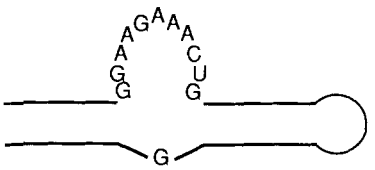
FAD-20 N_{27}-UGGUGAGGCAGUCGAAAGGAAGUGUAGGUUGCUUCACCA-N_2

Scheme 3. FMN- and FAD-binding RNA sequences. Selected RNAs were treated with reverse transcriptase and amplified by PCR with the M27.39 and M20.106 primers (see Scheme 2a). The M27.39 primer was employed to provide the DNA with *EcoRI* restriction sites. After digestion with *EcoRI* and *BamHI*, the excised fragment was cloned into the vector pGem3z (Promega) [7] and sequenced following the dideoxy method [8]. Only those bases are shown which are relevant in forming the binding motifs shown above each set of sequences. The consensus sequences and a schematic representation of the stem region are also shown.

Table 2. Dissociation constants K_d for the binding of FMN-2, 35FMN-2, FAD-1, and 27FAD-1 to various ligands in solution [a].



Ligand	K_d [μM]			
	FMN-2	35FMN-2	FAD-1	27FAD-1
FMN	0.5	0.5	84	280
FAD	1.4	0.7	137	273
1	0.5	0.3	23	35
ATP	250	163	4×10^3	2×10^3
GTP	$>5\times10^4$	$>5\times10^4$	3×10^3	3×10^3

[a] The K_d values were determined by elution of ^{32}P-labeled RNA from a column, which contained 1.0 mL of a 0.5 mM FMN or 3 mM FAD agarose, and were calculated according to the equation $K_d = [L]\times\{(V_{el}-V_o)\times(V_e-V_{el})\}$ [1f]. [L] is the concentration of the ligand in the solution, V_{el} the elution volume in the presence of the ligand in solution, V_e the elution volume with buffer solution in the absence of the ligand, V_o the void volume of the column (0.7 mL).

order. This finding in particular strongly supports the proposed secondary structure. The FAD selection provided another binding motif, the conserved 13-mer 5′-PuAAAGGAAGUGUA-3′, which is flanked by pairing base pairs, leading to formation of the stem-loop structure shown in Scheme 3. This motif was found in five sequences (FAD-1, FAD-4, FAD-9, FAD-11, and FAD-20). The affinity of FAD-1 for FAD or FMN is significantly lower than the affinity of the FMN-2 motif for these ligands (Table 2). FAD-1 also recognizes exclusively the flavin portion of FAD, since binding to **1** (K_d = 23 μM) is significantly better than binding to FMN (84 μM), and there is virtually no affinity for the adenosine portion of FAD ($K_d^{ATP} \geq$ 4.0 mM). FAD-1 likewise does not bind to GTP. A minimal 27-mer RNA based on the secondary structure of FAD-1 (27FAD-1 = 5′-GGCAGUCGAAAGGAAGUGUAGACUGCC-3′) and containing the consensus sequence and the stem region exhibits binding constants that are somewhat weaker but on the same order of magnitude as those of the full-length aptamer FAD-1.[5] It is, therefore, one of the smallest specific ligand-binding RNAs known to date. The corresponding DNA sequence of this aptamer has no measurable affinity for FAD.

Why was only one binding motif with affinity for the flavin portion obtained in the FMN selection, whereas in the FAD selection a second motif of significantly lower affinity could also be isolated? This may well be explained by the different concentrations of the ligand in the FMN and the FAD agaroses (FMN: 0.5 mM; FAD: 3.0 mM). A comparison of the elution volumes V_e of FAD-1 for the two derivatized agarose types, V_e = 2 mL for the FMN agarose and V_e = 13 mL for the FAD agarose, provides values of K_d of a similar magnitude. This implies that all FAD-1-type binding species were removed from the FMN agarose with the 5.0 mL washing employed during selection and as a result were not enriched.

All sixteen NAD^+-binding sequences contained the base sequence GGAAGAAACUG. This same consensus sequence is a component of an ATP-binding RNA motif isolated recently by Sassanfar and Szostak.[1d] Indeed, the aptamers that we isolated can fold into the identical motif (Scheme 4). This aptamer binds to the adenosine portion of ATP with a K_d of 4.0 μM and also has affinity for NAD^+. To enrich aptamers, which may be present in small concentrations in the selection pool and which require the NMN^+ portion for binding to NAD^+, we performed three additional selection cycles, in which a negative selection with ATP preceded the elution with NAD^+. However, no further binding species were obtained. This result was confirmed by an NMN^+ selection (Table 1), which likewise did not lead to an enrichment of binding species over eight cycles. The simplest explanation for these results would be that the pool does not contain a single sequence capable of binding to NMN^+.[6]

Scheme 4. RNA-binding motif [1d] for the adenosine portion of ATP or NAD^+.

What is remarkable about this result with NAD^+ and ATP selections[1d] is the fact that two completely independent selections employed for the structurally related, but yet different agaroses and ligands (and nucleic acid pools) led to identical aptamers, and indeed exclusively to those with affinity for the adenosine portion of the ligand. The fact that this motif can be isolated repeatedly from independent pools with a complexity of 10^{14}–10^{15} sequences illustrates the high certainty and precision of this selection technique. Furthermore, this result indicates that the adenosine-specific aptamer is the "optimal sequence solution" for the molecular recognition of adenosine by RNA.

In conclusion, we were able to select new RNA motifs for the specific recognition of biological cofactors from randomized RNA pools. The aptamers described recognize preferentially certain regions of a ligand. Other regions were only poorly bound or not at all. The RNA motifs 35FMN-2 and 27FAF-1 represent a new class of supramolecular systems for the highly specific recognition of flavins based on "irrational receptor design".[9, 10]

[5] It is striking that FAD-1 and 27FAD-1 bind to **1** more strongly than to FAD or FMN. An explanation for this could be that **1** does not have a negatively charged phosphate group and thus repulsion of the RNA phosphate backbone is not possible. Similar explanations have been given for comparable observations (see ref. [1d]). Other possible explanations include gain or loss of binding entropy as a result of differences in the hydrate shell of **1** and FMN or FAD, aryl stacking interactions, and steric phenomena. Detailed structural investigations would provide a greater insight into such observations.

[6] It is possible that the stringency of the selection conditions did not allow isolation of aptamers that bind NMN^+ or the NMN^+ portion of NAD^+. We are currently examining different buffer conditions, metal ions, and ligand concentrations as well as elution volumes (as with FAD-1), which could lead to isolation of specific motifs. However, the pool certainly did not contain motifs specific for NMN^+ with K_d values comparable to those of the ATP-binding species (1–10 μM).

Functionalization of C_{60} Buckminsterfullerene by [8 + 2] Cycloaddition: Spectroscopic and Electron-Transfer Properties of a Tetrahydroazulenofullerene**

Ernst Beer, Michaela Feuerer, Andreas Knorr, Albert Mirlach, and Jörg Daub*

8-Methoxyheptafulvene (**1**) has pronounced π-donor properties[1] and reacts with acceptor-substituted alkenes to form tetrahydroazulenes in a regiospecific [8 + 2] cycloaddition.[2] In contrast, buckminsterfullerene C_{60} (**2**) has a high electron affinity (E_A = 2.6–2.8 eV).[3] This is the reason for the electrophilic nature of the π-system: reactions normally occur at the double bond common to two annulated six-membered rings (6,6 bonds), and **2** can be reduced to the hexaanion.[4, 5] Owing to these properties, the [8 + 2] cycloaddition of **1** with **2** should lead to annulated fullerenes,[6] which would open up a potential route to polyfunctional fullerene derivatives with opto-electronic properties. We report here for the first time on an [8 + 2] cycloaddition of **2** (Scheme 1).

1 **2** **3**

Scheme 1. Reaction of 8-methoxyheptafulvene (**1**) with C_{60} (**2**).

Treatment of 8-methoxyheptafulvene (**1**) with C_{60} (**2**) (in toluene, under a nitrogen atmosphere, at room temperature) gave a mixture of products whose HPLC trace shows more than 90% of one main product. The main fraction from gel permeation chromatography (GPC) on polystyrene gel (eluent: chloroform) was further purified by column chromatography (SiO_2, eluent: toluene/hexane, 6:4).[7] The structure and stereochemistry of the main product were determined by mass spectrometry, and NMR and electron spectroscopy. A peak at *m/z* 854 in the mass spectrum (negative ion, secondary ion mass spectrometry) proves the formation of a monoadduct. In addition, the C_{60} signal at *m/z* 720 indicates that a thermal retro-[8 + 2] cycloaddition occurs. The ^1H NMR spectrum displays the typical resonance signals of a tetrahydroazulene moiety:[8] the signals for 1′-H, 8′-H, 3′a-H in **3** are shifted downfield in comparison to those of structurally related tetrahydroazulenes, reflecting the magnetic anisotropy of the spherical C_{60} unit. In contrast to the C_{60} derivatives studied up to now, the reduced symmetry of **3** (C_1 rather than I_h) results in the separation of all signals in the ^{13}C NMR spectrum. The two signals at δ = 75.13 and 71.58 due to the quaternary aliphatic carbon atoms show conclusively that no bonds within the carbon sphere were broken. Further proof supporting the proposed structure comes from ^{13}C NMR polarization transfer experiments (^{13}C DEPT). The seven methine carbon atoms and the carbon atom of the methoxy group give positive signals. The UV/VIS spectrum shows a band at λ = 432 nm, which is also observed in other C_{60} cycloadducts bridged at a 6,6 bond.[9] The [8 + 2] cycloaddition can take place at either the 6,6 or the 5,6 double bond. Reaction at the 6,6 linkage would produce two *cis*/*trans* diastereomers and at the 5,6 bond up to four diastereomers. Because of the slowness of the [8 + 2] cycloaddition and by analogy with known examples, we assign structure **3** to the major product. In this case the 6,6 double bond in **2** reacts with the sterically less hindered side of **1**, giving **3** with hydrogen atoms C-3′a and C-1′ in the *cis* configuration. The spatial proximity of 3′a-H and 1′-H was confirmed by NOE experiments. The regioselectivity of the reaction is also supported by semiempirical calculations (MNDO, AM1, PM3).[10] The calculated heats of formation H_f of the possible isomers as well as the length of the bridged single bond length in the C_{60} unit are shown in Table 1.

Cyclovoltammetric and spectroelectrochemical studies[11,12] show that the cyclopentane-annulated fullerene **3** is reduced in four reversible or quasi-reversible steps (Table 2, Fig. 1). The radical anion $\mathbf{3}^{\bullet-}$, dianion $\mathbf{3}^{2-}$, and radical trianion $\mathbf{3}^{\bullet 3-}$ were

Isomer	Method MNDO	AM1	PM3
		H_f [kcal mol^{-1}]	
cis-6,6	851.51	954.75	797.53
cis-6,5	866.69	972.51	815.32
Δ-*cis*-(6,6-6,5)	15.81	17.76	17.79
		d [Å]	
cis-6,6	1.616	1.580	1.586
cis-6,5	1.640	1.623	1.618

Table 2. Half-step potentials determined by cyclic voltammetry for the reduction of C_{60} (**2**) and the C_{60} derivative (**3**) in different solvents.

Potential [mV][a]	Compound and solvent C_{60} in benzene/CH_3CN 10:1	C_{60} in toluene/CH_3CN 8:2	**3** in THF	**3** in toluene/CH_3CN 8:2
$E^{I}_{1/2}$	−990	−1000	−1090	−1120
$E^{II}_{1/2}$	−1370	−1410	−1640	−1510
$E^{III}_{1/2}$	−1900	−1910	−2260	−2080
$E^{IV}_{1/2}$	−2410	−2380	−2710	−2520

[a] Potentials vs. ferrocene/ferrocenium.

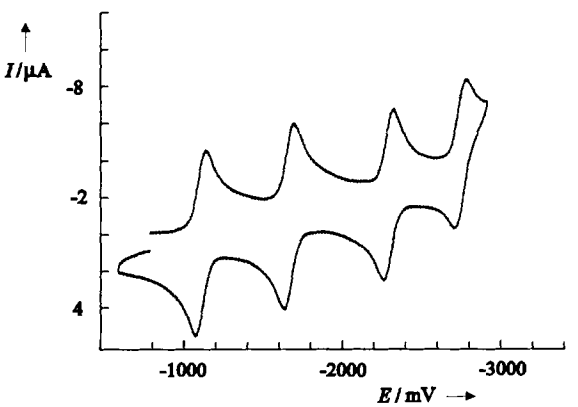

Fig. 1. Cyclic voltammogram of **3** in THF, 0.1 M Bu_4NPF_6, 500 mV s^{-1}; potentials vs. ferrocene/ferrocenium.

clearly identified by UV/VIS/NIR spectroscopy (Fig. 2, Table 3). The reversibility of the reduction steps was confirmed by the isosbestic points. In comparison to the parent compound C_{60} (**2**), compound **3** has a more negative reduction potential for each reduction, in other words, the annulated fullerene derivative **3** is less easily reduced. The longest wavelength bands from the radical anion and radical trianion are the furthest shifted in the NIR region ($\mathbf{3}^{\bullet-}$: 984 nm/1.26 eV; $\mathbf{3}^{\bullet 3-}$: 1342 nm/0.92 eV). In the dianion the lowest energy absorption is at 864 nm/1.43 eV.

This [8 + 2] cycloaddition of buckminsterfullerene C_{60} points out a route to chiral fullerene derivatives containing a tetrahydroazulene unit, making possible the synthesis of fullerenes containing nonalternant substructures with electron-transfer properties. Preliminary studies indicate that the reaction of **3** with triphenylmethylium hexachloroantimonate to give a fullerene tropylium ion proceeds by hydride cleavage. In addition, the cycloheptatriene unit undergoes cycloadditions with 4-methyl-1,2,4-triazol-3,5-diones. We are currently studying C_{60} compounds made from electron-rich fulvenoids and nonfulvenoid π-systems.

Table 3. UV/VIS-NIR data for the radical anion, dianion, and radical trianion of **3** in THF. The lowest energy absorption of C_{60}(**2**) is given for comparison.

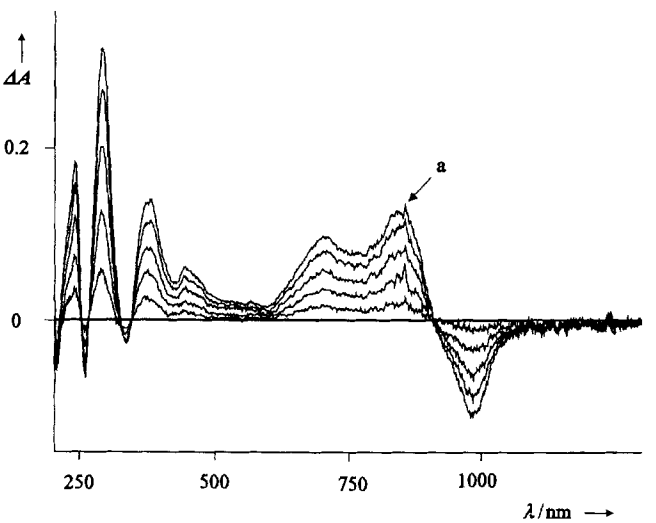

Fig. 2. UV/VIS-NIR potential step difference spectroscopy. Curve a is the spectrum of $\mathbf{3}^{\bullet-}$ subtracted from the spectrum of $\mathbf{3}^{2-}$. The electrochemical uniformity of the conversion of $\mathbf{3}^{\bullet-}$ into $\mathbf{3}^{2-}$ can be seen in the other curves.

Experimental Procedure

8-Methoxyheptafulvene (**1**) (121 mg, 0.9 mmol) was dissolved in 350 mL dry toluene under a nitrogen atmosphere. To this brown solution was added C_{60} (500 mg, 0.7 mmol), and the mixture was stirred for one week at room temperature. The reaction mixture was then concentrated to 50 mL and cooled to 0 °C. This led to precipitation of product, which was isolated by decanting the supernatant, washing with toluene and diethyl ether, and then drying under vacuum (0.01 Torr) at room temperature. This gave 401.4 mg of black-brown powder. The HPLC trace showed C_{60} along with several reaction products, of which the main one was present to >90%. A saturated solution (30 mL) of the crude product in $CHCl_3$ was purified by GPC [7]. The fraction that eluted with a retention time of 30.1 min was chromatographed on a SiO_2 column (3 × 40 cm, toluene/hexane 6:4) under a nitrogen atmosphere to provide pure **3** (17 mg).

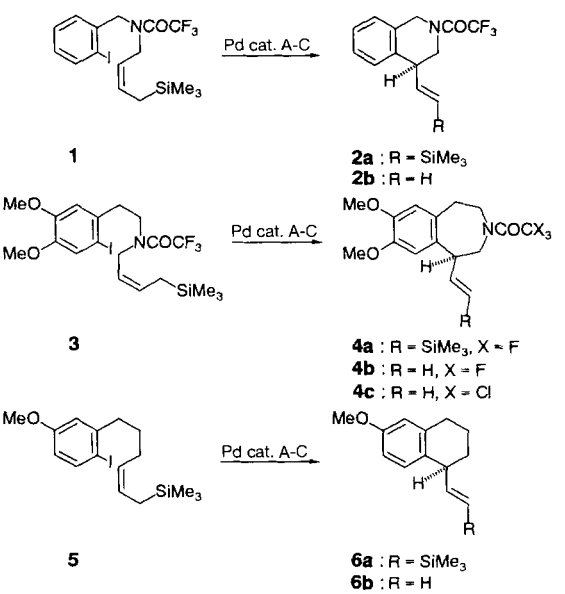
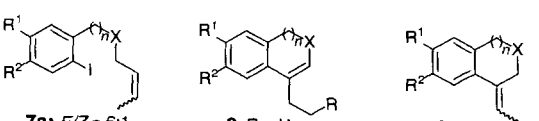
[13] Compound **3** reacts completely within 20 min to produce a very polar species. Treatment of **3** with 4-methyl-3*H*-1,2,4-triazol-3,5-dione gives a mixture of at least three isomers according to the 400 MHz ^{1}H NMR spectrum; only one peak for the molecular ion at *m/z* 968 is seen in the mass spectrum of the reaction mixture.
[14] Dissolved **3** reacts with oxygen.

Regio- and Enantioselective Silane-Terminated Intramolecular Heck Reactions**



Lutz F. Tietze* and Ralph Schimpf

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday



The Pd^0-catalyzed reaction of an aryl or vinyl halide (RX) with an alkene known as the Heck reaction is an important method of C–C bond formation, which has already been used in numerous syntheses of natural products.[1, 2] In addition this reaction is of great significance for the chemical industry. A distinct disadvantage of this C–C bond forming reaction, however, is the frequently low selectivity with regard to the position of the double bond in the product.[2–4] This can be traced back, firstly, to the β-hydride elimination, which occurs in the catalytic cycle, and which can often proceed in different directions; and secondly, to the tendency of the eliminated HPdX species to undergo readdition and subsequently elimination once again.

Thus, the regioselective formation of tertiary sp^3 C centers, which is of importance for the asymmetric Heck reaction, is possible in only a limited number of cases. Enantioselective Heck reactions are therefore currently more or less restricted to cyclic olefins, in which only one direction of elimination is allowed, and to reactions in which quaternary stereogenic centers are formed.[5, 6] We have now been able to demonstrate that tertiary sp^3 centers can be formed in a highly selective manner by using an intramolecular Heck reaction in which the alkene component is an allylsilane.[7] In this way, depending on the reaction conditions, vinyl- or (*E*)-trimethylsilylvinyl-substituted hetero- and carbocycles can be prepared in good yields. Moreover, when (*S*)-2,2'-bis(diphenylphosphino)-1,1'-binaphthyl ((*S*)-BINAP) is used as a ligand, enantioselectivities of up to 90% *ee* can be achieved.

In order to document the significance of the trimethylsilyl group in substrates such as **1**, **3**, and **5** for the direction of

elimination, we have also examined, as a comparison, the Heck reaction of the corresponding compounds **7a–c**, which do not contain a trimethylsilyl group. Three catalyst systems were used: $Pd(OAc)_2/PPh_3/KOAc/NPr_4Br$ (A),[3, 8, 9] $Pd_2(dba)_3/PPh_3/Ag_2O$ (B),[9] and $[Pd_2(dba)_3]$/(*S*)-BINAP/Ag_3PO_4 (C)[6]

(dba = dibenzylidenacetone). The reaction of compound **1** with catalyst system A yielded exclusively the vinyl-substituted 1,2,3,4-tetrahydroisoquinoline **2b** in 81% yield, whereas with catalyst system B a mixture of **2a** and a small amount of **2b** (93:7) was obtained in 69% yield. Comparable selectivity and yields were also obtained in the conversion of **3** into the 2,3,4,5-tetrahydro-1*H*-3-benzazepine derivatives **4a** and **4b**. Double bond isomers such as **8**–**11** could not be detected in any of these reactions (Table 1). Compound **5** showed somewhat different behavior. In this case reaction with catalyst system A gave a mixture of 1,2,3,4-tetrahydronaphthalenes **6a** and **6b** and 3,4-dihydronaphthalene **9c** in 70% yield; on the other hand, the use of catalyst system B led exclusively to **6a** in 60% yield (Table 1).[10]

Table 1. Heck reactions of **1**, **3**, and **5** with catalyst systems A–C.

[a] A: 5 mol% $Pd(OAc)_2$/10 mol% PPh_3/3 equiv KOAc/1 equiv NPr_4Br, dimethylformamide (DMF); B: 2.5 mol% $[Pd_2(dba)_3]$/10 mol% PPh_3/1 equiv Ag_2O, DMF; C: 2.5 mol% $[Pd_2(dba)_3]$/7 mol% (*S*)-BINAP /1 equiv Ag_3PO_4, DMF (**1**, **5**) or dimethylacetamide (**3**). [b] The product mixture was separated by chromatography on silica; for **6a** and **6b** silica doped with $AgNO_3$ (10%) had to be used. The ratio of **6a**, **6b**, and **9c** was determined by ^1H and ^{13}CNMR spectra. [c] $[\alpha]_D^{20} = +70.2$ ($c = 1.0$, $CHCl_3$). [d] $[\alpha]_D^{20} = +44.5$ ($c = 1.0$, $CHCl_3$). [e] $[\alpha]_D^{20} = +94.3$ ($c = 1.0$, $CHCl_3$).

The conversions of **1**, **3**, and **5** with the chiral catalyst system C is naturally of particular interest. The highest enantioselectivity of 90% *ee* was obtained for the cyclization of **5** to give **6b**. Similarly, for the formation of **2b** from **1** and **4b** from **3**, respective selectivities of 72% and 64% *ee* were achieved;[11] **4b** could be obtained in enantiomerically pure form by recrystallization.[12] For the determination of absolute configuration **4b** was converted to the trichloroacetyl derivative **4c**. A crystal structure analysis of this derivative indicated that the stereogenic center has the (*S*) configuration.[13] On the basis of the very similar optical rotations of **2b**, **4b**, and **6b**[12] it was assumed that **2b** and **6b** also have the (*S*) configuration. Remarkably, the vinylsilanes **2a**, **3a** and **6a**, which are formed as side products, display very little optical activity. Isomerization experiments proved that **2a**,**b**, **4a**,**b**, and **6a**,**b** are stable under the reaction conditions. Therefore it must be assumed that the cyclization giving vinyl- and trimethylsilylvinyl-substituted compounds follows a different mechanism, at least when catalyst system C is used. It is also surprising that the directing effect of the silver salt is canceled by addition of (*S*)-BINAP. This effect can be seen by comparison of the product ratios obtained from the conversion of **1**, **3**, and **5** with the catalyst systems B and C (Table 1).

The conversion of **7a**–**c** yielded as expected a more or less inseparable mixture of **2b**, **4b**, and **6b**, and **8a**–**c**, **10a**–**c**, and **11a**–**c**, respectively.[14] Remarkably, in contrast to literature results,[15] the addition of silver salts scarcely improved the selectivity. The reaction of **7a** with catalyst system A provided **2b** and **10a**/**11a** in a ratio of 2.5:1, and with catalyst system B in a ratio of 4.1:1. Similar results were obtained for **7b** and **7c** (for **7b**, **4b**:**10b**/**11b**; A = 1:1; B = 1.4:1; for **7c**, **6b**:**8c**; A = 1.2:1; B = 1.3:1).

A conclusive explanation of the different phenomena, in particular the influence of silver salts on the product distribution in the silane-terminated reactions, is not yet possible; nevertheless, we assume that the presence of a silver salt causes the initially formed aryliodopalladium species **12** to give AgI and an aryl Pd^+ intermediate **13**,[16] which reacts further either via **15** or the silylethyl cation **17** (Scheme 1). Owing to the lack of a nucleophile such as I^-, the intermediate undergoes base-induced elimination of a proton with the formation of **2a**, **4a**, and **6a**, respectively.[17] The formation of the vinyl-substituted cycles **2b**, **4b**, and **6b** can be explained by an inter- or intramolecular nucleophilic attack, for example by I^-, on the trimethylsilyl group in **14**. For the reaction with silver salts in the presence of (*S*)-BINAP another intermediate such as **16** may be assumed (Scheme 1).

Scheme 1. Postulated mechanism for the selective formation of **2a**,**b**, **4a**,**b**, and **6a**,**b** from **1**, **3**, and **5**.

The results indicate that the direction of elimination in the intramolecular Heck reaction can be directed through the use of allylsilanes as alkene components and results in the regioselective formation of a tertiary sp^3 center. In addition, when (*S*)-BINAP is used as a chiral ligand, these centers can also be formed with good enantioselectivity.

Experimental Procedure

To 20 mL of degassed DMF under argon was added $[Pd_2(dba)_3]$ (0.025 mmol) and (*S*)-BINAP (0.07 mmol). The reaction mixture was slowly heated to 50 °C with vigorous stirring to achieve a homogeneous system (ca. 30 min). Finally, Ag_3PO_4 (1.1 mmol) and **1**, **3**, or **5** (1 mmol) were added and the mixture heated to the temperature indicated in Table 1. After the reaction was complete (TLC), the solid residue was filtered off and washed with ether (20 mL). Water (20 mL) was added to the filtrate. The ether phase was separated, the aqueous phase washed twice with ether (2 × 5 mL), and the combined ether phases washed with water (10 mL) and saturated aqueous NaCl solution (10 mL). After drying over $MgSO_4$ and removal of the solvent under vacuum, the crude product was chromatographed on silica (petroleum ether/ether = 100:1 [**6**], 20:1 [**2**]; petroleum ether/ethyl acetate = 4:1 [**4**]).

Effects of Metal-Ion Dopants on the Photocatalytic Reactivity of Quantum-Sized TiO_2 Particles**

Wonyong Choi, Andreas Termin, and Michael R. Hoffmann*

Photocatalytic destruction of chemical compounds in the presence of TiO_2 appears to be a viable process for pollution control.[1] In order to enhance the photocatalytic activity of TiO_2 several investigators have attempted doping with metal ions.[2–8] However, many of these investigations have been focused primarily on the photophysical properties of the doped material and less on the photochemical reactivity.[9–11]

In this communication we report on a systematic survey of the photoreactivities of 21 doped TiO_2 colloids with quantum (Q)-sized particles (transparent particle suspensions). Dopant ions that have an ionic radius similar to that of Ti^{4+} (0.75 Å) were chosen for substitution into the lattice. Their ionic radii[12] are given in Figure 1 along with photoreactivity data. The photoreactivity of each metal-doped TiO_2 system was quantified in terms of $CHCl_3$ oxidation[13] by valence band holes (or trapped holes) [Eq. (a)][14] and CCl_4 reduction[15] by conduction band electrons (or trapped electrons) [Eq. (b)]. In these reactions h_{vb}^+ refers to a valence band hole or a trapped hole, $>OH^\bullet$ to a surface-bound OH radical, and e_{cb}^- to a conduction-band electron or a trapped electron. In our experiments the intrinsic quantum yield for each reaction could be measured precisely since transparent colloidal suspensions, which exhibit negligible light-scattering, were used.

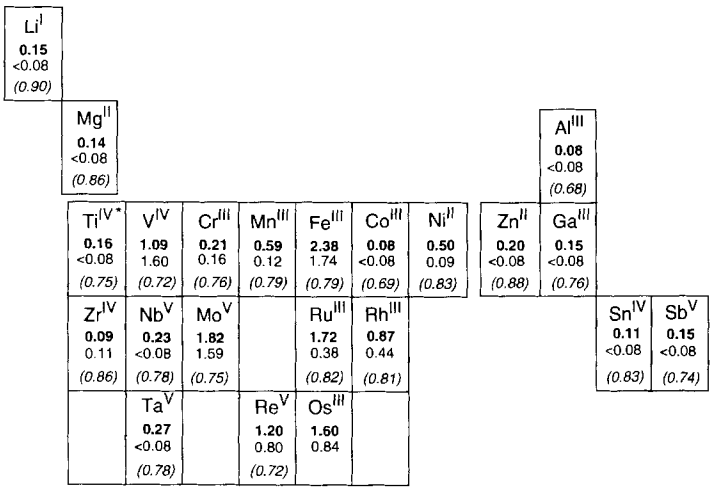

Fig. 1. The metal ions used to dope TiO_2 and their photocatalytic effects. The bold-faced numbers are the quantum yields (%) for the oxidative chloroform degradation ($\Phi_{CHCl_3} = 1/3\{(d[Cl^-]/dt)/I_a\}$) ($I_a$ = absorbed light intensity; the lower numbers are the quantum yields (%) for Cl^- production from the reductive dechlorination of carbon tetrachloride ($\theta_{CCl_4/Cl^-} = (d[Cl^-]/dt)/I_a$). The numbers in the parentheses are the ionic radii (Å) [12] for the metal ion with coordination number 6. All dopant concentrations are 0.5 atom% except Mo^V (0.1%). Ti^{IV}* refers to the undoped TiO_2 (see Experimental Procedure for details).

$$CHCl_3 + h_{vb}^+ (\text{or } >OH^\bullet) \rightarrow H^+ (\text{or } H_2O) + CCl_3^\bullet \quad \text{(a)}$$

$$CCl_4 + e_{cb}^- \longrightarrow Cl^- + CCl_3^\bullet \quad \text{(b)}$$

The measured photoreactivities are summarized in Figure 1 for all of the samples in terms of the quantum yields for $CHCl_3$ oxidation and for CCl_4 reduction. For the majority of dopants the most efficient concentration was 0.5 atom%. However, Mo^V showed a maximum photoreactivity at a doping level of 0.1 atom%. All the dopant concentrations mentioned here are nominal concentrations based upon the assumption of quantitative incorporation of the dopant. The two sets of quantum yields presented in Figure 1 are plotted against each other in Figure 2. Several dopants increased the photoreactivity for the $CHCl_3$ oxidation significantly compared with undoped TiO_2 colloids with Q-sized particles: Fe^{III} (15-fold), Mo^V (11-fold), Ru^{III} (11-fold), Os^{III} (10-fold), Re^V (7.5-fold), V^{IV} (7-fold), and Rh^{III} (5-fold).

Metal-ion dopants may influence the photoreactivity of TiO_2 by acting as electron (or hole) traps and by altering the electron/hole recombination rate.[9, 16] The general correlation between

[**] This research was supported by the Advanced Research Projects Agency and the Office of Naval Research (N0014-92-J-1901).

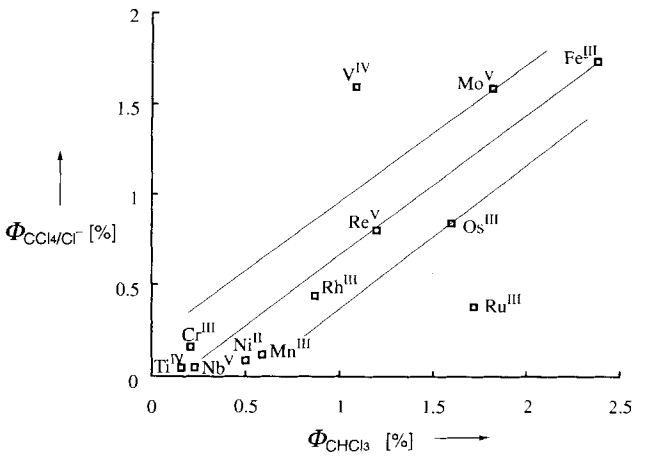

Fig. 2. Correlation plot between the oxidation (chloroform degradation) quantum yield (θ_{CHCl_3}) and the reduction (dechlorination of carbon tetrachloride) quantum yield ($\theta_{CCl_4\text{-}Cl^-}$) from the data of Fig. 1. Some dopants, which show little effect on the photoreactivity, are omitted for clarity. The straight lines are drawn only as a visual guide.

the two quantum yields in Figure 2 suggests that an altered recombination rate influences the interfacial charge transfer of both electrons and holes to a similar extent regardless of the nature of the dopant (i.e. electron trap or hole trap). The significant deviation of V^{IV} and Ru^{III} from the apparent linear correlation indicates that they may act as irreversible hole and electron traps, respectively, and thus prevent the trapped charge carriers from migrating to the solid–solution interface. This irreversibility may arise, in part, from the stable, closed-shell electron configuration of V^{V} (d^0) and the partly filled, low-spin configuration of Ru^{II} (t_{2g}^6 with octahedral coordination). Thus, all of the dopants with closed-shell configurations—Li^{I}, Mg^{II}, Al^{III}, Zn^{II}, Ga^{III}, Zr^{IV}, Nb^{V}, Sn^{IV}, Sb^{V}, and Ta^{V}—have little effect on the observed photoreactivity of TiO_2.

According to the energy level diagram for dopants suggested by Mizushima et al.,[17] V^{IV}, Mn^{III}, and Co^{III} can act as both hole and electron traps, while Fe^{III}, Cr^{III}, and Ni^{II} can serve only as hole traps. However, the energy levels given by Mizushima et al.[17] do not provide a unifying explanation that is consistent with our observations. Even though both Fe^{III} and Cr^{III} have similar energy levels in the TiO_2 lattice (0.2–0.4 eV above the valence band edge), their efficiencies as dopants are substantially different. This suggests that the different electronic configurations (d^5 vs. d^3) may be responsible for the observed photoreactivities. It is interesting to note that all the dopants with d^5 (Fe^{III}, Ru^{III}, and Os^{III}) and d^1 configurations (V^{IV} and Mo^{V}) enhanced the photoreactivity for both oxidation and reduction.

The photoreactivity of doped TiO_2 appears to be a complex function of the dopant concentration, the energy level of dopants within the TiO_2 lattice, their d-electronic configurations, their oxidation states, and the type of defects (substitutional or interstitial) in the host lattice. Some attempts have been made to correlate dopant photoactivity with a simple parameter such as the oxidation state for several dopants.[8, 18] However, we have shown that this simple explanation may be inadequate. In particular the d-electronic configuration and the actual energy level of dopants within the lattice seem to have a significant impact on photoactivity. A more detailed study of the effects of dopants on photoactivity in Q-sized semiconductors is in progress. In conclusion, we feel that the periodic chart of the dopant effects presented here may serve as a useful guide for those who study doping effects of photocatalysts.

Experimental Procedure

Colloid synthesis and characterization: Colloidal Q-sized TiO_2 particles were prepared from the hydrolysis of titanium tetraisopropoxide at pH 1.5 (adjusted with nitric acid) and 5 °C as described previously [19]. The solvent in the resulting transparent colloidal suspension was evaporated to give powders with Q-sized particles. The particle diameters were determined to be in the range of 2–4 nm by transmission electron microscopy (TEM). X-ray diffraction (XRD) and Raman spectroscopy analysis showed that the colloidal TiO_2 was exclusively in the anatase form. These suspensions of Q-sized TiO_2 particles showed an equivalent band-gap transition at 360 nm. The doped systems were prepared according to the above procedure with added metal salts [20] to give a doping level between 0.1 to 3 atom %. Absorption spectra of some doped colloids (e.g. with Fe^{III}, V^{IV}, and Mn^{III}) showed a red-shift in the band-gap transition as we increased the dopant concentration, which verified the incorporation of the doping metal ions into the TiO_2 nanoparticles. In the unique case of Ru^{III} incorporated into the TiO_2 lattice, a strong resolved absorption band centered at 437 nm was observed. No information about the homogeneity of the dopants in the particles was available owing to analytical difficulties.

Photoreactivity measurement: Both reactions (a) and (b) were followed by measuring the Cl^- production after 1 h of UV irradiation with a chloride ion selective electrode. Cl^- production was linear over this time period. Reaction (a) was performed at pH 11.0 ± 0.2 with $[CHCl_3]_0 = 3.15$ mM, and reaction (b) at pH 2.8 ± 0.1 with $[CCl_4]_0 = 5.1$ mM and $[CH_3OH]_0 = 0.1$ M. In each case [TiO] = 0.5 g L^{-1}, $[O_2]_{diss} \approx 0.2$ mM, $I_0 = 1.28 \times 10^{-4}$ Einstein L^{-1} min^{-1} (at 320 nm, full width at half-maximum 15 nm) with a total reactor volume of 35 mL. The light intensity measurement was performed by chemical actinometry using (*E*)-α-(2,5-dimethyl-3-furylethylidene)(isopropylidene)succinic anhydride (Aberchrome 540). [21]

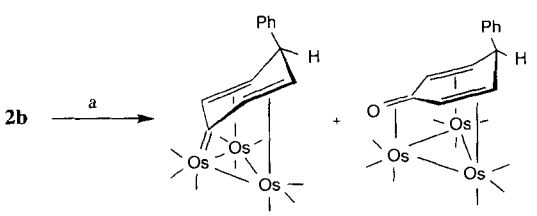
A Triosmium Cluster Complex with a Carbene Ligand in an Unusual Coordination Mode**

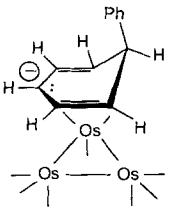
Andrew J. Edwards, Mark A. Gallop,
Brian F. G. Johnson, Jochem U. Köhler, Jack Lewis,*
and Paul R. Raithby



Transition metal clusters which contain π-arene ligands where the arene ligands adopt a face-capping bonding mode are interesting as model compounds for chemisorption of arenes to metal surfaces.[1] This coordination mode was first established for the octahedral Ru_6 carbido cluster $[Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_6)(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)]$[2] and for the trinuclear cluster compounds $[M_3(CO)_9(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)]$ (M = Os[2] (**1**), Ru[3]), and $[(CpCo)_3(\mu_3\text{-arene})]$.[4] Until now little was known about the reactivity of these face-capping arene ligands. The triosmium benzene cluster **1** reacts with carbanions (PhLi, MeLi) and with $LiBHEt_3$ (or $LiBDEt_3$) to form an *exo*-addition product of an anionic cluster (**2a–d**) with a triply bridging cyclohexadienyl ligand (Scheme 1).[5]

1

Scheme 1. Reaction of **1** with carbanions. a) $+R^-$, THF, −78 °C; b) $+[N(PPh_3)_2]Cl$, *i*PrOH.



In the case of **2a** hydrogen can be abstracted as a hydride by the triphenylmethyl (trityl) cation to give cleanly the original compound **1**. Labeling with deuterium (**2d**) shows that there is a stereospecific abstraction of the *exo*-hydrogen.[5] Although in the most cases of mononuclear complexes the *exo*-hydrogen is abstracted as well, there are a few reports of *endo*-hydrogen removal from coordinated π-hydrocarbons by the trityl cation.[6] The abstraction of the *endo*-hydrogen from the anionic μ_3-cyclohexadienyl complexes (**2b, c**) would lead to face-capping arene clusters $[Os_3(CO)_9(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_5R)]$ (R = Ph, Me). However, after reaction at −78 °C between **2b** and the trityl cation, and after purification with thin-layer chromatography (TLC), two different products have been obtained: an orange triosmium carbene complex **3** and an orange triosmium cyclohexadienone complex **4** (Scheme 2).

3 **4**

Scheme 2. Reaction of **2b** with the trityl cation. a) $+Ph_3C^+BF_4^-$, CH_2Cl_2, −78 °C.

It seems that an abstraction of the *endo*-hydride by the sterically demanding trityl cation is not possible, because of the phenyl group in *exo*-position and the CO groups in the equatorial positions on the osmium core. From the resonance structure of **2b** (Scheme 3) it is obvious that an abstraction of the hydride in position 4 results in the carbene structure, and so provides an alternative and novel form of bonding of an isomer of benzene to a transition metal cluster.

2b

Scheme 3. Resonance structure of **2b**.

This carbene carbon is coordinated to the osmium metal core in an unusual bonding mode which has not been observed previously. The structure of **3** has been established by a X-ray analysis (Fig. 1).[7] The distance between the carbene carbon, C12, and Os3 is 2.05(2) Å, which is in the range of usual distances of carbene carbons of the Fischer type coordinated to triosmium clusters (between 1.88(6) Å and 2.14(1) Å).[8] However, this carbene carbon lies above the osmium triangle (as in the face-capping mode), and it is possible that there is a weak interaction to both of the other osmium atoms (Os2–C12 2.582 Å; Os1–C12 2.55(2) Å). The formal double bonds of the ring are also coordinated to these osmium atoms. The six-membered ring is still in a face-capping position ($\mu_3\text{-}\eta^2\text{:}\eta^1\text{:}\eta^2$), but it has a "chairlike" conformation because the carbene carbon has moved out of the plane of C13, C14, C16, and C11 towards the Os3. Nevertheless, the carbene ligand seems to be "side-on" coordinated rather than in the usual end-on way. The second product **4** of the reaction was analyzed by X-ray diffraction and its structure is shown in Figure 2.[9]

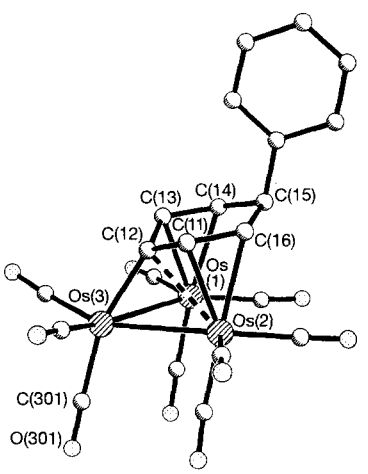


Fig. 1. Crystal structure of **3**: Selected bond lengths [Å]: Os3-C12 2.05(2), Os2-C12 2.58(2), Os1-C12 2.55(2), Os1-C13 2.21(2), Os1-C14 2.33(2), Os2-C11 2.22(2), Os2-C16 2.36(2), C12-C11 1.44(3), C12-C13 1.48(3), C13-C14 1.37(3), C11-C16 1.35(3), C14-C15 1.52(3), C16-C15 1.54(3), Os3-C301 1.93(3), C301-O301 1.17(3).

A side-on coordination of keto functions has been observed rarely. To our knowledge this is the first cyclohexadienone ligand coordinated in this way to a triosmium cluster, and may be viewed as the stabilization of a keto form of an enol of a phenolic group. The cyclohexadienone moiety of the ligand is nearly parallel to and lies above the osmium core. The C–O distance of 1.27(2) Å is between a C=O bond (1.22 Å) and a C–O bond (1.42 Å)[10] and seems to be shorter than distances in η^2-aldehyde/keto ligands of mononuclear complexes.[11] An absorption band in the IR spectrum of **4** at 1515 cm^{-1} (the only addi-

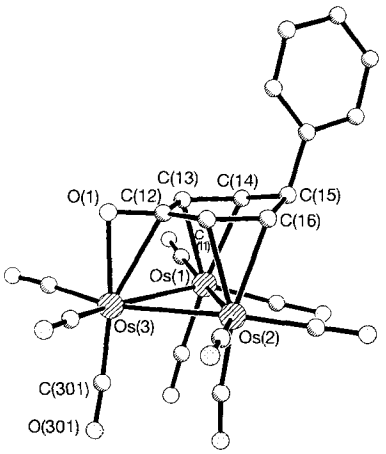

Fig. 2. Crystal structure of **4**: Selected bond lengths [Å]: O1-C12 1.27(2), Os3-O1 2.208(10), Os3-C12 2.45(2), Os1-C13 2.25(2), Os1-C14 2.31(2), Os2-C11 2.28(2), Os2-C16 2.32(2), C12-C11 1.46(2), C12-C13 1.45(2), C13-C14 1.44(2), C11-C16 1.39(2), C14-C15 1.50(2), C16-C15 1.52(2), Os3-C301 1.85(2), C301-O301 1.16(2).

tional band compared to the carbene complex **3**) is assigned to a C=O vibration. This band appears at higher frequencies than those of complexes described in the literature. This is in accordance with the relatively short C–O distance.[11]

There is no hint from the spectroscopic data (IR, NMR) that **4** is present in the reaction solution. Furthermore, the carbene complex **3** is stable in air, even if dissolved in CH_2Cl_2. There is no conversion, when the solution is stored under air for several days. However, if triethylamine is added to this solution or **3** is dissolved in methanol, a fast conversion to **4** takes place (within minutes). We suppose that in the first step the carbene carbon is attacked by a Lewis base, and in the second step there is a reaction with oxygen from the air. This reaction does not proceed under an atmosphere of nitrogen.

During the purification by TLC most probably free electron pairs of silanol and siloxane groups on the surface of the silica gel act as Lewis bases and cause a partial conversion of **3** to **4**. In a related reaction the electrophilic methylidene complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(=CH_2)]^+PF_6^-$ reacts with iodoso benzene ($C_6H_5I^+\text{-}O^-$, an oxygen nucleophile) to form a η^2-formaldehyde complex.[12]

Experimental Procedure

A yellow solution of **2b** (100 mg) in CH_2Cl_2 (10 mL) was cooled to −78 °C and treated dropwise with a solution of $[Ph_3C][BF_4]$ (25 mg, 1.2 mol equiv) in CH_2Cl_2 (3 mL). The color changed to orange. The solution was warmed up to room temperature, and the reaction solution purified by thin layer chromatography (silica gel). Elution with CH_2Cl_2 (40%)/hexane (60%) afforded the major product **3** (high R_f value; 38 mg (60%) yield), and the minor product **4** (low R_f; 8 mg (13%) yield) as orange, air-stable products.

3: ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 7.31–7.42 (m, 5H, Ph), 5.04 (d, ^3J(H, H) = 6.4 Hz, 2H; CH), 4.51 (t, ^3J(H, H) = 2.1 Hz, 1H; CHPh), 3.08 (dd, 2H; CH); ^{13}C {^{1}H} NMR (62.9 MHz, CD_2Cl_2): δ = 206.4 (1C; carbene-C), 190.8 (6C; CO), 177.7 (3C; CO), 144.6 (1C; ipso-C), 129.4 (2C; Ph), 128.5 (1C; Ph), 126.8 (2C; Ph), 54.8 (1C), 52.8 (2C), 39.9 (2C); IR (CH_2Cl_2): $\tilde{\nu}$[cm^{-1}] = 2080(m), 2037(vs), 2031(vs), 2006(m), 1992(m), 1969(w); MS (FAB): *m/z* 982; correct elemental analysis.

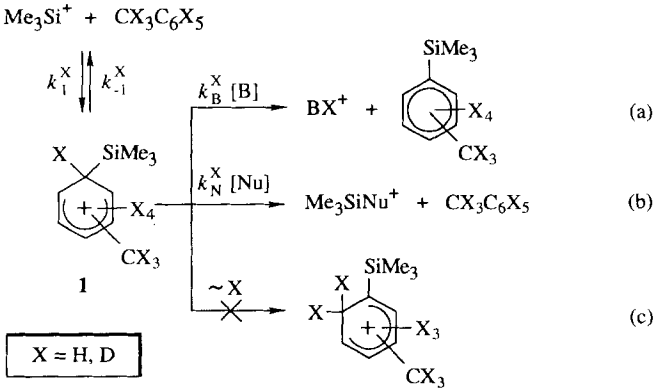
Long-Lived *ipso*-Silylated *p*-Toluenium Ions: Evidence from a Kinetic Isotope Effect**



Maria Elisa Crestoni and Simonetta Fornarini*

A recent report[1] in the long-standing search for isolable silyl cations in condensed phase described the crystal structure of an alleged Et_3Si^+ ion, remote from the Ph_4B^- counter ion but within approximate bonding distance (2.18 Å) from the *p*-C atom of a "solvent" toluene molecule. The basis for this interpretation has been questioned after model ab initio calculations

favored an $[Et_3Si\text{-toluene}]^+$ σ complex,[2] which emphasizes that the attainment of a free silylium ion is a difficult problem to tackle in condensed phase, despite promising advances.[3] It is also our view, based on a fairly extensive body of experimental data recently made available on the interaction of Me_3Si^+ ions with arenes in the gas phase,[4-8] that the Et_3Si^+–toluene pair is best interpreted as a σ complex. In fact, the gas-phase addition of Me_3Si^+ to toluene, previously observed by high-pressure mass spectrometry,[4] leads to a σ complex, rather than to the originally postulated π complex. We now present positive evidence for the existence of long-lived σ-complex intermediates **1**, that is, silyl-substituted toluene protonated at the silicon-bearing ring carbon, displaying a primary hydrogen kinetic isotope effect (KIE) to deprotonation. This finding follows our studies on aromatic silylation by Me_3Si^+ ions in the gas phase.[7-9] Direct aromatic trimethylsilylation has in fact been accomplished for the first time in the gas phase by the radiolytic technique,[10] operating at about 1 atm, once it was realized that a highly efficient and specific base was necessary to deprotonate the *ipso* arenium ion **1**, in order to compete with an easy desilylation process.[8] In the absence of a suitable base (a nitrogen base, preferably sterically hindered), desilylation of **1** occurs by assistance of trace oxygen nucleophiles. In the fairly detailed mechanistic picture thus obtained, a noteworthy feature is the relative stability of **1** towards isomerization by H-shifts to adjacent ring positions (c), a process normally occurring in other arenium ions, and therefore it undergoes exclusively deprotonation (a) or desilylation (b).

This behavior follows from the significantly high basicity of the silyl-substituted position, which is responsible, inter alia, for the facile *ipso* attack by electrophilic agents and for the acid-induced desilylation processes common in solution as well as in the gas phase.[11] The persistence of the *ipso* hydrogen at the silylated position emerged from the reaction of Me_3Si^+ with selectively deuterated toluenes, which showed practically complete loss of the H or D atom originally bound to the substituted carbon.[9] In order to substantiate this finding and to see if and to what extent the deprotonation step might affect the overall electrophilic substitution sequence, we studied the competitive reaction of PhMe and $[D_8]$PhMe with gaseous Me_3Si^+ ions and observed a primary KIE (Table 1). The overall k_H/k_D values reported in Table 1 show a dependence of the proton affinity (PA)[12] on the structural features and, in certain cases, on the concentration of the added base. The strongest base used, $Me_2N(CH_2)_2NMe_2$, gives a negligible primary KIE, which, however, tends to increase with decreasing PA up to a value of about 4 in the case of NH_3. Ammonia is the closest in proton

Table 1. Gas-phase trimethylsilylation of PhMe/$[D_8]$PhMe by free Me_3Si^+ ions [a].

[a] All gaseous systems contained PhMe/$[D_8]$PhMe (2–3 Torr), Me_4Si (20 Torr), CH_4 (630–680 Torr) and a radical scavenger (O_2, 10 Torr). [b] Data from Ref. [12a]. In a revised PA scale [12b] the proton affinity of NH_3 is set at 203.5 kcal mol^{-1} and some amines are about 2 kcal mol^{-1} more basic than in Ref. [12a]. [c] Normalized undeuterated to deuterated product ratio: $k_H/k_D = ([CH_3C_6H_4SiMe_3]/[CD_3C_6D_4SiMe_3]) \times ([D_8]PhMe]/PhMe])$. Values affected by approximately ±10% error. [d] ±2% error.

affinity to $Me_3SiC_6H_4Me$, the conjugate base of **1**, whose PA may be estimated at 200 kcal mol^{-1}.[4, 12] Unfortunately, the PA range of the bases used can not be extended further downward because this would require oxygenated compounds, which do not yield neutral silylated products, attacking preferably the silyl group [reaction (b)] rather than the proton [reaction (a)]. Such PA dependence is expected for a primary KIE in the hydron transfer from **1** to the base B (k_B^H/k_B^D).[13] A discontinuity in the trend of the ratio k_H/k_D with PA(B) occurs for $(iPr)_2NEt$, a severely hindered base. Again, the observation of a significant primary KIE involving hindered bases, for example, 2,6-dialkylpyridines, is a common finding, both in the gas phase and in solution.[13-14] Although the k_H/k_D data appear to include a primary KIE, k_B^H/k_B^D, as a major factor, they do not result from a rate-determining hydron transfer, representing instead an example of a hidden isotope effect.[13a, c] In fact, the silylation step, k_1, is by no means reversible under the present experimental conditions. Even if k_1 approached the collision limit of 10^{-9} cm^3 s^{-1}, the known K_1[4] would give $k_{-1} = 0.15$ s^{-1}, vanishingly small in comparison with a $k_B[B]$ term of about 10^8 s^{-1}, typical of collision-controlled deprotonation at base pressures around 1 Torr. The observed k_H/k_D ratio reflects instead the competition of the k_B step, which involves the isotopically labeled hydrogen, in which a common step leads to different products (k_N).[15] Neglecting k_{-1}, the k_H/k_D values reflect the k_B^H/k_B^D ratios [Eq. (1)], modified by two factors.[16] The first (k_1^H/k_1^D)

$$\frac{k_H}{k_D} = \frac{k_A^H}{k_1^D} \times \frac{k_B^H}{k_B^D} \times \frac{(k_N^D[Nu] + k_B^D[B])}{(k_N^H[Nu] + k_B^H[B])} \qquad (1)$$

should include a small inverse secondary KIE due to isotopic substitution at the *ipso*-carbon undergoing change of hybridization, besides higher order KIEs due to H/D substitution of hydrogen atoms farther from reaction site. Similar secondary KIEs may affect k_N^H/k_B^H. Moreover, the k_B^H/k_B^D ratio itself should contain secondary KIE components. To assess the contribution from such secondary KIEs, the silylation of *m*-$CH_3C_6H_4D$ (*m*-**D**) was performed. The *meta*-silylated product arises from attack at either of two *meta* positions, differing in the hydrogen isotope (Scheme 1).

Scheme 1. *meta*-Silylation of *m*-[D_1]toluene with Me_3Si^+.

Whereas the kinetic scheme is essentially the same as for the competition between unlabeled and perdeuterated toluene, the degree of isotopic substitution and hence the incursion of secondary KIEs is vastly reduced. The values of the ratio of deuterated to undeuterated *m*-trimethylsilyl-toluene products, which reflect k_H/k_D, of 2.0 (0.7 Torr pyridine) and 1.5 (0.8 Torr Et_3N) are close to the 2.3 and 1.3–1.4 values obtained for the competition between PhMe and [D_8]PhMe, within the combined error limits, and show that secondary KIEs due to β or more remote hydrogens are minor.

The dependence of k_H/k_D on the base concentration predicted by Eq. (1) does not clearly emerge from Table 1. This may be explained by the narrow concentration range of B explored, which is limited upward by the vanishing amounts of products formed in the presence of excess amine, which interceps Me_3Si^+ or even its precursor ions. On the other hand, the weight of the k_N[Nu] term can not be reduced, as oxygen-containing nucleophiles are unavoidably present as trace impurities in the bulk gas or formed by its radiolysis.[17] A second reason may be traced to the role which may be played by the base itself, especially if sterically unhindered, in the desilylation.[18] It is significant in this respect that when the base cannot conceivably act as a nucleophile, as is the case of $(iPr)_2NEt$, a decrease of k_H/k_D at the highest base concentration distinctly emerges above the error limits. Such base-concentration dependence supports a two-step pathway for the overall silylation reaction via the discrete intermediate **1**.[19]

It follows from the above discussion that the k_H/k_D ratios summarized in Table 1, including the highest value of about 4, represent a lower limit for the k_B^H/k_B^D ratio. Such sizeable KIEs, relatively little affected by secondary contributions, are associated with the deprotonation of **1** and are allowed to manifest themselves by the competition between deprotonation by B and desilylation by Nu (and B). They represent a positive confirmation of the stability of **1** and of the role played by **1** in the cationic aromatic silylation in the gas phase. Finally the ready availability of silylium ions in the gas phase[20] makes the gaseous environment the ideal medium in which their reactivity can be explored, in marked contrast to the strenuous efforts required to obtain isolable silylium ions in the condensed state,[21] and provides the experimental counterpart to theoretical calculations.

Experimental Procedure

The gaseous samples containing accurately weighted amounts of PhMe/[D_8]PhMe were prepared in 135 mL glass vessels by standard vacuum line procedures with research grade gases (Mathesen) and irradiated by ^{60}Co emission in a 220 Gammacell (Nuclear Canada Ltd.) at 35 °C with a total dose of 1×10^4 Gy, which corresponds to less than 1% substrate conversion into silylated toluenes (radiochemical yield ranged from 1×10^{-3} to 0.1 μmol J^{-1}). The radiolytic product mixture was recovered by repeated freeze–thaw cycles with ethyl acetate as solvent. The end solution was analyzed by GLC-MS (60-m long, 0.25 mm i.d., fused silica SPB-20 column (Supelco) coated with a 0.25 μm film of 20% diphenyl – 80% dimethylpolysiloxane; Hewlett Packard 5890 A; Model 5970 B mass selective detector). The relative amounts of isotopomeric products were obtained from the integrated areas of the $[M]^+$ and $[M - CH_3]^+$ ion intensities, which were acquired both in total-ion and in single-ion monitoring mode.

[15] The KIE observed in elimination reactions from β-substituted silanes derived from a similar branching: S. L. Jones, C. J. M. Stirling, *J. Chem. Soc. Chem. Commun.* **1988**, 1153.
[16] Equation (1) is derived by assuming the steady-state approximation is valid for **1**, and relying on the nearly constant concentrations of $CX_3C_6X_5$, added base (B), and nucleophiles (Nu) in the radiolytic experiments, which typically run to less than 1% substrate conversion, and on the fast deprotonation of **1** (k_B^X[B]), which has to compete with a highly efficient desilylation process (k_N^X[Nu]). See Refs. [4] and [7].
[17] Unfortunately, the branching of reactions (a) and (b) can not be obtained from our radiolysis experiments based on the analysis of neutral final products, since direct silylation of Nu by Me_3Si^+ yields the same products as reaction (b). Thus, a quantitative evaluation of the relative weight of the individual terms of Eq. (1) is prevented, but this does not affect the qualitative conclusions drawn.
[18] According to Equation (1) a decrease of k_H/k_D with increasing base concentration [B] is expected (since when k_B[B] ≫ k_N[Nu], Eq. 1 reduces to $\frac{k_H}{k_D} = \frac{k_1^H}{k_1^D}$). However, if the desilylating reactivity of B overwhelms that of Nu within the explored concentration range, no dependence of k_H/k_D on concentration of B would emerge. Equation (1) would in fact reduce to $k_H/k_D = (k_1^H/k_1^D) \times (k_B^H/k_B^D) \times ((k_B^D + k_{NB}^D)/(k_B^H + k_{NB}^H))$, where k_{NB}^N and k_{NB}^D refer to desilylation by the base B of unlabeled and deuterated **1**, respectively.

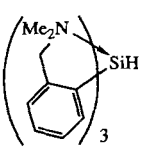
Structure of a (4 + 4)-Coordinate Silicon Compound, a Precursor of Hypercoordinate Silyl Mono- and Dications

Francis Carré, Claude Chuit, Robert J. P. Corriu,* Ahmad Mehdi, and Catherine Reyé



The silicon atom in hydrosilanes is able to expand its coordination number to become penta-[1] (as in compound **1**) or hexacoordinate (as in compound **2**)[2] by formation of donor–acceptor interactions. Moreover, "heptacoordination" at silicon has also been inferred[3] from the molecular structure of silanes **3** and **4**, established by X-ray diffraction analysis. In both compounds, three weak Si ← N interactions are displayed giving rise to the tricapped tetrahedron geometry. In a continuation of our study on silicon species with unusual coordination numbers, we investigated the geometry of organosilanes bearing the potentially bis-chelating ligand **A**[4, 5] and now report the synthesis and the structural determination of a silane with two hydrogen substituents and two such ligands. This compound was found to be a precursor of a silyl cation and by an unexpected reaction, of a silyl dication.

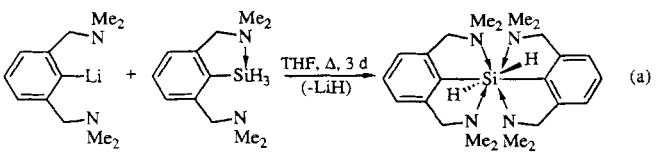
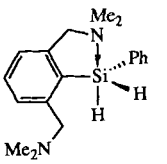
2

3



4

A



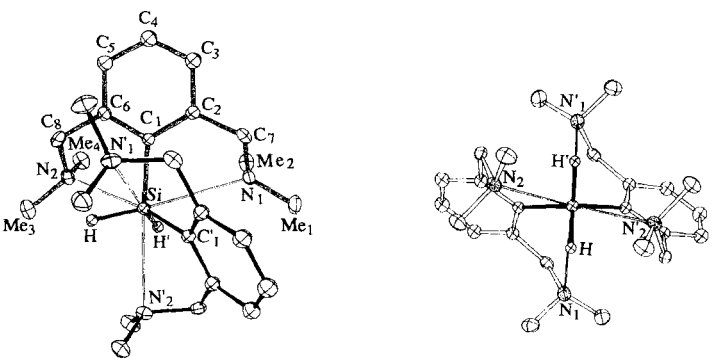
The reactions between the silane **5** and an equimolar amount of 2,6-bis(dimethylaminomethyl)phenyllithium[6] results in the formation of the silane **6** in 68% yield [Eq. (a)]. The equivalence

(a)

5 **6**

of all the NMe_2 groups at 20 °C is shown by the singlet observed for these groups in the ^1H NMR spectrum. A single signal is also observed for all the CH_2N protons. The ^{29}Si NMR chemical shift ($\delta = -61.6$) is upfield of the signal of the silane **7**[7] with only one ligand **A** ($\delta = -51.5$). To establish the nature of the interaction between the NMe_2 groups and the silicon atom a single crystal X-ray diffraction study[8] was performed on **6**. The ORTEP view (Fig. 1) reveals a C_2 axis passing through the silicon atom and bisecting the H-Si-H′ and C1-Si-C′1 angles. The basic tetrahedral structure around the Si atom is maintained, the lone pairs of the NMe_2 groups being directed towards the Si center. The Si–N1 distance, *trans* to the Si–H bond is 3.117 Å, and the N1-Si-H angle 177.5°, whereas the Si–N2 distance *trans* to the Si-C′1 bond is shorter (2.895 Å), and the N2-Si-C′1 angle smaller (168.5°). Thus the molecule can be described as a tetracapped tetrahedron, in which the Si atom is (4 + 4)-coordinated. Interestingly, in contrast with the reported structure of complexes bearing the ligand **A**,[9] the two nitrogen atoms are not in a *trans* arrangement as shown in Figure 1 (right); the N1-Si-N2 angle is 116.7(1)°.

7



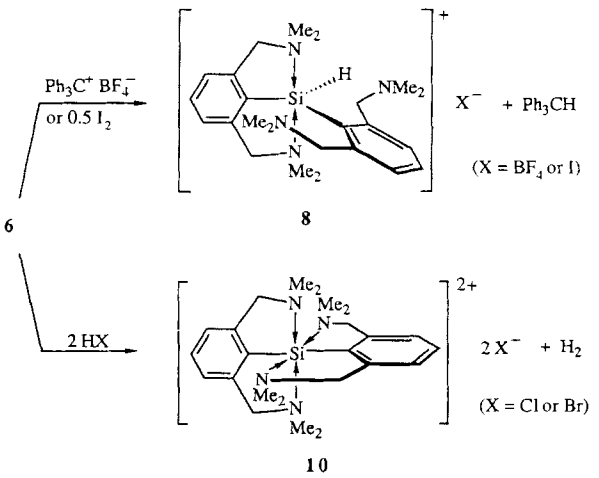


Fig. 1. Left: Crystal structure of **6** (ORTEP representation; hydrogen atoms are omitted for clarity. Ellipsoids are at the 10% probability level). Important bond lengths [Å]: Si–H 1.435(36), Si–C1 1.901(5), Si–N1 3.117(6), Si–N2 2.895(5). Selected angles [°]: H-Si-H′ 114.8 (2.9), C1-Si-C′1 113.2(3), C1-Si-H 108.7 (1.5), C1-Si-H′ 105.8 (1.5). Right: The molecular structure of **6** viewed along its C_2 axis. (Ellipsoids are at the 10% probability level.)

The equivalence of the four NMe_2 groups observed by ^1H NMR at room temperature can be explained by dynamic coordination: the NMe_2 groups displace each other rapidly on the ^1H NMR time scale.

In spite of the steric hindrance around the silicon atom, treatment of the silane **6** with 1 equiv of $Ph_3C^+BF_4^-$ in CH_2Cl_2 solution results in a high yield of Ph_3CH and a silicon-containing species that was identified as the ionic compound **8**. The same silyl cation is obtained by reaction of **6** with 1/2 equiv of I_2 (Scheme 1).

The ^1H NMR spectrum of **8** is reported in Figure 2. The signal at $\delta = 5.07$ was assigned to the SiH protons. By comparison with the ^1H NMR spectrum of the silanium ("siliconium") ion **9**,[7] the two singlets of equal intensity (at $\delta = 2.18$ and 2.65) were assigned to the two NMe_2 groups of one ligand **A**. These two units are magnetically equivalent and exhibit two diastereotopic methyl groups as the result of the coordination of the two nitrogen atoms to the silicon atom. Moreover, a well-defined AB pattern is observed at $\delta = 4.13$ for the corresponding two CH_2N groups. The singlets at $\delta = 1.47$ and 2.25 were assigned to the other two NMe_2 groups, the CH_2N protons appearing as singlets at $\delta = 2.83$ and $\delta = 3.50$, respectively. The existence of

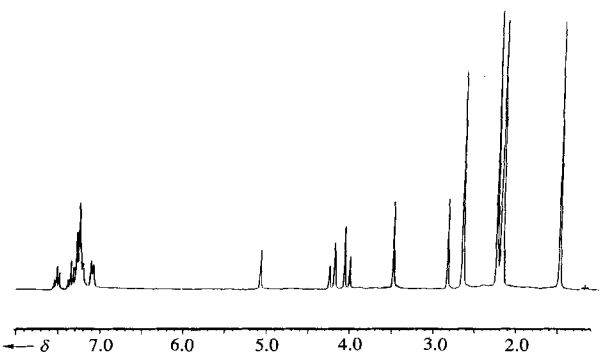
Scheme 1.



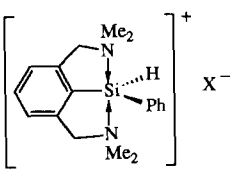


Fig. 2. ^{1}H NMR spectrum ($CDCl_3$, 250 MHz) of **8** at room temperature.

three types of NMe_2 groups was confirmed by ^{15}N NMR spectroscopy. Since the ^{15}N NMR shift of **9** is at $\delta = -337$, the signal at $\delta = -340.4$ is assigned to the two chelating NMe_2 groups, and the other two upfield signals ($\delta = -347.2$ and -348.7) are attributed to the two noncoordinated NMe_2 groups. Thus it can be concluded that cation **8** is pentacoordinated. Moreover, the magnetic nonequivalence of the two noncoordinated NMe_2 groups shown in the ^{1}H NMR spectrum of **8** means that rotation about the corresponding Si–aryl bond is hindered. In the ^{1}H-coupled ^{29}Si NMR spectrum of **8**, a doublet is observed at $\delta = -29$ [$^1J_{Si,H} = 283$ Hz], which is downfield with respect to the corresponding chemical shift observed for the starting silane **6** [$\delta = -61.6$ (t, $^1J_{Si,H} = 213$ Hz)], but in the same range as that for **9** [$\delta = -29.7$, d, $^1J_{Si,H} = 280$ Hz].[7]

9

The IR spectrum of **8** in $CHCl_3$ shows an absorption band for the ν(Si–H) stretch at 2248 cm^{-1} that is at a higher frequency than that for **6** (2174 cm^{-1}) and in the range of other Si–H stretches observed for silyl cations.[7, 10] The positive-ion FAB mass spectrum of **8** shows the parent ion at m/z 411; this corresponds to the mass of the silyl cation.

More surprisingly, the reaction of **6** with two molar equivalents of HCl or HBr gives rise to the dicationic species **10** with loss of H_2 (Scheme 1). Abstraction of two hydrogens is confirmed by ^{1}H and ^{29}Si NMR as well as IR spectroscopy. Moreover, the ^{1}H and ^{29}Si NMR spectra of the products are identical irrespective of the reagent acid used. The ^{1}H NMR spectrum is very simple: there is one signal for all the methyl groups ($\delta = 2.15$) and one signal for the CH_2N protons ($\delta = 3.75$). Absence of a signal corresponding to a Si–H bond was inferred from the ^{1}H-coupled ^{29}Si-NMR spectrum of **10** (a singlet is observed at $\delta = -30.5$) and from the IR spectrum (disappearance of the Si–H stretch). The mass spectrum (EI, 70 eV) shows the parent ion at m/z 410 (corresponding to the mass of the dication). Evidence for the ionic nature of the salts **8** and **10** was provided by conductivity data. The specific conductance of a CH_2Cl_2 solution of **6** increases during the addition of 1/2 equiv of I_2 to give **8** and during the addition of two molar equivalents of HCl to give **10** (Fig. 3).

An interesting feature in the reaction between **6** and HX (X = Cl, Br) is the abstraction of hydrogens with loss of H_2, a reaction which does not occur with Ph_2SiH_2. This redox reaction is an indication of the strong interaction between the NMe_2 groups and the Si center. The addition of one equivalent of HX does not give the silylmonocation **8**, but instead leads to a mixture of the starting compound and the dication **10**.

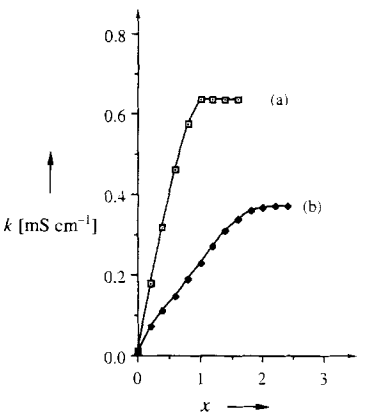

Fig. 3. The conductivity (κ) as a function of the amount of reactant added to a solution of silane **6** in 50 mL of CH_2Cl_2: a) amount of iodine (x [mol equiv I] added to 0.460 mmol of **6**; b) amount of HCl (x [mol equiv]) added to 0.485 mmol of **6**.

In conclusion, use of the 2,6-bis(dimethylaminomethyl)phenyl ligand has permitted the preparation of the novel (4 + 4)-coordinate silicon species **6**, which proves that the Si atom can expand its coordination number beyond six. The very high ability of the ligand **A** to chelate the silicon atom enabled the preparation of not only a silyl cation but also a silyl dication.

Experimental Procedure

6: A THF solution (50 mL) of 2,6-bis(dimethylaminomethyl)phenyllithium [6] (12.4 mmol) was added dropwise at 0 °C to a stirred THF solution of **5** (2.35 g, 12.4 mmol) under argon. The reaction mixture was then heated at reflux for 3 days. After the solvent had been removed, a light brown oil was obtained, which was purified by distillation (115–145 °C/0.025 Torr) followed by recrystallization from pentane to give transparent crystals. Yield: 68%; m.p. 71–74 °C. ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 1.96$ (s, 12H, $N(CH_3)_2$), 3.24 (s, 4H, CH_2N), 4.87 (s, 2H, SiH), 7.08–7.14 (m, 3H, Ar); ^{29}Si NMR (200 MHz, $CDCl_3$): $\delta = -61.6$ (t, ^1J(Si,H) = 213 Hz), (solid state ^{29}Si NMR: $\delta = -57.2$); IR ($CHCl_3$): $\tilde{\nu}$[cm^{-1}] = 2174.3 (Si–H). Correct elemental analysis for C,H,N.

8: A CH_2Cl_2 solution (10 mL) of $Ph_3C^+BF_4^-$ (0.86 g, 2.6 mmol) was added dropwise at 0 °C under argon to a stirred CH_2Cl_2 solution (15 mL) of silane **6** (1.13 g, 2.73 mmol). Progressive decoloration of the trityl solution occurred during the addition. After addition was complete, the reaction mixture was allowed to warm to 25 °C and stirred for 2 h. The solvent was then removed under vacuum and the residue washed three times with Et_2O to eliminate Ph_3CH. After drying under vacuum a beige powder was obtained (1.2 g, 92% yield). ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 1.47$ (s, 6H), 2.18 (s, 6H), 2.25 (s, 6H), 2.65 (s, 6H), 2.83 (s, 2H), 3.5 (s, 2H), 4.13 (q, ^2J(H,H) = 15.6 Hz, 4H), 5.07 (s, 1H), 7.07–7.58 (m, 6H); ^{29}Si NMR (200 MHz, $CDCl_3$): $\delta = -29.0$ (d, ^1J(Si,H) = 283 Hz); ^{15}N NMR ($CDCl_3$, ref CH_3NO_2): $\delta = -340.4$, -347.2, -348.7; IR ($CDCl_3$): $\tilde{\nu}$[cm^{-1}] = 2248; positive-ion FAB-MS (2-nitrophenyl octyl ether matrix) m/z 411 $(M - BF_4)^+$; negative-ion FAB-MS m/z: 87 $(BF_4)^-$.

10: 20 mL of a 0.0472 M solution of HCl (0.944 mmol) in CH_2Cl_2 was added dropwise under argon to a stirred CH_2Cl_2 solution (50 mL) of **6** (0.2 g, 0.485 mmol) at room temperature. After 1 h, the solvent was removed to give 0.2 g (92% yield) of

an oily solid: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.15 (s, 12H), 3.75 (s, 4H), 7.2–7.45 (m, 3H); ^{29}Si NMR (200 MHz, $CDCl_3$): δ = – 30.5; MS (70 eV): *m/z* 410 $[M - 2Cl]^+$, 38%.

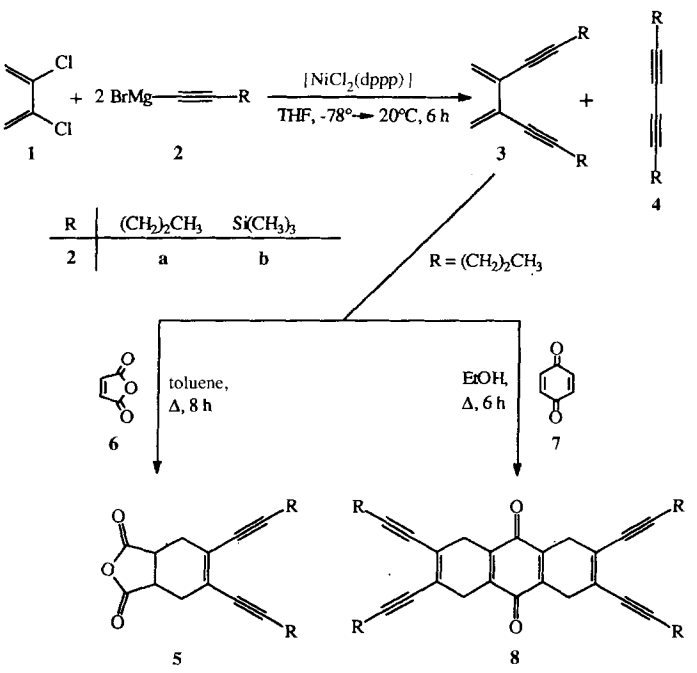
Synthesis of Enediynes by Diels–Alder Addition**

Henning Hopf* and Marcus Theurig



Dedicated to Professor Maximillian Zander on the occasion of his 65th birthday

The hex-3-en-1,5-diyne system forms the core structural element and reaction-initiating component of enediyne antibiotics, which, owing to their DNA-cleaving properties, have catapulted to the forefront in the development of antitumor agents.[1] The synthesis of enediynes has been accomplished to date either through elimination reactions (generation of the central double bond with the ethynyl groups already present[2]) or through coupling reactions (connection of the triple bonds to an existing, usually halogenated olefin[3]).

[**] New Dienes and Dienophiles, Part 5. This research was supported by the Fonds der Chemischen Industrie. – Part 4: H. Hopf, B. Witulski, *Nachr. Chem. Techn. Lab.* **1991**, *39*, 286.

We now present a fundamentally new route to enediynes, which generates the highly unsaturated system in a simple manner by a [2 + 4] cycloaddition and thereby permits the introduction of (different) substituents in all four positions of the parent hydrocarbon.

Coupling of 2,3-dichloro-1,3-butadiene (**1**) with the terminal alkenes **2**, in the presence of the catalyst [1,3-bis(diphenylphosphino)propane]nickel(II) chloride [$NiCl_2$(dppp)] (tetrahydrofuran, $-78 \rightarrow 20$ °C) generates the 3,4-bis(methylene)-1,5-hexadiyne derivatives **3** in 62–80% yield, in addition to the side products **4**, which arise through dimerization of **2**. The structure of **3** is derived unambiguously from spectroscopic and analytical data.[4] As hoped, the derivatives **3** undergo [2 + 4] cycloadditions smoothly. Thus, reaction with maleic anhydride under the conditions given in the scheme affords the 1:1 cycloadduct **5**, which is obtained as a colorless solid in 36% yield.[4] The double dienophile *p*-benzoquinone (**7**) furnishes the bis(enediyne) system **8** (32%) in the form of yellow needles.[4] Since **7** was used in excess, the formation of this bis(didehydro) derivative of the primary adduct is not surprising. We attribute the comparatively low yields for the unoptimized addition to the susceptibility of the 2,3-functionalized butadienes towards polymerization, which was not taken into account during workup. The cycloadducts are nevertheless conveniently accessible in gram quantities.

We shall report shortly on the use of this synthesis in the preparation of enediynes with additional functionalization in the side chain R, as well as on further reactions of **5** and **8** (aromatization, annelation).

Experimental Procedure

Synthesis of **3b**: A solution of methylmagnesium bromide (3 M, 16.7 mL, 50 mmol) in ether was added dropwise at 0 °C to a solution of trimethylsilylacetylene (4.91 g, 50 mmol) in anhydrous THF (50 mL). The white suspension was allowed to warm to room temperature over 30 min and was then heated at reflux for 1 h. After the reaction mixture was cooled to -78 °C, **1** (2.66 g, 22 mmol) and [$NiCl_2$(dppp)] (0.92 g, 1.7 mmol) were added. The red-brown reaction mixture was allowed to warm to room temperature over 2 h and then stirred for an additional 4 h. Saturated ammonium chloride solution (50 mL) was added to quench the reaction, and the organic phase was separated, washed with water, and then dried over magnesium

sulfate. After the solvent was removed in vacuo, the residue was purified by column chromatography (silica gel, pentane) to give **3b** (3.35 g, 62%) as a yellow solid, m.p. 56 °C.—^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.21$ (s, 18H), 5.71 (d, $J = 2.3$ Hz, 2H), 6.01 (d, $J = 2.3$ Hz, 2H).—^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): $\delta = -0.11$ (s), 97.88 (s), 101.25 (s), 125.44 (t), 128.55 (s).—IR (KBr): $\tilde{\nu} = 2960$, 2900, 2161, 1698, 1517, 1470, 250 cm^{-1}.—UV/VIS (acetonitrile): $\lambda_{max}(\varepsilon) = 212$ (7800), 220 (9700), 244 (10000), 280 (5900), 292 (5100), 326 nm (750).—MS (70 eV): m/z (%) = 246 (22) [M^+], 231 (40), 108 (18), 73 (100).

Stable Highly Concentrated Fluorocarbon Gels**

Marie-Pierre Krafft and J. G. Riess*

Highly viscous phases are often found in ternary hydrocarbon/water/surfactant systems. Gels can be found in systems composed of two interlocking continuous phases, one of which is liquid and the other of which consists of long-chain solid or liquid-crystalline material.[1] Both micelles in water and inverted micelles were recently reported to form cylindrical micelles; as the surfactant concentration is increased, they start to entangle and form a dynamic network similar to semidilute polymer solutions.[2–3]

Structures composed of packed, compartmentalized domains can also display a gel-like appearance. Microemulsion gels (so-called ringing gels), which require large amounts of surfactant, were shown to consist of closely packed globular aggregates filled with hydrocarbon, while water forms the continuous phase.[4] Such systems can form cubic phases.[5] When large volumes of a dispersed phase and small amounts of surfactant are used, other viscoelastic gels referred to as high internal phase ratio emulsions (HIPRE) can be obtained. These were shown to consist of polyhedral hydrocarbon cells (polyaphron) delimited by a layer of hydrated surfactant.[6, 7] Gels of this type, which contain up to 99% v/v of a hydrocarbon, were obtained.[4] Their preparation usually requires the use of two surfactants—one oil-soluble and the other water-soluble. As far as water-in-oil emulsions are concerned, concentrated aqueous gels have been reported that contain roughly 50–98% v/v of water as the internal phase and a hydrocarbon or a fluorocarbon as the continuous phase.[8–9]

We wondered whether gels with a high internal fluorocarbon content could be obtained with low amounts of a single fluorinated surfactant and water as components of the cell walls. Such gels would exploit the unique properties of fluorocarbons to spread easily on amphiphilic surfaces and of fluorinated surfactants to stabilize fluorocarbon dispersions, as demonstrated for fluorocarbon emulsions formulated for in vivo oxygen delivery.[10–11]

We found it possible to prepare stable gels consisting of very large amounts of fluorocarbons, exceptionally low amounts of a fluorinated surfactant, and water. We utilized a variety of linear and cyclic fluorocarbons, including some lipophilic ones, with a range of molecular weights, for example perfluorooctyl ethane, perfluorooctyl bromide, perfluorodecalin, a mixture of perfluoro-*n*-butyldecalin (15–20%) and perfluoroperhydrophenanthrene (80–85%) (APF 215), perfluorodiisopropyldecalin (APF-240), and a mixture of perfluorodixylylmethane (60%) and perfluorodixylylethane (40%) (APF-260)[12] Fluorocarbons with a higher boiling point were chosen preferentially to meet the requirement of one of the targeted applications (topical administration of drugs) to prevent the system from rapid evaporation when left open to air. The fluorinated surfactants used were the neutral amine oxide **1** and the zwitterionic phosphocholine derivative **2**.[13, 14] Both were monodispersed, pure, and well defined.

$C_7F_{15}C(O)NH(CH_2)_3N(O)(CH_3)_2$ **1**

$C_8F_{17}C_2H_4OP(O)_2^-C_2H_4N^+(CH_3)_3$ **2**

The new gels were prepared under nitrogen at room temperature by slowly adding the fluorocarbon to a foamy aqueous solution of the fluorinated surfactant. Little energy is required, gentle shaking by hand suffices. As the gel forms, the rate of fluorocarbon addition can be increased. Gels did not form when the surfactant solution was added all at once to a relatively large amount of fluorocarbon. Interestingly, high-energy mechanical homogenization or sonication lead to rapid phase separation. After preparation the gels can be degassed by centrifugation at room temperature (1000 rpm, 15 min).

Typical formulations used for one high molecular weight fluorocarbon, perfluorodiisopropyldecalin, are listed in Table 1. These gels contain up to 99% v/v of the fluorocarbon and

as little as 0.2% w/v (weight per volume) of the fluorinated surfactant **1** along with roughly 1% v/v of water. Their yield point value is high enough to prevent flow under gravitational forces. Other gels containing larger amounts of water (e.g. 10–20% v/v), have been prepared, since they could incorporate water-soluble drugs. In this case greater amounts of surfactant would also be needed. The gels can be characterized by their fluorocarbon/water (FC/W) and surfactant/water (S/W) ratios. For a given amount of surfactant, the larger the FC/W ratio, the more viscous and elastic (as determined by high yield points) the preparation, in analogy to the gel prepared from hydrocarbon HIPRE.[6] For a given fluorocarbon content, viscosity increases when the S/W ratio increases. A S/W ratio of 1/3 to 1/5 appears to be optimal for gel consistency. Transparency increases with the boiling point of the fluorocarbon.

A freeze fracture electron micrograph of a concentrated (98.5% v/v) fluorocarbon gel shows that its structure consists of a matrix of submicronic polyhedral domains of fluorocarbon surrounded by thin shells of hydrated surfactant (Fig. 1), in agreement with a polyaphron structure.[7] Standard tests with a water-soluble dye or with dry paper impregnated with a 20% cobalt chloride solution confirm that water is the continuous phase.

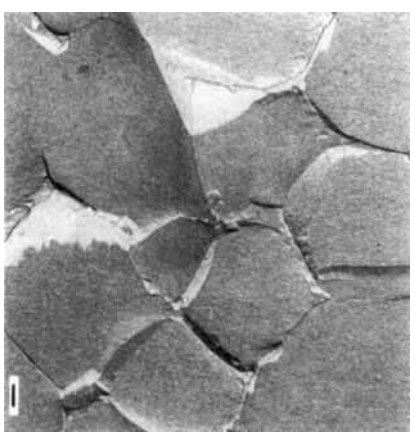

Fig. 1. Freeze fracture transmission electron micrograph of a concentrated fluorocarbon gel (APF-260, 98.5% v/v). The length of the bar corresponds to 220 nm.

It is remarkable that only one water-soluble surfactant is necessary to produce gels when fluorocarbons constitute the dispersed phase. In the case of hydrocarbon polyaphrons, the presence of an oil-soluble surfactant was considered a requirement, so that the oil can spread on the surface of water;[7] however, hydrocarbon polyaphrons were reported which were prepared with only sodium dodecyl sulfate (SDS) as surfactant.[4] In our case we attribute this to the good spreading characteristics of fluorocarbons,[10] as well as to the strong hydrophobic interactions that stabilize the films and vesicles formed by fluorinated surfactants.[15] The gel structure obtained is very similar to that of air bubbles in foams.[16] The easy preparation of fluorocarbon polyaphrons thus calls to mind the analogy drawn between fluorocarbons and gases.[17]

The preparation of the fluorocarbon gels requires a remarkably low amount of energy. The gels are stable enough to withstand heat-sterilization under standard conditions (121 °C, 15 min, $10^5\ Nm^{-2}$). No change in the macroscopic appearance or transparency was observed for both sterilized and nonsterilized gels after one year at room temperature. Neither crystallization of the surfactant nor phase separation was observed.

A thin layer of fluorocarbon can appear with time on the surface of the gel. This is due to the fact that the encapsulating surfactant film is submitted to unbalanced forces at the air interface; thus, the polyhedra tend to burst, releasing the fluorocarbon phase.[7] Once this thin film of fluorocarbon has formed, the system does not change further. The exuded fluorocarbon can easily be reincorporated in the gel by gentle shaking by hand. The gels can be diluted in water to give transparent homogeneous dispersions. After a while, however, the gels tend to form again by sedimentation of the dispersed phase.

The new fluorocarbon gels have potential for topical applications, since they could protect the skin or a wound while remaining permeable to gases. They repel all forms of contaminants, including bacteria. Water-soluble drugs (such as antibiotics), nutrients, and other substances of therapeutic value would be incorporated in the aqueous film, which can also act as a moisturizer. More complex formulations could be designed to allow the simultaneous transport of lipidic and hydrophilic drugs.

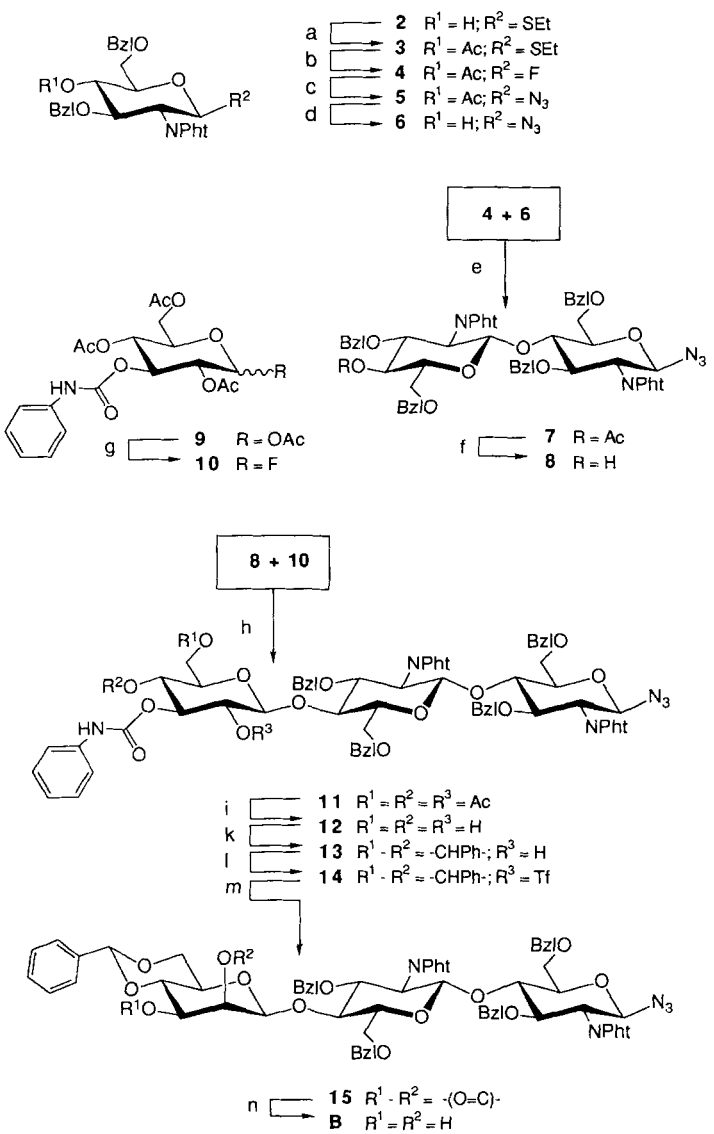
Synthesis of a Biantennary Heptasaccharide by Regioselective Glycosylations **

Carlo Unverzagt*

The oligosaccharides of glycoproteins and glycolipids have been increasingly recognized as carriers of biological information;[1] of special interest are the phenomena of cellular recognition. However, investigations into the function of oligosaccharides found on glycoproteins are at a very early stage. In the case of recombinant erythropoietin, the degree of branching of asparagine-bound carbohydrates (N-glycans) has a great influence on its activity and stability.[2] In cancer cells the occurrence of an additional β-(1 → 6)[3] branch on N-glyans is correlated to the metastatic potential. To study the function of N-glycans in peptides and proteins in detail, it is necessary to provide model compounds like the undecasaccharide-asparagine **1** in sufficient quantity. Compound **1** represents the smallest complete structure of complex type N-glycans frequently found on the glycoproteins of the serum and the cell surface. The isolation of pure N-glycans from glycoproteins is feasible only on a milligram scale. The difficulties caused by the microheterogeneity of the natural material encourage the synthesis of N-glycans with a defined structure. This work describes the synthesis of the branched heptasaccharide **A** as a precursor for compound **1** by two regioselective glycosylations at the β-mannosyl residue of trisaccharide **B** with the disaccharide donors **C** and **D** (Scheme 1).

Scheme 1. The undecasaccharide-asparagine **1** as a model compound for complex type N-glycans. **A** is the branched, core heptasaccharide that was prepared in protected form via the key compounds **B**, **C**, and **D**.

The synthesis of N-glycans and their partial structures[4, 5] is a particular challenge. Already in the mid eighties Ogawa's group synthesized the undecasaccharide **1** without the asparagine moiety by chemical methods.[5] Following the known procedures, many steps are required resulting in a low overall yield. As an alternative to classical chemical approaches in oligosaccharide synthesis, enzymatic methods have become established.[6] A new strategy was developed to obtain the biantennary undecasaccharide-asparagine **1** efficiently. By combining chemical and enzymatic glycosylations, the number of synthetic steps can be reduced. First, the heptasaccharide **A** is synthesized chemically. The protective group pattern is chosen to allow later chemo-enzymatic extension to undecasaccharide-asparagine **1**. Both terminal *N*-acetylglucosamine residues may serve as acceptors for glycosyltransferases.[7] In an enzymatic "one-pot" reaction, glycosides of *N*-acetylglucosamine (GlcNAcβ-R) were elongated to give sialyl-*N*-acetyllactosamine (Neu5Acα-(2 → 6)-Galβ-(1 → 4)-GlcNAcβ-R) in high yields.[8]



Retrosynthetic analysis of the heptasaccharide **A** suggests a disconnection into trisaccharide acceptor **B** and donors **C** or **D**. The formation of the β-mannosidic bond in **B** is very critical. It can be accomplished by the elegant procedure introduced by Kunz et al. of inverting β-glucosides at C-2 in an intramolecular reaction.[9] To facilitate the connection of aspartic acid to the heptasaccharide **A**, the precursor **B** was equipped with an azide group at the reducing end. The azide group serves as a protective function for the anomeric center[10] and can be transformed to an amine by selective reduction with Raney-nickel.

Trisaccharide **B** was prepared from monosaccharide units, starting at the reducing end. Fluoride **4** is a central compound in the synthesis of chitobiosyl azide **7**, serving as a glycosyl donor and as a precursor of the acceptor **6**. Starting from thioglycoside **2**, prepared in six steps from D-glucosamine hydrochloride,[11] followed by acetylation to **3**, the fluoride **4** can be obtained. Activation of thioglycoside **3** with *N*-bromosuccinimide in the presence of HF–pyridine complex[12] gives the crystalline fluoride **4** in high yield. The latter is converted into azide **5** by reaction with trimethylsilyl azide and catalytic amounts of borontrifluoride–ether. Deacetylation of **5** gives the desired acceptor **6** that was glycosylated with fluoride **4**, to furnish chitobiosyl azide **7** in 83.4 % yield. After removal of the acetate group, the disaccharide acceptor **8** is obtained, whose benzyl ether and phthalimido groups are favorable for the reaction sequence leading to the β-mannoside. As a suitable donor fluoride **10** was chosen, which is accessible from peracetylated 3-phenylcarbamoylglucose[11] (**9**) by reaction with HF–pyridine complex. Glycosylation of disaccharide **8** with **10** gives the β-*gluco*-configurated trisaccharide **11** (85.4%). To perform the intramolecular inversion, the 2″-OH function of the glucose

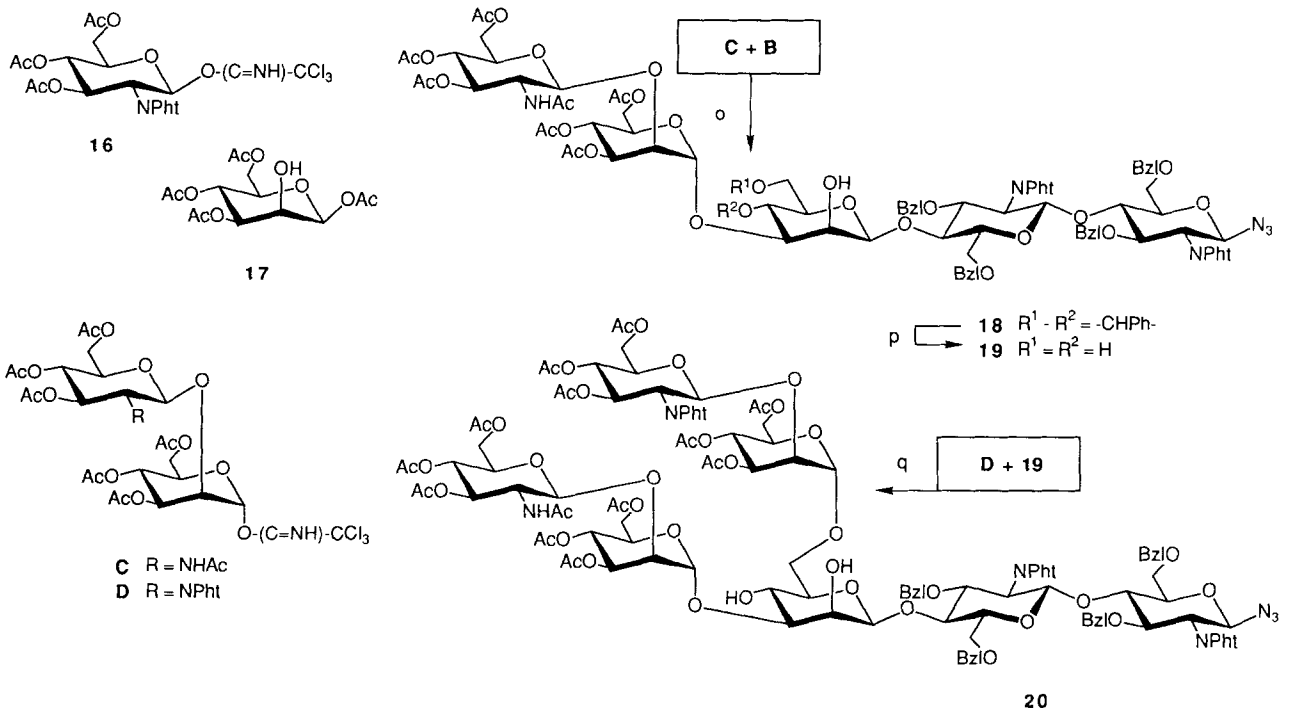
moiety needs to be free.[8] However, removal of the acetates under basic conditions proved problematic, especially for the acetate in position 2″. During the long reaction times the phthalimido moiety was partly cleaved, which explains the low yield. Acyl groups located between sterically demanding residues tend to be difficult to remove.[13] Triol **12** was benzylidenated with (dimethoxymethyl)benzene (α,α-dimethoxytoluene) and converted into the triflate by trifluoromethanesulfonic anhydride–pyridine. Crude β-*gluco*-triflate **14** is heated to 60 °C and inverts to a β-*manno*-configurated imidocarbonate,[9] which hydrolyzes to the carbonate under mild conditions. Basic methanolysis of the carbonate group furnishes the trisaccharide acceptor **B.** Each step of this inversion sequence can be monitored by thin-layer chromatography. Based on trisaccharide **13** the β-mannoside **B** was obtained after five steps in 70% overall yield. Following this procedure, more than 10 g of trisaccharide **B** were prepared (Scheme 2).

Scheme 2. a) Ac_2O, pyridine (99%); b) *N*-bromosuccinimide, HF/pyridine, CH_2Cl_2, 0 °C (93%); c) trimethylsilylazide, BF_3/OEt_2, CH_2Cl_2 (91%); d) K_2CO_3, MeOH, 0 °C (65%); e) BF_3/OEt_2, molecular sieves 4 Å, CH_2Cl_2 (83%); f) K_2CO_3, MeOH, 0 °C (79%); g) HF/pyridine, (56%); h) BF_3/OEt_2, molecular sieves 4 Å, CH_2Cl_2 (85%); i) K_2CO_3/MeOH, 0 °C; k) α,α-dimethoxytoluene, TosOH, CH_3CN (44% based on **11**); l) Tf_2O, pyridine, CH_2Cl_2, −20 °C; m) 1. dimethylformamide, pyridine, 65 °C; 2. AcOH, dioxane, H_2O, 0 °C; n) NaOMe, MeOH, CH_2Cl_2 (70% based on **13**). – Tf = F_3C-SO_2.

The disaccharide trichloroacetimidates[14] **C** and **D** were synthesized to elongate trisaccharide **B** containing two free hydroxyl groups. Donor **C** was developed in the group of Paulsen[15] and prepared by a modified procedure.[16] A considerably faster route leads to donor **D**[16] in three steps from imidate **16**[17] and tetraacetylmannose **17**.[18]



To glycosylate the 3″-OH group of the diol **B** selectively, an acetyl group can be introduced at 2″O by isomerization of a cyclic 2″,3″-orthoester.[11] However, this strategy involving protection at 2″-OH can be circumvented. Diol **B** reacts with the disaccharide imidate **C** selectively at the desired 3″-OH function. Pentasaccharide **18** was isolated in 62% yield; other stereoisomers could not be detected. The α-(1 → 3)-mannosidic linkage formed without neighboring group participation was confirmed by 2D-NMR spectroscopy. The proton-coupled HMQC spectrum yielded a C-1/H-1 coupling constant for the α-mannosyl residue of 177.7 Hz while the β-mannoside expectedly has a lower value of 163.3 Hz.[18] Apparently, the equatorial 3″-OH group is markedly more reactive than the axial 2″-OH function. For β-mannoside acceptor **B**, the observed reactivity corresponds to the preferred glycosylation of the equatorial 3-OH group in galactosides with multiple free hydroxyl functions.

Acidic cleavage of the benzylidene acetal in pentasaccharide **18** gives triol **19** which was examined for a selective elongation of the primary 6″-OH group. Glycosylation of pentasaccharide **19** with 1.7 equiv of disaccharide donor **C** at −10 °C gave only 20% α-(1 → 6)-linked heptasaccharide and 15% of a product with multiple glycosylations, in addition to 55% of unchanged acceptor **19**. Under similar conditions the phthalimido protected donor **D** (1.5 equiv) gave 27% heptasaccharide und 28% of a compound with an additional glycosylation. In contrast, donor **D** (1.2 equiv) reacts highly selectively with **19** at lower temperature (−40 °C) and a diluted reaction mixture, to furnish heptasaccharide **20** (52%), a protected form of the target molecule **A**. The structure of **20**[21] is confirmed by 2D-NMR spectroscopy and FAB-mass spectrometry. Removal of the phthalimido groups from **20** occurs readily following the commonly used procedure with hydrazine hydrate in ethanol (Scheme 3, see next page). Currently the attachment of aspartic acid and the enzymatic elongation to **1** are under investigation.

Crucial to the synthesis of the branched heptasaccharide **20** is the extension of the trisaccharide building block **B**. A temporary protection of the β-mannoside with a benzylidene acetal is sufficient for directing the glycosylation to position 3″. This minimal protection strategy allows the introduction of other branching sugars found in nature at position 2″ and 4″ after reaction of the primary 6″-OH group.

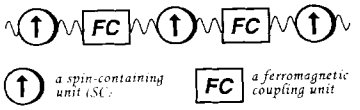
Combination of Superexchange and Spin-Polarization Mechanisms Leads to a Novel Hydrocarbon Tetraradical with a High-Spin Ground State**

S. Joshua Jacobs and Dennis A. Dougherty*

An understanding of the factors that control local spin–spin interactions is crucial to the rational development of new magnetic materials.[1] Such insight should allow the design of long-range, three-dimensional interactions that will ultimately produce bulk magnetic ordering. Studies of organic diradicals with triplet ground states have led to the discovery of three separate mechanisms that can produce ferromagnetic (high-spin) coupling between a pair of electrons: A) dynamic spin polarization in delocalized, planar π-systems with appropriate topologies, as in trimethylenemethane and *m*-xylylene; B) superexchange (through-bond) coupling of localized radical centers, as in cyclobutanediyls and cyclopentanediyls; and C) one-center interactions between orthogonal orbitals (analogous to Hund's rule), as in carbenes and nitrenes.

These three mechanisms may also act in concert to produce structures with very large spin quantum numbers. The famous polycarbenes are examples of compounds in which mechanisms A and C are both in effect (CACAC ... structures),[1b, d, 2] and we have recently described high-spin tetraradicals with ABA frameworks.[3] We now provide the first report of a compound with a BAB arrangement, which also leads to a high-spin ground state. In tetraradical **1** the coupling between centers 1 and 2 (and that between 3 and 4) relies on the superexchange mechanism (B), while centers 2 and 3 should be ferromagnetically coupled by the spin-polarization mechanism (A). Alternatively, structure **1** can be viewed as another example of the paradigm shown in Scheme 1[1a, 4] in which *m*-phenylene serves as the FC, and for the first time the spin-containing unit (SC) is a localized diradical, a 1,3-cyclobutanediyl. In addition to establishing a new strategy for the design of high-spin systems, this study illustrates the power of current methods for predicting and analyzing the EPR spectra of very high spin structures such as **1**.



1

Compound **5**, the bisdiazene precursor to **1**, was prepared by an adaptation of transformations developed previously in these laboratories[5–7] via the tricyclic urazole **2** (Scheme 2). Fol-

[**] Contribution No. 8885.

Scheme 1. Representation of a spin system with ferromagnetic coupling.

lowing conversion of **2** into **3** a Wittig reaction gave bisurazole **4** with predominantly (*Z*) configuration.[8] Subsequent transformation of **4** into bisdiazene **5** proceeds under standard hydrolysis conditions was followed by low-temperature oxidation. The high overall yield of this synthesis establishes it as a viable route to many unsymmetrically substituted urazoles.[9]

Scheme 2. Synthesis of **5**. DCC = dicyclohexylcarbodiimide, 4-PPy = 4-pyrrolidinopyridine.

A Heisenberg Hamiltonian may be employed to model the energies of the spin states of tetraradical **1**.[2a, 3] The coupling of electron spins in **1** by mechanism A may be characterized by one magnetic exchange parameter, J_A, while the coupling due to mechanism B is represented by another parameter, J_B. The four-spin system can be described by the Hamiltonian defined in Equation (1). The six covalent electronic states and corresponding state energies resulting from the interactions among the four spins are summarized in Scheme 3.

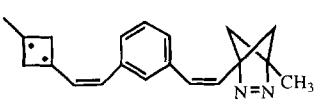
$$\mathcal{H} = -J_A \boldsymbol{S}_2 \cdot \boldsymbol{S}_3 - J_B((\boldsymbol{S}_2 + \boldsymbol{S}_3) \cdot (\boldsymbol{S}_1 + \boldsymbol{S}_4)) \quad (1)$$

Only if $J_A > 0$ *and* $J_B > 0$ will a high-spin Q ground state result. Results from extensive experimental studies of organic diradicals with triplet ground states employing mechanisms A and B lead one to expect both of these conditions to be satisfied.[1, 2]

In addition, analysis of structure **1** according to established models allows its EPR spectra to be largely foretold. The zero-field splitting (zfs) tensor $\boldsymbol{D}^Q$ for a tetraradical such as **1** can be related to the zfs tensors of the diradical components[2a] according to Equation (2), where $\boldsymbol{D}^B$ represents the dipolar interaction

Quintet (Q): $E_Q = -\frac{J_A}{2} - 2J_B$ Singlet (S_1): $E_{S_1} = -\frac{J_A}{2} + 4J_B$

Triplet (T_1): $E_{T_1} = -\frac{J_A}{2}$ Triplet (T_3): $E_{T_3} = \frac{3J_A}{2}$



Triplet (T_2): $E_{T_2} = -\frac{J_A}{2} + 2J_B$ Singlet (S_2): $E_{S_2} = \frac{3J_A}{2}$

Scheme 3. Spin states of **1** and corresponding energies.

$$\boldsymbol{D}^Q = \frac{\boldsymbol{D}^B + \boldsymbol{D}^B}{6} + \frac{\boldsymbol{D}^A}{3} \quad (2)$$

across a cyclobutane ring (mechanism B), and $\boldsymbol{D}^A$ represents the dipolar interaction through the *m*-phenylene linker (mechanism A).

Based on previously established[5] substituent effects on the *D* values of cyclobutanediyls, one can predict that $|D^B/hc|$ (and also the *D* value for monodiazene diradical **6**) is approximately 0.060 cm^{-1}.[10] For *m*-xylylene, $|D/hc| = 0.011\ cm^{-1}$,[11] but to obtain D^A this value must be scaled by $\frac{1}{2} \cdot \frac{1}{2}$, since the spin density at the *m*-xylylene centers is only $\frac{1}{2}$.[12] Thus, $|D^B| \gg |D^A|$,[11] and the approximate expression for the *D* value of the tetraradical is $D^Q \approx D^B/3$. This model thus predicts that the *D* value of the quintet state of **1** should be $|D/hc| \approx 0.020\ cm^{-1}$.

6

Since the outer $\Delta m_s = 1$ lines of a triplet EPR spectrum are separated by 2*D*, while the corresponding separation in a quintet spectrum is 6*D*, the outer lines in the $\Delta m_s = 1$ region of the spectra of ^{3}**6** and ^{5}**1** are expected to be coincident. The only features that will allow unambiguous assignment of an observed EPR spectrum to ^{5}**1** will be peaks due to the inner quintet lines, which are associated with transitions between the intermediate magnetic sublevels. Ambiguity in interpreting the experimental spectra can be minimized by full computer simulation of triplet- and quintet-state EPR powder spectra. Such simulations are an indispensable tool in the study of structures such as **1**.[3, 9]

When a frozen solution of **5** in methyltetrahydrofuran is photolyzed in an EPR spectrometer at 4 K, EPR spectra become apparent after brief photolysis (Fig. 1). If the outer four lines the $\Delta m_s = 1$ region are due to a

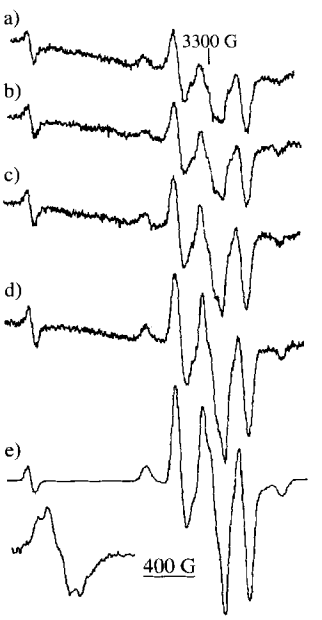


Fig. 1. EPR spectra recorded during photolysis of **5** at 4 K. Photolysis times: a) 75 s, b) 90 s, c) 120 s, d) 180 s, e) 80 min. Inset to e) is an enlargement of the $\Delta m_s = 2$ region.

triplet, $|D/hc| = 0.057\ cm^{-1}$ and $|E/hc| = 0.0009\ cm^{-1}$ is implied, in good agreement with the predictions of for ^{3}**6**. A prominent feature of the spectra recorded after short photolysis times is a $\Delta m_s = 2$ transition (Fig. 1a), a signature of a spin state with $S \geq 1$. The hyperfine splitting observed in this transition is also typical of a cyclobutanediyl and strongly resembles that of the analogous compound 3-ethyl-1-vinylcyclobutanediyl.[5]

As photolysis continues, changes occur throughout the spectrum (Fig. 1b–d), and after extended photolysis, the spectra include a new, large, structured feature in the central region (Fig. 1e). Simulation of a triplet-state EPR spectrum with the zfs parameters assigned above to ^{3}**6** (Fig. 2a) establishes that a triplet state cannot account for all of the fine structure observed. The obvious candidate for the species giving rise to these additional lines is ^{5}**1**.

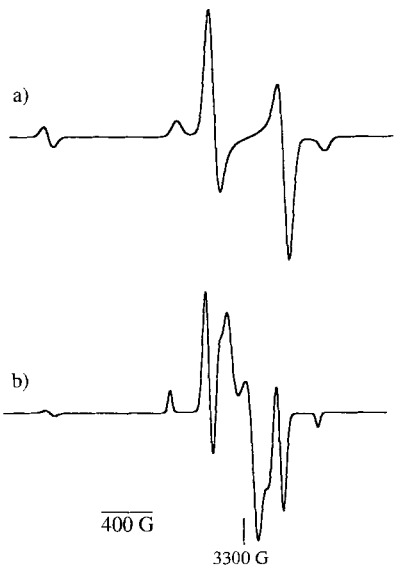

Fig. 2. a) Simulated triplet EPR spectrum with $|D/hc| = 0.057$, $|E/hc| = 0.0009\ cm^{-1}$; b) simulated quintet EPR spectrum with $|D/hc| = 0.0193$, $|E/hc| = 0.00035\ cm^{-1}$.

Several lines of evidence lead us to conclude that the sequence of spectra shown in Figure 1a–e is best interpreted as fitting a system that is initially dominated by ^{3}**6** (Fig. 1a) but evolves on extended photolysis to one that is to a large extent (and perhaps exclusively) ^{5}**1**. First, if Figure 1e is a quintet spectrum, it implies $|D/hc| = 0.019\ cm^{-1}$ and $|E/hc| = 0.00035\ cm^{-1}$, in good agreement with the predicted value for ^{5}**1**. In addition, a computer-simulated spectrum with these zfs values (Fig. 2b) shows good agreement with the observed spectrum in two important regards. First, the $\Delta m_s = 1$ region of the quintet spectrum is much more prominent that the $\Delta m_s = 2$ region, relative to the same comparison for the triplet spectrum (Fig. 2a). A similar relationship is seen in the experimental spectra (Fig. 1e vs. Fig. 1a). Second, the simulation of the quintet spectrum shows a large structured feature in the central region (ca. 3300 G) that is similar to the central feature that grows in on extended photolysis. The general spectral shape is similar to that of other quintet systems we have examined.[13] The fine structure in the central region is not perfectly matched by the simulation, but simulations of powder EPR spectra of quintet systems include a large number of variables, including many linewidth parameters and (possibly) an anisotropic g tensor. We felt no need to attempt to optimize all these and are satisfied with the qualitative agreement.

One could argue that the new central feature is due to monoradical (doublet) impurities or a triplet state with a small D value (e.g., a radical pair), either of which could form on extended photolysis. Several lines of reasoning argue against this. First, the fine structure of the central feature and its breadth (note the 400 G scale bar) are inconsistent with a doublet signal. Second, cyclobutanediyls generally do not produce intense doublet or radical pair signals on generation from diazene precursors (see Fig. 1 or ref. [5]). Third, the asymmetry of the central signal (the low-field component is shorter than its neighbor, while the higher field component is larger than its neighbor), typical of quintet states and reproduced in the simulation is completely inconsistent with doublet or triplet spectra. Fourth, the signals of a secondary photolysis product (doublet system or triplet radical pair) would be expected to grow in at the expense of those of ^{3}**6**. This is clearly not the case, as the growth in the central feature is accompanied by a growth of the outer two pairs of signals (but a relative drop in the $\Delta m_s = 2$ region) as expected for a quintet system.[13] The high intensity of these signals at such low temperatures (4 K) makes it highly probable that the quintet is the ground state of **1**.

The observation of a quintet ground state for tetraradical **1** shows that superexchange and spin-polarization mechanisms can act in concert to produce wholly ferromagnetic coupling in a high-spin organic molecule with a BAB structure. This study further expands the scope of *m*-phenylene as an FC, establishes the suitability of cyclobutanediyls as SCs, and again demonstrates the power of current models and methods in predicting and interpretating the EPR spectra of complex systems.

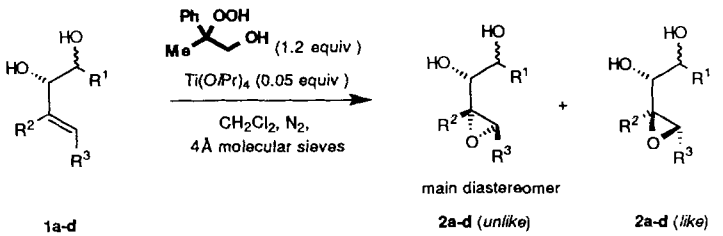
[13] We cannot rule out the presence of ^{3}**6** signals in the final spectrum (Fig. 1e), given the high degree of overlap between the expected spectra of ^{3}**6** and ^{5}**1** (cf. Fig. 2).

Tridentate β-Hydroperoxy Alcohols as Novel Oxygen Donors for the Titanium-Catalyzed Epoxidation of γ,δ-Unsaturated α,β-Diols: A Direct Diastereoselective Synthesis of Epoxy Diols**

Waldemar Adam,* Karl Peters, and Michael Renz

Dedicated to Professor H. Quast on the occasion of his 60th birthday



The titanium(IV)-catalyzed expoxidation of allylic alcohols with hydroperoxides, typically *t*BuOOH, is an efficient and convenient method for preparing synthetically valuable epoxy alcohols.[1] In the presence of optically active tartrate as a chiral auxiliary (Sharpless reaction) the oxyfunctionalization can be performed with high enantioselectivity. An attractive extension is our direct hydroxy-epoxidation of allylic hydroperoxides catalyzed by $Ti(OiPr)_4$ (the masked Sharpless reaction), in which the hydroperoxy functionality acts as an oxygen atom donor and the allylic alcohol (generated by reduction of the allylic hydroperoxide) as an oxygen acceptor.[2]

Scheme 1. Two routes to epoxy diols [3]. d.r. = diastereomeric ratio.

The two routes are illustrated in Scheme 1.[3] The direct hydroxy-epoxidation with the unsaturated hydroperoxy alcohol (on the left) proceeds nearly spontaneously (≤ 5 min), whereas the conversion of the analogous enediol with *t*BuOOH as oxygen donor (on the right) is minimal even after three days reaction time and with 50 mol% $Ti(OiPr)_4$. Presumably the bidentate oxidant *t*BuOOH is not able to displace the epoxy diol by ligand exchange to generate the active, so-called *loaded* complex necessary for the catalytic cycle. In contrast, the tridentate hydroperoxy alcohol displaces the epoxy diol readily, and thus oxygen transfer can take place efficiently.

To test the above hypothesis we used a β-hydroperoxy alcohol, 2-hydroperoxy-2-phenyl-1-propanol (easily available by reaction of α-methylstyrene oxide with hydrogen peroxide[4]), as a tridentate oxygen donor for the epoxidation of γ,δ-unsaturated α,β-diols. Such β-hydroperoxy alcohols have not yet been used as oxygen donors in the Sharpless reaction. Indeed, we demonstrate herein that enediols **1** can be epoxidized very efficiently to give epoxy diols **2**, whereby two additional, neighboring stereogenic centers are generated rapidly with high diastereoselectivity (Scheme 2). The configurations of the new chiral centers are determined by that of the β carbon atom.

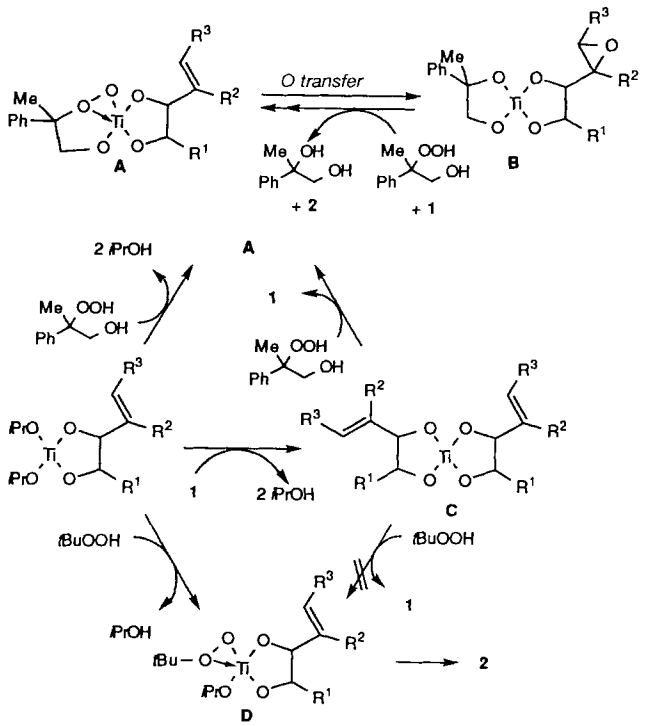
Scheme 2. Conversion of **1** into **2**; for an explanation of *unlike* and *like* see text.

Generally for the titanium(IV)-catalyzed epoxidation of substrates with more than one hydroxyl functionality it has been necessary to protect all except the allylic hydroxyl group[5] to avoid long reaction times[3b] and irregular stereochemistry.[6] The data in Table 1 show that direct epoxidation of unprotected unsaturated diols **1** with the β-hydroperoxy alcohol proceeds in good yields and with (almost) complete conversion within minutes.

Table 1. Reaction conditions, yields, and diastereomeric ratios for the titanium-catalyzed epoxidation of enediols **1** with 2-hydroperoxy-2-phenylpropan-1-ol to give epoxy diols **2**.

Entry	R^1	R^2	R^3	T [°C]	t [h]	Mass balance [%]	Conversion [%]	Yield [a] [%]	*d.r.* [b]
1 **1a**	H	Me	H	23	2.0	75	81	86	90:10
2 **1b** [c]	Me	Me	H	−25	17.0	83	96	70	89:11
3 **1b** [c]	Me	Me	H	0	3.0	92	88	88	86:14
4 **1b** [c]	Me	Me	H	23	0.5	92	100	88	82:18
5 **1c** [d]	Me	H	nPr	23	0.5	78	100	63	85:15
6 **1d** [e]	Ph	H	Ph	23	0.5	77	100	71 [f]	>90:10

[a] Based on consumed starting material. [b] Diastereomeric ratio (*d.r.*) of *unlike*:*like* products, determined after column chromatography by quantitative analysis of characteristic signals in the ^1H NMR spectrum; error is ±5% of the stated value. [c] A diastereomeric mixture of (1*R**,3*R**):(2*S**,3*R**) = 90:10 was used. [d] Only the (2*R**,3*R**-*E*) diastereomer was analyzed. [e] A diastereomeric mixture of (1*R**,2*R**): (1*S**,2*R**) = 75:25 was used. [f] Isolated in part as tetrol (34%).



As predicted, the tridentate β-hydroperoxy alcohol (oxygen donor) and the bidentate enediol (oxygen acceptor) are able to regenerate the active, *loaded* complex **A** (Scheme 3) from the inactive complex **B** by efficient displacement of the epoxy diol product and the diol derived from the β-hydroperoxy alcohol. The efficiency of the catalytic cycle is thus ensured. The inactive titanium complex **C** also undergoes ligand exchange to the active, *loaded* titanium complex **A**, and the oxygen transfer proceeds smoothly.

In contrast, bidentate *t*BuOOH displaces the enediol moiety in the coordination step only with difficulty. When only small amounts (ca. 5 mol%) of $Ti(OiPr)_4$ are used, fast formation of the inactive complex **C** ties up all the catalyst (Scheme 3). Since for the latter, ligand exchange to the active, *loaded* complex **D** is slow, the reaction is terminated before it has even started!

Owing to the stronger binding of the epoxy diol product and of the diol derived from the β-hydroperoxy alcohol in the titanium complex **B**, a higher reaction temperature is required for regeneration of the loaded complex **A**. Presumably this is the reason why the oxygen transfer from the β-hydroperoxy alcohol to enediol **1** is very slow at −25 °C (Table 1, entry 2), although this is the temperature of choice for the conventional Sharpless reaction. In our variant substantial acceleration is possible by increasing the reaction temperature to room temperature (Table 1, entry 4).

Scheme 3. Ligand exchange processes for the bi- (*t*BuOOH) and tridentate (β-hydroperoxy alcohol) oxygen donors in the generation of the *loaded* titanium templates **A** and **D** required for the oxygen transfer (**1** → **2**).

The advantage of our modification is the high diastereoselectivity, which ranges from 82:18 up to 90:10 in favor of the *unlike* isomer (see Table 1; *unlike* refers to the β and γ carbon atoms of the substrate). The diastereomeric ratios were determined by quantitative analysis of characteristic signals in the ^{1}H NMR spectra. The main isomer was assigned by comparison with reported spectral data.[3b] The structure of the new epoxy diol **2d** was established by X-ray structure analysis (Fig. 1).[7]

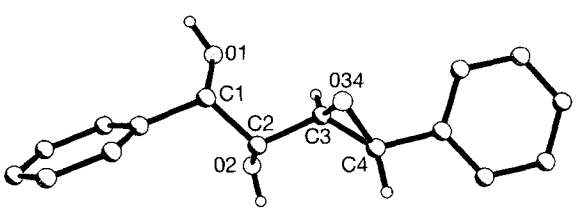

Fig. 1. Crystal structure of (1*S**,2*R**)-1-phenyl-2-[2α(*S**),3β-phenyloxiran-2-yl]-1,2-ethanediol (**2d**) (ORTEP) [7].

The high diastereoselectivity can be traced back to the very rigid transition state for the oxygen transfer, which is stabilized by a number of oxygen–titanium bonds, similar to the active, *loaded* complex **A** (Scheme 3). Unquestionably, the additional homoallylic alcohol functionality of enediol **1** and the hydroxyl group of the β-hydroperoxy alcohol play a decisive role in providing more order through better coordination. Furthermore, the S_N2 mechanism requires that the nucleophilic attack of the π double bond on the oxygen atom to be transferred occurs in the same direction as the activated peroxide bond in the titanium template.[1d] This stereoelectronic requirement and the tighter coordination dictate the high diastereoselectivity. Although it is still uncertain how many titanium atoms are involved in the template, the oxygen donor (β-hydroperoxy alcohol) and acceptor (enediol) must be coordinated to the same titanium atom for effective oxygen transfer.

This epoxidation with a tridentate β-hydroperoxy alcohol offers new preparative perspectives for the direct and stereoselective epoxidation of allylic alcohols bearing additional hydroxyl groups. Such substrates are problematic in the conventional Sharpless epoxidation with bidentate *t*BuOOH and require cumbersome protecting group methodology. It would be of interest to use enantiomerically pure β-hydroperoxy alcohols as oxygen donors, as they have recently become conveniently available through kinetic resolution catalyzed by horseradish peroxidase.[8]

Experimental Procedure

A solution of 1.50 mmol of enediol **1** and 1.80 mmol of the hydroperoxy alcohol in 7 mL of dichloromethane was dried over 4 Å molecular sieves. Ti(O*i*Pr)$_4$ (75.0 μmol) was added under a nitrogen atmosphere. After 30 min the reaction was stopped by addition of 0.1 mL of saturated, aqueous NH_4F solution and the precipitate removed by filtration. The solvent was evaporated by distillation (23 °C, 17 Torr) and the residue purified by column chromatography on silica gel. Conversions, yields, and diastereomeric ratios are given in Table 1.

Ozone Formation through Decomposition of CFCs in the Stratosphere**

Gustavo A. Argüello, Bernd Jülicher, and Helge Willner*

The first chlorofluorocarbons (CFCs) were synthesized in 1930 in the research labs at General Motors as substitutes for the refrigerants SO_2 and NH_3. These exceedingly useful, nontoxic compounds have received a lot of negative headlines over

the last decades because they are partly responsible for the increasing ozone depletion in the stratosphere. The high-energy UV radiation in the stratosphere cleaves the chemically inert CFCs to produce chlorine atoms which convert ozone into oxygen in a photocatalytic cycle.

CF_2Cl_2, a typical chlorofluorocarbon, yields in addition to chlorine atoms [Equations (a) and (b)] a further photolysis frag-

$$CF_2Cl_2 + h\nu(\lambda < 346\ nm) \longrightarrow CF_2Cl + Cl \quad (a)$$

$$CF_2Cl_2 + h\nu(\lambda < 221\ nm) \longrightarrow CF_2 + 2Cl \quad (b)$$

ment, difluorocarbene CF_2[1] [Equation (b)]. In the singlet electronic ground state[2] this fragment has remarkably low reactivity,[3] dimerizing with a rate coefficient of 4.3×10^{-14} cm^3 molecule^{-1} s^{-1},[4] and reacting only rather slowly with oxygen.[5] In contrast, a faster reaction has been suggested for step (c).[6] The formation of F_2CO in the thermal[7] and photochem-

$$^3CF_2 + {}^3O_2 \longrightarrow [CF_2O_2]^* \longrightarrow F_2CO + O \quad (c)$$

ical[5] reaction of C_2F_4 with O_2 has been explained by (c). However, experimental evidence for (c) has been obtained up to now only indirectly by capture reactions involving organic compounds.[8]

During our investigations of the elementary reactions of CF_2 we also examined the reaction with oxygen, which plays a significant role in the chemistry of the stratosphere. We used difluorodiazirine **1** as a clean source of CF_2.[9] CF_2 is produced quantitatively when **1** is irradiated with light of wavelength longer than 320 nm at 15 K in an O_2 matrix. It reacts completely to F_2CO and O_3 in an approximate 1:1 ratio only after excitation of the matrix-isolated CF_2 by light of about 250 nm (absoption maximum of the transition $A\,^1B_1 \leftarrow X\,^1A_1$).[4] Ozone formation was not observed in control experiments with pure solid O_2 at 15 K under the same photolysis conditions. The formation of ozone in the presence of CF_2 can be interpreted as follows:

1

The electronically excited $CF_2(A\,^1B_1)$ is converted by intersystem crossing into $CF_2(^3B_1)$, which then reacts[10] almost without an activation barrier with O_2 to form $F_2CO + O$ [Eq. (c)]. The O atom reacts in turn with the O_2 matrix to ozone. There is no evidence for either the intermediate formation of difluorodioxirane (**2**), which has only recently been synthesized,[11] or for any other CF_2O_2 species.

2

In addition, the observations made for the O_2 matrix were supplemented by those from gas-phase investigations. Mixtures of **1** in O_2 (1:125) were prepared in a UV gas cell at a total pressure of about 1 bar. The UV photolysis was performed through the cell window with a medium pressure mercury lamp in combination with 320 or 225 nm cut-off filters. Photoysis with light of wavelength longer than 320 nm yielded exclusively C_2F_4 through dimerization of the CF_2 formed in the primary process [see Eq. (k)]. This allowed confirmation of the observation described in reference [5], which indicates that singlet CF_2 reacts only slowly if at all with oxygen at room temperature. On the other hand, ozone formation is observed if light of longer wavelength than 225 nm is used (Fig. 1a). Additional products detected by IR spectroscopy include C_2F_4 and F_2CO. Whereas in the matrix experiment only reactions of individual CF_2 molecules can take place, the course of the reaction in the gas phase is more complex.

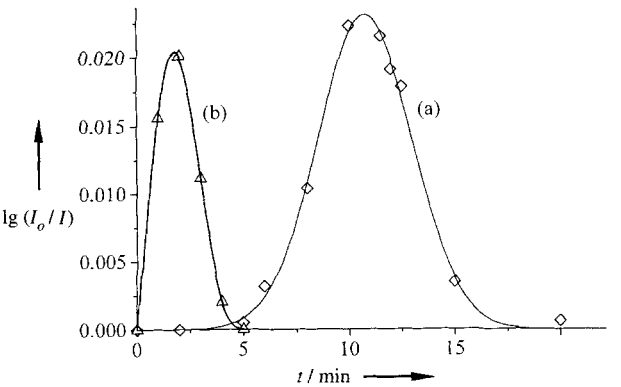

Fig. 1. Time dependence of the O_3 extinction at $\lambda = 258$ nm during the gas-phase photolysis ($\lambda > 225$ nm) of (a) **1** in O_2 and (b) **2** in O_2.

Of particular note is the long induction period of five minutes until the rapid appearance and likewise fast decomposition of O_3 occurs. This reproducible time-behavior could be interpreted in terms of a photochemically controlled cycle (Scheme 1).

$$\mathbf{1}(X\,^1A_1) + h\nu(\lambda = 352\ nm) \longrightarrow CF_2(X\,^1A_1) + N_2 \quad (d)$$

$$CF_2(X\,^1A_1) + h\nu(\lambda = 249\ nm) \longrightarrow CF_2(A\,^1B_1) \quad (e)$$

$$CF_2(A\,^1B_1) \longrightarrow CF_2(^3B_1) \quad (f)$$

$$CF_2(^3B_1) + {}^3O_2 \longrightarrow [CF_2O_2]^* \longrightarrow F_2CO + O \quad (g)$$

$$\downarrow h\nu \quad (h)$$

$$h\nu(\lambda = 225\ nm) + {}^1CF_2 + 2O$$

$$O + O_2 + M \longrightarrow O_3 \quad (i)$$

$$CF_2 + CF_2 \longrightarrow C_2F_4 \quad (k)$$

$$CF_2 + O_3 \longrightarrow F_2CO + O_2 \quad (l)$$

$$C_2F_4 + O_3 \longrightarrow F_2CO + O_2 + {}^3CF_2 \quad (m)$$

$$O_3 + h\nu(\lambda = 255\ nm) \longrightarrow O_2 + O \quad (n)$$

Scheme 1. Photochemically induced reactions likely to occur in the system $\mathbf{1}/O_2$.

A stationary concentration of electronically excited $^1CF_2$ is gradually established through the reactions (d) and (e). As shown by the matrix experiment, intersystem crossing of $CF_2(A\,^1B_1)$ to $CF_2(^3B_1)$ should be possible [Eq. (f)]; the $CF_2(^3B_1)$ then reacts further with O_2 according to Equation (g) [identical to Eq. (c)]. In order to explain the overproportional increase in the O_3 concentration, we postulate that the resulting vibrationally excited CF_2O_2 after photochemical excitation [Eq. (h)] can decay into CF_2 and two O atoms. The energy resulting from the sum of the singlet–triplet energy separation[12] for CF_2 (236.4 kJ mol^{-1}) and the photon energy for $\lambda = 225$ nm (532 kJ mol^{-1}) is sufficient to dissociate O_2 ($D^0 = 498.3$ kJ mol^{-1}) (Fig. 2), which can not be directly cleaved because of its extremely low absorption at wavelengths $\lambda > 225$ nm. The $^1CF_2$ arising from Equation (h) could reenter the cycle at Equation (f), while the O atoms would be captured by O_2 to form O_3 [Eq. (i)]. The sudden increase in the O_3 concentration can thus be understood by such a CF_2-sensitized photochemical cleavage of O_2.

The rapid decay of O_3 results from the reactions (l), (m),[12] and (n). It should be pointed out here that the intensively studied oxidation of carbenes CX_2 (X = H, organic group)[13] can-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1010-1109 $ 10.00+.25/0

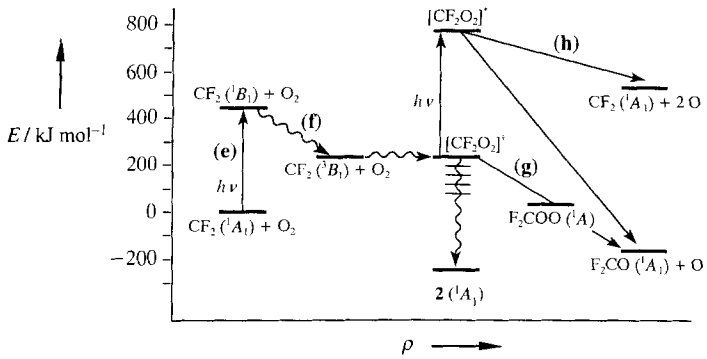

Fig. 2. Energy dependence of the reaction steps (e) to (h), referred to the energy of $CF_2(^1A_1) + O_2$. The thermodynamic data are taken from the refs. [2, 8].

not be compared to the CF_2/O_2 chemistry presented here because of the reversed singlet–triplet sequence.

In order to test for the possible existence of an energetic CF_2O_2 intermediate stage, an analogous experiment with difluorodioxirane **2** ($X\,^1A_1$) has been carried out, and its UV spectrum recorded for the first time. Two absorption bands[14] are apparent in the region of the incident light ($\lambda > 225$ nm) used for the photolysis of **1**, so a photochemical excitation of **2** should also be feasible. Both absorption bands lack any fine structure, which can be considered as evidence for a dissociative excited state. Ozone is formed directly during the photolysis of **2** in an excess of oxygen according to Equations (g) and (i) (Fig. 1b), which indicate that **2** is *one* possible precursor for the ozone formed in the presence of CF_2. Since the rate constants for reactions (f), (g), and (l) are not known, it is not feasible to make an assertion about the branching ratio of the reactions (g) and (h). The ratio (h)/(g) should increase, though, at low pressure and low temperature, since the deactivation of vibrationally excited CF_2O_2 will be slower.[15] Under the conditions used in our work (1 bar, 298 K), reaction (h) still has a certain importance.

The experiments described here show quite clearly that CF_2 can also contribute to ozone formation under stratospheric conditions, regardless which energized CF_2O_2 intermediate is present. This is of importance for the debate over CFC-substitutes, since fluorocarbons are considered as possible replacements. The CF_2 fragment will at least counteract any possible ozone depletion potential. Just how much O_3 is formed through our suggested mechanism can only be calculated when quantitative information over the entire reaction mechanism is available.

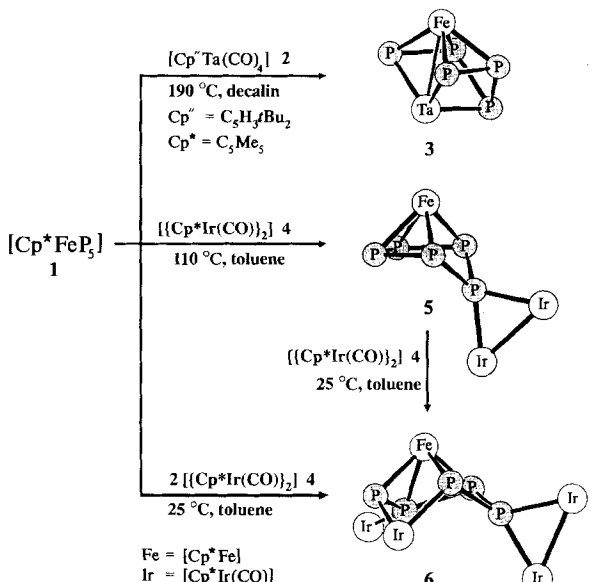
[Cp*Fe(η^5-P_5)], a Sandwich Complex with Diverse Ligand Properties**



Michaela Detzel, Thomas Mohr, Otto J. Scherer,* and Gotthelf Wolmershäuser

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

The pentaphosphacyclopentadienyl anion P_5^- holds a key position in the series of *cyclo*-P_n complex ligands.[1] Examples are the sandwich complexes [Cp*M(η^5-P_5)], M = Fe (**1**), Ru[1a] and Os[2] as well as the compounds MP_5, M = Li, Na, K,[3] which can be prepared as stable solutions.

The ferrocene analogue **1**[4] shows diverse ligand properties. The *cyclo*-P_5 building block remains intact and planar both in the terminal coordination of two $Cr(CO)_5$ fragments[5] and in a stacking reaction to give the cationic triple-decker [CpFe(P_5)FeCp*]$^+$ complex[5] with 30 valence electrons.

Two remarkable P_5 ring-opening reactions are observed in the reaction of **1** with the tantalum complex **2** and the iridium binuclear complex **4**.

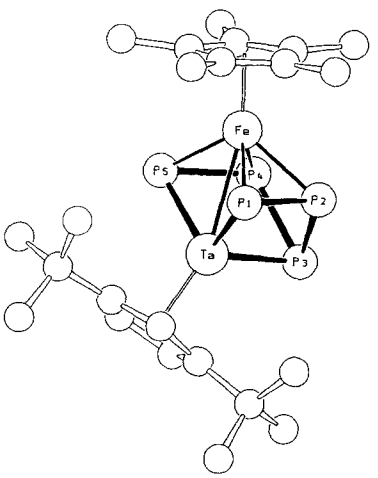
[**] This work was supported by the Graduiertenkolleg "Phosphorchemie als Bindeglied verschiedener chemischer Disziplinen" and the Fonds der Chemischen Industrie. We thank Degussa AG for a gift of $IrCl_3 \cdot 3H_2O$. The help of Dr. Öfele, München, in preparing compound **1** is gratefully acknowledged. Cp* = pentamethylcyclopentadienyl.

The decisive precursor for the formation of **3** is the dimetal complex **7**,[6] which is prepared by a short period photolysis and can be subsequently isolated. In **7** the intact *cyclo*-P_5 ligand is coordinated terminally to the $Ta(CO)_3Cp''$ fragment. The photochemical as well as the thermal elimination of CO from **7** leads to the formation of **3** with cleavage of a P–P bond.

$[Cp^*Fe(\mu\text{-}\eta^5\text{:}\eta^1\text{-}P_5)\{Ta(CO)_3Cp''\}]$ **7**

The compounds **3**, **5**, and **6** form black-green crystals which can be handled in air for a short period; they are sparingly soluble in pentane, soluble in toluene, and very soluble in dichloromethane. The yields of the corresponding reactions lie between 52 and 90%. The ^1H and ^{31}P NMR data for the new complexes[6] are in agreement with the X-ray crystallographic results.[7] The X-ray structure analysis reveals a distorted TaP_5 Dewar benzene as the framework of **3**, whose two P=P bonds (P1–P2 2.150(2), P4–P5 2.152(2) Å) are capped by the 13 valence electron fragment FeCp* (Fig. 1). The iron center



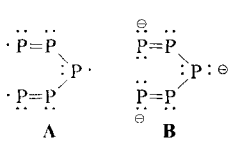


Fig. 1. Crystal structure of **3**. Selected distances [Å] and angles [°]: Ta-Fe 2.854(1), Ta-P1 2.378(2), Ta-P5 2.377(2), Ta-P3 2.391(2), Fe-P1 2.357(2), Fe-P5 2.369(2), Fe-P2 2.300(2), Fe-P4 2.281(2), P1-P2 2.150(2), P4-P5 2.152(2), P2-P3 2.271(2), P3-P4 2.265(2), P2···P4 2.80, P1···P5 3.60, Fe-$Cp^*_{(centr.)}$ 1.723, Ta-$Cp''_{(centr.)}$ 2.106; Ta-P1-P2 74.63(6), Ta-P5-P4 74.56(6), P1-P2-P3 111.40(8), P3-P4-P5 111.23(8), P2-P3-Ta 72.26(6), P4-P3-Ta 72.32(6), P1-Ta-P3 99.99(6), P3-Ta-P5 99.74(6), P1-Ta-P5 98.51(5), P2-P3-P4 76.37(7), sum of the angles of the four-membered rings: Ta,P1,2,3 358.3, Ta,P3,4,5 357.8, Fe,P1,Ta,P5 345.8, Fe,P2,3,4, 352.6, dihedral angle: P1,2,4,5|P2,3,4 108.8.

achieves the 18 valence electron configuration through a Ta–Fe bond (metal–metal distance 2.845(1) Å). The other P–P bonds (P2–P3 2.271(2), P3–P4 2.265(2) Å) are significantly longer. The P_5 ligand of **3** can be described as a triradical pentaphospha-1,4-pentadiene-1,3,5-triyl (**A**) or as a trianion P_5^{3-} (**B**).

In LaP_5 ($La^{3+}P_5^{3-}$), whose P atoms of one layer are linked to give a network comprising condensed twelve-membered rings with a $^2_\infty(P_5^{3-})$ anion lattice, the P–P distances range from 2.16 to 2.22 Å.[8] Whereas in **3** the Ta–P bond lengths (2.377(2)–2.391(2) Å) differ only slightly, the Fe–P distances can be subdivided into two shorter (Fe–P2 2.300(2), Fe–P4 2.281(2) Å) and two longer ones (Fe–P1 2.357(2), Fe–P5 2.369(2) Å). The plane P1,2,4,5 and the plane of the ring-C atoms of the Cp* ligand are arranged almost parallel to each other (deviation 3°), the same is true for the P1,3,5 plane and the plane of the ring-C atoms of the Cp'' ligand (deviation 2.3°).

The X-ray structure analysis[7] shows the P_5 ligand of **5** to be a *cyclo*-P_5 with an envelope conformation (Fig. 2). In addition

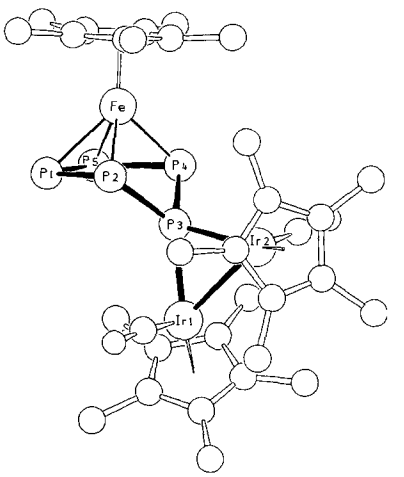

Fig. 2. Crystal structure of **5**. Selected distances [Å] and angles [°]: Fe-P1 2.327(3), Fe-P2 2.310(3), Fe-P4 2.311(3), Fe-P5 2.322(3), Ir1-P3 2.288(2), Ir2-P3 2.305(2), Ir1-Ir2 2.776(1), P1-P2 2.146(4), P2-P3 2.170(3), P3-P4 2.166(3), P4-P5 2.137(4), P1-P5 2.160(5), P2···P4 3.16, Fe-$Cp^*_{(centr.)}$ 1.702, Ir1-$Cp^*_{(centr.)}$ 1.907, Ir2-$Cp^*_{(centr.)}$ 1.903; P2-P1-P5 103.5(2), P1-P5-P4 103.6(2), P5-P4-P3 100.6(2), P1-P2-P3 101.1(2), P2-P3-P4 93.7(1), P2-Fe-P4 86.4(1), sum of the angles: Fe,P2,3,4 359.6, dihedral angles: P2,3,4|P2,1,5,4 121.8, Fe,P2,3,4|P3,Ir1,2 89.0.

to two shorter P–P bonds (P1–P2 2.146(4), P4–P5 2.137(4) Å), two slightly longer ones are observed (P2–P3 2.170(3), P3–P4 2.166(3) Å), which, however, are still considerably shorter than those in the five-membered phosphacycles $(PR)_5$ with an envelope conformation (R = CF_3, C_6H_5, $\bar{d}$(P–P) 2.22 Å).[9] Cp*Fe caps the planar unit P1,2,4,5 almost symmetrically (Fe–P 2.310(3)–2.327(3) Å). In the spirocycle **5** the planes P3,Ir1,2 and P2,3,4,Fe are perpendicular (89°), the ligands at the Ir atoms are arranged *trans*. The $FeIr_2$ complex **5** is diamagnetic, possibly because the Fe atom is negatively and the P3 atom (Fig. 2) is positively charged.

Compound **5** reacts with additional $[\{Cp^*Ir(CO)\}_2]$ (**4**) under mild conditions. In this way a P–P bond of the *cyclo*-P_5 unit and the Ir–Ir bond of the starting material **4** are cleaved, and this in turn leads to the formation of an IrP_5 six-membered ring, which, as the X-ray structure analysis shows,[7] has a strongly distorted chair conformation (Fig. 3) and P–P bonds of considerably different lengths (2.126(6)–2.198(5) Å). This results in an unsymmetrical capping by the Cp*Fe fragment (Fe–P 2.259(6)–2.363(5) Å). Going from **5** to **6** the *trans* configuration of the ligands at Ir1 and Ir2 is retained, the plane of the three-membered ring and the Fe,P2,3,4 plane now form an angle of 84°, thus they deviate more strongly from orthogonality than in complex **5**. The P–Ir distance between terminal Cp*(CO)Ir ligand and P_5 unit (Ir4–P5 2.232(4) Å) is significantly shorter than the corresponding distances between an inserted Cp*(CO)Ir group and a P_5 unit (Ir3–P1,2 2.371(4)–2.408(5) Å); similar

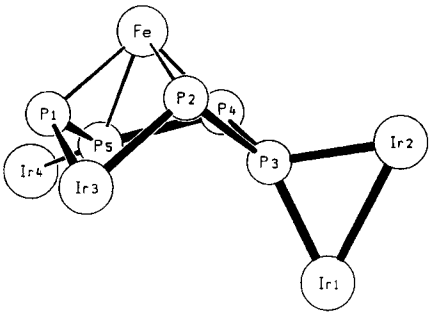

Fig. 3. Crystal structure of **6** (Cp* and CO ligands are not shown). Selected distances [Å] and angles [°]: Fe-P1 2.259(6), Fe-P2 2.322(5), Fe-P4 2.272(5), Fe-P5 2.363(5), Ir1-P3 2.296(4), Ir2-P3 2.312(4), Ir3-P1 2.371(4), Ir3-P2 2.408(5), Ir4-P5 2.232(4), Ir1-Ir2 2.757(1), P2-P3 2.198(5), P3-P4 2.162(6), P4-P5 2.144(7), P1-P5 2.126(6), P1 ··· P2 2.64, P2 ··· P4 3.14, P3 ··· P5 3.40, P3 ··· Ir3 3.73, P5 ··· Ir3 3.84, Fe ··· Ir3 3.86, Fe-$Cp^*_{(centr.)}$ 1.748, Ir1-$Cp^*_{(centr.)}$ 1.918, Ir2-$Cp^*_{(centr.)}$ 1.915, Ir3-$Cp^*_{(centr.)}$ 1.949, Ir4-$Cp^*_{(centr.)}$ 1.932; P2-Ir3-P1 67.2(2), Ir3-P1-P5 117.1(2), P1-P5-P4 111.0(3), P5-P4-P3 104.3(3), P4-P3-P2 92.1(2), P3-P2-Ir3 108.3(2), P2-Ir3-P1 67.2(2), sum of the angles: Fe,P2,3,4 359.3, P1,Ir3,P2,Fe 360.0, dihedral angle: Fe,P2,3,4|P3,Ir1,2 84.0.

relationships are observed in [(triphos)Ir(η^3-P_3)] (triphos = $MeC(CH_2PPh_2)_3$).[10] Compound **6** is also diamagnetic.

Experimental Procedure

3: **1** (64 mg, 0.19 mmol) and **2** (97 mg, 0.21 mmol), dissolved in decalin (30 mL), were heated to reflux and stirred for about 10 h (until the disappearance of the CO band of **2** in the IR spectrum). The color changed from yellow-green to brown-green. After removal of the decalin under vacuum, the residue was taken up in a small amount of CH_2Cl_2, adsorbed onto silica gel (ca. 1 g; 2% H_2O) and dried. The column chromatographic workup (column 16 × 1.5 cm, packed with SiO_2/petroleum ether) gave, after a petroleum ether fraction which contained small amounts of **2**, a dark green fraction (petroleum ether:toluene 10:1) from which green-black crystals of **3** were obtained after removal of the solvent and recrystallization from a saturated *n*-hexane solution at −78 °C. Yield: 68 mg (52%).

5 [**6**]: **1** (138.4 mg, 0.4 mmol) [103.8 mg, 0.3 mmol)] and **4** (284.4 mg, 0.4 mmol) [426.6, 0.6 mmol] were dissolved in toluene (20 [30] mL) and stirred for 20 min at 110 °C [25 °C] (IR control as for the synthesis of **3**). The dark green reaction mixture was concentrated to about half the volume, silica gel (ca. 1 g, 2% water) was added [filtered through filter flakes] and **5** worked up by column chromatography [left standing at −78 °C; the supernatant solution was pipetted off and the black-green crystals of **6** were washed with cold *n*-hexane, yield 323 mg (61%)] (column 20 × 1.5 cm, packed with SiO_2/petroleum ether). Traces of unreacted starting material **1** were eluted with petroleum ether, with toluene a dark green fraction of **5** (380.5 mg, 90%) was obtained, which gave black-green needlelike crystals on crystallization from toluene at room temperature.

High-Pressure Synthesis of K_2PtH_6, a Saltlike Hydride with the K_2PtCl_6 Structure**

Welf Bronger* and Gudrun Auffermann

The hydrides A_2PtH_4 and A_3PtH_5 (A = K, Rb, Cs)[1–4] have been prepared by a reaction of the binary alkali metal hydrides AH with platinum sponge in an extremely pure hydrogen atmosphere according to Equation (a). The reaction temperatures lay between 580 and 700 K, and the hydrogen pressures between 1 and 10 bar.

$$x\,AH + Pt + (z - x)/2\,H_2 \rightarrow A_xPtH_z \qquad (a)$$

The planar $[PtH_4]^{2-}$ building unit is characteristic of the crystal structures of these ternary hydrides. Compounds of the type A_3PtH_5 additionally contain discrete hydride ions, which are coordinated in an octahedral fashion by A^+ ions as in binary alkali metal hydrides. In contrast to analogous halogen compounds, the mobility of the hydrogen atoms within the $[PtH_4]^{2-}$ building units gives rise to phase transitions. Whereas the planar anions are ordered in the low-temperature modifications, the

[**] This work was supported by the Bundesministerium für Forschung und Technologie and by the Fonds der Chemischen Industrie. In addition we were financed by the International Centre for Diffraction Data (ICDD) Grant-in-Aid Program and by the Large Installation Plan of the Commission of the European Community. We thank Dr. P. Müller for performing the neutron diffraction experiments. We are grateful to the Risø National Laboratory for the measurement time made available to us.

averaged structure in the high-temperature modification involves an octahedral coordination of the platinum atoms with an occupation factor of 2/3 for the hydrogen positions.[5] This factor arises because the four hydrogen atoms rapidly change sites within the octahedron. The question whether further hydrogen could be incorporated into the structure under higher H_2 pressure, and thus whether the platinum could be oxidized beyond the oxidation state II, remained unanswered. In the initial experiments with a newly developed high-pressure autoclave capable of a hydrogen reaction pressure of 1500–1800 bar and a temperature of 775 K, we have now synthesized in the potassium/platinum/hydrogen system the compound K_2PtH_6. Potassium hydride[6] and platinum sponge (Degussa, specified purity 99.9%) were employed in a molar ratio of 2:1. The duration of the experiment was 6 h, and its course could be followed directly with a pressure gauge. The uptake of hydrogen, determined from the pressure difference, was 2 mol H_2 per mol Pt. The very air- and moisture-sensitive product is a colorless powder in a uniform phase. To characterize the powder samples, X-ray analyses were performed at room temperature, which showed that the platinum and potassium atoms form an atomic arrangement analogous to that in fluorite. They therefore also correspond to the arrangement in the K_2PtH_4 type. A comparison of the lattice parameters determined by X-ray diffraction for the two phases showed that the unit cell of the new, hydrogen-enriched phase is marginally larger (Table 1).

Table 1. K_2PtH_6 and K_2PtH_4: comparison of the lattice constants [Å] from X-ray diffraction investigations with the low-temperature Guinier camera G645.

Cmpd.	T [K]		
	295	9	
K_2PtH_6	$a = 8.1760(2)$	$a = 8.1116(2)$	
K_2PtH_4	$a = 8.0653(4)$	$a = 5.6215(8)$	$c = 8.122(2)$

Since K_2PtH_4 undergoes a reversible phase change at 195 K as a consequence of the mobility of the hydrogen atoms, comparative X-ray diffraction investigations of K_2PtH_6 and K_2PtH_4 with a low-temperature Guinier camera (model G645, from Huber, Rimsting; temperature range 9–300 K) were conducted to provide further support for the postulated composition K_2PtH_6. The samples were contained in shallow sample holders developed specifically for extremely air- and moisture-sensitive substances during diffractometer imaging. The analysis of the data showed that, as expected, the new phase K_2PtH_6 does not undergo the phase change (cubic → tetragonal) corresponding to that experienced by K_2PtH_4 on cooling (Fig. 1). Furthermore, complementary experiments with a Guinier heating camera showed that K_2PtH_6 can be converted into K_2PtH_4 above 500 K with concomitant H_2 loss. The process is reversible at a suitable H_2 pressure.

For conclusive elucidation of the composition and structure of K_2PtH_6, the corresponding perdeuterated compound, which was synthesized analogously to the hydride, was studied by elastic neutron diffraction at 295 and 8.5 K at the TAS I workstation of the DR 3 reactor in the Risø National laboratory (Denmark). An aluminum tube (inner diameter 10 mm, length 40 mm, wall thickness 0.05 mm) served as sample holder, into which the sample was loaded under argon before closure with a Viton seal. For the low-temperature measurements a closed-cycle, helium-operated refrigerator was used. The analysis of the data was performed with the program DBWS 9006.[7] The neutron experiments confirmed that each platinum is surrounded

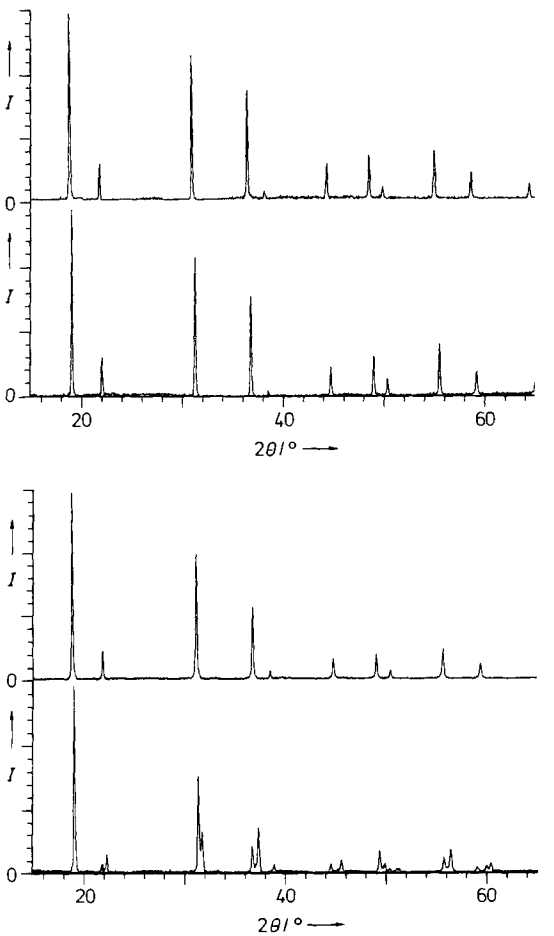

Fig. 1. Sections of the Guinier diffractometer images of K_2PtH_6 and K_2PtH_4 (total range: $10° < 2\theta < 100°$, step size in 2θ:0.004°). Represented from top to bottom are K_2PtH_6 at 295 K, K_2PtH_6 at 9 K, K_2PtH_4 at 295 K, and K_2PtH_4 at 9 K. Both compounds have the same metal-atom arrangement at room temperature, which is maintained at 9 K for K_2PtH_6. In contrast, K_2PtH_4 has undergone a phase change cubic → tetragonal by this temperature. I = measured relative intensity.

by six deuterium atoms in a regular octahedron, and thus the atomic arrangement in K_2PtD_6 is isotypic with that of K_2PtCl_6 (Fig. 2). Final refinements (Table 2) with floating occupation

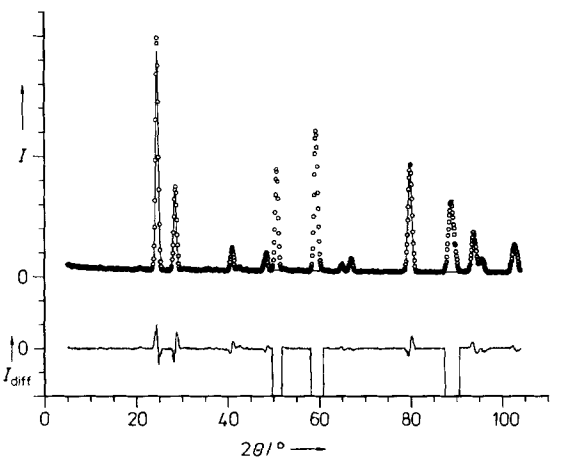

Fig. 2. Neutron diffraction diagram of K_2PtD_6; in addition to the measured (o) and the calculated (—) profiles the difference profile is shown. For the three ranges in which the Bragg reflections of K_2PtD_6 overlap with those of the aluminum tube, only the measured profile is given, since these three regions are also excluded from the refinement. I = measured or calculated relative intensity; I_{diff} = difference between the measured and calculated relative intensities.

Table 2. K_2PtD_6: results of the elastic neutron diffraction at TAS I at room temperature (space group: $Fm3m$, $Z = 4$).

Range					$5° < 2\theta < 105°$
Wavelength					2.01405 Å
Lattice parameter					$a = 8.1399(6)$ Å
Number of reflections considered in the refinement					12
Atomic site parameters and temperature factors					
Pt in (4a)	0	0	0		$B_{iso} = 0.4(5)$ Å^2
K in (8c)	1/4	1/4	1/4		$B_{iso} = 1.0(8)$ Å^2
D in (24e)	x	0	0	x = 0.2015(5)	$B_{iso} = 1.6(4)$ Å^2

parameters for the deuterium positions yielded no deviation from a complete occupation of the octahedral positions. The calculations converged per formula unit K_2PtD_z to a value of $z = 6.00 \pm 0.03$. A phase change at low temperatures was not observed. The structures of K_2PtD_6 and K_2PtD_4 are contrasted in Figure 3. The Pt–D distances at 295 K of 1.640(4) Å in K_2PtD_6 are slightly longer than those in K_2PtD_4 (1.62(1) Å). The phase sequence K_2PtH_4, K_3PtH_5, K_2PtH_6 with increasing hydrogen pressure is in agreement with the trend for the decrease in the volume increment for hydrogen.

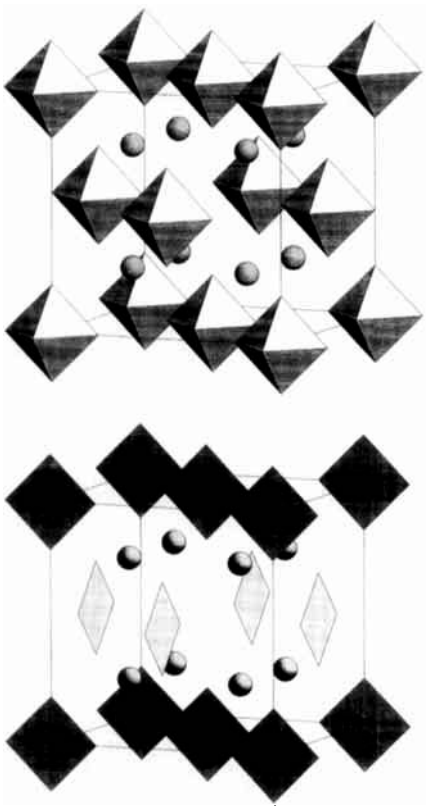

Fig. 3. Comparison of the structures of K_2PtD_6 and the high-temperature modification of K_2PtD_4 (top) with the low-temperature modification of K_2PtD_4 (bottom). Represented are the platinum–deuterium octahedra, whose D-positions are completely occupied for K_2PtD_6 and 2/3 occupied for K_2PtD_4, the platinum–deuterium squares, and the positions of the potassium ions. The structure of the low-temperature form of K_2PtD_4 is shown from the same viewpoint as the high-temperature form, although it may be described by a tetragonal unit cell that is half as large and that has the following cell parameters: $a_{tetr} = a_{cub}/\sqrt{2}$ and $c_{tetr} = a_{cub}$.

The hydride obtained in the high-pressure synthesis enables an extended comparison between metal–hydrogen and metal–halogen complexes. For the hydrogen pressures previously applied, only those hydrides A_xMH_z in which the transition metals M do not attain the highest oxidation states observed for the corresponding ternary fluorides or chlorides were synthesized.[5] Now hydrides are accessible that contain transition metals in the same oxidation states as the halides.

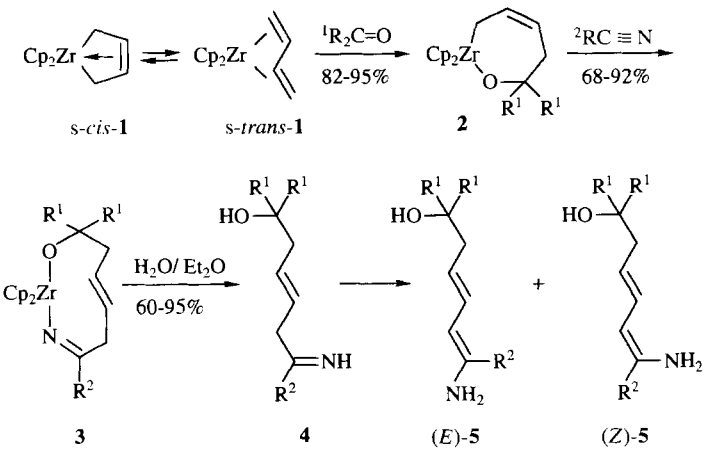
A Template Synthesis of Stable Conjugated Primary Enamines from Ketones, Nitriles, and Butadiene**

Luis López, Martin Berlekamp, Dorothee Kowalski, and Gerhard Erker*



In the 1970s the research groups of H. Ahlbrecht and others showed that β-aryl-substituted primary enamines and their imine tautomers exist in equilibrium at room temperature in an approximately equimolar ratio.[1–3] It is now known that the thermochemical conjugation energy of (heteroatom-free) arylalkenes is about 2 kcal mol^{-1} less than that of the analogous conjugated dienes.[4] If this is also the case for the NH_2-substituted system, simple *conjugated* primary enamines should be significantly favored in this equilibrium over the corresponding imine tautomers. Using a template synthesis[5] we have prepared compounds with which this fundamental relationship can be confirmed experimentally for the nitrogen-substituted frameworks. In this simple fashion stable 1-aminobutadienes that do not contain other enamine-stabilizing substituents[2b] can thus be obtained under thermodynamic control.

During the last few years we have shown that (butadiene)zirconocene reacts with two equivalents of a nitrile to form metallacyclic nine-membered ring compounds that can be hydrolyzed to give 1,6-diaminohexatrienes.[6] We have now treated the (butadiene)zirconocene reagent **1**,[7] first with benzophenone to give the diphenyloxazirconacycloheptene **2a**,[8] and then with one equivalent of 4-methylbenzonitrile. The C-C coupling reaction to give the substituted 1-aza-3-oxa-2-zirconacyclononа-

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Alfried Krupp von Bohlen and Halbach Foundation. Dr. L. López thanks the Ministerio de Educacion y Ciencia, Madrid, and the Alexander von Humboldt Foundation for research grants. We thank Prof. Dr. W. R. Roth for interesting discussions and suggestions.

6,9-diene system **3a** took place smoothly at 60 °C within 18 h. The product **3a** contains a *trans* double bond in the ring and is chiral [^{1}H NMR ([D$_6$]benzene, 200 MHz, 300 K): Cp resonance

2a, R^1 = Ph; **2b**, R^1 = –CH$_2$CH$_2$–; **2c**, R^1 = CH$_3$

3–5	**a**	**b**	**c**	**d**	**e**	**f**	**g**	**h**

signals at δ = 6.06 and 5.69; diastereotopic methylene protons at C8 and C5 (3.48, 3.13, 2.98, 2.74)]. Compound **3a** is an organometallic/heterocyclic analog of *trans*-cyclononene and exhibits, as expected, a similar activation barrier for the intramolecular enantiomerization by ring inversion ($\Delta G^{\ddagger}_{ent}$(322 K) = 15.6 ± 0.5 kcal mol^{-1}).[9] Hydrolysis of **3a** in the two-phase system Et$_2$O/H$_2$O (room temperature, 1 h), gave (*3E,5Z*)-6-amino-1,1-diphenyl-6-(*p*-tolyl)-3,5-hexadien-1-ol [(*Z*)-**5a**, 60%] as the sole organic product.[10] Compound (*Z*)-**5a** shows the typical ^{13}C NMR signals of the 1-aminobutadiene unit at δ = 146.7, 100.9, 130.5, and 121.8 ([D$_6$]benzene). The ^{1}H NMR signal of the amino group was recorded at δ = 3.69, that of the OH group at δ = 2.71.

With benzonitrile and **2a** we obtained **3b**, hydrolysis of which gave a mixture of ketimine **4b** (about 40%) and the conjugated primary enamines (*Z*)-**5b** and (*E*)-**5b** (4:1). After 2 h in benzene the ketimine component could no longer be detected.

Terephthalic acid dinitrile reacted with **2a** in a 1:1 molar ratio to give mainly the metallacyclic nine-membered ring **3c**, which still contained a free cyano group (IR: $\tilde{\nu}$(C≡N) = 2229 cm^{-1}, Table 1) that was hydrolyzed to a mixture of the (*E*)/(*Z*) isomeric ketimines **4c** in a 4:1 ratio [^{1}H NMR: δ (=NH) = 9.78 and 9.43]. In solution the ketimines tautomerize rapidly even at room temperature to give the thermodynamically favored conjugated primary enamines **5**. After 1 h in benzene at 20 °C only a single aminobutadiene derivative was found by NMR spectroscopy, to which we assign the structure of (*3E,5Z*)-6-amino-6-(4-cyanophenyl)-1,1-diphenyl-3,5-hexadien-1-ol [(*Z*)-**5c**]. It is no longer possible to detect the ketimine in the equilibrium in this system by NMR spectroscopy ([D$_6$]benzene). The reaction of **2a** with fumaric acid dinitrile took a similar course. With an equimolar ratio the reaction cleanly gave the organometallic 1:1 adduct **3d**. Subsequent hydrolysis gave, under kinetic control, a 3:2 mixture of the ketimines (*E*)-**4d** and (*Z*)-**4d**, from which the functionalized aminohexatriene (*2E,4Z,6E*)-4-amino-9-hydroxy-9,9-diphenyl-2,4,6-nonatriene nitrile (*Z*-**5d**) is formed under equilibrium conditions as sole product.

Table 1. Characteristic data for compounds **3**–**8**.

3a: 560 mg (72%), m.p. 101 °C (decomp., DSC); correct analysis (C,H,N); IR(KBr): $\tilde{\nu}$ = 1654 (C=N), 1640 cm^{-1}; ^{1}H NMR (200 MHz, 300 K, [D$_6$]benzene): δ = 7.64–7.11 (several m, 14H, arom.), 6.06, 5.69 (s, each 5H, Cp), 5.28 (m, 2H, 6-H, 7-H), 3.48, 3.13, 2.98, 2.74 (m, each 1H, CH$_2$), 2.20 (s, 3H, CH$_3$); ^{13}C NMR (50 MHz, 300 K, [D$_6$]benzene): δ = 167.6, 139.3, 137.0 (C), 131.8, 130.2, 129.3, 128.5, 128.0, 127.5, 127.1, 110.4 (CH$_2$), 86.3 (C), 47.7, 39.4 (CH$_2$), 21.3 (CH$_3$)

3b: 430 mg (68%), m.p. 108 °C (decomp., DSC); correct analysis (C,H,N); IR(KBr): $\tilde{\nu}$ = 1653 (C=N) cm^{-1}; ^{1}H NMR ([D$_6$]benzene): δ = 7.69–7.10 (m, 15H, arom.), 6.09, 5.68 (s, each 5H, Cp), 5.28 (m, 2H, 6-H, 7-H), 3.36, 3.06, 2.85, 2.66 (m, each 1H, CH$_2$); ^{13}C NMR ([D$_6$]benzene): δ = 167.6, 139.3, 131.8, 130.3, 129.4, 128.6, 128.3, 127.1, 126.8, 110.5, 110.4 (CH), 86.3 (C), 47.8, 39.5 (CH$_2$)

3c: obtained only as a mixture with terephthalic acid dinitrile (ca. 30%) and the bisadduct (ca. 10%); IR(KBr): $\tilde{\nu}$ = 2229 (C≡N), 1654 (C=N) cm^{-1}; ^{1}H NMR ([D$_6$]benzene): δ = 7.40–7.15 (m, 14H, arom.), 6.10, 5.62 (s, each 5H, Cp), 5.19 (m, 2H, 6-H, 7-H), 3.12, 2.68 (m, each 2H, CH$_2$). (The 2:1-adduct from **2a** and terephthalic acid dinitrile shows Cp-signals at δ = 6.09 and 5.72); ^{13}C NMR ([D$_6$]benzene): δ = 165.6 (C9), 141.5 (*ipso*-C, Ph), 132.3, 132.0, 131.1, 130.6, 127.0, 126.8 (C6, C7, C(Ph)), 119.0 (CN), 112.9 (*ipso*-C, Ph), 110.6 (Cp), 86.5 (C4), 47.5, 39.4 (C8, C5)

3d: 570 mg (72%) violet crystals, m.p. 101 °C (decomp., DSC); correct analysis (C,H,N); IR(KBr): $\tilde{\nu}$ = 2220 (C≡N), 1660 (C=N), 1635 cm^{-1}; ^{1}H NMR ([D$_6$]benzene): δ = 7.39–7.08 (m, 10H, arom.), 6.23, 5.17 (AX, ^3J = 16.4 Hz, 2H, CH=CHCN), 5.85, 5.52 (br. s, each 5H, Cp), 5.03 (m, 2H, olef.), 3.02 (m, 1H), 2.61 (m, 2H), 2.38 (m, 1H, CH$_2$); ^{13}C NMR ([D$_6$]benzene): δ = 164.4 (C), 147.1, 131.1, 129.9, 127.9, 126.9 (CH), 118.3 (C), 110.7, 101.0 (Cp), 86.7 (C), 47.3 (CH$_2$), 40.7 (CH$_2$). 1 *ipso*-C not observed

4b: ^{1}H NMR (as a mixture with the enamines, [D$_6$]benzene): δ = 9.61 (s, 1H, =NH), 7.52–6.91 (m, 15H, arom.), 2.8 (m, 4H, CH$_2$), OH not observed

4c: ^{1}H NMR (as a mixture with the second imine isomer [**4c'**] and terephthalic acid dinitrile, ([D$_6$]benzene): δ = 9.78 (s, 1H, =NH) [**4c'**: 9.43], 7.52–6.94 (m, 14H, arom.), 5.34, 5.07 (m, each 1H, CH=CH), 2.82, 2.48 (m, each 2H, CH$_2$), 2.22 (s, 1H, OH)

4d: only characterized spectroscopically, 2 isomers; IR(KBr): $\tilde{\nu}$ = 3444, 3376, 3236 (OH, NH), 2229, 2228 (C≡N), 1644 (C=N), cm^{-1}; ^{1}H NMR (CDCl$_3$, only one isomer observed): δ = 9.76 (s, 1H, =NH), 7.44–7.16 (m, 10H, arom.), 6.93, 5.94 (^3J = 16.8 Hz, 2H, CH=CHCN), 5.43 (m, 2H, olef.), 3.10, 2.95 (m, each 2H, CH$_2$), 2.39 (m, 1H, OH); in [D$_6$]benzene two isomers in the ratio 3:2 were observed (δ(=NH) = 9.77, 8.93); ^{13}C NMR (CDCl$_3$): δ = 172.3 (C), 149.5 (CH), 146.2 (C), 133.8, 128.3, 127.2, 126.0, 125.2 (CH), 121.0 (C), 105.2 (CH), 45.5, 39.5 (CH$_2$), quaternary C under the solvent signal.

5a: 210 mg (60%) oil, which still contains ca. 5% solvent and unidentified impurities; IR: $\tilde{\nu}$ = 3447, 3368, 3270 (NH$_2$, OH), 1617 cm^{-1}; ^{1}H NMR (CDCl$_3$, 200 MHz): δ = 7.49–7.14 (m, 14H, arom.), 6.41, 5.37, 5.31 (m, each 1H, olef.), 3.69 (br. m, 2H, NH$_2$), 3.13 (m, 2H, CH$_2$), 2.71 (br. s, 1H, OH), 2.32 (s, 3H, CH$_3$); ^{13}C NMR (CDCl$_3$): δ = 146.7, 141.8, 138.0, 136.1 (C), 130.5, 129.0, 128.0, 126.7, 126.0, 125.3, 121.8, 100.9 (CH), 77.1 (C), 46.3 (CH$_2$), 21.1 (CH$_3$)

5b: 260 mg (69%) oil, 2 isomers; IR: $\tilde{\nu}$ = 3539–3177, 1610 cm^{-1}; ^{1}H NMR (CDCl$_3$): major component: δ = 7.50–7.08 (m, 15H, arom.), 6.43, 5.42, 5.34 (m, each 1H, olef.), 3.70 (br. s, 2H, NH$_2$), 3.15 (m, 2H, CH$_2$), 2.69 (br. s, 1H, OH); byproduct **5b'**: δ = 6.20 (m, 1H), 5.15 (m, 1H, olef.), 2.94 (m, 2H, CH$_2$), otherwise as for **5b**; ^{13}C NMR (CDCl$_3$, 50 MHz): δ = 146.7, 141.8, 139.0 (C), 130.4, 128.4, 128.2, 128.1, 126.7, 126.0, 125.5, 122.4, 101.6 (CH), 77.2 (C), 46.4 (CH$_2$)

5c: 200 mg (60%) isolated as a mixture with ca. 20% terephthalic acid dinitrile; IR(KBr): $\tilde{\nu}$ = 3467, 3438, 3361 (NH$_2$, OH), 2232 (C≡N), 1602 cm^{-1}; ^{1}H NMR (CDCl$_3$): δ = 7.57–7.1 (m, 14H, arom.), 6.39, 5.52, 5.41 (m, each 1H, olef.), 3.66 (br. s, 2H, NH$_2$), 3.16 (m, 2H, CH$_2$), 2.61 (br. s, 1H, OH); ^{13}C NMR (CDCl$_3$): δ = 146.5 (CNH, 139.5 (*ipso*-C, arom.), 132.7 (CH, arom., double intensity), 132.3 (*ipso*-C, arom.), 132.2 (C4), 128.1, 126.8, 125.9 (CH, arom.), 125.4 (C3), 116.1 (CN), 111.0 (*ipso*-C, arom.), 104.6 C5), 77.2 (C1), 46.3 (C2)

5d: 180 mg (64%) recrystallized from benzene, m.p. 175 °C (DSC); correct analysis (C,H,N); IR(KBr): $\tilde{\nu}$ = 3530, 3460, 3375 (NH$_2$, OH), 2219 (C≡N), 1637 cm^{-1}; ^{1}H NMR (CDCl$_3$): δ = 7.50–7.10 (m, 10H, arom.), 6.66, 5.25 (AX, ^3J = 16.2 Hz, 2H, CH=CHCN), 6.28 (m, 1H), 5.67 (m, 1H), 5.33 (m, 1H, olef.), 3.31 (br. s, 2H, NH$_2$), 3.16 (m, 2H, CH$_2$), 2.39 (br. s, 1H, OH); ^{13}C NMR (CDCl$_3$): δ = 148.2, 146.3, 136.6, 130.9, 128.3, 127.1, 126.0, 118.2, 116.1, 93.1, 77.2, 46.4

5e: from **2a** by treatment with pivalonitrile and subsequent hydrolysis, 170 mg (82%) oil, 2 isomers (9:1); main component: IR(NaCl): $\tilde{\nu}$ = 3527, 3481, 3398 (NH$_2$, OH), 1635 cm^{-1}; ^{1}H NMR ([D$_6$]benzene): δ = 7.57–6.99 (m, 10H, arom.), 6.20, 5.39, 4.92 (m, each 1H, olef.), 3.08 (m, 2H, CH$_2$), 2.89 (br. s, 2H, NH$_2$), 2.56 (br. s, 1H, OH), 0.91 (s, 9H, *t*Bu); ^{13}C NMR ([D$_6$]benzene): δ = 151.1, 147.8 (C), 131.4, 128.5, 126.8, 126.6, 120.1, 96.2 (CH), 47.0 (CH$_2$), 34.9 ((CH$_3$)$_3$C), 28.8 ((CH$_3$)$_3$C)

(Table 1 continued on next page)

Table 1. (continued)

5f: from **1** by treatment with cyclopentanone and benzonitrile and subsequent hydrolysis. 540 mg (95%) oil, 2 isomers (7:3); major component: IR(NaCl): $\tilde{\nu}$ = 3557, 3467, 3364 (NH_2, OH), 1680, 1639, 1620 cm^{-1}; ^1H NMR ($CDCl_3$): δ = 7.6–7.1 (m, 5H, arom.), 6.31, 5.67, 5.44 (m, each 1H, olef.), 3.71 (br., 2H, NH_2), 2.41 (m, 2H, CH_2), 1.9–1.3 (m, 9H, OH, CH_2); ^{13}C NMR ([D$_6$]benzene): δ = 141.6, 140.2 (C), 129.2, 128.6, 128.1, 126.0, 124.7 (CH), 102.4, 81.5 (C), 45.8, 39.7, 24.3 (CH_2)

5g: from **1** by treatment with cyclopentanone and pivalonitrile and subsequent hydrolysis. 1.24 g (89%) oil, 2 isomers (95:5); major component: IR(NaCl): $\tilde{\nu}$ = 3541, 3468, 3375 (NH_2, OH), 1634 cm^{-1}; ^1H NMR ([D$_6$]benzene): δ = 6.18, 5.58, 5.12 (m, each 1H, olef.), 2.97 (br., 2H, NH_2), 2.35 (m, 2H, CH_2), 1.9–1.3 (m, 8H, CH_2), 1.15 (br. s, 1H, OH), 0.99 (s, 9H, H from *t*Bu); ^{13}C NMR ([D$_6$]benzene): δ = 150.2 (C), 129.2, 122.4, 96.6 (CH), 81.5 (C), 45.8 (CH), 39.7 (CH_2), 34.9 (C from *t*Bu), 29.0 (CH_3 von *t*Bu), 24.3 (CH_2)

5h: from **1** by reaction with acetone and benzonitrile and subsequent hydrolysis, 320 mg (81%) oil, 2 isomers (4:1); main component: IR(NaCl): $\tilde{\nu}$ = 3548, 3437, 3364 (NH_2, OH), 1680, 1639, 1618 cm^{-1}; ^1H NMR ([D$_6$]benzene): δ = 7.5–7.0 (m, 5H, arom.), 6.18, 5.62, 5.52 (m, each 1H, olef.), 2.97 (br., 2H, NH_2), 2.24 (m, 2H, CH_2), 1.34 (br. s, 1H, OH), 1.14 (s, 6H, CH_3); ^{13}C NMR ([D$_6$]benzene): δ = 141.6, 140.1 (C), 129.0, 128.6, 128.1, 126.0, 124.5, 102.4 (CH), 70.3 (C), 48.1 (CH_2), 29.4 (CH_3)

6: 160 mg (84%), m.p. 100 °C (DSC); correct high resolution mass spectrum; IR(KBr): $\tilde{\nu}$ = 3479 (OH), 1677 (C=O), 1604 cm^{-1}; ^1H NMR ($CDCl_3$): δ = 7.81–7.19 (m, 14H, arom.), 5.85, 5.44 (m, each 1H, olef.), 3.64, 3.09 (m, each 2H, CH_2), 2.98 (br. s., 1H, OH), 2.41 (s, 3H, CH_3); ^{13}C NMR ($CDCl_3$): δ = 197.7, 146.6, 143.9, 133.9 (C), 129.4, 129.2, 128.8, 128.3, 128.1, 126.7, 125.9 (CH), 76.7 (C), 45.5, 42.1 (CH_2), 21.6 (CH_3)

8: 140 mg (75%) oil; correct high resolution mass spectrum; IR(Film): $\tilde{\nu}$ = 1678(C=O) cm^{-1}; ^1H NMR ($CDCl_3$): δ = 7.90–7.22 (m, 14H, arom.), 4.73 (m, 1H), 3.58 (m, 1H), 3.08 (m, 1H), 2.64 (m, 2H), 2.42 (s, 3H, CH_3), 2.26 (m, 1H), 1.77 (m, 1H); ^{13}C NMR ($CDCl_3$): δ = 198.1, 146.9, 146.3, 143.8, 134.6 (C), 129.2, 128.3, 128.1, 128.0, 126.6, 125.8, 125.7 (CH), 88.1 (C), 75.5 (CH), 45.1, 38.6, 31.6 (CH_2), 21.6 (CH_3)

Aliphatic ketones (cyclopentanone **2b**, acetone **2c**) can also be used as building blocks in this template synthesis (see Table 1, **5f–h**). As expected,[4] the primary enamine with aliphatic substituents in the α-position is also energetically preferred over the corresponding imine tautomer (**5g**) under equilibrium conditions. Also in this case the imine is formed first under kinetic control.

These experiments have shown that the thermochemical conjugation energy of an additional C–C double bond is sufficient to make the formation of simple, conjugated primary enamines under equilibrium conditions energetically much more favorable than that of the corresponding ketimine tautomers. In this fashion 1-aminobutadienes and related compounds have been made accessible by thermodynamic control. Using this basis we have now begun to develop simple new routes to and preparative applications of these interesting synthetic building blocks.[11]

The Grand Old Man of Polymer Science

Peptide and Protein Hormones. Structure, Regulation, Activity. A Reference Manual. By *W. König*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. X, 280 pp., hardcover DM 198.00, $ 135.00.—ISBN 3-527-28417-6/1-56081-211-7

The author of this book is a well-known expert in the field of structure–activity relationships of peptide hormones. It is 25 years since the publication of *The Peptides* by Schröder and Lübke; now at last we again have a handbook which serves as a guide and rapid source of information on most aspects of peptide hormones. The most important qualities that one looks for in a reference book on this extremely active field of research are that it should be clearly set out and up-to-date.

A very brief introduction is followed by nine clearly set out review chapters. The list of references in the appendix mainly covers work published in the period 1985 to 1990. It gives only the first authors, without titles or final page numbers, and in this way the publishers have saved fifty to a hundred pages. To have included the titles of the papers would have been very helpful for readers who want quick access to the original literature without having to make a computer search and read abstracts.

The families of hormones covered in the individual chapters are as follows. Chapter 2: gonadoliberins, thyroliberins, gonadotropines; Chapter 3: parathyroid hormones and calcitonins; Chapter 4: corticoliberin-proopiomelanocortins, opioide peptides, etc.; Chapter 5: blood pressure regulating peptides; Chapter 6: cholecystokinins and gastrins; Chapter 7: the secretin family; Chapter 8: neurotensins; Chapter 9: motilins; Chapter 10: pancreatic spasmolytic peptides. Each of these chapters describes the occurrence and distribution, receptors, and biological effects or functions of the hormones, and also the structure–activity relationships for agonists and antagonists, and the applications. The clearly set out tables showing peptide sequences based on single-letter symbols are especially useful.

It is pleasing to note that the author has had the boldness to be brief. From the many synthetic peptide hormone analogues, which already run into thousands for the well-known examples of oxytocin and vasopressin and into hundreds for the more recently discovered hormones, the author has in nearly every case given only the most important results. He has avoided discussing structure–activity relationships based on molecular geometry, apparently preferring not to give an opinion on the well-worn theme of the relevance of three-dimensional structures in solution and at the receptor. Nevertheless, many readers would have appreciated some references to the literature on hormone studies using NMR spectroscopy and molecular dynamics silmulations (MDS), especially since the book's subtitle refers to "structures", not merely to sequences.

One hopes that this work of reference will be updated every three to five years and enlarged as appropriate. The book will be a valuable resource for all scientists working in relevant interdisciplinary fields and needing to have access to the most recent published work on peptide hormones. However, it is not a substitute for a textbook, nor does it claim to be.

der Universität Tübingen (FRG)

From Small Organic Molecules to Large: A Century of Progress. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *H.F. Mark*. American Chemical Society, Washington, DC, 1993. XXVI, 148 pp., hardcover $ 24.95.—ISBN 0-8412-1776-9

Although he was not the world's first polymer chemist, Herman Francis Mark was known as the father of polymer science because of his many contributions to polymer science education and research, first in Europe and then in the United States. His fundamental contributions to science were multidisciplinary. His elder son Hans, a physicist and public official who served as Undersecretary of the U.S. Air Force and Chancellor of the University of Texas, said of him that "My father's greatest accomplishment was as a pioneer in applying modern physics to chemistry." Furthermore, no less an authority than Linus Pauling wrote of Mark, "He was ... one of the leading investigators in ... the use of X-ray diffraction for the determination of the structure of crystals in the years 1923 to 1928, and it was through this work that he developed the feeling for atoms and their interaction with one another that permitted him, later on, to make an effective attack on the problem of the structure and properties of macromolecules. ... I think of him ... as a pioneer in modern structural chemistry and an important early contributor to its development."

Unfortunately, the grand old man of polymer science did not live to see the publication of this autobiography; Mark died on April 6, 1992, less than a month before his 97th birthday. Fortunately, however, his friend and former student Herbert Morawetz not only contributed wonderful anecdotes to this posthumous volume but also edited and proofread the manuscript in its final stages. Furthermore, series editor Seeman has supplemented Mark's account of his life and work by judiciously adding throughout the book material provided by Mark and others that was previously published in *Polymer Science Overview: A Tribute to Herman F. Mark*, edited by G. A. Stahl, American Chemical Soci-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Review Editor, Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ety, Washington, DC, 1981. Thus the picture of Mark that emerges from the book under review here is a complete and insightful one.

Mark was born in Vienna on May 3, 1895, the oldest of the three children of Dr. Herman Carl Mark, a Jewish surgeon who had become converted to Lutheranism, and his wife Lili (née Mueller), a Lutheran. Most of the elder Mark's friends were Jewish, and some were Zionists; later the younger Mark and his wife Marie (Mimi, née Schramek), a Catholic whom he had married in 1922, became ardent Zionists and traveled to Israel on several occasions. An older friend who was a physics student at the University of Vienna took young Mark to hear lectures by such scientific luminaries as Emil Fischer, Albert Einstein, Ernest Rutherford, and Marie Curie.

After graduating from high school (*Gymnasium*) in July, 1913, Mark decided to discharge his military obligation by enlisting in the Austrian army as a one-year volunteer (*einjährig-Freiwilliger*) in the fall of 1913, intending to begin his university studies in the fall of 1914. The outbreak of World War I frustrated his plans, and he served five years in a mountain infantry regiment on the Italian front, being wounded three times, earning fifteen medals, and becoming Austria's most decorated company-grade officer. At the end of the war, in November 1918, his entire division was captured by the Italians and he spent eleven months in a prison camp at a former convent in Monopoli, where he studied Italian, French, and English and with the help of the Italian textbooks organized a course in general chemistry. Always one to turn adversity to his own advantage, Mark later said of his imprisonment, "I have never since learned so much in so many different areas as in the Convento San Francisco" (p. 13). On returning to Vienna in 1919 he immediately returned to his study of chemistry at the university, which he had begun for one semester in 1915 during his recovery from a war wound. In July, 1921, he received his doctorate *summa cum laude* under Wilhelm Schlenk's direction with a dissertation on the pentaphenylmethyl free radical, the subject of the first of his more than 600 publications.

In 1922 Mark joined the most outstanding scientific institute of the time, the Kaiser-Wilhelm-Institut in Berlin-Dahlem, where he used newly developed experimental methods such as X-ray diffraction to study the molecular structures of natural textile fibers (e.g., cellulose, silk, and wool), which he showed to consist of long-chain molecules with molecular weights above 100,000. On the recommendation of K-W-I Director Fritz Haber, Mark then became an Assistant Director in the largest German chemical corporation of the time, IG Farbenindustrie, at Ludwigshafen am Rhein. There, during the period 1927–1932, he worked on electron diffraction and the synthesis and practical application of his results, but he still continued his fundamental studies of macromolecules and published two books. His process for the catalytic production of styrene from ethylbenzene, developed with Carl Wulff, lowered the cost of styrene and made possible the manufacture of polystyrene and Buna S synthetic rubber.

In view of the growing Nazi threat, Mark left Germany to become Professor of Chemistry at the University of Vienna (1932–1938), where, in addition to teaching physical chemistry, he developed the world's first academic curriculum in polymer science and technology at a time when only a few laboratories, mostly in industry, cultivated the subject and when no organized university courses were available. Here he authored two more books, continued his research, and traveled abroad extensively and routinely lectured at international conferences to publicize both his laboratory and the new discipline of modern polymer science.

Once again fate intervened. After helping Jewish colleagues to leave Austria, including Max Perutz, the future (1962) Nobel chemistry laureate, Mark was arrested on March 12, 1938, the day after Hitler's invasion, and imprisoned and interrogated for several days in a Gestapo prison in Vienna. In April, with only their clothes hung on covered coathangers made of platinum wire as a way of taking their valuables with them, Mark, his wife, two young sons, and his Jewish niece, crossed the border into neutral Switzerland disguised as alpine vacationers. After several months of traveling, the family finally arrived in Hawkesbury, Ontario, where Mark became Research Manager for the Canadian International Pulp and Paper Company (1938–1940). Here he modernized the methods and equipment, trained the laboratory personnel, and applied recent fundamental knowledge to practical production procedures. During this time he initiated the publication of the *Polymer Bulletin* and began the monograph series *High Polymers and Related Substances* (Interscience), which now contains more than forty volumes.

Having successfully completed his mission at Hawkesbury, in 1940 Mark became Adjunct Professor at the Polytechnic Institute of Brooklyn, which also provided a teacher's visa and a consultancy with the DuPont Company. He became Professor in 1942, and during World War II he directed a number of research projects that did not concern polymers for the U.S. government. In 1944 he organized the Institute of Polymer Research, the first of its kind in the United States, and continued as its Director until 1964. He was Dean of the Faculty (1961–1974) and continued to be active as a lecturer and writer long after his formal retirement in 1964 at the age of 69. The recipient of many honorary degrees and numerous honors, including the U.S. National Medal of Science in recognition of a lifetime of achievements in polymer science, Mark continued his extensive travels, visiting throughout his career more than a thousand scientists and engineers in more than a hundred countries (he traveled abroad about 500 times and visited every continent, including Greenland and Antarctica). When one of Mark's many students asked him how he managed to keep up the pace at an advanced age, Mark disclosed the secret of his longevity: "I guess I have no time to get old" (p. 122).

Mark's dominant personality trait was optimism, and although he could have dwelt on the misfortunes and indignities that he suffered during the 1930s, his narrative betrays no trace of bitterness, and he relates his achievements with a great degree of modesty. He prefers to concentrate on the chemistry itself; even his detailed account of his celebrated controversy with Hermann Staudinger over the nature of macromolecules, which Staudinger considered a personal affront, is free of any discussion of personalities, for Mark "had the amazing capacity to see the good side of everything and of everyone" (p. xxiii). Yet this book, which is replete with 41 formal and informal photographs, is an intensely personal one. It abounds with frank confessions that are also good advice for correct behavior. For example, on his concluding page Mark admits, "the treatment of people (scientists, executives, and government representatives) was sometimes so complicated that I never knew whether I was doing the right thing or not. There was only one simple overriding rule: keep cool and never lose your composure!" We warmly recommend this slim volume to scientists (polymer and otherwise), historians of science and technology, and anyone interested in polymers—the substances with which half of all professional chemists work.

Laurie M. Kauffman
California State University
Fresno, CA (USA)

Organic Superconductors (Including Fullerenes). Synthesis, Structure, Properties, and Theory. By *J. M. Williams* et al. Prentice Hall, Englewood Cliffs, NJ (USA), 1992. 400 pp., hardcover $ 91.10.—ISBN 0-13-640566-5

The authors of this book, most of whom are at the Argonne National Laboratory, Illinois, are international leaders in the field, with complementary expertise in the areas of organic and inorganic materials chemistry, theoretical chemistry, spectroscopy, X-ray crystallography, and solid state physics. They have combined forces to deliver an excellent up-to-date overview of organic superconductors and related highly conducting organic molecular materials (conducting polymers are excluded). This book will be welcomed by active researchers and interested spectators alike. These materials are crystalline charge-transfer salts formed by combinations of specific organic π-donor or π-acceptor molecules. The first organic superconductor was discovered in 1979 and since then there has been vigorous interest in this multi-disciplinary field of research. About 70 organic superconductors are now known, with transition temperatures as high as 33 K in the fullerene series.

The book is divided into eight chapters with three appendices. The main topics are: organic synthesis of the constituent electron donor and acceptor building blocks; structural aspects of these molecules and their derived salts; electrical and superconducting properties; spectroscopic, magnetic, and theoretical studies. A list of well-selected references is given at the end of each chapter. The book is well produced and the reviewer found no factual or typographical errors. Good use is made of diagrams (especially X-ray crystal structures) and tables of data, for ease of correlation of the structural, electrical, and magnetic properties of series of salts where there are minor changes in the constituent moieties. The inter-relationship between different solid-state properties is emphasized. For example, the key role of crystal stacking motifs in determining the transition temperature for the onset of superconductivity is discussed in detail.

The book focuses mainly on tetrachalcogenofulvalene systems; superconducting salts of fulleride anions are described briefly in an appendix which is mainly based on the 1991 literature, so some of this section is rapidly becoming out of date. The book also contains a list of the names and addresses of researchers in the field of organic superconductivity, although it is not quite clear what the criteria are for inclusion in this list! The book concludes with an adequate index of the key materials and subjects covered in the text.

The past decade has witnessed such dramatic, and often unexpected, advances in organic superconductors that it is impossible to predict what the future holds. However, there is no doubt that exciting new experimental and theoretical discoveries could emerge at any time, and that this topic will remain at the forefront of science for a long time. A key goal is to synthesize organic materials with transition temperatures raised to above 100 K, to compete with the ceramic superconductors. This is the best single volume on the subject that has been published, and it has a valuable place in the fast-growing literature on organic superconductors.

Antibiotics and Antiviral Compounds. Chemical Synthesis and Modification. Edited by *K. Krohn, H. A. Kirst* and *H. Maag*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 482 pp., hardcover DM 128.00, £ 53.00.—ISBN 3-527-29040-0/1-56081-745-3

This book contains a detailed report of an international conference on the synthesis of antibiotics, which has taken place at two-yearly intervals since 1988. The 1992 meeting reported here was held in Kloster Banz, Bavaria (FRG). The subject of antibiotics syntheses is now more topical than ever before. One reason for this is that the synthesis of antibiotics (and other natural products), which initially served to give final proof of a proposed structure, has now developed so that versatile methods for targeted syntheses make it possible to explore variations of essential structural elements and to progress in a systematic way on the basis of structure–activity relationships. A second reason is that there is a growing need to develop ever more effective and selective drugs to combat resistant strains of bacteria, as well as cancer and retroviruses, so as to maintain the present high standard of available therapeutic measures. The subject of antibiotics syntheses as originally understood has therefore been enlarged to include "New Methods" (of making antibiotics) and "Antiviral Agents" (undoubtedly connected with the pressures on the science generated by AIDS), each of these topics being represented by a chapter in the book. The other five chapters are concerned with particular groups of antibiotics, three with the important and well-established areas of macrolides, β-lactams, and carbohydrates (insofar as these are involved in the synthesis of antibiotics), and two with newer areas, firstly peptides and glycopeptides, and secondly the enediyne antibiotics that have become so important in cancer chemotherapy. General aspects, such as synthetic methods and strategies, receptors research, and conformational analyses of bioactive natural products of current interest, are scattered throughout the chapters.

The editors have tried to avoid the heterogeneity usually associated with conference reports by arranging the contents in seven chapters and presenting an outward appearance of uniformity. Nevertheless, the way in which the individual contributions have been assigned to chapters sometimes seems rather forced, and is even wrong in a few cases (for example, the article on echinocandins, which are cyclopeptides, has been allocated to the chapter on macrolides).

The "New Methods" range from organometallic reactions, such as Pd^0-catalyzed allyl substitutions (B. M. Trost), cross-couplings in combination with direct *o*-metallization reactions (V. Snieckus), and the use of Pd^0 reagents to synthesize cyclopropanes which can then be rearranged to give medium-sized O-heterocycles (R. K. Boeckmann), through the use of thiazoles as masked formyl groups in the synthesis of β-amino-α-hydroxyacids (A. Dondoni), to the derivatization of antibiotics using microorganisms (A. Zeeck et al.).

The chapter on macrolides includes descriptions of total syntheses of rutamycin B (J. D. White), erythronolide A (R. W. Hoffmann et al.), and erythronolide B (J. Mulzer et al.). Also some new methods are reported here; for example, White describes the thermal decomposition of ω-hydroxy-*S*-acylxanthates, and Hoffmann describes a stereoselective crotylboration. The convergent synthesis described by Mulzer et al. uses the acetonide of the glyceraldehyde as the only chiral building element; it is a nice example of the modern trend towards versatile synthetic methods mentioned earlier, since in addition to the original target molecule it can be used to prepare various derivatives. To end this chapter G. Höfle and H. A. Kirst discuss new macrolides and their semi-synthetic derivatives, as well as their biological effects, etc.

The chapter on β-lactams describes the penems that are marketed commercially

as antibiotics, followed by new synthetic monobactams, and penicillin and monobactam analogues which act as peptidase inhibitors. This work is being carried out by industrial research teams. The last two articles, one on the chemistry of quinolones (D. Bouzard) and the other on syntheses of cyclopentanoid antibiotics using organophosphorus and organosulfur reagents (M. Mikolajczyk), do not fit well into this chapter.

The topics covered in the peptides chapter include the synthesis of dipeptides with antimycotic activity (H. Wild), studies of structure–activity relationships and mode of action for cyclopeptides with immunosuppressive activity (H. Fliri) and conformational analysis of these agents (H. Kessler et al.), and two contributions on glycopeptides, describing partial syntheses of virus outer shell proteins and tumor-associating antigens (H. Kunz) and attempted total syntheses of vancomycins, an important class of antibiotics (A. V. Rama Rao).

Work by American research groups on the total synthesis of the enediyne antibiotics (antitumor agents) caused a considerable sensation in recent years, so it is unfortunate that none of the eminent chemists who lead these groups attended the Kloster Banz symposium. Consequently the chapter on the enediynes is rather meager. New strategies developed at the Institute Chemie de Substances Naturelles in France and by M. Isobe and T. Nishikawa in Japan for the synthesis of various enediyne antibiotics (esperamicins, calicheamicins, dynemicin) are described. M. Hirama reports on methods for the synthesis of DNA-breaking model substances which contain the ten-membered core ring of neocarcinostatin, and on conformational studies of the neocarcinostatin complex by NMR spectroscopy. Lastly, D. Schinzer describes the use of allylsilanes as the basis of a method that can be used generally in natural products syntheses, and is especially useful for synthesizing calicheamicin model compounds.

The chapter on "Carbohydrates in Antibiotics Research" has as its introduction a contribution by P. Sinay with the same title. This is followed by descriptions of syntheses starting from sugar lactones or sugars as chiral elements (G. W. Fleet, H. J. Altenbach, and Y. Chapleur), and methods for synthesizing common antibiotic sugars, such as amino sugars (J. Jurczak et al.), and deoxy sugars (W. Klaffke), the latter via an enzyme cascade. P. Welzel discusses the role of carbohydrates in the biological activity of various antibiotics, taking the transglycosylase inhibitor moenomycin as an example; much knowledge of structure–activity relationships has been obtained from breakdown and synthesis studies.

Lastly, Chapter 7 is devoted to antiviral agents, especially nucleoside analogues with activity as HIV inhibitors. Here TSAO derivatives seem very promising, and their chemical synthesis, structure–activity relationships, and mode of action are described by J. Balzarini, E. De Clercq, and coworkers. Starting from 4′-azidothymidine as the lead structure, H. Maag has investigated other 4′-substituted nucleosides, whereas G. Jähne and coworkers have concentrated on carbocyclic phosphonate nucleoside analogues and A. Holy and coworkers on acyclic nucleotide analogues. E. Uhlmann discusses antisense technology and oligonucleotides that form triple helices, which offer promise as future alternatives to nucleoside analogues in the areas of antiviral agents and conventional therapies based on small-molecule agents.

The editors have devoted much effort to creating a unified whole from the texts supplied by the authors using a variety of word-processing and formula-drawing systems, resulting in a book which looks far better than most symposium reports, which merely collect together the individual typescripts. Despite this, it has not been possible to completely eradicate a certain amount of nonuniformity: for example, not every article has a summary, and there are differences in the method of giving literature references. Also it would have been useful to include a concise introduction to each of the seven topic areas. The comprehensive subject index is very good, enabling the reader to locate a particular topic without difficulty, and to find information on problems of current importance in the synthesis of active agents. Compared with the report by C. Bleasdale and B. T. Golding on the conference "Molecular Mechanisms in Bioorganic Processes" held in Newcastle upon Tyne (UK), this book is of a similarly high standard but does not go beyond that. It will be of interest to everyone involved in any way with biologically active natural products.

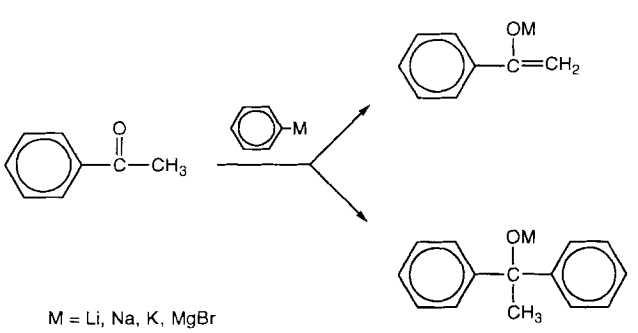
Are Polar Organometallic Compounds "Carbanions"? The Gegenion Effect on Structure and Energies of Alkali-Metal Compounds

Christoph Lambert and Paul von Ragué Schleyer*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday



Polar organometallic compounds such as alkyllithium compounds or Grignard reagents often are conceived as "carbanions", although it is well known from experiments that the metal gegenions may have a strong, and often directing, influence on the reactivity (for example, the basicity vs. the nucleophilicity) of the "carbanion". This demonstrates that "carbanions" are tightly associated ion pairs, at least in commonly used less polar or nonpolar solvent systems like ethers or hydrocarbons. However, despite about ninety years of widespread application of these organometallic compounds as bases or nucleophilic reagents, the role of the gegenion is not yet understood fully. The focus of this review is on the inherent influences of the metal gegenion on the structures, reaction energies, and activation barriers of some representative alkali-metal compounds. While most comparisons of physical and chemical properties determined experimentally for Group I compounds are precluded due to different substituents, solvents, ligands, etc., ab initio calculations of model compounds can yield intrinsic data that are useful for a better understanding of chemical behavior. For this reason, most of the data reviewed in this article are based on quantum chemical calculations, which are compared with experimental data where available.

1. Introduction

The term *carbanion* was proposed for the first time in 1933 by E. S. Wallis to designate negatively charged carbon ions in contrast to the positively charged carbonium ions.[1] Most textbooks on Organic Chemistry use this term interchangeably for polar organometallic compounds (like alkyllithium derivatives, Grignard reagents, etc.) and for free carbanions. While this oversimplification may be useful for educational purposes, it hinders the proper insight into the chemistry of polar organometallic (*carbanionoid*) compounds. Very few synthetically important polar organometallic compounds undergo complete ion separation in solution, and even those do not involve "free" carbanions. For example, enolates and even large carbanions without heteroatom substituents are stabilized in alcoholic solvents by hydrogen bonding.[2] The carbanion moiety of most carbanionoid compounds like alkyl- or aryllithium derivatives in ether or hydrocarbon solvents are stabilized electrostatically by the metallic gegenion: contact ion pairs (CIP) with a distinct C–M bonding component are present. Moreover, most polar organometallic compounds do not exist as monomers but as higher aggregated species in which the metal may be associated with more than one carbanion center.[3]

Really free carbanions are present only in the gas phase.[3c, 4] However interesting, the gas phase chemistry of carbanions has not yet achieved any preparative application. In contrast, polar organometallic compounds like alkyllithium bases or Grignard compounds are widely used reagents in both preparative organic and inorganic chemistry.[5] Therefore, chemists are increasingly interested not only in synthetic applications but also in more basic aspects of the chemistry of carbanionoid compounds in condensed phase.

It is often observed that reactions with polar organometallic reagents may take totally different courses with different metal gegenions, even with the alkali metals.[6] For example, the attack of phenyl–M (M = Li, Na, K, MgBr) derivatives on acetophenone can yield two different products (Scheme 1):[7] eno-

Scheme 1. Metalation of acetophenone with phenylmetal compounds.

lates (by α-deprotonation) and carbinolates (by addition to the CO double bond).

The ratio enolate/carbinolate strongly depends on the metal gegenion. While phenylpotassium mainly results in enolate formation (enolate/carbinolate 10/1), the lithium and Grignard reagents give carbinolates predominantly (1/23 and $1/\infty$, respectively). Phenylsodium affords a 2:1 mixture. The regiospecificity was explained by the fact that the phenyl compounds of the heavier alkali metals have higher ionicity and thus stronger basicity than the Li derivative. However, as we will see later, the ionicity of all alkali-metal compounds with σ- *and* π-donating substituents (like the phenyl group) is very high and increases only slightly from Li to K.

In general, direct comparison of the gegenion influences on the reactivity suffers from some difficulties: the metal compounds (starting materials and products) may be differently aggregated depending on the metal. The type of solvents may influence the regiospecificity. Additional alkali-metal salts (depending on the experimental procedure used) also may alter the reaction course. The derivatives of the heavier alkali metals are not or only slightly soluble in hydrocarbons, and inhomogenous mixtures form. Unfortunately, more polar solvents are readily attacked by the bases. Complications due to additional coligands or varying substituents also preclude direct comparison of the gegenion influence.

Extensive work has been done to elucidate the gegenion effect on the reactivity in order to achieve specific synthetic purposes.[6] However, much-needed fundamental data are lacking, and there are few general concepts that might provide better insight into gegenion effects. While experimental measurements suffer from the problems associated with the complexity of the reagents, gas-phase investigations, which might yield basic data, are quite rare for polar organometallic compounds. However, ab initio SCF methods enable the behavior of polar organometallic molecules to be computed without interfering influences from solvation or aggregation.[8] This permits the elucidation of *intrinsic* gegenion effects—the prerequisite for the interpretation of experimental data. Ab initio calculations allow derivatives of all Group I metals to be compared on a common basis. This is often difficult or impossible by experimental methods. Therefore, most of data reviewed in this article are based on ab initio calculations. Comparisons are made with experimental data where available.

The following chapters focus on gegenion influences on the polarities, the structures, and the energies of the polar organometallic derivatives R^-M^+ (M = Li, Na, K, Rb, Cs). The polarity of a C–M bond is a basic property, as it is commonly expected that the more ionic the bond of the organometallic derivative the more carbanion-like it will be. The structures of polar organometallic compounds, particularly as demonstrated by X-ray methods, have recently been extensively reviewed.[9] We emphasize here examples that reveal *intrinsic* gegenion effects on the structure of the carbanionic moiety. While R^- is in most cases derived from a C–H acid, we will also regard the alkali-metal derivatives of some N–H acids, as these behave like carbanionoid compounds. Alkali-metal amides are often used as nonnucleophilic alternatives for alkyl- or aryllithium bases in synthetic organic chemistry.[5]

P. von R. Schleyer

C. Lambert

Paul von Ragué Schleyer was born in 1930 in Cleveland, Ohio, USA. After education at Princeton and Harvard Universities he obtained his Ph.D. with P. D. Bartlett at Harvard (1957). He became Full Professor at Princeton in 1965 and finally Eugene Higgins Professor there in 1969. In 1976 he accepted his present position as Professor and Codirector of the Institut für Organische Chemie der Universität Erlangen-Nürnberg. Amongst his many honors he received the Dr. honoris causa of the University of Lyon, the Adolf von Baeyer Memorial medal of the Gesellschaft Deutscher Chemiker, the James Flack Norris Award in Physical Organic Chemistry of the American Chemical Society, the C. K. Ingold Medal and Lectureship of the Royal Society of Chemistry, London, and the A. C. Cope Scholar Award of the American Chemical Society. He is a Fellow of the Bayerische Akademie der Wissenschaften and has been guest professor at nearly 30 universities. He is coauthor and editor of seven books on carbonium ions, quantum chemistry, and lithium chemistry. At present he is the president of the World Association of Theoretical Organic Chemists. His research interest covers experimental and theoretical studies on hydrocarbon cage compounds, carbocations, organic and inorganic lithium compounds as well as boron cage compounds.

Christoph Lambert, born in 1966 in Nürnberg, graduated in chemistry at the University of Erlangen-Nürnberg with a diplom thesis on water-complexed organolithium structures with Professor Schleyer, under whom he completed his Ph.D. degree in 1993. His major interests are experimental and theoretical investigations of the mechanisms of the lithiation of NH, CH, and OH acidic compounds, the solid-state structures of lithiated heterocycles, and the influence of gegenions in alkali-metal compounds. He received the doctoral award of the Hoechst AG as well as a doctoral grant from the Fonds der Chemischen Industrie. Since October 1993 Lambert has held a postdoc position with R. Snaith at the University of Cambridge, England, as a NATO research fellow.

2. The Carbon–Metal Bond in Polar Organometallic Compounds

The nature of the carbon–lithium bond has been examined in many theoretical and experimental investigations.[10] While the degree of ionicity of the C–Li bond is not a measurable quantity, the behavior of organolithium derivatives should be more carbanion-like, if the C–M bond is more polar. After many years of controversy, the highly ionic character of the C–Li bond is now well established.

The erroneous early conclusion that lithium–carbon bonding is predominantly covalent was based on the low melting points, the solubility in nonpolar solvents, and the high volatility of some organolithium compounds.[11] These properties contrasted with those typical of, for examples, the alkyl derivatives of the heavier alkali metals. However, these differences in physical properties reflect the structures of discrete organolithium *aggregates*: the outer sphere of ethyllithium tetramer[12] and *n*-butyllithium hexamer,[13] for instance, offer only hydrocarbon environments externally. Such compounds behave similarly to hydrocarbons, despite the ionic nature of their central cores.

The experimental observation of $^{13}C,^{6}Li$ and $^{13}C,^{7}Li$ NMR coupling[14] and early INDO (INDO = intermediate neglect of differential overlap) calculations (which overestimated the magnitude) of the coupling constants[10c] also provided evidence for at least some covalent bonding: the C,Li coupling is due to the Fermi-contact term, involving s-orbital contributions from both atoms.[15] The small change in the ^{13}C NMR chemical shift of the lithiated carbon, for example, in methyllithium relative to methane also seems to be consistent with a covalent C–Li bond.[16] However, this NMR evidence has been reinterpreted more recently. IGLO chemical shift calculations (IGLO = individual gauge for localized orbitals) shows that ^{13}C chemical shifts of the carbanionic carbons of alkyllithium compounds do not depend on the charge, and differ little from the shifts of the parent hydrocarbons.[17]

The $^{13}C,^{6}Li$ coupling constants depend only on the aggregation and *not* on the carbon hybridization.[18] This contrasts with the behavior of the covalent C–H bonds (see Table 1) and supports an ionic C–Li bonding concept. The very small but decreasing C–Li covalency from sp^3 through sp^2 to sp carbon hybridization compensates for the small but increasing carbon s-orbital contribution from sp^3 through sp^2 to sp: the product of C–Li bond order and s-orbital character in % of the carbon is nearly constant (see Table 2).

Table 1. $^{6}Li,^{13}C$ Coupling constants [Hz] of differently aggregated organolithium compounds [18b] and $^{1}H,^{13}C$ coupling constants [Hz] of some hydrocarbons [15].

		$^{1}J(^{13}C,^{6}Li)$		$^{1}J(^{13}C,^{1}H)$

tetramer	$(n\text{BuLi})_4$	5.5		
	$(H_2C{=}CHLi)_4$	5.8		
	$(t\text{BuC}{\equiv}\text{CLi})_4$	6.0		

Table 2. Calculated NLMO C–Li bond orders [a] (MP4SDTQ(FC)/6-31++G**//MP2(FU)/6-31G** level) and contributions of s orbitals for some organolithium compounds [19].

	C-Li bond order	s character of the C σ bond orbital [%]	Product of bond order and s character [%]
CH_3Li	0.144	19	2.7
$H_2C{=}CHLi$	0.099	28	2.8
HC≡CLi	0.046	52	2.4

[a] NLMO = Natural Localized Molecular Orbital [24].

The experimentally determined (as well as the computed[46]) high dipole moment (6 D) of methyllithium[20] as well as ESCA shifts (ESCA = electron spectroscopy for chemical analysis)[21] of MeLi and EtLi also support a high degree of ionic character in the C–Li bonding.

Wiberg and Rablan[22] recently reviewed several quantum chemical population analysis procedures critically. While these provide easily obtained estimates of the C–Li bond ionicity, they are based on different definitions. Among others, the Mulliken analysis,[23] Natural Population Analysis (NPA) by Reed and Weinhold et al.,[24] and the AIM topological density analyses by Bader et al.[25] (AIM = atoms in molecules) were applied to calculate the partial charges of methyllithium. While the Mulliken and the NPA analysis are founded on orbital transformations (for NPA the natural atomic orbitals (NAO)) Bader analysis is based on electron density. The partial charges based on partitioning of the basis functions in the Hilbert space as it is performed in the Mulliken or the NPA analysis is not a quantum mechanical observable. Thus, it is not a physical reality but an interpretation.[26] In contrast, the total electron density is an observable and can be measured by X-ray scattering experiments or computed ab initio.

The Mulliken population analyses of organolithium compounds calculated ab initio show a polar but nevertheless predominantly covalent C–Li bonding (16–57% ionic, depending on the basis set used).[8a] This is now recognized as an artifact. The Mulliken population analysis overestimates the electron density on alkali metals and thus underestimates the polar character of the carbon–metal bond.[24a, 27] In contrast, NPA gives a seemingly more realistic picture almost independent of the basis set. This population analysis indicates about 80–90% ionic character for the C–Li bond.[24a, 28]

Both the integrated spacial electron population by Collins and Streitwieser[29] and the Laplacian density analysis (topological density analysis) by Bader et al.[25, 30] are based on electron density. The latter defines regions in a molecule by calculating zero-flux surfaces. Integration of the electron density within these regions gives the charge of the atom. Both analyses also reveal an 80–90% ionic bonding contribution in the C–Li bond of methyllithium.[29, 30]

However, calculations of the electron deformation density $\Delta\rho$ from experimental electron densities ($\Delta\rho = \rho_{exp} - \rho_{calc}$; ρ_{exp}: electron density from X-ray structures; ρ_{calc}: electron density of a "promolecule" with spherical electron densities on the atomic centers[31]) did not allow definite conclusions on the nature of the C–Li bonding, since changes in electron density derived from X-ray diffractions are not significant enough to distinguish between Li^0 and Li^+ atoms.[32]

Streitwieser et al.[33] argued that the small electron density within the C–Li bond is a criterion for a very weak covalent bond contribution (about 80% ionic). However, other ab initio calculations on MeLi by Lipscomb et al.[34] showed that this argument cannot be applied as an indicator for the degree of covalency, since, for example, the purely covalent Li_2 has a lower charge density in the Li–Li bond than MeLi. These authors estimate the ionic contribution in the C–Li bond to be only 55–60%.

Horn and Ahlrichs[35] used a different approach to evaluate the high ionicity of MeLi. The Hartree-Fock/self-consistent field (HF/SCF) energy change ($\Delta E = E^k_{SCF} - E_{SCF}$) when MeLi was forced to have a pure ionic bonding was calculated. The SCF energy (E_{SCF}) of methyllithium was subtracted from the SCF energy (E^k_{SCF}) of a completely ionic methyllithium computed without any 2 s and 2 p valence orbitals on lithium. The small energy difference of $\Delta E = 7.0$ kcal mol^{-1} (compared with the homolytic bond dissociation energy of 46.4 kcal mol^{-1}[46]) reflects the covalent contribution and shows the bond to be highly ionic.

The linear correlation of calculated dimerization energies for some lithium compounds with Pauling electronegativities also implies mainly electrostatic bonding.[36] A nearly identical correlation resulted from a point charge model using the ab initio geometries.[8c, 36] However, electrostatic point charge calculations of tetrameric lithium compounds do not agree with the oligomerization energies derived from ab initio calculations.[37] Purely electrostatic calculations of some aggregates of lithium and cesium compounds (using point charge models and hard sphere electrostatic calculations) resulted in structural conclusions that are in good agreement with experimental observations.[38] Alternative explanations use covalent multicenter bondings (electron-deficient bondings) similar to those in diborane.[8c, d, 39] However, this model is inadequate, since polar organometallic compounds do not seek to fulfill the "octet rule". This becomes obvious in the numerous higher coordination modes of the metal cation in alkali-metal complexes,[40] in which the number of electrons formally assigned to the metal exceeds eight, for example in [CpLi([12]crown-4)],[41] where the number of electrons at Li formally is 14! Hence, "electron counting" plays no role in the discussion of polar organometallic chemistry. Likewise, it is misleading to regard these compounds as being electron-deficient. There is no electron-sufficiency or electron-deficiency in highly ionic species.

The mainly ionic nature with small but not negligible covalent contributions (revealed, for example, by the $^{13}C,^6Li$ coupling) of the C–M bonds in alkali-metal compounds is now widely accepted. The ionicity agrees with the common observation that polar organometallics mostly react by ionic mechanisms.[5] Compounds of alkaline earth metals and some other organometallic derivatives also have strongly ionic C–M bonding. Table 3 shows the natural charges (NPA) calculated ab initio on the metal of the methyl compounds of alkali, alkaline earth, and other main-group and late transition metals.[3c]

The NPA charges reveal an ionic bonding contribution of 74–94% for the M–CH_3 bond in the methyl derivatives of the alkali and alkaline earth metals. The NPA charges on both alkali-metal and alkaline earth methanides are quite similar within each period. However, methyllithium is more ionic than dimethylberyllium and even than methylsodium. Figure 1 shows the NPA metal charges of some alkali-metal compounds MX (X = H, CH_3, NH_2, OH, F, cyclopentadienyl (Cp)).[42]

Table 3. Natural charges [a] on the metal of some methyl metal compounds calculated ab initio. The charges in brackets are the total charges on the metal divided by the number of methyl groups [3c].

MCH_3	$M(CH_3)_2$	$M(CH_3)_2$	$M(CH_3)_3$	$M(CH_3)_4$
Li (0.87)	Be 1.49 (0.74)		B 1.02 (0.36)	C −0.12 (−0.03)
Na (0.79)	Mg 1.55 (0.77)		Al 1.87 (0.62)	Si 1.85 (0.46)
K (0.90)	Ca 1.78 (0.89)	Zn 1.41 (0.71)	Ga 1.68 (0.56)	Ge 1.69 (0.42)
Rb (0.90)	Sr 1.82 (0.91)	Cd 1.36 (0.68)		Sn 1.95 (0.49)
Cs (0.93)	Ba 1.88 (0.94)	Hg 1.17 (0.59)		Pb 1.74 (0.44)

[a] The charges were calculated at the HF level. Ab initio pseudopotential calculations were used for the methyl compounds of Li, Na, K, Rb, Cs, Ca, Sr, Ba, Zn, Cd, Hg, Cd, Sn, and Pb. All other compounds were calculated at the HF/6-31 + G* level.

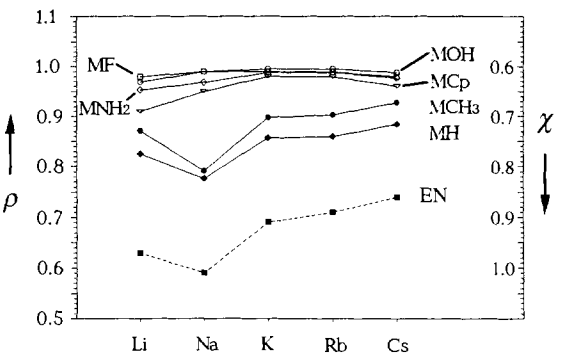

Fig. 1. Natural charges (ρ) on the metal calculated ab initio at the HF level (left scale) for the MX compounds (M = Li–Cs; X = CH_3, H, NH_2, OH, F, Cp) and Allred–Rochow electronegativities EN (χ, right scale) of the alkali metals [43].

While the NPA charges of MX compounds with σ-donor substituents (H, CH_3) follow the nonmonotonous trend of the Allred–Rochow electronegativities χ,[43] the MX derivatives with highly electronegative σ- *and* π-donating substituents (X = NH_2, OH, F, Cp) are distinctly more ionic and do not show any irregular behavior. In the MH and MCH_3 species Li is less electronegative than Na, while the electronegativity decreases from Na to Cs. This was attributed to the better shielded nuclear charge in Li than in Na and in the other heavier alkali metals: the effective nuclear charge eZ_{eff} is lower in lithium, and therefore a relatively small electron-attracting force (= electronegativity) of $F = e^2Z_{eff}/r^2$ (r = covalent radius) is observed for Li. (For a thorough discussion of the "inverted" Na–Li electronegativity, see Ref.[42].) That Li rather than Na behaves irregularly can also be seen in the relatively low IP of Li compared to the general trend for the other alkali metals (Fig. 2).[44]

In derivatives with π-donating substituents the larger polarity of Li compounds is compensated by small π populations on the metal. Thus, a monotonous trend of the ionicity for Li to Cs species results. Two kinds of organo alkali-metal species (σ-bonded such as MCH_3 and σ- + π-bonded such as MCp) must be distinguished, due to their different electronic structures.

Owing to the general high polarity of the organometallic compounds of alkali and alkaline earth metals, it seems reasonable to regard the M–X (X = CR_3, NR_2, OR, F) bond as fully

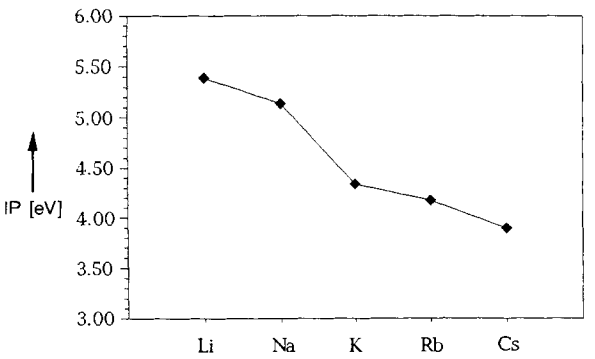

Fig. 2. Experimental ionization potentials (IP) of the alkali metals [44].

ionic. Small σ- and π-back donation from the substituent to the metal slightly reduces the ionicity.

Whereas the methyl derivatives of zinc and cadmium also show significantly polar M–C bonding, the C–Si to C–Pb bonds in $M(CH_3)_4$ have more covalent than ionic character (see Table 3). The bonding of mercury, aluminum, and gallium methanides is intermediate.

The polarity of the Li–C bond increases with the s-orbital contribution to the carbon hybridization: $sp^3 < sp^2 < sp$ (see Table 4).[9b, 45] The NPA charge in methyllithium does not increase monotonously with the degree of aggregation. However, the polarity is slightly higher in the dimer and the tetramer than in the monomer.[28, 45, 46] Ab initio calculations of methyllithium show that the NPA charge on the metal *decreases* upon dimethyl ether solvation. In contrast, the metal charge increases slightly for methylsodium and dimethylmagnesium (Table 4).[47] Therefore, an increase in the polarization of the C–M bond (and thus an increase in the reactivity) upon solvation is not general for all metals.

Table 4. Natural charges ρ on the metal depending on the carbon hybridization, the aggregation [45], and the solvation by dimethyl ether [47].

	ρ_{NPA} (M)		ρ_{NPA} (M)		ρ_{NPA} (M)

3. Stability of Organo Alkali-Metal Compounds

3.1. Stabilization by Contact Ion Pair Formation

In solution as well as in the solid state, carbanions are stabilized by the gegenion; contact ion pairs (CIP) form often. The stabilization energy is very high and can be estimated by simple electrostatic point charge calculations: a $C^- - Li^+$ distance of 2.0 Å corresponds to a coulombic attraction of 166 kcal mol^{-1},[3c] which is in good agreement with the heterolytic bond dissociation energy of $LiCH_3$ (168.9 kcal mol^{-1}).[48] The stabilization energy is smaller for larger cations and decreases with increasing ionic radius: Li > Na > K > Rb > Cs. Ab initio calculations of the heterolytic bond dissociation energies of the alkali-metal cyclopentadienides ($CpM \rightarrow Cp^- + M^+$) confirm this trend: 182.4 (CpLi), 145.4 (CpNa), 132.2 (CpK), 126.0 (CpRb), and 124.0 kcal mol^{-1} (CpCs).[49] Experimental solvation enthalpies of the alkali-metal cations in water are considerably smaller: Li (119.4), Na (93.2), K (73.1), Rb (67.2), and Cs (59.3 kcal mol^{-1}).[50]

Solvent-separated ion pairs (SSIP) in which the anion and the cation are separated by their solvent shells [Eq. (a)] may form in some cases.[51] This depends on the competition between the

$$\underset{\text{CIP}}{[R^-M^+]_{solv}} \rightleftharpoons \underset{\text{SSIP}}{[R^-||M^+]_{solv}} \rightleftharpoons \underset{\text{dissociated ion pair}}{[R^-]_{solv} + [M^+]_{solv}} \quad \text{(a)}$$

solvation of the cation (solvation of the anion is less important, since the commonly used ether solvents are better at solvating cations than anions) and the electrostatic stabilization of the carbanion by the gegenion. The more delocalized the charge on the anion (this is, the weaker the anion–cation interaction) and the more polar the solvent, (that is, the stronger the cation–solvent interaction) the likelier is the formation of SSIPs. Since the cation–solvent interaction is stronger for smaller cations, lithium salts of resonance-stabilized anions in weakly polar solvents like THF form SSIPs, whereas analogous cesium salts in THF form CIPs. The formation of SSIPs of lithium cations with resonance-stabilized anions is exemplified in some solid-state structures of, for example, fluorenyl anion systems.[52] In some cases, solvent-shared ion pairs form, in which the cation and the carbanion are bridged by solvent molecules. In these ion pairs, the carbanionic moiety is solvated by hydrogen bonding from the solvent molecules.[53] Dissociated ion pairs only occur to a significant extent in very dilute solutions of lithium salts if the negative charge of the carbanion is delocalized and the cations are strongly coordinated by the solvent.[54]

3.2. Relative Metalation Energies

A direct measure for the stability (energy) of an alkali-metal compound is its ion pair acidity relative to a standard compound [Eq. (b)].[55]

$$RH + R'M \rightleftharpoons RM + R'H \quad \text{(b)}$$

The ion pair acidities of many compounds were determined by Streitwieser et al. in various solvent systems like cyclohexylamine[56] and THF[57] by equilibrium or kinetic methods. RM compounds derived from very acidic CH acids and in which the negative charge is delocalized form SSIPs when lithium is the gegenion[57c] and CIPs when cesium is the gegenion (at 10^{-4} M concentration range).[54, 58] The ion pair acidities of these lithium and cesium compounds are very similar.[54, 3c] However, the

acidity of anions with localized charge may be quite different: the acidity of the cesium ion pair of phenylacetonitrile in THF is 22.7 and of the corresponding lithium ion pair, 17.7.[59] This is due to the formation of monomeric CIPs of the lithium salt; the Li^+ ion is attached to the nitrile group.[60] The lithium cation stabilizes the phenylacetonitrile anion better than the cesium cation because of the smaller Li–N distance. Thus, phenylacetonitrile appears to be more acidic as an ion pair with lithium than with cesium. A similar behavior was observed for NH acids. The acidity of the cesium ion pair of carbazole is 19.1, whereas that of the analogous lithium ion pair is 13.8.[61] The enhancement of the acidity of CH acids was considerably weaker because of the formation of aggregates.[62]

Although the results from equilibrium acidity measurements in THF are quite instructive, they only refer to very acidic CH acids. The alkyl and aryl alkali-metal compounds used widely in synthesis are too basic to be measured in THF. The proton transfer is too slow, and solvent decomposition becomes a serious problem. However, the solvating power of less acidic and inert solvent systems like hexane is too weak, and aggregates form. Arnett et al. reported the deprotonation enthalpies of alcohols by many synthetically important lithium and potassium alkyl and aryl compounds, as well as amides and alkoxides (for some examples see Table 5).[63] Since these compounds are aggregated to different extents, direct comparisons are complicated. Figure 3 shows a reasonably good correlation (slope = 1.07) between the experimental stabilization energies (relative to *t*BuOLi) and calculated stabilization energies[92, 94] of some monomeric organolithium bases. Only methyllithium significantly deviates from the correlation, which is certainly due to the different solvent used (diethyl ether). Nevertheless, the deprotonation enthalpies are a valuable estimate of basicity since the data pertain to "realistic" conditions.

Table 5. Enthalpies ΔH [kcal mol^{-1}] for the metalation of isopropyl alcohol by some synthetically important organolithium bases and potassium bis(trimethylsilyl)amide in hexane/ether (90/10) [63], as well as the experimentally determined and calculated (MP2(FU)/6-31G*//MP2(FU)/6-31G* level [92, 94]) stabilization energies ΔE, referred to *t*BuOLi (RLi + *t*BuOH → RH + *t*BuOLi) [kcal mol^{-1}].

Base	$-\Delta H$	$-\Delta E_{exp.}$	$-\Delta E_{calcd}$
tert-butyllithium	56.2 ± 1.8	54.1	56.5
sec-butyllithium	52.8 ± 1.0	50.7	54.9
n-butyllithium	50.0 ± 0.7	47.9	52.4
phenyllithium	42.3 ± 0.3	40.2	42.6
methyllithium	41.6 ± 0.7 [a]	39.5	34.6
lithium diisopropylamide	28.6 ± 1.0	26.5	
lithium 2,2,6,6-tetramethylpiperidide	30.4 ± 1.6	28.3	
lithium bis(trimethylsilyl)amide	15.2 ± 0.5	13.1	
potassium bis(trimethylsilyl)amide	2.9 ± 0.3 [b]	0.8	
lithium *tert*-butoxide	2.1 ± 0.6	0.0	0.0 [c]

[a] In diethyl ether. [b] In THF/toluene (85/15). [c] MP2(FC)/6-31+G*//MP2(FC)/6-31+G*.

However, metalation equilibria of some simple monomeric alkali-metal derivatives calculated ab initio can yield intrinsic C–M bond strengths. As we learned in Section 2, we have to distinguish between two kinds of alkali-metal compounds:[42] slighty covalent MX species with almost exclusively σ-donating substituents (e.g., X = H, CH_3) and almost fully ionic MX compounds with highly electronegative σ- and π-donating substituents (X = NH_2, OH, F, Cp). From these two sets we can form three types of metalation reactions: firstly, reactions between compounds of the σ-donating group [(c)]; secondly, metalation reactions between species from different groups [(d)–(g)]; and thirdly, reactions between compounds of the σ- and π-donating group [(h)].

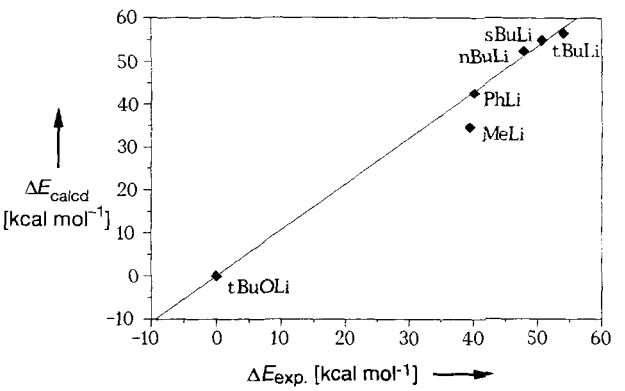

Fig. 3. Calculated (MP2(FU)/6-31G*//MP2(FU)/6-31G* level, ΔE_{calcd}) vs experimental ($\Delta E_{exp.}$) stabilization energies relative to *t*BuOLi. The data are from Table 5; the data point of MeLi was not used for the calculation of the correlation line (slope = 1.07).

$$MCH_3 + H_2 \rightarrow MH + CH_4 \quad (c)$$

$$MCH_3 + NH_3 \rightarrow MNH_2 + CH_4 \quad (d)$$

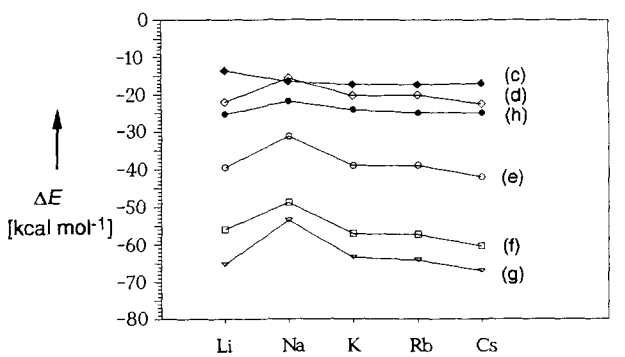
$$MCH_3 + H_2O \rightarrow MOH + CH_4 \quad (e)$$

$$MCH_3 + HF \rightarrow MF + CH_4 \quad (f)$$

$$MCH_3 + CpH \rightarrow MCp + CH_4 \quad (g)$$

$$MOH + CpH \rightarrow MCp + H_2O \quad (h)$$

The reaction energies for reactions (c) to (h) are displayed in Figure 4. Since covalent contributions strengthen the M–X bonds, the different ionicity (see Fig. 1) directly influences the relative metalation energies of alkali-metal compounds. The reaction energies of (c) are nearly independent of the metal, since the trends in ionicity (and thus the stability) in MH and MCH_3



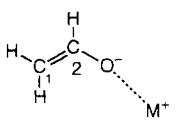


Fig. 4. Metalation energies (ΔE) for the reactions (c) to (h) calculated ab initio at the MP4 level (MP2 for (g) and (h)) [42].

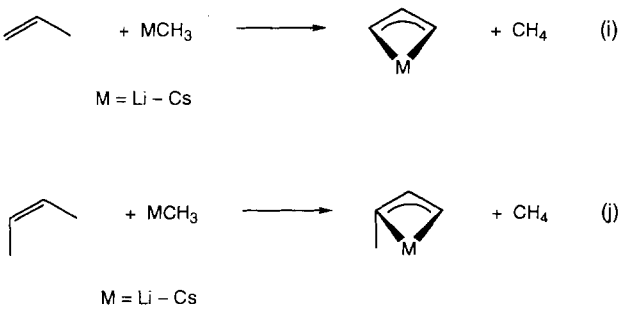
compounds are parallel. In contrast, reaction energies between MCH_3 (σ-donating ligand) and NH_3, H_2O, HF, and CpH (σ- and π-donating ligand) show a nonmonotonous trend along the Li to Cs series [(d) to (g)]. The metalation reactions are more exothermic for Li than for Na since $LiCH_3$ is more ionic (less stable) than $NaCH_3$. Reactions between compounds of the group with σ- and π-donating substituents [e.g. (h)] are also almost independent of the metal.

3.3. Charge Localization by the Gegenion: a Destabilizing Effect

Although the overall coulombic cation–anion interaction is highly favorable (see Section 3.1), the gegenions serve to *localize* the charge of the anion. This competes, in effect, with delocalization by resonance, negative hyperconjugation, and polarization.



The degree to which the charge-localizing effect of the metal cation destabilizes anions has been evaluated by ab initio calculations of, for example, the geometries, the electronic structures, and the metalation energies of alkali-metal acetaldehyde enolates **1** (Table 6).[64] All the metal ions have near unit charges (0.96 to 1.00). Both the total and the π charges on oxygen are distinctly smaller in the free enolate anion than in the alkali-metal derivatives. The polarizing, charge-localizing influence of the cations is responsible for the larger harges on oxygen in the metal enolates. However, there is only a slight decrease from the Li to the other alkali-metal enolates.

1 M = Li – Cs

The energetic consequences of charge localization are dramatic: the stabilization of the enolate anion relative to that of the hydroxyl anion is very large (about 33 kcal mol^{-1}) (see Table 6). The gegenions in the metalated enolates reduce the stabilization to only 9–14 kcal mol^{-1} relative to MOH. However, the variation in the stabilization along the Li to Cs series is only modest and does *not* reflect the large increase in the O–M distances. Due to the charge-localizing gegenion effect, the resonance stabilization in the alkali-metal enolates is about 19 to 24 kcal mol^{-1} smaller than in the free enolate. The localizing influence is still very effective for long O–M distances (e.g., O–Cs, 2.547 Å).

Similar trends were observed for the metalation of propene and butene with MCH_3, yielding the allyl[65, 66] (e.g. **4**) and the crotyl[66] alkali-metal derivatives, respectively [reactions (i) and (j), Table 7]. Again, the metalation energies show a non-

monotonous trend since a σ-bound alkali-metal derivative (MCH_3) is transformed into a π-bound species (allyl–M) (cf. 3.2). The reaction energies of the metal derivatives are considerably lower than those of the free anions. Even for rubidium the energies do not approach the values for the free anions. The attenuation of charge stabilization in the allyl and crotyl metal

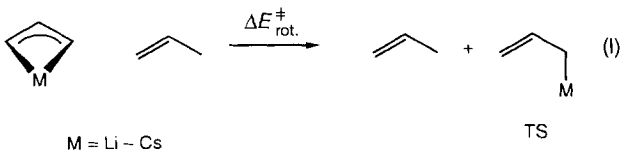
species is due to charge localization at C1 and C3 by the gegenion (see **4**, Section 4.2). Since the metal cations are situated above the plane of the π system, the charge localization acts *perpendicularly* in the allyl and crotyl derivatives. Hence, the localizing effect (and the destabilization relative to the free anion) is smaller than in the alkali-metal acetaldehyde enolates, where the charge localization acts less symmetrically *in* the plane of the π system.

Charge localization also influences the UV/VIS absorption maxima of alkali-metal compounds. The closer the gegenion is to the anion (i.e., the smaller the cation), the stronger the charge-localizing influence. The electrostatic stabilization of the anion in the ground state relative to the excited state increases with this size trend from Cs to Li. Thus, the excitation energy increases, and a red shift of the absorption maximum is observed in CIPs when going from the Li to the Cs salts. The effect is even more pronounced in SSIPs.[58, 67]

3.4. Rotation and Inversion Barriers in Organometallic Compounds of Alkali Metals

The alkali-metal salts of allyl anions are the prototypes of π-bound polar organometallic species. While allyllithium is an unsymmetrical dimer in THF solution,[68] allylsodium and allylpotassium are symmetrical monomers.[69] NMR studies[70] as well as ab initio calculations[65] were carried out to determine the rotational barrier about the C–C bonds via a *syn*-M–C_3H_5 transition state [Eq. (k)]. Table 8 shows that theoretical and experimental data are in good agreement if a dimeric structure is assumed for allyllithium. With increasing ionic radius of the gegenion, the rotational barriers approach the value of the free allyl anion.



(k)

$\Delta E^{\ddagger}_{rot.}$ (calcd)	13.0 [c]	13.4 [d]	17.4 [d]	19.0 [d]	21.8 [d]	21.7 [f]

[a] Ref. [70a]. [b] Ref. [70b]. [c] Dimer, 3-21G. [d] Monomer, MP2(FU)/6-31 + G* (Huzinaga basis set for K, Rb, Cs). [e] ΔE^{*}. [f] MP2(FU)/6-31 + G**. [g] Determined as ΔG.

If the transition state is regarded as a vinylmethyl anion σ-bound to the metal, the rotation refers to a metalation reaction in which a π-bound alkali-metal derivative is converted into a σ-bound species [Eq. (l)]. As mentioned in Section 3.2, this type

(l)

of reaction should result in a *nonmonotonous* trend of the reaction energies along the Li to Cs series. Indeed, this is found for the rotational barriers of the monomeric alkali-metal allyl derivatives (Fig. 5). The example shows very well that the intrinsic course of reaction (activation) energies can be hidden by the formation of aggregates.

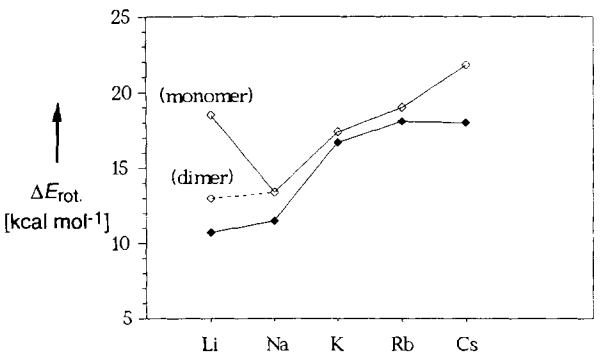

Fig. 5. Experimental (•) and calculated (◇) rotational barriers ($\Delta E^{\ddagger}_{rot.}$) of the allyl alkali-metal compounds (see Table 8) [65].

Whereas the inversion barrier of the free methyl anion is quite low (smaller than 2 kcal mol^{-1}),[71] that of monomeric methyllithium is considerably higher (28.0 kcal mol^{-1}, MP2(FU)/6-31 + G*//MP2(FU)/6-31 + G*).[72] In tetrameric methyllithium the barrier is 14.3 kcal mol^{-1} (combined ab initio/MNDO calculations),[45] in good agreement with the inversion barrier of 2-methylbutyllithium (approximately 15 kcal mol^{-1}).[73] Thus the inversion behavior of monomeric MeLi is not equivalent to that of the methyl anion.

4. Influence of Gegenions on the Structures

4.1. Methyl Derivatives

The solid-state structures of all the alkali-metal methyl compounds were determined by Weiss et al.[74] Both methyllithium[75a–c] and methylsodium[75d–f] crystallize in a cubic space group as tetrameric aggregates. The metal atoms form a tetrahedron and the methyl anions are centered above the tetrahedral faces. In contrast, potassium,[76] rubidium, and cesium methanides[77] crystallize in a hexagonal space group of the NiAs type. Only the cell parameters increase from K to Cs (however, a recent neutron diffraction study including hydrogen atom positions revealed a larger orthorhombic cell for KCH_3[76b]). The deviation in lattice types for $LiCH_3$ and $NaCH_3$ from those for the heavier alkali-metal methanides is rationalized by the different ratios of ionic radii of the alkali-metal cations and the methyl anion. Li^+ (0.69 Å) and Na^+ (0.97 Å) have similar

ionic radii, as do K^+ (1.33 Å), Rb^+ (1.47 Å), and Cs^+ (1.67 Å).[9b]

Although the hydrogen atom positions were determined in some cases by neutron diffraction methods, different aggregation and crystal types preclude direct comparison of the structures of the methyl anion moieties. Ab initio calculations of the monomeric alkali-metal methyl compounds[42] yield C–M distances that are systematically too short due to the monocoordination of the metal cations (Table 9). However, the M-C-H

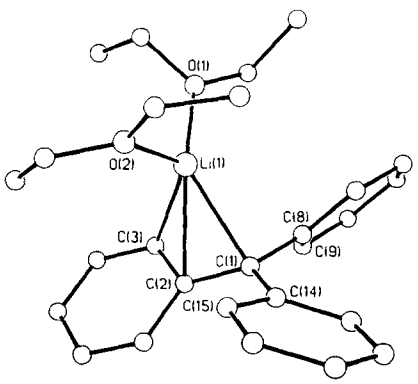
angles follow the trend of the natural charges on the metal. $CsCH_3$ is the most polar compound and has the widest M-C-H angle (112.8°), that is, the most pyramidal CH_3^- group. $NaCH_3$ shows the smallest angle (111.0°) corresponding to the smallest metal charge. The more polar the C–M bond, the more pyramidal the methyl anion. The M-C-H angle does not approach the value for the angle between the CH bond and the C_{3v} axis in the free methyl anion (109.5°)[78] when going from Na to Cs. Instead, *all* M-C-H angles are wider (the methyl anion is more pyramidal). This is due to the charge-localizing effect of the gegenions: the anionic lone-pair orbital is more localized (has more s character) in the metal species, and thus, the CH_3^- group is more pyramidal than in the free anion. The M-N-H angles of the alkali-metal amides also follow the ionicity of the M–N bond (see Table 10). Parallel with the smooth increase of the polarity from Li to Rb, the smallest M-N-H angle is found in $LiNH_2$ and the widest in $RbNH_2$.[42]



The charge-localizing, pyramidalizing influence can also be observed in the alkali-metal derivatives of triphenylmethane, where charge localization by the gegenion competes with charge delocalization into the phenyl groups. The X-ray structures are known for all the alkali metals (for example, for $Ph_3CLi \cdot 2\,Et_2O$ **2** and for $Ph_3CCs \cdot PMDTA$ **3** (Figs. 6, 7))[79–82] as is a structure of a solvent-separated ion pair with $[Li([12]crown-4)_2]^+$ as the gegenion[83] (Table 11). The monomeric lithium CIP derivatives display a distinctly pyramidal methyl carbon atom (12 pm out of the plane formed by the *ipso* carbon atoms C2, C8, and C14), whereas the triphenylmethyl anion moiety is

4.2. Allyl Derivatives

Ab initio calculations predict symmetrically bridged structures for the monomeric alkali-metal allyl compounds (e.g. **4**, Fig. 8).[65] In all cases, the hydrogen atoms are bent out of the C1-C2-C3 plane. Because of the antibonding character of the HOMO and the charge repulsion of C1 and C3, a wider C1-C2-C3 angle than in propene is expected in the allyl anion. The C1-C2-C3 angle of the allyl as well as the crotyl alkali-metal compounds increase on going from the Li to the Cs derivatives (Table 12). The electrostatic interaction of the small lithium cation with C1 and C3 results in the smallest C1-C2-C3 angle. The large Cs^+ is further away from C1 and C3. Thus, a C1-C2-C3 angle nearly as wide as that of the free anion results for allylcesium. In contrast, the C1–C2 and C2–C3 distances (1.398–1.400 Å) only vary to a minor extent along the Li to Cs series. Although some solid-state structures are known for allyllithium[87] and sodium[88] derivatives, direct comparison with the calculations is precluded by the different allyl substituents and ligands attached to the metal cation. The experimental values for the C1-C2-C3 angles range between 125° and 132° for the allyllithium derivatives and between 127° and 130° for the sodium species.

4

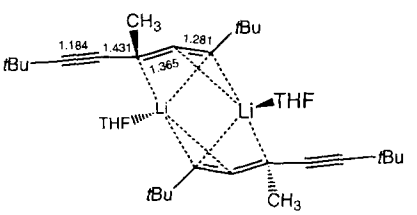
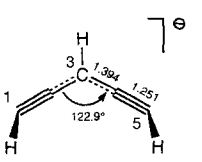
4.3. Acetaldehyde Enolates



The charge-localizing influence of the gegenion on the geometries of the alkali-metal acetaldehyde enolates (**1**) also is apparent (Table 6; see Section 3.3).[64] The C1–C2 separation is shortest in the vinyl alcohol (1.318 Å) (which has no charge and only modest resonance stabilization). The C–C length increases to 1.332 Å in CH_2CHOLi, but then only approximately an additional 0.01 Å along the Na to Cs series. The free acetaldehyde enolate anion has by far the longest C–C distance (1.372 Å). The variations in the C–O distances are complementary. The shortest separation (1.244 Å) is found in the enolate anion and the largest (1.340 Å) in vinyl alcohol. Due to the partial C–O double-bond character, the values in the metal enolates are intermediate (about 1.29 Å). The known X-ray structures of Li, Na, and K enolates[9c,d] do not show any regular variation in the C–C and C–O bond lengths. Again, different aggregation states, solvation, and substituents are responsible for the irregularities. The quite different structures of the Cs enolate and the free enolate anion show again that the charge-localizing influence is still significant for long M–O separations.

4.4. Allenyl Derivatives

Carbanionoid allenyl compounds exhibit unusual structural features. Allenyllithium compounds are not vinylic derivatives. Instead, a nonclassically 1,3-bridged structure (**5**) with a distinctly bent carbon skeleton is preferred, because the metal cation is



5 C_s MP2(FU)/6-31G*

6

7 C_s MP2(FU)/6-31+G*

8 C_s MP2(FU)/6-31+G*

coordinated to the second double bond.[89] This arrangement is exemplified in the X-ray structure of the dimeric, lithiated 2,2,5,8,8-pentamethyl-3,6-nonadiyne **6**.[9a, 90] In contrast, the free allenyl anion **7** is almost linear.[89c, 91] The vinylic alternative of allenyllithium where the Li^+ is sited in the direction of the former hydrogen atom is not a minimum structure on the hypersurface: optimization of this structure leads without barrier to the bridged structure **5**.[89a] The free parent carbanion (**8**, diethynylmethyl anion) of the lithium compound **6** has a symmetrical C_s structure (MP2(FU)/6-31+G*);[92] the negative NPA-charge is localized at C1, C3, and C5. In contrast, the lithium compound **6** is an unsymmetrically bridged allenyl derivative. The metal cation localizes the negative charge within the allenyl moiety.[93] That the alkynyl substituent does not stabilize the charge effectively by π conjugation is apparent from the similar C–C distances within the allenyl moiety (1.37 and 1.28 Å), but the quite different C–C distances within the alkynyl substituent (1.43 and 1.18 Å). The sodium salt of 2,2,5,8,8-pentamethyl-3,6-nonadiyne is a nonbridged monomer.[93] The C–C distances are analogous to those of **6** (in the allenyl moiety 1.38 and 1.24 Å, in the alkynyl substituent 1.44 and 1.19 Å).

5. Conclusions

The NPA population analyses of several alkali-metal derivatives MX with M = Li, Na, K, Rb, Cs and various X (H, CH_3, NH_2, OH, F, Cp) show that the M–X bond is predominantly ionic in all cases. Moreover, one has to distinguish two different types of organometallic MX species: derivatives with σ-donor substituents (prototype MCH_3) and species with σ- *and* π-donor substituents (prototype MCp). While the former are slightly covalent and show a nonmonotonous trend of ionicity from Li to Cs, the latter are almost fully ionic. Metalation reactions between these groups exhibit a nonmonotonous trend following the (weak) covalency (bond strength) of the σ-donor compounds. Reaction energies within each group are nearly independent of the metal.

Despite the high polarity of the metal derivatives, the energetic properties of these compounds (such as relative metalation energies) do not necessarily tend toward those for the free anions on going from Li to Cs. The energies of some reactions (like the metalation of vinyl alcohol with MOH or the metalation of propene with MCH_3) are smaller than that of the corresponding reaction with the free anion because of charge localization by the gegenion. Even for large cations (e.g. Cs^+), the reaction energies are considerably lower than those of the free anions. In contrast, the rotation barriers of the allyl alkali-metal compounds approach the value of the free anion for larger gegenions (Rb^+ and Cs^+).

The influence of the gegenions on the geometries of the carbanion moiety also is significant. For example, the gegenion localizes the charge and enhances the pyramidalization with respect to the methyl anion in methyl alkali-metal compounds. The allenic structure of salts of the dialkynylmethyl anion also is due to charge localization.

Both the intrinsic structures and energies of polar organometallic compounds are influenced substantially by the gegenion. The description of polar organometallic compounds as "*carbanions*" is inadequate and misleading and should be avoided. Further theoretical and experimental work is needed to elucidate the gegenion influence on the energies of aggregates and solvated species as well as on the activation barriers of reactions of polar organometallic compounds.

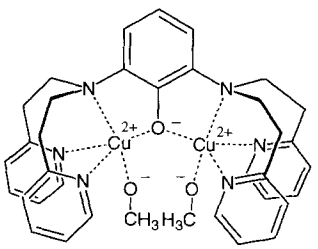
Binuclear Metal Complexes as Efficient Intermediaries in Biochemically Relevant Hydrolysis Reactions

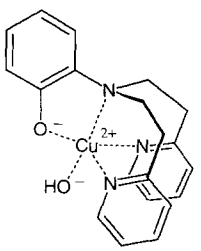
Michael W. Göbel*

Enzymes set chemists a high standard for synthetic catalysts with their often astoundingly high selectivity and simultaneous enormous acceleration of reactions. This goal is very difficult to achieve, let alone to better. The elucidation of enzyme mechanisms is therefore counted among the important tasks of science, to which a wide variety of research disciplines can contribute. In recent years X-ray crystal structure analysis, in particular, has made available a wealth of detailed structural information that can serve a foundation for the formulation of mechanistic proposals. Further refinement of such models is then possible through site-directed mutagenesis and calculations. In the light of the success of scientific methods, which in a certain sense can give a multifaceted view of the problem, the role preparative chemistry may play nowadays in elucidating enzyme catalysis is questioned. Is the synthesis of low molecular weight models of enzymes actually still relevant?

I am convinced that this question can be answered with a decisive yes. One misunderstanding, however, must be avoided. Models of enzymes that describe the complex structure and dynamics of a proteinogenic catalyst are, as a rule, not achieved in the attempts of synthetic chemists. This is also not the goal of such research. The aim of investigations on small, well-defined molecules is far more to probe a particular aspect of the enzyme in question, for example, to consider in isolation the special arrangement of functional groups obtained from crystal structure data and to test the relevance of such an arrangement with respect to the reaction mechanism. In this way individual principles of function are determined, which are useful for a deeper understanding. Another advantage of the reductionistic view lies in the potential for using the principles found in the model to construct totally novel, enzyme-analogous catalysts that could attain practical importance in the future.



A good example for the value of such model systems is the series of papers that have recently appeared on binuclear metal complexes. Beside the long-known iron–sulfur proteins of the respiratory chain, enzymes and proteins have been described recently in which the active sites contain two or three interacting metal ions (for example, Zn, Fe, Cu).[1] The biological tasks cover oxygen transport to oxygenase and hydrolase activity. Since the structure–function relationship of these enzymes are by no means solved, the synthesis of simplified model complexes is an important goal. Typically, symmetrical ligands linked by *meta*-substituted arene units are used. In this way, with **1** Karlin et al. have prepared a binuclear copper complex along the lines of hemocyanin, the copper-containing O_2-transport protein of molluscs. At low temperature **1** binds O_2 reversibly.[2a] The oxygen associate of complex **2** is more stable.[2b] In the presence of dimethylformamide (DMF) or dimethylacetamide, however, this associate reacts instantaneously to form **3**, whose structure



has been solved by X-ray crystallography. In analogous copper complexes the remarkable redox reaction of hydroxylation of the arene and oxidation of the copper ions occurred earlier.[2c] Completely unexpected was the fate of the amide: it was hydrolyzed to the formate ion. In the light of the high kinetic stability of carboxylic amides, whose half-lives in neutral water lies in the range of years, the hydrolysis of DMF within seconds is a new speed record! Where can the reason for this enormous acceleration be found? The presence of both copper ions appears to be essential. While **4** hydrolyzes DMF with a rate constant of about 0.3 h^{-1}, no reaction can be detected with the mononuclear complex **5**.[3] Probably the first Cu ion of **4** coordinates a hydroxide ion, while the second Cu cation binds the

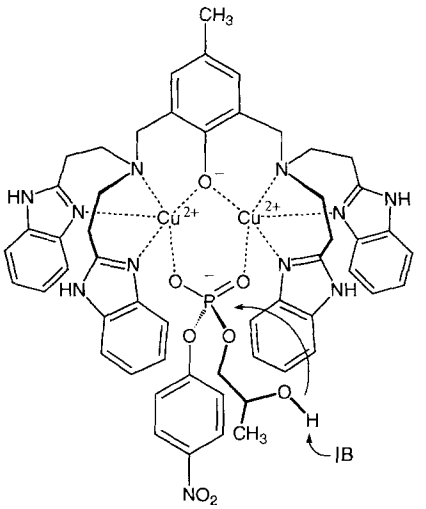
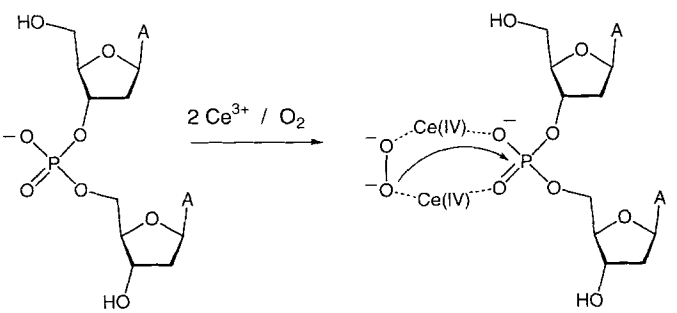
5

oxygen atom of DMF and activates it as Lewis acid for the intramolecular addition of the nucleophile (Scheme 1). With respect to its reactivity, **4** is comparable with the known metal catalysts of amide hydrolysis;[3] nevertheless, the oxygen associate of **2** is unparalleled. As is known, the nucleophilicity of OOH^- ions is drastically enhanced over that of the OH^- ion on account of the α effect. The authors therefore surmise that the species that is responsible for the hydrolysis is a copper complex with peroxido ligand that arises in the primary redox reaction. Scheme 2 depicts the assumed mechanism. The study of complex **2** thus led not only to the answer of the original question on the binding of oxygen in copper complexes, but simultaneously to a novel approach to the construction of artificial peptidases.



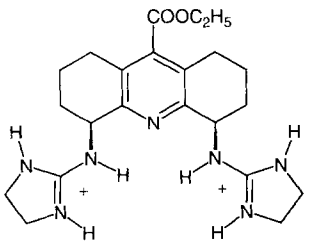
Scheme 1. Postulated mechanism of the amide hydrolysis with **4** as catalyst.



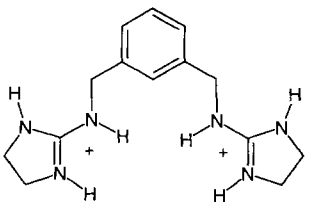
Scheme 2. Postulated mechanism of the amide hydrolysis with **2** as catalyst.

In nature multinuclear metalloenzymes, under which the RNAse H of the HIV reverse-transcriptase is classified, serve as catalysts for several acyl and phosphoryl transfer reactions. Chin et al. chose a binuclear copper complex related to **1** to accelerate the reaction of a phosphoric acid diester anion (Scheme 3).[4] This reaction can be considered a model for the first step of the hydrolysis of RNA, in which the alcohol function of the side chain attacks the phosphoryl center as nucleophile in a ring closure reaction. As in the case already described, the binuclear copper complex was compared with the analogous mononuclear complex: the approximately 50 times larger rate constant of the binuclear complex shows that here, too, the two metal ions probably cooperate.[5] Because on cyclization of the substrate the transition state structures have a higher negative charge density at the phosphoryl group, the interaction with several electrophilic metal sites is advantageous. Analogous zinc complexes have already been used for the hydrolysis of similar model substrates.[6] The ultimate test for every synthetic hydrolase, however, is the phosphoric diester group of DNA. Since an entropically favored intramolecular course of reaction is not

Scheme 3. Model reaction for the first step of the hydrolysis of RNA. B = base.



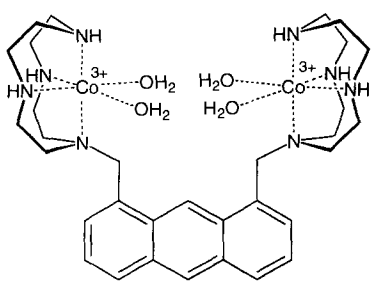
possible, in contrast to RNA, because of the missing hydroxyl function at C2′ in DNA, these phosphoric acid esters show an extreme kinetic stability to substitution. With the redox-active Ce^{3+}/O_2 system, Chin et al. have now been able to perform the *hydrolytic* cleavage of deoxyribodinucleotides as well in convincing style.[7] Although the mechanism of the hydrolysis has not been completely elucidated, the assumption of a reaction of Ce^{3+} ions with oxygen to give a complex of two Ce^{4+} ions and the dianion O_2^{2-} as active agent (Scheme 4) seems plausible. The pathway should be characterized by a similar combination of electrophilic and nucleophilic properties as the intermediate in the amide hydrolysis observed by Karlin et al.



Scheme 4. Conjectured mechanism of the hydrolysis of deoxyribodinucleotides effected by Ce^{3+}/O_2.

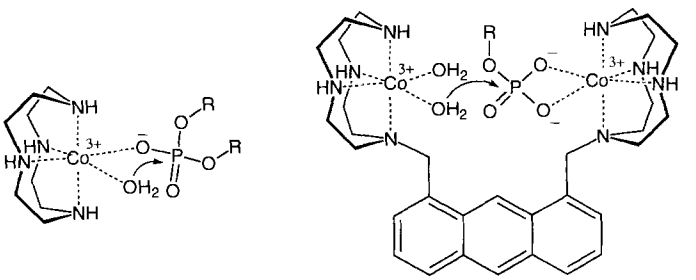
To achieve an electrophilic activation (similar to a Lewis acid) of substrates, enzymes are not, however, exclusively dependent on metal ions. Often guanidinium ions of arginine side chains also perform this function. In this way the Staphylokokkus nuclease accelerates the hydrolysis of phosphoric acid diester anions by sixteen orders of magnitude (!), although the active site contains only one calcium ion. The decisive factor is the additional presence of two guanidinium ions that display both the electrostatic and the structural complementarity of the dianionic, trigonal-bipyramidal transition structures of the substrate hydrolysis. To date already three research groups have attempt-

ed to employ the bis(guanidinium) substructure of the Staphylokokkus nuclease as active principle for synthetic catalysts with phosphodiesterase activity.[8] In compounds **6** and **7** the cationic groups are linked to each other in such a way that four hydrogen



6

7



bonds can form simultaneously to a tetrahedral or trigonal-bipyramidal oxo anion to be complexed. As was hoped, **7** and analogous compounds strongly accelerate substitution reactions of phosphoric acid diesters in dipolar, aprotic solvents.[8c, d] Anslyn, Smith et al. could even catalyze the cleavage of RNA in water with **6**.[8b]

The binuclear Co complex **8** described by Czarnik et al.[9] differs from those already mentioned. The two metal ions are held so far apart by the spacer that no direct dimerization of the two subunits through oxygen is possible. Complex **8** accelerates the hydrolysis of phosphoric acid diester anions by seven orders of magnitude, but still does not exceed the activity of mononuclear complexes. In Co^{3+} complexes nucleophile and phosphoric acid diester bind to the same metal ion and react intramolecularly via a four-membered transition state (Scheme 5, left). The high efficiency of **8** is therefore not attributable to a cooperativity of the two Co^{3+} ions. On the other hand **8** increases the rate of hydrolysis of phosphoric acid monoesters about ten times more than the corresponding mononuclear complexes. Probably one metal ion coordinates the nucleophilic water molecule, while the second binds the phosphoryl group in the form of a four-membered ring.[3] The reaction of the phosphoric acid monoester can therefore profit from the special arrangement of the metal ions in **8** (Scheme 5, right).

8

This small selection of examples is intended to demonstrate that synthetic metal complexes provide a plethora of subtle insights into the structure–activity relationships, which may also be valid for enzymes. Finely adjusted modifications are much more difficult to achieve in proteins and still more difficult to test. Moreover, the presented model systems show substantial reactivities in spite of their simple construction. The compounds are indeed of practical interest, perhaps as artificial proteases or as synthetic ribonucleases that—together with antisense oligonucleotides—can effect a hydrolytic deactivation of pathogenic messenger-RNA.

Scheme 5. Postulated mechanism for the hydrolysis of phosphoric acid esters.

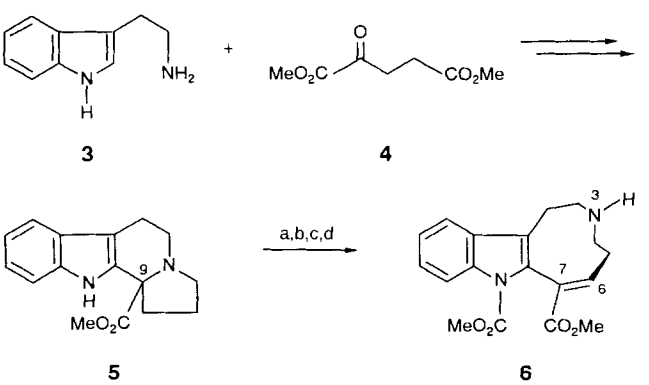
New Total Syntheses of Strychnine

Uwe Beifuss*

Strychnine (**1**), the active component of a notorious arrow poison in Southeast Asia, has a mysterious history. It is a convulsant blocking postsynaptic inhibition in the spinal cord by acting as an antagonist of the inhibitory neurotransmitter, glycine.[2] In therapeutic doses strychnine has a mildly analeptic effect; in toxic doses it leads to uncoordinated tonic convulsions induced by acoustic, tactile, or optical stimuli. Paralysis of the respiratory organ results in death; 100–300 mg is the lethal dose for an adult human.[2c]

1

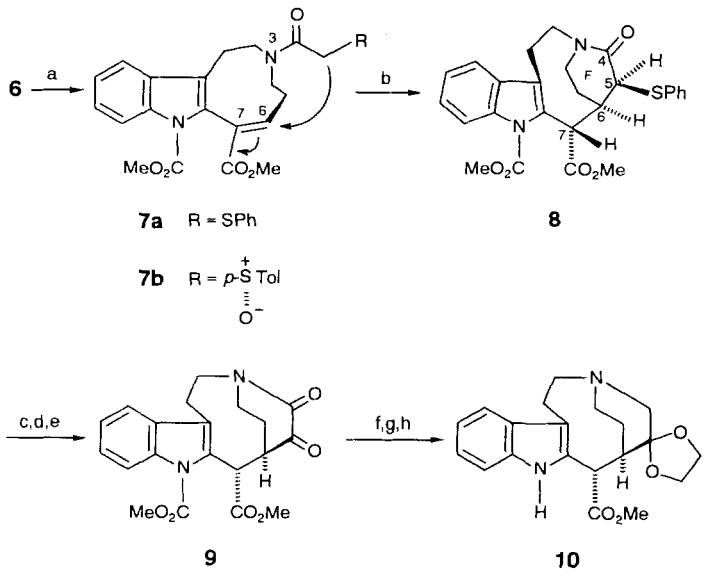


2

In 1818 strychnine (**1**), which occurs in larger amounts in the poison nut (*Strychnos nux vomic L.*) and the Saint-Ignatius's-bean (*Strychnos ignatii Bergius*), was isolated by Pelletier and Caventou[3] and was one of the first alkaloids obtained in pure form. The structure determination by chemical degradation of the natural product, a complex structure with seven rings and six stereogenic centers, proved to be difficult and tedious. Many structural formulas were proposed and rejected before Robinson et al. (1946) and Woodward et al. (1947) presented the correct formula.[4] The relative and absolute configuration was determined by X-ray crystallography a few years later.[5]

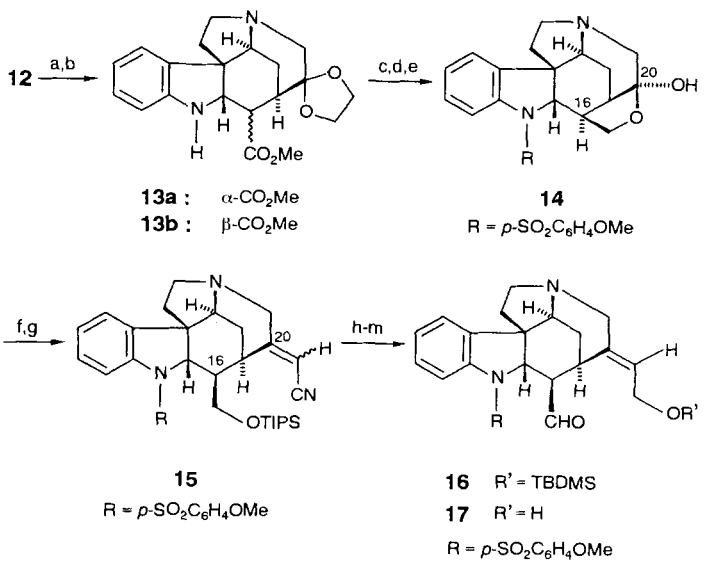
The structure determination culminated with the total synthesis of **1** by Woodward et al., which was the only total synthesis of this natural product for nearly forty years.[6] Even today this synthesis is still considered a highlight in the development of modern organic synthesis, since at that time the deliberate design and execution of the synthesis of a molecule of this complexity was unprecedented. Despite the rapid development of organic chemistry since then, strychnine has remained an attractive, challenging synthetic target. A number of novel approaches to the strychnos alkaloids have been devised,[7, 8] but the molecules prepared frequently lack the functionalities required for the construction of the seven-membered allylic ether G ring of strychnine. Recently, almost forty years after Woodward's synthesis, four research groups achieved the total synthesis of strychnine. In 1992 Magnus et al. reported on the successful conclusion of the second total synthesis of strychnine and at the same time the first total synthesis of the so-called Wieland–Gumlich aldehyde **2**.[9] Shortly afterwards Overman et al. published the first, and so far only, enantioselective route to strychnine (**1**),[10] and in the meantime Kuehne et al.[11] and Rawal et al.[12] have also completed their total syntheses. This certainly provides ample grounds for discussing these four new syntheses.

Magnus' synthesis[9] follows the retrosynthetic analysis of the strychnos framework employed successfully by Harley-Mason in the syntheses of several natural products in the 1960s and 1970s.[13] The key step in this strategy is the transannular iminium ion cyclization of a nine-membered ring for the stereoselective construction of rings D and E of the strychnos alkaloids. Magnus follows the classical approach right from the start with the multistep conversion of the tetracyclic amine *rac*-**5**, which is readily accessible from **3** and **4**, into **6** (Scheme 1). A crucial step



3 **4** **5** **6**

Scheme 1. a) $ClCO_2CH_2CCl_3$, CH_2Cl_2; b) NaOMe, MeOH; c) 50% aq NaOH, CH_2Cl_2, $ClCO_2Me$, benzyltriethylammonium chloride; d) Zn, CH_3COOH, THF.



is the β,β,β-trichloroethyl chloroformate induced fragmentation of the tertiary amine *rac*-**5** to provide the expanded nine-membered ring system. One of the most remarkable steps in the remainder of the synthesis is the construction of the F ring by intramolecular conjugate addition. For this purpose amide **7a** is prepared and treated with sodium hydride in THF, which results in the facile, diastereoselective transformation into *rac*-**8**. The stereoselectivity of this 1,4-addition is attributed to the protonation of the intermediate ester enolate from the top face. Oxidation of *rac*-**8** to give the corresponding mixture of sulfoxides is then followed by a Pummerer reaction and Hg^{2+}-mediated hydrolysis to furnish *rac*-**9** (Scheme 2).

Magnus et al. obtained both enantiomers of **9** with considerable effort by acylation of **6** with (+)-(*R*)-*p*-toluenesulfinylacetic acid and cyclization of the resulting sulfoxide **7b**, separation of the four diastereomers formed in this way, combination of the pairs with the same absolute configurations at C-6 and C-7, and subsequent conversion into the two enantiomers **9** and *ent*-**9**.[9a] The cyclization of sulfoxide **7b** yields the two products enantiomeric at C-6 and C-7 in a 55:45 ratio. This is why this route is not only laborious but also only insignificantly more efficient than resolution.

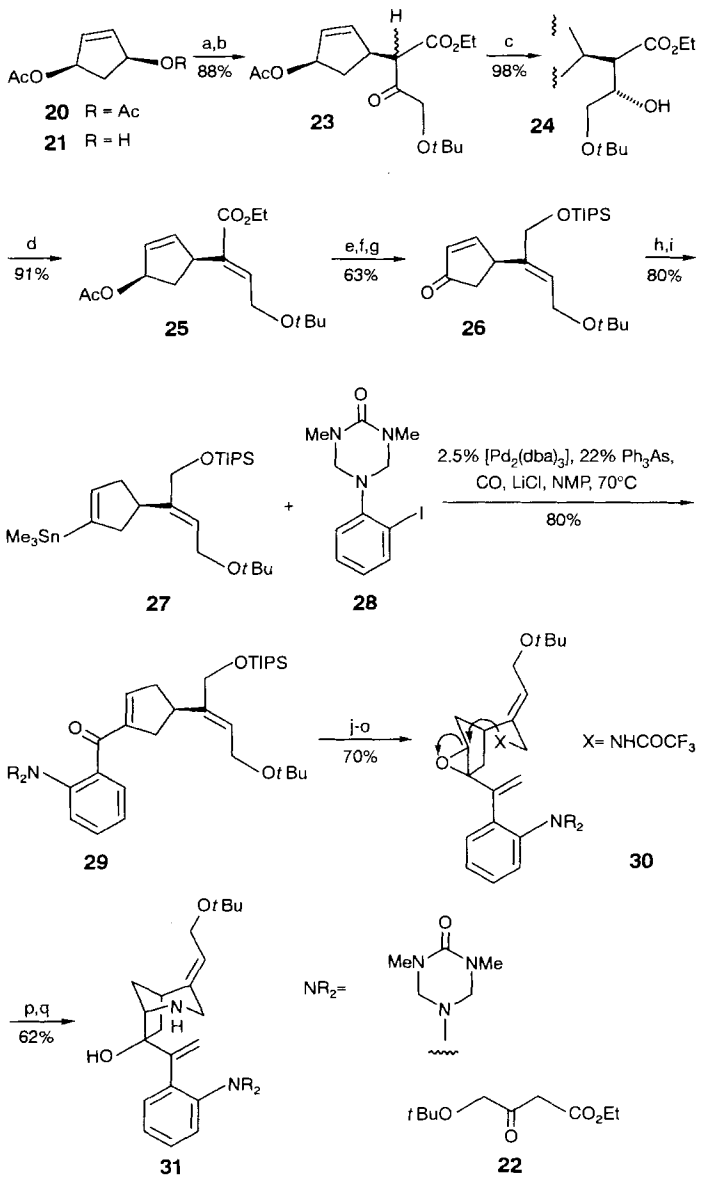
After transformation of *rac*-**9** into acetal *rac*-**10** (Scheme 2) rings D and E are constructed in the most critical step of the entire synthesis. A transannular iminium ion cyclization[7, 13] provides predominantly *rac*-**12** in 65% yield with remarkable regio- and stereoselectivity.[14] It is assumed that treatment of *rac*-**10** with mercury(II) acetate in acetic acid leads primarily to the cyclic iminium ion *rac*-**11** which then gives *rac*-**12**.

A number of steps are required for the conversion of *rac*-**12** into the cyclic hemiacetal *rac*-**14** (Scheme 3). This compound is important for the rest of the synthesis, since it cannot only be prepared from tryptamine (**3**) and dimethyl 2-ketoglutarate (**4**), but can also be obtained readily in substantial amounts and in enantiomerically pure form by degradation of strychnine. Once enough of this relay hemiacetal has been secured, assembly of the G ring can be tackled.

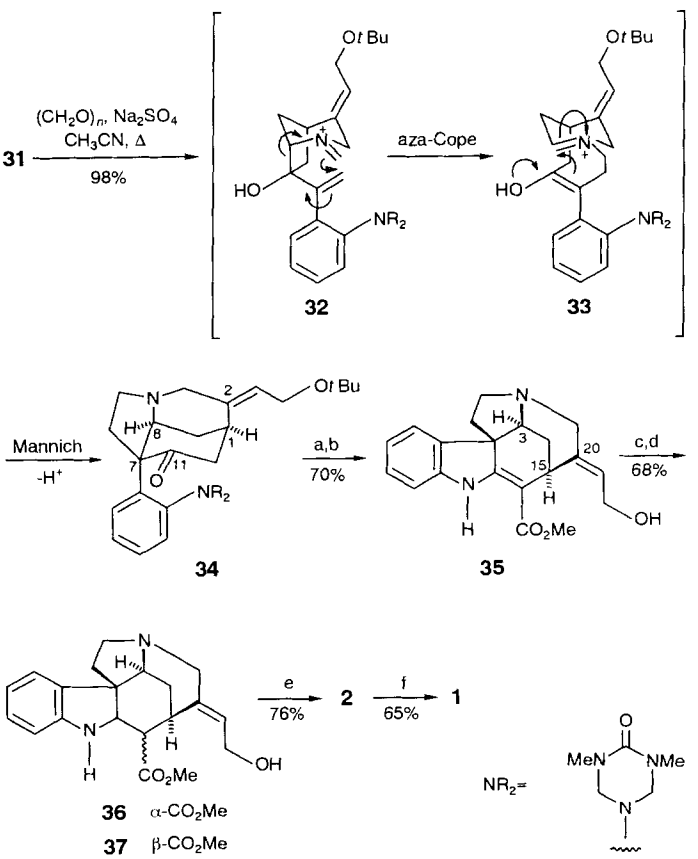
As only a compound with an (*E*)-configurated double bond as in **17** can be used for the synthesis of the G ring, the construction of the hydroxyethylidene double bond must be diastereoselective. This problem had challenged Woodward et al., and like those pioneers Magnus et al. were also foiled: Wittig–Horner reaction furnishes the α,β-unsaturated cyanide **15** as a 2:3 mixture of the (*Z*) and (*E*) isomers. Although the undesired (*Z*) isomer can be isolated and isomerized photochemically to give a mixture of both isomers, this step is far from being optimal.

The next steps in the synthesis include the multistep conversion of (*E*)-**15** into **16**, subsequent cleavage of the silyl ether protecting group, and cyclization of **17**, which cannot be isolated, to provide hexacyclic **18**. With the reductive removal of the



sulfonamide Magnus et al. arrived at their first goal, the total synthesis of the Wieland–Gumlich aldehyde **2**. The conclusion of the total synthesis of strychnine is also within reach; the authors succeeded in converting **2** into the natural product in a one-step reaction with malonic acid, following the method of Robinson et al.[15] With 27 steps this synthesis is only negligibly shorter than Woodward's 28-step synthesis from 1954. But Magnus et al. achieved an overall yield of roughly 0.03%, which is more than 1000 times greater than Woodward's overall yield of 0.00006%. This result would have been impossible without powerful new synthetic methods. Magnus' synthetic strategy has a classical form, and he prepared enantiomerically pure compounds

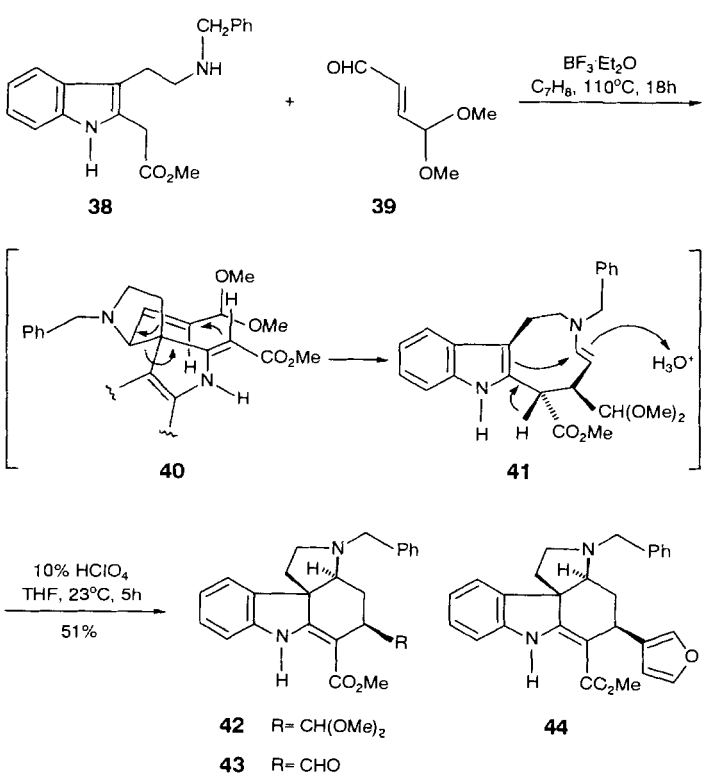
very effectively by traditional means, namely via a relay compound obtained by degradation of the natural product itself.



The third total synthesis of strychnine (**1**), so far the only enantioselective route to the natural product, was accomplished by Overman et al.[10] The key to their approach to **1** is the sequential cationic aza-Cope rearrangement/Mannich cyclization, which is frequently employed with success in alkaloid synthesis. With the synthesis of akuammicine *rac*-**19** the authors proved that this strategy offers an efficient route to the strychnos alkaloids.[8g]

The crucial compound in this strychine synthesis is azabicyclo[3.2.1]octane **31**, which is the substrate for the aza-Cope–Mannich sequence (Scheme 4). In the preparation of **31**, *meso*-diester **20** is subjected to acetylcholine esterase catalyzed hydrolysis to yield **21** with high enantiomeric purity. Eighteen ensuing steps then provide **31** in 14% yield. The allylic carbonate obtained from **21** is used in a palladium-catalyzed allylic substitution with **22** to furnish the *cis* products **23**, which are reduced with high diastereoselectivity (>20:1) in accord with the Felkin–Anh model to provide a mixture of the *trans*-β-hydroxy esters **24**. Subsequent *syn* elimination affords the (*E*) isomer **25** almost exclusively (97:3). In this way Overman et al. succeeded in solving the problem of the stereoselective construction of what will become the allylic ether double bond at C-20 of the natural product early in the synthesis. The next important intermediate is the α,β-unsaturated ketone **29**, which is accessible by the palladium-catalyzed, carbonylative cross-coupling of vinyl stannane **27** with the triazone-protected *o*-iodoaniline **28**. In turn, **27** is prepared by the palladium-catalyzed Stille coupling of the enol triflate obtained regioselectively from **26**. The key step in the transformation of **29** into **31** is the stereoselective, intramolecular aminolysis of epoxide **30**, which is the product of the substrate-controlled stereoselective epoxidation and subsequent Wittig methylenation of **29**.

Now the aza-Cope–Mannich cascade must be triggered, in other words, amine **31** must be converted into the corresponding formaldiminiun ion **32** (Scheme 5). This is achieved by reaction with paraformaldehyde without added acid. Intermediate **32** undergoes cationic [3,3] sigmatropic rearrangement under these



Scheme 4. a) $ClCO_2Me$, pyridine, CH_2Cl_2, 23 °C; b) $tBuOCH_2COCH_2CO_2Et$ (**22**), NaH, 1% $[Pd_2(dba)_3]$, 15% PPh_3, THF, 23 °C; c) $NaCNBH_3$, $TiCl_4$, −78 °C; d) dicyclohexylcarbodiimide (DCC), CuCl, C_6H_6, 80 °C; e) DIBAL, CH_2Cl_2, −78 °C; f) TIPSCl, tetramethylguanidine, *N*-methyl-2-pyrrolidone (NMP), −10 °C; g) Jones oxidation, −5 °C; h) L-Selectride, $PhNTf_2$, THF, −78 → 0 °C; i) Me_6Sn_2, 10% $[Pd(PPh_3)_4]$, LiCl, THF, 60 °C; j) $tBuO_2H$, Triton-B, THF, −15 °C; k) $Ph_3P{=}CH_2$, THF, 0 → 23 °C; l) tetrabutylammonium fluoride (TBAF), THF, −15 °C; m) methanesulfonyl chloride (MsCl), iPr_2NEt, CH_2Cl_2, −23 °C; n) LiCl, DMF, 23 °C; o) NH_2COCF_3, NaH, DMF, 23 °C; p) NaH, C_6H_6, 100 °C; q) KOH, EtOH-H_2O, 60 °C.

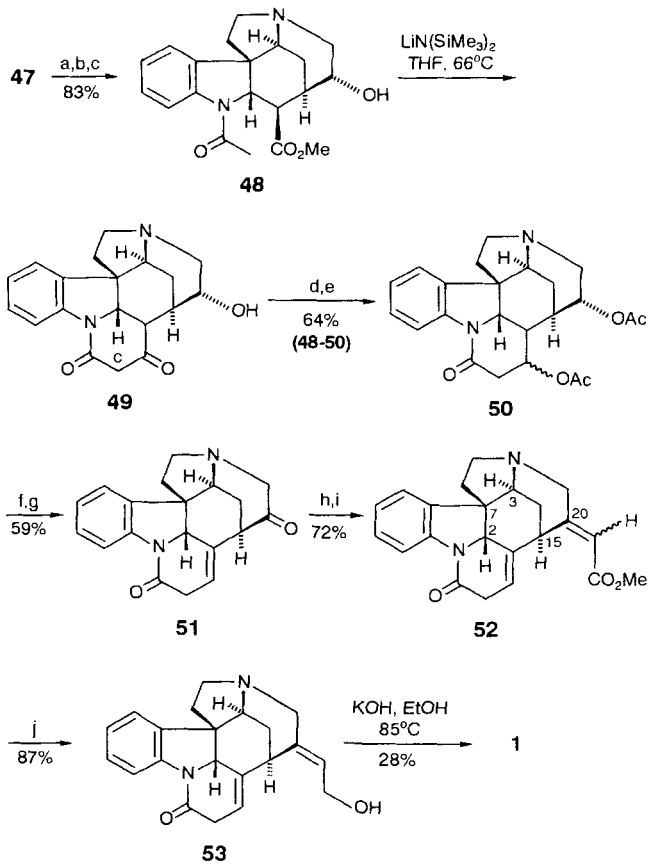
reaction conditions to give **33**, which contains all the structural features that are required for the ensuing intramolecular Mannich cyclization. At the end of the sequence **34** is obtained stereoselectively and almost quantitatively (98% yield)—an outstanding example of the efficiency and flexibility of this synthetic strategy. The cyclization product **34** is then acylated with methyl cyanoformate, and cleavage of the triazone protecting group affords pentacycle **35**, which contains all of the C atoms required for the synthesis of the Wieland–Gumlich aldehyde **2**. The conversion of **36** into strychnine (**1**) by conventional means is the concluding step in the first synthesis of this natural product proceeding without the resolution of racemates and without relay compounds. Overman et al. accomplish this in a total of 25 steps and with an overall yield of approximately 3%. This first enantioselective total synthesis is achieved in excellent yield. But just as impressive is the underlying retrosynthetic analysis, which is then followed by combining several modern palladium-catalyzed reactions and the elegant aza-Cope–Mannich sequence, a distinctive feature of Overman's work.

The beginning of Kuehne's total synthesis of racemic strychnine *rac*-**1**[11] is promising, since the highly diastereoselective construction of the tetracycle *rac*-**42** from tryptamine **38** and butenal **39** proceeds in only one synthetic operation (Scheme 6). The yield for this novel and efficient sequential reaction is 51% after cleavage of the acetal to provide aldehyde *rac*-**43**. Presumably the cyclizing Mannich reaction that leads to *rac*-**40** is followed by a [3,3] sigmatropic rearrangement giving *rac*-**41**, which in turn undergoes acid-catalyzed cyclization to afford *rac*-**42**. This new method also provides access to the indolenine *rac*-**44**,[8e] a compound containing all but two carbon atoms of ring C of the target molecule. However, it has not been possible so far to employ the furan ring in **44** for the construction of rings F and G in strychine. This is why Kuehne et al. relied on *rac*-**42** in their approach to the natural product.

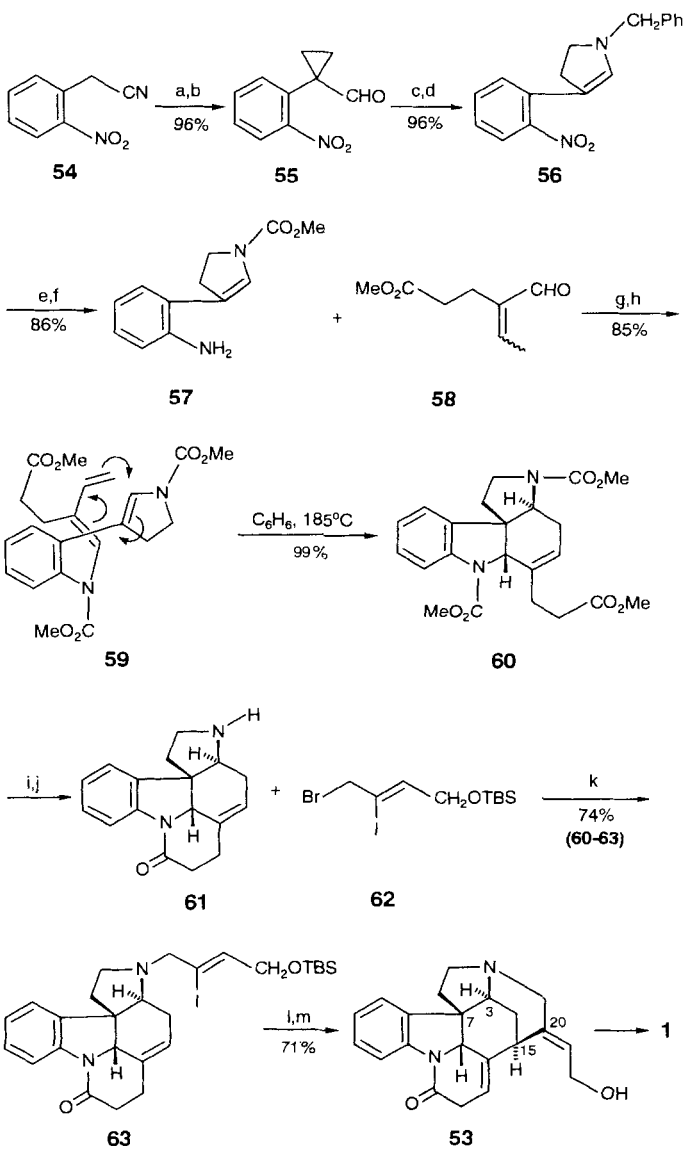


Scheme 6.

This entailed the lengthy and difficult successive construction of the three missing rings F, G, and C. The synthesis of the F ring is the least troublesome, as it succeeds in only three steps and with 67% yield (*rac*-**43** → *rac*-**47**) (Scheme 7). The key step is the intramolecular nucleophilic ring-opening of the unisolated epoxide *rac*-**45**; the thermodynamically controlled reaction yields *rac*-**46** exclusively.

Scheme 7.

In contrast to Magnus and Overman, who directed their syntheses towards the Wieland–Gumlich aldehyde *rac*-**2** and its straightforward conversion into strychnine *rac*-**1**, Kuehne focused on the synthesis of isostrychnine *rac*-**53** (Scheme 8) and had to rely on the isostrychnine–strychnine transformation, which Woodward had already recognized as being exceptionally difficult. First, ring C is assembled. The key step is the intramolecular Claisen reaction of the acetamido ester *rac*-**48** to give ketolactam *rac*-**49**. Although the overall yield for the construction of the C ring is good (*rac*-**47** → *rac*-**51**), the eight steps are relatively laborious. In the next part of the synthesis Kuehne, like Magnus, learned by experience that the (*E*)-selective construction of the allylic ether group at C-20, which is critical for closure of the G ring, is not possible at such a late stage in the synthesis. Wittig olefination of *rac*-**51** provides a 1:1 mixture of the (*E*) and (*Z*) isomers of *rac*-**52**, which can be enriched by irradiation in favor of the required (*E*)-acrylic ester (8:1). The reduction of (*E*)-*rac*-**52** to isostrychnine *rac*-**53** is straightforward; as expected, however, the last step of the synthesis, the problematic conversion of **52** to isostrychnine *rac*-**53** is straightforward; as expected, however, the last step of the synthesis, the problematic conversion of isostrychnine *rac*-**53** into strychnine *rac*-**1**, could not be solved in



Scheme 8. a) $NaBH_3CN$, HOAc, 23 °C; b) Ac_2O, pyridine; c) NaOMe, MeOH, 0 °C; d) $NaBH_4$, MeOH; e) Ac_2O, pyridine; f) DBU, dioxane-H_2O, 100 °C; g) Swern oxidation; h) $(EtO)_2P(O)CH_2CO_2Me$, $KN(SiMe_3)_2$, THF, 23 °C, 2 h; i) *hv*; j) DIBAL, $BF_3 \cdot Et_2O$, −78 °C.

a satisfactory manner: strychnine *rac*-**1** was isolated in only 28% yield in addition to 61% unreacted starting material. One could argue that not every step in Kuehne's synthesis proceeds with the desired selectivity and yield and that the synthesis is not enantioselective. Yet it should be stressed that this synthesis, designed around a new and efficient key sequence, is one of the shortest routes to strychnine *rac*-**1** with 17 steps and an overall yield of roughly 2%. The efficiency of the synthesis could also be improved by avoiding the isostrychnine–strychnine conversion and the consequent time-consuming assembly of the C ring.

A strategy combining the advantages of both the intramolecular Diels–Alder reaction and the intramolecular Heck reaction was successfully tested in Rawal's synthesis of *rac*-**1**.[12] Heating precursor *rac*-**59**, which is prepared from **54** in eight steps, to 185 °C provides tetracycle *rac*-**60** in 99% yield as the sole product of the Diels–Alder reaction (Scheme 9). The rapid construction of the C ring by intramolecular amide formation in only two steps is also remarkable. Allylation of *rac*-**61** with **62** furnishes *rac*-**63**. Subsequent intramolecular Heck reaction leads to the diastereoselective ring closure providing the bridged piperidine system with retention of the stereochemistry at the double bond of the vinyl iodide. Deprotection concludes this hitherto shortest synthesis of racemic isostrychnine *rac*-**53** which has 14 steps and a 35% yield. But Rawal et al. are confronted with the problem of the inefficient final transformation to give *rac*-**1**. If one assumes Kuehne's reported yield of 28% for this step,[16] then Rawal formally achieves the synthesis of the natural product—albeit in racemic form—in only 15 steps and with almost 10% yield, which is on the order of the results of Overman and Kuehne.

Whether the four new total syntheses represent a *fundamental* improvement over Woodward's strychnine synthesis and the extent of this improvement can certainly be debated. However, it cannot be contested that Overman et al. accomplished the first and only enantioselective synthesis of the natural product, and that Kuehne and Rawal with their respective 17- and 15-step syntheses devised approaches with markedly fewer reaction steps than Woodward's 28-, Magnus' 27-, and Overman's 25-step syntheses. The considerable improvement in the overall yields relative to that of the first total synthesis is also noteworthy. Whereas Magnus improved the yield by a factor 1000, Overman, Kuehne, and Rawal upped the overall yield by a factor of

Scheme 9. a) $BrCH_2CH_2Br$, 50% NaOH, CH_3CN, nBu_4NBr, 23 °C; b) DIBAL, C_7H_8, −78 °C, H_3O^+; c) $BnNH_2$, Et_2O; d) Me_3SiCl, NaI, DMF, 60 °C; e) $ClCO_2Me$, acetone, 23 °C; f) 10% Pd/C, HCO_2NH_4, MeOH; g) 23 °C; h) $ClCO_2Me$, $PhNEt_2$; i) Me_3SiI, $CHCl_3$, 61 °C, 5 h; j) MeOH, 65 °C, 6 h; k) DMF, acetone, K_2CO_3; l) $Pd(OAc)_2$, Bu_4NCl, DMF, K_2CO_3, 70 °C, 3 h; m) 2 N HCl, THF.

100000! These impressive numbers cannot be attributed solely to improved synthetic methods and modern reagents, but emphasize the importance that sequential reactions[17] have achieved in the construction of complex natural products.

The four new total syntheses demonstrate that some of the difficulties in the synthesis of strychnine, such as the diastereoselective construction of the double bond at C-20, can now be solved elegantly, but that others like the isostrychnine–strychnine conversion remain unsolved. Thus it can be expected that the search for improved solutions for the efficient synthesis of strychnine and stychnos alkaloids will continue.

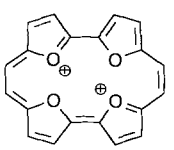
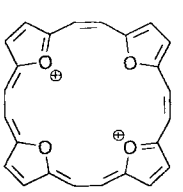
Tetraoxa[22]porphyrin(2.2.2.2) Dication and Tetraoxa[24]porphyrinogens(2.2.2.2)



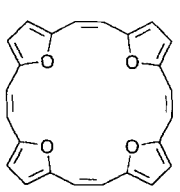
Gottfried Märkl,* Heinrich Sauer, Peter Kreitmeier, Thomas Burgemeister, Fritz Kastner, Georg Adolin, Heinrich Nöth, and Kurt Polborn

Dedicated to Professor Hans Bock

In addition to the porphyrin homologues ([22]porphyrin-(2.2.2.2)[1] and [26]porphyrin(3.3.3.3)[2]) and the porphyrin analogues ([18]porphyrin(2.0.2.0)[3] and [22]porphyrin-(1.3.1.3)[4]), the dicationic [18]porphyrinoids(1.1.1.1) **1** prepared by E. Vogel et al. are among the exciting new developments in porphyrin chemistry.

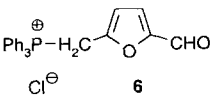


1, X = O
2, X = NMe



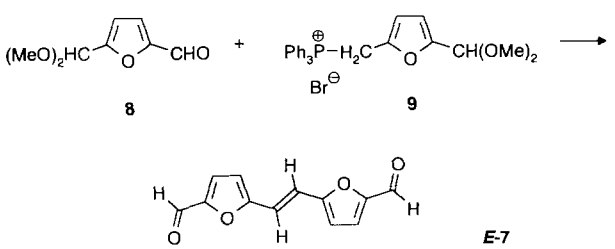
3

E. Vogel et al.[5] described first in 1988 the tetraoxa[18]porphyrin(1.1.1.1)dication **1** (R = H), which is formally analogous to the *N,N',N'',N'''*-tetramethylporphyrin dications **2**,[6] as an aromatic system. Recently, with the synthesis of an octaethyl derivative of **1** (R = H)[7] and tetraalkyl derivatives of **1** (R = alkyl)[7] substituted in the *meso* positions, access to these porphyrinoids has been decisively improved. The porphyrinoid analogue, tetraoxaporphyrin(2.0.2.0) dication **3** (tetraoxaporphycene dication), which is an isomer of **1**, was also prepared by E. Vogel et al.[8]



We describe here for the first time the next highest homologue to **1**, the tetraoxa[22]porphyrin(2.2.2.2)dication **4**. Tetraoxaporphyrinogen(2.2.2.2) **5** ([24]annulene tetroxide), the required precursor to **4**, was prepared in 1969 by J. A. Elix[9] by self-condensation of the ylid obtained from 5-formyl-2-furfuryltriphenylphosphonium chloride **6**.

4



5

6

In addition to traces of a pentamer and a hexamer, he isolated two isomers of **5** each in 0.7% yield, which he assigned the *cis,trans,trans,trans* configuration **5a** (violet-black prisms, m.p. 215–217 °C) and the all-*trans* configuration **5b** (violet prisms, m.p. 269–270 °C).

We synthesized **5** by McMurry dimerization[10] of dialdehyde **7**, which, following the report of H. Saikachi et al.,[11] is accessible by Wittig reaction of the monoacetal **8**[12] of 2,5-furan dialdehyde and phosphonium salt **9**. The pure *trans* isomer (*E*)-**7**

8 **9**

E-7

is obtained from the isomeric mixture (*E*/*Z*)-**7** by recrystallization. McMurry dimerization of (*E*)-**7** was carried out with $TiCl_4$/Zn/Cu in anhydrous tetrahydrofuran. After chromatography on silica gel/CH_2Cl_2 and silica gel/cyclohexane/THF, **5** was obtained in 7% yield (stable black-violet crystals, m.p. > 300 °C). The melting point and spectroscopic data of our compound are not consistent with either of the isomers (**5a, b**) described by J. A. Elix; thus we will refer to the isomer we obtained as **5c**.

In the UV/VIS spectrum of **5c** (Table 1), absorptions with high molar extinctions are evident at short wavelengths (λ_{max} = 346 and 358 nm), and a band with low molar extinction is observed at 471 nm. The deep color of the substance can be attributed to a very broad absorption band with a low extinction centered at approximately 500 nm.

In contrast to tetraoxa[20]porphyrinogen(1.1.1.1),[13] the strong temperature dependence of the ^{1}H NMR spectra of **5c** (400.13 MHz, [D_8]THF, Table 1) points to high molecular dynamics. The ^{1}H NMR spectra at 65 °C and −78 °C are shown in

Table 1. Spectroscopic data (MS, UV/VIS, ^{1}H and ^{13}C NMR) for **5c** [15].

5c: MS (EI, 70 eV): *m/z* 369 (M^+ + H, 26%), 368 (M^+, 100), 184 (M^{2+}, 15); UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 346 (128000), 358 (175000), 471 (2300); ^{1}H NMR (400.13 MHz, [D_8]THF, 65 °C): δ = 8.52 (br. s, H-5,6,17,18), 5.60 and 5.52 (AB, H-3,8,15,20 and H-2,9,14,21, ^3J = 3.5 Hz), 4.81 (s, H-11, 12, 23, 24); ^{1}H NMR (400.13 MHz, [D_8]THF, −78 °C): δ = 12.38 and 5.30 (AX, H-6,18 and H-5,17, ^3J = 16.2 Hz), 5.73 and 5.56 (AB, H-8,20 and H-9, 21, ^3J = 3.6 Hz), 5.50 and 5.45 (AB, H-3,15 and H-2,14, ^3J = 3.5 Hz), 4.72 and 4.66 (AB, H-11,23 and H-12,24, ^3J = 13.8 Hz); ^{13}C NMR (100.61 MHz, [D_8]THF, 21 °C): δ = 157.6 and 155.9 (quat. C), 117.9 (C-5,6,17,18, $^1J(^{13}C,H)$ = 157 Hz), 117.1 (C-2,9,14,21, $^1J(^{13}C,^1H)$ = 174 Hz), 113.4 (C-11,12,23,24, $^1J(^{13}C,^1H)$ = 154 Hz), 111.1 (C-3,8,15,20, $^1J(^{13}C,^1H)$ = 173 Hz); ^{13}C NMR (100.61 MHz, [D_8]THF, −78 °C): δ = 158.0, 157.2, 156.7, 155.6 (quat. C), 118.3 (C-9,21), 118.1 (C-5,17), 117.4 (C-6,18), 117.0 (C-3,15), 114.5 (C-2,14), 114.0 (C-11,23), 112.6 (C-12,24), 108.5 (C-8,20).

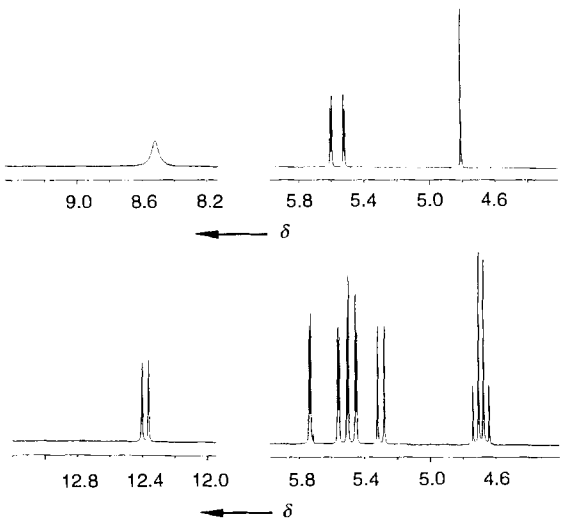
Figure 1. The ^{1}H NMR spectra indicate a highly flexible ring system, leading to the rapid equilibration of ring protons H-5/H-6 and H-17/H-18. Semiempirical calculations (AM1, RHF)[14]



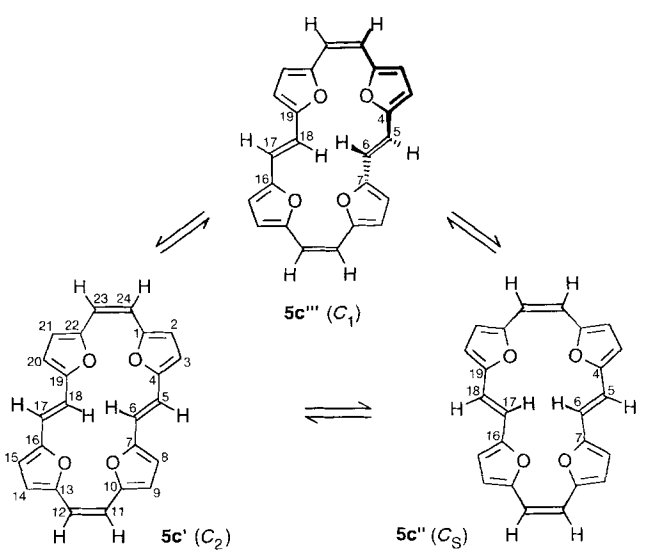


Fig. 1. ^{1}H NMR spectra of *cis,trans,cis-trans*-**5c** at +65 °C (top) and −78 °C (bottom).

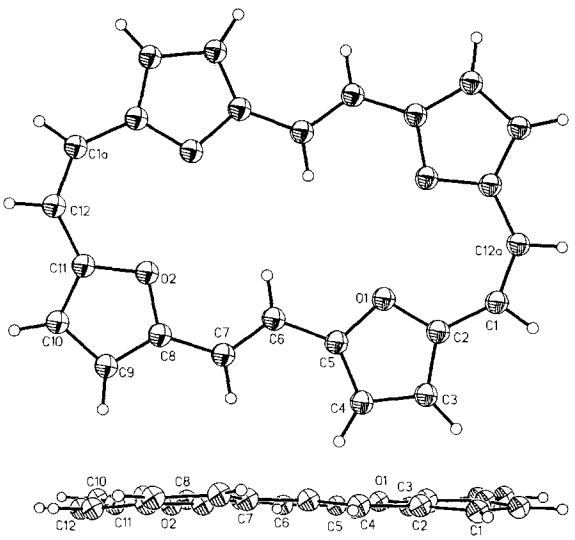
indicate a very flat potential energy surface with regard to the rotation of the *trans* double bonds about the 4,5/6,7 and 16,17/18,19 single bonds. Three defined minimum structures are found: **5c′** (approximately C_2-symmetric with boat-type distortion, $\Delta H_f = 95.88$ kcal mol^{-1}), **5c″** (approximately C_s-symmetric with boat-type distortion, $\Delta H_f = 97.13$ kcal mol^{-1}), and **5c‴** (C_1-symmetric with a helical arrangement of the four furan rings, $\Delta H_f = 97.56$ kcal mol^{-1}). A degenerate conversion of **5c′** by synchronous rotation of both *trans* double bonds cannot be discounted based on the potential energy surface. The energy barriers for interconversion of the three conformers **5c′**, **5c″**, and **5c‴**, and the degenerate conversion of **5c′** are less than 10 kcal mol^{-1}.

It can be deduced from the low-temperature spectrum that the *cis,trans,cis,trans*-configurated molecule **5c** is frozen in the **5c′** conformation with C_2 symmetry. In the paratropic 24π ring system the signals of the inner protons H-6, H-18 appear at $\delta = 12.38$, those of the outer protons H-5, H-17 appear at $\delta = 5.30$ as an AX system with $^3J = 16.17$ Hz. With increasing temperature, rotation around the 4,5/6,7 and 16,17/18,19 single bonds occurs, and the inner protons H-6, H-18 equilibrate with the outer protons H-5, H-17. At 65 °C only an averaged signal at $\delta = 8.52$ is observed for H-5, H-6, H-17, H-18 (Fig. 1 b, top). $\Delta G^{\neq}$ is estimated from the coalescence temperature to be approximately 11 kcal mol^{-1}, in good agreement with the results from semiempirical calculations.

The ^{1}H broad-band decoupled ^{13}C NMR spectra of **5c** (100.61 MHz, [D$_8$]THF) at 21 °C and at −78 °C (Table 1) complemented by ^{13}C NMR DEPT measurements at 21 °C and 65 °C and gated decoupling measurements at 21 °C confirm the molecular dynamics of this compound. The ^{1}H NMR signals at 65 °C are assigned based on an NOE difference spectrum measured at 21 °C. The ^{13}C NMR signals at 21 °C and −78 °C are assigned by ^{13}C-^{1}H correlation (Table 1).

X-ray structure analysis[16] confirms that **5c** is in the **5c′** conformation in the solid state. These results are consistent with the conformation found in solution at low temperatures. In the crystal form **5c′** has an inversion center; the nonequivalent furan rings are twisted in opposite directions by approximately 10° (Fig. 2).



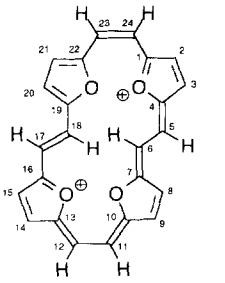


Fig. 2. Crystal structure of **5c′** (ORTEP). Top: view of the molecule from the top; bottom: side view. Selected bond lengths [Å] and angles [°] (standard deviation in parentheses): O1-C2 1.370(2), O1-C5 1.378(2), O2-C8 1.369(2), O2-C11 1.374(2), C1-C2 1.423(3), C1-C12a 1.346(3), C5-C6 1.427(3), C11-C12 1.428(3); C2-O1-C5 107.3(1), C8-O2-C11 107.1(1), O1-C5-C4 108.9(2), O1-C5-C6 117.5(2), C2-C1-C12a 135.6(2), C1-C2-C3 127.7(2), C1-C12a-C11a 134.2(2). Angles formed by the normals to the planes. [°]: O1C2-C5/O2C8-C11 11.5, O2C8-C11/C5-C8 1.2, O1C2-C5/V5-C8 11.1, C5-C8/C11C12C1a-C2a 9.1.

When **5c** is treated with an equimolar amount of bromine in methylene chloride at 0 °C, oxidation to the aromatic tetraoxa[22]porphyrin(2.2.2.2) dication **10** occurs. This compound can be isolated as the bisperchlorate salt in the form of a microcrystalline, blue powder with a metallic sheen (decomp > 300 °C).

The spectroscopic data (Table 2) support the assumption that **10**, like **5c**, has the *cis,trans,cis,trans* configuration with a C_2-symmetric conformation. The assignment of the ^{1}H NMR signals was done with the aid of NOE difference spectroscopy. The results obtained can be applied qualitatively to the ^{1}H NMR

10 (C_2)

spectrum of **5c** at −78 °C. Owing to the low solubility of **10**, ^{13}C-^{1}H correlation spectra could not be measured. In the UV/VIS spectrum of **10** (in 70% perchloric acid) all maxima are red-shifted approximately 100 nm relative to those of **5c**, and the molar extinctions are significantly greater (Fig. 3, Table 2).

The ^{1}H NMR spectrum (400.13 MHz, CF_3COOD, 21 °C) provides clear proof for the configuration of **10**. The protons inside

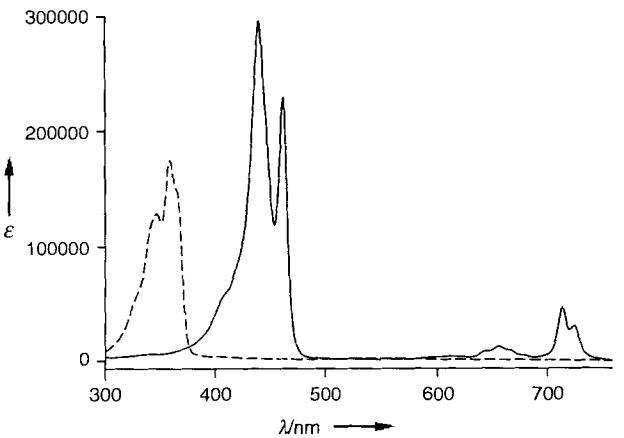

Fig. 3. UV/VIS spectra of **5c** (---) and **10** (—).

the aromatic ring current, H-6 and H-18, are shifted drastically upfield [$\delta = -8.08$ (d, ^{3}J(H,H) = 14.47 Hz)] in comparison with the corresponding protons of **5c** ($\delta = 12.38$). The outer protons

Table 2. Spectroscopic data (MS, UV/VIS, ^{1}H and ^{13}C NMR) for **10** [15].

10: MS(FAB): *m/z* 369 ($(M - 2\,ClO_4 + H)^+$, 49%), 368 ($(M - 2\,ClO_4)^+$, 100); UV/VIS ($HClO_4$): λ_{max} [nm] (ε) = 438 (295600), 460 (229000), 643 (8300), 655 (12600), 666 (9300) sh, 678 (4300) sh, 712 (46000), 723 (30000); ^{1}H NMR (400.13 MHz, CF_3COOD, 21 °C, TMS): δ = 13.66 and −8.08 (AX, H-5,17 and H-6,18, ^{3}J = 14.5 Hz), 12.17 and 11.17 (AB, H-8,20 and H-9,21, ^{3}J = 4.8 Hz), 11.21 and 11.04 (AB, H-3,15 and H-2,14, ^{3}J = 4.6 Hz), 11.50 and 11.42 (AB, H-11,23 and H-12,24, ^{3}J = 13.8 Hz); ^{13}C NMR (100.61 MHz, CF_3COOD, 21 °C, TMS): δ = 166.3, 161.5, 160.4, 159.5 (quart. C), 141.1, 140.3, 136.7, 133.0, 127.4, 126.6, 117.3, 116.7 (CH).

H-5, H-17 are also clearly shifted downfield from $\delta = 5.30$ (d) in **5c** to $\delta = 13.66$ (d) in **10**. In the transition from an antiaromatic to an aromatic system (**5** → **10**) the protons along the inner perimeter are shifted upfield ($\Delta\delta = 20.46$), while the outer protons H-5, H-17 are shifted downfield ($\Delta\delta = 8.36$)! The upfield shift of the protons along the inner perimeter is comparable with the values obtained for octaethyl[22]porphyrin(2.2.2.2)[11] ($\delta = -7.50$) and octaethyl[22]porphyrin(1.3.1.3) ($\delta = -9.54$).[4] The absolute values of the shift on transition from the antiaromatic to the aromatic system are not known in this case, since the [24]porphyrinogens have not yet been described.

The highly dynamic 24 π electron system of **5c** apparently loses its flexibility when it is oxidized to aromatic **10**. In ^{1}H NMR measurements performed on **10** in concentrated D_2SO_4 no dynamic effects are observed up to +180 °C, although the relative integration of the outer protons begins to decrease at 130 °C. This can be attributed to either H/D exchange or sulfonation.

[15] The ^{1}H and ^{13}C NMR spectra were measured with an ARX 400 spectrometer (Bruker Analytische Messtechnik). The measuring frequencies were 400.13 MHz (^{1}H) and 100.61 MHz (^{13}C). For the ^{1}H NMR spectra TMS was used as internal standard, or when D_2SO_4 was the solvent TMS was used as external standard. For ^{13}C NMR spectra the solvent was used as standard, or if D_2SO_4 was used as solvent, TMS was employed as external standard. The concentrations of the solutions measured were 4 mg **10** in D_2SO_4, 1 mg **10** in CF_3COOD, and 4 mg **5** in [D_8]THF; each sample was prepared with 0.6 mL solvent.
[16] Crystal structure of **5c**': Enraf-Nonius CAD four-circle diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator. Crystal fragment; size: 0.10 × 0.33 × 0.40 mm. Crystallographic data: $C_{24}H_{24}O_4$, $M_r = 368.39$, $a = 19.330(12)$, $b = 6.765(1)$, $c = 13.603(1)$ Å, $\beta = 97.462(4)°$, $V = 1.7638$ nm^3, monoclinic, space group $C2/m$, $Z = 4$, $\varrho_{calcd} = 1.387$ g cm^{-3}, $\mu = 0.088$ mm^{-1}, $F(000) = 768$. Data collection: 2Φ range: 4–46° in $-h, -k, \pm l$, scan range = 0.65° + 0.35 tan Φ, measuring speed: max. 45 s, 1402 measured reflections, of which 1354 were independent and 966 observed ($F \geq 3\sigma(F)$). Structure solution and refinement: direct methods, anisotropic description of non-hydrogen atoms, H atoms with fixed U_i, 127 variables, $R = 0.0361$, $R_w = 0.0464$. 3*H*-Indole**

Ivo G. Gut and Jakob Wirz*

We report on the first spectroscopic identification of 3*H*-indole (**1**) and on its kinetic and thermodynamic stability in aqueous solution. A number of reactions of indole (1*H*-indole, **2**) and its derivatives proceed via the 3*H*-tautomers,[1] for example, the

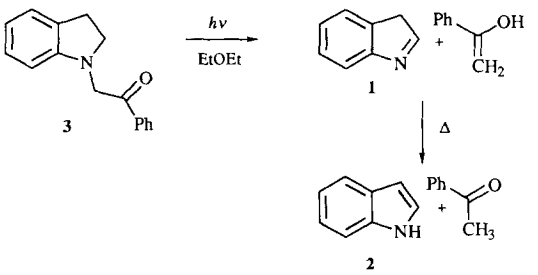
Strasser, Basel, for experimental cooperation and Profs. A. J. Kresge, University of Toronto, and J. Liebman, University of Maryland, for helpful suggestions.



Scheme 1.

acid-catalyzed exchange of the hydrogen atom at C-3 of **2** with the solvent[2] (Scheme 1) and the reactions catalyzed by tryptophanase and tryptophan synthase.[3]

Hill et al. identified **2** and acetophenone as the photoproducts of *N*-indolinylacetophenone (**3**) and proposed that **1** and the enol of acetophenone are the primary photoproducts formed by Norrish type-II fission of **3** (Scheme 2).[4]

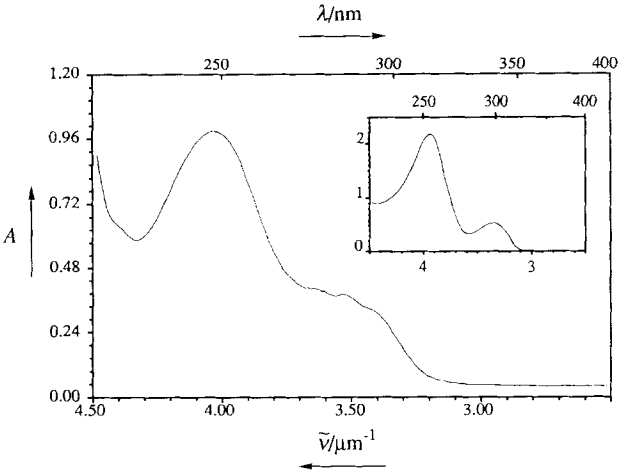
When we irradiated (308 or 313 nm) a dilute solution of **3** (10^{-4} M) in anhydrous diethyl ether at room temperature, the

Scheme 2.

changes in the UV spectrum did not correspond to the formation of a 1:1 mixture of acetophenone and **2**. Only when the irradiated mixture was left in the dark did its absorption spectrum change, with a half-life of about 10 h, to that of the final products. This slow reaction is attributed to the ketonization of the enol of acetophenone. The characteristic sharp peak of indole at 287 nm was evident immediately after the irradiation and did not increase in intensity during the dark reaction. Subtraction of the spectrum of indole from the spectrum of the initial photoproduct left a broad, Gaussian-shaped band, λ_{max} = 255 nm, which extended to roughly 300 nm. This spectrum corresponds to that of the enol of acetophenone, which was obtained previously by spectrographic flash photolysis of γ-hydroxybutyrophenone in aqueous solution.[5] Thus, the enol of acetophenone persists for several hours in anhydrous diethyl ether at ambient temperature. In contrast, the tautomerization **1** → **2** appears to be much faster in the same medium.

Completely different UV spectral changes were observed upon irradiation of **3** in anhydrous diethyl ether at −100 °C. In particular, the sharp peak of indole at 287 nm was now absent in the product spectrum. However, when the solution was briefly warmed to −50 °C, the spectrum previously observed shortly after irradiation at room temperature was obtained. These results indicate that 3*H*-indole is stable at −100 °C but is rapidly converted to the 1*H*-tautomer on warming to −50 °C.

Treatment of the solutions with trifluoroacetic acid or ammonia vapor before or after irradiation strongly accelerated the dark reactions. The tautomerization **1** → **2** was less sensitive to base catalysis than the ketonization of the enol of acetophenone: when a solution of **3** in diethyl ether was treated with a trace of ammonia vapor, the spectral changes occurring in the dark at −100 °C indicated ketonization of the enol of acetophenone; the peak of indole at 287 nm was absent. Subtraction of the spectrum of acetophenone provided the absorption spectrum of **1**, which is quite similar to that of 3,3-dimethyl-3*H*-indole[6] (Fig. 1). The tautomerization **1** → **2** now required warming to −20 °C.



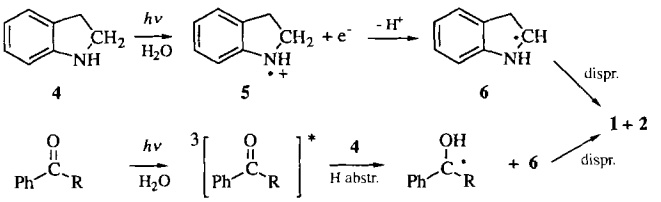


Fig. 1. Absorption spectrum of **1** (diethyl ether, −20 °C); λ_{max}/nm (log ε/($M^{-1}cm^{-1}$)): 248 (4.0), ca. 290 (3.6). Inset: absorption spectrum of 3,3-dimethyl-3*H*-indole (diethyl ether, 25 °C): 255 (4.03), 299 (3.42).

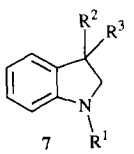
To identify 3*H*-indole by ^{1}H NMR spectroscopy, a solution of **3** (1 mg mL^{-1}) in anhydrous [D_{10}]diethyl ether was treated with a trace of ammonia vapor, irradiated (λ > 345 nm) in an NMR tube at −80 °C, and transferred to the NMR sample chamber, which was also kept at −80 °C. A first spectrum was recorded, the tube was warmed in a bath at −20 °C for 5 min, and a second spectrum was recorded at −80 °C. Finally, the sample was warmed to room temperature for 5 min before a third spectrum was recorded at −80 °C. Comparison of the three spectra with those of authentic samples of **3**, acetophenone, and **2** showed that the first contained predominantly 3*H*-indole (**1**) (δ = 8.40 (s, 1H), 3.79 (s, 2H)) and the enol of acetophenone (δ = 9.8 (s, 1H), 4.64 (s,[7] 1H), 4.31 (s,[7] 1H)). The second spectrum corresponded to a mixture of all tautomers, and the third to one of only **2** and acetophenone. The formation of indole was best monitored by its characteristic peak at δ = 6.49. ^{1}H NMR signals in the aromatic region (δ = 7–8) overlap and could not be analyzed.



To obtain a reproducible pH–rate profile of the tautomerization **1** → **2** we attempted to generate **1** by flash photolysis in aqueous solution. However, the Norrish type-II photoreaction of **3** is quenched in protic solvents, presumably because an intramolecular charge transfer state is stabilized by solvation.[8] We thus turned to indoline (2,3-dihydroindole, **4**) as an alternative photochemical precursor of **1**; irradiation of a mixture of **4** and acetophenone in ether has been reported to give 2,3-diphenylbutane-2,3-diol and **2**.[4] We found that acetophenone is not necessary for the photo-oxidation of **4** in aqueous solution. Plausible mechanisms for the direct and sensitized photoreactions of **4** are shown in Scheme 3.

Flash photolysis of **4** in aerated aqueous buffer solutions was done with conventional quartz discharge lamps (20 μs pulse width at half intensity). Within 100 μs after irradiation a transient absorption appeared at wavelengths below 320 nm, part of which subsequently decayed by first-order kinetics on the millisecond timescale. The assignment of this transient absorption to 3*H*-indole (**1**) rests on the following observations and is cor-

Scheme 3.

roborated by the kinetic data, which will be discussed later. The absorption onset of the transient coincides with that of **1** (Fig. 1). Variations in alkyl substitution (structures **7**) gave the results expected based on the proposed reaction mechanism (Scheme 3): transients attributable to the corresponding 3*H*-indoles *were* observed with 2,3-dihydrotryptophan (**7**, $R^1 = R^2 = H$, $R^3 = CH_2CHNH_2CO_2H$) and 2,3-dihydroskatol (**7**, $R^1 = R^2 = H$, $R^3 = CH_3$), but *not* with 3,3-dimethylindoline (**7**, $R^1 = H$, $R^2 = R^3 = CH_3$) or *N*-methylindoline (**7**, $R^1 = CH_3$, $R^2 = R^3 = H$). Intermediate **1** was also formed by reaction of indoline with triplet benzophenone or with OH radicals, which were produced by the reaction of triplet benzophenone with an excess of hydrogen peroxide. The transient appeared only in the pH range from about 4.5 to 9. Protonation of **4** ($pK_{a,c} = 5.48 \pm 0.03$)[9] inhibits photoionization in more acidic solutions. In basic solutions the formation of **1** is suppressed by deprotonation of the intermediate radical cation **5** (the pK_a of aniline radical cation is 7.0).[10]

7

The decay rate of **1** depended linearly on proton and on buffer concentrations. Bilinear regression of the rate data obtained with acetic acid buffers versus [HAc] and [Ac^-] as independent variables indicated that only the acid contributes significantly to buffer catalysis. The slopes and extrapolated intercepts of the buffer dilution plots at constant buffer ratio are given in Table 1. Rate constants at zero buffer concentration, which were determined from the intercepts, were accurately proportional to proton concentration throughout the accessible pH range from 4.5 to 9. Contributions from a pH-independent reaction were not detectable down to the lowest proton concentrations, $k_0 \leq 0.01\ s^{-1}$, nor was saturation of acid catalysis apparent at the highest proton concentrations accessible, $[H^+] \cong 10^{-5}$ M. The last result provides an upper limit for the NH dissociation constant of protonated indole, pK_a^{NH} (**2**-H^+) ≤ 4.3, since proton catalysis is expected to reach a plateau when **1** is protonated at nitrogen. The rate constant for catalysis by acetic acid (weighted average of the slopes determined from the buffer dilution plots, Table 1) is $k_{HAc} = (2.2 \pm 0.2) \times 10^3\ M^{-1} s^{-1}$, and that for proton catalysis (weighted average of intercepts divided by [H^+], Table 1) is $k_{H^+} = (4.9 \pm 0.3) \times 10^6\ M^{-1} s^{-1}$. The ratio of these catalytic coefficients, k_{H^+}/k_{HAc}, is $(2.2 \pm 0.3) \times 10^3$.

Table 1. Buffer dilution regression analyses for the decay rates of **1** in aqueous solution at 25 °C. Ionic strength was held at $I = 0.1$ M by the addition of NaCl. Total buffer concentration ranges were 0.02–0.1 M.

Buffer	[HA]/[A]	$[H^+]$/M [a]	No. of date points	Slope k_{HA}/($M^{-1} s^{-1}$)	Intercept $k_{H^+}[H^+]/s^{-1}$

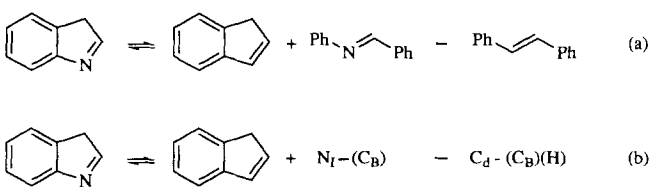
[a] $[H^+]$ was calculated using the concentration quotients $pK_{a,c}$(HAc, $I = 0.1$ M, 25 °C) = 4.55 [11] and $pK_{a,c}$($TrisH^+$, $I = 0.1$ M, 25 °C) = 8.12 [12]. The calculated values agreed with the readings of a calibrated [13] glass electrode to within 0.02 log units. [b] Tris = tris(hydroxymethyl)methyl amine.

Rate constants for the displacement of deuterium and tritium from the 3-position of [D_1]indole and [T_1]indole, respectively, were determined by Challis and Millar[2] for aqueous acetic acid buffer solutions at 25 °C and ionic strength $I = 0.1$ M. The incidence of general acid catalysis was attributed to protonation at C-3 by the general acid. The same authors have estimated, on the basis of the relation by Swain et al.,[14a] the ratio of the rate constants of proton and deuterium loss from C-3 of protonated indole [D_1]**2**-H^+ as $k_2^H/k_2^D = 5.6 \pm 0.3$ for the reaction with solvent water and $k_2^H/k_2^D = 5.3 \pm 0.4$ for the reaction with acetate ion. They noted explicitly that these estimates did not account for the secondary isotope effects involved. To obtain a more accurate estimate we used the method of Kresge and Chiang,[14b] which gave ${}^Dk_2^H/{}^Hk_2^D = 6.3 \pm 1.3$ for the reaction with solvent water, and ${}^Dk_2^H/{}^Hk_2^D = 6.2 \pm 1.3$ for the reaction with acetate ion. The rate constant for the protonation of indole is then given by ${}^Hk_1^H = (1 + {}^Dk_2^H/{}^Hk_2^D)^D k_{obsd}({}^Hk_1^H/{}^Dk_1^H)$. The kinetic data of Challis and Long for deuterium displacement, ${}^Dk_{obsd}$, thus provide estimates for the rates of protonation of **2** by protons, $k_{H^+} = {}^Hk_1^H(H^+) = 6.2 \pm 1.6\ M^{-1} s^{-1}$, and by acetic acid, $k_{HAc} = {}^Hk_1^H(HAc) = (5.2 \pm 1.4) \times 10^{-3}\ M^{-1} s^{-1}$, in water at 25 °C. The ratio of the two constants is $k_{H^+}/k_{HAc} = (1.2 \pm 0.5) \times 10^3$.



The ratio of the two catalytic coefficients must be the same for the forward and backward reaction **1** ⇄ **2**. The ratio determined from the data of Challis and Long, $k_{H^+}/k_{HAc} = (1.2 + 0.5) \times 10^3$, is, on a purely statistical basis, significantly different from our value of $(2.2 \pm 0.3) \times 10^3$ given above. But considering the various possible sources of systematic errors in both of the completely independent determinations and the necessity of correcting for the unknown secondary isotope effect in the literature data,[2] the near agreement may be considered to be satisfactory. Moreover, catalysis by acetate ion was consistently insignificant in both studies. These results lend further support to the assignment of the transient absorbance observed by flash photolysis of **4** to 3*H*-indole (**1**). The equilibrium constant of tautomerization, $K_T = [\mathbf{1}]/[\mathbf{2}]$, can now be calculated from the ratio of the rates of the forward and backward reactions catalyzed by protons, $K_T = (1.3 \pm 0.4) \times 10^{-6}$, and by acetic acid, $K_T = (2.4 \pm 0.7) \times 10^{-6}$. The average of these values is $K_T = (1.7 \pm 0.6) \times 10^{-6}$, $pK_T = 5.8 \pm 0.2$.

Hinman and Lang estimated the C–H acidity of protonated indole **2**-H^+, $pK_a = -3.5$, by spectrophotometric determination of its ionization ratio in concentrated sulfuric acid solutions.[16] Bunnett and Olson later reevaluated these data by using their improved acidity function which gave $pK_a = -2.5$.[17] We have reevaluated the same data using the *X* acidity function of Cox and Yates[18] and have obtained the same value. Thus the value $pK_a = -2.5$ should be a good approximation of the thermodynamic acidity constant of **2**-H^+ in aqueous solution. The activity coefficients of **2**-H^+ and H^+ should largely cancel at ionic strength $I = 0.1$. We therefore assume the same value for the concentration quotient, $pK_{a,c}^{CH}(I = 0.1\ M) = -2.5 \pm 0.2$, where the error range indicates our estimate of the possible systematic errors involved. The N–H acidity constant of **2**-H^+ may then be calculated from the thermodynamic cycle

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1155 $ 10.00+.25/0

shown in Scheme 1, $pK_{a,c}^{NH}(I = 0.1\,M) = pK_T + pK_{a,c}^{CH}(I = 0.1\,M) = 3.3 \pm 0.4$, which is consistent with the upper limit of 4.3 given above. For comparison, we determined[9] the acidity constant of protonated 3,3-dimethyl-3*H*-indole to be $pK_{a,c}^{NH} = 2.85 \pm 0.01$.

We calculated the enthalpy of isomerization $\mathbf{1} \rightarrow \mathbf{2}$ with the semiempirical methods MNDO,[19a] AM1,[19b] and PM3[19c] of the Spartan 2.0 program package and obtained the values $\Delta_{1\rightarrow 2}H = -9.6$, $+41.8$, and $+78.2\,kJ\,mol^{-1}$, respectively. Much simpler, and probably more reliable estimates of the gas-phase heat of formation of **1** are obtained from the isodesmic reactions shown in Scheme 4. For reaction (a) we used

Scheme 4.

the experimental enthalpies of formation of a) indene, $\Delta_f H_m^{\ominus}(g, 298\,K) = 163.6 \pm 1.5\,kJ\,mol^{-1}$,[20a] *trans*-stilbene, $\Delta_f H_m^{\ominus}(g, 298\,K) = 236\,kJ\,mol^{-1}$,[20b] and *N*-benzylidenaniline, $\Delta_f H_m^{\ominus}(g, 298\,K) = 278.7 \pm 2.2\,kJ\,mol^{-1}$,[20c] and for reaction (b) the first value and Benson's increments for the groups $N_I-(C_B) = 69.9$ and $C_d-(C_B)(H) = 28.4\,kJ\,mol^{-1}$.[21] Both approaches (a) and (b) give nearly identical estimates for the gas-phase heat of formation of **1**, $\Delta_f H_m^{\ominus}(g, 298\,K) = 206 \pm 5\,kJ\,mol^{-1}$. Comparison with the heat of formation of indole, $\Delta_f H_m^{\ominus}(g, 298\,K) = 186.6 \pm 4.6\,J\,mol^{-1}$,[20a] then gives $\Delta_{1\rightarrow 2}H = 19 \pm 10\,kJ\,mol^{-1}$. From the equilibrium constant $pK_T = 5.8 \pm 0.2$ determined in this report we obtain $\Delta_{1\rightarrow 2}G^{\ominus}(aq, 298\,K) = 33 \pm 1\,kJ\,mol^{-1}$ for the Gibbs free energy change in aqueous solution.

In conclusion, the hitherto unknown 3*H*-isomer of indole is remarkably stable in slightly basic aqueous solutions ($\tau \cong 100$ s at pH $\cong$ 9 and 25 °C). The equilibrium constant for the tautomerization of indole **2** to 3*H*-indole (**1**) is $pK_T = 5.8 \pm 0.2$ in aqueous solution; in other words, the equilibrium concentration of **1** is about 1 to 2 ppm. The tautomerization is catalyzed by acid and, less efficiently, by base. The catalytic coefficients for the reaction $\mathbf{1} \rightarrow \mathbf{2}$ are $k_{H^+} = (4.9 \pm 0.3) \times 10^6\,M^{-1}\,s^{-1}$ and $k_{OH^-} \cong 1 \times 10^2\,M^{-1}\,s^{-1}$.[22]

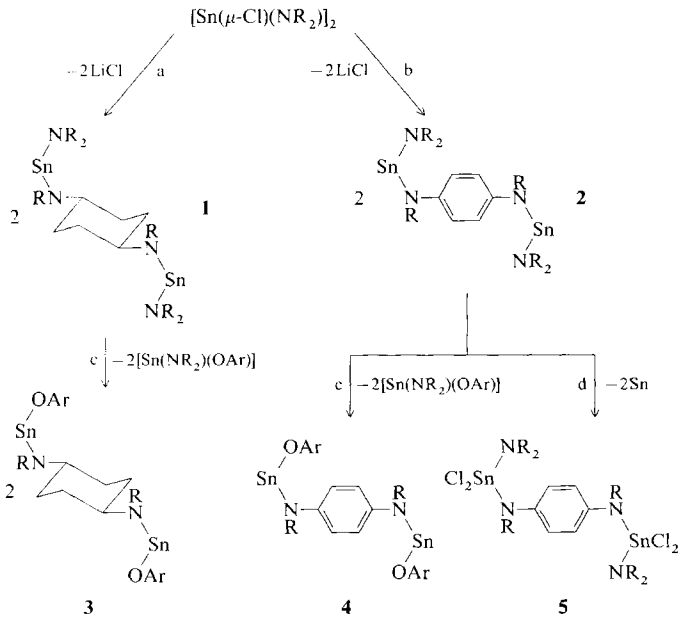
Synthesis, Structures, and Reactions of Two Bis(diaminostannylene)s and a Bis(diaminogermylene) Containing a Central C_6 Ring**

Holger Braunschweig, Peter B. Hitchcock, Michael F. Lappert,* and Luc J.-M. Pierssens



Until about 20 years ago thermally stable bivalent compounds of Ge, Sn, and Pb (=M), the heavier Group 14 element analogues of carbenes, were unknown. Since then a number of mononuclear, homoleptic, thermally stable but highly reactive, colored, diamagnetic compounds MX_2 have been described, in which the monohapto ligand X^- was bulky and free from β-hydrogen atoms. Among those to have been X-ray-characterized are those having X = NR_2,[1, 2] OAr,[3] or SAr,[4] while $M'(CHR_2)_2$ (M' = Ge or Sn) had the same V-shaped (X-M'-X = 88–105°) structure in the gas phase,[5] but were dimeric (*trans*-M'_2X_4) in the crystal.[6] A recent development concerns the first heteroleptic compounds, the stannylenes SnXX', including the structurally authenticated $[Sn(NR_2)(OAr)]$[7a] and the germylene $[Ge(CR_3)(CHR_2)]$.[7b][***]

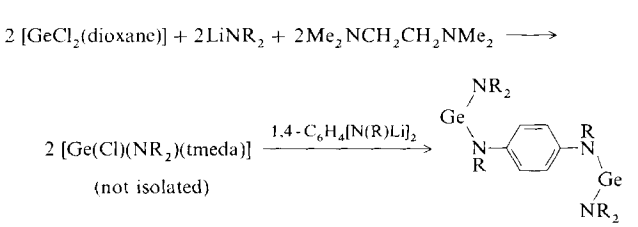
[**] We thank Deutsche Forschungsgemeinschaft for the award of a fellowship to H. B., Science and Engineering Research Council for support, and Dr. B. Mathieu for the Mössbauer data.



[***] Throughout the communication R stands for $SiMe_3$ and Ar for 2,6-tBu_2-4-MeC_6H_2.

We have now prepared the binuclear compounds XM′–Z–M′X in which the bridging group Z^{2-} is the *N*,*N*′-bis(trimethylsilyl)-*trans*-1,4-cyclohexanediamido or its aromatic equivalent the 1,4-benzenenediamido ligand. The synthesis of such heteroleptic bis(stannylene)s **1** and **2** (X = NR_2) is shown in Scheme 1. Both **1** and **2** could be converted into the corresponding aryloxides [(ArO)M′-Z-M′(OAr)] **3** and **4**, respectively, by treatment with $Sn(OAr)_2$;[3] this metathetical exchange reaction parallels that between $Sn(NR_2)_2$ and $Sn(OAr)_2$ which leads to the formation of $[Sn(NR_2)(OAr)]$.[1] Surprisingly, however, whereas $Sn(NR_2)_2$ and $SnCl_2$ react to give $[Sn(\mu\text{-}Cl)(NR_2)]_2$,[8] treatment of **2** with $SnCl_2$ led to the redox products **5** and tin. A single precedent appears to be in the reaction of $Sn(CHR_2)_2$ with $SnCl_2$ which gave $[Sn(CHR_2)_2Cl_2]$ and tin.[5]

Scheme 1. Synthesis of the bis(diaminostannylene)s **1** and **2** and their conversions into the bis[amino(aryloxy)stannylene]s **3** and **4**, respectively, and into the bis[diamido(dichloro)tin(IV)] compound **5**. Reagents and conditions: a) 1,2-$C_6H_{10}[N(R)Li]_2$ [from *trans*-1,4-$C_6H_{10}(NHR)_2$], C_6H_{14}, 25 °C, 2 h; b) as a) but with 1,4-$C_6H_4[N(R)Li]_2$ [10]; c) (NMR expt. for **3**) $2Sn(OAr)_2$, toluene, 25 °C, 16 h; d) (NMR expt.) $2SnCl_2$, Et_2O, C_6D_6, 20 °C, 7 d.

Although a germanium analogue of $[Sn(\mu\text{-}Cl)(NR_2)]_2$ has not been reported, the reaction in Scheme 2 (tmeda = $Me_2NCH_2CH_2NMe_2$) yielded the bisgermylene **6**, presumably via this intermediate. Some data on **1**–**6** are given in Table 1; ^{119}Sn NMR spectroscopy was diagnostic in following the reactions leading to **1** and **5**, since each compound has a distinct $^{119}Sn\{^1H\}$NMR signal, which differs from those of possible coproducts. Compounds **1**, **2**, **4**, and **6** were also characterized

Scheme 2. Synthesis of the bis(diaminogermylene) **6**.

Table 1. Some analytical and spectroscopic data of **1**–**6**. ^1H NMR: 360 MHz, 305 K, C_6D_6; $^{119}Sn\{^1H\}$ NMR: 186.42 MHz, 300 K, C_6D_6 [a].

1: Yellow; 46% yield; $\delta[^{119}Sn\{^1H\}] = 694$; $\delta(^1H) = 0.25$ (s, 36H; $SiMe_3$), 0.43 (s, 18H; $SiMe_3$), 1.76–1.78 (m, 4H; CH_2), 1.85–1.88 (m, 4H; CH_2), 4.85 (br., 2H; CH)

2: Orange; 70% yield, $\delta[^{119}Sn\{^1H\}] = 606$; $\delta(^1H) = 0.10$ (s, 36H; $SiMe_3$), 0.28 (s, 18H; $SiMe_3$), 6.72 (s, 4H; C_6H_4)

3 [b]: Orange; 100% yield; $\delta[^{119}Sn\{^1H\}] = 283$

4: Yellow; 50% yield; $\delta[^{119}Sn\{^1H\}] = 173$; $\delta(^1H) = -0.86$ (s, 18H; $SiMe_3$), 1.19 (s, 6H; Me), 6.65 (s, 4H; C_6H_4), 6.86 (s, 4H; C_6H_2)

5 [b]: Yellow; 100% yield; $\delta[^{119}Sn\{^1H\}] = 61.1$

6: Orange; 77% yield

[a] $\delta[^{119}Sn\{^1H\}]$ value for $Sn(NR_2)_2$ at 283 K 766, for $Sn(OAr)_2$ −192, for $Sn(NR_2)(OAr)$ 277, for $[Sn(\mu\text{-}Cl)(NR_2)]_2$ 138. [b] This was an NMR experiment; not isolated in the solid state.

by their ^1H and ^{13}C NMR spectra and microanalyses, and **1**, **2**, and **4** by ^{119}Sn Mössbauer spectra (isomer shifts of 2.92 ± 0.6 $mm\,s^{-1}$ and quadrupole splitting of 3.21 ± 0.15 $mm\,s^{-1}$).

The structures of the crystalline bis(stannylene)s **1** (Fig. 1) and **2** (Fig. 2) and the bisgermylene **6** (isomorphous with **2**) (Fig. 2)[9] revealed that the two M′(NR_2) fragments are *trans* to one another. The angle between the aromatic ring and the plane containing M′-N(1)-Si(1) in **2** and **6** is 83°. This conformation is

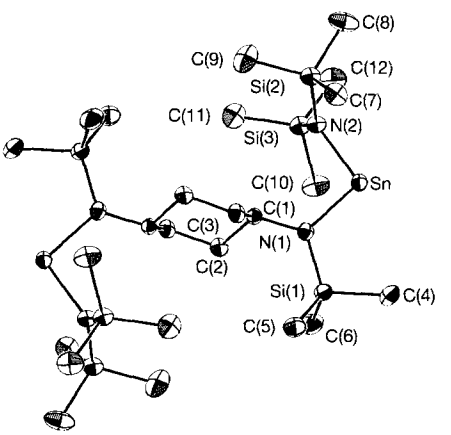


Fig. 1. Molecular structure of **1**. Selected bond lengths [Å] and angles [°]: Sn-N(1) 2.062(2), Sn-N(2) 2.117(2), N(1)-C(1) 1.482(3); N(1)-Sn-N(2) 99.78(8), Sn-N(2)-Si(2) 116.3(1), Sn-N(1)-C(1) 120.7(2).

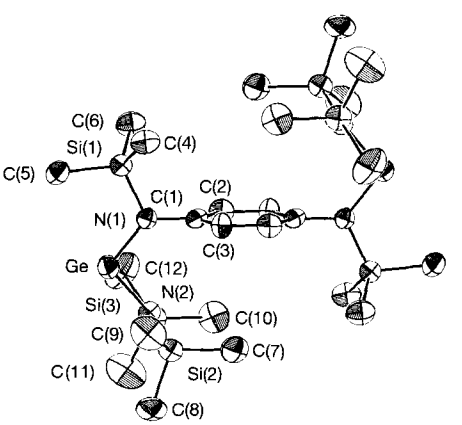

Fig. 2. Molecular structure of **2** and **6** (shown). Selected bond lengths [Å] and angles [°]; data for **6** in square brackets: M′-N(1) 2.066(6) [1.855(2)], M′-N(2) 2.082(7) [1.885(5)], N(1)-C(1) 1.449(11) [1.444(9)]; N(1)-M′-N(2) 101.8(3) [104.7(2)], M′-N(2)-Si(2) 115.3(4) [116.8(3)], M′-N(1)-C(1) 124.8(5) [126.1(4)].

probably retained in C_6D_6 solution because the ^1H and $^{13}C\{^1H\}$ NMR spectra showed a single CH (**2** or **6**) or CH_2 (**1**) environment in the appropriate six-membered ring; alternatively, there may have been fast rotation about the C–N bonds. The M′–N bond lengths and N-M′-N bond angles may be compared with those [2.096(1) and 2.088(6) Å; 104.7(2)°] in crystalline $Sn(NR_2)_2$[2] and [1.878(5) and 1.873(5) Å; 107.1(2)°] in crystalline $Ge(NR_2)_2$.[11] It is noteworthy that the M′–N(aryl) bond in **2** or **6** is significantly shorter than the M′-NR_2 bond, the latter being slightly shorter than in $M'(NR_2)_2$.

The new bridging ligands 1,4-$C_6H_4(NR)_2$ may well prove to have a useful role in a wider range of coordination chemistry, in particular, in the context of determining whether the metal fragment at one nitrogen can "communicate" with the other, as may well be the case for the aromatic system.

Experimental Procedure

2: 1,4-Bis(trimethylsilylamino)benzene [12] (8.0 g, 31 mmol) in hexane (70 mL) was treated with two molar equivalents of an *n*BuLi (41 mL, 62 mmol in *n*-hexane) solution at 25 °C. The mixture was stirred for 12 h. Volatiles were removed in vacuo to yield the yellow solid 1,4-$C_6H_4[N(R)Li]_2$ (8.1 g, 98%). The latter (1.30 g, 4.92 mmol) in *n*-hexane (40 mL) was added to $[Sn(\mu\text{-}Cl)(NR_2)]_2$ [8] (3.09 g, 4.92 mmol) at 25 °C and the mixture was stirred for 2 h, and then filtered. Volatile components were removed from the filtrate in vacuo; the residue was extracted with diethyl ether (10 mL). After 2 d at −30 °C, orange crystals of **2** (2.78 g, 70%) were obtained; correct elemental analysis.

1 and **6**: These were prepared by a similar procedure from *trans*-1,4-$C_6H_{10}[N(R)Li]_2$ and $[Sn(\mu\text{-}Cl)(NR_2)]_2$ (**1**) or for **6** from 1,4-$C_6H_4[N(R)Li]_2$ and $[GeCl(NR_2)$-(tmeda)]. The latter (2.86 g, 86%) (as colorless crystals) was obtained by mixing $[GeCl_2$(dioxane)] (2.00 g, 8.64 mmol), $LiNR_2$ (1.45 g, 8.64 mmol), and $[(Me_2NCH_2)_2$(tmeda)] (1.00 g, 17.28 mmol) in Et_2O (30 mL) by stirring for 16 h at 25 °C, freeing from volatiles in vacuo, and extracting with toluene/hexane (1:1).

4: Toluene (40 mL) was added to **2** (1.5 g, 19 mmol) and $Sn(OAr)_2$ (2.1 g, 37 mmol) at 25 °C. The pale brown reaction mixture was stirred for 16 h, then filtered. The filtrate was concentrated in vacuo and cooled (−5 °C) to yield crystalline **4** (0.86 g, 50%); correct elemental analysis.

Toward Polyphospholes: Synthesis and Structure of an α-Linked Quaterphosphole

Eliane Deschamps, Louis Ricard, and François Mathey*

Among cyclic phosphanes, phospholes display two particular properties that deserve special attention. Firstly, the inversion barrier for the pyramidal phosphorus center, roughly 16 kcal mol^{-1}, is exceptionally low,[1] owing to extensive electronic delocalization within the planar transition state. This means that for phospholes the phosphorus center inverts easily, slightly above room temperature. Secondly, phospholide ions resulting from the cleavage of the P–R exocyclic bond of phospholes are highly aromatic.[2] These two specific properties suggest the possible use of phospholes as building blocks for: a) flexible phosphorus macrocycles that can adapt their conformation at phosphorus to the stereochemical requirements of the metals to be complexed;[3] b) porphyrin-like phosphorus macrocycles with a delocalized π-electron system; and c) electroconducting polyphosphole chains similar to the classical polypyrrole and polythiophene chains.[4] For the preparation of these interesting compounds, a method for the difunctionalization of phospholes on the α and α′ carbon atoms of the ring is essential. Here we report such a technique and its application to the synthesis of 2,2′-biphospholes functionalized at the 5- and 5′-positions and the first α-linked quaterphosphole.

Our approach relies on the quantitative and instantaneous bromine–lithium exchange in 2-bromophospholes.[5] As a first step, we synthesized 2,5-dibromophosphole **5** (Scheme 1; for spectroscopic data for this and other new compounds, see Table 1). The formation of intermediates **2**–**4** was monitored by ^{31}P NMR analysis of the reaction mixtures. All the reactions, except the final reduction step, are almost instantaneous and

Scheme 1. Synthesis of **5**. The overall yield of **5** is given in parentheses.

Table 1. Selected spectroscopic data for compounds **5**–**12**.

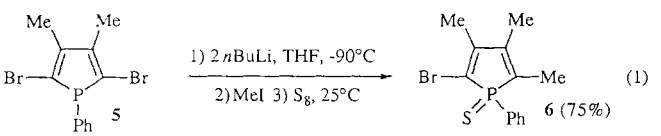
5. ^{31}P NMR (CH_2Cl_2): $\delta = +17.04$; ^{1}H NMR ($CDCl_3$): $\delta = 2.22$ (d, ^4J(H-P) = 2.2 Hz, 6H, Me), 7.44–7.54 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$): $\delta = 16.79$ (s, Me), 121.80 (d, ^1J(C-P) = 19.6 Hz, C-Br), 146.76 (d, ^2J(C-P) = 8.2 Hz, Me-*C*=); MS (EI, 70 eV): *m/z*: 345 ($M^+ - H$, ^{79}Br + ^{81}Br, 100%), 265 ($M^+ - Br$, ^{79}Br, 75).

6: ^{31}P NMR (CH_2Cl_2): $\delta = +54.4$; ^{1}H NMR ($CDCl_3$): $\delta = 1.88$ (dq, ^3J(H,P) = 14.1 Hz, ^5J(H-H) = 1.2 Hz, 3H, α Me), 2.07 (dq, ^4J(H-P) = 2.5 Hz, ^5J(H-H) = 1.2 Hz, 3H, β Me), 2.11 (d, ^4J(H-P) = 2.1 Hz, 3H, β' Me); MS: *m/z*: 314 (M^+, ^{81}Br, 57%), 312 (M^+, ^{79}Br, 54), 233 ($M^+ - Br$, 100).

7: ^{31}P NMR ([D$_6$]DMSO): $\delta = +14.96$; ^{1}H NMR ([D$_6$]DMSO): $\delta = 2.09$ (d, ^4J(H-P) = 2.9 Hz, 3H, Me), 2.50 (d, ^4J(H-P) = 4.2 Hz, 3H, Me), 12.4 (br, 1H, CO_2H); ^{13}C NMR ([D$_6$]DMSO): $\delta = 25.23$ (s, Me), 25.73 (s, Me), 139.38 (d, ^1J(C-P) = 13.9 Hz, C-Br), 142.90 (s, *C*-CO_2H), 157.32 (d, ^2J(C-P) = 7.8 Hz, Me-*C*=), 168.18 (d, ^2J(C-P) = 9.8 Hz, Me-*C*=), 174.85 (d, ^2J(C-P) = 19.8 Hz, CO_2H).

8: ^{31}P NMR (THF): $\delta = +12.07$; ^{1}H NMR ($CDCl_3$): $\delta = 2.11$ (d, ^4J(H-P) = 2.9 Hz, 3H, Me), 2.44 (d, ^4J(H-P) = 4.8 Hz, 3H, Me), 9.95 (d, ^3J(H-P) = 11.7 Hz, 1H, CHO); ^{13}C NMR ($CDCl_3$): $\delta = 15.23$ (s, Me), 15.41 (s, Me), 136.23 (d, ^1J(C-P) = 16.0 Hz, C-Br), 143.60 (d, ^1J(C-P) = 4.7 Hz, *C*-CHO), 147.71 (d, ^2J(C-P) = 6.6 Hz, Me-*C*=), 160.57 (d, ^2J(C-P) = 10.0 Hz, Me-*C*=), 185.54 (d, ^2J(C-P) = 15.9 Hz, CHO).

9: ^{31}P NMR (THF): $\delta = +23.5$; ^{1}H NMR ([D$_8$]THF): $\delta = 1.77$ (s, 6H, Me), 1.93 (s, 6H, Me), 7.16 (pseudo s, 10H, Ph); MS: *m/z*: 534 (M^+, ^{81}Br, 55%), 531 (100), 453 ($M^+ - Br$, ^{81}Br, 33), 371 ($M^+ - 2Br - H$, 60).

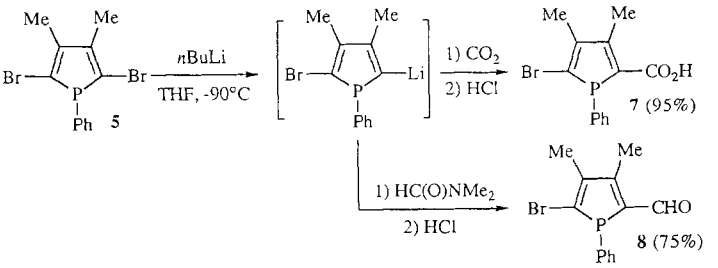


10: ^{31}P NMR (THF): $\delta = +23.3$; ^{1}H NMR ([D$_8$]THF): $\delta = 1.87$ (pseudo t, 6H, Me), 2.42 (pseudo t, 6H, Me); ^{13}C NMR ([D$_8$]THF): $\delta = 15.64$ (s, Me), 16.10 (s, Me), 135.17 (s, *C*-CO_2H), 142.91 (pseudo t, bridge-C?), 148.03 (pseudo t, Me-*C*=), 160.35 (pseudo s, Me-*C*=), 166.53 (pseudo t, CO_2H); IR (Nujol): ν(CO) 1656 (s), 1638 (s) cm^{-1}.

11. ^{31}P NMR ($CDCl_3$): $\delta = +20.05$; ^{1}H NMR ($CDCl_3$): $\delta = 1.95$ (pseudo s, 6H, Me), 2.43 (pseudo t, 6H, Me), 10.00 (pseudo t, $|^3J$(H-P) + ^6J(H-P)$| = 12.3$ Hz, 2H, CHO); MS: *m/z* 430 (M^+, 58%), 252 (100%); IR (Nujol): ν(CO) = 1718(s).

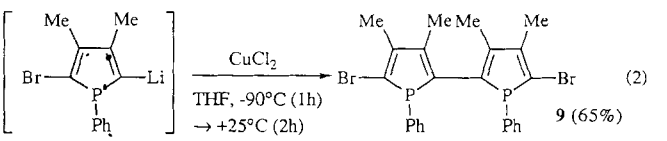
12: ^{31}P NMR (THF): AA'XX' spin system: δ(AA') = +29.69, δ(XX') = +21.29, ^3J(AX) = 61.4 Hz, ^3J(XX') = 55.5 Hz, ^6J(AX') = −0.36 Hz; PD-MS: *m/z*: 904 (M^+, ^{81}Br + ^{79}Br).

quantitative, and none of the intermediates were subjected to extensive purification. The reduction of **4** to **5** is more delicate. The use of pyridine as a cosolvent is absolutely essential to prevent the reduction of the dienic system of the phosphole. When pure, phosphole **5** is reasonably stable and displays good resistance toward oxidation by air.



When phosphole **5** is treated with one equivalent of butyllithium in THF at −90 °C, the rapid exchange of one bromine atom by one lithium atom takes place. An excess of butyllithium (2 equiv) does not lead to the exchange of the second bromine atom, as is clear from Eq. (1).

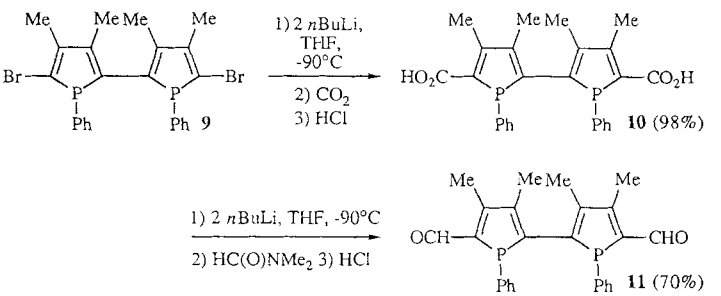
(1)



The molecular formula of sulfide **6** was established by mass spectrometry (M^+ at *m/z* 314 (^{81}Br) and *m/z* 312 (^{79}Br)) and by ^{1}H NMR spectroscopy (signal for the α-methyl group at δ = 1.88 (^3J(H−P) = 14.1 Hz)). The monolithio derivative of **5** proved to be an efficient starting material for the synthesis of 5-bromophospholes functionalized in the 2-position (Scheme 2).

In the NMR spectra of **8** in $CDCl_3$, the aldehyde group gives a characteristic ^{1}H resonance at $\delta = +9.95$ (^3J(H−P) = 11.7 Hz) and a ^{13}C resonance at $\delta = +185.54$ (^2J(C−P) = 15.9 Hz). In the ^{13}C NMR spectrum of **7** in [D$_6$]DMSO, the acidic carboxyl group appears at $\delta = +174.85$ (^2J(C−P) = 19.8 Hz). The oxidative coupling of the same monolithio derivative by

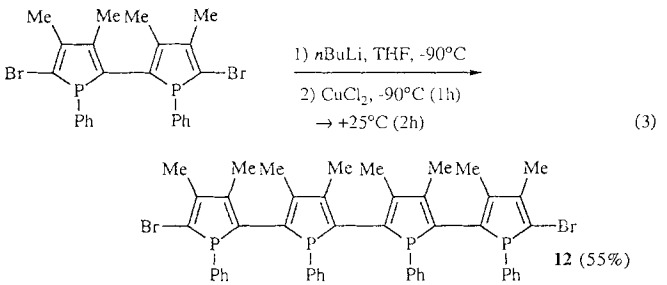
Scheme 2.



copper(II) chloride affords the 5,5'-dibromo-2,2'-biphosphole **9** [Eq. (2)].

(2)

According to the ^{31}P NMR spectrum (δ^{31}P (**9**) = +23.5 in [D$_8$]THF), only one of the two possible diastereomers of **9** is formed. It is always accompanied by traces of the corresponding 2,2'-biphosphole with H substituents in the 5- and 5'-positions, which has already been described.[5, 6] The molecular formula of **9** was unambiguously established by mass spectrometry; the molecular peaks are found in the range *m/z* 530–534 (^{79}Br and ^{81}Br) with the base peak at *m/z* 531.



The reactivity of **9** toward butyllithium was studied under our standard conditions (−90 °C, THF). The exchange of the first bromine atom by lithium takes place immediately upon addition of one equivalent of butyllithium. Addition of a second equivalent of butyllithium gives the 5,5'-dilithio derivative. 2,2'-Biphosphole **9** is thus the ideal starting material for the kind of chemistry we evoked in the introduction. As an illustration, we describe the synthesis of two 2,2'-biphospholes functionalized in the 5- and 5'-positions (Scheme 3), which are of potential inter-

Scheme 3.

est for the construction of flexible phosphorus macrocycles, and the synthesis of the first quaterphosphole [Eq. (3)] as a first step en route to polyphospholes.

According to ^{31}P NMR analysis, both **10** and **11** are pure diastereomers (meso or racemates) with the same geometry as **9**. In $CDCl_3$, the carbonyl groups of **11** give rise to a pseudo triplet at $\delta = +10.00$ in the ^{1}H NMR spectrum and at $\delta = +186.13$ in

the ^{13}C NMR spectrum. In THF, the CO_2H carbons of **10** appear as a pseudo triplet at $\delta = +166.53$. The case of **12** is more complex. According to its ^{31}P NMR spectrum, it exists as a mixture of diastereomers, one of which predominates. The simulation of the spectrum of this major diastereomer gave an AA'XX'-type spectrum: (X,X' stand for the "internal" phosphorus atoms): $\delta_{AA'} = +29.69$, $\delta_{XX'} = +21.29$, $^3J_{AX} = 61.4$ Hz, $^3J_{XX'} = 55.5$ Hz. This suggests a highly symmetrical geometry, which was confirmed by X-ray crystal structure analysis (Fig. 1). The molecule possesses a C_2 symmetry axis lying in the

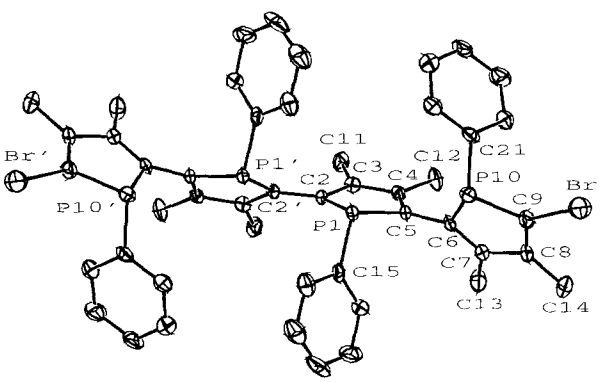


Fig. 1. Crystal structure of **12** [7]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond lengths [Å] and angles [°]: Br-C9 1.883(7), P1-C2 1.822(6), P1-C5 1.790(6), P1-C15 1.814(7), C2-C2' 1.43(1), C2-C3 1.374(8), C3-C4 1.445(8), C4-C5 1.383(8), C5-C6 1.451(8), C6-C7 1.345(8), C6-P10 1.812(6), C7-C8 1.491(9), C8-C9 1.37(1), C9-P10 1.784(7), P10-C21 1.815(6); C2-P1-C5 91.6(3), C2-P1-C15 106.7(3), C5-P1-C15 106.3(3), P1-C2-C2' 120.1(2), P1-C5-C6 121.8(5), C6-P10-C9 89.7(3), C6-P10-C21 100.3(3), C9-P10-C21 107.4(3), Br-C9-P10 122.3(4); P1'C2'C2P1 25.10(0.43), P1-C5-C6-P10 -49.72(0.60); C2-C5/C6-C9 interplane angle 67.75 ± 0.30.

mean plane of the four rings and bisecting the C2–C2' bond. The geometry of the four phospholes is normal. The C–C bridges (C2–C2' 1.43(1) Å, C5–C6 1.451(8) Å) are not shortened, and thus, conjugation between the phosphole rings is unlikely. With respect to the mean plane, the disposition of the phenyl substituents is up, down, up, down (Fig. 2). Since the coupling method leading to **12** very probably does not alter the conformation at the phosphorus centers, this result suggests that **9**, **10**, and **11** are racemates. Finally, the most surprising observation is that all the four phospholes are pointing in the same direction (Fig. 3); a head-to-tail arrangement was expected.

The recently reported synthesis of the first α-linked quaterpyrrole in three steps and 6.5% overall yield from a 2,2'-bipyrrole[8] well underlines the simplicity and efficiency of our route to difunctionalized α-linked polyphospholes.

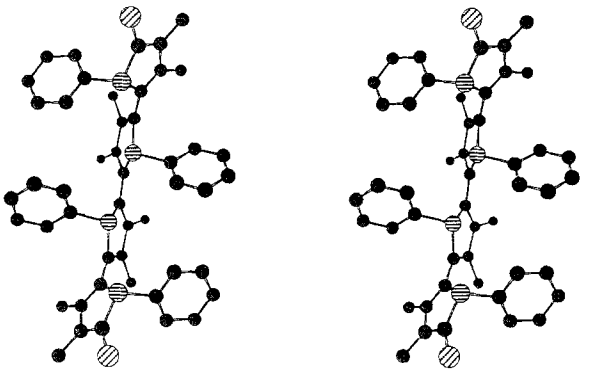

Fig. 2. Stereoview of **12** (C.S.C. Chem3D). The phenyl rings lie almost in the plane of the paper.

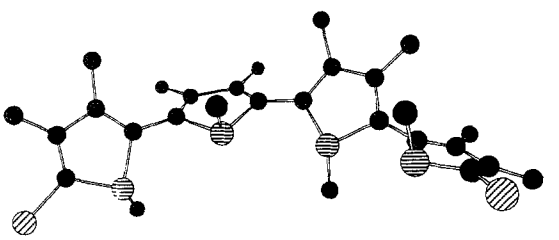

Fig. 3. View of **12** (C.S.C. Chem3D) showing the arrangement of the phosphole rings. Only the *ipso* carbon atoms of the phenyl rings are shown.

Experimental Procedure

5: To **1** [5] (20 g, 5.5×10^{-2} mol) in CH_2Cl_2 (400 mL) at +10 °C was added dropwise a solution of KOH (4.5 g, 8×10^{-2} mol) in methanol (50 mL). At the end of the addition, the quantitative formation of **2** can be monitored by ^{31}P NMR spectroscopy: $\delta^{31}P$ (**1**) = +28, $\delta^{31}P$ (**2**) = +38. The reaction mixture was hydrolyzed at 0 °C and washed with water until neutral. The organic layer was dried over $MgSO_4$. This dry organic layer was kept at 0 °C and treated with bromine (3.5 mL, 6.8×10^{-2} mol) in CH_2Cl_2 (50 mL). At the end of the dropwise addition, the bromination of **2** appeared to be complete according to the ^{31}P NMR spectrum: $\delta^{31}P$ = (**3**) +35. An excess of a solution of $NaHCO_3$ in water was then added all at once to the reaction mixture. The ^{31}P NMR spectrum showed the formation of **4**: $\delta^{31}P$ (**4**) = +32. The solution was treated with $Na_2S_2O_3$, washed with water until neutral, and dried over $MgSO_4$. The solvents were evaporated. Separately, a solution of $HSiCl_3$ (15 mL, 15×10^{-2} mol) in CH_2Cl_2 (30 mL) was added at 0 °C under N_2 to a solution of pyridine (26 mL, 32×10^{-2} mol) in CH_2Cl_2 (40 mL). To the resulting mixture was added dropwise a solution of crude **4** in CH_2Cl_2 (100 mL). At the end of the addition, the mixture was heated at 50 °C for 3 h. Monitoring of the reaction by ^3P NMR spectroscopy showed that the reduction of **4** was complete: $\delta^{31}P$ (**5**) = +17. The resulting suspension was slowly poured onto a mixture of ice and $NaHCO_3$ in water. The resulting thick gel was diluted in CH_2Cl_2 and filtered over celite. After decantation, the water layer was extracted three times with CH_2Cl_2. The organic solution was washed with 3 N HCl (100 mL), then with water until neutral, and dried over $MgSO_4$. After the solvent was removed, the organic residue was quickly chromatographed over silica gel (70–230 mesh) with deoxygenated hexane. The evaporation of hexane yielded 11 g of **5** as white crystals (58%).

6: A solution of phosphole **5** (0.7 g, 2×10^{-3} mol) in anhydrous, freshly distilled THF (10 mL) was prepared under dry N_2 in a Schlenk tube, which was previously dried in an oven at 130 °C. To this solution cooled at −90 °C was added by syringe butyllithium (2.54 mL, 1.6 M, 4×10^{-3} mol), and the mixture was kept at −90 °C an additional hour. Methyl iodide (0.27 mL, 4.4×10^{-3} mol) was then added, and the reaction mixture was kept at −90 °C another hour with stirring. After the reaction mixture was warmed to room temperature, sulfur (0.1 g) was added, and the mixture was stirred at room temperature for 0.5 h. The solvent was removed and the residue chromatographed with toluene. Yield of **6**: 0.48 g (75%) white crystals.

7: The lithium derivative of **5** was prepared as described for **6** from **5** (0.7 g) and butyllithium (1.27 mL, 1.6 M, 2×10^{-3} mol). The solution was kept at −90 °C for 0.5 h with stirring. Then a piece of dry ice was added to the mixture, which was kept at −90 °C for an additional 0.5 h. Hydrochloric acid (0.7 mL, 3 N) in THF (5 mL)

was added by syringe. The mixture was warmed to room temperature. Dichloromethane (50 mL) and aqueous 10% NaOH were added. The aqueous layer was washed several times with CH_2Cl_2, then acidified by 3 N HCl, and extracted six times with CH_2Cl_2. The CH_2Cl_2 extracts were washed with water and dried over $MgSO_4$. Evaporation of the solvent gave 0.6 g (95%) of **7** as white crystals.

8: The lithium derivative of **5** was prepared as described for **7**. After the reaction mixture was kept at $-90\,^{\circ}C$ for 0.5 h, dimethylformamide (0.17 mL, 2.2×10^{-3} mol) was added by syringe. After an additional 0.5 h, 3 N HCl (1.5 mL) in THF (5 mL) was added to the mixture. The reaction mixture was warmed to room temperature, and CH_2Cl_2 (30 mL) and water (30 mL) were mixed with the solution. The aqueous layer was extracted three times with CH_2Cl_2 under N_2. The CH_2Cl_2 layer was washed with water until neutral and dried over $MgSO_4$. After the solvent was evaporated, the organic residue was chromatographed over alumina with toluene to provide 0.46 g of **8** (75%) as yellow crystals. Mass spectrometry and elemental analysis were performed on the more stable P-$W(CO)_5$ complex.

9: The lithium derivative of **5** was prepared as described for **7**. The reaction mixture was kept 0.5 h at $-90\,^{\circ}C$, before copper(II) chloride (0.3 g, 2.2×10^{-3} mol) was added to the solution. After stirring for 1 h at $-90\,^{\circ}C$, the mixture was slowly warmed to room temperature over 2 h. At room temperature, CH_2Cl_2 (50 mL) and ammonia were added, and the mixture was stirred for 20 min. After decantation and extraction of the water layer, the organic phase was washed with water until neutral, dried over $MgSO_4$, and concentrated to dryness. The crude product was chromatographed with hexane/ether 95/5. Biphosphole **9** was obtained as pale yellow crystals in 65% yield (0.69 g).

10: A solution of biphosphole **9** (1.06 g, 2×10^{-3} mol) in THF (50 mL) was prepared in a Schlenk tube. The solution was cooled to $-90\,^{\circ}C$, and butyllithium (2.54 mL, 1.6 M, 4×10^{-3} mol) was added by syringe. After 30 min a piece of dry ice was added and the mixture stirred for another hour. 3 N HCl (1.4 mL) in THF (5 mL) was then added at $-90\,^{\circ}C$, and the mixture was warmed to room temperature. Dichloromethane (150 mL) and 10% NaOH were mixed with the solution. After decantation and washing with CH_2Cl_2, the aqueous layer was acidified by 3 N HCl and extracted several times with CH_2Cl_2 (**10** is poorly soluble in CH_2Cl_2). The CH_2Cl_2 extracts were washed with water, dried over $MgSO_4$, and concentrated to dryness. **10** was obtained in 98% yield (0.9 g) as a deep yellow microcrystalline powder.

11: The dilithio derivative of **9** was prepared as described for **10**. Dimethylformamide (0.34 mL, 4.4×10^{-3} mol) was added to the reaction mixture at $-90\,^{\circ}C$ by syringe. The solution was stirred for 1 h, then 3 N HCl (3 mL) in THF (5 mL) was added dropwise by syringe, and the reaction medium was warmed to room temperature. CH_2Cl_2 (100 mL) and water (20 mL) were mixed with the solution. After decantation, extraction, and neutralization, the organic layer was dried over $MgSO_4$. The organic product was chromatographed with dichloromethane. Yield of **11**: 0.6 g (70%), deep yellow solid.

12: The monolithio derivative of **9** was prepared by the reaction of **9** (2.13 g, 4×10^{-3} mol) with butyllithium (2.5 mL, 1.6 M, 4×10^{-3} mol) in THF (100 mL) at $-90\,^{\circ}C$. After 10 min copper(II) chloride (0.55 g, 4×10^{-3} mol) was added to the solution. After stirring for 1 h at $-90\,^{\circ}C$, the mixture was slowly warmed to room temperature over 2 h. At room temperature, toluene (100 mL) and ammonia were added, and the mixture was stirred for 20 min. After decantation and extraction of the water layer with toluene, the organic phase was washed with water until neutral, dried over $MgSO_4$, and concentrated to dryness. The residue was chromatographed on alumina with hexane/ether (95/5). The quaterphosphole **12** was obtained as deep orange crystals in 55% yield (1 g). Caution: **12** is sensitive to air, thus alumina and the solvents must be deoxygenated and the reaction product handled under nitrogen.

[7] X-ray structure analysis of **7**: Crystals of **7** ($C_{48}H_{44}Br_2P_4$) were grown by slowly cooling a warm solution of the compound in toluene. Data were collected at $-150\pm0.5\,^{\circ}C$ on an Enraf-Nonius CAD4 diffractometer. The crystal structure was solved and refined with the Enraf-Nonius MOLEN package. The compound crystallizes in space group *Pbcn*, $a = 30.254(3)$, $b = 8.164(1)$, $c = 17.608(2)$ Å; $V = 4348.98(1.45)$ Å^3, $Z = 4$, $\varrho_{calc} = 1.382$ g cm^{-3}; $Cu_{K\alpha}$ radiation ($\lambda = 1.54184$ Å), graphite monochromator; $\mu = 40.4$ cm^{-1}; $F(000) = 1848$. A total of 4114 unique reflections were recorded in the range $2^{\circ} \le 2\theta \le 140.0^{\circ}$ of which 779 were considered as unobserved ($F^2 < 3.0\,\sigma(F^2)$), leaving 3335 for solution and refinement. The structure was solved by direct methods. The hydrogen atoms were included as riding contributions in the final stages of least-squares refinement; anisotropic temperature factors were used for all other atoms. A non-Poisson weighting scheme was applied with a p factor equal to 0.08. The final agreement factors were $R = 0.069$, $R_w = 0.110$, G.O.F. = 3.13. The samples we tested have relatively poor quality. This probably results from the random inclusion of another isomer in the lattice and may explain that a large number of systematically absent $0kl$ reflections show a significant intensity and that a large number of medium-intensity reflections have computed structure factors that deviate considerably from the observed values. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57975.

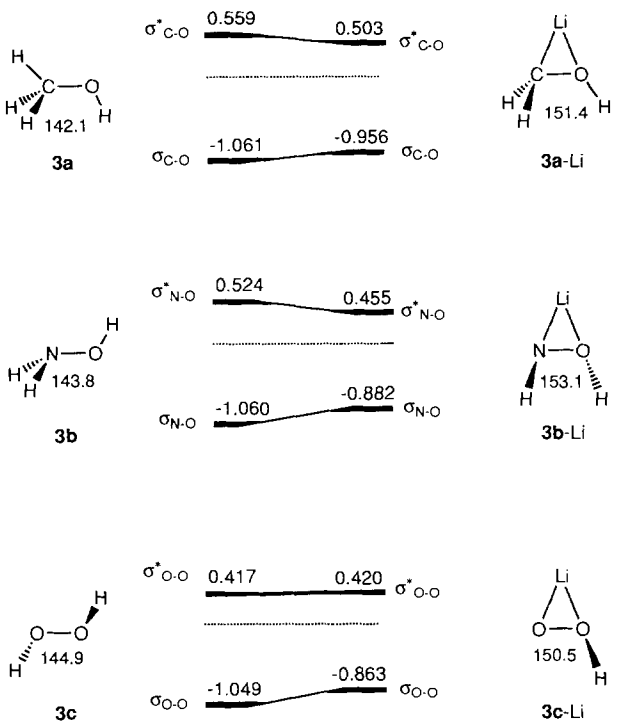
The Oxenoid Character of Metalated Hydroperoxides O(M)OR: Oxidation of Organometallic Compounds R′M′ to R′OH under Mild Conditions**

Gernot Boche,* Ferdinand Bosold, and John C. W. Lohrenz

Recently we reported on the carbenoid nature of α-lithiated ethers ("Li/OR carbenoids") **1a**-Li,[1] in which the C–OR bond is clearly lengthened (by 8–10 pm) in comparison to that of the corresponding ether. This correlates with the surprisingly easy substitution of the RO groups (even when sp^2 bonded) by a nucleophile R′M′ (M′ = Li) (**1a**-Li → **2a**-Li, [Eq. (1)]). An analogous increase of electrophilicity by metalation (!) is found in the N-lithiated hydroxylamines ("Li/OR nitrenoids") **1b**-Li. Owing to the weakening of the N–OR bond,[2a] these compounds can be used as electrophilic aminating agents for R′M′ (M′ = Li) (**1b**-Li → **2b**-Li, [Eq. (1)]).[2b-c]

1-Li **2**-Li (1)



This raises the question as to whether lithiated hydroperoxides **1c**-Li are "Li/OR oxenoids" and therefore especially good electrophiles that will also react with R′M′. This reaction corresponds to an oxidation of organometallic compounds R′M′ to R′OM′ or R′OH (**1c**-Li → **2c**-Li, [Eq. (1)]), a transformation that is still not represented in organometallic chemistry in a general fashion. A recent communication from M. Julia, V. P. Saint-Jalmes, and J.-N. Verpeaux[3] on this subject has encouraged us to report our own results.

Quantum chemical calculations show the close relationship between carbenoids **1a**-Li, nitrenoids **1b**-Li, and **1c**-Li. In

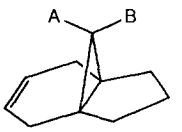
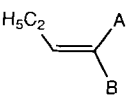
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 260) and the Fonds der Chemischen Industrie.

Scheme 1 the C(N,O)–OH bond lengths are listed for the model compounds methanol H_3C–OH (**3a**), C-lithiated methanol **3a**-Li, hydroxylamine H_2N–OH (**3b**), N-lithiated hydroxylamine **3b**-Li, hydrogen peroxide HO–OH (**3c**), and monolithiated hydrogen peroxide **3c**-Li (MP2/6-311 + + G(d,p) level). "Natural bond orbital analysis"[4] of the HF/6-311 + + G(d,p) wave function yielded the energies of the σ and σ* orbitals of the C(N,O)–OH bonds.



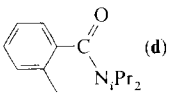
Scheme 1. Structures and bond lengths [pm] for **3a–c** and **3a**-Li to **3c**-Li from calculations at the MP2/6-311 + + G(d,p) level, together with the σ and σ* orbital energies [Hartree] (HF/6-311 + + G(d,p)) for these bonds.



On going from **3c** to **3c**-Li the O–O bond is lengthened by 5.6 pm. Correspondingly, the energy of the σ_{o-o} orbital is raised from −1.049 to −0.863 Hartree. A similar change is observed for the conversions giving carbenoid **3a**-Li[5, 6] and nitrenoid **3b**-Li.[7] In addition, in **3a**-Li and **3b**-Li the $\sigma^*_{C(N)-O}$ orbital is lowered. A similar lowering of the σ^*_{o-o} orbital does not occur in the change from **3c** to **3c**-Li, but the absolute energy of the σ^*_{o-o} orbital in **3c**-Li (0.420 Hartree) is lower compared with that of the σ^*_{c-o} orbital in **3a**-Li (0.503 Hartree) and the σ^*_{N-O} orbital in **3b**-Li (0.455 Hartree), such that an interaction with the nucleophile R′M′ is comparatively favorable. Thus, metalated hydroperoxides should be oxenoids. In addition, the greater tendency of **3c**-Li and methyllithium to form a mixed complex (**3c**·Li·$LiCH_3$: −55.2 kcal mol^{-1} (MP2/6-31G(d)) relative to that of nonlithiated **3c** and CH_3Li (**3c**·$LiCH_3$: −21.4 kcal mol^{-1}) indicates that the reaction of organometallic compounds R′M′ with **3c**-Li is energetically favored over the reaction with **3c**, which serves as a model for nonoxenoid peroxides of the type ROOR.[8, 9]

A search of the literature[10] and our own investigations are in agreement with the results of the quantum chemical calculations. The first suspicion that organometallic compounds R′M′ could react with metalated hydroperoxides O(M)OR (R = alkyl, aryl, etc.) arose during the study of the autoxidation of Grignard compounds R′MgHal with dioxygen O_2.[10d, 11–13] The reaction, which proceeds in two steps (1. R′MgHal + O_2 → O(MgHal)OR′; 2. O(MgHal)OR′ + R′MgHal → 2R′OMgHal), often leads in high yield (> 80%) to R′OMgHal in which R′ can be an alkyl, cycloalkyl, vinyl, aryl, or alkynyl group.[10d]

The first reaction of a lithiated hydroperoxide (lithiated tetralin hydroperoxide) with an organolithium compound (phenyllithium) was reported in 1939.[14] Phenol was obtained in 96% yield. Of special importance is the finding that the oxidation of the isomeric cyclopropyllithium compounds **4a,b**-Li[15] and the vinyllithium compounds **5a,b**-Li[16] with lithio-*tert*-butylhydroperoxide proceed to the corresponding alcoholates and enolates, respectively, with retention of configuration, which makes the intermediate formation of radicals unlikely, at least in these examples.[17]



4a-Li : A = H, B = Li[15]
4b-Li : A = Li, B = H

5a-Li : A = Ph, B = Li[16]
5b-Li : A = Li, B = Ph

Our own investigations confirm the easy oxidation of the organolithium compounds R′Li **6a–e** with lithiated cumenyl hydroperoxide O(Li)$OCMe_2$Ph. The corresponding alcohols R′OH were obtained in high yields after hydrolysis[18] (Table 1).

Table 1. Yields [%] for the oxidation of R′Li(MgBr) compounds **6**, cyanocuprates **7**, and "higher order" cyanocuprates **8** with O(Li)$OCMe_2$Ph to give alcohols R′OH.

R′Li(MgBr) **6**	Yield of R′OH from R′Cu(CN)Li **7**	$R'_2Cu(CN)Li_2$ **8**	R′
85	84	82	*n*Bu (**a**)
81	89	90	*t*Bu (**b**)
85	83	78	Ph (**c**)
70 [3]	77	86	 (**d**)
85 (72 [a, b])	56 [c]	67 [d]	$PhCH_2$ (**e**)
95 [a]	-	-	*n*-octyl (**f**)

[a] Grignard compounds R′MgBr. [b] 5% Bibenzyl. [c] 19% Bibenzyl. [d] 14% Bibenzyl.

The Grignard compound **6f** was also oxidized to the alcohol with O(Li)$OCMe_2$Ph. Of particular importance is the oxidation of the cyanocuprates R′Cu(CN)Li **7** corresponding to the lithium compounds **6** and the oxidation of the "higher order" cyanocuprates $R'_2Cu(CN)Li_2$ **8**, which previously could not be converted into alcohols of the type R′OH.[19] The reaction of the benzyl compounds **6e–8e** with O(Li)$OCMe_2$Ph (also) proceeded by electron transfer to give benzyl radicals, as indicated by the formation of bibenzyl.[20, 21]

To sum up: quantum chemical calculations show that metalated (lithiated) hydroperoxides O(M)OR are oxenoid in character and can therefore be regarded as analogues of carbenoids and nitrenoids. In agreement with this is their marked electrophilicity towards nucleophiles such as organometallic compounds of the type R′M′, which are converted into "alcohols"

R'OH under mild conditions. Cyanocuprates R'Cu(CN)Li and "higher order" cyanocuprates $R'_2Cu(CN)Li_2$ provide new examples for this reaction.

[6] The significantly higher electrophilicity of a MgCl/Cl carbenoid relative to that of the corresponding alkyl chloride is shown in the reaction of 1-chloropentylmagnesium chloride with n-$C_{11}H_{22}CH(Li)SO_2Ph$, which leads to electrophilic substitution already at −70 to −20 °C. In contrast, in the reaction of 1-chloropentane substitution is not observed even after 2 h at 20 °C: C. De Lima, M. Julia, J.-N. Verpeaux, *Synlett* **1992**, 133–134.

[7] Earlier calculations for **3b** and **3b**-Li: a) G. Boche, H.-U. Wagner, *J. Chem. Soc. Chem. Commun.* **1984**, 1591–1592; b) D. R. Armstrong, R. Snaith, G. T. Walker, *ibid.* **1985**, 789–791; c) M. L. McKee, *J. Am. Chem. Soc.* **1985**, *107*, 859–864.

[8] Analogous complexes have been calculated for the reaction of methyllithium with nitrenoids [7].

[9] The bridging of C(N,O)–OH by Li^+ (in general M^+) found in the calculations of **3a**-c-Li also indicates that the departure of OH^- is enhanced by Li^+ (M^+) during substitution. In the case of carbenoids such enhancement by Li^+ was called metal-assisted ionization: a) M. Duraisamy, H. M. Walborsky, *J. Am. Chem. Soc.* **1984**, *106*, 5035–5037; b) see also G. [18] Reaction of R'Li **6** with O(Li)$OCMe_2PH$: A solution of *n*BuLi in hexane (1.6 M, 1.25 mL, 2.00 mmol) was added dropwise to a solution of cumyl hydroperoxide (304 mg, 2.00 mmol) in diethyl ether at −78 °C. The solution was stirred for 30 min, and the corresponding R'Li **6** in 2 mL diethyl ether was added. After ca. 12 h the solution was warmed to room temperature. The mixture was hydrolyzed with 2 N HCl, extracted with diethyl ether, and purified by distillation or chromatography. The alcohols R'OH were identified by GC, ^1H and ^{13}C NMR spectroscopy, and mass spectrometry. Reaction of the cuprates **7** and **8**: A solution of the Li compound R'Li **6** in 5 mL THF at −78 °C was allowed to react with CuCN (1 mol equiv for **7**, 0.5 mol equiv for **8**). When the reaction mixture was warmed to −30 °C and stirred, a clear solution formed. The reaction mixture was cooled again to −78 °C, and the solution of the lithiated cumyl hydroperoxide in 5 mL THF was added by means of a cannula. The alcohols were isolated and identified as previously described.

[19] The preparation of unsymmetrical biaryls by the oxidation of the corresponding "higher order" cuprates with O_2 was recently reported: B. H. Lipschutz, K. Siegmann, E. Garcia, F. Kayser, *J. Am. Chem. Soc.* **1993**, *115*, 9276–9282, and references therein.

[20] In the oxidation of R'M' (M' = MgHal, Li) with dialkyl peroxides ROOR, which leads to R'OR, radicals are always formed. In addition this reaction only works with nonbulky residues R, see a) G. A. Baramki, H. S. Chang, J. T. Edward, *Can. J. Chem.* **1962**, *40*, 441–444; b) W. A. Nugent, F. Bertini, J. K. Kochi, *J. Am. Chem. Soc.* **1974**, *96*, 4945–4954; c) see also refs. [10] and [17d]. Oxidations of R'M' with $Me_3SiOOSiMe_3$ were reported by P. Dembech, A. Guerrini, A. Ricci, G. Seconi, M. Taddei, *Tetrahedron* **1990**, *46*, 2999–3006, and references therein; here not only $R'OSiMe_3$ but also $R'SiMe_3$ is formed.

[21] For the compound $(RO)_3TiOOtBu$, which is important in the Sharpless oxidation [22], we have carried out model calculations on $(HO)_3TiOOH$ (**9**) (MP2/O,H: 6-31G(d); Ti (6211111/5111111/3111) [23]) (bond lengths from ref. [24] in parentheses), as have R. D. Bach and H. B. Schlegel et al. [24]. In **9**, which has a bridged structure like that of O(Li)OH **3c**-Li, the O–O bond is 2.2 pm longer than that in HOOH (O–O 147.0 pm (MP2/6-31G(d)). Owing to its oxenoid character, **9** could also exhibit increased electrophilicity like **3c**-Li. Increased electrophilicity was calculated for the Fe^{III} hydroperoxide model **10** and its reaction with NH_3 ((MP2/WH; values in parentheses: CASSCF(7,7)/3-21G) [24]).

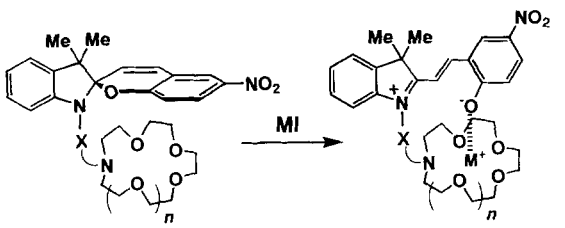
Sensitive and Selective Coloration of Cryptand-Type Crown Spirobenzopyrans for Alkaline-Earth Metal Cations**



Masahiko Inouye,* Yoshiyuki Noguchi, and Kakuzo Isagawa

The final aim of our research is to create "intelligent" supramolecules and supramolecular systems, in which several conjugated functions are induced by molecular recognition and the whole process is regulated at will.[11] In that connection, we recently developed a new class of spirobenzopyrans possessing a

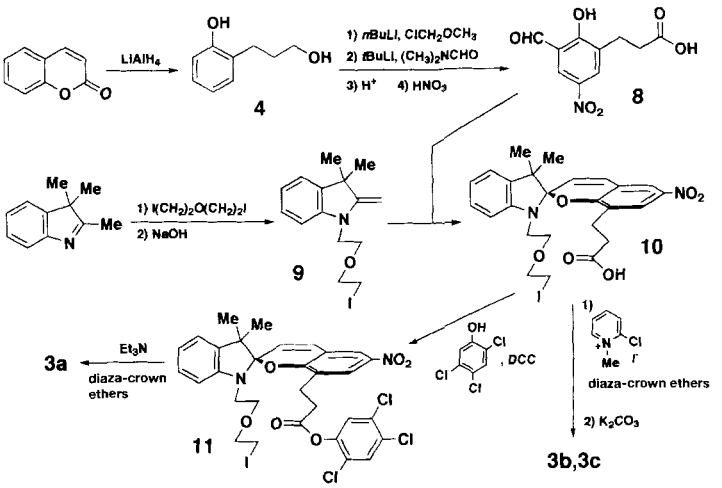
[**] We are grateful to Kenichi Takahashi (C. Itoh & Co., Ltd) for a gift of $[(Ph_3P)_3RhCl]$

crown ring as a recognition site, isomerization of which to the open-chain, colored merocyanines was induced by recognition of alkali-metal cations.[2] The spirobenzopyrans bearing a short linkage **1** showed distinctive colors for Li^+ ($n = 2$) and Na^+ ($n = 3$). For larger alkali-metal cations, however, distinctive coloration could not be obtained even in the cases of the $n > 3$ crown spirobenzopyrans. While spirobenzopyrans **2**, in which



the spiroenzopyran moiety was widely separated from the crown ether units by longer alkyl spacers (X) than in **1**, showed a small selective coloration for larger alkali-metal cations such as K^+ and Cs^+, the molar absorptivities in the presence of alkali-metal iodides were considerably smaller than those of **1**. We thought that the low coloring efficiency might result from unfavorable entropy effects: the probability of the existence of the complexed cations in the neighborhood of the phenolate oxygen of the merocyanines is reduced, and the electrostatic interaction between the complexed large univalent cations and the *p*-nitrophenolate dipole of the merocyanines is weak. Taking into account the above points, we developed cryptand type spirobenzopyran crown ethers (**3**). Here we present the synthesis and selective coloration effects of the new crown spirobenzopyrans on complexation with alkaline-earth metal cations (Scheme 1).

Scheme 1.

The cryptand spirobenzopyrans **3** were synthesized from three components, namely, nitrosalicylaldehyde **8**, indoline **9**, and diaza-crown ethers. The aldol-type cyclization of **8** with **9** gave spirobenzopyran **10** bearing carboxyl and iodoalkyl groups, which on condensation with diaza-crown ethers by Mukaiyama's or activated ester methods, followed by macrocyclization under high-dilution conditions yielded **3**. The key intermediates **8** and **9** were prepared by standard synthetic methods (Scheme 2).[3]

Scheme 2. DCC = dicyclohexylcarbodiimide.

The cryptand spirobenzopyrans **3** showed no absorption bands above 400 nm in aprotic solvents; which indicated closed spiropyran forms. Indeed, this interpretation was verified by NMR studies (see below). The absorption spectra were scarcely affected upon addition of any alkali-metal iodides in CH_3CN.[4] In the ^1H NMR spectra of **3b** in CD_3CN, however, downfield shifts (for aromatic and crown ring protons), splitting (crown ring and alkyl spacer protons), and sharpening (aromatic protons) of the signals in the spiropyran forms were observed after the addition of KI. This result clearly indicated that the alkali-metal cations were bound to the macrocycle of **3**, and that the colorless form was attributable to the weak electrostatic interaction between the complexed univalent cations and the *p*-nitrophenolate dipole of the merocyanines. Addition of alkaline-earth metal iodides to these CH_3CN solutions gave rise to changes in their spectra. Thus, **3a** gave the most intense coloration for Ca^{2+}, and **3b** for Sr^{2+} (Fig. 1). Titration experiments demonstrated that about one equivalent of SrI_2 is enough to obtain the maximum coloration of **3b**. Unfortunately, **3c** showed little changes and poor selectivity in its absorption spectrum under the same conditions. This may be because the crown ring is too flexible to interact strongly with the cations. As expected, little change in the spectra of **1** and **2** occurred under the same conditions.

The isomerization of the cryptand spirobenzopyran **3b** to the open-chain, colored merocyanine **3b'** in the presence of SrI_2 has been studied by ^1H NMR spectroscopy at 500 MHz. In several deuterated solvents ($CDCl_3$, CD_3CN, [D_6]DMSO, etc.), the ^1H NMR signals of **3b** were considerably broadened at room temperature. High-temperature NMR (85 °C) in [D_6]DMSO was able to resolve the identifiable species. (In contrast, spectra of **3a** and **3c** at room temperature in $CDCl_3$ were well-resolved.) To a solution of **3b** (20 μmol) in CD_3CN (0.7 mL) was added SrI_2 (40 μmol), and ^1H NMR spectra were measured as a function of time in the dark. After 30 min, new resonances, which were assigned to a merocyanine (**3b'**), were detected, and the remaining signals of the spiropyran form (**3b**) sharpened and shifted. Equilibrium was reached after 3 h (>80% conversion, Fig. 2). These observations suggested the fast and strong binding of Sr^{2+} by **3b**, and the slow isomerization of the resulting complex (**3b** · Sr^{2+}) to the merocyanine form (**3b'**).[5]

The fast and strong binding of Sr^{2+} by **3b** was corroborated on the basis of FAB mass spectrometry. Before addition of SrI_2, ion peaks for $[M + H]^+$ and $[M + Na]^+$ were detected; after the addition, these signals decreased and finally disappeared, while peaks for $(M - H + Sr)^+$ and $(M + Sr + I)^+$ appeared and increased.

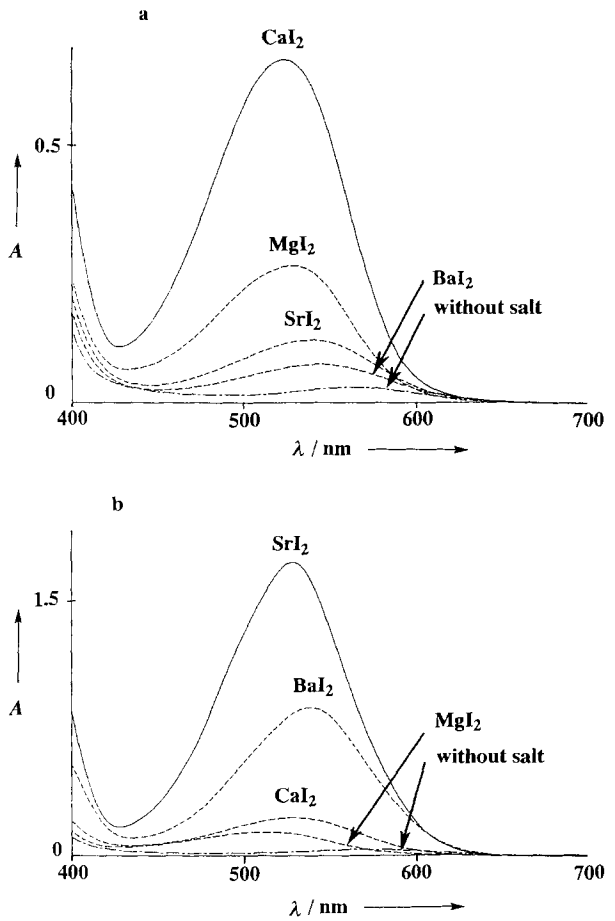


Fig. 1. Electronic absorption spectra of solutions of **3a** (a) and **3b** (b) in acetonitrile in the presence or absence of 1 equiv of alkaline-earth metal iodides [4].

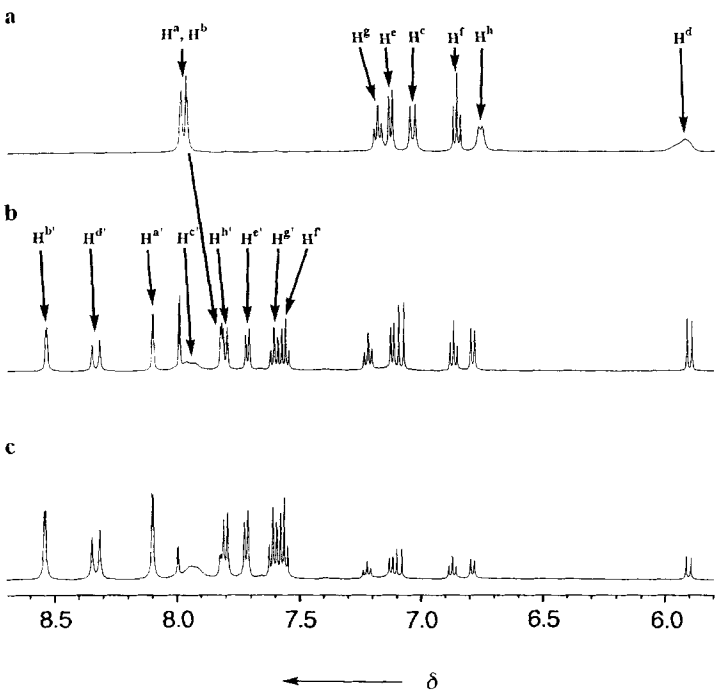

Fig. 2. ^{1}H NMR spectra (500 MHz) of **3b** in CD_3CN. a) Before addition of SrI_2, b) 30 min after the addition, and c) after 3 h. See Scheme 1 for proton labeling.

We have developed new crown spirobenzopyrans, cryptand-type spirobenzopyran. In these spirobenzopyrans, coloration was efficiently induced in the presence of 1 equiv of alkaline-earth metal iodides. The cryptand spirobenzopyrans represent highly sensitive and selective signaling receptors for alkaline-earth metal cations.

Experimental Procedure

4: A suspension of coumarin (17.54 g, 120 mmol), and $LiAlH_4$ (22.77 g, 600 mmol) in THF (300 mL) was heated at reflux for 48 h. A solution of H_2SO_4 (10%) was carefully added dropwise to the mixture at 0 °C until no more hydrogen evolved. The resulting mass was extracted with THF in a Soxhlet extractor (50 h), and the extract was evaporated to dryness. The residue was dissolved in water, extracted with CH_2Cl_2, and the extract evaporated and distilled under reduced pressure to give **4**: yield 57% (10.38 g); b.p. 122–128 °C (0.1 mmHg); IR (KBr): $\tilde{\nu}$ = 3367, 2943, 1593, 1456, 1244, 1107, 1030, 756 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.88 (quint, J = 6.1 Hz, 2H), 2.78 (t, J = 6.1 Hz, 2H), 3.64 (t, J = 6.1 Hz, 2H), 6.82–6.90 (m, 2H), 7.08–7.14 (m, 2H); ^{13}C NMR (67.8 MHz, $CDCl_3$) δ = 25.22, 32.27, 60.86, 116.16, 120.87, 127.24, 127.61, 130.66, 154.59; EI-MS (70 eV): *m/z* (%): 152 (100) [M^+], 134 (52) [$M^+ - H_2O$], 107 (70) [$M^+ - CH_2CH_2OH$], 77 (56)[$C_6H_4 + H^+$].

8: A solution of *n*-BuLi (103 mmol) in *n*-hexane was added dropwise at 0 °C to a solution of **4** (7.61 g, 50 mmol) in THF (50 mL). The solution was kept at 0 °C under stirring for 1 hr, upon which $ClCH_2OCH_3$ (32.21 g, 400 mmol) was added dropwise, and the reaction mixture was stirred for an additional 1 h at the same temperature, before filtration. The filtrate was evaporated to dryness, the residue dissolved in water, and the solution extracted with CH_2Cl_2 to give 1-(1,3-dioxabutyl)-2-(4,6-dioxaheptyl)benzene (**5**): yield 94% (11.26 g). To a solution of **5** (11.26 g, 47 mmol) in *n*-hexane (100 mL) at 0 °C was added dropwise a solution of *t*-BuLi (66 mmol)in *n*-pentane. At that temperature the solution was stirred for 2 h, and a solution of DMF (5.82 g, 80 mmol) in THF (45 mL) was added dropwise. The reaction mixture was warmed to room temperature and stirred for an additional 12 h. After addition of water (10 mL), the mixture was evaporated to dryness. The residue was dissolved in water and extracted with CH_2Cl_2 to afford 2-(1,3-dioxybutyl)-3-(4,6-dioxaheptyl)benzaldehyde (**6**): yield 93% (11.66 g). A solution of **6** (9.74 g, 36 mmol) in MeOH (150 mL), which contained a small amount of concentrated HCl solution (several drops), was heated at reflux for 9 h. The reaction mixture was neutralized to pH 7 with an aqueous solution of 1 N NaOH and evaporated to dryness. The residue was dissolved in water and extracted with CH_2Cl_2. The extract was evaporated and chromatographed (silica gel; eluent, AcOEt) to give 3-(3-hydroxypropyl)salicylaldehyde (**7**): yield 97% (6.39 g). At 0 °C **7** (1.80 g, 10 mmol) was added dropwise to 60% HNO_3 (15 mL), the reaction mixture stirred for 2 h, and then neutralized to pH 4 with a saturated solution of $NaHCO_3$ in water. The resulting precipitate was filtered and washed with cold (about 0 °C) AcOEt to give **8**: yield 47% (1.14 g); m.p. 175–179 °C (decomp.); IR (KBr): $\tilde{\nu}$ = 3288, 1736, 1662, 1618, 1444, 1346, 1296, 1277, 1209, 1163, 1109, 789, 762, 719 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 2.78 (t, J = 7.3 Hz, 2H), 3.09 (t, J = 7.3 Hz, 2H), 8.35 (d, J = 2.4 Hz, 1H), 8.45 (d, J = 2.4 Hz, 1H), 9.99 (s, 1H) 11.96 (s, 1H); ^{13}C NMR (67.8 MHz, [D_6]DMSO): δ = 24.44, 32.73, 120.72, 126.82, 130.54, 131.54, 139.78, 163.58, 173.74, 195.35; EI-MS (70 eV): *m/z* (%): 239 (28) [M^+], 193 (100) [$M^+ - CO_2H - H$], 165 (43) [$M^+ - CH_2CH_2CO_2H - H$]. Correct C,H,N analysis.

10: A solution of **8** (1.29 g, 5.4 mmol) and **9** [2c] (1.93 g, 5.4 mmol) in EtOH (45 mL) was stirred at room temperature for 3 h. After removal of the solvent, the residue was subjected to column chromatography (silica gel; eluent, CH_2Cl_2, AcOEt = 10:1) to give **10**: yield 67% (2.09 g); oil; IR (KBr): $\tilde{\nu}$ = 3450, 3421, 1711, 1651, 1608, 1520, 1483, 1454, 1336, 1273, 1167, 1095, 949, 935, 906, 744 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.21 (s, 3H), 1.27 (s, 3H), 2.41 (t, J = 7.3 Hz, 2H), 2.65–2.74 (m, 2H), 3.20 (t, J = 6.7 Hz, 2H), 3.28–3.71 (m, 6H), 5.98 (d, J = 10.4 Hz, 1H), 6.61 (d, J = 7.3 Hz, 1H), 6.85 (t, J = 7.3 Hz, 1H), 6.91 (d, J = 10.4 Hz, 1H), 7.08 (d, J = 7.3 Hz, 1H), 7.15 (td, J = 7.3, 1.2 Hz, 1H), 7.90 (d, J = 2.4 Hz, 1H), 7.94 (d, J = 2.4 Hz, 1H); ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 2.90, 19.88, 24.81, 25.97, 32.46, 43.55, 52.29, 69.08, 71.67, 106.58, 106.99, 118.35, 119.74, 121.30, 121.66, 125.99, 127.28, 127.69, 128.31, 135.81, 140.54, 146.57, 156.98, 177.74; EI-MS (70 eV): *m/z* (%): 578 (30) [M^+], 451 (89) [$M^+ - I$], 393 (88) [$M^+ - CH_2OCH_2CH_2I$].

3b: A solution of **10** (1550 mg, 2.7 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of 1,10-diaza-[18]crown-6 (1760 mg, 6.7 mmol), 2-chloro-1-methylpyridinium iodide (1030 mg, 4.0 mmol), and Et_3N (810 mg, 8.0 mmol) in CH_2Cl_2 (30 mL) at room temperature. The mixture was heated at reflux for 3 h and evaporated. The residue was dissolved in water and extracted with CH_2Cl_2 to yield a mixture of **3b** and noncyclized free monoamine product. A suspension of the mixture described above and finely ground K_2CO_3 (3730 mg, 27 mmol) in THF (250 mL) was heated at reflux for 30 h. After removal of the solvent, the residue was dissolved in water and extracted with CH_2Cl_2. The extract was evaporated to dryness and subjected to column chromatography (silica gel; eluent, AcOEt:Et_3N = 25:1; then ODS (Conmosil. 75C_{18}-OPN, Nacalai Tesque, Inc. Kyoto, Japan) reversed-phase silica gel with MeOH:H_2O = 5:1 as eluent) to afford

3b: yield 18% (334 mg); m.p. 70–72 °C (decomp.); IR (KBr): $\tilde{\nu}$ = 2933, 2889, 2866, 1639, 1606, 1520, 1483, 1452, 1336, 1273, 1119, 1097, 939, 905, 750 cm^{-1}; ^1H NMR (500 MHz, [D$_6$]DMSO, 85 °C) δ = 1.13 (s, 3H), 1.22 (s, 3H), 2.56–2.62 (m, 10H), 3.30–3.57 (m, 26H), 5.97 (d, J = 10.4 Hz, 1H), 6.71 (d, J = 7.3 Hz, 1H), 6.81 (t, J = 7.3 Hz, 1H), 7.12 (t, J = 7.3 Hz, 1H), 7.14 (dd, J = 7.3, 1.2 Hz, 1H), 7.16 (d, J = 10.4 Hz, 1H), 7.97 (d, J = 2.7 Hz, 1H), 8.03 (d, J = 2.7 Hz, 1H); ^{13}C NMR (67.8 MHz, [D$_6$]DMSO, 85 °C): δ = 19.73, 24.15, 25.29, 42.83, 51.91, 54.80, 55.31, 68.51–70.12, 106.31, 118.17, 118.98, 120.48, 121.16, 121.29, 127.29, 128.08, 128.36, 135.34, 140.03, 146.25, 156.20, 170.53; FAB-MS (in 3-nitrobenzyl alcohol): m/z (%): 695 (100) [M + H$^+$], 717 (5) [M + Na$^+$]. Correct elemental analysis.

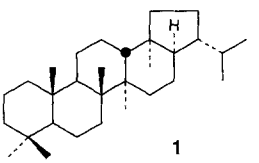
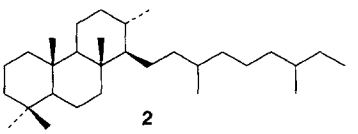
[3] All other new compounds provided spectra (^1H NMR, ^{13}C NMR, IR, MS) and elemental analyses in agreement with their structures. The full data and the experimental details will be reported elsewhere.



[4] The absorption spectra of 0.1 mM solutions of the spirobenzopyrans in CH_3CN were measured in the presence or absence of metal iodides after the solutions had been allowed to stand in the dark for 3 h.

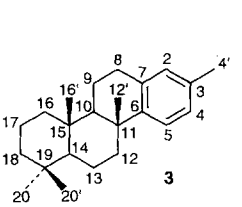
[5] This tendency was also observed for other spirobenzopyran crown ethers. See Ref. [2b].

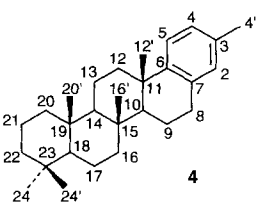


Novel Optically Active Hydrocarbons in Sediments: Evidence for an Extensive Biological Cyclization of Higher Regular Polyprenols**

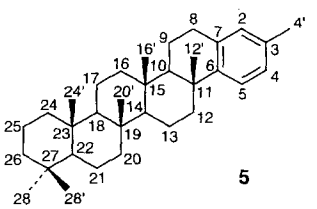
Philippe Schaeffer, Jacques Poinsot, Véréna Hauke, Pierre Adam, Patrick Wehrung, Jean-Michel Trendel, Pierre Albrecht,* Daniel Dessort, and Jacques Connan

Most polycyclic hydrocarbons occurring in sediments and petroleum are of biological origin. They can, with few exceptions, be related to biological precursors (steroids, terpenoids, etc.) by structural considerations which involve either known, often relatively simple, or hypothetical—but reasonable—geochemical transformations, therefore providing essential information on, for instance, the origin of organic matter in sediments.[1] In some cases, the precise characterization of new biological markers from sediments has had a considerable impact on fields such as microbial biochemistry, as exemplified by the story of geohopanoids, for example **1**.[2a] Thus, the identification and ubiquitous occurrence of geohopanoids in sediments preceded and triggered the discovery of their microbial precursors, the biohopanoids,[2b] a class of procaryotic lipids which play a major role as membrane reinforcers in bacteria. This unexpected pioneering role of geochemistry is further highlighted by the fact that molecular fossils have been found which still remain "orphan", that is, those, whose precursors are unknown as yet in organisms, such as "bacteriosteranes" (3-alkylsteranes)[3] or tricyclopolyprenanes such as **2**.[4, 5]

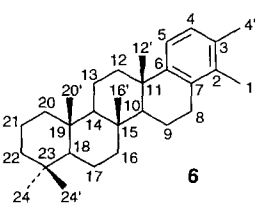




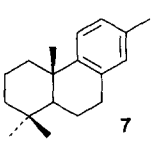
1



2



In the course of investigations of various sediments we have encountered a family of polycyclic hydrocarbons which reveal the existence of an unexpected, biological or at least enzyme-initiated, extended polycyclization of higher regular polyprenols (C_{25}–C_{45}).



Monoaromatic compounds **3**–**6**[6] were isolated from the organic extract of the Eocene Messel shale (FRG) by a combination of silica gel column chromatography and reverse-phase HPLC.[7] Electron impact (EI) mass spectra of hydrocarbons **3**, **4** and **5** exhibit molecular ion peaks at m/z 310 ($C_{23}H_{34}$), 378 ($C_{28}H_{42}$), and 446 ($C_{33}H_{50}$), respectively. The elemental compositions were confirmed by high-resolution mass spectrometry (HRMS) (Table 1). The mass spectra display a common fragmentation pattern similar to that of the podocarpa-8,11,13-triene derivative **7** which can be interpreted according to Azevedo et al.[8] This fragmentation pattern and the signals of smaller characteristic ions, suggest the presence of closely related polycyclopolyprenic structures differing by C_5 isoprenic units. The structures of the three hydrocarbons were unambiguously established by 1D and 2D NMR studies including homonuclear (^1H-^1H, COSY and NOESY) and heteronuclear (^1H-^{13}C, HMQC and HMBC) correlation experiments which also led to the complete assignment of the signals of the protons and carbon atoms (Table 2). Evidently, especially from the sequences of ^{13}C NMR signals, these compounds form a "preno-

Table 1. Selected analytical data for hydrocarbons **3**–**6** and **8**.

3: Waxy compound; $[\alpha]_D^{23} = -46$ ($c = 0.74$ in $CHCl_3$); ^1H NMR: see ref. [6]; UV (*n*-hexane): $\lambda_{max} = 206$ nm; MS (EI, 70 eV): *m/z* (%): 310 (32) [M^+], 295 (93), 199 (8), 197 (5), 185 (7), 183 (4), 171 (57), 159 (23), 158 (23), 157 (100), 145 (48), 137 (61), 131 (31). HRMS: *m/z* 310.2660 [M^+], calcd for $C_{23}H_{34}$ 310.2660; $\delta^{13}C = -31.1 \pm 0.8$‰

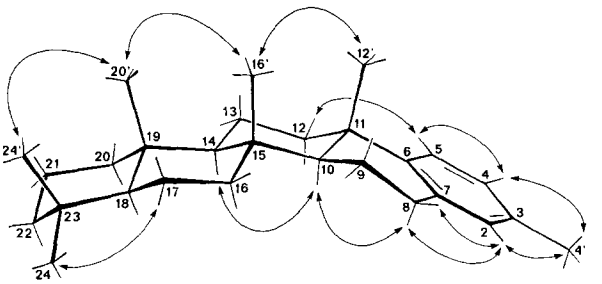
4: M.p. 202–203 °C (needles from CH_2Cl_2/CH_3OH); $[\alpha]_D^{23} = +45$ ($c = 0.77$ in $CHCl_3$); UV (*n*-hexane): $\lambda_{max} = 206$ nm; MS (70 eV): *m/z* (%): 378 (17) [M^+], 363 (54), 239 (2), 225 (3), 205 (13), 199 (3), 197 (4), 191 (5), 185 (3), 183 (5), 171 (100), 159 (14), 158 (12), 157 (28), 145 (17), 137 (9), 131 (15); HRMS: *m/z* 378.3283 [M^+], calcd for $C_{28}H_{42}$ 378.3286; $\delta^{13}C = -33.8 \pm 0.6$‰

5: M.p. 268–269 °C (thin plates from CH_2Cl_2/CH_3OH); $[\alpha]_D^{23} = -38$ ($c = 0.37$ in $CHCl_3$); ^1H NMR: not reported here; UV (*n*-hexane): $\lambda_{max} = 208$ nm; MS (70 eV): *m/z* (%): 446 (10) [M^+], 431 (32), 293 (1), 273 (2), 239 (2), 225 (2), 205 (2), 199 (2), 197 (3), 191 (6), 185 (2), 183 (4), 171 (100), 159 (10), 158 (9), 157 (18), 145 (14), 137 (6), 131 (11); HRMS: *m/z* 446.3917 [M^+], calcd for $C_{33}H_{50}$ 446.3912; $\delta^{13}C = -33.8 \pm 0.3$‰

6: ^1H NMR (assignments by analogy with **4**): $\delta = 7.00$ (d, ^3J(H,H) = 8.0 Hz; H–C(5)), 6.91 (d, ^3J(H,H) = 8.0 Hz; H–C(4)), 2.82 (br. dd, $^{2,3}J$(H,H) = 17.0, 6.0 Hz; Hβ–C(8)), 2.58 (m; Hα–C(8)), 2.36 (ddd, $^{2,3}J$(H,H) = 12.5, 3.0, 3.0 Hz; Hβ–C(12)), 2.22 (s; CH_3(4') or CH_3(1)), 2.09 (s; CH_3(4') or CH_3(1)), 1.20 (dd, ^3J(H,H) = 12.0, 2.0 Hz; H–C(10)), 1.162 (s; CH_3(12')), 1.13 (ddd, $^{2,3}J$(H,H) = 13.0, 13.0, 4.5 Hz; Hα–C(22)), 0.96 (ddd, $^{2,3}J$(H,H) = 12.5, 12.5, 4.0 Hz; Hα–C(16)), 0.929 (s; CH_3(16')), 0.869 (s; CH_3(20')), 0.843 (s; CH_3(24)), 0.825 (s; CH_3(24')); MS (70 eV): *m/z* (%): 392 (21) [M^+], 377 (58), 253 (2), 239 (3), 225 (3), 205 (12), 199 (4), 197 (5), 191 (5), 185 (100), 183 (4), 173 (16), 172 (14), 171 (38), 159 (25), 157 (13), 145 (14), 137 (10); HRMS: *m/z* 392.3436 [M^+], calcd for $C_{29}H_{44}$ 392.3443; $\delta^{13}C = -32.8 \pm 0.1$‰.

8: MS (70 eV): *m/z* (%): 582 (9) [M^+], 567 (27), 429 (6), 355 (10), 341 (6), 239 (7), 225 (5), 191 (13), 171 (100), 159 (9), 158 (11), 157 (18), 145 (11), 137 (5), 131 (10)

logue" series involving the addition of an identical C_5 unit regularly incorporated in the skeleton. These structural relationships are apparent from the striking similarities/analogies shown by the fine structure of the 2D NMR signals and by the coupling patterns of well-resolved signals in the ^1H NMR spectra. In each case, the basic carbon framework was deduced from the HMBC experiment (two- and three-bond heteronuclear correlations, starting from the methyl groups and individual protons). In particular, each methyl group located on a ring junction quaternary carbon atom could be linked to its neighbors (or to the geminal methyl groups) through one common remote connection (^3J) with a methine, therefore establishing the characteristic backbone of the saturated part of the molecule. The chemical shifts of proton and carbon atom signals strongly support a *trans-transoid-trans* stereochemistry with the ring-junction axial methyl groups on the same side of the mean plane of the molecules,[9] which was finally confirmed by the NOEs observed (Fig. 1).



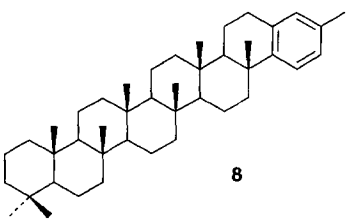


Fig. 1. Spatial representation of **4** (computed by SYBYL 60 software and adapted from a drawing obtained by ALCHEMY III, Tripos Associates Inc., St Louis, Missouri) showing the most important NOEs observed.

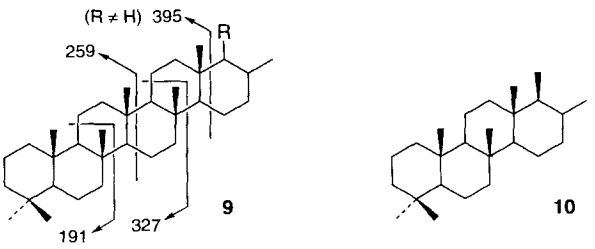
Mass spectrometry (including high resolution measurements) showed **6** has the molecular formula $C_{29}H_{44}$. In comparison with **4**, the prominent fragments containing the aromatic nucleus show a shift upwards of 14 Da, suggesting the presence of an additional methyl group on the aromatic moiety. ^1H NMR data of Table 1 unambiguously indicate that the extra methyl group is located at C(2), since compound **6** displays nearly identical resonances to those of **4** (Table 2), and instead of the signal for the aromatic C(2) proton (singlet), the signal for a methyl substituent on the aromatic ring is observed.

Furthermore, hepta- and octacyclic (**8**) analogues (C_{38} and C_{43}, respectively) of hydrocarbons **3**–**5** also occur in Messel shale, as can be inferred from their mass spectra (Table 1).



Parallel to the identification of these aromatic products, GC-MS investigations of the alkane fractions from Upper Cretaceous sediments (Lameignère quarry near Orthez, France) revealed a series of homologous highly cyclized hydrocarbons (at least up to seven rings) which, from their extremely informative mass

Table 2. ^{13}C NMR data [a] of hydrocarbons **3**–**5** and ^1H NMR data (500.1 MHz) of hydrocarbon **4** (CD_2Cl_2, δ relative TMS).

[a] Measured at 100.1 (**3**) and 125.8 MHz (**4** and **5**). [b] "Biogenetic" numbering. [c] Since absolute configurations are unknown, the α/β notation is relative to the configurations represented in the drawings. [d–f] Values with the same letter are interchangeable.

spectra, are clearly related to the previously identified compounds. Indeed, mass spectra[10] of the members of the usually predominant hexacyclic series, for which we propose structures **9** (R = H, alkyl), display two characteristic fragmentation patterns[11] in which the fragments are regularly shifted by 68 Da (unknown C_{34} hexacyclic compounds exhibiting similar mass spectra have also been detected in high abundance in Canadian sediments[12]). Our structural hypotheses are also strongly supported by mass spectral data reported for scalarane **10**[13] which shows a strikingly similar fragmentation pattern.

All these hydrocarbons can be interpreted in terms of "molecular fossils" of polycyclic precursors deriving from the proton-induced cyclization of all-*trans* regular isoprenoids, such as polyprenols or their equivalents. Figure 2 illustrates the formation

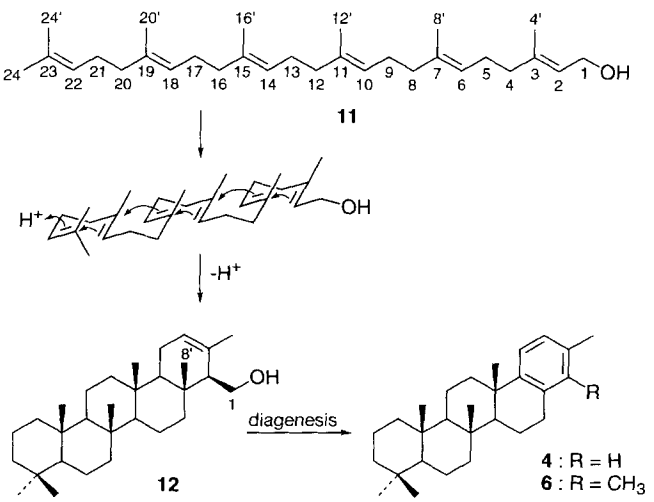

Fig. 2. Proposed biological and diagenetic formation for hydrocarbons **4** and **6**.

of a likely precursor for **4** and **6**, starting from the all-*trans* hexaprenol **11** folded in an all-pre-chair conformation. The resulting pentacyclic triterpenol **12** (or diol if the terminal cationic intermediate is trapped by water) could indeed account for the occurrence of **4** and **6** through well-established geochemical transformations: facultative specific loss of the functionalized C(1) atom (for instance, after oxidation and subsequent decarbonylation or decarboxylation, further facilitated by the presence of a double bond in the β-position, and aromatization starting in the functionalized ring with concomitant loss of the angular methyl group $CH_3(8')$) as commonly observed for pentacyclic triterpenes.[14] Alternatively, reductive processes could explain the presence of the saturated series in sediments. The homologous compounds might be formed by the progressive degradation of a side chain, the latter resulting from an incomplete cyclization of the acyclic precursor.

An important question which remains is whether this cyclization process is biological or not. Indeed, a clay-catalyzed cyclization of polyprenols in sediments such as **11** would, for instance, lead to a compound such as **12**. This can be inferred from the results of biomimetic cyclizations[15] of lower regular polyprenols and of related products catalyzed by acids or superacids as well as of a sesterterpenol (all-*trans* geranylfarnesol), the potential precursor of **3**. Specific rotation measurements (Table 1) showed that the isolated products **3**–**5** are optically active. Hence, if one precludes the very unprobable selective removal of one enantiomer, for instance by biodegradation processes, it is reasonable to assume that the cyclization is enzymatically initiated.[16]

The detection in sediments of high molecular weight biomarkers, which result from the cyclization of regular polyprenols, is not unprecedented, albeit as yet restricted to tricyclic compounds. Indeed, saturated (e.g. **2**) or aromatic (e.g. **7**) tricyclic hydrocarbons in the C_{19} to C_{54} range have been identified or detected in geological sources where they are widely distributed, though not as ubiquitous as the hopanoids.[4] These products have been interpreted as being the molecular fossils of natural as yet unknown tricyclopolyprenols arising from the partial, proton-induced, enzyme-mediated cyclization of higher polyprenols (C_{30} to C_{55}). Remarkably, a cell-free system from the protozoon *Tetrahymena pyriformis*, known to cyclize squalene to tetrahymanol, is also able to cyclize all-*trans* pentaprenyl and hexaprenyl methyl ether into various polycyclic isoprenoids, thus providing direct proof for a proton-induced enzymatic cyclization of higher polyprenol derivatives.[17] The cyclization of hexaprenyl ether led to di-, tri-, tetra-, and pentacyclic skeletons, suggesting the mediation of a rather low-specific enzyme, maybe squalene cyclase itself. With regard to these observations, it appears quite reasonable to envisage that any cyclase capable of (accidentally?) initiating a cyclization process which can proceed stepwise without enzymatic control (as in biomimetic experiments[15c]) might explain the formation of the fossil molecule precursors. Moreover, such a scenario could account for the existence of the diversely cyclized hydrocarbons in sediments, starting from *one* polyprenol precursor (long-chain all-*trans* polyprenoids are widespread in organisms, e.g. side chains of ubiquinones[18]), the side chain having been partially degraded or completely removed during the sedimentation process, as, for example, in the tricyclopolyprenic series. Another possible way of formation could involve an abiotical (clay-catalyzed?) cyclization of biogenic tricyclopolyprenols. In the Messel shale, however, no trace of side chain degradation intermediate products or even of the saturated tricyclopolyprenic series could be detected, making these hypotheses appear highly unlikely, and it is more probable that in this case compounds **3**–**6** and **8** result from the complete cyclization of different polyprenols.

The origin of the hydrocarbons discussed here is unknown. Only compound **3** can eventually be related to known precursors since scalarane derivatives have been described as abundant constituents of sponges (or their symbionts).[19] For the higher cyclized hydrocarbons, neither their presumed biogenic polycyclic precursors (polycyclopolyprenols) nor related biomolecules bearing a potentially adequate framework have as yet been found in living organisms.[20] The postulated precursors of these highly cyclized polyprenic hydrocarbons can be viewed as the representatives of a new class of molecules whose natural distribution and biological significance remains to be determined, although the possibility of "accidental" enzymatic cyclization of regular isoprenoids such as polyprenols by a cyclase with little substrate specificity cannot be ruled out.

[6] The structure of **3** was presented at the 13th International Symposium on Polynuclear Aromatic Hydrocarbons, Bordeaux, France, October 1–4, 1991: V. Hauke, J. M. Trendel, P. Albrecht in *Polycyclic Aromatic Compounds* (Eds.: P. Garrigues, M. Lamotte), Gordon and Breach Science Publishers, Switzerland, **1993**, p. 451.
[7] For isolation procedure of **3**, see ref. [6]. For isolation of **4**–**6**, the HPLC column used was a Du Pont Zorbax ODS 250 × 9.4 mm, 7 μm, 80 Å (MeOH/$CHCl_3$ 80:20). Compounds **3** (9 mg), **4** (10 mg), and **5** (5 mg) each represent about 10–20 ppm of the total organic extract (35 $g\,kg^{-1}$ shale) and their purity was at least of 94% (GC evaluation). **6** (0.2 mg) was contamined by a known compound (< 10%).
[8] D. A. Azevedo, F. R. Aquino Neto, B. R. T. Simoneit, *Org. Mass Spectrom.* **1990**, *25*, 475, and references therein.
[9] Thus, all methyl groups on ring junctions display high-field ^{13}C chemical shifts $\delta < 20$ (except for the C(12′) methyl: $\delta \approx 26$), which is consistent with their axial orientation on all-*trans* structures (presence of *γ-gauche* effects). The resonances of axial methylene (*J* ca. 13.0, 13.0, 4.0 Hz plus eventually a ^4J W-type coupling ≤ 1 Hz) and axial methine (*J* ca. 12.5, 2.0 Hz) protons which are *trans* relative to the axial methyl groups (i.e. for **4**, Hα–C(12), Hα–C(16), Hα–C(20), Hα–C(22), and H–C(10), H–C(14), H–C(18), respectively) appear at high-field (generally $\delta < 1.15$, less marked for Hα–C(12) and H–C(10) under the deshielding influence of the aromatic moiety). This observation combined with the deshielding of the associated methylene ($37 < \delta < 43$) and methine ($56 < \delta < 62$) carbon atoms point to the absence of *γ-gauche* effects with any of these methyl groups. Conversely, the high-field ^{13}C shifts recorded ($18 < \delta < 20$) for the remaining methylene moieties—C(8) excepted—(i.e. for **4**, C(9), C(13), C(17), and C(21)) together with the deshielding of their attached axial protons ($\delta > 1.2$) reflect double and triple *γ-gauche* interactions with the methyl groups.
[10] MS data (EI 70 eV): *m/z* (%): for **9**, R = H: 466 (25) [M^+], 451 (32), 327 (19), 285 (72), 259 (60), 217 (100), 191 (57), 149 (24); **9**, R = Me: 480 (30) [M^+], 465 (32), 395 (24), 327 (37), 299 (57), 259 (73), 231 (100), 191 (71), 163 (97); **9**, R = Et: 494 (22) [M^+], 479 (30), 395 (100), 327 (15), 313 (23), 259 (36), 245 (39), 191 (36), 177 (51); **9**, R = Pr: 508 (20) [M^+], 493 (25), 395 (100), 327 (45), 259 (70), 191 (59).
[11] The first fragmentation pattern, shown on structures **9**, remains unchanged along the hexacyclic series (the prominent ion peak at *m/z* 395 is present only when R ≠ H and becomes the base peak for R ≥ Et), whereas the second, which concerns the right part of the molecules bearing the side chain, displays ions whose masses are shifted according to the homologue under consideration (*m/z* $149 + n \times 14$, $217 + n \times 14$, $285 + n \times 14$, $n = 0$ and R = H for the C_{34} homologue).

[16] Furthermore, it should be noted that structures differing by a C_5 isoprenic unit have opposite signs of optical rotation. Therefore, if it is assumed that they also have alternate partial enantiomeric structures and that the immediate stereochemical surroundings of the aromatic ring—that is, configurations at C(10) and C(11)—is determinant for the sign of the optical rotation, we can tentatively assign the absolute configurations of the isolated hydrocarbons as being those represented, given that abieta-8,11,13-triene, which has a structure analogous to that of the tricyclic member of the series, **7**, (also present in the Messel shale) and the absolute configuration of which is known, is dextrorotatory (O. Jeger, O. Dürst, G. Büchi, *Helv. Chim. Acta* **1947**, *30*, 1853).

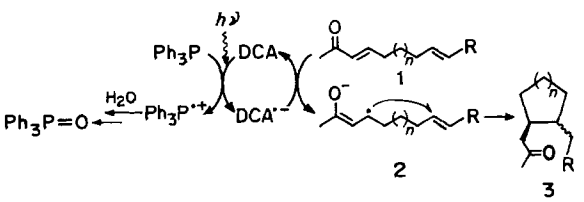
[20] Carbon isotopic compositions ($^{13}C/^{12}C$) of aromatic hydrocarbons **3**–**6**, measured by gas chromatography–isotope ratio mass spectrometry and expressed by the $\delta^{13}C$ values, fall within a rather narrow range (−30.5 to −34.5‰), hence indicating a probable common origin. These values are markedly different from those recorded, from the same Messel shale sample, for higher plant pentacyclic triterpene derivatives (−23 to −25‰) and at the boundary of those of aromatic and saturated hopanoid hydrocarbons (−34 to −66‰), a wide range reflecting the diversity of the procaryotic organisms operating in natural environments. It is interesting to note that the monoaromatic-ring-*A* gammacerane derivative, likely originating from protozoa (H. R. Harvey, G. B. McManus, *Geochim. Cosmochim. Acta* **1991**, *55*, 3387, and references therein), has a value (−33.1‰) which would fit well with those of our newly identified compounds. $\delta = 10^3[(R_x - R_s)/R_s]$, where $R = {}^{13}C/{}^{12}C$, x designates sample, s the PDB standard (PDB = Peedee Belemnite; the standard is a belemnite from the Pedee Formation in South Carolina) and $R_s = 0.0112372$. Mean values from at least three replicate measurements.

A Novel Photosystem for Harvesting Visible Light to Drive Photoinduced Electron Transfer (PET) Reductions: β-Activation of α,β-Unsaturated Ketones for Radical Cyclizations**

Ganesh Pandey* and Saumen Hajra

The past decade has witnessed substantial, multidisciplinary research efforts directed towards the conversion of solar light into useful chemical energy; most of the approaches are based on photoinduced electron transfer processes.[1] In organic chemistry several new and synthetically important organic photoreactions have been discovered that employ electron transfer (ET) to or from the substrate in the presence of an electron-rich donor or electron-poor acceptor.[2] Interestingly, remarkable progress has also been made in the area of photoinduced electron transfer (PET) reactions, though the chemistry of the radical cations generated by oxidative reactions remains at the focus.[3] Despite the great synthetic potentials of photosensitized one-electron reductions in organic synthesis, research in this area has been limited, owing to the lack of a suitable photosystem.[4]

Our own interest[3, 5] in this area has been centered on the application of PET oxidation reactions of select donors and cyanoarenes (ArCN) as light-absorbing electron acceptors. Our photosensitization concept relies on the thermodynamic feasibility of ET from $ArCN^{\bullet -}$ to O_2 followed by disproportionation of $O_2^{\bullet -}$ as shown in Scheme 1.



Scheme 1. Mechanism of the PET oxidation of an electron donor D.

The above mechanistic premise led us to envision that photochemical excitation of a system comprising a sacrifical electron donor and ArCN in argon atmosphere should be able to drive a second ET from $ArCN^{\bullet -}$ to another molecule, provided that

[**] This work was supported by the University Grant Commission, New Delhi (Research Fellowship to S.H.). We are grateful to Dr. S. Padhye and A. Kumbhar (University of Poona) for measuring the reduction potentials of the enones.

the redox potentials are matched. For this purpose we have developed a photosystem consisting of triphenylphosphane (Ph_3P) as the sacrificial electron donor and 9,10-dicyanoanthracene (DCA) as the visible-light-absorbing electron acceptor[6] for activating the β position of α,β-unsaturated ketones for radical cyclizations (**1** → **3**) by reductive transfer of one electron (Scheme 2). To our knowledge, the concept[7] described here provides a novel nonreagent-based strategy for the β-activation of enones for radical additions. The generation of radical cations by redox sensitization has been reported.[8] The synthetic potential of this work is comparable to only one other method reported recently[9] which makes use of a toxic and environmentally unfriendly stannyl reagent.

Scheme 2. Mechanism of PET-driven reductions with Ph_3P as a sacrificial electron donor.

The PET phenomena established by our group[6] between Ph_3P and ^{1}ArCN* and the efficient transformation of $Ph_3P^{\bullet+}$ to stable triphenylphosphane oxide (Ph_3PO) by reaction with water led us to select Ph_3P as the sacrificial electron donor. Furthermore, because of the efficiency of the transformation of $Ph_3P^{\bullet+}$ to Ph_3PO, we thought that Ph_3P would be an ideal substrate for controlling the impact of back electron transfer, the intrinsic limitation of PET processes[1] in our photosystem. We chose α,β-unsaturated ketones for the study of sensitized one-electron reduction processes, as they should be suited for testing our concept and for exploring the interesting synthetic avenues of free-radical reactions.

The feasibility of ET from $DCA^{\bullet-}$ to **1** was evaluated by estimating the Gibbs free energy change from the redox potentials of $DCA^{\bullet-}$ (−0.89 eV)[2] and **1** (−0.40 to −0.76 eV)[10, 11] according to $\Delta G_{ET} = E_{1/2}(ox) - E_{1/2}(red)$ (Table 1).

Table 1. Free energy change ΔG_{ET} for electron transfer from $DCA^{\bullet-}$ to enones **1**, **4**, and **7**.

Enone [a]	E_{red} [b, c] [eV]	ΔG_{ET} [kJ mol^{-1}]
1a	−0.40	−47.25
1b	−0.45	−42.43
1c	−0.73	−15.44
1d	−0.68	−20.25
4	−0.76	−12.51
7	−0.70	−18.30

[a] Formulas given in Table 2. [b] Determined by cyclic voltammetry, relative to SCE [10]. [c] Since the reductions are irreversible, the cathodic peak potentials are listed.

A solution of Ph_3P, DCA, and one of the enones **1a–d** in aqueous dimethylformamide (DMF)[12] with isopropyl alcohol as the H• donor was irradiated with visible light (λ = 405 nm) to provide cyclization products **3a–d** formed via free radicals (Table 2); the major diastereomer in each case has the *trans* configuration.[13] An alternative route for the formation of these products involving first [2 + 2]cycloaddition followed by one-electron reductive C–C bond cleavage[14] can be ruled out, since the enones do not absorb light under the experimental conditions. The quantum yields (ϕ = 0.011–0.063) for the product formation clearly indicates that the products are not arising through the chain reactions. Since the transformation of Ph_3P into Ph_3PO is a sequential, two-electron process,[6] Ph_3P can provide two successive electrons for reduction. Therefore, only one molecule of Ph_3P is required to reduce two molecules of enone. Secondary cyclization products such as bicyclo[3.3.0] compounds from the corresponding *cis* isomers of **3a–b** like those observed by Enholm and Kinter[9] were absent in our reactions, possibly because the β-carbon atoms of enolates are less nucleophilic than those of stannyl enolates.

Table 2. Photosensitized reductive cyclizations of enones **1**, **4**, and **7**.

Enone	Product(s) [a] (quantum yield, ϕ) [b]	t[h] [c]	Yield [%] (*trans*/*cis*) [a]
1	**3**		
a, n = 1, R = COOEt	(0.060)	28	98(85/15)
b, n = 1, R = CN	(0.063)	31	97(80/20)
c, n = 2, R = CN	(0.032)	42	94(68/32)
d, n = 2, R = COOEt	(0.030)	40	95(75/25)
4	**5** **6**		
	70:30	50	55
	(0.013) (0.006)		
7	**8** **9**		
	68:32	50	50
	(0.011) (0.005)		

[a] The *cis*/*trans* and product ratios were determined by gas chromatography (Perkin Elmer 8700; HP capillary column, cross-linked methyl silicone, 25 m). [b] Quantum yields were determined with an instrument from Applied Photophysics; light intensities estimated by using uranyl oxalate as a chemical actinometer; product formation measured by HPLC (Perkin Elmer 135C, diode-array detector, C_8 reversed-phase column).

We have also examined the cyclization of enones **4** and **7**, which are nonactivated alkene acceptors. Unlike Enholm and Kinter,[9] we found that these compounds underwent cyclization to produce **5** and **8**, albeit in slower rates, as well as reduction products **6** and **9**.

In summary, we have developed a novel photosystem for converting the photoenergy of visible light into chemical energy. This concept has potential in organic chemistry for a variety of one-electron reduction processes. Further studies are in progress.

Experimental Procedure

A solution of one of the enones **1a–d**, **4**, or **7** (3.60 mmol), Ph_3P (2.1 mmol), and DCA (1.4 mmol) in DMF/*i*PrOH/H_2O (88/10/2) was irradiated in Pyrex tubes under an argon atmosphere with light from a 450 W Hanovia medium-pressure lamp filtered by a $CuSO_4 \cdot 5H_2O \cdot NH_3$ solution (405 nm) [15]. The progress of the

reaction was monitored by GC. After considerable consumption (60–99%) of the starting enone (approximately 28–50 h) the solvent was removed by distillation under reduced pressure. Chromatographic purification (silica gel, 200 mesh) of the reaction mixture eluting with petroleum ether/ethyl acetate gave the cyclization product (**3a**–**d**, **5**, or **8**) along with Ph_3PO. DCA was recovered (98%). The products were characterized by ^1H and ^{13}C NMR spectroscopy and mass spectrometry. **3a** and **3b** were confirmed by comparing with authentic samples [9].

N-Heteroarene Dianions as Antiaromatic Ligands Bridging two Lanthanocene Moieties**

Joachim Scholz,* Annett Scholz, Roman Weimann, Christoph Janiak, and Herbert Schumann

Pyrazine serves as a model ligand for studying magnetic exchange phenomena,[1] electron transfer reactions,[2] or one-dimensional conductors.[3] With its two N-donor functions, this heterocycle can coordinate to Lewis acidic metal centers and at the same time bridge two metal atoms.[4] The π-acceptor characteristics (low-lying LUMOs) of this bridging ligand enable, under suitable conditions, the generation of, for example, stable radical ions from these binuclear complexes.[5]

Quinoxaline and phenazine represent benzo- and dibenzo-annelated derivatives of pyrazine, respectively; in contrast to the parent compound pyrazine, these heterocycles can be reduced to their dianions either electrochemically[6] or by alkali metals.[7] The formally antiaromatic systems with 12-π and 16-π electrons have high charge density and, so far, could be stabilized in only a few cases by presence of alkali and alkaline earth ions.[8] We have found now that the resulting electron-rich N-heteroarene dianions can bridge two lanthanocene moieties. Here we report on the synthesis and crystal structure analysis of complexes **4a** and **4b**, which are the first examples of this new class of compounds.

2,3-Dimethylquinoxaline (**1a**) is rapidly reduced by two equivalents of sodium in THF to give a deep blue solution containing the 12-π dianion **2a**. This dianion reacts with **3** in a 2:1 molar ratio to yield the novel, binuclear lanthanocene complex **4a**, which can be isolated as dark green, extremely air- and moisture-sensitive crystals (Scheme 1). On the basis of the NMR

Scheme 1. dme = dimethoxyethane.

spectra one can already expect unusual bonding properties for this compound. For example, the signals for H atoms H24 and H24a′ ($\delta = 4.22$) and for H25 and H25a′ ($\delta = 5.66$, AA′XX′ spin system, numbering scheme according to Fig. 1) of the 2,3-dimethylquinoxaline heterocycle are shifted to higher field by $\Delta\delta = 3$ and 2.4, respectively, when compared to the free ligand.[9] The nonuniform charge distribution is indicative of a paramagnetic ring current, which is characteristic for systems with $4n$ π electrons such as naphthalene–lithium $Li_2[C_{10}H_8]$.[10b] Atoms C24 and C24′ of the bridging ligand are also strongly shielded ($\delta = 89.9$). In contrast to the ^1H NMR signals, the ^{13}C NMR signal positions are barely influenced by ring-current effects and reflect, for the most part, the actual charge distribution. Hence, the negative charge density in the bridging ligand of **4a** is even higher than in 2,3-diphenylquinoxaline disodium $Na_2[C_8H_4N_2$-(2,3-Ph_2)] (corresponding signal at $\delta = 100.3$).[7] This observation contrasts with those for the recently described 1,4-dihydroquinoxaline derivative 1,4-$[Me_2(tBu)Si]_2(C_8H_6N_2)$ in which the charge density of the $4n$ π electron system is transferred to the stabilizing R_3Si-acceptor substituents through covalent N–Si bonds; moreover, the extent of electron delocalization from the heteroarene to the arene unit is small.[8e]

Figure 1 shows the result of the X-ray structure analysis of **4a**.[11] The two Cp^*_2La moieties face each other and are bound

to the planar quinoxaline dianion. From an electrostatic point of view the N atoms of the bridging ligand are the more favorable ligating atoms for the lanthanocene moieties; hence, the La–N contacts are short [La–N1 2.409(4), La–N1a 2.444(4) Å] and are of the same magnitude as La–N distances reported previously.[12] The two La atoms are located 1.770(5) Å below and above the quinoxaline plane. This finding is indicative of a partial π character for the La–N interactions. Additional interactions with quinoxaline atoms C24 and C24′ are in line with the tendency of La atoms to attain a higher coordination number. The La–C distances are only marginally larger than the average La–C_{Cp*} distance (2.789 and 2.806 Å) or those reported recently for the $[La(\eta^3\text{-}C_3H_5)_4]^-$ ion (La–$C_{average}$ 2.811 Å).[13] The remarkable high-field positions of the ^{13}C NMR signals of C24 and C24′ and the relatively small $^1J_{C,H}$ coupling constant of only 144.4 Hz indicate that these La–C interactions persist even in solution and that an agostic C–H → La bond is present.

The ^1H NMR spectrum of the phenazine complex **4b** points to a similar bonding arrangement. This complex is obtained in form of orange crystals when a bordeaux-red suspension of $Na_2[C_{12}H_8N_2]$ (**2b**, prepared by reacting phenazine (**1b**) with Na granules in THF for several days) is added to **3**. Complex **4b** is extremely air- and moisture-sensitive and is less soluble in *n*-pentane, diethyl ether, or toluene than **4a**. Figure 2 shows the structure of **4b** in the crystal.[11] The important structural characteristics of **4a** and **4b** are identical. As in **4a**, the La atoms in **4b** are bound to the planar bridging ligand by short contacts with the N atoms and by additional interactions with C22 and C22′. The La atoms are positioned 1.870(5) Å above and below the phenazine plane. The outstanding structural feature of **4b** is, without a doubt, the staggered arrangement of the two Cp^*_2La moieties on the periphery of the bridging ligand. In this arrangement the dipolar repulsion between the two Cp^*_2La moieties is minimized.

4b

The bonding interaction between the La atoms and the carbon atoms of the bridging ligands (i.e., C24 and C24′ in **4a**, C22 and C22′ in **4b**) can easily be rationalized. A PM3 calculation[14] for the phenazine- and the 2,3-dimethylquinoxaline dianion shows not only the expected high charge density on the N atoms but also charge maxima located at exactly those ring carbon atoms (Fig. 3). In contrast, quaternary C atoms (i.e., C23 and C23′ in **4a**, C21 and C21′ in **4b**) adjacent to the N atoms are positively polarized. Their relatively short distance to the La atoms is, therefore, not the result of a bonding interaction with the metal but is apparently forced by the special manner of coordination behavior of the bridging ligands. Relative and absolute bond length variations of the N heterocycles,[9] as determined by crystal structure analysis of **4a** and **4b**, can also be rationalized by PM3 optimization of their respective dianionic structures.

Even in unpolar solvents such as $[D_8]$toluene, the partial La–N π interaction, which explains the deflection of the Cp^*_2La moieties out of the heteroarene plane, is apparently removed. All four Cp* ligands of **4a** and **4b** show only one sharp signal in the ^1H NMR spectrum at room temperature. This Cp* signal, as well as the signals for the H atoms of the 2,3-dimethylquinoxaline in **4a** remain almost unchanged upon cooling the sample

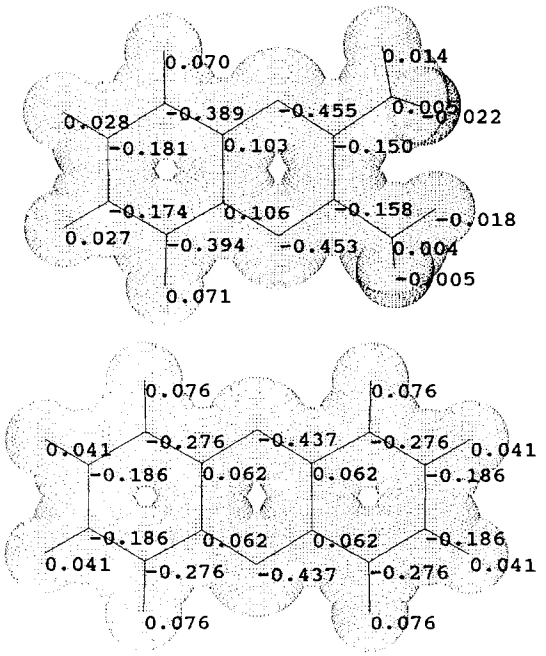

Fig. 3. Charge distribution for the PM3-optimized [14] 2,3-dimethylquinoxaline (top) and phenazine dianions (bottom).

to -80 °C (500 MHz; see Experimental Procedure). However, it cannot be ruled out that even at low temperatures the Cp^*_2La moieties, for example, rotate around the La–N bond. It is worth mentioning that cooling of a toluene solution of **4a** results in a reversible color change from green to dark red.

Complexes **4a** and **4b** represent a novel structural type for organolanthanides, which is reminiscent of the mostly ionic "aromatic alkali-metal amides".[15] Due to their high charge density both the quinoxaline and the phenazine dianions, which can be regarded as heteroatom-modified $4n\,\pi$ anti-Hückel systems, are of special interest as "molecular bridges". We are currently investigating complexes in which two paramagnetic metal centers are connected by these antiaromatic bridging ligands.

Experimental Procedure

All experiments were carried out with thoroughly dried and degassed solvents under an inert argon atmosphere.

4a: In 100 mL THF 2,3-dimethylquinoxaline (1.29 g, 8.15 mmol) was treated with sodium (0.375 g, 16.31 mmol), until all of the metal had been consumed and a deep blue solution was formed. This solution was then added dropwise at -50 °C to a solution of $[Cp^*_2La(\mu\text{-}Cl)_2K(dme)_2]$, prepared by adding $LaCl_3$ (4.0 g, 16.31 mmol) to [Cp*K(dme)] (8.61 g, 32.6 mmol) in 200 mL THF). After warming the reaction mixture to room temperature and removing the solvent under vacuum, **4a** was isolated by extraction of the residue with 100 mL diethyl ether. Recrystallization from *n*-pentane yielded 2.77 g (17%) of dark green crystals, which were suitable for crystal structure analysis. $T_{decomp.} \approx 115$ °C. Correct elemental analysis.—^{1}H NMR (300 MHz, C_6D_6, 20 °C): $\delta = 5.66$ (m, $^3J(H_A,H_X) = 6.0$ Hz, $^4J(H_A,H_X) = 1.3$ Hz, 2H; $C_8H_4N_2$-2,3-Me_2), 4.22 (m, $^3J(H_A,H_X) = 6.0$ Hz, $^4J(H_A,H_X) = 1.3$ Hz, 2H; $C_8H_4N_2$-2,3-Me_2), 2.22 (s, 60H; C_5Me_5), 1.50 (s, 6H; $C_8H_4N_2$-2,3-Me_2); ^{1}H NMR (500 MHz, [D$_8$]toluene, -80 °C): $\delta = 5.73$ (m, 2H; $C_8H_4N_2$-2,3-Me_2), 4.23 (m, 2H; $C_8H_4N_2$-2,3-Me_2), 2.04 (s, 60H; C_5Me_5), 1.50 (s, 6H; $C_8H_4N_2$-2,3-Me_2); ^{13}C NMR (75 MHz, C_6D_6, 25 °C): $\delta = 150.7$ (s, $C_8H_4N_2$-2,3-Me_2), 122.2 (s, $C_8H_4N_2$-2,3-Me_2), 119.8 (dd, $^1J(C,H) = 159.3$ Hz; $C_8H_4N_2$-2,3-Me_2) 119.1 (s, C_5Me_5), 89.9 (ddd, $^1J(C,H) = 144.4$ Hz; $C_8H_4N_2$-2,3-Me_2), 18.5 (q, $^1J(C,H) = 124.6$ Hz; $C_8H_4N_2$-2,3-Me_2), 9.6 (q, $^1J(C,H) = 125.2$ Hz; C_5Me_5).

4b: In 100 mL THF, phenazine (1.47 g, 8.15 mmol) was treated with sodium (0.375 g, 16.31 mmol). The resulting bordeaux-red suspension was then added dropwise at -50 °C to a solution of $[Cp^*_2La(\mu\text{-}Cl)_2K(dme)_2]$, prepared by adding $LaCl_3$ (4.0 g, 16.31 mmol) to [Cp*K(dme)] (8.61 g, 32.6 mmol) in 200 mL THF. After warming the reaction mixture to room temperature and removing the solvent under vacuum, the residue was extracted with diethyl ether. From this extract, **4b** separated in the form of orange-red crystals (yield 1.63 g, 10%). Recrystallization of this material from diethyl ether gave single crystals suitable for crystal structure analysis. $T_{decomp.} \approx 80$ °C. Catalytic Pt^+-Mediated Oxidation of Methane by Molecular Oxygen in the Gas Phase**

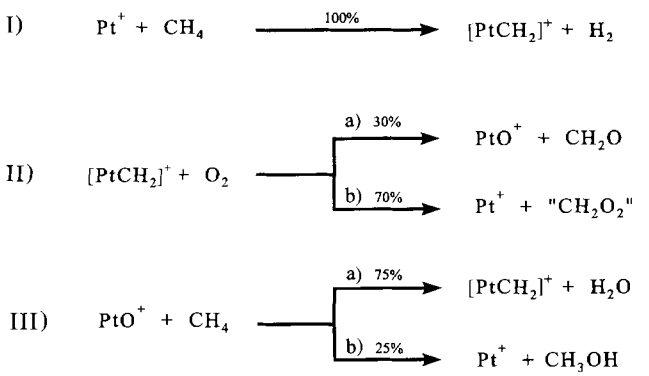
Ralf Wesendrup, Detlef Schröder, and Helmut Schwarz*

Dedicated to Professor Heinz-Georg Wagner on the occasion of his 65th birthday

The activation of methane represents a fundamental challenge in chemistry, and the catalytic conversion of methane to methanol or formaldehyde is both of scientific and economic interest.[1] At metal surfaces activation of methane often commences with a homolytic C–H bond cleavage and proceeds by reactions of the so-formed methyl radicals with an oxidant. Alternately, the reaction of methane with a transition metal center [M] may lead either to a metal-bonded hydrido methyl fragment, $H-M-CH_3$, or a carbene species, $M=CH_2$, with subsequent O-atom transfer to form the oxygenated products. Furthermore, direct oxidation of methane can be achieved by reactive oxo species, for example, high-valent transition metal oxides, which are recovered in the catalytic process. In a more classical fashion, methane functionalization may also proceed by ionic mechanisms in which either a proton or a hydride is abstracted or protonation take place.[2]



The high catalytic activity of platinum has been known since the last century, and platinum-based catalysts are widely used in reduction as well oxidation processes.[3] Although heterogeneous catalysis is one of the most actively pursued research areas, this approach often fails to provide an understanding of the chemistry at a molecular level. In contrast, more direct mechanistic information may be obtained in gas-phase experiments in which the reactions of "naked" metal ions with neutral substrates can be probed under relatively well-defined conditions.[4]

Recently, Irikura and Beauchamp[1b, 5] discovered that "naked" third-row transition metal cations are capable of dehydrogenating methane in a stoichiometric fashion in the gas phase to yield the methylene complexes $[M=CH_2]^+$.[6] Here, we report the design and realization of a catalytic cycle[7] for the gas-phase oxidation of methane under the conditions of Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry.[8]

As reported earlier,[5] thermalized Pt^+ ions dehydrogenate methane to yield the carbene complex $[PtCH_2]^+$ (Scheme 1, process I). Although the rate constant k_R ($k_R = 8.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) is somewhat smaller than the collision rate constant k_{ADO} ($k_{ADO} = 9.8 \times 10^{-10}$ cm^{-3} molecule^{-1} s^{-1}; ADO = average dipole orientation),[9] the reaction is quite efficient if one takes into account that CH_4 is a small, symmetric molecule with low polarizability and strong C–H bonds. Thermochemical considerations[10] lead to the conclusion that, since reaction I occurs at thermal energies, the reaction enthalpy (ΔH_r) for methane dehydrogenation is negative, and, thus, the heat of formation (ΔH_f) of $[PtCH_2]^+$ is smaller than 316 kcal mol^{-1}; furthermore, the observation of reaction II (see below) sets a lower limit for $\Delta H_f[PtCH_2]^+$ at 308 kcal mol^{-1}; in the following, we will use an averaged value of $\Delta H_f[PtCH_2^+] = 312 \pm 4$ kcal mol^{-1}; from this one derives a Pt^+-CH_2 bond dissociation energy of $BDE(Pt^+-CH_2) = 115 \pm 4$ kcal mol^{-1}.[10b]

Scheme 1. Formation and reactions of $[PtCH_2]^+$ and $[PtO]^+$, as well as the formation of the methane oxidation products CH_3OH, CH_2O, and "CH_2O_2".

The intramolecular kinetic isotope effects (KIEs) associated with the Pt^+-mediated dehydrogenation of CH_2D_2 can be deduced from the relative abundance of $[PtCD_2]^+$, $[PtCHD]^+$, and $[PtCH_2]^+$, which are formed in a 2.5:6.5:1.0 ratio. Because formation of $[PtCHD]^+$ from CH_2D_2 is favored by a factor of 4 over the other two isotopomers, the statistically weighted ratio is 2.5:1.6:1.0 for H_2, HD, and D_2 losses, respectively. According to the mechanism depicted in Scheme 2, these data can be

Scheme 2. Scheme for the kinetics of the reactions of Pt^+ and CH_2D_2.

analyzed in terms of intramolecular kinetic isotope effects associated with the rates of the insertion step (^1k), the α-hydrogen transfer (^2k), and the reductive elimination of dihydrogen (^3k),[11] as described in Equations (a)–(c).

$$k_{H_2}/k_{HD} = 0.5(^1k_H/^1k_D + {}^2k_H/{}^2k_D) \times {}^3k_{H_2}/{}^3k_{HD} = 1.6 \quad \text{(a)}$$

$$k_{H_2}/k_{D_2} = (^1k_H/^1k_D)(^2k_H/{}^2k_D)(^3k_{H_2}/{}^3k_{D_2}) = 2.5 \quad \text{(b)}$$

$$k_{HD}/k_{D_2} = 0.5(^1k_H/^1k_D + {}^2k_H/{}^2k_D) \times {}^3k_{HD}/{}^3k_{D_2} = 1.6 \quad \text{(c)}$$

Although an exact solution of the set of equations (a)–(c) is not possible, from (a) and (c) we can conclude that $^3k_{HD} = (^3k_{H_2} \times {}^3k_{D_2})^{1/2}$. Such a correlation is typical for a rate-determining reductive elimination of molecular hydrogen from a symmetrical transition structure.[12] Accordingly, $^1k_H/^1k_D$ as well as $^2k_H/^2k_D$ are close to unity, and the observed intramolecular kinetic isotope effect associated with the rate-determining reductive elimination step (^3k) is about 1.6 per H atom. It is noteworthy that in contrast to other methane activation processes,[1] for Pt^+ the initial C–H bond insertion does not contribute to the rate-determining step. In view of the differences usually expected for intra- and intermolecular kinetic isotope effects,[13] our findings are in good agreement with the minor KIE associated with the Pt^+-mediated activation of CD_4 ($k_H/k_D = 1.3$).[5]

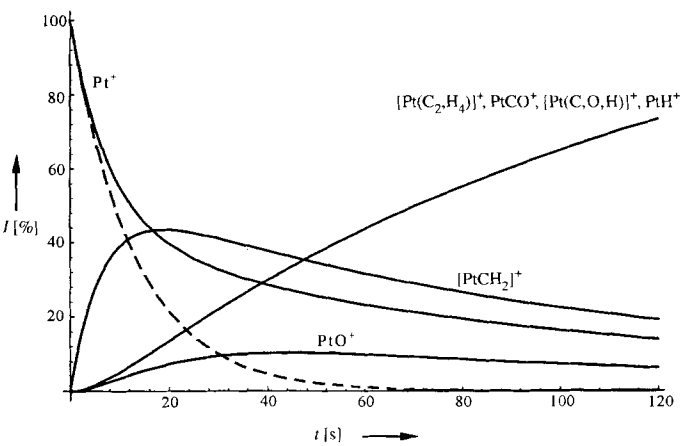
A catalytic process for the gas-phase oxidation of methane must regenerate the consumed Pt^+ for further cycles. The $[PtCH_2]^+$ intermediate must therefore be oxidized by an appropriate reagent. Interestingly, and in contrast to other examples,[14] nitrous oxide does not serve as an oxidant donating a single O atom, and N_2O is completely unreactive towards $PtCH_2^+$, although the formation of Pt^+, formaldehyde, and nitrogen is exothermic by 24 kcal mol^{-1}. However, $[PtCH_2]^+$ reacts with molecular oxygen to form Pt^+ and the monoxide PtO^+ as the ionic products (Scheme 1, reaction II); thermalized Pt^+ does not react with O_2, but with N_2O yields the monoxide cation PtO^+. Although reaction II is exothermic for both products (see below), it is relatively slow relative to the collision rate ($k_R = 0.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}; $k_{ADO} = 5.6 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}), which indicates that a barrier is associated with the activation of dioxygen by $[PtCH_2]^+$. We cannot deduce the structures of the neutral products in our experimental ICR setup; however, thermodynamic considerations imply that formaldehyde is formed in reaction IIa ($\Delta H_R = -4 \pm 4$ kcal mol^{-1}). In reaction IIb the situation is not as straightforward, since several possibilities such as formic acid or its thermolysis products carbon monoxide/water or carbon dioxide/dihydrogen are thermochemically accessible ($\Delta H_R = -69 \pm 4$ kcal mol^{-1} (HCO_2H), -63 ± 4 kcal mol^{-1} (CO/H_2O), and -73 ± 4 kcal mol^{-1} (CO_2/H_2O)).[15]

The PtO^+ cation also contributes to the catalytic cycle, since it is recovered as Pt^+ after reaction with methane (Scheme 1, reaction III). Not unexpected for a transition metal oxide cation (e.g. FeO^+),[16] reaction III is collision-controlled ($k_R = 10.5 \pm 10^{-10}$ cm^3 molecule^{-1} s^{-1}; $k_{ADO} = 9.8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) and gives rise to $[PtCH_2]^+$ and neutral water ($\Delta H_R = -61 \pm 4$ kcal mol^{-1}), or Pt^+ and methanol ($\Delta H_R = -30$ kcal mol^{-1}). When CH_2D_2 is employed as reaction partner, reaction III leads to $[PtCD_2]^+$, $[PtCHD]^+$, and $[PtCH_2]^+$, which are formed in a ratio of 2.1:5.3:1.0. An analysis similar to that performed for the reactions in Scheme 2 indicates that in reaction IIIa the reductive elimination of water from a $[(HO)(H)PtCH_2]^+$ intermediate contributes most to the rate-determining step; however, contributions of the other steps to the measured intramolecular isotope effect cannot be ignored entirely (Scheme 3).

Scheme 3. Formation of $[PtCH_2]^+$ from $[PtO]^+$ and CH_4.

Combining reactions I–III of Scheme 1 leads to a catalytic cycle under FT-ICR conditions in which Pt^+ ions mediate the oxidation of methane by molecular oxygen. This is the first successful demonstration of *catalytic* methane activation by a naked metal ion under oxidative conditions. Since the conversion of $[PtCH_2]^+$ (reaction II) is the slowest step in the cycle and $[PtCH_2]^+$ is also formed in reaction III, a large excess of oxygen is necessary for a satisfactory catalytic rate (typically, a ratio of $CH_4:O_2 = 1:20$ is sufficient).

The deviation of the Pt^+ concentration from the pseudo-first order exponential decrease (Fig. 1) clearly demonstrates the operation of a catalytic process in the present system; this supposition is further substantiated by the steady state concentrations for the reactive species Pt^+, $[PtCH_2]^+$, and $[PtO]^+$ at longer reaction times (>80 s). The slow reaction of $[PtCH_2]^+$ with methane[5] ($k_R = 0.2 \times 10^{-10}$ versus $k_R = 8.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for the activation of methane by naked Pt^+) that generates $Pt[C_2,H_4]^+$ (Scheme 4) and, after subsequent oxidation, $[PtCO]^+$, $Pt[C,O,H]^+$, and $[PtH]^+$, which neither react with oxygen nor with methane, limits the turnover of the overall process by the irreversible formation of unreactive products.



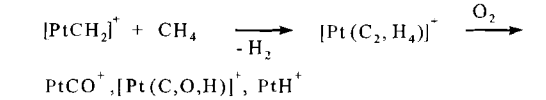


Fig. 1. Temporal evolution of the species involved in the Pt^+-catalyzed methane oxidation ($CH_4:O_2 = 1:20$). The dashed curve shows the decrease of the Pt^+ signal in the presence of methane only. All curves are based on a numerial solution of the appropriate differential equations on use of the k_R values given in the text. For the sake of clarity the experimentally measured data are omitted; these data agree with the computed ion abundancies within experimental error (± 5%). Ion losses at long storage time (>80 s) are taken into account.

By an iterative modeling of the kinetic data with the rate constants for the reactions depicted in Schemes 1 and 4, at a certain pressure[7c,i] ($p(CH_4) = 4 \times 10^{-9}$ mbar, $p(O_2) = 8 \times 10^{-8}$ mbar) a turnover number of about 6 is computed. Further-

Scheme 4. Formation and oxidation of $[Pt(C_2,H_4)]^+$.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1175 $ 10.00+.25/0

more, this analysis reveals that in the Pt^+-mediated oxidation, methane is converted into methanol (10%), formaldehyde (25%), and "CH_2O_2" (65%). The turnover of the system may be enhanced by increasing the oxygen excess to favor reactions II and III; however, this will result in a lowering of the overall rate of conversion. Similar to the effect observed in the reaction of Ir^+ with methane in the presence of oxygen,[5] reaction II accelerates slightly during the course of the catalysis; this may indicate the formation of excited $[PtCH_2]^+$ ions or of the presence of a structural isomer in reaction IIIa. This point will be addressed in forthcoming, more detailed kinetic studies.

In conclusion, the reaction sequence reported here describes for the first time a relatively efficient catalytic system for the gas-phase oxidation of methane by a bimolecular ion–molecule process. However, even in the gas phase the well-known problem of over-oxidation cannot yet be circumvented: the formation of "CH_2O_2" is observed as main reaction channel.

Experimental Procedure

Pt^+ ions were generated in the external ion source of a Spectrospin CMS 47X FT-ICR mass spectrometer [17] by either laser desorption/laser ionization by focusing a beam of a Nd:YAG laser ($\lambda = 1064$ nm) onto a platinum target [18] or glow-discharge ionization of a platinum wire in an argon plasma [19]. The cations were extracted from the source and transferred to the analyzer cell by a system of electric potentials and lenses. The isolation of the $^{195}Pt^+$ isotope and all subsequent isolation steps were performed by using FERETS [20], a computer-controlled ion-ejection protocol that combines single frequency ejection pulses with frequency sweeps to optimize ion isolation. After isolation the ions of interest were thermalized by collisions with either pulsed-in argon gas or the reaction gases, and the thermalized ions were subsequently reisolated. The degree of thermalization was assumed to be complete if no further change in reactivity occurs upon increasing the amount of pulsed-in argon gas [7*i*]. Methane and oxygen were admitted to the FTICR cell through leak valves (typical pressures about 4×10^{-9} mbar and 8×10^{-8} mbar, respectively). The pseudo-first order rate constants were derived from the decay of the precursor ion signals and converted to absolute rate constants by calibrating the ionization gauge measurements with rates of well-known ion–molecule processes [14b, 21, 22]; the error in the absolute rates is $\pm 25\%$ [14b]. All functions of the instrument were controlled by a Bruker Aspect 3000 minicomputer. Methane (Linde AG, 99.999%), [D_2]methane (Cambridge Isotope Laboratories, >98 atom% D), and oxygen (Linde AG, 99.995%) were used without further purification.

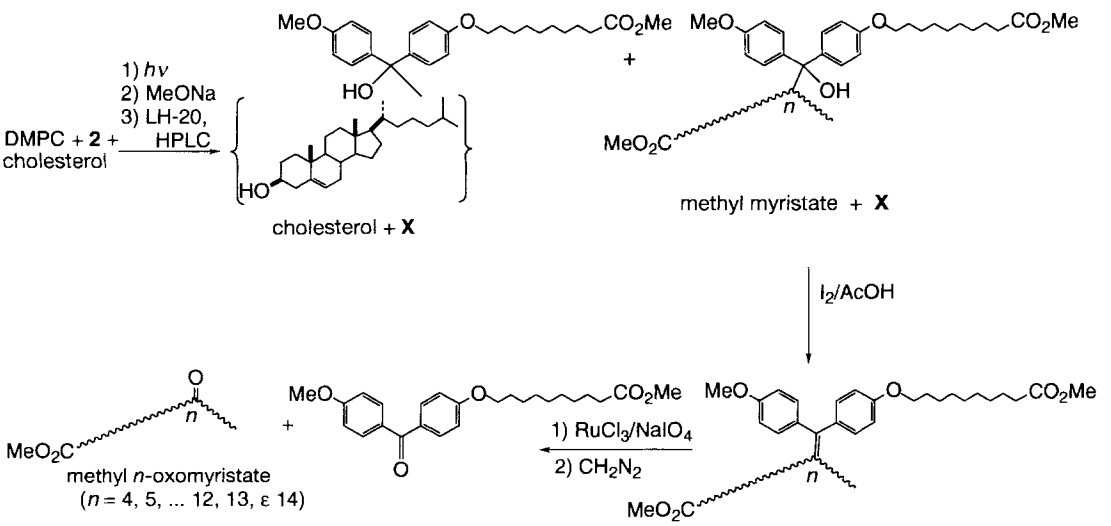
Increased Selectivity of a Simple Photosensitive Probe in the Presence of Large Proportions of Cholesterol**

Siw Bodil Fredriksen, Valérie Dollé, Masakuni Yamamoto, Yoichi Nakatani,* Maurice Goeldner and Guy Ourisson

We have recently described a photoactivatable phospholipidic transmembrane probe **1**,[1,2] which had a marked advantage over the simpler membrane probes described earlier by Khorana et al.[3] and Breslow et al.[4] It was much more site-selective and



1

attacked preferentially the terminal carbons of neighboring phospholipids. This selectivity was excellent in the presence of the near-physiological concentrations (33 mol%) of cholesterol, a normal constituent of eucaryotic membranes, which it reinforces by favoring a compact and regular arrangement of the phospholipids. The probe **1**, when used together with choles-

[**] This work was supported by the CNRS (Action Incitative de l'Interface Chimie-Biologie), by the Supermolecules Research Project of the Research Development Corporation of Japan and Université Louis Pasteur.

terol, is therefore a useful new tool for the investigation of the topography of membranes. However, its synthesis is not easy. Furthermore, we noted that our predecessors had not attempted to improve the very low selectivity of their simpler probes by adding cholesterol. The same is true of two studies recently published: one describing a different type of photoactivatable membrane - spanning probe,[5] and the other[6] dealing with simple benzophenone probes very similar to the one described below, but not more selective than those of Khorana or Breslow for the same reason.

Scheme 2. Reaction sequence for the determination by the photoreaction of the functionalized positions in the myristoyl chains in DMPC. **X** = probe fragment linked by photoactivation to cholesterol or methyl myristate.

We have synthesized the phospholipidic photoactivatable "half-probe" **2** by the route shown in Scheme 1 (all products have been fully characterized by ^{1}H NMR and ^{13}C NMR spectrometry and, for the end product, by MS and microanalysis). In analogy to its transmembrane counterpart **1**, addition of 5 mol% of the new probe **2** to 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) and organization by freeze–thaw cycles in water hardly depresses the phase-transition temperature T_m, which shows that **2** indeed does not perturb the double layers to be investigated. We then tested its behavior upon irradiation in vesicles of DMPC containing varying proportions of cholesterol. The products of the reaction were analyzed, as in ref. [2], by the reaction sequence summarized in Scheme 2, and the results obtained with increasing cholesterol content are reported in Figure 1; in Figure 2 they are compared at 33 mol% cholesterol content[7] with those previously obtained with the transmembrane probe **1**.

Scheme 1. Synthesis of the half-probe **2**. **A**: m.p. 139–140 °C; **B**: m.p. 93–94 °C; **C**: m.p. 138–139 °C; **D**: m.p. 127–128 °C; **2**: T_M = 46.3 °C (pure); 23.6 °C (5 mol% in DMPC). DMF = dimethylformamide, LMPC = 2-lysomyristoylphosphocholine.

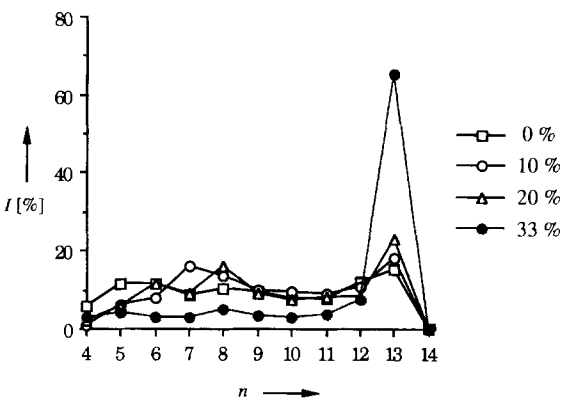

Fig. 1. Effect of cholesterol (mol% indicated on the right) on the distribution of DMPC positions functionalized by irradiation of the half-probe **2**. *I*: Percentage functionalization at carbon atom number *n* of the myristoyl chain.

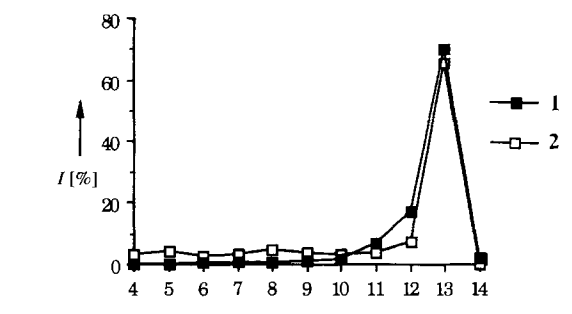

Fig. 2. Comparison of the effect of 33 mol% cholesterol on the distribution of DMPC positions functionalized by irradiation of the probes **1** and **2**. *I* and *n* as for Fig. 1.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1177 $ 10.00+.25/0

Without cholesterol or with low proportions of this membrane reinforcer, the selectivity is very low: all the carbon atoms of the chain up to C-4 are attacked, and there is no marked preference for the end of the chain, as expected by analogy with the results of Khorana, of Breslow, or of Lala.[3, 4, 6] However, near 33 mol% cholesterol, the picture changes drastically, and the selectivity becomes nearly as good as that observed with the transmembrane probe.

The loss of selectivity observed in all cases by halving the probe is in agreement with expectation: the transmembrane probe *must* be more ordered than the half probe. However, the difference of selectivity is so low at high cholesterol concentrations, and the synthesis of the half-probe is so much more straightforward, that its use, or that of analogues, will probably be warranted for the exploration of the topography of the inside of membranes, in particular of membrane-inserted proteins. The radius around a photoexcited benzophenone carbonyl group within which hydrogen can be abstracted to oxygen has been evaluated by Winnik[8] to be about 2 Å. Thus, our results indicate in both cases highly ordererd bilayer systems; the selectivity can probably not be increased with this chromophore.

The effect of added cholesterol should lead also unavoidably to its attack. This is indeed the case: we have isolated small amounts of products which, after transmethylation, were separated and analyzed by mass spectrometry and ^{1}H NMR and ^{13}C NMR spectroscopy. Three of these products have the expected mass for the dehydrated cholesterol + probe photoproduct. Their NMR spectra suggest they are substituted in the side chain, but they have not yet been more precisely characterized.

The structure of the half-probe leads necessarily, in its photoreaction with chiral substrates such as cholesterol or proteins, to diastereomeric heterogeneity. This, and the relative inconvenience of the necessarily complex handling of the photoproducts, justifies improvements in the design of future analogues.

Synthesis and Characterization of Thiolato Complexes with Two-Coordinate Iron(II)**

Jeffrey J. Ellison, Karin Ruhlandt-Senge, and Philip P. Power*

Stable complexes with two-coordinate, open shell, transition metal centers are quite rare and, almost without exception, are confined to derivatives of bulky alkyl or amido ligands.[1] For ligands with bonding atoms from the third period, for example, sulfur or phosphorus, twofold coordination is currently unknown in the condensed phase and three-coordinate species are very rare.[2] Transition metal complexes with low coordination numbers (2 or 3) have recently assumed a new importance owing mainly to the disclosure of the crystal structure of the nitrogen-fixing FeMo cofactor of *Azotobacter vinelandii* in which six of the seven iron centers are, most probably, three-coordinate and ligated by sulfur atoms (sulfido ligands)[3a] (Fig. 1). Moreover,

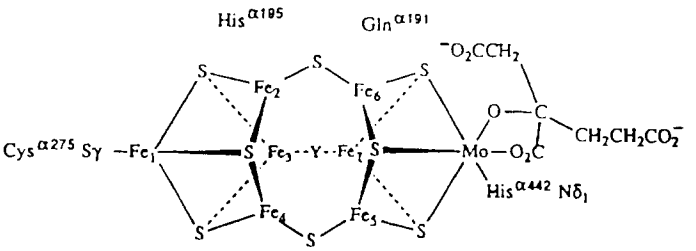

Fig. 1. Schematic drawing (from ref. [3b]) for the binding of nitrogen to MoFe cofactor of nitrogenase.

it has been proposed that the dinitrogen molecule coordinates to the six iron centers within the central Fe_6 cage which is in its reduced form.[3b] The, as yet incompletely defined,[3c, d] site Y (Fig. 1) may also involve an N or O species. The participation of this ligand site in facilitating access of the dinitrogen molecule to the core irons is also a possibility. In this case, it is conceivable that an iron center coordinated by two sulfido ligands may be involved as an intermediate during the reduction process. In this paper the first two thiolato complexes **1** and **2** (Mes = 2,4,6-$Me_3C_6H_2$) which have essentially two-coordinate iron centers are now described.

Compounds **1** and **2** were synthesized by the reaction of one or two equivalents of the new thiol HS(2,6-$Mes_2C_6H_3$) with

$[Fe\{S(2,6\text{-}Mes_2C_6H_3)\}\{N(SiMe_3)_2\}]$ **1** $[Fe\{S(2,6\text{-}Mes_2C_6H_3)\}_2]$ **2**

$[Fe\{N(SiMe_3)_2\}_2]$. The X-ray crystallographic data[4] show that **1** (Fig. 2) and **2** (Fig. 3) are monomers with no close interactions between neighboring molecules. Two crystallographically independent, but chemically identical, monomers and two toluene molecules are observed in each asymmetric unit in the case of **1**. Both **1** and **2** possess a bent geometry at the iron center; the S-Fe-N angles in **1** are 118.9(2) and 120.8(2)°, while in **2** the S-Fe-S angle is very similar, 121.8(1)°. The Fe–S and Fe–N bond lengths in **1** are 2.308(2) and 2.314(2), and 1.913(6) and 1.923(5) Å, respectively; in **2** the Fe–S distances are 2.277(2) and

[**] This work was supported by the National Science Foundation and the Petroleum Research Fund.

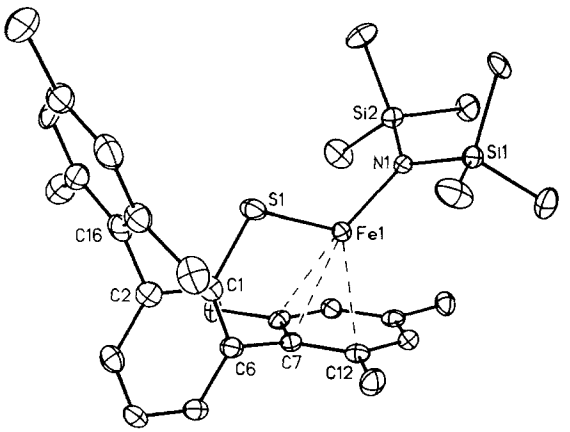

Fig. 2. Crystal structure of **1**. H atoms are not shown for clarity. Selected bond lengths [Å] and angles [°] with values for the second molecule of the asymmetric unit in square brackets: Fe-S 2.314(2) [2.308(2)], Fe-N 1.913(6) [1.923(5)], Fe···C7 2.457 [C37 2.423], Fe···C8 2.551 [C38 2.518], Fe···C12 2.519 [C42 2.533], S-Fe-N 118.9(2) [120.8(2)], Fe-S-C 107.8(3) [105.7(2)].

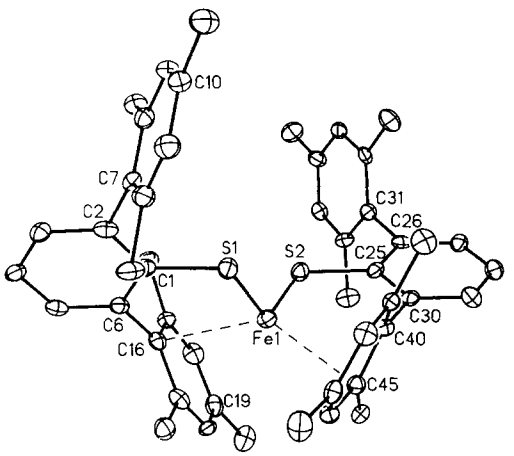

Fig. 3. Crystal structure of **2**. H atoms are not shown for clarity. Bond lengths [Å] and angles [°]: Fe-S 2.277(2), 2.275(2), Fe···C16 2.535, Fe···C45 2.470, S-Fe-S 121.8(1), Fe-S-C 106.2(2), 108.7(3).

2.275(2) Å. Thus, the Fe–S bonds in **1** and **2** are somewhat shorter than those observed for four-coordinate anionic thiolatoiron(II) complexes $[Fe(SPh)_4]^{2-}$[5] (2.338(2)–2.360(2) Å and $[Fe_2(SEt)_6]^{2-}$[6] (2.304(4) Å); however, those in **2** (2.277(2), 2.275(2) Å) are similar to the terminal Fe–S bond lengths observed in the three-coordinate iron thiolate dimers $[\{Fe[S(2,4,6\text{-}tBu_3C_6H_2)]_2\}_2]$[7a] (2.262(3) Å) and $[\{Fe[S(2,4,6\text{-}Ph_3C_6H_2)]_2\}_2]$[7b] (2.256(3) Å). Further metal–ligand interactions with an *ortho*-mesityl group of a thiolato ligand are observed in both **1** and **2**. For **1**, the shortest of these distances are Fe1···C7 (2.457) and Fe2···C37 (2.423 Å). Interactions with other C atoms in the mesityl group lie in the range 2.518–2.730 Å. In **2** the closest contacts are Fe···C45 (2.470) and Fe···C16 (2.535 Å). It is notable that these distances are well outside the sum of the radii of iron (1.25 Å)[8a] and sp^2-hybridized carbon (0.74 Å).[8b] Furthermore, they are significantly longer than the Fe–C distances observed (usually in the range 1.9–2.25 Å) in iron complexes that have η^2–η^6 π-bonded hydrocarbyl ligands.[9] The weakness of these interactions is confirmed by a variable temperature ^{1}H NMR spectroscopic study of **2** in [D_8]toluene, since the paramagnetically shifted peaks show no splitting at temperatures as low as −95 °C. A significant (ca. 8–10 kcal mol^{-1}) Fe···Mes interaction should have been apparent (through splitting of the Mes ^{1}H NMR peaks) at this low temperature. The ^{1}H NMR spectrum of **1** in [D_8]toluene solution is more complex and indicates that **1** disproportionates to a significant extent (ca. 10%) in solution to give **2** and $[Fe\{N(SiMe_3)_2\}_2]$. The magnetic moments of **1** and **2** show that the Fe^{II} centers in both complexes possess a high-spin configuration. The UV/VIS spectra of the two compounds are featureless and display a slow rise in absorption toward higher energy. The IR spectra of **1** and **2** and the precursor thiol indicate that the ligand C–H stretching frequencies are not significantly altered by coordination of the thiolato ligand to the iron center.

The structural and spectroscopic data support the view that the iron centers in **1** and **2** are primarily two-coordinate with minor interactions with the π-electron density of the *ortho*-mesityl group of the thiolato ligand. The relatively small (ca. 120°) ligand-metal-ligand angle in **1** and **2** is probably a consequence of the following: 1) the low valence electron count (10 e$^-$) at the iron center, which leaves several empty metal orbitals available to accept electron density; 2) the "soft" interligand angle at the iron atom, which can be relatively easily distorted from the idealized 180° geometry; and 3) ease of rotation around the M–S bond, which permits the organic substituent to adopt a variety of orientations (subject to steric constraints) thereby permitting the Fe···C interactions to occur.

Clearly, the unique steric and electronic properties of the ($S(2,6\text{-}Mes_2C_6H_3)$) ligand enable twofold coordination at the iron centers in **1** and **2** to be observed. Although the FeMo cofactor does not contain bulky nonprotein substituents, and only one thiolato (cysteine) ligand, the environment provided by the protein apparently produces a similar effect in the stabilization of low coordination numbers at iron.[3] Compound **2** does not, of course, represent a model for a nitrogen-fixing site in the MoFe cofactor; however, both **1** and **2** show that it is feasible to prepare stable complexes with two-coordinate iron centers in which sulfur is the main ligating atom.

Experimental Procedure

All reactions were performed under anaerobic and anhydrous conditions. I(2,6-$Mes_2C_6H_3$) [10] and $[Fe\{N(SiMe_3)_2\}_2]$ [1c] were prepared by published procedures:

HS(2,6-$Mes_2C_6H_3$): I(2,6-$Mes_2C_6H_3$) (4.4 g, 10 mmol) was dissolved in THF (80 mL) and cooled in a dry-ice bath. *n*BuLi (10 mmol, 6.25 mL of a 1.6 M solution in hexanes) was added by syringe. The solution was stirred at −78 °C for 1 h whereupon a threefold excess of sulfur (0.86 g, 30 mmol) was added. After stirring for 2 h at −78 °C, the deep red solution was allowed to warm to room temperature. It was then added slowly to $LiAlH_4$ (2.5 g) suspended in ether (10 mL) with cooling in an ice bath. After stirring for 10 h the excess $LiAlH_4$ was destroyed with water (10 mL) and 10% HCl (50 mL) was added. The organic layer was separated and the aqueous layer was extracted with diethyl ether (2 × 70 mL). The combined phases were dried (1 h) over K_2CO_3 and filtered. The solvent was removed under reduced pressure and the residue was crystallized from ethyl acetate as a colorless solid in about 60% yield: M.p. 213–215 °C. IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 2545 w (ν(S-H)), 585 m, 570 w, 545 w, 505 w, 482 w, 457 w, 345 m; ^{1}H NMR (200 MHz, [D_8]toluene, 25 °C): δ = 2.05 (s, 12H, *o*-Me), 2.36 (s, 6H, *p*-Me), 3.05 (s, 1H, S-H), 7.00 (s, 4H, *m*-H (Mes)), 7.06 (2H, d, *m*-H(Ph), ^4J = 9 Hz), 7.26 (1H, *p*-H ^4J = 9 Hz).

1: HS(2,6-$Mes_2C_6H_3$) (0.69 g, 2 mmol) was dissolved in a 1:1 mixture of hexane and toluene (40 mL). This solution was added dropwise with a cannula to $[Fe\{N(SiMe_3)_2\}_2]$ [1c] (0.75 g, 2 mmol) in hexane (10 mL) with stirring. After 2 h the solution had become pale yellow. It was then filtered and the volume was reduced to about 3 mL. Cooling overnight in a freezer at −20 °C produced large yellow crystals of **1** in 60% yield. M.p. 150 °C. μ = 4.5 μ_B at 25 °C. IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 695 s, 665 s, 630 w, 610 w, 585 w, 460 m, 410 w, 355 m.

2: HS(2,6-$Mes_2C_6H_3$) (0.69 g, 2 mmol) was suspended in hexane (25 mL) and $[Fe\{N(SiMe_3)_2\}_2]$ (4.0 mL of a 0.247 M solution in toluene) was added dropwise with a syringe. The solution became dark red upon stirring for 2 h, whereupon it was concentrated to incipient crystallization under reduced pressure. The mixture was then filtered and cooled for 24 h in a freezer at −20 °C to afford **2** as red needles in

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1179 $ 10.00+.25/0

quantitative yield. M.p. 250–253 °C. $\mu = 4.3\ \mu_B$ at 25 °C. IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 585 m, 565 w, 542 w, 462 m, 387 m, 339 m. ^{1}H NMR (200 MHz, [D$_8$]toluene, isotropic shifts at ca. 25 °C): δ = 49.48 (br. s, 2H), 41.28 (br. s, 6H), 6.9 (br. s, 12H), −22.36 (br. s, 4H), −24.55 (br. s, 1H).

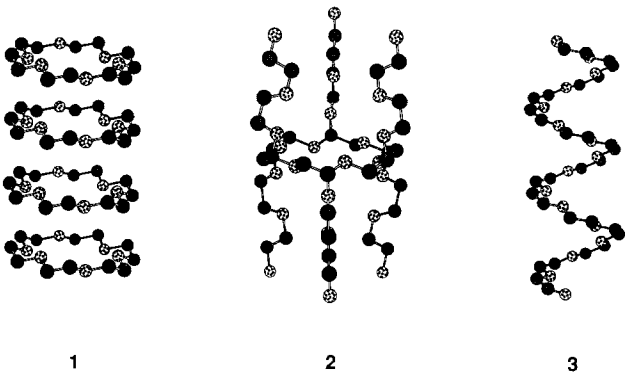
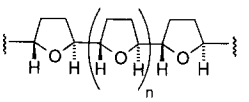
A Convergent Synthesis of 2,5-*trans*-Linked Oligo(tetrahydrofuran)s: Potential Building Blocks for a Polyether Helix with Ion Channel Activity**

Ulrich Koert,* Matthias Stein, and Klaus Harms

Examination of the structure, function, and regulation of membrane-bound ion channels is the focus of an interdisciplinary research area.[1] Through the design and synthesis of artificial ion channels,[2] chemists have access to model systems that may lead to a better understanding of biological ion channels. Polyether-based structures are particularly suitable for the transport of Na^+ and K^+ ions. Figure 1 shows a comparison of various ion channel models based on polyethers.





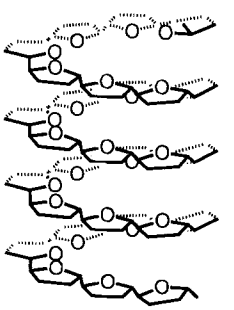


Fig. 1. Ion channel models based on polyethers. **1**: cylindrical arrangement of crown ethers, **2**: polyether strands. **3**: polyether helix. Dark spheres: carbon atoms; stippled spheres: oxygen atoms.

To date, ion channels have been formed by the cylindrical packing of crown ether molecules **1**[3] or by the bundling together of polyethylene glycol strands **2**.[4] In a cylindrical arrangement of crown ethers **1** a cation is relatively strongly bound within one crown ether unit. An energy barrier must be overcome in order for this cation to jump to the neighboring crown ether molecule. The unfavorable energy associated with discontinuous transport is largely avoided in polyether helix **3**. Here we report on a new synthesis of oligo(tetrahydrofuran)s,[5] a class of polyethers that could be used as building blocks for polyether helices.

CPK models show that oligomer **4a** (Scheme 1) formed from *trans*-linked tetrahydrofuran units will adopt a helical confor-

4a

4b

Scheme 1. 2,5-Linked oligo(tetrahydrofuran)s **4a** with the relative configuration *trans-anti-trans* and a schematic illustration of a polyether helix **4b**.

mation (**4b**) if the relative configuration of the tetrahydrofuran oligomer is *trans-anti-trans*.[6] This type of polyether helix is expected to be a functional ion channel when located within a membrane.

X-ray structural analysis (Fig. 2)[7] of the dimeric THF lactone **5**, with its 2,5-*trans*-linkage, supports this idea of a polyether helix constructed from 2,5-*trans*-linked oligo(tetrahydrofuran)s. The two oxygen atoms of the THF units in **5** are

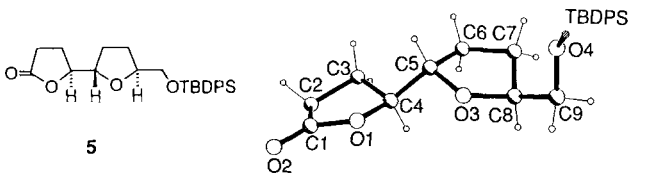
gauche to each other. This *gauche* conformation of the C4–C5 bond is a prerequisite for a THF helix structure. A THF-polyether helix can be further stabilized in a membrane through hydrophobic interactions between the THF methylene groups and the alkyl chains of the membrane lipids. A helix coiled four to five times with seven oxygen atoms per spiral should be sufficiently long to traverse a membrane 5 nm thick.



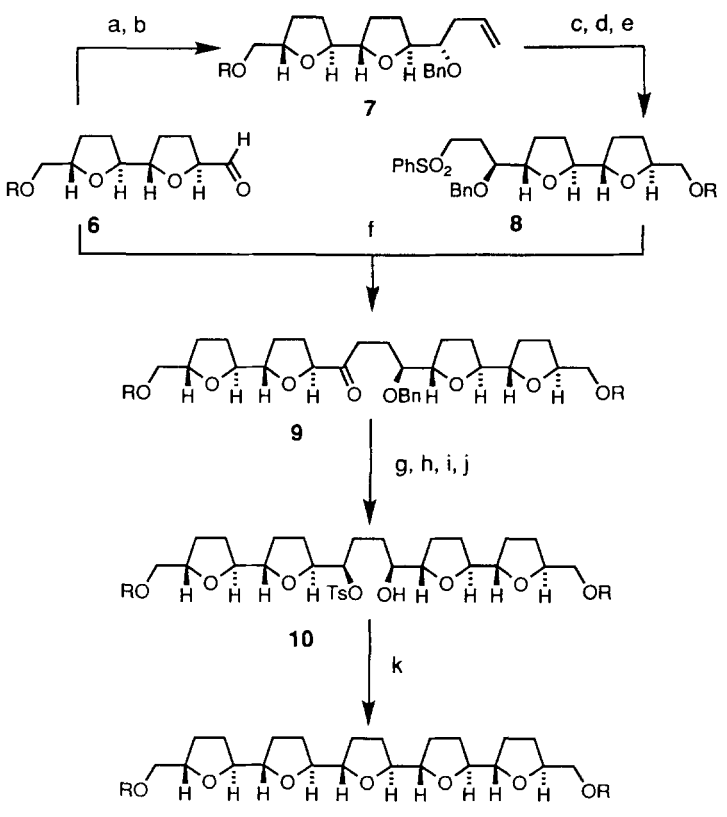


Fig. 2. Crystal structure of the dimeric tetrahydrofuran derivative **5**. For clarity the three alkyl groups on the Si atom of the protective group are not shown. TBDPS = *t*-butyldiphenylsilyl.

A helix can exist in the form of either of its enantiomers (the *P* or *M* isomer). The helical sense of the THF-polyether helix is determined by the absolute configuration of the chiral THF unit. In order to form a polyether helix with a predictable conformation, it is first necessary to synthesize an enantiomerically pure oligo(tetrahydrofuran) of type **4**. Here we report on a convergent method for obtaining enantiomerically pure 2,5-*trans*-linked oligo(tetrahydrofuran)s.[8]

Scheme 2. Convergent synthesis of tetrahydrofuran pentamer **11**. R = TBDPS. Bn = benzyl. The starting point for the synthesis of the tetrahydrofuran pentamer **11** was the enantiomerically pure aldehyde **6** (Scheme 2).[8] A reagent-controlled allyl boration as described by H. C. Brown et al.[9] gave the homoallyl alcohol (*ds*: 85:15), which was converted into the benzyl-protected compound **7**. The relative configuration of the newly formed stereocenter was determined by using reference compounds[8] whose relative configurations had been previously established by X-ray structural analysis. The terminal double bond of compound **7** was ozonized. Reductive workup of the alcohol obtained from the ozonolytic cleavage gave an alcohol that was then converted into sulfone **8**. The lithiated sulfone was coupled with aldehyde **6**. After Swern oxidation and desulfonation the stereochemically pure ketone **9** was obtained. In preparation for the ring closure of the tetrahydrofuran ring the keto group was reduced and the resulting alcohol tosylated. The benzyl protective group was cleaved by catalytic hydrogenation to provide compound **10**. Finally, the tetrahydrofuran ring was closed by an intramolecular substitution reaction proceeding with inversion. The C_2 symmetry of the tetrahydrofuran pentamer **11** was verified by the half signal set of the ^1H and ^{13}C NMR spectra (Table 1).

11: colorless oil; $[\alpha]_D^{20} = -10.4$ ($c = 0.60$, $CHCl_3$); ^1H NMR [c]: $\delta = 1.04$ (s, 18H), 1.60–2.03 (m, 20H), 3.60 (dd, $J = 10.4$, 5.7 Hz, 2H), 3.69 (dd, $J = 10.4$, 4.3 Hz, 2H), 3.85–3.97 (m, 8H), 4.10–4.15 (m, 2H), 7.35–7.37 (m, 12H), 7.65–7.68 (m, 8H); ^{13}C NMR [d]: $\delta = 19.3$ (s), 26.9 (q), 28.0 (t), 28.1 (t), 28.2 (t), 28.3 (t), 28.5 (t), 66.6 (t), 79.7 (d), 81.6 (d, 2C), 81.8 (d), 81.9 (d), 127.6 (d), 129.5 (d), 133.8 (s), 135.6 (d), 135.7 (d); HR-MS for $C_{54}H_{72}O_7Si_2$: calcd.: 888.4816; found: 888.4951

[a] 300 MHz ($CDCl_3$), 20 °C; [b] 75 MHz ($CDCl_3$), 20 °C; [c] 500 MHz ($CDCl_3$), 20 °C; [d] 126 MHz ($CDCl_3$) 20 °C.

Seven oxygen atoms from compound **11** would suffice to form one full turn in a helical spiral. In order to traverse a membrane, molecules with a length encompassing four to five helical turns are required, and thus longer oligo(tetrahydrofuran)s are necessary. To this end two approaches appear particularly promising: the use of a bidirectional synthetic strategy and the coupling of oligo(tetrahydrofuran) units through amide linkages.

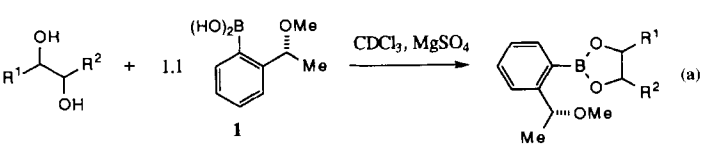
A Reagent for Determining Optical Purities of Diols by Formation of Diastereomeric Arylboronate Esters

Kevin Burgess* and Alexander M. Porte



Optical purities of alcohols are often determined by forming diastereomeric methoxyphenyltrifluoromethyl acetates ("Mosher's esters"),[1] mandelates,[2] trivalent phosphorus derivatives,[3] and organoboron[4] or organosilicon compounds.[5] None of these methods is particularly suitable for diols. Syntheses of bis-Mosher's esters, for instance, are especially susceptible to kinetic resolutions, and substrate diols with inequivalent OH functionalities give two sets of NMR marker peaks in narrow regions of the ^1H and ^{19}F NMR spectra. Moreover, some of the commercial derivatizing agents are not optically pure (97.9–99.7% *ee* for Mosher's acid)[6] hence significant cumulative errors occur when two such groups are introduced. Despite this, formation of bis-Mosher's esters is used,[7–10] presumably because there has been no alternative derivatizing agent that is clearly superior. We report here a synthesis of the optically pure boronic acid **1**, and simple applications of this for determining enantiomeric excesses of 1,2- and 1,3-diols.

Scheme 1 shows the asymmetric synthesis of **1**. Optical activity was introduced by the reduction of *ortho*-bromoacetophenone **2** with BH_3 in the presence of a chiral catalyst.[11] The asymmetric induction obtained in this step was not critical since samples of alcohol **3** of about 85% *ee* were upgraded to optically pure form after one or two recrystallizations from hexane; enantiomeric trifluoroacetates of **3** were nicely resolved by capillary GC with a chiral stationary phase, thus the optical purity of **3** is easily confirmed. Methyl ether **4** was made from **3**, and a transmetalation procedure was used to convert **4** into the corresponding boronic acid **1**,[12] which was purified by recrystallization. No chromatographic separations were required in this synthesis.

Scheme 1. Asymmetric synthesis of boronic acid **1**.

Derivatization of diols using the arylboronic acid **1** is simple. A slight excess of **1** was mixed with the diol in toluene, THF, or $CDCl_3$ in the presence of a dehydrating agent (ground molecular sieves or $MgSO_4$) [Eq. (a)]. The reaction mixture was filtered and the ^1H NMR spectrum of the filtrate was recorded. Complete conversion of the substrate to a boronic ester was observed for all the substrates tested, so kinetic resolutions were not a concern. In most cases the position of the OCH_3 signal of the excess reagent **1** was distinct from that of the OCH_3 signal of the diastereomeric boronic ester products, and the enantiomeric excesses were deduced immediately by integration. Sometimes, overlap of the product and reagent OCH_3 signals complicated the spectra. If this occurred, the crude reaction mixture was loaded onto a short column of silica gel and eluted with diethyl ether containing a trace of triethylamine. Excess reagent **1** was retained on the column, and the ^1H NMR spectrum of the material which passed through was analyzed without difficulty.

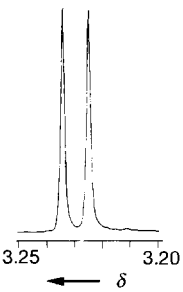
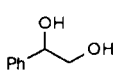
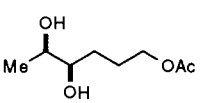
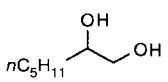
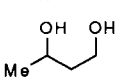
Figure 1 shows an expanded region of the ^{1}H NMR spectrum of the diastereomeric boronate ester from racemic 2,3-butanediol. The resolution of the OCH_3 resonance signals is representative. Table 1 summarizes the data obtained for all the substrates. Six 1,2-diols (entries 1–6), two 1,3-diols (entries 7 and 8), a 2-hydroxy acid (entry 9), and a 2-amino alcohol (entry 10) were analyzed in this way. Generally, baseline resolution was obtained by using a 400 MHz instrument and $CDCl_3$ as solvent, although occasionally 200 MHz was sufficient (entry 2). Better resolution of the two diastereomers may be observed when C_6D_6 is used as solvent (entry 2). An attractive feature of this derivatization technique is that the OCH_3 resonance used for the analyses originated from the reagent, thus it is a probe which is independent of the spectroscopic properties of the substrate. This reagent-derived OCH_3 resonance was baseline-resolved for entries 1–9, and almost baseline-resolved for entry 10. Resonances derived from the substrate were also resolved in some experiments (entries 4, 5, and 10), and can be a better marker of the enantiomeric excess than the OCH_3 signal (cf. entry 10). Entries 9 and 10 suggest this technique may also be useful for substrates other than diols.

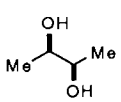


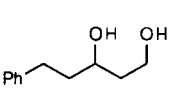


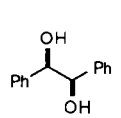


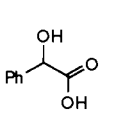


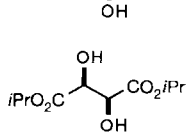












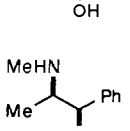


Fig. 1. Expanded region of the ^{1}H NMR spectrum showing the OCH_3 signals of the diastereomeric boronate esters from **1** and racemic 2,3-butanediol (at 400 MHz in $CDCl_3$).

Table 1. Results from the ^{1}H NMR spectra of racemic substrates derivatized with **1** [a].

[a] In $CDCl_3$. [b] Diastereomeric oxazaborolidines were formed in this case by mixing the amino alcohol and boronic acid **1** (1.1 equiv) in toluene at 110 °C, and azeotropic removal of water.

The value of diols as chirons is increasing as enantioselective bishydroxylations[13–15] become standard techniques in organic synthesis. Methods for determining optical purities of diols therefore have assumed greater significance. Chromatographic methods to measure optical activities have the advantage of high accuracy but they are not always convenient, particularly if the required stationary phases are unavailable or the compound has inconvenient physical properties. Consequently, derivatization methods for accessing optical purities by NMR spectroscopy have considerable appeal. Boronic acid **1** can be obtained in optically pure form, it is easily converted to arylboronate esters, and kinetic resolutions are easily avoided. We do not claim that this reagent will be suitable for determining enantiomeric excesses of all diols, but Table 1 contains a comprehensive list of the 1,2- and 1,3-diols screened by us so far.[16]

Experimental Procedure

3: Neat *ortho*-bromoacetophenone **2** (9.085 g, 4.5 mmol) was added dropwise to a solution of catalyst, 4,5,6,7-tetrahydro-1-methyl-3,3-diphenyl-1*H*,3*H*-pyrrolo[1,2-*c*]-[1,3,2]oxazaborole-borane, (0.655 g, 2.25 mmol) and BH_3·Me_2S (4.5 mL, 45 mmol) in dichloromethane (3 mL) at −20 °C. The mixture was allowed to stand for 8 h at −20 °C. The mixture was added carefully to methanol (10 mL) precooled to −20 °C; evolution of gas occurred. After removal of the solvent additional methanol (10 mL) was added and removed, thus eliminating $B(OMe)_3$ and $MeB(OMe)_2$ [11]. The residual oil was dissolved in methanol and passed quickly through Amberlyst 15 (NH_4^+ form) eluted with methanol. The product was crystallized from *n*-hexane (6.9 g, 39.4 mmol, 84%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.60 (m, 2H), 7.35 (m, 1H), 7.10 (m, 1H), 5.23 (q, J = 6.4 Hz, 1H), 2.30 (s, 1H), 1.47 (d, J = 6.4 Hz, 2H).

4: The alcohol, **3**, (1.00 g, 4.90 mmol) was added to a slurry of NaH (0.176 g, 7.35 mmol) in dimethylformamide (4 mL). After gas evolution ceased, MeI (2.78 g, 19.6 mmol) was added, and the solution was stirred for 12 h. Et_2O (30 mL) was added, and the solution washed with brine (4 × 10 mL). The organic layer was dried over Na_2SO_4 and the solvent was evaporated. The product was used in the next step without further purification (1.05 g, 11.95 mmol, 100%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.50 (dt, J = 7.9 Hz, 1.3 Hz, 2H), 7.3 (m, 1H), 7.12 (m, 1H), 4.71 (q, J = 6.4 Hz, 1H), 3.25 (s, 3H), 1.40 (d, J = 6.4 Hz, 2H); ^{13}C NMR: δ = 143.3, 133.2, 129.2, 128.4, 127.5, 123.2, 78.6, 57.0, 22.7; $[\alpha]_D^{20}$ = −100.8 (c = 6.4, CH_2Cl_2).

1: The ether **4** (0.500 g, 2.33 mmol) in Et_2O (5 mL) at −78 °C was transmetalated by the addition of *tert*-butyllithium (3.89 mL, 5.4 mmol, 1.4 M in pentane). After warming to room temperature for 0.5 h the solution was again cooled to −78 °C. This orange solution was cannulated into a solution of triisopropylborate (0.438 g, 2.33 mmol) in Et_2O (5 mL) also at −78 °C. The mixture was stirred for 3 h while allowing it to warm to 25 °C. A solution of HCl (1 M) in Et_2O (3.00 mL, 3.00 mmol) was added at 0 °C to the above mixture and then stirred for 1 h. The solution was cannulated from the solid and the solvent evaporated. The boronate ester was distilled (90–100 °C, 0.5 Torr). Following the distillation the boronate ester was hydrolyzed to the boronic acid **1** in water (2 mL) and stirred for 0.5 h giving a white solid. The boronic acid was recrystallized from *n*-hexane (0.209 g, 1.16 mmol, 50%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.05 (m, 1H), 7.36 (m, 2H), 7.19 (m, 1H), 6.90 (s, 2H), 4.45 (q, J = 6.72 Hz, 1H), 3.30 (s, 3H), 1.56 (d, J = 6.72 Hz, 2H); ^{13}C NMR: δ = 146.5, 137.7, 130.4, 128.9, 127.8, 83.5, 56.3, 22.6; m.p. 72–74 °C; $[Ga]_D^{25}$ = +27 (c = 0.5, CH_2Cl_2).

Derivatization method: Boronic acid **1** (0.055 mmol), racemic mandelic acid (0.05 mmol), and $MgSO_4$ (300 mg) were placed in $CDCl_3$ (2 mL). The solution was stirred for 3 h, filtered, and the NMR spectrum was recorded. In this case the OCH_3 resonance of the excess reagent was well resolved from the product. For some other substrates it was necessary to remove the excess boronic acid by passing the product through a small plug of silica with diethyl ether/triethylamine, and subsequently to rerecord the NMR spectrum.

[16] After this paper had been submitted we became aware of another method wherein 1,2-diols were derivatized with a boronic acid derivative (W. Tokles and J. K. Snyder, *Tetrahedron Lett.*, **1988**, *29*, 6063). However, no resolution of protons was obtained in that work, instead enantiomeric excesses were measured by integration of resonances in ^{13}C spectra.

Structural and Magnetic Characterization of a Novel Heptanuclear Hydroxo-Bridged Copper(II) Cluster of the Corner-Sharing Dicubane Type**

José Antonio Real, Giovanni De Munno, Rosaria Chiappetta, Miguel Julve,* Francesc Lloret, Yves Journaux,* Jean-Christophe Colin, and Geneviève Blondin

Transition metal clusters with a cubane-like structure are a very important class of compounds.[1] In the case of copper(II), several examples of alkoxo-bridged Cu^{II} tetramers with cubane-like cores are known, and their magnetic properties were adequately described by considering exchange interactions between all four metal ions.[2, 3] Their structure can be viewed as the result of the association of two planar dinuclear di(μ-alkoxo)-copper(II) complexes through weak Cu–alkoxo apical interactions. The structural similarity of these alkoxo-bridged and the hydroxo-bridged copper(II) compounds is illustrated in the first hydroxo-bridged $Cu_4(OH)_4$ tetramer, $[Cu(bpy)(OH)]_4(PF_6)_4$ (bpy = 2,2′-bipyridine),[4] where two almost planar di(μ-hydroxo)-copper(II) dimers are held together by long out-of-plane Cu–OH bonds. The spin ground state in the $Cu_4(OH)_4$ cubane is a quintet arising from a weak ferromagnetic interaction between the two low-lying triplet states of the two dimers. In fact, all examples of di(μ-hydroxo)copper(II) species containing bpy as terminal ligand exhibit ferromagnetic coupling between the dimers. A similar situation occurs when bpy is replaced by 2,2′-bipyrimidine (bpym), as illustrated by $[Cu_2(bpym)_2(OH)_2]X_2 \cdot 6H_2O$ ($X = ClO_4^-$, NO_3^-).[5, 6] In this case, the bischelating ability of bpym led to the polymerization of the dinuclear unit to yield one-dimensional chains of Cu^{II} ions alternately bridged by bpym and two hydroxo groups. The chains exhibit a regular alternation of ferro- and antiferromagnetic interactions.[6, 7]

In the scope of our continuous research in this field we prepared the compound **1**, which, as far as we are aware, is the first

$[Cu_7(bpym)_6(OH)_8(H_2O)_2](NO_3)_6 \cdot H_2O$ **1**

hydroxo-bridged $Cu_7(OH)_8$ dicubane-like compound. It was characterized by elemental analysis, variable-temperature magnetic measurements, and X-ray structural analysis.[8]

The crystal structure of **1** consists of a discrete centrosymmetric hydroxo-bridged $[Cu_7(bipym)_6(OH)_8(H_2O)_2]^{6+}$ heptameric entity exhibiting core of two corner-sharing cubane-like units (Fig. 1), six uncoordinated nitrate groups, and a water molecule of crystallization. The cationic complex can be described in terms of three fragments: a central centrosymmetric trinuclear unit containing the Cu(3), Cu(4), and Cu(3a) copper atoms, and two symmetry-related Cu(1)–Cu(2) and Cu(1a)–Cu(2a) dinuclear entities in which bpym acts as terminal ligand in both cases. The two dimeric units are connected to the trinuclear one

by long axial Cu–O bonds ranging from 2.425(8) [Cu(2)–O(4)] to 2.951(10) Å [Cu(4)–O(2)] in such a way that a $Cu_7(OH)_8$ double cubane-like core results.

The Cu^{II} centers have the geometry expected as a result of vibronic Jahn–Teller forces [strongly axially elongated octahedra for Cu(1) and Cu(4) and square pyramids for Cu(2) and Cu(3)]. The three copper atoms from the central centrosymmetric fragment are held together by four hydroxo groups in equatorial positions. Two nitrogen atoms from bpym and two hydroxo groups occupy the basal positions around Cu(3), whereas four hydroxo groups build the equatorial plane around Cu(4). The axial position of Cu(3) is occupied by the O(1) hydroxo atom from the doubly hydroxo-bridged dimer, and the copper atom is displaced by 0.041(2) Å from the mean basal plane towards this axial oxygen. The axial positions around Cu(4) are filled by the O(2) and O(2a) hydroxo atoms from the two symmetry-related dimers. Cu(4) is forced by symmetry to be in the basal plane defined by the O(3), O(4), O(3a), and O(4a) atoms. The dihedral angle between the basal planes of Cu(3) and Cu(4) is 26.6(2)°. The values of the Cu(3)-O(4)-Cu(4) and Cu(3)-O(3)-Cu(4) angles are 96.3(3) and 95.6(3)°, respectively. The Cu(2) and Cu(1) atoms from the dimeric fragment are (4 + 1) and (4 + 2)-coordinated, respectively. Their equatorial planes are formed by two nitrogen atoms from bpym and two hydroxo groups, and the axial positions are filled by the hydroxo O(4) oxygen in the former and the O(3) hydroxo and O(16) water oxygens in the latter. Both copper atoms are slightly displaced from their mean basal planes [0.008(2) and 0.040(3) Å, respectively]. The dihedral angle between the equatorial planes of Cu(1) and Cu(2) of 8.7(2)° reveals that bending within the dimer is smaller than that within the trinuclear unit. The values of the Cu(1)-O(1)-Cu(2) and Cu(1)-O(2)-Cu(2) angles are 94.5(4) and 98.0(5)°, respectively. The bending around the O(1)···O(2) axis in the $Cu(1)(OH)_2Cu(2)$ unit contrasts with the situation found in the related compounds $[Cu_2(bpym)_2(OH)_2]X_2 \cdot 6H_2O$ ($X = ClO_4^-$, NO_3^-) mentioned above, which exhibit a planar, centrosymmetric $Cu(OH)_2Cu$ network.

The Cu(1)···Cu(2), Cu(1)···Cu(3), Cu(1)···Cu(4), Cu(2)···Cu(3), Cu(2)···Cu(4), and Cu(3)···Cu(4) intracluster metal–metal separations are 2.901(3), 3.407(3), 3.520(3), 3.360(3), 3.467(3), and 2.869(2) Å, respectively.

Figure 2 shows the magnetic behavior of **1** in the form of the dependence of $\chi_M T$ on temperature and of M on the magnetic field H. A Curie law corresponding to seven uncoupled copper(II) ions is valid between room temperature and 60 K. Below this temperature, $\chi_M T$ steadily increases and reaches a value of 5.20 $cm^3 mol^{-1} K$ at 1.8 K. This value, which is greater than that expected for one quadruplet and two triplets that do not

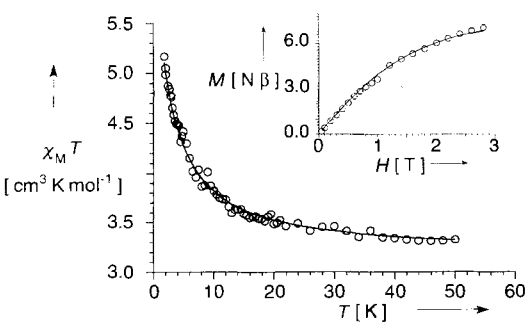

Fig. 2. Temperature dependence of $\chi_M T$ (χ_M: the magnetic susceptibility per seven copper(II) ions) for **1**: (○) experimental data; (—) best theoretical fit. The inset shows the magnetization data of **1** at 2.0 K; the solid line represents the behavior of a cluster with an $S = 7/2$ ground state with a Landé factor of 2.20.

interact, reveals that ferromagnetic interactions between the dinuclear and trinuclear entities occur. The experimental magnetic data were analyzed with the Hamiltonian operator $\mathcal{H} = -J_1[S_1S_2 + S_{1a}S_{2a}] - J_2[S_3(S_1 + S_2) + S_{3a}(S_{1a} + S_{2a})] - J_3[S_4(S_3 + S_{3a})] - J_4[S_4(S_1 + S_2 + S_{1a} + S_{2a})]$. A schematic drawing showing the distribution of the exchange interaction parameters in **1** is given in Figure 3. The expressions of the

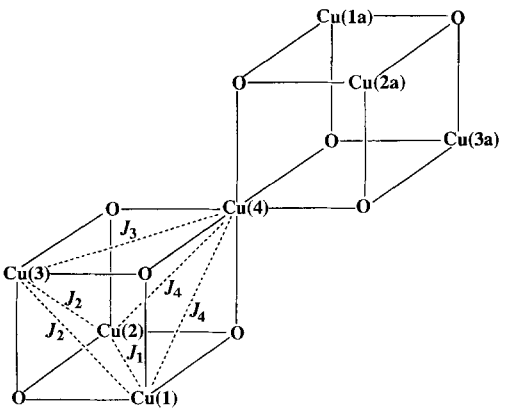

Fig. 3. Diagram of the $Cu_7(OH)_8$ core showing half of the exchange parameters.

magnetic susceptibility and magnetization were obtained by diagonalization in the subspaces of spin S varying between $S = 7/2$ and $S = 1/2$. The final values of the exchange parameters and the Landé g factor were determined with a least-square fit of both susceptibility and magnetization data; the reliability factor R was defined as in Equation (a). The correlation ob-

$$R = (\Sigma[(\chi_M T)_{obsd} - (\chi_M T)_{calcd}]^2 + \Sigma[(M)_{obsd} - (M)_{calcd}]^2)/(\Sigma[(\chi_M T)_{obsd}]^2 + \Sigma[(M)_{obsd}]^2) \quad (a)$$

served among the J values makes the fit difficult, and therefore an iterative procedure was used.[13] The best fit values ($R = 1.4 \times 10^{-5}$) of $J_1 = 5.1\ cm^{-1}$, $J_2 = 0.4\ cm^{-1}$, $J_3 = 5.4\ cm^{-1}$, and $g = 2.20$ were obtained by setting $J_4 = 0$. This set of values are reliable in the light of the structural data. The average θ values in the $Cu(1)(OH)_2Cu(2)$ (dinuclear) and $Cu(3)(OH)_2Cu(4)$ (trinuclear) networks are smaller than 97.5°, and consequently, ferromagnetic interactions within these entities are expected according to the known J versus θ relationship.[14] The significant bending that they display accounts for their reduced values.[4] On the other hand, the small spin density of the d_{z^2} orbital causes the weak ferromagnetic interaction between the dinuclear and the trinuclear fragments through the long out-of-plane Cu–(OH) bonds which connect them. Finally, the magnetization studies at 2 K supports the occurrence of an energetically low-lying octet state in **1**. The present compound provides us with an example of a high-spin complex with ferromagnetic interactions between seven copper(II) ions in a double cubane arrangement. More efforts are justified to prepare more complex high-spin systems taking advantage of the bridging capability of bpym.

Experimental Procedure

A mixture of polyhedral emerald green crystals of **1** and blue-green rhombohedral crystals of $[Cu_2(bpym)_2(H_2O)_2(OH)_2](NO_3)_2 \cdot 4H_2O$ were grown by slow evaporation of blue aqueous solutions containing copper(II) nitrate trihydrate, bpym, and

sodium carbonate in a 1:0.85:0.6 molar ratio. The crystals of **1** were handpicked for X-ray diffraction and magnetic measurements. Correct elemental analysis (C, H, N, Cu).

[8] X-ray structure analysis: Siemens R3m/V automatic diffractometer, $Mo_{K\alpha}$, $\lambda = 0.71073$ Å, graphite monochromator, 298 K, Lorentz polarization and Ψ-scan absorption correction [9]. Data collection, solution, and refinement: ω-2θ, standard Patterson methods with subsequent Fourier recycling, SHELXTL-PUS [10]. Two nitrate groups and a water molecule are disordered. The disorder of each nitrate anion has been treated assuming a population factor of 0.5 for the nitrogen and for one of the oxygens. The oxygen of the disordered water was also given a 0.5 population factor. Data collection on a different crystal of **1** was also carried out at 120 K in order to reduce the degree of disorder and to get a more accurate description of its structure. Unfortunately, the disorder was not reduced by cooling, thus proving that it is mainly statistical. Only the structural data at room temperature are reported because the final discrepancy indices at low temperature were not better. All non-hydrogen atoms, except the oxygen atoms of water molecules, and oxygen and nitrogen atoms of disordered nitrate groups, were refined anisotropically. The hydrogen atoms of the bpym ligand were set in calculated positions and refined as riding atoms. They were all refined isotropically. Final geometrical calculations and graphical manipulations were performed with the PARST program [11] and the XP utility of the SHELX-PLUS system, respectively. **1**: $C_{48}H_{50}N_{30}Cu_7O_{29}$ ($M_r = 1937.9$), triclinic, space group $P\bar{1}$, $a = 11.553(7)$, $b = 13.164(7)$, $c = 13.419(8)$ Å, $\alpha = 70.66(4)$, $\beta = 82.21(5)$, $\gamma = 64.14(4)^\circ$, $V = 1733(2)$ Å^3, $Z = 1$, $\rho_{calcd.} = 1.857$ g cm^{-3}, $\mu = 22.13$ cm^{-1}, 2θ range 3–54°, crystal size $0.34 \times 0.18 \times 0.08$ mm^3, $F(000) = 967.7581$ unique reflections, 3862 observed with $I > 3\sigma(I)$, 498 parameters, $R(F_o) = 0.0744$, $R_w(F_o) = 0.0795$ and $S = 1.735$ with $w^{-1} = \sigma^2(F_o) + 0.0021\,(F_o)^2$. [12] Bond distances and angles in the bpym ligands are in agreement with those reported in the literature. The pyrimidyl rings of bpym are planar. However, the bpym as a whole is not planar: the dihedral angles between the pyrimidyl rings of the bpym ligands bound to Cu(1), Cu(2) and Cu(3) are 3.6(3), 2.5(3), and 4.6(4)°, respectively.

[13] At first we considered only the interactions within the two dimers and the trinuclear entity and the best fit was made on J_1 and J_3 as variables with $J_2 = J_4 = 0$. Then we kept these J_1 and J_3 values constant and fit on J_2 and J_4. This procedure is continued until self-consistent values for all parameters are found.

The First Zwitterionic, Optically Active Disilicate with Pentacoordinate Silicon**

Reinhold Tacke,* Mathias Mühleisen, and Peter G. Jones

The study of compounds with higher coordinate silicon atoms is currently one of the main areas of research in silicon chemistry.[1] In the past few years, *ionic* λ^5Si-silicates have been investigated particularly intensively. With the systematic elaboration of a new class of substances, the spirocyclic *zwitterionic* λ^5Si-silicates, this area of research has recently expanded.[2, 3] These compounds are neutral molecular λ^5Si-silicates in which two diolato(2−) ligands and one ammonio-substituted organic group are bound to the Si coordination center. The bidentate diolato(2−) ligands thus far employed are derived from diols of the catechol and glycolic acid types. The zwitterions **1**[2e] and **2**,[2h] which may be classified as molecular mononuclear complexes of pentacoordinate silicon, are typical examples of this class of compounds.

With the synthesis of (+)-bis[(ammonio)methyl]bis[μ-(*R*,*R*)-tartrato(4−)-O^1,O^2:O^3,O^4]disilicate (+)-**4**, we have now succeeded in obtaining a molecular binuclear λ^5Si,λ^5Si′-silicon complex for the first time (Scheme 1). In this compound, two tetradentate (*R*,*R*)-tartrato(4−) ligands bridge the two Si atoms, and each ligand bonds to each of the Si atoms at two coordination sites. The disilicate (+)-**4** has a pentacyclic molecular framework and contains two pentacoordinate (formally negatively charged) Si atoms and two tetracoordinate (formally positively charged) N atoms. To the best of our knowledge, this is the first

optically active compound of pentacoordinate silicon. Its optical activity results from the presence of the two chiral (*R*,*R*)-tartrato(4−) ligands and the two chiral $Si(\overline{OO}')_2C$ units.

Compound (+)-**4** was prepared by reaction of (aminomethyl)triethoxysilane[4] **3** with (*R*,*R*)-(+)-tartaric acid (molar ratio 1:1) in aqueous solution and isolated as a 2:1 mixture of (+)-**4** and (+)-**4**·3 H_2O (yield approx. 88%). The formation of (+)-**4** (100% *ee*, 100% *de*) occurred stereospecifically. Compounds (+)-**4** and (+)-**4**·3 H_2O were obtained in pure form by mechanical sorting and then characterized.[5] The trihydrate was structurally characterized by X-ray diffraction on a single crystal;[6] this was not possible in the case of the water-free compound because of its poor crystal quality.

The molecular structure of (+)-**4** in the crystal of (+)-**4**·3 H_2O is shown in Figure 1. The coordination polyhedra sur-

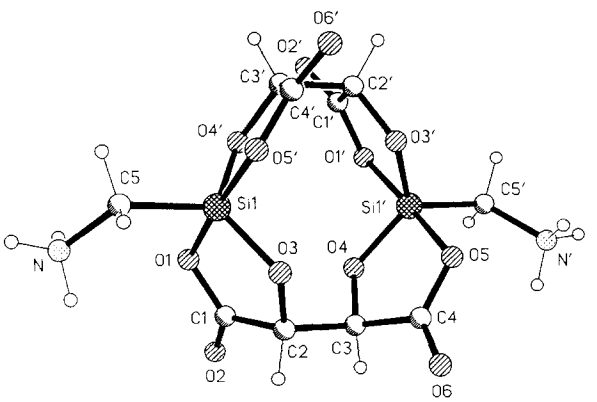

Fig. 1. Molecular structure of (+)-**4** in the crystal of (+)-**4**·3 H_2O. Selected distances [pm] and angles [°] (standard deviations in parentheses): Si1-O1 179.1(2), Si1-O3 167.5(2), Si1-O4′ 166.5(2), Si1-O5′ 182.0(2), Si1-C5 188.5(3), Si1′-O1′ 182.5(2), Si1′-O3′ 166.9(2), Si1′-O4 166.6(2), Si1′-O(5) 179.7(2), Si1′-C5′ 188.4(3); O1-Si1-O3 89.07(9), O1-Si1-O4′ 90.06(10), O1-Si1-O5′ 175.56(9), O1-Si1-C5 95.45(11), O3-Si1-O4′ 121.18(10), O3-Si1-O5′ 87.85(9), O3-Si1-C5 120.04(12), O4′-Si1-O5′ 88.79(9), O4′-Si1-C5 118.58(12), O5′-Si1-C5 88.87(11), O1′-Si1′-O3′ 88.21(9), O1′-Si1′-O4 88.87(9), O1′-Si1′-O5 175.13(9), O1′-Si1′-C5′ 89.28(11), O3′-Si1′-O4 122.57(10), O3′-Si1′-O5 88.68(9), O3′-Si1′-C5′ 120.23(11), O4-Si1′-O5 89.64(9), O4-Si1′-C5′ 117.06(11), O5-Si1′-C5′ 95.52(11).—The molecular symmetry of (+)-**4** may be described as approximately D_2 if the ammoniomethyl groups are ignored.

rounding the atoms Si1 and Si1′ can be described to a first approximation as slightly distorted trigonal bipyramids [transition trigonal bipyramid → square pyramid: 7.7% Si1; 10.6% Si1′],[7] in which each of the axial positions is occupied by carboxylate oxygen atoms. Several intermolecular N−H···O and O−H···O hydrogen bonds are present in the crystal structure of (+)-**4**·3 H_2O. The construction of the three-dimensional H-bonding system is complicated and characterized by a large acceptor excess (D/A ratio 12:30), such that generally only one of the acceptor sites on the oxygen atoms is used (exceptions: use of two acceptor sites by the carbonyl oxygen atoms O2, O2′, and O6′ as well as nonparticipation of the atoms O4, O4′, and O5′ in hydrogen bonding).

It follows from NMR spectroscopic investigations[8] that the zwitterionic binuclear complex (+)-**4** is also present in solution ([D_6]DMSO, D_2O). The presence of pentacoordinate Si atoms of the type SiO_4C is clearly indicated by the characteristic ^{29}Si chemical shifts ([D_6]DMSO: $\delta = -91.7$; D_2O: $\delta = -90.0$), and the presence of tetracoordinate N atoms of the ammonium type can be indirectly confirmed by the identification of the NH_3 group by ^1H NMR spectroscopy ([D_6]DMSO: $\delta = 7.1$).

The results presented here suggest that a rich complex chemistry of higher coordinate silicon in aqueous solution may be developed, in which diolato ligands derived from natural products (such as tartaric acid in this case) are of particular interest: it has been speculated in the literature[9] that silicon transport in biological systems might be based on higher coordinate Si species, and complexes such as the title compound could be of interest as model systems in this respect.

Experimental Procedure

(+)-**4**/(+)-**4**·3 H_2O: **3** [4] (800 mg, 4.14 mmol) was added to a stirred solution of (*R*,*R*)-(+)-tartaric acid (622 mg, 4.14 mmol) in water (120 mL) at room temperature. The resulting clear solution was concentrated at 60 °C/40 Torr to a volume of 100 mL and then allowed to stand undisturbed at room temperature for 96 h (formation of the first crystals ca. 24 h after the reactants were mixed). The solid formed was filtered off and washed with ethanol (3 × 10 mL) and then dried at room temperature in a nitrogen stream; yield 780 mg (ca. 88%) of a crystal mixture composed of (+)-**4** (colorless, thin needles) and (+)-**4**·3 H_2O (colorless rhombuses) in a ratio of roughly 2:1 (^1H NMR spectroscopic determination of the proportion of H_2O in the mixture). (+)-**4** and (+)-**4**·3 H_2O were isolated in pure form by mechanical sorting under the microscope.

(+)-**4**: M.p. > 350 °C; $[\alpha]_{589}^{20} = +86$ (DMSO, $c = 1.00$); correct C, H, N analysis; ^1H NMR ([D_6]DMSO): $\delta = 2.05$ (br. s, 2H; $SiCH_2N$), 4.15 (s, 4H; CH), 7.1 (br. s, 6H; NH); ^1H NMR (D_2O): $\delta = 2.56$ (br. s, 2H; $SiCH_2N$), 4.68 (s, 4H; CH); ^{13}C NMR ([D_6]DMSO): $\delta = 28.2$ ($SiCH_2N$), 75.5 (CH), 173.3 (C=O); ^{13}C NMR (D_2O): $\delta = 29.3$ ($SiCH_2N$), 77.7 (CH), 178.2 (C=O); ^{29}Si NMR ([D_6]DMSO): $\delta = -91.7$; ^{29}Si NMR (D_2O): $\delta = -90.0$; FAB-MS (glycerol as matrix, xenon as neutral gas), *m*/*z* (%): 409 (100) [$M - H^+$], 411 (100) [$M + H^+$].

(+)-**4**·3 H_2O: M.p. > 350 C; $[\alpha]_{589}^{20} = +84$ (DMSO, $c = 1.14$); correct C, H, N analysis. The ^1H, ^{13}C, and ^{29}Si NMR data and the FAB-MS data were identical with those obtained under the same measurement conditions as used for (+)-**4** [exception: an additional resonance signal in the ^1H NMR spectrum ([D_6]DMSO) at $\delta = 3.35$ (s, 6H; H_2O)].

[5] The levorotatory antipode (−)-**4** [(−)-**4**·3 H_2O] can be obtained by the reaction of **3** with (*S*,*S*)-(−)-tartaric acid in an analogous manner.

[6] Crystal data for (+)-**4**·3 H_2O: $C_{10}H_{20}N_2O_{15}Si_2$, monoclinic, space group $P2_1$, $a = 815.2(3)$, $b = 1045.1(4)$, $c = 1089.1(3)$ pm, $\beta = 103.06(3)°$, $V = 0.9039(5)$ nm^3, $Z = 2$, $T = -130$ °C. A colorless prism (0.90 × 0.15 × 0.15 mm) was mounted in inert oil (type RS3000; donation from Riedel de Haën). 5624 Intensities were measured on a diffractometer (Stoe, type STADI-4) ($Mo_{K\alpha}$ radiation, $2\theta_{max} = 60°$), of which 5299 were independent ($R_{int} = 0.035$). The structure was solved by direct methods and refined on F^2 (program SHELXL-93, G. M. Sheldrick, Universität Göttingen). The final $R_w(F^2)$ value was 0.111, the conventional $R(F)$ value was 0.043 (for 282 parameters). The absolute configuration of (+)-**4** was confirmed by means of an *x* refinement [$x = 0.02(11)$] (cf. H. D. Flack, *Acta Crystallogr. Sect. A* **1983**, *39*, 876–881). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-400670.

[7] The quantification of the distortion in this form relates to the transition from the ideal trigonal bipyramid toward the ideal square pyramid along the reaction coordinate of the Berry pseudorotation. The degree of distortion was calculated according to the dihedral angle method described in the literature [10], using the values given there for the reference geometry of the ideal square pyramid.

[8] Measurement conditions: 250.1 (^{1}H), 62.9 (^{13}C), and 49.7 MHz (^{29}Si); approx. 22 °C; [D$_5$]DMSO ($\delta = 2.49$) and $(CH_3)_3Si(CH_2)_3SO_3Na$ ($\delta = 0$) as internal ^{1}H standards in [D$_6$]DMSO or D$_2$O; [D$_6$]DMSO ($\delta = 39.90$) and $(CH_3)_3Si(CH_2)_3SO_3Na$ ($\delta = 0$) as internal ^{13}C standards in [D$_6$]DMSO or D$_2$O; TMS ($\delta = 0$) and $(CH_3)_3Si(CH_2)_3SO_3Na$ ($\delta = 0$) as internal ^{29}Si standards in [D$_6$]DMSO or D$_2$O.

[$Zr_3Cp_2(O_2CNiPr_2)_6(\mu_3$-O)($\mu_2$-CCO)], the First Crystallographically Established Ketenylidene Complex; A Model for CO Reductive Cleavage on Metal Surfaces**

Fausto Calderazzo, Ulli Englert, Alessandro Guarini, Fabio Marchetti, Guido Pampaloni,* and Annalaura Segre

The formation of carbon–carbon bonds from the C_1 feedstock, CO, is a fundamental reaction in organometallic chemistry. Reductive coupling of CO to give fragments containing C-C multiple bonds has been reported.[1] In these reactions exhaustive transfer of oxygen from CO to cations of early transition metals, lanthanides, or actinides occurs. On the other hand, less extensive reductions of carbon monoxide occurs with alkali metals or solutions of them to yield $(CO)_n^{m-}$ species, $n = m = 2$;[2] $n = 4$, $m = 2$;[3] $n = m = 6$.[4] To our knowledge, only one case exists[5a] of the intermediate reduction of CO to the ketenylidene ligand, namely in the reaction of [Ta(tBu$_3$SiO)$_3$] with CO at low temperature and pressure, which gives an almost equimolar mixture of [TaO(tBu$_3$SiO)$_3$] and [Ta(CCO)(tBu$_3$SiO$_3$]; the latter compound is not isolated, but contains a terminal ketenylidene ligand according to spectroscopic data. The reaction of [Sm(C$_5$Me$_5$)$_2$(thf)$_2$] with CO was reported to yield the metal-substituted ketenecarboxylic acid in [Sm$_2$(C$_5$Me$_5$)$_4$(O$_2$CCCO)(thf)]$_2$.[5b]

In continuation of our studies on redox reactions with *N*,*N*-dialkylcarbamato complexes of transition elements,[6] we now report[7] that the reaction of [Cp$_2$Zr(CO)$_2$] with [Zr(O$_2$CNR$_2$)$_4$] (R = Et, *i*Pr) in refluxing toluene affords colorless crystals of the diamagnetic compounds **1a** (R = Et) and **1b** (R = *i*Pr) in satisfactory yields [Eq. (a)].

$$[Cp_2Zr(CO)_2] \xrightarrow{[Zr(O_2CNR_2)_4]} \underset{\mathbf{1}}{[Zr_3Cp_2(O_2CNR_2)_6(\mu_3\text{-}O)(\mu_2\text{-}CCO)]} \quad (a)$$

Compounds **1** are poorly soluble in aliphatic hydrocarbons and slightly soluble in aromatic hydrocarbons and THF. The μ-ketenylidene derivatives **1** are characterized by a sharp IR absorption at 2013 cm^{-1} (in toluene or as nujol mull), which shifts to 1951 cm^{-1} in the ^{13}C-labeled compound prepared from [Cp$_2$Zr(^{13}CO)$_2$] and [Zr(O$_2$CNiPr$_2$)$_4$], thus showing that the carbon atoms of the μ-ketenylidene ligand come from the carbonyl groups of the zirconium(II) complex. No shift of the 2013 cm^{-1} band is observed in the compound obtained from the reaction of [Cp$_2$Zr(CO)$_2$] with [Zr(O$_2$^{13}CNiPr$_2$)$_4$].

The ^{13}C NMR spectrum of the ^{13}C-labeled product [Zr$_3$Cp$_2$(O$_2$CNiPr$_2$)$_6$(μ_3-O)(μ_2-^{13}C^{13}CO)] shows two doublets at $\delta = 181.5$ and 112.4 ($J_{C,C} = 78.9$ Hz); the former resonance is assigned to the carbon adjacent to the oxygen atom of the ketenylidene ligand, in agreement with the reported values for bridging ketenylidene groups.[8]

Figure 1 shows the molecular structure[9] of **1b**, which consists of a μ_3-O-bridged triangle of zirconium atoms. Two of the metal atoms (Zr2 and Zr3) are coordinated to bridging carbamates and to the cyclopentadienyl and μ-CCO ligands; the third zirconium atom (Zr1) has bridging and terminal carbamato ligands. A similar essentially planar Zr_3 (μ_3-O) moiety has been observed[10] in [Zr$_3$Cp$_3$(μ_2-OH)(μ_3-O)(μ_2-PhCOO)$_3$]$^+$PhCOO$^-$ [Zr–O (mean value) 2.071(11) Å, Zr-O-Zr (mean value) 108.1(8)°; Zr···Zr (mean value) 3.354(12) Å; see caption to Fig. 1 for the corresponding values for **1b**]. The μ-ketenylidene ligand is substantially linear [C1-C2-O2, 179(1)°]; the C1-C2 and the C2-O2 bond lengths of 1.31(2) and 1.24(1) Å, respectively, are in accord with the reported values.[8]

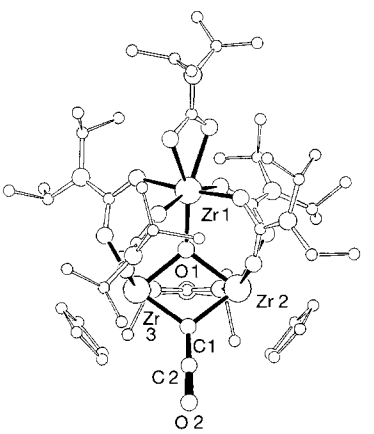

Fig. 1. Crystal structure of **1b** [19]. Selected distances [Å] and angles [°]: Zr1–O1 2.049(5), Zr2–O1 2.140(5), Zr3–O1 2.126(5), Zr2–C1 2.122(8), Zr3–C1 2.138(8), Zr···Zr (mean value) 3.597(1); Zr1-O1-Zr2 125.0(2), Zr1-O1-Zr3 130.0(3), Zr2-O1-Zr3 103.8(2), O1-Zr2-C1 73.7(2), O1-Zr3-C1 73.6(2), Zr2-C1-Zr3 104.0(4), Zr2-C1-C2 126.8(8), Zr3-C1-C2 128.1(8).

The ketenylidene ligand has been assembled around a transition metal cation by four synthetic methods: a) reductive dehalogenation or dehalogenation of a metal-coordinated C–X_n fragment, such as the dehalogenation[11] of [Co$_3$(CO)$_9$C–Cl] by AlCl$_3$ in the presence of CO; b) reductive cleavage (by an external reducing agent such as an alkali metal) in a trinuclear or tetranuclear metal cluster of a CO *single* bond obtained by a preliminary electrophilic activation of a metal-coordinated carbonyl group;[12] c) reaction of a low-valent metal complex with C_3O_2;[13] d) carbonylation of a diazomethyl complex.[14] Furthermore, a silver ketenylidene complex has been prepared[15] from a silver salt and ketene or ketene precursors. The isolation of compounds **1** corresponds to a new preparative method by which the Zr-coordinated carbonyl groups are reduced to the μ_2-ketenylidene ligand without addition of an external reducing agent. The four reducing equivalents required by this process ($2CO \rightarrow C_2O + O$) are provided by zirconium(II).

The proximity of the metal atoms in **1** may establish similar conditions to those at a metal surface on which an analogous process might take place. The simplicity and the high chemoselectivity of the reaction reported in this paper, and the high

stability of the μ_2-*bridged* ketenylidene ligand characterized by a strong IR stretching band in the same region as that of terminal metal-coordinated carbonyl groups suggest that metal surfaces or reduced metal oxides may lead more frequently than originally thought to surface-coordinated ketenylidene groups as intermediates or end products of the CO chemisorption process.[16] Thus the earlier suggestions[5, 8, 12] that ketenylidene might be a surface-bonded species are considerably strengthened by these novel findings. IR-active $\geq C=C=O$ sequences absorbing around 2100 cm^{-1} were postulated for carefully dehydrated MgO exposed to carbon monoxide.[17]

In agreement with the nucleophilic character of the α carbon atom in organic ketenes,[18] the zirconium(IV) complex **1b** reacts with substrates containing the $\geq C=O$ group. With carbon dioxide, after appropriate workup, the μ-oxo derivative **2** was isolated and characterized by elemental analysis, ^{13}C NMR spectroscopy, and mass spectrometry (protonated molecular ion: $m/z = 1297$). X-ray diffraction data on **2** show the com-

$[Zr_3Cp_2(O_2CN\mathit{i}Pr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}O)]$ **2**

pound to have a substantially similar structure to **1b** in which the μ_2-CCO group of **1b** is replaced by the μ_2-oxo ligand. The reaction of the ^{13}C-labeled **1b**, $[Zr_3Cp_2(O_2CN\mathit{i}Pr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}{}^{13}C{}^{13}CO)]$, with acetone led, inter alia, to the same $(\mu_3\text{-}O)(\mu_2\text{-}O)$ derivative as in the reaction with CO_2, and to the compounds $Me_2C={}^{13}CH{}^{13}C(O)N\mathit{i}Pr_2$, $\mathit{i}Pr_2N{}^{13}C(O){}^{13}CH_3$, and $\mathit{i}Pr_2N{}^{13}C(O){}^{13}CH_2C(OH)Me_2$ detected by GC-MS, which clearly contain the ketenylidene fragment. Mesityloxide was found among the volatile products.

Experimental Procedure

All experiments were performed under an inert atmosphere of argon, unless otherwise stated. IR, ^1H and ^{13}C NMR spectra, and mass spectra (desorption chemical ionization with isobutane as the reagent gas) were measured with Perkin Elmer FT 1725X, Varian Gemini 200, Bruker AM 200, and Finnigan MAT 8400 double-focusing reverse-geometry instruments, respectively. Satisfactory elemental analyses were obtained for all compounds reported in this paper.

1: Only the preparation of the compound with R = *i*Pr is described in detail. The ethyl derivative was prepared analogously. A solution of $[ZrCp_2(CO)_2]$ (8.08 g, 29.1 mmol) and $[Zr(O_2CN\mathit{i}Pr_2)_4]$ (19.3 g, 28.9 mmol) in toluene (250 mL) was heated at reflux for 1.5 h. After cooling to room temperature, an IR spectrum of the solution revealed a strong absorption band at 2013 cm^{-1}. After filtration of some dark insoluble material and evaporation of about 150 mL of toluene under reduced pressure, a colorless crystalline solid precipitated, which was filtered off, washed with toluene (5 × 10 mL), and dried in vacuo at room temperature (8.67 g). The diamagnetic solid was identified as **1b**. IR (Nujol and polychlorotrifluoroethylene mulls): $\tilde{\nu}$ = 3110 m-w, 2970 m-s, 2930 m, 2870 w, 2013 s, 1964 w, 1580 w, 1530 vs, 1510 vs, 1385 s, 1360 vs, 1210 m, 1160 m-w, 1135 w, 1075 m, 1020 m-w, 900 w, 870 w, 820 m, 800 m-s, 785 vs, 730 m-w, 680 m-s, 660 w, 600 m-s, 570 m-s, 530 m-s and 470 m-w cm^{-1}; IR(THF): $\tilde{\nu}$ = 2015 cm^{-1}; IR(CH_2Cl_2): $\tilde{\nu}$ = 2010 cm^{-1}. ^1H NMR ([D_6]-benzene, 20 °C, TMS): 6.7 (10 H, s), 3.8 (6 H, multiplet), 1.2 (72 H, multiplet). ^{13}C NMR ([D_8]toluene, 20 °C, TMS): 181.5 (d, *C*CO); 169.5, 162.4, 161.0 (s, CO_2); 112.4 (d, *C*CO); 114 (s, Cp); 46.9, 45.7 [s, $CH(CH_3)_2$]; 22 (s, CH_3, partial overlap with the solvent). A further corp (2.3 g) of the spectroscopically pure compound was obtained from the filtrate by reduction of the volume of the solution to 25 mL and addition of heptane (25 mL). The resulting pale brown solid was filtered and washed with heptane (about 10 × 30 mL) (43% overall yield based on the total zirconium). The average yield on a set of fifteen preparations is around 50%.

The Determination of Maximum Common Substructures by a Genetic Algorithm: Application in Synthesis Design and for the Structural Analysis of Biological Activity

Markus Wagener and Johann Gasteiger*

The comparison of the structures of two compounds is a widespread problem in chemistry, for instance, in the analysis of biological activity, in the search for promising starting materials for the synthesis of a target compound, in the elucidation of biosynthetic pathways, and in the determination of the atoms and bonds directly involved in a reaction. An essential task for the comparison is the determination of the largest substructure common to the two structures (maximum common substruc-

ture; MCSS). Therefore, the search for an MCSS plays an important role in the computer-assisted processing of chemical information. This is reflected by the high number of publications suggesting solutions to this problem.[1] In the end, all methods have to explore the set of all possible solutions and provide different heuristics to keep the search within bounds. We will show here that the MCSS problem can also be solved by a genetic algorithm. This allows one to avoid a time-consuming systematic search and is thus particularly advantageous for larger structures.

Genetic algorithms (GA) are optimization methods that model mechanisms used by nature to adjust to a changing environment.[2] Initially, a number of randomly determined solutions (population) for a problem is given. These solutions are all approximations to the optimum sought, but differ in their "fitness". A set of genetic operators usually having an analogy in natural genetics is then iteratively applied to this population (Fig. 1).

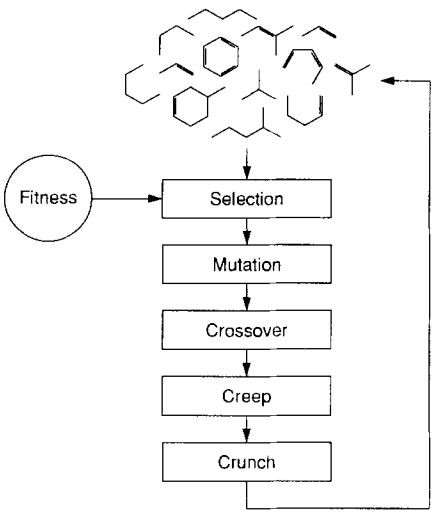

Fig. 1. Overview of the genetic algorithm used here. The boxes represent the genetic operators, and the population is indicated by the structure fragments.

The selection operator favors those solutions (individuals) for the next generation that have a high fitness value. This progressively reduces the number of unfavorable solutions, that is, those with a low fitness value, in the population. The other operators form new individuals with potentially better properties from the present population.

Genetic algorithms are robust and can therefore be applied to a host of problems.[2] However, in chemistry they have not yet found much use except in chemometric methods[3] and for the determination of the minimum chemical distance.[4]

In our method for searching for the maximum common substructure of two compounds by a genetic algorithm, bonds in the two molecules considered are assigned to each other. Such an assignment corresponds to an individual of the GA-population. This bond matching might represent a common substructure but need not. The fitness of such a bond matching is calculated by Equation (a).

$$F = N - V - (T_1 + T_2 - 2) \qquad \text{(a)}$$

N is the total number of bonds in the two structures that participate in the bond matching. V specifies how often two adjacent bonds in one structure are assigned to two nonadjacent bonds in the other structure. Thus, the higher the value of V, the worse the matching of the two substructures. T_1 and T_2 give the number of unconnected parts in the two structures. The value of 2 was introduced to ensure that F gives the number of matching bonds if a coherent and fitting substructure is found. The upper part of Figure 2 shows a comparison of cyclobutane and methylbutane. Bonds shown in bold are assigned to each other. Thus, bond b is assigned to bond 2 and bond c to bond 4, as also shown in the table to the right of the two structures. The other bonds of cyclobutane are not assigned to any bonds of methylbutane (indicated by an asterisk). The fitness value of -1 is calculated as follows: Altogether, four bonds are assigned to each other ($N = 4$). The two bonds are adjacent in cyclobutane but not in methylbutane and thus all four violate the neighborhood relationship ($V = 4$). The substructure in cyclobutane consists of only one part ($T_1 = 1$), but in methylbutane there are two fragments ($T_2 = 2$).

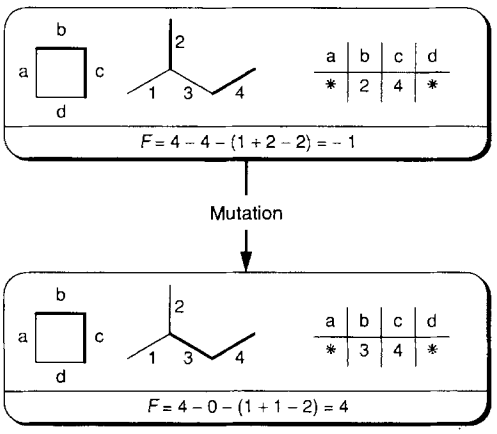

Fig. 2. The mechanism of the mutation operator: the assignment of bond b in cyclobutane to bond 2 in methylbutane is changed to an assignment to bond 3, which raises the fitness (F) from -1 to $+4$.

A population of such individuals consisting of pairs of mutually assigned structures is converted into a new population by five genetic operators: selection, mutation, crossover, creep, and crunch.[5] Selection uses a procedure[6] that reduces the number of stochastic errors relative to other selection methods. Mutation arbitrarily changes the assignment of one bond pair. Figure 2 shows how bond b is reassigned by mutation from bond 2 to bond 3 of methylbutane. This increases the fitness from -1 to $+4$. Crossover exchanges partial solutions in the form of partial structure assignments between two individuals. Figure 3 shows how the assignment of bond c to bond 4 is transferred from the right to the left individual and thus increases the common substructure.

Two additional operators, creep and crunch, that are specifically tailored to the problem at hand were developed to increase the efficiency of the MCSS search. They use information on the constitution of the structures investigated, quite in contrast to the classical operators mutation and crossover, and aim at individuals with higher fitness values. The creep operator increases the assignment of bonds by one bond pair if this is possible without violating neighborhood relationships in the two structures investigated (cf. the quantity V in the fitness function (a)). This is particularly helpful if only one bond pair is missing to the maximum common substructure. Thus, the last step of the global maximum can be made with the creep operator particularly easily.

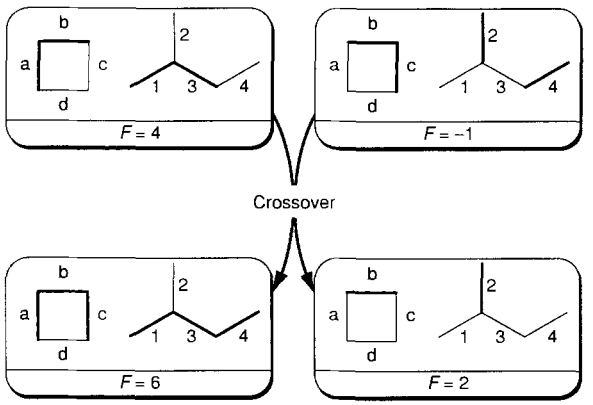

Fig. 3. The mechanism of the crossover operator: the assignment of bond c to bond 4 is transferred from the second pair of structures (individual) to the first.

The crunch operator, on the other hand, decreases the number of assigned bonds. If a partial structure is not contiguous the crunch operator will delete all bonds of the smallest fragment. In this way, local maxima that are quite often characterized by small disconnected fragments can safely be escaped.

Strong competition between the individuals of a population particularly in the initial phases of the optimization can result in finding only a local maximum due to early convergence. In order to avoid such a situation the population is divided into separate partial populations called niches. Competition then mainly occurs within a niche but is reduced between niches.

Genetic algorithms are methods that are driven by chance and consequently do not necessarily lead to the global optimum. Therefore, each substructure assignment problem was separately treated 50 times with different initializations of the populations in the following three examples. The results of these 50 separate runs allow an estimate of how safely the genetic algorithm finds the global optimum. The bond order (single, double, or triple bonds) of the assigned bonds was not considered in these studies in order to find substructures that are as large as possible. A single run of a genetic algorithm was performed for 400 generations. Each population comprised 100 individuals; the size of an individual was determined by the number of bonds in the larger of the two structures. Each of the following examples illustrates a different field of application.

The structural prerequisites of biological activity can be analyzed with this method. Figure 4 shows the two strong analgesics morphine (**1**) and methadone (**2**), and the MCSS (in bold, fitness 34.0) found in 48 of the 50 program runs. A program run took 20 s on a Sparc Station 10/20. The average fitness of the 50 runs was 33.9. Clearly, final conclusions on the biological activity can only be drawn by comparison of the three-dimensional structures. We are therefore working on an extension of the method for the determination of the maximum common three-dimensional substructure by a genetic algorithm.

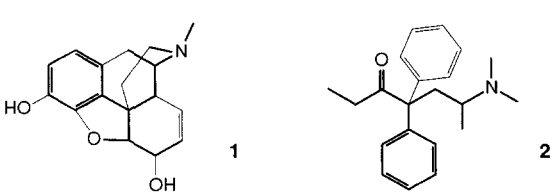

Fig. 4. The maximum common substructure of the two analgesics morphine (**1**) and methadone (**2**) indicated in bold.

The method can also be used for the analysis of biosynthetic pathways. Geissoschizine (**4**) is an important intermediate in the biosynthesis of the monoterpene alkaloids.[7] Figure 5 shows the largest substructure common to strychnine (**3**) and geissoschizine (**4**) (fitness 48.0) that was obtained in 31 of the 50 optimization experiments. The average fitness attained in 50 runs was 44.0. All details of the transformation of geissoschizine into the strychnos alkaloids are not yet known; the common substructure found here can give important hints worthy of further experimental investigations.

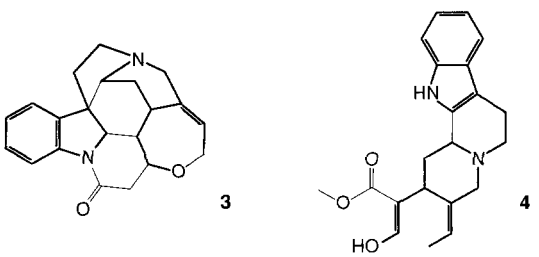

Fig. 5. The largest substructure common to strychnine (**3**) and geissoschizine (**4**).

The synthesis of strychnine by Woodward et al.[8] serves as an illustration of a search for appropriate starting materials for the synthesis of a desired target compound. Figure 6 shows the maximum common substructure between strychnine (**3**) and 2-veratrylindole (**5**) which was used as a starting material in the synthesis. A substructure of this size (fitness 34.0) was found 35 times in 50 program runs with an average fitness of 32.1. The common substructure nearly covers the entire skeleton of **5**, and therefore this compound is an attractive starting material. This high similarity was also utilized by Woodward et al. in their synthesis: all atoms of the MCSS in veratrylindole except the one marked by an asterisk were used as assigned by the genetic algorithm to build the skeleton of strychnine.

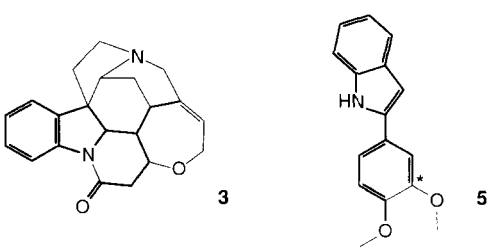

Fig. 6. The largest common substructure of strychnine (**3**) and 2-veratrylindole (**5**), a starting material in the synthesis of **3**.

The search for appropriate starting materials for a synthesis can also benefit from a search for duplicate substructures in one and the same molecule. This can indicate that instead of two different starting materials only one has to be made and used twice in the course of the synthesis. The larger the structure of the precursor that is used several times, the more efficient the synthesis strategy. Nature also often utilizes this principle; the most notable examples are the terpenes constructed from isoprene units.

The described genetic algorithm was extended to find the largest substructure contained twice in a molecule. The extended procedure works with the same fitness function [Eq. (a)] and with the genetic operators selection, mutation, crossover, creep and crunch as previously described. However, the way the sub-

structure is represented had to be changed in order to allow both substructures to be contained in a single molecule. This requires restrictions to prevent an atom or a bond from appearing in both substructures.

The search for the largest two identical substructures in badion A (**6**), the natural dye in the cap of *Xerocomus badius*,[9] with the extended genetic algorithm provides the result shown in Figure 7. The substructure contained twice in this molecule is highlighted in bold. This substructure corresponds to pulvinic acid (**7**), also found in *Xerocomus badius* and presumably an intermediate in the biosynthesis of badion A, which can be formed from it by oxidative dimerization.[10] The substructure shown in Figure 7 (fitness 54.0) was found 27 times in 50 runs of the genetic algorithm (average fitness 48.1).

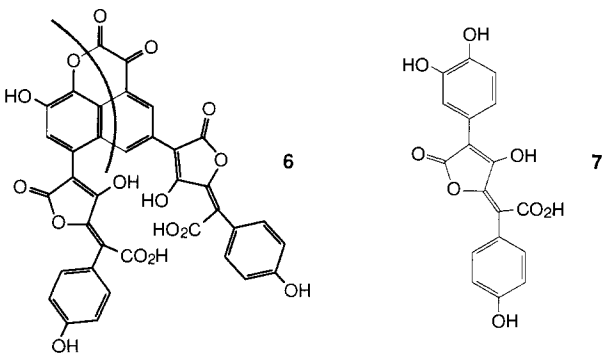

Fig. 7. Badion A (**6**) and the potential intermediate in its biosynthesis, pulvinic acid (**7**). The substructures shown in bold and separated by an arc were found by the genetic algorithm.

A systematic search in a reaction database was made to investigate how often this synthesis principle is used and which types of structures and reactions are employed. Six hundred reactions were selected randomly from the update 1991 of the Chem Inform-RX reaction database.[11] Among these the genetic algorithm found 30 reactions where a starting material was incorporated twice into the reaction product. One of these reactions, the condensation of an arene with formaldehyde, is shown in Figure 8. This example shows that the method also allows the analysis of reactions in which a molecule contains parts from starting materials other than the matching substructures.

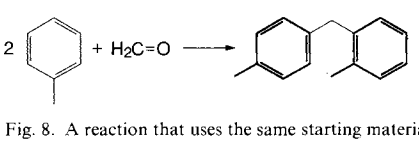

Fig. 8. A reaction that uses the same starting material twice. It is representative of the 30 reactions found in a systematic search in a randomly chosen part of the ChemInform-RX reaction database.

The example also illustrates that considerations of symmetry in a molecule do not suffice to decipher this synthesis strategy. It is only the search for the maximum matching substructures that enables planning of such syntheses.

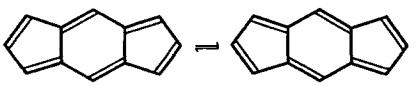
s-Indacene: A Delocalized, Formally Antiaromatic 12 π Electron System**

Roland H. Hertwig, Max C. Holthausen, Wolfram Koch,* and Zvonimir B. Maksić



s-Indacene is a planar, conjugated, tricyclic hydrocarbon with 12 π electrons. Formally it can be considered as a [12]annulene perturbed by two cross links or alternatively as a molecule obtained by fusion of two fulvenes (Scheme 1). According to the Hückel ($4n + 2$) rule it is an antiaromatic system.[1] Thus, the equilibrium structure of the lowest energy singlet state is expected to be C_{2h}-symmetric with localized double bonds (**2**) and not D_{2h}-symmetric with a delocalized π electron system (**1**).[2] Indeed, in early HMO[3] and semiempirical studies[4] on the equilibrium structure of *s*-indacene the localized structure was found to be more stable than the delocalized one. This conclusion was very recently supported by Gellini et al. by Hartree–Fock (HF) MO calculations using medium-sized basis sets.[5] The authors arrive at an energy difference of 5.6 kcal mol^{-1} in favor of the C_{2h} structure **2**. However, unsubstituted *s*-indacene is extremely reactive and decomposes immediately,[6] and structural investigation by X-ray diffraction is not possible. In addition, the

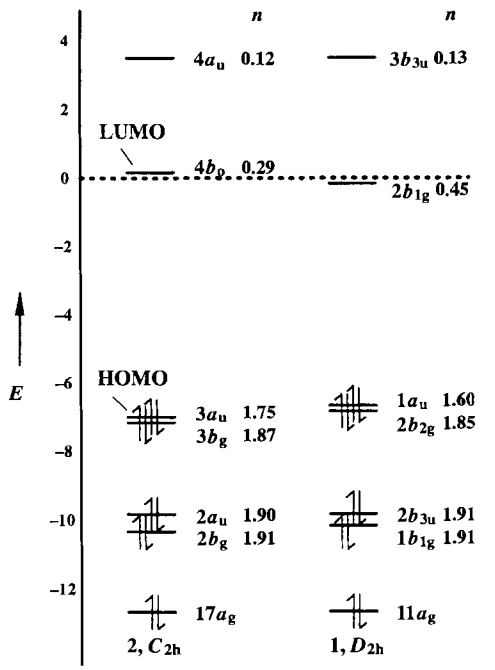
2, C_{2h} **2**, C_{2h}



Scheme 1. Delocalized (D_{2h}-symmetric) and localized (C_{2h}-symmetric) forms of *s*-indacene.

reported calculations are not at a level high enough to allow for an unambiguous conclusion, and hence the exact equilibrium structure of *s*-indacene is still not known. It was pointed out that substitution at symmetry-equivalent positions can lead to greater delocalization of the π electrons.[1, 4, 7] The most prominent example is 1,3,5,7-tetra-*tert*-butyl-*s*-indacene, whose carbon skeleton has effective D_{2h} symmetry according to the X-ray structure analysis reported by Hafner et al.;[4] this structure was later confirmed by Dunitz et al.[8] In addition, only four peaks appear in ^{13}C NMR spectrum for the 12 carbon atoms in the ring system, even at −130° C.[4] It is possible that the crystal structure obtained does not correspond to the ground state, but to the saddle of the valence isomerization, owing to the stabilization afforded by crystal packing effects.[8] However, the NMR results can be explained only by a very low energy barrier between the two degenerate C_{2h} valence isomers or by a completely delocalized π electron system.

A qualitative rationalization of the substituent effect on the delocalization in such systems has recently been given by Heilbronner and Yang using simple HMO theory.[7] Their model indeed shows that 1,3,5,7-tetra-*tert*-butyl-*s*-indacene should have a stronger tendency towards delocalization than the parent *s*-indacene; however this model provides no clear-cut answer to whether *s*-indacene prefers a localized or delocalized structure. *s*-Indacene is a borderline case, and it appears that its geometrical structure depends on subtle details of the electron density distribution.

We report here on our high-level quantum chemical calculations on the equilibrium structure of the lowest energy singlet state of *s*-indacene. We tackled this problem using two independent theoretical approaches: conventional ab initio methods with inclusion of correlation effects,[9] and methods based on density functional theory, in which electron correlation is implicitly contained in the functional used.[10]

Inspection of the computed (HF/6-31G*[11]) orbital energies shows that the simple, one determinant based picture of HF theory is probably not adequate for a proper description of the electronic structures of **1** and **2**. The energy of the highest occupied molecular orbital (HOMO) is relatively high, whereas the energy of the lowest unoccupied molecular orbital (LUMO) is around 0 eV and thus very low. Hence, the Slater determinant corresponding to the excitation of two electrons from the HOMO to the LUMO can be expected to be an important contributor to the ground-state wave function. Complete active space SCF (CASSCF) calculations for MP2-6-31G* optimized geometries[12] in which all possible distributions of 12 π electrons are considered for the 12 MOs constructed from the carbon $2p_z$ orbitals revealed that the electronic structure of both isomers of *s*-indacene is indeed very complex. The HF determinants of **1** and **2** have a weight of only 64 and 71%, respectively. Excitations to the LUMO are very prominent; this formally empty orbital is occupied with 0.45 (**1**) and 0.29 electrons (**2**), and the next orbital is also partially occupied (>0.1 electrons; Scheme 2). At the CASSCF level **2** is predicted to be 5.7 kcal mol^{-1} more stable than **1**.[13]

Scheme 2. Orbital energies *E* [eV] (HF/6-31G*), symmetries, and occupation numbers *n* [electrons] of natural orbitals (CASSCF/6-31G*) of **1** and **2**.

The qualitative implication of this result is that **1** and **2** are not pure closed-shell systems but have substantial singlet diradical character. The CASSCF treatment, however, accounts only for the energetic near-degeneracy of Slater determinants, the so-called nondynamic electron correlation, but not for dynamic electron correlation. Further refinement of the level of theory is required for accurate results. Thus, in a subsequent step we computed the energies of **1** and **2** by using the CASPT2 method, a multireference version of second-order many-body perturbation theory developed recently by Roos et al.,[14] in which all but the carbon 1s electrons are correlated. The full CASSCF wavefunction was used as reference space in the CASPT2 calculations. At this level both the multireference character of the wavefunction and the dynamic electron correlations are included. At this highest ab initio MO level the delocalized, D_{2h}-symmetric form **1** of *s*-indacene is 3.1 kcal mol^{-1} *more* stable than its localized, C_{2h} counterpart.[15]

In our second set of calculations we used density functional theory employing the local density approximation (LDA) with local Slater exchange functional and correlation functional parametrization on the homogeneous electron gas of Vosko, Wilk, and Nusair.[16] Nonlocal gradient corrections according to Becke[17] and Perdew[18] (LDA + BP) for exchange and correlation, respectively, were also added. Here, nondynamic as well as dynamic electron correlation is implicitly accounted for through the form of the functional used. For example, whereas HF calculations on azulene erroneously give a localized, C_s-symmetric equilibrium structure, LDA plus nonlocal corrections yields the

correct, delocalized structure.[19] With both approximations, LDA and LDA + BP, optimizations of **1** and **2** starting from the MP2/6-31G* structures lead only to the delocalized structure **1**. A C_{2h}-symmetric minimum structure corresponding to **2** was not found. Determination of the harmonic frequencies at the LDA + BP level by numerical differentiation of the analytical gradients showed that **1** is indeed a minimum structure with only real frequencies.

The structural parameters of **1** as determined by MP2/6-31G* and LDA + BP are summarized in Table 1 and compared to the X-ray structure data of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene. Even though the *tert*-butyl substituents certainly influence the geometry of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene, the agreement between the experimental and computed data is excellent. The root mean square deviations for the C–C bonds are only 0.005 Å (MP2) and 0.006 Å (LDA + BP), and the differences between the two methods are only marginal.

Table 1. Calculated bond lengths [Å] and angles [°] of **1** and the data from the X-ray structure analysis of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene [8].

Parameter	MP2/6-31G*	LDA + BP/TZP	Exp. [a]
C(1)-C(2)	1.404	1.408	1.406, 1.408
C(3)-C(3a)	1.429	1.427	1.434, 1.438
C(3a)-C(4)	1.397	1.401	1.394, 1.395
C(3a)-C(8a)	1.437	1.445	1.442
C(1)-H	1.087	1.091	
C(2)-H	1.085	1.089	
C(4)-H	1.092	1.095	
C(1)-C(2)-C(3)	108.6	108.5	110.8
C(2)-C(3)-C(3a)	108.5	108.7	106.8, 106.9
C(3)-C(3a)-C(8a)	107.2	107.1	107.6, 107.9
C(4)-C(3a)-C(8a)	120.9	120.9	120.4
C(3a)-C(4)-C(4a)	118.1	118.2	119.2
C(8a)-C(1)-H	125.5	125.5	
C(1)-C(2)-H	125.7	125.8	
C(3a)-C(4)-H	120.9	120.9	

[a] Since the X-ray structure does not show strict D_{2h} symmetry, two values are given for one parameter where necessary.

Since the conventional ab initio MO method and the approach based on density functional theory converge to give the same answer concerning the structure of *s*-indacene, we conclude that the equilibrium structure of *s*-indacene has D_{2h} symmetry and a completely delocalized 12 π electron system, despite its formal classification as a $4n$ π antiaromatic system. It follows that the D_{2h}-symmetric X-ray structure of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene is not a "frozen transition state"[8] but corresponds to the ground state structure of this molecule. The high reactivity and elusiveness of *s*-indacene can most likely be explained by its considerable singlet diradical character.

[9] The Hartree-Fock and MP2 calculations were performed using Gaussian 92 [20] with a standard 6-31G* basis set. The CASSCF and CASPT2 energy determinations used the same basis set and were performed with the MOLCAS-2 program package [21]. The number of configuration state functions included in the CASSCF wavefunction was 56928 for **1** and 113456 for **2**. Since geometry optimizations were not possible at these levels, the CASSCF and CASPT2 energy calculations were based on the MP2/6-31G* geometries.
[10] The density functional calculations were performed using ADF, Version 1.0.2 [22]. An uncontracted triple ζ-STO basis set, which was augmented with one 3d (2p) and one 4f (3d) polarization function for carbon (hydrogen) was used (TZP). The carbon 1s electrons were treated in the frozen core approximation. The total molecular electron density was fitted in each SCF iteration by an auxiliary basis set of s, p, d, f, and g STO functions.
[11] At the HF/6-31G* level **2** is computed to be more stable than **1** by 9.2 kcal mol^{-1}; E_{tot} (**2**) = −459.00322 Hartree.
[12] At the MP2/6-31G* level **2** is computed to be more stable than **1** by 0.7 kcal mol^{-1}; E_{tot} (**2**) = −460.52091 Hartree.
[13] The total energy of **2** at this this level is −459.16212 Hartree.

Controversial Life Now Acclaimed

The Quiet Revolution: Hermann Kolbe and the Science of Organic Chemistry. By *A. J. Rocke*. University of California Press, Berkeley, 1993. XIII, 501 pp., hardcover $ 50.00.—ISBN 0-520-08110-2

Adolf Wilhelm Hermann Kolbe (1818–1884) is primarily known today for his scathing and ridiculing attacks on August Kekulé and Jacobus Henricus van't Hoff and for his polemical criticisms of other contemporaries in the pages of the *Journal für praktische Chemie*, which he edited from 1870 until his death. His vituperative writings were so intemperate that many contemporary and later observers believed that he may have been mentally ill. Yet such a view of Kolbe is woefully incomplete. He was a brilliant experimenter who discovered many important organic compounds and reactions. He helped develop the German system of science education, and his laboratory in Leipzig, the largest and best equipped of his day, attracted numerous students from many countries. He was the leader of synthetic organic chemistry during the 1850s and 1860s, and his synthesis of acetic acid from its elements in 1844 provided a significant attack on the concept of vitalism, which had not been completely overthrown by Wöhler's earlier (1828) and better known synthesis of urea.

Kolbe was the influential, pivotal figure in what Alan J. Rocke, Professor of History at Case Western Reserve University and a leading authority on 19th-century chemistry, calls the "quiet revolution". This change emerged during the 1850s from the turbulent disputes about theories of chemical types, radicals, and constitutions, which during the 1860s gave birth to the new science of structural organic chemistry, the last major transition leading to modern chemistry. Kolbe employed all his talents and characteristics—his aggressive intellectual debate, political influence, violent temper, ardent chauvinism, and anti-French xenophobia—to maintain his position in the German academic world. A profound conservative, he vigorously attacked structural formulas and structural chemistry; he considered himself as bearing the mantle of the great classical chemists, especially Berzelius, whose copula theory he retained as the last major element of dualism left in organic chemistry.

Although Rocke's volume (the 11th in the California *History of Science* series) is the first book-length biography of Kolbe in any language, it is much more. The author has used Kolbe's life and career to highlight and chronicle an important period of chemistry in more depth than has hitherto been attempted: "By looking at the field through Kolbe's eyes we see the transformations of this period from the perspective of a man who was at once both an insider and an outsider" (p. 5). Rocke has made extensive use of hitherto unexploited documents from many archives, German and otherwise, as well as literally hundreds of blunt revealing letters from Kolbe and other chemists, to endow his account of the "quiet revolution" with a thrilling immediacy. He also details the social, educational, institutional, and cultural milieu in the various German states in which Kolbe worked, as well as in France and Great Britain (Kolbe spent the period 1845–1847 in London as Lyon Playfair's assistant and was a close friend of Edward Frankland and other English chemists).

Rocke's multifaceted and interpretative account includes biographies of figures pertinent to his story, such as von Baeyer, Berzelius, Bunsen (Kolbe's *Doktorvater*), Dumas, Erlenmeyer, Frankland, Gerhardt, von Hofmann, Kekulé, Laurent, Liebig, Volhard, Williamson, Wöhler, and Wurtz. He explores the influence of these and other personalities, patterns of state support, laboratory organization, teaching methods, and academic publishing (Kolbe was associated with the publishers Eduard and Heinrich Vieweg many years). Eighteen photographs, numerous formulas, equations, tables, notes (83 pp.), a glossary of German and chemical terms (9 pp.), a bibliography (11 pp.), and an index (17 pp., 2 cols. per page) are also provided. This important contextualized study will not only be useful to historians of chemistry and of 19th-century German science as well as to chemists, but should also be of interest to the history of science community in general, because of its novel aspects and historiographic richness.

Applied Laser Spectroscopy. Techniques, Instrumentation, and Applications. Edited by *D. L. Andrews*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. IX, 471 pp., hardcover DM 198.00.—ISBN 3-527-28027-3/1-56081-023-8

Spectroscopy in the visible, ultraviolet, and infrared spectral regions is nowadays performed, almost as a matter of course, using lasers, and there are probably more lasers than monochromators and spectrographs in the laboratories. The well-known properties of lasers as light sources, such as spatial resolution limited only by diffraction, narrow spectral bandwidth, and short pulse duration with high peak intensity, have in the last ten years become more easily and cheaply available. Rapid strides have also been made in the development of detectors (whether for charged particles or for photons). Lastly, the high electric field strengths generated by lasers allow the study of nonlinear processes in the samples under investigation. The combination of a wide variety of laser light sources, of materials investigated, and of light-induced processes, together with appropriate detection methods, has led to a plethora of spectroscopic techniques

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Review Editor, Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1195 $ 10.00+.25/0

known to insiders by their corresponding acronyms. Thus, the beginner needs an introductory overview of the fascinating capabilities of laser spectroscopy.

That is the purpose of the book reviewed here. The authors of its ten chapters report on the present situation in their special fields. In their treatment of molecular spectroscopy there is a definite emphasis on smaller molecules in the gas phase. In accordance with the aims of the book, the basic principles of each spectroscopic method are simply described rather than explained in detail, referring the interested reader to more advanced publications. This is usually followed by descriptions of practical layouts and instrumentation with specific examples. The literature coverage extends to about the end of 1990; however, a beginner interested in a particular topic could certainly locate important recent publications by intelligent forward searching.

The book begins with two introductory chapters giving an overview of laser properties, the achievable photon fluxes, the probability of multiphoton processes, types of lasers, and instrumental aspects such as wavelength calibration. Electronic spectroscopy is then treated in two extensive chapters: "Electronic Photoabsorption Spectroscopy" (W. Demtröder) and "Laser-Induced Fluorescence Spectroscopy" (J. Pfab), the second of these emphasizing the role of the dynamics of photodissociation. In the chapter "High-Resolution Infrared Spectroscopy" B. J. Howard and J. M. Brown describe the use of tunable IR lasers, for example in studies of hollow cathodes, cold jets, and photolysis products. This is followed by chapters on "Modern Techniques in Raman Spectroscopy" (M. D. Morris), "Nonlinear Raman Spectroscopy" (H. Berger, B. Lavorel, G. Millot), "Multiphoton Absorption Spectroscopy" (L. Goodman, J. Philis), and "Laser Mass Spectroscopy" (K. W. D. Ledingham, R. P. Singhal). The contribution on "Ultrafast Spectroscopic Methods" (P. A. Anfinrud, C. K. Johnson, R. Sension, R. M. Hochstrasser) is very up-to-date.

A consequence of this form of treatment is that the special research interests of the authors are strongly represented in their contributions. Also, as already mentioned, condensed phases are only considered in a few of the chapters. A chapter on the topical subject of hole-burning spectroscopy could usefully have been included to complement the others.

The quality of the figures is very mixed. Figures afford a simple way of conveying a lot of information, and for this reason a wasted opportunity is a double cause for regret. For example, the CW laser shown in Figure 2.7 will have poor mode quality, the DFDL lasers in Figures 2.9 and 2.10 will produce mainly amplified spontaneous emission, and in Figure 6.3 we find an optical path which is truly a "black box". However, these criticisms are fairly trivial in view of the wealth of material on methods and examples.

To summarize, this book provides a very useful description of spectroscopic principles, the relevant techniques, and their applications in the area of molecular spectroscopy, especially of small molecules in the gas phase. It offers the reader a quick overview of all the topics covered, and some chapters provide easy access to more detailed treatments.

Inorganic Biochemistry. An Introduction. By *J. A. Cowan.* VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1993. XII, 349 pp., hardcover DM 69.00.— ISBN 1-56081-537-X/3-527-89537-X

If Alfred Werner were alive today, what branch of chemistry would he choose? Possibly inorganic biochemistry. This modern version of coordination chemistry is becoming increasingly popular, as is shown by the ever growing number of publications. During the last twenty years Werner's 'descendants', whose interests lie in the overlapping regions of inorganic chemistry, bioscience, and physics, have worked in collaboration with spectroscopists, theoreticians, electrochemists, biochemists, and molecular biologists to open up a fascinating new field of research. Although the importance of metals in life processes is still only incompletely understood, the subject is ripe for textbooks to be written. Nowadays every modern textbook of inorganic chemistry contains a chapter on inorganic biochemistry. But surprisingly, despite the obviously good market prospects for textbooks devoted solely to this subject, very few are available. In this introductory text J. A. Cowan has set out to remedy the situation. The book is intended mainly for advanced students and interested nonspecialists from other areas of chemical research. It can be said at the outset that it meets the needs of these readers very well and is a significant addition to the range.

The first two chapters, which make up about a quarter of the book, equip the reader with the necessary toolkit, i.e., the basic principles of the chemistry of complexes. Chapter 1 deals first with the concepts of crystal field theory and the kinetics and mechanisms of reactions of transition metal complexes. This is followed by a short excursion into basic principles of biochemistry, in which the author sketches the essential features of the structures of proteins and nucleotides, cell biology, and molecular biology. Chapter 2 describes the spectroscopic and biochemical techniques needed for characterizing metalloproteins. The presentation of these topics is excellent. The basic principles of each spectroscopic or electrochemical method are described in such a way that the reader can easily work through the chapters that follow.

The main part of the book is concerned with the role of metals in life processes, which is treated on the basis of the concepts already introduced. The subject matter is arranged according to biochemical functionality. Chapter 3 describes the uptake, transport, and storage of metals in organisms. Chapters 4 and 5 then deal with the functions of metalloproteins as oxygen carriers, hydrolases, and redox systems. Chapter 6 describes the functions of alkali metals in the regulation of membrane potentials, the activation of enzymes, and biomineralization, and Chapter 7 the role of alkaline-earth metals in the regulation of biochemical processes. Chapter 8 is concerned with the toxic effects of oxygen and heavy metals. Chapter 9 describes the use of metals in conjunction with chemical or spectroscopic methods to elucidate the structures and reactive properties of compounds. Lastly, Chapter 10 discusses two particular examples in detail, namely cytochrome-C-oxidase and mercury(II)-reductase.

The book is well structured from a learning standpoint. Each chapter begins by describing the basic features of the biochemical processes concerned. This conceptual framework is then brought to life by discussing suitably chosen examples. The excellent illustrations and the brief summaries at the ends of the chapters help the reader to assimilate the new material. A selected bibliography, mainly references to monographs and reviews covering results up to 1992, is given at the end of each chapter, thus enabling the reader to refer to the original literature. As an example of this structure, Chapter 3 begins with a general description of the metal balance of cells. This is followed by a section on ion transport through membranes, subdivided into the topics of the structure of membranes, ion transport, ionophores, siderophores and ion chan-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1111-1196 $ 10.00+.25/0

nels, and lastly ion pumping. The chapter ends by discussing metal transport and storage in vivo, illustrated by the examples of transferrin and ferritin.

The publishers too have done what is necessary to ensure a successful final result. The good typesetting and print quality make the book a pleasure to read. The price of DM 69.00 is not exactly cheap for a textbook of this size, but is appropriate for this quality. How well the book will become accepted is largely a question of how it compares with the competition. Two other textbooks are to be published soon, one by Berg and Lippard and the other by Lippard and Bertini. The only comparable book available at present is that by Kaim and Schwederski, which offers more material at a lower price, but is published in 'copy-ready' form. For my taste the arrangement of the subject matter in 'Kaim and Schwederski' seems less clear and convincing, whereas in Cowan's book the essential nature of the role of metals in life processes is brought out more clearly by a deliberate avoidance of too much detail.

Who will benefit most from this book? It can definitely be recommended for reading by final-year students, organic chemists, and biochemists with interests in inorganic complexes; it will certainly also be a welcome additional resource for readers working in the biosciences or medicine.

Conjugate Addition Reactions in Organic Synthesis. (Tetrahedron Organic Chemistry Series, Vol. 9, series editor: *J. E. Baldwin.*) By *P. Perlmutter.* Pergamon, Oxford, 1992. XIX, 373 pp., paperback £ 28.50, hardcover £ 58.95.—ISBN 0-08-0370675 (paperback), 0-08-0370667 (hardcover)

Conjugate additions of nucleophiles to acceptor systems are among the most useful reactions of organic chemistry. This book treats the subject under the headings of the various acceptor groups, with special emphasis on stereoselectivity. The individual chapters also contain descriptions of many natural products syntheses.

The author has taken much care in the writing of the introduction. An account of the history of the Michael addition reaction is followed by a precise and detailed treatment of the classification of reaction types, the nomenclature, and the mechanisms of 1,4 addition reactions. Adequate attention is given here to regio- and stereochemical aspects including chiral systems and chiral catalysis. The role of the nucleophile is also clearly explained, with an especially detailed discussion of cuprate chemistry. Control of reactions by the addition of Lewis acids, polar reagents, or metal salts is described. This extensive and very useful introduction concludes with the Baldwin rules, and general statements about stereoselective ring closure and tandem reactions.

Chapter 2 deals with alkenals and alkenones. A detailed discussion of the Robinson anellation, an important reaction for forming bi- or polycyclic enones, also draws attention to its disadvantages. The author goes on to treat acyclic systems, and discusses stereochemical models relating to stereoselectivity in such systems. Cyclic 1,3-diketones are also discussed as important intermediates in syntheses. On the subject of 1,3-diketones, asymmetric induction is also considered, of course. Next the author deals with cuprates, organozinc, and organosilicon compounds (Sakurai reactions). Here again special attention is given to stereochemical yields, so that the reader gets a good idea of the possibilities for stereoselective syntheses in a variety of systems. The author discusses all the relevant models that have been proposed for transition states in Lewis acid catalyzed addition reactions of allyl silanes. Free radical additions and reactions involving silyl enol ethers are then described. The chapter ends with a discussion of heteroatoms as nucleophiles, covering N, P, S, Si, and Sn.

Chapter 3 is concerned with cycloalkenones, beginning with additions of stabilized carbanions. Here again the main emphasis is on stereochemical effects. After reporting the findings their applications are well illustrated by examples in syntheses of natural products, notably of prostaglandins. Next stereochemical aspects of cuprate addition reactions are discussed in detail, including even medium-sized and large rings, as also are additions to bicycloenones. After the cuprates an assortment of other organometallic compounds follows, including those of zinc and silicon. Chiral systems are treated next, followed by intramolecular processes involving stabilized carbanions and intramolecular Sakurai reactions for the stereoselective synthesis of bicycloketones. Both methods of activation, using fluoride ions or Lewis acids, are described. This is followed by free radical reactions and addition reactions of heteronucleophiles such as oxygen or sulfur. An important class of natural products, the cytotoxic calicheamicins, are described; here an intramolecular 1,4 addition with sulfur as nucleophile serves as activator for a subsequent Bergmann cyclization.

Chapter 4 is devoted to addition reactions involving unsaturated acids and their derivatives, beginning with ketone enolates and their reactions with unsaturated esters, nitriles, and amides. Next the author describes reactions involving ester enolates, then further sections deal with nitro- and sulfur-stabilized additions. Here again the focus is on stereochemical aspects. Special attention is given to cuprate additions, and tandem reactions yielding cyclic compounds are also treated. Even such "exotic" compounds as unsaturated acyl-iron complexes are discussed in detail, so that the reader is given a complete overview. Also included, of course, are double Michael additions, which allow the diastereoselective synthesis of cyclic compounds with useful functionalities. Considerable space is devoted to intramolecular processes, and even complex functionalized systems are included. Following the pattern already seen in earlier chapters, Chapter 4 ends with free radical cyclizations, enamine reactions, and additions involving heteronucleophiles.

Chapter 5 deals with addition reactions of lactones and lactams. The section on cuprate additions also covers reactions of bicyclic and macrocyclic lactones. This is followed by reactions of heteronucleophiles; these include the very useful silyl cuprates, which can be regarded as masked (partly blocked) alcohols. The book ends with two short chapters on nitroalkenes and alkenyl sulfoxides and phosphonates (Chapter 6) and on alkyne additions (Chapter 7). Here, as before, the reactions of stabilized carbanions are followed by those of cuprates, other organometallic compounds, and heteronucleophiles.

To summarize, this book is the first comprehensive monograph on conjugate addition reactions and fills a genuine gap; it should therefore be in every chemical library. Moreover, it will please every research chemist since it contains an almost unlimited abundance of important methods for bond formation. The arrangement of the material is logical throughout, and the importance of the book is further enhanced by the well chosen examples, in which there is a strong emphasis on stereoselective reactions. Many interesting examples from the area of natural products syntheses are described and thoroughly discussed, thus giving the reader a very broad overview of the appli-

Handbook of Hot Atom Chemistry. Edited by *J.-P. Adloff, P. P. Gaspar, M. Imamura, A. G. Maddock, T. Matsuura, H. Sano* and *K. Yoshihara*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York/Kodansha, Tokyo, 1992. XVIII, 702 pp., hardcover DM 330.00.—ISBN 3-527-29001-X/1-56081-271-0/4-06-205851-0

The "Handbook of Hot Atom Chemistry" is essentially a revised and updated version of the book "Hot Atom Chemistry" published in 1984 with T. Matsuura as editor. In the preface the editors regret the fact that this wide-embracing field of study has been little recognized up to now, despite the important contributions that it has made to fundamental knowledge and applications in many areas of chemistry. Moreover, they point out that financial support for and interest in hot atom chemistry research have been severely reduced throughout the world in the last few years. This phenomenon, also shared by its parent disciplines of radiochemistry and nuclear chemistry, is a temporary situation resulting from the current debate about nuclear energy. For many radiochemists their first contact with their chosen area of research came from investigating the chemical effects of nuclear reactions, briefly described as the "chemistry of hot atoms" or "recoil chemistry". Following a nuclear reaction the newly formed "hot" atoms are able, due to their high energy, to take part in unusual processes leading sometimes to unusual products. Radioactive recoil atoms are easy to detect through their subsequent decay, and can therefore serve as probes yielding information about their chemical environment.

The handbook sets out, in about 700 pages, to provide a wider readership with a survey of the aims, current state of knowledge, techniques, and applications of hot atom chemistry, and to draw attention to some hitherto unsolved questions and potential further applications. The editors hope thereby to reawaken interest in this field of research, and also to help avert a possible future shortage of people with the technical skills for dealing competently with radioactive materials. The initiative for preparing the book has come from T. Matsuura of the Nuclear Institute of Rikko University, Japan. Four of the editors and 30 of the authors are Japanese scientists, while a further 16 authors are from the USA and 14 from Europe.

The book begins with several short reviews outlining the origins of hot atom chemistry and some important developments. The second section then deals with the behavior of hot atoms of halogens and of tritium, and of recoiling atoms of C, O, N, and S, which are of special importance for organic chemistry. The third section introduces some fundamental aspects of theoretical models for describing the processes that occur. Next the behavior of recoil atoms in solids and liquids is considered from several different viewpoints, including the effects of radiochemical and related processes on the reaction medium. A further section discusses the ways in which other nuclear techniques, such as Mössbauer spectroscopy, measurements of the effects of chemical processes on the angular distribution of the emitted nuclear radiation, or positronium chemistry, can contribute to studies of recoil atoms. The last group of articles deals with applications of knowledge of recoil chemistry and with techniques used in nuclear medicine, geochemistry, cosmic chemistry, nuclear engineering, and environmental science.

In a work described as a handbook one expects to find a comprehensive, balanced, and systematically arranged survey. With 56 individual contributions this can only be achieved by applying strict guidance to the authors, since only in this way can one avoid frequent overlapping. Here the wide variations between contributions in the amount of detail (with lengths varying from three to 24 pages) and the use of different typefaces emphasizes the overall impression of a lack of uniformity. Also the grouping of the articles into topic areas has not been achieved in a convincing way. In view of the wide-ranging and heterogeneous variety of topics that are embraced by the term "hot atom chemistry", especially those concerned with radiochemistry and nuclear chemistry, one can appreciate the difficulty of devising a clear and meaningful subdivision of the subject matter. In fact the handbook is more a loose collection of review articles in which leading experts have summarized the current state of knowledge in their own or closely related fields. The literature references enable the interested reader to explore in greater depth. It is not practicable here to describe the individual contributions in detail, nor is it necessary. As well as articles aimed at enabling even those without previous knowledge to understand the most important relationships, there are others that inform specialists about comparatively recent results in particular areas.

Although one's expectations, from the description "handbook", of a systematic, comprehensive, and balanced treatment are not realized, this collection of articles nevertheless provides an up-to-date insight into some of the most important research areas, methods, and applications of recoil chemistry. Furthermore, reading selected articles could give advanced students of chemistry or physics the awakened interest in this special field that the editors desire, and may stimulate some scientists to use the knowledge and methods of recoil chemistry in their own research. In a few years time it will undoubtedly again become necessary to present the status of this field to a wider circle of people for reconsideration. Then it will certainly be possible, with a tighter and more systematic arrangement of the heterogeneous subject matter, a smaller number of review articles treating clearly defined areas, and (as in the 1984 version) a uniform and easily readable typeface, to make hot atom chemistry attractive to a wider readership.

The Polymerase Chain Reaction (Nobel Lecture)**

Kary B. Mullis*

In 1944 Erwin Schrödinger, stimulated intellectually by Max Delbruck, published a little book called *What is Life?* It was an inspiration to the first of the molecular biologists, and has been, along with Delbruck himself, credited for directing the research during the next decade that solved the mystery of how "like begat like".

Max was awarded the Nobel Prize in 1969, and rejoicing in it, he also lamented that the work for which he was being honored before all the peoples of the world was not something which he felt he could share with more than a handful. Samuel Beckett's contributions in literature, honored at the same time, seemed to Max somehow universally accessible to anyone. But not his. In his Nobel lecture Max imagined his imprisonment in an ivory tower of science.

"The books of the great scientists," he said, "are gathering dust on the shelves of learned libraries. And rightly so. The scientist addresses an infinitesimal audience of fellow composers. His message is not devoid of universality but its universality is disembodied and anonymous. While the artist's communication is linked forever with its original form, that of the scientist is modified, amplified, fused with the ideas and results of others, and melts into the stream of knowledge and ideas which forms our culture. The scientist has in common with the artist only this: that he can find no better retreat from the world than his work and also no stronger link with his world than his work."

Well, I like to listen to the wisdom of Max Delbruck. Like my other historical hero, Richard Feynman, who also passed through here, Max had a way of seeing directly into the core of things and clarifying it for the rest of us. But I am not convinced with Max that the joy of scientific creation must remain completely mysterious and unexplainable, locked away from all but a few esoterically informed colleagues. I lean toward Feynman in this matter. I think Feynman would have said, if you can understand it, you can explain it.

So I'm going to try to explain how it was that I invented the polymerase chain reaction (PCR). There's a bit of it that will not easily translate into normal language. If that part weren't of some interest to more than a handful of people here, I would just leave it out. What I will do instead is let you know when we get to that and also when we are done with it. Don't trouble yourself over it. It's esoteric and not crucial. I think you can understand what it felt like to invent PCR without following the details.

In 1953 when Jim Watson and Francis Crick published the structure of DNA, Schrödinger's little book and I were eight years old. I was too young to notice that mankind had finally understood how it might be that "like begat like". The book had been reprinted three times. I was living in Columbia, South Carolina, where no one noticed that we didn't have a copy. But my home was a few blocks away from an undeveloped wooded area with a creek, possums, racoons, poisonous snakes, dragons, and a railroad track. We didn't need a copy. It was a wilderness for me and my brothers, an unknown and unregimented place to grow up. An if we got bored of the earth, we could descend into the network of storm drains under the city. We learned our way around that dark, subterranean labyrinth. It always frightened us. And we always loved it.

By the time Watson and Crick were being honored in Stockholm in 1962, I had been designing rockets with my adolescent companions for three years. For fuel, we discovered that a mixture of potassium nitrate and sugar could be very carefully melted over a charcoal stove and poured into a metal tube in a particular way with remarkable results. The tube grew larger with our successive experiments until it was about four feet long. My mother grew more cautious, and often her head would appear out of an upstairs window, and she would say things that were not encouraging. The sugar was reluctantly furnished by her own kitchen, and the potassium nitrate we purchased from the local druggist.

Back then in South Carolina young boys seeking chemicals were not immediately suspect. We could even buy dynamite fuse from the hardware store with no questions asked. This was good, because we were spared from early extinction on one occasion when our rocket exploded on the launch pad, by the very reliable, slowly burning dynamite fuses we could employ, coupled with our ability to run like the wind once the fuse had been lit. Our fuses were in fact much improved over those Alfred Nobel must have used when he was frightening his own mother. In one of our last experiments before we became so interested in the maturing young women around us that we would not think deeply about rocket fuels for another ten years, we blasted a frog a mile into the air and got him back alive. In another, we inadvertently frightened an airline pilot, who was preparing to land a DC-3 at the Columbia airport. Our mistake.

At Dreher High School we were allowed free, unsupervised access to the chemistry lab. We spent many an afternoon there tinkering. No one got hurt and no lawsuits resulted. They

wouldn't let us in there now. Today we would be thought of as a menace to society. If I'm not mistaken, Alfred Nobel for a time was not allowed to practice his black art on Swedish soil. Sweden, of course, was then and still is way ahead of the United States in these matters.

I never tired of tinkering in labs. During the summer breaks from Georgia Tech, Al Montgomery and I built an organic synthesis lab in an old chicken house on the edge of town where we made research chemicals to sell. Most of them were either noxious or explosive. No one else wanted to make them, somebody wanted them, and so their production became our domain. We suffered no boredom and no boss. We made enough money to buy new equipment. Max Gergel, who ran Columbia Organic Chemicals Company, and who was an unusually nice man, encouraged us and bought most of our products, which he resold. There were no government regulators to stifle our fledgling efforts, and it was a golden age, but we didn't notice it. We learned a lot of organic chemistry.

By the time I left Georgia Tech for graduate school in biochemistry at the University of California at Berkeley, the genetic code had been solved. DNA did not yet interest me; I was excited by molecules. DNA before PCR was long and stringy, not really molecular at all. Six years in the biochemistry department didn't change my mind about DNA, but six years of Berkeley changed my mind about almost everything else.

I was in the laboratory of Joe Neilands who provided his graduate students with a place to work and very few rules. I'm not even sure that Joe knew any rules except the high moral ground of social responsibility and tolerance. Not knowing that the department did have rules, I took courses in astrophysics instead of in molecular biology, which I figured I could learn from my molecular biologist friends. I published my first scientific paper in *Nature* in 1968. It was a sophomoric astrophysical hypothesis called "The Cosmological Significance of Time Reversal." I think *Nature* is still embarrassed about publishing it, but it was immensely useful to me when it came time for my qualifying examination. The committee would decide whether or not I would be allowed to earn a PhD without coursework in molecular biology. And my paper in *Nature* helped them to justify a "yes". In retrospect, the membership of that committee is intriguing.

Don Glaser, who received the Nobel Prize in physics in 1960 at age 34, would later be one of the founders of Cetus Corporation, where I was working when I invented PCR. Henry Rapoport, who discovered psoralens, would be the scientific advisor to my department at Cetus, and would coauthor two patents with me. Alan Wilson, now sadly passed away, would be the first researcher outside of Cetus to employ PCR. And Dan Koshland would be the editor of *Science* when my first PCR paper was rejected from that journal and also the editor when PCR was three years later proclaimed "Molecule of the Year". I passed. None of us, I think, as we walked out of that room, had any conscious inkling of the way things would turn out among us.

In Berkeley it was a time of social upheaval, and Joe Neilands was the perfect mentor to see his people through it with grace. We laughed a lot over tea at four every afternoon around a teakwood table that Joe had brought from home and oiled once a month. Our lab had an ambience that was special. I decided to become a neurochemist. Joe was the master of microbial iron transport molecules. Our lab was different than most, where the head of the lab would prefer that you help advance his career by elaborating on some of his work. Not so with Neilands. As long as I wrote a thesis and got a degree, he didn't care what else did, and I stayed in his lab happily, following my own curiosity even if it carried me into music courses, for as long as Joe thought we could get away with it. The department was paying me a monthly stipend from the National Institutes of Health, and eventually we knew I would have to leave.

After six years I headed east with a PhD and confidence in my education. My wife of a few months went to Kansas to go to medical school, and I followed her there. That was 1972.

I had made no professional plans that would work in Kansas, so I decided to become a writer. I discovered pretty quickly that I was far too young. I didn't know anything yet about tragedy, and my characters were flat. I didn't know how to describe a mean spirit in terms someone else could believe.

So I had to get a job as a scientist. I found a job at the medical school working with two pediatric cardiologists and a pathologist. It was a very fortunate accident. For one thing pediatricians are always the nicest doctors, and for another thing these doctors were very special: Leone Mattioli, whose wife could cook, Agostino Molteni, and Richard Zakheim. For two years I did medical research, learned how to appreciate old-world values from two Italians and a New York Jew, and learned human biology for the first time.

Marriage over, I returned to Berkeley, working for a time in a resturant and then at the University of California at San Francisco killing rats for their brains. I heard Max Delbruck lecture, but I don't think I understood the significance of who he was, nor was I influenced by him to go into molecular biology. I was working on the enkephalins.

But then there was a seminar describing the synthesis and cloning of a gene for somatostatin. That impressed me. For the first time I realized that significant pieces of DNA could be synthesized chemically and that they were likely to be very exciting. I started studying DNA synthesis in the library. And I started looking for a job making DNA molecules.

Cetus hired me in the fall of 1979. I worked long hours and enjoyed it immensely. DNA synthesis was much more fun than killing rats, and the San Francisco Bay Area was a good place to be doing it. There were a number of biotechnology companies and several academic groups working on improving the synthesis methods for DNA. Within two years, there was a machine in my lab from Biosearch of San Rafael, California, turning out oligonucleotides much faster than the molecular biologists at Cetus could use them. I started playing with the oligonucleotides to find out what they could do.

The lab next door to me was run by Henry Erlich and was working on methods for detecting point mutations. We had a number of oligonucleotides for them. I started thinking about their problem and proposed an idea of my own which they ended up calling oligomer restriction. It worked as long as the target sequence was fairly concentrated, like a site on a purified plasmid, but it didn't work if the site was relatively rare, like a single copy gene in human DNA.

I apologize to those of you who just got lost, but I do have to say a few things now that are going to be difficult. I will get back to the story in a few minutes.

The oligomer restriction method also relied on the fact that the target of interest contained a restriction site polymorphism, which kept it from being universally applicable to just any point mutation. I started thinking about doing some experiments wherein an oligonucleotide hybridized to a specific site could be extended by DNA polymerase in the presence of only dideoxynucleoside triphosphates. I reasoned that if one of the dideoxynucleoside triphosphates in each of four aliquots of a reaction was radioactive, then an analysis of the aliquots on a gel could indicate which of the dideoxynucleoside triphosphates had added to the hybridized oligonucleotide and therefore which base was adjacent to the 3'-end of the oligonucleotide. It would be like doing Sanger sequencing at a single base pair.

On human DNA it would not have worked because the oligonucleotide would not have specifically bound to a single site. On a DNA as complex as human DNA it would have bound to hundreds or thousands of sites depending on the sequence involved and the conditions used. What I needed to make this work was some method of raising the relative concentration of the specific site of interest. What I needed was PCR, but I had not considered that possibility. I knew the difference numerically between five thousand base pairs as in a plasmid and three billion base pairs as in the human genome, but somehow it didn't strike me as sharply as it should have. My ignorance served me well. I kept on thinking about my experiment without realizing that it would never work. And it turned into PCR.

One Friday night I was driving, as was my custom, from Berkeley up to Mendocino where I had a cabin far away from everything off in the woods. My girlfriend, Jennifer Barnett, was asleep. I was thinking. Since oligonucleotides were not that hard to make anymore, wouldn't it be simple enough to put two of them into the reaction instead of only one, such that one of them would bind to the upper strand and the other to the lower strand with their 3'-ends adjacent to the opposing bases of the base pair in question. If one oligonucleotide were made longer than the other, then their single-base extension products could be separated on a gel from each other and one could act as a control for the other. I was going to have to separate them on a gel anyway from the large excess of radioactive nucleoside triphosphate. What I would hope to see is that one of them would pick up one radioactive nucleotide and the other would pick up its complement. Other combinations would indicate that something had gone wrong. It was not a perfect control, but it would not require a lot of effort. It was about to lead me to PCR.

I liked the idea of a control that was nearly free in terms of cost and effort. And also, it would help use up the oligonucleotides that my lab could now make faster than they could be used.

As I drove through the mountains that night, the stalks of the California buckeyes heavily in blossom leaned over into the road. The air was moist and cool and filled with their heady aroma.

Encouraged by my progress on the thought experiment, I continued to think about it and about things that could possibly go wrong. What if there were deoxynucleoside triphosphates in the DNA sample, for instance? What would happen? What would happen, I reasoned, is that one or more of them would be added to the oligonucleotide by the polymerase prior to the termination of chain elongation by addition of the dideoxynucleoside triphosphate; it could easily be the wrong dideoxynucleoside triphosphate, and it surely would result in an extension product that would be the wrong size, and the results would be spurious. It would not do. I needed a way to ensure that the sample was free from contamination from deoxynucleoside triphosphates. I could treat the sample before the extension reaction with bacterial alkaline phosphatase. The enzyme would degrade any triphosphates present down to nucleosides, which would not interefere with the main reaction. But then I would need to deactivate the phosphatase before adding the dideoxynucleoside triphosphates, and everyone knew at that time that BAP, as we called it, was not irreversibly denaturable by heat. The reason we knew this was that the renaturation of heat-denatured BAP had been demonstrated in classic experiments that had shown that a protein's shape was dictated by its sequence. In the classical experiments the renaturation had been performed in a buffer containing lots of zinc. What had not occurred to me or apparently many others was that BAP could be irreversibly denatured if zinc was omitted from the buffer, and that zinc was not necessary in the buffer if the enzyme was only going to be used for a short time and had its own tightly bound zinc to begin with. There was a product on the market at the time called matBAP wherein the enzyme was attached to an insoluble matrix that could be filtered out of a solution after it had been used. The product sold because people had the impression that you could not irreversibly denature BAP. We'd all heard about, but not read, the classic papers.

This says something about the arbitrary way that many scientific facts get established, but for this story, its only importance is that, had I known then that BAP could be heat-denatured irreversibly, I may have missed PCR. As it was, I decided against using BAP and tried to think of another way to get rid of deoxynucleoside triphosphates. How about this, I thought. What if I leave out the radioactive dideoxynucleoside triphosphates, mix the DNA sample with the oligonucleotides, drop in the polymerase, and wait? The polymerase should use up all the deoxynucleoside triphosphates by adding them to the hybridized oligonucleotides. After this was complete I could heat the mixture, causing the extended oligonucleotides to be removed from the target, then cool the mixture allowing new, unextended oligonucleotides to hybridize. The extended oligonucleotides would be far outnumbered by the vast excess of unextended oligonucleotides and therefore would not rehybridize to the target to any great extent. Then I would add the dideoxynucleoside triphosphate mixtures, and another aliquot of polymerase. And now things would work.

But what if the oligonucleotides in the original extension reaction had been extended so far that they could now hybridize to unextended oligonucleotides of the opposite polarity in this second round. The sequence that they had been extended into would permit that. What would happen?

EUREKA!!! The result would be exactly the same, only the signal strength would be doubled.

EUREKA again!!! I could do it intentionally, adding my own deoxynucleoside triphosphates, which were quite soluble in water and legal in California.

And again, EUREKA!!! I could do it over and over again. Every time I did it I would double the signal. For those of you who got lost, we're back to the story.

I stopped the car at mile marker 46.7 on Highway 128. In the glove compartment I found some paper and a pen. I confirmed that two to the tenth power was about a thousand and that two to the twentieth power was about a million and that two to the thirtieth power was around a billion—close to the number of base pairs in the human genome. Once I had cycled this reaction thirty times I could read the sequence of a sample with an immense signal and almost no background.

Jennifer wanted to get moving. I drove on down the road. In about a mile it occurred to me that the oligonucleotides could be placed at some arbitrary distance from each other, not just flanking a single base pair and that I could make an arbitrarily large number of copies of any sequence I chose, and what's more, most of the copies after a few cycles would be the same size. That size would be up to me. They would look like restriction fragments on a gel. I stopped the car again.

"Dear Thor!" I exclaimed. I had solved the two most annoying problems in DNA chemistry in a single lightening bolt. Abundance and distinction. With two oligonucleotides, DNA polymerase, and the four nucleoside triphosphates I could make as much of a DNA sequence as I wanted and I could make it on a fragment of a specific size that I could distinguish easily.

Somehow, I thought, it had to be an illusion. Otherwise it would change DNA chemistry forever. Otherwise it would make me famous. It was too easy. Someone else would have done it, and I would surely have heard of it. We would be doing it all the time. What was I failing to see? "Jeniffer, wake up. I've thought of something incredible."

She wouldn't wake up. I had thought of incredible things before that somehow lost some of their sheen in the light of day. This one could wait till morning. But I didn't sleep that night. We got to my cabin, and I starting drawing little diagrams on every horizontal surface that would take pen, pencil, or crayon until dawn, when with the aid of a last bottle of good Mendocino County cabernet, I settled into a perplexed semiconsciousness. Afternoon came, along with new bottles of celebratory red fluids from Jack's Valley Store, but I was still puzzled and alternated between being absolutely pleased with my good luck and clever brain, and being mildly annoyed at myself and Jennifer Barnett for not seeing the flaw that must have been there. I had no phone at the cabin, and there were no other biochemists besides Jennifer and me in Anderson Valley. The conundrum which lingered throughout the weekend and created an unprecedented desire in me to return to work early was compelling. If the cyclic reactions which by now were symbolized in various ways all over the cabin really worked, why had I never heard of them being used? If they had been used, I surely would have heard about it, and so would everybody else including Jennifer, who was presently sunning herself by the pond and taking no interest in the explosions that were rocking my brain.

Why wouldn't these reactions work?

Monday morning I was in the library. The moment of truth. By afternoon it was clear. For whatever reasons, there was nothing in the abstracted literature about the success or failure of amplifying DNA by the repeated reciprocal extension of two primers hybridized to the separate strands of a particular DNA sequence. By the end of the week I had talked to enough molecular biologists to know that I wasn't missing anything really obvious. No one could recall such a process ever being tried.

However, shocking to me, not one of my friends or colleagues would get excited over the potential for such a process. True, I was always having wild ideas, and this one maybe looked no different than last week's. But it was different. There was not a single unknown in the scheme. Every step involved had been done already. Everyone agreed that you could extend a primer on a DNA template, and everyone knew you could melt double-stranded DNA. Everyone agreed that what you could do once, you could do again. Most people don't like to do things over and over, I in particular. If I had to do a calculation twice, I preferred to write a program instead. But no one thought it was impossible. It could be done, and there was always automation. The result on paper was so obviously fantastic that even I had little irrational lapses of faith that it would really work in a tube. Most everyone, who would take a moment to talk about it with me felt compelled to come up with some reason why it wouldn't work. It was not easy in that postcloning, prePCR year to accept the fact that you could have all the DNA you wanted. And that it would be easy.

I had a directory full of untested ideas in the computer. I opened a new file and named this one polymerase chain reaction. I didn't immediately try an experiment, but all summer I kept talking to people in and out of the company. I described the concept around August at an in-house seminar. Every Cetus scientist had to give a talk twice a year. But no one had to listen. Most of the talks were dry descriptions of labor performed, and most of the scientists left early without comment.

One or two technicians were interested, and on the days when she still loved me, Jennifer thought it might work. On the increasingly numerous days when she hated me, my ideas and I suffered her scorn together.

I continued to talk about it, and by late summer had a plan to amplify a 400 base pair fragment from human nerve growth factor, which Genentech had cloned and published in *Nature*. I would start from whole human placental DNA from Sigma, taking a chance that the cDNA sequence had derived from a single exon. No need for a cDNA library. No colonies, no nothing. It would be dramatic. I would shoot for the moon. Primers were easy to come by in my lab, which made oligonucleotides for the whole company. I entered the sequences I wanted into the computer and moved them to the front of the waiting list.

My friend Ron Cook, who had founded Biosearch, and produced the first successful commercial DNA synthesis machine, was the only person I remember during that summer who shared my enthusiasm for the reaction. He knew it would be good for the oligonucleotide business. Maybe that's why he believed in it. Or maybe he's a rational chemist with an intact brain. He's one of my best friends now, so I have to disqualify myself from claiming any really objective judgement regarding him. Perhaps I should have followed his advice, but then things would have worked out differently, and I probably wouldn't be here on the beach in La Jolla writing this, which I enjoy. Maybe I would be rich in Tahiti. He suggested one night at his house that since no one at Cetus had taken it seriously, I should resign my job, wait a little while, make it work, write a patent, and get rich. By rich he wasn't imagining 300 million dollars. Maybe one or two million. The famous chemist Albert Hofmann was at Ron's that night. He synthesized LSD in 1943. At the time he didn't realize what he had done. It only dawned on him slowly, and then things worked their way

out over the years like no one would have ever predicted, or could have controlled by forethought and reason.

I responded weakly to Ron's suggestion. I had already described the idea at Cetus, and if it turned out to be commercially successful they would have lawyers after me forever. Ron was not sure that Cetus had rights on my ideas unless they were directly related to my duties. I wasn't sure about the law, but I was pretty happy working at Cetus and assumed innocently that if the reaction worked big-time I would be amply rewarded by my employer.

The subject of PCR was not yet party conversation, even among biochemists, and it quickly dropped. Albert was much more interesting, even for me. He had given a fine talk that afternoon at Biosearch.

Anyhow, my problems with Jennifer were not getting any better. That night was no exception to the trend. I drove home alone feeling sad and unsettled, not in the mood for leaving my job or for any big change in what was left of stability in my life. PCR seemed distant and very small compared to our very empty house.

In September I did my first experiment. I like to try the easiest possibilities first. So one night I put human DNA and the nerve growth factor primers in a little screw-cap tube with an O-ring and a purple top. I boiled the mixture for a few minutes, cooled it, added about 10 units of DNA polymerase, closed the tube, and left it at 37 °C. It was exactly midnight on the ninth of September. I poured a cold Beck's into a 400 mL beaker and contemplated my notebook for a few minutes before leaving the lab.

Driving home I figured that the primers would be extended right away, and I hoped that at some finite rate the extension products would come unwound from their templates, be primed, recopied, and so forth. I did not relish the idea of heating, cooling, and adding polymerase over and over again, and held this for a last-resort method of accomplishing the chain reaction. I was thinking of DNA–DNA interactions as being reversible with all the ramifications thereof. I wasn't concerned about the absolute rate of dissociation, because I didn't care how long the reaction took as long as nobody had to do anything. I assumed there would always be some finite concentration of single strands, which would be available for priming by a relatively high concentration of primer with pseudo-first-order kinetics.

For a reaction with the potential which I dreamed of for this one, especially in light of the absence of anything else that could do the same thing, time was only a very secondary consideration. If it would work at all was important. The next most important thing was, would it be easy to do? Then came time.

At noon the next day I went to the lab to take a 12-hour sample. There was no sign by ethidium bromide of any 400 base pair bands. I could have waited another hundred years, as I had no idea what the absolute rates might be. But I succumbed slowly to the notion that I couldn't escape much longer the unpleasant prospect of cycling the reaction between temperatures for the single- and double-stranded states. This also meant adding the thermally unstable polymerase after every cycle.

For three months I did sporadic experiments while my life at home and in the lab with Jennifer was crumbling. It was slow going. Finally I retreated from the idea of starting with human DNA, I wasn't even absolutely sure that the Genentech sequence from *Nature* that I was using was from a single exon. I settled on a target of more modest proportions, a short fragment from pBR 322, a purified plasmid. The first successful experiment happened on December 16th. I remember the date. It was the birthday of Cynthia, my former wife from Kansas City, who had encouraged me to write fiction and bore us two fine sons. I had strayed from Cynthia eventually to spend two tumultous years with Jennifer. When I was sad for any other reason, I would also grieve for Cynthia. There is a general place in your brain, I think, reserved for "the melancholy of relationships past". It grows and prospers as life progresses, forcing you finally, against you will, to listen to country music.

And now as December threatened Christmas, Jennifer, that crazy, wonderful woman chemist, had dramatically left our house and the lab, and headed to New York and her mother, for reasons that seemed to have everything to do with me but which I couldn't fathom. I was beginning to learn tragedy. It differs a great deal from pathos, which you can learn from books. Tragedy is personal. It would add strength to my character and depth someday to my writing. Just right then, I would have preferred a warm friend to cook with. Hold the tragedy lessons. December is a rotten month to be studying your love life from a distance.

I celebrated my victory with Fred Faloona, a young mathematician and a wizard of many talents whom I had hired as a technician. Fred had helped me that afternoon set up this first successful PCR reaction, and I stopped by his house on the way home. As he had learned all the biochemistry he knew directly from me he wasn't certain whether or not to believe me when I informed him that we had just changed the rules in molecular biology. "Okay, Doc, if you say so." He knew I was more concerned with my life than with those cute little purple-topped tubes.

In Berkeley it drizzles in the winter. Avocados ripen at odd times, and the tree in Fred's front yard was wet and sagging from a load of fruit. I was sagging as I walked out to my little silver Honda Civic, which never failed to start. Neither Fred, empty Beck's bottles, or the sweet smell of the dawn of the age of PCR could replace Jenny. I was lonesome.

Synthetic DNA and Biology (Nobel Lecture)**

Michael Smith*

Most of the significant work has been summarized in a number of reviews and articles. In these there was, of necessity, a good deal of simplification and omission of detail.... With the passage of time, even I find myself accepting such simplified accounts.
F. Sanger[1]

Introduction

I had the good fortune to arrive in the laboratory of Gobind Khorana, in September 1956, just one month after he had made the accidental discovery of the phosphodiester method for the chemical synthesis of deoxyribooligonucleotides,[2] a synthetic approach whose full exploitation led to elucidation of the genetic code and the first total synthesis of a gene.[3-5] An identifying characteristic of the Khorana approach to the production of synthetic polynucleotides for the solution of biological problems has been a willingness to use both chemical and enzymatic tools as appropriate,[5, 6] and this catholic approach is the foundation of all the molecular technology employed in modern molecular genetics.[7-9] It had a major impact on my thinking.

During my post-doctoral time in the Khorana group I was mainly involved in small molecule synthesis: nucleoside-5′ triphosphates[10] and nucleoside-3′,5′ cyclic phosphates.[11] However, I was able to contribute to the technology of polynucleotide synthesis by the development of the methoxytrityl series of 5′-hydroxyl protecting groups[12] and with a first approach to the chemical synthesis of ribooligonucleotides.[13]

In 1961 I left the Khorana group to join the Fisheries Research Board of Canada Vancouver Laboratory. Whilst much of my research effort was directed at studies on salmonid physiology and endocrinology, it was possible to continue studies on the chemistry of phosphodiester synthesis, and this resulted in a new method for nucleoside-3′5′ cyclic phosphate synthesis by alkaline transesterification under anhydrous conditions, a reaction which obviated the need for chemical protecting groups on the heterocyclic bases.[14, 15]

In 1966, I became a faculty member in the Department of Biochemistry of the University of British Columbia, which has been my academic home ever since. Studies on oligonucleotide synthesis continued, directed at the reaction of deoxyribonucleoside phosphorofluoridates in anhydrous alkaline conditions.[16] Although this method, in making base protecting groups redundant, represented a significant advance, it did not have the generality required of a universal synthetic method.[17, 18]

An approach to deoxyribooligonucleotide synthesis that did prove to be versatile, simple, and useful, although inefficient, involved the extension of short primers using *E. coli* polynucleotide phosphorylase, in the presence of Mn^{2+} and NaCl, with deoxyribonucleoside-5′ diphosphates as substrate.[19-22] This procedure, which made possible the synthesis of deoxyribooligonucleotides up to 12 to 13 nucleotides in length, proved to be a significant breakthrough for our small group, because it allowed us to undertake a number of fairly ambitious molecular biological projects at a time (between 1970 and 1980) when oligonucleotides were not generally accessible. Of course, it has been displaced as a routine synthetic procedure with the advent of automated chemical synthesis (which still uses the methoxytrityl protecting group) with nucleoside-3′ phosphoroamidites as the key intermediates.[23-25]

Model Studies on Oligonucleotide Double Helix Stability and Specificity

In 1968 planned studies on the biosynthesis of salmonid protamine[26] and on the sequence of dA,dT-rich crab DNA[27] became impossible for personal or for technical reasons. Casting around for a new project, I suggested to Caroline Astell, who was studying for her Ph.D, a series of model studies with chemically synthesized oligonucleotides directed at defining the stability and specificity of oligonucleotide duplexes of defined sequence. The objective was to see if a synthetically accessible oligonucleotide could be a tool for identifying and isolating a specific messenger RNA based on Watson–Crick hydrogen bonding. From the statistical point of view it should be possible, since the length required of an oligonucleotide in order for it to be unique in a given genome size ranges from 9 nucleotides for λ phages with a genome of 4.6×10^4 base pairs to 18 for the higher plants, such as *A. cepa* with a genome of 1.5×10^{10} base pairs (Table 1). Also relevant was the work of Michelson and Monny[28] and of Niyogi and Thomas[29] on interactions of ribooligonucleotides with ribopolynucleotides, which indicated that stable double helices can be formed with as few as seven base pairs and, equally importantly, which demonstrated that

			B. rerio	10^9	16
			M. musculus	2.2×10^9	17
			H. sapiens	3.3×10^9	17

[a] Recognition by the nucleotide is unique when $4^N \geq 2 \times Z$. [b] Z = the number of base pairs in the genome. [c] N = number of nucleotides in the oligonucleotide.

there is a significant increase in duplex stability for each additional base pair up to about 16 base pairs (Fig. 1). The work of Gilham et al. with random length oligothymidylates covalently attached to cellulose demonstrated their potential power for affinity chromatography,[30, 31] which led to an important procedure for isolation of eukaryote mRNAs.[32] However, although data was available on duplex stability involving *mixtures* of oligonucleotides of defined length with DNA,[33, 34] there was no systematic data obtained with pure oligonucleotides of defined sequence and length.

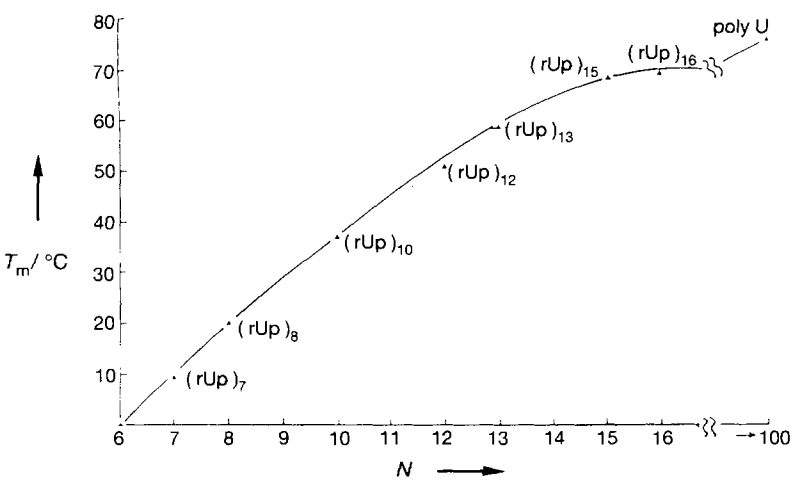

Fig. 1. The relationship between oligouridylate length and the T_m of double helices with polyadenylate in 0.02 M NaCl, 0.01 M sodium cacodylate ($Me_2As(O)O^-Na^+$), pH 7.0 [28]. N = number of uridine residues.

Our approach was to prepare deoxyribooligonucleotide celluloses by using simple oligonucleotides of defined length and sequence synthesized by the Khorana method and to employ these oligonucleotide celluloses, in the form of thermally eluted columns, to establish the stability of duplexes with a variety of complementary, or partially complementary, deoxyribo- and ribooligonucleotides.[35–38] The results and conclusions of this time-consuming but critical series of experiments has been summarized in more detail elsewhere,[39] and only some highlights will be discussed here.

First, it was clear that, under appropriate conditions of ionic strength, stable duplexes containing as few as six dA–dT base pairs can be formed (Fig. 2). Further, additional base pairs increase duplex stability significantly, but in a nonlinear manner; the incremental increase in stability diminishes with increased length. Also, a single base-pair mismatch of dT with dT or of dT with dG decreases duplex stability by the same amount (equivalent to removing about two base pairs), but duplex formation is still possible at low temperature (Fig. 2). In addition, it was obvious that oligonucleotide duplexes form rapidly at low temperatures, conditions under which denatured double-strand DNA does not reanneal.

These experiments convinced me that it would be possible to use a synthetic oligonucleotide to identify an RNA or a DNA containing the exact Watson–Crick complement of its sequence and to differentiate it from similar but not identical sequences. An opportunity to demonstrate this principle was provided by mutants in the lysozyme-encoding locus of phage T4.[40] Also, at a later date, the data made me realize that it should be possible to use short synthetic deoxyribooligonucleotides as specific mutagens and to differentiate between a point mutant and wild-type DNA.

Experiments on the interaction of deoxyribooligonucleotide celluloses and ribooligonucleotides confirmed the results of earlier studies on the relative stabilities of DNA–DNA and DNA–RNA double strands.[39, 41] They also demonstrated a further important principle: a dT, rG

Michael Smith, born in Blackpool, Great Britain, on April 26, 1932, studied Chemistry at the University of Manchester from 1950 to 1953. He finished his Ph.D. there in 1956 with H. B. Henbest on cyclohexane diols and then joined the group of Gobind Khorana in Vancouver, Canada, as Postdoctoral Fellow to work on biologically important organophosphates. In 1960 he moved with the group to the Institute for Enzyme Research at the University of Wisconsin and worked on the synthesis of ribooligonucleotides. In 1961 he accepted a post at the Fischeries Research Board of Canada Laboratory in the grounds of the University of British Columbia in Vancouver. He was awarded the position of Medical Research Associate of the Medical Research Council of Canada at this university in 1966. A new interdisciplinary Institute, the Biotechnology Laboratory, came into being in 1986 with his help. After a heavy load of administrative tasks recently, he is looking forward to returning to the bench.

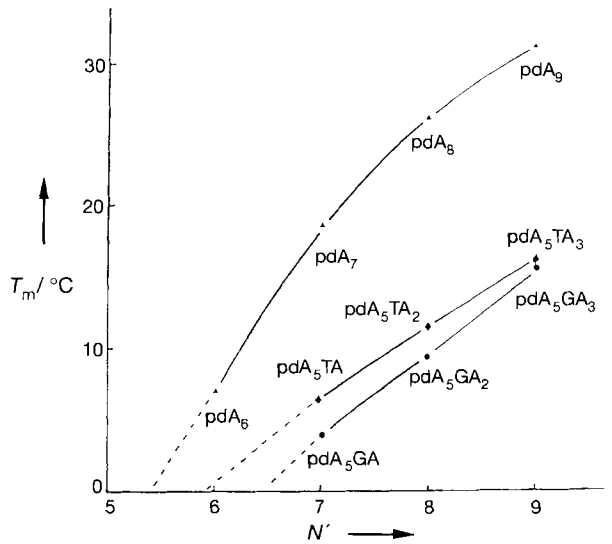

Fig. 2. The T_m values of the duplexes of complementary oligodeoxyribonucleotides with cellulose-pdTq in 1 M NaCl, 0.01 M sodium phosphate, pH 7.0 [38]. The oligodeoxyribonucleotides of the two lower curves each contain a single base-pair mismatch. N' = number of the deoxyribonucleotide residues.

base pair is relatively stable (Fig. 3). Differences in the stability of dT, dG and dT, rG base pairs (compare Figs. 2 and 3), presumably, reflect differences in the base pairing allowed in the B forms and the A forms of double helix.[42] The observation has two practical implications. First, the most specific and stringent interaction of an oligonucleotide probe will be the one between a deoxyribooligonucleotide and DNA. Second, one cannot assume that duplex structures that are formed by RNA will be formed by DNA or by deoxyribooligonucleotides. In connection with this, I have always been puzzled by the widespread acceptance of the idea that deoxyinosine is precocious in base pairing because inosine behaves in a precocious manner in tRNA duplex interactions. Studies on deoxyinosine, in fact, indicate that it functions as a specific analog of deoxyguanosine, although it does not self-aggregate as does deoxyguanosine.[7, 8, 42]

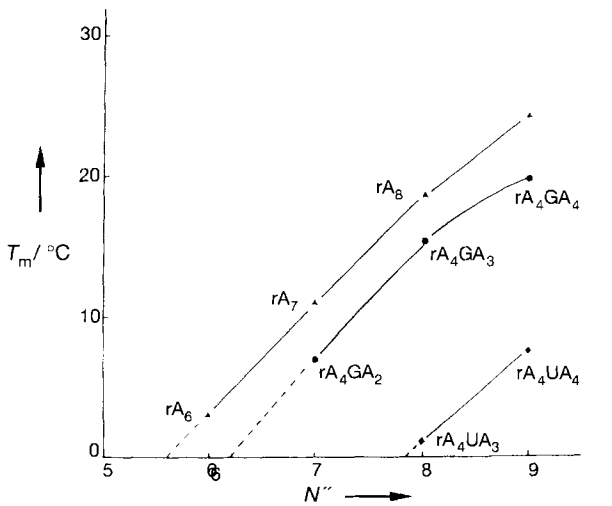

Fig. 3. The T_m values of the duplexes with cellulose-pdTq in 1 M NaCl, 0.01 M sodium phosphate, pH 7.0 [38]. The oligoribonucleotides of the two lower curves each contain a single base-pair mismatch. N'' = number of ribonucleotide residues.

The above empirical studies and related ones not discussed here[39] provided the direct inspiration for and commitment to our use of synthetic deoxyribooligonucleotides as probes for isolation of specific DNA fragments, as primers for the direct sequencing of double-stranded DNA, as primers for precise definition of the ends of mRNAs, as specific mutagens, and as tools for the identification and isolation of point mutations.

Deoxyribooligonucleotides as DNA Probes

When the model studies described in the foregoing section were commenced, in 1968, the intent was to develop a method for isolation of specific mRNAs by affinity chromatography. However, the development of the full panoply of DNA cloning techniques in the early 1970s[9] made it clear that the prime target for work with synthetic deoxyribooligonucleotides should be a method for monitoring gene isolation. Discussions with Dr. Benjamin D. Hall made me aware of the important studies of F. Sherman on double-frameshift mutants of yeast cytochrome *c*.[44] Knowledge of the amino acid sequence of these mutants allowed the unambiguous prediction of the N-terminal coding sequence and, hence, provided a specific target for an oligonucleotide of defined sequence. A second attractive feature about a yeast gene as a first target was the fact that the length of oligonucleotide required for a specific probe (13 nucleotides, Table 1) was close to the limit for our enzymatic method of synthesis.[19, 21, 22] The required probe was synthesized by means of the enzymatic method[45] and was used to isolate the gene, albeit with some difficulty,[46] thus clearly validating the principle that a synthetic oligonucleotide could function as a probe for gene isolation. The subsequent generalization of the method using mixtures of oligonucleotides[47, 48] has made this approach to gene isolation into a powerful tool in molecular genetics.[7, 8]

Sequencing Double-Stranded DNA with Oligonucleotide Primers

At the time when the iso-1-cytochrome *c* gene was isolated, the chemical method for DNA sequence determination[49] and the chain terminating enzymatic method[50] had newly been developed; the former is applicable to double-stranded DNA and the latter to single-stranded DNA. The sequences of the ends of the Eco RI-Hind III DNA fragment containing the cytochrome *c* coding sequence were obtained by the chemical method.[46] Based on my conviction that an oligonucleotide should hybridize *at low temperature* with a complementary DNA strand of a denatured DNA double helix in solution, even though the second DNA strand was present and capable of producing a thermodynamically much more stable structure, I decided to investigate the possibility of directly sequencing double-stranded DNA by the enzymatic method with synthetic oligonucleotide primers. The critical question was whether the second DNA strand would displace a short oligonucleotide from a complex with the complementary DNA strand under the conditions of the Sanger enzymatic sequencing method.[51] The first experiment was completely successful, an enormously excit-

ing event. As a consequence, the sequence of the gene was completed by "walking" along the sequence with a series of short oligonucleotide primers nine or ten nucleotides in length.[52] I believe that the full potential of this approach to gene sequencing has yet to be realized.

Another important application of oligonucleotide-primed sequencing of double-stranded DNA is the precise identification of point mutations produced by classical genetic techniques at a given locus. A particular good example was in the analysis of a large number of independently isolated point mutations in a yeast suppressor tRNA gene.[53, 54]

Defining the Ends of mRNAs Precisely

It is important to define the sequences at the 5'- and 3'-ends of mRNAs exactly. For the 3'-end of an mRNA, this can be done by oligonucleotide-primed sequencing with reverse transcriptase for the Sanger sequencing method with RNA enriched for the desired mRNA as template. The family of 12 deoxyribooligonucleotides consisting of a tract of dT residues terminated at the 3'-end by two other deoxyribonucleotides can be annealed to the 3'-end of polyladenylated eukaryotic mRNA. If the transcribed sequence has a unique 3'-end, only one of the twelve oligonucleotides should act as a specific primer. This strategy was used to define the sequence of the unique 3'-end of bovine growth hormone mRNA[55] and to demonstrate and precisely define the microheterogeneity at the 3'-end of the bovine prolactin mRNA transcript.[56] The iso-1-cytochrome *c* proved to have a unique 3'-end,[57] while the 5'-end of the same mRNA is very disperse indeed, as was shown by oligonucleotide primed extension using the mRNA as template.[58] There are no other methods for defining the 5'- and 3'-ends of mRNAs with this precision, a degree of precision that is essential to the accurate definition of transcription initiation and termination signals.[57, 58]

Oligonucleotide-Directed Mutagenesis

I strongly believe that, through the products of organic synthesis, it will be possible to gain influence over the development of organisms and to produce changes that surpass all that can be achieved by conventional breeding.
Emil Fischer[59]

"The ignis fatuus *of Genetics has been the specific mutagen, the reagent that would penetrate to a given gene, recognize it, and modify it in an specific way."*
J. Lederberg[60]

Initiation of the project to isolate the yeast cytochrome *c* gene made me realize that I needed to learn about DNA sequence determination. I was lucky to be able to spend a year, starting in the fall of 1975, in Fred Sanger's laboratory working with the "plus-minus" sequencing method as part of the team that was attacking the sequence of the *E. coli* phage ΦX174.[61, 62] There are three pairs of overlapping genes in the 5386 nucleotide genome.[63–65] All genes are encoded on the same DNA strand, and each overlapping pair uses different codon reading frames. An essential integral component of defining the position and reading frame of these genes was the availability of nonsense mutants suppressible by amber or ochre suppressors. This use of precisely located mutants of a particular phenotype highlighted the need for a very specific mutagenic method that would define the target to a specific base pair in the genome and introduce a predetermined change with sufficiently high efficiency to allow genomic screening in order to identify phenotypically silent mutants. Since the DNA of phage ΦX174 is single stranded and the complete sequence of its genome was known from our earlier studies, the demonstration that small oligonucleotides as short as seven nucleotides in length could form stable duplexes at low temperature even with a mismatch (Fig. 2) suggested that oligonucleotide-directed mutagenesis should be possible. There was additional useful information: *Point mutants can be reverted*, albeit with low efficiency, by annealing mutant phage ΦX174 DNA with fragments from the complementary strand of wild-type DNA prior to transfection.[66, 67] However, fragments very much longer than those that we could readily synthesize were needed, and the low efficiency precluded genotypic screening.[66, 67] In discussing these issues, Clyde Hutchison (who, also was spending one year in Fred Sanger's group and whose biological knowledge of ΦX174 was invaluable to the sequencing project) and I realized that the studies of Kornberg and Goulian.[43, 68–70] provided an obvious route to a mutagenic method, since they had demonstrated that an oligonucleotide as short as nine nucleotides in length could act as a primer for *E. coli* DNA polymerase I on a circular single-strand template, and that the product could be converted into a closed circular duplex by enzymatic ligation. It was also known that most of the primer molecule is excised from the product,[72] presumably due to the 5'-exonuclease activity of *E. coli* DNA polymerase I.[71] With this information and our knowledge that the stability of duplexes involves a mismatched oligonucleotide, we decided to use a 12 nucleotide oligomer, with a centrally positioned single nucleotide mismatch, as primer and with ΦX174 DNA as template and *E. coli* DNA polymerase I in which the 5'-exonuclease had been inactivated by subtilisin[73–75] to construct a closed, circular, double-stranded DNA with the oligonucleotide in one strand. Transfection of *E. coli* with this DNA should produce wild-type and mutant phage. The specific mutations chosen for the first experiment were the production and reversion of a known nonsense mutation *am3* in the lytic function, gene E, of ΦX174, since convenient phenotypic screens for these mutations were available. The mutations involved the interconversion of a Trp codon TGG and an amber codon TAG by G–T and A–C mismatches.[76] In the first experiments, mutation was achieved but at low efficiency. This was increased to a very encouraging level of about 15% after removal of incompletely closed duplexes by adsorption to nitrocellulose or treatment with a single-strand specific nuclease under conditions in which a single base-pair mismatch was not degraded.[76] Further studies directed at optimizing the mutagenic conditions resulted in efficiencies of up to 39% with a 12 nucleotide mutagenic primer and significant mutation with a heptamer mutagenic primer.[77] The wisdom of using subtilisin-treated DNA polymerase is evident from comparison of these results with those of another study which employed intact *E. coli* DNA polymerase I.[78]

Further studies on the mutagenesis of phage ΦX174 demonstrated that, in addition to the two transition mutations of the first experiments, it was possible to produce transversion mutations and single nucleotide deletions, also by using very short oligonucleotides.[79] Clearly, the method was highly specific, efficient, and general within the context of the genome of ΦX174. It was time to generalize the method further so that it could be applied to any cloned fragment of DNA. The icosahedral bacteriophages, such as ΦX174, are not potential vectors for recombinant DNA because the amount of DNA that can be accommodated in the viral particle is limited. The filamentous bacteriophages, on the other hand, can accommodate additional DNA incorporated into the genome. At the time when Mark Zoller and I were planning the generalization of the method, there were those that argued in favor of a methodology applied to double-stranded recombinant plasmids. It seemed to us that the biology of a filamentous bacteriophage, which produces single-stranded, circular DNA and then purifies it as phage particles, argued overpoweringly in favor of phage DNA as vector. Subsequent developments in recombinant phage biology and in the construction of phagemids[7, 8] have vindicated this strategic decision, although viable procedures for plasmid mutagenesis are available.[80–82] Oligonucleotide mutagenesis with filamentous phage DNA as template proved to be more difficult than with ΦX174 DNA, presumably because of a greater degree of secondary structure that inhibited the production of full-length, double-stranded circles. Consequently, new procedures for enhancing the efficiency of the mutagenic procedure had to be developed.[83–86] The power of the methodology was graphically illustrated by our first involvement in protein engineering in collaboration with Greg Winter and Alan Fersht.[87] This, of course, presaged the enormous use of the methodology in protein structure–function analysis that has become a feature of modern biochemistry.

Genotypic Selection or Screening for Mutants

Because the immediate product of the enzymatic incorporation of a mutagenic oligonucleotide into a double-stranded recombinant DNA is a heteroduplex, biological replication of the DNA will produce mutated and unmutated progeny DNAs, providing there is no asymmetry in the mechanism of DNA replication or providing there is not an asymmetric mismatch-repair mechanism. In fact, it is possible to achieve mutagenic efficiencies of close to 50% by using standard procedures[77, 85] With this level of efficiency, screening by DNA sequence determination is the most effective procedure for detecting the desired mutant DNA. However, often the yield of mutant is considerably less than 50%. It is my opinion that the predominant reason for this is the use of template DNA that is contaminated with random oligonucleotides resulting from bacterial DNA degradation; others ascribe it to biological mismatch-repair favoring the sequence of the template DNA.[80] Whatever the cause of the reduced yield of mutant, procedures other than sequence determination are required for mutant identification. The ones that are available fall into two categories: those using the mutagenic oligonucleotide as a tool for identifying mutant DNA and those which select for progeny derived from the newly synthesized, oligonucleotide-containing DNA strand.

The significantly enhanced stability of a perfectly matched oligonucleotide duplex relative to one with a mismatch (see Fig. 2) suggested that a mutagenic oligonucleotide should be able to identify mutant complementary DNA. This principle was used to develop a method for *selection* of mutant DNA. In this procedure the mixture of wild-type and mutant single-stranded phage DNA produced by oligonucleotide mutagenesis acts as a template for double-stranded DNA synthesis with the mutagenic oligonucleotide as primer under conditions that should not form a mismatched duplex.[88] Following transfection into *E. coli*, this procedure can select mutant DNA with close to 100% efficiency.

An alternative procedure is to use the mutagenic oligonucleotide as a probe to screen for mutant DNA in plaques produced by *E. coli* with mutagenized phage.[83, 84] Again, this procedure is very reliable in the identification of mutant DNA. The same principle is used in the identification of point mutations in human DNA[89] where, of course, the complexity of the human genome requires a probe containing a minimum of 17 nucleotides (see Table 1).

A number of procedures for selection of progeny derived from the DNA strand containing the mutagenic oligonucleotide have been developed.[80] Two of these, one based on in vivo selection and the other on in vitro selection have proved most popular and are widely used. In vivo selection involves a template DNA in which about 1% of the deoxythymidine residues have been replaced by deoxyuridine residues. This template is incorporated into double-stranded DNA in which the mutagenic oligonucleotide is part of the in vitro synthesized second strand. On transfection of an appropriate *E. coli* host, the deoxyuridine strand is selectively degraded by the bacterium's DNA damage-repair system, resulting in progeny derived primarily from the mutant strand.[90] In vitro selection involves a normal recombinant phage template DNA with the mutagenic oligonucleotide incorporated in the second strand that contains enzymatically synthesized thiophosphate internucleotide linkages. These are resistant to cleavage by restriction endonuclease, which, as a consequence nicks the template. The nicked template is partially degraded with an exonuclease and then repaired by a DNA polymerase and DNA ligase. The result is a double-stranded DNA which, predominantly, is mutant in both strands and which produces, predominantly, mutant recombinant phage on transfection of *E. coli*.[91]

Conclusion

This concludes my account of our studies on the use of synthetic deoxyribooligonucleotides as tools for characterizing naturally occurring nucleic acids, which is as accurate as I can make it, bearing in mind the caveat of Fred Sanger[1] cited at the beginning of this article. Clearly, many other applications of oligonucleotide in biology exist, notably the polymerase chain reaction[92] and its multitudinous variations, but also in double-strand DNA synthesis and in the use of oligonucleotide probes in vitro and in vivo. In the latter area there is the potential for development of a whole new chemistry directed at pharmaceuti-

cals that block the expression of specific genes and at diagnostic agents.[93, 94]

With regard to our own work, it is very satisfying that the model studies started in 1968 provided the inspiration for so many applications and scientific collaborations (only a few of which are cited in this article). The potential of oligonucleotide-directed site-specific mutagenesis was apparent from the outset as confirmed by the following quote:

> *"This new method of mutagenesis has considerable potential...to define the role of... origins of DNA replication, promoters, and the sequences for ribosome-building sites ... specific mutation within protein structural genes ... will allow precise studies of protein structure–function relationships"*
> Hutchison et al.[76]

However, we could not have anticipated the explosion of gene isolations, the improvements in DNA sequence determination methodology, and the advances in the chemistry of nucleic acids synthesis that have occurred since 1978. This has resulted in an amazing increase in the use of site-directed mutagenesis as an analytical tool in biochemistry and biology. And it has been accompanied by continual improvements in the basic methodologies and versatility of site-directed mutagenesis[80–82] and the initiation of new scientific publications such as Protein Engineering and Protein Science. It would not be too much of an exaggeration to say that the prediction of Emil Fischer in 1917[59] has been fulfilled, and the dilemma posed by Joshua Lederberg in 1959[60] has been resolved.

My career in nucleic acid research would not exist without the example and inspiration of Gobind Khorana. Also, I am indebted to the many young scientists who have been members of my group over the past 30 years, but especially to Caroline Astell, Shirley Gillam, Patricia Jahnke, and Mark Zoller, who were the individuals primarily responsible for the studies discussed in this article, as well as to Tom Atkinson who undertook the arduous task of manual chemical synthesis of oligonucleotides in the time immediately prior to the introduction of automated synthesizers. Two crucial, indispensible collaborators, whose biological expertise and commitment were essential to these studies, were Ben Hall in the studies on the isolation of the yeast cytochrome c gene and Clyde Hutchison in the development of oligonucleotide-directed mutagenesis. And my year in Fred Sanger's laboratory was wonderful in its excitment and in its timeliness. Research funding support by the U.S. National Institutes of Health was essential in allowing me to continue synthetic nucleotide chemistry in the years immediately after I left the Khorana group. Since 1966, the Medical Research Council of Canada has continuously provided me with the salary support and research grants that have been the stable and very much appreciated foundation for my more speculative research activities. I have also received, for more limited periods, research support from the British Columbia Health Research Foundation and from the National Cancer Institute of Canada. For the past four years I have been Scientific Leader of the Canadian Protein Engineering Network of Centres of Excellence, a country-wide collaboration on protein structure-function analysis, generously funded by the Network of Centres of Excellence program. Finally, firstly at the British Columbia Research Council, then at the Fisheries Research Board of Canada Vancouver Laboratory, mostly in the Department of Biochemistry and more recently in the Biotechnology Laboratory, the campus of the University of British Columbia has been my scientific home since 1956. I am very grateful for the environment that it has provided, especially in the Department of Biochemistry where the studies described in this article were carried out.

In every laboratory you need your set of

Methods of Immunological Analysis
edited by R. Masseyeff, W. Albert, and N.A. Staines

Now available! A complete practice-oriented introduction to immunoanalysis. Three detailed volumes packed with the most comprehensive and up-to-date collection of analytical techniques employing immunological methods.

Indispensable for both specialists and non-specialists!

Volume 1: Fundamentals
ISBN 3-527-27906-7

Volume 2: Samples and Reagents
ISBN 3-527-27907-5

Volume 3: Cells and Tissues
ISBN 3-527-27908-3

Save 20% by ordering the whole set!

Single volume price: DM 410.00 each. Set price: DM 330.00 per volume. Series ISBN 3-527-27905-9.
Please write for our comprehensive prospectus!

A Growing Collection for a Growing Science!

Human Protein Data
edited by A. Haeberli

First Installment. 1992. XLV, 424 pages with 59 figures. Ring Binder. DM 275.00. Subscription price DM 225.00. ISBN 3-527-28211-4

Second Installment. 1993. LVII, 192 pages with 30 figures. Ring Binder. DM 175.00. Subscription price: DM 150.00. ISBN 3-527-30015-5

Third Installment. 1994. Ca 200 pages. Looseleaf. Ca DM 175.00. Subscription price: ca DM 150.00. ISBN 3-527-30056-2

A unique compendium of data on human proteins, collected from leading laboratories worldwide.
With the Third Installment now available, this superb reference work covers over 300 human proteins!
Condensed and still comprehensive (contains physico-chemical data, structures, and physiological and pathological mechanisms), the work is extraordinarily up-to-date.
In addition, the convenient loose-leaf format facilitates regular updating.

Special feature: a computer retrieval program on diskette which allows easy searches through the data.

An Amazing Distortion in DNA Induced by a Methyltransferase (Nobel Lecture)**

Richard J. Roberts*

Much of my work in biology has been driven by my early training in chemistry. In the study of a new chemical compound, the first and most important thing is to determine its detailed molecular structure. For a molecular biologist that usually means determining some DNA sequence, since an accurate knowledge of sequence will then allow the proper design of experiments to examine function. I was first exposed to the idea of macromolecular sequences while I was a postdoctoral fellow with Jack Strominger at Harvard. During that time I briefly visited Fred Sanger's laboratory in Cambridge, England, to learn the methodology of RNA fingerprinting and sequencing.

Shortly before moving to Cold Spring Harbor Laboratory, I learned of restriction enzymes from a lecture by Dan Nathans and immediately decided that here was the key to DNA sequencing. The idea was that by mapping restriction sites and sequencing small fragments, longer gene-sized sequences could be put together. My laboratory set out to isolate and characterize as many restriction enzymes as possible.[1] We began to use these enzymes to map Adenovirus-2 DNA[2] and to identify small fragments that might be worth sequencing. One such fragment would contain the 5'-end of an Adenovirus-2 mRNA and the eukaryotic promoter that controlled its expression. It was the hunt for this promoter-containing fragment that led to our discovery of split genes and RNA splicing.[3-6] By this time, Fred Sanger and Walter Gilbert had developed DNA sequencing methods, and we focused our attention on the sequence requirements for RNA splicing. Joe Sambrook, Walter Keller, and others cloned the tripartite leader that was present on Adenovirus-2 late mRNAs, and Sayeeda Zain determined its sequence.[7] Soon we undertook the complete sequencing of the Adenovirus-2 genome, which was eventually finished as a collaborative effort with Ulf Pettersson's laboratory.[8]

We realized early on that computational help would be essential for the sequencing project, and we developed many programs for assembling and analyzing DNA sequences.[9-14] During this time we and others began to clone and sequence the genes for restriction enzymes and their companion methyltransferases (MTases).[15,16] Our initial naive assumption was that in any given restriction–modification system there would be a common region in the protein sequence of the restriction enzyme and the MTase that would pinpoint the region responsible for DNA sequence recognition. This was based on the fact that both enzymes had to recognize exactly the same DNA sequence. Once this common protein sequence had been recognized, we thought it likely that in vitro manipulation would allow us to change the DNA sequence recognized and so create new restriction enzymes by protein engineering. This proved hopelessly naive. Not only was there no similarity between the sequences for restriction enzyme and MTase genes, there was also no similarity between the genes for different restriction enzymes. There was, however, considerable sequence similarity among the genes for MTases, which was especially strong for the enzymes forming 5-methylcytosine. This observation has shaped the last few years of my research efforts and has led to our latest discovery, which is the topic of this lecture.

Methylation of adenine and cytosine residues is commonly found in prokaryotes, and cytosine methylation is widespread in eukaryotes. In bacteria, DNA methylation serves as a component of restriction–modification systems[17] and also as part of mismatch repair systems.[18] In higher eukaryotes, methylation of cytosine residues appears to be essential[19] and is involved in the control of gene expression, developmental regulation, genomic imprinting, and X-chromosome inactivation.[20]

There are three kinds of methylation that bacteria use to protect their DNA against the action of restriction enzymes: at the 5- (m5C) and N4-positions of cytosine (m4C), and at the N6-position of adenine (m6A). To date, 50 different m5C-MTase genes have been sequenced.[21] When we first began comparing the sequences of these genes in 1987, the available computer software was unable to provide good alignments of many of these sequences because the similarity between them was limited to short patches, which we now call motifs, that were separated by quite dissimilar regions. The similarity could be detected by eye, however. Janos Pósfai in my laboratory began developing algorithms that could find these small patches of similarity among proteins.[22] The program searched for the presence of small triplet patterns (Fig. 1) and then combined them into motifs that represented well-conserved regions within each of the set of proteins being aligned. These motifs then anchored the inital alignment. By reducing the stringency of the triplet search and limiting it to the regions between the main motifs, weaker motifs could be found, which enabled a more complete alignment.

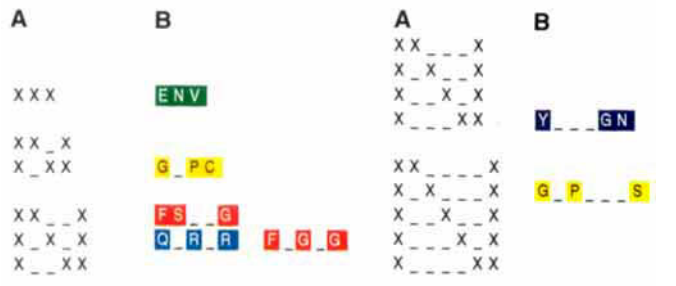

Fig. 1. A) Examples of the triplet patterns used to align multiple sequences. Each pattern contains three specific amino acids each at a set position X; any amino acid is allowed at positions _. The simplest pattern (top) consists of all possible simple tripeptides ($20 \times 20 \times 20 = 8000$ combinations). All sequences are searched for each of these patterns (224000 total for 10 amino acids) and their frequencies recorded. B) Examples of common patterns found in the m5C-MTases.

Finally gaps could be introduced to complete the alignment. We have since refined these programs and included a user interface with graphic output that enables the overall architecture of a group of proteins to be visualized. The relationships among the m5C-MTases is illustrated schematically in Figure 2. There are six regions of strong similarity and four more regions of lesser similarity that can be used to anchor the alignments between these sequences. Connecting these motifs are regions that vary in length and sequence. Similar analyses of the m5C-MTase have been reported by others.[23]

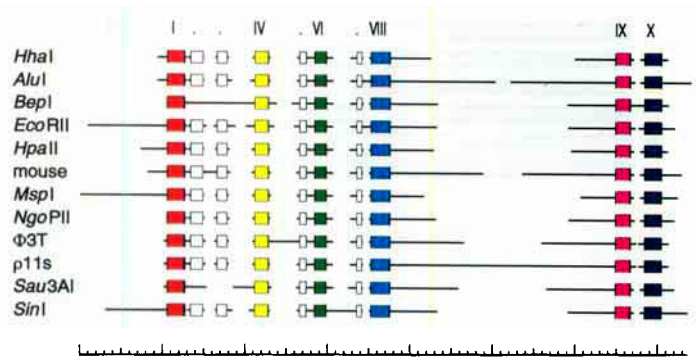

Fig. 2. Schematic representation of the alignment of twelve representative m5C-MTases. The six well-conserved motifs that anchored the original alignment are shown in color (light red: motif I, F-G-G; yellow: motif IV, PC; green: motiv VI, ENV; light blue: motif VIII, Q-R-R; dark red: motif IX, RE; dark blue: motif X, GN). The open boxes represent the four weakly conserved motifs. The organisms from which these enzymes were obtained are listed on the left.

Among the six well-conserved motifs, two could be assigned functional significance. Motif IV, which is shown in block form in Figure 3a, contains a cysteine residue that was postulated by Santi and Danenberg to be a key catalytic residue.[24] They had proposed (Fig. 3b) that an initial step in the reaction involved the formation of a covalent complex between this cysteine residue in the MTase and the 6-position of cytosine in a Michael reaction. This activates the 5-position of cytosine and permits transfer of the methyl group from the cofactor *S*-adenosylmethionine (AdoMet). Much biochemical evidence was available to support this mechanism, including the important observation that 5-fluorocytosine was a mechanism-based inhibitor.[25] Later work has enabled the isolation of the covalent intermediate,[26–28] and the cysteine within motif IV has been shown directly to be the site of covalent bond formation.[26] Recent experiments have shown that mutation of this cysteine residue to glycine, serine, or other amino acids blocks MTase action.[29–31]

Motif I could also be assigned a functional role. It contained three highly conserved residues FGG (Fig. 4a). Importantly, it

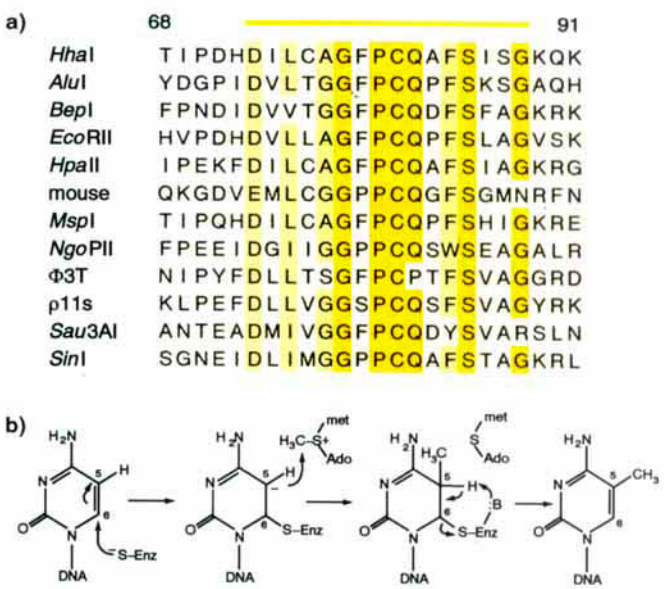

Fig. 3. a) Block diagram showing the well-conserved motif IV (PC). Residues conserved among all m5C-MTase sequences are strongly highlighted in yellow, and those that show three or fewer variants are lightly shaded. b) Schematic representation of the reaction pathway for the methylation of cytosine.

Richard J. Roberts, born in 1943 in Derby, England, obtained his Ph.D. in organic chemistry at Sheffield University in 1968. Following a postdoctoral stay with J. L. Strominger at Harvard University, he worked at Cold Spring Harbor Laboratory from 1972 to 1992, where he advanced to be Assistant Director of Research. He is currently Director of Eukaryotic Research at New England Biolabs in Beverly, Massachusetts. In addition to intensive studies on the type-II restriction enzymes, his research has focused on Adenovirus-2. In recent years his work has centered around DNA methyltransferases. He was one of the pioneers in the development of computer-aided sequence analysis for proteins and nucleic acids.

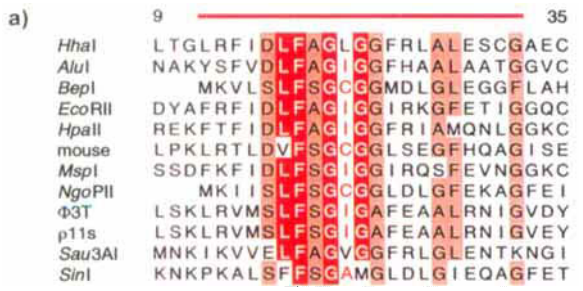

Fig. 4. a) Block diagram showing the well-conserved motif I (FGG). Residues conserved among all m5C-MTase sequences are strongly highlighted in red, and those that show three or fewer variants are lightly shaded. b) Consensus sequences for motif I and its relatives in other MTases (based on ref. [32]).

shows distinct similarities to motifs found in other MTases (Fig. 4b). It can be seen that all three classes of DNA MTases, m5C-, m4C-, and m6A-MTases as well as protein and RNA MTases contain a related motif. The common functional feature is that each MTase uses AdoMet as the methyl donor, and so motif I was suggested to be involved in binding to the cofactor.[32, 33]

We were interested in trying to define the region within the m5C-MTases that was responsible for sequence-specific recognition of the DNA substrate. Because the shared function of this group of MTases was the chemistry of the reaction, we argued that each of the common regions, exemplified by motifs I and IV, must be directly involved, either by interacting with the cofactor or providing residues important for catalysis. Since the precise DNA sequence recognized by each enzyme was different, we expected that this recognition would be mediated by a region that differed among the sequences. Only one region, the so-called variable segment located between motifs VIII and IX, appeared a reasonable candidate. Examination of these variable regions shows that not only the amino acid sequence but also the lengths of the segments vary considerably from MTase to MTase.

Although most of the known m5C-MTases are monospecific, that is, they recognize a single sequence, some MTases are known that recognize more than one specific sequence. These are the so-called "multispecific" MTases that are encoded by several *Bacillus* bacteriophages. These enzymes are single polypeptides like the monospecific enzymes, but they have the unusual property of methylating several quite different sequences. One example is M.Φ3TI, which recognizes and methylates the sequences GGCC and GCNGC.[34] This enzyme is included in Figure 2, and there it can be seen that its variable region is extraordinarily long. A series of elegant studies carried out in Tom Trautner's laboratory has showed convincingly that single mutations within the variable regions of M.Φ3TI and other multispecific MTases knock out the ability of the enzyme to recognize one of the specific sequences, while still allowing the others to be recognized.[35, 36] In the case of the monospecific MTases, a comparable experiment was not possible, since mutations that prevented DNA recognition would also block MTase activity. Saulius Klimasauskas and Janise Nelson in my laboratory undertook a series of experiments in which they swapped domains between two of the monospecific MTases.[37] We chose M.*Hpa*II (recognition sequence: CmCGG) and M.*Hha*I (recognition sequence: GmCGC), because they both recognize tetranucleotide sequences and because the base methylated is located at an equivalent position within the recognition sequences. The variable regions, with or without flanking sequences, were swapped as illustrated in Figure 5. In several cases, active MTases resulted, and comparison of the hybrids showed clearly that sequence specificity lay entirely within the variable region. Surprisingly, hybrids in which the variable region plus its adjacent motif IX were transferred showed much higher methylation activity than hybrids in which just the variable region had been swapped.

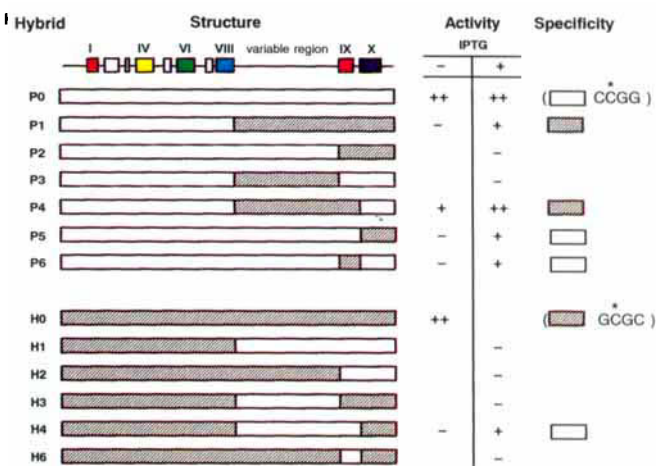

Fig. 5. Schematic representation of the hybrids P1–P6 and H1–H6 between M.*Hpa*II (P0) and M.*Hha*I (H0). The MTases were under the control of an IPTG-inducible promoter on a pBR322 derivative. Sequences derived from M.*Hpa*II are shown by open boxes; those from M.*Hha*I are shown by shaded boxes. The column labeled Activity shows the extent of protection of plasmid DNA in vivo, as measured by restriction enzyme cleavage in vitro, either before (−) or after IPTG induction (+) (− indicates no protection, + indicates weak protection, ++ indicates > 90% protection). The specificity of the hybrid methyl transferase is shown on the right.

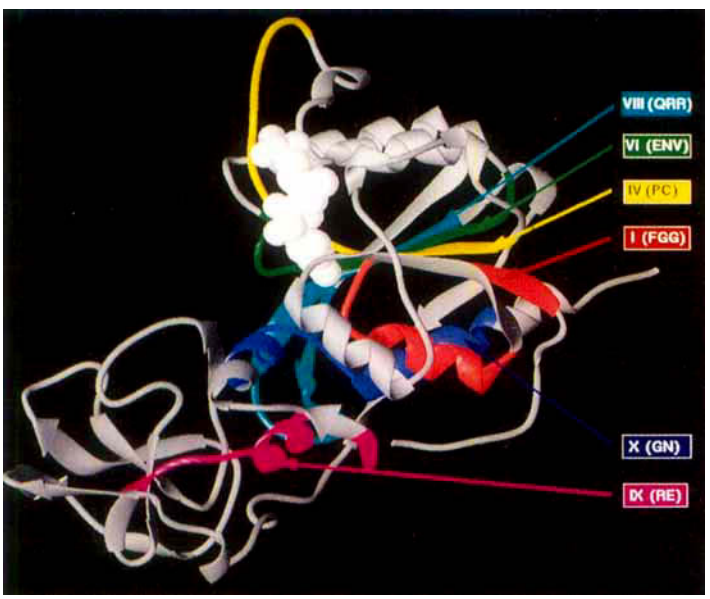
In another series of experiments, Mi Sha swapped the variable regions from M.*Hpa*II and M.*Msp*I. These enzymes both recognize the sequence CCGG, but M.*Msp*I transfers the methyl group to the first cytosine residue in the sequence,[38] whereas M.*Hpa*II transfers the group to the second cytosine residue.[39] The results of these experiments showed that the choice of base to be methylated also depends upon the variable region.[40]

While we were pursuing our studies of the biochemistry and molecular biology of MTases, it became apparent that a crystal structure would be essential if we were to understand fully the reaction mechanism. Ashok Dubey in my lab began a collaboration with Xiaodong Cheng, who was working in Jim Pflugrath's laboratory at Cold Spring Harbor. They purified and attempted to crystallize M.*Msp*I, which we had studied extensively.[41–43] Later they tried to crystallize M.*Hpa*II, on which we had also worked.[44] In both cases, the efforts were unsuccessful. How-

ever, the third attempt with M.*Hha*I was quite successful. This enzyme forms part of the *Hha*I restriction system from *Haemophilus haemolyticus*, which had been discovered in my laboratory.[45] It is one of the smallest of the m5C-MTases, containing 327 amino acids ($M_r \approx 37$ kDa). Its gene has been cloned and sequenced,[46] and the protein was overexpressed in *E. coli*[37, 46a] and subjected to detailed kinetic studies.[25] Sanjay Kumar purified the enzyme, and in December 1991 it crystallized readily—a wonderful Christmas present! Within eleven months Xiaodong Cheng had a structure for the binary complex between M.*Hha*I and AdoMet at 2.5 Å resolution.[48]

The structure was most revealing (Fig. 6); it was composed of a large domain and a small domain forming a cleft that appeared ideal for accomodating a DNA helix. Motif I (FGG) was confirmed to be involved in AdoMet binding, while another of the conserved motifs, X (GN), was also implicated in AdoMet binding. Motif IV (PC) was positioned close to the AdoMet-binding site on the same side of the cleft. Motif VIII (QRR) lay at the base of the cleft, where one could imagine that the positively charged residues of the motif could play a role in binding to the phosphodiester backbone of the DNA helix. Conserved motif IX (RE) threaded its way through the small domain, which otherwise consisted of almost the entire variable region. Motif IX appeared to form a backbone responsible for bracing the structure of the small domain. Finally, conserved motif VI (ENV) was clearly involved in correctly positioning motif IV.



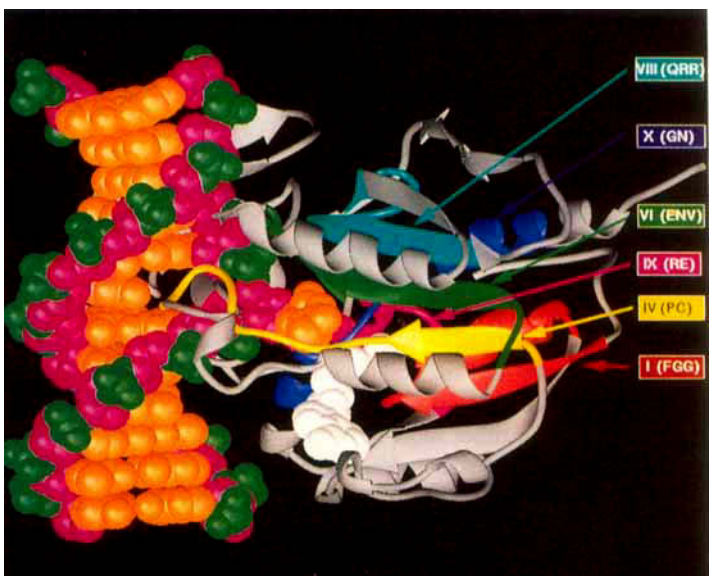


Fig. 6. The structure of M.*Hha*I in a binary complex with its cofactor AdoMet. The motifs are colored as in Figure 2. The cofactor, AdoMet, is shown in white as a space-filling model.

The structure provided a clear explanation for our earlier observation that domain swaps that included both motif IX and the variable region gave more active MTases than those involving just the variable region.[37, 40] Although motif IX is quite highly conserved among the MTases, there are differences from one MTase to another, and these could be expected to influence the ability of a heterologous motif IX to brace the structure of the small domain.

Soon after we obtained crystals of the binary complex between M.*Hha*I and AdoMet, we set about trying to obtain cocrystals that would also include DNA. Two kinds of complexes were envisioned. One would contain M.*Hha*I together with native DNA and *S*-adenosylhomocysteine (AdoHcy), while another would contain M.*Hha*I with AdoMet and a DNA duplex substituted with 5-fluorocytosine at the target. The latter would be expected to form a covalent intermediate in which the methyl group had transferred to the 5-position of cytosine, but release

of the DNA from the covalent complex with the protein would be inhibited by the presence of the fluorine atom, which is a poor leaving group. Such a complex could almost be viewed as a model of the transition state in DNA methylation.

Saulius Klimasauskas jointed the project for the cocrystallization, and we were fortunate in obtaining good crystals fairly readily with both native DNA and DNA containing 5-fluorocytosine. Xiaodong Cheng, who now has his own laboratory at Cold Spring Harbor, has solved the cocrystal structure at 2.8 Å resolution (Fig. 7).[49] We had expected to find that the DNA helix would be distorted in some way to allow the chemical reaction to take place, because the chemistry requires that the cysteine residue must approach the cytosine in a direction perpendicular to the plane of the ring. We imagined at most some extreme bending of the DNA. Unexpectedly, the distortion is much greater than a bend and much more elegant. The target cytosine flips right out of the axis of the DNA helix and into a pocket in the enzyme that contains the catalytically important cysteine residue. The rest of the helix is relatively undistorted. Another large conformational shift has taken place in the active site loop which encompasses motif IV. The entire 20-residue loop rotates through almost 180° from its original position to bring the catalytically active cysteine into contact with the target cytosine (Fig. 8).

The position in the DNA helix that was occupied by the target cytosine is now filled by two residues. One is a glutamine residue from the small domain, and the other is a serine residue from the active site loop. Surprisingly, neither of these residues is conserved among other m5C-MTases, which suggests that many residues could assist in opening a helix in this manner. As can be seen from Figure 7, the interaction between M.*Hha*I and DNA can be thought of as the enzyme embracing the DNA with two arms that penetrate the helix during the embrace and assisting in the extrusion of the target cytosine.

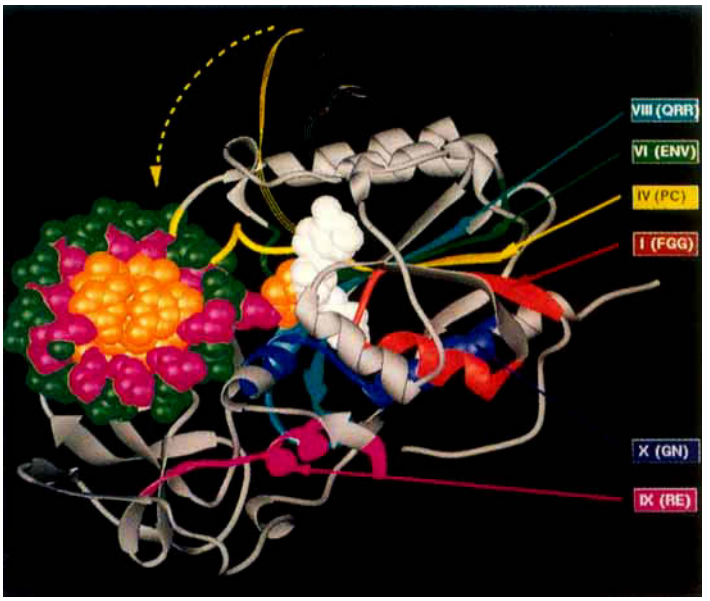

Fig. 8. Composite of the M.*Hha*I structures with and without DNA showing the conformational changes that take place upon binding to DNA (colors as in Fig. 7). The active site loop (yellow) is shown as a solid line to indicate its position in the ternary complex structure (with DNA) and as a triple-stranded ribbon in the binary complex structure (no DNA).

The sequence-specific interactions between M.*Hha*I and its substrate mainly involve two distinct loops (the sequence recognition loops) from the small domain. One loop is responsible for interactions with the orphan guanosine that is left after the cytosine has flipped and makes specific contacts with the adjacent bases on the same strand. It also provides the glutamine residue that fills the hole left after the target cytosine is flipped. The second recognition loop interacts predominantly with the

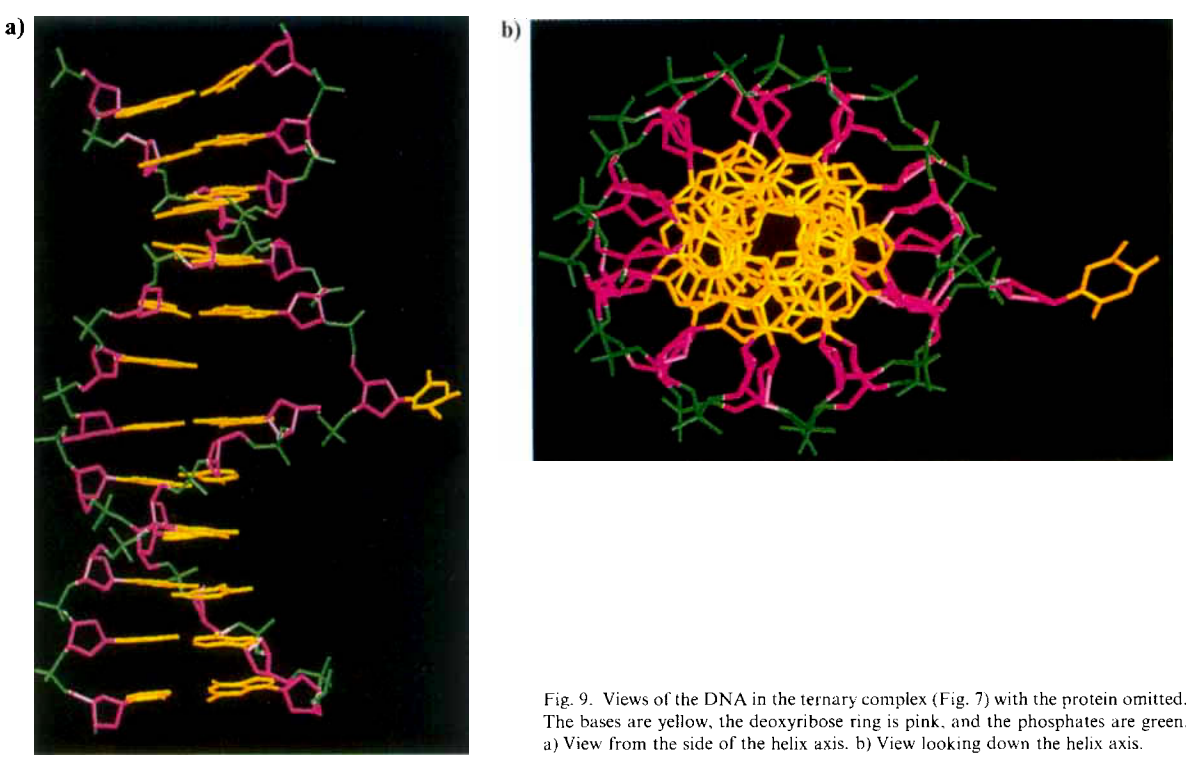

Fig. 9. Views of the DNA in the ternary complex (Fig. 7) with the protein omitted. The bases are yellow, the deoxyribose ring is pink, and the phosphates are green. a) View from the side of the helix axis. b) View looking down the helix axis.

strand containing the target cytosine. However, the interactions in the covalent complex should be viewed as an end point of a more complicated interaction. They may not be an accurate reflection of the initial events that led to recognition. More information on these initial events may be provided by studies of mutant proteins or DNA analogues that can form complexes without flipping the target cytosine. It should be noted that none of the well-characterized DNA binding motifs[50] appear to play a role in this system.

Previous studies of DNA–protein interactions have shown quite dramatic distortions induced in DNA by proteins, but usually these have involved bends or kinks; one of the most dramatic was the flattening and bending of DNA induced by the TATA-box binding protein.[51, 52] There have been no previous examples of proteins interacting with DNA and causing a base to flip out of the helix. Since the DNA bases lie buried in the inside of the helix in normal DNA, the mechanism presented here provides an elegant means by which complete access to the base becomes possible. We anticipate that other proteins performing chemistry on DNA bases also use this mechanism. Obvious candidates would be the MTases that form N^6-methyladenine or N^4-methylcytosine. Some of the enzymes, such as DNA glycosylases, that repair DNA damage might also flip the damaged base out of the helix prior to its excision. Many proteins that interact with DNA need to open up the helix. Some examples are topoisomerases, helicases, DNA polymerases and/or their auxiliary proteins that operate at replication origins, RNA polymerases, and recombination enzymes. In the structure shown in Figure 9 the phosphodiester bonds adjacent to the target cytosine are distorted from their positions in normal B DNA, and one might imagine that the continued unzipping of the helix would be easy.

Surprisingly, the interaction between M.*Hha*I and DNA requires no external energy source. Conformational rearrangements within the protein combined with specific interactions between protein and DNA likely provide the energy to open the helix. The energy is then stored for use during the return of the target cytosine. It would be surprising if this mechanism is not used elsewhere. Split genes were discovered unexpectedly but proved to be easily found once we knew they were there. This mechanism of flipping a base out of the DNA helix might also prove to be of widespread importance as a first step in opening up a DNA helix. We should lose no time in exploring the possibility.

I am most grateful to all of my colleagues who have worked so hard in my laboratory to ensure our success. None of this would have been possible without their input. In addition to those mentioned explicitly in the text I thank Phyllis Myers, Kathy O'Neill, Margaret Wallace, Louise D'Allessandro, Jodie Freyer, Carol Marcincuk, Dana Macelis, and Ching Lin, whose dedication has been especially important in making my life easier. I thank Jim Watson for persuading me to go to Cold Spring Harbor Laboratory and for many stimulating conversations. Among many colleagues, Ashok Bhagwat, Mike Botchan, Don Comb, Greg Freyer, Rich Gelinas, Tom Gingeras, David Helfman, Winship Herr, Adrian Krainer, Stu Linn, and Ira Schildkraut have been good friends and valuable sources of criticism and advice. I thank the National Institutes of Health and the National Science Foundation for much support over the years. Finally, I am indebted to my wife, Jean, and my children, Alison, Andrew, Christopher, and Amanda, who have been supportive and understanding of my addiction to science.

Split Genes and RNA Splicing (Nobel Lecture)**

Phillip A. Sharp*

Introduction

By the late 1970s the physical structure of a gene was firmly established from work in bacteria. The sequences of the gene, the RNA, and the protein were colinearly organized and expressed. Since the science of genetics suggested that genes in eukaryotic organisms behaved similarly to those of prokaryotic organisms, it was naturally assumed that this bacterial gene structure was universal. It followed that if the gene structure was the same, the mechanisms of regulation were probably very similar, and thus what was true of a bacterium would be true of an elephant.

However, many descriptive biochemical aspects of the genetic material and its expression in cells with nuclei suggested that the simple molecular biology of gene expression in bacteria might not be universal. First, obviously, RNAs transcribed from nuclear genes are physically separated from the translational machinery in the cytoplasm. Thus, the nuclear compartment could be the site of selective RNA processing and transport. Second, the DNA content of eukaryotic germ cells varied significantly between organisms without an apparent variation in the number of genes. Some organisms appeared to have ten times as much DNA as was required to encode all of the proteins. Third, the previously described phenomenon of heterogeneous nuclear RNA (hnRNA) suggested that long RNAs were transcribed from diverse nuclear sequences.[1] These hnRNAs had a short half-life relative to cytoplasmic mRNAs and thus could potentially be precursors to mRNAs. Furthermore, both the long hnRNA and the shorter mRNA appeared to have modified 5′ and 3′ termini in common, a ^{7}mGpppX cap[2-4] and polyadenylation tracts,[5-7] respectively. The meaning of these observations concerning hnRNAs remained controversial as it was not possible to establish a precursor–product relationship between the nuclear RNA population and the cytoplasmic mRNA.

Whether or not the structure of genes in eukaryotic cells was the same as that in bacteria was not really questioned at that time. The important issue was to establish the exact biochemical pathway between a gene in the nucleus and its mRNA in the cytoplasm. This hypothetical pathway was pictured as beginning with initiation of transcription by RNA polymerase II(B) which would proceed through completion of transcription beyond the terminus of the gene. The nuclear precursor RNA transcribed from the gene was potentially processed, and the mRNA selectively transported to the cytoplasm. Regulation of gene expression, the basis of almost all interesting biology, including cancer, cellular responses to infection, and development would primarily result from changes in the rates or efficiencies of the various steps in the pathway. Thus, understanding the pathway of eukaryotic gene expression promised new insights into the mechanisms of regulation and the biochemical events controlling both diverse biological and biochemical phenomena.

Background

The late stage of adenovirus infection was chosen as the best system for studying the pathway of nuclear gene → nuclear precursor RNA → cytoplasmic mRNA → protein. We had previously established several restriction endonuclease cleavage maps of the viral genome (Fig. 1)[8] and had used fragments of the genome to map the positions of cytoplasmic mRNAs generated during the early and late stages of infection.[9] We had also determined the abundance (in copies per cell) of both nuclear and cytoplasmic RNAs,[10] and this suggested that RNAs from both compartments could be obtained in adequate amounts to compare their structures directly by using the electron microscope and the then recently developed RNA · DNA hybridization methods. Furthermore, these earlier studies established that sets of viral RNA sequences were restricted to the nucleus,

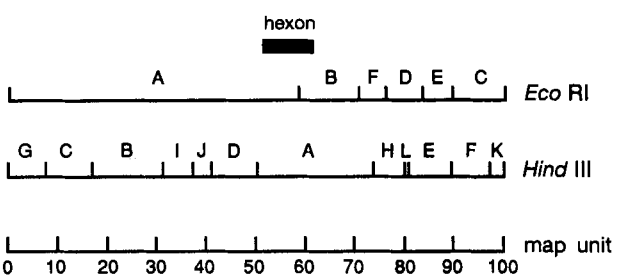

Fig. 1. Maps of cleavage sites for restriction endonucleases *Eco*RI (top) and *Hind*III (middle). The approximately 35000 base pairs of adenovirus 2 DNA was assigned as 100 map units (bottom). The positions of cleavage sites are denoted by vertical lines and fragments are lettered on the basis of length. The r and l viral strands are transcribed to the right and left, respectively. The sequences constitituting the body of mRNA specifying the abundant hexon (II) protein are encompassed by the bar about the boundary of *Eco*RI fragments A and B.

suggesting a selection in processing and/or transport of only certain RNA sequences to the cytoplasm.[11] Finally, several studies had established that long nuclear RNA was transcribed from the adenovirus genome during the late stages of infection[12] and the stable cytoplasmic RNAs were shorter than the predominant nuclear RNAs. Thus, the production of RNAs during the late stage of adenovirus infection presented a paradigm for the heterogeneous nuclear RNA phenomenon associated with cellular genes.

Discovery of RNA Splicing

Comparison of the structure of a cytoplasmic mRNA with that of a nuclear precursor RNA[13] required the purification of a specific homogeneous mRNA. The most abundant mRNA, which encoded the adenovirus hexon protein, was separated from other viral mRNAs by gel electrophoresis and used in electron microscope mapping studies.[14] Ray White, as a fellow at Stanford, was the first to recognize that RNA · DNA hybrids were more stable than DNA · DNA duplexes in high concentrations of formamide.[15] This phenomenon was characterized physically by Davidson et al.[16] and was the basis of a convenient R-looping technique in which RNA forms a hybrid with a DNA strand, displacing the other strand of DNA into an easily observed loop. The adenovirus mRNA for hexon protein was mapped by the R-loop method to the *Hind*III A fragment of adenovirus 2 (see Fig. 1).[13]

Inspection of the R-loops between the hexon-mRNA and the *Hind*III A DNA fragment with an electron microscope revealed the presence of RNA tails at both the 5′ and 3′ ends of the hybrid (Figs. 2A, B and C). The single-strand RNA tail at the 3′ end was expected, as the RNA was known to be polyadenylated post-transcriptionally. The single-strand RNA tail at the 5′ end of the hybrid was not expected; however, this 5′ tail of RNA could have been displaced from the RNA · DNA hybrids by formation of duplex DNA by a process called branch migration. In fact, similar 5′ tails had been observed previously in R-loop mapping of adenovirus mRNA and had been ascribed to such branch migration.[17, 18] Arguing against branch migration however was the finding that the lengths of the 5′ tails were relatively uniform, namely 170 nucleotides. To eliminate this potential of competing DNA sequences displacing RNA se-

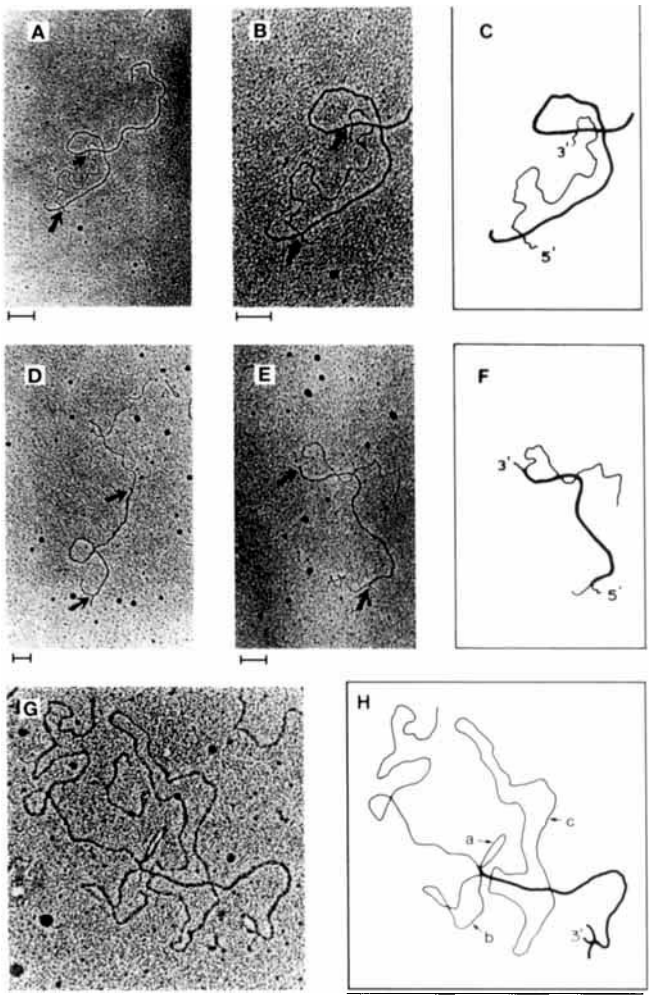

Fig. 2. Electron micrographs of hybrids of hexon mRNA and fragments of adenovirus 2 (Ad2) DNA [13]. A, B) Examples of R-loop hybrids observed after incubation of hexon mRNA and duplex *Hind*III A fragment DNA. C) Schematic representation of A and B. D, E) Two examples of hybrids of hexon mRNA and the single-stranded *Hind*III A fragment. F) A schematic representation of E. The single-stranded RNA at the end of the hybrid region is represented by a wavelike line. In A, B, D, and E the positions of the RNA tails at the 5′ and 3′ ends of the hybrids are denoted by arrows. G) An example of a hybrid between single-stranded *Eco*RI A DNA and hexon RNA. H) Schematic representation of G. The hybrid region is indicated by a heavy line; loops a, b, and c (single-stranded unhybridized DNA) are joined by hybrid regions resulting from annealing of upstrem DNA sequences to the 5′ tail of hexon mRNA. Bars on micrographs represent 0.1 μm.

Professor P. A. Sharp was born on June 6, 1944 in Kentucky. He obtained a B. A. in chemistry and mathematics from Union College, Kentucky, and a Ph.D. in chemistry from the University of Illinois, Champaign-Urbana. He carried out postdoctoral research with Prof. N. Davidson at the California Institute of Technology and with Prof. J. Watson at the Cold Spring Harbor Laboratory. Subsequently, he joined the Center for Cancer Research and Department of Biology at the Massachusetts Institute of Technology in 1974. In 1985 he succeeded Prof. S. E. Luria as Director of the Center for Cancer Research. He is currently Head of the Department of Biology, a position he assumed in 1991. His research interests have centered on the molecular biology of tumor viruses and the mechanisms of RNA splicing, which he discovered in 1977. His work provided one of the first indications of the startling phenomenon of split genes in the cells of mammals. His scientific achievements have resulted in numerous awards, the most prestigious of which was the Nobel Prize for Medicine in 1993.

quences, we used a denatured single strand of the *Hind*III fragment (Fig. 2D, E, and F) to form a RNA · DNA hybrid. Surprisingly, the 5′ RNA tail still did not form a hybrid with the adjacent viral sequences, suggesting that these RNA sequences were derived from other DNA sequences.

Could the DNA sequences transcribed to form the 5′ tail sequence, the leader RNA sequence, be located upstream of the body of the hexon mRNA, perhaps as part of the long nuclear RNA? To test this possibility, a strand of the *Eco*RI A DNA fragment was hybridized with the hexon mRNA. This DNA fragment contained all of the linear viral sequences which could have been transcribed by the polymerase before encountering the body of the hexon mRNA. Surprisingly, and wonderfully, the leader RNA sequences hybridized to three short tracts of DNA sequences, creating three different size loops a, b, and c of intervening single-strand DNA (Figs. 2G and H). The length of these loops mapped the positions of the leader sequences, L1, L2, and L3, to approximately 16.9, 19.8, and 26.9 map units on the genome, respectively. The distances between the bases of the three loops permitted an estimate of the lengths of the two internal leaders to be 80 and 110 nucleotides, respectively. The 5′ proximal leader was estimated to be quite short, but longer than fifteen nucleotides.

RNA splicing was the mechanism we proposed for generation of the final hexon mRNA.[13] It was known that the nucleus of virus-infected cells contained long RNAs transcribed from the viral sequences between the 5′ leader L1, located at 17 map units, and the body of the hexon mRNA, located between 51.7 and 61.3 map units.[19, 20] Thus the long nuclear RNA probably contained sequences for all three leaders, L1, L2, and L3, as well as for the body of the mRNA. These sequences were conjectured to be joined by excision of the intervening sequences and ligation of the flanking RNAs, a process dubbed RNA splicing (Fig. 3). In fact, the nuclear RNAs were quite abundant and were easily visualized by electron microscopy of the RNA · DNA hybrids.[21] Analysis of the structure of these RNA · DNA hybrids revealed the presence of potential intermediates, in which only L1 had been spliced to L2 or L1, L2, and L3 had been joined by splicing.

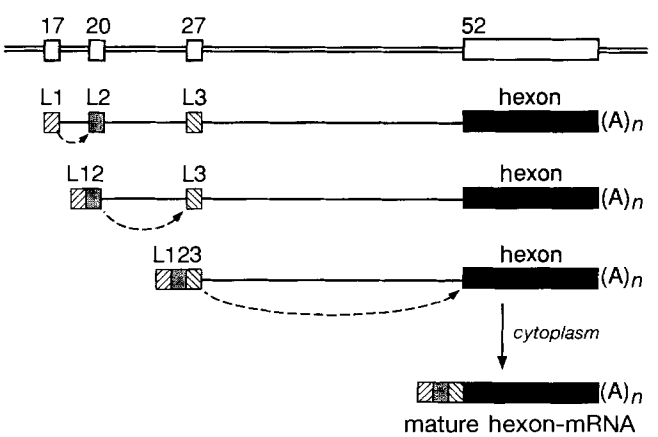

Fig. 3. Proposed RNA splicing mechanism for synthesis of mRNA for hexon protein. A long nuclear precursor RNA is transcribed from 16.9 map units through the polyA addition site at the end of the body of hexon mRNA. The region of the Ad2 genome from which the precursor RNA is transcribed is shown at the top of the figure. The four RNA segments in the cytoplasmic mRNA are processed from this precursor by excision of intervening sequences and ligation (denoted by dashed arrows).

The RNA splicing hypothesis reconciled many paradoxes. Both the longer nuclear RNAs and the shorter cytoplasmic mRNAs could share 5′ cap termini, ^{7}mGpppX, and 3′ polyadenosine tracts,[22] because internal sequences were removed from the nuclear precursor. More specifically for adenovirus, previous evidence had suggested that many different viral mRNAs appeared to share a common 5′ terminal sequence.[23] This sequence, a long T1 oligonucleotide, contained the cap and an apparently unique sequence eleven residues in length. If many of the late viral mRNAs were processed by splicing from the same type of precursor RNA, they could share a common sequence at their 5′ termini. More importantly, the RNA splicing hypothesis provided an explanation for the hnRNA phenomenology associated with cellular genes. Heterogeneous nuclear RNA transcribed from diverse cellular genes could be processed by RNA splicing into shorter cytoplasmic mRNAs. Thus, most cellular genes probably contained sequences which were removed by RNA splicing, that is they were split genes.

Split Genes: Intervening Sequences or Introns in Cellular Genes

Shortly after the discovery of RNA splicing and split genes in adenovirus, a number of cellular genes were also shown to have introns or intervening sequences. For example, the globin genes contained two intervening sequences,[24, 25] the ovalbumin gene was split into eight sets of sequences,[26] and the immunoglobulin genes contained both short and long introns.[27] In fact, the average cellular gene contains approximately eight introns and the primary transcription unit is typically four times larger than the final mRNA. Shortly thereafter, it was recognized that there was a limited set of conserved sequences at each intron boundary.[28] Interestingly, these consensus sequences were common of vertebrate, plant, and yeast cells[29] suggesting the splicing process was evolutonarily general. Introns in the latter organisms are generally shorter and have more highly conserved sequences at their boundaries.

Phylogenetic comparison of the sequences of homologous genes from a variety of organisms revealed that intron sequences had drifted much more rapidly than exon sequences. This suggested that intron sequences are generally not functional, at least in the context of requiring long tracts of specific sequences. Furthermore, the length of introns in homologous genes varied significantly during evolution, suggesting little constraint. Finally, it was clear that specific introns could be lost during evolution. The mechanism responsible for the exact deletion of introns is probably related to gene conversion using a cDNA copy of the mRNA or a partially spliced intermediate RNA. This process has been documented for the removal of introns from yeast genes[30] and raises the question of why introns persisted during evolution.

Mutations in Cellular Genes

Many human diseases are caused by mutations that interfere with RNA splicing. Approximately one quarter of all mutations

in the human globin genes underlying thalassemia are mutations in sequences specifying correct RNA splicing. Thus, conserving information for accurate splicing is a constraint on genetic systems. The limited nature of the mutations altering splicing in the globin family is interesting.[31] All of the characterized mutations either alter the conserved 5′ or 3′ splice site sequences at the boundaries of the intron, or are changes within introns that generate new consensus splice sites (Fig. 4). The former is simple: mutation of the highly conserved GU or AG sequences at the boundaries of the intron commonly inactivates splicing at that site, and this frequently leads to the activation of a nearby cryptic splice site. The latter is more complicated. In this case, a mutational change within an intron—CT → GT activates this site as a 5′ splice site and, as a consequence, an upstream AG is activated as a 3′ splice site for further splicing. This results in the generation of a short exon from the previous intron sequences (Fig. 4). Thus, mutations can alter both the position of splice sites and the number of exons to generate novel proteins.

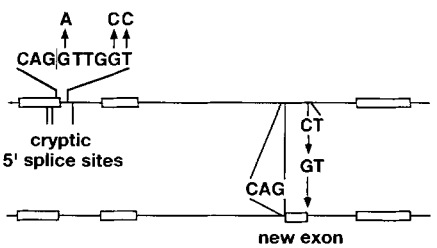

Fig. 4. β-Globin mutations. β-Globin genes of thalassemia patients possessing mutations which affect RNA splicing [31]. The single base changes in four independent patients are indicated by arrows from the diagram of the two intron structure of the β-globin gene. Three of the mutations alter conserved sequences of the 5′ splice site (left) and a fraction of the mRNA from these mutant genes is processed at the cryptic 5′ splice sites. The fourth mutation is within the sequences of the second intron (right) and creates a 5′ splice site at this position. This results in the induction of the indicated sequences as a new exon. Exon sequences are represented by rectangles, intron sequences by lines.

Mistakes are probably not uncommon in splicing of RNA from complex genes. Exons can occasionally be skipped and, in some cases, circular RNAs can be generated.[32, 33] Since specific functions have not been assigned to many of these RNAs, their generation may reflect noise in the system. Interestingly, it has recently been proposed that an mRNA surveillance system exists in cells which destroys RNAs as they enter the cytoplasm if they contain an open reading frame interrupted by a translational termination signal.[34] This system would probably degrade most mRNAs with splicing errors as they are transported to the cytoplasm.

Why Split Genes and RNA Splicing?

It is difficult to confidently account for why introns have been conserved during evolution within the genes of most, if not all, eukaryotes. Clearly the intron–exon structure of genes has been very important in the generation of new genes during evolution. For example, the fibronectin gene of man is composed of three types of exons, each of which encodes a specific type of protein folding domain (Fig. 5).[35] These same three protein-folding domains and corresponding exon structures are found in other

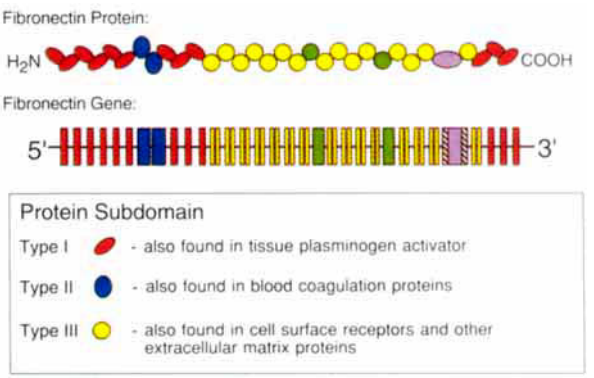

Fig. 5. Fibronectin gene evolved by exon duplication. The large extracellular matrix protein, fibronectin, is primarily composed of three types of protein subdomains, I, II, and III denoted as tilted red ellipsoids, vertical blue ellipsoids, and yellow circles, respectively. Each of these domains are encoded by a defined exon pattern, one or two exons, denoted as vertical rectangles. These exon units are duplicated in the fibronectin gene and also in the other genes containing these domains. In two cases, large green rectangles, the intron separating the typical two exon structures of the type III subdomain, have been deleted. These patterns suggest that descendants of a common progenitor exon configuration were used to generate parts of these genes [36].

genes, some of which encode cell surface receptors and blood coagulation proteins. Thus, the fibronectin gene was created by tandem and dispersed duplication of exon units using breakage and joining within the intron sequences. Since these exon units are assembled precisely by RNA splicing and encode functional protein domains, the final protein is stable and has multiple functions. Duplication and utilization of an exon unit has been a common mechanism for the generation of new genes encoding many cell surface receptors and other types of proteins in vertebrates. Thus, the presence of exon units which correspond to functional protein domains has been critical for the evolution of complex organisms.

The ability to alternatively select different combinations of exons at the stage of RNA splicing to generate proteins with different functions is clearly critical for the viability of many vertebrate organisms. Approximately, one of every twenty genes is expressed by alternative pathways of RNA splicing in different cell types or growth states. For example, nuclear precursor RNAs from the fibronectin gene are alternatively spliced into mRNAs that encode 20 different proteins. These proteins have slightly different functions reflecting their variant structures. Furthermore, a set of exons is not included in mRNAs processed in liver cells but is included in mRNAs in other cell types (Fig. 6). The fibronectin secreted by the liver more readily circulates in the blood stream because it has fewer protein domains which are recognized by receptors on the cell surface than the other forms of fibronectin.[36] The fibronectin secreted by other cells is more typically found in the intracellular matrix of solid tissue. A similar variation in cellular adhesion is observed with alternative splicing patterns in another part of the fibronectin mRNA. Thus, through alternative splicing, the same set of gene sequences can be utilized for different functions.

Alternative splicing of precursor RNAs in different cell types must reflect differences in the factors regulating the splicing process. Only in few cases have these factors been identified, primarily by the analysis of mutants which are defective in the regulatory step. The development of sexual dimorphism in the fruit fly *Drosophila* is regulated at the level of alternative RNA

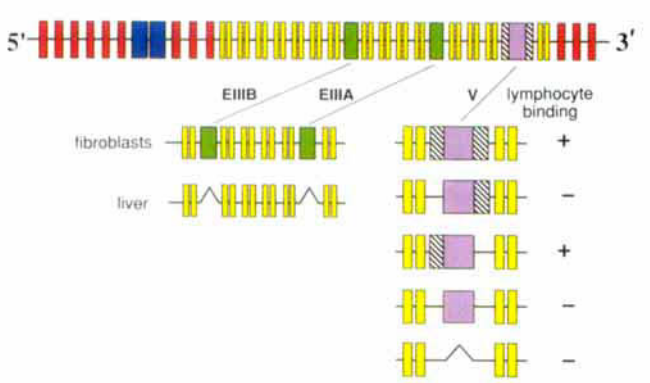

Fig. 6. Alternative splicing of RNA encoding fibronectin. The exons denoted as EIIIB and EIIIA are spliced into the mature RNA synthesized in many cell types including fibroblasts. However, in the liver, these two exons are not included, are skipped, in synthesis of the mRNA. Furthermore, five variations for the splicing patterns of the V region are shown. All of these variations on splicing are found in most cell types. The fibronectin proteins encoded by the first and third mRNA bind differentially to receptors on lymphocytes. In total, at least twenty different proteins are synthesized from the single fibronectin gene.

splicing by expression of a cascade of genes. Early in development, the female or male specific pattern of splicing is set by a reading of the ratio of sex chromosomes to autosomal chromosomes. After setting this switch, the developmental process is controlled by an autoregulatory process which maintains the male or female splicing pattern in many if not all cells.[37] Interestingly, most of the proteins encoded by these sex regulating genes are members of a family whose common features are one or more RNA recognition subdomains and a pronounced tract of the repeating amino acid sequence Arg-Ser.[38] It is likely that these factors directly interact through the Arg-Ser tract with other proteins critical for formation of the splicing machinery.

Split Genes in the Progenote?

The split gene structure must be very old, clearly predating the divergence of organisms that gave rise to plants, yeast, and man.[29] First, as will be described later, a complex splicing machinery, which involves greater than 50–100 proteins and five small RNAs, exists in the nucleus of all eukaryotes. This machinery is highly conserved and could not have arisen spontaneously in the various lineages. Second, introns are conserved in positions within homologous genes found in the lineages of plants and animals. This evidence established that split genes and RNA splicing were present in common progenitor organisms a billion years ago. Several scientists have speculated that genes originally evolved as exons and that the progenote organism from which current prokaryotic and eukaryotic organisms evolved may have had a split gene structure.[39–42] These primordial exons are pictured as encoding sequences for stable protein folding domains. Assembly of a number of exon sequences by RNA splicing would be expected to produce a protein composed of stable folding domains which have a high probability of being functional either structurally or catalytically. If genes originally evolved in this fashion, the positions of introns in relationship to protein secondary structure might not be random. Evidence to support this hypothesis has been sought in the exon–intron structure of evolutionarily old proteins critical for energy metabolism. For example, the enzyme pyruvate kinase is conserved in structure and functions in bacteria, yeast, and chicken (Fig. 7).[43] The gene is not interrupted with introns in bacteria and yeast, but contains ten introns in chicken, nine within the coding sequences. The positions of these nine

Fig. 7. The structure of pyruvate kinase and the intron positions [44] (reprinted with permission, Copyright © 1993, Cell Press, Cambridge, MA, USA). Pyruvate kinase is shown schematically as a protein with secondary and tertiary structure on the left. On the right, this structure is expanded at the positions of introns in the tertiary structure of the protein. Note that the first three introns all fall between α-helix (barrels) and β-sheet (arrows) repeats. Intron 8 is positioned in approximately equivalent positions in the mononucleotide binding fold of pyruvate kinase and maize alcohol dehydrogenase.

introns are not random when compared to the protein structure. First, in the N-terminal part of the protein, the first three introns are positioned between repeating structural motifs of α helix-β sheet. Second, in the mononucleotide binding fold, pyruvate kinase shares a common intron position with one other old metabolic enzyme, alcohol dehydrogenase. In pyruvate kinase, the eighth intron occupies a position similar to that of an intron in the dehydrogenase. Since the generation of these two enzymes from a common protein subdomain clearly predated the evolutionary divergence of prokaryotic and eukaryotic organisms, these results suggest that the progenitor organisms for both prokaryotic and eukaryotic organisms may have had a split gene structure more typical of a current eukaryotic cell (for discussion see ref. [44]).

Is the Gene an Exon?

The gene was first genetically defined as a unit of inheritance associated with a locus on a chromosome. The chemical definition of a gene has become much more difficult, however, as the complexity of genetic information and its modifications are discovered. The existence of alternative splicing of exons, where information at an exon unit can be optionally expressed in some cells and not in others, suggests that an exon might correspond to a gene. That is, an exon corresponds to the minimal amount of information which is expressed as a discrete unit. This concept becomes particularly relevant when the *trans*-splicing process is considered.[45] In this case, exons transcribed from different loci, and in many cases different chromosomes, are joined by RNA splicing. *Trans*-splicing of exons and introns has been established in the parasite trypanosomes,[46] the flat worm *C. elegans*,[47] and suggested for some human genes.[48] Clearly, in the case of *trans*-splicing, both the unit of inheritance and the locus on a chromosome can correspond to a single exon.

It is unlikely, however, that the current working definition of a gene as a linear collection of exons which are joined by RNA splicing will be radically altered in near future. This is probably wise, as the existence of multiple processes collectively called RNA editing further complicates the biochemical definition of a gene.[49] However, given the possibility that the earliest unit of genetic information may have evolved as an exon, the general concept of exons as gene units may be more valid than any other proposal.

Splicing of Nuclear Precursor RNAs to mRNAs

The development of a reaction composed of soluble cellular components which accurately processed precursor RNAs (pre-mRNAs) to mRNAs was critical for advancing our understanding of splicing.[50] When combined with the use of highly radioactive pre-mRNA substrates, a biochemical analysis of the splicing process became feasible.[51, 52] Not surprisingly, kinetic RNA intermediates in the splicing reaction were soon identified.[53, 54] Surprisingly, however, these intermediates had a lariat structure in which the 5′ nucleotide of the intron was joined in a 2′,5′-phosphodiester bond to an adenosine unit within the intron.)[55] Since the adenosine unit is covalently bonded through both 3′,5′- and 2′,5′-phosphodiester linkages, this forms an RNA branch. The existence of such branches was described from nuclease digestion studies of total nuclear RNA from human cells.[56] Formation of the branch appears simultaneously with cleavage at the 5′ splice site and generates the lariat RNA which typically migrates more slowly than the pre-mRNA during electrophoresis through a tight porosity polyarylamide gel.

The splicing of pre-mRNA proceeds in two steps (Fig. 8, left). As mentioned above, the first step consists of cleavage at the 5′ splice site with the concomitant formation of the branch. At this stage, the 5′ exon RNA has a 3′ hydroxyl group and the lariat intermediate RNA contains the intron and 3′ exon. The second step consists of cleavage of the RNA at the 3′ splice site with concomitant joining of the two exons. The intron is released as a lariat RNA and is reasonably stable in reactions in vitro. This contrasts with the situation in vivo where intron RNAs are almost always rapidly degraded.

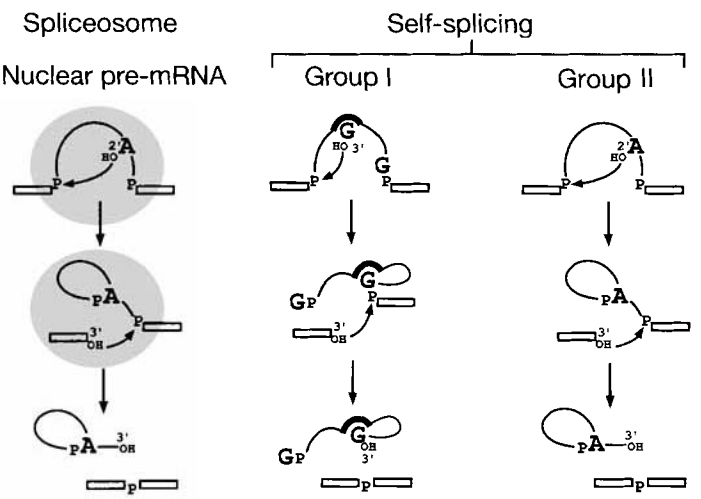

Fig. 8. Comparison of self-splicing and nuclear pre-mRNA splicing mechanisms. The first column outlines the mRNA precursor splicing mechanism. The shaded circle represents a multicomponent complex, the spliceosome, which promotes the splicing reaction. The second column outlines the splicing mechanism of self-splicing introns of the group I type. This process is catalyzed by RNA structures within the intron (dark semicircle), which contains a guanosine binding site, and utilizes a guanosine (G) factor in the first step. The third column outlines the splicing mechanism of self-splicing introns of the group II type. This process is also catalyzed by RNA structures within the intron but utilizes, instead of a cofactor, an adenosine residue (A) within the intron to form a lariat RNA. All three mechanisms proceed by two steps, reaction at the 5′ splice site and then reaction at the 3′ splice site.

The fact that the intermediate state, consisting of two RNAs, was efficiently converted to the final products strongly suggested that these RNAs remain bound in a complex. The complex was identified by its rate of sedimentation in a glycerol gradient (60S) and was designated to be a spliceosome or splicing body.[57, 58] As anticipated from earlier work which suggested the importance of small nuclear ribonucleoprotein particles in splicing, the spliceosome contained the small nuclear RNAs (snRNAs) U2, U4, U5, and U6 and, under certain conditions, U1.[59] Thus, the spliceosome, much like a ribosome, contains a substrate RNA and a number of stable cellular RNA-protein components.

Group I, Group II, and the Spliceosome

Comparison of the two steps in splicing by the spliceosome to the RNA-catalyzed self-splicing reactions of group I and II introns shows some striking similarities (Fig. 8). In all three cases, the first step is cleavage at the 5′ splice site. In group I introns, this cleavage requires a guanosine which specifically occupies a binding site in the catalytic intron sequences.[60] The 3′ hydroxyl group on this guanosine is activated and through a transesterification reaction displaces the 3′ hydroxyl of the 5′ exon. Group II self-splicing introns cleave at the 5′ splice site by activating the 2′ OH at the branch site, producing a lariat RNA[61, 62] much like that produced by the spliceosome. The second step for all three processes involves a reaction at the 3′ splice site to join the exons and displace the intron. The simplest mechanism for the second step of splicing of the group I and II introns is a single transesterification. This has been proven to be the case for reactions by group I introns.

The similarities between the spliceosomal process and the self-splicing introns suggested that these reactions might be

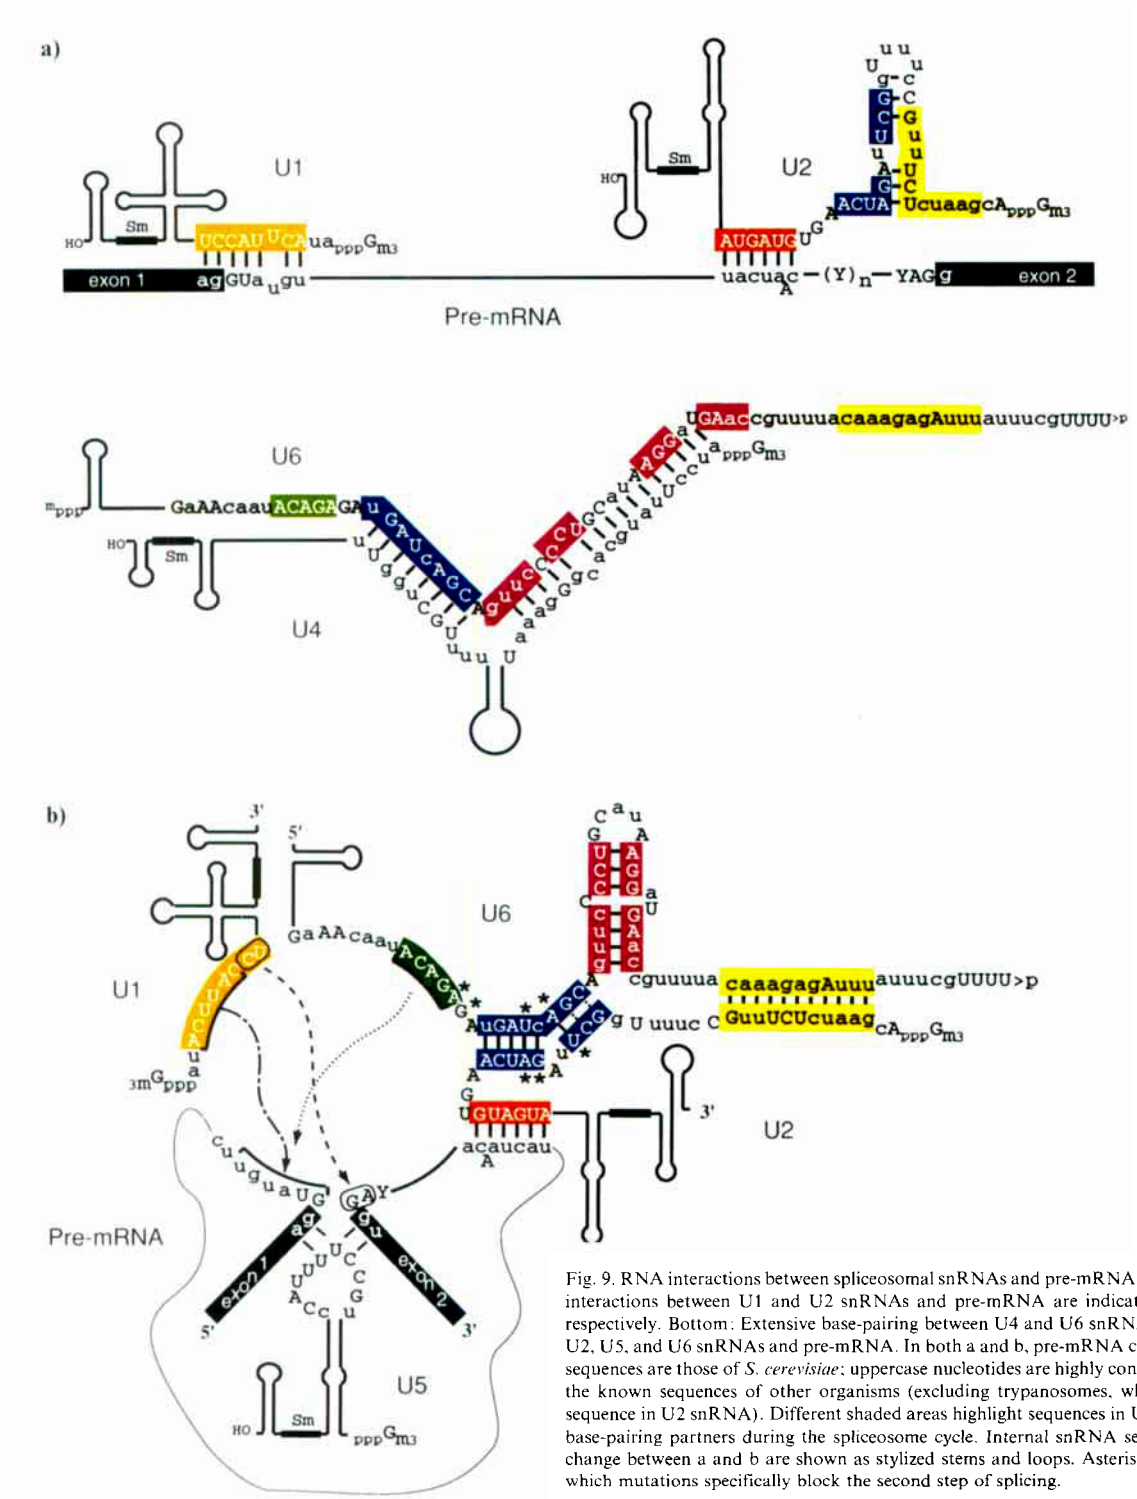

Fig. 9. RNA interactions between spliceosomal snRNAs and pre-mRNA substrates. a) Top: Base-pairing interactions between U1 and U2 snRNAs and pre-mRNA are indicated on left and right of intron, respectively. Bottom: Extensive base-pairing between U4 and U6 snRNAs. b) Interactions between U1, U2, U5, and U6 snRNAs and pre-mRNA. In both a and b, pre-mRNA consensus sequences and snRNA sequences are those of *S. cerevisiae*; uppercase nucleotides are highly conserved between *S. cerevisiae* and the known sequences of other organisms (excluding trypanosomes, which do not have a GUAGUA sequence in U2 snRNA). Different shaded areas highlight sequences in U2 and U6 snRNAs that change base-pairing partners during the spliceosome cycle. Internal snRNA secondary structures that do not change between a and b are shown as stylized stems and loops. Asterisks indicate snRNA positions at which mutations specifically block the second step of splicing.

evolutionarily related. This is particularly the case for the group II and spliceosome reactions. Thus, the snRNAs in the spliceosome might be pictured as a group II intron in pieces, where these RNAs form the catalytic sites for both reactions. The proteins in the spliceosomes could be necessary for recognition of the precursor RNA, arranging the snRNAs in catalytic structures and rearrangement of the components to facilitate completion of the process. Early in evolution all introns might have been self-splicing. Then, during the passage of time, *trans*-acting components may have developed which executed the splicing of introns by recognition of sequences at the splice sites, thus permitting atrophy of the *cis*-sequence within each intron.[63] *Trans*-acting segments of group II introns which complement the splicing of introns with partial catalytic structure have been documented (see ref. [63]).

Years after the discovery of the lariat intermediate in the *cis*-splicing process, studies of the *trans*-splicing reaction revealed a branched intermediate state. Thus, the chemistry of the *trans*-splicing reaction is very similar to that of the *cis*-splicing process.[64] It is therefore highly likely that the *cis*- and *trans*-splicing processes are variations of a single fundamental mechanism. Trypanosome parasites which exclusively synthesize mRNA by *trans*-splicing of a short leader RNA do not apparently express U1 snRNA or U5 snRNA, but do express U2, U4, and U6 snRNAs.[65]

The sequence complementarity between the 5′ end of U1 snRNA and the consensus sequences at the 5′ splice site led to the hypothesis that this interaction was critical for splicing.[66, 67] This hypothesis has been confirmed by a number of studies including the inhibition of splicing in vitro by addition of anti-sera specific for U1 snRNP.[68] After the discovery of lariat RNA, a consensus sequence was recognized in the region flanking the branch site. This consensus sequence is complementary to a conserved internal sequence in U2 snRNA, and mutational analysis has shown that this interaction is also critical in splicing.[69] U1 and U2 snRNAs recognize consensus sequences at the 5′ splice site and branch site as early steps in the splicing reaction (Fig. 9a). At the same stage of splicing U4 and U6 snRNAs are bound to one another through an extended region of complementarity.[70] SnRNA U6 is unique relative to the other snRNAs in that: it is not bound by core peptides recognized by the Sm lupus antisera, it is transcribed by a different polymerase, and it has a different type of modification at its 5′ terminus. U6 snRNA is also the most conserved member of the snRNA family and may have a unique catalytic role. The U4/6 snRNP forms a specific complex with U5 snRNP and this tri-snRNP complex is thought to bind to the other components in formation of the spliceosome.[71]

After formation of the spliceosome, there are major rearrangements of the snRNAs (Fig. 9b). Both genetic and biochemical experiments show that U6 and U2 snRNAs are paired through an extensive tract of complementarity in the spliceosome.[72, 73] Formation of the U2 and U6 structure requires dissociation of U4 snRNA from U6 snRNA. In fact, U4 snRNA can be released from the active spliceosome after this transition. The complementarity between U1 snRNA and the 5′ splice site sequence is probably also dissociated before the first step of splicing. The 5′ splice site almost certainly pairs with another region of U6 snRNA.[74, 75] U5 snRNA is thought to be important in recognition of the exon sequences immediately flanking the splice sites. Mutations in these flanking sequences frequently have significant effects on splicing efficiency and these effects can be reduced by complementary changes in U5 snRNSs.[76] It is possible that there are further rearrangements in the secondary structures formed by the snRNAs between the first and second steps in splicing. There are mutational changes in U2 and U6 (positions denoted by * in Fig. 9) which only inactivate the second step.[72, 73] Inspection of the network of complementarity formed between snRNAs and the pre-mRNA in the spliceosome reveals a concentration of snRNA structure, perhaps tertiary, near the branch site and 5′ splice site sequences. This arrangement of snRNAs might form the catalytic site for the first step. Perhaps further rearrangements would form another catalytic site for the second step.

Formation of the Spliceosome

A number of stable complexes containing snRNAs and pre-mRNA have been partially characterized and placed in a spliceosome cycle (Fig. 10).[77] The commitment complex CC

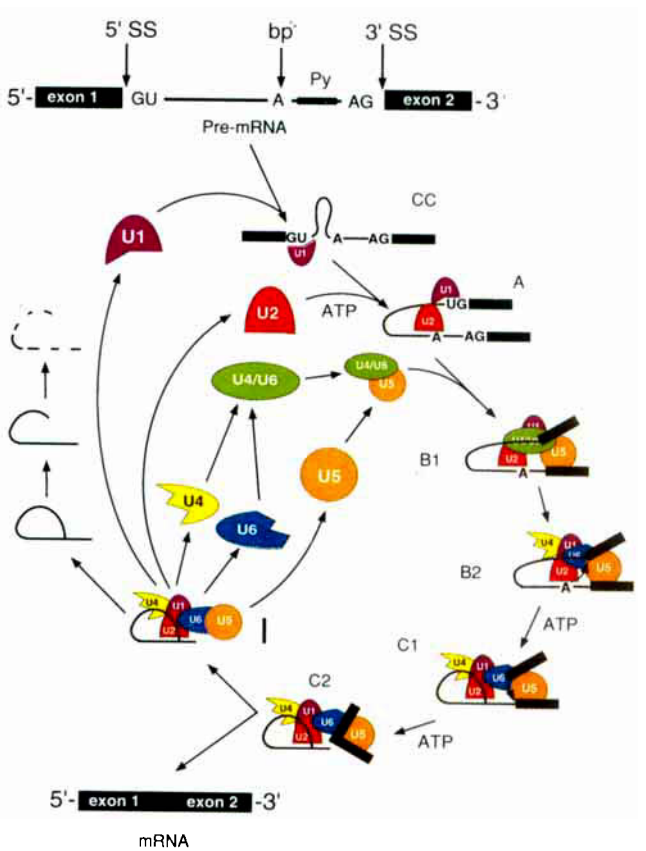

Fig. 10. Schematic representation of the spliceosome cycle in terms of the role of small nuclear ribonucleoprotein (snRNP) particles in pre-mRNA splicing. Pre-mRNA (top), containing two exons separated by an intron, enters splicing complexes with snRNPs and exits as mRNA (bottom) and excised lariat intron (left). Other, non-snRNP factors are required for spliceosome formation, but have been omitted for simplicity. CC, A, B1, B2, C1, C2, and I represent complexes within the splicing pathway that have been distinguished biochemically and/or genetically. 5′ SS, 3′ SS, bs, and Py indicate 5′ and 3′ splice sites, branch site, and polypyrimidine tract, respectively. The individual snRNPs indicated are U1, U2, U4, U5, and U6.

forms on the pre-mRNA by recognition of the 5′ splice site sequence by U1 snRNP and sequences encompassing the branch site and 3′ splice sites.[78–80] For mammalian systems, a pyrimidine tract near the 3′ splice site and branch site is particularly important. The subsequent binding of U2 snRNP to the pre-mRNA results in formation of the very stable A complex. The stable binding of U2 snRNP to the pre-mRNA depends critically on a protein U2AF,[81] which recognizes the polypyrimidine tract through prototypical RNA-binding domains and signals interactions with the other splicing components through a tract of Arg-Ser amino acid repeats. Interestingly, U1 snRNP which is also required for stable U2 snRNP binding, has a bound protein with a tract of Arg-Ser repeats, the U1-70 kd polypeptide. Whether U2AF and U1-70 kd directly communicate across the intron is not clear.

The B1 spliceosome forms when the U4/U6/U5 tri-snRNA complex binds the A complex. It is probably in the B1 complex that U4 snRNA dissociates from U6 snRNA and perhaps U1 snRNA from the 5′ splice site. These events define the B2 complex which is the precursor of the C1 complex. The first step of splicing has occurred in the C1 complex. In generation of the C2 complex, it is likely that there are further rearrangements that are necessary to catalyze the second step in splicing. The C2 complex dissociates and the newly joined exons are released from the snRNP · intron complex I. In the cell, the spliced product migrates to the cytoplasm. The lariat intron is retained with the snRNPs and this complex I turns over. The snRNPs are recycled for further splicing in vivo, while the intron RNA is degraded. Since all snRNAs are very stable, a particular snRNA likely participates in many splicing cycles.

Assembly and rearrangements of complexes as elaborate as those in the spliceosome cycle would be expected to require a number of proteins. Sophisticated genetic analysis has identified a number of yeast gene products that are important for splicing either in vivo or in vitro.[82, 83] Temperature-sensitive mutations in *p*recursor *R*NA *p*rocessing (PRP) genes cause the accumulation of unspliced pre-mRNA in the nucleus and/or generate extracts defective for splicing in vitro (Fig. 11). Surprisingly, it is estimated that at least a hundred different genes encode products important for RNA splicing, about 2% of the total yeast genome. Thus, the splicing apparatus is a significant component of the nucleus. The amino acid sequences predicted for some of the PRP genes suggest that they have functions such as RNA binding, RNA helicase and protein–protein interaction properties. Matching these hypothetical functions to processes in spliceosomes will be challenging.

Reassuringly, the steps in the spliceosome cycle where particular PRP proteins are required (Fig. 11) are consistent with the cycle as defined by kinetic and biochemical methods. Most transitions between specific forms of the spliceosome require one or more specific proteins. Furthermore, a number of PRP mutants are defective in splicing because of their inability to reassemble snRNPs for further splicing. Thus, both genetic and biochemical results prove that the spliceosome cycle is the process responsible for excision of introns from split genes.

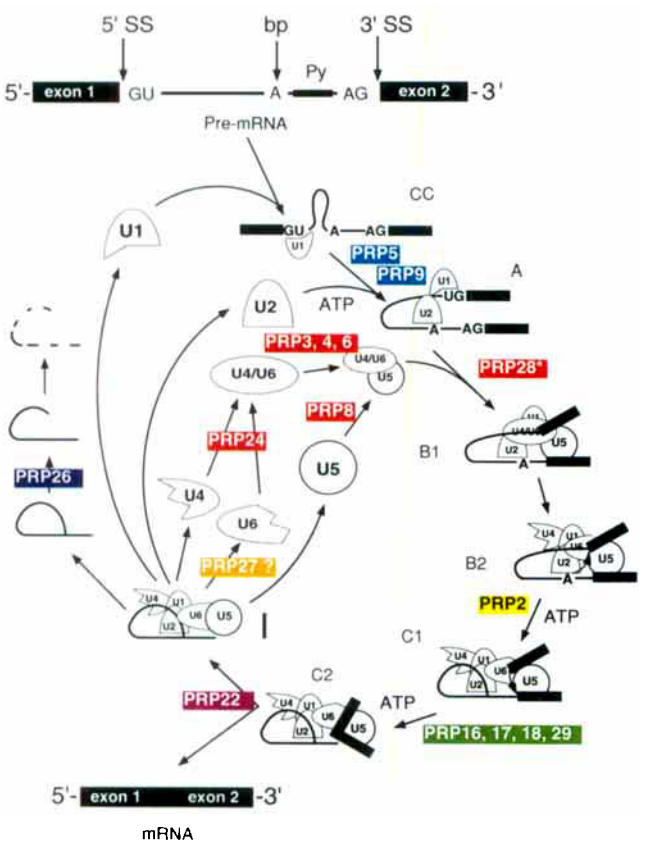

Fig. 11. Transitions in the spliceosome cycle which require a PRP protein. The particular PRP mutant is listed beside the arrow indicating the transition in the cycle in vitro requires the mutant protein.

The Chemistry of the Spliceosome

Both steps in the spliceosome process involve reactions between hydroxyl groups and a phosphodiester bond. The products and substrates in both steps contain the same number of covalent bonds and thus each step could be accomplished with a single transesterification reaction. This has been shown to be the case for group I self-splicing introns by analysis of the stereochemistry of the two reactions (Fig. 12).[84–86] Phosphorothioates in diester bonds of RNA are chiral, having either R_p or S_p stereochemistry depending upon the position of the sulfur

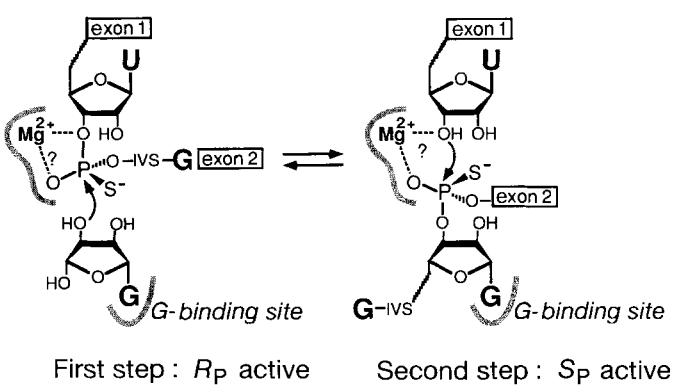

Fig. 12. The stereochemistry of the first and second step reactions of the group I self-splicing site. A sulfur atom is indicated at the positions where it does not inhibit the reactions, R_p and S_p positions for the first and second steps, respectively [84–86]. The interactions between the oxygen group on the phosphate and the Mg^{2+} groups are hypothetical, proposed to explain why a phosphorothioate with the sulfur atom in this position is not reactive.

atom. The specific stereochemistry can be determined by its sensitivity to particular nucleases. If a chiral phosphorothioate group participates in a single transesterification reaction, its stereochemistry is inverted, for example, from R_p to S_p. This fact permits counting of the number of transesterification reactions in a process and, thus, the detection of any potential transient intermediate.

As implied above, R_p and S_p phosphorothioates are not equally active in many catalytic sites. This is commonly interpreted as reflecting the unique role of one of the oxygen groups on the phosphate in interaction with a metal ion, a role which could not be equally well-fulfilled by a sulfur group. These principles of phosphorothioate chemistry have been analyzed for the group I self-splicing intron and now have been studied in the spliceosome.

The two steps of splicing by the group I intron are probably executed as forward and reverse reactions at a single catalytic site (Fig. 12). In the first step, the guanosine cofactor is bound to the G binding site and its 3′ OH group is activated for the transesterification reaction. In this reaction, the R_p configurated phophorothioate is active while the S_p is not. This suggests that the oxygen group in the equivalent S_p position is uniquely recognized in this reaction, perhaps by a metal ion. Consistent with a single transesterification mechanism during the first step, the R_p chiral center is converted to a S_p phosphorothioate product.[84] In the second step, the guanosine group at the 3′ splice site occupies the G binding site and the 3′ OH of the 5′ exon is activated for the transesterification reaction. As would necessarily be the case by the principle of microscopic-reversibility, the S_p configurated phosphorothioate is active in this reaction and the R_p is not.[86] The S_p substrate phosphodiester bond generates a R_p product. Thus, stereochemical analysis of the group I process strongly supports the hypothesis of a single catalytic center for both steps.

The stereochemistry of the two steps in the spliceosome process was investigated by synthesis of substrate RNAs containing either a R_p or S_p phosphorothioate at either the 5′ or 3′ splice site.[87] The particular stereoisomer was incorporated by a combination of chemical synthesis, oligo-primed transcription, and ligation of RNAs by use of a bridging oligodeoxynucleotide and T4 DNA ligase).[88] Splicing of the phosphorothioate-containing RNA substrates was tested in nuclear extracts after different periods of incubation. Analysis of the substrate and product RNAs showed that a) both steps in splicing involve a single transesterification reaction with inversion of the chiral center of the active phosphorothioate, and b) the S_p diastereomer was the active phosphorothioate in both steps, while the R_p diastereomer was not.[87]

A comparison of the stereochemistry and critical components in the two steps in splicing for the group I self-splicing process and the spliceosome process is informative (Fig. 13). As discussed before, the two steps in the group I case are forward and reverse reactions within a single catalytic center. This is almost certainly not the situation for the spliceosome process. In both steps of the latter process, the S_p phosphorothioate was active; thus, the second step is not a reverse of the first step. These results are most consistent with the proposal that the spliceosome generates two different catalytic centers for the two steps. The constituents in these centers may partially overlap but

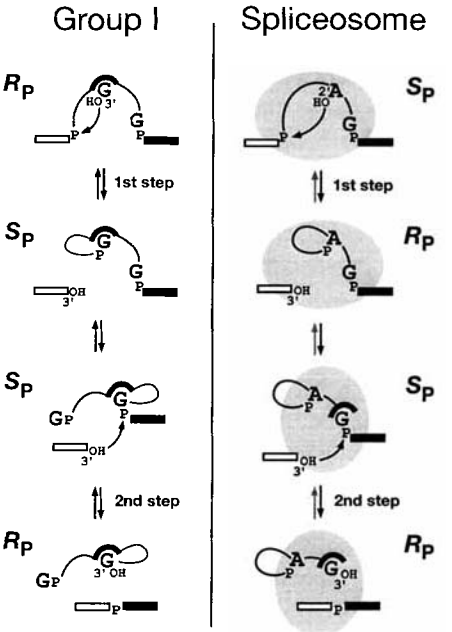

Fig. 13. Chemical mechanisms and stereochemical configurations of the two steps of pre-mRNA splicing (right) and group I intron self-splicing (left). First-step differences between spliceosomal and group I splicing include opposite phosphorothioate diastereomer preferences, different reaction nucleophiles (2′-OH versus 3′-OH), differential placement (5′ versus 3′) of the conserved guanosine (G) with respect to the phosphate at the 5′ splice site. Second-step similarities include preference for the S_p phosphorothioate diastereomer, use of a 3′-OH as the nucleophile and a conserved guanosine (G) attached through a 3′ oxygen to the phosphate at the 3′ splice site. The phosphorothioate diastereomer (R_p or S_p), which is not significantly inhibitory, is indicated for the substrate for each step. The diastereomer that results is indicated for the product of each step. Small dashed arrows indicate the potential (but not yet observed) reversibility of each step of nuclear pre-mRNA splicing. The dark hemicircle, indicated in the spliceosome for the second step, designates a hypothetical site similar to that of group I introns.

the centers must be distinct. This is also consistent with the different chemical nature of reaction components in the two steps. A 2′ hydroxyl group on an adenosine is activated in the first step, while a 3′ hydroxyl group on the 5′ exon is activated during the second step. Furthermore, the conserved guanosine residue is linked to the activated phosphate by a 5′ bond in the first step and a 3′ bond in the second. Thus, the spliceosome process, and probably the group II self-splicing process, must involve two distinct catalytic sites.

The catalytic site in the spliceosome responsible for the second step is probably similar to that of the group I self-splicing introns. These two sites share several common characteristics. Both catalyze the transesterification reaction using a) an S_p, and not R_p, phosphorothioate at the active site, b) the activated phosphate is linked to the 3′ position to a conserved guanosine residue, and c) both activate a 3′ hydroxyl group on the 5′ exon. These similarities are probably determined by some common chemical structure among the two catalytic sites. Perhaps this common microstructure reflects a shared RNA tertiary structure for the catalytic centers and a shared evolutionary origin.

Nuclear Structure and RNA Splicing

The processing of introns occurs from both nascent RNA which is being extended by polymerase and from post-transcrip-

tional precursor RNA.[89] Thus, the splicing apparatus must be located proximal to the gene, as well as in the regions between the gene and the nuclear pores. After completion of splicing, the mRNA is transported to the cytoplasm through one of the approximately 4000 nuclear pores of a typical mammalian cell.[90] The mechanism by which nuclear RNAs are transported from sites of transcription and splicing to pores remains a mystery.

The subnuclear locations of a number of proteins and RNAs important for RNA splicing have been studied by light and electron microscopy. The most striking feature is the concentration of snRNPs, U2, U4/6, and U5 in 20–50 speckled structures and also in 1–5 foci called coiled bodies (Fig. 14).[91, 92] This

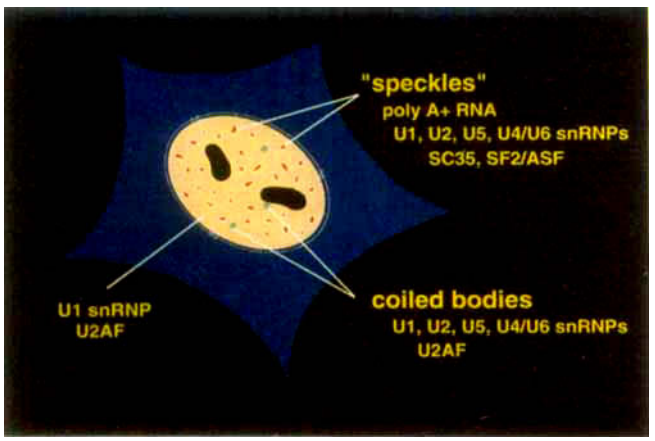

Fig. 14. Subnuclear localization of splicing factors in the nucleus. Specific antisera and in situ hybridization methods have been used to localize components of the spliceosome and splicing factors in the nucleus of mammalian cells. The outline of the cell is shown without structure in the cytoplasm. Three nuclear pores are diagrammed in the nuclear membrane. The large dark structures are nucleoli, site of ribosomal RNA synthesis. Some of the components of the speckles, regions containing pre-mRNA, are listed. The coiled bodies are different and do not appear to contain pre-mRNAs [93]. The general pink shadowing represents the nuclear distribution of U1 snRNP and U2AF.

contrasts with the subnuclear location of U1 snRNP, which, although also concentrated in speckles and foci, is more uniformly dispersed throughout the nucleus. These speckled structures correspond to regions described by electron microscopists as interchromatin granule clusters and the perichromatin fibril network. High-resolution in situ hybridization methods and pulse labeling studies locate newly synthesized RNA in the speckled regions and also in curvilinear tracks which extend from the gene toward the nuclear periphery.[93, 94] The further the nuclear precursor RNA is located along the tracks which lead from its gene of origin, the lower the relative concentration of intron sequences as compared to exon sequences. This suggests that the precursor RNA moves through the speckled structures as it is being processed and transported.[94] Active spliceosomes are probably concentrated in these regions.

Several proteins important for RNA splicing are also concentrated in speckled structures with the snRNPs. These include the Arg/Ser proteins SF2/ASF[95, 96] and SC35.[97] Surprisingly, these proteins, as well as the snRNPs in active spliceosomes, are probably attached to an operationally defined nuclear matrix. This matrix is the structure that remains in the nucleus after almost all of the chromatin proteins and DNA are extracted by sequential treatments with DNase 1 and high salt concentration.[98] The integrity of the fibrillar matrix which remains is sensitive to RNase, suggesting a major role for RNA in its structure. Spliceosomes have been shown to be associated with the nuclear matrix as it has been possible to process pulse-labeled endogenous precursor RNA extracted as part of the matrix.[98]

Active spliceosomes may be associated with the nuclear matrix through interactions with proteins in the Arg/Ser family.[99, 100] A panel of monoclonal antibodies has been generated to components in the nuclear matrix of human cells. Three of these monoclonal antibodies specifically stain the matrix and extensively colocalize with the snRNPs in the speckled structures. Surprisingly, these three antibodies specifically immunoprecipitate spliceosome complexes which contain exon sequences.[101] Thus, the antibodies immunoprecipitate a fraction of the precursor RNA, the lariat intermediate RNA and the associated 5′ exon, and the spliced exon product RNAs. The antibodies do not immunoprecipitate the intron containing spliceosome complex I even though it contains most of the snRNPs and associated protein components. These remarkable results suggest that the matrix components bind to exon RNA sequences that are specifically assembled into splicing complexes.

The proteins recognized by the monoclonal antibodies to the nuclear matrix are most likely members of the Arg/Ser family of proteins or are associated with the Arg/Ser proteins. Precursor RNAs are not immunoprecipitated from reactions containing nuclear extracts depleted of Arg/Ser proteins. Further addition of preparations of purified Arg/Ser proteins will block specific immunofluorescence staining of subnuclear structures. These results are consistent with a model where the Arg/Ser family of proteins are associated with or form the nuclear matrix.[101] Newly synthesized RNA sequences are recognized by the Arg/Ser proteins such as SC35, ASF, the U1 70 kd, and U2AF and become associated with the matrix, perhaps, through interactions of the Arg/Ser tracts. On this structure, complete spliceosomes would form, encompassing the matrix proximal splice sites and execute splicing. The exon product RNAs would remain matrix bound and move by some unknown mechanism to the nuclear pore.

Conclusion

The discovery of split genes and RNA splicing has been critical for studies of the biology of eukaryotic organisms. Gene regulation is central to all biological phenomena and RNA splicing is important in the regulation of genes, particularly when precursor RNAs are pocessed by alternative pathways to generate mRNAs encoding different proteins. The mechanism of splicing by the spliceosome is probably related to the self-splicing process of group I and II introns. The spliceosome process is old in an evolutionary sense, perhaps as old as the ribosomal process responsible for translation. Thus, the eukaryotic cell can be conjectured as consisting of two compartments, the nucleus where the spliceosome processes RNA precursors by RNA catalysis and the cytoplasm where the ribosome translates mRNAs by RNA catalysis. The distinct subnuclear locations of spliceosome-related components suggest a compartmentalized

organization for the nucleus. Further studies of RNA splicing and transport hold promise of revealing the nature of the organizational specificity of the nucleus.

Recombinant Whole Cells as Catalysts for the Enzymatic Synthesis of Oligosaccharides and Glycopeptides**

Guido F. Herrmann, Peng Wang, Gwo-Jenn Shen, and Chi-Huey Wong*

Syntheses of oligosaccharides[1] using isolated glycosidases[2] or glycosyl transferases,[3] or a combination of both,[4] have been studied extensively during the last decade. A general limitation of this methodology is the low availability and the high cost of glycosyl transferases, though some glycosyl transferases can be obtained in sufficient amounts for synthesis by cloning and overexpression.[5] Recently we reported on the expression of a cloned α-1,2-mannosyl transferase (α-1,2-ManT) in *E. coli* XL1-Blue strain at the level of ≈ 1 U L^{-1} for use in the mannosylation of saccharides and glycopeptides.[6] Since isolation of the enzyme and other glycosyl transferases in general is not trivial, we decided to exploit the feasibility of using whole cells of the recombinant *E. coli* as catalysts. Although biotransformations based on whole cells such as bakers' yeast[7] are common, no example has been reported in which recombinant cells are used for glycosyl transfer reactions. To demonstrate the feasibility of the concept, we examined several acceptors for the enzymatic mannosylation reaction with GDP-Man as mannosyl donor (Fig. 1).

1, R = H, 75% (α/β = 7/3)

2, R = Me, 53%

3, R = , 72%

4, R = , 42%

Fig. 1. Enzymatic synthesis of disaccharides **1** and **2**, and glycopeptides **3** and **4** by using recombinant *E. coli* whole cells. Man = mannose, GDP = guanosine diphosphate. Cbz = benzyloxycarbonyl, Boc = *tert*-butoxycarbonyl.

The disaccharides Manα1,2Man **1** and Manα1,2ManOMe **2**, and the dimannosylated glycopeptides Cbz-α[Manα1,2Man]Thr-OMe **3** and Boc-Tyr-α(Man(α1,2Man]-Thr-Val-OMe **4** were obtained in moderate to good yields. As inhibition of the reaction by the released guanosine diphosphate (GDP) was not observed, addition of alkaline phosphatase to decompose GDP was omitted. While it is not clear how mannosylation takes place, the cell walls of *E. coli* XL1-Blue strain used in this study might be leaking, which would allow the transport of products and substrates. Leakage of α-1,2-ManT from the periplasmic space of *E. coli* into the medium was dismissed, as no mannosylation activity was detected in the fermentation broth after isolation of cells.

In summary, this report illustrates the convenient use of recombinant glycosyl transferase in oligosaccharide and glycopeptide synthesis without the tedious procedure of enzyme purification. Immobilization (e.g. by gel entrapment)[8] of the recombinant cells may permit a feasible reactor design for large-scale synthesis. Additionally, the use of two or more recombinant *E. coli* strains expressing different glycosyl transferases may allow the one-pot synthesis of oligosaccharides.

Experimental Procedure

Cultivation of recombinant E. coli [ATTC #77379]

The *E. coli* strain containing the plasmid pManflag20 was grown in shaking flasks as described elsewhere in detail [6]. Usually 2 - 4 g of wet cells can be obtained per liter of fermentation broth. The cells were isolated by centrifugation. The resulting pellet was washed once with 10 mM HEPES buffer (pH 7). Subsequently the cells were stored in a 50% (w/w) suspension in 10 mM HEPES (pH 7) at −20 °C. Storage of the cells at −20 °C did not affect the activity of α-1,2-ManT over a period of several months.

Enzyme Assay

α-1,2-ManT activity was determined using the following assay conditions: A solution containing 1 mM GDP-Man [9], 15.6 nCi GDP-[^{14}C]-Man (Amersham, UK), 100 mM ManOMe, 50 mM HEPES (pH 7.2), 0.1% Triton X, 10 mM $MnCl_2$, phosphatase inhibitors [10] (5 mM ATP, 3 mM Theophylline, 3 mM Cimetidine) and 10 μL ca. 50% (w/w) intact recombinant *E. coli* cells in a total volume of 40 μL was incubated for 15–60 min at 37 °C. The reaction was stopped by adding 400 μL of ice-cold QAE Sephadex A-25 in H_2O (50% (v/v)). The mixture was centrifuged for 10 min at 10000 g, and a 200-μL aliquot of the supernatant was used to determine the radioactivity in 10 mL Scinti Verse SX 1-4 (Fisher, USA).

1 [11]: To 1.5 mL of the buffer described above was added GDP-Man (24.2 mg, 20 mM), Man (72 mg, 200 mM), and recombinant *E. coli* cells (0.5 mL, 50% (w/w)). The mixture was stirred for 23 h at room temperature, and the reaction was followed by TLC (system I: $CHCl_3$/MeOH/H_2O = 6/2.5/0.25 (v/v/v): R_f(Man) = 0.18, R_f(**1**) = 0.08; system II: *i*PrOH/H_2O/NH_3 = 7/2/1 (v/v/v): R_f(Man) = 0.36, R_f(**1**) = 0.26, R_f(GDP-Man) = 0.16). Subsequently the *E. coli* cells were removed by centrifugation at 10000 g for 15 min. The pellet was washed twice with 3 mL H_2O, and the combined supernatants were combined with 40 mL MeOH and stirred for 15 min. The precipitated proteins were centrifuged at 10000 g for 20 min, and the supernatant was lyophilized and applied to a Biogel P4 column (120 × 4 cm) with water as the eluent. The desired fractions were lyophilized to yield product **1** as a 71/29 mixture of the α and β anomers (10.3 mg, 75% yield). The ^{1}H NMR (500 MHz, D_2O) data were consistent with those reported [12]. The ^{1}H NMR spectrum of **1** indicates the α-selectivity of α-1,2-ManT, as signals corresponding to a α-mannosidic linkage were not detected. This finding confirms our previous results with purified α-1,2-ManT [6].

2: The reaction was carried out in analogy to that giving **1** except that ManOMe (38.8 mg, 100 mM) was used as acceptor. The mixture was stirred for 20 h at room temperature and the reaction followed by TLC (system I: R_f(ManOMe) = 0.39, R_f(**2**) = 0.12; system II: R_f(ManOMe) = 0.48, R_f(**2**) = 0.32). Following the same workup procedure as for **1**, the supernatant obtained was lyophilized and the product purified by silica gel column chromatography (system I) to yield **2** (7.6 mg, 53% yield). ^{1}H NMR (500 MHz, D_2O) and ^{13}C{^{1}H} NMR (D_2O) spectra were identical with those reported previously [6]. HRMS for $C_{13}H_{24}O_{11}Cs^+$ [$M + Cs^+$]: calcd. 489.0373; found 489.0370.

3a: To a solution of 2,3,4,6-tetra-*O*-acetyl-D-mannopyranosyl bromide (2.0 g, 4.86 mmol) in dry dichloromethane (30 mL) was added at −20 °C Cbz-Thr-OMe

(1.3 g, 4.86 mmol), silver triflate (1.5 g, 1.2 equiv, 5.84 mmol), and triethylamine (0.59 g, 1.2 equiv, 5.84 mmol). The suspension was stirred at −20 °C for 4 h and then filtered through a bed of Celite. The filtrate was washed twice with water and twice with saturated sodium bicarbonate. The organic layer was dried over anhydrous $MgSO_4$ and concentrated in vacuo, and the residue was chromatographed with silica gel (eluted with EtOAc/hexane = 6/1 (v/v)) to give the desired product **3a** as a white solid (1.9 g, 68% yield). ^{1}H NMR (500 Hz, $CDCl_3$) δ = 1.30 (d, J = 6.5 Hz, 3H), 1.91 (s, 3H), 1.98 (s, 3H), 2.01 (s, 3H), 2.02 (s, 3H), 3.77 (s, 3H), 4.00 (m, 1H), 4.06 (dd, J = 2.5, 12.5 Hz, 1H), 4.21 (dd, J = 6.0, 12.5 Hz, 1H), 4.35 (dd, J = 2.5, 6.5 Hz, 1H), 4.43 (dd, J = 2.5, 9.5 Hz, 1H), 4.82 (d, J = 1.5 Hz, 1H), 4.96 (s, 1H), 5.12 (s, 2H), 5.21 (dd, J = 1.5, 4.5 Hz, 2H), 5.46 (d, J = 9.5 Hz, 1H), 7.25–7.32 (m, 5H); ^{13}C{^{1}H} NMR ($CDCl_3$) δ = 17.6, 20.4, 20.6, 52.6, 58.3, 62.1, 62.2, 65.9, 67.0, 68.2, 68.3, 69.3, 98.5, 127.7, 127.9, 128.0, 128.3, 135.7, 156.3, 169.4, 169.6, 170.3; HRMS for $C_{27}H_{35}N_1O_{14}Cs^+$ [M + Cs^+]: calcd. 829.1796; found 829.1796.

3b: To a solution of **3a** (300 mg, 0.28 mmol) in 20 mL of anhydrous methanol at 0 °C was added 1% MeONa in anhydrous methanol (about 500 μL). The solution was stirred at 0 °C for 1.5 h, and then Dowex H^+ was added until the mixture reached pH 4.0. After filtration the solvent was removed in vacuo to give the desired product **3b** as a colorless liquid (152 mg, 82% yield). $[\alpha]_D^{20}$ = + 44.11 (c = 0.045 in MeOH); ^{1}H NMR (500 MHz, CD_3OD) δ = 1.12 (d, J = 6.0 Hz, 3H), 3.19 (m, 1H), 3.43–3.48 (m, 2H), 3.52–3.58 (m, 3H), 3.63 (s, 3H), 3.68 (dd, J = 1.5, 11.5 Hz, 1H), 4.22 (m, 2H), 4.65 (s, 1H), 5.00 (s, 2H), 7.20–7.28 (m, 5H); ^{13}C{^{1}H} NMR (CD_3OD) δ = 18.9, 52.8, 60.3, 62.9, 67.9, 68.5, 72.1, 72.2, 75.1, 77.0, 103.1, 128.9, 129.0, 129.5, 138.1, 159.1, 172.6; HRMS for $C_{19}H_{27}N_1O_{10}Cs^+$ [M + Cs^+]: calcd. 562.0073; found 562.0098.

3: To 0.375 mL of buffer [10] containing GDP-Man (6.15 mg, 20 mM) and **3b** (4.29 mg, 20 mM) was added 25 μL of acetone and 10 μL of 50 mM phenylmethylsulfonyl fluoride (PMSF) dissolved in DMF. Recombinant *E. coli* cells (0.125 mL, 50% (w/w)) were added, and the mixture was stirred for 20 h at room temperature. The reaction was followed by TLC (system I: R_f(**3b**) = 0.68, R_f(**3**) = 0.36; system II: R_f(**3b**) = 0.8, R_f(**3**) = 0.65). The product obtained from the supernatant was purified by silica gel column chromatography (system I) to yield **3** (4.29 mg, 72% yield). ^{13}C{^{1}H}NMR (CD_3OD) δ = 18.7, 30.2, 30.8, 53.1, 60.4, 62.9, 63.0, 67.9, 68.5, 68.9, 71.7, 71.8, 72.4, 74.9, 75.1, 77.0, 77.3, 80.9, 101.4, 104.3, 128.9, 129.1, 129.5; HRMS for $C_{25}H_{37}NO_{15}Na^+$ [M + Na^+]): calcd. 614.2061; found 614.2078.

4: To 0.375 mL buffer [10] containing GDP-Man (6.15 mg, 20 mM) and **4a** (6.57 mg, 20 mM) [6] was added 10 μL of the PMSF solution and 25 μL of acetone. Recombinant *E. coli* cells (0.125 mL, 50% (w/w)) were added, and the mixture was stirred for 17.5 h at room temperature. The reaction was monitored by TLC (system I: R_f(**4a**) = 0.81, R_f(**4**) = 0.5). The solid product obtained from the supernatant was purified by silica gel column chromatography (system I) to yield **4** (3.4 mg, 42% yield). ^{13}C{^{1}H}NMR (CD_3OD) δ = 18.6, 19.5, 28.7, 31.8, 38.3, 42.1, 52.7, 57.5, 58.4, 59.3, 63.0, 63.4, 68.9, 69.1, 71.8, 72.4, 75.1, 76.6, 80.5, 101.3, 101.7, 104.1, 116.2, 129.2, 131.4, 143.5, 157.2, 171.1, 173.52; HRMS for $C_{36}H_{57}N_3O_{18}H^+$ [M + H^+]: calcd. 820.3715; found 820.3710.

Remarkable Stereoselectivity in the Inhibition of α-Galactosidase from Coffee Bean by a New Polyhydroxypyrrolidine Inhibitor**

Yi-Fong Wang, Yoshikazu Takaoka, and Chi-Huey Wong*

Many naturally occurring and synthetic polyhydroxypyrrolidines and piperidines (referred to hereafter as azasugars) have been developed as inhibitors of glycosidases and glycosyl transferases.[1] Of these azasugars, six-membered derivatives in both chair and flattened-chair conformations,[2, 3] and five-membered derivatives have been commonly used.[1, 3] These inhibitors are considered to mimic the high-energy intermediate in the cleavage of a glycosidic bond that presumably proceeds through a transition state with substantial sp^2 character and positive charge at the anomeric center.[1]

In general, the six-membered azasugars with a chair conformation specifically inhibit the enzymes that catalyze hydrolysis of the corresponding structurally related glycosides[1] (e.g. 1-deoxynojirimycin inhibits α-glucosidase with K_i = 8.7 μM but not α-galactosidase).[4] The flattened-chair six-membered[2] and five-membered[1, 5] azasugars are, however, more flexible: different stereoisomers may exhibit the same degree of inhibition toward one enzyme, and one stereoisomer may inhibit several glycosidases equally well. It was postulated that the shape recognition and electrostatic interaction between the enzyme and inhibitor play more important roles than the stereochemical differentiation in the stabilization of the transition state.[2, 4] Contrary to this hypothesis, we report here that α-galactosidase is inhibited by a new five-membered azasugar (K_i = 5 × 10^{-8} M) at least 1000-fold more effectively than by diastereomers **2** and **3** (Fig. 1).

We describe two routes for the synthesis of **1** (Schemes 1 and 2). Compound **6** prepared from 5-keto-D-fructose[6] or **2**[5a] was treated with 1.25 equivalents of 2-methoxypropene in the presence of *p*-toluenesulfonic acid to give the *cis*-monoacetonide **7** as the only product. Protection of the primary hydroxyl function as a *tert*-butyldiphenylsilyl ether, oxidation of the secondary hydroxyl group with periodinane,[7] and stereospecific reduction with diisobutylaluminum hydride gave the inverted isomer **10**. After treatment with tetrabutylammonium fluoride and *p*-

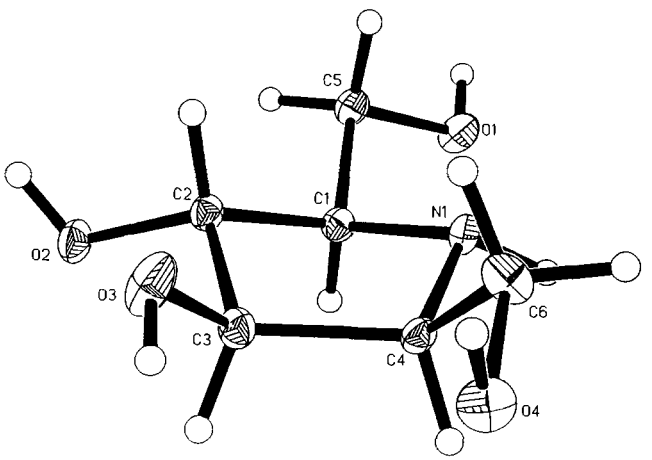

Fig. 2. Crystal structure of **2** (ORTEP representation). See also ref. [11].

toluenesulfonic acid, and hydrogenation on $Pd(OH)_2$, **1** was obtained in 38% yield from **6**.

A much shorter synthesis of **1** is illustrated in Scheme 2. Fuculose-1-phosphate aldolase[8] was used to catalyze the aldol reaction of dihydroxyacetone phosphate (DHAP)[9] and aldehyde **12**. After dephosphorylation the aldol product was converted into **1** by reductive amination. Inhibition analysis[4] of **1** against α-galactosidase from coffee bean at pH 5.5 indicated a competitive type of inhibition with $K_i = 5 \times 10^{-8}$ M. To our knowledge, this is the best pyrrolidine inhibitor of α-galactosidase known to date. It appears that the stereocenters at the 2- and 4-positions are very critical. A marked decrease of inhibition activity was observed when either one of these two centers was inverted. Since pyrrolidines exist in an envelope conformation, as shown by the X-ray structure of **2** (an inhibitor of α-glucosidase, $K_i = 2.8\,\mu$M;[5a] Fig. 2), compound **1** may mimic the conformation and charge distribution of the transition state structure for the cleavage of the glycosidic bond (Fig. 3). It is noted, however, that **1** binds the enzyme less

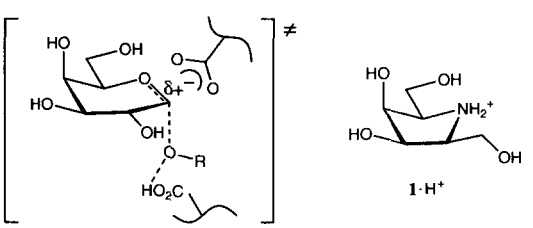

Fig. 3. Proposed transition state structure for the α-galactosidase reaction. Compound **1** is a mimic of the galactosyl cation.

tightly than does 1-deoxy-D-galactonojirimycin, which has a chair conformation ($K_i = 1.6 \times 10^{-9}$ M).[4b]

In summary, we have shown that five-membered azasugars can act as potent glycosidase inhibitors and that the inhibition rently using chemoenzymatic methods to prepare other pyrrolidines for evaluation of their inhibition.

Experimental Section

7: To a solution of **6** (9.9 g, 30 mmol) in 180 mL anhydrous dichloromethane/tetrahydrofuran (1:1) was added 2-methoxypropene (2.4 mL, 25 mmol) and *p*-toluenesulfonic acid (3 g) under N_2. The solution was stirred at room temperature. After 20 h, another 1.2 mL of 2-methoxypropene was added, and the solution was allowed to stir for an additional 26 h. Saturated $NaHCO_3$ solution (10 mL) was added to terminate the reaction. The organic solvent was removed under reduced pressure. Water (50 mL) was then added, and the mixture was extracted with ethyl acetate (3 × 50 mL). The organic layer was dried over Na_2SO_4 and then concentrated to give a residue which was purified by silica gel column chromatography (ethyl acetate/hexane = 1/1 to 1/0) to yield 4.8 g of **7** and 3.2 g of recovered substrate. **7**: $[\alpha]_D^{23} = -63$ ($c = 1.1$, MeOH); $R_f = 0.18$ (ethyl acetate/hexane = 1/1); ^{1}H NMR (500 MHz, $CDCl_3$/TMS): $\delta = 1.29$ (3H, s), 1.30 (3H, s), 3.08 (1H, dd, $J = 5.0$, 10.3 Hz), 3.25 (1H, ddd, $J = 5.2$, 5.9, 6.4 Hz), 3.32 (1H, dd, $J = 5.9$, 11.7 Hz), 3.37 (1H, dd, $J = 6.4$, 11.7 Hz), 3.51 (1H, dd, $J = 5.0$, 10.5 Hz), 3.66 (1H, t, $J = 10.5$ Hz), 4.18 (1H, s), 4.20 (1H, d, $J = 5.2$ Hz), 5.11 (1H, s), 7.17–7.53 (10H, m); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 21.9$, 26.5, 63.0, 64.0, 64.3, 72.3, 74.0, 78.4, 79.4, 99.8, 128.1, 128.3, 129.3, 129.5, 129.9, 144.8, 145.3.

8: To 450 mg (1.22 mmol) of compound **7** was added 2 mL pyridine. The mixture was stirred at room temperature and then 549 mg (2 mmol) of *tert*-butyldiphenylsilyl chloride was added by syringe. The mixture was stirred at room temperature for 1 h. After addition of ethyl acetate (15 mL) the mixture was washed with H_2O, 1 N HCl, and saturated aqueous $NaHCO_3$, and then dried over Na_2SO_4. The organic solvent was removed under vacuum. The residue was purified by silica gel column chromatography (ethyl acetate/hexane = 1/10 to 1/5) to furnish 683 mg of **8** in 92% yield; $[\alpha]_D^{23} = -54.8$ ($c = 0.61$, MeOH); $R_f = 0.63$ (ethyl acetate/hexane = 1/2); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 0.96$ (2, 9H), 1.25 (s, 3H), 1.29 (s, 3H), 3.09 (ddd, 1H, $J = 10$, 10, 10 Hz), 3.29 (m, 3H), 3.59 (m, 1H), 3.80 (dd, 1H, $J = 10$, 10 Hz), 4.19 (dd, 1H, $J = 2.0$, 4.5 Hz), 4.48 (dd, 1H, $J = 2.0$, 2.0 Hz), 4.95 (s, 1H), 7.38 (m, 20H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 22.3$, 25.7, 26.0, 26.8, 61.7, 62.9, 65.6, 71.4, 74.0, 77.5, 79.0, 98.8, 127.1, 127.3, 127.6, 128.1, 128.2, 128.3, 128.6, 129.5, 129.6, 135.3, 135.5, 143.3, 143.4; HRMS for $C_{38}H_{45}O_4NSiCs$ [$M + Cs^+$]: calcd 740.2172, found 740.2168.

9: To a solution of periodinane [7] (548 mg, 0.9 mmol) in 10 mL CH_2Cl_2 was added 548 mg of **8** in 2 mL CH_2Cl_2. The mixture was stirred at room temperature for 3.5 h, 2 mL of 1 N NaOH was added, and the mixture was stirred for additional 10 min. The organic layer was then washed with 1 N NaOH and dried over $MgSO_4$, and the solvent was removed under vacuum to give 438 mg of **9** in 80% yield; $[\alpha]_D^{23} = -19.0$ ($c = 1.05$, MeOH); $R_f = 0.41$ (ethyl acetate/hexane = 1/4). ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 1.06$ (s, 9H), 1.33 (s, 6H), 3.39–3.46 (m, 1H), 3.48 (dd, 1H, $J = 6.0$, 11 Hz), 3.50 (dd, 1H, $J = 3.0$, 10.5 Hz), 3.53 (ddd, 1H, $J = 8.5$, 6, 8.5 Hz), 3.81 (dd, 1H, $J = 11$, 8.5 Hz), 3.87 (dd, 1H, $J = 10.5$, 3.5 Hz), 4.31 (dd, 1H, $J = 8.5$, 1 Hz), 4.74 (s, 1H), 7.07–7.74 (m, 20H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 25.3$, 25.5, 26.8, 54.1, 62.0, 64.0, 67.3, 71.7, 71.8, 127.5, 127.6, 127.7, 128.3, 128.3, 128.7, 129.7, 129.7, 135.8.

10: To a solution of **9** (400 mg, 0.66 mmol) in 5 mL toluene at −78 °C was added diisobutylaluminum hydride (0.5 mL, 1.0 M in hexane) dropwise by syringe. After the addition was complete, the mixture was stirred at −78 °C for 0.5 h. The reaction was then quenched with 400 μL methanol followed by addition of 4 mL of 10% aqueous solution of Rochelle's salt (potassium sodium tartrate) and 16 mL ether. The mixture was stirred at room temperature for 1 h, and the organic layer was washed with 1 N HCl and saturated aqueous $NaHCO_3$, and dried over $MgSO_4$. The solvent was removed under vacuum and the residue purified by silica gel column chromatography (ethyl acetate/hexane = 1/10 to 1/3) to give 366 mg of **10** in 91% yield; $[\alpha]_D^{23} = -7.2$ ($c = 1.15$, MeOH); $R_f = 0.59$ (ethyl acetate/hexane = 1/2); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 0.96$ (s, 9H), 1.33 (s, 3H), 1.40 (s, 3H), 3.05–3.08 (m, 1H), 3.30–3.41 (m, 3H), 3.74 (dd, 1H, $J = 10$, 5.5 Hz), 4.27 (t, 1H, $J = 5.5$ Hz), 4.37–4.45 (m, 2H), 4.79 (s, 1H), 7.47 (m, 20H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 21.8$, 26.5, 26.7, 59.8, 62.5, 63.3, 66.9, 71.4, 73.8, 73.9, 127.2, 127.3, 127.8, 128.3, 128.4, 128.5, 129.6, 129.7, 135.3, 135.4; HRMS for $C_{38}H_{45}O_2NSiCs$ [$M + Cs^+$]: calcd 740.2172, found 740.2170.

1: To a solution of **10** (296 mg, 0.49 mmol) in 8 mL THF was added 1 mL of 1.0 M tetrabutylammonium fluoride in THF. The mixture was stirred at room temperature for 30 min. The solvent was then removed under reduced pressure, and the residue was dissolved in 15 mL methanol treated with 200 mg of *p*-TsOH·H_2O. The mixture was stirred at room temperature overnight. After 2 mL of saturated aqueous $NaHCO_3$ was added, the resulting mixture was stirred for another 10 min. The methanol was removed under vacuum and the residue extracted with ethyl acetate and purified by silica gel column chromatography (ethyl acetate) to give 121 mg of **10a** in 75% yield. $[\alpha]_D^{25} \pm 0$ ($c = 1.0$, CH_3OH); $R_f = 0.18$ (ethyl acetate); ^{1}H NMR (500 MHz, CD_3OD): $\delta = 3.1–3.2$ (m, 2H), 3.40 (dd, 2H, $J = 3.0$, 11.0 Hz), 3.45 (dd, 2H, $J = 6.0$, 11.0 Hz), 4.05–4.15 (m, 2H), 5.11 (s, 1H), 7.1–7.5 (m, 10H); ^{13}C NMR (125 MHz, CD_3OD): $\delta = 61.5$, 65.8, 72.8, 73.1, 128.3, 129.2, 130.2, 143.4; HRMS for $C_{19}H_{23}NO_4$ [$M + H^+$]: calcd 330.1713, found 330.1711.

1: A solution of **10a** (90 mg, 0.27 mmol) in 10 mL methanol was hydrogenated with 30 mg of $Pd(OH)_2$ under hydrogen atmosphere at room temperature. After 6 h the catalyst was filtered off and washed with methanol. The combined methanol solutions were concentrated and the oily residue purified by silica gel column chromatography ($CHCl_3/CH_3OH/H_2O/NH_4OH$ = 5/4/1/0.08) to give **1**: ^{1}H NMR (500 MHz, CD_3OD): $\delta = 3.55–3.65$ (m, 2H), 3.88 (dd, 2H, $J = 8.0$, 12.0 Hz), 3.92 (dd, 2H, $J = 5.0$, 12.0 Hz), 4.3–4.4 (m, 2H); ^{13}C NMR (125 MHz, CD_3OD): $\delta = 59.45$, 63.08, 71.69; HRMS for $C_6H_{13}NO_4$ [$M + H^+$]: calcd. 164.0923, found 164.0911; correct C,H,N analysis.

Chemoenzymatic synthesis of **1**: Ozone was bubbled through a solution of **11** [10] (302 mg, 1.6 mmol) in methanol (10 mL) at −78 °C until the reaction solution became pale blue. After nitrogen was passed through the solution to remove excess ozone, the ozonide was treated with dimethylsulfide (1 mL) and water (1 mL) for 12 h at room temperature. Methanol was removed under vaccuum, and the residue was then purified by chromatography on Amberlite XAD-II (3.0 × 10 cm, H_2O) to yield **12**, which was added to an aqueous solution of dihydroxyacetone phosphate (DHAP, 11 mL, 0.3 mmol). The pH of the solution was adjusted to 7.5 with 0.5 N NaOH. Fuculose-1-phosphate aldolase (2.0 mL, 70 U) was added to this solution and the mixture stirred slowly for 1 d at room temperature. After an enzymatic assay indicated that DHAP was completely consumed, the mixture was adjusted to pH 4.7 with 1 N HCl, acid phosphatase (from sweet potato, type XA, 0.8 mL, 200 U) was added, and the mixture was then stirred slowly at room temperature for 1 d. The mixture was adjusted to pH 7.0 with 0.5 N NaOH, and water was removed under reduced pressure. The residue was treated with methanol, and the soluble portion was collected and purified by silica gel chromatography ($CHCl_3/MeOH/H_2O$ = 8/2/0.1) to yield compound **13** (50.4 mg, 82%). $[\alpha]_D^{23} = -13.5$ ($c = 0.60$, MeOH); ^{1}H NMR (400 MHz, D_2O): $\delta = 3.50$ (1H, d of AB type, $J = 11.8$ Hz), 3.60 (1H, t, $J = 10.8$ Hz), 3.71 (1H, d of AB type, $J = 11.80$ Hz), 3.75 (1H, ddd, $J = 10.80$, 9.92, 5.60 Hz), 3.84 (1H, dd, $J = 10.80$, 5.60 Hz), 3.88 (1H, d, $J = 3.24$ Hz), 3.92 (1H, dd, $J = 9.92$, 3.24 Hz); ^{13}C NMR (100 MHz, D_2O): $\delta = 58.70$, 60.85, 64.25, 69.68, 70.37, 98.65; HRMS for $C_6H_{11}N_3O_5Na$ [$M^+ + Na$]: calcd 228.0596, found 228.0590.

A solution of **13** (28.4 mg, 0.14 mmol) in ethanol (10 mL) was hydrogenated with 10% Pd-C (10 mg) under 50 psi of hydrogen for 12 h. The catalyst was removed by filtration, and the solvent was evaporated under vacuum. The residue was purified by silica gel chromatography ($CHCl_3/MeOH/H_2O/NH_4OH$ = 6/4/1/0.1) to yield compound **1** (14 mg, 61%). The NMR data (^{1}H and ^{13}C) are the same as those for **1** prepared chemically.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Mes = mesityl.

hydroxide oxide was not observed. The commercially used, partially hydrolyzed alkylaluminum compounds[2] and the corresponding gallium compounds[3] are important cocatalysts for metallocenes of group 4 of the periodic table. In considering polymerization reactions with metallocenes containing fluorine and methylaluminoxane as cocatalyst[4] we were chiefly interested in the function and structure of the cocatalyst systems.

$$\underset{\mathbf{1}}{Mes_2GaCl} + KOH \xrightarrow[-KCl]{} Mes_2GaOH \qquad (a)$$

$$6\,Mes_2GaOH + 2\,H_2O \xrightarrow[-6\,MesH]{} \underset{\mathbf{3}}{Mes_6Ga_6O_4(OH)_4} \qquad (b)$$

$$6\,\underset{\mathbf{2}}{Mes_3Ga} + 6\,H_2O \xrightarrow[-6\,MesH]{\text{toluene}} 6\,Mes_2GaOH \xrightarrow[-6\,MesH]{+H_2O} \mathbf{3} \qquad (c)$$

In order to obtain crystalline products, we carried out hydrolysis with Mes_2GaCl (**1**) and Mes_3Ga (**2**) (Mes = mesityl). Compound **1** reacts with hydrated KOH in THF leading to the formation of KCl and probably Mes_2GaOH [Eq. (a)], which condenses to give $Mes_6Ga_6O_4(OH)_4$ (**3**) [Eq. (b)]. The resulting KCl could be separated by filtration and MesH could be detected by ^{1}H NMR spectroscopy. In order to confirm this reaction pathway, we treated **2** with water in toluene [Eq. (c)], since the hydrolysis of organogallium compounds affords the corresponding gallium hydroxides.[5] The reaction led to the formation of **3** and MesH. The condensation of the homologous aluminum compounds[6] has so far not been explained unambiguously.

The IR spectrum of $[\mathbf{3}(thf)_4]$ shows the characteristic OH vibrations: a sharp band at 3671 for free and a broad band at 3521 cm^{-1} for bridging OH groups, which can be explained by partial release of the coordinating THF molecules. The EI mass spectrum shows the peak for the molecular ion at $m/z = 1264$ and that of the hydroxide-free hexameric galloxane at $m/z = 1228$ (100% rel. intensity, $M^+ - 2H_2O$). In the ^{1}H NMR spectrum, two signals each are observed for the ring protons ($\delta = 6.73-6.71$) as well as for the *ortho* ($\delta = 2.57-2.53$) and the *para* ($\delta = 2.18$) methyl protons of the mesityl group. Thus, the mesityl groups are arranged differently. This is confirmed by the distorted octahedral structure in the solid state. The OH protons occur at $\delta = 6.37$.

Single crystals suitable for X-ray structure analysis[7] were obtained from THF. In addition to the four THF molecules coordinated to **3**, six uncoordinated THF molecules are present per formula unit. As a result of the latter the crystals disintegrate very rapidly as soon as the mother liquor is removed. The selection of the crystal and subsequent application was therefore carried out at $-50\,^\circ$C.[8] The hexanuclear mesitylgalloxane hydroxide **3** crystallizes in the space group *R*3*c*. The oxygen atoms O4 and O3 lie on the threefold axis (Fig. 1). To a first approximation the structure can be described as a distorted octahedron of six gallium atoms. Each face of this octahedron per hemisphere is capped alternately by an μ_3-oxygen atom and a μ_3-hydroxide group. All gallium atoms are formally in the oxidation state + III and are five-coordinate. This degree of coordination is not unusual for gallium compounds (e.g. in $Me_2GaO_2C_7H_5$; $O_2C_7H_5$ = α-tropolyl).[12] The hydroxidic oxygen atoms form significantly longer Ga–O distances than the oxidic oxygen atoms (221 and 245 pm for O1 and O3, respectively, in contrast to 187 and 189 pm for O2 and O4, respectively). Furthermore, the environment of the hydroxidic oxygen atoms is more pyramidalized than that of the oxidic oxygen atoms (Ga-O-Ga for O1 and O3 88.1 and 78.6°, respectively; in contrast for O2 and O4 110.7 and 108.9°, respectively). This observation is consistent with the one made for $Mes_6Ga_6F_4O_4$,[13] namely that the oxidic oxygen atoms form a comparable mean angle of 111.6° (105.9–117.7°) with the two bound gallium atoms. The average Ga–C distance of 196 pm is in the range typical for arylgallium compounds.[14] THF molecules in the spaces left by the six mesityl ligands coordinate by hydrogen bonds to the four OH functions of the $Ga_6O_4(OH)_4$ framework (O1···O5 273 and O3···O6 252 pm). Coordination of this sort has already been described for $[(tBu_2AlOH)_3 \cdot 2thf]$.[11]

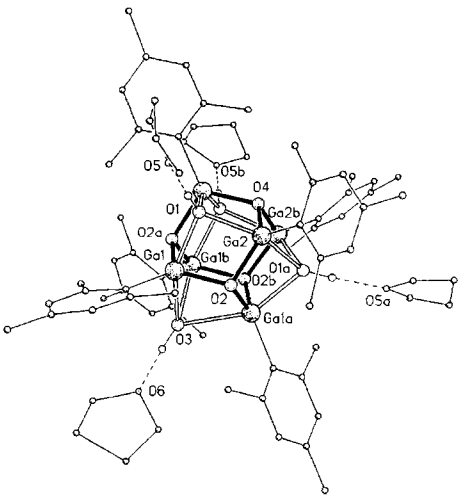

Fig. 1. Crystal structure of $[\mathbf{3}(thf)_4] \cdot 6$THF. The six noncoordinated THF molecules are not shown. The bond lengths [pm] and angles [°] labeled with an * are average values, the numbers in square brackets are the range of values, the standard deviations are extreme values: O1–Ga 221(1)* [213(1)–230(1)], O3–Ga 245(1), O2–Ga 187(1)* [185.5(9)–189(1)], O4–Ga 189.3(5), Ga–C 196(1)* [195(1)–197(1)]; Ga-O1-Ga 88.1(4)* [87.5(3)–88.6(3)], Ga-O3-Ga 78.6(4), Ga-O2-Ga 110.7(5)* [107.6(4)–113.0(5)], Ga-O4-Ga 108.9(5).

It is thus possible to prevent condensation through reaction of all hydroxide groups by the use of sterically demanding substituents. In addition Neumüller and Gahlmann observed the formation of the hexanuclear organogallium fluoride oxide $Mes_6Ga_6F_4O_4$, isoelectronic to **3**,[13] in the partial hydrolysis of Mes_2GaF. It may well be possible that OH–metal interactions play a role not only in the polymerization, but also in the water-accelerated zirconium-catalyzed carbalumination of alkynes.[15]

Experimental Procedure

3: a) A solution of $GaMes_3$ (1.4 g, 3.3 mmol) in THF (20 mL) was added dropwise to a solution of $GaCl_3$ (0.3 g, 1.7 mmol) in THF (20 mL) and stirred for 30 h at room temperature. Subsequently KOH (0.28 g, 5.00 mmol, not dried) was added to this solution and the resulting mixture was stirred for 5 d at room temperature under an inert atmosphere. After the KCl had been filtered off, the filtrate was concentrated under vacuum and the white solid obtained was washed with *n*-hexane (20 mL). Crystallization from THF afforded 0.9 g (66%) $[\mathbf{3}(thf)_4]$. The decomposition temperature of the THF-free compound **3** lay above 350 °C. Correct elemental analysis for C, H, Ga.

^{1}H NMR (250 MHz, [D$_8$]THF, TMS$_{ext}$): $\delta = 6.73-6.71$ (m, Ar-H), 6.37 (s, OH), 2.57–2.53 (m, 2,6-CH$_3$), 2.19–2.17 (m, 4-CH$_3$); IR (nujol): $\tilde{\nu}$[cm^{-1}] = 3671 s, 3521 s, br., 3015 s, 1719 m, 1601 vs, 1558 s, 1412 m, 1292 m, 1056 vs, 1028 vs, 848 s, 703 s, 589 m, 543 s.

b) Degassed water (106 μL, 5.9 mmol) was added by syringe to a solution of $GaMes_3$ (2.52 g, 5.9 mmol) in toluene (100 mL) at $-78\,^\circ$C and the mixture was stirred and slowly allowed to warm to room temperature. Subsequently it was stirred for 3 d, the volatiles were removed under vacuum, the white residue washed with *n*-hexane (20 mL) and filtered. The residue was dried under vacuum (10^{-4} mbar) for about 15 h. Yield of **3** (0.72 g, 58%). Correct elemental analysis of C and H for $Mes_6Ga_6O_4(OH)_4$. IR and NMR spectra in [D$_8$]THF were consistent with those for the product prepared according to method a).

[7] Crystal data of $[3(thf)_4]\cdot 6THF$: $M = 1986.46$, rhombohedral, space group $R\bar{3}c$, $a = b = 2353.6(3)$, $c = 3133.0(6)$ pm, $V = 15.030(4)$ nm^3, $Z = 6$, $\rho_{calcd} = 1.317$ Mgm^{-3}, $F(000) = 6264$, $\lambda = 71.073$ pm, $T = -120\,^{\circ}C$, $\mu(Mo_{K\alpha}) = 1.651$ mm^{-1}, crystal dimensions: $0.7 \times 0.5 \times 0.5$ mm, $6^{\circ} \le 2\theta \le 40^{\circ}$; of the 6127 collected reflections, 2440 are independent, and these were used for the refinement of 164 parameters with the help of 198 restraints; maximal residual electron density: 899 e nm^{-3}, $R1(F > 4\sigma(F)) = 0.069$ and $wR2 = 0.199$ (all data) with $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR2 = (\Sigma w F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2)^{0.5}$. The data were collected on a Stoe-Huber diffractometer. Intensities of a rapidly cooled crystal in an oil drop [8] were collected by $2\theta/\omega$ method. Semiempirical absorption corrections were carried out on all data. The structure was solved by direct methods (SHELXS-90) [9] and refined by least squares on F^2 [10]. The disorders of the THF solvent molecules were refined with distance restraints. The refinement of the inversion twinning paramter [11] ($x = 0.00(4)$ for $x = 0$ for the correct absolute structure and $x = +1$ for the inverted structure) confirmed the absolute structure of **3**. The solution of the structure and the refinement in the space group $R\bar{3}c$ were unsuccessful. The structure could be solved in the space group Cc, but a refinement was also here unsuccessful. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ, on quoting the full journal citation.

Benziporphyrin, a Benzene-Containing, Nonaromatic Porphyrin Analogue

Kurt Berlin and Eberhard Breitmaier*

An interesting approach for modifying the basic porphyrin framework for the most varied applications[1] is replacing the pyrrole ring by another five-membered ring heteroarene such as furan and thiophene,[2] or by pyridine[3, 4] or benzene. When 1,3-disubstituted six-membered rings are incorporated, the macrocycle can achieve 18 π aromaticity only at the expense of the 6 π aromatic system. The obvious question is which of the two rings wins this competition. Recently we reported on the synthesis of a modified porphyrinogen in which a pyrrole is replaced by a pyridine unit.[4] However, we could not obtain the 18 π aromatic tautomer with maximum unsaturation which corresponds to a porphyrin. The oxidation of the pyriporphyrinogen[4] leads to the ketone instead.

We report here on the first benzene-containing macrocycle that is a porphyrin analogue, which in contrast to the pyriporphyrins,[4] was obtained simply by oxidation of the appropriate porphyrinogen **3**. Tripyrranedicarboxylic acid **2b**[5] was decarboxylated in situ and condensed with isophthalaldehyde (**1**) in dichloromethane/THF with 33% HBr in glacial acetic acid as the catalyst. The resulting macrocycle was then oxidized in situ with *p*-chloranil to give **4**. In analogy to pyriphorphin we propose the name benziporphin for the unsubstituted framework and the numbering shown for **4a**.

The spectroscopic data for the compound give no indication of 18 π aromaticity and cyclic conjugation in the tautomer. The UV spectrum, for example, does not display the Soret band (420 nm, $\lg\varepsilon > 4$) characteristic of porphyrins, and in the ^{1}H NMR spectrum the pyrrole-NH protons ($\delta = 8.90$) and the inner benzenoid protons ($\delta = 7.88$) do not show the shielding typical for the inner protons of an [18]annulene. Thus the tautomers **4a/b** (4:1 in $CDCl_3$) have an intact benzenoid arene unit. It is apparent that the aromatic 18 π tautomer does not exist even when only one 6 π arene would have to be sacrificed. Thus **4**, a prototype of macrocycles in which benzenoid rings successively replace the pyrrole rings of porphyrin, indicates that porphyrin analogues with more than one 6 π arene[6] cannot be [18]annulenes.

The successful preparation of **4** also implies that the surprising behavior of the "pyriporphyrinogens"[4] towards oxidants results from the side reaction of the reactive α-alkyl group of the pyridine rings and is not a consequence of the unattainable 18 π aromaticity.

Experimental Procedure

Diester **2a** (635 mg, 1 mmol) was dissolved in 80 mL of anhydrous THF and treated with 200 mg of Pd/C (10% Pd) and 0.1 mL of triethylamine. After 3 h of hydrogenation at ambient pressure the catalyst was removed by vacuum filtration and the filtrate (**2b**) added dropwise to a solution of isophthalaldehyde (**1**) (134 mg, 1 mmol) in 800 mL of dichloromethane. Argon was then bubbled through the reaction mixture for 15 min, and then 1.8 mL of a solution of HBr in glacial acetic acid (33%) was added. The reaction mixture was stirred for 4 h with exclusion of light, 750 mg of *p*-chloranil was added, and 15 min later the reaction mixture was neutralized with 2.5 mL of triethylamine and left to stand ca. 15 h. The solvent was removed under

Synthesis and Reactivity of a Naphtho[1,8-*bc*]boret**

Achim Hergel, Hans Pritzkow, and Walter Siebert*

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

1,8-Bridged naphthalene derivatives are interesting not only structurally because of the distortion of their arene framework, but also because of their synthetic potential owing to the strained four-membered ring. Up to now compounds of this type have been synthesized with sulfur, carbon, and silicon in the bridging position;[1–3] all attempts to prepare the corresponding nitrogen and oxygen analogues have failed.[4, 5]

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 247), the Fonds der Chemischen Industrie, and BASF AG.

We have now succeeded in synthesizing the first boron-bridged naphthalene, **2**, in a yield of 89% by the reaction of 1,8-dilithionaphthalene (**1**) with Cl_2BNiPr_2. Colorless, crystalline **2** is thermally stable and can be sublimed without decomposition. On the basis of spectroscopic data the molecule appears to have C_2 symmetry, which is confirmed by a crystal structure analysis (Fig. 1).[6] The slightly shortened B–N bond (1.37 Å) lies almost in the plane of the naphthalene framework, and the angles within the boret ring indicate that the ring is very strained.

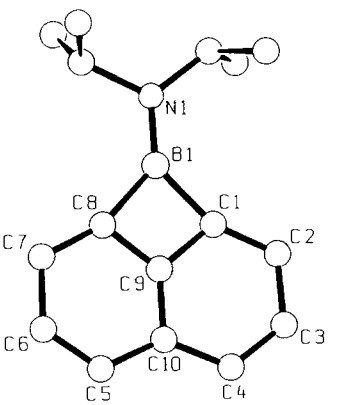

Fig. 1. Molecular structure of **2**. Selected distances [Å] and angles [°]: B1-N1 1.375, 1.369(5), B1-C1 1.599, 1.601(5), B1-C8 1.602, 1.601(5), C1-C9 1.404, 1.403(4), C8-C9 1.397, 1.406(4); C1-B1-C8 86.2, 86.7(3), B1-C1-C9 85.6, 85.2(3), B1-C8-C9 85.7, 85.1(3), C1-C9-C8 102.6, 103.0(3).

Compound **2** reacts under mild conditions with BX_3 (X = Cl, Br) to give naphtho[1,8-*cd*][1,2,6]azadiborinin **4a, b** by a novel ring expansion. The first step is assumed to be the cleavage of a B–C bond in **2** by BX_3 leading to the nonisolable intermediate **3**, which gives rise to the naphthoannelated heterocycle **4** by elimination of *i*PrX (or propene + HX). Reaction of **2** with diborane and diethylborane (X = H, Et) provides the μ-diisopropylaminodiboranes **5a, b**. In this case a B–H–B bridge forms which prevents further reaction. Compound **5a** is thus a stabilized isomer of **3** (X = H). The proof for this is provided by the replacement of the three hydrogen atoms bound to boron in **5a** by ethoxy groups. **3** (X = OEt) reacts with elimination of ethyl isopropyl ether (or propene + EtOH) and formation of **4c**.

The crystal structure analysis[7] of **5b** (Fig. 2) indicates that the boron atoms lie almost in the plane of naphthalene. The B-N-B angle (75.5(3)°) is remarkably small, and the atoms B-N-H form approximately a right angle.

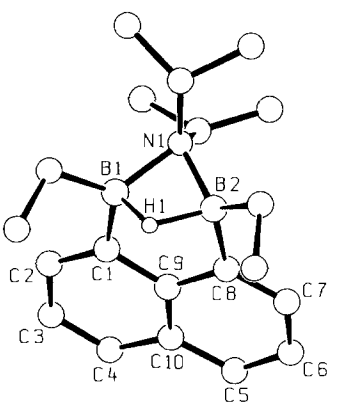

Fig. 2. Molecular structure of **5b**. Selected distances [Å] and angles [°]: N1-B1 1.615(6), N1-B2 1.613(5), B1-C1 1.606(6), B2-C8 1.609(6), B1-H1 1.25(3), B2-H1 1.35(3), C1-C9 1.424(5), C8-C9 1.419(5); B1-N1-B2 75.8(3), N1-B1-C1 111.8 (3), N1-B2-C8 112.3(3), B1-C1-C9 114.3(3), B2-C8-C9 114.0(3), C1-C9-C8 116.1(3).

Compound **5a** displays temperature-dependant molecular dynamics; the ^{1}H NMR spectrum at 220 K confirms the constitu-

tion in the solid state. Besides the splitting pattern for the signals of the naphthalene protons, the spectrum exhibits two doublets and two septets for the two isopropyl groups. At higher temperatures the signals in the aliphatic region coalesce, and at 370 K one doublet and one septet are evident. Compound **5a**, in contrast to **5b**, undergoes an exchange process at higher temperatures, in which the two methine protons and the four methyl groups are equivalent on the NMR timescale. We assume that a transition state **3** (X = H) is formed by opening of the μ-bridge; both hydrogen atoms of the BH_2 unit are now capable of forming a new bridge, and thus on the NMR timescale both isopropyl groups become equivalent. The temperature-dependent ^{11}B NMR spectrum confirms this. At room temperature a slightly broadened doublet can be seen (coupling of μ-H—B is not resolved) which is converted into a quartet at higher temperatures (370 K). This observation can be explained by the rapid, oscillating motion of the three hydrogen atoms around the boron atoms, such that they appear equivalent to the boron nucleus. This phenomenon is comparable to the exchange process of the hydrogen atoms in μ-dimethylaminodiborane(6).[8] In this case the ^{11}B NMR spectrum displays a doublet of triplets at 283 K and a sextet at 377 K.

Experimental Procedure

2: A solution of **1** (28.05 mmol) in ether (70 mL) at −30 °C was added to a solution of Cl_2BNiPr_2 (84.15 mmol) in hexanes (60 mL) cooled to −20 °C. Filtration and sublimation (52 °C, 0.001 Torr) yielded **2** in 89% yield, m.p. 84 °C. ^1H NMR (200 MHz, $CDCl_3$): δ = 7.70 (dd, 2H), 7.60 (dd, 2H), 7.45 (dd, 2H), 3.90 (sept, 2H), 1.47 (d, 12H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 163 (br.), 148 (br.), 129.4, 126.0, 122.6, 121.8, 49.3, 24.3; ^{11}B NMR (29 MHz, $CDCl_3$): δ = 37; Electron Impact (EI)-MS: *m/z* (%): 237 (26) [M^+], 194 (56) [$M^+ - i$Pr].

4a: BCl_3 was treated with **2** in hexane at −20 °C. Workup by recrystallization provided **4a** in 92% yield, m.p. 89 °C (decomp). ^1H NMR (200 MHz, C_6D_6): δ = 8.49 (dd, 2H), 7.60 (dd, 2H), 7.23 (dd, 2H), 4.96 (sept, 1H), 1.48 (d, 6H); ^{13}C NMR (75 MHz, C_6D_6): δ = 139.7, 137.6, 133.8, 126.8, 51.6, 22.6; ^{11}B NMR (29 MHz, C_6D_6): δ = 43.9; EI-MS: *m/z* (%): 275 (43) [M^+], 260 (100) [M^+ − Me].

4b: Preparation analogous to **4a**, yield 53%, m.p. 75 °C (decomp). ^1H NMR (300 MHz, $CDCl_3$): δ = 8.71 (dd, 2H), 8.12 (dd, 2H), 7.66 (dd, 2H), 5.25 (sept, 1H), 1.73 (d, 6H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 142.2, 136.5, 133.3, 131.0, 126.2, 55.7, 22.7; ^{11}B NMR (29 MHz, $CDCl_3$): δ = 43.6; EI-MS: *m/z* (%): 365 (68) [M^+], 350 (100) [M^+ − Me].

5a: **2** and $LiBH_4$ in hexanes were treated with boron trifluoride–ether in ether. Filtration and recrystallization from hexane yielded **5a** in 93% yield, m.p. 110 °C (decomp). ^1H NMR (200 MHz, $CDCl_3$, 220 K): δ = 7.76 (dd, 2H), 7.71 (dd, 2H), 7.45 (dd, 2H), 2.7 (sept, br., 1H), 2.58 (sept, 1H), 2.0 (br., 1H), 1.49 (d, 6H), 0.98 (d, 6H); ^1H NMR (200 MHz, C_7D_8, 370 K): δ = 7.59 (dd, 2H), 7.51 (dd), 2H), 7.23 (dd, 2H), 2.68 (sept, 2H), 2.0 (br, 1H), 0.88 (d, 12H); ^{13}C NMR (75 MHz, C_6D_6): δ = 146.9, 143 (br.), 131.2, 130.7, 126.9, 126.5, 59 (br.), 50 (br.), 21.8; ^{11}B NMR (64 MHz, C_7D_8, 270 K): δ = −10.3 (d, br.); ^{11}B NMR (64 MHz, C_7D_8, 350 K): δ = −10.3 (q); EI-MS: *m/z* (%): 251 (23) [M^+], 208 (100) [$M^+ - i$Pr].

5b: Diethylborane was slowly added to **2** in hexane. **5b** was obtained after recrystallization in 82% yield, m.p. 108 °C (decomp). ^1H NMR (200 MHz, C_6D_6): δ = 7.69 (dd, 2H), 7.61 (dd, 2H), 7.43 (dd, 2H), 3.10 (sept, 1H), 2.77 (sept, 1H), 2.11 (br., 1H), 1.3–1.7 (m, 4H), 1.22 (t, 6H), 1.07 (t, 6H), 0.59 (d, 6H); ^{13}C NMR (50 MHz, C_6D_6): δ = 147.4, 144 (br.), 131.8, 129.7, 126.9, 126.1, 56.5, 51.1, 25 (br.), 23.1, 14.7, 8.8 (br.); ^{11}B NMR (29 MHz, C_6D_6): δ = 1.0; EI-MS: *m/z* (%): 307 (6) [M^+], 236 (100) [M^+ − Et − iPr].

4c: **5a** was treated with ethanol and recrystallized from hexane. Yield : 95%, m.p. 85 °C. ^1H NMR (200 MHz, C_6D_6): δ = 8.40 (dd, 2H), 7.72 (dd, 2H), 7.35 (dd, 2H), 4.1 (q, br., 4H), 2.59 (sept, 1H), 1.23 (t, br., 6H), 0.90 (d, 6H); ^{13}C NMR (50 MHz, C_6D_6): δ = 142.3, 134.5, 132.2, 132.0, 125.8, 59 (br.), 47.9, 18.9, 17 (br.); ^{11}B NMR (29 MHz, C_6D_6): δ = 29.4.

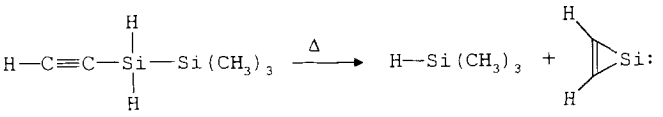
C_2H_2Si Isomers: Generation by Pulsed Flash Pyrolysis and Matrix-Spectroscopic Identification**

Günther Maier,* Hans Peter Reisenauer, and Harald Pacl

The matrix-spectroscopic identification[1] and photochemical interconversion[1] of the isomeric carbenes cyclopropenylidene (**1**), propynylidene (**2**), and propadienylidene (**3**) are of interest in many ways. For one, the isolation of **1**–**3** as well as their chlorinated[2] and fluorinated[3] derivatives serves to illustrate the potential of matrix isolation spectroscopy. In addition, the structural assignments for these species are based on the comparison of the experimentally observed and calculated IR spectra and therefore emphasize the importance of simultaneously applying quantum chemical calculations and spectroscopic measurements. Moreover, reactions **1** ⇌ **2** ⇌ **3** are carbene–carbene rearrangements, and only few examples exist for this class of reactions. Lastly, **1**[4] and **3**[5] have also been shown to play a decisive role in the chemistry of interstellar clouds.[6]



According to calculations by H. F. Schäfer et al.[7] **6** is expected to be the most stable C_2H_2Si species. Thus, it has been discussed as the adduct of a Si atom with acetylene.[8, 9] H. Schwarz et al. have shown[10] that if one ionizes chlorotrimethylsilane in the gas phase, neutralization–reionization mass spectrometry allows

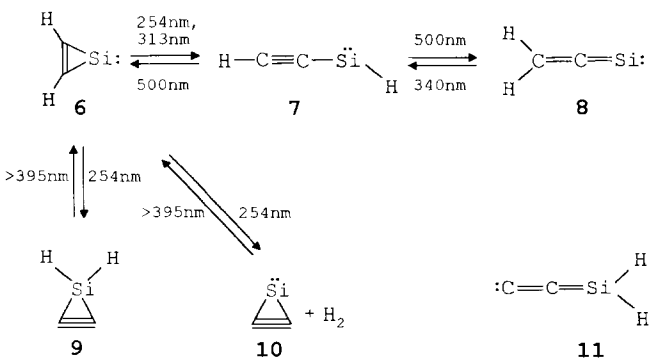
detection of a particle whose connectivities are indicative of structure **6**.



4 **5** **6**

Better experimental access to the C_2H_2Si potential energy surface is offered by pyrolysis of 2-ethynyl-1,1,1-trimethyldisilane (**4**). Compound **4** can be prepared by reaction of 1,1,1-trimethyl-2-phenyldisilane[11] with trifluoromethanesulfonic acid (toluene, 4 h, room temperature)[12] to give the corresponding triflate. The triflate is then treated with mesityllithium (15 min, −40 °C) to form 2-mesityl-1,1,1-trimethyldisilane (44%), which upon further reaction with trifluoromethanesulfonic acid (pentane, 4 h, 0 °C)[13] and treatment with sodium acetylide (suspension in diethyl ether) yields **4**. The reaction product is distilled under vacuum and isolated by preparative gas chromatography [silicon phase OV 101, 175 °C; yield: 25%; ^{1}H NMR (capillary): $\delta = 0.89$ (s, 9H, $Si(CH_3)_3$), 3.00 (t, $^4J(H,H) = 1.5$ Hz, 1H, H–C), 4.34 (d, $^4J(H,H) = 1.5$ Hz, 2H, SiH_2); ^{13}C NMR: $\delta = -1.0$ ($Si(CH_3)_3$), 80.4 ($CSiH_2$), 98.3 (HC); ^{29}Si NMR: $\delta = -85.7$ (SiH_2), −16.3 ($Si(CH_3)_3$)].

Gaseous mixtures of disilane **4** and argon (1:1000–2000) were subjected to flash pyrolysis at various temperatures and pressures. After leaving the hot zone the reaction products were directly condensed onto a CsI or BaF_2 window at 10 K. The matrix-isolated products were studied by IR and UV/VIS spectroscopy. Under the conditions of *high-vacuum* flash pyrolysis (quartz tube: diameter 8 mm, length of heated zone 5 cm; ca. 10^{-3} mbar, 600 °C) only trimethylsilane (**5**) and small amounts of acetylene were detected. Any C_2H_2Si isomer that might have formed was too unstable to be detected under these pyrolysis conditions.

Pulsed flash pyrolysis proved more successful. The gaseous mixture (regulated by a pulsed magnetic valve) was expanded through a corundum tube (inner diameter 1 mm, length of heated zone 10 mm, heated to ca. 1100 °C by a tungsten resistance wire)[14] directly into the high vacuum of the cryostat. The products were condensed onto the matrix window at 10 K.

6 **7** **8**

9 **10** **11**

Under these pyrolysis conditions the IR spectrum shows, apart from the bands for trimethylsilane (**5**), those of another compound. This compound is identified as 1-silacyclopropenylidene (**6**)—even though the structure of reactant **4** suggests formation of ethynylsilanediyl (ethynylsilylene) (**7**)—by comparison with the IR spectra for **6**, **7**, and **8** calculated by ab initio methods in 1986.[7a] Furthermore, **6** exhibits a weak, broad UV absorption between 320 and 260 nm ($\lambda_{max} = 286$ nm). Irradiation into this band with monochromatic light of wavelength 313 nm results in a rearrangement to give ethynylsilanediyl (**7**). During this photoreaction only the absorbances of **6** and **7** change, and thus the IR and UV/VIS spectra of both compounds can be determined by subtraction. Figure 1 shows the difference IR spectrum and the calculated spectra for **6** and **7**.[7a]

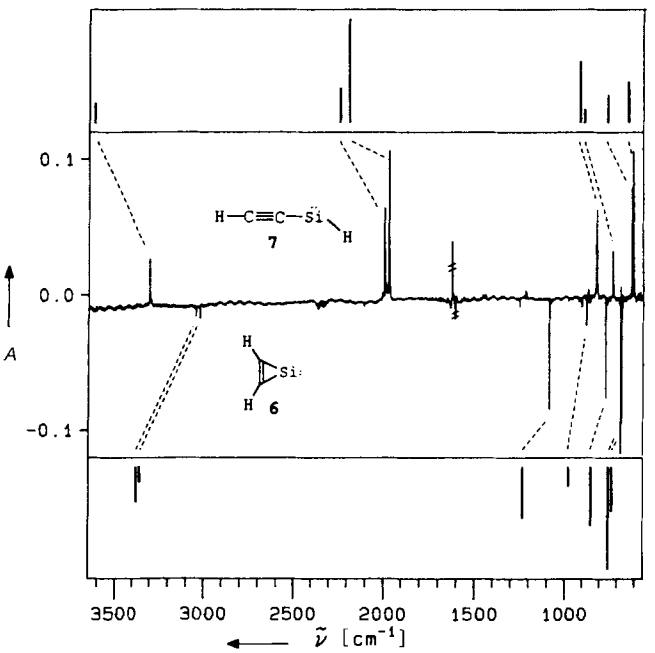


Fig. 1. IR spectra of **6** and **7**. Middle: difference IR spectrum for the photoreaction **6** → **7** (Ar matrix, 10 K). Top: calculated [7a] IR spectrum for **7**. Bottom: calculated [7a] IR spectrum for **6**; IR bands due to water have been crossed.

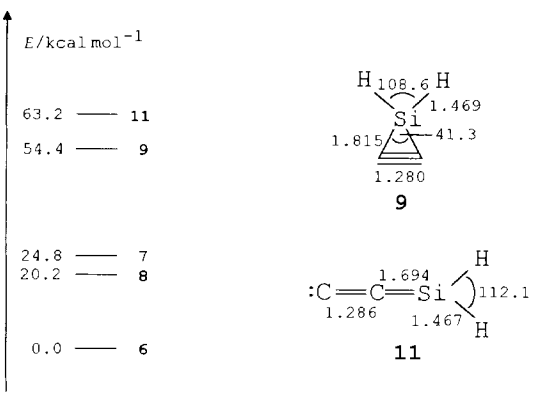
Particularly characteristic for **7** are the bands of the CH (3304.1 cm^{-1}), the CC (1995.5 cm^{-1}), and the SiH (1969.5 cm^{-1}) stretching vibrations. The spectral pattern of the remaining bands at lower wavenumbers (cf. Table 1) is also in satisfactory agreement with the calculation.

Table 1. Experimentally determined IR absorptions (argon matrix, 10 K) of **6**–**9** ([cm^{-1}]; relative integrated intensities in parentheses).



6	**7**	**8**	**9**
3048.5 (10)	3304.1 (31)	1667.5 (100)	2228.9 (49)
3026.3 (9)	1995.5 (27)	957.5 (100)	2214.4 (49)
1085.8 (87)	1969.5 (100)		1769.9 (7)
875.1 (26)	1216.0 (3)		1023.1 (100)
761.8 (56)	814.8 (49)		836.5 (50)
677.4 (100)	722.7 (14)		600.7 (7)
672.1 (90)	613.8 (32)		
	605.1 (41)		

This is also true for 1-silacyclopropenylidene (**6**) (cf. Table 1). In accordance with the calculation its IR spectrum shows two bands for the CH stretching vibrations (3048.5 and 3026.3 cm^{-1}) and five additional absorptions between 1100 and 600 cm^{-1}, which, by calculation, can be attributed to HCSi bending vibrations and SiC stretching vibrations. A band for the CC stretching vibration is not observed; theory[7b] predicts a corresponding

band at 1569 cm^{-1} in the IR spectrum with a relative intensity of $<1\%$, which is apparently too weak to be detected.

For silanediyl (**7**) a broad absorption band is recorded in the visible region of the spectrum ($\lambda_{max} = 500$ nm). It is therefore not surprising that irradiation of **7** with visible light of wavelength 500 nm mainly leads to reisomerization to give 1-silacyclopropenylidene (**6**). A small amount of a new species is also formed, and two weak IR bands at 1667.5 and 957.5 cm^{-1} and a UV band with fine structure (λ = 340, 325, and 310 nm) are recorded. Irradiation into this absorption (λ = 340 nm) leads to reisomerization to **7**; hence, this species is another isomer of C_2H_2Si. By comparison with the calculated IR spectra this isomer is identified as vinylidenesilanediyl (**8**), for which the strongest IR band (CC stretching vibration) is predicted at 1859 cm^{-1}.[7a]

Irradiation of **6** with light of wavelength λ = 254 nm leads to the formation of **7** and two new compounds. One of these can easily be identified by its characteristic IR bands at 1745.3/1741.0 and 826.4 cm^{-1} (ref. [15a–c]: 1741 and 824 cm^{-1}) and by its electronic transition band[15c] as the well-known,[15d] cyclic C_2Si (**10**). The second compound shows IR absorptions at 2228.9 and 2214.4 cm^{-1}, which are typical for SiH_2 groups (symmetric and asymmetric SiH stretching vibrations). Furthermore, a weak band at 1769.9 cm^{-1} and additional bands at 1023.1, 836.5, and 600.7 cm^{-1} are observed. Therefore, the fourth isomer must either be of constitution **9** or **11**. Silacyclopropyne (**9**) was initially dismissed as an unlikely candidate, as calculations[7a] indicate that this structure represents a transition state. Thus, it was important to calculate IR spectra for **9** and **11**, something that had not previously been done. Calculations at the MP2/6-31G** level[16] led to two important findings. Firstly, when the electron correlation energy is taken into account (cf. Scheme 1) **9** is a minimum. Secondly, the experimentally

Scheme 1. Relative energies E[kcal mol^{-1}] calculated at the MP2/6-31G** level for the isomers **6**–**9** and **11** (energy minima) and optimized geometries (bond lengths [Å] and angles [°]) for **9** and **11**.

measured and calculated spectra are in satisfactory agreement for **9**, but not for **11** (cf. Scheme 1 and Table 2). We therefore prefer the structure of silacyclopropyne (**9**) for the fourth isomer.

Table 2. IR absorptions for **9** and **11** ([cm^{-1}], absolute intensities [km mol^{-1}] in parentheses) calculated at the MP2/6-31G** level.

9		**11**	
2371 (148)	819 (88)	2391 (100)	690 (78)
2362 (127)	697 (68)	2374 (74)	684 (73)
1779 (<1)	420 (114)	1967 (345)	122 (<1)
1102 (214)	375 (0)	1052 (126)	120 (<1)
858 (106)		798 (10)	

This is also supported by the observation that the bands at 1769.9 (CC stretching vibration) and 836.5 cm^{-1} (symmetric CSi stretching vibration) have similar positions in the C_2Si molecule **10** (1745.3/1741.0 and 826.4 cm^{-1}, respectively). The band at 836.5 cm^{-1} is assigned to the calculated absorption at 858 cm^{-1}. Theory predicts a second, relatively intense band at 819 cm^{-1}. As this absorption is missing in the experimentally recorded spectrum, the question arises whether further calculations at a higher level are necessary. We will attempt to definitively assign the structure of **9** by studying a ^{13}C isotopomer. To the best of our knowledge **9** would represent the first example of a cyclopropyne.

Upon irradiation ($\lambda > 395$ nm) compound **9** is transformed into **6** (therefore, both compounds are indeed isomers). Simultaneously, C_2Si (**10**), which is formed concurrently with **9**, reacts with eliminated hydrogen that is trapped in the same matrix cage to also give **6**. Trapping reactions of this kind have also been observed for various other unsaturated silicon compounds.[17]

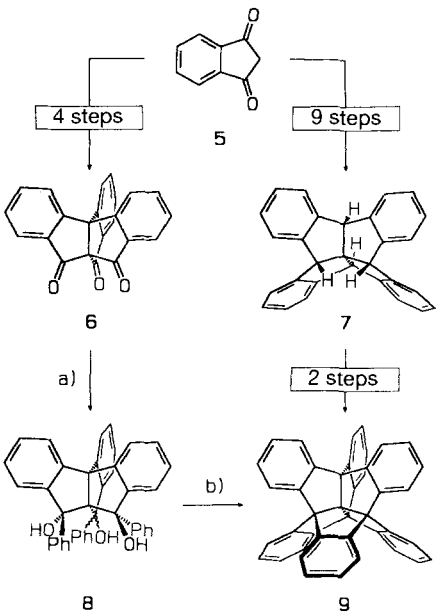
Synthesis of Centrohexacyclic Hydrocarbons by the Propellane Route: Centrohexaindan and Tribenzocentrohexaquinane**

Dietmar Kuck,* Bernd Paisdor, and Detlef Gestmann

Dedicated to Dr. Howard E. Simmons, Jr. on the occasion of his 65th birthday



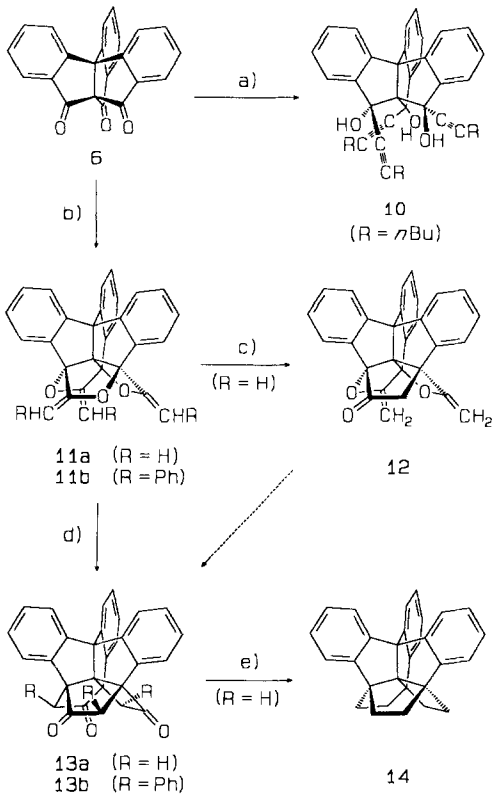
The construction of centrohexacyclic hydrocarbon frameworks with the general structure **1** (centrohexacyclanes;[1] Scheme 1) continues to present a challenge in organic polycycle chemistry. In these types of structures six annelated carbocycles share a central neopentane unit of five quaternary carbon atoms and form a microlattice with nonplanar topology.[2] The compounds with six centrally annelated cyclopentane rings should be relatively strain-free.[1, 3] Thus relatively undistorted frameworks of, for example, perhydrotriquinacene and all-*cis*-[5.5.5.5]fenestrane can be found in the yet unknown parent structure, centrohexaquinane **2**, which can be considered to be the condensation center of four pentagon dodecahedrane units.[1] Nevertheless, synthetic routes to **2** and centrohexaquinacene **3**, which was first

Scheme 1.

proposed in 1978,[4] must take into account considerable steric compression and/or fragmentation between the components that are to be joined. Therefore, not surprisingly, centrohexacyclic hydrocarbons[5, 6] and the corresponding heterocycles[7–9] have remained quite rare. Only one directed synthesis of a centrohexacyclic hydrocarbon framework was reported previously, namely the synthesis of the sixfold benzoannelated derivative of **2**, centrohexaindan **9**.[5] We have now discovered a new route to **9** and centrohexacyclic triethers related to the "Simmons–Paquette molecule" **4**[8, 9] and have developed a synthesis of the novel tribenzocentrohexaquinanes.

In our first synthesis of **9** the already highly condensed fenestrindan **7**, which is thus protected against fragmentation, was bridged twice (route **b** to **1** in Scheme 1 and route **5** → **7** → **9** in Scheme 2). A newer alternative synthesis, the propellane route, starts with 9,10,11-triptindantrione **6**,[10] a [3.3.3]propellane accessible from 1,3-indandione **5** in only four steps (route **a** to **1** in Scheme 1 and route **5** → **6** → **8** → **9** in Scheme 2).

Scheme 2. Synthesis of centrohexaindan **9** by the propellane route and by the fenestrane route. **5** → **6**: ref. [10]; **5** → **9**: ref. [5]. a) PhLi (20 mol) in benzene/Et_2O/c-C_6H_{12}; H_2O; b) H_3PO_4/xylene, Δ; yield 40% of **6**.



Three equivalents of aliphatic Grignard compounds like CH_3MgBr and $C_6H_5CH_2MgBr$ can be added to triptindantrione **6** with remarkable ease and without ring opening. Only two equivalents of phenylmagnesium bromide react with **6**;[10] however, threefold addition is possible if phenyllithium is employed in a poorly solvating medium. After hydrolysis a mixture of isomeric triols **8** is obtained, which can be cyclodehydrated with acid catalysis to give **9**. These two steps, in which a total of six C–C bonds are formed, conclude the synthesis of centrohexaindan **9** from **5** in only six steps and with a total yield of up to 24%.[11]

The propellane route was then used for the first construction of centrohexaquinanes with *partial* benzoannelation. The synthesis of tribenzocentrohexaquinane **14** is shown in Scheme 3. In this synthesis a C_2 synthon was required which, in analogy to the sequence **6** → **8** → **9**, would undergo threefold nucleophilic addition to **6** and subsequent cyclization to yield the triquinacene framework complementary to the [3.3.3]propellane unit. Neither the application of the strategies used by Simmons III and Maggio,[8] and by Paquette et al.[9] (e.g. rearrangement of a trispiro[[3.3.3]propellanetris(oxirane)] to **4**) to the triptindan system nor other approaches of our own were successful.[10, 12, 13] A surprisingly direct route to **14** and interesting derivatives is based on the threefold reaction of **6** with lithium acetylides.

Unexpectedly, the reaction of triptindantrione **6** with three equivalents of lithium acetylide in THF furnishes not triol **10** (R = H) but tris(enol ether) **11a**, the first derivative of the "Simmons–Paquette molecule" **4**. The excessive steric bulk of the neopentane core of the triptindan framework apparently favors the nucleophilic addition of the intermediate alcoholate to the *syn*-1,3-ethynyl group.[14] The intramolecular additions can be completed by treating the reaction mixture with aqueous sodi-

Table 1. Physical and spectroscopic data for compounds **11**, **13**, and **14**.

11a: Colorless crystals, m.p. >360 °C; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 4.61, 4.67 (AB spectrum, ^2J = 2.8 Hz, 6H), 7.38 (m, 6H), 7.54 (d, 3H), 7.78 (d, 3H); IR (KBr): $\tilde{\nu}$ = 1656 cm^{-1} (C=C); MS (EI, 70 eV): *m/z*: 414 ($M^{+\cdot}$, 36), 386 (36), 358 (42), 330 (100); HRMS: ($C_{29}H_{18}O_3$) calcd 414.1256; found 414.1265

11b: Colorless crystals, m.p. 272 °C; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 5.97 (s, 3H), 7.14 (t, 3H), 7.30 (t, 6H), 7.41 (m, 6H), 7.66 (d, 6H), 7.74 (m, 3H), 7.80 (m, 3H); IR (KBr): $\tilde{\nu}$ = 1671 cm^{-1} (C=C); MS (EI, 70 eV): *m/z*: 642 ($M^{+\cdot}$, 100), 614 (20), 586 (35), 558 (16); HRMS: ($C_{47}H_{30}O_3$) calcd 642.2195; found 642.2186

13a: Colorless crystals, m.p. >360 °C; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 2.84, 3.27 (AB spectrum, $|^2J|$ = 19.6 Hz, 6H), 7.30 (m, 9H), 7.84 (d, 3H); IR (KBr): $\tilde{\nu}$ = 1745 cm^{-1} (C=O); MS (EI, 70 eV): *m/z*: 414 ($M^{+\cdot}$, 49), 386 (41), 358 (39), 330 (100); HRMS: ($C_{29}H_{18}O_3$) calcd 414.1256; found 414.1257

13b: Colorless crystals, m.p. 298 °C; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 4.74 (s, 3H), 6.34 (d, ^3J = 7.8 Hz, 3H), 6.50 (br. d, ^3J = 7.0 Hz, 6H), 6.90 (td, ^3J = 7.5 Hz, ^4J = 0.8 Hz, 3H), 7.05 (t, $^3J \approx 7.5$ Hz, 6H), 7.14 (d, $^3J \approx 7.4$ Hz, 3H), 7.27 (td, ^3J = 7.5 Hz, ^4J = 0.9 Hz, 3H), 7.82 (d, ^3J = 7.8 Hz, 3H); IR (KBr): $\tilde{\nu}$ = 1741 cm^{-1} (C=O); MS (EI, 70 eV): *m/z*: 642 ($M^{+\cdot}$, 100), 614 (53), 586 (75), 558 (32); HRMS: ($C_{47}H_{30}O_3$) calcd 642.2195; found 642.2194

14: Colorless crystals, m.p. 264 °C; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): δ = 1.93, 2.17 (AA'BB' spectrum, 12H), 7.10 7.25 (m, 9H), 7.67 (d, ^3J = 7.4 Hz, 6H); MS (EI, 70 eV): *m/z*: 372 ($M^{+\cdot}$, 100), 358 (13), 343 (15), 329 (13), 316 (15); ^{13}C NMR (62.9 MHz, $CDCl_3$, TMS): δ = 39.83 (t, CH_2), 65.88 [s, *C*(C)(Ar)(CH_2)$_2$)], 77.22 [s, C(Ar)$_3$], 123.58 (t), 124.25 (t), 127.58 (t), 127.63 (t), 148.36 (s), 150.34 (s), the signal of the centro-C atom is missing; HRMS: ($C_{29}H_{24}$) calcd 372.1878; found 372.1879

um carbonate; unfortunately, the yield of **11a** is only 25%. The analogous reaction with phenylacetylene provides **11b** in 27% yield, but so far the reaction with 1-hexyne has only given triol **10** (R = *n*Bu).

Tris(enol ether)s **11** are characterized by mass spectrometry and IR and NMR spectroscopy (Table 1). The high molecular symmetry is reflected in the simple ^{1}H and ^{13}C NMR spectra; the AB pattern of the signals for the olefinic methylene protons of **11a** (^2J = 2.8 Hz) is particularly characteristic. In the mass spectra of the enol ethers the elimination of up to three equivalents of CO is evident in the upper mass range. This indicates that heterocycles **11a** and **11b** rearrange to the corresponding carbocycles **13a** and **13b** not only in the mass spectrometer, but possibly also on the preparative scale. Whereas attempts with Brønsted and Lewis acids (H_2SO_4/H_2O/THF, $AlBr_3/CH_2Cl_2$) and with $LiCl_4$/ether[15] were not successful, the thermolysis[16] of **11a** in decalin at 300 °C provided the desired trione **13a** in 30%; **11b** was converted diastereoselectively into the triphenyl derivative **13b** in even 60% yield.[17] As expected, the mass spectra of the two triones are very similar to those of compounds **11**, but features typical of cyclopentanone rings are observed in the ^{1}H and ^{13}C NMR, and IR spectra, for example an AB spectrum with $^2J = -19.6$ Hz (**13a**). Thermolysis of **11a** for shorter periods resulted in the product of a single rearrangement, monoketone **12**. The parent compound of the new centrohexacycles, tribenzohexaquinane **14**, was obtained by Wolff–Kishner reduction of **13a** and also characterized unequivocally (Table 1).

We are currently trying to convert centrohexaquinanetrione **13** into the corresponding (unsaturated) tribenzocentrohexaquinacenes. These types of triquinanetriones and triquinacenes, which have their convex molecular faces completely shielded,[18, 19] may be key intermediates in new, promising approaches to pentagon dodecahedranes from two triquinacene units.[18c, 18d, 20–22]

In conclusion we note that the propellane route described here for the construction of centrohexacyclic hydrocarbons may serve as an example of how the a priori unfavorable steric relations mentioned at the beginning of this report may also be advantageous for such compact structures. The remarkably facile formation of tris(enol ether) **11** is apparently a result of a proximity effect, and the subsequent consecutive rearrangements do not provide any possibility for the fragmentation of the molecular framework. The next particularly challenging step is determining whether the new propellane route leading to benzoannelated centrohexaquinanes like **9** and **14** may also be useful in the synthesis of the parent compound, centrohexaquinane **2**.

Experimental Procedure

9: A suspension of **6** (3.36 g, 10.0 mmol) in 250 mL of benzene was prepared with exclusion of air and moisture. A solution of phenyllithium (2 M, 100 mL) in diethyl ether/cyclohexane was then added and the reaction mixture heated at 40 °C for 12 h. After hydrolysis the organic phase was dried and concentrated, and the biphenyl formed removed by Kugelrohr distillation. The remaining triol **8** was dissolved in 250 mL of xylene and treated with 5 mL of orthophosphoric acid, and the reaction mixture was heated for 24 h with a water separator. After the reaction mixture had cooled, the organic layer was decanted off, dried over sodium sulfate, and concentrated. The brown residue was filtered over silica gel ($CHCl_3$) and recrystallized from dichloromethane/hexane. Pure **9** (MS, NMR [5]) was obtained as colorless needles (2.07 g, 40%).

11a and **11b**: A suspension of **6** (3.36 g, 10.0 mmol) in 200 mL of THF was added dropwise over 30 min to a solution of lithium acetylide [23] (1.06 g, 33.0 mmol) in 200 mL of THF cooled at −90 °C. The temperature was not allowed to exceed −80 °C during the addition. After the addition was complete, the red-brown solution was stirred for 60 min before it was allowed to warm to room temperature. Water (80 mL) and then solid Na_2CO_3 were added until the aqueous layer had a pulpy consistency. After a further 12 h of stirring, the organic layer was decanted off and the residue washed with $CHCl_3$ (2 × 200 mL). The combined organic layers were dried with Na_2SO_4 and concentrated. Column chromatography on silica gel ($CHCl_3$/hexane) provided **11a** (1.04 g, 25%). – When lithium phenylacetylide (3.57 g, 33.0 mmol) was used and the reaction conducted at room temperature, **11b** (1.73 g, 27%) was obtained after analogous workup.

13a and **13b**: A mixture of **11a** (200 mg, 480 μmol) or **11b** (200 mg, 310 μmol), 8 mg of hydroquinone, and 10 mL of anhydrous decalin was sealed under nitrogen in a thick-walled glass ampule and heated at 300 °C in an oven for 24 h. After cooling to room temperature, the light brown reaction solution was treated with pentane to precipitate the product as a beige powder, which was washed with pentane and

purified by column chromatography (silica gel, CH_2Cl_2/ethyl acetate 60:1) to give **13a** (60 mg, 30%) or **13b** (120 mg, 60%).

14: Triketone **13** (16.0 mg, 38.6 μmol) was heated with 5 mL of diethylene glycol, 1 mL of hydrazine hydrate, and 50 mg of KOH at 140 °C for 3 h and then at 210 °C for 4 h. The reaction mixture was allowed to cool, 5 mL of water was added, and the mixture was extracted with $CHCl_3$ (2 × 10 mL). Filtration through silica gel ($CHCl_3$) gave **14** (3.0 mg, 21%).

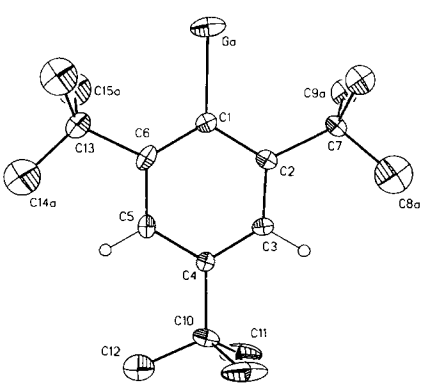
Base-Free Monomeric Organogallium Hydrides**

Alan H. Cowley,* François P. Gabbaï, Harold S. Isom, Carl J. Carrano, and Marcus R. Bond

Information on neutral gallium mono- and dihydrides is quite sparse.[1] Structurally characterized examples of such species are confined to the dimers $[Me_2Ga(\mu\text{-}H)]_2$,[2] $[H_2Ga(\mu\text{-}Cl)]_2$,[3] $[H_2Ga(\mu\text{-}NMe_2)]_2$,[4] and $[H_2Ga(\mu\text{-}H)_2BH_2]$[5] and the novel monomer $[HGa(BH_4)_2]$ with a pentacoordinate gallium atom.[6, 7] However, the recent detection of the tricoordinate monomers $GaHCl_2$ and GaH_2Cl in argon matrices[8] suggested that monomeric organogallium hydrides might become isolable if sufficiently bulky substituents were employed.

Treatment of $[Ga(Ar)Cl_2]$[9] (Ar = 2,4,6-$tBu_3C_6H_2$) with $LiGaH_4$ in Et_2O at −78 °C afforded a 73% yield of colorless crystalline **1**. In the CI mass spectrum of **1** the base peak appears at *m/z* 315 and corresponds to $[Ga(Ar)H]^+$. This assignment was confirmed by a high-resolution mass spectrum (HRMS).[10] The detection of a terminal GaH_2 moiety in the neutral molecule was evident from the presence of infrared peaks in the terminal Ga–H stretching region ($\nu_s = 1908\ cm^{-1}$(sh), $\nu_{as} = 1887\ cm^{-1}$) and the relative intensities of the GaH_2 resonance and those of the aryl substituent in the ^1H NMR spectrum.[10] Moreover, the deshielded position of the GaH_2 resonance ($\delta = 6.41$) was suggestive of a base-free product since, for example, amine-gallane adducts exhibit hydride resonances in the range $\delta = 4.5–5.0$.[11] The monomeric nature of **1** was confirmed by an X-ray structure analysis.[12] Individual molecules of **1** (Fig. 1) reside on a crys-

1



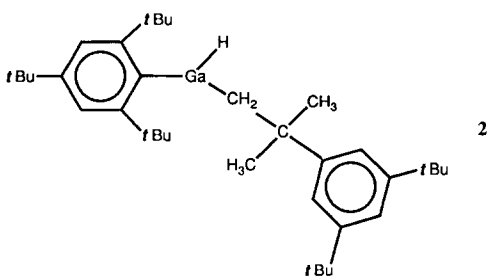


Fig. 1. View of **1** showing the atom labeling scheme. The *t*Bu groups at C2 and C6 are disordered and only the two highest occupancy methyl carbon atoms are shown. The hydrogen atoms on the gallium atom were not located. Selected distances [Å]: Ga–C1 1.942(7), Ga···C8 and Ga···C14 2.56(2).

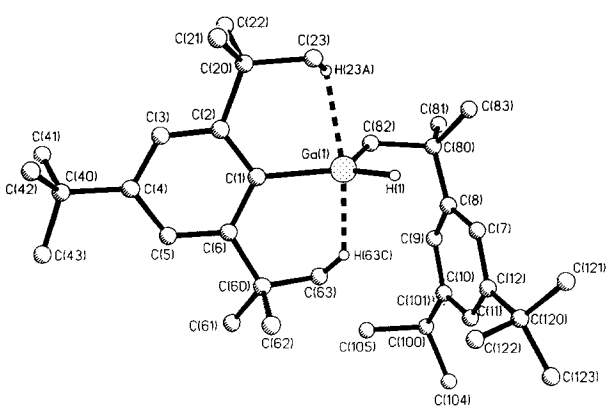
tallographic mirror plane located at $y = 1/4$ in the space group $P2_1/m$; there are no unduly short intermolecular contacts. The *t*Bu groups at C2 and C6 are disordered about two orientations which are related by 180° rotations around the C2–C7 and C6–C13 bonds. Because of this disorder and weak scattering it was not possible to locate the hydrogen atoms on gallium in the Fourier difference map. The Ga–C bond length in **1** (1.942(7) Å) is virtually identical to that in $[Ga(Ar)Cl_2]$;[9] the Ga···C8 and Ga···C14 contacts are both short (2.56(2) Å). Compound **1** survives sublimation at 80 °C (10^{-2} Torr); however, solutions of **1** in benzene undergo rapid photolysis with 254 nm light to give Ga^0, H_2, and 1,3,5-$tBu_3C_6H_3$.

The expected product of the reaction of $[Ga(Ar)_2Cl]$[13] with $LiGaH_4$ in Et_2O at −78 °C was the monohydride $[Ga(Ar)_2H]$. However, while peaks attributable to $[Ga(Ar)_2H]^+$ and $[Ga(Ar)_2]^+$ were evident in the CI mass spectrum and a terminal Ga–H moiety was detected in the IR spectrum, the *t*Bu and aromatic C–H regions of the ^1H NMR spectrum of **2** were

2

considerably more complex than anticipated.[10] X-ray structure analysis revealed that the colorless, crystalline product is, in fact, an isomer of the target compound (Fig. 2).[12]



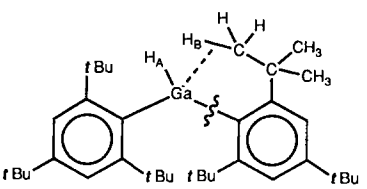


Fig. 2. View of **2** showing the atom labeling scheme. All hydrogen atoms except H(1), H(23A), and H(63C) are omitted for clarity. The *t*Bu groups at C(4) and C(10) are disordered. Important distances [Å] and angles [°]: Ga(1)–C(1) 1.983(17), Ga(1)–C(82) 1.972(17), Ga(1)–H(1) 1.43(10), C(80)–C(82) 1.551(23) Ga(1)···H(23A) 2.28(2), Ga(1)···H(63C) 2.03(2); C(1)-Ga(1)-C(82) 120.2(6), C(1)-Ga(1)-H(1) 131(5), C(82)-Ga(1)-H(1) 108(5), Ga(1)-C(82)-C(80) 119.2(11), H(23A)-Ga(1)-H(63C) 168.4(7).

The hydride **2** is monomeric in the solid state and there are no unusual intermolecular interactions. In this case it was possible to detect the hydrogen atom attached to gallium in the final Fourier difference map. Although the metric parameters are not very accurate, it is clear that the environment of the gallium atom is trigonal planar. There are no previous experimental values for a terminal Ga–H bond length involving tricoordinate gallium. The Ga–H bond length in **2** (1.43(10) Å) may be compared with the range of bond lengths (1.487–1.586 Å) established for tetra- and pentacoordinate species by gas-phase electron diffraction[2–6] and the value of 1.527 Å for $GaHCl_2$ calculated by ab initio methods.[8] The Ga–C(Ar) bond length in **2** (1.983(17)Å) is slightly longer than that in **1** (1.942(7) Å), ostensibly due to the more sterically encumbered environment in the former. A further point of structural interest relates to the short contacts between the gallium atom and one of the hydrogen atoms on each of the two *ortho*-*t*Bu groups (Fig. 2). One of these distances (Ga(1)···H(63C) = 2.03(2) Å) is shorter than the other (Ga(1)···H(23A) = 2.28(2) Å), and the calculated position of H(63C) is such that this atom points directly at the gallium center. On the other hand H(23A), which was located in the final Fourier difference map, adopts a location that places the mid-point of the C(23)–H(23A) bond near the quasi threefold axis of the gallium atom, thus suggesting the presence of an agostic interaction. Such interactions may, in fact, explain the isomerization of $[Ga(Ar)_2H]$ to **2**. As shown in Scheme 1, an agostic interaction between the gallium atom and a C–H bond of one of the *ortho*-*t*Bu methyl groups ($C-H_B$) could result in transfer of the H_B atom to the gallium atom and formation of a new Ga–C bond in concert with the cleavage of a Ga–C(*ipso*) bond and 1,2 transfer of H_A to the aryl ring.

Scheme 1. Postulated rearrangement mechanism for the isomerization to give **2**.

It is germane to point out that Meller et al.[13] have reported that $[Ga(Ar_2)Cl]$ is converted to $[Ga(CH_2CMe_2C_6H_3\{3,5\text{-}tBu_2\})(Ar)(Cl)]$ and a benzo[*b*]gallolane by heating in high vacuum at 140–160 °C. Presumably, the mechanism of this reaction is different because we do not observe gallolane formation. Moreover, the putative isomerization of $[Ga(Ar_2)H]$ to **2** takes place under significantly milder conditions (ambient pressure and a maximum temperature of 25 °C).

Finally, attempts to prepare the analogous indium hydrides have been unsuccessful so far. For example, reaction of the new monomeric indium chloride $[In(Ar)_2Cl]$ (**3**) with $LiGaH_4$ in Et_2O at −78 °C results in **1** by aryl cleavage and transmetalation.

Experimental Procedure

1: A solution of $LiGaH_4$ (8 mmol) in Et_2O (20 mL) was added to a solution of $[Ga(Ar)Cl_2]$ [8] (0.39 g, 1.0 mmol) in Et_2O (3 mL) at −78 °C. The resulting reaction mixture was allowed to warm slowly to 25 °C and was stirred for a further 20 h at this temperature. The solvent and volatiles were removed under reduced pressure and the resulting white residue was extracted with hexane (10 mL). After 3 h this stirred solution was filtered, and the volume of the filtrate reduced to 3 mL. X-ray quality crystals of **1** were grown by cooling the saturated solution to −20 °C. The yield of **1** was 73% (0.23 g). (M.p. 134 °C). Compound **2** was prepared in 42% yield by a similar procedure. (M.p. 180 °C, decomp.).

3: A slurry of $InCl_3$ (1.11 g, 5.0 mmol) in hexane (50 mL) was added to a suspension of ArLi (2.52 g, 10 mmol) in hexane (200 mL). The reaction mixture was heated to reflux for 18 h. The solvent and volatiles were removed under reduced pressure and the resulting residue was washed with pentane (3 × 20 mL). The pentane extracts were filtered through diatomaceous earth and the volume of the filtrate was reduced

by 50%. Small colorless crystals of **3** formed in 18% yield (0.58 g) after storage of this solution at −20 °C for several days. (M.p. 170 °C).

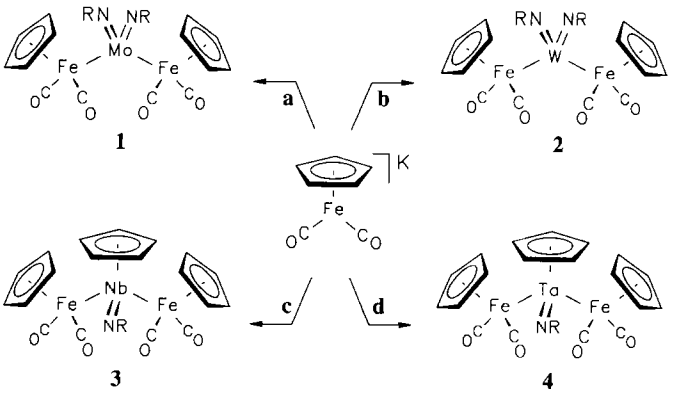
The Bonding Capability of Imido Complex Fragments of Groups 5–7 with Regard to the Isolobal Relationship**

Jörg Sundermeyer* and Diane Runge

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

In bond theory organoimido and cyclopentadienyl ligands show surprising parallels.[2] If they are considered as anionic ligands, they both make a maximum of six electrons available for bonding with a metal cation.[3] Both are σ,2π-bonding ligands,[4] which form σ and π bonds with metal orbitals of the same symmetry.[5] If the $C_5R_5^-$ anion binds to a d^n-M metal center (e.g., d^0-W^{6+}) and the dianion NR^{2-} to an isoelectronic d^n-M′ metal center from the following group in the periodic table (e.g., d^0-Re^{7+}), two entities with the same electron count and comparable valence orbitals result (e.g., $[W(\eta^5\text{-}C_5R_5)]^{5+}$ or $[Re(NR)]^{5+}$). Schrock et al.[6] have already pointed out parallels in the chemistry of complexes with the entity $[M(NAr)_2]$ (M = Mo, W; Ar = 2,6-*i*$Pr_2C_6H_3$) and those containing the metallocene unit $[Cp_2M]$ (M = Ti, Zr, Hf; Cp = η^5-C_5H_5). Gibson et al. extended this relationship to the linking fragments [CpM(NR)] (M = Nb, Ta) and confirmed the isolobal character of these three complex fragments by quantum-mechanical calculations[7] and reactivity studies[8] (Scheme 1, top). Recently we reported on M–M′ coupling reactions of the two homoleptic imidoyl cations $[Re(NR)_3]^+$ and $[Mo(NR)_2]^{2+}$ (R = *t*Bu) with carbonyl metalates $[Cp_nM(CO)_m]^-$ of Groups 6–8.[9] It was shown that a direct metal–metal interaction is possible between high- and low-valent metal centers. These results prompted us to the question whether the bonding capability (concept according to R. Hoffmann[10a]) of imido complex fragments $[Cp_nM'(NR)_m]$ (M from Groups 5, 6, or 7) can be determined along the route of selective M–M′ coupling reactions, by binding representative complex fragments with these entities to the classic 17 valence electron unit $[CpFe(CO)_2]$. Extrapolation of these studies could lead to the derivation of a new isolobal relationship between carbonyl and imido complex fragments $[Cp_nM'(NR)_m]$.



Scheme 1. Isolobal relationships in imido complex fragments.

According to the cyclopentadienyl–imido analogy, not only the homoleptic imido complex fragments $[Mo(NtBu)_2]^{2+}$ and

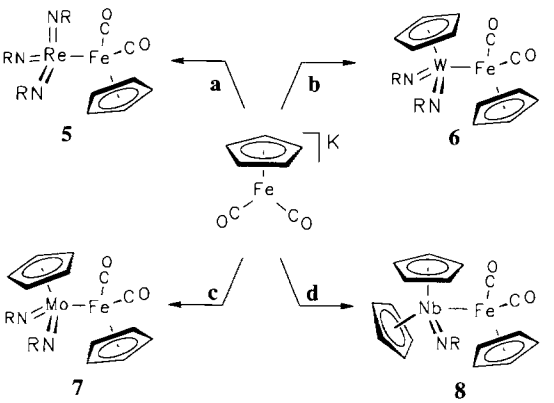
[**] High-valent derivatives of the d-metal acids. Part 11. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (SFB 347). We thank Professor Helmut Werner for his support and the company H. C. Starck, Goslar, for a gift of high purity grade metal oxides and chlorides. Part 10: Ref. [1].



$[W(NtBu)_2]^{2+}$ can be used as building blocks for the synthesis of trinuclear complexes [Fe]–[M″]–[Fe] ([Fe] = $[CpFe(CO)_2]$), but also the metal Lewis acids of Group 5 $[CpNb(NtBu)]^{2+}$ and $[CpTa(NtBu)]^{2+}$[1] (Scheme 2). The reactions indicate that

Scheme 2. The bonding capability of electronically related imidoyl complex fragments $[Cp_nM'(NR)_m]$ of Groups 5 and 6. a) $[Mo(NtBu)_2Cl_2]$, b) $[W(NtBu)_2Cl_2(py)_2]$, c) $[CpNb(NtBu)Cl_2]$, d) $[CpTa(NtBu)Cl_2]$. R = *t*Bu, py = pyridine.

these d-metal acids are electronically related, and the isolobal relationship with the carbonyl complex fragments is thereby established. On the basis of the spectroscopic data of **1**–**4** (Table 1), the presence of bridging ligands can be excluded. On the other hand, according to the isolobal principle[10] the characterization of **1**–**4** sets up a conceptual bridge between the doubly metalated zirconocene [Ru]–$[Cp_2Zr]$–[Ru], described by Casey et al. ([Ru] = $[CpRu(CO)_2]$[11]) and stannylene-bridged complexes of the type [M]–$[SnR_2]$–[M] (M = Fe, Ru, Mo, etc).[12]

We now contrast this series of—in the broadest sense—carbene-like[13] imido complex fragments with a series of radical complex fragments (Scheme 1, bottom). The radical fragments have not yet been isolated as monomeric d^1 species; however, they form homonuclear, diamagnetic dimers by direct M–M coupling,[1, 14] similar to 17VE metal carbonyl complex fragments. Cross dimerization of these metal radicals with the 17VE complex fragment $[CpFe(CO)_2]$ has now led to a series of diamagnetic, mixed-valent imido complexes that we were able to characterize. The formal principle of the series rests upon the cyclopentadienyl–imido analogy. Like the parent compound **5**,[9] **6**–**8** can be synthesized by reaction of the metal nucleophile $[CpFe(CO)_2]^-$ with the organometallic Lewis acids $[CpW(NtBu)_2]^+$,[15] $[CpMo(NtBu)_2]^+$,[15] and $[Cp_2Nb(NtBu)]^+$[1] (Scheme 3). The spectroscopic data of **6**–**8** clearly indicate a nonbridged metal–metal bond, as is present in $[(tBuN)_3Re–Mo(CO)_3Cp]$[9] and $[Cp^*(O)_2W–W(CO)_3Cp^*]$ ($Cp^* = \eta^5$-C_5Me_5) (Table 1).[16] The results make it seem plausible that the imido complex fragments depicted at the bottom of Scheme 1 are not only isolobal to one another, but that they should also have similar valence orbitals to a (R_3E) group (E = Si, Ge, Sn) or the 17VE carbonyl complex fragments.[17]

Scheme 3. The bonding capability of electronically related imidoyl complex fragments $[Cp_nM'(NR)_m]$ of Groups 5–7. a) $[Re(NtBu)_3Cl]$, b) $[CpW(NtBu)_2Cl]$, c) $[CpMo(NtBu)_2Cl]$, d) $[Cp_2Nb(NtBu)Cl]$. R = *t*Bu.

Table 1 summarizes selected spectroscopic data of the complexes **1**–**8**, which have also been characterized by elemental analysis. A comparison of the position of the IR bands ν_s(C=O) and ν_{as}(C=O) in complexes of the type [M″]–$[Fe(CO)_2Cp]$ allows conclusions to be drawn about the decrease of electron den-

sity induced by the metal acid [M″] at the neighboring metal center. The following qualitative ordering of the acceptor character of the cationic Lewis acids $[M'']^{n+}$ can be derived from the extent of the backbonding to the CO ligands (Scheme 4, Table 1, cf. footnote [a]). A similar comparative look at the CO vibra-

$$[SnMe_2]^{2+} > [W(N\mathit{t}Bu)_2]^{2+} \cong [Mo(N\mathit{t}Bu)_2]^{2+} > [CpTa(N\mathit{t}Bu)]^{2+} \cong [CpNb(N\mathit{t}Bu)]^{2+}$$

$$[H]^{+} > [SnMe_3]^{+} \cong [Re(N\mathit{t}Bu)_3]^{+} > [CpW(N\mathit{t}Bu)_2]^{+} \cong [CpMo(N\mathit{t}Bu)_2]^{+} > [Ti(NMe_2)_3]^{+} > [Cp_2Nb(N\mathit{t}Bu)]^{+}$$

Scheme 4. The acceptor character decreases from left to right.

tional bands shows that the oxidation state, despite its formal nature, makes a larger contribution to the Lewis acidity of cationic metal acids—for example $[(\mathit{t}BuN)_3Re]^{+}$ in contrast with $[(Me_2N)_3Ti]^{+}$[19]—than the position of the central atom in the periodic system. It is, after all, the ligands that influence the acceptor character of a metal center decisively by their π-donor ability. In this context the amido (NMe_2) and cyclopentadienyl ligands (η^5-C_5H_5) are stronger donors than the imido ligand ($N\mathit{t}Bu$).

It is worth mentioning that the reactivity of the anion $[Re(NAr)_3]^{-}$ (Ar = 2,6-iPr$_2$C$_6$H$_3$) resembles that of the carbonyl metalates $[Cp_nM(CO)_m]^{-}$.[20] As a result protonation yields a hydride complex with an acidic hydrogen atom. In this regard a comparison with $[R_3Sn-H]$ is also obvious. The hydride complexes $[(\eta^5\text{-}C_5Me_5)_2(PhN)Ta-H]$,[21] $[(\eta^5\text{-}C_5H_5)_2(\mathit{t}BuN)Nb-H]$,[22] and $[(\eta^5\text{-}C_5Me_5)_2(ArN)W-H]$[23] that are isoelectronic with $[(ArN)_3Re-H]$ in the sense of the thesis presented here were also described recently.

Both the reviewed results on hydrides and our own suggest the isolobal relationship formulated in Scheme 1, which is derived from the following rule: If in a complex fragment $[(\eta^5\text{-}C_5R_5)M]$ the ligand η^5-C_5R_5 is substituted for NR and the central atom d^n-M (n = 0, 1, 2) is replaced by an isoelectronic metal center d^n-M′ from the next higher group of the periodic table, a complex fragment [(RN)M′] that has the same number of valence orbitals and valence electrons, and valence orbitals of similar symmetry and energy results.

[3] The "closed-shell anion" RN^{2-} is considered a six-electron donor to a d^n-metal cation, and the "nitrene" RN a four-electron ligand to a metal atom. Irrespective of whether the hetero- or homolytic view is favored, a maximum of one σ and two π bonds to the metal is possible. A comparable statement is valid for the six- and five-electron donors $(\eta^5\text{-}C_5H_5)^{-}$ and $(\eta^5\text{-}C_5H_5)^{\cdot}$. In complexes with several competing π donors, the bond order deviates from the maximum value of 3 depending on the molecular symmetry. The bond description M=NR chosen consistently in this paper includes the high triple-bond component M≡NR that is typical for d-electron-poor complexes: W. A. Nugent, J. M. Mayer, *Metal-Ligand Multiple Bonds*, Wiley, New York, **1988**.

Soc.* **1992**, *114*, 10557–10563; d) M. H. Schofield, T. P. Kee, J. T. Anhaus, R. R. Schrock, K. H. Johnson, W. M. Davis, *Inorg. Chem.* **1991**, *30*, 3595–3640; e) see also [6], [7] and [20].
[5] If the two ligands approach the metal center along the z axis, orbitals of the same symmetry interact: σ, 2π-donor RN^{2-}: N(sp hybrid, p_z, s) → M(d_{z^2}, p_z, s); N(p_x) → M(d_{xz}, p_x); N(p_y) → M(d_{yz}, p_y). σ, 2 π-Donor $C_5H_5^{-}$: $C_5(a_1, a_2)$ → M(d_{z^2}, p_z, s); $C_5(e_1)$ → M(d_{xz}, p_x); $C_5(e_1)$ → M(d_{yz}, p_y). A δ-backbond M(d_{xy}, $d_{x^2-y^2}$) → $C_5(e_2)$ has no or a comparatively small significance in d-electron-poor complexes of d^n (n = 0, 1, 2) configuration.

[**] Alkyl- and Arylmetal Compounds, Part 52. This research was supported by the Fonds der Chemischen Industrie. We thank Prof. K. Weighardt, Universität Bochum, for the gift of *N,N′,N″*-trimethyl-1,4,7-triazacyclononane L. – Part 51: [1].

monomeric or dimeric adducts $[MgR_2L_n]_m$ ($m = 1,2$).[1-4] In a few cases[5, 6] treatment with cryptands or crown ethers leads to disproportionation into organomagnesium cations and anions (organomagnesates).[4]

As part of our ongoing systematic investigations we tested the cyclic tripod amine ligand *N*,*N*′,*N*″-trimethyl-1,4,7-triazacylononane (tacn),[7] introduced into coordination chemistry by K. Wieghardt et al., for its suitability as a basic solvent for dimethylmagnesium. The nonequimolar reaction[8] of $[MgMe_2]_n$ with tacn (7:4) in benzene [Eq. (a)] also proceeded by

$$7\,MgMe_2 + 4\,tacn \xrightarrow{C_6H_6} \underset{\mathbf{1}}{[(tacn)Mg(\mu\text{-}Me)_3Mg(tacn)]_2^+[Mg_3Me_8]^{2-}] \cdot 1.5\,C_6H_6} \quad (a)$$

disproportionation and unexpectedly yielded the product bis[tri-μ-methyl-bis(tacn)-dimagnesium] octamethyltrimagnesate · 1.5 benzene **1**, which provided the crystal structure shown in Figures 1 and 2 (cited in ref.[2]).

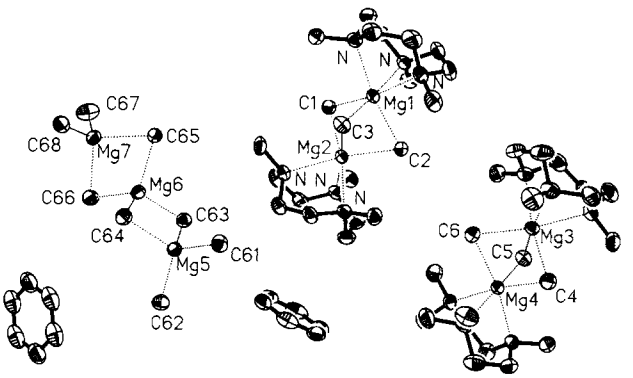

Fig. 1. Crystal stucture of **1** [10] (asymmetric unit with benzene molecules). Selected distances [pm] and angles [°] in the anion: Mg5-C61 217.4(2), Mg5-C62 216.0(3), Mg5-C63 235.7(2), Mg5-C64 234.5(3), Mg6-C63 222.6(3), Mg6-C64 224.2(2), Mg6-C65 223.8(3), Mg6-C66 222.9(2), Mg7-C65 236.5(2), Mg7-C66 235.4(3), Mg7-C67 216.1(3), Mg7-C68 215.7(3); C63-Mg6-C64 108.4(1), C63-Mg6-C65 103.5(1), C63-Mg6-C66 112.0(1), C64-Mg6-C65 120.1(1), C64-Mg6-C66 107.2(1), C65-Mg6-C66 105.8(1), C61-Mg5-C62 117.7(1), C67-Mg7-C68 123.4(1).

Recently, similar disproportionation products, namely $[MgR(14N4)]^+[MgRX_2]^-$ and $[MgR(14N4)]^+X^-$ (R = *i*Pr, *i*Bu, etc., 14N4 = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, X = halogen) were described but were only characterized by NMR spectroscopy.[9]

The asymmetric structural unit of **1**[10] (Fig. 1) contains two cations that are only slightly different crystallographically, which may be described as triple-decker complexes: two Mg atoms coordinated to tacn ligands are bridged by three central methyl groups. The latter are arranged in staggered positions with respect to the N atoms of the tacn ligands as is shown in a projection along the Mg–Mg axis (Fig. 2). This structure type is new for organomagnesium compounds; a similar cation is found only in $[(pmdta)Mg(\mu\text{-}Me)_2Mg(pmdta)]^{2+}(fluorenide)_2^-$ (pmdta = $Me_2N(C_2H_4)N(Me)(C_2H_4)NMe_2$) described recently by us which contains only doubly bridged and pentacoordinated Mg atoms.[11] By contrast, in **1** the Mg atoms of the cation are bridged by three methyl groups and have octahedral coordination (C-Mg-C angle ca. 90°). The Mg-C-Mg angle is very small in the cations of **1** (ca. 68°) compared with those in $[MgR_2]_n$. The Mg–Mg distance (262.9 pm) is the smallest yet observed in organomagnesium compounds characterized by X-ray analysis.[4, 11-13, 15] Recently a metal–metal interaction was considered for a Mg–Mg distance of 276.8 pm.[15]

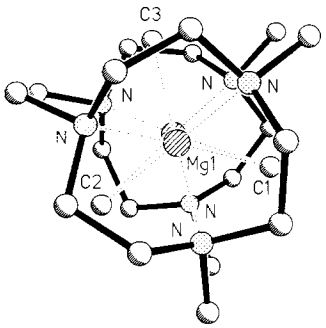

Fig. 2. Triple-decker cation of **1**; view along Mg1–Mg2 (similar to Mg3–Mg4). Selected distances [pm] and angles [°]: Mg1-C1 232.3(2), Mg1-C2 237.8(3), Mg1-C3 237.8(2), Mg2-C1 235.7(2), Mg2-C2 232.5(2), Mg2-C3 236.8(2), Mg-N 230.6(2)–231.9(2), Mg-Mg 262.9(1); C-Mg1-C 90.8(1)–92.2(1), C-Mg2-C 91.6(1)–92.4(1), Mg1-C-Mg2 67.3(1)–68.4(1).

The anion $[Mg_3Me_8]^{2-}$ is the first trimagnesate.[2] It can be described as a section of a polymer chain $[MgMe_2]_n$; however, there are three different groups of Mg–C distances in the anion. Only the distances from Mg6 to the neighboring C atoms (223–224 pm) correspond to the value in $[MgMe_2]_n$ (224 pm[11]). On the one hand, the Mg–C distances between terminal atoms Mg5 and Mg7 and the bridging methyl groups (ca. 235 pm) are clearly longer and correspond to the values in the cations. On the other hand, the Mg–C distances between the terminal Mg atoms and the terminal methyl groups (ca. 216 pm) are shortened and comparable to those in simple dimethylmagnesium compounds $MgMe_2L$.[3, 14]

The C-Mg-C bond angles at Mg6 are clearly different (103.5 to 120.1°) but correspond, on the average, to those reported for the polymer. The angle between the terminal methyl groups and their Mg atoms (123.4 and 117.7°) is greatly expanded in comparison to the tetrahedral angle (109.5°). The Mg–Mg distances, 280.6 and 277.6 pm, are larger than those in the cations and in the dialkylmagnesium polymers.

Experimental Procedure

Dimethylmagnesium (0.5 g, 9 mmol) and tacn (1.0 mL, 0.85 g, 5 mmol) were dissolved in 50 mL of benzene with rigorous exclusion of air and water. After the solution had been stirred for three days it was filtered, concentrated to the saturation point, and kept at 7 °C during crystallization. Colorless crystals, yield 0.7 g (46% based on $MgMe_2$), soluble in benzene, very sensitive to air and hydrolysis. Correct analytical values were obtained for C, H, N, Mg.

A Kinetic Study of the Hydrolysis of Phosgene in Aqueous Solution by Pulse Radiolysis**

Ralf Mertens, Clemens von Sonntag,* Johan Lind, and Gabor Merenyi

Phosgene is a very important industrial product with an annual production of approximately 2 million tons.[1] Phosgene is also an end product of the free radical induced degradation of chlorinated hydrocarbons (this is well-documented in the gas phase).[2] In recent years "advanced oxidation processes", which are based on the formation of OH radicals (e.g. UV/hydrogen peroxide, UV/ozone, ozone/hydrogen peroxide), have been gaining in importance for the treatment of not only wastewater but also polluted drinking water.[3] The mechanism of the OH•-induced degradation of chlorinated hydrocarbons can be readily studied by pulse radiolysis using conductometric detection, since the liberation of chloride ions (and concomitantly protons) in the course of the oxidative degradation cascade is accompanied by a conductance change. In order to assign one of the kinetic components of this conductance change to a given elementary step, for example the hydrolysis of phosgene, the kinetic parameters of the reaction must be determined independently. Two reports focus on the rate of reaction of phosgene with water,[4, 5] but only one of them is relevant to the present work.[5] In that study, pure phosgene gas was dissolved in short laminar jets of aqueous solutions, the hydrochloric acid taken up by the aqueous solutions titrated, and the results interpreted within the framework of nonsteady-state absorption-plus-reaction theory. The reported rate constants extrapolated to 25 °C were $6\ s^{-1}$ for the spontaneous and $1.6 \times 10^4\ dm^3\ mol^{-1}\ s^{-1}$ for the OH^--induced hydrolysis. We report here on our determination of these rate constants by a different approach: the pulse radiolysis technique. This technique is largely used for the investigation of free-radical reactions.[6, 7] However, our results show that pulse radiolysis is also suitable for studying the kinetics of nonradical reactions, which are of wider interest.

In the radiolysis of water, OH radicals, solvated electrons, and H atoms are formed as free-radical intermediates [reaction (1)]. Hydroxyl radicals and solvated electrons are formed in about equal amounts [$G(^{\bullet}OH) \approx G(e_{aq}) \approx 2.8 \times 10^{-7}\ mol\ J^{-1}$; G = amount of a given species formed in mol relative to the absorbed energy of ionizing radiation in J], while the formation of H atoms is less significant [$G(H^{\bullet}) \approx 0.6 \times 10^{-7}\ mol\ J^{-1}$].[8] The OH radicals do not react with carbon tetrachloride in solution, but solvated electrons and the H atoms readily yield trichloromethyl radicals [reactions (2) and (3), $k_2 = 1.6 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$, $k_3 = 3.8 \times 10^7\ dm^3\ mol^{-1}\ s^{-1}$].[9] Two conceivable routes lead from the trichloromethyl radical to phosgene via the (potentially very shortlived) intermediate, trichloromethanol: the trichloromethyl radical can react with the OH radical [reaction (4)], or the trichloromethyl radical can react with O_2 to give the trichloromethylperoxyl radical [reaction (5)], which is then reduced with the iodide ion [reaction (6)].[10] In reactions (4)–(7) trichloromethanol and phosgene are formed in situ very rapidly, and their hydrolysis [reactions (7)–(9)] can be followed by changes in conductivity. We will discuss both routes.

$$H_2O \xrightarrow[\text{radiation}]{\text{ionizing}} e_{aq}, {}^{\bullet}OH, H^{\bullet}, H^+, OH^-, H_2O_2, H_2 \quad (1)$$

$$CCl_4 + e_{aq} \longrightarrow {}^{\bullet}CCl_3 + Cl^- \quad (2)$$

$$CCl_4 + H^{\bullet} \longrightarrow {}^{\bullet}CCl_3 + H^+ + Cl^- \quad (3)$$

$${}^{\bullet}CCl_3 + {}^{\bullet}OH \longrightarrow CCl_3OH \quad (4)$$

$${}^{\bullet}CCl_3 + O_2 \longrightarrow CCl_3OO^{\bullet} \quad (5)$$

$$CCl_3OO^{\bullet} + 3I^- + 3H^+ \longrightarrow CCl_3OH + I_2 + I^- + H_2O \quad (6)$$

$$CCl_3OH \longrightarrow Cl_2C{=}O + H^+ + Cl^- \quad (7)$$

$$Cl_2C{=}O + H_2O \longrightarrow CO_2 + 2H^+ + 2Cl^- \quad (8)$$

$$Cl_2C{=}O + OH^- \longrightarrow CO_2 + H^+ + 2Cl^- \quad (9)$$

Argon-purged, aqueous solutions saturated with CCl_4 were subjected to 1-μs pulses of high-energy electrons (2.7 MeV). Right after the pulse, when the excess conductivity due to the formation of H^+ and OH^- during the pulse had decayed, an increase in conductivity was observed which was equivalent to $3.4 \times 10^{-7}\ mol\ J^{-1}$ (based on the formation of a proton and an anion) (Fig. 1). This increase in conductivity can be accounted

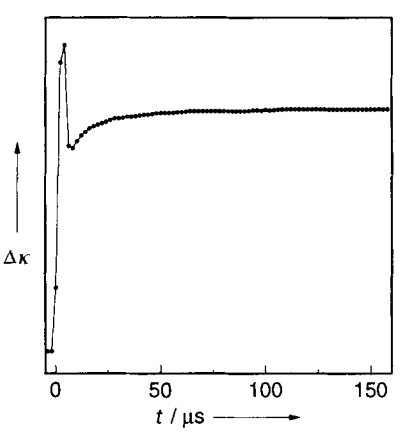

Fig. 1. Pulse radiolysis of an Ar-purged aqueous CCl_4 solution at 25 °C. The change of conductivity κ as a function of time (up to 150 μs) reflects the reaction of solvated electrons and H atoms with CCl_4 and the formation and (instantaneous) decay of CCl_3OH.

for by reactions (2) and (3). The radicals formed, $^{\bullet}CCl_3$ and $^{\bullet}OH$, react bimolecularly according to reactions (4), (10), and (11). The rate constants of reactions (10) and (11) are known ($2k_{10} = 7.4 \times 10^8$ dm^3 mol^{-1} s^{-1};[11] $2k_{11} = 1.1 \times 10^{10}$ dm^3 mol^{-1} s^{-1}[9]). Considering the large rate constant for dimeriza-

$$2\,^{\bullet}CCl_3 \longrightarrow C_2Cl_6 \quad (10)$$

$$2\,^{\bullet}OH \longrightarrow H_2O_2 \quad (11)$$

tion of the OH radical, we may assume k_4 to be 6×10^9 dm^3 mol^{-1} s^{-1}. For applied doses of 12 to 60 Gy per pulse this leads to a first half-life of radical decay in the order of 5 to 16 μs and the formation of CCl_3OH of about 30% of the primary CCl_3 radicals (estimated by computer simulation). After the neutralization of H^+ and OH^- formed during the pulse [reaction (1)] there is an increase in conductivity between 5 and 16 μs (Fig. 1). An exact evaluation of the yield of this conductivity increase is not possible, since decay by neutralization and buildup overlap. An increase in conductivity means that at the given pH (ca. 5.5–6.0) CCl_3OH is either fully deprotonated [reaction (12)] or it hydrolyzes as soon as it formed ($k_7 \geq 8 \times 10^4$ s^{-1}).

Assuming $pK_a(CH_3OH) = 16$ and using the reported[12] increments for the electron-withdrawing effect of Cl substituents, one estimates $pK_a(CCl_3OH)$ to be 3.5–4 [equilibrium (12)/(−12)]. Even this very rough estimate indicates that at the pH of the above experiments the observed increase in conductivity may in fact be due to reaction (12). However, after the deprotonation of CCl_3OH, the subsequent chloride ion loss must be very fast, and hence we conclude that CCl_3OH must hydrolyze very rapidly indeed. The previously mentioned value of $k_7 \geq 8 \times 10^4$ s^{-1} is, of course, only a lower limit. The hydrolysis of CCl_3OH can, in fact, be much faster. A geminal chlorohydrin similar to trichloromethanol (albeit with an unpaired electron in the β position) is formed when the OH radical reacts with tetrachloroethene [reaction (13)]. In this case HCl is liberated within 3 μs [reaction (14)],[13] which implies $k_{14} \geq 7 \times 10^5$ s^{-1}. We thus conclude that phosgene is produced in situ at times ≤ 50 μs. Any further increase of conductivity in this system must then be due to its hydrolysis.

$$CCl_3OH \rightleftharpoons CCl_3O^- + H^+ \quad (12/-12)$$

$$CCl_2{=}CCl_2 + {}^{\bullet}OH \longrightarrow {}^{\bullet}CCl_2{-}CCl_2OH \quad (13)$$

$$^{\bullet}CCl_2{-}CCl_2OH \longrightarrow {}^{\bullet}CCl_2{-}C(O)Cl + H^+ + Cl^- \quad (14)$$

As can be seen from Figure 2 there is a third conductivity increase in the 100-ms time range. This increase is equivalent to 2.2×10^{-7} mol J^{-1}, and its half-life is independent of the dose rate (dose per pulse). From these data it follows that the rate constant of the spontaneous hydrolysis of phosgene at 25 °C is $k_8 = 9$ s^{-1}.

Additional experiments have been conducted in basic solutions. There, formation of H^+ and Cl^- leads to a decrease in conductivity, since the strongly conducting OH^- ions are replaced by the less conducting Cl^- ions. The conductivity decrease in the third time domain was measured as a function of the OH^- concentration, and it was found that the rate of conductivity change increases with increasing OH^- concentration. In basic solutions the kinetics of the conductivity change are not monoexponential. This was expected, since the reported[5] value of $k_9 = 1.6 \times 10^4$ dm^3 mol^{-1} s^{-1} is close to that of the reaction of OH^- with CO_2 [$k(OH^- + CO_2 \rightarrow HCO_3^-) = 6.9 \times 10^3$ dm^3 s^{-1}].[14] The conductivity in the present experiments was evaluated by fitting only the first (faster) part of the conductivity change to a first-order reaction. The results are shown graphically in the inset in Figure 2 (○). The data fall on a straight line, whose slope yields $k_9 = 2.8 \times 10^4$ dm^3 mol^{-1} s^{-1} which is in very reasonable agreement with the literature value.[5]

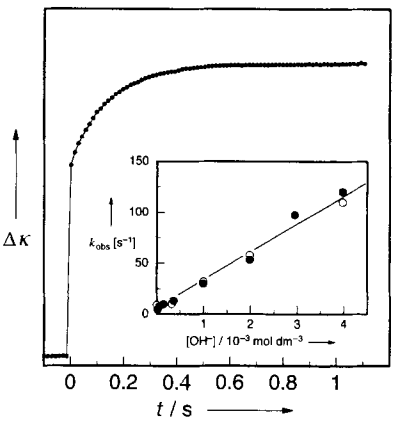

Fig. 2. Pulse radiolysis of an Ar-purged aqueous CCl_4 solution at 25 °C. The change of conductivity as a function of time (up to 1 s) reflects the hydrolysis of phosgene. Inset: Hydrolysis of phosgene in basic solution; observed rate of conductivity change as a function of the OH^- concentration. ○: $^{\bullet}CCl_3$ plus $^{\bullet}OH$ route; ●: $CCl_3O_2^-$ plus I^- route.

We conducted some γ-radiolysis and product analysis studies to confirm the formation of phosgene in the present system. We found that CO_2 [$G(CO_2) = 1.0 \times 10^{-7}$ mol J^{-1}], C_2Cl_6 [$G(C_2Cl_6) = 0.5 \times 10^{-7}$ mol J^{-1}], and Cl^- [$G(Cl^-) = 6.8 \times 10^{-7}$ mol J^{-1}] form. These data are not expected to fully reflect the pulse radiolysis results, since under the conditions of γ-radiolysis the OH radicals not only undergo reactions (4) and (11) but also react with the products, bicarbonate and H_2O_2. Strong evidence for the scavenging of OH radicals by the radiolysis products is given by the low H_2O_2 yield, $G(H_2O_2) = 0.55 \times 10^{-7}$ mol J^{-1}, which is only one-third of the value expected based on the total amount of H_2O_2 [from reactions (1) and (11)]. These side reactions do not play a role in the single-pulse experiments described previously and do not affect the kinetic data.

Trichloromethylperoxide radicals that form in oxygen-containing aqueous solutions react readily with iodide ions.[10] An adduct forms [reaction (15)], which reacts with a further iodide ion, whereby a trichloromethoxyl radical is formed and a molecule of iodine is liberated [reaction (16)]. In a subsequent step the trichloromethoxyl radical is reduced by an iodide ion to the trichloromethanol anion [reaction (17)], which loses a chloride ion to form phosgene [reaction (18)].

$$CCl_3OO^{\bullet} + I^- \longrightarrow [CCl_3OOI]^{\bullet -} \quad (15)$$

$$[CCl_3OOI]^{\bullet -} + H^+ + I^- \longrightarrow CCl_3O^{\bullet} + I_2 + OH^- \quad (16)$$

$$CCl_3O^{\bullet} + I^- \longrightarrow CCl_3O^- + I^{\bullet} \quad (17)$$

$$CCl_3O^- \longrightarrow Cl_2C{=}O + Cl^- \quad (18)$$

Under our experimental conditions (CCl_4 and iodide ions both 10^{-3} mol dm^{-3}, pH 4, Ar:O_2 = 10:1) the OH radical generated by radiolysis is scavenged by the iodide ion [reaction (19)]. Although both molecular iodine and iodine atoms form complexes with iodide ions [reactions (20) and (21)], this

$$^{\bullet}OH + I^- \longrightarrow OH^- + I^{\bullet} \quad (19)$$

$$I_2 + I^- \rightleftharpoons I_3^- \quad (20/-20)$$

$$I^{\bullet} + I^- \rightleftharpoons I_2^{\bullet -} \quad (21/-21)$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1212-1260 $ 10.00+.25/0

does not cause a change in conductivity. This whole sequence of reactions proceeds at times $\leq 40\ \mu s$,[10] much faster than the subsequent hydrolysis of phosgene. Hence the kinetics of this reaction can be studied fairly easily.

Following radiolysis carbon dioxide was also measured ($G(CO_2) = 2.45 \times 10^{-7}\ mol\,J^{-1}$). Considering that under our experimental conditions all H atoms and 5% of the solvated electrons are scavenged by O_2, one would expect CO_2 to be formed with $G(CO_2) = 2.65 \times 10^{-7}\ mol\,J^{-1}$. The measured value agrees well with that calculated and thus supports the proposed mechanism.

In acid solutions the sum of reactions (1), (2), (5), and (15)–(19) leads to a drop in conductivity (consumption of 2 mol equiv of H^+). The hydrolysis of phosgene [liberation of 2 mol equiv of H^+, reaction (8)] causes the conductivity to return to its prepulse value (Fig. 3).

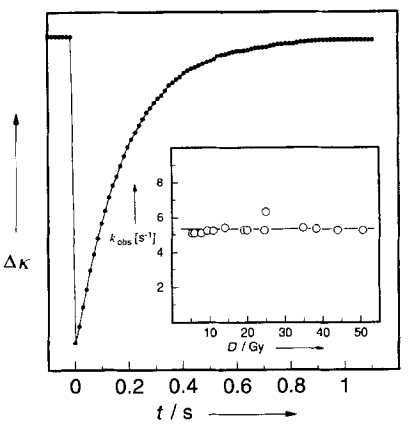

Fig. 3. Pulse radiolysis of aqueous CCl_4 solutions containing O_2 and iodide ions at 20 °C. The recovery of the conductivity drop reflects the hydrolysis of phosgene. Inset: The observed rate constant of phosgene hydrolysis as a function of dose D.

A series of experiments were also conducted at high pH to obtain additional data for the OH^--induced hydrolysis of phosgene [reaction (9)]. These data are included in the inset in Figure 2 (●). They agree well with the values determined with the $^{\bullet}CCl_3 + {}^{\bullet}OH$ method (○).

The data shown in Figure 3 are from experiments carried out at 20 °C, that is, at a lower temperature than those in Figure 2. Since the rate of the spontaneous hydrolysis of phosgene strongly increases with increasing temperature,[5] it is not surprising that at 20 °C $k_8 = 5.3\ s^{-1}$ is found (cf. inset in Fig. 3).

In the earlier study[5] the hydrolysis of phosgene was studied at only two temperatures (open circles in Fig. 4). The pulse-radiolysis technique allows a larger temperature range, and hence more reliable kinetic parameters can be obtained. Figure 4 shows an Arrhenius plot covering the temperature range from 13 to 59 °C. The slope of the straight line drawn through the experimental points yields $A = 1.4 \times 10^{10}$ and $E_a = 53\ kJ\,mol^{-1}$.

Figure 4 shows that the data from the two different approaches we used agree very well, and that the data obtained by the laminar jet method[5] are not very far off. This was not expected, since many assumptions were made in the evaluation of the laminar jet data.[5] Our value for the hydrolysis of phosgene is also in the range of activation energies reported for the gas-phase reaction ($14-60\ kJ\,mol^{-1}$).[1] It is noted that in the gas phase this activation energy is much more difficult to determine[1] and fraught with larger errors (e.g. wall effects) than those encountered in our pulse-radiolysis experiments.

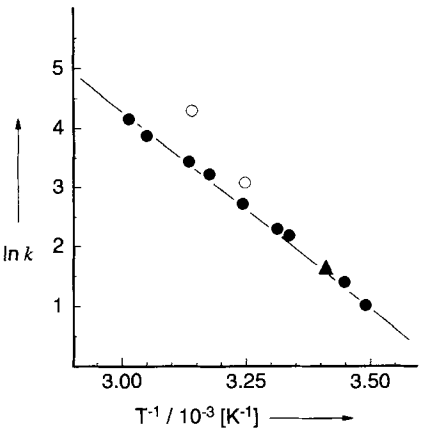

Fig. 4. Arrhenius plot of phosgene hydrolysis. ●: pulse radiolysis, $CCl_3O_2^-$ plus I^- approach; ▲: pulse radiolysis, $^{\bullet}CCl_3$ plus $^{\bullet}OH$ approach; ○: laminar jet method [5].

Experimental Procedure

Aqueous solutions saturated with CCl_4 (>99% Merck), which contained an excess of CCl_4 to guarantee saturation, were purged with argon (99.99%) to free the solutions from oxygen. For pulse radiolysis a 2.7 MeV Van de Graaff electron accelerator delivering electron pulses of 1-μs duration was used. Details have been described in ref. [7]. For measuring the temperature dependence of the kinetics of the phosgene hydrolysis, the solution was kept in a thermostated reservoir. A thermocouple was inserted into the waste tube of the conductivity cell [7] to measure the temperature as closely as possible. The dose rate of the γ-radiolysis experiments was $0.19\ Gy\,s^{-1}$. Hydrogen peroxide was determined according to ref. [15], carbon dioxide according to ref. [16], and chloride ions by ion chromatography (Dionex 2010i).

Determination of the Kinetics of Vinyl Radical Reactions by the Characteristic Visible Absorption Spectra of Vinylperoxyl Radicals**

Ralf Mertens and Clemens von Sonntag*

Vinyl radicals are quite ubiquitous. They are formed, for example, when vinyl halides are photolyzed [e.g. reaction (1)][1]

$$Cl_2C{=}CCl_2 + h\nu \longrightarrow Cl_2C{=}CCl^{\bullet} + Cl^{\bullet} \quad (1)$$

and are thus important intermediates in the photodegradation of anthropogenic environmental pollutants such as tetrachloroethene, trichloroethene, and vinyl chloride. *cis*-Dichloroethene and vinyl chloride also arise from the bacterial degradation of tetrachloro- and trichloroethene contaminants in the soil. 5-Bromouracil (5-BrUra) may be used to substitute thymine in DNA. This renders the 5-BrUra-substituted strand photolabile, and again vinyl radicals play an important role.[2] Vinyl radicals are also generated when free radicals add to acetylene and its derivatives.[3]

For our ongoing studies on the UV photolysis of vinyl halides in air[4] and in oxygenated aqueous solutions[5] we required further kinetic data concerning the fate of these radicals in the presence of oxygen. To ascertain whether these radicals react readily with oxygen, as nearly all carbon-centered radicals do,[6] we used the pulse radiolysis technique[7, 8] which has proven to be an excellent tool for studying the formation and reactivity of peroxyl radicals in aqueous solutions.[9]

Carbon-centered peroxyl radicals usually show noncharacteristic UV absorption spectra in the range $\lambda < 300$ nm and no significant absorption in the visible region. Surprisingly, the vinylperoxyl radicals, especially the chlorine-substituted ones, showed a strong absorption in the visible region, which can be used to study the kinetics of vinylperoxyl radical reactions as well as of the reactions of the vinyl radicals and their competing reaction with oxygen.

Vinylperoxyl radicals were generated by pulse radiolysis.[8] A short pulse (1 μs) of high-energy electrons (2.8 MeV) applied to an O_2-containing aqueous solution of vinyl halides (10^{-3} mol dm^{-3}) gives rise to solvated electrons (e_{aq}), OH radicals, and H atoms [reaction (2)]. Their radiation chemical yields are $G(e_{aq}) \approx G(^{\bullet}OH) \approx 2.8 \times 10^{-7}$ mol J^{-1} and $G(H^{\bullet}) \approx 0.6 \times 10^{-7}$ mol J^{-1}. The solvated electrons react rapidly with the vinyl halides by dissociative electron capture, yielding vinyl radicals and chloride ions[10] [e.g. reaction (3); $k_3 = 1.3 \times 10^{10}$ dm^3 mol^{-1} s^{-1}],[11] in competition with their reaction with oxygen [reaction (4); $k_4 = 1.9 \times 10^{10}$ dm^3 mol^{-1} s^{-1}].[11] The OH radicals and the H atoms add to the double bond of the vinyl halide [e.g. reaction (5); $k_5 = 2.6 \times 10^9$ dm^3 mol^{-1} s^{-1}];[11] in other words, about half of the radical yield consists of vinyl radicals. It is not possible to study the fate of the vinyl radicals separately from that of the OH-adduct radicals generated in reaction (5); however, if the solvated electrons are converted into further OH radicals by saturating the solution with N_2O [reaction (6); $k_6 = 9.1 \times 10^3$ dm^3 mol^{-1} s^{-1}],[11] vinyl radicals are no longer formed.

$$H_2O \xrightarrow{\text{ionizing radiation}} e_{aq}, {}^{\bullet}OH, H^{\bullet}, H^+, H_2O_2, H_2 \quad (2)$$

$$e_{aq} + Cl_2C{=}CCl_2 \longrightarrow Cl_2C{=}CCl^{\bullet} + Cl^- \quad (3)$$

$$e_{aq} + O_2 \longrightarrow O_2^{\bullet -} \quad (4)$$

$$^{\bullet}OH(H^{\bullet}) + Cl_2C{=}CCl_2 \longrightarrow HOCCl_2{-}CCl_2^{\bullet}\ (HCCl_2{-}CCl_2^{\bullet}) \quad (5)$$

$$H_2O + N_2O + e_{aq} \longrightarrow {}^{\bullet}OH + N_2 + OH^- \quad (6)$$

The OH-adduct radicals formed in reaction (5) are known to lose HCl rapidly [reaction (7); $k_7 > 7 \times 10^5$ s^{-1}].[10] The absorption spectrum of the resulting intermediate is shown in Figure 1. In the presence of oxygen this spectrum changes owing to the formation of the corresponding peroxyl radicals [reaction (8)].

$$HOCCl_2{-}CCl_2^{\bullet} \longrightarrow HCl + Cl(O)C{-}CCl_2^{\bullet} \quad (7)$$

$$Cl(O)C{-}CCl_2^{\bullet} + O_2 \longrightarrow Cl(O)C{-}CCl_2O_2^{\bullet} \quad (8)$$

These peroxyl radicals display the typical noncharacteristic UV absorption ≤ 260 nm. The rate of their buildup as a function of the O_2 concentration (inset in Fig. 1) yields a bimolecular

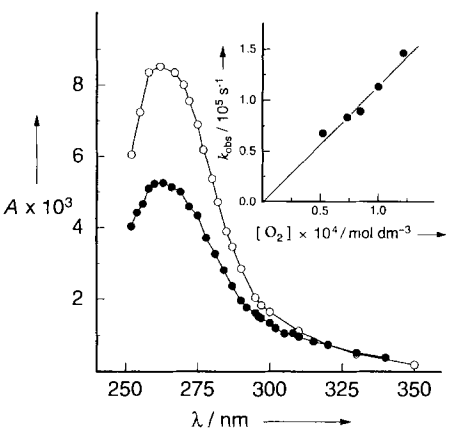

Fig. 1. Pulse radiolysis of N_2O- (○) and N_2O/O_2-saturated (●) aqueous solutions of tetrachloroethene (10^{-3} mol dm^{-3}). Inset: Rate of buildup of the peroxyl radical absorption at 260 nm as a function of the O_2 concentration.

rate constant $k_8 = 1.2 \times 10^9$ dm^3 mol^{-1} s^{-1}. Thus there is nothing unexpected in the behavior of these peroxyl radicals.

When Ar/O_2-saturated, N_2O-free tetrachloroethene solutions are pulse-irradiated, the absorption spectrum shown in Figure 2

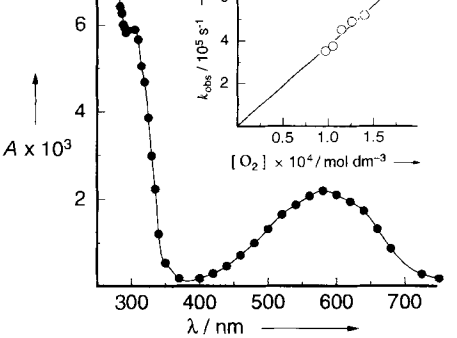

Fig. 2. Pulse radiolysis of Ar/O_2 (9/1)-saturated aqueous solution of tetrachloroethene. Absorption spectrum after completion of the reactions with O_2. Inset: Rate of buildup of the trichlorovinylperoxyl radical absorption at 580 nm as a function of the O_2 concentration.

develops. Besides an absorption in the UV there is now also a strong absorption in the visible. The data in Figure 2 (inset) yield a rate constant $k_9 \approx 3.8 \times 10^9\ dm^3\,mol^{-1}\,s^{-1}$. Since this absorption did not occur in the absence of trichlorovinyl radicals (see above), we assume that the trichlorovinyl radical reacts very rapidly with oxygen [reaction (9)] and that the species with

$$Cl_2C{=}CCl^{\bullet} + O_2 \longrightarrow Cl_2C{=}CClO_2^{\bullet} \quad (9)$$

the absorption maximum at 580 nm is the trichlorovinylperoxyl radical. The shoulder at 305 nm is also assigned to this radical, as the peroxyl radicals resulting from OH and H addition [reactions (5)–(8)] absorb at shorter wavelengths (cf. Fig. 1). Further vinylperoxyl radicals are produced from trichloroethene, *cis*- and *trans*-1,2-dichloroethene, 1,1-dichloroethene, vinyl bromide, and 5-bromouracil. Pulse-irradiation of trichloroethene generates 1,2- and 1,1-dichlorovinyl radicals in a ratio of 4:1, (R. Mertens, C. von Sonntag, unpublished results); in the other cases only one vinyl radical species is generated. The absorption spectra of the corresponding peroxyl radicals are shown in Figure 3; the absorption maxima and molar absorption coefficients are compiled in Table 1. The dichlorovinylperoxyl radical, like

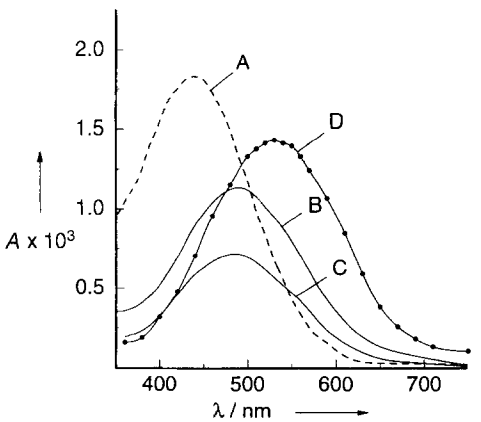

Fig. 3. Absorption spectra of halogenated vinylperoxyl radicals in the visible: A: vinylperoxyl, B: 2-chlorovinylperoxyl, C: 1-chlorovinylperoxyl, D: 1,2-dichlorovinylperoxyl/1,1-dichlorovinylperoxyl (4/1).

are compiled in Table 1. The dichlorovinylperoxyl radical, like the trichlorovinylperoxyl radical, displays a shoulder in the UV [$\varepsilon(300\ nm) \approx 3000\ dm^3\,mol^{-1}\,cm^{-1}$]. The absorptions of the other vinylperoxyl radicals also increase in the UV (< 330 nm) without exhibiting well-defined maxima or shoulders at $\lambda > 280$ nm. The vinyl halides and oxygen compete for the solvated electron [cf. reactions (3) and (4)]. On account of the high volatility of most of the vinyl halides used in this study, their concentrations are not known as exactly as would be required for assessing the molar absorption coefficients with an accuracy of better than 10%.

Table 1. Absorption maxima of vinylperoxyl radicals in the visible region and the corresponding molar absorption coefficients.

Radical	λ_{max} [nm]	ε [$dm^3\,mol^{-1}\,cm^{-1}$]	Radical	λ_{max} [nm]	ε [$dm^3\,mol^{-1}\,cm^{-1}$]
$H_2C{=}CHO_2^{\bullet}$	440	1100 [a]	$Cl_2C{=}CClO_2^{\bullet}$	580	1300
$ClHC{=}CHO_2^{\bullet}$ [b]	480	890	uracil-5-$O_2^{\bullet}$	570	950
$ClHC{=}CHO_2^{\bullet}$ [c]	480	900	phenyl-$O_2^{\bullet}$	490	1600
$H_2C{=}CClO_2^{\bullet}$	480	530	anisyl-$O_2^{\bullet}$	600	2100
$ClHC{=}CClO_2^{\bullet}/Cl_2{=}CHO_2^{\bullet}$ (4/1)	540	1100			

[a] Lower limit; the vinyl bromide concentration was difficult to control because of the high volatility of vinyl bromide. [b] From *cis*-dichloroethene. [c] From *trans*-dichloroethene.

With an increasing number of chlorine substituents the absorption maximum of the peroxyl radicals undergoes a red-shift. It can be readily calculated that the energy of the transition drops by about 22 $kJ\,mol^{-1}$ per Cl substituent; it does not seem to matter whether the Cl atom is α or β to the peroxyl radical function.

The nature of the transitions that cause these surprising spectra is not yet known. It is noted, however, that the arylcarbinyloxyl radicals $ArCR_2O^{\bullet}$,[12] analogues of the arylperoxyl radicals $ArO_2^{\bullet}$ (cf. Table 1, see also ref. [13]), and the alkylthioperoxyl radicals RSO_2[14] both show absorption in the visible. Thus it may well be possible that these transitions are made possible by the interaction of the unpaired electron with the π system or the d orbitals at sulfur, respectively. These transitions are then possibly a kind of charge transfer band (cf. ref. [12]).

When the inverse of the first half-life of the decay of the vinylperoxyl and the chlorinated vinylperoxyl radicals is plotted as a function of the dose per pulse (i.e. initial peroxyl radical concentration), a straight line with an intercept close to zero is obtained. This means that they largely decay by reacting with one another and with the other peroxyl radicals present in these systems. Rate constants for the bimolecular termination on the order of $10^9\ dm^3\,mol^{-1}\,s^{-1}$ are calculated from this kind of plot. They are not much different from those found for the OH$^{\bullet}$ addition reaction [reaction (5); cf. Table 2].

However, very different behavior is displayed by the 5-bromouracil-derived vinylperoxyl radical, which undergoes very rapid unimolecular decay ($k = 6 \times 10^4\ s^{-1}$). In view of such a high rate it is not expected that bimolecular decay processes could compete significantly, given the relatively low peroxyl radical concentrations obtainable in our pulse-radiolysis experiments. Hence its decay is practically independent of the dose rate, in contrast to the other vinylperoxyl radicals. In agreement with the existence of a true unimolecular reaction the half-life is independent of the 5-bromouracil concentration. The final product of this reaction has been reported to be isodialuric acid.[15] It had in fact been postulated[15] to arise from some kind of an unimolecular decay process, but experimental evidence was lacking until now; further details still remain to be elucidated.

The addition of halogenated alkylperoxyl radicals such as trichloromethylperoxyl radicals to olefins has been reported recently, and the rate of this reaction has been shown to depend strongly on the Taft σ^* values of the substituents on the olefin.[16] No such first-order decay component was observed in the present systems at a concentration of the chlorinated olefin of about $10^{-3}\ mol\,dm^{-3}$. This is not surprising, since with chlorine substituent(s) at the C=C double bond the rate constant of peroxyl radical addition should be drastically reduced. Product analyses of the degradation of chlorinated olefins in aqueous solutions at low dose rates ($0.25\ Gy\,s^{-1}$) and upon UV photolysis (fluence at 254 nm $9\ Wm^{-2}$) indicate that the addition reaction of vinylperoxyl radicals to the chlorinated olefin must be very slow indeed and does not compete with the bimolecular decay of the peroxyl radicals.

Vinyl radicals do not show an appreciable absorption in the easily accessible spectral region[10] (confirmed in the present study); hence it is not possible to measure by spectroscopy their rate of reaction with a substrate as long as the ensuing substrate

Table 2. Compilation of rate constants determined by pulse radiolysis. The starred values were determined by product analysis.

Reaction	k [$dm^3 mol^{-1} s^{-1}$]	Reaction	k [$dm^3 mol^{-1} s^{-1}$]
$H_2C=CH^{\bullet} + O_2$	4.6×10^9	ClHC=CCl•/$Cl_2C=CH^{\bullet}$ (4/1) + propan-2-ol	6.3×10^6
$ClHC=CH^{\bullet}$ [a] + O_2	4.6×10^9		8.4×10^6
ClHC=CCl•/$Cl_2C=CH^{\bullet}$ (4/1) + O_2	4.3×10^9	$ClHC=CH^{\bullet}$ [a] + propan-2-ol	5.6×10^6
$Cl_2C=CCl^{\bullet} + O_2$	3.8×10^9	$H_2C=CH^{\bullet}$ + propan-2-ol	2.0×10^5
phenyl + O_2	4.6×10^9	phenyl + propan-2-ol	1.2×10^7
p-anisyl + O_2	4.3×10^9	*p*-anisyl + propan-2-ol	1.4×10^7
$COCl-CCl_2O_2^{\bullet} + COCl-CCl_2O_2^{\bullet}$	1.0×10^9	$Cl_2C=CCl^{\bullet}$ + methanol	2.9×10^6
$H_2C=CHO_2^{\bullet} + RO_2^{\bullet}$	1.1×10^9	ClHC=CCl•/$Cl_2C=CH^{\bullet}$ (4/1) + methanol	6.3×10^5
$ClHC=CHO_2^{\bullet}$ [a, b] + $RO_2^{\bullet}$ [c]	8.8×10^8	$ClHC=CH^{\bullet}$ + methanol	2.1×10^5
$ClHC=CClO_2^{\bullet} + RO_2^{\bullet}$ [c]	9.6×10^8	$Cl_2C=CCl^{\bullet}$ + 2-methylpropan-2-ol	1.6×10^5
$H_2C=CClO_2^{\bullet} + RO_2^{\bullet}$ [c]	9.0×10^8	$H_2C=CHO_2^{\bullet}$ + ascorbate	1.9×10^8
$Cl_2C=CClO_2^{\bullet} + RO_2^{\bullet}$ [c]	8.0×10^8	$HCCl=CHO_2^{\bullet}$ + ascorbate	1.6×10^8
uracil-5-$O_2^{\bullet}$ (unimolecular decay)	6.0×10^4 [d]	$HCCl=CClO_2^{\bullet}$ + ascorbate	2.9×10^8
$Cl_2C=CCl^{\bullet}$ + propan-2-ol	4.1×10^7	$H_2C=CClO_2^{\bullet}$ + ascorbate	2.6×10^8
	2.4×10^7	$Cl_2C=CClO_2^{\bullet}$ + ascorbate	2.3×10^8

[a] From *trans*-dichloroethene. [b] From *cis*-dichloroethene. [c] $RO_2^{\bullet}$ results from the bimolecular decay of vinylperoxyl radicals or from the peroxyl radical that arises from the addition of 'OH to the vinyl halide [reaction (5)]. [d] Dimension: s^{-1}.

radical also has no significant absorption. Alcohols are another example. Their radicals resulting from H-abstraction do not absorb strongly in either the UV or the visible.[17] Vinyl radicals undergo rapid H-abstraction reactions [e.g. reaction (10)];[18]

$$Cl_2C=CCl^{\bullet} + HC(CH_3)_2OH \longrightarrow Cl_2C=CHCl + {}^{\bullet}C(CH_3)_2OH \quad (10)$$

now, despite the poor detectability of both the starting and product radical species in reactions such as (10), rate constants can be determined by competition experiments with O_2 [cf. reaction (9)]. Rate constants can be determined in two ways: a) by product analysis: at a fixed O_2 concentration and increasing propan-2-ol concentration the yield of trichloroethene must go up; b) by pulse radiolysis: the absorbance of the vinylperoxyl radical must go down. Rate constants obtained from such measurements are compiled in Table 2.

It can be seen that the rate of reaction of vinyl radicals with alcohols increases with the number of chlorine substituents. The H atoms in methanol and 2-methylpropan-2-ol are more strongly bound than the tertiary one in propan-2-ol. Hence the reactivity of the vinyl radicals with these alcohols is much lower. This competition experiment does not allow the determination of rate constants smaller than 10^6 $dm^3 mol^{-1} s^{-1}$ as long as O_2-saturated solutions ($[O_2] = 1.25 \times 10^{-3}$ $mol\,dm^{-3}$) are used and the alcohol concentration is not increased much above 1 $mol\,dm^{-3}$. However, the range may be extended downward by an order of magnitude when the O_2 concentration is reduced to one-tenth by saturating the solutions with Ar/O_2 in a ratio of 10:1. The rate constants that fall into the range of 10^5–10^6 $dm^3 mol^{-1} s^{-1}$ were determined under these conditions.

Vinylperoxyl radicals are oxidants and may undergo electron transfer reactions, for instance with ascorbate ions. The rate constants were determined by following the buildup of the ascorbate radical absorption at 360 nm. It had been ascertained with the 2-chlorovinylperoxyl radical that its decay corresponds to the buildup of the ascorbate radical. It is noted that these rate constants (Table 2) are similar to those reported for chlorinated alkylperoxyl radicals.[19]

Experimental Procedure

For pulse radiolysis, purified (Millipore Milli-Q) water was saturated with Ar/O_2 mixtures, prior to the addition of appropriate amounts of the (volatile) halides, which were dissolved by prolonged stirring. The purity of the commercially available halides was ≥98%. Because of the high rate constants for the reaction of the halides with solvated electrons [cf. reaction (3)], impurities do not have a material impact on the spectra observed. The pulse-radiolysis setup has been described recently [8]. Some additional experiments were done conducted with ^{60}Co γ-radiation at a dose rate of 0.26 $Gy\,s^{-1}$.

Oxygen-Induced Structural Transformation of the Polynuclear Organoaluminum Complex $[Al_4(\mu_3\text{-8-quinolylimide})_2(CH_3)_8]$ to $[Al_4(\mu_3\text{-8-quinolylimide})_2(CH_3)_7(\mu\text{-}OCH_3)]$**

Steven J. Trepanier and Suning Wang*

Organoaluminum amido and imido complexes have attracted much attention on account of their rich structural and bonding features and potential applications.[1-3] Most of the previous studies focused on the synthesis, structures, and thermal properties of alkylaluminum compounds with monodentate amido or imido ligands, although a few alkylaluminum complexes with bidentate amido ligands have been reported.[2-4] The extensive investigations into the chemical reactivities of trialkylaluminum were promoted by their valuable industrial applications.[5] In contrast, little is known about the reactivity of alkylaluminum amido or imido compounds. We report here the synthesis and structures of two novel tetranuclear alkylaluminum complexes with 8-quinolylimide ligands (**1** and **2**) and their unusual reactivities with oxygen.

The reaction of $Al(CH_3)_3$ with 8-quinolylamine in a 2:1 ratio in toluene at 23 °C produced the colorless compound **1** in high yield. This compound has been fully characterized by ^{1}H NMR and single-crystal X-ray diffraction analyses.[6] The structure of **1** (Fig. 1) has an inversion center. The imido nitrogen atom N2 has tetrahedral geometry and bridges three aluminum atoms with nearly equal Al–N2 bond lengths. The Al2–N1 distance of 1.993(6) Å lies within the same range. Each aluminum atom is also coordinated to two methyl groups, thus attaining tetrahedral geometry. The Al1–Al1′ separation of 2.788(5) Å is similar to those observed previously in dinuclear aluminum amido complexes.[1-3] If **1** retains the same structure in solution as that in the solid state, four methyl signals should have been observed in the ^{1}H NMR spectrum. Because only two methyl signals with nearly equal intensity appear in the ^{1}H NMR spectrum of **1** at 298 K we conclude that in solution compound **1** has C_{2h} symmetry with the two quinoline rings in the mirror plane.

Reactions between trialkylaluminum and primary amines usually yield amido complexes.[1-4] Tetranuclear aluminum complexes with monodentate imido ligands and cubane structures were typically obtained by heating the corresponding dinuclear amido complexes.[2c, 3b] In contrast, tetranuclear **1** was obtained readily by the direct reaction of $Al(CH_3)_3$ with 8-quinolylamine at 23 °C, perhaps promoted by the presence of the pyridyl group. Such a reactivity has not been observed in monodentate aromatic primary amines such as 8-naphthylamine, which forms a dinuclear aluminum amido complex[3a] upon reaction with $Al(CH_3)_3$.

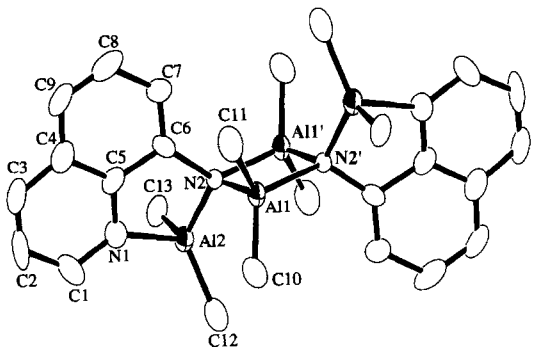

Fig. 1. An ORTEP diagram showing the molecular structure of **1** with labeling scheme (50% thermal ellipsoids). Selected bond lengths and angles: Al1-N2 1.992(7), Al1-N2′ 1.941(6), Al1-C10 1.97(1), Al1-C11 1.969(9), Al2-N1 1.993(6), Al2-N2 1.930(7), Al2-C12 1.946(9), Al2-C13 1.98(1); N2-Al1-N2′ 89.7(2), C10-Al1-C11 109.3(4), N1-Al2-N2 85.6(3), C12-Al2-C13 117.5(4), C6-N2-Al2 103.8(4), Al1-N2-Al1′ 90.3(3).

The most interesting property of **1** is its reaction with oxygen and transformation to **2**. Compound **2** was initially isolated in the synthesis of **1** as a minor orange product. NMR and single-crystal X-ray diffraction analyses[6] revealed that there is a methoxy ligand in **2**, which was confirmed by independent synthesis by reaction of $Al(CH_3)_3$ with 8-quinolylamine and methanol in a 4:2:1 ratio in toluene at 23 °C (yield 40%). Since there were no sources of methanol available in the original synthesis of **1**, we postulate that the methoxy group was produced by the reaction of the methyl ligand with a trace amount of oxygen present in the reaction medium; thus, **1** may be the direct precursor to **2**. In fact, when **1** was exposed to 0.5 equiv. of O_2 in toluene at 23 °C, it was converted into **2** nearly quantitatively after about 24 h (monitored by ^{1}H NMR spectroscopy).

As shown in Figure 2, the oxidation has caused a dramatic change in the coordination environments and the arrangement of the four aluminum centers, from a butterfly structure in **1** to a tetrahedron in **2**. Although it is not unexpected that the re-

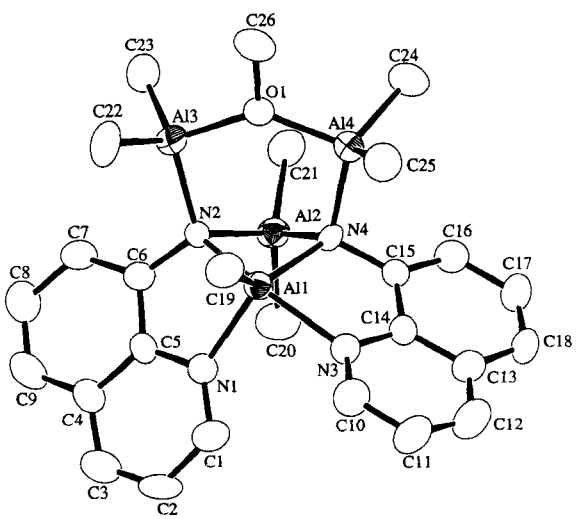

Fig. 2. An ORTEP diagram showing the molecular structure of **2** with labeling scheme (50% thermal ellipsoids). placement of a methyl group by a methoxy group causes a significant structural change since the methoxy group has a stronger tendency than a methyl group to be a bridging ligand, structural evidence for this type of transformation, especially that induced by oxidation with oxygen, is scarce in organoaluminum amido and imido complexes. As in **1**, the imido nitrogen atom in **2** bridges three aluminum centers with nearly equal Al–N distances. Both pyridyl nitrogen atoms are coordinated to the Al1 atom with slightly longer Al–N distances than those of imido nitrogen–aluminum bonds. The complex contains three types of aluminum centers, a five-coordinate Al1 with one carbon and four nitrogen atoms, a four-coordinate Al2 with two carbon and two nitrogen atoms, and four-coordinate Al3 and Al4 with two carbon atoms and one nitrogen and one oxygen atom. The environment about the five-coordinate Al1 could be described as a distorted trigonal bipyramid in which N2 and N3 occupy the axial positions. Although such a geometry is not very common for organoaluminum complexes, it has been reported previously.[1–3] The four aluminum atoms have an approximate tetrahedral arrangement. The shortest separation (2.801(3) Å) is between Al1 and Al2, which is apparently caused by the two imido nitrogen bridges. The longest separation (3.460(3) Å) is between Al3 and Al4, which are bridged by the methoxy ligand.

The crystal structure of **2** is asymmetric. Every one of the seven methyl groups bonded to the aluminum centers have different chemical environments in the solid state. If the structure of **2** is the same in solution as in the solid state, seven chemical shifts due to the seven methyl groups bonded to the aluminum centers should be detected in the ^{1}H NMR spectrum. Since for these methyl groups the ^{1}H NMR spectrum at 186–197 K shows only five chemical shifts in the region of $\delta = 0.5$ to -2.0 with a ratio of 1:2:1:2:1, we deduce that in solution **2** has a symmetric structure with a mirror plane containing Al1, Al2, and the methoxy group.

Compound **2** is much more stable toward oxygen oxidation than **1**. After the toluene solution of **2** had been exposed to one atmosphere of O_2 for about 12 h at 23 °C, no decomposition could be detected by ^{1}H NMR spectroscopy. Significant decomposition of **2** was observed only after the soluton was exposed to oxygen for several days. The decomposition products have not been characterized.

The behavior of **1** and **2** toward oxygen is unusual. Trialkylaluminum complexes react rapidly with oxygen to produce alkoxide products via the peroxide intermediate, and very often these reactions are so fast that little control of the desired products is possible unless extreme reaction conditions such as low temperature are employed.[7] Both imido and methyl ligands in **1** are susceptible to oxidation, but only one of the methyl ligands was oxidized by oxygen, and **2** was the only product. This implies that the alkyl group in alkylaluminum imido complexes is more susceptible to oxygen than the imido ligand. The high stability of **2** toward oxygen could be attributable to the bridging and electronic effects of the methoxy and imido ligands.

Experimental

All synthetic manipulations were performed under an inert atmosphere (dried argon).

1: $Al(CH_3)_3$ (2.0 M, 2.0 mL) in toluene (0.004 mol) was added to 8-quinolylamine (0.29 g, 0.002 mol) in toluene (10 mL) at 23 °C. The mixture was stirred for 30 minutes. Upon concentration of the solution colorless crystals of compound **1** precipitated in nearly quantitative yield. ^{1}H NMR ([D$_8$]toluene, 25 °C): $\delta = -0.22$ (s, 12H, CH_3), -0.06 (s, 12H, CH_3), 6.35 (m, 2H, CH), 6.82 (d, 2H, CH), 7.30 (m, 4H, CH), 7.62 (m, 2H, CH), 8.24 (m, 2H, CH). Elemental analysis: Calcd for $C_{26}H_{36}Al_4N_4$: C, 60.98; H, 7.03; N, 10.95. Found: C, 60.79; H, 7.08; N, 10.65.

2: $Al(CH_3)_3$ (2.0 M, 2.0 ml) in toluene (0.004 mol) was added to 8-quinolylamine (0.29 g, 0.002 mol) in toluene (10 mL) at 23 °C. After the mixture was stirred for 10 min, methanol (0.032 g, 0.001 mol) was added. The resulting orange-brown solution was stirred for 30 minutes. Upon concentration of the solution yellow-orange crystals of **2** were obtained in nearly quantitative yield. ^{1}H NMR ([D$_6$]benzene, 25 °C): $\delta = -1.83$ (s, 3H, CH_3), -0.60 (s, 6H, CH_3), 0.01 (s, 3H, CH_3), 0.13 (s, 6H, CH_3), 0.27 (s, 3H, CH_3), 3.59 (s, 3H, CH_3), 6.46 (m, 2H, CH), 6.81 (d, 2H; CH), 7.12 (m, 2H, CH), 7.42 (m, 2H, CH), 7.75 (m, 4H, CH). ^{13}C NMR ([D$_6$]benzene, 25 °C): $\delta = -9.13$; -6.02; -4.11 (CH_3), 50.17 (OCH_3), 117.80; 120.66; 122.73; 129.65; 130.49; 140.96; 143.88; 145.41; 149.60 (aromatic C). Elemental analysis: Calcd. for $C_{26}H_{36}Al_4ON_4$: C, 59.14; H, 6.82; N, 10.61. Found: C, 57.08; H, 6.31; N, 10.25. The low C, H, and N content of this sample are probably caused by the partial decomposition of this material during analysis.

Transformation of **1** to **2**: O_2 (4.80 cm^3 at 1 atm; 0.196 mmol) was introduced to a toluene solution (15 mL) containing **1** (0.20 g, 0.391 mmol) by syringe at 23 °C. After 48 h **1** was completely converted into **2**, as shown by ^{1}H NMR spectra.

The First Cycloaddition Reactions of Dimeric Arsenium Cations**

Neil Burford,* Trenton M. Parks, Pradip K. Bakshi, and T. Stanley Cameron*

Small molecules containing coordinatively unsaturated centers are excellent foundations from which to develop new directions in synthetic chemistry. The *carbenes* **1** are perhaps the best known examples,[1] and recently a number of new reactions have been reported.[2] The chemistry of the analogous *phosphenium cations* **2** is also extensive and represents a principal direction in the development of modern phosphorus chemistry.[3] We have recently synthesized simple compounds containing *arsenium* centers and shown them, in the absence of a π-delocalized framework,[4] to adopt weakly associated dimeric structures **3** in the solid state.[5] Here we report the first cycloaddition reactions for these cations, demonstrating dramatic contrasts to observations for phosphenium cations. Additionally, we show surprising differences between the reactivity of **3a** and **3b**.

1 **2**

3a: X = NMe
b: X = S

The tetrachlorogallate salts of **3a** and **3b** each react rapidly with 2,3-dimethyl-1,3-butadiene in CH_2Cl_2 to give bicyclic cationic products. Reaction of **3a**-$(GaCl_4)_2$ gives the ammonium salt **4**-$GaCl_4$[6] in essentially quantitative yield (as shown by ^1H NMR spectroscopy of the reaction mixture).

4 **5** **6**

Crystallographic characterization of **4**-$GaCl_4$ confirms the bicyclic structure of the cation, and an expected pyramidal geometry for arsenic (Fig. 1).[7] The cross-ring As1–N2 bond is significantly longer [2.056(10) Å] than that of As1–N1 [1.797(11) Å], and both are slightly longer than those observed in the dication **3a** [tetracoordinate As to N, 1.949(4) Å; tricoordinate As to N, 1.752(5) Å]. Published values for As–N bonds are limited, but are typically in the range of 1.82 to 1.88 Å.[8] For further comparison we have also determined the structure of the neutral dimethyldiazarsolidine **5**[5] [As–N: 1.830(8) and 1.77(1) Å].[9]

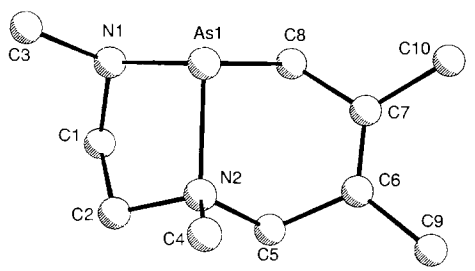

Fig. 1. PLUTO plot of cation **4**. Hydrogen atoms omitted for clarity.

2,3-Dimethylbuta-1,3-diene reacts with **3b**-$(GaCl_4)_2$ to give a mixture (^1H and ^{13}C NMR spectra show a multitude of complex and broad signals) from which we have isolated the $GaCl_4^-$ salt of 1-thionia-4,6-dithia-5-arsabicyclo[3.3.0]octane (**6**).[10] Crystallographic characterization[11] reveals a bicyclic structure for cation **6** (Fig. 2), reminiscent of **4**. The unexpected structure of **6** can be considered in terms of an extrusion of an As–S^+ moiety from the dimer **3b**, perhaps by an initial interaction with butadiene in a fashion similar to its analogous reaction with **3a**. We have also been able to synthesize **6**-$GaCl_4$ quantitatively (as shown by ^1H and ^{13}C NMR spectroscopy of the reaction mixture) from **7**[12] with $GaCl_3$. Comparison of the cross-ring bonds in **6** [As1–S2, 2.390(4); As2–S5, 2.347(4) Å] and **7** [As–S, 2.719(3) Å][13] reveals that heterolytic As–Cl bond cleavage of **7** enhances the S → As cross-ring donation. The long cross-ring bonds in both **4** and **6** allow a classification of these compounds as intramolecular base-stabilized[14] arsenium cations.

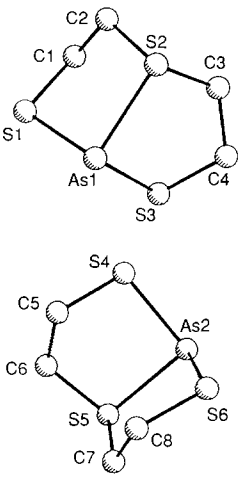

Fig. 2. PLUTO plot of cation **6**. Two molecules are present in the asymmetric unit. Hydrogen atoms are omitted for clarity.

Reactions of **3** with 2,3-dimethylbutadiene are in dramatic contrast to the corresponding established cycloaddition chemistry of this butadiene with phosphenium cations, which provide the spirocyclic phosphonium cation **8**.[15] Although the nature of the arsenium cations in solution is not clear,[5] the quantitative formation of **4** implies a concerted process, possibly a Diels–Alder type cycloaddition involving the As–N bond of either the dimer or the monomer as dienophile. We conclude that the electronic structure of the arsenium cations differs significantly from the phosphenium analogues in terms of the relative energy of the LUMO and of the nonbonding electron pair at the arsenic center. However, the reactivity of the arsenium cations may be biased by the penchant for dimer formation, which is not observed for phosphenium cations.[16]

Experimental Procedure

NMR: Bruker AC250 (250 MHz for ^1H, 62.89 for ^{13}C) and Bruker AMX400 spectrometers (400 MHz for ^1H, 100.6 for ^{13}C). Shifts are reported relative to TMS and referenced to the internal solvent signal. IR: Nicolet 510P FT-IR spectrometer. All reactions were performed in evacuated vessels [17].

4-$GaCl_4$: 2,3-Dimethylbutadiene (0.11 g, 1.3 mmol) in CH_2Cl_2 (about 7 mL) was added dropwise (8 min) to a stirred solution of **3a**-$(GaCl_4)_2$ (0.32 g, 0.42 mmol) in CH_2Cl_2 (about 37 mL). Slow removal of solvent in vacuo gave colorless crystals of **4**-$GaCl_4$ (55% yield). Very air-sensitive.

[**] In this paper the terms phosphenium and arsenium ion are used instead of phospharylium and arsanylium ion recommended by IUPAC.

6-$GaCl_4$: 2,3-Dimethylbutadiene (0.14 g, 1.7 mmol) in CH_2Cl_2 (about 10 mL) was added dropwise (8 min) to a stirred solution of **3b**-$(GaCl_4)_2$ (0.35 g, 0.46 mmol) in CH_2Cl_2 (about 50 mL). Slow removal of solvent (>75%) in vacuo gave pale yellow crystals and a dark brown powder. The crystals were characterized as **6**-$GaCl_4$ (crude yield 57%). Very air-sensitive. The brown powder was not characterized.

6-$GaCl_4$: $GaCl_3$ (0.27 g, 1.5 mmol) in CH_2Cl_2 (about 24 mL) was added dropwise (55 min) to a stirred solution of **7** (0.40 g, 1.5 mmol) in CH_2Cl_2 (about 36 mL). Precipitation resulted in a white powder. Characterized as **6**-$GaCl_4$ (78% yield). Very air-sensitive.

Metalation of Tris(trimethylsilyl)- and Tris(dimethylphenylsilyl)methane with Methylsodium: The First Dialkylsodate**

Salih S. Al-Juaid, Colin Eaborn, Peter B. Hitchcock, Keith Izod, Michael Mallien, and J. David Smith*

The diorganolithate $[Li(thf)_4][LiR_2]$, where R = $C(SiMe_3)_3$, the first example of a species that had been postulated many years earlier but never observed, was obtained in 1983 by metalation of $(Me_3Si)_3CH$ with MeLi in tetrahydrofuran.[1] Two further salts, $[Li(tmen)_2][LiR_2]$[2] (tmen = $Me_2N(CH_2)_2NMe_2$) and [(pmdeta)Li(μ-Cl)Li(pmdeta)][LiR_2],[3] pmdeta = $Me_2N(CH_2)_2NMe(CH_2)_2NMe_2$, were subsequently isolated, but no other diorganolithate or diorganosodate has been reported, although organosodium compounds have been known for more than 70 years.[4] We now describe the preparation and structural characterization of such a species.

The metalation of $(Me_3Si)_3CH$ by MeNa in Et_2O[5] was rather slow, and complicated by reaction between the alkylsodium and the solvent. However, in the presence of tmen reaction was rapid. The product was isolated as colorless plates that were air- and moisture-sensitive and was shown by X-ray diffraction to be **1**.[6] The ether was rapidly lost in vacuum; no trace of it

$[Na(tmen)_2(Et_2O)]\,[Na\{C(SiMe_3)_3\}_2]$ **1**

was detected in the ^{1}H NMR spectrum of a sample that had been pumped on for about 30 s.

As shown in Figure 1 the structure consists of discrete cations and anions. The sodium atoms in both ions are in special positions: the anion lies across a center of symmetry and is therefore linear, and the cation is on a two-fold axis along Na2–O. The Na–C bond length of 247.9(6) pm is unusually short;[7] that in polymeric $NaCH(SiMe_3)_2$,[8] in which the Na is also two-coordinate but with weak interactions to adjacent hydrogen atoms, is 255.5(10) pm. Most other organosodium compounds have

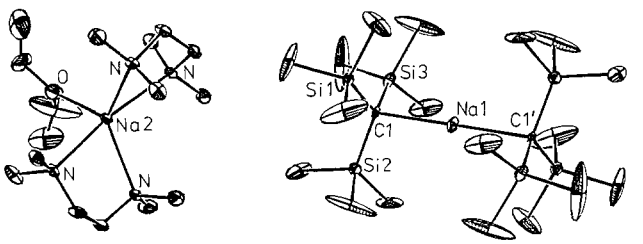

Fig. 1. Structure of the ions in **1** [6]. Important distances [pm] and angles [°] with values for $[Mg\{C(SiMe_3)_3\}_2]$ [9] in parentheses: mean Si–C(M) 181.7(8) (187.7(3)), Si–Me 183.4(10) (188.1(4)), Si-C-Si 115.9(3), (112.6(1)), Me-Si-Me 103.0(5) (105.4(2)).

structures in which the sodium has a coordination number of between 4 and 6.

Comparison of the structure of the anion in **1** with the neutral isoelectronic MgR_2[9] is revealing. As expected the Na–C bond is longer than the Mg–C bond [211.6(2) pm]. The outstanding feature is that the Na atom in **1** is sterically much less shielded than the Mg atom in MgR_2. In the latter (as in the related neutral species MR_2 with M = Hg,[10] Zn,[11] or Mn[12]) one of the Me groups of each Me_3Si group projects in towards the center of the molecule, and the carbon atoms of the six Me_3Si groups interlock, effectively hiding the metal. In **1** one Me of each Me_3Si group points directly away from the metal, and the other two point only slightly inwards. Because of this and the relatively long metal–C bond, the metal is considerably more exposed. The presence of the negative charge (and possibly its partial delocalization over the R groups) may be responsible for the fact that the mean Si–C(M) bond length in **1** is markedly shorter than that in MgR_2, and the mean Si-C-Si angle substantially larger than the corresponding angle in MgR_2. (The mean Si–Me bond length in **1** is also apparently shorter than that in MgR_2, and the mean Me-Si-Me angle is apparently narrower than that in MgR_2, but this may be an artefact arising from the large libration indicated by the elongated thermal ellipsoids of the carbon atoms of the Me groups in **1**.) It is noteworthy that short Si–C(Na) bond lengths (180.6(3) pm) are also found in $[NaCH(SiMe_3)_2]_n$.[8]

In contrast, **2** is readily formed in Et_2O and isolated as solvent-free yellow plates. An X-ray study[13] shows that the solid contains pairs of molecules linked together into chains (Fig. 2).

$Na[C(SiMe_2Ph)_3]$ **2**

The molecules within each pair have similar but not quite identical dimensions; each Na atom is close to the central carbon

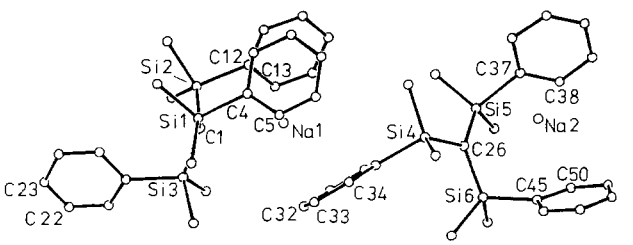

Fig. 2. Molecular structure of **2** [13]. Important distances [pm] and angles [°]: Na1–Cl 275.4(14), Na1–C4 280.9(13), Na1–C5 291.5(14), Na1–C12 280.1(13), Na1–C13 282.0(15), Na1–C32 293.3(13), Na1–C33 286.5(14), Na1–C34 306.7(13), Na2–C22′ 290(2), Na2–C23′ 281(2), Na2–C26 298.3(14), Na2–C37 282.0(13), Na2–C38 290(2), Na2–C45 283.1(14), Na2–C50 301(2), all other Na–C > 310, mean Si–C 181.2(12), Si–Me 187.2(12), Si–Ph 191.4(14), Si1-C1-Si2 119.6(6), Si1-C1-Si3 120.3(6), Si2-C1-Si3 115.0(6), Si4-C26-Si5 120.7(7), Si4-C26-Si6 117.8(7), Si5-C26-Si6 119.8(7). Adjacent pairs of molecules along the chain are related by the *c* glide plane.

atom of the same molecule and to three asymmetrically coordinated Ph groups, two from the same molecule (closest Na–C contact to the *ipso* carbon) and one from an adjacent molecule (closest Na–C contact to *meta* and *para* carbon atoms). The coordination at the central carbon is almost planar (sum of angles 355° for C(1) and 358° for C(26)), as found in [Na(tmen)][CPh_3][14] and $[NaCH(SiMe_3)_2]_n$;[8] in contrast, the methyl anions in solid NaMe are pyramidal.[5]

The structure of **2** may be compared with those of **3**,[15] isolated as a thf adduct, and **4**.[16] In all cases there are significant

$(Me_2PhSi)_3CLi$ **3** $(Me_2PhSi)_3CK$ **4**

interactions between the metal and the phenyl groups of the ligand. As the size of the metal increases these interactions become progressively more important (η^1 in **3**, η^2 or η^4 in **2**, or η^6 in **4**) relative to interactions with the central carbon. This is reflected in physical properties: the sodium compound is more soluble in ether or toluene than the potassium derivative, which suggests that the chains are more readily broken by solvation. The coordination around sodium **2** can be viewed as that of a distorted tetrahedron with one bond to the central carbon and three to Ph groups. As far as we are aware, such a coordination sphere has not been observed in other organosodium compounds, but two η^6-Ph ligands are found in $[Ph_2C{=}CHCPh_2Na]\cdot OEt_2$,[17] two η^6-Ph, and one η^2-Ph ligand in $[(Et_2O)_2Na_2][Ph_2C{-}CPh_2]$,[18] and two η^3- and two η^1-Ph ligands in $K[(PhCH)_2PMe_2]$.[19] One η^6-Ph ligand is found in 1-phenylcyclohexenylsodium · pmdeta.[20]

Experimental Procedure

1: A solution of MeLi (20 cm³, 0.7 M) in Et_2O was added to a cold (0 °C) solution of NaO*t*Bu (13.8 mmol) in Et_2O. The mixture was allowed to warm to 5 °C and kept at that temperature for 10 min. The white precipitate of MeNa was then filtered off, washed three times with 20 cm³ Et_2O at 0 °C, and stirred with Et_2O (30 cm³), tmen (10.0 mmol), and $(Me_3Si)_3CH$ (11.0 mmol) at 0 °C. The mixture was allowed to warm to 20 °C, and stirred for 12 h. The slightly cloudy solution was filtered, solvent removed in vacuum from the filtrate, and the colorless residue washed with petrol (b.p. 40–60 °C, 25 cm³) and recrystallized from cold ether. M.p. 128–130 °C. ^{1}H NMR (C_6D_6, chemical shifts relative to $SiMe_4$, 25 °C): δ = 0.43 (s, 18H, Me_3Si), 1.54 (s, 4H), and 1.69 (s, 12H, tmen); ^{13}C NMR: δ = 3.9 (CSi_3), 8.3 (Me_3Si), 45.4, and 56.6 (tmen); ^{29}Si NMR: δ = −11.1.

2: A solution of $(Me_2PhSi)_3CH$ (5.6 g, 13 mmol) in cold (−10 °C) diethyl ether (40 cm³) was added to solid methylsodium (0.49 g, 13 mmol), and the mixture allowed to warm slowly to 20 °C and then stirred for 12 h. The slightly turbid solution was filtered, and solvent removed under vacuum. The pale yellow solid residue was washed with petrol (b.p. 40–60 °C, 4 × 40 cm³) and recrystallized from hot toluene to give yellow hexagonal plates of **2**. M.p. 195° (decomp). ^{1}H NMR ([D_8]thf, 25 °C): δ = 0.00 (s, 18H, $SiMe_2$), 6.93 (m, 3H, *p*-C, Ph); 7.03 (m, 6H, *m*-C, Ph), 7.79 (m, 6H, *o*-C, Ph). ^{13}C NMR: δ = − 6.4 (CSi_3) 6.93 ($SiMe_2$), 125.4, 126.3, 135.3, 155.1 (Ph). ^{29}Si NMR: δ = −13.9.

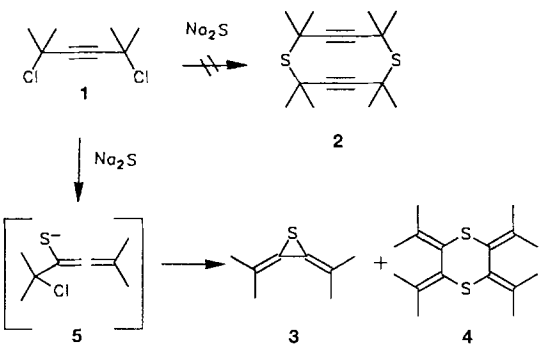
Efficient Synthesis of Heteroradialenes by SN′ Reaction**

Rolf Gleiter,* Harald Röckel, Hermann Irngartinger, and Thomas Oeser



Dedicated to Professor Margot Becke-Goehring on the occasion of her 80th birthday

Radialenes, a relatively new class of compounds first mentioned in the sixties, are not only aesthetically pleasing, but are also interesting objects of study for theoretical chemists or researchers in material science because of their electronic properties.[1] Over the last few years new and simple synthesis have made alicyclic radialenes readily accessible. Photoelectron spectroscopic studies have shown that permethylated alicyclic radialenes have energetically high-lying occupied molecular orbitals.[2] They should therefore be suitable as electron donors in donor–acceptor complexes. These complexes have aroused interest as conductors and organic ferromagnetics.[3] Heteroradialenes have been investigated by Maercker et al.[4] and Ando et al.[5] Thiaradialenes, however, could so far only be synthesized by a multistep procedure,[5] which may be the reason why so little is known about their physical-chemical properties. We now report a synthesis affording thiaradialenes from simple and easily accessible starting materials.

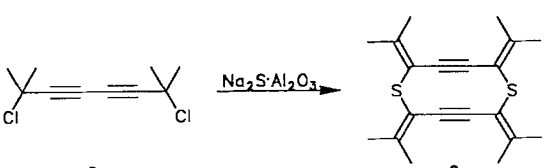
Treatment of 2,5-dimethyl-2,5-dichloro-3-hexyne (**1**) with $Na_2S \cdot Al_2O_3$[6] does not react by nucleophilic substitution at the propargyl C atom to the expected octamethyl-1,6-dithia-3,8-cyclodecadiyne (**2**), but to the methyl derivatives of thia[3]radialene (**3**) and dithia[6]radialene (**4**). These two compounds were first synthesized by Ando et al. by another procedure.[5] This unexpected result can be explained by an SN′ mechanism (Scheme 1). We assume that substitution of chloride

Scheme 1.



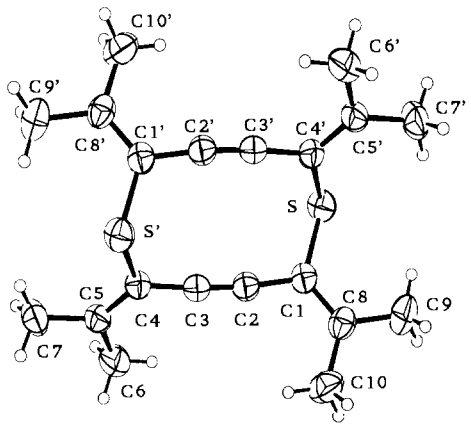
with the sulfide anion by the SN′ reaction leads to compound **5** as an intermediate, which cyclizes in a further step either intramolecularly to **3** or intermolecularly to **4**.

The reaction of **1** with other nucleophiles yields 2,3-disubstituted 1,1,4,4-tetramethyl-1,3-butadienes. As an example the reactions of 1-lithio-1-hexyne and $NaCN \cdot Al_2O_3$ are shown in Scheme 2. They lead exclusively to the SN′ products **6** and **7**.

Scheme 2.

Consequently now, in addition to earlier work of Hopf,[7] 2,3-dialkynyl-substituted 1,3-butadienes are readily available by this easy synthesis. Both products **6** and **7** have interesting cross-conjugated multiple-bond systems and are promising starting materials for reactions at the conjugated triple bonds, or at the diene system.

Scheme 3.



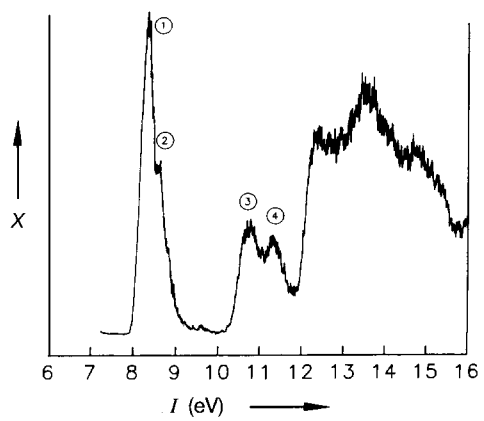


Fig. 1. Crystal structure of **9**; selected bond lengths [Å] and angles [°]: C1–C2 1.430(3), C2–C3 1.201(3), C3–C4 1.426(3), C4–C5 1.346(3), C1–C8 1.346(2), S–C1 1.792(2), S–C4′ 1.798(2); C1-S-C4′ 102.6(1), S-C4′-C5′ 121.4(1), S-C1-C8 121.9(1), S-C1-C2 115.0(1), S-C4′-C3′ 115.1(1), C1-C2-C3 173.9(2), C2-C3-C4 173.6(2), C2-C1-C8 123.0(2), C3-C4-C5 123.3(2), C6-C5-C7 115.6(2), C9-C8-C10 115.2(2).

We consider that the reaction of 2,7-dimethyl-2,7-dichloro-3,5-octadiyne (**8**) with $Na_2S \cdot Al_2O_3$ has particular scope. It is similar to the preceding reactions and furnishes 2,5,7,10-tetra-isopropylidene-1,6-dithia-3,8-cyclodecadiyne (**9**) (Scheme 3). Diyne **9** may also be considered as an expanded dithia[6]radialene. As is apparent from Figure 1 the ten-membered ring in **9** adopts chair conformation.[8] The transannular distance between the triple bonds is 3.085(2) Å. The minor decrease in this distance relative to that in the structurally related 1,6-dithia-3,8-cyclodecadiyne,[9] for which a transannular distance of 3.102(2) Å is reported, is probably due to the exchange of the four sp^3-carbon atoms for sp^2-carbon atoms in **9**. The bond angles at the sp centers are 173.6(2)° and 173.9(2)°; hence, the linear arrangement of the triple bonds is bent by 6.4(2)° and 6.1(2)°, respectively. Similar deformations have been observed for all ten-membered diyne systems known to date.[10] The torsion angle of the two isopropylidene groups along the triple bond is 66.9(3)° (C5–C4···C1–C8).

By photoelectron spectroscopy (PE) and cyclic voltammetry (CV) it is possible to verify that the obtained radialenes, especially **3** and **4**, are indeed electron-rich π systems. At the top of Figure 2 the He(I)-PE spectrum of **3** is shown and at the bottom the cyclic voltammograms of **3** and **4**. In Table 1 the first vertical ionization energies are listed.

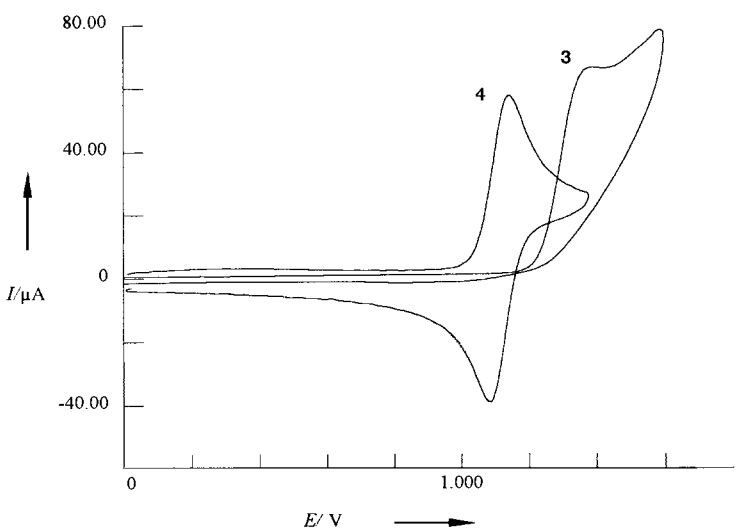

Fig. 2. Top: He(I)-PE spectrum of **3**. x = count rate. Bottom: Cyclic voltammograms of **3** and **4** in $CH_2Cl_2/(n\text{Bu})_4N\ PF_6$; scan rate: 100 mV/s^{-1}, reference electrode: saturated calomel electrode.

Table 1. Vertical ionization energies and oxidation potentials of radialenes **3** and **4**.

thia[3]radialene (**3**)	dithia[6]radialene (**4**)
ionization energies	
8.0 eV	7.1 eV
8.3 eV	7.5 eV
10.5 eV	8.3 eV
11.1 eV	9.1 eV
oxidation potentials [a]	
1600 mV	1115 mV

[a] The oxidation potentials were measured with a HEKA potentiostat (PG 28) in CH_2Cl_2 as solvent and $(n\text{Bu})_4N\ PF_6$ as electrolyte. The working electrode was a Metrohm disk electrode (radius = 3 mm) and reference electrode a saturated calomel electrode (SCE), which was separated from the call by a frit and a luggin capillary. The oxidation potential of ferrocene/ferrocenium (480 mV) was taken as standard.

The PE spectrum of **3** shows a sharp band at 8.0 eV, assigned to the sulfur 3p lone pair. The following band at 8.3 eV represents the HOMO of the tetramethyl butadiene fragment. The next two bands at 10.5 and 11.1 eV are assigned to Walsh-like orbitals arising from the 3p orbital of sulfur and the two carbon atoms of the three-membered ring. While the first ionization energy of **3** is similar to that of other sulfides,[11] there is a significant decrease to 7.1 eV in the case of **4** that can be explained by interaction of the sulfur 3p lone pairs with the butadiene system. The relatively high-lying HOMO is also observable by cyclic voltammetry. Thia[3]radialene **3** shows an irreversible oxidation at 1600 mV, as is common for alicyclic radialenes,[1] but **4** shows a reversible single-electron oxidation at 1115 mV (vs SCE).

The reactions described in this paper allow the investigation of the chemistry of a number of new radialenes. Furthermore they have made possible the simple synthesis of 2,3-dialkynyl-1,3-butadienes, a class of interesting compounds that have thus far been difficult to investigate.

Experimental Procedure

3 and **4**: To a suspension of $Na_2S \cdot Al_2O_3$ (19.2 g) [6] in 80 mL THF/DMPU (10:1, DMPU = *N*,*N*′-dimethyl-2,6-diazacyclohexanone) was added dropwise under reflux **1** (1.78 g, 10 mmol) dissolved in 30 mL of the solvent. After 12 h the solution was distilled under reduced pressure to recover the starting material (50%). After chromatography of the residue (silica/cyclohexane) **3** (420 mg, 3 mmol) and **4**

(300 mg, 1.07 mmol) were isolated. **3**: ^{1}H NMR: δ = 1.98 (s, 6H), 2.07 (s, 6H); ^{13}C NMR: δ = 22.64, 23.00, 111.37, 115.00; EI-MS: *m/z*: 140 (M^+); **4**: ^{1}H NMR: δ = 1.84 (s, 6H), 1.67 (s, 6H); ^{13}C NMR: δ = 21.06, 21.90, 125.55, 130.43; EI-MS: *m/z*: 280 (M^+)

6 (see also ref. [12]): 1-Hexyne (1.64 g, 20 mmol) was dissolved in THF (50 mL) at -78 °C and deprotonated with *n*-butyllithium (1.6 M in *n*-hexane). This solution was added dropwise to a refluxing solution **1** (890 mg, 5 mmol) in THF/DMPU (5:2) 60 mL. After 12 h the reaction was quenched with water and extracted with ether (3 × 50 mL), dried over Na_2SO_4, and purified by chromatography (silica/cyclohexane). Isolated yield of **b**: 150 mg (0.55 mmol, 11%). ^{1}H NMR: δ = 0.89 (t, 6H, ^3J = 7.1 Hz), 1.38–1.59 (m, 8H), 1.64 (s, 6H), 1.93 (s, 6H), 2.33 (t, 4H, ^3J = 6.9 Hz); ^{13}C NMR: δ = 13.66, 19.39, 20.62, 21.97, 22.62, 31.15, 79.54, 92.20, 116.56, 141.12; EI-MS: *m/z* 270 (M^+)

7: Hexyne **1** (1.78 g, 10 mmol) dissolved in 30 mL of the solvent mixture was added to a suspension of NaCN · Al_2O_3 (1:1 4.0 g) in THF/DMPU (10:1) 80 mL under reflux within 5 h. After 12 h the solution was worked up as above. After chromatography (silica/cyclohexane) **7** was isolated as a colorless liquid. Yield: 976 mg (6.2 mmol, 61%). ^{1}H NMR: δ = 1.88 (s, 6H), 2.16 (s, 6H); ^{13}C NMR: δ = 21.36, 24.04, 103.05, 116.06, 160.45; EI-MS: *m/z*: 160 (M^+)

9: To a suspension of Na_2S · Al_2O_3 in the solvent mixture described above, **8** (2.03 g, 10 mmol) in 30 mL of the solvent was added, and the mixture was heated at reflux for 12 h. **9** was isolated as above in 10% yield (328 mg) after chromatography (silica/cyclohexane). ^{1}H NMR: δ = 2.04 (s, 12H), 2.08 (s, 12H); ^{13}C NMR: δ = 21.97, 24.11, 93.56, 111.58, 147.14; CI-MS: *m/z* 328 (M^+). The crystals for X-ray analysis precipitated from CH_2Cl_2 at −30 °C.

New Types of Metal-Stabilized Cyclobutadiene Superphanes**

Rolf Gleiter,* Heinrich Langer, and Bernhard Nuber

The metal-catalyzed trimerization of alkynes to aromatic compounds is a useful reaction.[1–3] Cobalt-catalyzed [2 + 2 + 2] cycloadditions are sometimes accompanied by a side reaction, the dimerization to metal-stabilized cyclobutadiene complexes. These complexes are considered inert towards further cycloaddition reactions.[4] If cyclic diynes are used as starting materials, the tricyclic cyclobutadiene complexes are usually the main product.[5, 6] In the case of the reaction of [CpCoL$_2$] (Cp = η^5-cyclopentadienyl; L$_2$ = 2CO, 1,5-cyclooctadiene (cod)) with 1,6-cyclodecadiyne, 1,8-cyclotetradecadiyne, or 1,10-cyclooctadecadiyne an intermolecular reaction is even possible, which leads to CpCo-stabilized superphanes such as **1**.[6] These species are not only aesthetically attractive, but also useful for preparing cage compounds such as the fourfold bridged derivatives of tricyclo[4.2.0.0^{2,5}]octa-3,7-diene (**2**), its isomer (**3**), and the cubane derivative (**4**).[6]

Scheme 1. Ox = oxidation.

In connection with mechanistic investigations of the photochemistry of **2** we wanted to synthesize superphanes with different chain lengths. To this end the recently published stepwise path to metal-stabilized superphanes seemed appropiate.[7] In this paper we report on the first verification of this concept to yield a CpCo-stabilized cyclobutadiene superphane with different chain lengths. In addition we describe another new type of superphane and a novel CpCo complex of a fourfold bridged bicyclo[4.2.0]octa-2,4,7-triene.

Starting point of our synthesis is 6-undecynol (**5**),[8] which was converted into the tricyclic cyclobutadiene complexes (**6**) by reaction with [CpCo(cod)] in 70% yield (Scheme 2). The mixture of the isomeric alcohols **6** was oxidized to the diketone **7** by the Oppenauer procedure with acetone in 83% yield. In the next step the diketone **7** was transformed into the bisselenadiazoles **8a**/**8b** in 35% yield with a procedure first devised by Lalezari et al.[9] Without further purification the mixture **8a**/**8b** was treated with *n*BuLi at −40 °C to give a 1:1 mixture of the tricyclic diynes **9a**/**9b** in 70% yield.
