising a

precise array of ultrafine, atomic-scale conducting wires embedded in the aluminosilicate zeolite framework.

Experimental Procedure

The compound K_1/K_9-L was prepared through the controlled reaction (in sealed quartz reaction tubes) of dehydrated potassium zeolite LTL (K_9-L) (supplied by Laporte) with an amount of potassium vapor equivalent to one potassium atom per zeolite unit cell; the general procedure has been described in detail elsewhere [5]. The ESR spectrum of the resultant pale blue powder was recorded on a Varian E-109 spectrometer operating at X-band frequencies (9.3 GHz) witb 100 kHz field modulation. The microwave frequency was measured with a Hewlett-Packard 5342A frequency counter to an accuracy of ± 1 kHz, and g-values were determined through comparison of the resonant field with that of the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical ($g = 2.0036$).

Neutron diffraction measurements were performed at room temperature on the POLARIS diffractometer at the ISIS pulsed source of the Rutherford Appleton Laboratory. Since the alkali metal loaded zeolites exhibit great air sensitivity, and dehydrated zeolites readily absorb water, the materials were studied in their original quartz reaction vessels. In order to eliminate the background signals of amorphous silicon dioxide, data were also collected from an empty sample tube. These data were then smoothed, appropriately scaled, and subtracted from the zeolite diffraction patterns to produce an essentially flat background. Rietveld refinement of the structure used the least squares program TF14LS based on the Cambridge Crystallographic Subroutine Library [10]. Scattering lengths for K, Si, Al, and O were taken to be 0.367, 0.41534, 0.3449, and 0.5803×10^{-12} cm, respectively [11]. The structure was refined in the space group *P6/mmm* as reported in previous studies by Barrer and Villiger [7], and Newsam [12]. The positions of the framework atoms were refined before introduction of the potassium cations. Although Newsam [12b] reported different site preferences for silicon and aluminium, in view of the similarity in scattering lengths, we fixed the Si:Al ratio at the theoretical value of 3.0 for both sites throughout the analyses. Difference Fourier methods were used to search for additional potassium sites in K_1/K_9-L.

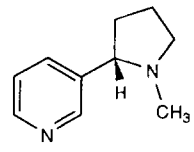
Mapping the Electrostatic Potential of Muscarinic and Nicotinic Agonists with Artificial Neural Networks**

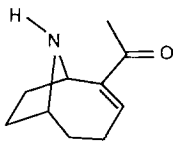
Johann Gasteiger* and Xinzhi Li

Signals in biological neural networks are transmitted between neurons by chemicals, called neurotransmitters, that are released at the terminus of the axon of one neuron, cross the synaptic gap, and then bind to receptors in the postsynaptic membrane of a dendrite of another neuron where they cause an electrical signal. Acetylcholine is such a neurotransmitter occurring in a variety of neuron types of the sympathetic and parasympathetic nervous system. It binds to at least two different receptors, the muscarinic and the nicotinic receptor.

The ring system makes muscarine structurally fairly rigid; thus it can only bind to the receptor that has been given its name. Scheme 1 shows muscarine and three other molecules that are agonists of muscarine and likewise bind only to the muscarinic receptor.



Scheme 1. Muscarine and three of its agonists, atropine, scopolamine, and pilocarpine.



Similarly, nicotine has such a rigid structure that it binds only to the nicotinic receptor as do the other three molecules of Scheme 2.

nicotine

(+)-anatoxin-a

mecamylamine

pempidine

Scheme 2. Four molecules that only bind to the nicotinic receptor: nicotine, anatoxin-a, mecamylamine, and pempidine.

In this study we report how similarities in the compounds that bind either to the muscarinic or nicotinic receptor can be found. Furthermore, dissimilarities between these two classes of compounds can be recognized.

The investigation of molecular electrostatic potentials (MEPs) is a commonly used method for unraveling the secrets of biological activity. Particularly, the MEP on a molecular surface is calculated and visualized by projection onto a computer screen. However, such projections are linear transformations and thus can only provide insight into one part of the three-dimensional molecular surface. To obtain a full picture of the entire MEP a series of observation points and associated projections is needed. We will show here that maps of the MEP obtained by Kohonen neural networks indicate characteristics common to musearinic agonists or to nicotinic agonists. The neural network paradigm that was developed by Kohonen models an important feature of the human brain, namely, the development of maps of the sensory environment in the cortex of the brain.[1, 2] The Kohonen network employs a competitive learning method that maps a point of a space (body, measurement space) into a single neuron of a two-dimensional network while conserving the topology of the information, that is, the neighborhood relationship of the points in the space.

The self-organizing formation of topological feature maps of Kohonen neural networks can be utilized as a method for the nonlinear transformation of a high-dimensional space into a one- or two-dimensional network.[3, 4] In our application, points of the three-dimensional van der Waals surface of a molecule are mapped into a two-dimensional space. In order to have a two-dimensional space in which each neuron has the same number of neighbors the projection was made onto a space without boundaries: the surface of a torus. For easier visualization the torus will be cut along two perpendicular lines and the surface spread out to form a plane which gives a rectangular array of neurons (Fig. 1).[3, 4]

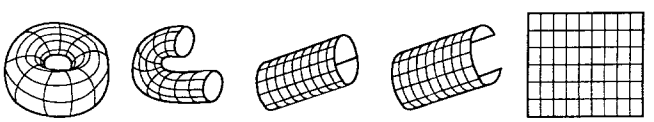

Fig. 1. The surface of a torus is cut along two perpendicular lines and spread into a plane. The little boxes of the rectangle symbolize the neurons of the network.

Learning in a Kohonen network is an unsupervised process. In our case, only the three Cartesian coordinates of the points on the van der Waals surface of a molecule are used, but not the property existing at such a point (e.g., the MEP). With three input variables, each neuron j also has three weights $\boldsymbol{w}_j = (w_{j1}, w_{j2}, w_{j3})$. Each point $\boldsymbol{x}_s = (x_{s1}, x_{s2}, x_{s3})$ on the surface will be mapped into that central neuron c_s that has weights, $\boldsymbol{w}_{c_s} = (w_{c_s1}, w_{c_s2}, w_{c_s3})$, closest to $\boldsymbol{x}_s$ with respect to the Euclidean distance [Eq. (1)]. The neuron c_s is usually referred to as the winning

$$\| \boldsymbol{x}_s - \boldsymbol{w}_{c_s} \| = \min_j \| \boldsymbol{x}_s - \boldsymbol{w}_j \| \qquad (1)$$

neuron of the input $\mathbf{x}_s$. The weights of all neurons are adjusted in the learning process iteratively for each randomly selected point $\mathbf{x}_s$ on the molecular surface.

The basic methodology for obtaining Kohonen maps of the MEP of the molecules shown in Schemes 1 and 2 is as follows:

1. Three-dimensional atomic coordinates are calulated by the automatic 3D-structure generator CORINA.[5, 6]

2. Partial atomic charges are calculated by the empirical PEOE procedure.[7, 8]

3. The electrostatic potential at points of the van der Waals surface is calculated as classical coulomb potential. (Clearly, more sophisticated quantum mechanical methods and other molecular surfaces, such as the solvent accessible surface,[9] can be used as well.)

4. 20000 points are randomly selected from the van der Waals surface with a grid of 100 points per Å^2 and used for training a Kohonen map with 100×100 neurons.

In the self-organization of the Kohonen map, points that are elose to each other on the van der Waals surface are mapped into the same or nearby neurons.

Two methods are used for visualizing the mapping of a molecular surface. In the first approaeh, a neuron of the two-dimensional Kohonen network (it is, in fact, the surface of a torus) is colored aceording to the value of the eleetrostatic potential observed at the points on the van der Waals surface that have been mapped into this neuron. A strongly negative potential is indicated in red; in order, yellow, green, blue, and purple indicate increasingly morc positive values of the MEP. This leads to maps of the MEP of the entire molecular surface.

In the second approach, the van der Waals surface is dissected into areas originating from the individual atoms of a molecule. Those parts of the surface belonging to a specific atom or group of atoms are distinguished by color. A neuron of a Kohonen map is colored according to the particular atom surface assignment (ASA) of the origin of the point mapped into this neuron. In this way, the nonlinear mapping of certain parts of the molecular surface can be identified.

Figure 2a shows a Kohonen map of the MEP on the van der Waals surface of muscarine. With this map, the entire MEP can be viewed in a *single* picture, quite in contrast to the usual representations of MEP that need a series of different viewpoints to obtain an overall impression of the MEP.

The map of Figure 2a was obtained by cutting the surface of a torus at two perpendicular lines (see Fig. 1). Such cuts can be made at arbitrary lines and thus the map of Figure 2a can be shifted into any direction. In fact, Figure 2a was obtained by centering the map on the large positive part of the MEP of muscarine—effectively putting the positively charged nitrogen into the center of the map. Figure 2b shows the same map, now centered on the negative part of the MEP. In order to show this self-containment of the Kohonen maps we have found it quite useful to put several identical maps together like tiles. This is

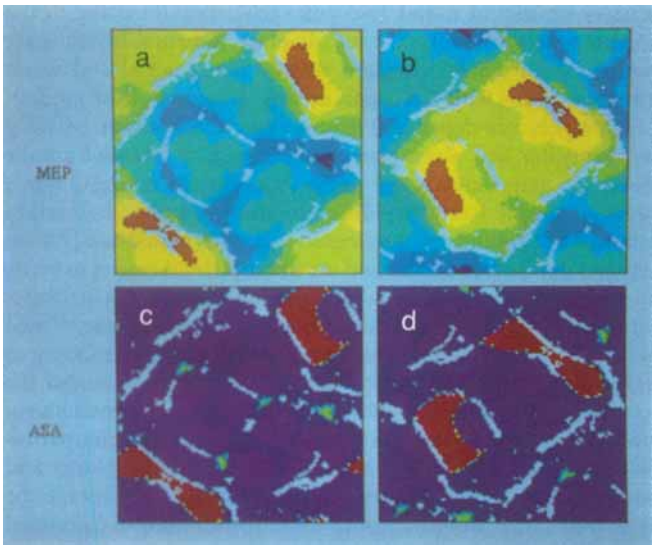

Fig. 2. Maps of the van der Waals surface of muscarine. For details see text.

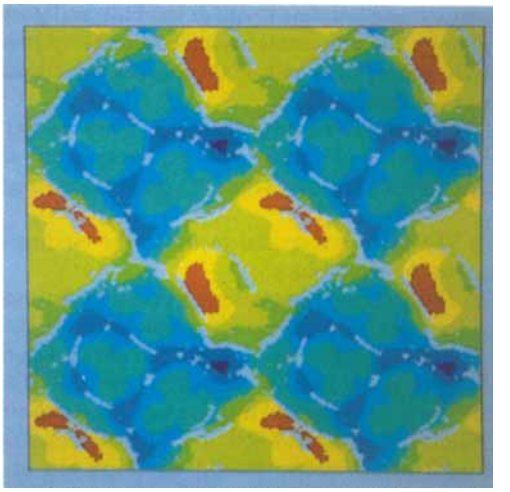

Fig. 3. Four identical maps of the MEP of muscarine put together like tiles.

shown in Figure 3 where Figure 2a has been replicated four times. Both Figure 2a and 2b can clearly be distinguished as parts of Figure 3.

While the neurons in the Kohonen map of Figure 2a and Figure 2b have been identified by the MEP observed at the points on the van der Waals surface, these Kohonen maps can be associated with any other molecular surface property. Figure 2c and Figure 2d show the very same maps of Figures 2a and 2b, now indicating the atomic surface assignment (ASA).

These ASA maps give a clearer picture of how the nonlinear transformation leads to the self-organization of the neurons. The representative surface was colored in such a way that those parts mapped by hydrogen are shown in purple and those by carbon in dark blue. The contribution of nitrogen to the van der Waals surface is indicated in green and that of the two oxygen atoms in red. Clearly, the van der Waals surface is dominated by hydrogen atoms. The carbon atoms, and particularly the nitrogen atom, are buried deeper in the molecule and are much less visible, but can still be located. The two oxygen atoms, on the other hand, can be clearly identified.

The Kohonen maps of the electrostatic potential on the van der Waals surfaces of the eight structures shown in Schemes 1 and 2 are given in Figure 4. To allow for a correct comparison, the neutral molecules were protonated at the most basic site, since this also occurs when they are bound to their receptors.[10, 11] The large positive MEP associated with the positively charged quaternary nitrogen atom clearly has a profound influence on the binding of these substrates to their respective receptors. Therefore, the maps of the MEP of these eight molecules have been arranged so that this positive MEP is in the center of the image in order to see variations at this binding site most directly.

A detailed discussion of these Kohonen maps goes beyond the scope of this paper. However, it can be seen that the maps of the four muscarinic compounds shown in the top row have some distinct common features. A regular rhomboid pattern of white lines indicating empty neurons is centered in the map. These empty neurons result from topological distortions occurring during the mapping of the molecular surface onto the topologically different surface of a torus.[12] The rhomboid pattern of empty neurons in the maps of the muscarinic compounds encloses the blue area of the positive MEP.

The maps of the four nicotinic compounds in the bottom row of Figure 4 have rather irregular patterns of empty neurons. The topological distortions indicated by these empty neurons occur directly adjacent to those parts of the molecular surface having the largest positive MEP; that is, the pattern of the white lines

of empty neurons cuts through the blue and purple areas. Furthermore, the blue areas are more elongated than for the muscarinic compounds and in some cases extend across the entire area of the map.

The similarities in the Kohonen maps of the MEPs of the agonists either of muscarine or of nicotine, and the clear differences between the two series of compounds suggest the following:

1. The MEP is a crucial factor in the binding of these molecules to their receptors.

2. The Kohonen maps retain essential features of the MEP and thus can help in screening biologically active compounds.

The self-organization in Kohonen networks enables the projection of properties of molecular surfaces. The mapping of MEP can give important insights into the similarity of molecules essential for biological activity. The present study shows that artificial neural networks can be employed to shed light on essential mechanisms of information processing in biological neural networks.

The Equilibrium Distribution of Semivolatile Organochloro Compounds between Atmosphere and Surface Water in the Atlantic Ocean**

Jörn Schreitmüller and Karlheinz Ballschmiter*

The distribution of chemicals in the environment is described with several unit-world models,[1] of which the fugacity approach of Mackay is the most universal. This model attributes the distribution of a substance to the tendency to achieve the same chemical potential and thus attain a thermodynamic equilibrium in all relevant environmental compartments.

For the abundance of anthropogenic or biogenic trace substances in the marine atmosphere, three situations that are interconvertible must be discussed: 1. a temporally and spatially fluctuating content as a result of varying uptake through the aerial transport path (Schlieren model; an example is the short-term, massive uptake of α and also γ-hexachlorocyclohexane in the northern hemisphere); 2. a steady-state nonequilibrium state caused by an almost constant uptake along aerial and water transport paths with the ocean as sink or source (flow model); 3. a temperature-dependent equilibrium distribution between surface water and atmosphere with only a differential uptake along the aerial and water paths (equilibrium model). For a constant supply from very different sources and a slow establishment of equilibrium, a potential thermodynamic equilibrium between the oceanic system and the atmosphere is easiest to verify by measurements in regions far from the sources. An air/water equilibrium for the distribution of hexachlorocyclohexane,[3] used as insecticide, has already been discussed in the Arctic Ocean as well as in the eastern North Pacific.[4] We have measured the content of α- and γ-hexachlorocyclohexane (HCH), pentachloromethoxybenzene (pentachloroanisol, PCA) and tetrachloro-1,4-dimethoxybenzene (TMB) in air and water of the North and South Atlantic (Fig. 1); in the process we did not average the measured values in order not to lose the information contained in the individual results.

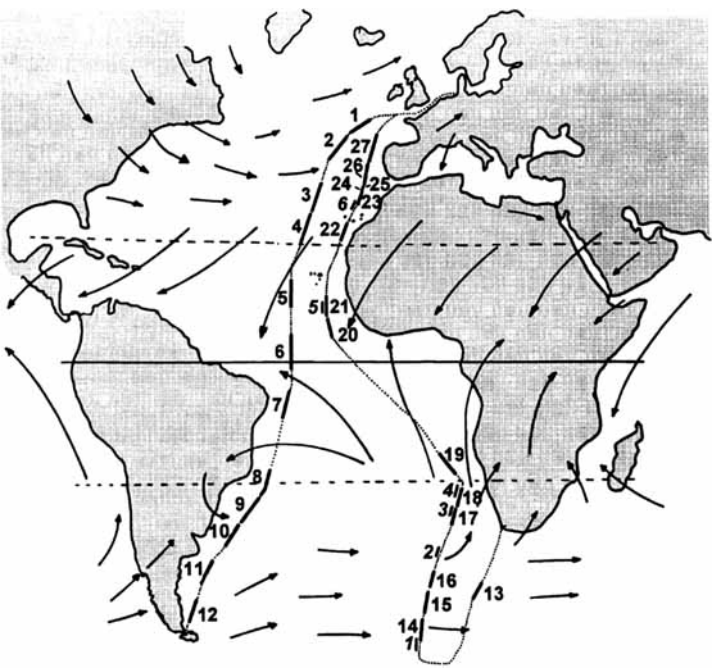

Fig. 1. Sampled zones for air samples (1–27) and water samples (1–6) in the Atlantic Ocean on the north/south cruises of the research vessel "Polarstern". The air samples 1–12 were taken in autumn 1990 on the voyage ANT IX/1 from Bremerhaven to Punta Arenas (Chile), the air samples 13–27 and the water samples 1–6 on the voyage ANT IX/4 from Cape Town to Bremerhaven. The prevailing wind directions are indicated by arrows.

The semivolatile organochloro compounds were determined in the lower troposphere and in surface water (6–8 m depth) of the Atlantic Ocean between 50 °N and 50 °S. The sampling region includes both the northern hemisphere in which the majority of the anthropogenic compounds are taken up,[1] and the southern hemisphere which functions as a global dilution zone. The two chloromethoxybenzenes are considered products of the biotransformation of pentachlorophenol[5] and via this intermediate also as metabolites of hexachlorobenzene[6] and the HCH isomers.[7] The close correlation of the concentrations of α- and γ-HCH with those of PCA and TMB in marine air confirms this interrelationship (Fig. 2).

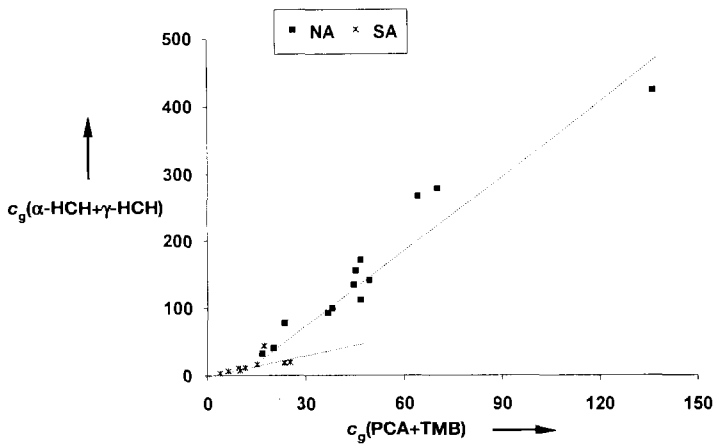

Fig. 2. Correlation of the sum of the concentrations c_g [pg m^{-3}] of α- and γ-HCH with those of pentachloromethoxybenzene and tetrachloro-1,4-dimethoxybenzene in the troposphere of the Atlantic Ocean. NA: North Atlantic, SA: South Atlantic.

The assignment of a vast meridional gradient of organochloro compounds in the lower atmosphere to a temperature-regulated, thermodynamically determined equilibrium of the air/water exchange will be described here for the first time. In addition the burden of the South Atlantic with the compounds mentioned above is documented for the first time.

The relation (1), where ΔG is the Gibbs partition energy, R the gas constant, and T the absolute temperature, is generally valid for the temperature dependence of an equilibrium constant K.

$$\ln K = -\Delta G\,(RT)^{-1} \tag{1}$$

Accordingly Equation (2), where ΔH_{gw} is the gas/water partition enthalpy and ΔS_{gw} the gas/water partition entropy, is valid

$$\ln K_{gw} = -\Delta H_{gw}\,(RT)^{-1} + \Delta S_{gw} R^{-1} \tag{2}$$

for the equilibrium distribution between atmosphere and surface water, described by the gas/water partition coefficients $K_{gw} = a_g a_w^{-1} = f_g c_g (f_w c_w)^{-1}$, ($a_g$, a_w are activities in the gaseous and aqueous phases, respectively; f_g, f_w: activity coefficients; c_g, c_w: concentrations).

The assumption f_g, $f_w = 1$ allows Equation (2) to be transformed into Equations (3.1) and (3.2), in which $A = -\Delta H_{gw} R^{-1}$ and $B = \Delta S_{gw} R^{-1}$. For a value of the gas/water partition coefficient K_{gw} of less than 10^{-2}, the change in the concentration in water resulting from evaporation or absorption as a consequence of the temperature dependence of K_{gw} is not measurable. Assumption of a virtually constant concentration in the surface water leads to the form (3.3) for Equation (3.2) ($C = \Delta S_{gw} R^{-1} + \ln c_w \approx$ constant). The slope of the linear regression function thus corresponds to $-\Delta H_{gw} R^{-1}$ and the intercept to $\Delta S_{gw} R^{-1} + \ln c_w$.

$$\ln c_g = -\Delta H_{gw}\,(RT)^{-1} + \Delta S_{gw} R^{-1} + \ln c_w \tag{3.1}$$

$$\ln c_g = A\,T^{-1} + B + \ln c_w \tag{3.2}$$

$$\ln c_g = A T^{-1} + C \tag{3.3}$$

Different contents in water at a distribution equilibrium and the same partition enthalpy are recognizable by the presence of parallel lines [Eq. (3.1)]. A plot of $\ln c_g$ vs. the reciprocal average temperature of the surface water in Kelvin yields the relationships depicted in Figures 3a–d for the studied compounds in

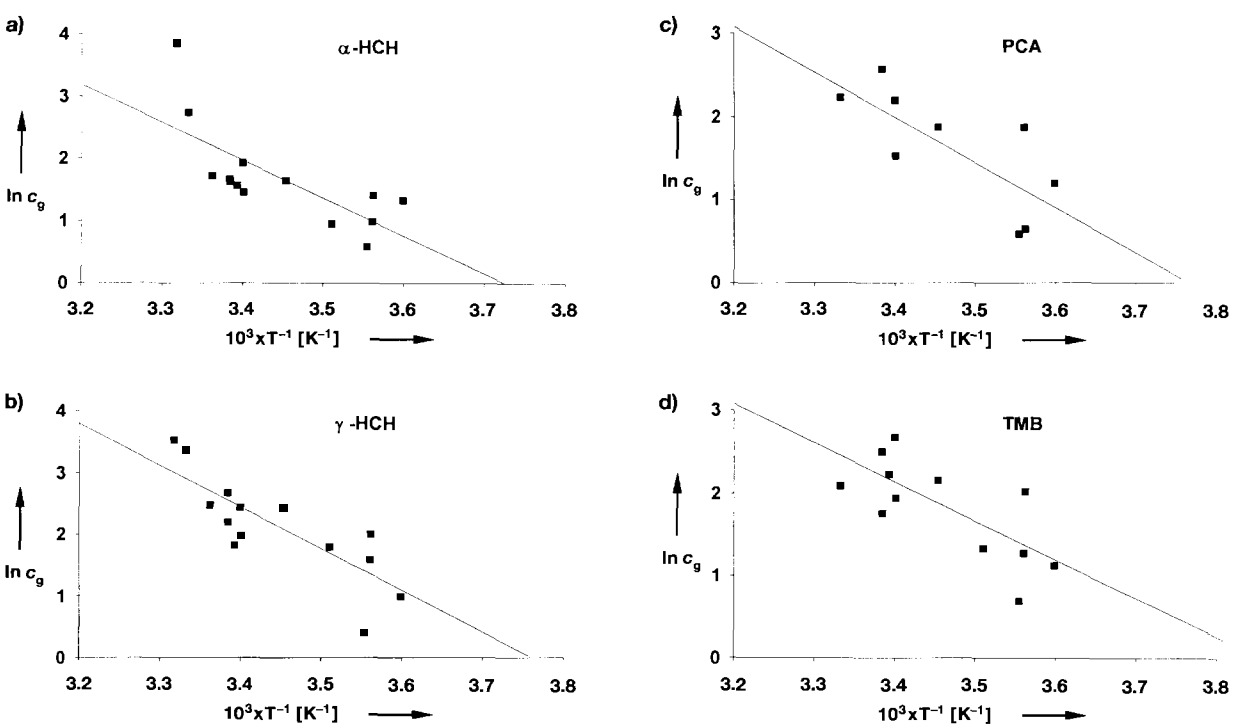

Fig. 3. Relationship between the concentrations c_g [pg m^{-3}] of α-HCH (a), γ-HCH, (b) pentachloromethoxybenzene (c), and tetrachloro-1,4-dimethoxybenzene (d) in the lower layer of the troposphere of the South Atlantic (air samples 6–12 and 13–19 from Fig. 1) and the reciprocal average water temperature at which each air sample was taken. Linear regression functions: a) $\ln c_g = -6170 \times T^{-1} + 22.94$, $r = -0.73$; b) $\ln c_g = -7130 \times T^{-1} + 26.68$, $r = -0.82$; c) $\ln c_g = -5380 \times T^{-1} + 20.31$, $r = -0.75$; d) $\ln c_g = -4730 \times T^{-1} + 18.20$, $r = -0.72$.

the South Atlantic. All air samples collected on both cruises of the "Polarstern" south of the high-rising, intertropical convergence zone (ITCZ) formed by the convergence of the north eastern and south eastern Trades[11] were plotted. For the South Atlantic it was shown that a largely uniform distribution of the four compounds in water is valid.

Deviations from linearity according to Equation (3.3) result from a not yet completely established equilibrium. This situation can arise, for instance, when rapid air movements bring air masses from colder or warmer regions, and the equilibrium with the water has not yet compensated the depleted or enriched contents in the atmosphere. On the other hand, interactions in the aqueous phase lead to a decrease in activities ($a_w = f_w c_w$ in which $f_w < 1$), and also noticeable fluctuations in the concentrations in surface water itself, cause apparent deviations from the equilibrium state, because then the conditions for Equation (3.3) no longer hold. Despite these fundamental parameters of influence, the observed relationship over a large region of the South Atlantic is surprisingly close to the linear behavior of Equation (3.3).

From the slopes of the lines, ΔH_{gw} was determined and compared with measured values (Table 1).[8] The data calculated from our measurements in the environment for the HCH isomers correspond to a good approximation with the values determined experimentally in the laboratory for the partition enthalpies.

Table 1. Comparison of the partition enthalpies from environmental measurements in the South Atlantic with experimentally determined partition enthalpies [8]. The calculated values for the chloromethoxybenzenes have no laboratory counterpart yet.

	K_{gw} (20 °C, sea water [8])	ΔH_{gw} [a] (South Atlantic) [kJ mol^{-1}]	ΔH_{gw} [b] (Laboratory [8]) [kJ mol^{-1}]
α-HCH	3.2×10^{-3}	51 ± 11	55 ± 4
γ-HCH	2.4×10^{-3}	59 ± 11	52.5 ± 5.5
TMB		38 ± 11	
PCA		45 ± 11	

[a] The deviation is the consequence of a statistical error of ±20% in the results of the analyses. [b] The values were calculated from the Henry constants given in ref. [8] (sea water between 0.5 and 23 °C).

Furthermore, the content in the atmosphere was compared with the equilibrium concentrations defined by the physical and chemical properties of the substances under investigation. From the measured content in six water samples and the experimentally determined values for K_{gw} of HCH at each water temperature,[8] the corresponding equilibrium concentration in the air was calculated. The results are depicted in Figure 4. Only the air samples taken on the same section of the cruise as the water samples are considered ("Polarstern" ANT IX/4 from Cape Town to Bremerhaven, air samples 13–27, water samples 1–6). In the northern hemisphere the equilibrium values in air calculated from the water samples for α-HCH are lower than the measured values; that is, the surface water is distinctly depleted with respect to α-HCH.[9] Besides the decomposition by OH radicals (lifetime τ_{OH} = 25 days[10]), a net loss of this compound from the atmosphere by gas diffusion into the surface water takes place. In contrast, in the southern hemisphere to a large extent an equilibrium between α-HCH concentrations in air and surface water exists. The surface water functions as source and balances the loss in the atmosphere caused by decomposition by OH radicals. For γ-HCH the air/water system in the North Atlantic—with the exception of areas characterized by a large continental uptake of γ-HCH—approaches the equilibrium state, whereas in the South Atlantic the air/water equilibrium, as for α-HCH, has been established. For both HCH isomers the establishment of the air/water equilibrium must be faster than the loss by decomposition by OH radicals.

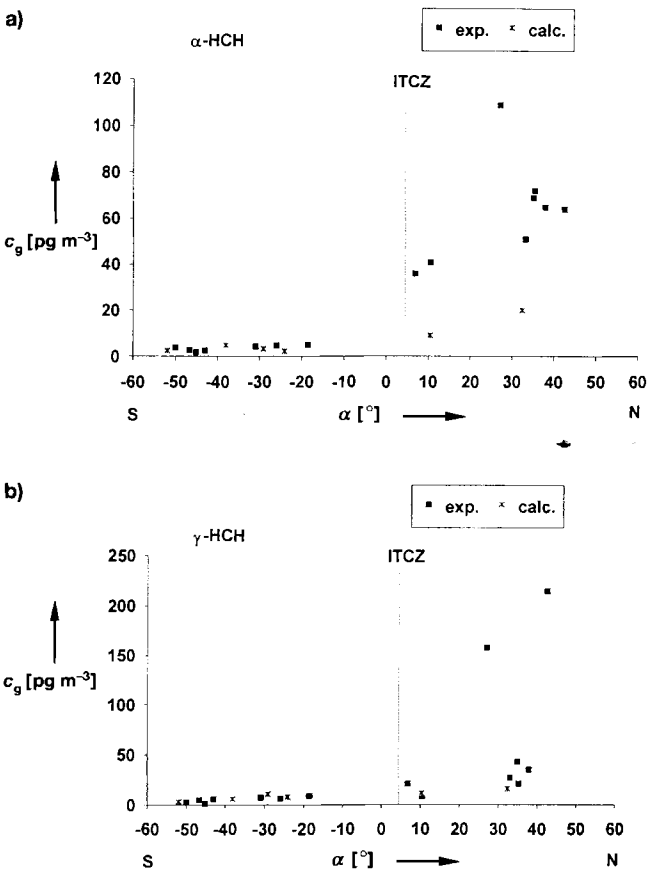

Fig. 4. Comparison of measured concentrations c_g of α-HCH (a) and γ-HCH (b) in the lower layer of the troposphere in the Atlantic (air samples 13–27) with calculated concentrations obtained from the water samples 1–6 from experimentally determined, temperature-dependent gas/water partition coefficients K_{gw} (from ref. [8]). exp.: measured concentrations; calc. calculated concentrations, α: degree of latitude.

The proof of a temperature-regulated equilibrium in the sense of classical thermodynamics of anthropogenic environmental chemicals between the atmosphere and surface water for the global dimension of the South Atlantic has far-reaching practical consequences for the interpretation of measured content of anthropogenic as well as biogenic trace substances in the marine atmosphere of the southern hemisphere and beyond. Current uptake of contaminated air from the continents and also of undercontaminated or noncontaminated air from the backstream from the stratosphere in the region of the subtropic high-pressure zones would be recognizable as deviations from the equilibrium concentrations till relaxation of the disturbed air/water equilibri-

um occurs.[11] Furthermore, the long-term role of the oceans as sink and as source for the uptake into the atmosphere becomes clear. The results show that with correct and significant data—a prerequisite demanded of the analytical processes of modern analytical chemistry—general chemical relationships for global environmental chemistry become clear. They are then able to be modeled on facts, and thus some aspects become predictable.

Experimental Procedure

Details of sampling on board the "Polarstern" on cruises from Bremerhaven to Punta Arenas (Chile) in 1990 (air samples 1–12) and from Cape Town to Bremerhaven in 1991 (air samples 13–27, water samples 1–6) may be found in ref. [12, 13]. The sampling zones are shown in Figure 1.

Further details on the determination of the atmospheric trace substances by adsorption from high-volume samples (500–1000 m^3) on prepurified silica gel and sample workup under strict control for potential contamination, preseparation by adsorption liquid chromatography, and separation and detection by high-resolution capillary gas chromatography with electron-capture detection (HRGC–ECD) are described in ref. [13]. The hexachlorocyclohexanes in surface water were analyzed according to a method described in ref. [14] (adsorption on prepurified polystyrene–divinylbenzene copolymer (XAD-2), sample workup and determination with HRGC–ECD) [12].

[11] The mass flow in the atmosphere and in the global oceanic system has scarcely been considered previously in the discussion of the spread of organic trace substances [1]. The exchange of air masses between troposphere and stratosphere is often underestimated (E. R. Reiter, *Rev. Geophys. Space Phys.* **1975**, *13*, 459–474). We could test by measurement of the content in the air in a sufficiently wide region along the coast of Chile whether a similar temperature-regulated air/water equilibrium to that of the South Atlantic is present in the eastern South Pacific. The content in surface water then can be calculated from the values in the air alone. The concept of a global environmental chemistry, which we dubbed the "Ulmer 4-W approach" (Was, Wieviel, Wo, Warum: what, how much, where, why) that attempts to relate the chemistry of studied compounds and the global mass-flow phenomena on the basis of an efficient analytical chemistry is confirmed in the results described here in an exemplary manner.

Zigzag Channels in the Structure of Sebaconitrile/Urea **

Mark D. Hollingsworth,* Bernard D. Santarsiero, and Kenneth D. M. Harris

Dedicted to the memory of Professor Margaret C. Etter

Since their discovery by Bengen and Schlenk,[1] hundreds of urea inclusion compounds have been studied by various techniques. In these crystals, long-chain alkanes and their substituted analogues are enclosed within continuous, linear hexagonal channels formed by a hydrogen-bonded array of urea molecules. Because the internal diameter of the channel (about 5.3–5.7 Å) is somewhat larger than the van der Waals envelope of an alkyl chain, the guest molecules are held loosely, and typically undergo substantial translational and reorientational motions.[2] Thus far, with the exception of urea inclusion compounds with trioxane,[3] 5-undecanone[4] and certain short-chain α,ω-dihaloalkanes,[5] the incommensurate[6] repeat distances of host and guest along the channel is a common feature of virtually all urea inclusion compounds, and the guest molecules pack within van der Waals contact of each other. In some cases particularly at low temperatures, the host is distorted slightly, but the repeat length along the channel axis is uniformly close to the standard value of 11.0 Å.[7] If a guest species cannot be accommodated by the conventional hexagonal channel, it is ordinarily not included within urea,[8] and either separate phases or specific cocrystals[9] are formed.

Our cross-polarization magic angle spinning (CP-MAS) NMR studies of urea inclusion compounds have focused on interactions between functional groups that are isolated as pairs within the urea channels.[10] For the incommensurate urea inclusion compounds, ^{13}C MAS NMR ordinarily yields extremely narrow bands with characteristic chemical shifts for given pairs of functional groups. However, we were intrigued by the unusual behavior of the sebaconitrile/urea (**1**/urea) inclusion compound. For guest molecules in **1**/urea, chemical shifts of the nitrile and α carbons are different from those in the doubly homologous 1,10-dicyanodecane/urea (**2**/urea). Magnetic field dependence (Fig. 1) and ^{15}N-labeling experiments demonstrate that the $^{13}C-^{14}N$ residual dipolar splittings[11] of the nitrile carbon are much larger in **1**/urea, and suggest substantial loss of motional freedom for this shorter guest molecule.[12] Although the crystal habit of **1**/urea (flat hexagonally shaped plate instead of

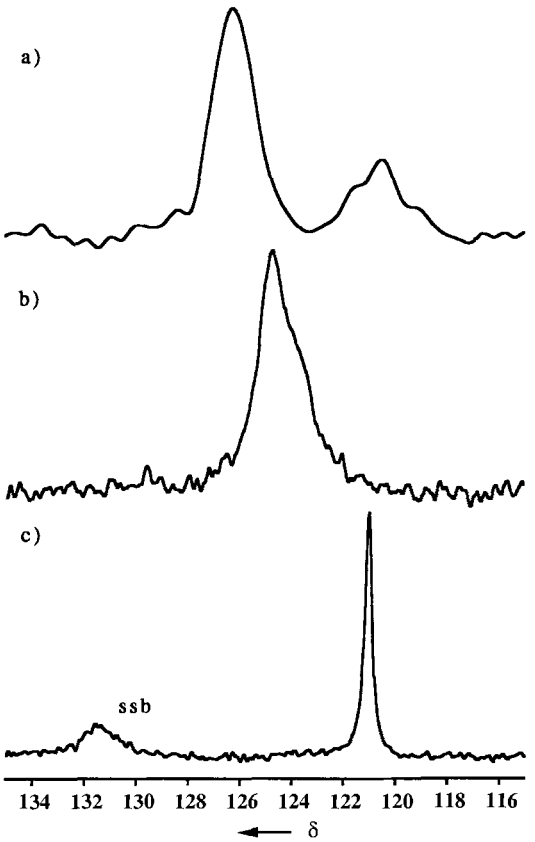

Fig. 1. Nitrile carbon region of ^{13}C CP-MAS NMR spectra of **1** urea at 50.3 MHz (a) and at 125.7 MHz (b), and of **2**/urea at 125.7 MHz (c). In **2**/urea (c), which is typical of incommensurate nitrile/urea systems, large amplitude motions of the nitrile group average the residual dipolar interaction between ^{13}C and ^{14}N to less than 30 Hz. In contrast, the spectra of **1**/urea show much larger residual dipolar interactions. ssb = spinning side band.

the typical hexagonal needle) might have been rationalized in terms of poisoning of the {0001} faces of a normal urea inclusion compound by **1**, the birefringence exhibited for light entering normal to the plate face could not be understood in terms of a simple uniaxial (hexagonal) crystal.[15]

Our X-ray diffraction investigations reveal that **1** forms commensurate inclusion compounds with urea, and although this structure exhibits a number of features common to conventional urea inclusion compounds, the differences are striking: the structure[16] is monoclinic, not hexagonal, and though the stoichiometry (**1**: urea = 1:6) suggests a commensurate structure, the unit cell axes have no simple relationship to the normal 11.0 Å repeat along the channel axis. A view down the channel axis (Fig. 2) shows only modest distortions from the conventional hexagonal host structure near the middle of the sebaconitrile molecule. However, at the junction between adjacent antiparallel nitriles within a channel, the linear channel structure is interrupted by a *kink* in which two linear, parallel segments are offset by significant amounts. Although one might expect that the kink in the channel is caused by the steric bulk of the nitriles (which should be tethered strongly by dipole–dipole interactions),[14] these two groups are well beyond van der Waals contact from each other. (For adjacent nitriles, the interatomic distances are 3.841(7) Å (C–C), 3.911(7) Å (C–N), and 4.290(6) Å (N–N). Instead, and in contrast with urea inclusion compounds studied previously, there is hydrogen bonding between the host and guest, and each nitrile is tethered to two different urea molecules in the next segment of the channel (Fig. 3). This hydrogen bonding disrupts the network of urea molecules and gives rise to a longer repeat distance of 13.26 Å (usual: 11.0 Å) in each channel segment. As a result, the guest molecules are significantly bowed along the *b* axis by several small angle torsions near the chain termini.

Thus, the nitrile–urea hydrogen bonding is the dominant source of the restricted motion that gives rise to the large residual dipolar splitting in the MAS NMR spectrum. The consequential disruption of host–host hydrogen bonding is presumably the source of the unusual flat plate habit of these crystals, in which material is added preferentially to the sides of the channels instead of along their long axes. However, the exact reasons for the morphology change are unknown.

Apart from an uncharacterized premelting transition within 5° of the melting point,[16] differential scanning calorimetry (DSC) shows no discernible phase transitions above 220 K. Lattice parameters also show smooth temperature dependences from 97–312 K. To date, we have not been able to generate the normal hexagonal form of **1**/urea, even by seeding with hexagonal urea inclusion compounds, by grinding, or by growing crystals from solutions containing small amounts of guests that ordinarily form hexagonal urea inclusion compounds. However, we have been able to form hexagonal needles of **1**/[D_4]urea (from MeOD solution), quite reliably by seeding with tiny amounts of hexagonal inclusion compounds of 1-cyanooctadecane/urea or its [D_4]-urea analogue. (The long chain guests impart low solubility to the seed crystals.) Unless they are collected immediately after they are formed, these hexagonal needles of **1**/[D_4]urea undergo a solvent-mediated phase transition to the monoclinic plate form.

DSC on the three available crystal forms provides some clues about the nature of the isotope effect in this system. Although the

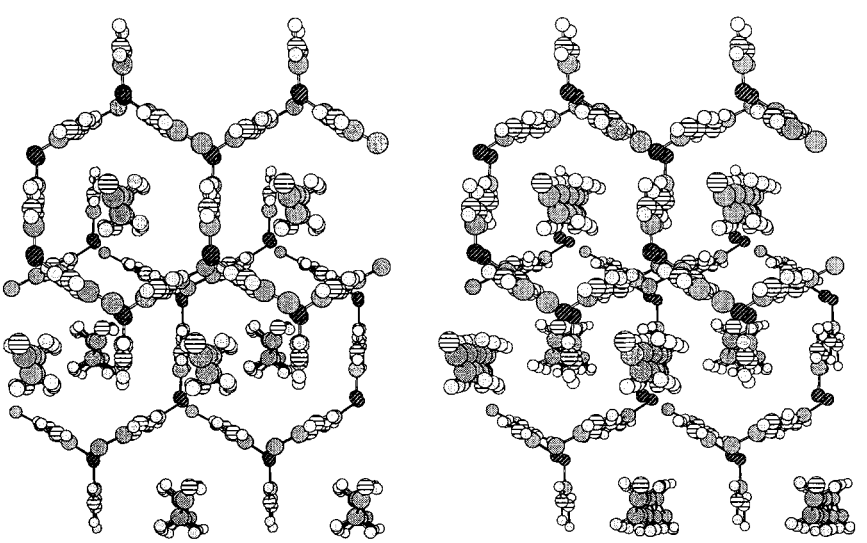

Fig. 2. Stereoview down the channel axis of two unit cells of **1**/urea. The (doubled) *b* axis is horizontal, and the view is 29° from the *c* axis of the crystal. The rear channel segment is offset by 2.3 Å along *b*, and by 0.9 Å along the vertical direction of this diagram. Nitriles in the front segment of the channel are bowed by 0.55 Å along *b* so that their nitrile groups can hydrogen bond with urea molecules of the rear channel segment. Guests in the rear segment are bowed along $-b$. The offset channels bring nitriles in *adjacent* channels to within 5 Å of each other. (Oxygen: dark diagonally hatched circles, nitrogen: horizontally hatched circles, carbon: mottled gray, hydrogen: light gray.)

protiated plates melt at a higher temperature than the deuterated plates (onsets at 371.2 and 364.2 K, respectively; 5 K min^{-1}), the measured enthalpy of melting (or decomposition) is *lower* for the protiated form (11.8 vs. 17.7 cal g^{-1}), indicating a process controlled by entropy. At the same time, cell constants for the deuterated and protiated forms are identical between 97 and 312 K,[19] which suggests that zero-point energies, not equilibrium structures, constitute the main differences between these isotopomorphs. The melting transition occurs at a lower temperature for the **1**/[D_4]urea needles (onset at 351.5 K) but the heat of fusion (14.1 cal g^{-1}) and melting temperature cannot be interpreted in the absence of similar data for the protiated needles.

Even though the solvent-mediated phase transition severely limits the size of hexagonal needles of **1**/[D_4]urea that one can grow, these crystals are stable in the absence of water vapor, and can be studied by X-ray diffractometry at room temperature. Although the metric propeties of the guest structure have not yet been determined, diffractometry shows that the host retains its normal channel structure, but that the channel diameter is approximately 0.05 Å wider, and the periodic repeat distance is about 0.04 Å shorter than the hexagonal channels formed in the presence of 'typical' guests.[20] The wider channels can probably better accommodate the molecules of **1**, which are expected to exhibit rhombohedral interchannel ordering that occurs for $NC(CH_2)_{10}CN$ and several other guests of the formula $X(CH_2)_nX$.[21] If they could be prepared, the hexagonal crystals of **1**/urea would show whether these cell constant differences were due to the strain induced by the guest, or to the replacement of hydrogen by deuterium. Our diffractometric studies of deuterated and protiated forms of several other hexagonal inclusion compounds suggest the former.[22] Further studies of this unusual system, including deuterium fractionation and spectroscopic and structural measurements, will appear in forthcoming publications.

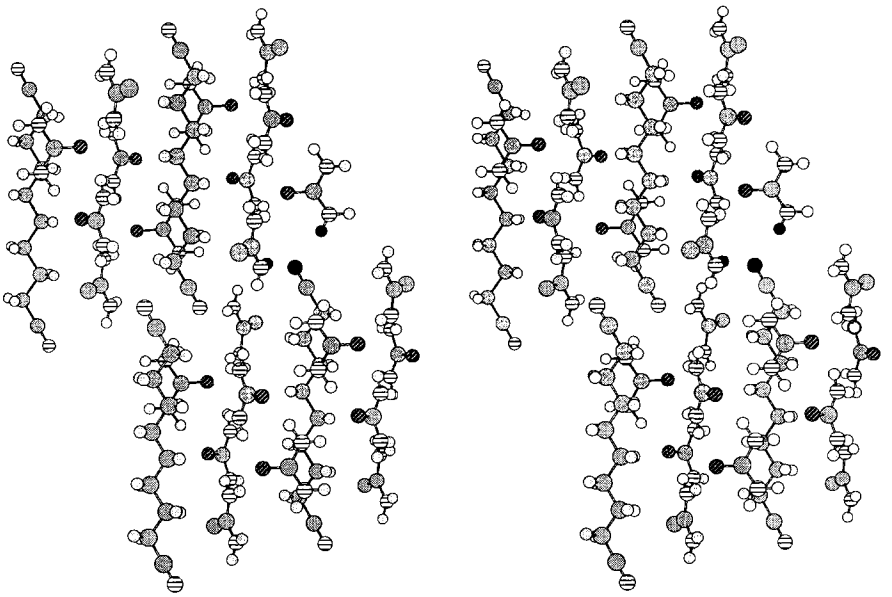

Fig. 3. Stereoview down the *b* axis of **1**/urea. The vertical axis (which lies very close to the bisector of *a* and *c*) gives the repeat of the two segments. One set of atoms involved in host-guest hydrogen bonding is shaded black. Distances between the nitrile and urea protons are N···H(syn) 2.36(4) Å, N···H(anti) 2.45(4)) angles are C–N···H(syn) 117.2(10)°, C–N···H(anti) 119.4(10)°, N–H(anti)···N 159(9), and N–H(syn)···N 157(7)°.

Experimental Procedure

[1,8-$^{13}C_2$]Sebaconitrile (98.4% enrichment) was prepared by heating $Na^{13}CN$ (0.126 g, 2.52 mmol) and 1,8-dibromooctane (0.329 g, 1.21 mmol) in DMF (6.8 mL) for 5 h at 115 °C. After addition of H_2O (25 mL), the product was extracted with pentane/diethyl ether (1:2), dried, and then distilled (92–96 °C/0.05 mm Hg) to give 0.60 g (93.1%) of a clear oil. [$^{15}N_2$]Sebaconitrile (99.0% enrichment) was prepared by a similar procedure. Inclusion compounds were formed by dissolving **1** (0.10 g) in a solution of urea (1.8 M) in MeOH (2.3 mL) at 26 °C and then slowly cooling to 5 °C over a period of 8–10 hours. Although hexagonal **1**/[D_4]urea could be formed from MeOD by the same method, these crystals were formed most reliably by adding **1** (0.7 mL) to a hot solution (70 °C) of [D_4]urea (0.45 g) in MeOD (1.33 g) and then cooling with seeding to 40 °C over 20–25 min. The ratio of MeOD to guest in these crystals was in some cases as large as 1:5. The sebaconitrile used in these experiments was made highly pure by dissolving monoclinic **1**/urea crystals in H_2O, extracting with diethyl ether, drying, and condensing.

[12] An earlier study [13] of stearonitrile/urea concluded that at 50.3 MHz, the 92 Hz splitting in the nitrile ^{13}C resonance was due to residual dipolar coupling between ^{13}C and ^{14}N that had been attenuated by the motional averaging of the nitrile group in the channel. Our field dependence and ^{15}N labeling studies show that for this unsymmetric nitrile, this 92 Hz splitting is actually due to two different arrangements of guests (head to head or head to tail), and that for incommensurate urea inclusion compounds containing nitriles, large amplitude motions of the nitrile collapse the residual dipolar interactions to within the linewidth of each individual resonance. See also ref. [14].

A Novel Route to Diastereomerically Pure (*E*)-Alkene Dipeptide Isosteres from β-Aziridinyl-α,β-enoates by Treatment with Organocopper Reagents**

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

The growing importance of peptide mimetics[1] in synthetic and medicinal chemistry has created a need for efficient routes to the (*E*)-alkene dipeptide isosteres.[2] We have been interested in the synthetically useful ring-opening reactions of N-activated aziridines in connection with studies on peptide isosteres with stereochemically well-defined structures. Although the ring-opening reactions of γ,δ-epoxy-α,β-enoates **1** with a variety of organometallic reagents have found widespread application in the stereocontrolled synthesis of many acyclic systems,[3] prior to the initiation of our studies no information was available regarding the regio- and stereochemistry of organocopper-mediated reaction of β-aziridinyl-α,β-enoates such as **2**. Very recently, a report on the palladium-catalyzed selective hydrogenolysis of β-aziridinyl-α,β-enoates with formic acid appeared.[4]

[**] This work was supported in part by Grants-in-Aid for Scientific Research from the Japanese Ministry of Education, Science and Culture and by the CIBA-GEIGY Foundation.

In principle, there are four reactive positions for nucleophilic attack (denoted by a, b, c, and d in enoate **2**). Thus, it is not an easy matter to predict where attack occurs primarily in the reaction of **2** with organocopper reagents. The S_N2' reaction of δ-*tert*-butoxycarbonylamino-γ-mesyloxy-α,β-enoates with organocopper reagents offers a valuable route to (*E*)-alkene dipeptide isosteres, though, in some cases, its application is hindered by rather low stability of the γ-mesyloxy-α,β-enoates.[5]

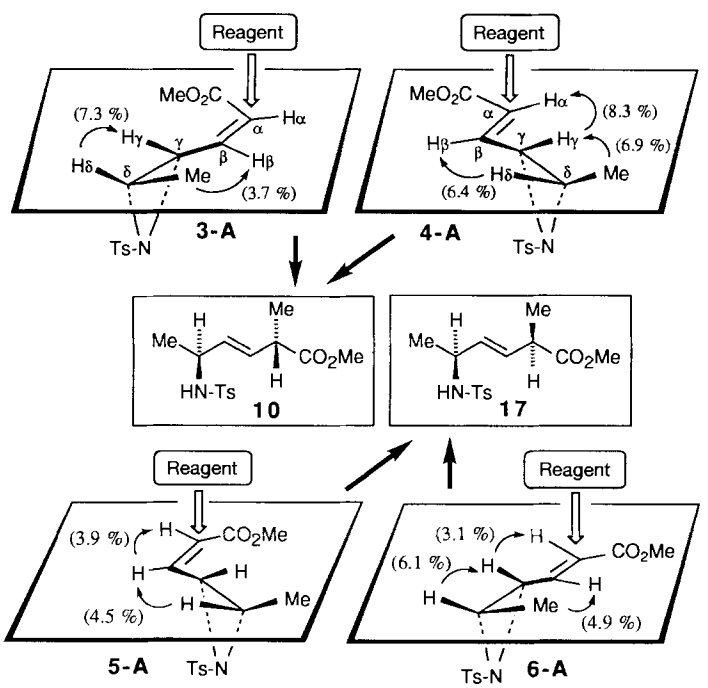
From an experimental point of view, the β-(*N*-tosylaziridinyl)-α,β-enoates **2**, R = Tos, have the advantage that they are more stable and are readily purified by recrystallization. The present study had two goals: 1) to find reaction conditions whereby (*E*)-alkene dipeptide isosteres can be synthesized from readily available β-aziridinyl-α,β-enoates in high chemical yields, and 2) to examine the stereochemical relationship between substrate and product stereochemistry.

We report here on a new synthesis of (*E*)-alkene dipeptide isosteres suitable for large-scale preparation by an anti-S_N2' reaction of diastereomerically pure β-aziridinyl-α,β-enoates with organocopper reagents (Scheme 1). The requisite four diastereomerically pure stereoisomeric starting materials **3**–**6** were readily prepared in acceptable yields from either L-threonine or

Scheme 1. Ts = *p*-toluenesolfonyl.

D-allothreonine according to the usual method.[6] To test the feasibility of an organocopper-mediated allylic substitution for the synthesis of (*E*)-alkene dipeptide isosteres, we examined the reaction of **3** with a variety of organocopper reagents (see Table 1). Selection of the organometallic reagent is very important and holds the key to success. Enoate **3** reacted smoothly with both Me_3ZnLi in the presence of 30 mol% of CuCN and MeCu(CN)Li to give the required N-protected isostere **10** in high yields along with small amounts of **7** (entries 1 and 4 in Table 1).[7] A comparable result was obtained by reaction of **3** with Me_2Zn in the presence of 20 mol% of CuCN (entry 3 in Table 1). This strategy allows flexibility in introducing substituents such as *n*Bu, *i*Pr, $iPrOSi(Me)_2CH_2$, and *p*-F-C_6H_4-CH_2 at the position α to the ester group merely by changing the reagent (entries 5–8 in Table 1). In a similar manner, exposure of isomeric enoates **4**–**6** to either Me_2Zn in the presence of 20 mol% of CuCN or MeCu(CN)Li gave the expected (*E*)-alkene dipeptide isosteres as the major products in very high yields and with high optical purity (diastereoselectivity >99:1; entries 9–14 in Table 1).

Table 1. Reaction of β-(*N*-tosylaziridinyl)-α,β-enoates **3**–**6** with organometallic reagents[a].



Entry	Cmpd.	Reagent [b]	Products (yield [%]) [c] S_N2 product	*anti*-S_N2' product
1	**3**	Me_3ZnLi; 30 mol % CuCN	**7** (4)	**10** (90)

13	**6**	Me_2Zn; 20 mol % CuCN	**18** (2)	**17** (88)
14	**6**	MeCu(CN)Li	**18** (3)	**17** (92)

[a] Reaction conditions: −78 °C, 30 min (exception, entry 7: 0 °C, 30 min), 3–4 mol equiv of reagents in THF/Et_2O (ca. 5/1, entries 1–5 and 9–14) or THF (entries 6–8). [b] Me_3ZnLi and Me_2Zn were prepared as LiBr complexes from $ZnCl_2$ and MeLi in Et_2O. MeCu(CN)Li was prepared as the LiBr complex from CuCN and MeLi in Et_2O. [c] All the new compounds were fully characterized by spectroscopy and their composition determined by high-resolution mass spectrometry and/or elemental analysis. Diastereoisomeric purities (>99%) of all isolated compounds were determined by HPLC. [d] Could not be isolated.

The desired (*E*) configuration of the double bond in isosteres **10**–**14** and **17** was easily established from the coupling constant (ca. 15.5 Hz) of the two olefinic protons in the ^1H NMR spectra. The absolute configuration of the alkylated carbon center at the α position in isosteres **10**–**14** and **17** was conveniently determined by a circular dichroism (CD) measurement.[8] The structure and stereochemistry of the S_N2 side products **7**, **15**, **16**, and **18** were confirmed by comparison of their spectral data (^1H NMR, IR) and HPLC retention times with those of authentic samples prepared by an unambiguous, independent synthetic route.[16]

As mentioned previously, enoates **3** and **4**, and **5** and **6** gave dipeptide isosteres **10**–**14** and **17**, respectively, as the major products upon treatment with organozinc reagents in the presence of CuCN or lower order organocyanocuprates. The question remains of why both the (*E*)- and (*Z*)-α,β-enoates are transformed into the (*E*)-alkene isosteres. Is there any logical reason why enoates **3** and **4** yield **10**–**14** and the isomeric enoates **5** and **6** give **17**? In the preferred conformation of many olefins containing a propene moiety a hydrogen atom at the sp^3 carbon in the propene unit eclipses the double bond.[9] In this conformation allylic 1,3 strain is minimized.[10] Hoffmann has recently reviewed the use of allylic 1,3 strain as a controlling factor in highly stereoselective reactions of alkenes and heteroalkenes.[11] The preferred conformations of the four stereoisomeric compounds **3**–**6** have been determined by variable-temperature ^1H NMR spectroscopy[12] in $[D_8]THF$ (all reactions were carried out in solvent mixtures containing THF). In addition, an X-ray analysis of the (*Z*)-enoate **3** and (*E*)-enoate **4** has been carried out.[13]

The ^1H-^1H COSY and selective decoupling experiments for **3**–**6** suggest that the preferred conformations are **3-A**, **4-A**, **5-A**, and **6-A** (Scheme 2). These are in agreement with the preferred conformations in related systems such as vinylcyclopropane[14] and vinyloxiranes.[15] The X-ray structure analyses of **3** and **4** indicate that the conformation in the crystal is quite similar to that in solution (Fig. 1). Thus organocopper reagents attack the α position on the most abundant conformer **3-A**–**6-A** *anti* to the C_γ–N bond that breaks to give the anti-S_N2' products **10**–**14** and **17**, respectively, as the major products.

Scheme 2. Preferred conformations **3-A**, **4-A**, **5-A**, and **6-A** of compounds **3**–**6** in solution ($[D_8]THF$, 600 MHz, 300 K). The NOE values are given in parentheses.

In summary, the reaction of N-sulfonylated β-aziridinyl-α,β-enoates with organometallic reagents (Scheme 1 and Table 1) provides a simple and efficient route to diastereomerically pure (*E*)-alkene dipeptide isosteres that may have biological significance. The absolute configuration at the alkylated α position and the (*E*) configuration of the S_N2' products completely reflect the most abundant conformation of substrates **3**–**6**.

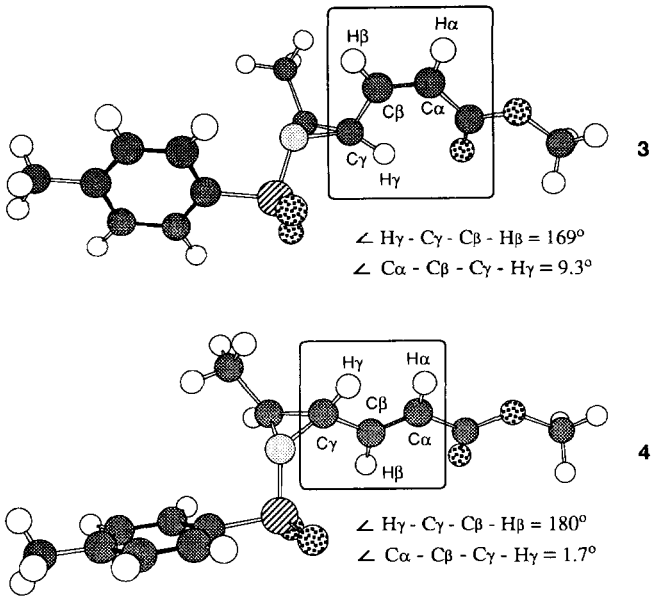

Fig. 1. Crystal structures of **3** and **4** with the values of the angles relevant to the conformation of the propene unit.

Experimental Procedure

Representative procedure for the synthesis of (*E*)-alkene dipeptide isosteres, compound **14** (Table 1, entry 8): To a stirred solution of CuCN (358 mg, 4 mmol) and LiCl (339 mg, 8 mmol) in 5 mL of dry THF at −78 °C was added by syringe 5.33 mL (4 mmol) of 0.75 M *p*-fluorobenzylmagnesium chloride in THF. The mixture was allowed to warm to 0 °C and was stirred at this temperature for 10 min. A solution of enoate **3** (295 mg, 1 mmol) in dry THF (2 mL) was added dropwise to the above reagent at −78 °C with stirring, and the stirring was continued for 30 min followed by quenching at −78 °C with 4 mL of a mixture of saturated NH_4Cl solution and 28% NH_4OH solution (1/1). The mixture was extracted with Et_2O/CH_2Cl_2 (4/1), and the extract was washed with brine and dried over $MgSO_4$. The solvent was removed under reduced pressure, and the residue was purified by flash chromatography on silica gel (*n*-hexane/EtOAc 3/1) to give 397 mg (98% yield) of **14** as a colorless oil. This compound was fully characterized by spectroscopic means (IR ($CHCl_3$), ^1H and ^{13}C NMR ($CDCl_3$), CD (isooctane), and MS). Diastereomeric purity (>99%) was determined by HPLC (chiral column: Chiralcel OD).

[6] Synthesis of the starting compounds: **3** and **6**: L-Threonine methyl ester hydrochloride (1 equiv), prepared by reaction of L-threonine (1 equiv) with $SOCl_2$ (2 equiv) in MeOH under reflux for 2.5 h, was tosylated with *p*-toluenesulfonyl chloride (1 equiv) and Et_3N (3 equiv) in dimethylformamide at 25 °C for 18 h to give *N*-*p*-toluenesulfonyl-L-threonine methyl ester (78% yield, m.p. 99 °C (*n*-hexane/Et_2O 1/1), $[\alpha]_D^{20} = -3.27$ ($c = 0.917$ in $CHCl_3$)). Diethyl azodicarboxylate (1.5 equiv) was added dropwise to a stirred mixture of the above ester (1 equiv) and PPh_3 (1.5 equiv) in THF at 0 °C, and the mixture was stirred for 18 h at room temperature. The mixture was concentrated under reduced pressure, and the residual oil was purified by flash chromatography on silica gel (*n*-hexane/EtOAc 3/1) to yield (3*S*)-methyl-*N*-*p*-toluenesulfonylaziridine-(2*S*)-carboxylic acid methyl ester (92% yield, m.p. 61 °C (*n*-hexane/Et_2O 1/4), $[\alpha]_D^{20} = -38.9$ ($c = 0.81$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD)). Diisobutylaluminum hydride in toluene (1.1 equiv) was added dropwise to a stirred solution of the above aziridine (1 equiv) in CH_2Cl_2 at −78 °C, and the mixture was stirred for 2 h. The reaction was quenched with a saturated NH_4Cl solution at −78 °C with vigorous stirring. After the addition of (methoxycarbonylmethylene)triphenylphosphorane (1 equiv) at −78 °C, the reaction mixture was stirred for 18 h and allowed to warm to room temperature. The inorganic salts were removed by filtration through Celite. The usual workup of the filtrate gave a yellow, oily residue, which was purified by flash chromatography on silica gel (*n*-hexane/EtOAc 3/1) to yield, in order of elution, **6** (6% yield) and **3** (91% yield). The (*E*)-enoate 6 can be obtained as the major product (**6**:**3** = 83:17; 92% combined yield) by the use of a sodium salt of trimethylphosphonoacetate instead of (methoxycarbonylmethylene)triphenylphosphorane. In a similar manner, the β-aziridinyl-α,β-enoates **4** and **5** were synthesized via *N*-*p*-toluenesulfonyl-D-*allo*-threonine methyl ester (m.p. 100 °C (*n*-hexane/Et_2O 1/10), $[\alpha]_D^{20} = -20.7$ ($c = 0.987$ in $CHCl_3$)) and (3*S*)-methyl-*N*-*p*-toluenesulfonylaziridine-(2*R*)-carboxylic acid methyl ester (colorless oil, $[\alpha]_D^{20} = 15.6$ ($c = 1.2$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD)) from D-*allo*-threonine in comparable yields. – **3**: m.p. 75–77 °C (*n*-hexane/Et_2O/CH_2Cl_2 4/4/1), $[\alpha]_D^{27} = 10.1$ ($c = 0.915$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD); **4**: m.p. 84 °C (Et_2O), $[\alpha]_D^{20} = 28.4$ ($c = 1.07$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD); **5**: m.p. 51 °C (*n*-hexane/Et_2O 1/2), $[\alpha]_D^{20} = -181$ ($c = 1.13$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD); **6**: m.p. 92–93 °C (*n*-hexane/Et_2O 2/1), $[\alpha]_D^{32} = -89$ ($c = 0.725$ in $CHCl_3$), >99% *de* (HPLC, Chiralcel OD).

[13] The X-ray structure analysis showed that enoate **4** has two conformers in its unit cell. Interestingly, the dihedral angle (H_β-C_β-C_γ-H_γ) of both conformers is 180°. The two conformers of **4** differ slightly in the orientation of the *N*-*p*-toluenesulfonyl moiety. Consequently, only one conformer is shown in Figure 1. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, GB-Camhridge CB2 1EZ (UK), on quoting the full journal citation.

Synthesis and Third-Order Nonlinear Optical Properties of a Conjugated Porphyrin Polymer**

Harry L. Anderson,* Simon J. Martin, and Donal D. C. Bradley*

Materials with large third-order optical nonlinearity are potentially useful for the fabrication of fast optical switches, but very few materials have sufficiently high susceptibility, $\chi^{(3)}$. There is particular demand for materials with high $\chi^{(3)}$ ($> 10^{-8}$ esu) in the near IR region (ca. 1 μm wavelength) for telecommunication switches. The molecular design features for a high $\chi^{(3)}$ material are poorly understood, although long conjugation lengths and low HOMO–LUMO gaps both appear to be important.[1] Porphyrins are appealing units from which to build high $\chi^{(3)}$ materials because of their large polarizable π systems. Here we report the synthesis of a conjugated porphyrin polymer (**1**), which exhibits an unusually high susceptibility $\chi^{(3)}$, as revealed by its electroabsorption (Stark effect) spectrum, which is much more intense than those of model compounds such as the dimer **2** and the monomer **3**.

Compound **1** is the first soluble conjugated porphyrin polymer. Edge-fused conjugated porphyrin oligomers, and an insoluble polymer, have previously been synthesized.[2] Coordination polymers have also been investigated[3] in which the metalloporphyrins are linked face-to-face; these exhibit much less intermacrocycle electronic coupling than polymer **1**, in which the π systems are edge-to-edge. Compound **1** was synthesized by Glaser–Hay coupling of the *meso*-diethynyl zinc porphyrin **4**.[4] Hay's coupling conditions were originally developed for polymer synthesis[5] and have previously been used to prepare high molecular weight conjugated polymers from simple heterocycles.[6] The polymer **1** is extremely soluble in chlorinated solvents in the presence of a ligand such as pyridine which can coordinate to the zinc sites. Solutions of the polymer are viscous, which broadens the NMR signals; at 100 °C the ^{1}H NMR line widths (in $C_2D_2Cl_4/C_5D_5N$) are around 65 Hz, but the expected features are evident, including a signal at $\delta = 10.1$ characteristic for the *meso* protons. The ^{13}C NMR spectrum shows sharp signals for the mobile sidechain carbon atoms (ca. 3 Hz line width), and broader signals for the pyrrole ring, the ring methyl and the propanoate methylene groups (ca. 30 Hz); the acetylene and *meso* carbon atoms on the backbone of the polymer are even broader (ca. 50 Hz) and are difficult to identify. The similarity between the chemical shifts for the polymer and those of model compounds, **2** and **3**, supports the proposed structure. The NMR line widths and the high intrinsic viscosity ($[\eta] = 180 \pm 10$ mL g^{-1})[7] are consistent with a polymeric structure. The presence of the butadiyne link is demonstrated by a band at 2120 cm^{-1} in the IR spectrum. Neither in the IR nor in the NMR spectrum are any signals from acetylene end-groups detected, which indicates a degree of polymerization greater than 10.[8]

Simple porphyrins, such as zinc octaethylporphyrin (ZnOEP), show two $\pi-\pi^*$ absorption bands: a Soret, or B, band at about 400 nm and a weaker Q band at about 600 nm.[9] The absorption spectrum of the polymer **1** in solution is compared with those of the dimer **2** and the monomer **4** in Figure 1. As the conjugation

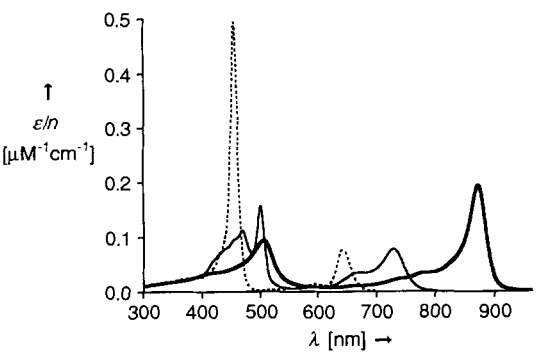

Fig. 1. Absorption spectra of **1** (bold), **2**, and **4** (dashed) in 1% pyridine/dichloromethane (extinction coefficient per porphyrin unit).

length is increased there is a dramatic red shift and intensification of the Q band; in the polymer this is the most intense peak and occurs in the infra red region. Even the Q band of the bisacetylenic monomer **4** is red shifted and intensified when compared with that of ZnOEP. This can be seen from the dipole strengths[10] per porphyrin unit and band energies in Table 1.

Table 1. Transition dipole strengths and energies for porphyrin B and Q bands [a].

Porphyrin	μ_B^2 [D^2]	μ_Q^2 [D^2]	E_B [eV]	E_Q [eV]
ZnOEP	83	10	3.0	2.3, 2.1
4	106	14	2.9	2.1, 2.0
3	142	32	2.7	2.2, 1.9
2	123	58	2.6, 2.5	1.7
1	102	100	2.5	1.4

[a] All spectra were recorded in 1% pyridine/dichloromethane at 25 °C.

The Soret dipole strengths, μ_B^2, are fairly constant, although they increase with the conjugation length per porphyrin, in the order ZnOEP < **4** ≈ **1** < **2** < **3**. In contrast, the Q dipole strengths μ_Q^2 increase with the total conjugation length of the molecule in the order ZnOEP < **4** < **3** < **2** < **1**. The energy of the Q band, and to a lesser extent the B band, decreases as the total conjugation length increases. The low Q band intensity of simple porphyrins is a consequence of accidental degeneracy between the two highest occupied π orbitals $3a_{2u}$ and $1a_{1u}$.[9] In **1** the Q and B bands have similar dipole strength, so this degeneracy must have been removed, which is not surprising because the $3a_{2u}$ orbital has large coefficients at the *meso* carbon atoms whereas the $1a_{1u}$ orbitals has nodes at these positions. However, the total dipole strength of **1** per porphyrin ($\mu_B^2 + \mu_Q^2$) is more than twice that of ZnOEP, indicating that the electronic structure of **1** is too different from that of a simple porphyrin for it to be treated as a slight perturbation of the "four-orbital" model.

The electronic structure of **1** was also investigated by using electroabsorption spectroscopy. This is a useful technique for probing the details of electronic transitions and determining the spectral dependence of the quadratic electrooptic susceptibility $\chi^{(3)}(-\omega;0,0,\omega)$[11-13] which can be related to the nonlinear refractive index n_2, the response of importance in optical switching. In probing electronic spectra the technique allows identification of charge transfer bands,[14,15] discrimination between exciton and band-to-band transitions, and, through its symmetry breaking effect, allows the observation of dipole-forbidden transitions to states of the same parity as the ground state. Electroabsorption spectra show the change in absorbance of a sample in response to a sinusoidal electric field of frequency f (in this work 5 kHz, 10–100 kVcm^{-1}). Centrosymmetric materials give no linear response at the incident frequency f, but only a quadratic response at the second harmonic $2f$.

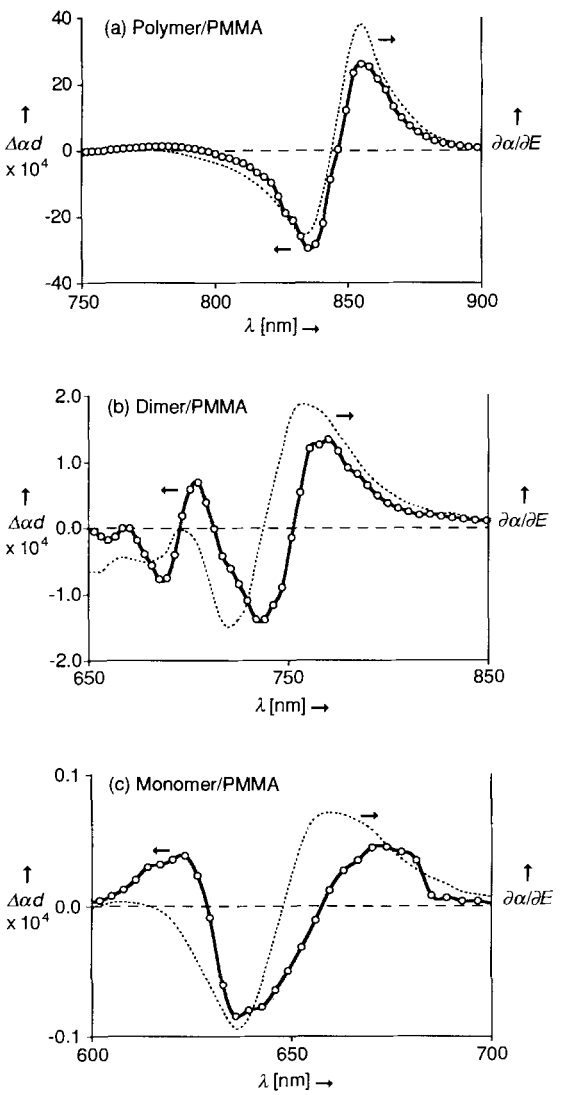

Fig. 2. Electroabsorption spectra ($\Delta\alpha d$, bold) and the first derivative absorption spectra ($\delta\alpha/\delta E$) of (a) **1**, (b) **2** and (c) **3** as thin films of 10% porphyrin/PMMA (all scaled to 35 kVcm^{-1} field strength; **1** and **2** are at 77 K, **3** is at 300 K).

The electroabsorption spectra of the polymer **1**, the dimer **2**, and the monomer **3** are compared with the first derivatives of their absorption spectra, $\delta\alpha/\delta E$, in Figure 2 ($\Delta\alpha$ is the field-induced change in absorption, d is the film thickness). These spectra were recorded on solutions of the porphyrins in polymethylmethacrylate (10% porphyrin/PMMA, spun cast from solution in 10% $C_5H_5N/CHCl_3$). All films gave $2f$ responses proportional to the square of the electric field strength, but the shapes of the spectra were field-independent. The polymer **1** gave a strong response closely resembling $\delta\alpha/\delta E$, which shows that the absorption is due to neutral localized excitons, whereas the monomer **3** gave a much weaker response resembling the second derivative of its absorption spectrum, $\delta^2\alpha/\delta E^2$, implying that its transitions have more charge transfer character.[14] The magnitude of the electrooptic response decreases with decreasing conjugation length in the order **1** > **2** > **3**.

High-quality thin films of the pure polymer are readily cast from solution. The electroabsorption spectra of these films are similar to those of **1** in PMMA, but they are more readily transformed into quadratic electrooptic susceptibilities.[16] The real and imaginary components of $\chi^{(3)}(-\omega;0,0,\omega)$ calculated[11] from these spectra are plotted in Figure 3. The peak resonant

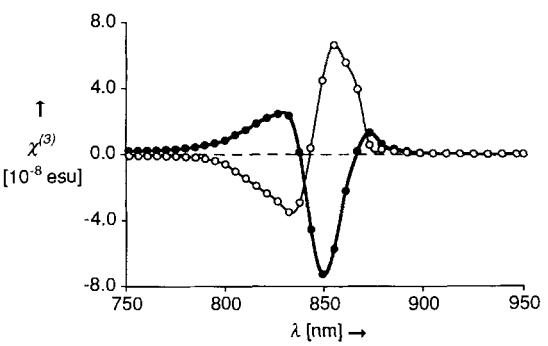

Fig. 3. Real (bold) and imaginary $\chi^{(3)}(-\omega;0,0,\omega)$ spectra of pure **1** calculated from the electroabsorption spectra (35 kVcm^{-1}, 77 K, 800 Å thick, spun coated on spectrosil from a 1% solution in 10% $C_5H_5N/CHCl_3$).

$\chi^{(3)}(-\omega;0,0,\omega)$ of **1**, (7.3×10^{-8} esu) compares favorably with those of other conjugated polymers such as polyacetylene (2.5×10^{-8} esu),[12] polydiacetylene (2×10^{-8} esu),[13] and polythienylenevinylene (7×10^{-9} esu).[11,17] The high near-IR $\chi^{(3)}$ of this new type of conjugated polymer opens the way for the development of a new class of material for nonlinear optics applications.

Experimental Procedure

1: A solution of **4** (400 mg, 0.3 mmol) in dichloromethane (400 mL) was vigorously stirred with CuCl (2.4 g, 24 mmol) and *N,N,N',N'*-tetramethylethylenediamine (TMEDA) (3.4 mL, 22 mmol) under dry air. The green solution became brown and viscous, and no unreacted **4** could be detected by TLC after 5 min. After 30 min the mixture was washed with water (3 × 500 mL) and passed through a silica flash column, eluting with 1% pyridine/dichloromethane to remove baseline contaminants. The eluate was centrifuged (2.2 kG, 2 × 20 min) to remove colloidal copper salts, then treated with methanol (20 mL) to precipitate the polymer. The product was isolated by centrifugation (2.2 kG, 20 min), washed with methanol and diethyl ether, and dried in vacuo to yield 230 mg (58%) of a leathery lustrous green solid. m.p. > 300 °C; ^{1}H NMR (400 MHz, $C_2D_2Cl_4/C_5D_5N$, 100 °C): δ = 0.8–1.5 (76 H), 3.3 (8 H), 4.1–4.5 (28 H), 10.1 (2 H); ^{13}C NMR (100 MHz, $C_2D_2Cl_4/C_5D_5N$, 100 °C): δ = 16.6, 19.3, 21.9, 22.2, 24.2, 27.5, 30.0, 35.6, 37.0, 37.2, 39.0, 63.1, 81.2 (v br), 92.8, (v br) 99.5 (v br), 138.0, 141.3, 145.5, 151.1, 172.6; IR (1% C_5H_5N/CCl_4): $\tilde{\nu}$[cm^{-1}] = 2120 (C≡C), 1730 (C=O); UV/VIS (1% C_5H_5N/CH_2Cl_2): λ_{max} [nm] (log ε) = 505 (4.97), 873 (5.29); correct C, H, N analysis for $C_{80}H_{114}N_4O_8Zn$. Electroabsorption spectra were recorded and transformed into $\chi^{(3)}$ spectra as described previously [11].

[16] We have not yet calculated $\chi^{(3)}(-\omega;0,0,\omega)$ for the porphyrin/PMMA films because the algorithm we use to compute linear optical constants, by iterative Kramers–Kronig analysis of the transmission data, does not converge well when the absorption per unit thickness is small.
[17] The $\chi^{(3)}$ values reported for most porphyrins are less than 10^{-10} esu; a few give $\chi^{(3)}(-\omega;\omega,\omega,-\omega)$ of up to 10^{-7} esu (A. Grund, A. Kaltbeitzet, A. Mathy, R. Schwarz, Ç. Bubeck, P. Vermehren, M. Hanack, *J. Phys. Chem.* **1992**, **96**, 7450–7454), but for a given material these three-photon resonant $\chi^{(3)}(-\omega;\omega,\omega,-\omega)$ values are expected to be much larger than one-photon resonant $\chi^{(3)}(-\omega;0,0,\omega)$ values (A. Willetts, J. E. Rice, D. M. Burland, D. P. Shelton, *J. Chem. Phys.* **1992**, *97*, 7590–7599).

Hydroxylamine, Hydrazine, and Diazene as Unidentate Ligands in Osmium and Ruthenium Complexes**

Tan-Yun Cheng, Adrian Ponce, Arnold L. Rheingold, and Gregory L. Hillhouse*

Diazene NH=NH is one of the most reactive of the nitrogen hydrides, undergoing disproportionation at −150 °C in the condensed phase to N_2 and N_2H_4.[1] Nevertheless, it is a molecule of fundamental importance, useful as a reagent in stereoselective *cis* hydrogenation of unsaturated organic compounds, and of possible relevance to inorganic and bioinorganic N_2-reduction processes.[2] The stability of diazene is greatly enhanced in solution, especially in liquid ammonia,[3] and by coordination to transition metals (usually in a bimetallic fashion through both nitrogen lone pairs).[4] Herein we report the syntheses of new diazene complexes of Ru and Os, including the first structural characterizations of complexes containing η^1-coordinated H_2NNH_2 and HN=NH ligands.

The hydrido complexes **1a** and **1b** react with trifluoromethanesulfonic acid (triflic acid) to give H_2 and the corresponding trifluoromethanesulfonato complexes **2a** ($\tilde{\nu}$(CO) = 2071, 2006; $\tilde{\nu}(OSO_2CF_3)$ = 1329 cm^{-1}) and **2b** ($\tilde{\nu}$(CO) = 2054, 1985; $\tilde{\nu}(OSO_2CF_3)$ = 1335 cm^{-1}). Hydroxylamine and hydrazine displace the triflate ligands in these complexes to afford the salts **3**

and **4**, in which hydroxylamine and hydrazine, respectively, coordinate in a unidentate fashion to the metal center through one of the nitrgen atoms. The spectroscopic data of the complexes are summarized in Table 1. The hydrazine complexes **4** can be oxidized with $Pb(OAc)_4$ at low temperature to give the stable diazene complexes **5**. The complexes **5** exhibit lowfield ($\delta = 17-15$) ABX_2 patterns in their ^1H NMR spectra characteristic of the diazene protons of unidentate *trans*-HN=NH ligands coupled to two equivalent ^{31}P atoms.[5] This synthetic protocol is analogous to that used to prepare the related diazene complex $[W(HN{=}NH)(CO)_2(NO)(PPh_3)_2][SO_3CF_3]$ which we recently reported.[5] We have not yet been successful in isolating stable complex cations containing nitrosyl hydride ligands (M←NH=O) from the analogous oxidation of **3a** or **3b**, although a similar neutral Os complex with this ligand, $[Os(Cl)_2(CO)(NH{=}O)(PPh_3)_2]$ (**6**), is known.[6]

The molecular structures of **4b** and **5b** have been determined by X-ray diffraction analyses and are interesting because they allow for comparison of hydrazine (**4b**) and diazene (**5b**) ligands in identical coordination environments.[7] Both complex cations are pseudooctahedral with *cis* carbonyl and *trans* phosphane ligands. The Os–N (2.181(3) Å) and N–N (1.451(7) Å) bonds in **4b** are in the normal range for single bonds (Fig. 1); the Os-N-N angle (119.3(3)°) is somewhat opened from the tetrahedral value.[8]

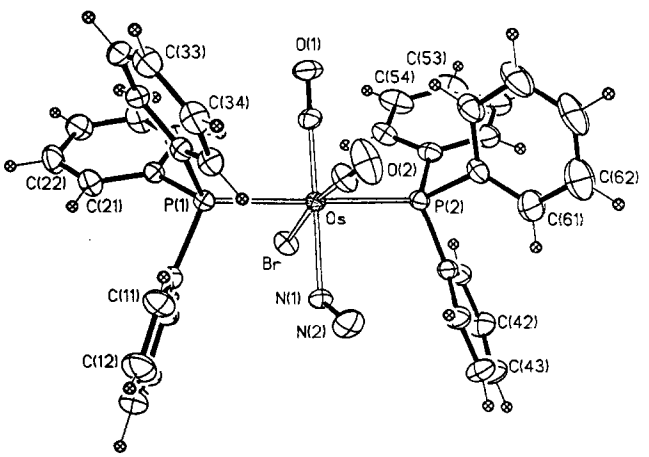

Fig. 1. A perspective view of the complex cation of **4b**.

The most significant structural feature of **5b** (Fig. 2) is the unambiguously characterized unidentate *trans*-HN=NH ligand coordinated to the Os atom. The positions of the H atoms of the diazene were located and refined.[9] The N–N (1.166(17) Å) bond length in **5b** is short, but it is within experimental error of that expected for a N=N bond. The Os–N (2.118(12) Å) bond length is shorter than that in **4b**, consistent with the smaller covalent radius for the sp^2-hybridized N atom in diazene compared to the sp^3-hybridized N atom in hydrazine. The Os-N-N angle (135.9(10)°) in **5b** is significantly more obtuse than the idealized 120° trigonal value. A comparison of the metrical parameters of the diazene ligand of **5b** with those of the isoelectronic HN=O ligand in **6** (in which the nitrosyl hydride ligand is also unidentate) reveals striking similarities: in **6**, N–O 1.193(7), Os–N 1.915(6) Å, and ∢ Os-N-O 136.9(6)°.[6]

It is noteworthy that while monosubstituted diazenes usually coordinate to metals as *cis*-NH=NR ligands,[10] complexes of the parent diazene show only *trans*-HN=NH ligation. With several complexes containing diazene ligands coordinated in a unidentate fashion now in hand, we are currently exploring the reaction chemistry of these molecules.

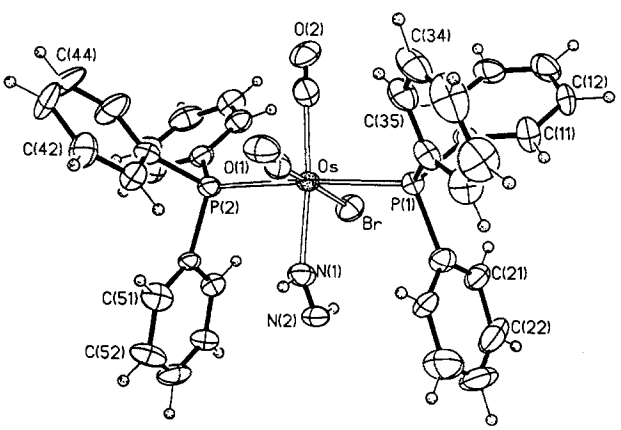

Fig. 2. A perspective view of the complex cation of **5b**.

Experimental Procedure

All reactions were carried out under argon using dry, air-free solvents.

2b: To a stirred solution of **1b** (1.00 g, 1.17 mmol) [11] in CH_2Cl_2 (35 mL) was added $HOSO_2CF_3$ (0.11 mL). When gas evolution ceased, the solvent volume was reduced and Et_2O was added to precipitate 0.88 g (75% yield) of **2b** as white crystals. **2a** was prepared analogously in 70% yield from **1a**.

3b: To a stirred solution of **2b** (0.15 g, 0.15 mmol) in CH_2Cl_2 (10 mL) was added NH_2OH (0.025 g, 0.75 mmol) [12]. The solution was stirred for 15 min, additional NH_2OH (0.025 g) was then added, and stirring was continued for 10 min. The reaction mixture was filtered through Celite, the volume of the filtrate was reduced, and Et_2O was added to precipitate 0.077 g (50% yield) of **3b** as a white powder. **3a** was prepared analogously in 90% yield from **2a**.

4b: To a solution of **2b** (0.50 g, 0.50 mmol) in CH_2Cl_2 (30 mL) was added 98% NH_2NH_2 (1.24 mL, 0.75 mmol). The solution was stirred for 15 min, additional NH_2NH_2 (0.5 mL) was then added, and stirring was continued for 15 min. The solution was filtered, the solvent volume was reduced, and Et_2O was added to precipitate 0.41 g (80% yield) of **4b** as a white powder. **4a** was prepared analogously in 90% yield from **2a**.

5b: A sample of **4b** (0.10 g, 0.10 mmol) was placed in a two-necked 25 mL flask fitted with a solids–addition sidearm containing $Pb(OAc)_4$ (0.05 g, 0.12 mmol). The system was evacuated, $CHCl_3$ (5 mL) was vacuum transferred at −40 °C into the flask, and the $Pb(OAc)_4$ was added portionwise to the cold, stirred solution. After 10 min, the solvent was removed under vacuum, and the residue was extracted with CH_2Cl_2 (10 mL). The solution was filtered, the solvent volume was reduced, and petroleum ether was added to precipitate 0.064 g (64% yield) of **5b** as a pale yellow

powder. **5a** was prepared analogously in 40% yield from **4a**, except that the reaction temperature was maintained at −78 °C.

Stable Germirane Derivatives**

Wataru Ando,* Harunobu Ohgaki, and Yoshio Kabe

1,2-Additions of carbene analogues of the heavier group 14 elements with alkenes and alkynes have been used for the synthesis of the corresponding three-membered metallacycles.[1] Germirane (germacyclopropane) has been proposed to exist as an intermediate in reactions of germanediyls ("germylenes") with alkenes, dienes, and enones, but they have never been isolated.[2] Neumann et al.[2e] proposed a germirane or germylene–olefin complex as a intermediate in the reaction of dimethylgermylene with styrene, which resulted in the formation of a germacyclopentane. Several other approaches for the preparation of germiranes have been unsuccessful, for example, reductive elimination of bromine from di(bromomethyl)germanes by Seyferth et al.,[2d] CH insertion of germylcarbenes by M. Jones, Jr. et al.,[2c] and extrusion of N_2 from a germapyrazoline from Nefedov, Krebs, et al.[2f] and Satge et al.[2g,h] In every case only olefins and polygermanes were detected. These experimental results were supported by recent ab initio calculations which indicated that germiranes are the most likely of the group 14 metallacycles to undergo cycloelimination.[3] Herein we describe the reactions of the stable germylene **1**[4] with 2,5-dimethyl-2,3,4-hexatriene ("tetramethylbutatriene" **2**) and *N*-phenylmaleimide (**5**) which yield the first isolable germirane derivatives, bis(alkylidene)germirane **3** and bicyclic germirane **8** (Scheme 1), which were characterized by X-ray crystallography.

Scheme 1. R = $(Me_3Si)_2CH$.

Our first approach was the construction of a germirane with two alkylidene substituents. Tetramethylbutatriene **2** was thought to be a suitable electron-rich triene for the introduction of *exo*-alkylidene moieties to germirane. Similar reactions have been successful in the preparation of bis(alkylidene)silirane.[1h] Thus when a yellow solution of **1** in benzene was treated with tetramethylbutatriene **2**, immediate decolorization was observed and **3** was isolated from the reaction mixture in 33% yield. The

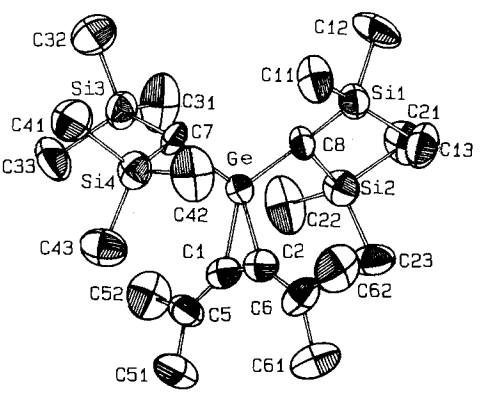

Fig. 1. Crystal structure of **3** (ORTEP). Selected bond lengths [Å] and angles [°]: Ge-C(1) 1.95(1), Ge-C(2) 1.96(1), Ge-C(7) 1.95(9), Ge-C(8) 1.99(1), C(1)-C(2) 1.46(2), C(1)-C(5) 1.34(2), C(2)-C(6) 1.33; C(1)-Ge-C(2) 44.0(5), Ge-C(1)-C(2) 68.3(7), Ge-C(2)-C(1) 67.7(7), Ge-C(1)-C(5) 148(1), Ge-C(2)-C(6) 146(1), C(1)-C(2)-C(6) 140(1), C(2)-C(1)-C(5) 138(1).

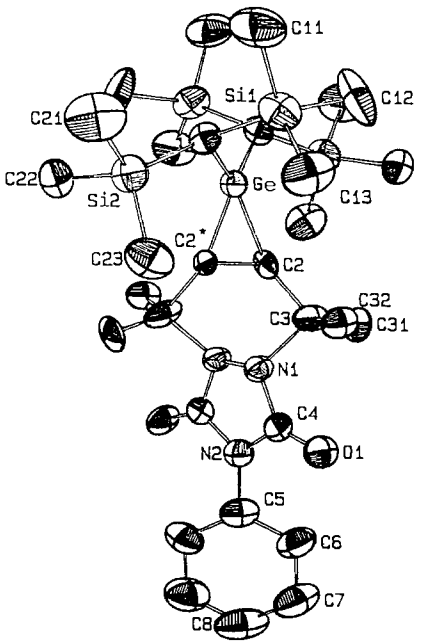
[**] This work was supported by a Grant-in-Aid for Scientific Research for Ministry of Education, Science and Culture of Japan. The authors are greatful to Asai Germanium Institute, Shin-Etsu Co. Ltd., and Tosoh Akzo Corp. for generous gifts of trichlorogermane, chlorosilanes, and alkyllithium.

^{1}H NMR spectra of compound **3** exhibit one signal for the $SiMe_3$ groups and two signals for the alkylidene CH_3 groups, which indicates that the molecule has C_{2v} symmetry.[5] Conclusive evidence for **3** was obtained by X-ray analysis (Fig. 1).[6] Compound **3** underwent [4 + 2] cycloaddition with 4-phenyl-1,2,4-triazoline-3,5-dione (TAD, **4**) to afford the tricyclic germirene **5**[5] in 48% yield; this compound was also characterized by X-ray structure analysis (Fig. 2).[6] On hydrolysis of **3** the



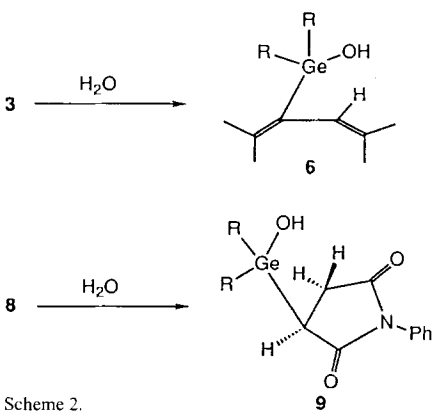


Fig. 2. Crystal stucture of **5** (ORTEP). The molecule has C_2 symmetry; the twofold axis passes through Ge, N(2), C(5), and C(8). Selected bond lengths [Å] and angles [°]: Ge-C(1) 1.93(1), Ge-C(2) 1.88(1), C(2)-C(2)* 1.39(1), C(2)-C(3) 1.55(1); C(2)-Ge-C(2)* 43.2(2), Ge-C(2)-C(2)* 68.4(2), Ge-C(2)-C(3) 161.4(7).

Ge–C bond was cleaved to give the corresponding germanol **6** quantitatively (Scheme 2).[5]

Scheme 2.

Dialkylgermylenes such as **1** are known to undergo [4+1] cycloadditions with acyclic electron-deficient enones.[2a] Since this reaction is not possible for cyclic enediones such as *N*-phenylmaleimide (**7**), one might expect a [2 + 1] cycloaddition of germylene to a C–C double bond. Indeed after treatment of *N*-phenylmaleimide (**7**) with **1** in benzene, the bicyclic germirane **8** was isolated (Scheme 1) as moderately air- and moisture-sensitive colorless crystals in 78% yield and purified by repeated recrystallization from hexane. The most characteristic signals in the ^{1}H and ^{13}C NMR spectra of **8** are sets of resonances for the germirane protons and carbon atoms at $\delta = 2.70$ and 29.4, respectively.[5] The two signals each for the CH and Me_3Si groups of the $(Me_3Si)_2CH$ substituents are consistent with the C_s molecular symmetry of **8**.[5] Hydrolysis of **8** yielded germanol **9** quantitatively (Scheme 2), which exhibits four resonances for the Me_3Si groups and three doublet of doublets for the CH and CH_2 protons in the five-membered ring.[5]

The X-ray structure analysis of **8** (Fig. 3)[6] was hampered by the small data set, which was caused by decomposition of the crystal in the X-ray beam and the existence of two independent molecules. Nevertheless, it is evident that the average Ge–C and

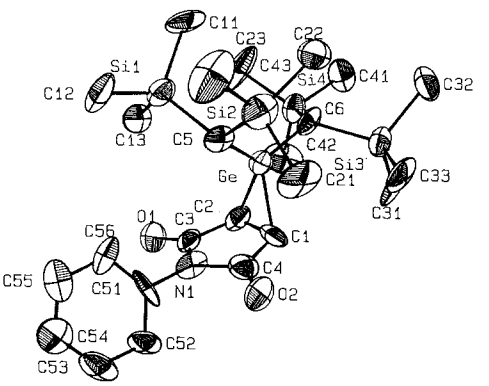

Fig. 3. Crystal structure of **8** (ORTEP). Since two independent molecules are present in the asymmetric unit, the following bond lengths [Å] and angles [°] are given in pairs: Ge-C(1) 1.92(2)/1.97(2), Ge-C(2) 1.98(2)/2.07(2), Ge-C(5) 1.90(2)/1.99(2), Ge-C(6) 1.90(2)/1.93(2), C(1)-C(2) 1.51(3)/1.62(3), C(1)-C(4) 1.42(3)/1.46(3), C(2)-C(3) 1.46(3)/1.55(3); C(1)-Ge-C(2) 45.0(8)/47.7(8), Ge-C(1)-C(2) 68(1)/71(1), C(5)-Ge-C(6) 126.5(8)/123.5(7), Ge-C(2)-C(1) 61.4(9)/67(1), Ge-C(1)-C(4) 115(1)/118(1), Ge-C2-C3 111(2)/113(1), C(1)-C(2)-C(3) 102(1)/104(2), C(2)-C(1)-C(4) 104(1)/107(2).

C–C bond lengths of 1.99 Å and 1.56 Å, respectively, fall within the range of normal Ge–C (1.96–2.01 Å) and C–C (1.44–1.54 Å) separations. Furthermore, among the germirane and germirene derivatives **3**, **5**, and **8** the C-Ge-C bond angles as well as C–C bond lengths decrease in the order **8** (averaged values for two molecules 46.3°, 1.56 Å), **3** (44.0°, 1.46 Å), and **5** (43.2°, 1.387 Å). The smallest values (40.5°, 1.33 Å) were observed for a germirene isolated by Krebs et al. and Nefedov et al.[1m,n] Of particular interest is that the ring Ge–C bond lengths of **3** (1.95 Å) and **5** (1.88 Å) are, as predicted, shorter than those of **8** (averaged values for two molecules 1.99 Å). This observation implies that these unsaturated ring systems are somewhat stabilized by delocalization.

Now that the first germiranes **3** and **8** have been isolated and characterized, the higher homologues, stanniranes (stannacyclopropanes), should be of great interest.

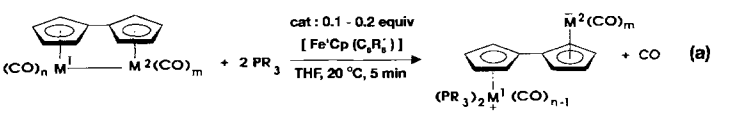
In the COLOC spectra of **6** olefinic CH and the neighboring quaternary carbons ($\delta = 126.9$ and $\delta = 134.0$, respectively) show cross peaks to two CH_3 protons ($\delta = 1.55$, 1.79), while the other olefinic quaternary carbons ($\delta = 138.1$, 141.7) correlated with two other CH_3 protons ($\delta = 1.64$, 1.98). – **8**: Colorless crystals; decomp. 108.7 °C; ^{1}H NMR (400 MHz, C_6D_6): $\delta = -0.03$ (s, 1H), 0.07 (s, 1H), 0.15 (s, 18H), 0.24 (s, 18H), 2.70 (d, 2H), 7.05 (t, 1H), 7.27 (t, 2H), 7.8 (d, 2H); ^{13}C NMR (100 MHz, C_6D_6): $\delta = 3.1$ (q), 3.5 (q), 3.7 (d), 7.1 (d), 29.4 (d), 126.3 (d), 127.3 (d), 128.3 (s), 128.8 (d), 173.9 (s); MS: *m/z*: 565 (M^+), 550 ($M^+ - Me$). – **9**: Colorless powder; ^{1}H NMR (400 MHz, C_6D_6): $\delta = 0.02$ (s, 1H), 0.14 (s, 9H), 0.22 (s, 9H), 0.26 (s, 9H), 0.36 (s, 9H), 0.45 (s, 1H), 2.32 (s, 1H), 2.72 (dd, 1H, $J_{AB} = 10.1$ Hz, $J_{BC} = 17.7$ Hz), 2.81 (dd, 1H, $J_{AB} = 10.1$ Hz, $J_{AC} = 4.90$ Hz), 2.93 (dd, 1H, $J_{AC} = 4.90$ Hz, $J_{BC} = 17.7$ Hz), 7.05 (t, 1H), 7.22 (t, 2H), 7.53 (d, 2H); ^{13}C NMR (100 MHz, C_6D_6): $\delta = 3.3$ (q), 3.5 (q), 3.6 (q), 3.8 (q), 9.5 (d), 11.6 (d), 32.3 (t), 34.9 (d), 126.5 (d), 128.2 (d), 128.9 (d), 133.0 (s), 175.0 (s), 178.6 (s); MS: *m/z*: 583 (M^+), 568 ($M^+ - Me$); HRMS: calcd. for $C_{24}H_{47}O_3NSi_4{}^{74}Ge$ 583.1844, found 583.1844. In the C-H COSY spectra of **9** the signal for the CH_2 carbon ($\delta = 32.3$) shows cross peaks to H^B ($\delta = 2.72$) and H^C ($\delta = 2.93$). The *J* values of H^A (2.81 Hz), H^B, and H^C establish the proton connectivities and the *trans* relationship between H^A and H^C. The four Me_3Si signals in the ^{1}H and ^{13}C NMR spectra of **9** are assigned to the two diastereotopic $(Me_3Si)_2CH$ groups, since the carbon attached to germyl substituent is chiral and each Me_3Si group is also diastereotopic due to the unsymmetrically substituted germanium.



[6] Crystal data: **3**: $C_{22}H_{50}GeSi_4$, $M_r = 499.6$, triclinic with $a = 9.217(6)$, $b = 11.384(8)$, $c = 15.861(9)$ Å, $\alpha = 76.60(4)$, $\beta = 87.33(4)$, $\gamma = 72.78(5)°$, $V = 1545.9$ Å^3, space group *P*-1, $Z = 2$, $\mu(Mo_{K\alpha}) = 11.4$ cm^{-1}, $\varrho_{calcd} = 1.15$ g cm^{-3}. **5**: $C_{30}H_{55}GeSi_4N_3O_2$, $M_r = 674.73$, orthorhombic with $a = 15.157(1)$, $b = 15.546(1)$, $c = 16.059(1)$ Å, $V = 3784.1$ Å^3, space group *Pbcn*, $Z = 4$, $\mu(Mo_{K\alpha}) = 9.5$ cm^{-1}, $\varrho_{calcd} = 1.189$ cm^{-3}. **8**: $C_{29}H_{45}NO_2Si_4Ge$, $M_r = 624.62$, triclinic with $a = 9.454(1)$, $b = 15.905(3)$, $c = 21.086(4)$ Å, $\alpha = 87.50(2)$, $\beta = 79.04(1)$, $\gamma = 88.90(1)°$, $V = 3109.8$ Å^3, space group *P*-1, $Z = 4$, $\mu(Mo_{K\alpha}) = 11.5$ cm^{-1}, $\varrho_{calcd} = 1.33$ g cm^{-3}. The 2175 (**3**), 1411 (**5**), and 2637 (**8**) independent reflections [$2\theta \leq 50°$; $|F_o 2| > 3\sigma|F_o 2|$] were measured on an Enraf–Nonius CAD4 diffractometer using $Mo_{K\alpha}$ irradiation and ω-2θ scan. An empirical absorption correction based on a series of Ψ-scans were applied to the data (0.82/1.00 for **3**; 0.92/1.00 for **5**; 0.863/0.999 for **8**). The structures were solved by direct methods, and all non-hydrogen atoms were refined anisotropically to $R = 0.065$ ($R_w = 0.076$), $R = 0.066$ ($R_w = 0.077$) and $R = 0.066$ ($R_w = 0.081$) for **3**, **5**, and **8**, respectively. Electron-Reservoir Complexes [Fe^{I}Cp(arene)] as Selective Initiators for a Novel Electron Transfer Chain Catalyzed Reaction: General Synthesis of Fulvalene-Bridged Homo- and Heterodinuclear Zwitterions**

David S. Brown, Marie-Hélène Delville-Desbois, Roland Boese, K. Peter C. Vollhardt,* and Didier Astruc*

Dedicated to Professor Henri Bouas-Laurent on the occasion of his 60th birthday

Many non-redox reactions proceed by the electron-transfer chain (ETC) mechanism.[1, 2] We now report ETC catalysis of a redox reaction, the intramolecular disproportionation of dinuclear fulvalene carbonyl complexes in the presence of PR_3 (R = Me, OMe).[3] The result is the cleavage of the metal–metal bond, replacement of one CO by two PR_3 ligands at a single metal center, and intramolecular electron transfer [Eq. (a); R′ = H, Me in the Fe catalyst]. The starting materials and products are listed in Table 1.

(a)

Table 1. Summary of the starting materials and products for reaction (a).

Starting material	Product	M^1	M^2	*n*	*m*	R
1	**2**	Mo	Mo	3	3	Me
3	**4**	W	W	3	3	Me
5	**6**	Fe	W	2	3	OMe
5	**8**	Fe	W	2	3	Me
9	**10**	Ru	Mo	2	3	Me
11	**13**	Ru	W	2	3	Me

Electron-reservoir complexes [Fe^{I}Cp(C_6R_6)],[4] the most electron-rich, stable neutral compounds known (based on ionization potential values[5b]), are ideal mediators allowing reduction at very negative potentials ($E^0 = -1.3$ to -1.9 V vs. SCE).[5] They can be used in precise amounts, and their redox potentials

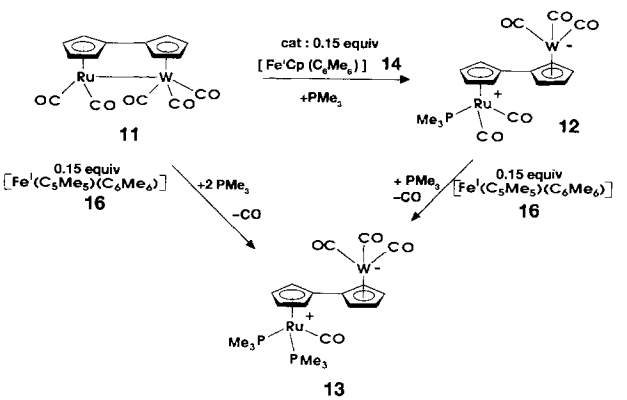
[**] This work was supported by the University of California at Berkeley and the Université Bordeaux I, the Centre National de la Recherche Scientifique (CNRS), the Région Aquitaine, the National Science Foundation (NSF), NATO (CRG 900479), and the Director of the Office of Energy Research, Office of Basic Energy Sciences, Materials Science Division of the US Department of Energy (DE-AC-03 76SF00098).

$E^0_{Fe^I/Fe^{II}}$ can be adjusted by the choice of the ring substituents, which provides selectivity, as will be shown here.[5]

With these Fe^I initiators, the ETC-catalyzed synthesis of fulvalene-bridged homo- and heterobimetallic zwitterions proceeds very smoothly (20 °C, a few minutes) in good yields. The ready synthesis of organometallic zwitterions bridged by a ligand and with a delocalized π-electron system has potential, for instance, for the preparation of materials with nonlinear optical properties.[6] Some of the zwitterions could be synthesized thermally, but the reactions needed heating for days, gave low yields, and required decomplexation of one metal center.[7]



The respective prototypical homodinuclear Mo and W fulvalene carbonyl complexes **1** and **3**[8] react with excess PMe_3 in THF in the presence of 0.1–0.2 equiv $[Fe^ICp(C_6Me_6)]$ (**14**) ($E^0 = -1.55$ V vs. SCE, in dimethylformamide (DMF)) to give the zwitterions **2** (60%) and **4** (70%), respectively, in a few minutes at 20 °C. Monophosphane zwitterions are not detected.

For the heterobimetallic FeW complex **5**,[8] we know that reduction differentiates the two metal centers (recognition), since two distinct one-electron waves were found (W reduction at −1.05 V vs. SCE, Fe reduction at −1.6 V vs. SCE, in THF).[9] Thus, single-electron reduction of **5** provides the radical anion $Fe^{\bullet}W^-$, and the ligand-exchange reactions with PR_3 (R = Me, OMe) proceed at the radical iron center in the chain propagation step. ETC catalysis can be initiated by either **14** or $[Fe^ICp(C_6H_6)]$ (**15**) ($E^0 = -1.30$ V vs. SCE, in DMF), owing to an exergonic electron transfer in the initiation step ($\Delta G^0 < -24$ kJ mol^{-1} with **15**). Not unexpectedly, cobaltocene proved an inefficient initiator, since its E^0 value (−0.9 V vs. SCE) is too low.[10] Complex **7** undergoes (like **5**) ETC reaction initiated with **14** to give zwitterions **6** and **8** [Eq. (b); R′ = H, Me in the Fe catalyst]. Only the bis-PMe_3 complex **8** forms upon reaction with PMe_3, which indicates that PMe_3 displaces $P(OMe)_3$ during the ETC reaction.

Of particular interest is the RuW complex **11**, since differentiation between the two metal centers is not observed by cyclic voltammetry; instead an irreversible two-electron reduction to the dianion $[Fv\{W(CO)_3^-\}\{Ru(CO)_2^-\}]$ occurs.[9] The ETC reaction, however, does differentiate between the two metal centers, since two PMe_3 ligands are bound regiospecifically at the Ru center [Eq. (a)]. ETC-catalyzed syntheses provide either the monophosphane zwitterion **12** (the only one in the series) or the diphosphane zwitterion **13**, depending on the reductive power of the electron-reservoir complex. Using **14** as the initiator specifically leads to **12**, whereas the use of $[Fe^I(C_5Me_5)(C_6Me_6)]$ (**16**) ($E^0 = -1.85$ V vs. SCE in DMF) provides only **13**. Accordingly, it is also possible to synthesize **13** from **12** when **16** is used as the ETC initiator (Scheme 1).

Note that the first reaction (**11** → **12**) represents an ETC catalysis of net phosphane addition, a simple but new reaction, whereas the second (**12** → **13**) is only a classical substitution of CO by PMe_3. Despite the simplicity of ETC-catalyzed substitution reactions, there are very few reports of such a reaction for

Scheme 1. ETC reactions starting with **11**.

mononuclear complexes.[2b, 11] This is because of side reactions of the radical anion involved in the chain propagation step. The efficiency in the reactions described here is explained by the effectiveness of the fulvalene ligand as an electron sink, similar to clusters.[2a, 12] The remarkable selectivity indicates that the electron transfer between **12** and **14** is too endergonic to occur.[13] Since Cp permethylation (**14** → **16**) shifts the E^0 value of the initiator negatively by 300 mV, reduction of **11** by **16** is exergonic, thus very efficient.

The molecular structure of the zwitterions was proven by elemental analysis, high-resolution ^1H, ^{13}C, and ^{31}P NMR spectroscopy, and mass spectrometry.[14] In the case of **8**, the X-ray crystal structure[15] shows the *anti* conformation of the two metal complex fragments (Fig. 1), which is most probably common to all the zwitterions reported here. Cyclic voltammetry was used to monitor the ETC-catalyzed process by following the disappearance of the starting complexes and appearance of the zwitterions. (Details will be provided in a full paper.)

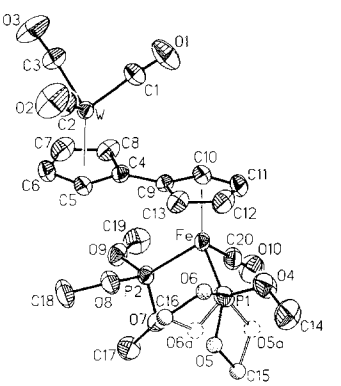


Fig. 1. Crystal structure of **8** (ORTEP).

In conclusion, we have carried out a series of ETC-catalyzed reactions providing fulvalene-bridged homo- and heteronuclear zwitterions. The selectivity, generality, and efficiency of this reaction, as well as the role of three Fe^I electron-reservoir ETC initiators, was demonstrated.

Experimental Procedure

Under inert gas a Schlenk tube was charged with the fulvalene dimetal carbonyl complex (0.1 mmol) and THF (10 mL); PR_3 (100 μL, 1 mmol) was added by syringe, followed by a solution of Fe^I complex (0.01 mmol) in dimethoxyethane. After 5 min analysis by thin-layer chromatography (silica gel, 1/1 THF/hexane) indicated that no starting material remained. The solvent was removed in vacuo. The residue was dissolved in MeCN and filtered through a plug of Celite (1 × 4 cm). The solvent was removed in vacuo and the residue recrystallized from acetone/ether at −78 °C or −30 °C.

3-Phosphonio-1,2-diphosphaindenides and the Electrophilic Substitution of *C*-Phenyl-Substituted Ylides**

Georg Jochem, Alfred Schmidpeter,* Martina Thomann, and Heinrich Nöth

A *C*-phenyl-substituted phosphonium ylide $R_3P{=}CR{-}C_6H_5$ can also be regarded as an ylide-substituted benzene. Although textbooks do not include ylides in the list of substituents affecting electrophilic aromatic substitution, indubitably they should belong to the class of rate-increasing, *o,p*-directing substituents. Indeed, CNDO calculations on compounds of this type indicate a strong perturbation of the benzene π-electron system by an ylide substituent, which is in agreement with their photoelectron spectra. In addition, upfield shifts of the ^{13}C NMR signals relative to the benzene resonance confirm the calculated charge transfer from the ylide carbon atom to the carbon atoms in the *ortho* and *para* positions.[1] To our surprise we could not find any examples of electrophilic substitution reactions at the *C*-phenyl ring of an ylide. During the preparation of *C*-chlorophosphino- and *C*-bromophosphino-ylides[2] we recently encountered an unexpected side reaction, which comprises this type of substitution. Further examples were found during model reactions to determine the reaction pathway.

The reaction of benzyltriphenylphosphonium bromide (**1**) with phosphorus trichloride or tribromide and triethylamine leads to the *C*-dihalophosphino-*C*-phenyl ylides **2**.[2] In addition, in both cases the formation of a further product, which presents a conspicuous ABC spin system in its $^{31}P\{^1H\}$ NMR spectrum, is observed and was identified as 1,2-dihalo-3-triphenylphosphoranediyl-1,2-diphosphaindane **3** (Table 1).[3] Its yield increases

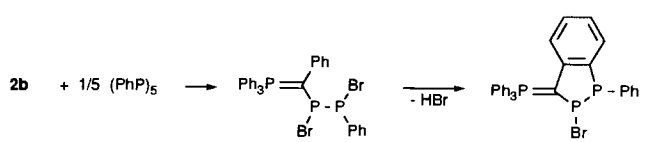
with reaction time, and for X = Br product **3** can account for up to 50% of the reacted trihalide.

The corresponding reactions of (3-methylbenzyl)triphenylphosphonium bromide (≙ **1**, with 3-$MeC_6H_4CH_2$ instead of $PhCH_2$) with PCl_3 and PBr_3 yield the isomer mixtures **3c**, **d** and **3e**, **f**, respectively, as side products (Table 1). This type of side product is not observed in analogous reactions of other phosphonium bromides of type **1**, in which the benzyl group bears a $-M$ group (NO_2) or in which both *ortho* positions have chlorine substituents.



3c X = Cl **3d**

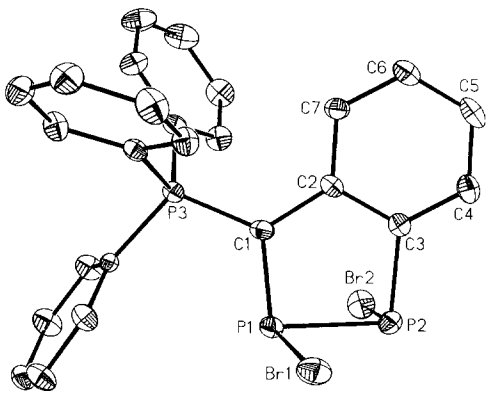
3e X = Br **3f**

Compounds **3** are most likely formed from **2** by *ortho* substitution of the phenyl ring and reduction. A second molecule of **1** acts as reductant and is transformed into the *C*-halo-substituted ylide.[4] Alternatively, added triphenylphosphane can act as reductant, whereby it is transformed into the dihalide. The first alternative was found to be more suitable for workup. To demonstrate that the formation of **3** from **1** proceeds via **2**, we showed that isolated **2b** can be transformed into **3b** in the same manner. For instance, **3b** is formed when a suspension of **2b** in benzene is simply heated to reflux for several days.

The order in which substitution and reduction occur cannot be determined unequivocally; the fact that only *ortho* substitution and no *para* substitution is observed supports an initial P–P linkage. This is expected for an intramolecular reaction but not for an intermolecular process (see below). The proposed intramolecular substitution[5] is further supported by the formation of 2-bromo-1-phenyl-3-triphenylphosphoranediyl-1,2-diphosphaindane (**5**) in the reaction of **2b** with phenyldibromophosphane, triphenylphosphane, and triethylamine, or with pentaphenylcyclopentaphosphane and triethylamine. In the second synthesis **4** is the only reasonable intermediate formed in a precedented manner from **2b** by the insertion of a phosphinidene unit into the P–Br bond.[6]

4 **5**

The values of the $^1J_{PP}$ coupling constants for **3** and **5** (Table 1) confirm the expected *trans* arrangement of the substituents on the phosphorus atoms. The unusually small shielding of P-2, especially compared to P-1, should also indicate structural differences. According to the crystal structure of **3b**,[7] the diphosphaindane backbone, including the exocyclic phosphorus atom, is essentially planar and has bromine atoms located *trans* to each other (Fig. 1). The two P–Br bonds are very different; the bond directly adjacent to the ylide carbon atom is longer (2.42 Å) than



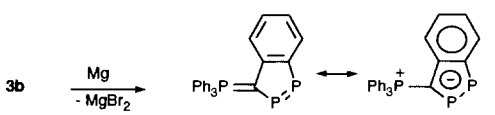


Fig. 1. Crystal structure of **3** (thermal ellipsoids with 50% probability). Selected bond lengths [Å] and angles [°]: P1-Br1 2.424(2), P2-Br2 2.303(2), P1-P2 2.201(3), P2-C3 1.819(6), P1-C1 1.733(6), P3-C1 1.726(6), C1-C2 1.470(7), C2-C3 1.410(9); C1-P1-P2 93.9(2), C1-P1-Br1 103.6(2), Br1-P1-P2 85.8(1), P1-P2-C3 93.0(2), P1-P2-Br2 92.5(1), C3-P2-Br2 97.9(2), P3-C1-P1 118.8(3), P3-C1-C2 123.6(4), P1-C1-C2 117.5(4).

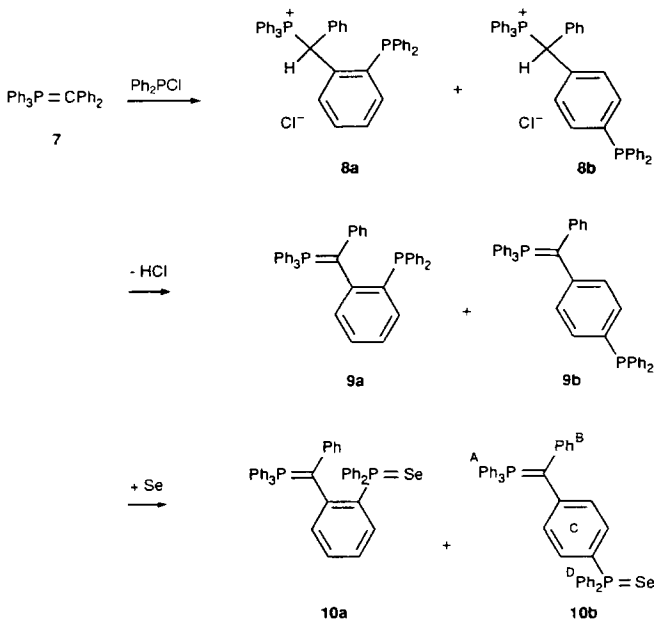
all P–Br bonds previously reported.[8, 9] This can be attributed to its nearly parallel orientation to the p_z orbital of the ylide carbon atom, which enables some charge transfer from there into the antibonding orbital of the P–Br bond.[10]

Compound **3b** can be reduced with magnesium in THF to yield **6a**. This is the first example for formation of a diphosphene by the reduction of a dihalodiphosphane.[11] **6a** is obtained as orange-yellow crystals from THF and as yellow-green crystals upon recrystallization from benzene. **6a** and its 5-methyl (**6b**) and 7-methyl (**6c**) derivatives[12] (Table 1) are also formed as side products in the reaction of **2a** or the corresponding *meta*-tolyl compound (≙ **2a**, with 3-MeC_6H_4 instead of Ph) with Na_2S or Na_2Se.[13]



6a

According to the resonance formula on the right, **6a** can be viewed as a 3-phosphonio-1,2-diphosphaindenide with a ring structure isoelectronic to 2,3-diphosphaindole.[14] In fact, the ^{31}P NMR spectra of both compounds are in good agreement with respect to the different downfield shifts and the strong coupling of the signals stemming from the phosphorus atoms in the ring. The $^2J_{PP}$ coupling constant corresponds to that in a diphosphonio-isophosphindolide.[15] In addition, the downfield shift of the ^{13}C NMR signal of C-3, compared to that in **3b**, also indicates the formation of a cyclic conjugated system.

We assumed the electrophilic substitution on the phenyl ring of the ylide to be the crucial step in the formation of the five-membered rings in **3** and **5**. The question arose whether such a substitution by a phosphorus(III) halide could also be realized independent of ring formation. Indeed, PCl_3 adds smoothly at room temperature to triphenylphosphonio-diphenylmethanide (**7**) with PCl_2 substitution in the *para* position of one *C*-phenyl ring and a proton shift to the ylide carbon atom.[16] Even the significantly less electrophilic diphenylchlorophosphane is added in the same fashion with substitution in the *ortho* and *para* positions. The two isomeric phosphonium chlorides **8** are formed in a mole ratio of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0606-0664 $ 10.00+.25/0

9:10. Ylides **9**, the neutral substitution products, can be obtained by treatment of **8** with sodium bis(trimethylsilyl)amide. After selenation to give **10** one of the isomers can be crystallized in pure form and is identified as the *para* compound **10b**. This enables the assignment of the ^{31}P NMR signals also in the mixtures of **8**, **9**, and **10**.

Experimental Procedure

3b: A suspension of 30.60 g (71.0 mmol) of **1** in 150 mL of dichloromethane and 80 mL of benzene was stirred for one day at about 20 °C with 14.40 g (142.0 mmol) of Et_3N and 19.22 g (71.0 mmol) of PBr_3. The reaction mixture slowly turned red and was filtered. Cooling the filtrate to 0 °C led to the separation of **3b**·$2C_6H_6$ as red platelets. The mother liquor was concentrated and cooled again to give a second fraction. Yield 8.75 g (34%), m.p. 205–206 °C, correct C,H, Br analysis. ^1H NMR (CD_2Cl_2): δ = 6.45 (m, 1H), 6.94 (m, 2H), 7.31 (s, 12H; C_6H_6), 7.60 (m, 6H; *m*-H), 7.70–7.80 (m, 9H; *o*,*p*-H), 7.96 (m, 1H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 69.4 (ddd, $^1J(PC)$ = 98.6 Hz, $^1J(PC)$ = 70.1 Hz, $^2J(PC)$ = 50.0 Hz; C-3), 121.4 (dd, $J(PC)$ = 8.5 Hz, $J(PC)$ = 1.9 Hz), 122.8(t, $J(PC)$ = 4.2 Hz), 123.8 (dd, $^1J(CP)$ = 89.6 Hz, $^3J(PC)$ = 6.1 Hz; *i*-C), 128.4 (s, C_6H_6), 129.6 (d, $^3J(PC)$ = 12.3 Hz, *m*-C), 131.0 (d, $J(PC)$ = 1.9 Hz), 133.7 (d, $^4J(PC)$ = 2.9 Hz; *p*-C), 134.0 (d, $J(PC)$ = 3.8 Hz), 134.2 (dd, $^2J(PC)$ = 10.4 Hz; $^4J(PC)$ = 1.4 Hz; *o*-C), 142.1 (dd, $^1J(PC)$ = 52.2 Hz, $^2J(PC)$ = 17.8 Hz; C-7a), 153.4 (ddd, $^2J(PC)$ = 13.8 Hz, $^2J(PC)$ = 7.6 Hz, $^2J(PC)$ = 2.8 Hz; C-3a).

6a: A solution of 3.70 g (6.5 mmol) of **3b** in 40 mL of THF was stirred for 15 h at 20 °C with 0.16 g (6.5 mmol) of magnesium shavings. After solvent removal under vacuum, the residue was extracted three times with 30 mL of hot benzene. Light green prisms of **6a**·$1/2C_6H_6$ separated from the extract. Yield 2.21 g (75%), m.p. 198–200 °C, correct C,H analysis. ^1H NMR ([D_8]THF): δ = 6.73 (t, $^3J(HH)$ = 7.6 Hz, 1H) 6.86 (t, $^3J(HH)$ = 7.5 Hz, 1H), 7.15 (d, $^3J(HH)$ = 7.7 Hz, 1H; 4-H), 7.24 (s, 3H, C_6H_6), 7.52 (m, 6H; *m*-H), 7.63–7.68 (m, 9H; *o*, *p*-H), 8.12 (t, $^3J(PH)$ = $^3J(HH)$ = 7.7 Hz, 1H; 7-H); $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 103.1 (dd, $^1J(PC)$ = 84.4 Hz, $^1J(PC)$ = 82.0 Hz; C-3), 117.6 (d, $^3J(PC)$ = 14.7 Hz; C-4), 121.8 (s), 122.8 (s), 125.9 (d, $^1J(PC)$ = 88.7 Hz; *i*-C), 130.0 (d, $^3J(PC)$ = 12.3 Hz; *m*-C), 130.8 (d, $^2J(PC)$ = 26.5 Hz; C-7), 133.9 (d, $^4J(PC)$ = 2.8 Hz; *p*-C), 135.1 (d, $^2J(PC)$ = 10.0 Hz, *o*-C), 151.1 (dd, $^2J(PC)$ = 13.7 Hz, $^2J(PC)$ = 8.1 Hz; C-3a), 164.2 (dd, $^1J(PC)$ = 61.1 Hz, $^2J(PC)$ = 23.2 Hz; C-7a).

10b: A solution of 3.44 g (15.6 mmol) of Ph_2PCl in 20 mL of CH_2Cl_2 was added over 1 h to a stirred solution of 6.68 g (15.6 mmol) of **7** in 100 mL of CH_2Cl_2. After 15 h at room temperature the solvent was removed under vacuum. The residue was stirred with 2.43 g (13.3 mmol) of $NaN(SiMe_3)_2$ for 15 h at room temperature. Removal of all volatiles under vacuum yielded a red oil, which solidified upon tituration with 50 mL of pentane. 2.58 g of the resulting orange-red powder was dissolved in benzene and stirred at room temperature with 0.45 g (5.7 mmol) of gray selenium. After 15 min the suspension was heated to 50 °C and filtered while hot. $^{31}P\{^1H\}$ NMR: **10a**: δ = 10.2, 34.4 ($^1J(SeP)$ = 731.4 Hz); **10b**: δ = 10.3, 33.7 ($^1J(SeP)$ = 719.2 Hz). A total of 0.82 g of **10b**·C_6H_6 crystallized as orange-red needles from the filtrate, m.p. 201–203 °C, correct C,H analysis. ^1H NMR (CD_2Cl_2): δ = 6.40 (m, 2H; *o*-H^C), 6.92–6.97 (m, 3H; *p*-H^B + *m*-H^C), 7.03 (t, $^3J(HH)$ = 7.3 Hz, 2H; *m*-H^B), 7.07 (dt, $^3J(HH)$ = 8.3 Hz, $^4J(HH)$ = $^4J(PH)$ = 1.7 Hz, 2H; *o*-H^B), 7.28 (s, 6H; C_6H_6), 7.39–7.47 (m, 12H; *m*-H^A + *m*,*p*-H^D), 7.54 (tq, $^3J(HH)$ = 5.6 Hz, $^4J(HH)$ = $^5J(PH)$ = 2.0 Hz, 3H; *p*-H^A), 7.60 (m, 6H; *o*-H^A), 7.68 (m, 4H; *o*-H^D). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 49.3 (d, $^1J(PC)$ = 124.6 Hz; C(ylide)), 110.4 (d, $^1J(PC)$ = 89.6 Hz; *p*-C^C), 120.0 (dd, $^3J(PC)$ = 10.4 Hz, $^3J(PC)$ = 13.3 Hz; *o*-C^C), 125.0 (d, $^5J(PC)$ = 2.4 Hz; *p*-C^B), 127.2 (d, $^1J(PC)$ = 86.7 Hz; *i*-C^A), 128.3 (d, $^3J(PC)$ = 12.3 Hz; *m*-C^D), 128.5 (s, C_6H_6), 128.5 (s, *m*-C^B), 128.9 (d, $^3J(PC)$ = 11.8 Hz; *m*-C^A), 131.0 (d, $^4J(PC)$ = 2.9 Hz, *p*-C^D), 132.0 (d, $^2J(PC)$ = 14.2 Hz; *m*-C^C), 132.1 (s, *p*-C^A), 132.6 (d, $^2J(PC)$ = 10.4 Hz, *o*-C^D), 134.1 d, $^2J(PC)$ = 9.5 Hz; *o*-C^A), 134.1 (d, $^1J(PC)$ = 76.3 Hz; *i*-C^D), 136.3 (d, $^3J(PC)$ = 3.8 Hz; *o*-C^B), 141.3 (d, $J(PC)$ = 15.2 Hz; *i*-C^B), 151.6 (dd, $^2J(PC)$ = 13.7 Hz, $^4J(PC)$ = 2.4 Hz; *i*-C^C); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 10.5 (s, 50%), 33.3 (s 47%, d 3%, $^1J(SeP)$ = 718.5 Hz). (C_6H_6): δ = 10.1, 34.3 ($^1J(SeP)$ = 735.4 Hz); $^{77}Se\{^1H\}$ NMR (CD_2Cl_2): δ = −258.9 (d, $^1J(SeP)$ = 712.2 Hz).

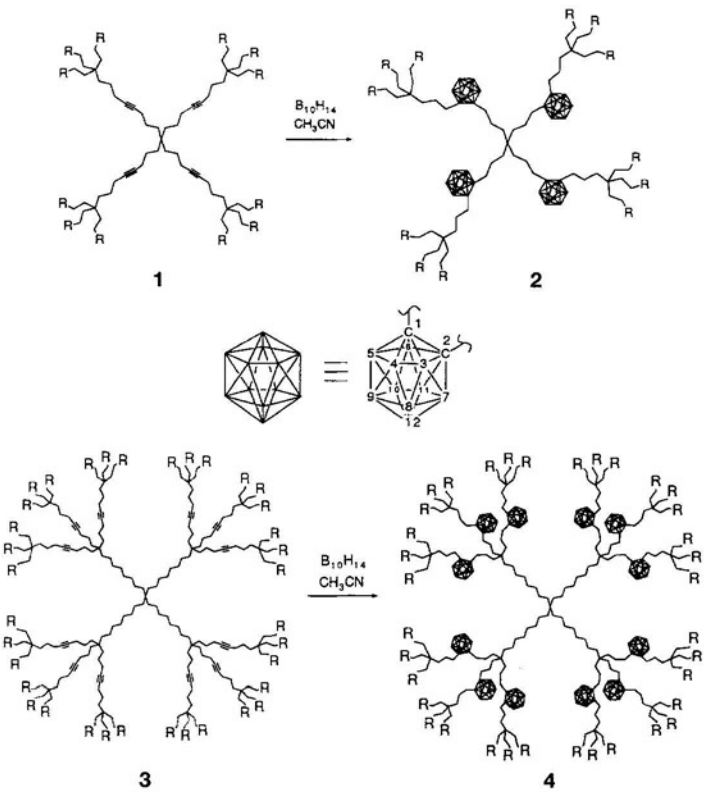
Chemistry within a Unimolecular Micelle Precursor: Boron Superclusters by Site- and Depth-Specific Transformations of Dendrimers**

George R. Newkome,* Charles N. Moorefield, John M. Keith, Gregory R. Baker, and Gregory H. Escamilla



To date, researchers concerned with dendritic (cascade) polymer chemistry have primarily focused on the preparation of new materials based upon the sequential connection of monomeric building blocks to affect properties in the interior or on the surface of the new macromolecule, such as flexibility, solubility, porosity, and lipophilicity. Monomer addition, and thus cascade construction, have been achieved by convergent and divergent approaches, as well as combinations of the two.[1] Also, the ability of molecules to penetrate the interior of the cascade framework, through nonbonding interactions, has demonstrated the unimolecular micelle concept.[2] Elegant exploitation of this concept was recently reported;[3] the solubility of polyaromatic hydrocarbons in water was effected by a polyether cascade. Investigations into the potential to specifically incorporate and manipulate functionality in the interior of the cascade molecule have been largely neglected except for the interesting case of "superbases" acting on poly(benzyl ether) dendrimers for internal electrophilic introduction.[4] However, these transformations were not tier- or group-specific. We herein report our preliminary results on the ability to transform sites of reactivity between branching centers chemically[5] after cascade construction, without branch degradation. Ramifications include the precise placement of covalently bonded organic, inorganic, and metal-containing moieties, or any compatible combination at different generations, within a cascade superstructure; the aim is ultimately to provide a method for concentrating aqueous or nonaqueous insoluble functionality within a desired medium.

The creation in our laboratories of the hydrocarbon-based, unimolecular micelles, termed micellanes,[2] provided the impetus to employ internal functionality for *endo*- and *regio*-specific[6] chemical modifications in the interior of the cascade infrastructure. During micellane construction, facile, palladium-catalyzed, heterogeneous reduction of interior alkyne moieties to produce saturated hydrocarbon branches attest to reactivity in the interior of the cascade molecule, which suggested that branches are flexible and the cascade molecule permeable. Initial experiments focused on the first and second generation polyalkyne, the micellanoic acid precursors **1** and **3** (Scheme 1), and capitalized on the propensity of alkyne moieties to react with decaborane, $B_{10}H_{14}$, to afford 1,2-dicarba-*closo*-dodecaboranes (*o*-carboranes). The potential to render boron clusters soluble in an aqueous environment is of interest because of their use in cancer treatment by Boron Neutron Capture Therapy[7] (BNCT) and in catalysis.[8]

Cardullo, E. C. Constable, C. N. Moorefield, A. M. W. Cargill Thompson, *J. Chem. Soc. Chem. Commun.* **1993**, 925.

Treatment of the tetra- and dodecaalkynes **1** and **3** with excess $B_{10}H_{14}$, activated by acetonitrile, in toluene under reflux for 24 h gave the corresponding tetra- and dodeca-*o*-carboranes **2** and **4** (89% and 77%, respectively),[9] as viscous oils. Excess decaborane was decomposed by the addition of 10% HCl and MeOH followed by heating under reflux for 24 h.

Scheme 1. Preparation of *o*-carborane superclusters **2** and **4** by treatment of polyalkyne cascade precursors **1** and **3** with $B_{10}H_{14}$. Also depicted is the *o*-carborane numbering scheme. R = $CH_2OCH_2C_6H_5$.

Evidence for the transformations (Table 1) was provided by the disappearance of ^{13}C NMR signals at $\delta = 19.3$ ($C{\equiv}CCH_2$) and 80.9 ($C{\equiv}C$), as well as the appearance of new peaks at $\delta = 23.5$ ($B_{10}H_{10}C_2CH_2CH_2$ and CH_2CH_2O) and 29.5 ($B_{10}H_{10}C_2CH_2$). The expected resonances (^{13}C NMR) at $\delta = 71.2$ (CH_2O) and 72.8 ($OCH_2C_6H_5$) were also observed. Broadening of the ^{13}C NMR signals for the first- and second-generation, boron superclusters was observed, although it was more pronounced in the dodeca-*o*-carborane (**4**) spectrum. The absence of ^{13}C NMR peaks assigned to the *o*-carborane carbons ($B_{10}H_{10}C_2$) was attributed to the rapid quadrupolar relaxation of the connected ^{11}B nuclei, as well as the multiplicity of the signal.[10]

Broadened signals in the ^1H NMR spectrum of both **2** and **4** were recorded at the expected chemical shifts [$\delta = 3.40$ (CH_2O) and 4.46 ($OCH_2C_6H_5$)], including a hydrocarbon envelope centered at $\delta = 1.51$ (**2**, 136 H; **4**, 472 H), while the IR spectra exhibited prominent peaks at 2575 cm^{-1} (ν_{B-H}). The symmetry of both the ^{13}C and ^1H NMR spectra of **1** and **3** was maintained in the spectra of **2** and **4**, which further supports complete transformation of the cascade interior; however, the broadened resonances suggested decreased chain flexibility.

The ^1H decoupled ^{11}B NMR spectra[11] of the poly(*o*-carboranes) **2** and **4** displayed similar patterns; peaks occur at $\delta =$

Table 1. Spectroscopic data for boron superclusters **2** and **4**–**6** [a].

2: ^{13}C NMR: δ = 23.5 ($B_{10}H_{10}C_2CH_2CH_2$ CH_2CH_2O), 29.6 ($B_{10}H_{10}C_2CH_2$), 32.4 ($CH_2CH_2CH_2O$), 36.5 (C_4, $B_{10}H_{10}C_2CH_2CH_2CH_2$), 71.2 ($CH_2O$), 72.8 ($OCH_2C_6H_5$), 127.3, 127.4, 128.3, 138.6 (C_6H_5); ^{1}H NMR: δ = 0.85–2.10 [m, $(CH_2)_3B_{10}H_{10}C_2(CH_2)_3C\{CH_2CH_2\}_3$, 136 H], 3.40 (br. s, CH_2O, 24 H), 4.46 (br. s, $OCH_2C_6H_5$, 24 H), 7.30 (br. s, C_6H_5, 60 H); ^{11}B NMR (^{1}H-decoupled): δ = −19.6 (s, $B_{3,6}$), 0.5 (m, $B_{4,5,7,11}$), 23.6 (s, $B_{8,10}$), 35.6 (br. s, $B_{9,12}$); ^{11}B NMR: (^{1}H-coupled) δ = −19.6 (d, $B_{3,6}$, J = 145.2 Hz), 0.5 (m, $B_{4,5,7,11}$), 23.6 (d, $B_{8,10}$, J = 119.5 Hz), 35.6 (br. s, $B_{9,12}$); IR $\tilde{\nu}$ = 3080, 3030, 2920, 2860, 2575, 1100, 745, 700 cm^{-1}.

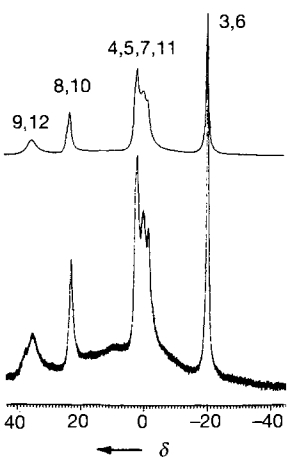
4: ^{13}C NMR: δ = 22.5 [$C(CH_2CH_2)_4^{int}$], 23.5 [$C(CH_2CH_2)_4^{ext}$, CH_2CH_2O], 29.0 [$C(CH_2CH_2CH_2CH_2)_4^{int}$], 29.5 ($B_{10}H_{10}C_2CH_2$), 31.5 [$C(CH_2CH_2CH_2)_4^{int}$], 32.6 ($CH_2CH_2CH_2O$), 36.6 [m, C_4, $C_4(CH_2)_4$], 71.3 (CH_2O), 72.8($OCH_2C_6H_5$), 127.3, 127.4, 128.3, 138.6 (C_6H_5); ^{1}H NMR: δ = 0.70–2.15 [br. s, $(CH_2)_8^{int}$, $(CH_2)_3B_{10}H_{10}C_2(CH_2)_3C\{CH_2CH_2\}_3^{ext}$, 372 H], 3.41 (br. s, CH_2O, 72 H), 4.47 (br. s, $OCH_2C_6H_5$, 70 H), 7.30 (br. s, C_6H_5, 180 H); ^{11}B NMR (^{1}H-decoupled): δ = −19.6 (s, $B_{3,6}$), 0.5 (m, $B_{4,5,7,11}$), 23.6 (s, $B_{8,10}$), 35.6 (br. s, $B_{9,12}$); IR: $\tilde{\nu}$ = 3080, 3030, 2920, 2860, 2575, 1100, 745, 700 cm^{-1}.

5: ^{13}C NMR (D_3COD): δ = 27.4 (CH_2CH_2OH), 30.6 ($B_{10}H_{10}C_2CH_2CH_2$), 33.6 ($CH_2CH_2CH_2O$, $B_{10}H_{10}C_2CH_2CH_2$), 37.9 (C_4), 64.0 (CH_2OH); ^{1}H NMR (D_3COD): δ = 1.05–1.80(m, $(CH_2)_3B_{10}H_{10}C_2(CH_2)_3C\{CH_2CH_2\}$, 136H), 3.44 (br. t, CH_2OH, 24H); ^{11}B NMR (D_3COD): δ = −14.5 (br. s, $B_{3,6}$), −6.2 (br. s, $B_{4,5,7,11}$), 22.4 (s, $B_{8,10}$), 35.8 (br. s, $B_{9,12}$); IR: $\tilde{\nu}$ = 3700–3000, 2570 cm^{-1}.

6: ^{13}C NMR: δ = 27.5 ($CH_2CH_2CH_2O$), 29.0 [$C(CH_2CH_2CH_2)_4^{int}$], 30.7 ($B_{10}H_{10}C_2CH_2CH_2$), 33.6 [$CH_2CH_2CH_2O$, $C(CH_2)_4$], 37.6 (C_4), 63.8(CH_2OH); ^{1}H NMR: δ = 0.90–1.90 [br. envelope, $(CH_2)_8^{int}$, $(CH_2)_3B_{10}H_{10}C_2(CH_2)_3C\{CH_2CH_2\}_3^{ext}$, 472H], 3.41 (br. t, CH_2OH, 72H); ^{11}B NMR (^{1}H-decoupled) δ = −14.6 (br. s, $B_{3,6}$), −6.2 (br. s, $B_{4,5,7,11}$), 22.6 (s, $B_{8,10}$), 35.8 (br. s, $B_{9,12}$); IR: $\tilde{\nu}$ = 3700–3000, 2920, 2860, 2575 cm^{-1}.

[a] Acceptable spectral and analytical data was obtained for the new materials. All NMR data were recorded on a Bruker 360 MHz AMX spectrometer. Solvent: $CDCl_3$ (^{13}C NMR, δ = 77.0); internal standards: Me_4Si (^{1}H NMR, δ = 0) or $BF_3 \cdot Et_2O$ (^{11}B NMR, δ = 0).

−19.6, 0.5, 23.6, and 35.6 ($B_{3,6}$, $B_{4,5,7,11}$, $B_{8,10}$, and $B_{9,12}$, respectively). The observed absorptions attributed to the boron nuclei at carborane positions 4, 5, 7, and 11 (Fig. 1) are not significantly different, as might be expected, considering that two atoms are oriented toward the core and the other two toward the exterior. It is assumed that these positions are in similar environments because they are surrounded by similar bishomoneopentyl moieties. The ^{1}H-coupled ^{11}B NMR spectrum of **2** displays doublets at δ = −19.6 ($B_{3,6}$, J = 145.2 Hz) and 23.6 ($B_{8,10}$, J = 119.5 Hz).



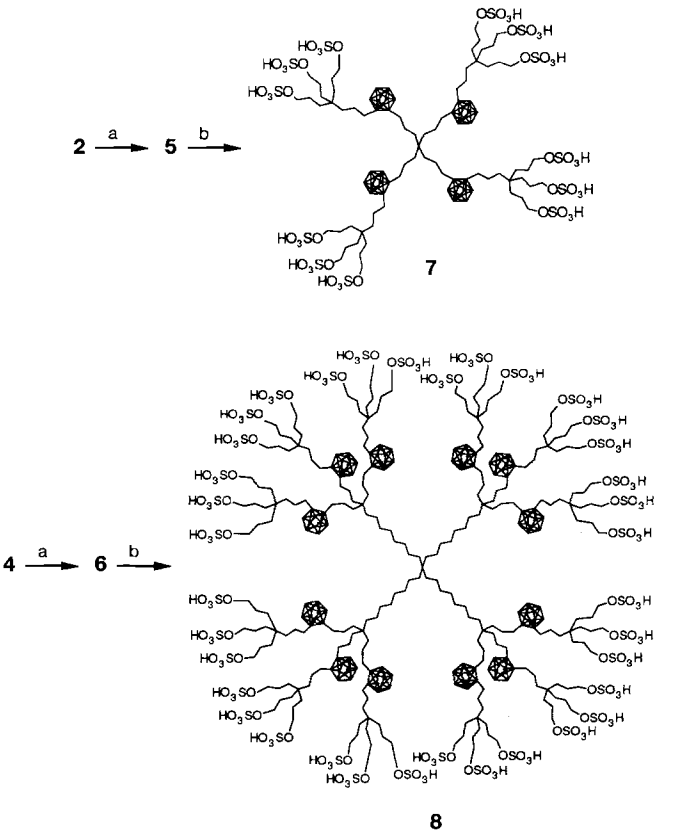


Figure 1. ^{1}H-decoupled ^{11}B NMR spectra of **2** (top) and **4** (bottom). The numbers indicate the assigned boron atoms.

The stability of carborane moieties under diverse reaction conditions is well documented.[12] Thus reaction of **2** with $PdO_2 \cdot xH_2O$, cyclohexene, and EtOH[13] smoothly afforded the dodecaalcohol **5** (yield 91%, Scheme 2). Salient features on comparison of the ^{13}C NMR spectra of **2** and **5** included the disappearance of peaks in the arene region as well as at δ = 71.2 and 72.8 and the appearance of signals at 63.8 (CH_2OH), 33.6 ($CH_2CH_2CH_2O$), and 27.4 (CH_2CH_2O). The ^{1}H NMR spectrum exhibited a poorly resolved triplet at δ = 3.43 (CH_2OH) and no downfield signals, which further supports complete deprotection. Resonances in the ^{11}B NMR spectrum were observed at δ = 37.8 ($B_{9,12}$) and 22.4 ($B_{8,10}$) that were nearly identical to those recorded for the precursor **2**; however, resonances assigned to $B_{4,5,7,11}$ (δ = −6.2) and $B_{3,6}$ (δ = −14.5) appeared as severely broadened envelopes. Treatment of **4** under the same reductive conditions yielded the polyol **6** (87%) that was characterized by virtually identical ^{13}C, ^{1}H, and ^{11}B NMR spectra to that observed for first tier polyol **5**.

Scheme 2. Syntheses of water-soluble boron superclusters **7** and **8** by transformation of the termini of the polyols **5** and **6** into sulfate moieties. a: $PdO2 \cdot xH_2O$, cyclohexene, EtOH, 4 days under reflux; b: $ClSO_3H$, 0 °C, 1 hour.

Water solubility (at high and low pH) was imparted to the carborane polyols **5** and **6** by reaction with $ClSO_3H$[14] (0 °C, 1 h) to afford the corresponding polysulfates **7** and **8** (Scheme 2). Evidence for the transformation of the alcohols to the desired boron superclusters included ^{13}C NMR spectra showing peaks at δ = 68.5 (CH_2OSO_3H) and 29.5 ($B_{10}H_{10}C_2CH_2$), and ^{1}H NMR spectra with broad signals at 3.72 (CH_2OSO_3H) and 1.35 [$(CH_2)_3B_{10}H_{10}C_2(CH_2)_3C\{CH_2CH_2\}_3$]. Raising the pH of a D_2O solution of the dodecasulfatetetra-*o*-carborane **7** with solid Na_2CO_3 produced a downfield shift of the ^{1}H NMR signal assigned to the terminal sulfatomethylene moieties to δ = 3.98.

Computer-generated space-filling models[15] of the superclusters, with termini soluble either in aqueous or nonaqueous media, reveal ample cascade "*void volume*" for the placement of multiple, icosahedral, *o*-carborane units within the cascade framework. Models of individual icosahedrons were created by using X-ray diffraction data;[16] they possess a diameter of 5.6 Å. In a fully extended conformation, the distances between branching centers of interest, before and after treatment with $B_{10}H_{14}$, were determined to be 11.1 and 9.6 Å, respectively.

In summary, we have demonstrated the ability to modify the cascade interior at precise depths on the macromolecular framework. Well-conceived cascade construction should allow the covalent incorporation of a variety of metals and nonmetals at predetermined sites provided that dense packing limits have not been reached. The attachment of different, as well as similar, guests onto successive generations should also be possible. Construction of cascades bearing interior, covalently bonded metallic or organic species is currently in progress.

1(9)-Homocubene and 9-Homocubylidene: Theoretical Investigation of Structures, Energies, and Rearrangement Reactions**

Max C. Holthausen and Wolfram Koch*

The synthesis of 1(9)-homocubene (**1**) was described both by Eaton and Hoffmann and by Chen and Jones.[1] **1** is an unusual olefin: the double bond is located at a bridgehead atom contrary to Bredt's rule and is also extremely twisted. The 2p atomic orbitals of this π bond are rotated by almost 90° to each other, such that no bonding overlap is possible. Thus, the question arises of the extent **1** may still be described as an olefin in the singlet state, or if it more closely resembles a singlet diradical. Closely associated with the electronic structure of the "double bond" in **1** are its equilibrium geometry and, in particular, the length of the C1–C9 bond. Unfortunately no experimental information is available. The unusual bonding situation in **1** is also evident from its reversible rearrangement[2] into the isomeric carbene 9-homocubylidene (**2**).[1] This type of rearrangement of an olefin into a carbene is extremely rare. Eaton and White have carried out in-depth experiments on the mechanism for the analogous rearrangement of 9-phenyl-1(9)-homocubene using isotopically

labeled compounds.[3] They found that the reaction proceeds by a C–C bond shift in the homocubane skeleton rather than by phenyl migration. We report here on quantum chemical ab initio calculations of the equilibrium geometries of the singlet and triplet ground states of 1(9)-homocubene (**1S** and **1T**, respectively) and of 9-homocubylidene (**2S** and **2T**, respectively), and those of the intermediates for the H migration and the C–C shift which revisibly interconvert **1** and **2**.[4]

The calculated equilibrium geometry of the singlet ^1A ground state of **1S** shown in Figure 1 confirms that the C1–C9 bond (1.453 Å) differs markedly from a conventional double bond (1.34 Å). This is a consequence of the strong twisting of both of the R_2C units at the bond.

As is apparent in the Newman projection in Figure 2, both carbon atoms of the C=C bond are distinctly pyramidalized. The orbitals forming the double bond are not coplanar, as is necessary for optimal overlap; but form an angle of 49.7°. Figure 3 depicts the (formally) highest occupied (HOMO) and the lowest unoccupied (LUMO) molecular orbitals, which show the reduced overlap. A CASSCF calculation shows that **1** cannot be regarded as having a conventional closed-shell singlet state, and that **1** exhibits distinct diradical character. The Hartree–Fock (HF) configuration, which corresponds to that of a conventional double bond, is weighted only 71%, whilst the configuration in which two electrons have been excited from the HOMO into the LUMO accounts for 28% of the wave function. The HOMO is occupied by merely 1.43 electrons instead of by 2, and the LUMO, which is unoccupied in the HF description, shows an increased occupancy of 0.57.

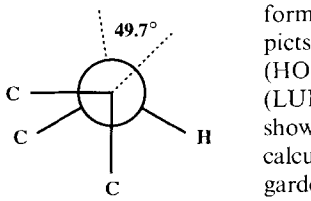

Fig. 2. Newman projection along the C1–C9 bond in structure **1S**.

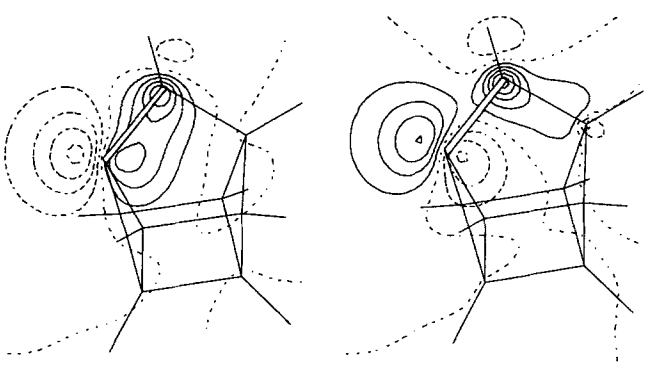

Fig. 3. Contour plots of the HOMO (left) and LUMO (right) of **1**.

The diradical character of **1S** is also revealed by the very small difference in energy to the corresponding triplet state **1T**, which is calculated to be only 1.5 kcal mol^{-1} less stable than **1S** (Table 1). The HOMO and LUMO in **1T** are each singly occupied, and the C1–C9 bond has no double bond character. The geometries of **1T** and **1S** differ only marginally. The C1–C9 bond in **1T** (ca. 1.50 Å) is somewhat longer than that in **1S**. These results lead to the conclusion that 1(9)-homocubene (**1**) is indeed formally an olefin; however, it has no double bond and is therefore better described as a singlet diradical. The Mulliken partial charges at the C1 and C9 centers are + 0.02 (+ 0.03) and −0.04 (− 0.06) for **1S** (**2T**), respectively.

Table 1. Calculated relative energies [kcal mol^{-1}] of **1** and **2**.

State	Singlet CASSCF/ 3-21G	CASSCF/ DZP	State	Triplet ROHF/ 3-21G	ROHF/ DZP
1S	0.0 [a]	0.0 [b]	**1T**	1.3	1.5
2S	2.2	−3.1	**2T**	−4.1	−2.0
TS1S	97.3	88.5	**TS1T**	98.2	93.5
TS2S	25.8	23.5	**TS2T**	34.5	34.8

[a] E_{tot} = − 343.31570 Hartree. [b] E_{tot} = − 345.18936 Hartree.

The C_{2v}-symmetrical 9-homocubylidene (**2S**), which is isomeric to **1**, is structurally much less different from carbenes than **1S** is from olefins (Fig. 1). The bond angle at the carbene center in **2S** is somewhat reduced compared to an open-chain carbene because of ring strain (96.6 compared to 103.2° in methylene).[5] The carbene character of **2S** is also evident in the CASSCF wave function of the $^1A_1$ state. In analogy to methylene, the formal b_1 LUMO in **2S** is partly occupied at the expense of the a_1 HOMO (calculated occupancy: 1.93 (HOMO), 0.07 (LUMO) for **2S**; 1.92 (HOMO) and 0.08 (LUMO) for CH_2). **2S** is calculated (DZP basis set) to be roughly 1.1 kcal mol^{-1} more stable than the corresponding **2T** state; in other words, the singlet state is the stable species here in contrast to methylene. (With the smaller 3-21G basis set the relative stabilities are also close together; however, **2T** is calculated to be more stable than **2S**, which in turn is less stable than **1T**.) The calculational level used is insufficient for quantitative evaluations about the singlet/triplet energy difference (at the same level the $^3B_1$ state in methylene is 13.9 kcal mol^{-1} more stable than the $^1A_1$ state, whereas the experimental energy difference is 9 kcal mol^{-1} [6]). However, the finding that the singlet and triplet states of **2** are energetically close to each other is certainly correct. For ethylidene, for example, the triplet state is only 3 ± 2 kcal mol^{-1} more stable than the singlet state.[7] Furthermore, the effect of ring strain on the carbene angle destabilizes the triplet state more than the singlet state, because triplet carbenes usually have bond angles of 130°;[5] in **2T** this angle is only 101.7°. Our calculations also show **2S** to be slightly more stable than **1S**, which is in accord with the observed reversible rearrangement **1** → **2**.

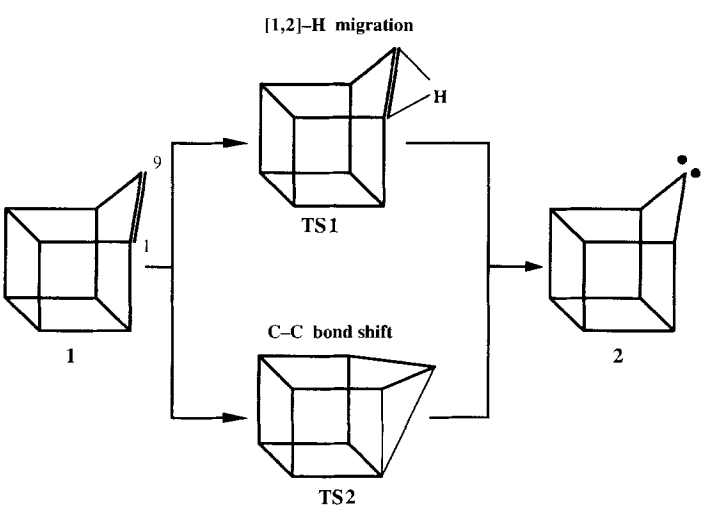

Fig. 4. Possible rearrangement mechanism **1** ⇌ **2**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0606-0669 $ 10.00+.25/0

By which mechanism does this rearrangement occur? Two possibilities are conceivable: either a [1,2]-H migration or a C–C bond shift (Fig. 4). For both alternative pathways the saddle points were located and characterized by analysis of the force constant matrix as unambiguous transition structures (one negative eigenvalue). The saddle point associated with the [1,2]-H migration, **TS1S**, is very high in energy (88.5 kcal mol^{-1} higher than **1S**); in comparison that associated with the C–C bond shift, **TS2S**, is clearly more favorable (23.5 kcal mol^{-1} higher in energy than **2S**). As is clear from Table 1, **TS1T** is also much higher in energy than **TS2T**. The quantitative energy differences may be somewhat different at a higher level of theory, but the qualitative result that the C–C bond shift is clearly favored over H migration should remain unchanged. This result confirms the experimental findings of Eaton and White[3] for the 9-phenyl-substituted derivative of **1** and **2**.

Because of the extremely strained structure, the double bond character of **1** is significantly reduced, and **1S** is only a formal olefin. As a result of the destabilization of **1S**, the isomeric **2S** becomes similar in energy, which is reflected in the reversible rearrangement **1** $\rightleftharpoons$ **2** observed experimentally. This rearrangement occurs by a C–C bond shift with a relatively low activation barrier.

[4] The geometry optimizations were carried out by employing analytical gradients and the 3-21G basis set[8]. The diradical character of the singlet wave function was determined by a multiconfigurational SCF calculation of the CASSCF type[9]. The two molecular orbitals relevant for the diradical were selected as active. The occupation of these two orbitals by two electrons leads to a maximum of three configurations in the CASSCF calculation. The ROHF approximation was used in the calculation of the triplet states. Energy calculations were then carried out with the same approximations on the optimized geometries by using the DZP basis set (polarization functions only at the carbon atoms)[10]. Additional, more accurate calculations were not possible because of the size and low symmetry of the molecules, but qualitative trends should be reproduced correctly. Software packages GAMESS[11], GAUSSIAN-92[12], and MOLCAS-2[13] were used.

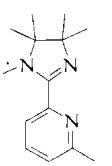
Fairly Strong Ferromagnetic Interactions between Imino Nitroxide Ligands through a Diamagnetic Cu^{I} Ion in $[Cu^{I}(im\text{-}mepy)_2](PF_6)$**



Hiroki Oshio,* Takashi Watanabe, Akihiro Ohto, Tasuku Ito,* and Umpei Nagashima

Molecular units which exhibit inter- or intramolecular ferromagnetic interactions are indispensable for the construction of molecular-based ferromagnets. In order to attain magnetic ordering at high temperature, strong ferromagnetic interactions are necessary. These propagate if the magnetic orbitals are orthogonal.[1] The orthogonal arrangement of the paramagnetic building blocks has been used to attain the parallel spin alignment in paramagnetic compounds, for instance, in Cu^{II}–$V{=}O^{IV}$[2] and Cr^{III}–Ni^{II}[3] systems. Recently this approach has also been applied to diamagnetic metal complexes with organic radicals. In Ti^{IV}–[4] and Ga^{III}–semiquinone complexes,[5] the semiquinone ligands show ferromagnetic interactions, and magnetic susceptibility measurements gave exchange coupling constants J of $-56\ cm^{-1}$ ($H = JS_1S_2$) and $7.8\ cm^{-1}$ ($H = -2J\Sigma S_iS_j$), respectively.

Nitronyl nitroxide and imino nitroxide radicals were first prepared by Ullman et al.,[6] and their paramagnetic metal complexes have been extensively studied, and some of these have been reported to show spontaneous magnetization.[7] Cu^{I} ions are known to favor a tetrahedral coordination geometry;[8] when two bidentate radical ligands complete the tetrahedral coordination sphere, two planes of the two ligands form a dihedral angle of 90° (or two magnetic orbitals on the radical ligands are orthogonal), hence, the interaction between the two ligands should be ferromagnetic. Here we report on a fairly strong ferromagnetic interaction of this type between two imino nitroxide ligands in the Cu^{I} complex **1**.

$[Cu^{I}(im\text{-}mepy)_2](PF_6)$ **1**

im-mepy =

Complex **1** was synthesized by adding the bidentate radical ligand im-mepy[10] (0.32 g) to a solution of $[Cu^{I}(CH_3CN)_4](PF_6)$[9] (0.25 g) in ethanol (25 mL) under a nitrogen atmosphere. The reaction mixture was allowed to stand overnight during which time dark red crystals precipitated which were then filtered. The results of the X-ray structural analysis of **1**[11] are shown in Figure 1. The copper atom sits on a twofold axis and is coordinated by two im-mepy ligands, which are thus related by the twofold symmetry. The tetrahedral coordination sphere of the copper atom is completed by four nitrogen atoms from the imino and pyridyl groups. The dihedral angle between the two planes Cu-N2-C7-N3-O1 and Cu-N2*-C7*-N3*-O1* is 88.7°.

The UV/VIS spectrum of **1** in acetonitrile shows absorption bands at 464 nm ($\varepsilon = 6300\ M^{-1}cm^{-1}$) and 766 nm ($\varepsilon = 5000\ M^{-1}cm^{-1}$) which are assigned to the charge transfer bands

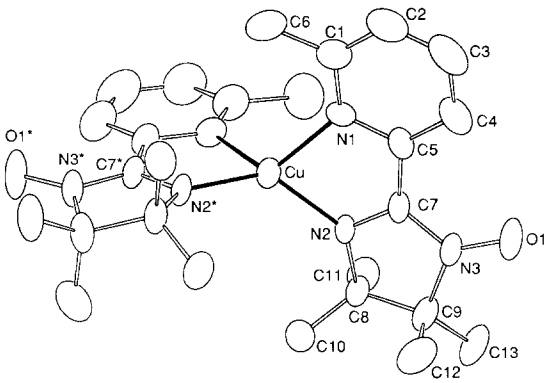

Fig. 1. The crystal structure of the cation of **1** (ORTEP; 30% thermal ellipsoids). Important bond lengths [Å] and angles [°]: Cu-N1 2.081(6), Cu-N2 1.953(5), O1-N3 1.273(7), N2-C7 1.271(7); N1-Cu-N2 81.1(2), N1-Cu-N1* 116.8(2), N1-Cu-N2 126.0(2), N2-Cu-N2* 131.2(2), Cu-N1-C1 128.4(6), Cu-N1-C5 111.9(4), C1-N1-C5 119.7(7), Cu-N2-C7 114.2(4), Cu-N2-C8 135.3(4), O1-N3-C7 126.1(7), N2-C7-N3 112.5(6).

from the copper (dπ) to ligand π* orbitals primarily localized on pyridyl imine[12] and imino nitroxide moieties,[13] respectively. The temperature dependence of the magnetic susceptibility was measured down to 2.0 K; a plot of $\chi_m T$ vs. T is shown in Figure 2 (χ_m = molar magnetic susceptibility). The $\chi_m T$ values

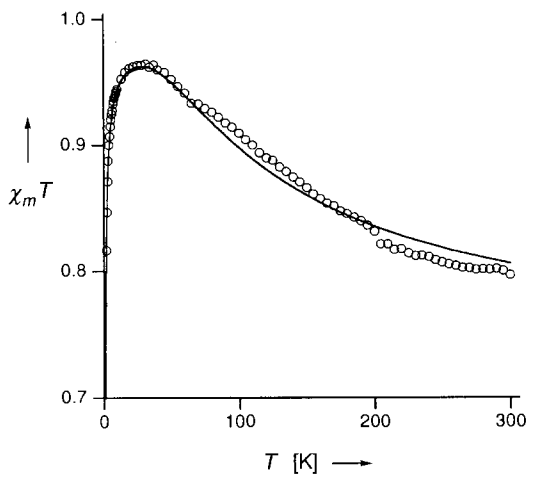

Fig. 2. Temperature dependence of $\chi_m T$ [emu mol^{-1} K] for **1**. The solid line corresponds to the least-squares fit obtained by using the Bleaney-Bowers equation and the parameters described in the text.

show a gradual increase as the temperature decreases, reaching a plateau (0.96 emu mol^{-1} K) at 40 K; the spin-only value for $S = 1$ is 1.0 emu mol^{-1} K. The copper(I) cation (d^{10} configuration) is diamagnetic and a solution of **1** in ethanol is ESR inactive at 293 K. Thus, it is concluded that the magnetic behavior of **1** indicates an intramolecular ferromagnetic interaction between the imino nitroxide ligands. An abrupt decrease of the $\chi_m T$ values below 20 K might be due to an intermolecular antiferromagnetic interaction. The magnetic susceptibility data were analyzed by using a Bleaney-Bowers equation ($H = -2JS_1S_2$) of the form (1),[14] where the contribution of the

$$\chi_m = \frac{Ng^2\beta^2}{k(T-\theta)}\left[\frac{2}{3+\exp(-2J/kT)}\right] \quad (1)$$

intermolecular antiferromagnetic interaction was included in the term θ. The best-fit parameters were $2J = +102(2)$ cm^{-1}, $g = 1.977(3)$, and $\theta = -0.36(2)$ K.

Magnetic interactions occurring between paramagnetic metal ions through a diamagnetic metal ion have been considered to be negligibly small or weakly antiferromagnetic. Trinuclear systems such as dimethylglyoximato-bridged Cu^{II}-Ni^{II}(LS)-Cu^{II}[15] (LS = low spin) and Fe^{III}-Fe^{II}(LS)-Fe^{III} complexes[16] show weak antiferromagnetic interactions ($J = -2.6$ and -4.4 cm^{-1}, respectively) between terminal metal ions, while a moderately strong antiferromagnetic interaction ($J = -36$ cm^{-1}) in an analogous Cu^{II}-Pd^{II}-Cu^{II} complex is exceptional.[15] In diamagnetic semiquinone–metal complexes,[4, 5] however, the occurrence of ferromagnetic interactions between the semiquinone ligands was due to their orthogonal arrangement. The Cu^{I}–imino nitroxide complex reported here shows a fairly strong ferromagnetic interaction ($2J = +102(2)$ cm^{-1}; $H = -2JS_1S_2$) compared with that of Ti^{IV}- and Ga^{III}-semiquinone complexes, which can be interpreted by the orthogonal arrangement of the radical ligands. Furthermore, a strong charge transfer interaction between the copper dπ to radical π* orbitals may play an important role in stabilizing the high-spin state. Thus, the copper(I) cation appears particularly suitable for linking organic radicals and in this way for building molecular-based ferromagnets.

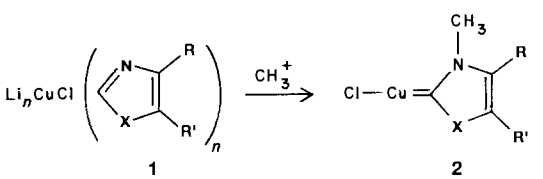
Synthesis and Crystal Structure of a Monocarbene Complex of Copper



Helgard G. Raubenheimer,* Stephanie Cronje, Petrus H. van Rooyen, Pierre J. Olivier, and James G. Toerien

Dedicated to Professor E. O. Fischer on the occasion of his 75th birthday

In certain copper(I)-catalyzed reactions, such as the cyclopropanation of alkenes and alkynes with diazoalkanes and diazoketones,[1] and the formation of formamides from isocyanides and alcohols,[2] the existence of copper–carbene intermediates have been proposed. Recently Arduengo et al.[3] reported the preparation of the first isolable homoleptic copper–carbene and silver–carbene complexes. However, no X-ray crystal structure was reported for the copper complex. We now report a simple new route to an unusual thiazolylidene complex of copper(I), which has been extended to include imidazolylidene Cu^{I} complexes, as well as the first X-ray crystal structure of a copper–carbene complex.

The treatment of [Au(Cl)tht] (tht = tetrahydrothiophene) with two equivalents of a lithiated thiazole leads to the formation of aurates, which can be protonated or alkylated to produce stable mono- or biscarbene complexes of gold(I) in high yields.[4] Similarly, it is possible to form cuprates[5] by treating a suspension of CuCl in THF with lithiated thiazoles or imidazoles.[6]

Alkylation of the cuprate **1** (Scheme 1) with CF_3SO_3H afforded a clear solution from which the crystalline air-sensitive copper–carbene **2a** was obtained.[7, 8] By contrast, protonation

1 2

Scheme 1. **a**, X = S, R, R' = CH_3; **b**, X = S, R' = CH_3, R' = H; **c**, X = S, R, R' = $-(CH)_4-$; **d**, X = NCH_3, R, R' = H; **e**, X = NCH_3, R, R' = $-(CH)_4-$.

of the 4,5-dimethylthiazolyl, 4-methylthiazolyl, or benzothiazolyl cuprate with CF_3SO_3H did not yield the expected copper–carbene complexes. Instead complexes of the type $[\{Cu(\mu\text{-Cl})(thiazole)_2\}_2]$ were obtained; protonation had clearly occurred on the metal-bonded C^2 atom.

The exact composition of the 4,5-dimethylthiazolyl cuprate **1** is not known,[5] but it represents an aggregate containing chloride ions that are also present in the products obtained after alkylation or acidification.

The X-ray structure of **2a**[9] (Fig. 1) indicates that the copper atom is essentially two-coordinate, bonded to the carbene carbon of the thiazolylidene ligand (Cu–C1 1.888(6) Å)[10] and a chloride (Cu–Cl 2.122(2) Å)[11] in an approximately linear fashion (C1-Cu-Cl 166.9(2)°).[12] However, association of the copper atom and the chloride of adjacent molecule (Cu···Cl 2.905 Å)[13] results in the apparent dimeric nature of the compound in the solid state. The two molecules constituting the "dimer" lie in a plane; the largest deviation from the best-fit plane as defined by the non-hydrogen atoms is 0.087 Å for the two Cl atoms. None of the other atoms deviate more than 0.03 Å from the plane.

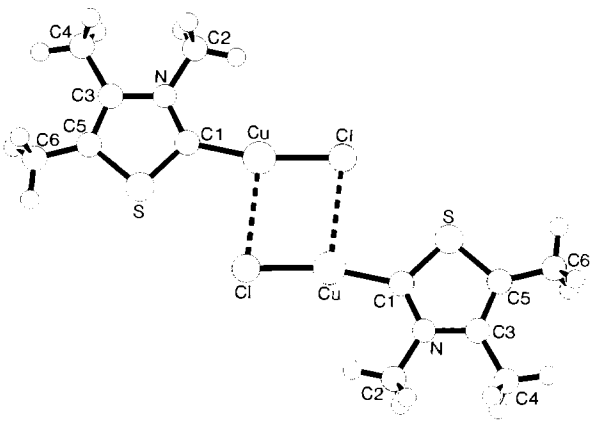


Fig. 1. Crystal structure of **2a** (SCHAKAL representation). Selected distances [Å] and angles [°]: Cu–Cl 2.122(2), Cu-Cl 1.888(6), C1-N 1.350(6), C1-S 1.665(6), Cl-Cu-C1 166.9(2), Cu-C1-N 128.0(5).

Experimental Procedure

2a: A suspension of CuCl (0.37 g, 3.7 mmol) in THF (40 mL) was added to 4,5-dimethylthiazol-2-yllithium, prepared from 4,5-dimethylthiazole (0.80 mL, 7.6 mmol) and 1.6 M *n*BuLi in hexane (4.6 mL, 7.4 mmol) in THF (40 mL), at −80 °C. The mixture was stirred for 2 h before adding $CF_3SO_3CH_3$ (0.40 mL, 3.6 mmol) at −80 °C. Stirring was continued at this temperature for 1 h, then for 1.5 h at −50 °C, and finally at −20 °C for 1 h, before the mixture was warmed to room temperature. After filtration through anhydrous $MgSO_4$ (18 g) and concentration in vacuo to about 75 mL, light brown crystals (0.46 g, 55%) formed at −20 °C. Crystals suitable for X-ray structure determination were obtained from the mother liquor of the first crystallization.

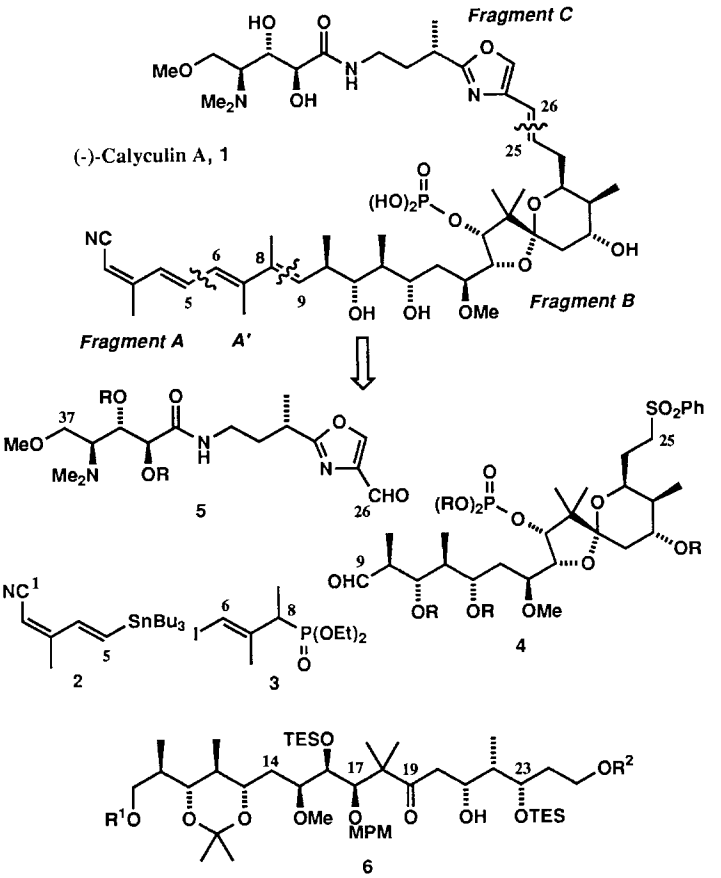
Chem.* **1989**, *42*, 137: Cu–Cl = 2.177(3), 2.475(3), 2.168(3), and 2.510(3) Å in [(oha)$CuCl_2$Cu(oha)], oha = 1,2,3,4,5,6,7,8-octahydroacridine; b) see also [11a], Cu···Cl 2.618(1) Å in $[Cu(HBpz_3)(C_6H_{10})CuCl]$.



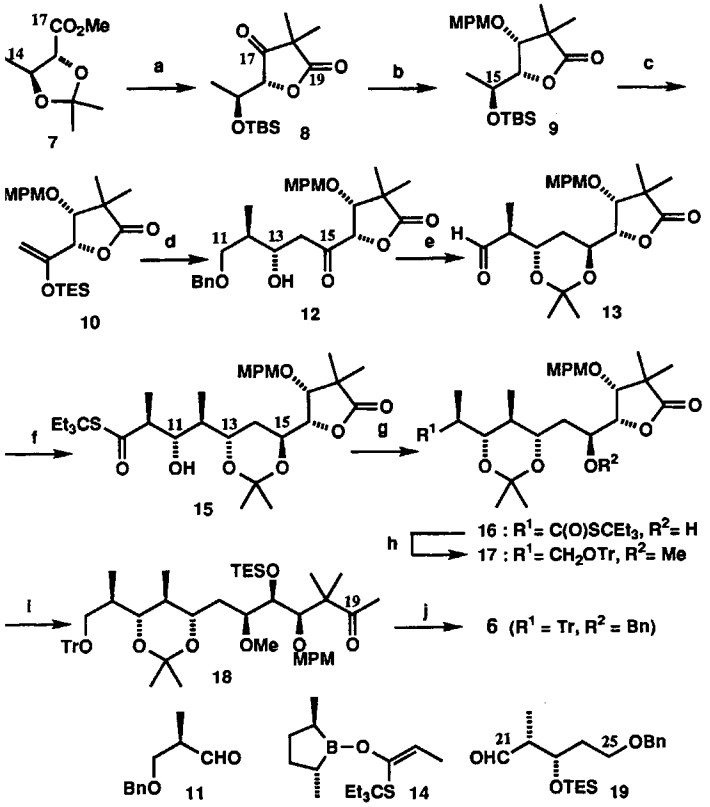
The Synthesis of Naturally Occurring (−)-Calyculin A**

Norihiko Tânimoto, Samuel W. Gerritz, Akiyoshi Sawabe, Takeshi Noda, Sandra A. Filla, and Satoru Masamune*

Calyculin A (**1**), isolated in 1986 from the marine sponge *Discodermia calyx*,[1] has aroused considerable interest among synthetic chemists mainly for two reasons: 1) this marine product exhibits striking biological activity exemplified by the inactivation of the serine/threonine protein phosphatases 1 and 2A,[2] and 2) it possesses a functionally and stereochemically unique structure as demonstrated by X-ray crystallography (which clarified the relative stereochemistry).[1] In late 1991 two studies[3] established the absolute stereochemistry as shown in **1**, which was enantiomeric to that depicted in the original 1986 report. While all synthetic efforts recorded thus far[4] had selected *ent*-**1** as the target molecule, we promptly modified our synthetic plan towards **1** and now describe the synthesis of *naturally occurring* calyculin A (**1**).

As noted previously,[5] retrosynthetic dissection as shown by the wavy lines superimposed on **1** provides fragments A (**2**, C1–C5), A′ (**3**, C6–C8), B (**4**, C9-C25), and C (**5**, C26-C37). As shown in Equation (a), the order of fragment coupling was carefully selected so that the sensitive tetraene portion (C1–C8) was introduced at a late stage in the synthesis. Since fragments A, A′, and C were already available,[5] the synthesis of fragment B and the assembly of calyculin A are outlined below. Several aldol reactions used for the fragment B construction address a previously unsolved problem in this methodology: the stereoselective coupling of chiral fragments through the aldol reaction.[6]

$$B \xrightarrow{C} BC \xrightarrow{A'} A'BC \xrightarrow{A} AA'BC \qquad (a)$$



All stereocenters embedded in fragment B (**4**) are contained in the acyclic intermediate **6** (TES = triethylsilyl, MPM = *p*-methoxyphenylmethyl), which was selected after numerous model studies and prepared according to Scheme 1. The initial task was the construction of the central portion C14–C19 of **6** through a sequence of standard conversions: a) the Claisen condensation of **7** with the lithium enolate derived from methyl isobutyrate followed by lactonization and alcohol protection to provide **8** (TBS = *tert*-butyl(dimethyl)silyl), b) stereoselective (>10:1) reduction of the C17-ketone and MPM-protection of the resulting alcohol to afford **9**,[7] and c) liberation of the C15 alcohol, Swern oxidation, and enol silylation to provide **10**. The Ti^{IV}-mediated, chelation-controlled, Mukaiyama-type aldol reaction of aldehyde **11** with **10** proceeded smoothly to provide **12** with 10:1 diastereoselection (step d). Apparently the chirality present in **10** has a limited effect on the diastereoselectivity of the reaction,[8] an important observation for the stereoselective coupling of two *chiral* components. The C11, C13, and C15 oxygen functionalities in **12** were modified to those shown in **13** (step e). This modification set the stage for the subsequent aldol reaction, which involved the construction of the 10,11-*anti*, 11,12-*anti*, 12,13-*anti* aldol **15**, the 'worst' mismatched pair possible for a product of the aldol reaction.[9] Fortunately, the extraordinarily high diastereoselectivity of the *E*(O) enolate **14** (derived from propanethiolate with (*R*,*R*)-2,5-dimethylboro-

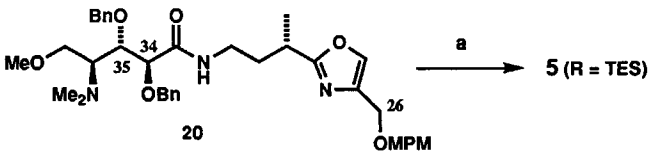
[**] This work was supported by the National Institutes of Health, USA (CA 48175). We gratefully acknowledge valuable contributions made by Drs. H. A. Vaccaro, T. Jaetsch, D. E. Levy, E. Parmee, and L.-Y. Chen in the early stage of the synthesis. A sample of (−)-calyculin of natural origin was made available to us by Professor N. Fusetani as a generous gift.



lanyl triflate)[10] overrode that (1:4) of **13** to provide **15** with 12:1 diastereoselection (step f). All other chiral reagents tested failed to provide the desired diastereomer as the major product.[11] The above successful stereochemical control to form an *anti, anti, anti* product represents one of the rare recorded examples of this case. With all the carbons in place, **15** was further modified: conversion of the 13,15-*anti* acetonide into the more stable 11,13-*syn* acetonide (**16**) (step g), followed by reduction of the thiol ester[12] to the corresponding C9 primary alcohol, and finally the protection of the C9 and C15 alcohol groups with trityl (Tr) and methyl groups, respectively, to provide **17** (step h).[7]

Scheme 1. Synthesis of intermediate **6**; reagent, conditions, and yield. a) 1. Methyl isobutyrate, lithium diisopropylamide (LDA), THF/hexane, then **7**, −78 °C–25 °C; 2. Dowex-50 × 8 (H^+), MeOH; 3. *t*BuMe$_2$SiOTf, 2,6-lutidine, CH_2Cl_2, 25 °C (84%, three steps). b) 1. KEt$_3$BH, THF, −78 °C, then AcOH (85%); 2. MPMBr, *n*Bu$_4$NI, KH, THF (82%); c) 1. *n*Bu$_4$NF, THF, 25 °C; 2. Swern oxidation; 3. Et$_3$SiOTf, 2,6-lutidine, CH_2Cl_2 (83%, three steps). d) **11**, $TiCl_4$, CH_2Cl_2, then **10**, −78 °C (84%, 13*S*:13*R* = 10:1); e) 1. Me$_4$NHB(OAc)$_3$, CH_3CN-AcOH (1:1), 2. Me$_2$C(OMe)$_2$, TsOH (83%, two steps); 3. W-2 Raney Ni, EtOH; 4. Swern oxidation (89%, two steps). f) (*E*)-enolate **14**, hexane/CH_2Cl_2, −78 °C (82%, 11,12-*anti*:11,12-*syn* = 12:1); g) camphorsulfonic acid (CSA), acetone, 25 °C (100%). h) 1. Hg(CF$_3$CO$_2$)$_2$, NaH$_2$PO$_4$, THF (98%; 2. ClCO$_2$Et, Et$_3$N, THF, then NaBH$_4$, H_2O (85%); 3. Ph$_3$CCl, Et$_3$N, 4-dimethylaminopyridine (DMAP), 4. KH, [18]-crown-6, MeI, THF (86%, two steps). i) 1. LiOH, *t*BuOH-H_2O, 2. CH_2N_2, Et$_2$O; 3. reagents as for c, 3; 4. Me$_3$SiCH$_2$Li, THF, then MeOH (95%, four steps). j) (cHex)$_2$BCl, Et$_3$N, CH_2Cl_2, then **19** (93%). Tf = trifluoromethanesulfonate, Ts = tosyl.

The utility of the above acetonide migration strategy deserves a special note, as it enables us to differentiate between the secondary hydroxyl groups at C11 and C15, thereby freeing the C15 hydroxyl group for subsequent methylation as required in **1**. Transformation of **17** into the methyl ketone **18** was effected with a set of standard reactions (step i), and then the coupling of the two chiral fragments **18** and **19** (C21–C25)[13] constituted the final aldol reaction needed for the assembly of **6**. The $BF_3 \cdot OEt_2$-promoted aldol reaction[14] of the TMS enol ether of **18** (TMS = trimethylsilyl) proceeded slowly (5–7 days) and in low yield (about 50%) prompting an investigation of the aldol reaction mediated by a variety of achiral boron reagents. This survey of boron reagents revealed that the size of the alkyl ligands on boron had a pronounced effect on the diastereoselectivity of the aldol reaction; the increase in the size of the ligands attached to B enhanced the ratio of **6** to its 21-epimer (**6a**). Thus, the use of the bulky reagent dicyclohexyl boron chloride brought about the exclusive formation of **6**, the C21 stereochemistry of which was confirmed by its conversion into the corresponding spiroketal **21** (see below).

Precursor **20** to fragment C prepared from D-galactose by analogy to our previously reported synthesis of *ent*-**20**,[5] was futher modified to **5** (R = TES) (Scheme 2) in order to secure a fragment BC suitable for final coupling with fragments A and A′. It is noteworthy that selective deprotection of the C34 and

Scheme 2. Synthesis of fragment C, reagents, conditions, and yield. a) 1. 10% Pd/C, 4.4% HCO_2H/MeOH (63%); 2. Et$_3$SiOTf, 2,6-lutidine, CH_2Cl_2 (81%); 3. dichlorodicyanoquinone (DDQ), CH_2Cl_2/H_2O/*i*PrOH (62%), 4. Swern oxidation (89%).

C35 benzyloxy groups in the presence of the C26 OMPM group was not a trivial task and proceeded under the unusual conditions specified in Scheme 2, step i.[15]

Table 1. Stereoscopic data of selected synthetic intermediates (**5**, **21**, and **26**).

Intermediate **6** to fragment B also had to undergo several critical manipulations. Thus, removal of the TES groups at C16 and C23 from **6** followed by treatment with 1:1 formic acid/ether[16] provided the single spiroisomer **21** (Scheme 3, step a; 70% yield),[17] the stereochemistry of which was ascertained by extensive nuclear Overhauser enhancement (NOE) experiments.[7] After silylation of the C9 and C21 hydroxyl groups and oxidative removal of the C17 MPM group (step b), the liberated C17 alcohol was converted to its bis(2-trimethylsilylethyl)phosphate triester (**23**, step c) as described earlier.[18] The transformation of the C25 benzyl group of **23** into the C25 sulfone group (**24**) proceeded in the usual manner (step d). The selection of a protecting group for the C9 hydroxyl function proved to be problematic, because the group must be stable to the Julia-Lythgoe coupling[19] conditions, yet more labile than the C34 and C35 OTES groups. After extensive experimentation, a TMS group was found to satisfy these requirements, and compound **25** (step e) was ready for the B–C coupling.

Scheme 3. Synthesis of fragment B and subsequent reactions leading to calyculin A **1**; reagents, conditions, and yield. a) 1. nBu$_4$NF, THF, 0 °C (95%); 2. HCO_2H-Et_2O (1:1), 25 °C (70%). b) 1. tBuMe$_2$SiOTf, 2,6-lutidine, CH_2Cl_2; 2. DDQ, CH_2Cl_2/H_2O (10:1) (75%, two steps); c) $Me_3SiCH_2CH_2OPCl_2$, pyridine, 0 °C, then $Me_3SiCH_2CH_2OH$, 25 °C, then 30% H_2O_2 (70%, two steps) d) 1. 10% Pd/C, H_2, MeOH (92%); 2. MsCl, Et_3N, CH_2Cl_2, 0 °C; 3. PhSNa, DMF, 4. *meta*-chlorperbenzoic acid (mCPBA), CH_2Cl_2 (92%, three steps). e) 1. HF-pyridine, THF-pyridine, 2. Me_3SiCl, Et_3N, CH_2Cl_2 (93%, two steps). f) 1. PhLi, THF, −78 °C, then **5** (56%). 2. PhCOCl, Et_3N, DMAP, CH_2Cl_2; 3. Na-Hg, MeOH-EtOAc, −20 °C (68%, two steps). g) Swern oxidation (82%). h) **28**, PhLi, THF, −78 °C, then **27**, 0 °C, then I_2 (53%). i) **2**, $[Pd(Ph_3P)_2Cl_2]$, DMF (67%); j) CH_3CN/47%HF/H_2O 85:5:10 (57%).

The anion derived from **25** with phenyllithium reacted with aldehyde **5** to provide the corresponding adduct (step f) without losing the C9 TMS group, and the adduct, after benzoylation, was subjected to reductive elimination with sodium amalgam to provide the *E*-olefin **26** as the predominant product ($J_{25,26}$ = 16.0 Hz). The C9 OH group was liberated in this last step of the Julia coupling. Since the nucleophilic attack of the anion of **25** on **5** proceeded much faster than deprotonation of the amide group present in **5**, temporary protection of the amide was unnecessary. With the BC fragment fully protected except for the C9 alcohol, the construction of the tetraene moiety on **26** was carried out as shown earlier.[5] Thus, the Horner–Emmons reaction of **27**, derived from **26** (Swern oxidation, step g), with the anion generated from **28** with phenyllithium provided the unstable vinyltin intermediate, which was converted in situ into the corresponding iodide **29**. The product was almost exclusively the *E,E* isomer. The final coupling utilized the Stille coupling[20] of **29** and **2** with the aid of $[PdCl_2(Ph_3P)_2]$, and complete removal of all the protecting groups of **30** with CH_3CN/HF completed the synthesis of (−)-**1**, which was found to be identical in every respect to naturally occurring calyculin A.

Titanium Complexes with Tripodal Amido Ligands: Building Blocks for Stable Bimetallic Coordination Compounds Containing Highly Polar Metal–Metal Bonds**

Stefan Friedrich, Harald Memmler, Lutz H. Gade,* Wan-Sheung Li, Mary McPartlin

Focusing the chemical reactivity at an early transition metal center upon a single "activated" site while effectively shielding the remaining coordination sphere is an underlying motivation of the recent interest in the development of polydentate amido ligands.[1] A notable example is the reactivity of a series of complexes containing the silylated tren ligand (tren = tris(2-aminoethyl)-amine) of the type $[N\{CH_2CH_2NSiRMe_2\}_3MX_n]$ (R = Me, *t*Bu; M = Ti, V, Cr, Mn, Fe, Ta; X = Cl, PR; n = 0, 1, 2) reported by Schrock et al.[2] The anticipated stabilization of a high-valent early transition metal shielded, and thus kinetically stabilized, by a polyfunctional ligand appeared to us to provide the key to a general strategy for the synthesis of thermally stable dinuclear complexes containing highly polar unsupported metal–metal bonds. Despite the activities in the chemistry of early–late heterobimetallics there are still but a few stable species of this kind,[3] and their different sets of ligands have hampered a systematic comparative study of their structure and reactivity.[4] This led us to develop new tripodal amides[5] (type **A**) which leave a greater coordination arc at the reactive center than the tren derivatives (Fig. 1)[6], thus potentially facilitating M–M′ bond formation. These complexes indeed satisfied the expectations.

A **B**

Fig. 1. Titanium-containing building blocks of type **A** and **B** for the synthesis of stable heterobimetallic complexes with unsupported metal–metal bonds.

We have now extended this approach to the synthesis of a new class of titanium amido halides (type **B**) and report the synthesis of one member, **2**.[7]

The amido titanium bromide **2** is readily obtained by reaction of the trilithiated amino-functionalized trisilylmethane with $[TiBr_4(thf)_2]$ [Eq. (a)].

$$[HC(SiMe_2N(Li)C_6H_4CH_3)_3] \xrightarrow{[TiBr_4(thf)_2]} [HC(SiMe_2NC_6H_4CH_3)_3TiBr] \quad (a)$$
2

The spectroscopic data of the moisture-sensitive, red, crystalline compound (Table 1) are in accordance with the structure depicted in Figure 1. Reaction of the complex **1**[6a] or **2** with carbonyl metallate derivatives according to Scheme 1 leads to the coupled heterobimetallic, dinuclear complexes **3**–**5** and **6**–**8**, respectively. The Ti–Fe complexes, **3** and **6** are the first compounds with an unsupported Ti–Fe bond that are stable in solution at ambient temperatures and chemically fairly robust towards attack by weak nucleophiles unless activated thermally or photochemically.[8]

Table 1. Selected spectroscopic data. NMR spectra recorded at 200.13 MHz (^{1}H), 50.32 MHz (^{13}C), 77.78 MHz (^{29}Si), and 81.03 MHz (^{31}P) in C_6D_6. Correct elemental analyses were obtained for all compounds.

The existence of Ti–M bonds in **3**–**8** was initially established by IR spectroscopy. The ν_{CO} bands of the dimers are shifted to higher wavenumbers relative to those of the alkali metal salts of the anions,[8, 9] as would be expected for metal–metal bonded structures (Table 1). The absence of ν_{CO} absorptions attributable to bridging carbonyl or isocarbonyl ligands supports the structural arrangements shown in Scheme 1. Free rotation about the Ti–M bonds is inferred from the effective threefold symmetry of the titanium–amide moiety observed in the NMR spectra. Cooling solutions of **3**, **4**, **6** and **7** in [D$_8$]toluene 190 K leads to a broadening of the resonances assigned to the amido ligand; however, it proved impossible to reach the low temperature limit.

Single crystal X-ray structure analyses of **3** and **4**[10] have established that while the compounds differ significantly with regard to their packing in the crystal and thus space group symmetry, their molecular structures are very similar (Fig. 2). The central structural unit is the free Ti–M bond (M = Fe, Ru), which is effectively shielded by the tripodal amido ligand at the Ti center as well as the set of ligands coordinated to the late

McP.). We thank Prof. H. Werner for his support. We are also grateful to Wacker Chemie AG and Degussa AG for gifts of basic chemicals.

Scheme 1. Condensation of **1** (type **A**) and **2** (type **B**) with late transition metal carbonylates.

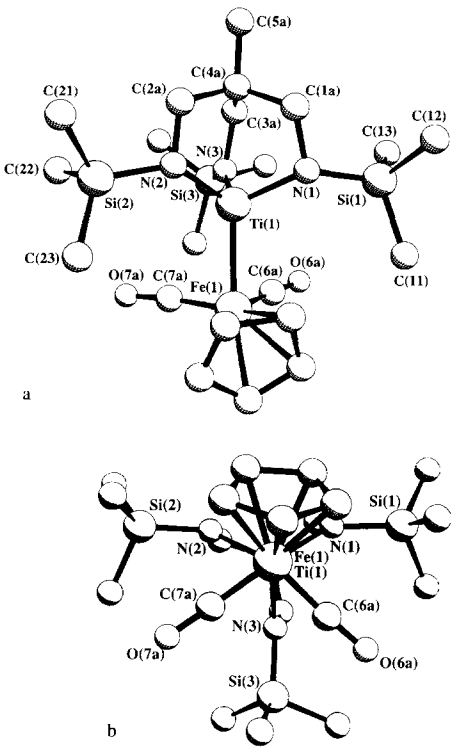

Fig. 2. a) Molecular structure of **3**; b) view along the Fe–Ti axis of **3**. Selected mean bond lengths [Å] and interbond angles [°] for the two independent molecules in the asymmetric unit: Ti-Fe 2.433(5), Fe-C6 1.73(2), Fe-C7 1.68(2), Ti-N1 1.90(2), Ti-N2 1.88(2), Ti-N3 1.89(2); Ti-Fe-C6 81.3(8), Ti-Fe-C7 83.8(8), C6-Fe-C7 96(1), Fe-Ti-N1 114.1(5), Fe-Ti-N2 116.1(5), Fe-Ti-N3 117.3(6). Corresponding bond parameters of **4**, which has a very similar molecular structure (but only one molecule in the asymmetric unit): Ti-Ru 2.527(1), Ru-C6 1.840(9), Ru-C7 1.835(9), Ti-N1 1.907(5), Ti-N2 1.905(6), Ti-N3 1.907(6); Ti-Ru-C6 79.6(3), Ti-Ru-C7 81.9(3), C6-Ru-C7 93.1(4), Ru-Ti-N1 118.1(2), Ru-Ti-N2 115.3(2), Ru-Ti-N3 113.1(2).

transition metal. The average Ti–Fe distance of 2.433 Å in the structure of **3** and the Ti–Ru distance of 2.527(1) Å in that of **4** are significantly shorter than the corresponding bond lengths observed in $[Cp(CO)_2MTi(NMe_2)_3]$ [d_{av}(Ti–Fe) = 2.568,[4b] d(Ti–Ru) = 2.663(1) Å][11a] and $[Cp(CO)_2RuTi(NMe_2)(2,6\text{-}Me_2C_6H_3O)_2]$ [d(Ti–Ru) = 2.573(1) Å].[11b] In fact, the Ti–Fe bond length in **3** is the shortest hitherto observed for an unsupported transition metal–metal single bond in a molecule,[12] a consequence both of the high bond polarity and the low steric hindrance of the two halves of the molecule.[13]

The essentially linear carbonyl ligands lean markedly towards the Ti atoms [mean Ti-Fe-CO 82.6° (**3**); mean Ti-Ru-CO 80.8° (**4**)], but the Ti $\cdots$ CO distance of about 2.8 Å in each compound precludes any "semi-bridging" interaction[14] and indicates that the disposition of these ligands is largely determined by the steric requirements of the bulky cyclopentadienyl group. Repulsion between this ligand and the large N-bonded Me_3Si groups at the other side of the Ti–Fe or Ti–Ru bond results in two silyl groups being forced apart (as can be seen in Fig. 2b), thus breaking the otherwise threefold symmetry of the Ti complex fragment. The polydentate triamido ligand is clearly sufficiently flexible to accommodate these distortions without a significant destabilization of the bimetallic molecule.

In order to establish the basic structural arrangement in the bimetallic complexes derived from **2**, an X-ray structure analysis of **7** was carried out (Fig. 3).[15] A striking feature is the lampshade arrangement of the tripodal amide in which the tolyl groups are oriented almost orthogonally to the radial planes spanned by the Ti, N, and Si atoms.[16] That this orientation of the amido tolyl groups is retained in solution may be inferred from the shift of the signals of the Cp protons in the ^{1}H NMR spectrum of **7** to higher field (δ = 4.07 in comparison to 4.99 in **4**). The Ti–Ru bond therefore appears less shielded than in **4**, and it may be due to this situation that the metal–metal bond [d(Ti–Ru) = 2.503(4) Å] is even shorter than that observed in **4**. All other structural features related to the metal–metal bond

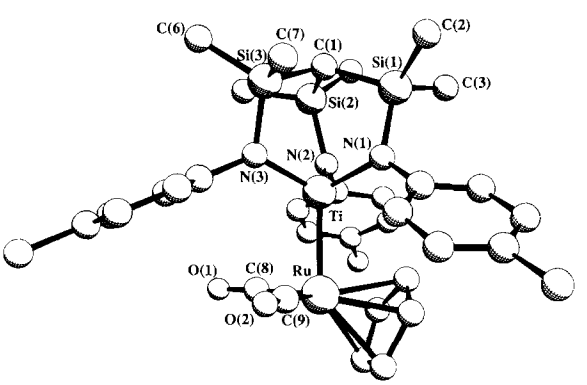

Fig. 3. Molecular structure of **7** in the crystal. Selected bond lengths [Å] and interbond angles [°]: Ti-Ru 2.503(4), Ru-C8 1.81(2), Ru-C9 1.80(2), Ti-N1 1.93(1), Ti-N2 1.90(1), Ti-N3 1.90(1); Ti-Ru-C8 87.8(7), Ti-Ru-C9 88.4(8), C8-Ru-C9 91.2(8), Ru-Ti-N1 113.9(4), Ru-Ti-N2 112.7(5), Ru-Ti-N3 117.7(5).

resemble those of **3** and **4**. In view of the similarity of the NMR data of **6** and **7** as well as the band-to-band analogy of the IR spectra, an almost identical structure may be assumed for the Fe analogue **6**.

The general applicability of the concept of Ti–M bond stabilization by use of Ti complex fragments containing polydentate amido ligands was demonstrated by the synthesis of the Ti–Co species **5** and **8**. Stable dinuclear compounds with this structural element have been elusive until recently[17] due to their extreme thermal lability. Both **5** and **8** can be readily handled in solution and were found to be sufficiently stable at ambient temperature to enable a systematic investigation into their reactivity.[18] In general, type **A** and **B** Ti amides therefore appear to "do the trick" in stabilizing Ti–M (M = late transition metal) heterobimetallics.

Experimental Procedure

2: A 2.5 M solution of *n*-butyllithium in hexanes (5.72 mL) was added to a mixture of $HC(SiMe_2NHC_6H_4CH_3)_3$ (2.41 g, 4.72 mmol) [5b] in pentane (30 mL) and diethyl ether (2 mL), which was cooled at −50 °C. The reaction mixture was subsequently warmed and stirred at room temperature for 2 h. The resulting lithium amide suspension was then cooled to −50 °C, solid $[TiBr_4(thf)_2]$ (2.69 g = 5.25 mmol) was added, and the reaction mixture warmed to room temperature over 20 h. Evaporation of the solvent, extraction of the residue with toluene (20 mL), and filtration yielded a deep red filtrate, which was concentrated to 10 mL and stored at −40 °C to yield **2** as red crystals. Yield: 1.65 g (55%).

3–**8**: Solid alkali carbonyl metalate (1 mmol) was added to a solution of **1** or **2** (1 mmol; for **1** 458 mg, for **2** 631 mg) in toluene (30 mL) cooled at −70 °C, and the reaction mixture warmed to room temperature over a period of 20 h. Evaporation of the solvent, extraction of the residue with pentane (20 mL), and subsequent filtration yielded yellow-orange solutions of the heterobimetallic complexes. Evaporation of the solvent yielded the reaction products as microcrystalline solids, which were washed with cold pentane; isolated yields: **3** 59%, **4** 68%, **5** 48%, **6** 61%, **7** 73%, **8** 39%. Single crystals suitable for X-ray crystallography were obtained by slow cooling of solutions of the compounds in toluene.

[13] Whether d_π–d_π backbonding plays a role in these heterobimetallics as invoked for the ligand-bridged Zr–Rh complex $[Cp^*Zr(\mu\text{-}OCH_2Ph_2P)_2RhMe_2]$ [*d*(Zr–Rh) = 2.444(1) Å] (G. S. Ferguson, P. T. Wolczanski, L. Párkányi, M. C. Zonnevylle, *Organometallics* **1988**, *7*, 1967) remains to be investigated in MO calculations of appropriate model systems.

[14] See, for example, F. A. Cotton, *Prog. Inorg. Chem.* **1976**, *21*, 1; F. A. Cotton, J. M. Troup, *J. Am. Chem. Soc.* **1974**, *96*, 1233; W. I. Bailey, D. M. Collins, F. A. Cotton, *J. Organomet. Chem.* **1977**, *135*, C53.

[15] Crystal data of **7**: $C_{35}H_{45}N_3O_2Si_3TiRu$, monoclinic, space group $I2/c$, $a = 24.473(3)$, $b = 15.417(3)$, $c = 20.783(4)$ Å, $\beta = 104.20(2)°$, $M = 772.92$, $V = 7601.84$ Å^3, $Z = 8$, $\varrho_{calcd} = 1.351$ g cm^{-3}, $F(000) = 3200$, $R = 0.0663/R_w = 0.0667$ for 1904 reflections with $I/\sigma(I) > 3.0$ corrected for absorption [$\mu(Mo_{K\alpha}) = 6.9$ cm^{-1}]. Further details of the crystal structures are available on request from the Director of the Cambridge Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK on quoting the full journal citation.

[16] A preliminary X-ray structure analysis of the sterically less crowded precursor **2** has revealed a similar arrangement of the tolyl groups [7b], which is therefore not to be interpreted as solely a consequence of the steric interaction with the Ru complex fragment.

[17] D. Selent, R. Beckhaus, J. Pickardt, *Organometallics* **1993**, *12*, 2857. The only other structurally characterized example of a compound containing an unsupported Ti–Co bond was reported by G. Schmid, B. Stutte, R. Boese, *Chem. Ber.* **1978**, *111*, 1239.

[18] If solutions of **5** or **8** in benzene are stirred at room temperature over a period of *several days*, slow decomposition sets in and generates $[\{Co(CO)_3(PPh_3)\}_2]$ which precipitates from the solution.

Direct Metal–Metal Bonds Between High and Low Valent Complex Fragments: The Reaction of Metal Bases with the Metal Acids $[Re(NR)_3]^+$ and $[Mo(NR)_2]^{2+}$ **

Jörg Sundermeyer,* Diane Runge, and John S. Field

Dedicated to Professor Wolfgang Sundermeyer on the occasion of his 65th birthday

The synthesis of heterobimetallic complexes in which a metal center deficient in d-electrons (f block element, metal of the group 4 or 5) with a complex fragment rich in d-electrons (typically a metal of group 8) fixed in close proximity is enjoying steadily growing interest. The combination of antipodes of the periodic system (early–late heterobimetallics)[1] holds the promise of cooperative behavior on the part of the metal centers in the activation of smaller molecules,[2] an increased catalytic activity in the homogeneous phase, or at least an insight into the interaction of immobilized catalysts with oxide support materials.[3] Comparable synergistic effects could also be achieved by the combination of the same metal, or of two metals close to one another

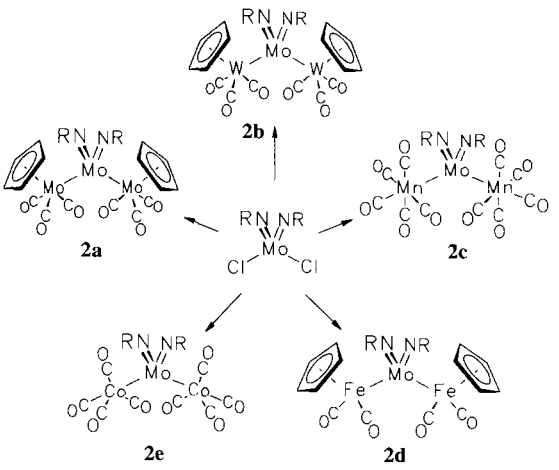
in the periodic system. A prerequisite for this, however, is that one metal center may be considered as electron-deficient because of its formally high oxidation state ($\geq +5$), the other as low valent and electron-rich (oxidation state +1, 0). Unequivocal evidence of a direct interaction between the metal atoms would be a M–M′ bond wholly unsupported by bridging ligands. The only compound which, to our knowledge, fulfills these criteria, is the complex [Cp*W(O)$_2$–W(CO)$_3$Cp*] (Cp* = η^5-C$_5$Me$_5$), which was synthesized by autoxidation of [{Cp*W(CO)$_2$}$_2$] by H. Alt et al.[4] This was reason enough for us to search for synthesis strategies for the isoelectronically related compounds of the type [L$_x$(O)$_y$M]–[M′(CO)$_m$L′$_n$] and [L$_x$(RN)$_y$M]–[M′(CO)$_m$L′$_n$].

Nucleophilic substitution reactions compete with electron-transfer processes in the reaction of electron-deficient oxo complexes with potentially reducing nucleophiles as a matter of course. The selectivity in favor of the substitution increases when the oxo function, O^{2-}, is replaced by the isoelectronic, yet more strongly π-basic imido function, $(RN)^{2-}$. A very fruitful branch of organometallic chemistry has developed in the last few years, in which reactions of high valent imido complexes with carbanions[5–7] and phosphorus ylides [8], as well as the activation of C–H bonds,[9] stand in the foreground. The imido function continued to prove itself as a useful protecting group in the masking of oxo functions, for example in the synthesis of organometallic functionalized oxometalates, such as NBu$_4$[Cp*MO$_3$] (M = Mo, W)[7] through selective hydrolysis of the imido precursors. For this reason, we directed our attention primarily at metalated imido complexes.



Recent works by R. R. Schrock,[10] G. Wilkinson,[11] and M. L. H. Green[12] report that, in the reduction of high valent imido complexes with Na/Hg or [Co$_2$(CO)$_8$], Re–Hg, Re–Co and Mo–Hg bonds can be formed. A first early–late heterobimetallic complex containing bridging imido ligands has just been described by R. G. Bergman et al.[13] In the following we report on a series of bimetallic compounds which have been prepared in good yields in targeted syntheses by reactions of [Re(N*t*Bu)$_3$Cl][5b] and [Mo(N*t*Bu)$_2$Cl$_2$][5c] with carbonyl metalates of groups 6–8 (Schemes 1 and 2). Compounds **1a–e** and

Scheme 1. Reaction of [(*t*BuN)$_3$ReCl] with the carbonyl metalates.

2a–e were obtained in adequate purity for analytical purposes after workup by sublimation, crystallization, or column chromatography. A selection of spectroscopic and analytical data is shown in Table 1.

The absence of a tendency for the complexes to form clusters of higher nuclearity by loss of carbonyl groups under normal conditions, as is observed in the reaction of [Re(N*t*Bu)$_3$Cl] with [Co$_2$(CO)$_8$],[11] is rather surprising. Only rotamers can be identified spectroscopically; no isomers with bridging carbonyl, isocarbonyl,[14] or imido ligands can be identified even at low temperatures. This explains why no spontaneous redox reaction takes place through intramolecular ligand exchange under normal conditions.[15]

Scheme 2. Reaction of [(*t*BuN)$_2$MoCl$_2$] with the carbonyl metalates.

Compounds **1a–e** and **2a–e** are formed by metalation of the formally heptavalent and hexavalent cationic Lewis acids, $[Re(NR)_3]^+$ and $[Mo(NR)_2]^{2+}$ respectively, with carbonyl complex fragments isolobal with CH_3^-. The compounds **1a–e** can be described as a combination of a 16 VE (valence electron) and an 18 VE building block. The donor and acceptor centers are connected to one another by a polar metal–metal bond, which is not supported by ligand bridges. The recently reported homobinuclear d^1–d^1 dimer [(ArN)$_3$Tc–Tc(NAr)$_3$] (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$)[16] is comparable in its overall electron balance. In contrast, **2a–e** are electronically unsaturated. Even if both imido ligands are considered as using their donor capability to the full extent, that is, one σ and two π bonds each, only 16 VE can be assigned to the central molybdenum atom in each case. The difference $\Delta\delta$ in the ^{13}C resonance signals of the quaternary and primary carbon atoms in *tert*-butylimido complexes is a useful spectroscopic probe for the estimation of the electron density on the metallic center.[17] The $\Delta\delta$ values for **1a–e** and **2a–e** correlate with the M′H acidities of the corresponding metal carbonyl hydrides.[18] As the metal basicity and σ-donor ability (nucleophilicity) of metal carbonyl fragments are influenced to varying extents by steric factors, a tendency,[19] but not a linear correlation of $\Delta\delta$(M=N*t*Bu)/pK_s(M′H), can be recognized (Table 1).

Additional evidence for the structures given in Schemes 1 and 2 is provided by the results of crystal structure analyses on single crystals of **1a** (Fig. 1) and **2a** (Fig. 2).[20] The molecular framework of **1a** has C_s symmetry in the crystalline state. A mirror plane runs through the atoms Re, Mo, C2, O2, C8, N1, and C9. The Re–Mo distance of 2.844(1) Å is considerably shorter than comparable Re–Mo single bonds. The metal–metal bond of 3.12 Å in [(OC)$_5$Re–Mo(CO)$_3$Cp][21] for example, in which none of the ligands plays a bridging role, or the asymmetrical CO-bridged bond of 2.959(1) Å in [CpRe(μ-CO)$_2$MoCp$_2$][22] are significantly longer. Considered separately, neither of the metal

complex fragments is found to deviate characteristically from known structures of the respective homonuclear complexes.[5b, 23] Compound **2a** has crystallographically imposed C_2 symmetry. The Mo1 center has distorted tetrahedral coordination; the two-fold screw axis bisects the extended angles Mo2-Mo1-Mo2′ and N-Mo1-N′ (124.7(1)° and 114.6(6)°, respectively). The carbonyl groups C1–O1 and C2–O2 formally fulfill the criteria[24] for semibridging CO ligands. This can be regarded as a possible mechanism by which the molecule compensates the different charge densities on the Mo1 and Mo2 centers. The interactions are so weak, however, that they can equally plausibly be explained by the forced spatial proximity of four CO groups to the sterically shielded Mo1 center. The Mo1–Mo2 distance of 2.875(1) Å is considerably shorter than other known Mo–Mo single bond values in the absence of ligand bridges. Examples are $[Cp(CO)_3Mo-Mo(CO)_3Cp]$[23] (3.235(1) Å) and $[CpMo(CO)_3Mo-Mo(CAr_2)(NNCAr_2)Cp]$[24] (3.052(1) Å).

We assume that the very short M–M distances are due to coulombic forces; more precisely, due to the electrostatic attraction in the dipolar structural unit $M^{\delta+}-Mo^{\delta-}$. The smaller radii of Re^{7+}/Re^{6+} and Mo^{6+}/Mo^{4+} as compared to the zero valent and monovalent metal centers also contribute to the shortening of the M–M bond. Just how large the difference between formal oxidation state and the distribution of real charge density actually is in these simply built, symmetrical molecules remains a domain reserved for the analysis of photoelectron spectra and quantum mechanical calculations.

The electronically unsaturated character and the low coordination number of the central diimido unit in compounds **2a–e** promises further interesting chemistry when these are used as starting materials. We have these reactions currently under investigation with particular attention to the linking of imido and

carbonyl ligands through the mediation of the metal centers to give isocyanates. It is also hoped that selective hydrolysis or metathesis reactions will provide a general preparative route to mixed metal carbonyl–oxo complexes containing M–M′ bonds. Furthermore, the especially volatile compounds **1a–e**, **2c**, and **2e** are promising starting materials for the deposition of thin layers $[M_mM'_nN_x]$ from the gas phase using the metal-organic chemical vapor deposition technique.

[14] Isocarbonyl bridges [M′]–C≡O–[M] are often found for very hard Lewis acids [M], or for [M] fragments with high steric requirements. They are a result of the ambident character of the metal nucleophiles. For a representative example, see D. M. Hamilton, Jr., W. S. Willis, G. D. Stucky, *J. Am. Chem. Soc.* **1981**, *103*, 4255–4256.
[15] Interestingly, bridging imido and carbonyl ligands were recently identified in homobinuclear Mo and W complexes with more strongly balanced charge densities on both metal centers: M. D. Curtis, M. S. Hay, W. M. Butler, J. Kampf, A. L. Rheingold, B. S. Haggerty, *Organometallics* **1992**, *11*, 2884–2892.

[19] As expected, the weakest metal base $[Co(CO)_4]^-$ led to the largest $\Delta\delta$ value, and the strongest metal base $[CpFe(CO)_2]^-$ to the smallest. When the pK_s values show only small differences from one another, the σ-donor capability is found to be largely dependent on the steric requirements of the metal carbonyl fragments.
[20] a) Crystal structure analysis of **1a**: $C_{20}H_{32}MoN_3O_3Re$, $M = 644.64\ g\,mol^{-1}$, orthorhombic, space group: *Pbca*, $a = 8.866(2)$, $b = 17.262(3)$, $c = 33.519(6)$ Å, $V = 5130(2)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.669\ g\,cm^{-3}$, crystal size = 0.75 × 0.15 × 0.19 mm, $\mu(Mo_{K\alpha}) = 54.94\ cm^{-1}$. Intensity measurement: Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, 22 °C, $2\theta_{max} = 46°$, 2864 reflections measured, of which 1953 observed ($I > \sigma_I$), semi-empirical absorption correction (ψ scan). Structure refinement: H atoms were not found. C atoms of the *t*Bu group were input as part of a rigid group. All atoms other than hydrogen were refined anisotropicically. $R = 0.0409$, $R_w = 0.0423$, $w = 1/[\sigma^2(F) + 0.0007F^2]$ max. shift/e.s.d. = 0.518, 235 parameters, remaining electron density = 0.86 e Å^{-3}. b) Crystal structure analysis of **2a**: $C_{24}H_{28}Mo_3N_2O_6$, $M = 742.33\ g\,mol^{-1}$, monoclinic, space group: *C2/c*, $a = 17.725(3)$, $b = 16.107(3)$, $c = 9.588(3)$ Å, $\beta = 91.95(3)°$, $V = 2735(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.803\ g\,cm^{-3}$, crystal size = 0.42 × 0.31 × 0.25 mm, $\mu(Mo_{K\alpha}) = 13.72\ cm^{-1}$. Intensity measurement: Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, 22 °C, $2\theta_{max} = 46°$, 2488 reflections measured, of which 1425 observed ($I > 3\sigma_I$), semi-empirical absorption correction (ψ-scan). Structure refinement: H atom positions were calculated. Methyl C and H atoms were input as part of a rigid group. All atoms other than hydrogen were refined anisotropicically, H atoms were refined isotropically. $R = 0.0492$, $R_w = 0.0481$, $w = 1/[\sigma^2(F) + 0.0010F^2]$ max. shift/e.s.d. = 0.128, 187 parameters, remaining electron density = 1.0 e Å^{-3}. The programs SHELX-86 and SHELX-76 were used to solve and refine both structures [20c]. Tetrakis(hypersilyl)dithallium(*Tl–Tl*): A Divalent Thallium Compound**

Sonja Henkel, Karl Wilhelm Klinkhammer,* and Wolfgang Schwarz

Molecular compounds with divalent boron have been known for a long time in the form of diboranes(4), whereas Uhl et al. achieved the first preparation and unequivocal characterization of element-homologous dialuminum, digallium, and diindium compounds only a few years ago.[1] Hitherto, only for the heaviest element of the third main group, thallium, were no analogous compounds known.[2] We report here on the synthesis and structural characterization of one such dithallium compound.

Organothallium(I) compounds with σ-bound substituents and corresponding derivatives with Tl–Si bonds have so far not been synthesized,[3] in contrast, the related trivalent thallium com-

[**] For the term "hypersilyl" see ref. [5].

pounds have been prepared, for example, from bis(triorganylsilyl)mercury derivatives and trimethylthallium.[4]

A feasible route to kinetically stabilized, silyl-substituted thallium(I) compounds would be the reaction of thallium(I) halides with metal derivatives of a sterically demanding silane. Corresponding experiments with alkali metal derivatives of tris(trimethylsilyl)silane ("hypersilane"),[5] however, did not lead to a compound with a Tl–Si bond but, analogous to the corresponding reactions with lead(II) halides, to the silane **1** and elemental thallium [Eq. (a)].[6]

$$2\,TlX + 2\,MSi(SiMe_3)_3 \longrightarrow 2\,Tl + 2\,MX + \underset{\mathbf{1}}{(Me_3Si)_3Si\text{–}Si(SiMe_3)_3} \quad (a)$$

X = Cl, I; M = Li, Na, K, Rb, Cs

However, if, instead of a thallium(I) halide, the thallium(I) bis(trimethylsilyl)amide (**2**), soluble in hydrocarbon solvents and readily accessible from thallium(I) chloride and $LiN(SiMe_3)_2$ in toluene, is used, initially no metal precipitates out but a clear blood red solution is formed.

The expected thallium(I) derivative has, however, so far not been isolated nor spectroscopically detected. Also in this case already after a few minutes elemental thallium is precipitated, but without a loss of color of the solution [Eq.(b)].[3] A fractionating crystallization from *n*-pentane affords in addition to the colorless, sparingly soluble rubidium bis(trimethylsilyl)amide, dark red, platelike crystals of tetrakis(hypersilyl)dithallium(*Tl–Tl*) (**3**).

$$4\,(Me_3Si)_3SiRb + 4\,TlN(SiMe_3)_2 \longrightarrow \underset{\mathbf{2}}{} \quad (b)$$

$$4\,RbN(SiMe_3)_2 + \underset{\mathbf{3}}{[(Me_3Si)_3Si]_2Tl\ Tl[Si(SiMe_3)_3]_2} + 2\,Tl$$

The thallium(II) compound **3** dissolves well in aliphatic and aromatic hydrocarbons but only sparingly in polar solvents such as diethyl ether or acetonitrile. On standing a renewed temperature-dependent deposition of thallium is observed from these solutions. This takes place already after a few minutes at $+20\,^{\circ}C$ or after a few hours at $-60\,^{\circ}C$, and proceeds with a continual clarification of the solution. In addition, the simultaneously formed silane **1** can be detected by NMR spectroscopy.

As a result of its readiness to decompose in solution, compound **3** has so far not been satisfactorily characterized by spectroscopy. Furthermore, in the NMR spectra there are indications of dynamic processes, which we are currently investigating in more detail. Surprisingly, no radicals with longer lifetimes seem to participate in the decomposition of the compound, since the solution in *n*-pentane is ESR inactive, even after irradiation with shortwave UV light.

Raman spectra of compound **3** could only be obtained from concentrated *n*-pentane solutions and even then only under constant rotation of the sample tube, since the crystalline compound decomposes very rapidly in laser light with the deposition of thallium and the formation of a colorless material. In addition to a few low-intentsity bands, a very intense absorption band is found at 78 cm^{-1}, which we assign to the Tl–Tl vibrational stretch. Correspondingly, the IR spectrum also shows a medium-strong, broad absorption band in this range, at about 82 cm^{-1}. Since the dithallium compound **3** can be handled in the crystalline state without any visible decomposition (also in air!) for quite some time, it was investigated by X-ray crystallography (Fig. 1).[7] The central structural element of the compound is a dumbbell constructed from two trigonal-planar coordinated thallium atoms. The angle between the two planes which are each defined by a thallium atom and the bound silicon atoms

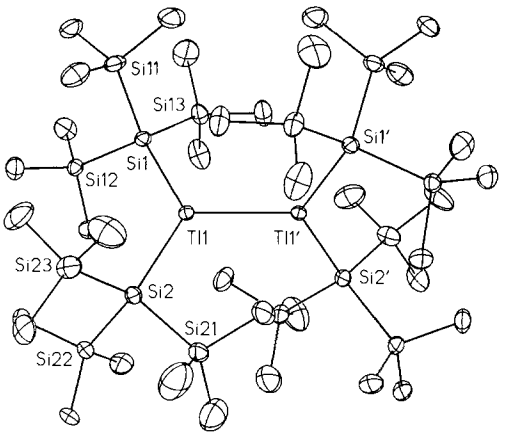

Fig. 1. Molecular structure of **3** in the crystal (thermal ellipsoids at 30% probability level). Selected bond lengths [pm] and angles [°]: Tl1-Tl1' 291.42(5), Tl1-Si1 266.4(2), Tl1-Si2 268.5(2), Si1-Si11 236.1(3), Si1-Si12 234.2(2), Si1-Si13 235.5(3), Si2-Si21 237.4(4), Si2-Si22 236.0(4), Si2-Si23 235.5(4), Si1-Tl1-S2 125.07(8), Si1-Tl1-Tl1' 116.85(4), Si2-Tl1-Tl1' 118.06(7), Si11-Si1-Tl1 117.12(8), Si12-Si1-Tl1 111.71(7), Si13-Si1-Tl1 107.95(8), Si21-Si2-Tl1 107.6(1), Si22-Si2-Tl1 119.2(2), Si23-Si2-Tl1 112.1(1), Si1-Tl1-Tl1'-Si1' +78.1(1).

is 78.1° (Fig. 2). The molecule has crystallographically imposed C_2 symmetry and its Tl_2Si_8 framework even shows approximate D_2 symmetry. In the tetraaryldigallium and -diindium compounds recently synthesized by Power et al. and Cowley et al. the substituents are also staggered.[8] According to ab initio

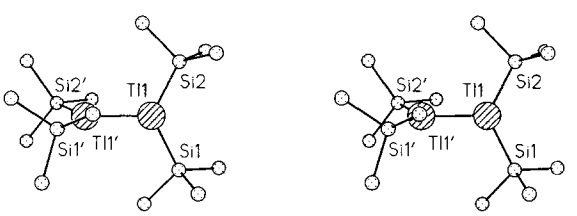

Fig. 2. Stereoscopic representation of the molecular framework of **3**. Only the thallium and silicon atoms are represented (as spheres of arbitrary sizes).

calculations by Treboux and Barthelat this staggered arrangement is also the energetically most favorable for the parent compounds M_2H_4.[9a] Only the tetraalkyldialuminum, -digallium, and -diindium compounds prepared by Uhl et al. exhibit an almost planar C_4M_2 framework, probably as result of hyperconjugative interactions of the empty p orbitals of the central metal atoms with the substituents.[1] The Tl–Tl bond length in **3** is 291.4 pm at $-100\,^{\circ}C$.[10] This value is about 20 pm less than twice the value of the covalent radius of the element (310 pm[11]).[12] The Tl–Tl distance in the comparable Tl_2 dumbbell of the molybdate $Sn_{0.8}Tl_{0.6}Mo_7O_{11}$ studied by Simon and Dronskowski is about an additional 7 pm less;[13] the latter value is in excellent agreement with the bond length (284 pm) for Tl_2H_4 optimized with SCF calculations at the Hartree–Fock and MP2 level.[9d] The distances of the thallium atoms to the central silicon atoms of the hypersilyl group (Σr_{cov} = 272 pm[11]) also appear slightly shortened (267 pm). The Si–Si bond lengths (236 pm) lie in the expected range. As a consequence of the greater electronegativity of thallium, the Si-Si-Si angles are somewhat larger (105 to 108°) than the Si-Si-Si angles of corresponding alkali metal derivatives.[14] The comparatively small angle (125°) between the sterically very demanding hypersilyl groups leads to the tilting of the

substituents away from the Si–Tl bond, which results in an increase of one Tl-Si-Si angle to almost 120°. Only in bis(hypersilyl)lead(II) do even smaller Si-Pb-Si angles of about 115° lead to even greater distortions in the geometry of the ligand.[15]

Experimental Procedure

3: A solution of $TlN(SiMe_3)_2$ [16] (0.438 g, 1.201 mmol) in *n*-pentane (10 mL) at −30 °C was quickly added dropwise to a solution of $RbSi(SiMe_3)_3$ [14c] (0.400 g, 1.201 mmol) in toluene (10 mL) and stirred. The solution immediately turned blood red. In the course of 14 h at −60 °C most of the $RbN(SiMe_3)_2$ precipitated in the form of colorless crystals. After repipetting the solution and removal of the solvent under vacuum at room temperature, the residue was taken up in *n*-pentane (10 mL) and the solution formed was filtered off from the insoluble gray solid. After a further 14 h, in addition to thallium, dark red, square platelets of **3** precipitated; 0.197 g, 0.300 mmol, yield 47%, based on the $RbSi(SiMe_3)_3$ used, m. p. 130 °C; correct elemental analysis; ^1H NMR (60 MHz, [D$_6$]benzene, 22 °C, TMS): $\delta = 0.46$ (br); ^{13}C NMR (50.324 MHz, [D$_8$]toluene, 27 °C, TMS): $\delta = 5.9$ (d(br), $^3J(CTl) = 48.2$ Hz); ^{29}Si NMR (39.761 MHz, [D$_8$]toluene, 27 °C, octamethylcyclotetrasilonane (OMCT)): $\delta = 2.42$ (d(br), $^2J(SiTl) = 22.4$ Hz, Si_3Si; $Si_3\mathit{Si}$ not observed); IR (Nujol, FT, 20–500 cm^{-1}): $\tilde{\nu}$[cm^{-1}] = 465(w), 443(sh), 434(vs), 386(m), 286(s), 260(w), 232(sh), 220(s), 146(mw, br), 80(m); Raman (*n*-pentane, FT): $\tilde{\nu}$[cm^{-1}] = 380(w, br), 280(mw), 144(sh), 133(m), 78(vs).

[2] G. E. Coates and K. Wade cited in *Organometallic Compounds* Vol. 1 (Eds.: G. E. Coates, R. L. H. Green, K. Wade), 3rd edition, Methuen, London, **1967**, p. 372, a personal communication by C. A. Wilkie and J. P. Oliver, according to which the latter are supposed to have prepared a thallium(II) salt of the composition $K_2Tl_2Me_6$ with a Tl–Tl bond by reduction of trimethylthallium with potassium in 1,2-dimethoxyethane. However, to our knowledge this work has never been published.

[3] During the reaction of thallium(I) halides with organolithium or -magnesium compounds disproportionation reactions also take place (see for example: H. Gilman, R. G. Jones, *J. Am. Chem. Soc.* **1946**, *68*, 517; G. Bähr, P. Burba, *Methoden Org. Chem. (Houben-Weyl) 4th ed. 1952-*, Bd. 13/4, **1970**, p. 369). However, to date in these cases no thallium(II) derivatives have been detected; instead the corresponding, apparently thermodynamically favored organothallium(III) compounds are formed. For the hypersilyl substituent, bowever, the formation of a thallium(III) derivative may well be kinetically hindered because of a steric overloading of the thallium atom with these sterically extremely demanding groups. The reaction of bis(hypersilyl)lead [15], also synthesized by us, with hypersilyl alkali metal derivatives to give tris(hypersilyl)plumbates $MPb[Si(SiMe_3)_3]_3$ (M = K, Cs) shows that an arrangement of three hypersilyl groups [5] around an atom of the size of thallium is in principle possible.

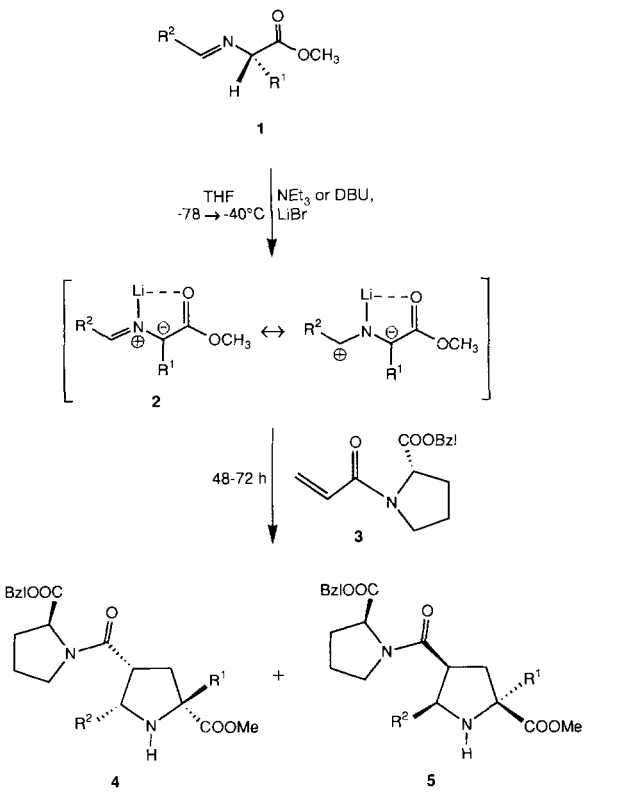
Asymmetric Synthesis of Highly Substituted Pyrrolidines by 1,3-Dipolar Cycloadditions of Azomethine Ylides with *N*-Acryloylproline Benzyl Ester**

Herbert Waldmann,* Edwin Bläser, Martin Jansen, and Hans-Peter Letschert

Dedicated to Professor János Rétey on the occasion of his 60th birthday



1,3-Dipolar cycloadditions are among the most efficient methods of organic synthesis. For example, the reaction of azomethine ylides with alkenes makes possible the simultaneous construction of up to four stereocenters and thus provides a direct and efficient entry to highly substituted pyrrolidines.[1] These heterocycles occur as structural elements in several biologically significant alkaloids[1] and are also of considerable interest in the field of medicinal chemistry, for example as highly effective glycosidase inhibitors[2] and as antagonists of excitatory amino acids.[3] Cycloadditions of azomethine ylides are thus increasingly important as key steps in the synthesis of complex natural products and pharmaceuticals.[4] Thus, the development of efficient chiral auxiliaries, with which the stereochemical path of these reactions can be controlled, has recently been intensively investigated. Despite these efforts, the results obtained have been mixed.[5] We have now found that highly stereoselective 1,3-dipolar cycloadditions of azomethine ylides can be successfully carried out with proline benzyl ester as chiral auxiliary.[6]

Schiffs bases **1** of amino acid esters can be prepared simply by condensation of the appropriate aldehyde and an amino acid ester in dichloromethane in the presence of $MgSO_4$ as water absorbent.[7] These imines are then converted by deprotonation

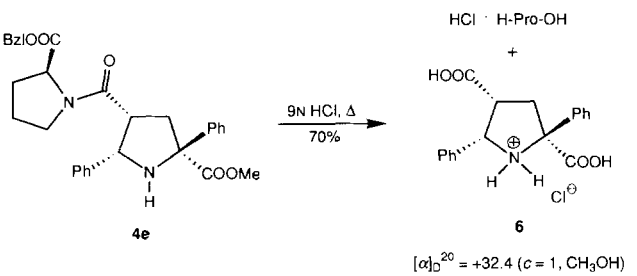
with triethylamine or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to the azomethine ylides, which give metalated 1,3-dipoles of fixed configuration in the presence of anhydrous LiBr (Scheme 1).[8]



Scheme 1. Asymmetric 1,3-dipolar cycloadditions between *N*-acryloyl-(*S*)-proline benzyl ester and metalated azomethine ylides. Bzl = benzyl.

The complexes **2** react with *N*-acryloyl-(*S*)-proline benzyl ester **3** in THF to give the pyrrolidines **4** and **5** in satisfactory yields and very high stereoselectivity even at temperatures between $-78\,^{\circ}C$ to $-40\,^{\circ}C$ (Table 1). In each case only four of the eight possible diastereoisomers could be detected; one stereoisomer of each was always formed in large excess. When lithium diisopropylamide was used as base and for the formation of the metal complex,[9] or when acetonitrile was used as solvent, mixtures of products were formed in which the stereoselectivity was lower.

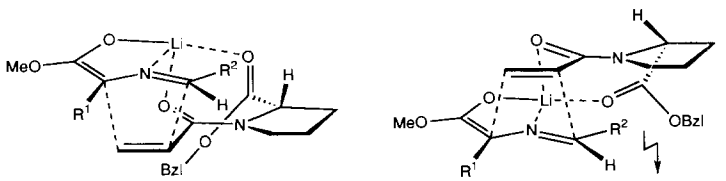
Imines of aliphatic and aromatic amino esters can be used as precursors to the 1,3-dipoles (Table 1). In each case the desired cycloadduct is formed with almost complete *endo*/*exo* selectivity (regularly >99:1). Only in the case of **4f** is the *exo* adduct detected. In the case of the asymmetric cycloadditions of proline benzyl ester **3**, the prefered *endo* isomers **4** are formed with excellent diastereomeric excesses. The stereoselectivity of the reaction increases as the steric demands of the amino acid side chains of the 1,3-dipole increase (Table 1). Thus **4a** and **4b**, which are derived from the benzaldimines of glycine and alanine methyl esters, are formed with diastereomeric ratios of 93:7 and 91:9 respectively. (Table 1, Nos. 1 and 2). On the other hand, the Schiffs bases obtained from the methyl esters of valine, isoleucine, and phenylglycine deliver products with isomeric ratios of >95:5 to >99:1 (Nos. 3–7). In the cases of pyrrolidines **4c**, **4d**, and **4e**, the corresponding *endo* isomer **5** was completely undetectable. The ratios of stereoisomers were determined by high performance liquid chromatography (HPLC) of the crude reaction mixtures. The major isomers could be easily separated by simple flash chromatography as colorless solids. Their absolute configurations were unambiguously assigned by crystal structure analysis of the pyrrolidine **4e**.[10]

The removal of the chiral auxiliary from the cycloaddition products was carried out in high yield simply by acid hydrolysis of the proline amide bond with the concomitant hydrolysis of the ester group of the pyrrolidine. This approach is exemplified by compound **4e** in Scheme 2. The liberated proline can easily be recovered, for example, by chromatography.

$[\alpha]_D^{20} = +32.4$ ($c = 1$, CH_3OH)

Scheme 2. Removal of the chiral auxiliary from the cycloadducts.

Enantiomerically pure pyrrolidine-2,4-dicarboxylic acids such as **6** are of interest not only as precursors in the field of alkaloid synthesis,[1, 2] but also in their own right as potential pharmaceuticals, since they act as antagonists of the excitatory glutamic acid and can be used in the study of the glutamic acid receptor.[3]



In order to explain the almost total *endo*/*exo* selectivity and the very high face selectivity attained through the 1,3-dipolar cycloaddition of the α,β-unsaturated proline benzyl ester amide **3** with the metalated azomethine ylides **2**, we assume that the reaction proceeds preferentially via the highly ordered *endo*

Table 1. Results of the 1,3-dipolar cycloadditions between azomethine ylides (**2**) and *N*-acryloyl-(*S*)-proline benzyl ester (**3**) yielding the pyrrolidines **4** and **5**.

No.	Cmpd.	R^1	R^2	*T* [°C]	Reaction time [h]	$[\alpha]_D^{25}$ ($c = 2$, CH_2Cl_2)	M.p. [°C]	Yield [%] [a]	*endo*/*exo*-ratio	**4**:**5** [b]
1	**4a**	H	Ph	−78 → 25	72	−99.3	87	43	>99:1	93:7
2	**4b**	CH_3	Ph	−40 → 25	72	−251.0	Öl	48	>99:1	91:9
3	**4c**	*i*Pr [c]	Ph	−40 → 25	72	−128.0	95	30	>99:1	>99:1
4	**4d**	*i*Bu [c]	Ph	−40	72	−153.5	119	30	>99:1	>99:1
5	**4e**	Ph	Ph	−78 → 25	48	−74.8	115	67	>99:1	>99:1
6	**4f**	Ph	4-NO_2Ph	−40	48	−77.5	160	60	93:7	97:3
7	**4g**	Ph	4-MeOPh	−40	48	−79.8	53	65	>99:1	95:5

[a] The yields are based on pure diastereoisomer **4** after chromatographic purification. All pyrrolidines **4** were identified from 400 MHz NMR spectra ($CDCl_3$), and all gave the correct elemental analyses. [b] Determined from the crude reaction mixture by HPLC. [c] DBU was used as base.

transition states **A** and **B** (Fig. 1). In both these transition states the lithium cation is coordinated to the azomethine ylide and to the dipolarophile, in such a way that a compact and efficient ordering of the reaction partners results. If the dipole had an *exo*

A **B**

Fig. 1. Possible transition states consistent with the stereoselection found in the 1,3-dipolar cycloadditions between *N*-acryloyl-(*S*)-proline benzyl ester and metalated azomethine ylides.

orientation, such double coordination would not be possible. To allow the lithium cation to coordinate through the amide and ester carbonyl groups of the dipolarophile, the acrylamide must assume the proposed *cis–anti* conformation.[6] In the corresponding *cis-syn* configuration the dipoles of the carbonyl groups would, for electrostatic reasons, lie in an antiparallel, and therefore more favorable, conformation. However, this effect is overridden by the additional coordination of the lithium cation by the ester group. Of the two *endo* transition states, **A** is the energetically more favorable, because in **B** the group R^2 of the dipole lies close to the COOBzl group of the proline benzyl ester, while in **A** only an interaction with the sterically undemanding α-hydrogen of the proline has to be considered.

Vanadium(II)- and Niobium(III)-Induced, Diastereoselective Pinacol Coupling of Peptide Aldehydes to C_2-Symmetrical HIV-Protease Inhibitors**

Bernhard Kammermeier,* Gerhard Beck, Detlev Jacobi, and Heiner Jendralla*

In 1993 fifteen European and American pharmaceutical companies decided to collaborate on medicinal AIDS control.[1] Possible synthetic approaches to finding a method for chemotherapeutic intervention in the complex reproduction cycle of the Human Immunodeficiency Virus (HIV) are both diverse and beset with problems. They range from blocking of the viral gp120 surface structure to the inhibition of the virus-specific enzyme reverse transcriptase (RT) or to inhibition of the HIV protease, an aspartyl protease whose structure was elucidated in 1989, and which is essential for the maturation of infectious virus particles.[2] In particular, inhibition of the C_2-symmetrical HIV protease by compounds with structures of type **1** (see Scheme 1)[3] has crystallized as a promising therapeutic target. This is primarily for two reasons. First, proteases of the host organism are unable to carry out the proteolytic tasks of an inhibited HIV protease, and second, the aspartyl protease class, which also includes renin and pepsin, for example, is a class of mechanistically well-characterized proteolytic enzymes.

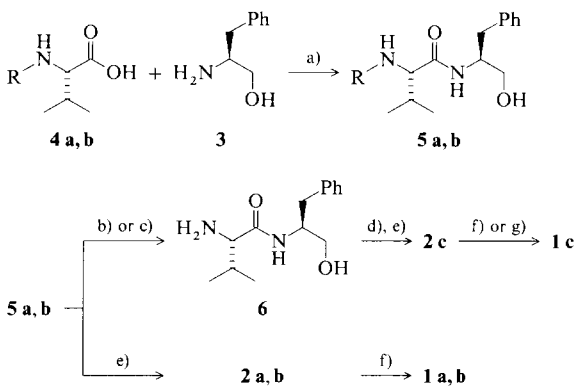
2d DSNP-OH

Scheme 1. HIV protease inhibitors **1** and "half" precursor molecules **2**. Cbz: benzyloxycarbonyl, Boc: *tert*-butyloxycarbonyl.



C_2-symmetrical inhibitors were first synthesized and their biological activity studied by Kempf and Erickson et al. in 1990.[4] A crucial problem in the synthesis of these aminodiols is stereoselective access to the most effective diastereomer type **1**.[5] Because of the molecular symmetry of the com-

pounds, a synthesis based on the two "molecular halves" **2** (Scheme 1) characteristically requires very few synthetic steps. The customary reductive dimerizations do not in this case lead to the target: both titanium(III)-catalyzed McMurry couplings[6] and samarium(II)-induced dimerizations[3] yield only diastereomeric mixtures that are difficult to separate.

We report here on vanadium- and niobium-induced couplings of homochiral peptide aldehydes, which proceed in high yield and diastereoselectively to afford inhibitors of type **1**, from the readily available compounds of type **2**. The dimerization takes place with simultaneous control of all four stereo centers shown in **1**. According to Pedersen and Konradi,[7] pinacol coupling of **2d** to **1d** with $[V_2Cl_3(thf)_6]_2[Zn_2Cl_6]$ proceeds in 76% yield. Using a catalyst generated in situ, we were now able to couple homochiral peptide aldehydes as large as the formal tripeptide aldehyde **2c** and dimerize these to the vicinal aminodiol **1c**. These reactions are also practicable on a kilogram scale.[8]

The synthetic route (Scheme 2) starts with the phosphonic anhydride-induced peptide coupling of (*S*)-phenylalaninol (**3**) and N-terminal protected (*S*)-valine (**4**), leading to the protected dipeptide analogs **5** in at least 94% yield. Under Swern-oxida-

Scheme 2. Diastereoselective synthesis of C_2-symmetrical HIV protease inhibitors (R see Scheme 1): a) *n*-propyl phosphonic anhydride, NEt_3, EtOAc, room temperature (RT), 94%; b) HCl(gas), MeOH, RT, 92%; c) MeOH/HCl (pH 6), H_2, Pd/C, RT, 94%; d) dicyclohexylcarbodiimide, hydroxybenzotriazole, DSNP-OH, RT, 75%; e) $(COCl)_2$, dimethylsulfoxide (DMSO), NEt_3, CH_2Cl_2, −60 °C, 72–89%; f) VCl_3, Zn, 1,3-dimethyl-2-imidazolidinone, THF, reflux, 62–72%; g) $[NbCl_3(dme)]$, THF, reflux, 40%.

tion conditions, these can be directly transformed to the aldehydes **2a** and **2b** (72–89% yield). However, depending on the protecting group used, **5** can also be deprotected at the amino-terminus by hydrogenolysis or protonation (>92% yield). The free amine **6** is now coupled either to a further amino acid unit or to another carboxylic acid, such as DSNP-OH (see Scheme 1),[9a] through its active ester.[9] This affords the corresponding alcohol, which is formally a tripeptide alcohol (75%yield). The product is then subjected to a Swern oxidation that has been optimized for use on a kilogram scale to give rise to the diastereomerically pure peptide aldehyde **2c** in the (*S,S,S*)-form (72% yield). In the key reaction of the synthetic sequence, the peptide aldehydes **2** are reductively dimerized by using a vanadium complex (55–76% yield). The procedure used here is significantly different in several aspects from the known methods for amino aldehydes. Since the catalyst is generated in situ, it is possible to avoid both the isolation of oxygen-sensitive complexes like $[VCl_3(thf)_3]_{10}$ and the change to chlorinated solvents.

For the dimerization, VCl_3 is heated at reflux for five hours in THF, followed by addition of 0.5 equivalents zinc powder, 1,3-dimethyl-2-imidazolidinone as a complexing agent, and aldehyde **2c**, for example. The reaction is heated for a further hour at reflux, and then subjected to an aqueous workup. This one-pot method yields the diol **1c** with the desired configuration and with good diastereoselectivity[11] in 65% yield, and is practicable on a kilogram scale.[5] From the increasing size of the aldehydes **2d**[7] to **2c** which can be reductively dimerized, it is clear that the amino protecting groups in **2b** and **2c** can also be replaced by further amino acid units or by "chain-lengthening" carboxylic acids. The reaction mechanism itself does not restrict the nature of the aldehydes to be dimerized at all. Clearly, the amide units function in the transition state as good chelating groups for the dinucleate vanadium(II) complex.[7]

Remarkably, **2c** could also be transformed to **1c** on a gram scale by the niobium(III) complex ($[NbCl_3(dme)]$, dme = dimethoxyethane) introduced by Pederson et al.[12] for the reductive coupling of imines with aldehydes. The dimerization catalyst is in this case freshly prepared before the coupling reaction. $NbCl_5$ is added to a solution of Bu_3SnH in DME at −78° C, and the brick-red precipitate is filtered off under inert gas. Compound **2c** is then heated at reflux in THF with an equimolar amount of the freshly prepared niobium catalyst. This represents – despite the low yield of barely 40% of **1c**—the first coupling of homochiral peptide aldehydes with this niobium catalyst, which in addition proceeds with higher diastereoselectivity.[13, 14]

These results demonstrate that the application spectrum for both these dimerization reagents is broad, both with respect to the scale of the reaction and to the size of the substrate and its functional groups. Both types of catalysts are simple to synthesize, and the vanadium complex, at least, can also be generated in situ. Finally, the higher selectivity of these reducing agents for activated aldehyde functional groups has the advantage that dimerizations can also be carried out in the presence of other functional groups such as amides and sulfones within the molecule concerned.

Experimental Procedure

1c: VCl_3 (678 g, 4.3 mol) were heated at reflux in anhydrous THF (24 L) under nitrogen for 5 h. Zinc powder (160 g, 2.4 mol), 1,3-dimethyl-2-imidazolidinone (1.6 L), and **2c** (1.2 kg, 2.1 mol) in THF (6 L) were then added to the mixture. The reaction was heated for 1 h at reflux, cooled to room temperature, and diluted with 10% aqueous citric acid (19 L) and ethyl acetate (18 L). After separating the phases, the organic phase was washed several times with water, dried over Na_2SO_4, filtered, and the solvent removed under vacuum. The solid residue was recrystallized first from ethanol and then from ethyl acetate, and yielded 720 g **1c** as colorless crystals; m.p. 189 °C [14].

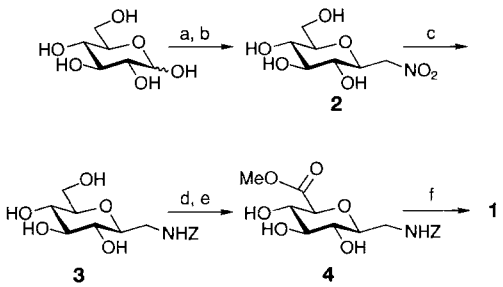
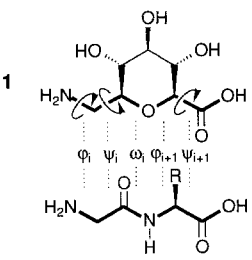
A Sugar Amino Acid as a Novel Peptidomimetic**



Erich Graf von Roedern and Horst Kessler*

Amino acids and peptide units with nonnatural structures are being employed with increasing frequency as components of peptide-based drugs, since they can be used to modify pharmacokinetics and metabolic stability.[1] We report here on the simple synthesis of the sugar amino acid H-Gum-OH **1**,[2] a new type of dipeptide isostere. We demonstrate the effect of H-Gum-OH **1** on the structural and biological properties of peptides with cyclic somatostatin analogues and a linear enkephalin analogue. H-Gum-OH **1**, which can be prepared from glucose in four steps, is characterized structurally by the rigid, pyranoid framework of the sugar residue. The conformations of peptides containing **1** are thus restricted. The free hydroxyl groups increase the hydrophilicity of the peptides; with nonpolar protective groups the opposite effect can be induced.



1

Although pyranoid rings are found frequently in natural products of therapeutic importance,[3] we know of only one case in which this structure occurs in a peptide chain.[4] Glucose has already been used as the framework of a nonpeptidic peptidomimetic[5] but not to modify a peptide backbone. H-Gum-OH **1** was synthesized (Scheme 1) in only 12% overall yield; however, since glucose and the reagents employed are inexpensive, the synthesis can be conducted on a large scale.

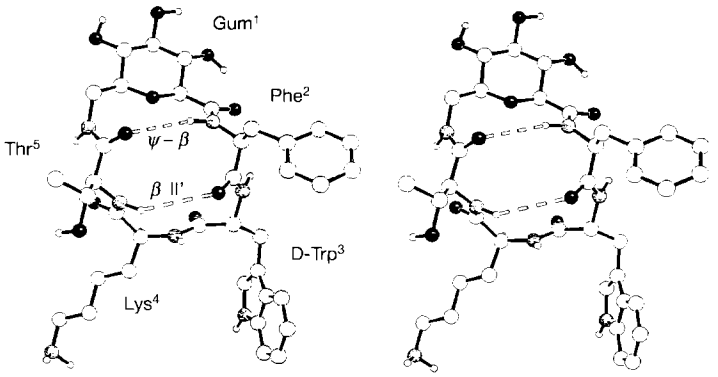
Scheme 1. a) CH_3NO_2, NaOMe; b) H^+/H_2O, ΔT; c) H_2, Pd/C, Z-Cl (Z = benzyloxycarbonyl); d) O_2, Pt/C; e) MeOH, DCC/DMAP (dicyclohexylcarbodiimide/*N*,*N*-dimethylaminopyridine); f) NaOH, H_2, Pd/C.

Analysis of the $^3J_{H,H}$ coupling constants[6] of **1** indicates that the pyranoid ring is in the all-equatorial chair conformation typical for sugars ($^4C_1$ analogues). The backbone bonds and the dihedral angles of the dipeptide isostere **1** are compared to those of a natural dipeptide in Scheme 2. The cyclic structure of H-Gum-OH **1** fixes the ω_i angle at 180°, which corresponds to a *trans* amide bond. The φ_{i+1} angle in **1** is also fixed at 180°; this is often found in natural β-sheet structures. However, **1** is not a β-sheet mimetic, since it has no amide groups for hydrogen bonding. **1** has "free rotation" about the φ_i angle and both ψ angles. Accordingly, peptidomimetic **1** can be used to replace two adjacent amino acids having conformational restriction at the ω_i and φ_{i+1} angles. A comparison of the "side chains" of **1** with those of a natural dipeptide shows that **1** is structurally related to H-Gly-Ser-OH and H-Gly-Thr-OH (Scheme 2). To determine

Scheme 2. Comparison of the torsion angles of H-Gum-OH **1** with those of a dipeptide (H-Gly-AA-OH (AA = amino acid)). The freely rotating bonds of **1** are marked with arrows.

the effect that H-Gum-OH **1** exerts on the conformation of a peptide, we incorporated **1** into a cyclic hexapeptide[7] by replacing two neighboring amino acids (Table 1).

Table 1. The synthesized cyclopeptides, the reference peptide **8**, and their activities as somatostatin analogues.



Compound [a]	IC_{50}[μM] [b]
cyclo(-Gum^1-Phe^2-D-Pro^3-Ala^4-Phe^5-) **5**	[c]
cyclo(-Gum^1-Tyr^2-D-Trp^3-Lys^4-Val^5-) **6**	0.47
cyclo(-Gum^1-Phe^2-D-Trp^3-Lys^4-Thr^5-) **7**	0.15
cyclo(-Pro-Phe-D-Trp-Lys-Thr-Phe-) **8** [d]	0.002

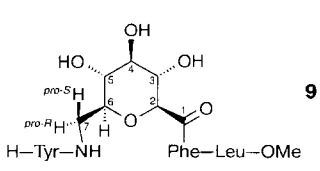
[**] We thank Dr. B. Kutscher and Dr. M. Bernd, Asta Medica AG, Frankfurt am Main (FRG), for providing the biological somatostatin tests, and Prof. Dr. P. W. Schiller, Clinical Research Institute of Montreal, for measuring the biological activity of the enkephalin analogue.

Interproton distances were determined by 250 MHz ROESY (rotating frame Overhauser effect spectroscopy) and 500 MHz NOESY (nuclear Overhauser effect spectroscopy); these served as restrains in the force field in molecular dynamics (MD) simulations (programs DISCOVER and GROMOS[10]) in dimethyl sulfoxide (DMSO).[11] The structure of cyclo(-Gum^1-Phe^2-D-Trp^3-Lys^4-Thr^5-) **7** is shown in Figure 1 as an example of the synthesized cyclic peptides.



7

Fig. 1. Stereoplot of the average structure of **7** (80 ps MD simulation); for clarity only the polar hydrogen atoms are shown.

In the cyclic peptides the six-membered ring of Gum^1 is found in the chair conformation described above and occupies the $(i+1)$ and $(i+2)$ positions of a pseudo-β turn. Since Gum^1 is only a weak hydrogen bond acceptor (ring oxygen atom), owing to its lack of an amide group, and does not have any hydrogen bond donor groups, stabilizing hydrogen bonds can form only between Xxx^2 and Xxx^4 (Table 1). As expected, D-Xxx^3, which induces the βII′ turn, is in the $(i+1)$ position. The peptide ring is distinctly bent because of the steric repulsion of the ring oxygen atom of **1** and the carbonyl oxygen atom of the neighboring Xxx^5 (Fig. 1). In contrast, the two β turns in a "normal" cyclic hexapeptide with six natural amino acids are almost coplanar.[12]

Most of the the known active somatostatin analogues contain the partial sequence -Phe-D-Trp-Lys-Thr- or -Tyr-D-Trp-Lys-Val- forming a βII′ turn.[9] Peptides **6** and **7** (Table 1) are derivatives of cyclic somatostatin analogues, in which the cyclizing amino acids -Pro-Phe- or a cystine disulfide bridge are replaced by Gum. **6** and **7** are biologically active in the submicromolar range for the inhibition of the release of growth hormone (Table 1). In fact, compound **7** is only 75 times less active than the highly potent somatostatic analogue **8**. This is particularly remarkable, since **7** does not have the lipophilic residues on both sides of the active tetrapeptide sequence that are important for the increase in somatostatin activity.[9]

The effect of Gum on linear peptides was examined with the Leu-enkephalin analogue **9**, in which the Gly-Gly unit of natural Leu-enkephalin is replaced by **1**. The homonuclear $^3J_{H,H}$ coupling constants between the methylene protons on C7 and 6-H in **9** are 1.0 and 8.5 Hz. This indicates that the free rotation about the C6–C7 bond in **9** is restricted such that one of the two methylene protons is antiperiplanar to 6-H. The assignment of the two diastereotopic protons on C7 is difficult, owing to the overlap with the chemical shifts of the ring protons of Gum. However, the interproton distances obtained from a 500 MHz NOESY spectrum assign *pro-S*7-H to be antiperiplanar to 6-H, as shown in the structural formula. Thus Gum most likely forms a loop-type structure in linear peptides as well. Compound **9** does not show biological activity analogous to that of enkephalin up to a concentration of 10^{-5} M.

9

The easily accessible sugar amino acid **1** is the first example, in which a basic sugar unit is employed as a peptidomimetic within a peptide chain. It most likely functions as a dipeptide isostere and induces a β turn in linear peptides, even though it has only partial conformational restriction. Gum is the first of a series of sugar-based peptide building blocks that can be used to adjust the structures and properties of peptides. Thus not only can the secondary structure be influenced (e.g. turn mimetics), peptide side chains can also be mimicked by the selective functionalization of the OH groups of sugar amino acids.

Experimental Procedure

A solution of D-β-Glucopyranosylnitromethane (**2**)[13] (5 g) in methanol (80 mL) and water (20 mL) was hydrogenated with 10% Pd-C (3 g, Degussa, ca. 50% H_2O) under an atmosphere of hydrogen for 24 h (H_2 consumption ca. 3.5 L)[14]. The catalyst was filtered off and washed. The filtrate was treated with $NaHCO_3$ (10.5 g) and benzyl chloroformate (17 mL) and stirred vigorously. After 1 h H_2O (50 mL) was added to the reaction mixture, and the methanol was removed under vacuum. The aqueous solution was washed with diethyl ether and concentrated to dryness under vacuum. The residue was taken up in anhydrous acetone (80 mL), and the inorganic salts were removed by filtration and washed with acetone. The filtrate was concentrated under vacuum and dried giving 7.21 g (98.5%) of **3** as a colorless, hard foam.

Compound **3** (5 g) was dissolved in H_2O (100 mL) and stirred with 10% Pt-C (2.5 g, Degussa, ca. 50% H_2O) at 90 °C under a steady stream of O_2[15]. The gas was pumped through the closed apparatus and purified by passing it through 4 N NaOH. The pH of the reaction mixture was maintained between 7 and 8 by addition of 10% $NaHCO_3$ every hour. Catalyst was added after 8 and 18 h (2 g each time). After the reaction was complete (monitored by TLC), ion-exchange resin (10 g, Aldrich, Amberlyst 15, strongly acidic, H^+ form) was added and the reaction mixture stirred for 10 min. The ion-exchange resin was filtered off and washed with H_2O. The filtrate was concentrated under vacuum and lyophilized. The powdery residue was dissolved in anhydrous methanol (100 mL), DCC (2.9 g) and DMAP (0.2 g) were added, and the reaction mixture was stirred for 1 h. Insoluble residue was removed by filtration, and the filtrate was concentrated almost to dryness under vacuum. The resulting syrup was chromatographed on silica gel (100 g silica gel, eluent $CHCl_3$/methanol 9/1) and then recrystallized from H_2O to provide 1.9 g (34%) of **4**[16] as colorless needles. The methyl ester was prepared, since it is more readily purified and isolated. After saponification of the ester in methanol with 1 N NaOH (1.1 equiv) and cleavage of the Z protective group by hydrogenation, H-Gum-OH **1** was obtained quantitatively in crystalline form ($[\alpha]_D^{20} = -41.2$)[17].

Discrete M_6N Octahedra in the Subnitrides $Na_{16}Ba_6N$ and $Ag_{16}Ca_6N$: A Reconsideration of the Ag_8Ca_3 Structure Type**

G. Jeffrey Snyder and Arndt Simon*

The suboxides[1] of the heavy alkali metals are remarkable for the occurrence of ion clusters interacting through metallic bonding, leading to some unique physical properties. We have recently expanded this chemistry to barium subnitrides with the discovery of the infinite chain subnitride $NaBa_3N$.[2] Here we report the structure of $Na_{16}Ba_6N$ which contains discrete Ba_6N octahedral clusters. The existence of the isotypic $Ag_{16}Ca_6N$, previously known as Ag_8Ca_3,[3] indicates that subnitride chemistry may be more common than expected.

$Na_{16}Ba_6N$ was discovered in a capillary size sample, prepared as described for the single-crystal investigation of Na_2Ba.[4] Nitrogen originated from traces present in argon freed from water (molecular sieve) and oxygen (oxisorb catalyst[5]). A single crystal of $Na_{16}Ba_6N$[6] was found near the tip of the sample, together with sodium and polycrystalline NaBa[7] and Na_2Ba.

$Na_{16}Ba_6N$ has the metal atom arrangement as described for Ag_8Ca_3. The Ba–Ba distance (3.99 Å) is rather short compared to the distances of 4.54 and 4.52 Å found in the binary intermetallic compounds NaBa and Na_2Ba, respectively, but comparable to the average distance of 3.93 Å in $NaBa_3N$. This and the significant electron density of 3.3 e Å^{-3} at the center of the barium octahedron clearly indicate the presence of a light atom at this position. Refining the data with a nitrogen atom at this position significantly reduces $wR2$ from 0.159 ($R1 = 0.061$) to 0.119 ($R1 = 0.051$). After concluding that the Ba_6 octahedron in $Na_{16}Ba_6N$ must be occupied, we predicted that the center of the Ca_6 octahedron in "Ag_8Ca_3" should also be centered by a nitrogen atom, using the same bond length argument as above, only for Ca–Ca distances.

The structure of Ag_8Ca_3 had been solved by using film methods.[3] Analysis of the starting materials had revealed 0.01% nitrogen; however, after alloying, nitrogen was found "at the 0.1% level".[3] $Ag_{16}Ca_6N$ requires only 0.7% nitrogen.

Following the synthetic procedure for "Ag_8Ca_3"[3] in the absence of nitrogen produced Ag_7Ca_2 and no $Ag_{16}Ca_6N$. However, if the reaction is carried out under an N_2/Ar atmosphere,[8] $Ag_{16}Ca_6N$ is produced as a majority phase. $Ag_{16}Ca_6N$ forms golden metallic air-stable crystals, which are relatively brittle. Grinding the sample and removing malleable intermetallic byproduct (most likely Ag_7Ca_2) resulted in essentially phase pure $Ag_{16}Ca_6N$. The cell and atomic parameters given for "Ag_8Ca_3" are within one standard deviation of our data for $Ag_{16}Ca_6N$.[9] Refining the structure without nitrogen results in a residual electron density peak of 10 e Å^{-3} at the 2*a* position with $wR2 = 0.052$ ($R1 = 0.027$), while placing a nitrogen at this position reduces $wR2$ to 0.026 ($R1 = 0.017$).

The structure of $Na_{16}Ba_6N$ [and $Ag_{16}Ca_6N$] contains discrete regular octahedra of barium [calcium] atoms surrounding a central nitrogen atom. Figure 1 illustrates how these octahedra are separated by the matrix of sodium [silver] atoms. The Na1 [Ag1] atoms cap the faces of two opposing Ba_6N [Ca_6N] octahedra in a trigonal antiprismatic arrangement. The Na2 and [Ag2] atoms not only cap the faces of the Ba_6N [Ca_6N] octahedra, but are also arranged in a square. The metal coordination spheres for "Ag_8Ca_3" were well-described by Pearson.[10]

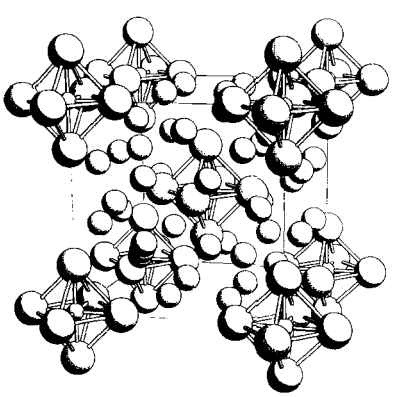

Fig. 1. Structure of $Na_{16}Ba_6N$ showing the Ba_6N octahedra drawn with bonds. The smaller nonconnected spheres represent sodium atoms.

The interatomic distances in $Na_{16}Ba_6N$ and $Ag_{16}Ca_6N$ indicate that there is ionic bonding within the subnitride units and metallic bonding outside. For $Na_{16}Ba_6N$ the Ba–Na and Na–Na average distances (4.48 Å and 3.62 Å, respectively) are similar to those found in the intermetallic phases NaBa (4.27, 3.72 Å) and Na_2Ba (4.32, 3.70 Å), and close to the sum of metal-

[**] We thank Dr. H. Borrmann and Dr. K. Peters for single-crystal data collection, Dr. P. Rauch and T. Gulden for starting materials and helpful discussion and the Hertz Foundation for financial support.

lic radii[10] (4.15, 3.82 Å). As mentioned above, the Ba–Ba distance is closer to those of the subnitrides than those of the binary intermetallic phases of Ba. The Ba–N distance (2.82 Å) is somewhat longer than the corresponding distance in $NaBa_3N$ (2.73 Å) or in Ba_2N (2.76 Å).[11]

For $Ag_{16}Ca_6N$, the average Ca–Ag and Ag–Ag distances (3.38, 2.89 Å) compare well with those of the intermetallic phases AgCa[12] (3.20, 2.88 Å), Ag_7Ca_2 (3.27, 2.92 Å), and the sum of metallic radii (3.42, 2.89 Å). The Ca–Ca distance in $Ag_{16}Ca_6N$ is considerably shorter (3.55 Å) than in the element (3.95 Å) or in the intermetallic phases AgCa (3.99 Å) and Ag_7Ca_2 (3.80 Å), but rather similar to that found in the phases Ca_3XN,[13, 14] which range from 3.4 to 3.5 Å. The Ca–N distance of 2.51 Å found in $Ag_{16}Ca_6N$ is longer than those of the more oxidized compounds Ca_3XN, ranging from 2.41 to 2.48 Å.

The molar volume of $Na_{16}Ba_6N$ can be well-described by using pure sodium metal and partially oxidized barium as a model. Subtracting the contribution due to metallic sodium leaves

$$V_m(Na_{16}Ba_6N) - 16\,V_m(Na) = V_m(Ba_6N) = 211\ cm^3 \cdot mol^{-1},$$

while summing the molar volumes [15] for the individual ions and atoms gives

$$\tfrac{2}{3}V_m(Ba^{2+}) + V_m(N^{3-}) + \tfrac{9}{2}V_m(Ba) = 209.5\ cm^3 \cdot mol^{-1}.$$

Heteropolarity of the bond between Ag and Ca, in contrast to the Na/Ba system,[4] leads to a volume contraction of about 11% for the intermetallic compounds, thus making further volume calculations for $Ag_{16}Ca_6N$ difficult.

Both $Na_{16}Ba_6N$ and $Ag_{16}Ca_6N$ must be metals. The expected metallic behavior is confirmed by four-probe electrical resistivity measurements[16] on $Ag_{16}Ca_6N$ (Fig. 2). The resistivity at room temperature is comparable with that of silver, 1.51×10^{-6} cm.

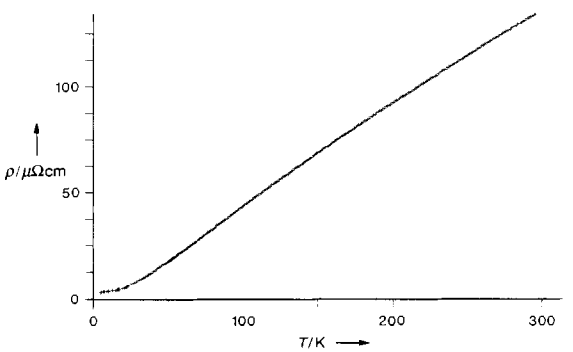

Fig. 2. Resistivity vs. temperature for a sample of $Ag_{16}Ca_6N$ (four-probe measurement) $0.5 \times 0.5 \times 0.5\ mm^3$ in size.

Numerous other phases have been considered to have the Ag_8Ca_3 structure type, $Ni_6Si_2(RE)_3$ (RE = Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu),[17] $Ni_6Ga_2(RE)_3$ (RE = Y, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm),[18] and $Ni_6Al_2(RE)_3$ (RE = Y, Gd, Tb, Dy, Er, Tm).[19] The question then arises whether the $(RE)_6$ octahedra are empty. So far only the series of compounds $(RE)_6Fe_{16}O_x$ ($x \leq 1$; RE = Gd, Tb, Dy, Ho, Er)[20] have been reported to have the Ag_8Ca_3 structure, but containing an oxygen or some other metalloid atom in the center of the rare-earth atom octahedron. Neutron powder diffraction data[21] on $Ho_6Fe_{16}O$ were consistent with full oxygen occupancy.

The discovery of $Na_{16}Ba_6N$ expands the realm of barium subnitride chemistry. Layers of edge-condensed Ba_6N octahedra are found in Ba_2N,[11] while these octahedra share faces to form chains in $NaBa_3N$ and Na_5Ba_3N, and now discrete Ba_6N octahedra have been found in $Na_{16}Ba_6N$. The existence of oligomeric clusters formed by a limited number of Ba_6N units may be anticipated, as found frequently with transition metals.[22]

The discrete Ba_6N subnitride unit in $Na_{16}Ba_6N$ also supplies the missing piece in suboxide cluster chemistry. The Rb suboxides, Rb_9O_2 and Rb_6O, contain two such face-sharing M_6O units. The Cs suboxides, $Cs_{11}O_3$, Cs_7O, and Cs_4O continue this condensation, combining three face-sharing M_6O units to form $Cs_{11}O_3$ clusters. The segregation of the sodium atom around an individual subnitride cluster in $Na_{16}Ba_6N$ is analogous to that of the rubidium atoms which surround a $Cs_{11}O_3$ cluster in $Rb_xCs_{11}O_3$ ($x = 1, 2, 7$).

Hypermetalated species such as Li_6C have been studied in the gas phase.[23] $Na_{16}Ba_6N$ and $Ag_{16}Ca_6N$ serve as examples where such hypermetalated species are stabilized in the solid state by insertion into a purely metallic matrix.

There is also the promise of other nitrides in the Ag-Ca-N system,[24] possibly with a similarly large variety of structures as seen in the Na-Ba-N system. The accessibility of air-stable single crystals of $Ag_{16}Ca_6N$ will allow detailed investigations on a system that may be termed a "void metal". At a microscopic level the compound is a metal with a periodic sublattice of N^{3-} ions 8.5 Å apart, which are repulsive to conduction electrons. As a consequence quantum size effects can be expected, as they have been demonstrated for related systems like $Cs_{11}O_3$.[25]

A Clathrate Hydrate of Nitric Oxide**

Andreas Hallbrucker*

Nitric oxide (NO) recently was found to be of crucial importance in biochemical processes.[1] The interaction of NO with the solvent water is one of its basic physical properties important in this context. However, measurements are scarce, for example, the stretching vibration of NO dissolved in water at ambient temperature, which might serve as an indicator for its perturbation by the solvent, has not been reported so far, probably because of experimental difficulties. The solvent–solute interaction of nonpolar or slightly polar gases in aqueous solution is often considered to resemble the arrangement of molecules in crystalline water clathrates.[2, 3] In the absence of experimental data, the interaction of NO with liquid water may be approximately described by this system. I show here that the clathrate hydrate of NO is prepared by adsorption of NO in highly porous, amorphous solid water at 77 K and subsequent heating of the sample to 197 K. It is characterized by X-ray diffraction and Raman spectra of the NO vibration. Unlike CO,[4] a molecule with very similar physical properties, NO is shown to form a clathrate hydrate of structure II.

Gas hydrates of small guests such as O_2, N_2, and CO are usually prepared by grinding ice at about 243 K under pressures >150 bar for several days.[5] Evidently, this method is only suitable for stable and inert guest gases. Only recently a new method for preparing these clathrate hydrates at low temperatures and pressures from microporous, amorphous solid water (ASW) was established.[6] ASW is formed by slow deposition of water vapor on a substrate held at 77 K in a vacuum system and exposed to moderate pressures of gas (<1 bar). On heating to about 120 K considerable amounts of this gas are irreversibly trapped in the ice matrix and transformed to a clathrate hydrate on further heating in vacuo.[6]

Samples of ASW with enclosed NO were initially prepared, by the method already described for O_2, N_2, CO, and Ar clathrate hydrates,[6] on an X-ray sample holder and on small brass plates for Raman probes. Briefly, water vapor was admitted to a vacuum system and condensed on the substrate cooled to 77 K at low base pressure (ca. 10^{-6} mbar) for about 6 h. This gave an amorphous ice layer of about 1 mm thickness. Subsequently, NO gas was condensed onto the ASW layer for 3 h at equally low base pressure. Practical grade NO was taken from a tank (Messer Griesheim, purity >99.85%), and purified by fractionating condensation.[7] The purity (i.e. the absence of N_2O and NO_2) was checked by IR spectroscopy. The samples were then heated to 140 K at which temperature considerable amounts of NO are irreversibly trapped in the pores and micropores of ASW. After recooling to liquid nitrogen temperature, sample holders were removed from the vacuum apparatus and transferred to the precooled X-ray camera, or into the cryostat for Raman measurements. All Raman spectra were recorded at 130 K, after recooling, because irradiation at elevated temperatures leads to reaction of NO.

The X-ray diffractogram of the sample after transfer to the X-ray camera and heating to 130 K is depicted in Figure 1, curve 1. Only two broad peaks at $2\theta = 24$ and 43° are observable, characteristic for ASW. In Figure 2, curve 1, the Raman spectrum of the NO stretching vibration region is represented, exhibiting two sharp peaks at 1868.8 and 1858.8 cm^{-1} and one broad and weak absorption band at about 1840 cm^{-1}. On heating to 173 K ASW largely crystallizes to cubic ice (Ic), evident by the sharp reflections in the X-ray diffractogram in Figure 1, curve 2. In Figure 2, curve 2, the Raman spectrum of the sample after heating to 173 K and recooling to 130 K is shown: it also exhibits three absorption bands at nearly the same positions (1868.1, 1858.6, and 1836.6 cm^{-1}) as those in curve 1 but with significant changes of their intensities. Whereas the total area under the three bands is almost unchanged, the intensity of the band at highest frequency is decreased, mainly at the expense of the band near 1858 cm^{-1}. The intensity of the band at lowest frequency is only slightly increased. Raman and X-ray samples were then heated to 197 K and recooled to 130 K. Four clearly

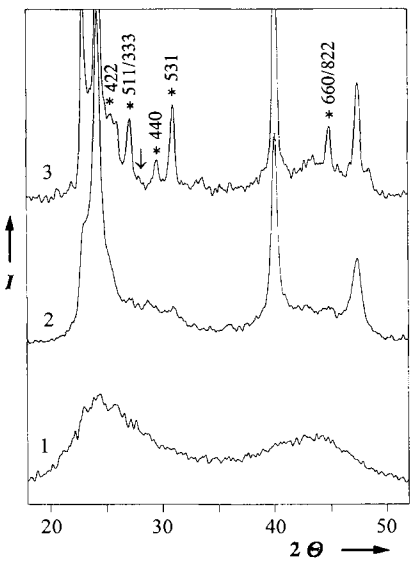

Fig. 1. X-ray diffractograms of amorphous solid water with enclosed NO recorded at 130 K: 1) on first heating starting from about 80 K, 2) after partial crystallization to cubic ice by heating to 173 K, and 3) after formation of NO clathrate hydrate at 197 K. Reflections due to NO clathrate hydrate are marked with * in curve 3 and indexed for a structure II clathrate hydrate. Curves are represented on the same scale with constant ordinate offset. The diffractograms were recorded with Kristalloflex 4 (Siemens) by using $Cu_{K\alpha}$ radiation.

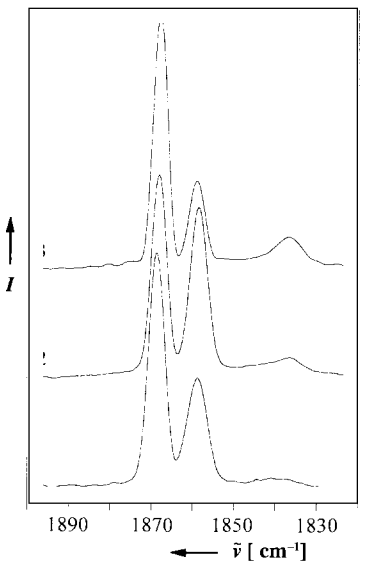

Fig. 2. Raman spectra of the NO stretching vibration region of NO absorbed in the micropores of amorphous solid water recorded at 130 K: 1) on first heating starting from about 80 K, 2) after crystallization to cubic ice by heating to 173 K, and 3) after formation of NO clathrate hydrate of strucutre II at 197 K. Curves were drawn on the same scale. All spectra were measured at 130 K on a Coderg PHO instrument with double monochromator and photon counting, slit with 4 cm^{-1}, 488 nm argon laser excitation with a power of 500 mW.

observable additional reflections in the diffractogram of this sample in Figure 1, curve 3, at $2\theta = 27.14$, 29.60, 31.01, and 44.89° indicate the formation of NO clathrate hydrate.[8] Clathrate hydrates formed this way from ASW necessarily contain a large amount of cubic and/or hexagonal ice, because it stabilizes the clathrate hydrate.[6] The four additional reflections mentioned above, which are clearly separated from the ice reflections, must be due to NO clathrate hydrate because they grow and disappear at the same rate, and formation of other clathrate hydrates by contaminants such as N_2, O_2, N_2O, NO_2, and CO, has been carefully excluded by Raman spectroscopy. A fifth reflection due to NO clathrate hydrate, at $2\theta = 25.50°$, is partly superimposed by the ice reflections at $2\theta = 24.38°$ (off scale) and 25.98°, but is also formed at a similar rate as the other four reflections due to NO clathrate hydrate. Its peak position is retained in diffractograms bandnarrowed by deconvolution. The total area under five NO clathrate hydrate reflections accounts for about 10% of the total area under the diffraction curve, this can also be used as the lower limit of the amount of clathrate hydrate formed.[6]

The assignment of NO clathrate hydrate to a clathrate hydrate of structure type II is based on the following, and its reflections (see Fig. 1) are indexed accordingly: 1) Whereas three of the well-separated clathrate hydrate reflections have counterparts at similar positions in the diffractogram of a clathrate hydrate of structure I, the reflection at $2\theta = 29.60°$ (index 440 for structure II) has none. This reflection clearly shows up in all of the common structure II clathrate hydrates with about half of the intensity of the reflections at 27.14 and 31.01° (index 511/333 and 531, respectively) at only slightly varying position.[6, 8, 9] 2) The most intense peak in clathrate hydrates of type I (index 321) is absent! Since the size of the cubic unit cell for clathrate hydrates of type I is always close to 11.9 Å, largely independent of the size and type of the guest molecule, this reflection (321) is always found at about 28.1°. At this position, which is marked by an arrow in Figure 1, curve 3, no intense peak is recognizable. For CO, a molecule resembling NO in size and polarity, but forming a clathrate hydrate of structure I, it occurs at 28.115° with maximum intensity.[4] The absence of this reflection is a strong argument in favor of a clathrate hydrate of type II, because this reflection is calculated and consistently observed as the most intense one in clathrate hydrates of type I.[4, 8, 10] 3) The reflection at $2\theta = 25.50°$, which is partly superimposed by the ice reflections, can easily be assigned to a clathrate hydrate peak of type II, with index 422.[9] In CO clathrate hydrate of type I the closest peak is at $2\theta = 25.98°$[4] which is outside the range expected for differences in lattice parameters.

In Figure 2, curve 3, the Raman spectrum of the sample containing NO clathrate hydrate is shown. It also exhibits three bands with maxima shifted only slightly (with respect to curve 2) to lower frequencies (1867.8, 1858.8, and 1836.6 cm^{-1}). The total area under the three absorption bands has decreased by about 13%, apparently due to loss of NO during clathrate hydrate formation. However, only the intensity of the band at the intermediate position has decreased, whereas the intensities of the bands at high and low frequency have in fact increased. The band at 1836.6 cm^{-1} is assigned to NO encaged in the lattice of the clathrate hydrate, because its absolute area increases from curve 1 to curve 3, parallel to the increase in clathrate hydrate formation observed by diffraction. This is not the case for the other two intense bands at about 1869 cm^{-1} and about 1859 cm^{-1}, which are observable already in the fully amorphous ASW sample (curve 1). These two bands are assigned to NO in two distinct trapping sites. In curve 1 a very weak and broad band at about 1840 cm^{-1} further indicates the presence of a third trapping site in the amorphous ice matrix which has a similar frequency to that of NO in the clathrate hydrate.

The stretching vibration of gaseous NO at 300 K is centered at 1877 cm^{-1}[11] and at 1875 cm^{-1} for NO in an Ar matrix at 4.2 K.[12] The frequency of the stretching vibration of the condensed states $(NO)_2$ is lowered to 1866 cm^{-1},[13] similar in frequency to one of the bands observed in the ice matrix. It is very unlikely, however, that considerable amounts of NO dimer exist at 130 K.[7] Moreover, a Raman spectrum recorded at 173 K gave the same pattern as curve 2 in Figure 2. The frequency of the stretching vibration of NO, enclosed in the cages of the clathrate hydrate, is further lowered to 1836.6 cm^{-1}. This indicates considerable interactions with the hydrate matrix. The shift of the NO stretching vibration by about 40 cm^{-1} to lower frequency, compared to the gas phase value, is much higher than the shift of about 10 cm^{-1} observed for O_2 clathrate hydrate.[14] Force constant calculations from observed frequencies give 1.45×10^3 N m^{-1} for $^{14}N^{16}O$ clathrate hydrate and 1.55×10^3 N m^{-1} for $^{14}N^{16}O$ in the gas phase or in an Ar matrix.

While originally the size of the guest molecule was anticipated to determine the structure of the hydrate formed, with small molecules forming type I,[15] clathrate hydrates of N_2 and O_2 were identified as being type II.[5, 6] Somewhat surprisingly CO clathrate hydrate proved to be type I.[4, 6] A small dipole moment, and a slightly higher quadrupole moment and molecular polarizability than O_2 and N_2 were considered to be responsible for this fact by Davidson et al.[4] This must now be considered inconclusive, since NO, with very similar properties to CO, forms a clathrate hydrate of structure type II.

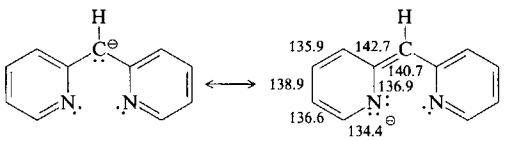
Rearrangement and Selective Transmetalation of Bis(pyridyl)methyllithium**

Heinz Gornitzka and Dietmar Stalke*

Recently we investigated the crystal structure of bis([12]crown-4)lithium bis[*N*,*N*′-bis(trimethylsilyl)phenylsulfinamidinato]lithiate.[1] The two inequivalent lithium atoms in $[Li([12]crown\text{-}4)_2]^+[Li(\{N(SiMe_3)\}_2SPh)_2]^-$ and the lithium atom in the transformation product $[PhS\{(Me_3Si)N\}_2$-Li([12]crown-4)] gave rise to three separate signals resolved for the first time in a ^7Li quadrupole nutation MAS NMR spectrum (MAS = magic angle spinning).



To elucidate the nature of the transformation in more detail, we synthesized bis(2,2′-pyridyl)methylbis(tetrahydrofuran)-lithium (**1**) and the corresponding lithium-lithiate compound **2**.

$[Li\{(2\text{-}NC_5H_4)_2CH\}(thf)_2]$ **1**

$[Li([12]crown\text{-}4)_2][Li\{(2\text{-}NC_5H_4)_2CH\}_2]$ **2**

In contrast to, for example, triphenylmethyl alkali metal derivatives,[2] in which the lithium atom is coordinated by the central carbon atom[3] or the heavier alkali metal atoms are coordinated by a phenyl ring,[4] the bis(2,2′-pyridyl)methyl substituent provides two additional nitrogen atoms in the heteroarene rings for coordination.

If bis(2,2′-pyridyl)methane[5–7] is treated with *n*BuLi, the central carbon atom of the CH_2 group of the starting material is deprotonated. However, as the crystal structure[8] of **1** shows, the deprotonated ligands contain in a formal sense a carbanionic noncoordinated center.[9] The average bond lengths (see **B**) in the bis(pyridyl)methyl ligands of the compounds **1**, **2**, and **4** show that the carbanionic mesomeric structure **A** with the double bonds at the positions 2 and 4 in the pyridine ring provides an inadequate description of the ligands; the mesomeric structure **B** describes the bonding better.

A **B**

As expected, the lithium atom is exclusively coordinated to the two nitrogen atoms of the pyridine rings and to two THF molecules (Fig. 1a). The lithium atom is within the plane of the chelating ligand, and one of the THF molecules lies above and one below that plane.[10] The Li–N bonds (196.6 and 197.3 pm) are of normal length.[11]

Compound **2** forms a solvent-separated ion-pair in the solid state (Fig. 1b).[8] Only two related structures of this lithium-lithiate type compound are known.[1, 12] The Li1 atom is coordinated to two $HC(2\text{-}NC_5H_4)_2$ ligands, giving the overall singly charged anion. The Li2 atom is complexed by two crown ether molecules, giving a singly charged cation. The Li–N bonds in **2** are slightly longer than those in **1**, reflecting the higher steric requirement of the two bis(pyridyl)methyl ligands coordinated

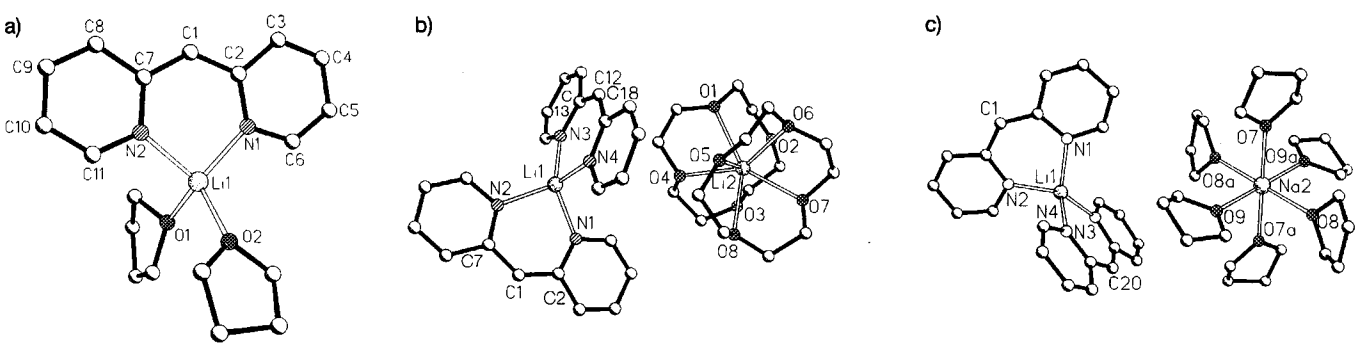


Fig. 1. a) The crystal structure of **1**; selected bond lengths [pm] and angles [°]: Li1-N1 196.6(4), Li1-N2 197.3(4), Li1-O1 199.4(4), Li1-O2 196.5(3); N1-Li1-N2 96.4(2), O1-Li1-O2 98.9(2), C2-C1-C7 130.9(2). b) The crystal structure of **2**; selected bond lengths [pm] and angles [°]: Li1-N1 201.5(5), Li1-N2 202.6(5), Li1-N3 200.1(5), Li1-N4 200.3(5), Li2-O 236.5(5) (average) (range 221.9–252.3); N1-Li1-N2 92.6(2), N3-Li1-N4 93.6 (2), C2-C1-C7 130.3(2), C13-C12-C18 130.8(2). c) The crystal structure of **4**; selected bond lengths [pm] and angles [°]: Li1-N1 201.0(5), Li1-N2 200.0(5), Li1-N3 200.4(5), Li1-N4 198.5(5), Na-O 237.8(2) (average); N1-Li1-N2 93.6(2), N3-Li1-N4 94.0(2).

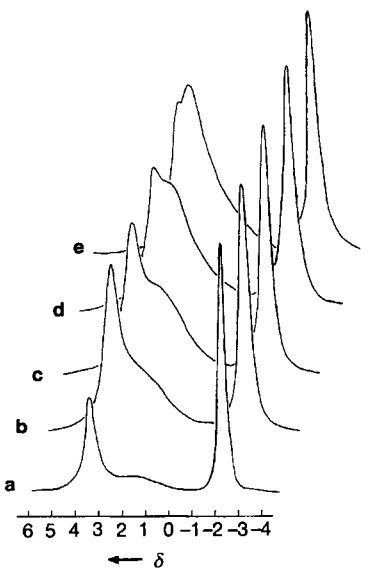
to just one lithium atom. The Li1 ··· C1 vector intersects the Li1 ··· C12 vector at an angle of 159.8°, and the planes of the anions are not exactly perpendicular (82.3°). We synthesized ^6Li-enriched **2** to investigate the dynamic behavior of the compound in solution and in the solid state by ^6Li NMR experiments. Unfortunately, **2** is not soluble enough in hydrocarbons

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0606-0693 $ 10.00+.25/0

to record the ^{6}Li NMR spectrum in solution. In [D$_8$]THF solution the different environments of the two lithium atoms level out giving rise to a single resonance signal at $\delta = 3.25$. As expected, the solid-state structure is not retained in donor solvents. Two resonance signals are observed in the ^{6}Li CP/MAS NMR spectrum (CP = cross polarization) at $\delta = -2.5$ and 3.3 (Fig. 2a). The spectrum a was recorded from a freshly crystallized sample ($t_0 = 0$). Even in this spectrum a broad signal at $\delta = 1.4$ indicates a third ^{6}Li magnetic environment. After the first measurement the rotor with the sample was stored for 3 h at room temperature in a dry argon atmosphere. The spectrum recorded subsequently (Fig. 2b) shows the growth of the signal at $\delta = 1.4$; storage for 12 h under the same conditions leads to further growth of the third signal (Fig. 2c). The spectra d and e in Figure 2 depict the ^{6}Li CP/MAS NMR spectra after additional warming to +50 °C for 2 h and 12 h, respectively. The spectrum e represents the end of the phase transition at +50 °C. Longer warming gives rise to the same signal pattern.



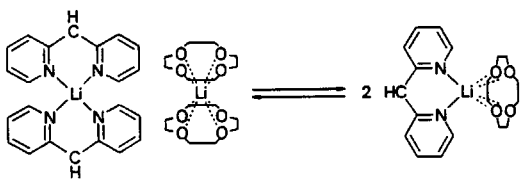


Fig. 2. The ^{6}Li CP/MAS NMR spectrum ($^6LiCO_3$ as external standard) depicting the partial transformation of **2** to **3**. a) Two signals at $t_0 = 0$ and $\delta = -2.5$, 3.3; b) $t_1 = t_0 + 3$ h; c) $t_2 = t_0 + 16$ h; d) $t_3 = t_2 + 2$ h at +50 °C; e) $t_4 = t_3 + 12$ h at +50 °C.

To explain the alterations in the spectra we suggest a rearrangement equilibrium of **2** to **3**, where in the product **3** one bis(pyridyl)methyl ligand and one crown ether molecule are coordinated to the lithium atom.

2 **3**

Compound **2** gives rise to two resonance signals, whereas **3** leads to a single resonance signal in the ^{6}Li CP/MAS NMR spectrum. After the experiment the orange powder of compound **2** consists of two phases. Compound **3** forms a purple semiplastic phase on the inner wall of the NMR rotor, while unrearranged **2** remains in the center of the rotor. Apparently, the considerable mechanical strain (12000 revs. s^{-1}) promotes the rearrangement of **2** to **3**.

Treatment of **1** with one equivalent of NaO*t*Bu in THF surprisingly leads to the first sodium lithiate complex **4** rather than to the total metal exchange product.

$$\underset{\mathbf{1}}{2[Li\{(2\text{-}NC_5H_4)_2CH\}(thf)_2]} \xrightarrow[-\ LiO\mathit{t}Bu\ -\ NaO\mathit{t}Bu]{\text{in THF}\ +\ 2\ NaO\mathit{t}Bu} \underset{\mathbf{4}}{[Na(thf)_6][Li\{(2\text{-}NC_5H_4)_2CH\}_2]}$$

Crystals of **4** were obtained at −35 °C from THF. The low melting single crystals (m.p. < −30 °C) were selected and transferred to the diffractometer at −80 °C.[13] To our knowledge **4** is the first example of a sodium lithiate although a few mixed lithium/sodium complexes are known.[14] The anion in **4** is very similar to the one in **2** (Fig. 1c). Formally the Li([12]crown-4)$_2$ cation in **2** is replaced by the very unusual [Na(thf)$_6$] cation.[15] The Li1 ··· C1 vector intersects the Li1 ··· C20 vector at an angle of 162.6° and, in contrast to **2**, the mean planes of the anions are almost perpendicular (91.7°).

Apparently, two CH(2-NC$_5$H$_4$)$_2$ anions accommodate a single Li cation so well that this structural motif is present in **2** and **4**. This might be the reason why complete metal exchange does not occur. Hence this reaction and the structure of **4** provide some insight to the function of superbases.[16] In the mixture of RLi/NaO*t*Bu the R$^-$ ion does not necessarily have to be a classical carbanion like Me$^-$ or Bu$^-$. The very attractive Li–O interaction is often regarded as the driving force in this type of reaction. Compound **4** appears to be the first example in which only one Li–O bond but six Na–O bonds are formed. With the right shape and basisity of the carbanion, selective transmetalation can be achieved. We are currently investigating the steric and electronic requirements necessary to vary the anion R$^-$ of the organolithium component RLi in other selective transmetalations by KO*t*Bu, RbO*t*Bu, and CsO*t*Bu.

Experimental Procedure

1: H$_2$C(2-NC$_5$H$_4$)$_2$ (0.681 g, 4 mmol) in THF (25 mL) was treated with the equimolar amount of *n*BuLi (1.74 mL of a 2.3 M solution) at −80 °C. Evaporating off the solvent gave an orange precipitate, which was washed twice with pentane (10 mL). Crystallization from THF yielded X-ray quality crystals. Yield 0.858 g; 67%, m.p. 40 °C. Decomposition at $T \geq 70$ °C, ^{1}H NMR ([D$_8$]THF, room temperature,TMS ext.): $\delta = 1.77$, 3.58 (THF), 4.63 (s, H1), 5.80 (ddd, $^3J_{5,4} = 6.61$, $^3J_{5,6} = 5.31$, $^4J_{5,3} = 1.11$ Hz; H5), 6.28 (ddd, $^3J_{3,4} = 8.65$, $^4J_{3,5} = 1.11$, $^4J_{3,1} = 1.11$ Hz; H3), 6.74 (ddd, $^3J_{4,3} = 8.65$, $^3J_{4,5} = 6.61$, $^4J_{4,6} = 1.91$ Hz; H4), 7.59 (dd, $^3J_{6,5} = 5.31$, $^4J_{6,4} = 1.91$ Hz; H6); ^{13}C NMR (THF/C$_6$D$_6$, room temperature, TMS. ext.): $\delta = 88.4$ (s, C1), 110.7 (s, C5), 122.8 (s, C3), 135.6 (s, C4), 141.2 (s, C6), 155.1 (s, C2); ^{7}Li NMR ([D$_8$]THF, room temperature, LiCl ext.): $\delta = 3.25$.

2 H$_2$C(2-NC$_5$H$_4$)$_2$ (1.702 g, 10 mmol) in hexane (30 mL) was treated with *n*Bu^{6}Li (5.4 mL, 1.85 M solution) at −80 °C. After stirring for 2 h [12]crown-4 (2.000 g, 11.349 mmol) was added. The reaction mixture was warmed to room temperature and the precipitate was redissolved in a small amount of THF. Storage at −35 °C yielded X-ray quality single crystals, yield 2.995 g; 85%, m.p. 193 °C. Decomposition at $T \geq 215$ °C. **2** is insoluble in hydrocarbons and NMR investigations in THF show similar chemical shifts as **1**.

4 NaO*t*Bu (0.769 g, 8 mmol) and Li(2-NC$_5$H$_4$)$_2$CH (1.409 g, 8 mmol) were stirred in THF (30 mL) at room temperature. The reaction mixture was directly transferred to a deep freezer. After three days at −35 °C colorless crystals were obtained; melting point about −30 °C; all NMR data were obtained from the vacuum-dried THF-free powder (decomp $T > 270$ °C). ^{1}H NMR ([D$_8$]THF, room temperature, TMS ext.): $\delta = 4.61$ (s, H1), 5.70 (ddd, $^3J_{5,4} = 6.55$, $^3J_{5,6} = 5.30$, $^4J_{5,3} = 1.1$ Hz; H5), 6.23 (d, $^3J_{3,4} = 8.60$ Hz, H3), 6.69 (ddd, $^3J_{4,3} = 8.60$, $^3J_{4,5} = 6.55$, $^4J_{4,6} = 1.99$ Hz; H4), 7.59 (dd, $^3J_{6,5} = 5.30$, $^4J_{6,4} = 1.99$ Hz, H6); ^{13}C NMR ([D$_8$]THF, room temperature, TMS ext.): $\delta = 87.8$ (s, C1), 105.9 (s, C5),120.1 (s, C3), 132.8 (s, C4), 148.1 (s, C6), 160.2 (s, C2); ^{7}Li NMR ([D$_8$]THF, room temperature, LiCl ext.): $\delta = 2.34$ (s); ^{23}Na NMR ([D$_8$]THF, room temperature, NaCl ext.): δ −0.49 (s, br.).

Simulation of Liquids

Theoretical Treatment of Liquids and Liquid Mixtures. (Series: Studies in Physical and Theoretical Chemistry, Vol. 80.) By *C. Hoheisel*. Elsevier, Amsterdam, 1992. XVI, 362 pp., hardcover HFl 320.00, $ 200.00.— ISBN 0-444-89835-2

This monograph is intended for scientists and students who already have a good knowledge of statistical mechanics. It is especially concerned with theoretical concepts for describing liquid mixtures. The introduction to statistical mechanics has therefore been kept very brief, and is confined to the fundamental relationships between the thermodynamic potentials and the quantities describing the canonical ensemble. The author then continues with some general observations regarding computer simulations. The next two chapters deal with Monte Carlo (MC) and molecular dynamics (MD) simulation methods, including fundamental relationships involving the properties of Markov chains and principles of simulations. Discussions of intermolecular interaction potentials are interspersed with descriptions of the MD method and of simulation techniques. At this point it is already becoming apparent that the main content of the book is devoted to descriptions of results obtained by simulation methods.

After looking through these first four chapters, which are evidently intended as an introduction, one has the impression that the style of presentation is sadly inferior to that in other monographs on the subject. Descriptions that are more didactically sound and understandable by the reader can be found in books such as K. Lucas's *Angewandte Statistische Thermodynamik* or D. Chandler's *Introduction to Modern Statistical Mechanics*. The reader seeking a systematic introduction to simulations of liquid systems would be better advised to consult *Computer Simulation of Liquids*, by Allen and Tildesley.

Chapter 5 deals with all the equilibrium properties, structures, and thermodynamics of liquid systems, Here the contradictions between the aims expressed in the preface and the actual content of the book become clearly evident. The descriptions of integral equation theories are very brief, and correspond to the state of knowledge about ten years ago. The detailed discussion of hard-sphere models includes comparisons with simulations using Percus–Yevick and hypernetted chain (HNC) calculations. Lennard–Jones systems are then treated in the same way. The emphasis here is on the discussion of additive and nonadditive mixtures. The author makes no reference to more recent developments such as the application of integral equations to inhomogeneous systems, rapid methods for the solution of the Ornstein–Zernike equation, or the LHNC and RHNC methods. Consequently, Figure A 33 and others give an outdated impression of the capabilities of theoretical treatments. The advice (e.g., on p. 115) in the phrase "The reader is referred to the existing relevant literature" hardly makes up for these deficiencies. Much more seriously, though, the author says nothing at all about polar systems, and devotes only five pages to molecular liquids. Here results from more recent theoretical developments are neglected, and the citations are limited to a few of the author's own papers.

The choice and style of treatment of the literature references invite criticism. Lists of publications are scattered throughout the chapters, but there are hardly any corresponding references in the text, so that the reader is left to decide which citations relate to which parts of the text. After reading Part A the verdict must be that the contents do not live up to the promise of the book's title.

At first sight the idea of treating equilibrium properties together with the dynamics of liquid systems appears promising, especially as the theoretical concepts overlap. However, to treat these two topics together in detail is a very ambitious task. Part B of the book, with 200 pages, is the main part both in length and subject matter. The main emphasis is again on simulations and their evaluation. However, close examination reveals some gaps and inadequacies in the descriptions of the theory and in the arrangement of material. Unfortunately, the theory is only treated in the amount of detail needed to interpret the simulations. There are frequent references to more detailed treatments in later chapters (e.g., on pp. 165, 182, 183, 185, 187, 188, 192, 244), giving the impression of a lack of systematization.

An introduction including continuity equations and examples of applications of the Navier–Stokes equation is followed by a chapter on time-correlation functions, which glosses over many of the points too briefly. The treatment of self-diffusion includes numerous simulations for Lennard–Jones systems, from which autocorrelation functions are derived and diffusion coefficients are determined. These values are then compared with results from the Enskog theory and the kinetic mean field theory, but not with experimental values (except in Table B 3). In (9.3.1.1.10) the last equations given appear to contain printing errors. The next chapter is devoted to transport coefficients. Starting from the Green–Kubo equations, simulations of Lennard–Jones mixtures are used to derive diffusion coefficients, viscosities, and thermal conductivities. Here the author makes systematic comparisons with the Enskog and kinetic theories, the Rice–Allnatt approximation, and the Gaussian memory function model, and discusses the results. The book concludes with discussions of nonequilibrium simulations and calculations of transport coefficients. Here, for the first time, comparisons with experimental data are introduced, enabling one to evaluate the simulation methods.

If the numerous references in this book to more advanced monographs and original publications are to be taken seriously, one must conclude that it would be better to simply read these sources instead.

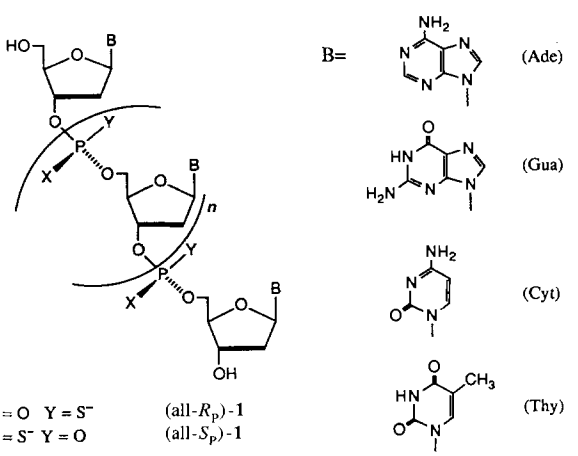
This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Stereocontrolled Synthesis of Oligo(nucleoside phosphorothioate)s

Wojciech J. Stec,* Andrzej Wilk



Encouraging results obtained for modulation of gene expression by antisense oligonucleotides and their analogues have kindled hopes for a new generation of therapeutics against viral infections, cancer, and many other diseases. Among such analogues, oligo(nucleoside phosphorothioate)s (Oligo-S) have generally shown the highest efficacy in inhibiting the biosynthesis of "unwanted" proteins. The first clinical trials of antisense agents are now in progress using Oligo-S against genital warts and acute myeloid leukemia, and tests of Oligo-S against AIDS should follow soon. Nevertheless, their mechanism of action, internalization, cellular trafficking, subcellular localization, and interaction with cellular proteins is still poorly understood. It is assumed a priori that application involves rapid and efficient molecular recognition of target RNA by Oligo-S; however, the effects of the chirality of Oligo-S have so far been unappreciated, because Oligo-S has not yet been synthesized with stereocontrol. Indeed, the diastereomeric composition of Oligo-S has never been determined, primarily because of the lack of appropriate analytical methods. Since each of the diastereomers is a stereochemically unique chemical entity, questions arise as to which diastereomer is responsible for an observed biological response, including positive (curative) or possibly negative (toxic) side effects.

In this review we intend provide a perhaps somewhat speculative assessment of the problems associated with the stereocontrolled synthesis of Oligo-S and to discuss the state-of-the-art in this field including strategies that may lead to Oligo-S of predetermined chirality. This article is not intended to discourage researchers from further studies of diasteromeric mixtures of Oligo-S as potential pharmaceuticals. Throughout the history of medicinal chemistry numerous useful medicines were discovered, developed, and employed without the detailed knowledge of their structure. Indeed, the composition of the vaccines discovered by Pasteur is a subject of vigorous study still today.

1. Introduction

Since the discovery that Oligo-S **1** can effectively protect cells from the lethal action of the HIV-1 virus,[1] a number of reports have appeared concerning improvements in their synthesis,[2] their purification and analysis,[3] cellular uptake, pharmacokinetics and toxicity,[4] mechanism of action,[5] and potential therapeutic applications.[6] In the first enzymatic[7] and chemical[8] syntheses of Oligo-S it was recognized that stereodefined 3′-*O*-deoxyribosyl and 5′-*O*-deoxyribosyl moieties surround the phosphorus atom of each phosphorothioate unit, and because of the stereogenicity of phosphorus, new centers of chirality are created in each molecule of **1**.

However, relatively little attention has been paid to the structural and biochemical consequences of this diastereomerism. The aim of the present review is to focus the attention of researchers, who are applying Oligo-S to antisense technology[9] and/or ribozyme technology,[10] on the problem of the polydiastereomerism of **1**, and to critically evaluate the potential strategies for stereocontrolled synthesis of Oligo-S leading to pure products with defined chirality at each phosphorus atom.

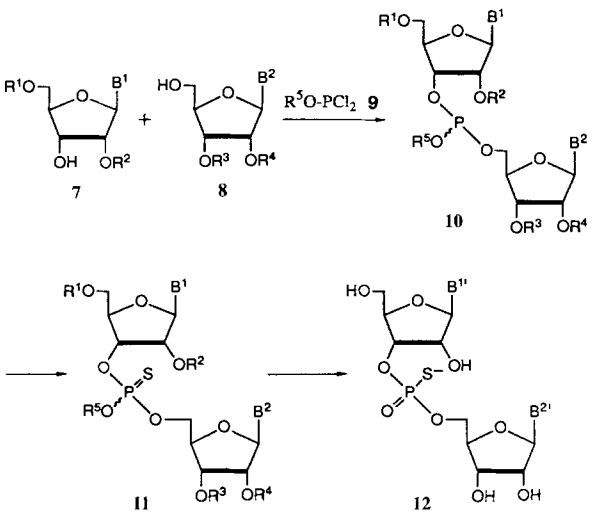
2. Nonstereocontrolled Synthesis of Oligo(nucleoside phosphorothioate)s

Antisense Oligo-S **1** are relatively short oligonucleotides (ca. 15- to 30-mers) with a defined sequence of nucleobases complementary to RNA (or ssDNA) in which each internucleotide phosphate is replaced by a phosphorothioate moiety. The sequence of nucleobases between the 5′-OH and 3′-OH end groups in these molecules is responsible for recognition of a complementary target RNA and specific alignment governed by Watson–Crick hydrogen bond formation.[11]

Oligo-S have been prepared until now by primarily two methodologies: a) stepwise phosphoroamidite coupling[12] followed by sulfurization[8, 13] of the intermediate *O*-alkylphosphite **5**, and b) tandem sulfurization of oligo(nucleoside *H*-phosphonate)s[2b, 14] bound to the solid support (Scheme 2). Sulfurization of either *O*,*O*,*O*-trialkylphosphites or *O*,*O*-dialkyl-*H*-phosphonates is itself stereoretentive.[15] Assuming that both methodologies are neither stereospecific nor stereoselective and that each *O*-alkyl phosphite internucleotide bond (as in **5**) or each *H*-phosphonate bond (as in **6**) is formed in a nonstereoselective manner, the resulting Oligo-S consists of a mixture of 2^n diastereomers, where n is the number of phosphorothioate internucleotide bonds. The content of any single diastereomer in this mixture should therefore be 2^{-n}. However, even from the pioneering works of Burgers and Eckstein[16] and Marlier and Benkovic[17] on the synthesis the stereoisomers **12**, $U_{PS}A$ and $A_{PS}A$, respectively, it was known that the quantities of diastereomers (R_P) and (S_P) were not equimolar. By applying phosphorodichloridite coupling (by means of **9**) followed by sulfurization of phosphite **10**, both groups independently obtained diastereomers of diribonucleoside 3′,5′-phosphorothioates **12** (Scheme 3) and assigned the configuration at the phosphorus atom. Moreover, recent studies have shown that condensation of 5′-*O*-DMT-nucleoside 3′-*O*-(*O*-2-cyanoethyl-*N*′,*N*′-diisopropylphosphoramidite)s with 5′-OH nucleoside bound to a solid support through the 3′-O atom gives after deprotection the diastereomeric mixtures of (R_P)- and (S_P)-dinucleoside 3′,5′-phosphorothioates in the ratios listed in the Table 1. (This condensation must be performed according to the generally accepted protocol for the synthesis of oligonucleotides, with the exception that the oxidation step with iodine is replaced by sulfurization.[8, 12g]) It was demonstrated earlier[8c] that the diastereomeric composition of the starting 5′-*O*-DMT-*N*-benzoylcytidine 3′-*O*-(*O*-methyl-*N*′,*N*′-diisopropylphosphoroamidites) does not influence the ratio of the resulting diastereomers of dicytidine 3′,5′-phosphorothioate.

Scheme 2. Synthesis of **1** with the phosphoroamidite (a) and *H*-phosphonate methods (b). a) 1. Sulfurization, 2. capping of the unreacted 5′-OH group, 3. removal of the 5′-trityl group, 4. condensation with **2**/tetrazole, 5. steps 1–4 are repeated n times. b) 1. Removal of the 5′-trityl group, 2. condensation with **3**/pivaloyl (adamantoyl) chloride, 3. capping of the unreacted 5′-OH group, 4. steps 1–3 are repeated n times, 5. final sulfurization. For both methods the product is then cleaved from the solid support, deprotected, and purified. R^1 = 4,4′-dimethoxytrityl (DMT); R^2 = CH_2CH_2CN, Me; R^3 = long chain amine controlled pore glass (LCA-CPG); B^1,B^2 = AdeBz, Gua*i*Bu, CytBz, Thy.



The composition of the mixture of diastereomers obtained with (R_P) diastereoselectivity x and (S_P) diastereoselectivity y ($y = 1 - x$) preserved at each of n couplings can be calculated from the polynomial Equation (a). The following example is

$$(x + y)^n = x^n + \binom{n}{1} x^{n-1} y + \cdots + \binom{n}{n-1} x y^{n-1} + y^n \qquad \text{(a)}$$

calculated for the pentamer (e.g. d[$(C_{PS})_4$C]) obtained with diastereoselectivity $x = 0.6$: $(x + y)^4 = x^4 + 4x^3y + 6x^2y^2 +$

Wojciech J. Stec was born in Warsaw, Poland, in 1940. He obtained his M. S. (1963) and Ph.D. (1968) from the Technical University of Lodz. After postdoctoral work at Vanderbilt University, Nashville, TN, USA (1970), he returned to Lodz and became Associate Professor in 1974. In 1979 he became Full Professor and Head of the Department of Bioorganic Chemistry. His research activity is focused on the synthesis and stereochemistry of organophosphates, the stereochemical analysis of cyclic phosphates, isotope labeling, the mechanism of action of alkylating anticancer drugs, and the stereoselective activity of enzymes. Recently he became involved in protein bioengineering and "antisense" technology. From 1983 to 1984 he was a Senior Visiting Scientist at the U.S. Food and Drug Administration; in 1992–1993 he was appointed Scholar-in-Residence at the U.S. National Institutes of Health. He was elected member of the Societas Scientiarum ac Litterarum Varsoviensis in 1981.

Scheme 3. The phosphite method used by Eckstein (a) and Benkovic (b) for the synthesis of diribonucleoside 3',5'-phosphorothioates [16, 17]. a) R^1 = *p*-chlorophenoxyacetyl; R^2 = methoxytetrahydropyranyl; R^3,R^4 = *O*-methoxymethylidene; R^5 = phenyl; B^1 = $B^{1'}$ = Ura; B^2 = N^6-benzoyl-Ade; $B^{2'}$ = Ade. b) R^1 = methoxytrityl; R^2 = *O*-nitrobenzyl; R^3,R^4 = benzoyl; R^5 = methyl; B^1 = N^6-benzoyl-Ade; B^2 = N^6,N^6-dibenzyl-Ade; $B^{1'}$ = $B^{2'}$ = Ade.

Table 1. Proportions of the (R_P) isomer in dinucleoside 3',5'-phosphorothioates ($N_{PS}N'$) in percent [a].

N'/N	dA	dG	dC	dT
dA	51.7	42.6	53.4	53.8
dG	55.3	51.0	55.2	56.0
dC	57.0	48.6	59.7	62.7
dT	58.6	50.8	60.0	59.6

[a] Dinucleoside 5',3'-phosphorothioates ($N_{PS}N'$ where N is at the 5'-end) were prepared according to the standard coupling method (DNA synthesizer, Applied Biosystems model 380 B), followed by sulfurization with a 0.08 M solution of bis-(diisopropoxyphosphinothioyl) disulfide in acetonitrile/pyridine (2/1) for 45 s (ca. 400 μL). The 5'-dimethoxytrityl group was removed in the final step in the synthesis. Crude mixtures were analyzed by HPLC (Supelcosil RP-18 column (5 μ, 2.3 mm × 250 mm), acetonitrile gradient in 0.1 M TEAB from 0%, 0.5% CH_3CN min^{-1}, flow rate 1 mL min^{-1}). The percent of the (R_P) isomer was obtained from peak integration. The coupling efficiency was not lower than >98%.

$4xy^3 + y^4 = 0.1296 + (4 \times 0.0864) + (6 \times 0.0576) + (4 \times 0.0384) + 0.0256$. Thus the mixture of sixteen diastereomers (2^4) contains 12.96% (all-R_P), 2.56% (all-S_P), four possible "(all-R_P) but one" diastereomers, each formed in 8.64% yield, six fragments with equal numbers of (R_P) and (S_P) internucleotide bonds, each with a yield of 5.76%, and four possible "(all-S_P) but one" diastereomers, each formed in 3.84% yield. It is worth mentioning that in the above example the ratio of (all-R_P) to (all-S_P) diastereomers is 5:1.

Indeed, it has been demonstrated roughly that the ratios of diastereomers of $d(C_{PS}C_{PS}C)$ are in agreement with calculated values: (R_P,R_P):(S_P,R_P):(R_P,S_P):(S_P,S_P) = (0.6 × 0.6):(0.6 × 0.4):(0.4 × 0.6):(0.4: × 0.4) (Fig. 1).[18] This assignment also indicates that the diastereoselectivity of subsequent steps of the coupling process is, in the case of cytidine components, nearly the same. That means that in oligo(cytidine phosphorothioate)s the ratio of phosphorothioates with (R_P) configuration at a particular position in the chain to those with (S_P) configuration will be close to 60:40. Further experimental data indicate that for oligo(deoxyadenosine phosphorothioate)s the relative ratio

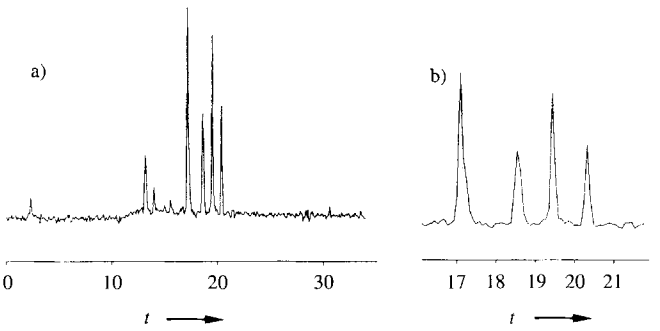


Fig. 1. Chromatogram from a RP-HPLC separation of the four diastereomers of $d(C_{PS}C_{PS}C)$ from the sample prepared by the phosphoroamidite method. For experimental details see Table 1. a) Entire chromatogram of crude material; b) expanded section showing the baseline separated peaks for the diastereomers. Retention time *t* in min.

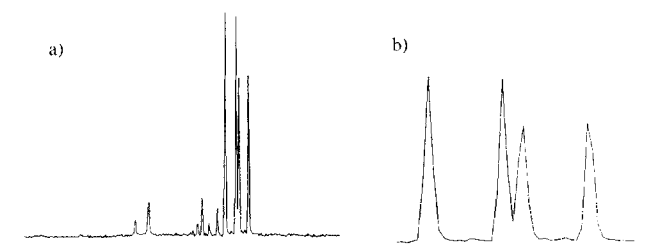
(R_P):(S_P) is 52:48 in the case of dimer formation (see Table 1) but increases roughly 1% per coupling. Thus, the second coupling occurs with 53% (R_P) selectivity, the third with 54%, etc. If this trend can be extrapolated, the 49th coupling should be 100% (R_P) diastereoselective. Perhaps the most convincing demonstration of the effect of the variable diastereoselectivity of the coupling process on the final composition of diastereomers is given in Figure 2. Here it is evident that even during the



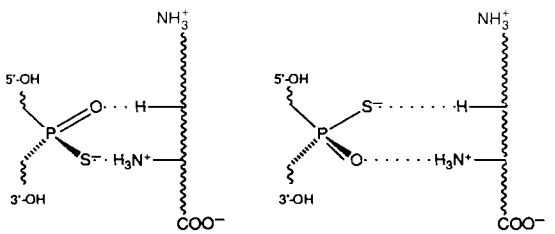


Fig. 2. RP-HPLC trace of crude trimer $d(A_{PS}A_{PS}A)$ prepared and analyzed as indicated in Figure 1. Complete baseline separation of (R_P,S_P) and (S_P,R_P) diastereomers (peaks in the middle of b) was not possible. Retention time *t* in min.

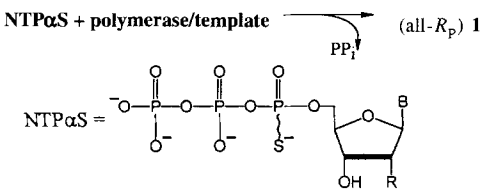
synthesis of the trimer $d(A_{PS}A_{PS}A)$ the ratio of the diastereomers obtained (R_P,R_P):(R_P,S_P):(S_P,R_P):(S_P,S_P) is 29.1:26.1:22.7:22.1.[18]

3. Biological Implications of the Chirality of Oligo-S

What are the consequences of a nonstatistical distribution of individual diastereomers in such constructs as **1**? One must accept the fact that if antisense oligonucleotides **1** are considered as potential therapeutics, their contact with proteins is unavoidable after introduction to the body. Recent results indicate that Oligo-S like $d[(C_{PS})_nC]$ with $n \geq 14$ can inhibit human DNA polymerase and RNase activities.[5a] Therefore, the most problematic consequence of varying the distribution of particular diastereomers of **1** may be the batch-to-batch irreproducibility of biological effects resulting from the different activity of individual diastereomers towards the variety of proteins in the inter-

and intracellular media. From the work initiated by studies of Eckstein,[19] Benkovic et al.,[20] and Frey[21] it is known that functional proteins such as polymerases and nucleases interact with phosphorothioate analogues of biophosphates in a diastereoselective manner.[22] However, the diastereoselectivity is not predictable, since for each enzyme it results from different spatial arrangements of functional groups in proteins (including orientations of peptide bonds), which can interact with phosphate oxygen atoms by means of hydrogen bonds and salt bridges.[23] Recently it has been hypothesized that the diastereoselectivity of enzyme-catalyzed processes in the degradation of oligonucleotides bearing phosphorothioate functions results from directional two-point interactions between the phosphorothioate unit and the protein (Scheme 4).[22f] This hypothesis is well

Scheme 4. Representation of the hypothetical directional two-point interaction between the phosphorothioate group and a protein, which is responsible for the diastereoselective action of some nucleases. Left: arrangement leading to a "productive" interaction of a phosphorothioate function with a protein (as seen with the natural oligonucleotide); right: arrangement leading to an "unproductive" arrangement.



supported by the results of studies on the interactions between oligonucleotides bearing the $^{5'-OH}\cdots GAATTC\cdots{}^{3'-OH}$ sequence and the restriction enzyme *Eco*RI. Replacement of the $\cdots A_pT\cdots$ internucleotide group with $\cdots A_{PS}T\cdots$ having an (S_P) configuration improves the binding between oligonucleotide and this particular enzyme.[22g] Moreover, the proposal that cellular uptake of oligonucleotide involves a specific receptor or transporting protein[4b, 24] implies that the passage through the cell membranes (either inward or outward) may be diastereoselective because of the chirality of both receptors and transporting proteins. This diastereoselectivity could be cell- or species-dependent and could affect both pharmacokinetics and biodistribution.

Finally, the principle of antisense activity of **1** implies the affinity of **1** towards target RNA (or DNA).[9] It is tempting to postulate, even on the basis of early, simplistic model studies,[25] that this affinity is also dependent on the configuration of the phosphorus atom (vide infra). On the other hand, it is reasonable to consider, in light of the unpredictable influence of the chirality of **1** on their interactions with proteins and/or RNA, that the most reliable approach to obtaining active antisense agents is to provide the living system with the pool of diastereomers of **1**. Then the competitive, natural selection of effective diastereomers in each step of the overall process would lead to biological activity. This assumes that the other "incorrect" components of this diastereomeric mixture neither prevent activity nor are harmful to the biological system. It should be emphasized that all biological results reported thus far, including those on the inhibitory effects of Oligo-S on protein biosynthesis, were obtained with diastereomeric mixtures of **1**.[4–6] Although the legal regulations[26] for a new potential drug insist on the precise stereochemical description of the molecule when and if possible, scholarly attitude alone requires chemists to work out the ideal solution—to design a methodology for the synthesis of **1** in a stereocontrolled manner which leads to a single desired diastereomer of **1**.

4. Stereocontrolled Chemical Synthesis of Oligo(nucleotide phosphorothioate)s

One approach to the stereocontrolled synthesis of organic molecules is to use enzymes. For the synthesis of **1** polymerases, transferases, and nucleases can be considered,[27] since these classes of enzymes can assist in the synthesis and degradation of phosphorothioate moieties.

The first synthesis of **1** performed enzymatically (with polymerase) proved to be (R_P) stereoselective (Scheme 5). The use of

Scheme 5. Enzymatic synthesis of (all-R_P)-poly(nucleoside phosphorothioate)s. Template = DNA; R = H, B = Ade, Gua, Cyt, Thy or R = OH, B = Ade, Gua, Cyt, Ura.

endonucleases for diastereoselective degradation of **1** having undesired (R_P) or (S_P) configurations has been studied but is limited in practice to short homopolymers like penta(cytidine phosphorothiate)s, $d[(C_{PS})_4C]$.[18, 28] A diastereomeric mixture of $d[(C_{PS})_4C]$ was exposed to endonuclease P1, which selectively cleaves all phosphorothioate diesters with (S_P) configuration.[22k] Besides intact (all-R_P)-$d[(C_{PS})_4C]$, the accompanying diastereomerically pure 5'-phosphorothioylated units were converted by alkaline phosphatase to the corresponding 5'-OH dimer, trimer, and tetramer having only (R_P)-configurated internucleotide phosphorothioate groups (Fig. 3). Diastereoselective degradation of Oligo-S with the "wrong" configuration at phosphorus is limited to phosphorothioates prepared diastereoselectively, in other words, Oligo-S with mainly (R_P) or (S_P) configuration. If this were not the case, diastereoselective enzymatic digestion would be impractical for most purposes, because in the statistically simplest case the desired product is only a small fraction (2^{-n}) of the starting mixture. Moreover, since an endonuclease with diastereoselectivity opposite to that of nuclease P1 has not been found, recovery of oligonucleotide **1** of (all-S_P) configuration, even from a mixture of diastereomers of predominantly (S_P) configuration, is not yet possible. Therefore, the only rational approach to the synthesis of Oligo-S having a predetermined sequence of nucleobases and predetermined chirality at each phosphorus atom is a stereocontrolled, and highly stereoselective chemical method.

What are the potential strategies for the synthesis of Oligo-S with defined stereochemistry at the phosphorus centers? Method-

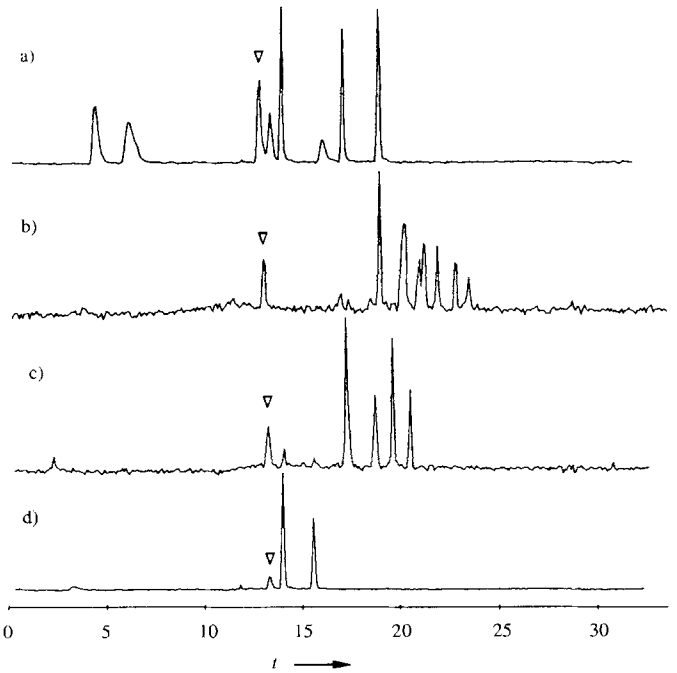


Fig. 3. RP-HPLC traces of a) the parent tetramer d($C_{PS}C_{PS}C_{PS}C$) after digestion with nuclease P1/alkaline phosphatase; b) crude tetramer d($C_{PS}C_{PS}C_{PS}C$) (mixture of eight diastereomers); c) crude trimer d($C_{PS}C_{PS}C$) (four diastereomers); d) crude dimer d($C_{PS}C$) (two diastereomers). Dimer, trimer, and tetramer were prepared by the phosphoroamidite/sulfurization method and analyzed as described in Table 1 with the exception that the gradient was 0.66% min^{-1}. Retention time t in min. Peaks marked with a triangle correspond to benzamide.

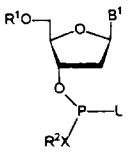
ologies developed during 100 years of phosphorus chemistry[29] that may be employed for the stereocontrolled synthesis of diastereomerically pure **1** are based on a) stereoselective or stereospecific nucleophilic substitution at tricoordinate phosphorus, b) stereoselective synthesis or stereoselective sulfurization of intermediates containing internucleotide *H*-phosphonates, c) stereoselective or stereospecific nucleophilic substitution at tetracoordinate phosphorus.



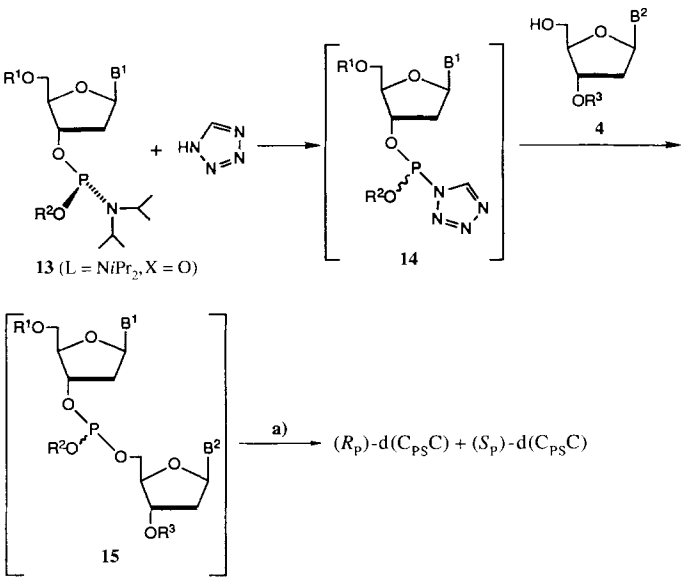
In choosing a potential strategy, one must consider that the diastereomeric purity (*dp*) of **1** is described by Equation (b).

$$dp = p_1 \cdot p_2 \cdot p_3 \ldots p_n \qquad \text{(b)}$$

If $p_1 = p_2 = \ldots = p_n$, then $dp = p^n$, where n is the number of internucleotide phosphorothioate units and $p_1, p_2, \ldots p_n$ designate diastereoselectivities of particular coupling steps. It is obvious that the diastereoselectivity of any single coupling must be greater than 0.95 for the effective application of this strategy.

4.1. Nucleophilic Substitution at Tricoordinate Phosphorus Centers

Stereoselective/stereospecific syntheses of **1** utilizing substrates **13** (Scheme 6), which contain a tricoordinate phosphorus center (P^{III}), have the following limitations: substrate **13** must be separable into its P enantiomers, the R^1 group must be an acid-labile protecting group, X must be an oxygen or sulfur atom, and R^2

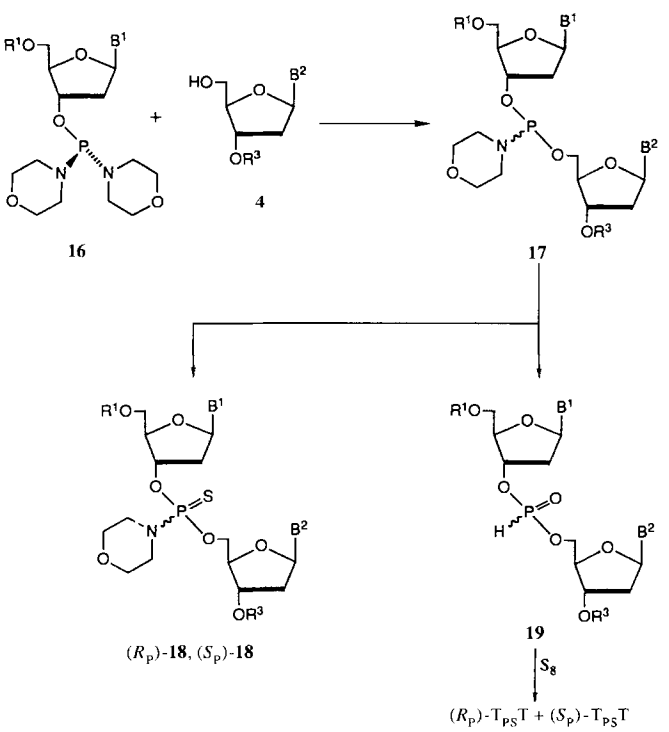


Scheme 6. R^1 = DMT, pixyl, etc.; R^2 = alkyl, aryl; X = S, O or R^2X = Me; B^1 = protected Ade, Gua, Cyt, Thy; L = leaving group.

13

should be removable by cleavage of the X–R^2 bond. If R^2X = L, prochiral **13** offers the possibility for diastereoselective exchange (replacement) of (*pro-R*) or (*pro-S*) groups.

In early attempts at the diastereoselective synthesis of **1**[8c] substrates **13** (R^1 = DMT, R^2X = MeO, L = iPr_2N, B^1 = CytBz) were obtained in diastereomerically pure form, but their activation by tetrazole appeared to cause P-epimerization. Besides protonation, activation of **13** by tetrazole also involves the substitution of the $NiPr_2$ group by tetrazole. Intermediate phosphorotetrazolidites **14** undergo fast P-epimerization in the presence of an excess of tetrazole, most probably by rapid exchange of substituents (Scheme 7).



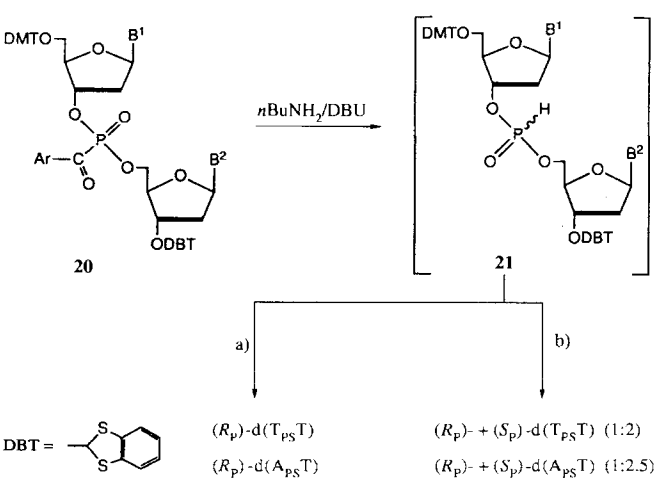
Scheme 7. Diastereomerically pure **13** undergoes P-epimerization in the presence of tetrazole, which impedes the stereocontrolled synthesis of **1** by phosphoroamidite methodology. a) 1. S_8, 2. deprotection. R^1 = DMT; R^2 = Me; R^3 = LCA-CPG; B^1 = B^2 = CytBz.

Detailed mechanistic studies confirmed this early hypothesis.[30] Accordingly, the resulting intermediate dinucleoside 3′,5′-*O*-methylphosphite **15** consists of a mixture of diastereomers. Stereoretentive sulfurization of **15** followed by deprotection of amino and hydroxyl functions, and cleavage from the solid support gave dicytidine 3′,5′-phosphorothioates with the ratio of diastereomers (R_P):(S_P) = 60:40. In similar studies on the diastereoselective synthesis of dinucleoside 3′,5′-methanephosphonates, Lebedev et al.[31] used diastereomeric substrates **13** (R^2X = Me, L = iPr_2N). The nucleoside component in this reaction was 5′-*O*-trifluoroacetyl-3′-*O*-acetylthymidine, and 4-dimethylaminopyridine (DMAP) was used as the catalyst. After mild oxidation and deprotection, the resulting dinucleoside

3′,5′-methanephosphonate appeared to consist of a 1:1 mixture of diastereomers.

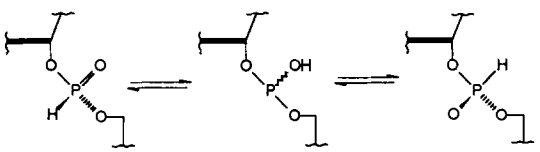
These discouraging attempts obviously do not preclude success with other P^{III} compounds. Perhaps substrates **13** bearing bulky and/or chiral R^2 groups (but offering selective R^2–X bond cleavage) can be constructed. Compounds with a different leaving group L may require a different type of activation than that used for substrates with L = NR_2. Alternatively, NR_2 groups that do not undergo ready exchange should be employed. A potentially good leaving group is 4-nitrophenoxyl,[32] but only under the condition that the resulting 4-nitrophenoxide ion is removed from the reaction medium immediately after release; otherwise, it may cause epimerization of **13**.

Selectivity may also be attained by the diastereoselective reactions of prochiral P^{III} substrates (**13**, R^2X = L) with the 5′-OH function of the nucleoside component. Diastereoselectivity within the coupling process is possible since both reagents (3′-*O*-phosphitylated nucleoside and 5′-OH nucleoside) bear chiral auxiliaries (2′-deoxyribosyl moieties), and one of the two competing routes (leading to the (S_P) and (R_P) diastereomers) can be considered to be kinetically favored. In the course of the development of the phosphorodiamidite approach to oligonucleotide synthesis[33] 5′-*O*-DMT-thymidine 3′-*O*-phosphorodimorpholidite **16** was synthesized and coupled with 3′-*O*-acetylthymidine **4** in the presence of tetrazole as the catalyst (Scheme 8). Unfortunately, neither phosphorothioate **18** nor *H*-phosphonate **19** were enriched in one diastereomer to a meaningful extent.[34] These results strengthen the hypothesis that any phosphoroamidite substrate like **13**, which is activated by an acid nucleophilic catalyst, is prone to P-epimerization.



Scheme 8. The synthesis of Oligo-S with the phosphoroamidite method could not be conducted diastereoselectively. R^1 = DMT; R^3 = Ac; B^1,B^2 = Thy. (R_P)-/(S_P)-**18** and (R_P)-/(S_P)-$T_{PS}T$ are both formed in approximately 1:1 ratios.

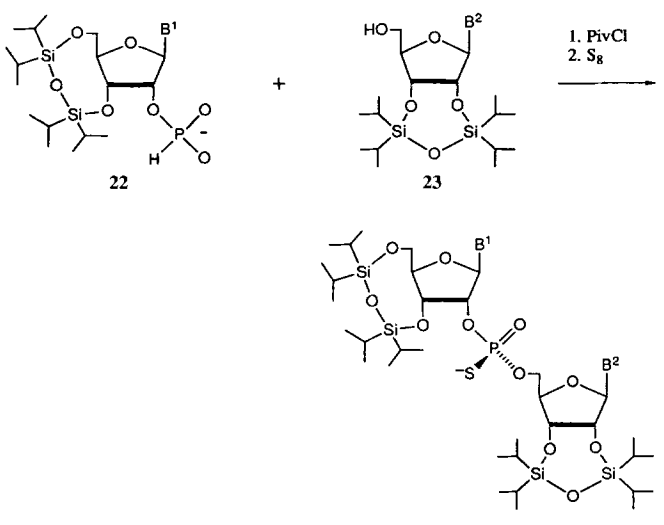
4.2. Stereoselective Formation and Sulfurization of Oligo(nucleoside *H*-phosphonate)s



The *H*-phosphonate approach to oligonucleotide synthesis involves 5′-*O*-DMT-nucleoside 3′-*O*-(H-phosphonate)s as P-prochiral substrates **3**. Their activation with sterically demanding pivaloyl[35a] or adamantoyl[35c] chloride may, in principle, be stereoselective and lead to chiral oligo(nucleoside *H*-phosphonate)s bound to the solid support. These, after tandem sulfurization, cleavage from the support, and nucleobase deprotection, give Oligo-S.[36] However, the ratio of diastereomers of di(deoxyribonucleoside) 3′,5′-*H*-phosphonates **6** is known to be close to 1:1,[37] which dictates that a similar ratio of the corresponding diastereomeric dinucleoside 3′,5′-phosphorothioates results from subsequent sulfurization.[36b] Very recently Stawinski et al. reported that diribonucleoside 3′,5′-*H*-phosphonate $C_{PH}U$ prepared by his method[35] consists of a mixture of diastereomers in the ratio 6:1.[38] Independently, it has been demonstrated that diastereomers of dinucleoside 3′,5′-*H*-phosphonates **6** can be separated by silica gel chromatography[37, 38] and sulfurized with retention of configuration. This P-configurational stability of unsymmetrical *O*,*O*-dialkyl *H*-phosphonates was, however, not surprising in light of classical studies on the preparation of diastereomerically pure *O*-menthylphenylphosphonates[39] and enantiomeric *O*-isopropylmethylphosphonates.[40] Moreover, sulfurization of P-chiral *O*,*O*-dialkyl *H*-phosphonates is known to be a stereoretentive process.[15] Therefore, stereocontrolled synthesis of oligo(nucleoside *H*-phosphonate)s as convenient precursors of Oligo-S (or other P-chiral analogues of oligonucleotides) seems to be a still-unexplored avenue that deserves more attention, especially in view of results reported by Hata et al.[41] and recently by Battistini et al.[42]

Hata et al. found that degradation of dinucleoside 3′,5′-α-ketophosphonates **20** by treatment with *n*-butylamine and 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) is stereoselective (Scheme 9). In these studies intermediate *H*-phosphonates **21** were not isolated but treated with trimethylsilyl chloride and sulfurized with

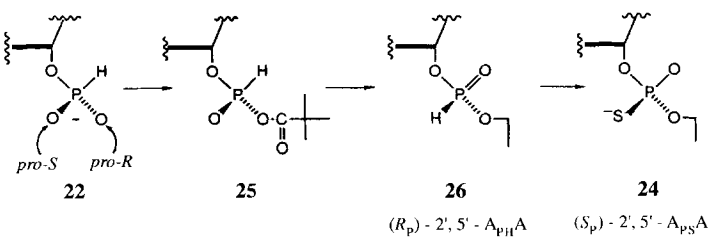
Scheme 9. The DBU-catalyzed aminolysis of phosphonates **20** was remarkably diastereoselective, as shown by the diastereomeric ratio of the sulfurized product. a) 1. S_8, 2. deprotection of OH groups; b) 1. deprotection of OH groups, 2. $Me_3SiCl/Et_3N + S_8$. B^1 = Ade, Thy; B^2 = Thy; Ar = phenyl, *p*-chlorophenyl.



elemental sulfur. Depending on the kind of protective groups and the sequence of deprotection/sulfurization steps, either pure (R_P)-dinucleoside 3',5'-phosphorothioate or a significantly enriched mixture of diastereomers [(S_P):(R_P) = 2.5:1] was obtained. As pointed out by the authors[41b] in the case of d(T_{PS}T), when a benzoyl or *tert*-butyldimethylsilyl group was used as the 3'-terminal protecting group instead of 1,3-benzodithiol-2-yl (DBT), the formation of the phosphorothioates was not stereoselective. Because the starting α-ketophosphonates **20** were used as a mixture of diastereomers for the DBU-catalyzed aminolysis, the conclusion drawn was that DBU influences the configurational equilibration of the resulting *H*-phosphonates **21** (Scheme 10). Hata et al. postulated[41b] that DBU, generally

Scheme 10. The effect of DBU in shifting the configurational equilibrium of **21**.

considered to be a nonnucleophilic base,[43] interacts with *H*-phosphonates to form pentacoordinated intermediates which epimerize at the phosphorus center by pseudorotation to give the thermodynamically more stable isomers. The thermodynamic preference is dictated by steric demands of bulky ligands (augmented by sterically demanding protecting groups at the 5'-*O* and 3'-*O* positions).[44]

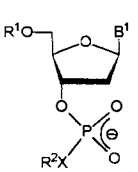


A different explanation must be given for the stereoselectivity in the synthesis of 2',5'-(A_{PS}A) reported by Battistini et al.[42] Condensation of N^6-benzoyl-3',5'-*O*,*O*-tetraisopropyldisiloxane adenosine 2'-*O*-(*H*-phosphonate) (**22**) with **23** in the presence of pivaloyl chloride provides exclusively (S_P)-configurated diadenosine 2',5'-phosphorothioate **24** after sulfurization (Scheme 11). Interestingly, introduction of a *tert*-butyldimethylsilyl protective group at 2'-O, which has more conformational

Scheme 11. Stereoselective synthesis of 2',5'-A_{PS}A. B^1 = B^2 = AdeBz; Piv = pivaloyl.

freedom than the cyclic 3',5'-*O*,*O*- or 2',3'-*O*,*O*-1,1,3,3-tetraisopropyl-1,3-disiloxanediyl protective groups, causes a reduction in diastereoselectivity [(S_P):(R_P) = 70:30].

These intriguing observations can be interpreted in terms of diastereoselective activation of the *H*-phosphonate function of protected **22** owing to the presence of sterically demanding protective groups at the nucleoside components. Presumably, for steric reasons, acylation of anionic **22** occurs exclusively at the (*pro-R*) oxygen atom, and anhydride **25** reacts stereospecifically with **23** leading to (R_P)-2',5'-A_{PH}A **26**; subsequent stereoretentive sulfurization gives (S_P)-**24** (Scheme 12). This explanation

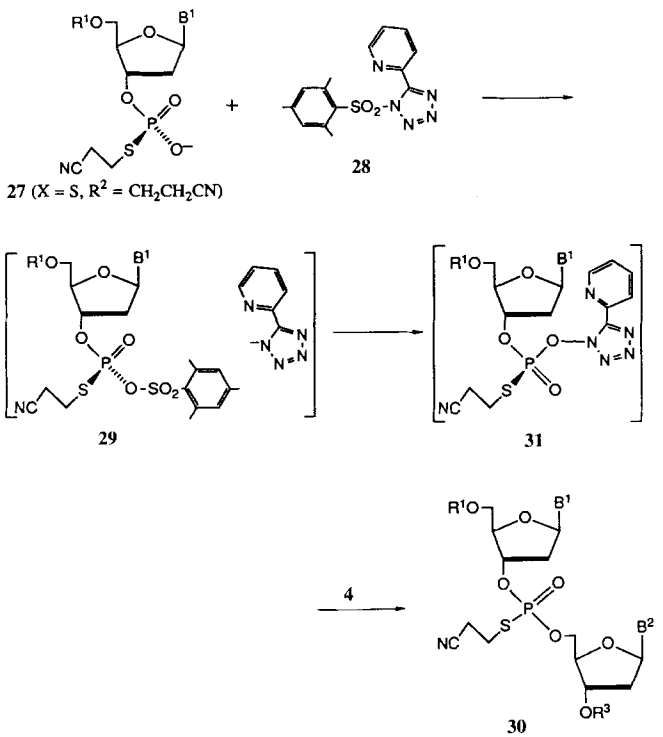


Scheme 12. (*pro-R*)-*O*-Acylation of **22** responsible for the diastereoselective synthesis of 2',5'-A_{PS}A.

implies that nucleophilic substitution at the phosphorus center in **25** occurs with an inversion of configuration; however, no examples of stereochemical transformations of compounds of type **25** have been reported thus far.

In light of the results of Hata et al. in the stereoselective synthesis of oligo(nucleoside phosphorothioate)s by DBU-catalyzed stereoselective epimerization of the internucleotide *H*-phosphonate functions, one should consider introducing specially designed sterically and/or stereoelectronically demanding protective groups into the participating nucleosides (nucleotides). In our own research a variety of potential catalysts for shifting the (R_P):(S_P) equilibrium of **21** have been studied, including optically active and sterically demanding acids and bases, but so far the process is not controllable.[34]

4.3. Diastereoselective Activation of Prochiral Substrates with Tetracoordinate Phosphorus Centers

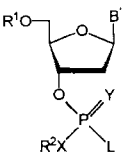


The P-prochiral substrates **27** (Scheme 13) are employed in the phosphotriester approach to oligonucleotide synthesis.[45] When R^2X was an alkoxy or aryloxy group, activation of phosphate function led to the formation of P-chiral dinucleoside 3',5'-*O*-aryl(alkyl)phosphates. Since the synthesis requires the subsequent removal of the *O*-aryl function, the diastereomeric ratio of the intermediate triester was not of interest. However, the prochirality of **27** suggests that the activation process could

Scheme 13. R^1 = DMT, pixyl, etc.; R^2 = alkyl, aryl; X = O; B^1 = protected Ade, Gua, Cyt, Thy.

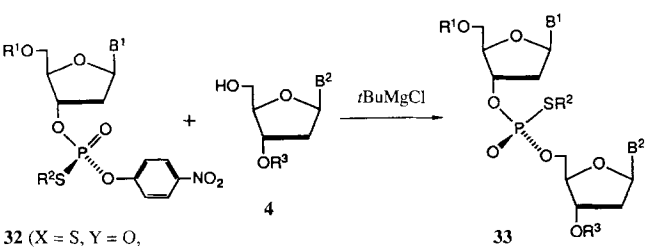
27

be diastereoselective. Indeed, in one well-documented case, Ohtsuka et al.[46] proved that the condensation of N^6,5′-*O*-bis-(dimethoxytrityl)adenosine 3′-*O*-[(*O*-2-chlorophenyl)phosphate] with N^6,3′-*O*-bis(dimethoxytrityl)adenosine in the presence of 1-(2,4,6-triisopropylbenzenesulfonyl)-5-(pyridin-2-yl)tetrazole as the activating agent gives, after deprotection, dideoxyadenosine 3′,5′-*O*-(2-chlorophenyl)phosphate with (S_P) configuration. This particular finding prompted Cosstick and Williams[47] to study the diastereoselective activation of **27** (B^1 = CytBz; Scheme 14). They demonstrated that reaction of



Scheme 14. Diastereoselective activation of P-prochiral phosphorothioate **27** by 1-(2,4,6-trimethylphenylsulfonyl)-5-(pyridin-2-yl)tetrazole.

27 with 3′-*O*-acetylthymidine (**4**, R^3 = Ac, B^1 = Thy) in the presence of **28** leads to the formation of the corresponding dinucleoside **30**, which after decyanoethylation at sulfur consists of the diastereomeric mixture of d(C_{PS}T) with a distinctive preponderance of the (S_P) diastereomer. In the best case the ratio of diastereomers (S_P):(R_P) was 79:21. Such enrichment, although not satisfactory in terms of a stereocontrolled synthesis of **1**, is worth deeper consideration and perhaps more extensive study. If the mechanism of activation of **27** involves stereoselective formation of the mixed phosphorothioic sulfonic anhydride **29**, and this undergoes double nucleophilic substitutions (first by **28** with transient formation of phosphorotetrazolidate **31** and subsequent reaction with **4** to give phosphorothioate triesters **30**), attempts at introducing sterically demanding protective groups on nucleobases and hydroxyl functions not participating in the coupling process increase the probability of diastereoselective formation of dinucleoside 3′,5′-phosphorothioates. This promising scenario must be taken with caution, because earlier studies of Knorre, Zarytova, et al. indicated that the phosphorylating intermediates in the triester approach to oligonucleotide synthesis are pyrophosphates;[48] their intermediacy and the possibility of equilibration at the phosphorus stereocenter may cancel the effects of diastereoselective activation of **27**.[49]

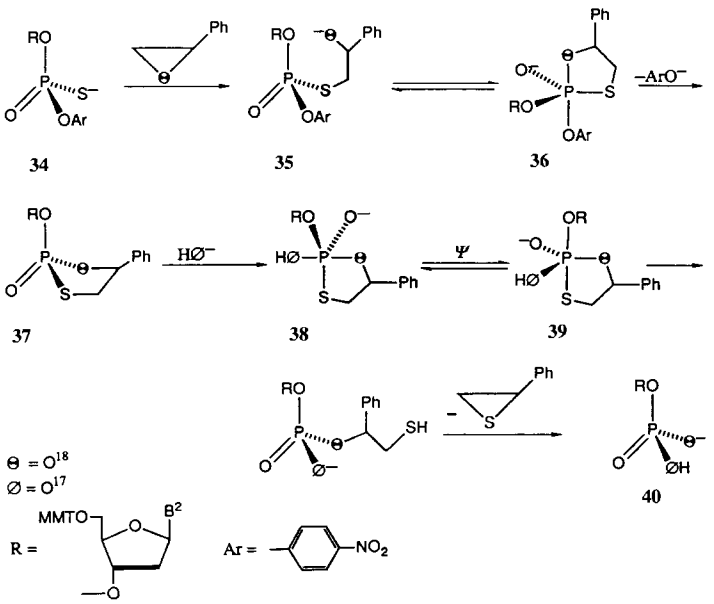


4.4. Stereoselective Nucleophilic Substitution at Tetracoordinate Phosphorus Centers

The most promising and straightforward approach to stereocontrolled synthesis of Oligo-S involves substrates **32** bearing leaving group L (R^2 = aryl, X = O, Y = S or R^2 = alkyl, X = S, Y = O; Scheme 15), which in the process of nucleophilic

Scheme 15. R^1 = DMT, pixyl, etc.; R^2 = alkyl, aryl; X,Y = S,O (X ≠ Y); B^1 = protected Ade, Gua, Cyt, Thy; L = leaving group.

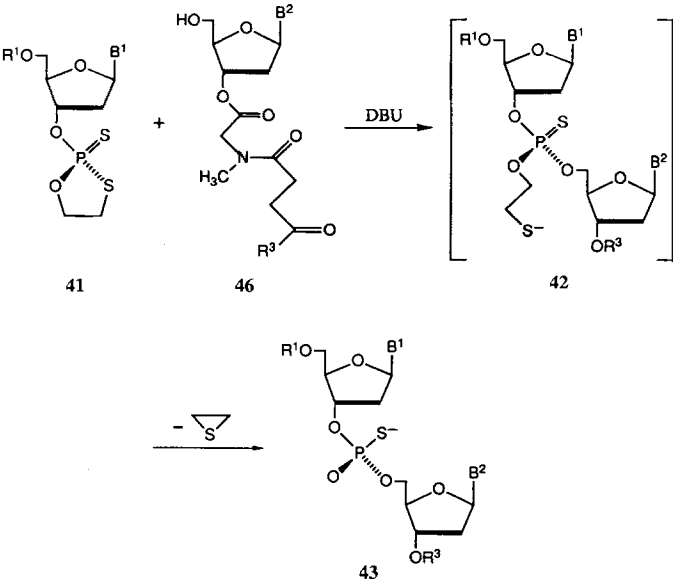
substitution at the phosphorus atom can be replaced by the 5′-OH function of the nucleoside or oligonucleotide in stereodefined manner. Such substrates **32** (R^2X = MeS, Y = O, L = 4-$NO_2C_6H_4O$) were first described by Lesnikowski et al.[50] The separated diastereomers of **32** reacted with 3′-*O*-acetyl nucleosides in the presence of *t*BuMgCl to give dinucleoside 3′,5′-(*S*-methyl)phosphorothioates **33** (Scheme 16). Cleavage of the CH_3–S bond (phosphorothioate deprotection) was achieved in a later step with PhSH/NEt_3. The coupling occurs with inversion of configuration at phosphorus with a stereospecificity of >95% and furnishes **33** in about 70% yield.



Scheme 16. Stereoselective nucleophilic substitution at the phosphorus center in **32**. This reaction is used for the synthesis of short Oligo-S. R^1 = monomethoxytrityl (MMT); R^2 = Me; R^3 = Ac; B^1 = B^2 = Thy.

Although this methodology cannot be used in solid-phase synthesis, Lesnikowski et al. were able to demonstrate that preparation of stereochemically pure trimers d($T_{PS}T_{PS}T$) and tetramers d($T_{PS}T_{PS}T_{PS}T$) is feasible if protective groups such as 4-chlorobenzyl are introduced at sulfur. Very recently, this strategy was applied to the synthesis of (R_P,R_P)- and (S_P,S_P)-$U_{PS}U_{PS}U$.[50c] In spite of efforts to find other catalysts, *t*BuMgCl, which was introduced for oligonucleotide chemistry by Hayakawa et al.[51] is the catalyst of choice; other catalysts such as *t*BuOK, DMAP, and DBU gave unsatisfactory yields or led to P-epimerization.[52]

4.5. Oxathiaphospholane Method for the Synthesis of Oligo-S



A novel strategy leading to stereodefined Oligo-S based on nucleophilic substitution at tetracoordinate phosphorus centers was elaborated following studies on the conversion of *O,O*-dialkylphosphorothioates into the corresponding [^{18}O]-phosphates.[53] Okruszek et al. observed that *O*-alkyl-*O*-arylphosphorothioates **34** undergo reaction with [^{18}O]styrene oxide/[^{17}O]water with replacement of sulfur by [^{18}O] and of the aryloxy group by [^{17}O]OH, respectively. Both replacements occur with full stereospecificity (Scheme 17).

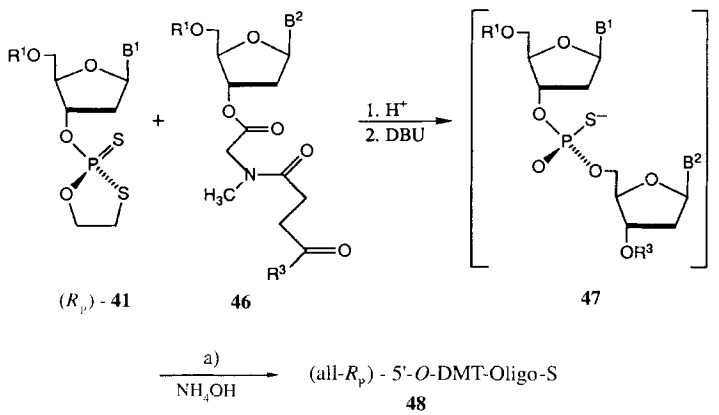
Scheme 17. Proposed mechanism for the stereocontrolled synthesis of nucleoside 3'-[^{16}O,^{17}O,^{18}O]phosphates **40**.

Detailed mechanistic studies showed that the initial attack of the sulfur atom of **34** on the carbon atom of styrene oxide results in intermediate **35**. Subsequent attack of the β-alkoxyl anion on the phosphorus center and elimination of ArO^- from **36** gives intermediate **37**. In the hydrolysis of oxathiaphospholane **37** by [^{17}O]H_2O the five-membered ring opens exclusively by cleavage of the P–S bond. Intermediate **38** is formed by attack of the water molecule on **37** from the side opposite to the endocyclic P–O bond. Pseudorotation then places the leaving group in an apical position in **39**. Cleavage of the P–S bonds is followed by fast elimination of the alkylene episulfide.

Following the stereocontrolled synthesis of monoalkyl-[^{16}O,^{17}O,^{18}O]phosphates **40**, the construction of oxathiaphospholanes such as **41** and their reaction with alcohols were of interest.[28] 5'-*O*-DMT-nucleoside 3'-*O*-(2-thio-1,3,2-oxathiaphospholane)s **41** were prepared and treated with 3'-*O*-acetylthymidine. In this case, the attack of the hydroxyl group on the phosphorus atom requires a basic catalyst. Although the reaction occurs in the presence of triethylamine (room temperature, 24 h, 5% yield) and diisopropylamine (room temperature, 4 h, 38% yield), DBU was the catalyst of choice. With DBU as catalyst a single coupling required 5 min and, after removal of protective groups, dinucleoside 3',5'-phosphorothioate **43** was obtained with >95% yield (Scheme 18). Separation of the diastereomers of **41** (B^1 = AdeBz, Gua*i*Bu, CytBz, Thy) was followed by studies of the stereoselectivity of the oxathiaphospholane ring opening, which was found to be higher than 98%.[28]

Scheme 18. Base-catalyzed alcoholysis of 1,3,2-oxathiaphospholanes **41**. R^1 = DMT; R^3 = Ac; B^1 = B^2 = Thy.

Model studies of (R_P,R_C)-2-[*N*-(α-naphthyl)ethylamino-2-thio]-1,3,2-oxathiaphospholane **44**[54] have shown that the ring opening with MeOH/DBU occurs by attack of the base-activated hydroxyl function of MeOH on phosphorus from the side opposite to the endocyclic P–O bond (Scheme 19). Collapse of



(R_P,R_C)-**44** (S_P,R_C)-**45**

Scheme 19. DBU-catalyzed methanolysis of **44**. α-$C_{10}H_7$ = α-naphthyl.

the pentacoordinate intermediate requires, according to Westheimer's rules,[55] pseudorotation placing the endocyclic P–S bond to be cleaved in the apical position. Cleavage of the P–S bond is followed by fast elimination of ethylene episulfide. The assignment of absolute configuration of substrates and products, namely (R_P,R_C)-**44** and (S_P,R_C)-**45** (resulting from *S*-methylation of the product of DBU-catalyzed methanolysis of **44**), and the analysis of the stereochemical course of the conversion of **44** into **45** also allowed tentative assignment of the absolute configuration at phosphorus in **41**. The quickly eluting diastereomers of **41**, which react with 5'-OH nucleosides to give (S_P)-d(N_{PS}N'), have (S_P) configuration at phosphorus, whereas the slowly eluting diastereomers of **41** have (R_P) configuration.[54]

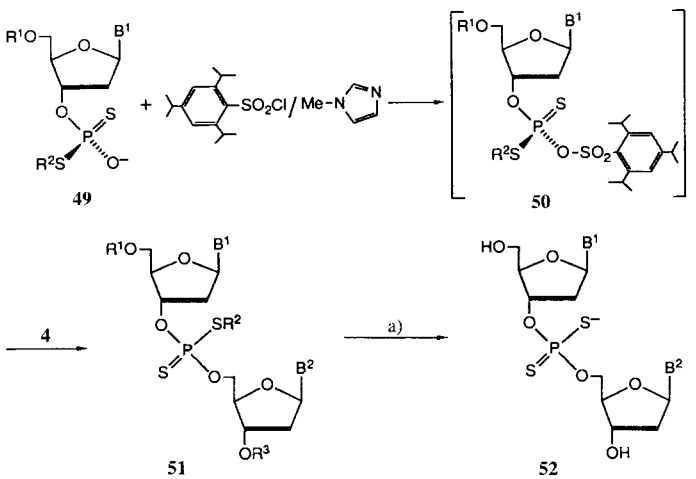
Detailed knowledge of the stereochemistry of substrates and products of the oxathiaphospholane method leading stereo-

selectively to dinucleoside 3',5'-phosphorothioates was still not sufficient for the stereocontrolled synthesis of Oligo-S. Since the succinyl linker typically used with solid supports is cleaved in the presence of DBU,[56] a succinylsarcosinyl type of linker was employed,[56c] which survives in 0.1 M DBU in acetonitrile during the solid-phase synthesis of oligonucleotides.[56d] All four support-bound nucleosides **46** were prepared and used for the DBU-catalyzed reaction with separated diastereomers of **41** (Scheme 20). Penta(deoxycytidine-, octa(thymidine-, and dodeca(deoxyadenosine phosphorothioate)s have been obtained in diastereomerically pure form.[28, 57] Following stereocontrolled synthesis of (all-R_P)- and (all-S_P)-d[$(A_{PS})_{11}$A] it was shown that the alignment of (all-S_P)-d[$(A_{PS})_{11}$A] to complementary dodecathymidylic acid is more effective (T_m = 34.4 °C) than that of (all-R_P)-d[$(A_{PS})_{11}$A] (T_m = 30.0 °C).[59] This experimental result is in agreement with the analysis of model duplexes of B conformation, which indicated that duplexes formed by Oligo-S with (R_P) configuration and the sulfur atoms directed "inward" relative to the axis of the double helix are sterically less favorable than those formed by (all-S_P)-Oligo-S in which all sulfur atoms are directed "outward". The higher steric demands of phosphorothioates in comparison to phosphates were also evident from earlier results concerning the synthesis, molecular mechanics calculations, and biological properties of adenosine-3',5'-cyclic phosphorodithioate.[60] Recent molecular mechanics and dynamics calculations on a simulated complete helical turn of DNA duplexes formed by unmodified oligonucleotide as well as homochiral (all-R_P)- or (all-S_P)-Oligo-S[61] confirmed the results of intuitive analysis and experimental facts. Independently, NMR spectroscopic[62] and T_m[63] studies of oligonucleotides containing phosphorodithioate functions also indicated a destabilizing effect of sulfur atoms on double-stranded constructs.

(R_p) - **41** **46** **47** **48**

Scheme 20. Stereocontrolled oxathiaphospholane method for the synthesis of **1**. a) 1. H$^+$; 2. **41** + DBU; 3. capping; 4. steps 1–3 are repeated n times. R^1 = DMT; R^3 = LCA-CPG, B^1 = B^2 = AdeBz, Gua*i*Bu, CytBz, Thy.

Unfortunately, the synthesis and isolation of satisfactorily pure Oligo-S longer than 12-mers by using oxathiaphospholane methodology is still difficult. Single-step coupling efficiency sometimes substantially lower than 96% may be responsible for the presence of "failed" sequences ($n-1$, $n-2$, $n-3$...), especially if the "capping" step is not 100% effective. Recently, acetic anhydride/*N*-methylimidazole, which was originally reported[28] for the capping of unreacted 5'-OH groups by acylation, has been replaced by acetic anhydride/4-dimethylaminopyridine. Moreover, because the water content in solvents and reagents is most likely a critical parameter (traces of water in the presence of DBU can initiate ring-opening polymerization of 1,3,2-oxathiaphospholanes), special precautions and strictly anhydrous reagents have been used. Also, the time of the coupling step has been shortened from 600 to 200 seconds. Although the conditions and parameters for the oxathiaphospholane method are still not completely optimized, Grajkowski et al. have accomplished, starting from diastereomerically pure substrates **41** (B^1 = CytBz), the synthesis of (all-R_P) and (all-S_P) diastereomers of d[$(C_{PS})_{27}$C] with 86% and 82% chain integrity, respectively, as proved by polyacrylamide gel electrophoresis (PAGE).[58] Analysis of the crude product by ^{31}P NMR spectroscopy did not show any evidence of phosphate contaminants, which are unavoidable when Oligo-S is prepared by other methods.[3c] Grajkowski et al. also prepared, starting from diastereomeric mixtures of **41**, a "mixed-sequence" 26-mer Oligo-S containing six dC, six dG, ten dT, and four dA, which by PAGE was comparable to the 26-mer prepared by the phosphoramidite/sulfurization method. Current efforts are being directed at further improving the yield of single steps and elucidating the structures of the products resulting from unexpected, obscure side reactions.

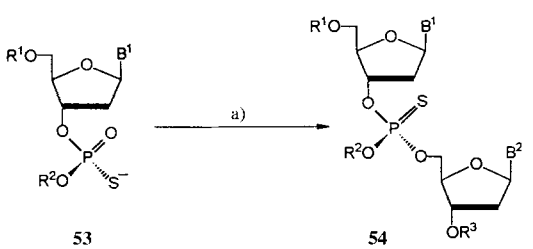


What kind of side reactions may be envisioned? An obvious one starts with the formation of an internucleotide phosphorothioate triester function containing the charged $CH_2CH_2S^-$ group, as in **42**. This moiety, although expected to be eliminated, may instead attack the nearest 5'-*O*-phosphorus-bound 5'-carbon atom, such that the phosphorothioate–carbon skeleton is extended by one CH_2CH_2S unit. This side reaction may proceed through a thermodynamically unfavorable seven-membered ring-transition state, and the enzymatic hydrolysis of the final Oligo-S should give modified nucleosides(tides), which does not appear to be the case. However, this possibility requires further investigation, since these contaminants are characterized by the same base composition and net negative charge as the expected product. Also under investigation is the possibility of "decapping" the 5'-*O*-acetyl group with DBU, which could be responsible for unwanted formation of ($n-1$), ($n-2$), ($n-3$) Oligo-S.[64]

Other studies in progress focus on the preparation of substrates like **41** without amide hydrogens, since activation by DBU and creation of the possible branching sites for growing polymer would be avoided. Efforts are also being made to construct the C-substituted oxathiaphospholanes **41**, which would still react with 5'-OH group, but the ring opening should not be followed by subsequent elimination of episulfide. S-Acylation of an intermediate like **42** would preserve the triester moiety until the end of desired chain extention, but one would also expect an increase in the undesired attack on the 5'-carbon atom as discussed above.[64]

Although beyond of the scope of this review, it is worth mentioning that modification of the oxathiaphospholane method by use of 5'-*O*-DMT-nucleoside 3'-*O*-(2-thiono-1,3,2-dithiaphospholane)s has allowed the preparation of oligo(nucleoside phosphorodithioate)s **52**.[65]

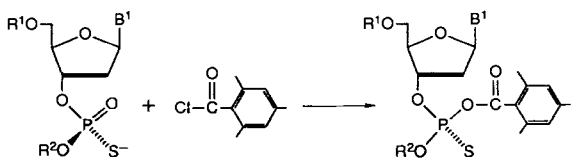
4.6. Other Possible Strategies for the Stereocontrolled Synthesis of Oligo(nucleoside phosphorothiate)s



Since we wish to direct the attention of phosphorus and biopolymer chemists to the problem of the stereocontrolled synthesis of Oligo-S and related DNA or RNA congeners, other, yet unexplored routes to P-chiral oligonucleotide analogues should be mentioned. A mixture of diastereomers of 5′-*O*-DMT-nucleoside 3′-*O*-[*S*-(2,4-dichlorobenzyl)phosphorodithioate] **49** was treated with 2,4,6-triisopropylbenzenesulfonyl chloride (TIPS-Cl) and *N*-methylimidazole to give 97% activation of the oxygen atom of the phosphorodithioate moiety as opposed to activation of the sulfur atom (Scheme 21). Although reaction of **50**

Scheme 21. Activation of phosphorodithioate **49** by TIPS-Cl/*N*-methylimidazole occurs in 97% at oxygen.

with 5′-OH nucleoside **4** gives a diastereomeric mixture of dinucleotide **51**, these undergo S-deprotection and provide P-achiral dinucleoside 3′,5′-phosphorodithioates **52**.[66]



This chemoselective activation, unexpected in the light of earlier works on the activation of ambident phosphorothioate anions,[49, 67] kindled some hopes that substrates **53** with OR^2 groups such as OMe, OEt, or OBn, after separation into diastereomeric species, could undergo selective activation of phosphorothioate anions at the oxygen center; subsequent reaction at phosphorus with an OH-nucleoside may then lead to diastereomerically pure (or highly enriched) dinucleoside 3′,5′-*O*-alkylphosphorothioates **54** (Scheme 22). Removal of the phosphorothioate protecting groups by attack on the carbon

Scheme 22. Phosphorothioates **53** are potential substrates for the stereocontrolled synthesis of **1**. a) 1. TIPS-Cl/*N*-methylimidazole; 2. **4**. R^1 = DMT; R^2 = Me, Et, Bz, allyl; R^3 = Ac; B^1 = B^2 = Thy.

atom should lead to Oligo-S. However, if a pyrophosphorothioate intermediate[48] follows the formation of thiophosphoric sulfonic anhydrides, this approach to the stereocontrolled synthesis of Oligo-S may fail.

Another possibility involves acylation of appropriately protected nucleoside 3′-*O*-(*O*-alkyl)phosphorothioate **53** with sterically demanding, substituted benzoyl chlorides and subsequent reaction of the resulting mixed anhydride **55** with a 5′-OH function of a nucleoside or or oligonucleotide (Scheme 23). Al-

Scheme 23. Anhydrides **55** are potential substrates for the stereocontrolled synthesis of **1**.

though mixed phosphoric carboxylic anhydrides are known to exhibit both acylating and phosphorylating properties,[68] there are few well-documented examples of their exclusive phosphorylating activity. Jackson et al.[68c] have pointed out the important change in regioselectivity depending on the nature of the nucleophile: aminolysis occurs by an attack at the carbonyl carbon, whereas alcoholysis takes place by an attack at phosphorus. Moreover, Lambie[68e] demonstrated that *O*-pentachlorobenzoyl *O*,*O*-diethylphosphate reacts as a phosphorylating reagent even with aniline. This distinctive phosphorylating ability prompted Wozniak to synthesize P-diastereomerically pure forms of nucleoside 3′-*O*-(methanethiophosphonic) carboxylic anhydrides as the potential substrates for the stereocontrolled synthesis of oligo(nucleoside methanethiophosphonate)s. So far, reactions of aforementioned mixed anhydrides with 5′-OH nucleosides 3′-*O*-bound to the solid support lead to the desired product in miserable yields that are unacceptable for repetitive multistep synthesis. The search for an appropriate catalyst for this reaction is in progress and, if successful, efforts will be undertaken to synthesize analogous substrates applicable to the synthesis of **1**.[69]

5. Analysis of the Diastereomeric Purity of Oligo-S

In the introduction to this review we mentioned how difficult it is to determine the diastereomeric purity of Oligo-S. Figure 4 presents our best results obtained to date for the RP-HPLC separation of eight diastereomers of $d[C_{PS})_4C]$ (Fig. 4a, b) and an HPL chromatogram of $d[(C_{PS})_4C]$ (Fig. 4c, d); both products were prepared by the nonstereoselective phosphoroamidite method. Figure 4b clearly indicates the limit of RP-HPLC for the separation of small Oligo-S.[18] Our earlier results also indicated that in the case of Oligo-S with (R_P) configuration at each internucleotide phosphorothioate, digestion with endonuclease P1 can be used to prove its structure. It can also be useful as a "purification" process because under appropriate conditions every phosphorothioate of (S_P) configuration is cleaved.[22k]

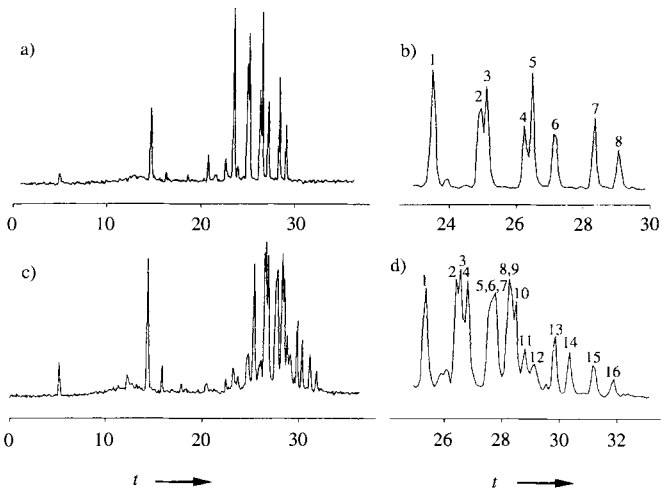


Fig. 4. RP-HPLC traces of tetramer d($C_{PS}C_{PS}C_{PS}C$): a) entire chromatogram; b) expanded section showing the presence of all eight diastereomers; c) and d) show the partial separation of 16 diastereomers of pentamer d($C_{PS}C_{PS}C_{PS}C_{PS}C$). For HPLC conditions see Table 1. Retention time t in min.

Moreover, exposure of d[$(C_{PS})_nC$] ($n = 1-4$, prepared as diastereomeric mixtures) to nuclease P1 followed by alkaline phosphatase gave the product, which was separated by RP-HPLC to give pure (R_P)-d($C_{PS}C$), (R_P,R_P)-d($C_{PS}C_{PS}C$), (R_P,R_P,R_P)-d($C_{PS}C_{PS}C_{PS}C$), and (R_P,R_P,R_P,R_P)-d[$(C_{PS})_4C$]. Similar treatment of the aforementioned diastereomeric mixtures of Oligo-S by means of snake venom phosphodiesterase (SVPDE), which is known to be (R_P) selective,[22i, j] was limited to digestion of 3'-terminal (R_P) internucleotide phosphorothioate because the enzyme has no endonucleolytic activity.[70]

Very distinctive differences in electrophoretic mobilities between (all-R_P)- and (all-S_P)-d[$(C_{PS})_9C$] have been found under nondenaturing conditions (Fig. 5). This observation could possibly indicate different self-organization (e.g. by base stacking) or interactions with a gel, which occur in P-homochiral Oligo-S, and may be considered as an indirect example of the effect of the chirality of Oligo-S on mobility. Important parameters such as cell membrane permeability may be influenced as well.

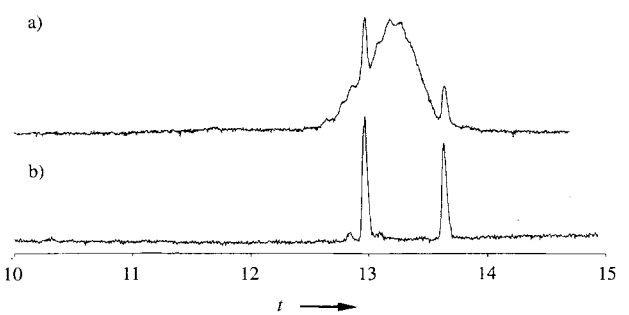

Fig. 5. High-performance capillary electrophoresis analyses were performed on an Applied Biosystems 270A-HT capillary electrophoresis instrument with MICRO-GEL_{100} (Applied Biosystems Inc., Foster City, CA) gel-filled capillaries (50 μm ID, effective length 27 cm; running buffer: 75 mM TRIS phosphate, pH 7.6, 10% methanol). Detection was at 260 nm, voltage 15 kV. Two individual diastereomers (all-R_P)- and (all-S_P)-d[$(C_{PS})_9C$] were mixed (b) and compared with the mixture of both diastereomers added to the sample of d[$(C_{PS})_9C$] prepared by phosphoroamidite/sulfurization method (512 diastereomers) (a).

6. Conclusions

Besides the biological consequences of the defined chirality of Oligo-S, there is another unanswered question: how far are we from solving the problem of the stereocontrolled synthesis of **1**? For oligopeptides it took nearly a century to solve the synthetic problem, and new enzymatic methods are being developed for enantiospecific synthesis.[71] As pointed out earlier, in every multistep synthesis the diastereomeric purity dp of the n-mer is roughly p^{n-1}, such that for a 28-mer prepared with $p = 0.98$ the $dp = 0.98^{27} = 0.56$. Therefore, is diastereoselective synthesis of chiral Oligo-S possible? Eckstein et al.[7] demonstrated that the polymerase-based synthesis of **1** with α-dNTPS leads to (all-R_P)-poly(nucleoside phosphorothioate)s. This type of enzymatic preparation of Oligo-S would be limited to the preparation of (all-R_P)-Oligo-S. In this review it has also been indicated that chemically synthesized (all-R_P)-Oligo-S can be stereochemically purified by digestion of contaminating (S_P)-phosphorothioates with nuclease P1. The next few years may bring the discovery of an effective (R_P)-diastereoselective endonuclease, or an appropriate enzyme may be developed by biotechnology. Such an endonuclease would not only be very useful for analytical purposes but would also be valuable for purification of (all-S_P)-Oligo-S contaminated with diastereomers possessing (R_P)-phosphorothioates. However, even if such endonucleases become available, their application in stereochemical degradation would not allow practical production of (all-S_P)-Oligo-S, since the content of the fraction with the desired homochirality in the diastereomeric mixture is approximately 2^{-n}. Efforts should also be directed toward the search for conditions under which a stereoselective endonuclease can work in a reversible manner. One can envision that matrix-directed synthesis of Oligo-S by means of phosphorothioate transferases will become feasible if studies are focused on, for example, the reversibility of the action of nucleases or phosphotransferases.

Alternatively, chemists must master the art of constructing substrates that allow the synthesis of Oligo-S with a diastereoselectivity >99% and a predetermined chirality at each internucleotide phosphorothioate function. However, progress seems to be rather slow on this front. Ten years after the first stereocontrolled synthesis of both diastereomers of dithymidine 3',5'-phosphorothioate[72] the demonstrated ability of stereocontrolled synthesis of **1** has extended only to dodecamers.[28] Undoubtedly, economic interests may provide enough incentive for the solution of this very challenging problem. If Oligo-S or synthetic ribozyme constructs containing nuclease-resistant components **1** responsible for recognition of appropriate target sequence within mRNA or pre-mRNA, are further evaluated as useful oligonucleotide therapeutics, then the stereocontrolled synthesis of **1** will be facilitated. Should that not be the case, there is still intellectual curiosity, which has always been an important factor in purely fundamental studies. Mission-oriented projects may not always succeed if they are not enforced by intellectual challenge.

This review was completed during the one-year appointment of one of the authors (W.J.S.) as Fogarty Scholar-in-Residence at the National Institutes of Health (NIH), Bethesda, MD (USA). We thank several colleagues and collaborators who contributed to the development of the first stereocontrolled methods for the syn-

thesis of Oligo-S; their names are given in the relevant references. Research projects were supported by the State Committee for Scientific Research (grant no. 0034/PZ/92/03). We would also like to express our gratitude to Dr. Gerald Zon of Lynx Therapeutics, Inc., Foster City, CA (USA) and to Dr. Jack Schmidt, Fogarty International Center, NIH, for critically reading several "mutations" of this review, and to Ms. Malgorzata Stec for typing this manuscript. We thank an anonymous referee for suggestions concerning another side reaction that may accompany the oxathiaphospholane ring-opening process.

[44] The influence of DBU on configurational stability of *P*-chiral organophosphates requires further study. Unpublished results from our laboratory (Z. J. Lesnikowski, L. Wozniak) indicate that diastereomers of dinucleoside 3',5'-methanephosphonates are not epimerized in the presence of DBU under conditions that lead to complete P-epimerization of diastereomerically pure nucleoside 3'-*O*-(*O*-4-nitrophenylmethanephosphonate)s or nucleoside 3'-*O*-(Se-methyl-methanephosphonate)s. Therefore, these last results can be explained in terms of DBU-catalyzed hydrolysis caused by traces of water; released *p*-nitrophenoxide ion or methylselenenyl ion, respectively, may cause epimerization of parent compounds in the presence of DBU by a ping-pong type mechanism.

Ladder Sequencing of Peptides and Proteins—A Combination of Edman Degradation and Mass Spectrometry

Jörg W. Metzger*

The most important method for the determination of the primary structure of proteins is the stepwise chemical degradation developed by Edman in 1950 (Edman degradation).[1] Reaction of the N-terminal amino group of the peptide or protein with phenylisothiocyanate gives the phenylthiocarbamoyl peptide **1**, which in acidic solution is cleaved to form a 2-anilinothiazolin-5-one **2**, and the peptide chain shortened by one amino acid **3** (Fig. 1). Thiazolinone **2** hydrolyzes to give the phenylthiocarbamoyl amino acid (PTC amino acid) **4**, which is converted by

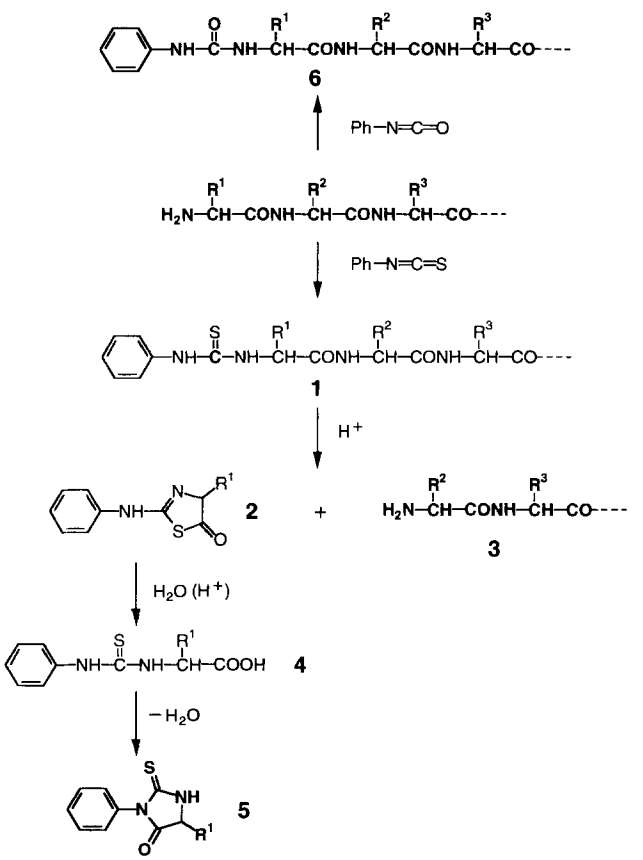

Fig. 1. Generation of the peptide ladder by Edman degradation in the presence of phenylisocyanate as the terminating reagent.

ring formation into the 3-phenyl-2-thiohydantoin (PTH amino acid) **5**. The PTH amino acid **5** is extracted and identified chromatographically. A major disadvantage of the fully automated Edman degradation by on-line HPLC is the relatively low sample throughput; even with the short analysis times possible by optimized chemical and analytical cycles, only about 60 residues per day can be determined.[2] Many unusual amino acids cannot be identified, and modified amino acids (e.g. phosphorylated amino acids) only with especially elaborated analytical procedures.[3]

Because of the excellent suitability of novel ionization techniques like matrix-assisted laser desorption (MALDI)[4] and electrospray ionization (ESI)[5] for peptide and protein analysis, mass spectrometric sequencing methods are gaining increasing importance. Tandem mass spectrometry[6] is used for obtaining sequence information for peptides and proteins.[7] This technique requires two mass analyzers (MS-MS). The molecular ion formed by ionization is selected in the first mass analyzer and reaches a collision cell, where it is fragmented by collision with argon atoms (collision-induced dissociation; CID). The fragment ions are separated according to their m/z ratio in the second mass analyzer and are registered in a "product" or "daughter ion" mass spectrum. Depending on the peptide sequence, this spectrum contains a series of N-terminal, C-terminal, or internal fragment ions formed by cleavage of bonds along the peptide backbone. In favorable cases it is possible to determine the entire sequence from the observed mass differences between corresponding mass peaks in the daughter ion spectrum. Depending on the collision energy, high- and low-energy CID spectra can be distinguished.

The potential of protein sequencing by tandem mass spectrometry is restricted because 1) many peptides undergo only a limited extent of fragmentation, 2) the interpretation of tandem mass spectra is often not trivial and unambiguous, and 3) the applicability is usually restricted to peptides with molecular masses of not more than 3000–4000 u.[7] However, fragmentation of multiply charged ions, as they are commonly found in ESI-MS, may provide sequence information for larger peptides and even proteins.[8] Usually, however, larger peptides are cleaved into smaller peptides by chemical or enzymatic degradation prior to tandem mass spectrometric investigation.

Mass spectrometric sequencing methods are also suitable for the sequencing of N-terminally blocked peptides and for the determination of posttranslational modification sites (acylation, phosphorylation, glycosylation, farnesylation, etc.). The amino acids Ile and Leu, which have the same nominal mass (isobaric

amino acids) can be distinguished by their different side-chain fragmentation patterns in the high-energy CID experiment (e.g. by using a four-sector instrument).[7] Lysine can be differentiated from isobaric glutamine after acetylation of the ε-amino group.[7]

The novel method of sequencing peptides by means of metastable ions in a time-of-flight mass spectrometer is quite promising.[9] This technique is characterized by high sensitivity, allowing sequencing in the femtomole range.

In other approaches Edman degradation and mass spectrometry are combined. Here, the basic idea is to replace the slow HPLC analysis of the PTH amino acids by a quicker mass spectrometric analysis. In order to determine the sequence of a peptide, either the mass of the cleaved PTH amino acid[10] or of the remaining peptide[11] can be determined after each degradation step. A modified Edman reagent containing a quaternary ammonium group was recently introduced to enhance the sensitivity of the detection step with ESI-MS.[10]

Chait et al. recently introduced the interesting method of ladder sequencing[12] which consists of two steps: 1. the chemical degradation of the protein into peptide fragments, each of which differ by one amino acid (generation of the "peptide ladder"). 2. readout of the sequence from the MALDI mass spectrum, which results from the mass differences between adjacent mass peaks. To generate the ladder stepwise Edman degradation with phenylisothiocyanate is performed in the presence of phenylisocyanate as the terminating reagent (ratio of phenylisothiocyanate to phenylisocyanate is ca. 95:5). The phenylcarbamoyl peptide (PC peptide) **6** is stable in acidic solution, whereas the phenylthiocarbamoyl peptide **1** is degraded (see Fig. 1). Thus, in each cycle a small amount of peptide is blocked N-terminally by PhNCO and protected from further Edman degradation. A defined number of degradation cycles (**1**–**5**) is performed without isolating and analyzing the reaction products formed with PhNCS. Only at the end is a MALDI mass spectrum of the whole mixture recorded. The spectrum contains the mass peaks of the individual phenylcarbamoyl peptides **6**. The mass difference of adjacent mass peaks corresponds to one particular amino acid residue, the order of their occurrence defines the sequence of the original peptide chain (Fig. 2).

The readout of the sequence in a single step is similar to the method of DNA sequencing by chain fragmentation developed by Maxam and Gilbert[13] and accelerates sequencing substantially. As the remaining peptide and not the cleaved amino acid is detected, the acid-catalyzed conversion step (1 M HCl or 25% trifluoroacetic acid, ca. 60 °C), which generates the stable PTH amino acid, is unnecessary (cf. Fig. 2). Thus, acid-labile phosphorylated amino acids like phosphoserine remain intact and can be identified directly by the respective mass difference in the spectrum. A further advantage is that the reaction yield does not have to be as high as in conventional Edman degradation. However, all peptides should be present quantitatively as carbamoyl peptides; this can be achieved by repeating the treatment of the reaction mixture with phenylisocyanate before analysis.

The potential of mixture analysis by MALDI mass spectrometry and the principle feasability of ladder sequencing was demonstrated by the investigation of a synthetic peptide mixture consisting of more than 30 peptides.[12] Although mass spectrometric discrimination effects are common for surface ionization techniques, each component gave a clear mass peak and total

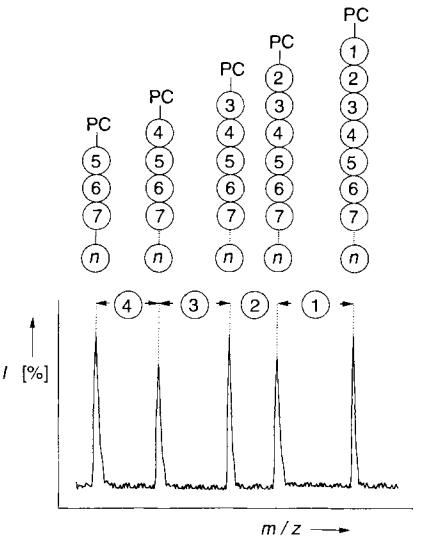

Fig. 2. Readout of a partial sequence of a peptide containing n amino acids by means of the MALDI mass spectrum (PC = phenylcarbamoyl). The mass difference between adjacent mass peaks corresponds to a particular amino acid (modified or unusual residues can also be determined; residues with the same nominal mass cannot be distinguished; N-terminally blocked peptides cannot be sequenced). The direction of readout of the sequence is from higher to lower mass, owing to the degradation from the N- to the C-terminus.

suppression of single components was not observed. Ladder sequencing with MALDI-MS is also suitable for larger peptides; however, the inaccuracy of the determination of individual residues increases with increasing molecular mass (up to 0.9 u for peptides with relative molecular masses >3500).[12] Due to the limited resolution of the mass analyzer, the residues Asp and Asn, Gln and Glu present in a ladder peptide of this high mass cannot be unambiguously differentiated. In contrast to tandem mass spectrometry, ladder sequencing does not allow the sequencing of N-terminally blocked peptides, because these are not amenable to the ladder-generating chemistry. The maximal sequencable length of a peptide by this technique is comparable to that achieved by conventional Edman degradation (the authors consider ca. 60 residues to be the limit).[12] On the other hand, a much higher sample throughput can be achieved.

Ladder sequencing could become an alternative to the slower Edman degradation in the HPLC-equipped protein sequencer, if it is possible to perform and fully automate the chemistry at a picomole scale. Recently, it was shown that the peptide ladder can be generated in a commercial protein sequencer.[14] Interestingly, the ladder could also be generated in the absence of a terminating agent by using very short contact times of the Edman reagent with the protein during the degradation steps.[14] On account of the high sensitivity in the mass spectrometric readout step (low femtomole range), no more than 10–100 picomoles of peptide is needed for the ladder-generating chemistry. ESI mass spectrometry, which also proved to be a highly potent technique for mixture analysis,[15] could also be used for the mass determination of ladder peptides. However, the occurence of multiply charged ions, which are commonly observed with this technique, might complicate the readout of the sequence. In addition, ESI is usually employed with quadrupole instruments, which usually have a slightly better mass resolution than the time-of-flight analyzers used with MALDI, but which

also have a limited mass range ($< m/z$ 4000, usually ca. 2000–3000). For the sequencing of larger peptides a time-of-flight analyzer, which in principle has no upper mass limit, is advantageous. Because of the rapid development of time-of-flight analyzers, development of novel matrices, and improvement of sample preparation,[16] considerable improvements in the mass accuracy and resolution can be expected in the near future.

The development of a fully automated protein sequencer with mass spectrometric detection based on the chemistry of ladder sequencing is feasible. However, it can be expected that the cost of such an analytical instrument will be clearly higher than that of conventional sequencers equipped with HPLC, because of the relatively expensive mass analyzers. Despite the high price, such instruments would be very interesting for peptide and protein chemists, especially because of the expected high sample throughput and the possibility of sequencing modified peptides and peptides with unusual amino acids.

A Structural Model for the Water-Oxidizing Manganese Cluster in Photosystem II

Karl Wieghardt*

Higher plants and cyanobacteria can generate chemical energy from light. In the water-oxidizing photosynthesis[1] this conversion proceeds by light-induced, transmembrane charge separation of protons and electrons at the reaction centers photosystem I and photosystem II (PS I, PS II) (Fig. 1), during which the water is oxidized in the active site of PS II at a (probably[2]) tetranuclear manganese cluster [Eq. (a)].

$$2\,H_2O \rightarrow O_2 + 4\,H^+ + 4\,e^- \qquad (a)$$

Pioneering work by Joliot and Kok has shown[3] that the O_2 cleavage occurs periodically after four light flashs.[3] In the catalytic cycle of Kok (Fig. 2) five oxidation states are therefore defined in the manganese-containing center in PS II, S_0–S_4; the four oxidation equivalents accumulate stepwise (one electron after the other is relinquished to PS I) and stored until in the

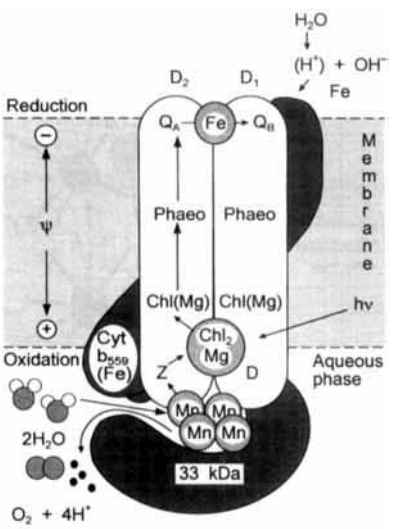

Fig. 1. Schematic arrangement of the proteins of PS II in the membrane: Chl = chlorophyll, Phaeo = phaeophytin, Q = quinone, Z = a tyrosine radical. Adapted from J. J. R. Frausto da Silva, R. J. P. Williams, *The Biological Chemistry of the Elements*, Clarendon, Oxford, **1991**.

transition $S_4 \rightarrow S_0$ molecular oxygen is released, and the cycle begins again. This cycle, which is responsible for all life on our planet (formation of an O_2-containing atmosphere) is still not understood on a molecular level, mainly because the structure of the manganese cluster is unknown. Also the role of the essential cofactors, the chloride and calcium ions, is not precisely known. The two ions can be replaced by bromide and strontium ions, respectively, without loss of function,[4] but fluoride ions inhibit O_2 evolution. PS I from *Synechococcus sp.* has been crystallized and its structure determined with 6 Å resolution by an X-ray structure analysis.[5] Such definitive experiments for PS II are still not available, although recently a three-dimensional structure of PS II at 2 nm resolution (!) was reported. These data were collected from electron-microscopic images of ordered two-dimensional arrangements of PS II in spinach chloroplast membranes,[5b] but still do not permit any statement on the structure of the manganese cluster.

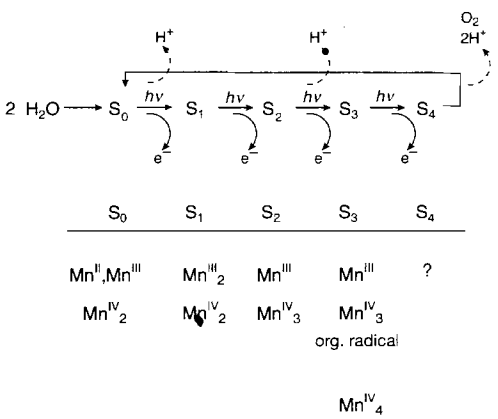

Fig. 2. Representation Kok's catalytic cycle. The scheme given at the bottom shows the most likely (according to present information) distribution of the oxidation steps in the tetranuclear manganese cluster in the S_0 to S_4 states of PS II [6].

At last the Berkeley group of K. Sauer and M. P. Klein has now published their structural model for the tetranuclear manganese cluster (Fig. 3),[6] which has been discussed for two years in the circle of PS II fans and which graced the cover of a book published as early as 1992.[7] It is the result of many years of

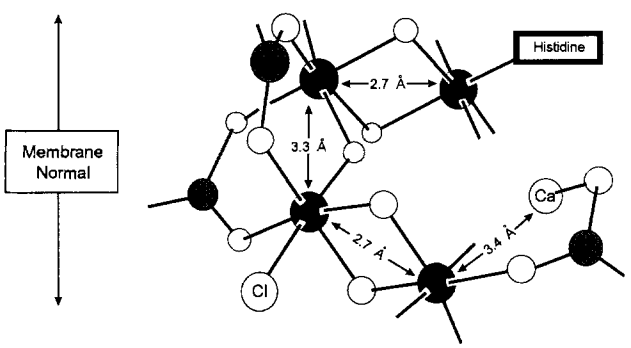

Fig. 3. Schematic representation of the Berkeley model [6] of a potential spatial arrangement of four manganese ions in PS II. According to this, the cofactors Ca^{2+} and Cl^- are also in the vicinity of the Mn cluster or coordinatively bound to a Mn ion. The N-coordination of a histidine residue has been proven by spectroscopy [15]; the nature and number of the bridging carboxylato groups is unknown. Black spheres = Mn centers, white spheres = O centers, cross-hatched spheres = C centers.

spectroscopic studies such as electron spin resonance (ESR) and, in particular, analyses of the Fourier transformed fine structure of the manganese X-ray absorption edge (EXAFS) of membrane-oriented preparations of PS II in S_0, S_1, S_2, and S_3 states and of synthesized model complexes with low molecular weight, which have contributed much to the calibration of these methods. The combination of these two manganese-specific spectroscopic methods enables conclusions to be drawn on 1) the oxidation state of the manganese ions in S_0, S_1, S_2, and—in a limited sense—S_3 states (S_4, as intermediate, cannot be isolated and therefore has not yet been characterized), 2) the electronic structure of the manganese cluster, and 3) (again with limitations) the spatial arrangement of the four manganese ions relative to one another.

That the four oxidation equivalents are stored stepwise, each after a light flash, is an intuitively obvious concept that is apparently difficult to prove. Witt et al. made this deduction indirectly, from changes in the UV absorption spectra and the electrochromic absorptions during the catalytic cycle.[8] In contrast, Klein et al.[9] concluded from changes in Mn near-edge X-ray absorption spectroscopy (XANES) that, for *cryogenic* temperatures, though the light-induced transitions $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_2$ do result in the oxidation of the manganese cluster, during the transition $S_2 \rightarrow S_3$ an organic radical (perhaps a histidine radical?) is formed without further oxidation of the manganese cluster and gives rise to an ESR signal, at least in Ca^{2+}-free preparations.[10] Repetition of the XANES measurements in which the S_x states ($x = 0-3$) were generated at *physiological* temperatures led to the conclusion that the $S_2 \rightarrow S_3$ transition is also associated with a further oxidation of the manganese cluster.[11]

This apparent contradiction is closely related to the problem of the generation of pure S_x states. In the dark adapted PS II samples are in the S_1 state, which, as Dexheimer and Klein[12] could prove by ESR spectroscopy, had a paramagnetic ground state probably with $S = 1$; in contrast, Brudvig et al.[13] postulated a diamagnetic ground state ($S = 0$) from measurements of the dipolar spin–lattice relaxation rate of the stable tyrosine radical in Mn-containing and Mn-free PS II in the S_1 state (resting state). Klein et al. must then have studied an active S_1 state that differs from Brudvigs only by the duration of the dark adaptation of PS II (?).

The ESR-active S_2 state is generated from the dark-adapted PS II by light flashs at 273 K or by continuous illumination during rapid freezing.[14] The famous ESR multiline spectrum discovered by Dismukes and Siderer[16] containing at least 19 manganese hyperfine lines at $g \approx 2.0$ has been the best studied. Attempts to simulate[17] this signal, as well as a theoretical analysis of the possible spin states have shown quite unambiguously that all four manganese ions of the cluster must be electronically coupled to each other and that they are present exclusively in the oxidation states + III and + IV.

A particularly interesting development in the synthesis of pure PS II in a defined S_x state is described by Bocarsly and Brudvig.[18] They succeeded in preparing the S_3 state in large yields in concentrated PS II preparations by the addition of redox-active herbicides that bind to the Q_B site (Fig. 1) and interrupt the catalytic electron transfer turnover.[18] The control of the catalytic turnover of PS II is very promising, because now the more

exact spectroscopic characterization of this and perhaps the S_0 and S_4 states will be possible.

The burgeoning development starting in about 1983 of the coordination chemistry of Mn^{III} and Mn^{IV} led to the synthesis and X-ray structural analysis of stable tetranuclear oxo-bridged complexes with adamantane, cubane, and butterfly frameworks (structures **A**, **B**, and **E** in Fig. 4),[19] which then became models for the first formulations of the catalytic cycles on the molecular level for the water oxidation in PS II.[20] Two of these suggestions, namely those of Brudvig and Crabtree[20a]on one hand and of Vincent and Christou[20b] on the other, immediately found their way into textbooks, not least because of their aesthetic qualities; however, it rapidly became clear that the EXAFS data of PS II could not be well correlated with those of the model complexes. These models are too symmetric.

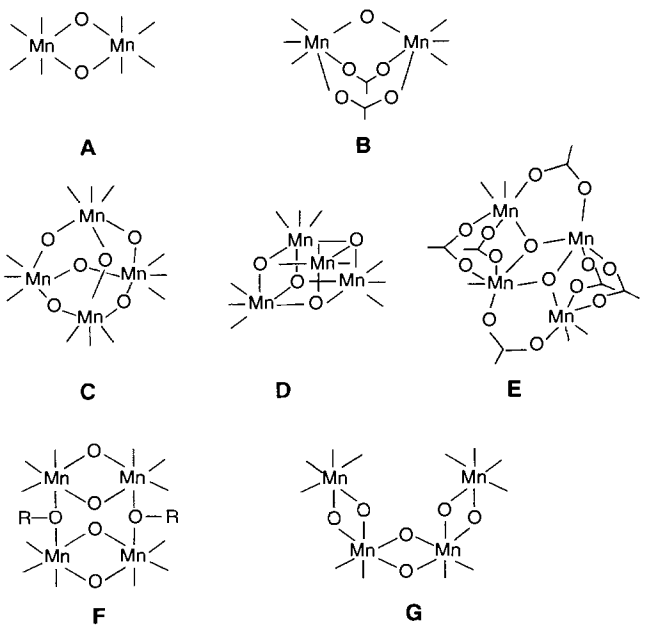

Fig. 4. Important structural types of Mn^{III} and Mn^{IV} complexes with oxo and alkoxo bridges characterized by X-ray analysis: **A**: edge-sharing, octahedral with Mn···Mn ≈ 2.7 Å; **B**: μ-oxo-di-μ-carboxylatodimanganese complexes with Mn···Mn 3.0–3.5 Å; **C**: adamantane-like $Mn_4^{IV}(\mu_2\text{-}O)_6$ skeleton; **D**: cubane skeleton $Mn_4^{IV}(\mu_3\text{-}O)_4$; **E**: butterfly framework $Mn_4(\mu_3\text{-}O)_2$; **F**: di-μ-alkoxo-bridged pair of di-μ-oxodimanganese units [21]; **G**: open-chain arrangement of four Mn^{IV} ions with six oxo bridges [22].

All EXAFS studies on PS II are in accord that the four manganese ions are situated in a ligand sphere consisting predominantly of oxygen donor atoms (oxo and carboxylato groups) and are bound to few, if any, nitrogen atoms. Furthermore, they show that on transitions $S_1 \rightarrow S_2$ and $S_2 \rightarrow S_3$, the structure of the manganese cluster changes only slightly; so no fundamental structural reorganization of the cluster takes place during the accumulation of the oxidation equivalents.

Interestingly an unambiguous Mn···Mn distance of 2.7 Å and a less certain and still controversial one of 3.3 Å, which can also be attributed to a Mn···Ca distance, were detected. The shorter Mn···Mn vector is typical for di-μ-oxodimanganese complexes (Fig. 4, structure **A**) with short $Mn-O_{oxo}$ distances of 1.8 Å, whereas in dinuclear μ-oxo-bis(μ-carboxylato)dimanganese complexes (Fig. 4, structure **B**) Mn–Mn distances between 3.0 and 3.5 Å were measured, depending on the oxidation state of the manganese ions. A combination of these two structural types leads logically to the Berkeley model in Figure 3.

Several other finer points should be mentioned: From the observed dichroism of these Mn···Mn vectors in ordered, oriented membranes with PS II in the EXAFS experiment, information on their spatial arrangement relative to each other in the S_1 state could be obtained. From the sensitivity of the EXAFS spectra (which are specific for manganese) to a substitution of the cofactor Ca^{2+} by Sr^{2+} the conclusion could be drawn that a Ca^{2+} ion must be coordinated in the vicinity of the manganese cluster. A similar situation occurs for Cl^- ions, because their substitution by Br^- likewise causes effects—though very small ones—in the Mn EXAFS spectrum.

The Berkeley group[6] itself warned of an overinterpretation of the attractive model in Figure 3. "Although we have provided evidence for the tetranuclear Mn model and the presence of Ca, halide, and histidine, we do not know their positions relative to each other at this time." This means that the actual structure could look significantly different. The recently characterized complexes $[(Mn_2O_2)_2(tphpn)_2]^{2+}$ (tphpn = *N*,*N*,*N*′,*N*′-tetra(2-methylpyridyl)-2-hydroxypropanediamine; Fig. 4, type **F**)[21] and $[Mn_4^{IV}O_6(bpy)_6]^{4+}$ (bpy = bipyridine; Fig. 4, type **G**)[22] are interesting, novel structural types, because they satisfy several EXAFS characteristics of PS II, and the former, as mixed valent $(Mn^{III}\text{–}Mn^{IV})_2$ complex models the electronic structure of PS II in the active S_1 state amazingly precisely—it has an electronic $S = 1$ ground state and shows an astoundingly similar ESR spectrum to that reported by Klein et al.[12] for PS II in the S_1 state.

Naturally, several questions remain open, which biochemists or biophysicists must answer together with inorganic chemists. For instance, the mechanism on a molecular level of the important step $S_4 \rightarrow S_0$ remains an enigma: when and how is the first O–O bond of the oxo groups or coordinated H_2O molecules formed? The coordination chemists are also challenged: why have we till today not been able to come up with a good tetranuclear water-oxidizing model complex in homogeneous phase? An attempt from theoretical chemistry to give answers to the last two questions has been published recently.[23] Here it is shown that the tri- or tetracoordination of a peroxo ligand to manganese ions facilitates its two-electron oxidation to molecular oxygen. Perhaps not surprising. The solution of the structure of an active site of a metalloprotein from spectral data in many respects resembles the building of a three-dimensional puzzle in which even a few spurious pieces (information) are included (that is, are wrong). I wonder whether in the near (or distant) future the crystallization of PS II and an X-ray structure analysis with sufficient resolution to recognize the manganese cluster will be achieved. It would be great!

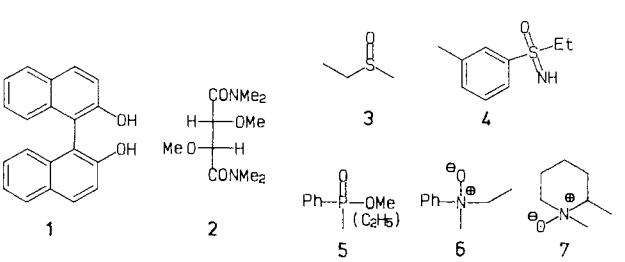
Resolution of Racemates by Distillation with Inclusion Compounds



Gerd Kaupp*

Chiral drugs and additives are generally not permitted to be used in racemic form (most important exception: DL-methionine) so that unintended side effects and unnecessary environmental hazards are avoided. Larger amounts of enantiomerically pure compounds are economically produced by fermentation or (complete) enzymatic conversion of racemates into the desired enantiomer. Thus, since 420000 t of L-glutamic acid and large quantities of L-aspartic acid and L-phenylalanine (for the sweetener aspartame) and D-phenylglycine are produced annually, excessive amounts of waste should and can be prevented.[1]

Absolute asymmetric synthesis, a rapidly developing field, is a simple approach to the synthesis of enantiomerically pure compounds and has low environmental impact; however, enantiomorphic crystals (with a chiral space group) are required, which are not necessarily formed by all compounds with prochiral centers.[2] Enantioselective syntheses with chiral auxiliaries and "without biology" have been fine-tuned most impressively and have a longer tradition,[3] but are still usually very costly and time-consuming. Several approaches to chemical synthesis may be outlined: the synthesis is conducted in chiral media (recently inclusion compounds have been shown to be efficient[4]) or with chiral catalysts. Alternatively, an optically active starting material is employed in a diastereoselective synthesis, and the portion of the molecule with the initial chiral center is cleaved off afterwards. This can be done with loss of chirality in the auxiliary (e.g. with the Seebach method[3]) or without loss (e.g. with the Schöllkopf method[5]); however, recovery of the auxiliary from small-scale reactions does not appear to be very worthwhile.[3] Upscaling for industrial applications is still problematic.[6] Apparently resolution of racemates following straightforward synthesis remains the most frequently applied method.

Supramolecular chemistry introduced new possibilities; inclusion compounds were systematically examined, and versatile clathrating agents were designed and employed.[7] These findings have been used since the early 1980s to selectively and reversibly include chiral guest molecules in host lattices of chiral molecules.[4] In contrast to the formation of diastereomeric salts, compounds with almost any functional group can be treated. The enantiomerically pure host and the racemic guest (or the racemic host and the enantiomerically pure guest) are dissolved, the inclusion compound composed of the better fitting set of enantiomers is allowed to precipitate, and the crystalline material is removed by filtration. The two enantiomers of the guest are obtained from the filtrate and from a solution of the crystals after the host is removed by chromatography on SiO_2, respectively.

The enantiomers (atropisomers) of 2,2′-dihydroxy-1,1′-binaphthyl (**1**) do not interconvert at normal temperatures. If a chiral compound like (*R*,*R*)-**2** (or *N*-benzylcinchonidinium chloride)[8] is dissolved with *rac*-**1**, only one of the diastereomeric inclusion compounds crystallizes on account of chiral recognition. (−)-**1**

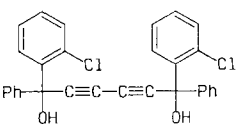
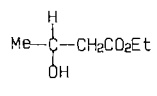
(and (+)-**1**) is obtained with >99% *ee* (from benzene) and separated from **2** by chromatography on SiO_2. The enantiomerically pure host (−)-**1** (and (+)-**1**) can now be used for a variety of difficult chiral resolutions (>99% *ee*) by inclusion crystallization, for example the resolution of racemic sulfoxides like **3**, sulfoximines like **4**, phosphinates/phosphanoxides like **5**, and aminoxides like **6** and **7**. Hundreds of resolutions of very diverse racemic compounds have been reported with a broad range of hosts.[4]



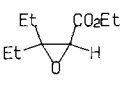
Recently an improvement in this separation technique was reported, which seemed to indicate that enantioselective inclusion in the lattices of chiral hosts could be employed on a large scale.[9] When crystalline hosts such as (*R*,*R*)-(−)-**8** (m.p. 196 °C),[10] (*R*,*R*)-(−)-**9** (m.p. 165 °C),[10] and (*S*,*S*)-(−)-**10** (m.p. 128 °C) are suspended in hexane or water, chiral guest molecules form the same inclusion compounds as in solution. This is by no

8

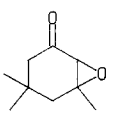
9



10



means self-evident, since inclusion compounds usually have different crystal lattices than the pure host crystals. Thus crystal/liquid reactions occur, and phase rebuildings analogous to those observed in gas/solid reactions[11] must take place. Yet this suspension technique is more selective and more effective than the initially developed solution technique. Numerous racemic alcohols like **11**, β-hydroxy esters like **12**, epoxy esters like **13**, and epoxy ketones like **14** were stirred a few hours with appropriate hosts (suspensions of **8**, **9**, and **10**) and formed 1:1 complexes that could be filtered off in yields of >85% and with *ee* values of >97% (the complex of **12** and **9** formed in hexane only; 80% *ee* in one step). Recrystallization of the inclusion compounds is not generally necessary; (−)-**11**, (+)-**12**, (+)-**13**, and (+)-**14** are released by heating under vacuum. Hosts **8**, **9**, and **10** can



11

12

13

14

then be used again in further resolutions. The procedure is simple, cheap, and environmentally safe. Of course, as with other resolutions, the undesired enantiomer must be disposed of, or better yet, converted into a racemic mixture and resolved again.

Another advantage of the new technique is the possibility of using a stoichiometric amount of the host relative to the racemate (in other words, in excess). The resolution can then be achieved by fractional (Kugelrohr) distillation. For example, 2 mmol of *rac*-**11** and 2 mmol of crystalline **8** in 1 mL of hexane were stirred for 1 h at room temperature and the mixture subsequently distilled. At approximately 70 °C uncomplexed (+)-**11** was collected with 59% *ee*; the distillation of the residue provided (−)-**11** in 69% yield and with 97% *ee* at roughly 150 °C. In a similar fashion fractional vacuum distillation of *rac*-**14** and **10** gave (−)-**14** (68% *ee*) and 63% (+)-**14** with 95% *ee*. If the process with the enantiomeric host is repeated, both enantiomers of the guest can be isolated in pure form. Since the hosts are not consumed and do not racemize, they can be employed in subsequent separations.

As upscaling this method for industrial applications is of particular interest, initial tests cannot be far off. In the distillation the heat transfer to the solid should not present any difficulties up to the kg scale, and technical solutions should be possible for larger scale separations.

It can be expected that the Toda procedure for obtaining enantiomerically pure compounds will find broad application very soon. This development could make preparative HPLC with chiral columns obsolete and be applied to distillable amino acid derivatives. After all, analytical resolution of amino acids was quite successful by host/guest complexation chromatography with reversed-phase packings loaded with Cram's chiral 1,1′-binaphthyl crown ethers (similar to **1**).[12]

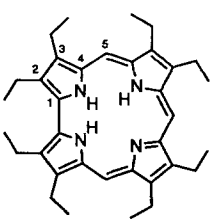
Metallocorroles with Formally Tetravalent Iron

Emanuel Vogel,* Stefan Will, Andreas Schulze Tilling, Ludger Neumann, Johann Lex, Eckhard Bill, Alfred X. Trautwein, and Karl Wieghardt

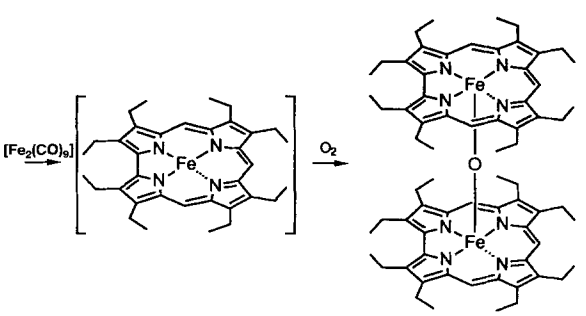
Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

The coordination chemistry of metals in unusual oxidation states is a fascinating aspect of research in the field of metalloporphyrins. Of particular significance in this respect are oxoiron porphyrins containing tetravalent iron, since complexes of this sort occur as reactive intermediates in numerous biological and biomimetic oxidation processes.[1] Iron(IV) porphyrins, in which the metal is not present as part of a [Fe=O] unit, are likewise known, but are rare species. To the best of our knowledge cationic σ-phenyliron(IV) porphyrins (type **1** in Scheme 1)[2] and dimethoxyiron(IV) porphyrins,[3] both of which are only stable at low temperatures, as well as some μ-nitrido- and μ-carbidoiron(IV) complexes[4] are the only representatives of this class of compounds so far characterized. A route to iron(IV) porphycenes (type **3**), constituting analogues of **1**, has very recently been opened up.[5]



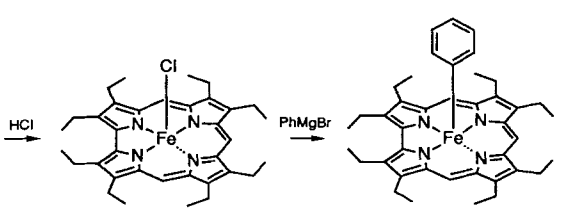
1 **2**

3 **4**



Scheme 1. Models of the iron(IV) complexes of porphyrin (**1**), corrole (**2**), porphycene (**3**), and isocorrole (**4**) with axial ligands (R = aryl, alkyl, and other substituents).

The existence of cationic iron(IV) complexes of types **1** and **3** suggested the possibility that the potentially trianionic porphyrinoids corrole[6]—the aromatic parent substance of corrin, the ring system of vitamin B_{12}—and isocorrole[7] may enable the preparation of the corresponding neutral complexes, that is, types **2** and **4**, respectively. This supposition appeared to be substantiated all the more so, as it was recently shown that stable iron(IV) complexes with ligands based on pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazides)—which are also trianionic—could be synthesized.[8, 9] We have now found that octaethylcorrole **5** can be readily converted into the triad of stable complexes **7**–**9**, all of which contain formally tetravalent iron.[10] Furthermore, the existence of the iron corrole **10** (bearing an axial pyridine ligand) with a formal oxidation state of the metal of + III was corroborated.



Iron(III) corroles, which might serve as starting materials for the synthesis of iron(IV) corroles, have already been described in the literature several times.[11] However, it is only recently that they have been thoroughly characterized spectroscopically, in work by T. Boschi et al.[11c, d] According to these investigations octamethylcorrole undergoes smooth metalation with iron trichloride or iron pentacarbonyl to give the neutral iron(III) corrole, which, on the basis of ^{1}H NMR spectroscopic findings, has a pronounced tendency to bind ligands in the axial position. Indications of a possible oxidation of iron(III) to iron(IV) corroles cannot be found in any of the published work. Two reasons led us to use the octaethyl compound **5**[12] rather than the

octamethyl compound as corrole ligand: first, the substantially better solubility of **5** and its metal complexes; second, a planned parallel study in the isocorrole series, for which the octaethyl compound corresponding to **5** was at our disposal.[7b]

The choice of **5** proved to be fortunate. As it turned out, treatment of **5** with nonacarbonyldiiron in toluene at 100–110 °C (2 h) under an argon atmosphere, followed by a workup with admission of air (causing a change in the color of the solution from brown to red), yielded as the only defined product the oxygen-bridged binuclear iron(IV) complex **7**, μ-oxo-bis[(octaethylcorrolato)iron(IV)]. This must have arisen from the spontaneous air oxidation of the iron(III) octaethylcorrole **6**, the assumed primary product. The new iron(IV) complex **7** can be easily isolated and is stable. After crystallization from hexane, it is obtained as black rhombohedra (m.p. >300 °C, yield 58%, see Experimental Procedure).

In the reaction of octamethylcorrole with iron transfer agents, the poor solubility of the intermediate Fe^{III} corrole complex slows down the air oxidation, and thus the Fe^{III}/Fe^{IV} conversion, which under suitable conditions is also observed in this system, was not detected.

A crystal structure analysis[13] of complex **7** (Fig. 1 and Table 1) confirms its molecular structure. The iron atoms in **7**

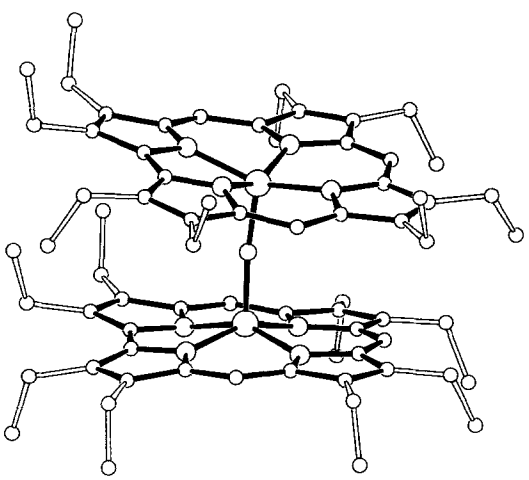

Fig. 1. Structure of the μ-oxodiiron(IV) corrole complex **7** in the crystal. Perspective view (without hydrogen atoms).

are coordinated in an approximately square-pyramidal fashion. The corrole ligands have—mainly because of steric interactions between the ethyl groups in the top and bottom halves of the molecule—ring frameworks that are twisted to varying degrees. However, in comparison to the free corrole, in which the spatial requirement of the imino hydrogen atoms causes a considerable deviation of the framework from planarity,[14] the corrole ligands in **7** have experienced a certain degree of flattening. The iron atoms are situated 0.403 Å (average value) above the planes formed by the N-donor atoms. The Fe–N bond lengths, which are within the range of those of known iron(IV) compounds,[8, 9] are significantly shorter than those in iron(III) porphyrins (1.96–2.09 Å).[15] The Fe–O bonds in **7** are also noticeably short [1.706 vs. 1.757 Å in the μ-oxodiiron(III) complex[16] derived from octaethylporphyrin]. The Fe-O-Fe angle is 170.0°, even though one would expect from theoretical arguments that a complex such as **7**, which has a (d^4–d^4) electronic configuration [as compared to μ-oxodiiron(III) porphyrins which have a (d^5–d^5) configuration], would exhibit a linear Fe-O-Fe unit.[17]

The magnetic susceptibility (measured in the range of 81–293 K)[18] and the ^{1}H NMR spectrum of **7** (Tables 2 and 3), which displays well-defined signals with small linewidth, indicate that the compound is effectively diamagnetic. The protons of the perimeter give rise to sharp singlets at $\delta = 6.66$ (H-5,15) and 6.62 (H-10), while those from the ethyl substituents appear as multiplets in the range $\delta = 2.82$–2.56 and as triplets at $\delta =$ 1.25, 1.17, 1.15, and 1.14. The shift of the resonances of the perimeter protons to higher field by no less than 2.7 ppm as compared to those of free octaethylcorrole, tantamount to substantial loss of the diamagnetic ring current of the ligand, demands interpretation by theory.[19] The ^{13}C NMR spectrum of **7** shows the expected 18 signals—again in the range in which diamagnetic compounds resonate. That the resonances of the *meso*-carbon atoms C-5,15 and C-10 have undergone a pronounced low-field shift of 17 and 21 ppm, respectively, compared with those in the uncomplexed **5** seems noteworthy. The singlet ground state ($S = 0$) observed for **7** at room temperature is caused by a very strong intramolecular antiferromagnetic coupling of the two iron(IV) ions with $S = 1$ ground states. It is interesting that in the analoguous μ-oxodiiron(III) porphyrins this coupling is considerably weaker,[20] since in these cases the ground state ($S = 0$), due to antiferromagnetic coupling of the two high-spin iron(III) ions ($S = 5/2$), is only observed at low temperatures ($T < 50$ K).

In analogy to μ-oxodiiron(III) porphyrins and porphycenes,[21] **7** experiences cleavage by acids to yield mononuclear complexes.[22] When, for example, **7** is allowed to react in dichloromethane with 1 M hydrochloric acid at room temperature, chloro(octaethylcorrolato)iron(IV) (**8**) is formed, which crystallizes from hexane/dichloromethane as black needles (m.p. >300 °C, yield 84%). Treatment of solutions of the chloro complex **8** with aqueous sodium hydroxide leads to the rapid reformation of **7**.

Chloro(octaethylcorrolato)iron(IV) (**8**) invited attempts to exchange the axial halogen ligand for aryl and alkyl groups by reaction with Grignard reagents, and thus provide access to the

organometallic σ-aryl- and σ-alkyl(octaethylcorrolato)iron(IV) complexes, respectively. Indeed, **8** could be smoothly transformed into the σ-phenyl complex **9** when it was treated with four equivalents of phenylmagnesium bromide (in ether) in dichloromethane. Crystallization of the product from hexane/dichloromethane afforded **9** as gray rhombohedra with metallic luster (decomp. >185 °C, yield 75%).

The isolation of complex **9** as a stable compound is surprising, considering the fact that cationic σ-phenyliron(IV) complexes in the porphyrin series (type **1**) rearrange rapidly even at room temperature to *N*-phenylated iron(II) complexes.[2] Whether a similar phenyl migration is possible in **9** at higher temperatures or by electrochemical means is currently under investigation. Insertion of oxygen into the iron–carbon bond, a reaction typical for σ-phenyliron(III) porphyrins,[23] has not been observed for **9**, since complex **9** is relatively air-stable in solution.

X-ray crystal structure analyses allowed an insight into the molecular structure of complexes **8** and **9** (Figs. 2 and 3, respectively, and Table 1).[13] In the chloroiron(IV) complex **8** the coordinative environment of the iron center corresponds to that found in the μ-oxo compound **7**, but the nitrogen atoms are better orientated towards the metal, allowing the ligand to adopt a more symmetric conformation. Otherwise **8** is characterized by a relatively long iron–chlorine bond [2.256 vs. 2.231 Å in high-spin chloro(octaethylporphyrinato)iron(III)[24]]. The phenyliron complex **9** is distinguished from **7** and **8** in so far as the distance between the metal and the N_4 plane is reduced to 0.272 Å (compared with 0.403 Å and 0.422 Å in **7** and **8**, respectively). Consequences of this are not only the shortening of the Fe–N distances, but also the almost complete flattening of the ring framework. Additionally, it is worth noting that **9**, in contrast to **8**, exists in the crystal as a π–π dimer with laterally shifted ring frameworks (intermolecular distance between the ring frameworks: 3.5–3.6 Å; Fe···Fe distance 5.437 Å).[15c]

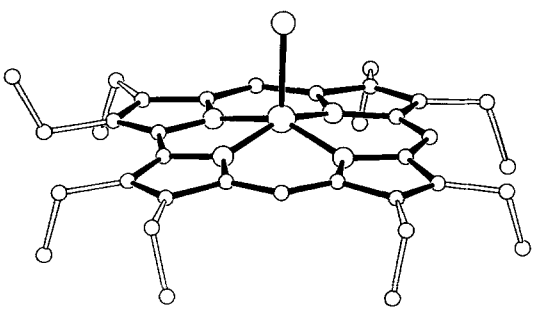

Fig. 2. Structure of the chloroiron(IV) corrole complex **8** in the crystal. Perspective view (without hydrogen atoms).

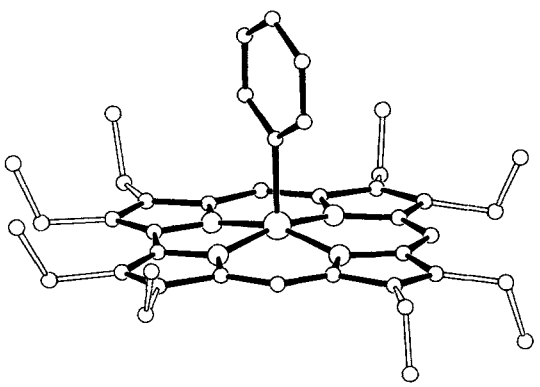

Fig. 3. Structure of the σ-phenyliron(IV) corrole complex **9** in the crystal. Perspective view (without hydrogen atoms).

The ^{1}H NMR spectra of complexes **8** and **9** are—in striking contrast to that of **7**—characteristic for paramagnetic compounds with broad unstructured signals over a wide range of absorptions (Tables 2 and 3).[25] In the case of **9** three further signals are observed at $\delta = -4.0$, -77.0, and -153.6, which can be attributed to the protons at the *meta*, *para*, and *ortho* positions, respectively, of the axially bound phenyl ligand.[26] The paramagnetism in **8** and **9** was confirmed by measurement of their magnetic susceptibility, from which it is evident that both complexes, similar to other iron(IV) compounds, exist in a spin triplet ground state ($S = 1$) ($\mu_{eff} = 2.97$ and $2.89\ \mu_B$, respectively, at 293 K).[8c] The Mössbauer spectra of **7**–**9**, measured at 4.2 and 77 K,[18] are in agreement with the formulation of these compounds as iron(IV) complexes. Small isomer shifts in the range $\delta_{Fe} = -0.11$ to -0.19 mm s^{-1} and relatively large quadrupole splittings $\Delta E_q = 2.35$–3.72 mm s^{-1} were observed (Table 3). Similar Mössbauer parameters have been reported for compounds I and II of heme peroxidases and related porphyrin model complexes.[27]

Table 3. Selected physical data for **7**–**10**. ^{1}H NMR: 300 MHz; ^{13}C NMR: 75.5 MHz; IR: CsI. The isomer shifts δ_{Fe} are relative to α-iron at 298 K. OEC = trianion of octaethylcorrole, py = pyridine

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0733 $ 10.00+.25/0

The possibility of stabilizing iron(III) corrole complexes by an axial pyridine ligand was demonstrated some time ago by Y. Murakami et al. with the example of 7,8,12,13-tetraethyl-2,3,17,18-tetramethylcorrole, but no details were given about the characterization of the complex.[11b] In parallel to this we have established that the product obtained from the metalation of **5** with nonacarbonyldiiron and subsequent removal of the solvent under vacuum yields the monopyridine complex **10** when treated with pyridine prior to the admission of air.

Alternatively, **10** can be obtained by reduction of **7** with hydrazine in the presence of pyridine. Complex **10** is stable in the solid state; however, in solution devoid of pyridine slow oxidation occurs to yield **7**. Treatment of a solution of **10** in dichloromethane with dilute hydrochloric acid leads to the immediate formation of the chloro complex **8**.

An X-ray crystal structure analysis[13] could also be carried out on complex **10** (Fig. 4 and Table 1). The distance between the iron atom and the N_4 plane (0.273 Å) is small and is similar to that in the phenyl compound **9**. Although all the nitrogen atoms

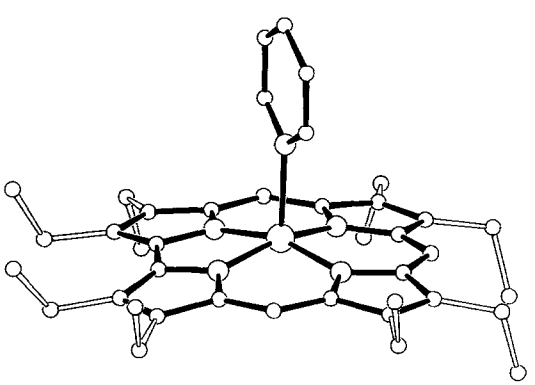

Fig. 4. Structure of the pyridine iron(III) corrole complex **10** in the crystal. Perspective view (without hydrogen atoms).

are in good alignment with the metal, the ring framework in **10** deviates from planarity more pronouncedly (the maximum distance of the C and N atoms from the mean plane of the ring is 0.219 Å) than is the case in the mononuclear complexes **8** and **9**. The Fe–N bond lengths in **10** are virtually the same as those found in the iron(IV) complexes **7**–**9**. This is unexpected, since one would have predicted an elongation towards the distances found in iron(III) porphyrins. The Fe–N distance between the iron atom and the pyridine ligand (2.188 Å) is similar to that in the cationic (3-chloropyridine)iron(III) complex of octaethylporphyrin (2.126 Å).[28] Finally, it should be noted that $\pi-\pi$ dimer formation in crystals of **10** is encountered by analogy to the situation in **9** (intermolecular separation of the ring frameworks: 3.6–3.7 Å; Fe···Fe distance: 6.221 Å).[15c]

The ^{1}H NMR spectrum of **10** (in [D_5]pyridine) corresponds in its kind to that expected for pentacoordinated paramagnetic high-spin iron(III) porphyrins:[25] the *meso* protons absorb at high field, the protons of the ethyl groups, on the other hand, at low field (Tables 2 and 3). On measuring the spectrum in carbon disulfide, three additional signals appear at $\delta = 11.4$, 7.7.1, and -3.3, which correspond to the protons in the α, β, and γ positions, respectively, of the axially coordinated pyridine ligand.[26] The positions of the resonances of the ligand protons change only slightly on altering the solvent from [D_5]pyridine to carbon disulfide; a tendency for **10** to form a six-coordinate dipyridine complex is thus not evident. Susceptibility measurements[18] indicate that **10** has a $S = 3/2$ ground state due to the observed temperature-independent magnetic moment of 3.80 μ_B (81–293 K). To our surprise, the Mössbauer spectrum of **10** exhibits parameters ($\delta_{Fe} = -0.09$ mm s^{-1} and $\Delta E_q = 3.88$ mm s^{-1} at 77 K) which are difficult to reconcile with the assumption of an iron(III) complex with a $S = 3/2$ ground state.[29] The observed isomer shifts and quadrupole splittings correspond rather as has also been established for the Fe–N bond lengths—to those in complexes **7**–**9**. We must therefore entertain the possibility that the formal Fe^{III} complex **10** should actually be considered as an Fe^{IV} corrole anion radical complex, whose magnetic properties ($S = 3/2$) come about as a result of ferromagnetic spin coupling of an iron(IV) metal center ($S = 1$) with a corrole anion radical ($S = 1/2$). Theoretical studies should shed further light on the electron distribution in **10**.

The synthesis of the iron(IV) corrole complexes **7**–**9** makes it conceivable that corroles might allow also the stabilization of unusual oxidation states of metals other than iron.[30] This possibility is directed, in particular, to the already well-known corrole complexes of copper and nickel, which, on the basis of chemical, UV/VIS, and ESR spectroscopic studies, have long been assumed to contain the metal in a divalent state.[6, 12] The conjecture that these complexes are actually Ni^{III} and Cu^{III} compounds is presently under investigation.

We are confident that research efforts in the field of metallocorroles, which have long stood in the shadow of metalloporphyrins, will now receive renewed impetus as a result of the access to iron(IV) complexes.

Experimental Procedure

7: Octaethylcorrole (**5**) (523 mg, 1 mmol) and nonacarbonyldiiron (1.8 g, 5 mmol) were heated together in toluene (25 mL) for two hours at 100–110 °C under an atmosphere of argon. Subsequently, the solution was concentrated under vacuum to 5 mL and air was introduced over 20 min, causing a change in color from brown to red. After filtration, the solution was stirred intensively for a further two hours under a current of air to complete the oxidation. The solvent was removed and the residue was subjected twice to chromatographic filtration (aluminum oxide, Woelm activity I, 10 × 2 cm, eluent diethyl ether). The μ-oxo complex **7** was eluted as an intensely red fraction, from which black rhombohedra were obtained after crystallization from hexane; m.p. >300 °C; yield 336 mg (58%).

8: A solution of the μ-oxo complex **7** (233 mg, 0.2 mmol) in dichloromethane (20 mL) was thoroughly stirred with hydrochloric acid (1 M, 20 mL) for 5 min. The organic phase was dried over sodium sulfate, and the residue obtained after removal of the solvent was chromatographically filtered (silica gel, 4 × 2 cm, eluent dichloromethane). The chloro complex **8** was eluted as the only fraction, which, after crystallization from hexane/dichloromethane (9:1), was obtained as small black needles; m.p. >300 °C; yield 204 mg (84%).

9: The chloro complex **8** (122 mg, 0.2 mmol) in dichloromethane (10 mL) was treated with four equivalents of phenylmagnesium bromide (solution in diethyl ether, ca. 0.5 M) over 5 min. After addition of water, the organic phase was separated, dried over sodium sulfate, and the solvent removed under vacuum. A chromatographic filtration (aluminum oxide, Woelm activity I, 10 × 2 cm, eluent diethyl ether) of the residue gave a red-orange eluate. This contained the phenyl complex **9**, which, after crystallization from hexane/dichloromethane (9:1), was recovered as gray rhombohedra with metallic luster; decomp. >185 °C; yield 98 mg (75%).

10: A solution of the μ-oxo complex **7** (233 mg, 0.2 mmol) in pyridine (5 mL) was treated with hydrazine hydrate (0.2 mL) and thereafter stirred for 5 min. After the addition of methanol (50 mL), the pyridine complex **10** was allowed to crystallize out at -30 °C. Subsequent crystallization from methanol/pyridine (5:1) gave **10** as gray rhombohedra with metallic luster; decomp. >160 °C; yield 210 mg (80%). All compounds gave correct elemental analyses (C, H, N, Cl).

[10] It should be noted here, that in the case of complexes containing ligands having extended π systems (so-called noninnocent ligands) the metal cannot be assigned a definite oxidation state—the reason for this is the mixing of metal and ligand orbitals. For discussion of this subtle problem see: F. C. Anson, T. J. Collins, T. G. Richmond, B. D. Santarsiero, J. E. Toth, B. G. R. T. Treco, *J. Am. Chem. Soc.* **1987**, *109*, 2974; reference [8c].

The synthesis of octaethylcorrole **5** by oxidative intramolecular coupling of 1,19-dideoxyoctaethylbiladiene-*ac*-dihydrobromide proceeds as follows: the tetrapyrrole starting material in methanol is treated with chloranil at room temperature in the presence of potassium hydrogen carbonate (5 min). After addition of hydrazine (to deprotonate the corrole hydrobromide and to reduce the excess chloranil) the corrole **5** separates, and is crystallized from methanol/chloroform (9:1) to give pure material; m.p. 226–227 °C (yield is increased from 19 to 60% compared with the previous method).

[13] **7**: $C_{70}H_{86}Fe_2N_8O$, crystals from hexane; monoclinic, space group $P2_1/n$, a = 15.589(4), b = 15.950(4), c = 25.933(7) Å, β = 90.84(2)°, Z = 4; ρ_{calcd} = 1.202 g cm^{-3}, μ_{Mo} = 4.98 cm^{-1}; 10412 observed reflections; θ_{max} = 27°; $R1$ = 0.0421, $wR2$ = 0.1178. **8**: $C_{35}H_{43}ClFeN_4 \cdot C_6H_6$, crystals from benzene; triclinic, space group $P\bar{1}$, a = 10.191(2), b = 13.973(3), c = 14.684(3) Å, α = 82.62(2), β = 71.19(2), γ = 69.65(2)°, Z = 2; ρ_{calcd} = 1.234 g cm^{-3}, μ_{Mo} = 5.12 cm^{-1}; 5844 observed reflections; θ_{max} = 27°; $R1$ = 0.0646, $wR2$ = 0.1614. **9**: $C_{41}H_{48}FeN_4$, crystals from hexane/ether; triclinic, space group $P\bar{1}$, a = 11.989(2), b = 12.443(2), c = 14.970(2) Å, α = 60.39(2), β = 68.50(2), γ = 67.88(2)°, Z = 2; ρ_{calcd} = 1.237 g cm^{-3}; μ_{Mo} = 4.64 cm^{-1}; 4908 observed reflections; θ_{max} = 25°; $R1$ = 0.0644, $wR2$ = 0.1882. **10**: $C_{40}H_{48}FeN_4$, crystals from pentane/pyridine; monoclinic, space group $P2_1/n$, a = 12.761(3), b = 14.644(4), c = 18.662(5) Å, β = 95.58(2)°, Z = 4; ρ_{calcd} = 1.253 g cm^{-3}, μ_{Mo} = 4.70 cm^{-1}; 6186 observed reflections; θ_{max} = 27°; $R1$ = 0.0361, $wR2$ = 0.1121. The measurement of the reflection intensities was carried out on an Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ radiation λ = 0.71069 Å). The structures were solved with direct methods and refined with F^2 for all independently observed reflections with ($F_o^2 > 2\sigma F_o^2$) (heavy atoms with anisotropic, H atoms with isotropic temperature factors); $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma(F_o^2)^2]^{1/2}$. Programs used: for solving the structures MolEN (Enraf-Nonius) and for the refinement SHELXL-93 (G. M. Sheldrick, Universität Göttingen). Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57965.

[17] K. Tatsumi, R. Hoffman, *J. Am. Chem. Soc.* **1981**, *103*, 3328. In an μ-oxodiiron complex containing a pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazonate) ligand, described in reference [8b], the Fe-O-Fe angle is only 153.7°.

[18] The susceptibility measurements were carried out on powdered samples in the temperature range of 81 to 293 K on a Faraday balance; the diamagnetic correction was calculated by using Pascal constants. The Mössbauer experiments were carried out on powdered samples at 4.2 K and 77 K in zero field.

[19] The perimeter protons in metalloporphyrin dimers are shifted to highfield due to the magnetic anisotropicy of the ligands. This shift amounts to about 0.5 ppm in the case of the *meso* protons in the μ-oxodiscandium complex of octaethylporphyrin (see ref. [22]). By the clamping together of two porphyrin units, the distance between the ring frameworks is reduced to 3.4 Å. In this way shifts of up to 1.5 ppm are observed (see M. O. Senge, K. R. Gerzevske, M. G. H. Vicente, T. P. Forsyth, K. M. Smith, *Angew. Chem.* **1993**, *105*, 745; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 750). Since the average separation of the ring frameworks in **7** is 4.3 Å, it seems unlikely that the shifts encountered in this work are solely due to a conventional anisotropy effect.

μ-Oxodiiron(III) Complexes of Porphycenes

Michael Lausmann, Ingeborg Zimmer, Johann Lex, Heiko Lueken, Karl Wieghardt, and Emanuel Vogel*

Porphyrin complexes with divalent iron, the highly reactive hemes, are the prosthetic groups of hemoglobin and myoglobin and, as such, are capable of reversibly binding dioxygen.[1] This function of the hemoprotein metal center was successfully simulated in the groups of Collman[2a] and Baldwin[2b] with the design and synthesis of the "picket fence" and "capped" porphyrins.[2c] In the case of simple iron(II) porphyrinates, the reversible binding of dioxygen is suppressed by the alternative irreversible oxidation step. The thermodynamically stable μ-oxodiiron(III) porphyrin complexes of type **1**,[3] the so-called μ-oxo dimers, are thus formed. Because of the role they play in dioxygen binding, their varied chemistry, and not least because of their interesting electronic structure and the magnetic interactions between the two Fe^{III} centers,[4] the μ-oxo dimers rank among the important iron porphyrin complexes.

1

2: R = *n*-C_3H_7
3: R = *t*-C_4H_9

In view of the similarity between metalloporphycenes and the corresponding metalloporphyrins,[5] it is very likely that iron(II) porphycenates, tailored after the heme models in their molecular architecture, are also capable of reversibly binding dioxygen. While porphycenates of this type still await synthesis, we report here on the preparation and properties of the first μ-oxodiiron(III) porphycene complexes; the sterically complementary complexes **2** and **3** of 2,7,12,17-tetra-*n*-propylporphycene (**4**)[5a] (H_2TPrPc) and 2,7,12,17-tetra-*tert*-butylporphycene (**5**) (H_2TBuPc), respectively.

The μ-oxodiiron(III) porphycenates **2** and **3** can readily be made following a well-established procedure for the synthesis of μ-oxodiiron(III) porphyrinates.[3] Porphycenes **4** and **5** were heated under reflux with tris(acetylacetonato)iron(III) in phenol to give the corresponding (phenolato)iron(III) porphycenates, which, after removal of the solvent, were treated with an aqueous sodium hydroxide solution. Chromatography and recrystallization furnished **2** and **3** in yields of 81 and 67%, respectively, (see Experimental Procedure) as stable compounds [**2**: violet-black, parallelepiped-shaped crystals (from benzene/pentane); m.p. 266–268 °C; **3**: violet, parallelepiped-shaped crystals (from hexane/dichloromethane); m.p. > 300 °C (decomp.)].

Due to the presence of the paramagnetic iron(III) ions, the ^{1}H NMR spectra (300 MHz, $CDCl_3$, room temperature) of the μ-oxodiiron(III) complexes **2** and **3** show unstructured, broadened resonance signals with unusual chemical shifts.[6] Signal assignments must therefore be based on an analysis of linewidths and comparison with the spectra of reference compounds.[7] The signals in the spectrum of **2** (Table 1) at $\delta = 14.4$ and 6.9 are thus assigned to the perimeter protons H-3,6,13,16 and H-9,10,19,20, respectively, while those at $\delta = 6.6$ and 5.4 (splitting caused by diastereotopism), 2.5, and 1.4 correspond to the α-CH_2, β-CH_2, and methyl protons, respectively. Since the spectra of **2** and **3** are, as far as they are comparable, very similar, the spectral assignment for **3** follows by analogy from that described above for **2**. An indication of how closely complexes **2** and **3** are related to μ-oxodiiron(III) porphyrinates in NMR-spectroscopic terms is provided by the observation that the two types of μ-oxo complexes have comparable isotropic shifts.[6] The electronic spectra of **2** and **3** exhibit porphyrinoid features, with a Soret band (at 367 and 370 nm, respectively) and a broad band at longer wavelength (632 and 628 nm, respectively). The Mössbauer spectra of **2** and **3** at room temperature show a near-symmetrical quadrupole split doublet with isomer shifts (δ_{Fe}) of 0.24 and 0.25 mm s^{-1}, respectively, and electric quadrupole splittings (ΔE_q) of 0.58 and 0.52 mm s^{-1}, respectively. These δ_{Fe} and ΔE_q values lie in the range characteristic of μ-oxo porphyrin complexes ($0.23 \leq \delta_{Fe} \leq 0.39$ mm s^{-1} and $0.54 \leq \Delta E_q \leq 0.74$ mm s^{-1} at $T = 298$ K[8]), and thus attest to the similarities between the porphycene complexes and their porphyrin counterparts already evident from the other spectral findings.

Cyclovoltammetric investigations, on the other hand, revealed remarkable differences in the redox behavior of μ-oxodiiron(III) porphycenates and μ-oxodiiron(III) porphyrinates. Compounds **2** and **3** both undergo four reversible one-electron oxidations and four reversible one-electron reductions. Four reversible one-electron oxidations are also observed for the porphyrin complexes, yet only one reversible one-electron reduction can be detected.[9]

The X-ray structure analysis of μ-oxodiiron(III) porphycenate complex **2** (Fig. 1) confirms its molecular structure.[10] Each of the iron atoms in **2** is coordinated in a square-pyramidal geome-

Table 1. Selected physical data of new compounds **2**, **3**, **5**, **7**–**9**. ^{1}H NMR: 300 MHz, room temperature; ^{13}C NMR: 75.5 MHz; MS: EI, 70 eV; IR: CsI; UV/VIS: CH_2Cl_2. Isomer shifts are quoted relative to α-iron at 298 K.

2: M.p. 266–268 °C (benzene/pentane); ^{1}H NMR ($CDCl_3$): $\delta = 14.4$ (br. s, 8H; H-3,6,13,16), 6.9 (br. s, 8H; H-9,10,19,20), 6.6 (br. s, 8H; α-CH_2), 5.4 (br. s, 8H; α-CH_2), 2.5 (br. s, 16H; β-CH_2), 1.4 (br. s, 24H; CH_3); MS: *m/z* (%): 1080 (24) [M^+], 532 (100) [M^+ – Fe(TPrPc)O]; IR: $\tilde{\nu} = 2957$, 2929, 2868, 1466, 1241, 1044, 968, 913, 844 [$\tilde{\nu}_{as}$(Fe-O-Fe)], 812 cm^{-1}; UV/VIS: $\lambda_{max}(\varepsilon) = 342$ (86100) sh, 367 (99600), 427 (23600) sh, 632 nm (55500); Mössbauer parameters (298 K): $\delta_{Fe} = 0.24$ mm s^{-1}, $\Delta E_q = 0.58$ mm s^{-1}

3: Decomp. > 300 °C (hexane/dichloromethane); ^{1}H NMR ($CDCl_3$): $\delta = 14.4$ (br. s, 8H; H-3,6,13,16), 7.3 (br. s, 8H; H-9,10,19,20), 2.5 (br. s., 72H; CH_3); MS: *m/z* (%): 1192 (48) [M^+], 588 (100) [M^+ – Fe(TBuPc)O]; IR: $\tilde{\nu} = 2963$, 2909, 2871, 1464, 1189, 1039, 1010, 976, 902, 823, 805 cm^{-1}; UV/VIS: $\lambda_{max}(\varepsilon) = 370$ (123000), 430 (21000) sh, 580 (31600) sh, 628 nm (89000); Mössbauer parameters (298 K): $\delta_{Fe} = 0.25$ mm s^{-1}, $\Delta E_q = 0.52$ mm s^{-1}

5: M.p. > 300 °C (acetonitrile/dichloromethane); ^{1}H NMR ($CDCl_3$): $\delta = 10.2$ (s, 4H; H-9,10,19,20), 9.4 (s, 4H; H-3,6,13,16), 3.6 (br. s, 2H; NH), 2.3 (s, 36H; CH_3); ^{13}C NMR ($CDCl_3$): $\delta = 153.5$, 142.5, 132.8, 121.9, 112.6, 34.3, 33.8; MS: *m/z* (%): 534 (100) [M^+]; IR: $\tilde{\nu} = 2960$, 2867, 1462, 1363, 1228, 1181, 1034, 999, 887, 823, 808 cm^{-1}; UV/VIS: $\lambda_{max}(\varepsilon) = 370$ (147000), 384 (96300) sh, 562 (33700), 601 (35300), 632 nm (48500)

7: M.p. 160–162 °C (methanol); ^{1}H NMR ($CDCl_3$): $\delta = 7.55$, 7.50, 7.40, 7.17, 5.87

8: Decomp. > 195 °C (pentane); ^{1}H NMR ($CDCl_3$): $\delta = 7.85$, 6.50, 6.10, 1.25

9: M.p. 299–301 °C (ethanol/dichloromethane); ^{1}H NMR ($CDCl_3$): $\delta = 12.40$, 10.03, 6.34, 1.46

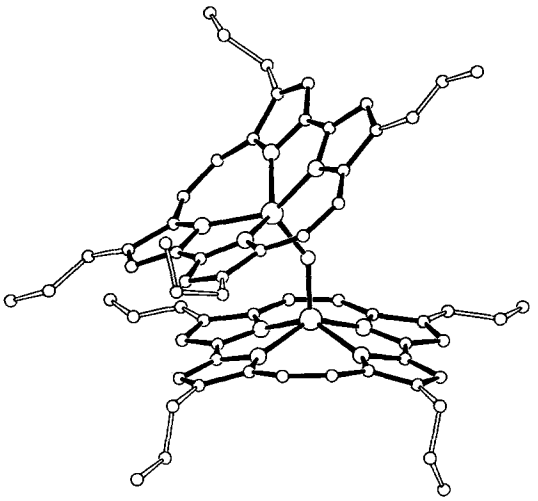

Fig. 1. Structure of the μ-oxodiiron(III) complex **2** in the crystal. Perspective view (hydrogen atoms omitted). Selected bond lengths and distances [Å] (mean values), and bond angles [°]: Fe–O 1.770, Fe–N 2.052, Fe···N_4 plane 0.670; Fe-O-Fe 145.3.

try. The porphycene ligand has a dome-shaped framework, and thus differs significantly from the free ligand 2,7,12,17-tetra-*n*-propylporphycene (**4**), in which—just like in its nickel(II) complex[5a]—the framework is planar. As can be deduced from Figure 1, the changes in the geometry of the macrocycle resulting from complexation can largely be explained in terms of the tendency shown by the nitrogen electron pairs and bonds to align themselves in such a way as to maximize bonding with the metal center. As a result, the ratios of the lengths of the sides in the N_4 core are reversed [N(1)···N(2)/N(1)···N(4): 2.629/2.851 Å; **4**: 2.831/2.651 Å], a phenomenon also observed in other metallo-2,7,12,17-tetra-*n*-propylporphycenes (nickel complex: 2.554/2.801 Å).[5a, 11] The distances of the iron atoms from the N_4 mean planes and from the mean planes of the ring frameworks of 0.67 and 0.84 Å, respectively (mean values), are noticeably larger than the corresponding values for the μ-oxodiiron(III) porphyrin complexes (0.50–0.54 Å and 0.42–0.67 Å).[12] The iron–nitrogen distances are, in contrast, slightly shorter than those observed in their porphyrin counterparts (2.052 and 2.078 Å, respectively, mean values).

According to an X-ray structure analysis,[10] the μ-oxodiiron(III) complex **3** (Fig. 2 top) of the tetra-*tert*-butylporphycene **5** has a crystallographic twofold axis of symmetry which bisects the angle of the Fe-O-Fe bridging unit. In the structural unit comprising the ligand and the incorporated iron atom, distances and bond lengths involving iron are very similar to those of **2**; however, the deviation from planarity of the ring framework is less pronounced (maximum deviation of the C and N atoms from the mean plane: ±0.26 Å vs. ±0.40 Å for **2**).

The most conspicuous result to emerge from the X-ray structure analyses of **2** and **3** is that the Fe-O-Fe angles in the two compounds differ substantially. Whereas the Fe-O-Fe unit in **2** is, as anticipated from theoretical considerations,[13] bent (at an angle of 145.3°), it is almost linear in **3** (178.5°). Steric interactions between the bulky *tert*-butyl groups, which are staggered (the porphycene ligands are twisted with respect to each other by ca. 39° in **3** and ca. 31° in **2**), evidently disfavor an approach of the two porphycene ligands, and thus prevent bending in the Fe-O-Fe unit of **3** (Fig. 2 bottom).[14] The Fe–O bond lengths in **2** and **3** are 1.770 and 1.748 Å, respectively. It is interesting to compare these values with the Fe-O-Fe bond angle of 171.8° and

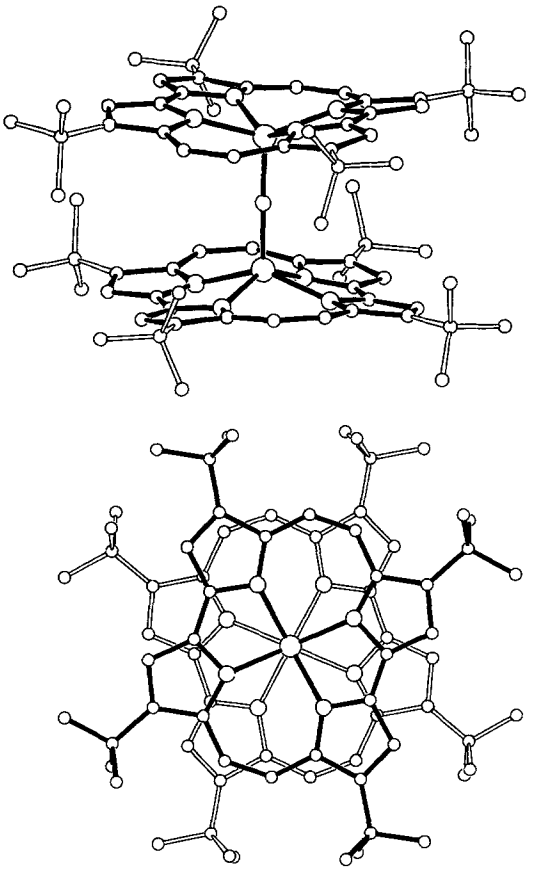

Fig. 2. Structure of the μ-oxodiiron(III) complex **3** in the crystal. Top: Perspective view (hydrogen atoms omitted); bottom: top view (hydrogen atoms omitted). Selected bond lengths and distances [Å] (mean values), and bond angles [°]: Fe–O 1.748, Fe–N 2.056, Fe···N_4 plane 0.600; Fe-O-Fe 178.5.

the Fe–O bond lengths of 1.754 and 1.760 Å found in the μ-oxodiiron(III) complex of octaethylporphyrin.[12d]

In order to determine the strength of the spin-spin interaction between the paramagnetic d^5 iron(III) centers in the dinuclear μ-oxo complexes **2** and **3**, the magnetic susceptibility[15] χ_M of both complexes was measured over the temperature range from 3.0 to 294 K (Fig. 3).[16] On application of the isotropic Heisenberg–Dirac–van Vleck model, the temperature-dependence in

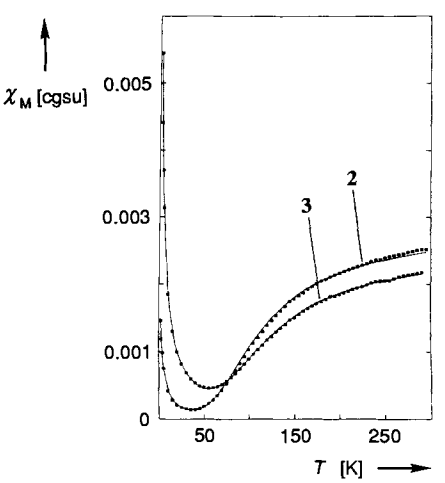

Fig. 3. Temperature dependence of the molar susceptibilities of the μ-oxodiiron(III) porphycenates **2** and **3**.

both series of measurements can readily be fitted to the spin-Hamiltonian operator $\mathscr{H} = -2J\boldsymbol{S}_1\cdot\boldsymbol{S}_2$ with $S_1 = S_2 = 5/2$, where $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$ are the total spins of the interacting ions 1 and 2, respectively, and J is the spin-exchange coupling constant. Using the Landé factor $g = 2.0$ and assuming that samples of **2** and **3** are contaminated with a small percentage α of a paramagnetic mononuclear iron(III) porphycenate with $S = 5/2$, the following numerical values for J were obtained: for **2**: $-114\ cm^{-1}$ ($\alpha = 0.1\%$) and for **3**: $-129\ cm^{-1}$ ($\alpha = 0.2\%$). These values suggest an intramolecular antiferromagnetic coupling between the iron(III) ions (d^5 high-spin electron configuration[17]) in **2** and **3**. The spin-exchange coupling constant J for **2** and **3** fall within the range reported for numerous Fe^{III}-O-Fe^{III}-bridged complexes.[3c] According to theoretical considerations[13, 18] and experimental data,[19] the dominant factor influencing the magnitude of J is the mean Fe–O bond length; the shorter the Fe–O distance the stronger the coupling. As indicated by the Fe–O distances observed for **2** and **3** (see discussion of the X-ray structure analyses), the coupling in **3** is slightly stronger than that in **2**.

These investigations emphasize, once again, the far-reaching parallels existing between the porphycenes and porphyrins, including their metal complexes. μ-Oxodiiron(III) porphycenates resemble the corresponding μ-oxodiiron(III) porphyrinates not only in most of the physical properties discussed here, close agreement is also observed in their chemical behavior. The fact that μ-oxodiiron(III) porphycenates are solvolyzed in weakly acidic media by compounds HX to yield mononuclear iron(III) porphycenates bearing an axial ligand X^--analogous to the class of compounds referred to as hemins—lends support to this statement. Further investigations into this type of complex, many examples of which have been prepared starting from **2** with the model compound **4** (H_2TPrPc) as ligand [Eq. (a)],[20] will be reported in another context.

$$(TPrPcFe)_2O \xrightarrow{HX} TPrPcFeX \quad (X = Cl, Br, N_3, O_2CCH_3, O_2CCF_3, OC_6H_5) \qquad (a)$$

Experimental Procedure

5: The ligand 2,7,12,17-tetra-*tert*-butylporphycene (**5**) was prepared according to Equation (b):

6[21]

7: R' = $SO_2C_6H_5$; R = H
8: R' = R = H
9: R' = H; R = CHO

6 → **7**: *n*-Butyllithium, 2,2,6,6-tetramethylpiperidine, THF, −78 °C, 1 h, then $CuCl_2$, −78 °C, 2 h; workup by hydrolysis with aqueous glycine solution (46%); **7** → **8**: KOH, methanol, reflux, 8 h (89%); **8** → **9**: $POCl_3$, dimethylformamide, 3 h, 60 °C; CH_3COONa, H_2O, 30 min, 90 °C (85%); **9** → **5**: $TiCl_4$, Zn, CuCl, THF, reflux, 1 h; hydrolysis with aqueous NH_3 solution (20%).

2: A mixture of 2,7,12,17-tetra-*n*-propylporphycene (**4**)[5a] (120 mg, 0.25 mmol), tris(acetylacetonato)iron(III) (265 mg, 0.75 mmol), and phenol (2.5 g) was maintained at 210 °C for 3 h. The phenol was removed by sublimation at 50 °C under high vacuum. The residue was dissolved in dichloromethane (60 mL), and the resulting solution was stirred with 10% aqueous sodium hydroxide solution (60 mL) for 30 min. After extraction with dichloromethane, the crude product was chromatographed on aluminum oxide (Woelm, neutral, act. IV, column: 3.5 × 30 cm). Unreacted porphycene **4** was eluted with hexane/dichloromethane (4:1). The μ-oxo complex **2** was then eluted with dichloromethane. Finally, crystallization from benzene/pentane gave **2** as violet-black, elongated parallelepiped-shaped crystals (109 mg, 81%); m.p. 266–268 °C.

3: The μ-oxo complex **3** of the tetra-*tert*-butylporphycene **5** was prepared from **5** by an analogous procedure to that described for the propyl compound **2**. Crystallization from hexane/dichloromethane (2:1) gave **3** as violet, parallelepiped-shaped crystals (100 mg, 67%); m.p. > 300 °C (decomp.).

All compounds gave correct elemental analyses (C, H, N).

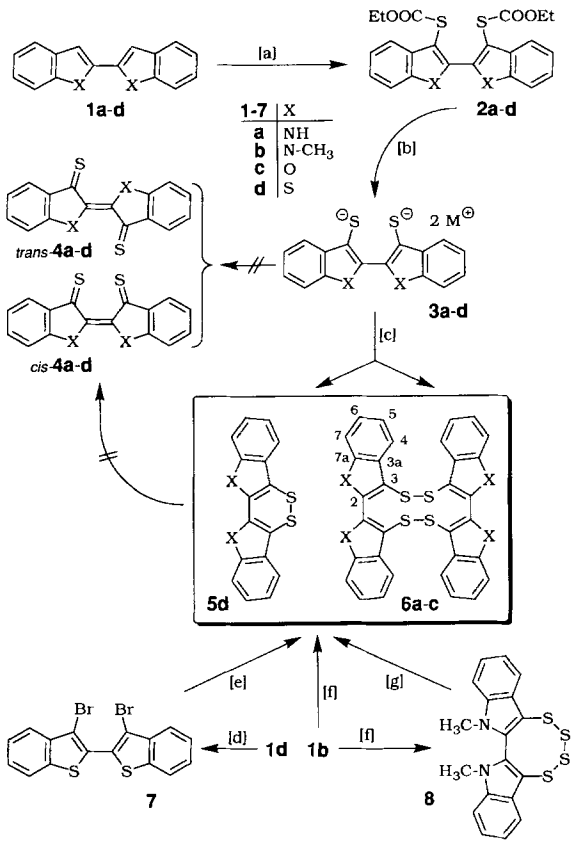
Concerning the Questionable Existence of Thioxoindigoid Compounds**

Werner Schroth,* Ekkehard Hintzsche, Michael Felicetti, Roland Spitzner, Joachim Sieler, and Rhett Kempe

Dedicated to Professor Hans Gross on the occasion of his 65th birthday

Indigoid compounds with thioxo instead of oxo groups as in **B** (Scheme 1) are probably[1] still unknown, although they should provide interesting information on structure–color relationships.[1, 2] Their synthesis is difficult, since the 1,4-dithioxo-2-butene structural element **D** incorporated in **B** is closely related, through its valence-isomeric *cis* form **E**, to the (colored) 1,2-dithiine type **F**, which is not known to undergo electrocyclic ring opening to **E** in either the solid state or solution.[3] In fact, oxidation of alkali metal dithiolates **A**, even though they are thio analogues of leucoindigo, does not lead to thioxoindigoid compounds **B** but rather, depending on the heteroatom X, to valence isomers or oligomeric cyclic dialkenyldisulfides **C**.

Scheme 1.



The dipotassium 3,3′-dithiolates **3a–d** corresponding to **A** were obtained by the conversion of 2,2′-biheteroaryls **1a–d**[4] into the 3,3′-di(ethoxycarbonylthio) derivatives **2a–d** by treatment with ethoxycarbonylsulfenyl chloride (Scheme 2). Saponification of **2a–d** with ethanolic potassium hydroxide[5] and in situ oxidation with aerial oxygen or $K_3[Fe(CN)_6]$ did not lead to the thioxoindigoid compounds **4a–d**, rather the following results were obtained:

a) For X = S, the di(benzo[*b*]thieno)-annelated 1,2-dithiine **5d**, a valence isomer of *cis*-**4d**, was formed exclusively as deep red needles [λ_{max}(MeCN) = 465 nm, lg ε = 4.413], which can be easily reduced back to dithiolate **3d** with $NaBH_4$. In addition **5d** was obtained by bromination of **1d** to give the 3,3′-dibromo derivative **7** followed by halogen–lithium exchange with *n*BuLi to provide 3,3′-dilithio-2,2′-di(benzo[*b*]thienyl) and, finally, by reaction with elemental sulfur.[6] The product proved to be identical with that obtained by heating 3-mercaptobenzo[*b*]thiophene and morpholine in toluene,[1b] which was referred to by the authors as "dithioxothioindigo" *trans*-**4d**. The results of an X-ray structure analysis (nonplanar ring, C-S-S-C dihedral angle 53.1°; S–S bond length 2.062 Å), the preparation, and the reactions are described in reference [7]. Unlike the nonannelated 1,2-dithiines,[3a, b] **5d** shows no tendency to extrude sulfur.

b) For X = NCH_3, O the relatively insoluble cyclic bisdisulfides **6b, c** predominate.[8, 9] According to the X-ray structure analysis of **6b** (Fig. 1),[10] two heteroarene rings (twisted relative to one other by ca. 180°) face each another, while the planes of the other two are tilted outwards; the planes of the 2,2′-biheteroaryl units are significantly twisted, in **6b** by 113.7°, in **6c** by 160.9° (C-S-S-C dihedral angles 89.5 and 75.4°, respectively). The ^1H and ^{13}C NMR spectra (Table 1) are characteristic of a dynamic structural system. In the electron impact mass spectrum (EI-MS) of **6b,c** the base peaks corresponding to the masses of **4b,c**/**5b,c** (*m*/*z* 322 and 296, respectively, are derived from twofold S–S cleavage.[11] The reaction of **1b** with S_2Cl_2 at −20 to −60 °C gave a mixture of products, from which **6b** and the cyclic tetrasulfide **8** were isolated in low yield; the structure of **8** was confirmed by X-ray structure analysis (twist of the indolyl planes 67.6°, S-S-S-S dihedral angle 78.6°). Reduction of **8** with $NaBH_4$ and subsequent aerial oxidation regenerated **6b**.
