Regio- and Diastereoselective Photooxygenation of Chiral 2,5-Cyclohexadiene-1-carboxylic Acids**

Torsten Linker* and Lothar Fröhlich

Highly functionalized chiral cyclohexanol derivatives are widespread substructures of natural products.[1] Previous synthetic approaches proceeded by stereoselective reductions or alkylations of cyclohexanones,[2] cycloadditions,[3] and enzymatic methods.[4] In the course of our investigations on the synthesis of dihydroxyvitamin D_3 (calcitriol),[5] we developed a new regio- and stereoselective entry to functionalized cyclohexenol derivatives, which constitute valuable building blocks for natural products.

Although the singlet oxygen ene reaction (Schenck reaction)[6] has been shown to be a powerful method for allylic oxyfunctionalization of cyclic[7] and acyclic[8] olefins, to date no example exists for chiral carboxylic acids. Therefore, we examined the triplet-sensitized photooxygenation of the racemic 2,5-cyclohexadiene-1-carboxylic acids **2a–c**. The substrates **2a–c** were prepared from 2-methylbenzoic acid (**1**) by Birch reduction[9] and subsequent alkylation in high yield. Photooxygenation afforded the hydroperoxides **3** in surprisingly high regio- and diastereomeric ratios (Scheme 1, Table 1). This is remarkable since

Scheme 1. Synthesis and photooxygenation of chiral 2,5-cyclohexadiene-1-carboxylic acids *rac*-**2a–c**. For clarity only one enantiomer of **3** is shown.

Table 1. Photooxygenation of 2,5-cyclohexadiene-1-carboxylic acids rac-**2** [a].

[**] This work was generously supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. W. Adam, Würzburg, for his constant support.

singlet oxygen ene reactions of cyclic alkenes usually proceed with low selectivities.[10] Furthermore, the products *trans*-**3** and *cis*-**3** were obtained diastereomerically pure by column chromatography. The stereochemical assignment of the hydroperoxides **3** is based on NOE experiments (NOE = nuclear Overhauser enhancement). Additionally, the relative configuration was established unequivocally by chemical transformations, which simultaneously demonstrate the synthetic potential of the hydroperoxides (Scheme 2). Thus, sodium borohydride reduction of *trans*-**3a** and treatment with diluted hydrochloric acid afforded the 3-hydroxycarboxylic acid **5a**, whereas, *cis*-**3c** yielded smoothly the lactone **6c** under identical reaction conditions.

Scheme 2. Transformations of hydroperoxides *trans*-**3a** and *cis*-**3c**.

The high diastereoselectivities in the photooxygenation of chiral 2,5-cyclohexadiene-1-carboxylic acids are due to both steric and electronic factors. In all examined cases, the *cis* selectivity increased drastically by changing the substituents from methyl to ethyl and to isopropyl, which can only be rationalized by steric interactions. On the other hand, the methyl-substituted carboxylic acid **2a** (entries 1–3), shows a strong preference for *trans* attack of singlet oxygen, which must be due to electronic factors. If only steric interactions were encountered, a 1:1 mixture of diastereomeric hydroperoxides **3** should result since methyl and carboxyl groups possess nearly the same steric demand.[11] Evidently, unfavorable electronic repulsions in the perepoxide *cis*-**7a**,[12] are responsible for the high *trans* selectivity (Scheme 3). Therefore, increasing the negative charge of the carboxyl group (e.g. by deprotonation) should afford *trans* configurated products to an even higher extent.

Scheme 3. Electronic interactions in the perepoxide intermediate **7** which favor the *trans* selectivity in the photooxygenations.

To prove this hypothesis, we conducted the photooxygenations in the presence of two equivalents of pyridine (method B, entries 2, 5, and 8) or with the corresponding sodium salts (method C, entries 3, 6, and 9). In fact, the *trans* selectivities were increased significantly in all examples. Furthermore, the slightly basic reaction conditions suppressed completely the undesired formation of arenes **4** (entries 1, 4, and 7). Apparently, acid-catalyzed Grob fragmentation[13] affords arenes **4**, in accordance with known aromatizations of 2,5-cyclohexadiene-1-carboxylic acids.[14]

The 1-ethyl-substituted carboxylic acid **2b** (entries 4–6) is a particularly interesting substrate for photooxygenations. Since steric and electronic interactions are counterbalanced in this acid, it is possible to invert the diastereoselectivity simply by changing from chloroform as solvent (entry 4) to the sodium salt in methanol (entry 6).

In summary, the above results show that the singlet oxygen ene reaction of chiral carboxylic acids is a useful method for the regio- and stereoselective synthesis of functionalized cyclohexenol derivatives. Further investigations are currently underway in which we are attempting to influence the diastereoselectivity of this reaction by using different functional groups, and to extend the synthetic potential of the reaction sequence Birch reduction/photooxygenation. Since enantioselective Birch reductions are known,[15] the present methodology should provide a valuable route to natural products.

Experimental Procedure

cis-**3c**: A solution of **2c** (900 mg, 5 mmol), pyridine (790 mg, 10 mmol), and tetraphenylporphine (TPP) (ca. 2 mg) in chloroform (70 mL) was irradiated for 24 h with two external Philips G/98/2 SON 250-W sodium lamps at −30 °C, while a stream of dry oxygen gas was passed continously through the reaction mixture. Removal of the solvent under reduced pressure (30 °C) followed by column chromatography on silica gel (CH_2Cl_2/MeOH/HOAc 98/2/0.1) yielded 1.03 g (97%) of crystalline *cis*-**3c** (m.p. 101–102 °C). Characteristic ^{1}H NMR data (250 MHz, $CDCl_3$): δ = 0.88, 1.03 (2 d, J = 6.7 Hz, 3H; $CH(CH_3)_2$), 2.52 (sep, J = 6.7 Hz, 1H; $CH(CH_3)_2$), 4.57 (dd, J = 3.0, 3.7 Hz, 1H; CHOOH), 5.44, 5.52 (2 s, 1H, $C=CH_2$); ^{13}C NMR (63 MHz, $CDCl_3$): δ = 17.92, 17.97 (2 q; $CH(CH_3)_2$), 32.80 (d; $CH(CH_3)_2$), 85.29 (d; CHOOH), 119.70 (t; $C=CH_2$), 141.02 (s; $C=CH_2$).

Tris(η^4-naphthalene)zirconate(2−)

Meehae Jang and John E. Ellis*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Naphthalene radical anion reductions of a variety of transition metal precursors including MCl_3 (M = V, Cr[1]), MCl_5 (M = Nb, Ta[2]), $TiCl_4$,[3] and $Co(C_5H_5)_2$[4] have been suggested or claimed to provide *anionic* homoleptic naphthalene complexes, but only one has been isolated, that is $[Ti(C_{10}H_8)_2]^{2-}$,[5] and none have been structurally characterized. Since naphthalene ligands can often be readily substituted by other Lewis bases,[6] compounds of the general formula $[M(C_{10}H_8)_x]^{z-}$ are potentially valuable synthetic equivalents for corresponding "naked" transition metal anions, M^{z-}, and are thereby related to Jonas's homoleptic ethylene complexes, $[Co(C_2H_4)_4]^-$ and $[Fe(C_2H_4)_4]^{2-}$.[7] For these reasons, we felt that it was important to determine the nature of an especially robust product obtained from the reaction of potassium naphthalenide and $ZrCl_4 \cdot 2THF$ (Scheme 1). To our surprise, salts **1** containing the anion $[Zr(\eta^4\text{-}C_{10}H_8)_3]^{2-}$ were obtained, instead of the expected and still unknown $[Zr(\eta^6\text{-}C_{10}H_8)_2]^{2-}$, which is isoelectronic with $[Mo(\eta^6\text{-}C_{10}H_8)_2]$.[6a, 8] The anion of **1** may be regarded as the first tris(arene)metal complex to contain only independent or unlinked arene ligands.[9, 10] It has also been identified in this study as the intermediate in the original synthesis of $[Zr(CO)_6]^{2-}$.[11]

$$ZrCl_4 \cdot 2THF + 6KC_{10}H_8 + 2nL \xrightarrow[-60 \rightarrow 0\,^\circ C]{DME} \underset{\mathbf{1}}{[KL_n]_2[Zr(C_{10}H_8)_3]} + 3C_{10}H_8 + 4KCl + 2THF$$

Scheme 1. **1a**: $n = 1$, L = [2.2.2]cryptand; **1b**: $n = 2$, L = [15]crown-5; DME = 1,2-dimethoxyethane.

Microcrystalline, deep red to nearly black **1a** and **1b** were isolated in 46 and 55% yields, respectively, as satisfactorily pure substances. Although highly reactive and air sensitive, they are thermally robust as dry solids and have survived for months at room temperature under an argon atmosphere without apparent deterioration. The ^1H and ^{13}C NMR spectra in solution and the CP/MAS ^{13}C NMR spectra of these salts showed that **1** was the only naphthalene complex present and established that its structure in solution and the solid state was identical. Also, the pattern of signals in the NMR spectra of **1** were independent of temperature (25 °C to −60 °C), solvent, concentration, counterion, and the presence of free naphthalene; this shows that the naphthalene ligands in **1** do not undergo facile exchange with free naphthalene at room temperature. The ^1H NMR spectra of **1** revealed that identical naphthalene groups were bound to zirconium through one ring each (i.e., four multiplets of equal intensity due to two AA'BB' systems of hydrogens were observed). Corresponding ^{13}C NMR spectra of solutions of **1** and the solid showed the presence of η^4-naphthalene ligands. The ^{13}C chemical shift value of the quaternary carbon in **1** ($\delta = +154$) is shifted downfield from that of free naphthalene and lies in the quaternary carbon region characteristic of previously reported η^4-naphthalene transition metal complexes.[12]

A single-crystal X-ray study on **1a** provided proof for the tris(η^4-naphthalene)zirconate(2−) formulation[13] and revealed a coordination environment about the zirconium of approximate C_{3v} local symmetry and trigonal-prismatic geometry as defined by midpoints of the long C–C vectors of the coordinated diene units (Fig. 1), similar to those previously observed for tris(η^4-butadiene)molybdenum(0)[14] and tris(cyclooctatetraene)niobate(1−).[15] The noncoordinating, planar six-membered ring and coordinated diene units of the naphthalene ring have corresponding dihedral angles of 37.1, 32.4, and 38.4°, which are within the range of values previously observed for other η^4-naphthalene complexes.[16, 17] The C–C distances in the η^4-diene units in **1** are similar to analogous ones in $[Ti(\eta^4\text{-}C_{10}H_8)_2(SnMe_3)_2]^{2-}$,[5] (s-*cis*-$\eta^4$-2,3-dimethylbutadiene)-zirconocene (**2**),[18] and $[Lu(\eta^4\text{-}C_{10}H_8)(\eta^5\text{-}C_5H_5)(dme)]$ (**3**).[17] In particular, these compounds exhibit a very similar long, short, long pattern in the C–C distances of the coordinated diene units, a feature characteristic of many early transition metal η^4-diene complexes[18, 19] and indicative of coordinated dienes which have some degree of anionic character.

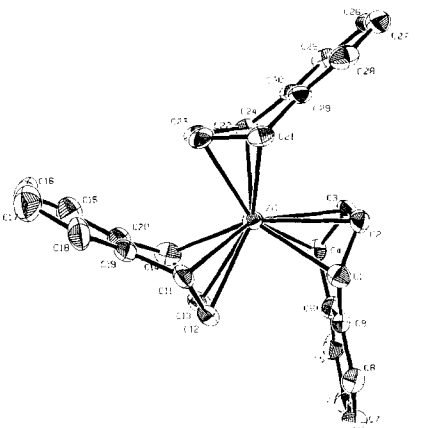

Fig. 1. Molecular structure of $[Zr(\eta^4\text{-}C_{10}H_8)_3]^{2-}$, 50% probability thermal ellipsoids. Important bond lengths [Å]: Zr-C1 2.482(6), Zr-C2 2.480(6), Zr-C3 2.474(6), Zr-C4 2.486(5), Zr-C11 2.480(6), Zr-C12 2.485(6), Zr-C13 2.471(6), Zr-C14 2.471(6), Zr-C21 2.496(5), Zr-C22 2.466(5), Zr-C23 2.470(6), Zr-C24 2.489(6), C1-C2 1.448(8), C2-C3 1.369(8), C3-C4 1.447(7), C1-C9 1.462(7), C4-C10 1.469(8), C11-C12 1.436(7), C12-C13 1.357(8), C13-C14 1.448(8), C11-C19 1.472(8), C14-C20 1.479(8), C21-C22 1.442(8), C22-C23 1.355(8), C23-C24 1.448(8), C21-C29 1.452(7), C24-C30 1.464(7). Mean C–C distance in the noncoordinating C_6 rings is 1.39(2) Å.

Structural and ^{13}C NMR data for the η^4-diene units bound to the metal atom in **1** and **2** are collected in Table 1 and indicate that the zirconium–diene interactions are remarkably similar in these otherwise very different compounds. For example, the ^{13}C chemical shift value for the atoms C2 and C3 in **1** is much closer to that of **2** than corresponding values previously reported for η^4-naphthalene complexes, (δ(C2,C3) = 84.0 for $[(\eta^4\text{-}C_{10}H_8)Cr(CO)_3]^{2-}$[12a]). Notably, however, the distinctive short, long, long, short patterns of the M–C(diene) bond

[a] See ref. [12a] for the numbering system of the naphthalene rings in **1**, counterion is $[K[2.2.2]cryptand]^+$. Data for **2** are from ref. [18]. [b] Chemical shifts are relative to Me_4Si, $^1J(C,H)$ in Hz. [c] $\delta(^1J(C,H))$ values for C1,C4 and C2,C3 of (*s-cis*-η^4-butadiene)zirconocene are 49.6 (144) and 112.0 (165), respectively [18]. [d] The average C–C and Zr–C distances in **1** are for corresponding carbon atoms of the three η^4-$C_{10}H_8$ groups.

On this basis, an unambiguous formal oxidation state assignment for the zirconium center in **1** cannot be made at this time, but the value is most likely to lie somewhere between the extremes of -2 and $+4$. The Zr–C bond lengths in **1** are within the range of average values (2.40–2.60 Å) previously observed for unsaturated hydrocarbon–zirconium complexes.[20] Also the [K([2.2.2]cryptand)] cations are well separated from the anions in the crystalline lattice and have structures which are essentially identical to those previously observed in the iodide salt.[21]

The chemical properties of **1** will be reported on separately, but its reaction with CO is described here to establish its role as an intermediate in the naphthalenide-promoted reductive carbonylation synthesis of $[Zr(CO)_6]^{2-}$.[11] For example, when 1.50 g of pure **1b** was treated with CO at atmospheric pressure in DME (50 mL) at $-55\,^\circ C$, the deep red brown reactant slowly changed to an insoluble purple product. Under the same conditions as originally described,[11] except the filtration step was conducted at $-30\,^\circ C$, 1.17 g (92%) of satisfactorily pure **4** was isolated. A ^1H NMR spectrum ($CDCl_3$, 20 °C) of the pentane-soluble component of this reaction showed only free naphthalene and small amounts of [15]crown-5, thus confirming that coordinated naphthalene was liberated during the carbonylation step [Eq. (a)].

$$\mathbf{1b} + 6\,CO \xrightarrow[DME]{-55\,^\circ C} \underset{\mathbf{4}}{[K([15]crown\text{-}5)_2]_2[Zr(CO)_6]} + 3\,C_{10}H_8 \qquad (a)$$

In summary, we have established that the reduction of $ZrCl_4 \cdot 2THF$ by naphthalene radical anion provides good yields of the first tris(naphthalene)metal complex, $[Zr(\eta^4\text{-}C_{10}H_8)_3]^{2-}$, which bears an obvious resemblance to the previously known neutral tris(butadiene) complexes of molybdenum and tungsten.[14, 22] Whether analogous or related anionic tris(arene) or tris(diene) complexes of the early transition metals are generally accessible by the methods described in this report is currently under examination in this laboratory.

Experimental Procedure

All operations were carried out under an atmosphere of argon.

1a: A cold ($-50\,^\circ C$) solution of $ZrCl_4 \cdot 2THF$ (1.00 g, 2.65 mmol) in DME (120 mL) was added to a stirred, cold ($-60\,^\circ C$) solution of $KC_{10}H_8$ (16.1 mmol, prepared in the usual way [23] from K (0.63 g, 16.1 mmol) and $C_{10}H_8$ (2.72 g, 21.2 mmol)) in DME (55 mL). The reaction mixture became orange-red within minutes and was stirred at $-60\,^\circ C$ for 12 h and then allowed to warm to $-10\,^\circ C$ over a period of about 3 h with constant stirring. It was then filtered into a stirred solution of [2.2.2]cryptand (2.00 g, 5.31 mmol) in DME (10 mL) at 0 °C, whereupon product began to precipitate. The mixture was cooled to $-60\,^\circ C$ with stirring and filtered at this temperature to collect a dark red microcrystalline powder, which was carefully washed with cold ($-60\,^\circ C$) DME (3 × 20 mL), pentane (2 × 20 mL), and dried in vacuo. By this procedure 1.58 g (46%) of **1a** was obtained, based on $ZrCl_4 \cdot 2THF$, m.p. 171–173 °C (decomp.), correct elemental analyses, IR (mineral oil mull in C=C region): 1560, 1541 cm^{-1}; UV/VIS (THF): 470 nm, $\varepsilon = 2400$; 275 nm, $\varepsilon = 9700\ L\,mol^{-1}\,cm^{-1}$; ^1H NMR: (500 MHz, $[(CD_3)_2N]_3PO$ or $[D_{18}]HMPA$, 20 °C), only resonances due to anion shown: $\delta = 2.64$ (*m*, H1,H4), 3.92 (m, H2,H3), 5.42 (m, H6,H7 or H5,H8), 5.69 (m, H5,H8 or H6,H7); ^{13}C NMR: (125.7 MHz, $[D_{18}]HMPA$, 20 °C): $\delta = 64.2$ (d, C1,C4, $^1J(C,H) = 151$ Hz), 112.0 (d, C6,C7 or C5,C8, $^1J(C,H = 146$ Hz), 112.6 (d, C2,C3, $^1J(C,H) = 161$ Hz), 117.2 (d, C5,C8 or C6,C7, $^1J(C,H) = 150$ Hz), 154.6 (s, C9,C10). Assignment of the C2,C3 resonance is based on its high $^1J(C,H)$ value and trends previously established for (*s-cis*-η^4-butadiene)zirconocene [18] and η^4-naphthalene complexes [12]. Based on this assigment, ^1H,^{13}C correlation NMR spectra were used to assign carbon and hydrogen resonances of the coordinated portion of the naphthalene, but no unique assignment of C5,C8, C6,C7 or corresponding hydrogen atoms was possible. CP/MAS $^{13}C\{^1H\}$NMR (25.1 MHz, 20 °C): $\delta = 63$ (s, C1,C4), 111 (s, br, C6,C7 or C5,C8, and C2,C3), 116 (s, C5, C8 or C6,C7), 153 (s, C9, C10), also resonances at 54 (br) and 70 (s) due to [2.2.2]cryptand. Single crystals of **1a** were prepared by dissolving 0.50 g of pure **1a** in HMPA (15 mL), in which the anion was shown to be stable for weeks at room temperature. The intensely red solution was filtered, and diethyl ether was carefully layered on it. After two days at room temperature well-shaped crystals had deposited. A red-black prism was selected for this X-ray study. Red-black needles were also present and were shown to contain **1a** in the same space group but different unit cell by an independent X-ray study. NMR spectra of the crystals grown for the X-ray study were identical to those of the bulk microcrystalline sample of **1a**.

1b: By the same procedure as described for **1a**, $ZrCl_4 \cdot 2THF$ (2.00 g, 5.30 mmol) was treated with $KC_{10}H_8$ (32.0 mmol) in DME (250 mL) at $-60\,^\circ C$. The reaction mixture was stirred over a period of 6 h while slowly warming to 0 °C, and then filtered into a solution of [15]crown-5 (5.5 g, 25 mmol) in DME (20 mL). After stirring the resulting deep red filtrate for 0.5 h at 0 °C, it was cooled to $-55\,^\circ C$ and stirred at this temperature for 12 h. The sparingly soluble product was separated by filtration at $-50\,^\circ C$, thoroughly washed with cold DME and methylbutane at $-50\,^\circ C$, and then dried in vacuo at room temperature. By this procedure deep red brown microcrystalline **1b** was obtained (4.2 g, 55% yield) based on $ZrCl_4 \cdot 2THF$, darkens above 135 °C, m.p. 179–181 °C (decomp.). Correct elemental analyses. IR, UV/VIS, and NMR spectra properties of **1b** were identical to those of **1a** except for absorptions due to the cations. When the above procedures were carried out in DME alone or with [18]crown-6 in DME, thermally stable red microcrystalline powders having the composition (by ^1H NMR spectroscopy) $K_2[Zr(C_{10}H_8)_3] \cdot DME$ or $[K([18]crown\text{-}6)]_2[Zr(C_{10}H_8)_3] \cdot 2THF$ (following crystallization from THF/pentane) were obtained in about the same yields. NMR spectra established that **1** was the only naphthalene complex present in these products.

An Anthracene-Based Fluorescent Sensor for Transition Metal Ions**

Luigi Fabbrizzi,* Maurizio Licchelli, Piersandro Pallavicini, Angelo Perotti, and Donatella Sacchi

Fluorescence quenching and enhancement can be used effectively for the identification of ions in solution. Fluorescent sensors have been and are currently being designed for various cations and anions.[1] A fluorescent sensor is essentially a two-component compound, in which a light-emitting group is covalently linked to a receptor specific for a particular ion. Sensor efficiency requires that the ion–receptor interaction modifies the fluorescence of the light-emitting unit. Changes of fluorescence intensity of two orders of magnitude and more are often observed, in other words the fluorescence can be switched on and off.[2] By virtue of its strong luminescence and chemical stability, the anthracene unit has been widely used in the design of fluorescent sensors. In the classical approach, a tertiary amino group is attached to the aromatic framework, and the thermodynamically favored amine-to-anthracene electron transfer quenches fluorescence.[3] Binding of H^+ [4] or a metal ion (e.g., Na^+,[5] Zn^{2+})[6] substantially increases the oxidation potential of the amine, thus preventing the photoinduced electron transfer and allowing fluorescence. Incorporation of the tertiary amino group in a crown ether type framework has paved the way to fluorescent sensors for alkali and alkaline-earth metal cations.[5]

We wished to extend this concept to the recognition of transition metal cations. To this end we attached a chelating dioxotetraaza unit to the 9-position of anthracene, according to the synthetic route outlined in Scheme 1.

Scheme 1. Synthesis of fluorescent sensor **2**. en = ethylenediamine.

Compound **2** (H_2L) displays the typical emission spectrum of anthracene in acetonitrile/water (4:1); the intensity does not change over the pH range 2–12. Its pK_{a1} and pK_{a2} values are 8.3 and 9.6, respectively. This indicates that the following three species are present in solution: H_4L^{2+}, in which the two terminal amino groups are protonated, the predominant species at pH < 8, H_3L^+ at pH values from 8 to 10, and H_2L at pH > 10. The protonation state of the dioxotetraaza unit does not alter the fluorescence of the adjacent anthracene unit. However, if one equivalent of Cu^{II} is added to an acidic solution of **2**, the fluorescence intensity I_F steadily decreases on titration with NaOH. Complete fluorescence quenching is observed when the excess strong acid has been neutralized and two further equivalents of OH^- have been added. The plot of I_F vs. pH (Fig. 1) displays a sigmoidal curve typical of a switching effect. Insights on the quenching mechanism are provided by an analogous titration experiment performed inside a spectrophotometric cuvette. On addition of base, the solution becomes pink-violet, and an absorption band at 520 nm develops. The absorbance A reaches its limiting value after neutralization of the excess strong acid and addition of two further equivalents of base. The plot of A vs. pH (Fig. 1) shows a sigmoidal curve, which is symmetrical

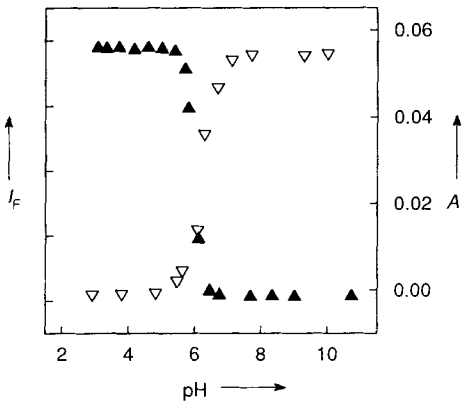

Fig. 1. Dependence of the fluorescence intensity (I_F, ▲) on pH and the absorbance of the band at 520 nm (A, ▽) for a solution of equimolar amounts of **2** and of Cu^{II} in $MeCN/H_2O$ (4:1).

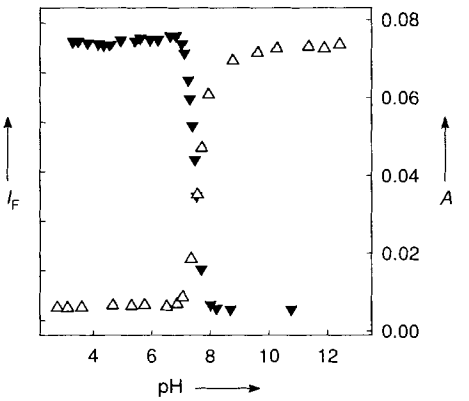

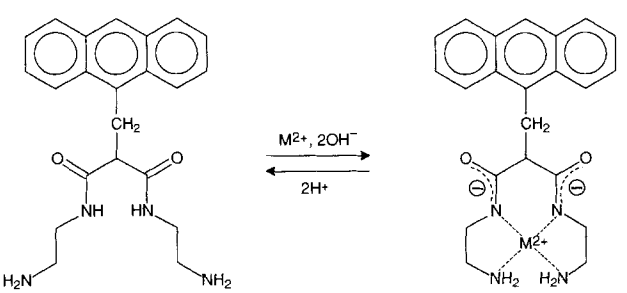

Fig. 2. Dependence of the fluorescence intensity (I_F, ▼) on pH and the absorbance of the band at 450 nm (A, Δ) for a solution of equimolar amounts of **2** and of Ni^{II} in $MeCN/H_2O$ (4:1).

to the I_F/pH profile and centered at the same pH (≈6). The pink-violet color arises from a d-d band of the square-planar complex **3** (M = Cu). Deprotonation of the two amide groups yields the tetradentate ligand L^{2-}, which chelates the metal atom. Copper(II)-promoted deprotonation of amide[7] and peptide[8] groups is a well-documented process in coordination chemistry and bioinorganic chemistry. Our findings demonstrate that the quenching of the anthracene fluorescence is associated with the coordination of the Cu^{II} ion by the dioxotetraaza unit of **2**. The radiationless deactivation of the excited state of the fluorophore can take place by means of either an energy transfer mechanism[9] (which should occur by electron exchange with an empty d orbital of the metal center[10]) or a Cu^{II}-to-anthracene electron transfer process (the oxidation of Cu^{II} to Cu^{III} is typically favored by the coordination of the deprotonated amide group).[11]

2 **3**

When one equivalent of Ni^{II} is added to a solution of **2** in aqueous acetonitrile, I_F decreases with increasing pH (Fig. 2). The plot of the absorbance at 450 nm (d-d transition) versus pH yields a symmetrical sigmoidal curve centered at pH ≈ 8. The absorption band at 450 nm corresponds to the yellow, low-spin, square-planar complex **3** (M = Ni).

It should be noted that if an acidic solution of **2** containing equimolar amounts of the 3d ions Mn^{II}, Co^{II}, and Zn^{II} (solution A) is titrated with base, I_F remains constant over the pH range 2–12. If one equivalent of Ni^{II} is added to solution A (to give solution B) titration with NaOH is accompanied by fluorescence quenching at pH ≈ 8 (sigmoidal curve similar to that in Fig. 2). Finally, if one equivalent of Cu^{II} is added to solution B and titration with base is performed, fluorescence is quenched at pH 6, as expected based on the results shown in Figure 1.

The absence of fluorescence quenching by Mn^{II} and Co^{II} ions is explained by the fact that these ions are not coordinated by the dioxotetraaza unit of **2**. The deprotonation of the amide group is very endothermic and can take place only if it is compensated energetically by the formation of a strong bond between the metal and the deprotonated amide group.[12] This is the case for the Cu^{II} and Ni^{II} ions, which profit greatly from ligand field stabilization effects. But it is not the case for divalent metal ions earlier in the first transition series such as Mn^{II} and Co^{II}. Spectrophotometric titration experiments confirm that Mn^{II} and Co^{II} ions are not coordinated by the dioxotetraaza unit of **2**: d-d bands are not observed even in strongly basic solutions. The shift of the I_F/pH sigmoidal curve to higher pH values upon transition from Cu^{II} to Ni^{II} reflects the stronger metal–ligand interactions and the greater stability of the Cu^{II} complex in solution in comparison to the Ni^{II} complex. The Zn^{II} ion (d^{10}) does not profit from ligand field effects and can thus neither promote deprotonation of amide groups nor be chelated by the dioxotetraaza unit in **2**. Zn^{II} is not redox active and does not possess any empty low-energy orbitals, which are essential for energy transfer and the radiationless decay of the anthracene excited state.

We have found that compound **2** is an efficient fluorescent sensor able to discriminate Cu^{II} and Ni^{II} ions from other divalent 3d metal ions. But can Cu^{II} and Ni^{II} be distinguished? It can be seen in Figures 1 and 2 that at pH ≈7, Cu^{II} promotes fluorescence quenching, while Ni^{II} does not. Thus, when a solution of

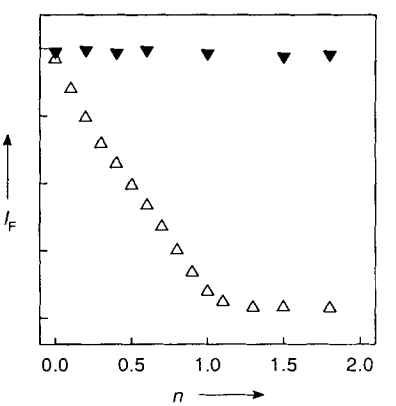

Fig. 3. Discrimination of Cu^{II} and Ni^{II} ions by the fluorescent sensor **2**. Ni^{II} is added to solution of **2** in $MeCN/H_2O$, which was adjusted to pH 7.1 with the 2,6-lutidine (▼). Then Cu^{II} is added (Δ). n = number of equivalents of the added metal ion.

2 was adjusted to pH 7.1 with 2,6-lutidine and Ni^{II} is added, no substantial decrease in I_F was observed, even after the addition of one or more equivalents of metal ion (Fig. 3). When Cu^{II} was added to the same solution, I_F decreased linearly and reached zero on addition of one equivalent of the metal ion (Fig. 3).

Until now anthracene-based fluorescent sensors for metal ions have been known primarily for alkali and alkaline-earth metal ions. Typically the uncomplexed sensor does not fluoresce and the binding of the metal to the receptor results in fluoresce; this switching mechanism is triggered by photoinduced electron transfer.[1] Compound **2** is the prototype of a new family of pH-sensitive anthracene-based fluorescent sensors for transition metal ions. Here the uncomplexed sensor fluoresces, and the interaction with the 3d metal ion leads to fluorescence quenching; this switching mechanism is triggered by energy transfer. Sensor selectivity towards transition metal ions can be modified by changing the structural features of the chelating unit: this unit can be cyclic or noncyclic, the number and arrangement of amide groups can be changed, and other heteroatoms can be included. We are currently designing and testing these types of sensors.

Experimental Procedure

1: Diethyl malonate (0.75 g, 4.72 mmol) and 9-chloromethylanthracene (0.91 g, 4.03 mmol) were added to a solution of sodium ethoxide in anhydrous ethanol (0.11 g, 4.72 mmol of Na in 20 mL of EtOH). The solution was heated at reflux for 18 h. The NaCl precipitate formed during the reaction was filtered off and the solvent evaporated in vacuo. The residue was redissolved in diethyl ether, and yellow crystals were obtained by slow evaporation. Yield: 68%. Correct C,H,N analysis for $C_{22}H_{22}O_4$.

2: Ethylenediamine (30 mL, freshly distilled over CaO) and **1** (0.5 g, 1.43 mmol) were stirred at room temperature under nitrogen for 7 d. Excess ethylenediamine was distilled off under reduced pressure. Treatment of the yellow residue with diethyl ether gave a pale yellow precipitate, which was filtered off and recrystallized from ethanol. Yield 74%, M.P. 205–208 °C. MS (70 eV): *m/z* 378 (M^+, 73%), 349 ($[M-CHNH_2]^+$, 52%), 191 ($C_{14}H_9CH_2^+$, 100%). Correct C,H,N analysis for $C_{22}H_{26}N_4O_2$.

Benzobis(thiadiazole)s Containing Hypervalent Sulfur Atoms: Novel Heterocycles with High Electron Affinity and Short Intermolecular Contacts between Heteroatoms**

Katsuhiko Ono, Shoji Tanaka, and Yoshiro Yamashita*

Heterocycles containing hypervalent sulfur atoms have attracted considerable attention owing to their unique electronic structures and reactivities.[1] 1,2,5-Thiadiazole rings containing a tetravalent sulfur atom are more stable than the related thiophene rings found in the stable pyrazine derivative **1**[2] and the stable bicyclic compound **2**.[3] Compound **1** is a strong electron acceptor[4] and forms a ribbonlike structure by short intermolecular contacts between the hypervalent S atoms and the N atoms. In this context heterocycle **3a** is expected to have a high electron affinity and form a unique molecular network. This compound resembles the framework of bis([1,2,5]thiadiazolo)-tetracyanoquinodimethane (BTDA-TCNQ **4**), which is an electron acceptor in organic metals and forms a sheetlike network through short S···N≡C contacts.[5] However, **5**, which was prepared from **4**, is its only reported derivative.[6] We have now synthesized the λ^2,λ^4-benzobis(thiadiazole) derivatives **3b** and

[**] This work was supported by research fellowships from the Japan Society for the Promotion of Science for Young Scientists. We thank Prof. Dr. K. Tanaka, Institute for Molecular Science, for conducting the X-ray crystallographic study, and Prof. Dr. S. Hirayama, Kyoto Institute of Technology, for the measurement of the fluorescence spectrum of **3c**.

3c and the analogous selenadiazoles **6b** and **6c**.[*] We report here their preparation and characterization, and the crystal structure of **3b**.

Reduction of dinitrobenzothiadiazole **7a**[7] with iron dust in acetic acid gave diamine **8a**.[8] Heterocycle **3b** was prepared in 74% yield by reaction of diamine **8a** with thionyl chloride in pyridine at room temperature. The analogous heterocycle **6b** was obtained in 40% yield from diamine **8a** and selenium dioxide. The palladium-catalyzed coupling ($[PdCl_2(PPh_3)_2]$) of bromide **7a** with phenyltributyl stannane[9] in tetrahydrofuran afforded **7b**, which was reduced with iron dust to give diamine **8b**. Heterocycle **3c** was prepared in 95% yield by reaction of diamine **8b** with *N*-thionylaniline and trimethylsilyl chloride in pyridine at 80 °C. The selenium compound **6c** was obtained in 82% yield from the diamine **8b** and selenium dioxide. These heterocycles were purified by sublimation under reduced pressure and isolated as deep red crystals for **3b** (decomp > 280 °C), purple prisms for **3c** (decomp 310–311 °C), purple crystals for **6b** (decomp > 280 °C), and blue crystals for **6c** (decomp 367–371 °C). The absorption maxima of **3b, c** and **6b, c** are listed in Table 1 and compared with that of benzobis(thiadiazole) **9**, whose thiadiazole ring can be represented by a standard Kekulé structure. The red shifts of **6b, c** from **3b, c** are regarded as a polar effect caused by the selenium atom. We thought that introduction of substituents in the 4- and 8-positions in **3** and **6** (**3a**/**6a** → **3b**, **c**/**6b**, **c**) would underscore this effect, since these positions have larger atomic orbital coefficients in the HOMO and the LUMO (Fig. 1).[10]

Table 1. Absorption maxima and fluorescence emission maxima of heterocycles **3**, **6**, and **9** [a].

Heterocycle	λ_{abs} [nm] (lg ε)	λ_{em} [nm]
3b	524 (3.64)	557
3c	558 (3.99)	642
6b	609 ([b])	643
6c	625 (4.01)	689
9	283 (4.57)	367

[a] In CH_2Cl_2. [b] Not obtained because of its low solubility.

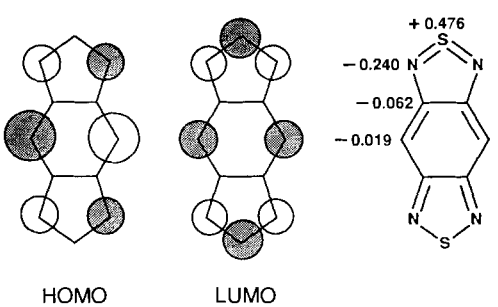

Fig. 1. HOMO, LUMO, and charge distribution of **3a** calculated by the MNDO-PM3 method.

The cyclic voltammograms (CV) of **3b, c** and **6c** in dichloromethane showed two reversible one-electron redox waves.[11] The half-wave reduction potentials are given in Table 2. The first reduction potentials of these heterocycles are comparable to that of *p*-benzoquinone ($E = -0.46$ V). The electron-withdrawing bromo groups at 4- and 8-positions further increase the reduction potentials (cf. **3b** and **3c**). The fact that the Kekulé-type isomer **9** is a weaker acceptor (Table 2) shows that the high electron affinity of **3** and **6** is attributable to the 14 π electron system containing a tetravalent sulfur atom, which generates more stable Kekulé-type thiadiazole moieties upon accepting an electron.

Table 2. Reduction potentials (in V) of heterocycles **3**, **6c**, and **9** [a].

Heterocycle	E_1	E_2	ΔE
3b	−0.35	−1.10	0.75
3c	−0.61	−1.30	0.69
6c	−0.53	−1.21	0.68
9	−1.45	–	–

[a] 0.1 M nBu_4NClO_4 in CH_2Cl_2, Pt electrode, scan rate 100 mVs^{-1}, potentials vs. standard calomel electrode (SCE).

A single crystal of **3b** obtained by recrystallization from benzonitrile was selected for X-ray structural analysis.[12] In the crystal the molecule is planar and has C_i symmetry (Fig. 2). The S–N bond lengths (given in Fig. 2) are shorter than those of **9** (1.615 and 1.620 Å),[13] and the N–C bond lengths longer (for **9**, 1.325 and 1.337 Å). The bond lengths in the thiadiazole rings are similar to those in the pyrazine derivative **1** (S–N 1.597 and 1.609 Å, N–C 1.347 and 1.370 Å).[2] Although the molecule is uniformly stacked along the *c* axis, the stacking shown in Figure 3a indicates less effective interactions between the HOMO and the LUMO (Fig. 1).

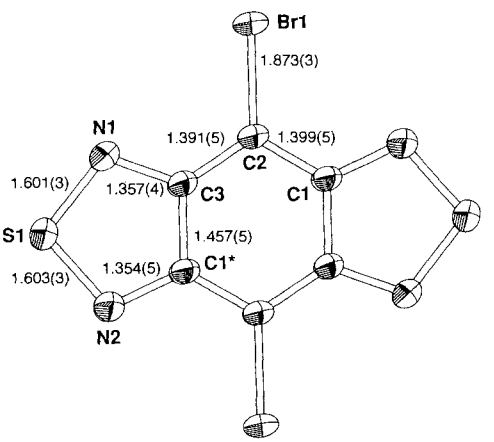

Fig. 2. Molecular structure of **3b** with bond lengths [Å] (ORTEP).

The crystal structure is composed of a set of two ribbon-type columns which extend in the [0 1 1] and [0 1 −1] directions and are characterized by short intermolecular S···N and N···N contacts (Fig. 3b). These columns interact with each other through short Br···N contacts to form a network. The distances of the relevant contacts, S···N, N···N, and Br···N, are significantly smaller than the sum of the van der Waals radii (3.35, 3.10, and 3.40 Å). According to the net atomic charges of **3a** calculated by the MNDO-PM3 method, the hypervalent S atoms have significant positive charge and the N atoms significant negative charge (Fig. 1). Thus, the S···N interactions are attributed to an electrostatic effect, which seems to induce dense packing in the crystal ($\rho_{calcd} = 2.58$ gcm^{-3}).

[*] Only one of the possible resonance forms is shown for each compound. For **6** the contribution of the structure containing a tetravalent Se atom is small.

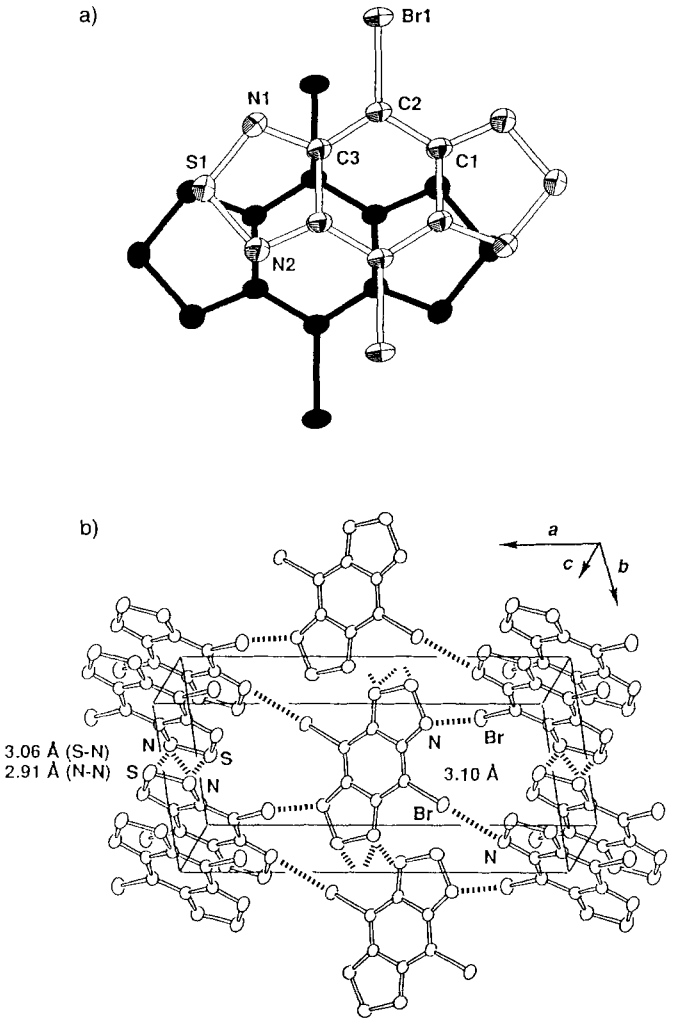

Fig. 3. Crystal structure of **3b**: a) stacking, b) ribbonlike network.

MNDO-PM3 calculations[10] for **3a** and **6a** also show that the energy levels of the HOMOs (− 8.73 eV for **3a** and **6a**) are higher than that of **9** (− 9.94 eV), and that the energy levels of the LUMOs (− 3.21 eV for **3a** and −3.30 eV for **6a**) are lower than that of **9** (−1.95 eV). These results are supported by the longer absorption maxima and the higher electron affinities of **3** and **6**. Thus, the electron properties of the heterocycles containing the hypervalent sulfur atoms are fairly different from those of the Kekulé-type isomer. On the other hand, substitution of a sulfur atom by a selenium atom little affects the HOMO and the LUMO of the 14π electron system.

Heterocycles **3** and **6** display fluorescence emission spectra, which have broad maxima (Table 1), upon photoexcitation in dichloromethane at room temperature.[14] Since **3** and **6** have high electron affinities, their photochemical behavior is of interest and currently under study.

Stereoselective Intramolecular Alkylation of Glycosylimides to Highly Functionalized Bicyclic 2,5-Azepanediones and Heterotricyclic [5.3.1.0^{2,6}]undecanamides**

Carsten Endres Sowa and Joachim Thiem*

N-Iodosuccinimide (NIS) is an effective and established reagent for the stereoselective glycosylation of glycals.[1] With secondary alcohols like, for example, cholesterol, the corresponding *N*-glycosylated succinimides could frequently be isolated as a by-product in substantial yields.[2, 3] In such cases, the succinimide anion apparently competes with weak nucleophiles to attack the intermediate iodonium ion. When no other nucleophiles or moisture is present and light is excluded, the stereoselective addition of NIS to the enol ether function of several glycals occurs with excellent yields.[4] The iodine substituent can always be quantitatively removed with Bu_3SnH/AIBN to give α-*N*-(2-deoxyglycosyl)succinimides.[4] This very simple preparative procedure and the high total yield is the motive for investigating the use of such glycosylimides in synthesis.

Kanaoka et al. photochemically converted *N*-alkylsuccinimides in a Norrish type II reaction to simple alkylated ε-lactams.[5, 6] In this way, *N*-cyclohexylsuccinimide, for example, was transformed in mg amounts into the enantiomeric mixture of 5,6-(perhydrobenzo)-4-oxo-ε-lactam, a bicyclic 2,5-azepanedione. In this reaction the α-position to the imide in the alkyl

[**] This work was supported by the Fonds der Chemischen Industrie.

residue undergoes *cis* radical alkylation, and the imide ring is expanded to the 4-oxo-ε-lactam. Griesbeck and Mauder applied this reaction to enantiomerically pure phthalimide derivatives of several simple amino acids.[7] As well as the predominantly β,γ-unsaturated amino acids, substituted dihydrobenzazepine-2,5-diones and a benzoannelated pyrrolizidinone were also isolated with remarkable diastereoselectivities.

It seemed of interest to investigate the corresponding reaction on highly functionalized monosaccharides. The model compound 3,4-dihydropyran (**1**) was treated with NIS and subsequently reduced to *N*-(tetrahydro-2-pyranyl)succinimide (**5**) with Bu_3SnH/AIBN. With this heterocyclic system, conformational aspects and also influences of protective groups in the saccharides could be excluded. The irradiation of **5** with UV light (254 nm) in acetonitrile proceeded regioselectively, as expected, to give the enantiomeric mixture of the bicyclic 2,5-azepanedione **9**. In this reaction the conditions, particularly the conversion, reaction time, and temperature, were optimized and then applied to the glycosylsuccinimides **6**, **7**, and **8** (Scheme 1).

The wavelength used precludes carbonyl, alkenyl, and phenyl groups as hydroxy protective groups, and silyl ethers proved to be advantageous. The 2-deoxyxylo derivative (**6**) produced the expected bicyclic 2,5-azepanedione **10** in a diastereoselective alkylation at C-2 with 52% yield. In contrast, the glycosylimides **7** and **8** react differently under the same conditions. The *tert*-butyldimethylsilyl-protected glycosylimide **7** forms the azepanedione **11** only as a by-product (21%) (Table 1). The main fraction results from a 1,7 hydrogen abstraction and subsequent C–C coupling at C-5 of the sugar to give the heterotricyclic compound **12** (62%). Changing the protective group to trimethylsilyl as in **8** gives a completely stereoselective alkylation of the monosaccharide to the tricyclic compound **13** with a yield of 83% (Table 1). The *exo* structure can be proven by a clear NOE effect of the alcoholic proton with the ring protons H-9 (5%) and H-10_{eq} (3%).

Scheme 1. Reaction mechanism of the photochemical cyclization of *N*-glycosylsuccinimides. TBDMS = *tert*-butyldimethylsilyl, TMS = trimethylsilyl.

[a] Correct elementary analyses have been obtained for all new compounds.

By selecting the monosaccharide and protective groups, both sets of products are possible. The different conformations and the type of substitution at C-5 have crucial influences.[8] The abstraction of the hydrogen H-5 creates in the case of hexopyranoses an axial, tertiary radical, which is additionally stabilized by the ring oxygen. The short distance between the carbonyl group and H-5 results in the selective alkylation at C-5 of derivative **8**, as the conformation is sufficiently flexible ($^1C_4$: $^4C_1$ ≈ 1:1 according to ^{1}H NMR spectroscopy). Surprisingly, the TBDMS derivative **7** is almost exclusively in the $^1C_4$ chair conformation (*trans*-$J_{1,2}$ = 11.2, $J_{4,5}$ = 2.0 Hz). Though the flexibility is low, it is apparently enough for the synthesis of the tricyclic compound **12**, not the azepanedione **11**, as the main product. This assumption is supported by the temperature dependence of the product distribution. The proportion of the azepandione derivative **11** increases from 21% (**12**: 62%) at room temperature to 31% (**12**: 45%) at −5 °C. The conversion, however, decreases considerably, and further cooling eventually stops the reaction totally. At the moment, bridged and thus 3,6-anhydro sugars fixed in the $^1C_4$ chair form are being investigated, from which the exclusive formation of azepanedione derivatives are expected.

An intramolecular, stereoselective alkylation underlies both sets of products, which leads to highly functionalized enantiomerically pure heterocyclic compounds. The azepanediones **9**–**11** are [5.4.0]bicyclic α-oxo-aminals and therefore contain a novel substructure. The biological properties of this new class of substance are presently being screened. It is emphasized that, in one step, two adjacent quaternary and functionalized bridge

heads result from the synthesis of the heteroundecanamides **12** and **13**.

In this intramolecular carbon chain elongation of the monosaccharide, a cyclic derivative of a nonose is formed.[9] We are attempting to synthesize higher functionalized components by varying the glycal and by using other imides.

Experimental Procedure

(1*S*,6*S*,7*R*,8*S*,9*R*)-6-hydroxy-8,9-bis(trimethylsiloxy)-7-(trimethylsiloxymethyl)-11-oxa-2-aza-tricyclo[5.3.1.$0^{2,6}$]undecane-3-one **13**: 250 mg **8** (0.62 mmol) were dissolved in degassed, anhydrous acetonitrile or *n*-hexane and irradiated for 4 h at 18 °C with UV light (λ = 254 nm, 60 W low-pressure mercury lamp). The solvent was removed, and the raw product purified on silica gel. From a conversion of 76%, 157 mg (83%) remain.

Homoleptic Thiolato Complexes: Di- and Trinuclear Ti^{IV} Complexes with Unexpected Metal–Sulfur Cores, $[NMe_2H_2][Ti_2(SMe)_9]$ and $[Ti_3(SMe)_{12}]$**

Wolfram Stüer, Kristin Kirschbaum, and Dean M. Giolando*

Normally six-coordinate metal centers have approximate octahedral symmetry (O_h).[1] Notable exceptions are transition-metal complexes of the type $[M(1,2\text{-}S_2C_2R_2)_3]^-$ and $[M(1,2\text{-}S_2C_6H_4)_3]^-$, the majority of which adopt approximate trigonal-prismatic symmetry (D_{3h}).[2] Only recently, $[ZrMe_6]^{2-}$ was reported to be the first homoleptic complex with unidentate ligands which exhibits non-O_h symmetry.[3] In the course of our interest in complexes with six-coordinate metal centers[4] we have recently reported an unusual C_2-distortion from O_h geometry in $[Ti(S_2C_6H_4)_3]^{2-}$; the coordination about Ti can be described as *skew*-trapezoidal bipyramidal or, alternatively, the S_6 polyhedron can be considered pentagonal-bipyramidal, lacking an equatorial vertex.[5] To gain insights into the factors governing this coordination geometry we have prepared six-coordinate Ti^{IV} complexes containing unidentate thiolato ligands. X-ray structural analysis has revealed a trigonal distortion of the octahedral coordination about the Ti center in $[Ti_2(SMe)_9]^-$, and a novel trigonal-prismatic coordination geometry about the central Ti atom with two face-sharing O_h-symmetric TiS_6 cores in $[Ti_3(SMe)_{12}]$. In addition titanium thiolato complexes are of current interest due to their suitability as precursors for the formation of titanium sulfide thin films by chemical vapor deposition techniques. Success in this area of research has been demonstrated with $[Ti(StBu)_4]$ and $[TiCl_4(HSR)_2]$, where R = *cyclo*-pentyl and *cyclo*-hexyl.[6, 7]

Titanium thiolato complexes have been studied to a limited extent, and general routes to homoleptic complexes have been particularly elusive.[8, 9] Early work employed the reaction of $[Ti(NR'_2)_4]$ (R' = Me or Et) and RSH (R = Me, Et, or *i*Pr) which afforded complexes of general formula $[Ti(SR)_4(HSR)_x(NHR'_2)_y]$, where $(x + y)$ varied from 0.8 to 1.33.[10] Attempts to prepare $[Ti(SR)_4]$ from the reaction of $TiCl_4$ and RSH/NH_3 were not entirely successful because a mixture of compounds $[TiCl_{4-x}(SR)_x]$, where x varies from 1 to 4, was obtained.[10]

When we treated $[Ti(NMe_2)_4]$ with seven molar equivalents of MeSH, a dark red microcrystalline product, $[NMe_2H_2]$-**1**, was obtained in good yield.[11] Almost black single crystals crystal-

$[NMe_2H_2][Ti_2(SMe)_9]$ $[NMe_2H_2]$-**1**

lize from CH_2Cl_2/hexane mixtures; Figure 1 shows the solid-state structure of the $[Ti_2(SMe)_9]^-$ ion.[12] Bond lengths and

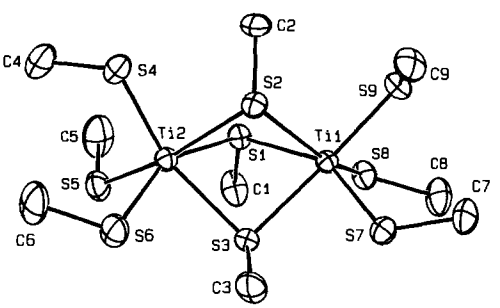

Fig. 1. Structure of **1**. Important distances [Å] and angles [°]: Ti-S (bridging) 2.511(1)–2.575(1) Å, Ti-S (terminal) 2.3211(9)–2.362(1) Å, *trans*-S-Ti-S 148.04(3) 162.42(4), *cis*-S-Ti-S 73.11(3)–115.63(3).

angles about the Ti centers compare well to those found for other Ti^{IV} complexes with MeS ligands.[13] The anion **1** contains two Ti atoms each coordinated by three terminal and three bridging MeS ligands. To a first approximation, the Ti_2S_9 framework may be described as a face-sharing bioctahedron which is unique for sulfur donor ligands; the closest structural analogue[14] is $[Ti_2Cl_9]^-$. While the $TiCl_6$ cores in $[Ti_2Cl_9]^-$ are close to the O_h limit, the TiS_6 cores in $[NMe_2H_2]$-**1** are significantly distorted with no major structural differences between the two TiS_6 cores. Both TiS_6 cores are trigonally distorted from O_h to the midpoint of the O_h-to-D_{3h} reaction coordinate: Ti1, twist angle of 31.10(4)° with dihedral angles between adjacent S_3 faces (δ) at b_1 of 40.37(4)° and b_2 of 92.50(3)°; Ti2, twist angle of 33.30(5)° with δ at b_1 of 42.83(5)° and b_2 of 92.13(3)°.[15] Interestingly, these MS_6 cores are similar to those observed for several $[M(1,2\text{-dithiolato})_3]^{2-}$ complexes, where M = Ti or Zr.[16]

[**] This work was supported by the petroleum Research Fund, administered by the American Chemistry Society.

The reaction of four equivalents of MeSH with $[Ti(NMe_2)_4]$ results in the isolation of red-brown single crystals of $[Ti_3(SMe)_{12}]$ (**2**).[17] Figure 2 shows the solid-state structure of the compound.[11] The bond lengths are similar to those observed in $[NMe_2H_2]$-**1**. Complex **2** lies on a crystallographic C_3 axis and has a linear chain of three Ti atoms, the two outer Ti atoms are coordinated by three terminal and three bridging MeS ligands, while the central Ti atom is coordinated by six bridging MeS ligands. Overall, the geometry of the Ti_3S_{12} framework may be described as a trigonal-prismatic center with a face-sharing octahedron on both trigonal faces. This novel arrangement has as its closest structural analogue in the metal thiolato-bridged "double cubane" complexes.[18] The arrangement of ligands in the two outer TiS_6 polyhedra is similar; both polyhedra are trigonally distorted from O_h: Ti2, twist angle of 49.22(3)° with δ at b_1 of 60.57(2)° and b_2 of 78.44(2)°; Ti3, twist angle of 44.50(3)° with δ at b_1 of 55.69(2)° and b_2 of 81.77(2)°.[15] A distortion is evidenced by the two Ti atoms being about 0.4 Å from the center of the S_6 core, shifted towards the external S_3 faces. For the central Ti atom the TiS_6 core is unusually close to the D_{3h} limit: Ti1, twist angle of 10.69(2)° with δ at b_1 of 14.44(7)° and b_2 of 109.60(2)°.

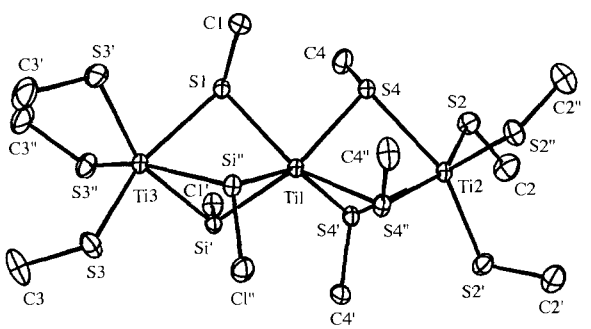

Fig. 2. Structure of **2**. Important distances [Å] and angles [°]: Ti2 and Ti3: Ti-S (bridging) 2.5580(8)-2.5732(9), Ti-S (terminal) 2.3134(7)-2.3177(7), *trans*-S-Ti-S 158.03(4)-159.62(4), *cis*-S-Ti-S 75.12(3)-101.88(4); Ti1: Ti-S 2.4319(8)-2.4355(8), *trans*-S-Ti-S 128.89(3)-143.74(3), *cis*-S-Ti-S 79.62(3)-84.14(2).

All of the trigonally distorted TiS_6 coordination geometries observed in $[NMe_2H_2]$-**1** and **2** are unexpected. Sterically, an O_h coordination, with a displacement of the Ti center towards the terminal MeS ligands, is anticipated. Computational studies[19] on d^0-ML_6 complexes suggest a tendency for a twofold distortion from O_h towards a bicapped tetrahedral (BCT) geometry, as observed[5] in $[Ti(S_2C_6H_4)_3]^{2-}$ which is midway along the O_h-to-BCT reaction coordinate. It is not readily apparent why the structural features of $[NMe_2H_2]$-**1** and **2** are observed. However, as discussed[3] for the D_{3h} structure of $[ZrMe_6]^{2-}$, a reduction of symmetry induced by a second-order Jahn-Teller effect may stabilize the trigonally twisted O_h coordination polyhedra. Noteworthy, non-O_h coordination geometries are favored by insignificant, or the absence of, M-L π-bonding.

The behavior of these compounds in solution is complicated and warrants further investigation. Our preliminary studies by NMR spectroscopy suggest that $[NMe_2H_2]$-**1** dissolves to afford **2** and at least one other compound. In dilute solutions (ca. 10^{-3} M, CD_2Cl_2, 21 °C) the ^1H NMR spectrum of $[NMe_2H_2]$-**1** contains two resonances at $\delta = 3.59$ and 3.13 (1:1 ratio), assigned to **2**, and single resonances assigned to coordinated Me_2NH ($\delta = 8.00$ and 2.42) and MeSH ($\delta = 2.05$ and 1.26). As the temperature decreases (−25, −60, and then to −85 °C) the NMR spectra undergo a series of changes: the resonances at $\delta = 8.00$, 3.59, and 3.13 are slightly broadened and shifted; a new feature at $\delta = 3.31$ appears as a sharp singlet at −25 °C, which is severely broadened at −85 °C; the resonance at $\delta = 2.42$ produces two broad singlets at $\delta = 2.77$ and 2.70 at −25 °C, which merge to a singlet at $\delta = 2.75$ at −60 °C and then reappear at −85 °C; and, those at $\delta = 2.05$ and 1.26 sharpen to a well-resolved doublet and quartet, respectively. For saturated solutions of $[NMe_2H_2]$-**1** at 21 °C a new, very broad feature at $\delta \approx 3.4$, is observed, while the resonance at $\delta = 3.13$ broadens and the remaining resonances are unchanged. Tentatively, these results indicate that on dissolution $[NMe_2H_2]$-**1** affords **2** and, possibly the mixed complex $[Ti(SMe)_4(SHMe)_x(NHMe_2)_y]$ identified in the earlier literature.[6]

Synthetic and structural studies on this class of compounds should have an impact on determining new aspects of six-coordinate complexes as well as providing advances to the development of titanium sulfide cathodes for battery technology. We are continuing our efforts to prepare homoleptic monotitanium complexes containing unidentate RS ligands and to elucidate the solution chemistry of this class of compounds.

Experimental Procedure

All reagents were purchased and used without further purification except where noted. All solvents were freshly distilled: hexanes and THF from Na/benzophenone; CH_2Cl_2 from P_2O_5. All experimental work was conducted under an inert atmosphere.

$[NMe_2H_2]$-**1**: A reaction flask containing $[Ti(NMe_2)_4]$ (0.450 g, 2 mmol) in THF (30 cm³) was immersed in liquid nitrogen, and MeSH (0.78 cm³, 14 mmol) was added in one portion. On warming the mixture to 21 °C the color changed from pale yellow to dark red-brown. Stirring was continued at 21 °C for 20 h. The solvent was evaporated under vacuum without warming and the resultant dark red microcrystalline solid was dried in vacuo for 2 h, correct C,H,N analysis. Single crystals suitable for X-ray crystallography were obtained after storage of a saturated hexane/CH_2Cl_2 solution at −10 °C for 1 week.

2: A reaction flask containing $[Ti(NMe_2)_4]$ (0.450 g, 2 mmol) in THF (30 cm³) was immersed in a dry-ice/acetone bath. MeSH (0.45 cm³, 8 mmol) was added in one portion. On warming the mixture to 21 °C the color changed from pale yellow to dark red-brown. Stirring was continued at 21 °C for 20 h. The solvent was evaporated under vacuum with the aid of a water bath. After removal of volatiles in vacuo the initially oily residue solidified. The dark red-brown solid was dissolved in a mixture of hexane (50 cm³) and CH_2Cl_2 (100 cm³) and stored at −10 °C. Dark red-brown single crystals suitable for X-ray crystallography were obtained, correct C,H,N analysis.

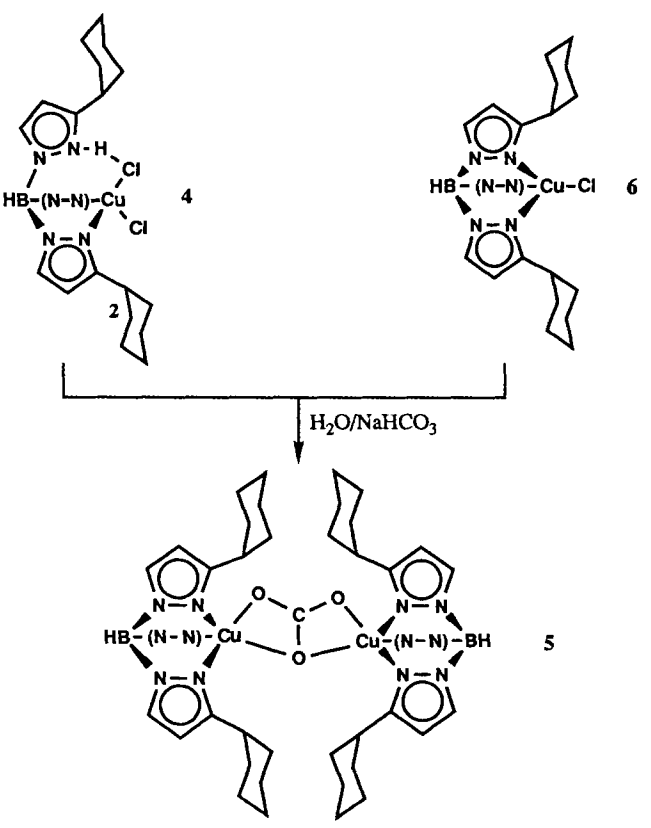
The First Structurally Characterized Metal Complex Involving the Free Acid of a New Tris(pyrazolyl)borate as Ligand

Arnold L. Rheingold,* Brian S. Haggerty, and Swiatoslaw Trofimenko*



In this communication we report the first example of an isolated and structurally characterized metal complex involving the free acid of a new tris(pyrazolyl)borate as ligand. The scorpionato (polypyrazolylborato) ligands,[1] which have been known for almost 30 years,[2] have been used in the form of their alkali metal or thallium salts to synthesize a plethora of metal complexes. By contrast, their free acids $[R_nB(pz^*)_{4-n}]H$ (pz^* = 1-pyrazolyl or 1-pyrazolyl derivative; pz = pyrazolyl), obtained on acidification of the anions $[R_nB(pz^*)_{4-n}]^-$, received scant attention, although they have been known as long as the ligands themselves.[3] Such protonated species are often the intermediate stage for ligand hydrolysis to boric acid and the corresponding pyrazole. It was noted quite early that the scorpionate free acids can, in some cases, be used to obtain the same metal complexes as those derived from the anions.[3] The use of free acids was at times even necessary if the metal coreactant was stable predominantly at low pH, as for instance in the preparation of complexes $[TpTcCl_2O]$[4] and $[TpReO_3]$ (Tp = $HB(pz)_3$).[5] The uncoordinated pyrazolyl groups in the pzTp-($B(pz)_4$) and Tp ligands retain their donor ability and can be protonated, as in $[(pzTp)_2M]$[3] or $[Tp^*Rh(CO)_2]$ (Tp^* = $HB(3,5\text{-}Me_2pz)$).[6] When two pyrazolyl groups are available, bis chelates can be formed as in $[(\eta^3\text{-}CH_2CRCH_2)\text{-}Pd(pz)_2B(pz)_2Pd(\eta^3\text{-}CH_2CRCH_2)]^+$.[7] A complex involving a homoscorpionate free acid with all pyrazolyl groups participating in coordination has, however, never been obtained.

We have now synthesized and studied a new homoscorpionate ligand, hydrotris(3-cyclohexylpyrazol-1-yl)borate (= Tp^{Cy}),[8] prepared from 3-cyclohexylpyrazole (**1**) and KBH_4. This ligand was expected to provide a larger hydrophobic pocket around the metal than the related 3-isopropyl analogue Tp^{iPr}[9] and its variants $Tp^{iPr,4Br}$,[9] $Tp^{iPr,Me}$,[10] and Tp^{iPr2},[11] it is of special interest because ligands of this type are used to construct model compounds mimicking a variety of enzymes (Scheme 1).[12]

Scheme 1. -(N-N)- denotes the third, hidden 3-cyclohexylpyrazol-1-yl group.

As part of our investigations into complexes of type $Tp^{Cy}MX$, we tried to prepare $[Tp^{Cy}CuCl]$ (**6**) by adding a solution of

[$Tp^{Cy}Tl$] (**2**) in dichloromethane to a solution of $CuCl_2 \cdot 2H_2O$ in THF. Much to our surprise, we obtained a bright orange compound **4** instead of the expected chestnut-red crystals. The IR spectrum of **4** is quite different from that typical of the tetrahedral complexes [$Tp^{Cy}MCl$] (M = Co, Ni, Zn) isolated under the same conditions, and also from that of an authentic sample of **6** produced as the only product in the reaction of **2** with anhydrous $CuCl_2$ in dichloromethane. A BH stretch at 2538 cm^{-1} is observed in the IR spectrum of **4** (cf., 2488 cm^{-1} for **6**, and 2490 $\pm$ 3 cm^{-1} for $TpH^{Cy}MCl$, where M = Co, Ni, Zn). Although **4** is paramagnetic, its ^1H NMR spectrum shows the presence of a protonated nitrogen atom and two types of pyrazolyl groups in 2:1 ratio. Complex **4** was identified as [{(Tp^{Cy})H}$CuCl_2$]. This is the first instance of a scorpionate free acid, namely [(Tp^{Cy})H] (**3**), acting as ligand; its structure was established by X-ray crystallography.[13]

A plane of symmetry in the plane of the protonated pyrazolyl group is observed in the crystal structure of **4** (Fig. 1). The copper atom is coordinated to two 3-cyclohexylpyrazolyl groups and two chlorine atoms in a distorted tetrahedral configuration. The hydrogen atom of the protonated pyrazolyl group forms a hydrogen bond with the nearest chlorine atom (Cl2). The Cl2–H distance is short (2.18 Å), while the Cu–Cl2 bond (2.29 Å) is 0.1 Å longer than the Cu–Cl1 bond.

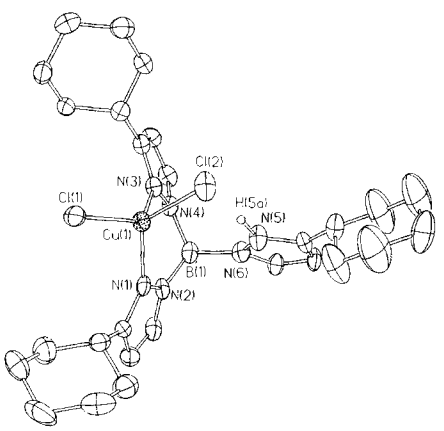

Fig. 1. ORTEP plot of the structure of **4** (ellipsoids at the 30% probability level). The hydrogen atoms, except H(5a), are omitted for clarity. Selected bond lengths [Å] and angles [°]: Cu(1)-Cl(1) 2.198(3), Cu(1)-Cl(2) 2.289(3), Cu(1)-N(1) 1.998(7), Cu(1)-N(3) 1.945(7), Cl(2)···H(5a) 2.184(9), N(5)-H(5a) 0.978(4); Cl(1)-Cu(1)-Cl(2) 104.4(1), Cl(1)-Cu(1)-N(1) 109.7(2), Cl(1)-Cu(1)-N(3) 127.7(2), Cl(2)-Cu(1)-N(1) 125.4(2), Cl(2)-Cu(1)-N(3) 95.6(2), N(1)-Cu(1)-N(3) 95.8(3), Cu(1)-Cl(2)···H(5a) 78.4(5), Cl(2)···H(5a)-N(5) 170.4(5).

Although **4** decomposes when chromatographed, it reacts cleanly with aqueous sodium hydrogencarbonate solution to yield the binuclear, deep emerald-green complex [($Tp^{Cy}Cu$)$_2$(μ-CO_3)]; the IR spectrum of **5** contains bands assigned to BH and CO at 2487 and 1584 cm^{-1}, respectively. The same binuclear complex is formed in the reaction of **6** with aqueous hydrogencarbonate solution; its structure was determined by X-ray crystallography.[14] In **5**, each Cu atom is bound to two oxygen atoms of the carbonato ligand and to three nitrogen atoms from the Tp^{Cy} ligand (Fig. 2). Two Cu–N bonds are marginally shorter than 2.0 Å and one is longer (2.25 Å). The structure is similar to that reported for [($Tp^{iPr2}Cu$)$_2$(CO_3)],[15] which was formed by reaction of [$Tp^{iPr2}Cu(OH)$] with CO_2; the Cu···Cu distance is slightly longer in **5** (4.058 versus 4.017 Å) because the steric bulk of the cyclohexyl group is somewhat greater than that of the isopropyl group. Incorporation of the cyclohexyl group thus causes a subtle change in the complex; this technique may assist in fine-tuning the various enzyme analogues that contain 3-isopropyl groups.

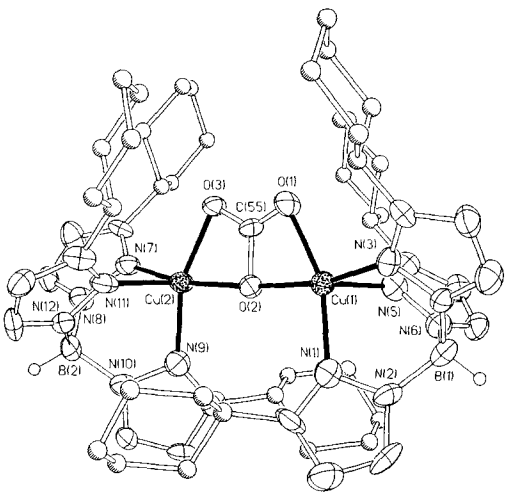

Fig. 2. ORTEP plot of the structure of **5** (ellipsoids at the 30% probability level). Only the atoms refined with anisotropic thermal parameters are shown as thermal ellipsoids. The hydrogen atoms, except those at B(1) and B(2), are omitted for clarity. Selected bond lengths [Å] and angles [°]: Cu(1)-O(1) 1.992, Cu(1)-O(2) 2.022, Cu(1)-N(1) 1.995, Cu(1)-N(3) 1.987, Cu(1)-N(5) 2.243, Cu(1)-C(55) 2.380, Cu(2)-O(2) 2.039, Cu(2)-O(3) 2.002, Cu(2)-N(7) 1.978, Cu(2)-N(9) 1.961, Cu(2)-N(11) 2.248, Cu(2)-C(55) 2.395, Cu(1)···Cu(2) 4.058; Cu(1)-N(1)-N(3) 92.0, Cu(1)-N(1)-N(5) 94.0, Cu(1)-N(5)-N(3) 85.7, Cu(1)-O(1)-N(1) 159.8, Cu(1)-O(1)-N(3) 102.3, Cu(1)-O(1)-N(5) 101.1, Cu(1)-O(2)-N(1) 98.1, Cu(1)-O(2)-N(3) 166.4, Cu(1)-O(2)-N(5) 102.5, Cu(1)-O(2)-O(1) 65.7, Cu(1)-O(1)-C(55) 31.7, Cu(1)-O(2)-C(55) 34.3, Cu(2)-N(9)-N(7) 91.0, Cu(2)-N(11)-N(7) 86.6, Cu(2)-N(9)-N(11) 95.4, Cu(2)-O(2)-N(7) 167.3, Cu(2)-O(2)-N(9) 97.7, Cu(2)-O(2)-N(11) 101.7, Cu(2)-O(3)-N(7) 103.9, Cu(2)-O(3)-N(9) 160.3, Cu(2)-O(3)-N(11) 98.3, Cu(2)-O(3)-O(2) 65.7, Cu(2)-C(55)-N(7) 135.4, Cu(2)-C(55)-N(9) 131.2, Cu(2)-C(55)-N(11) 100.6, Cu(2)-C855)-O(2) 34.0, Cu(2)-C(55)-O(3) 31.7.

We are unsure of the exact mechanism for the formation of **4** in this nonstoichiometric reaction and of the source of the proton, although it is likely to come from the water of hydration of $CuCl_2$. So far, the reaction of **2** with $CuCl_2$ in THF appears to be unique, since Co^{II}, Ni^{II}, and Zn^{II} chlorides produce only the expected [$Tp^{Cy}MCl$] complexes, as does anhydrous $CuCl_2$ in the absence of THF. Furthermore, the related ligand [$Tp^{iPr}Tl$] yielded, under the same conditions, only the expected $Tp^{iPr}CuCl$ complex, which can similarly be converted to the dinuclear complex [($Tp^{iPr}Cu$)$_2$(μ-CO_3)] with a CO band in the IR spectrum at 1600 cm^{-1}.

Experimental Procedure

1: Formylation of cyclohexyl methyl ketone with ethyl formate followed by reaction with hydrazine in a procedure similar to that used for preparing 3-isopropylpyrazole [9] yielded **1** as a viscous liquid in 64% yield: B.p. 150 °C/2.6 Torr; ^1H NMR: δ = 7.48 (d), 6.05 (d), 2.74 (tt), 2.03 (d), 1.80 (dt), 1.72 (d), 1.41 (sextet), 1.25 (m), signals in a ratio of 1:1:1:2:2:1:4:1; ^{13}C NMR: δ = 25.9 (4′-C), 26.1 (3′-C, 5′-C), 33.0 (2′-C, 6′-C), 36.0 (1′-C), 101.1 (4C), 134.9 (5C), 152.2 (3C).

2: A mixture of 3-cyclohexylpyrazole and KBH_4 (5:1) was heated until the theoretical amount of H_2 was given off. Excess 3-cyclohexylpyrazole was removed in vacuo. The crude product [$Tp^{Cy}K$] was then dissolved in dimethylformamide and converted to **2**: M.p. 142–143 °C; ^1H NMR: δ = 7.71 (d, broadened), 5.97 (d, even broader), 2.77 (m, very broad), 1.93 (s, broad), 1.81 (m), 1.74 (d), 1.40 (quin), 1.25 (tt), signals in a ratio of 1:1:1:2:2:1:4:1; ^{13}C NMR: δ = 26.1 (4′-C), 26.6 (3′-C, 5′-C), 34.2 (d, J = 51.4 Hz, 2′-C, 6′-C), 37.6 (d, J = 27 Hz, 1′-C), 100.9 (s, broad, 4C), 135.7 (s, somewhat broadened, 5C), 159.1 (d, J = 47 Hz, 3C).

4: A solution of **2** in CH_2Cl_2 was added to a rapidly stirred mixture of $CuCl_2 \cdot 2H_2O$ (in excess) in THF. After 30 min, the slurry was filtered through Celite, and the filtrate was evaporated. The dark brown residue was stirred with isopropyl alcohol, filtered, and washed with isopropyl alcohol. The bright orange solid [m.p. 156–158 °C (decomp.)] was recrystallized from CH_2Cl_2 (52% yield). IR: $\tilde{\nu}$(BH) = 2538 cm^{-1}; ^1H NMR: all peaks are broad, yet discernible: δ = 15.2 (NH), 8.30, 7.90 (pyrazolyl 5-H), 6.38, 6.28 (pyrazolyl 4-H), overlapping 2:1 patterns, 2.96 (H atom at the tertiary cyclohexyl C atom), 2.02, 1.84, 1.50, and 1.10 (4 × m, rest of the cyclohexyl protons).

5: A solution of **4** (or **6**) in CH_2Cl_2 was stirred with an aqueous solution of $NaHCO_3$. This resulted in a color change within seconds from orange to emerald green. The organic layer was separated and the solvent removed in vacuo. Green crystals of **5** were obtained in 76% yield: M.p. 200–202 °C (decomp.); IR: $\tilde{\nu}$(BH) = 2487, $\tilde{\nu}$(CO) = 1584 cm^{-1}.

6: A solution of **2** in CH_2Cl_2 was stirred with a large excess of anhydrous $CuCl_2$. After 20 min, the slurry was filtered through Celite, and the solvent was evaporated. A chestnut-red solid **6** was obtained in 82% yield: M.p. 156–158 °C; IR: $\tilde{\nu}$(BH) = 2488 cm^{-1}.

All the above compounds gave satisfactory elemental analyses.

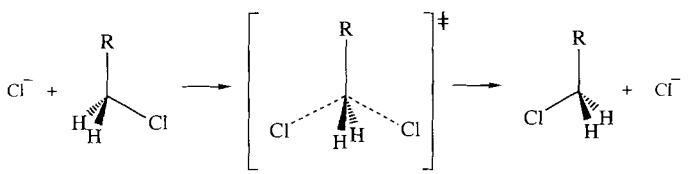
The $S_{RN}2$ Pathway—A Mechanistic Alternative for Radicals in Polar Media?**

Hendrik Zipse*

The $S_{RN}1$ mechanism has been shown to provide an alternative pathway in reactions of benzylic and aromatic halides in which the direct S_N2 route is hindered by inefficient leaving groups.[1] The critical stages of the mechanism (Scheme 1, top) involve the formation of radical anion **A** by single electron transfer, heterolytic cleavage of the β C–X bond to yield the benzylic radical **B**, and subsequent addition of the nucleophile to form a new radical anion **C**. Electron transfer to another substrate molecule perpetuates the chain reaction. An isoelectronic variant of the $S_{RN}1$ mechanisms has been invoked recently to explain the product distribution found in reactions of DNA radicals.[2, 3] These can be formed under radiolytic conditions or in the presence of radical-forming reagents by hydrogen atom abstraction from the carbohydrate backbone. Ribofuranosyl radicals **D** have then been suggested to undergo β C–X bond cleavage to yield the radical cation **E**, which can be trapped by external nucleophiles to yield the product radicals **F** (Scheme 1, bottom). In both these cases a mechanistic alternative exists in the $S_{RN}2$ mechanism in which C–X bond cleavage occurs simul-



Scheme 1. Two examples of an $S_{RN}1$ mechanism. In the second case, alternative transition states are depicted. B = nucleotide base.

taneously with C–Nu bond formation. This bimolecular pathway has been ruled out for the classic benzyl halide system through experiments utilizing optically active substrates. However, an analogous strategy can not be used to elucidate the fate of radicals **D**, since the relative positions of reaction centers are fixed by the ribofuranosyl ring structure. Still, the $S_{RN}2$ mechanism is not unlikely for these systems because of the presence of internal nucleophiles (nucleotide bases) and high observed stereochemistry in trapping experiments.[3] These observations can well be rationalized by assuming initial C–X bond cleavage with nucleophilic assistance through the nucleotide base leading to a bridged radical cation **G**. Attack of external nucleophiles can reopen the ring structure to give product **F** with net retention of configuration at C3 of the ribofuranosyl ring system. Since DNA appears to be stable under nonradiolytic conditions, this mechanism requires the barrier for the open-shell system to be significantly lower than for the closed-shell system. This hypothesis, however, is not supported by what is known about α-substituent effects on S_N2 processes in closed-shell systems,[4, 5] in which cyano or benzyl substituents hardly affect the intrinsic activation barrier, and differences in observed rates can be traced back to differences in complexation energies between reactants. The question of intrinsic barrier heights for substitution reactions in open- and closed-shell systems is therefore also relevant from a fundamental point of view.

We have chosen the $Cl^- + RCH_2Cl$ system with $R = CH_3$ and $CH_2^\bullet$ as a model to investigate the variation of S_N2 barrier on formation of a radical in an adjacent position (Scheme 2).

a, $R = CH_3$; **b**, $R = CH_2^\bullet$

Scheme 2. The model system for the study of the $S_{RN}2$ mechanism.

The identity reaction offers the important benefit of not perturbing the variations in activation barriers by different exothermicities. Gas-phase reaction paths for the open- and closed-shell systems have been calculated at the ab initio MP2(FC)/6-31G* level (Fig. 1).[6, 7] The reaction coordinate r is defined as the difference in lengths of the forming and the breaking C–Cl bonds. This choice ensures a truly symmetrical reaction profile. It also facilitates comparison with the results obtained by Jorgensen et al. in their classic study of solvent effects on the nucleophilic substitution of methyl chloride with chloride anions.[8] The open- and closed-shell systems both form the expected ion–dipole complexes known from methyl transfer reactions (Fig. 2). This has also been found in a recent theoretical exam-

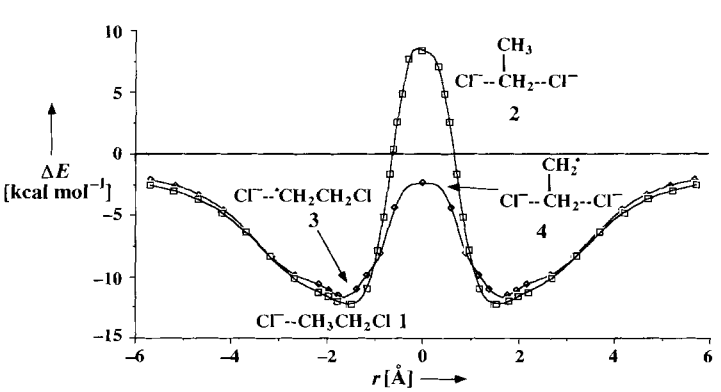

Fig. 1. Reaction paths for the S_N2 reaction of Cl^- + ethyl chloride (□) and the β-chloroethyl radical (○). Energies are given relative to separated reactants at the R/UMP2(FC)/6-31G* level of theory.

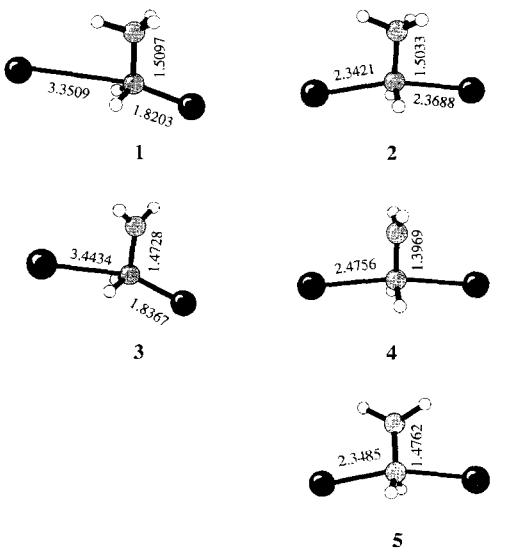

Fig. 2. Ion–dipole complexes and transition structures for the substitution reaction at ethyl chloride (**1**, **2**) and at the β-chloroethyl radical (**3**, **4**). (P)MP2(FC)/6-31G* optimized geometries are shown.

ination by Jensen.[9] The energy data for both systems have been collated in Table 1.[10] The complexation energy ΔE_c(MP2/6-31G*) is slightly larger for the closed-shell complex **1** (-12.3 kcal mol^{-1}) than for the open-shell analog **3** (-11.7 kcal mol^{-1}) or for the complex of methyl chloride and chloride anion (-10.3 kcal mol^{-1}).[8] This is probably due to favorable electrostatic attraction between the chloride ion and the CH_3 hydrogen atoms in **1**. Proceeding further along the reaction coordinate, the differences between the open- and closed-shell systems become much more drastic. The transition state for the closed-shell system **2** is located $+20.6$ kcal mol^{-1} above complex **1** and $+8.4$ kcal mol^{-1} above the separated reactants (ΔE_i and ΔE_a in Table 1). Transition structure **2** does not share the C_S symmetry of complex **1** since the methyl group rotation is not perfectly synchronized with the C–Cl bond breaking and making process.[9] A much smaller barrier is

Table 1. Complexation energies ΔE_c and activation barriers from separate reactants (ΔE_a) and from ion–dipole complexes (ΔE_i) in substitution reactions of between CH_3CH_2Cl or $^\bullet CH_2CH_2Cl$ and Cl^- [kcal mol^{-1}].

System and method	ΔE_c	ΔE_a	ΔE_i
$Cl^- + CH_3CH_2Cl$

found in the open-shell system. Here, transition structure **4** is separated by $+9.4\ kcal\,mol^{-1}$ from complex **3** and by $-2.4\ kcal\,mol^{-1}$ from the separated reactants. The results are surprisingly insensitive to the level of theory; single point calculations at very modest (UHF/STO-3G) or much higher level (PMP4(SDTQ)/6-311 + G**) predict essentially the same picture. At the best theoretical level, the intrinsic barrier in the closed-shell system is higher by $\Delta\Delta E_i = +11.5\ kcal\,mol^{-1}$ than that of the open-shell system. The inclusion of differences in zero point vibrational energies (ΔZPE) has no influence on this result. Analysis of the MP2/6-31G* charges (CHELPG) shows that the presence of the radical center hardly affects the charge of the chloride ion. The chloride carries a negative charge of $-0.94e$ in closed-shell complex **1** and $-0.95e$ in open-shell complex **3**. These values are significantly reduced to -0.74 and -0.73 in the closed- and open-shell transition states **2** and **4**, respectively.

A theoretical investigation of ionic substitution reactions is necessarily incomplete without consideration of solvent effects.[8] This is especially true since it has been shown that the energy required to desolvate the reactants far exceeds the intrinsic gas-phase barrier. We have therefore used Monte Carlo (MC) fluid simulations to estimate the free energy of solvation changes along the reaction coordinate by the free energy perturbation method.[11, 12] On addition of the free energy of solvation and gas-phase potential energy contributions, the potential of mean force (pmf) curves for the closed- and open-shell system are obtained (Fig. 3). In the early stages of the reaction, desolvation of the approaching chloride anion appears to be slightly more advanced in the closed-shell system. The pmf curves for both systems almost coincide again, but around $|r| = 2.0$ where the gas-phase complexes are located. The pmf curves for both systems show no sign of complex formation. This is because the energy gained by attractive electrostatic interactions between the reactants is completely offset by the desolvation free energy. For $|r|$ values less than 1.0, the closed-shell pmf curve deviates increasingly from the open-shell curve. Both curves peak around $|r| = 0.0$: $\Delta E(\text{pmf}) = +22.4$ (open shell) and $+37.2\ kcal\,mol^{-1}$ (closed shell), relative to the value at $|r| = 5.7$. The barrier differences in solution would therefore be approximately $\Delta\Delta E(\text{pmf}) = +14.8\ kcal\,mol^{-1}$, which is 3.3 $kcal\,mol^{-1}$ more than in the gas-phase. Given the root mean square deviation for the free energy of solvation calculations of around $\pm 0.6\ kcal\,mol^{-1}$ for both curves, solvation clearly dominates the absolute barriers for substitution in solution, but hardly affects the relative barrier heights for the open- and closed-shell systems. Considering the similar chloride ion charges for both systems, this result had to be expected if chloride ion solvation/desolvation is the determining factor for the solution barrier.

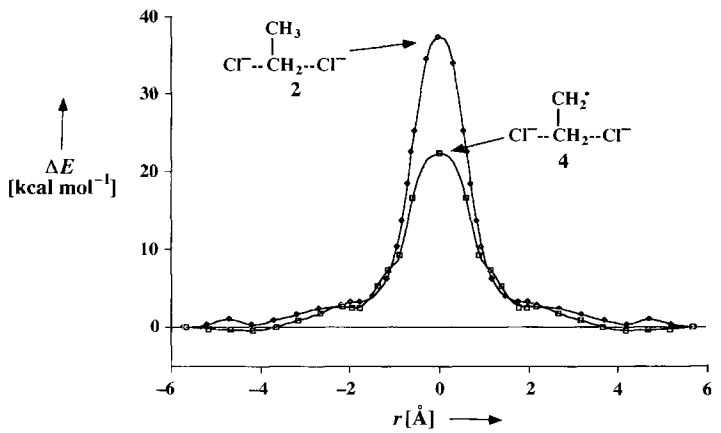

Fig. 3. Potential of mean force (pmf) in aqueous solution for the open- (□) and closed-shell (○) systems as a function of the reaction coordinate r.

The small differences in complexation energies ΔE_c in partial charge development and in solvation free energies convincingly rule out electrostatic effects as the source of differences in overall activation barriers between the open- and closed-shell systems. Steric effects can also be excluded, since open- and closed-shell species form ion–dipole complexes of similar strength. Also, the C–C bond connecting the reaction center with the substituent becomes shorter on going from the complex to the transition structure (Fig. 2), quite contrary to what would be expected if steric effects were a factor. This change is small for the closed-shell system ($\Delta R = -0.6$ pm), but large for the open-shell system ($\Delta R = 7.6$ pm). This bond length reduction indicates a stronger interaction between the CH_2 and Cl-C-Cl fragments in transition state **4** than in complex **3**. The magnitude of this increase can be estimated by the isodesmic reaction (a), in which the open- and closed-shell transition states are compared to methane and the methyl radical.

$$\text{TS (2)} + CH_3^{\cdot} \longrightarrow \text{TS (4)} + CH_4 \qquad \text{(a)}$$

With PMP2(FC)/6-31G*//UMP2(FC/6-31G* energies an energy difference ΔE of $-13.50\ kcal\,mol^{-1}$ is calculated. The Cl-C-Cl fragment in transition state **4** therefore stabilizes the radical center to a similar extent as benzyl or vinyl groups.[15] In complex **3**, the spin density is localized with coefficient 1.14 almost exclusively at the CH_2 carbon atom not involved in the reaction coordinate. All other centers have coefficients less than 0.1 (UHF/6-31G* values). In transition structure **4** the spin density is 0.85 at the methylene carbon atom and 0.18 at both chlorine atoms. Inspection of the molecular orbitals of transition structures **2** and **4** shows that the delocalization of spin density arises through mixing of the former radical SOMO (singly occupied molecular orbital) with the *lowest* of the three molecular orbitals building up the Cl-C-Cl fragment. Mixing of the SOMO with the second highest Cl-C-Cl molecular orbital is limited through the nodal characteristics of this MO. This finding also provides a rationale for the small effects α-nitrile substitution has on the S_N2 barrier, since stabilizing interactions with the lowest lying Cl-C-Cl fragment MO would then involve the π^*_{CN} orbitals, which have much higher orbital energies than the SOMO in the current case. The transition state stabilization by SOMO/NHOMO (NHOMO = next highest molecular orbital) interactions can also be estimated by calculation of the barrier for methylene group rotation in structure **4**. This strategy has been used before to estimate substituent effects for S_N2 reactions in model systems for closed-shell substitution reactions.[16] In the rotational transition structure **5** (see Fig. 2), no SOMO/NHOMO interactions are possible for geometric reasons. At the PMP2/6-31G*//UMP2/6-31G* level, the barrier for methylene group rotation in **4** is $+11.0\ kcal\,mol^{-1}$. This value is smaller than that derived from the isodesmic equation (a), but rather close to the difference in intrinsic barriers for the open- and closed-shell systems (PMP2/6-31G*: $+11.2\ kcal\,mol^{-1}$).

Since the barrier lowering for substitution reactions in open-shell systems has been predicted by theory, it is interesting to ask what further experimental evidence hints at $S_{RN}2$ reactions? The oligonucleotide radical studies by Giese et al. are closely related to DNA model studies by Murphy et al.[17] The authors noted

that, for the model system under study, only products from radical reactions are formed in systems lacking internal nucleophiles and only products from ionic reactions in otherwise similar systems that contain internal nucleophiles. In both cases the reactions were initiated by thermolysis of azobis(isobutylnitride) (AIBN). $S_{RN}1$ and $S_{RN}2$ reactions should also differ in their activation entropies. Because $S_{RN}2$ transition states are more ordered than the $S_{RN}1$ analogues, much more negative $\Delta S^{\neq}$ values (or smaller Arrhenius A factors) are expected for transition states with strong neighboring group participation. This has indeed been noted by Beckwith et al. for the acyloxy shift when highly substituted carbohydrate radicals are compared to smaller model systems lacking most of the sugar functionalities.[18] It thus appears that some experimental evidence justifies the assumption of $S_{RN}2$ pathways. The results of this theoretical study certainly encourage further exploration of the chemistry of radicals in polar media. This is, of course, most relevant to the study of radicals in biological environments.

[7] Geometry optimizations were performed at the RMP2(FC)/6-31G* level for the closed-shell system and at the UMP2(FC)/6-31G* level for the open-shell system (R = restricted, U = unrestricted, MP_n = *n*th order Møller-Plesset perturbation theory). MP2 energies given for the open-shell system are those obtained after spin projection of the lowest spin contaminant (PMP2). The $\langle S^2 \rangle$ values obtained after spin projection did not exceed 0.751. Single point energies have been calculated at the PMP4/6-311 + G** level of theory. The frozen core (FC) approximation has been used in all post-Hartree–Fock calculations.

[12] MC simulations employed a periodic box containing 396 TIP4P water molecules (TIP4P = transferable intermolecular potential, 4 point model) and one solute molecule. The solute was described by an all-atom model. Lennard-Jones potential parameters are identical to those employed in the $Cl^- + CH_3Cl$ study [8]. Coulomb parameters have been obtained by fitting the MP2/6-31G* electrostatic potential to point charges located at the atomic positions for a series of points along the reaction coordinate [13]. The free energy change for perturbation of one structure on the reaction coordinate to the next one was calculated by first equilibrating for 1×10^6 MC steps and then averaging for another 4×10^6 steps. All calculations have been performed with the BOSS program version 3.4 [14]. To cover the reaction path from $|r| = 0.0$ to $|r| = 5.7$, 25 steps were necessary in the open-shell system and 33 steps in the closed-shell system.

Corrigendum

In the communication "The Structures of Two Lithium Hydrazides: Is There Electron-Deficient Bonding?" by N. Metzler, H. Nöth, and H. Sachdev (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1746), the question was raised whether the compound $[t\mathrm{BuMe_2Si(Li)N-N(Li)SiMe_2}t\mathrm{Bu}]_3$ could be looked at as an electron-deficient compound. Although electron counting for this example would be compatible with a compound of the *arachno* type cluster, new examples of structures of compounds $[\mathrm{R(Li)N-N(Li)R}]_n$ and $[\mathrm{R(H)N-N(Li)NR}]_m$ (H. Nöth, H. Sachdev, M. Schmidt, and H. Schwenk, *Chem. Ber.* submitted; U. Klingebiel et al., *Proceedings VII. IRIS Conference*, Banff, **1994**) show that this is obviously an exception, and the coordination number greater or equal to 5 for the N atoms and greater or equal to 4 for the Li centers are due to the strongly polar contributions of the Li–N interactions.

Pleasure in Principles

Principles of Electrochemistry. By *J. Koryta, J. Dvorák* and *L. Kavan*. Wiley, Chichester, 1993. 486 pp., paperback £ 24.95.—ISBN 0-471-93838-6
Electrochemistry. Principles, Methods, and Applications. By *C. M. A. Brett* and *A. M. O. Brett*. Oxford University Press, Oxford, 1993. 427 pp., paperback £ 25.00.—ISBN 0-19-855388-9

Electrochemistry has been transformed into an interdisciplinary science during the last few decades. It encompasses such widely different fields as the characterization of complex electrode processes, applications in synthesis, energy technology, and sensors, and the extensive areas of materials research and the biosciences. Publishers are therefore aiming to reach a wide readership by offering up-to-date textbooks at affordable prices. Two recent examples are the books reviewed here, which stress different aspects of the subject. *Principles of Electrochemistry*, written by three well-known authors of the Czech school, is mainly a survey of the thermodynamics of electrolyte solutions and electrode equilibria and of electrode kinetics. In contrast the second book, *Electrochemistry*, belongs to the tradition of the English-speaking school of textbooks, and emphasizes electrochemical methodology and applications in sensor technology.

This difference in emphasis of the two textbooks is easily seen from a summary of their contents. The book by Koryta et al. begins with an introduction to the theory of electrolytes, dealing with ion–solvent interactions, acid–base equilibria, polyelectrolytes and ampholytes, and the classical Debye–Hückel theory of interactions between ions. The second chapter discusses transport processes, with the main emphasis on the conductivity phenomena associated with ion migration. Chapter 3 contains an introduction to the thermodynamics of electrode equilibria. As well as explaining basic concepts such as electromotive force and the voltaic (electrochemical) and electric potentials, this chapter describes practical applications, including the determination of pH values and measurements of activity coefficients and dissociation constants. Chapter 4 briefly discusses the properties of the electrical double layer, including the classical Gouy–Chapman–Stern theory and the more recently developed "jelly" model.

The last two chapters are mainly devoted to modern developments in electrochemistry. As well as an introduction to electrode kinetics these chapters include brief descriptions of some important electrochemical methods. The recently developed ultramicroelectrode is mentioned, as also are in-situ methods that allow simultaneous measurements of spectroscopic data and electrical quantities. Other aspects touched on include homogeneous processes, electrocatalysis, deposition and separation of metals, and the broad field of bioelectrochemistry. Due attention is also given to the electrochemistry of conducting polymers.

Despite the inclusion of recent results such as these, a detailed study of the book leaves one with the impression that the view of electrochemistry presented here is that of the older generation of electrochemists, with a strong emphasis on thermodynamic principles. The reader wishing to approach the subject by this conventional route will find that the new third edition of "Koryta" is a reliable guide and tutor.

The Bretts' textbook begins with a description of the thermodynamics of electrochemical cells. This is followed in Chapter 2 by a discussion of the electrode/electrolyte boundary, introducing the theory of the electrical double layer. The kinetics of heterogeneous and homogeneous charge transfer and transport processes are then treated in concisely written chapters. The second, more extensive, part of the book consists of six chapters devoted to methods for investigating electrochemical processes. Modern measurement techniques, ranging from the widely used method of cyclic voltammetry to the various impedance methods, are treated at considerable length. Further chapters describe the many in-situ and ex-situ methods that have considerably extended the electrochemist's armory of experimental capabilities in recent years, such as the quartz microbalance and spectroscopic techniques.

In the third and last part of the book the authors describe modern applications of electrochemistry in basic research and in industry. Important topics include sensors based on ion-selective electrodes or amperometric detectors, modified electrodes, and corrosion phenomena. Bioelectrochemical phenomena are also discussed, as well as industrial processes such as electrosynthesis and metals deposition, and processes involving the conversion and storage of energy. Lastly there is an appendix containing some important mathematical relationships used for solving partial differential equations, diagrams of equivalent circuits, and basic principles of digital simulation methods. As in Koryta's book, a comprehensive bibliography is provided to enable the reader to study topics in greater depth.

With its emphasis on modern techniques of electrochemistry, the Bretts' book is certainly well suited to meet the wide-ranging needs of readers wishing to apply such methods in chemistry, physics, bioscience, and materials science. Despite the mathematical complexity of the theoretical concepts, the presentation is clear and understandable, enabling both beginners and interdisciplinary scientists to quickly build up a knowledge of methods relevant to their needs. They will be greatly helped in this by the practical advice about electrode materials, cell construction, and instrumentation.

To summarize, both these new paperbacks on electrochemistry offer sound and reliable introductions to this well-established field of physical chemistry. Readers who are mainly interested in the thermodynamic fundamentals, including the properties of electrolyte solutions,

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/1919-1989 $ 10.00+.25/0*

should use the book by Koryta et al. For all those readers who wish to learn about the methods of electrochemistry and how to apply them, the book by Brett and Brett will prove a reliable guide.

Organic Photochemistry. Principles and Applications. By *J. Kagan*. Academic Press, London, 1993. 234 pp., hardcover £ 40.00.—ISBN 0-12-394320-5

Anyone hoping to find here an up-to-date textbook of organic photochemistry will be disappointed. In the first place, this is not a book oriented towards teaching, as is already evident from the statement in the preface that "the order of topics... is totally arbitrary". Secondly, many important principles and applications of photochemistry have either been simply left out or have received inadequate treatment with an underemphasis that is difficult to understand. The author's comment that "old and well-established reactions and processes are described without references" is not a justification for neglecting a number of fundamental points. This apparently very subjectively-based book consists of two main parts, dealing with photochemical and photobiological aspects, respectively.

The first chapter introduces principles and mechanistic models of photochemical and photophysical processes; with only 25 pages it is too short. Some important principles, such as the first law of photochemistry, the Kasha rule, and the Franck–Condon principle, are mentioned but are not explained in the usual way. The mechanisms involved in the decay of electronically excited states are described in more detail, with a surprisingly large amount of space devoted to the quenching of photooxidation reactions. Chapter 2 gives a brief outline of experimental methods; only four literature references are given, two of which are useless. Thus the reader may safely skip over the first two chapters, if necessary referring instead to other standard textbooks. Chapters 3 and 4 give a rough idea of the photochemistry of the CC and CO double bonds. A few synthetic applications are described (limited to intramolecular reactions), and the di-π-methane rearrangement is mentioned. The mechanism given for this is probably incorrect; in any case, the work of H. Zimmerman is not discussed or even cited. On the other hand the author cites Doering's synthesis of bullvalene—not very consistent. Ten pages are devoted to the chemistry of the photoexcited carbonyl group; however, the Paternò–Büchi reaction receives less than a page. What is the reader supposed to make of a statement such as "Fortunately, the reaction is usually rather selective"? Chapter 5 on fragmentations describes some interesting and topical applications. The author puts a much greater emphasis on oxidation processes, which are discussed in Chapter 6, "Photochemistry with Oxygen". Unfortunately though, the description of the electronic states of molecular oxygen is limited to only four lines; here the interested reader will need to refer to the up-to-date reviews by Frimer and Ando. An appropriate amount of space is devoted to the generation, detection, and reactivity of singlet oxygen. The author also discusses the properties of other reactive species that can be generated photochemically, such as superoxide anion, atomic oxygen, S_2, and SO. Reference is also made to the possible biological activity of singlet oxygen, anticipating a topic treated in the second part of the book. In Chapter 7, on photoelectron transfer (PET) processes, the author manages to treat this subject without mentioning any of the names Marcus, Rehm, or Weller. Some up-to-date applications of PET processes in organic synthesis are described, giving some indication of the potential of this important class of reactions. For readers who already have a good knowledge of the repertoire of organic photochemistry, Chapter 8 on "Synthetic Applications" offers a wealth of information about interesting applications, from which they will pick up lots of useful ideas. However, it was not necessary to mention the synthesis of a triquinane by Cossy, Belotti, and Pete twice, first under δ,ε-unsaturated carbonyl compounds (8.14) then again under photochemical reductions (8.20).

In contrast to the above highly critical comments on the first part of the book, the second part, beginning with Chapter 9, can be emphatically recommended for the interested photochemist. Here the author's own research interests become dominant, and this improves the quality and the thoroughness of the discussions. The ways in which photochemistry interacts with biochemistry, biology, and medicine are well illustrated in Chapters 9–11 respectively, which describe important and highly topical developments in these fields. After an introduction to the photochemistry of amino acids and nucleic acids, the ways in which light radiation interacts with DNA are described (photochemically induced chain breaking, production of photoadducts, photoaffinity labeling, etc.). The important role of photooxidation processes in biochemical reactions is also mentioned and clearly explained. Under the heading "Photochemistry and Biology" the phototoxic effects of compounds which act as sensitizing agents are described. Those processes that can be described as "photochemistry without light" are also included in the discussion. There is also a very competent and informative discussion on light-induced changes to the human skin and their harmful consequences. Chapter 11 describes the medical applications of photochemical reactions that are continuing to grow in importance (PUVA therapy, photodynamic therapy, photosensitized inactivation of viruses). This and the preceding two chapters undoubtedly form the main strength of the book. It ends, in Chapter 12, with a brief outline of some applications of photochemical processes (more or less arbitrarily chosen). This rather personal foray into photochemistry by Kagan has certainly not turned out to be a student textbook or a work of reference; instead it is a wide-ranging and not very orderly collection of various aspects of organic photochemistry. Many readers interested in the subject will find it a source of useful ideas.

Life During a Golden Age of Peptide Chemistry: The Concept and Development of Solid-Phase Peptide Synthesis. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *B. Merrifield.* American Chemical Society, Washington, DC, 1993. XXI, 297 pp., hardcover $ 24.95.—ISBN 0-8412-1842-9

Bruce Merrifield's 1984 Nobel chemistry prize "for his development of methodology for chemical synthesis on a solid matrix" is unusual in that it was awarded for work conceived and singlehandedly achieved within 44 months. On May 26, 1959, Merrifield recorded the basic concept in his laboratory notebook (reproduced on p. 56): "There is a need for a rapid, quantitative, automatic method for synthesis of long chain peptides. A possible approach may be the use of chromatographic columns where the peptide is attached to the polymeric packing and added to by an activated amino acid, followed by removal of the protecting group and with repetition of the process until the desired peptide is built up.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1919-1990 $ 10.00+.25/0

Finally the peptide must be removed from the supporting medium."

On January 31, 1963, he submitted to the *Journal of the American Chemical Society* his classic paper, "The Synthesis of a Tetrapeptide," which revolutionized peptide chemistry with his discovery of how to synthesize peptides in a "simpler, faster, more efficient way". Yet this unassuming, self-critical, and modest scientist says of this whirlwind tour de force: "When I look back at my old notebooks, I am amazed at how inefficient the early developmental work was. I seemed always to choose the wrong reaction to do first and was not able to identify the most important parameters as the work was progressing. At the end of the first two years the results were so poor, I wonder what made me think that this approach would ever succeed." (pp. 89–90).

He then reveals the secret of his success in research and simultaneously expresses his appreciation to his mentor and the institution to which he remained loyal throughout his career: "But from the outset I had a strong conviction that this was a good idea, and I am glad that I stayed with it long enough. I have always been grateful to Dr. Woolley for giving me the freedom in his laboratory to pursue the problem to the end and to the Rockefeller University for supporting me through a long nonproductive period." (p. 90).

Robert Bruce Merrifield was born on July 15, 1921, in Fort Worth, Texas, the only child of George Evan Merrifield, a furniture salesman, and Mittie Lorene Merrifield (née Lucas). The Great Depression forced his family to move frequently in search of work (he lived in 25 houses or apartments and had attended 11 schools by the time he started high school) and taught him the value of "steady, hard work and conservative approaches to problems" (p. 7). Raised primarily in California, he attended high school in Montebello, a small town east of Los Angeles, where he chose chemistry as a career as a result of an essay assignment on careers. He attended Pasadena Junior College for two years, followed by two years at the University of California, Los Angeles, from which he received his B. A. degree in 1943. He carried out routine work for a year at the Philip R. Park Research Foundation in San Pedro, California, but returned to UCLA for graduate work in biochemistry so that he could design his own experiments. Professor Max Dunn, with whom he had worked as an undergraduate, offered him a fellowship sponsored by the Anheuser Busch Company to develop ways to measure the purine and pyrimidine content of brewer's and baker's yeasts. While a teaching assistant in biochemistry, he met Elizabeth (Libby) Furlong, a biochemistry student who was to become his wife.

On June 19, 1949, Merrifield received his doctorate with a dissertation on microbiological assays of nucleic acid components; on June 20 he and Libby were married; and on June 21 they left for New York City. He had accepted a one-year postdoctoral appointment as research assistant to Dr. Dilworth Wayne Woolley at the Rockefeller Institute for Medical Research (since 1955 Rockefeller University), where he still works today. He considers Woolley "surely the most brilliant man I have known" and devotes almost an entire chapter to him. Merrifield became Associate Professor in 1957, Professor in 1966, and John D. Rockefeller, Jr. Professor in 1983.

Libby, who has been a close personal and professional partner in Merrifield's life, had received her master's degree in endocrinology at UCLA in 1947 and had completed all her examinations and requirements and almost all her doctoral research. However, upon her marriage she interrupted her studies, intending to return to them soon. The death of her Ph.D. supervisor and the rearing of six children (five girls and a boy) intervened. In 1980 she returned to the laboratory, collaborating with her husband on the synthesis of the antiviral protein interferon.

Merrifield's book is the longest volume to date in the "Profiles, Pathways, and Dreams" series, largely because of the detail with which he describes his work. After recounting his first published work on protein chemistry, coauthored with Woolley, which dealt with oxytocin, Merrifield presents his classic work on solid-phase peptide synthesis step-by-step, with page after page of day-to-day excerpts from his laboratory notebooks, including negative as well as positive experiments. To the best of our knowledge, no other author in this series makes such extensive use of primary experimental data. In so doing Merrifield provides the reader with a unique insight into the creative process as exemplified by the sequential thoughts of a master experimentalist. He also demonstrates the validity of his earlier statement: "the incidents that I recall the best are the negative experiences and the lessons I learned from them" (p. 10).

Through painstaking, meticulous research Merrifield determined the best conditions for his solid-phase peptide synthesis, and since his 1963 article appeared, thousands of peptides and other biological polymers, including carbohydrates and nucleic acids, have been synthesized using his method both by him and by others. In 1965, together with John Stewart, he automated the process, and today commercial models with microcomputer controls are available. In 1985 Richard A. Houghten, Jr. introduced the technique of using fine-mesh plastic bags ("tea bags") so that 10 to 50 or more peptides can be produced simultaneously. As many as 20.5 million different peptides can now be produced in a single synthesis. In related work Merrifield synthesized bradykinin (1963) and ribonuclease (1968), the latter being the first total synthesis of an enzyme.

Until 1969 Merrifield continued to work regularly at the laboratory bench, an activity that he truly enjoys, but he admits that "in recent years it has been very difficult to find a block of time large enough to be at all effective" (p. 97). Seemingly unaffected by receiving that "ne plus ultra" of the scientific life, the Nobel Prize, he sums up his career as follows: "I have lived my life by trying to make the best of what I have. I'm not a brilliant scientist who dashes into an area, hits the highlights, then dashes off to another. Rather, I am a conservative plodder. I like to focus on a subject that not too many are working on and stay with it until it's done, even if it doesn't seem to be working." (p. xxi).

We heartily recommend this autobiography of an extremely productive, hard-working, down-to-earth, family-oriented, and truly humble scientist to everyone interested in contemporary chemistry and the creative process.

Reactivity in Molecular Crystals. Edited by *Y. Ohashi.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York/Kodansha, Tokyo, 1993. 348 pp., hardcover DM 198.00, $ 130.00.—ISBN 3-527-29098-2/1-56081-857-3/4-06-206228-3

This book reports the results of a priority research project which was supported by the Japanese Ministry of Education, Science, and Culture in the period 1988–1990, and involved 34 scientists from the disciplines of physics, theoretical chemistry, crystallography, and organic chemistry. The considerable amount of new knowledge gained in this wide-ranging and fruitful area of fundamental physicochemical research is consolidated together

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1919-1991 $ 10.00+.25/0

here by the 38 Japanese authors named in the list of contents. It provides the reader with an overview of the present high standard of Japanese research in organic solid-state chemistry. On the other hand it also reveals which areas of research had not yet become established there, such as hole-burning, scanning tunneling microscopy, atomic force microscopy, small angle X-ray scattering, and gas–solid reactions. The arrangement of the contents in six chapters makes it easy to find one's way around the book, despite the scanty index in which only a few of the acronyms are explained. There is a noticeably high incidence of printing errors, but these do not affect the meaning.

Chapter 1 gives a useful survey of energy calculations for crystals. A new molecular dynamics method for predicting crystal packing patterns is also described and tested using benzene as an example. Chapter 2 reports significant new developments in fast time-resolved X-ray analysis. By applying high resolution electron spectroscopy to systems with high stability against electron-induced damage it is possible to obtain molecular-scale resolution, and one can study damage caused by electron bombardment. Organic films on graphite can be analyzed by Penning ionization electron spectroscopy, and CO adsorbates by time-resolved IR spectroscopy, while solid-state NMR spectroscopy is used to study the orientations of guest molecules in inclusion compounds. Polarized X-ray absorption fine structure analysis is used to study local asymmetric structures, while luminescence measurements can be used to detect energy transfer processes. Chapter 3 deals with "Crystalline-State Reactions", meaning very rare chemical reactions in which the crystals are retained with only very slight structural changes. Racemizations of cobaloximes and reversible intercalations in cholic acid crystals have been studied in detail by X-ray diffraction. In the photolysis of crystalline diazoalkanes and aryl azides it appears that the conditions for single-crystal to single-crystal reactions are only satisfied when the amounts converted are very small. Carbenes and nitrenes have been prepared at low temperatures with a view to possibly obtaining organic ferromagnetic materials. However, polycarbenes and polynitrenes which have long been known are not included here.

Chapter 4 contains a very useful summary of solid–solid reactions that have been investigated since 1987. Such reactions occur directly between powders when contacted with each other, without a solvent and (in most cases) without intermediate melting. Reactions that can occur in this way include rearrangements of pinacol, benzilic acid, and propargyl alcohol, Baeyer–Villiger oxidations, reductions using sodium borohydride, Grignard and Wittig reactions, oxidative couplings, dehydrations, etherifications, and the formation of host–guest complexes (sometimes enantioselectively). Also discussed incidentally in this chapter, although not falling within its main subject area, are some reactions of crystals with liquids and gases. However, solvents are excluded throughout.

The title of Chapter 5, "Stereoselective Solid-State Photoreaction", is surprising, since stereoselectivity is already well recognized as a property of innumerable photoreactions in crystals, such as four-center polymerizations of distyryl compounds, which are again included in this survey. Enantioselective syntheses can be carried out using clathrate crystals with a chiral host. Interestingly, dimerizations can occur despite the centers being separated by a distance of 7 to 10 Å. In the formation of ylides from photochromic heterocycles of the dihydropyridine type the question of stereoselectivity does *not* arise, and photoracemizations are certainly *not* stereoselective reactions.

The last chapter is again concerned with the relationship between crystal structure and reactivity. The polymerization efficiency of diethynylbenzenes is interpreted on the basis of purely static crystal structure considerations. In tunneling reactions of hydrogen or deuterium atoms with solid HD at 4.2 K and 1.9 K or with (apparently) glassy alkenes at 77 K, very large isotope effects were found, with selective formation of free radicals. Bimolecular Langmuir–Blodgett films are described in greater detail elsewhere. The crystal structures of complex sulfur heterocycles and the absolute configurations of chiral sulfoxides provide a starting point for research on new materials. Double macrocyclic inclusion complexes (cyclodextrin/crown-ether/metal ion or cyclodextrin/ferrocene) further extend the possibilities for molecular recognition with interesting crystal structures.

Not all the results from the project led to immediate practical applications, but many will be used for practical purposes in the near future. The book contains impressive evidence of fields in which Japanese solid-state research is ahead of that in the USA and Europe, and in particular shows that Japanese work will soon overtake that in Germany (in those areas where it still continues) unless the science ministries and regional parliaments of all the federal states quickly remove the legal obstacles to promoting first-class research projects in the universities.

Appearing as it does at the beginning of 1994, the book is two years too late, and is already outdated in many respects. Nevertheless, materials scientists will buy it as a useful reference source. During the next few years synthetic chemists, stereochemists, and crystallographers will expect it to be made available in their departmental libraries and will use it alongside more up-to-date sources.

Modern NMR Spectroscopy. 2nd Edition. By *J. K. M. Sanders* and *B. K. Hunter*. Oxford University Press, Oxford, 1993. 314 pp., paperback £ 23.50.—ISBN 0-19-855567-9

This book, whose first edition appeared in 1988, is intended for those chemists or NMR spectrometer users who do not have nor wish to acquire a deep understanding of NMR spectroscopy at a physical level, but who nevertheless want to be able to extract the maximum information from NMR spectra, mainly of liquid samples, using a few dozen routinely feasible techniques.

It consists of nine chapters, each of which begins by explaining the principles of the spectroscopic methods concerned using the classical vector formalism for the macroscopic magnetization. These explanations are excellently presented from a learning standpoint. Nevertheless, one cannot of course escape the inherent limitations of the vector representation, which is unable to give a satisfactory explanation of such important methods as the determination of pulses in the decoupler channel, which is essential for successful heteronuclear measurements, or multiple quantum spectroscopy. In each chapter an explanation of the basic principles is followed by a wealth of examples of applications in organic and organometallic chemistry, e.g. to steroids, alkaloids, oligosaccharides, rhodium carbonyls, vanadates, tin compounds, alkyllithium compounds, etc.

Chapter 1 is concerned with the basic one-dimensional single pulse experiment. Continuous wave (CW) spectroscopy is not discussed since it is nowadays obsolete. Basic concepts such as the rotating frame, the free induction decay (FID), digitization and its relationship to resolu-

tion, zero-filling, and dynamic range are explained. Here the authors are to be commended for aiming at consistency in the language used, at least within this book. In particular they point out a few misleading terms that have been adopted into NMR jargon but could cause problems for novices. Chapter 2 explains the concept of difference spectroscopy, with the main emphasis on homonuclear decoupling experiments. This chapter is very brief in accordance with the now minor importance of this method. Chapter 3, headed "Multiple-pulse Experiments", introduces the effects obtained with pulses of 180° (echoes, inversion) and 90° (polarization transfer, INEPT). However, whereas the vector formalism gives a simple and clear description of the effects of 180° pulses in coupled spin systems, the application to 90° pulses is considerably more difficult. These discussions are followed by useful hints for the operator on such matters as the calibration of pulses. Chapter 4 introduces two-dimensional NMR spectroscopy. Basic pulse sequences for identifying correlations due to scalar coupling through bonds are described (COSY, HMQC, INADEQUATE, TOCSY, etc.). Several pages are devoted to practical advice on matters such as spectral width and resolution in the newly added frequency dimension, phase cycles, field homogeneity, and apodization. However, as the instrument manufacturers use so many different programming languages the authors have not included actual pulse programs. Chapter 5 discusses strategies for molecular structure determination by correlation spectroscopy (COSY, H,C-COSY, INADEQUATE). The information yielded by such spectra is illustrated for both organic and inorganic molecules, some of which are quite complex. Chapter 6 is devoted to the use of cross-relaxation spectroscopy for obtaining qualitative and quantitative information about the local environments of nuclei. Here the nuclear Overhauser effect (NOE) is introduced and the most important measurement techniques are described (saturation-NOE, truncated NOE, and NOESY). Multiple spin effects and heteronuclear NOE measurements are discussed with suitable examples. The practical advice that is given, especially regarding the choice of mixing time and delay time in the NOESY experiment, will be very useful for the novice spectroscopist. Chapter 7 addresses the third basic type of interaction encountered in high-resolution NMR spectroscopy, chemical exchange. The nature of the spectra obtained for the cases of fast, medium, and slow exchange on the NMR time scale is described in a clear didactic way. The examples discussed range from tautomerism in organic compounds to fluxional exchange in inorganic complexes and to biochemical problems concerned with the binding of ligands to macromolecules. Chapter 8 is entitled "Editing". Here the word is used with a much wider meaning than usual, to include all the special techniques associated with modern pulse sequences, such as saturation of the water signal, heteronuclear decoupling, selective excitation using shaped pulses, and multiplicity editing. The last chapter briefly surveys the NMR spectroscopy of solids, introducing those interactions that are averaged out in high-resolution NMR spectroscopy of liquids, such as the dipolar coupling and the chemical shift anisotropy. The magic angle spinning (MAS) technique for averaging out tensor interactions and the cross-polarization technique for signal enhancement are described with examples. The discussion of 2D spectroscopy is limited to chemical shift correlations. This part of the book covers only the bare essentials, omitting important highlights of recent years such as the use of 2D spectra for directly studying dynamics in solids, and exact measurements of internuclear distances, e.g. between ^{13}C nuclei in a ligand bound to a protein within a solid membrane. The appendix summarizes the types of information obtainable by the different spectroscopic techniques, taking sucrose octaacetate as an example. This summary is very useful.

The book is written in a very readable style. Most of the figures are placed in the margins so that they do not interrupt the flow of the text, but at the same time are in a prominent position. Color has been used where it adds to the information content, e.g. in showing COSY spectra. The book gives an excellent survey of the most important NMR techniques and makes them accessible to a broad readership. However, in some places the authors' evaluation of the relative importance of particular methods differs from mine. For example, I feel that the 2D*J* technique is treated too prominently by being given five pages. On the other hand the heteronuclear techniques with proton detection (HMQC, HMBC, HSQC) are treated rather too briefly. Thus the HMBC method, which is an indispensable source of information on connectivity, especially for organic molecules, appears only as "HMQC tuned for long-range couplings", whereas the INADEQUATE technique, which is useless in most cases owing to low sensitivity, is nevertheless given several pages and some examples. The authors' verdict on ROESY that "This technique is far from straightforward and is not recommended for general use" also conflicts with my view. ROESY pulse programs are now available which work routinely without problems, often giving spectra of much better quality than those from NOESY.

To summarize, I strongly recommend this book for advanced undergraduate students and for research chemists who wish to gain maximum benefit from NMR spectroscopy in their preparative work and, where they have the opportunity, to make the best possible hands-on use of the capabilities of an NMR spectrometer. The many practical hints on performing NMR experiments will enable them to achieve that.

The Photochemical Synthesis of Fine Chemicals with Sunlight

Peter Esser, Bettina Pohlmann, and Hans-Dieter Scharf*

Dedicated to the memory of Klaus Gollnick

The light of the sun can be used directly for changing chemical structures photochemically. Any industrial application must conform to the limitations imposed by the spectral distribution of the photons from the sun, the interruptions to the radiation due to the day/night rhythm, and the weather. In this review, we describe the photochemical potential of the sun, give a fundamental treatment of the concept of photoreactors driven by sunlight (abbreviated to solar photoreactors), and give an account of the realization of this concept in the first pilot plant on the "Plataforma Solar de Almeria" in southern Spain and in other activities in this field. Based on experimental data from photochemical investigations on the pilot plant scale, possibilities, limitations, and the potential growth of solar photochemistry are described. Solar photochemistry, in our opinion, is a technique which could make a contribution to the chemistry of the future because of its photochemical synthesis potential, the avoidance of waste products, and the direct utilization of the sun, not only as a primary energy source, but also as a reaction partner.

1. Introduction

In photoreactions, in which the electronic excitation of a starting material is followed by chemical reaction, light must be regarded as a chemical reagent. The light must not only fulfill a particular quality requirement, namely that its wavelength must be able to be absorbed by the starting material, but, for single quantum processes, it must also be available in molar quantities. The efficiency of a photochemical reaction, the quantum yield, is the ratio of the amount of product in moles to the amount of absorbed radiation, measured in photons (1 Einstein = 1 mol photons). In photocatalytic chain reactions, the quantum yield can be considerably greater than 1. In the following article, interest is centered on so-called single quantum processes, that is, reactions with quantum yields less than or equal to 1. For this, it is necessary to provide the reagent photons quantitatively. Light, as a reagent, is remarkably reactive and selective. It can produce structural changes that either cannot be achieved by using ground state reactions or would require multistage processes. Photochemistry is in a position to make economically and ecologically valuable contributions to the synthesis of highly specialized products.

The normal route to artificial light starts from chemical energy (usually from coal and oil) or nuclear energy, which is changed first into electrical energy and then into light. The overall efficiency for this is at best only 9%. The use of fossil fuels leads to high emissions of carbon dioxide, and with nuclear energy the disposal of the used nuclear fuel and redundant equipment poses problems.

The utilization of solar photons provides an alternative. Here, a "renewable primary energy" can be directly linked to a chemical production process. The supply of radiation from the sun is affected both by the day/night rhythm and the weather, and is thus discontinuous. This has a decisive effect on process design and the siting of the plant with respect to geographical and climatic factors. The production location should not only enable the solar photochemistry to take place but should also provide all the peripheral energy for other reaction and processing stages before and after the solar photochemistry. Methods of technically utilizing sunlight in continuous processes may be divided into thermal and photon-linked branches (Fig. 1). The thermal energy of sunlight can be used directly, for instance for water desalination and solar thermal chemistry[1] or for the production of electricity.[2] The production of solar hydrogen deserves special mention because of its importance in both research and industry.[3] Methods for its production investigated range from the simple thermal decomposition of water to solar electrochemical processes and photocatalytic methods.[4] Hydrogen can be used as an energy carrier and as a chemical raw material. Another important branch of the technical utilization of solar radiation is photovoltaics.[5] In the primary step, a charge separation is produced by photons (photoelectric effect), and this can be used as electrical energy. Solar photochemistry can be divided into two main areas: solar detoxification processes (including

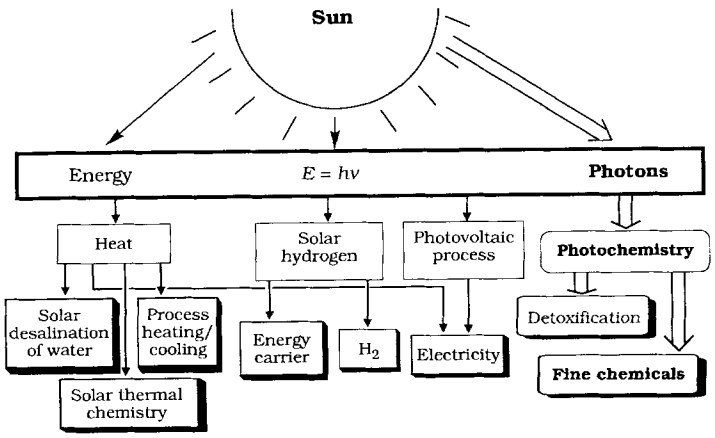

Fig. 1. The stream of photons from the sun can be used for energy production or can be directly coupled to a production process based on photochemistry. For a wide range of solar technologies, the concept of an energetically self-sufficient industrial unit can be realized.

the treatment of industrial waste water with a high concentration of halogenated hydrocarbons and the treatment of groundwater contaminated with pesticides to yield drinking water) and the solar photochemical synthesis of fine chemicals. This review deals only with the latter.

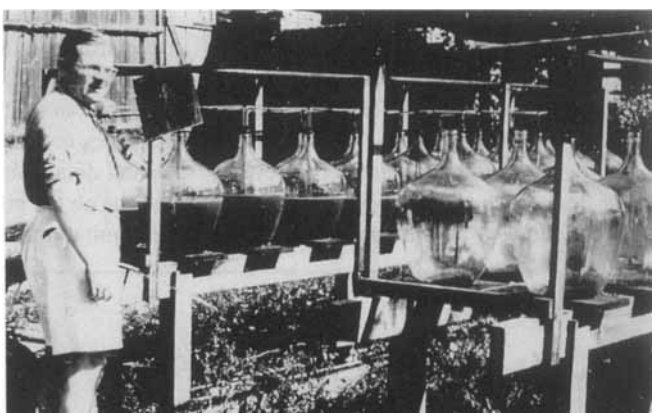
2. Earlier Work

The beginnings of organic photochemistry up to the first systematic research by Ciamician and Silber have been reviewed by Roth.[7] Early this century, photochemistry was closely linked to the use of the sun as the source of radiation, as in the investigations at Ciamician's laboratory on the roof of the chemical research buildings in Bologna.[7] It was also Ciamician who in 1912 in his New York lecture entitled "*The Photochemistry of the Future*"[8] presented a vision which is even more relevant today:

"*On arid lands there will spring up industrial colonies without smoke and without smokestacks, forests of glass tubes will extend over the plains, and glass buildings will rise everywhere; inside of these will take place the photochemical processes that hitherto have been the guarded secret of the plants, but that will have been mastered by human industry which will know how to make them bear even more abundant fruit than nature, for nature is not in a hurry and mankind is*".

In 1937, Alexander Schönberg, an emigrant from the National Socialist Republic of Germany, was appointed Professor at the Ain Shams University of Cairo. Here, he naturally found extremely favorable conditions for the investigation of photochemical reactions in sunlight. His work has led to his general recognition as a pioneer of preparative photochemistry.[9]

One of the first milestones in solar photochemistry was the synthesis of the anthelmintic ascaridol by Schenck et al. in 1943.[10] After the Second World War, Schenck erected the first solar chemical pilot plant for the synthesis of ascaridol in Ziegelhausen near Heidelberg, Germany, sponsored by the Marshall Plan (Fig. 2).[11] The plant was characterized by improvization



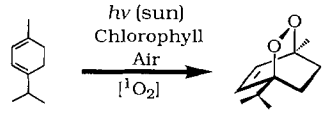


Fig. 2. Günther Otto Schenck and his pilot plant for the production of ascaridol in Ziegelhausen, near Heidelberg, Germany [11].

and simplicity. Air was passed into ordinary glass carboys containing α-terpinene in ethanol, with chlorophyll from the leaves of stinging nettles as the sensitizer. The sunlight and chlorophyll caused singlet oxygen to be produced from the oxygen of the air, and this caused the photooxidation of α-terpinene to ascaridol

Hans-Dieter Scharf, born 1930 in Leipzig, studied chemistry from 1949 to 1950 at the University of Leipzig and from 1954 to 1960 at the University of Bonn. After receiving his doctorate in 1960 for work on the Ipatiev reaction under the supervision of F. Korte he joined the staff of the Shell-Grundlagenforschungs GmbH in Birlinghoven near Bonn, where he carried out fundamental reseach, first as a research chemist, later as a section leader. From 1966 to 1968 he completed his habilitation at the University of Bonn on the theme "Photochemical [2 + 2] Cycloadditions" and shortly thereafter he accepted an appointment as Wissenschaftlicher Rat and as a Professor of Organic Chemistry at the Technische Hochschule Aachen. After rejecting several calls from other places, in 1972 he was appointed Full Professor and Director of the Institute for Organic Chemistry. His areas of reseach include photochemistry, chiral induction in photochemistry and energy storage, the synthesis of bicyclic acetal pheromones of pests and of deoxy sugars and their employment in the partial synthesis of antibiotics.

Scheme 1. Photooxidation of α-terpinene to ascaridol [10].

(Scheme 1). Discussion took place about the question of whether the oxidizing species was a sensitizer-oxygen complex, a view supported by Schenck et al.,[12] or was singlet oxygen, a theory originally proposed by Kautsky et al.[13] In 1964, Foote et al. showed that the latter theory was correct.[14]

Although the plant developed by Schenck was technically capable of improvement, this solar chemical production process was later abandoned because of the discontinuance of the pharmacological use of ascaridol due to its significant side effects.

The development of high-power lamps, especially low- and high-pressure mercury vapor lamps and subsequently lasers, enabled experimental photochemical plants to be moved from the roof to the laboratory. Photochemistry became a funded scientific area whose results have contributed greatly to the understanding of reaction mechanisms, stereochemistry, and the spectroscopic investigation of elementary steps and their kinetics. The outstanding work of Norrish and Porter on the photochemistry of free radicals in the gas phase led to the award of the Nobel Prize in 1967.[15] Furthermore, photochemistry has widened the range of available methods for preparative chemistry.

It is remarkable that in spite of scientific successes and insights in the area of photochemistry the technique has not been used on a large industrial scale for the production of chemical compounds. The reasons for this were and are first the high costs (electricity, limited lifetime of the lamps) of the molar quantities of photons necessary for single quantum processes where large amounts of product are desired (see Introduction). Second, standard chemical reactor technology cannot be applied to photochemical reactions. These reactions, which involve the interaction between light and matter, require new technological solutions (see Section 5).

Following the first oil crisis in the 1970s, research into the use of the sun as an energy source was revived and intensified. Photochemical reversible solar energy storage systems[16] and techniques for the production of solar hydrogen were investigated.[4, 17] Photochemical energy storage systems of quite acceptable capacities can be produced, although in general too few storage cycles are achievable for industrial applications.[18] These investigations therefore never went beyond the laboratory stage. However, more favorable conditions were found for inorganic reversible energy storage systems such as those based on magnesium hydride/magnesium, which are the subject of current research.[19] Intensive work is in progress on the solar production of hydrogen from water by photocatalytic decomposition as well as by electrolysis. A solar reactor with ruthenium complexes as photoredox catalysts has been described, but the long-term stability of this system is unacceptable for its use on an industrial scale.[20]

Since the end of the 1980s, intensive investigations into the solar detoxification of halogenated hydocarbons, especially using titanium dioxide catalysts, have taken place following the tightening of ecological standards. This has recently become the subject of solar field trials.[6] Experiments on the use of solar photons for the production of fine chemicals have been in progress since the beginning of the 1990s, following on from the earlier experiments in solar photochemistry.

3. Quality and Quantity of Solar Photon Streams

Sunlight strikes the earth's atmosphere with an intensity of 1367 Wm^{-2} (solar constant:[21] standard deviation ± 1.6 Wm^{-2}, maximum deviation ± 7 Wm^{-2}), but its intensity and spectral distribution is changed by its passage through the atmosphere (see ref. [21a] for a detailed discussion on solar radiation). Figure 3 gives a comparison between the extraterrestrial spectral distribution and the spectral distribution at the Plataforma Solar de Almeria (PSA, latitude 37.1° N, 500 m above sea level) on September 28, 1992 at 12:00 solar time (the sun at its zenith).

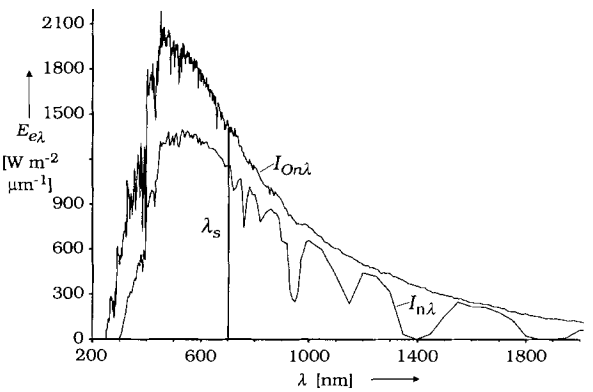

Fig. 3. Extraterrestrial spectral irradiance $I_{On\lambda}$ and direct normal spectral irradiance $I_{n\lambda}$ on the PSA on September 28, 1992 ($E_{e\lambda}$: spectral irradiance). The spectral distribution of the radiation on the PSA has been calculated, where l = 0.26 cm NTP, $\alpha = 0.7$, $\beta = 0.09$, and $w = 3$ cm (l: ozone layer thickness in cm NTP (normal temperature and pressure), α: wavelength exponent, β: Ångström's turbidity parameter, w: thickness of precipitable water vapor in a vertical column of air (cm)). The (fluid) limit of electronic excitation, 700 nm, is indicated in the diagram by a vertical line.

Of the extraterrestrial intensity, 1367 Wm^{-2}, the residual direct radiation intensity at the earth's surface is 892 Wm^{-2} in this example. At wavelengths less than 300 nm, almost no solar photons are detectable at the earth's surface. For photochemical purposes, only the region up to 700 nm is of interest, since photons of lower energy are in general not useful for photochemical reactions. Of the incident radiation (892 Wm^{-2}), 46% was in the photochemically interesting region (up to 700 nm) on the example day. In clear weather, as on the example day, the percentage distribution between visible and infrared radiation hardly changes on passage through the atmosphere. In cloudy weather, the ratio is shifted in favor of infrared radiation.

The attenuation of the extraterrestrial spectral irradiance $I_{On\lambda}$ by the atmosphere is described by Equation (a) in which $I_{b\lambda}$ is the

$$I_{b\lambda} = I_{On\lambda} \cos(\theta)\ \tau_\lambda \qquad \text{(a)}$$

direct spectral irradiance on a horizontal surface, θ is the zenith angle, and τ_λ is the spectral transmittance of the atmosphere. For surfaces tracking the sun in three dimensions, the expres-

sion simplifies to Equation (b), where $I_{n\lambda}$ is the direct spectral irradiance perpendicular (normal) to the irradiated surface.

$$I_{n\lambda} = I_{On\lambda}\,\tau_\lambda \qquad \text{(b)}$$

The spectral transmittance τ_λ of the atmosphere incorporates a number of transmittance coefficients [Eq. (c)], where $\tau_{r\lambda}$ is the

$$\tau_\lambda = \tau_{r\lambda}\,\tau_{a\lambda}\,\tau_{o\lambda}\,\tau_{g\lambda}\,\tau_{wa\lambda} \qquad \text{(c)}$$

spectral transmittance of the direct beam due to molecular (Rayleigh) scattering, $\tau_{a\lambda}$ is that for aerosols (scattering and absorption), $\tau_{o\lambda}$ is that of the ozone (absorption), $\tau_{g\lambda}$ is that of uniformly mixed gases (absorption by CO_2, O_2, N_2, N_2O, CO, CH_4...), and $\tau_{wa\lambda}$ is that of water vapor (absorption). For losses of light in the photochemically relevant region up to 700 nm, only the first three transmittances are significant. In particular, the transmittance due to molecular scattering $\tau_{r\lambda}$, decreases for short wavelengths. This leads to a higher proportion of short wave diffused radiation. Attenuation of wavelengths below 300 nm is caused by absorption by the ozone layer. This is shown in Figure 4 for the PSA on September 28, 1992. When

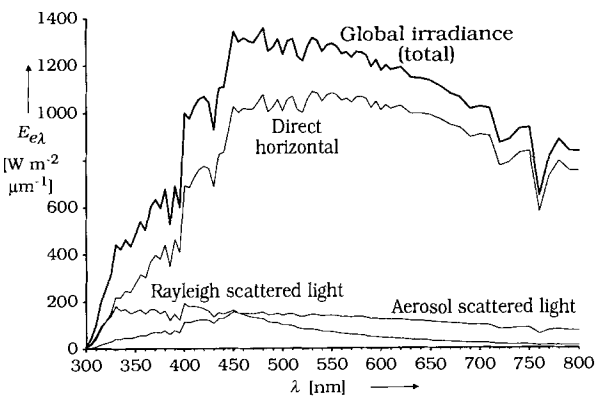

Fig. 4. The composition of the global spectral irradiance on a horizontal surface, which consists of direct spectral irradiance, Rayleigh scattered spectral irradiance, and aerosol scattered spectral diffuse irradiance is given for September 28, 1992 (a clear day) for the PSA. In clear weather other sources of diffuse radiation can be neglected.

direct normal and global horizontal radiation are compared, the result obtained with total spectral radiation is considerably different from that with UV (up to 385 nm) only (Fig. 5). Whereas for the total solar radiation and the range up to 700 nm (thick lines) the direct normal irradiance over the whole day is considerably more intense, the intensities of the direct and global radiation for the UV region (thin lines) are almost identical. The intensity of the direct UV radiation depends to a large extent on location. To illustrate the effect of location, Figure 5 also shows the calculated daily variation of direct normal irradiance for Aachen (51.8° N, 180 m above sea level) for both total spectral radiation and the UV range for identical weather data. The high quality of the weather data is in fact untypical for Aachen. The air normally is not as clear due to climatic and civilization effects.

Apart from the quality of the solar spectrum and its variations, the spectral distribution of the available photons is important for solar photochemistry. In Figure 6, the spectral photon irradiance $E_{p\lambda}$ is calculated from the spectral solar radiation in Figure 3. In Table 1, the available molar radiation figures up to certain wavelengths are given for the PSA location. Up to the photochemically useful wavelength of 700 nm at midday at the PSA on September 28, 1992 there was 6.65 mol($h\nu$)m^{-2}h^{-1} available.

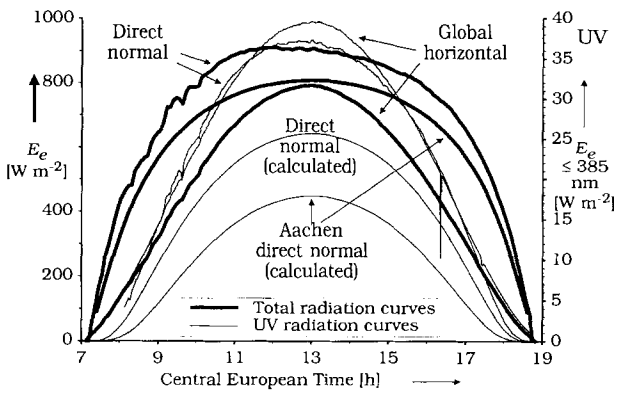

Fig. 5. Direct normal and global horizontal radiation on the PSA on September 28, 1992 during the course of the day (E_e: irradiation intensity). Direct and global total radiation is indicated by thick lines. UV radiation up to 385 nm is indicated by thin lines. With the aperture angle of the measuring equipment (ca. 5°, the sun being visible with an aperture angle of 0.52°) for the direct radiation and the high proportion of UV scattered light (see Fig. 4) which is deflected only minimally in clear weather (so-called circumsolar radiation), a high proportion of this scattered light is collected by the measuring equipment. Therefore, the calculated direct UV radiation is also shown by a thin line. To indicate the influence of location, based on the same weather conditions (l = 0.26 cm NTP, α = 0.7, β = 0.09, and w = 3 cm, see Legend for Fig. 3), a calculated plot of the direct UV and total radiation for Aachen is given. The UV part of the solar radiation is considerably more affected by weather and location.

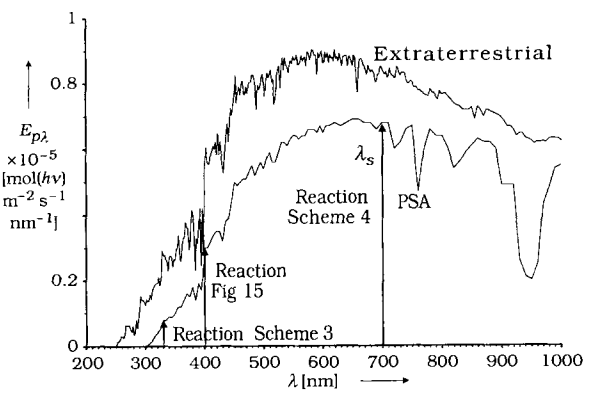

Fig. 6. Extraterrestrial and molar spectral direct solar irradiance on the PSA on September 28, 1992.

Table 1. Integration of the molar radiation from Figure 6 up to various wavelengths.

λ [nm]	Molar radiation [mol ($h\nu$) m^{-2} h^{-1}]
330	0.03
400	0.38
500	1.97
600	4.21
700	6.65

The measurement of direct normal solar radiation was carried out with pyroheliometers, and of global horizontal radiation with pyranometers.[21] The spectral range of the measurement can be restricted by the use of glass filters. It is necessary to make a calculation on the basis of the spectral transmittances from Equation (c) to derive the spectral photon distribution from these figures. The spectral distribution of the solar radiation can be calculated with good accuracy from the date, time, geographical location, and weather data,[21a] by adjustment of the measured values of the direct normal radiation.[22] (Note that in the Figures for which calculated radiation/time curves have been used, the weather data used are also given.)

4. The Photon Yields of the Solar Photochemical Synthesis of Fine Chemicals

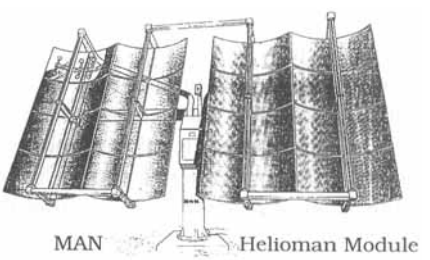
The degree of conversion of the quantity of photons provided by a light source into a product by a photoreaction is affected by loss factors in the photoreactor and in the photochemical system. The photoreactor efficiency η_{PR} is the fraction of the amount of available photons that reaches the reaction space. The effect of the photochemical system used can be divided into the absorption yield η_{abs} and the product quantum yield Φ_R. The absorption yield η_{abs} is the fraction of those photons reaching the reaction space that are absorbed by the photochemical system. The product quantum yield Φ_R is defined as the fraction of the absorbed photons that lead to the desired reaction. The emission spectrum of the light source and the wavelength dependence of the various factors must be considered when determining the total photon yield η_g. In Equation (d), $n_{h\nu}(\lambda)$ is the

$$\eta_g = \frac{\int_0^{\lambda} n_{h\nu}(\lambda)\ \eta_{PR}(\lambda)\ \eta_{abs}(\lambda)\ \Phi_R(\lambda)\ d\lambda}{\int_0^{\lambda} n_{h\nu}(\lambda)\ d\lambda} = \frac{n_B}{\int_0^{\lambda} n_{h\nu}(\lambda)\ d\lambda} \quad \text{(d)}$$

quantity of spectral photons and n_B the quantity of product. For the product quantum yield, not only the effect of wavelength, but also the effect of the extent of the reaction (the conversion) must be considered.

In the calculation of the total photon yield, either the photochemical system with its individual threshold wavelength limit λ_{gr} can be the point of reference for the maximum wavelength of the photons to be considered, or the light source (in this case the sun) and its emission spectrum. The total photon yield then also includes a measure of the utilization of this emission spectrum.

When the sun is used as the light source, it is appropriate when calculating the total photon yield only to consider photons with a wavelength up to 700 nm, which is introduced as the solar chemical threshold wavelength: $\lambda_s \equiv$ solar chemical threshold wavelength $\equiv$ 700 nm. This is logical, as electronic excitation in general takes place up to this limit, as described above.



In the following discussion the concept of solar photon yield is based on the utilization of the solar photon spectrum up to 700 nm, limited by the efficiency factors of the solar reactor used and the photochemical system being investigated. In contrast to the definition in Equation (d), the degree of conversion is used as a measure of the molar production rather than the product formation. The chemoselectivity of the reactions described is almost complete.

5. Solar Reactors

When surface reactors are used, as in the Schenck pilot plant (see Fig. 2), the light is directly absorbed, without prior concentration, by the total sum of all the effective liquid surfaces. The Schenck pilot plant, with its glass construction and reactor design, represented only what was feasible in the post-war period, and was not optimized with respect to the light yield. The advantage of this kind of construction lies in the possibility of using both direct and diffuse radiation. However, the radiation intensity of the sun being limited, the space-time yield is low and the demand for "optical windows" is high.

On the other hand, reactors that concentrate the light enable a considerable reduction in the area of the optical windows and a higher space-time yield to be achieved. A disadvantage of light-concentrating reactors is that only the direct fraction of global radiation can be concentrated. A further loss of light results from the efficiency factor of the concentrator.

From the research projects for the utilization of the thermal properties of sunlight, a number of concentrator systems are available.[2a, 21b] The only system so far used commercially (in California) is for electricity production, and involves two-dimensional parabolic trough-shaped (parabolic trough collector) tracking mirrors with linear focusing (Fig. 7). Instead of heating

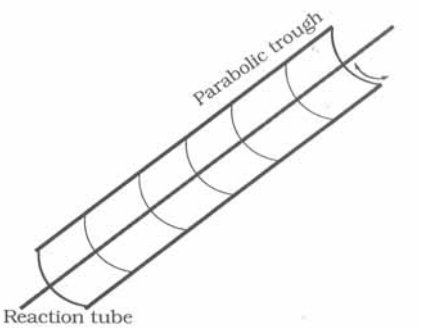


Fig. 7. Line-focusing parabolic trough collectors. Bottom: A two-dimensional trough that tracks the position of the sun. Top: A Helioman Module which can track in three dimensions, made by the company MAN [24]. It is fitted with a total of four parabolic troughs, and has a maximum height of 5.3 m and width of 8 m.

a temperature-stable oil at the line of focus of the parabolic mirrors, as is done when producing energy from the sun, photochemical reactions are carried out by irradiating the reaction solution in a glass tube located at the line of focus. This concentration system enables a degree of concentration corresponding to approximately 100 suns to be achieved in practice.[23] An advantage of this type of concentrator is its ease of manufacture.

A considerably higher degree of concentration of solar radiation can be produced by heliostat fields or parabolic mirrors (Fig. 8). Since the increased degree of concentration leads to an increase in the amount of heat entering the reaction solution, the degree of concentration of the solar radiation is limited by the temperature stresses in a given photoreaction and the extent to which these may be controlled by technical means. Eventually, most of the light absorbed by the reaction solution is converted into heat. The reaction enthalpy is usually small compared with the energy of the photochemical excitation. The heating can be limited by enabling the radiation not absorbed by the reaction solution to be transmitted through the reactor, or by preventing radiation with wavelengths above the wavelength limit of the photochemical reaction from entering the reaction solution at all by the use of a splitter mirror (short wave light passing through unhindered and long wave light being reflected). Reactors of this type (Fig. 8 bottom) are not yet used in practice.

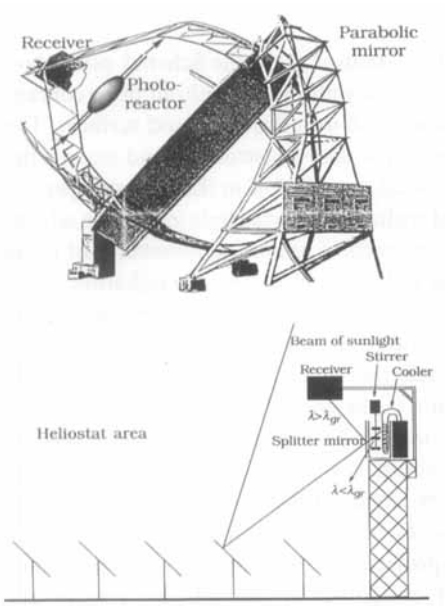

Fig. 8. Concentrating system: Top: A parabolic mirror (parabolic dish). A photoreactor is shown in front of the receiver for the utilization of thermal energy. For reactions that only use the UV part of solar radiation, there is enough energy remaining for its thermal properties to be utilized. Bottom: A heliostat area. The sunlight is concentrated on a tower by the mirror and heliostats. A solar photochemical reactor is shown on the tower. The long wave radiation is reflected by a selective mirror, increasing the total thermal efficiency of the equipment.

Special design problems are posed by reactions that need short wave solar light (ca. < 450 nm). Here, light concentration is frequently used to achieve high space-time yields. The choice of location is important. As short wave light is easily scattered, and, depending on the weather, is mostly deflected at small scattering angles, the use of a suitable design of the aperture angle of the light concentrating system can enable a large fraction of this circumsolar radiation to be collected (see also Fig. 5).

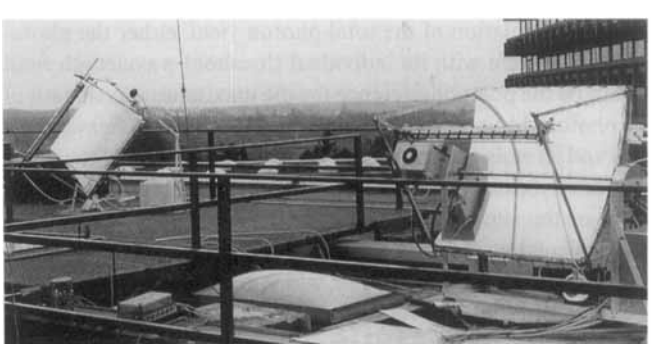
It could be objected that only a small part of solar UV light is used, and that it would be better to use the route: sun → electricity → UV artificial light. The production of UV light by this route is possible with an efficiency of about 3% (sun → electricity (e.g., photovoltaics) 10%; electricity → artificial light 30%). UV radiation (up to 400 nm) constitutes 8% of extraterrestrial solar radiation energy. At very good solar locations on the earth's surface (equatorial, high altitude, clear air), the figure becomes about 5% of the direct solar radiation. This approximate figure alone provides the justification for investigations into the utilization of solar UV radiation for photochemical purposes. If the solar UV radiation can also be concentrated, and the visible and IR radiation not used by the photochemical reactions can be utilized, for example by a thermal receiver (Fig. 8), attractive solar chemical systems present themselves.

The speed of photochemical reactions can be improved by high concentration of solar radiation as long as the starting materials do not undergo other types of excitation (such as excitation by two photons) which lead to side products or other types of products. Sizmann et al.[25] point out that a photon, which has the character of a particle, is a reactant subject to the thermodynamical law of mass action, indicating a photochemical reaction is reversible. That is, there can be a chemical equilibrium involving both the reactants and the radiation. Since photochemical reactions usually proceed at a point remote from equilibrium, and moreover the photochemical product formation is normally irreversible, the effect described by Sizmann et al. can be ruled out. The probability of two-photon processes is also improbable because of the need to observe thermal control in the reaction solution. It is therefore to be expected that the product formation will increase proportionally to the amount of radiation available.

For the more recent solar photochemical experiments in the field, parabolic trough collectors are used. At the present time, work commissioned by the AG Solar des Landes Nordrhein-Westfalen is being directed towards the development of experimental reactors in which the degree of solar concentration is high and variable. The first solar tests are planned for 1995 on the "Hochflussdichte-Sonnenofen", the construction of which has recently been completed, of the AG Solar in Köln Porz on land belonging to the Deutsche Forschungsanstalt für Luft- und Raumfahrt e. V. (DLR).

5.1. The Solar Reactors at the Max-Planck-Institut, Mülheim an der Ruhr, Germany

The solar reactors at the Max-Planck-Institut (MPI) for radiation chemistry in Mülheim an der Ruhr, Germany, are being operated on the roof of the Institute building (Fig. 9). Two types of reactor have been developed, with a single and double axis design, respectively.[26] At the heart of the solar reactors is a line focusing concentrator developed by the company HTC Solar (Lörrach) and included in the reactors built at the MPI.[27] The



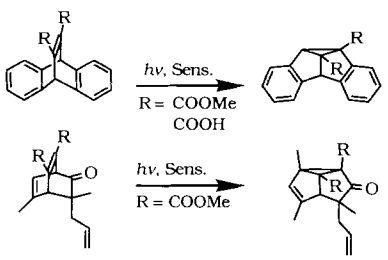


Fig. 9. Solar reactor equipment on the roof of the MPI in Mülheim.

reflector consists of a film of Hostaflon (100 cm × 100 cm) coated with aluminum by vacuum deposition and stretched over an aluminum chamber. A vacuum can be applied to the chamber, and a focus line can be produced by the film. Controlled defocusing can also be carried out to give control of the temperature of the reaction solution. At the focus line there is a silica tube 100 cm long and 1 cm in diameter. The theoretically possible concentration factor of 100 suns is reduced in practice to a maximum of 60 because of efficiency losses in the concentrating system. An automatic mechanism controlled by a photocell causes the mirror and reaction tube to track the sun. The solution is pumped at a rate of 90–100 $L\,h^{-1}$ through the irradiation tube. It then goes back into the storage vessel (2 L volume) through a cooling tower. Without cooling, this flow rate results in a maximum reaction temperature of 35 °C when water is the solvent.

This reactor has so far been used for photosensitized rearrangements of di-π-methane and oxadi-π-methane (Scheme 2)

Scheme 2. Di-π- and oxadi-π-methane rearrangement with sunlight [27]. Sens. = sensitizer.

in aqueous micellar solution.[28] The high heat capacity of the solvent water is an advantage. Moreover, no protective gas is required. In the micelles in which the photochemical reaction takes place, obviously only a very small oxygen concentration is present.

5.2. The SOLARIS Experiment

The SOLARIS experimental solar photochemical fine chemical syntheses were carried out at the Plataforma Solar de Almeria, Spain, by the Institut für Organische Chemie der Technischen Hochschule Aachen, Germany, in cooperation with the DLR, Köln, Germany. The conception and construction of the SOLARIS reactor was effectively carried out by G. Schneider (DLR). The solar experiments were performed between October 17, 1991 and February 15, 1992 and between September 18, 1992 and November 25, 1992. Three photochemical reactions with different threshold wavelengths were chosen as test reactions. The potential for solar irradiation in the different spectral regions with different threshold wavelengths had to be assessed experimentally. Other criteria, apart from the provision of the associated laboratory work, included a simple experimental procedure, availability of the starting materials, the use of solvents with the lowest possible toxic properties, a convenient method of following the reaction (by gas chromatography), and the suitability of the reaction products for synthesizing useful substances.

5.2.1. The SOLARIS Reactor

The SOLARIS reactor (loop) comprises the light concentration system, an absorber tube at the focal line of a parabolic trough collector, material feeding equipment, and a data collection system (Figs. 10–12). The feeding equipment (storage vessel, pump, heat exchanger, gas metering, etc.) of the loop is on a platform immediately next to the MAN Helioman Tracking

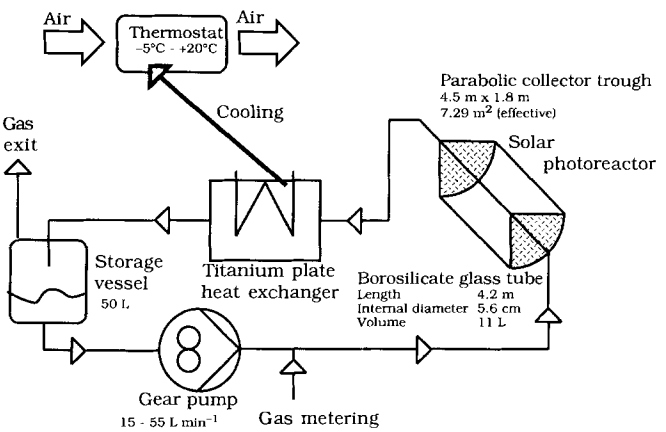

Fig. 10. Schematic diagram of the SOLARIS reactor.

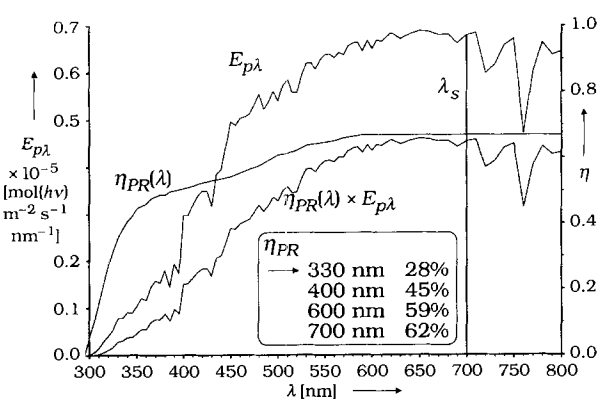
Fig. 11. The MAN Helioman Module is shown on the right (east), and the feed platform is on the left (west). The latter is protected from the weather by a corrugated steel shed. The red color of the sensitizer Rose Bengal can be clearly seen in the absorber tube. In the background on the right, a MAN Helioman Module for the detoxification loop can be seen. The absorber tube shines white due to scattering by the titanium dioxide.

Fig. 12. View of the feed platform, which opens towards the north. The storage vessel can be seen in the left foreground. The process cooler is in the background. The control cabinet is on the wall on the right, and the gas fittings, with three gas bottles for nitrogen, oxygen, and ethene, are in the foreground.

Module but outside its range of movement. The reactor is of the tube reactor type with a closed recirculation system. The reaction solution is pumped out of the storage vessel and through the recirculating system. This contains a gas metering device and a static mixer, both at the point of highest pressure. The solution then leaves the platform and is fed through a flexible pipe to the inlet of the absorber tube. This inlet is situated underneath the parabolic trough collector. The absorber tube is at the focus of one of the parabolic trough collectors that track the sun. The tracking is performed by a Helioman Module to which the mirror and absorber tube are fixed.[24] This follows the sun by automatic three-dimensional tracking on two axes. The photochemical reaction takes place in the absorber tube, from the top end of which the reaction solution flows into a flexible pipe and then back to the feed section. Here, the heat that has been absorbed by the solution, mainly during its passage through the absorber tube (thermalized solar radiation), is removed. A process cooler supplies the heat exchanger with a cooling medium. The reaction solution leaving the heat exchanger flows back into the storage vessel. The reaction solution is pumped round the recirculating system until the desired degree of reaction (conversion) has been achieved. The loop had a minimum operating volume of 35 L and a maximum of 70 L. When working with oxygen and organic solvents (Section 5.2.4), sources of ignition had to be strictly excluded.

The efficiency of the light-concentrating system is affected by tracking defects of the Helioman Module, the reflectivity of the mirror surface, and the transparency of the glass tube. The equipment provided by the PSA (J. Blanco, S. Malato) for the solar photochemical experiments on the Helioman Module was similar to that for the 12 Helioman Modules used in a loop for the detoxification of impure water (detoxification loop).[29] The Helioman Module has a tracking accuracy of 95%. The mirror surface is made of aluminum foil. The reflectivity of this foil is not the optimum,[30] but represents a compromise between cost on the one hand and a reactor concept suitable for the investigation of the selected test reactions in the UV region on the other. The transparency of the absorber tube of borosilicate glass (Pyrex) in the focal line of the parabolic mirror has a value of 89% at 385 nm.

The reflectivity of the mirror and the transparency of the absorber tube are wavelength-dependent. The efficiency of the photoreactor $\eta_{PR}(\lambda)$, which is wavelength-dependent, is shown in Figure 13. The efficiency of the photoreactor over the entire spectral range up to the solar chemical threshold wavelength is 62%. The direct solar radiation is concentrated by a factor of about 20 suns in the absorber tube.



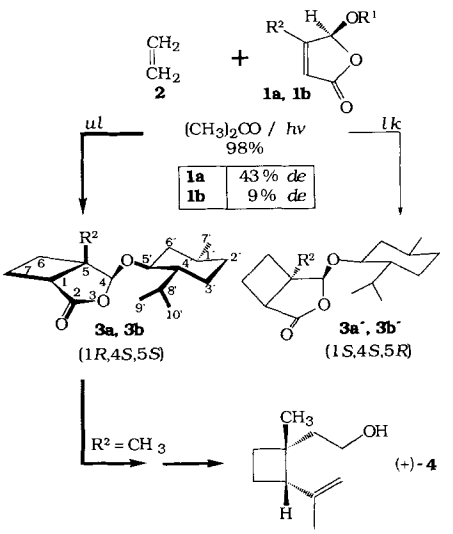


Fig. 13. The molar direct spectral irradiance ($E_{p\lambda} = n_{h\nu}(\lambda)$ per unit of surface and time) on the PSA on September 28, 1992, and the spectral radiation ($\eta_{PR}(\lambda) \times E_{p\lambda}$) (without reference to the concentration) influenced by the efficiency of the SOLARIS reactor ($\eta_{PR}(\lambda)$). The efficiency of the SOLARIS reactor for various spectral ranges is given in the box. Here, the spectral molar radiation shown is taken as the basis. The solar chemical threshold wavelength is also shown as a vertical line for orientation purposes.

5.2.2. *Photocycloaddition of Ethene to α,β-Unsaturated Carbonyl Compounds*

The acetone-sensitized [2 + 2] photocycloaddition[31] (Scheme 3) of ethene (**2**) to 5-alkoxy-[5*H*]-furan-2-one (**1**) has been investigated as a case of a photoreaction with sunlight with

Scheme 3. [2 + 2] Photocycloaddition reaction of **1** with **2**. R^1 = (+)-menthyl; **a**, R^2 = H; **b**, $R^2 = CH_3$.

a short wave limit. When acetone is used for sensitization, only light up to a threshold wavelength of 330 nm can be used for the photoreaction. The use of longer wavelength absorbing sensitizers was deliberately avoided. For the cyclobutanes **3b** and **3b'** from **2** and the 3-methylfuranone **1b**, or **3a** and **3a'** from **2** and the furanone **1a**, in the synthesis of grandisol **4** or its structural analogue demethylgrandisol[32] has been described. This reaction certainly shows no significant diastereoselectivity, but the diastereomers can be simply separated by chromatography.[33]

In the second SOLARIS phase, this type of reaction was carried out with the 5-ethoxyfuranone **1d** as the α,β-unsaturated ketone, which itself was a product of the first SOLARIS phase (see Section 5.2.4). The reaction is summarized in Figure 14. Using 2.1 mol of starting material, a conversion of 23% was obtained after two solar irradiation stages. After the first day, which was partly cloudy (Fig. 14), a partial conversion of only 6% was obtained, and, after a second day of clear, cloud-free weather, the figure was 16.4%. The radiation conditions on the second day can be regarded as the optimum for the location and time of year. In assessing the partial conversions, the unfavor-

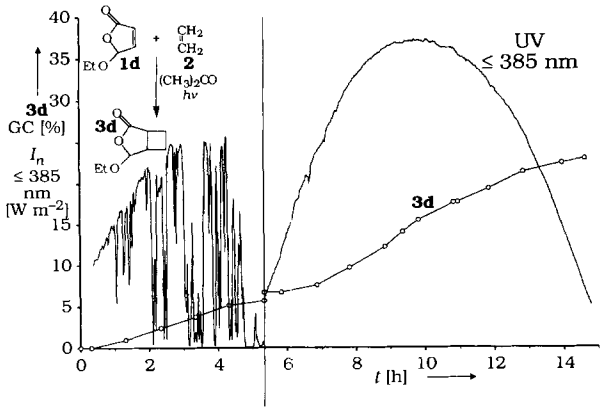

Fig. 14. The [2 + 2] photocycloaddition of **2** to **1d** was carried out on September 25 (left) and 28 (right), 1992 with 2.1 mol (270 g) starting material **1d** in acetone (36 L) at 10 °C). The progress of product **3d** formation (measured by GC analysis) is shown, and also the direct UV radiation up to 385 nm for the two days of the experiment, which are separated from each other by a vertical line. The radiation curve for the first day of the experiment shows a severely disturbed course, due to the passage of clouds. The smooth progress of the photoreaction leads to two product diastereomers in the ratio 2.6:1. The reaction solution, with a flow rate of 20 L min^{-1}, is heated 6 K between the inlet and outlet of the irradiation tube (September 28, maximum day temperature: 30 °C at midday). t = reaction time.

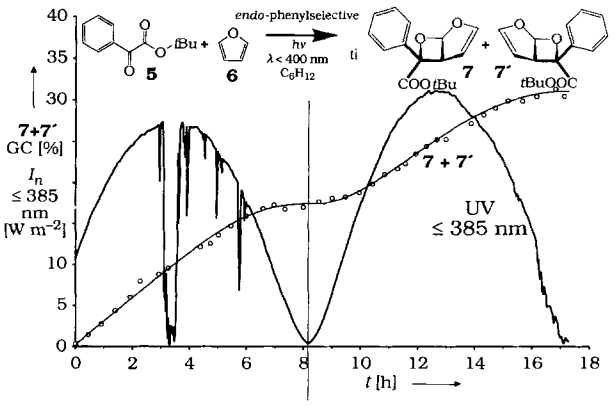

Fig. 15. **5** (1105 g, 5.2 mol) and **6** (2 L, 28 mol) in cyclohexane (33 L) were irradiated at 20 °C (temperature control) on two successive days (November 3, 4, 1992). The formation of **7** and **7′** was measured by GC analysis, and the direct solar UV irradiance was up to 385 nm for both days of the experiment. The two days are separated by a vertical line. The reaction solution, at a flow rate of 23 L min^{-1}, was heated 3 K between the inlet and exit of the irradiation tube (maximum day temperature: 26 °C).

able mirror area/reaction volume ratio for this reaction must be borne in mind, as well as the low molar solar radiation in the spectral range up to 330 nm, and the low photoreactor efficiency (28%) for this range. This results in a solar photon yield of just 0.1%. This reaction can be caused to give complete conversion with longer irradiation times, in a different part of the year, or with more irradiation stages. The solar photon yield can be further improved by reactor optimization by improving the glass and mirror materials.

5.2.3. *The Paternò–Büchi Reaction*

The photoinduced [2 + 2] photocycloaddition of carbonyl compounds to alkenes to form oxetanes offers an interesting possibility for synthesizing complex naturally-occurring and other substances.[34] Schreiber et al. have reported the synthesis of racemic asteltoxin,[35] avenaciolide,[36] a cadsurenone-ginkgolide hybrid,[37] and a seco-precursor of isolobophytolide.[38] Zamojski et al. was also able to synthesize a protected 3-deoxy-streptose derivative[39] from a furanooxetane precursor. Hambalek and Just used the method for synthesizing epioxetanocin.[40] Hoye and Richardson were able to achieve the shortest sarracenine synthesis so far using this key step.[41] A protected apiose,[42] a 3C-hydroxymethyl-branched pentose, was synthesized by photoaldolization of ((−)-8-phenylmenthyl)phenylglyoxylate with 2,2-dimethyl-1,3-dioxol, with complete asymmetric control.

The preparative use of the Paternò–Büchi reaction, especially of asymmetric compounds, is still in its infancy.

The reaction of (*tert*-butyl)phenylgloxylate (**5**) with furan (**6**) in cyclohexane was chosen as a model system to test the asymmetric Paternò–Büchi reaction under solar conditions. This reaction consistently proceeds regiochemically and stereochemically, as shown in Figure 15, to form **7** and **7′**. With a clean reaction, complete conversion based on the keto-component can be achieved. If the chiral phenylglyoxylate of 8-phenylmenthol or of *trans*-2-*tert*-butylcyclohexanol is used in the reaction,[43] the product oxetane is also diastereochemically uniform. The phenylgloxylates absorb light up to a wavelength of 400 nm from the molar spectral radiation of the sun (Fig. 16).

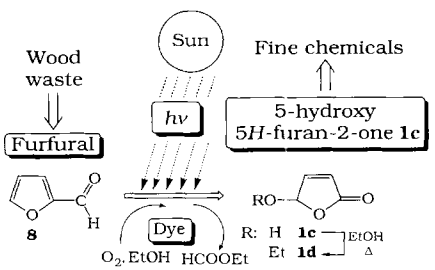

Fig. 16. Parabolic trough collector with absorptiopn tube. A Paternò–Büchi reaction takes place in the absorption tube (see Fig. 15). Since this reaction absorbs UV light, the reaction solution is colorless to pale yellow. A small flow of protective nitrogen gas is passed through, and some gas bubbles can be seen in the absorption tube.

The starting material shown as an example in Figure 15 was irradiated on two successive days. The radiation conditions on both days are certainly considerably worse than in the second day of the experiment described in Figure 14, but are classified as "good" for the time of year. On interrupting the reaction on the second day, a conversion of 32% was obtained. The size of the charge is so chosen that the UV light of the sun is almost completely absorbed within the cross-section (5.6 cm) of the absorber tube, up to a conversion of 95%. The photoreaction gives a quantum yield of about 0.1 at the chosen furan concentration (0.78 mol L^{-1}). The quantum yield is dependent on the concentration of the furan, and increases as its concentration increases.

The SOLARIS reactor does not have the optimum design for this reaction as far as the ratio of the reactor volume to the mirror surface is concerned. The photoreactor efficiency of 45% (see Fig. 13) for the spectral range up to 400 nm is capable of considerable improvement, especially with a better mirror surface. For the [2 + 2] photocycloaddition carried out, a solar photon yield of 0.3% is obtained. The overall photon yield for the utilization of solar radiation up to 400 nm is nevertheless in the region of 5% (photoreactor efficiency ca. 0.5 and product quantum yield ca. 0.1, see above).

5.2.4. *Singlet Oxygen Reactions*

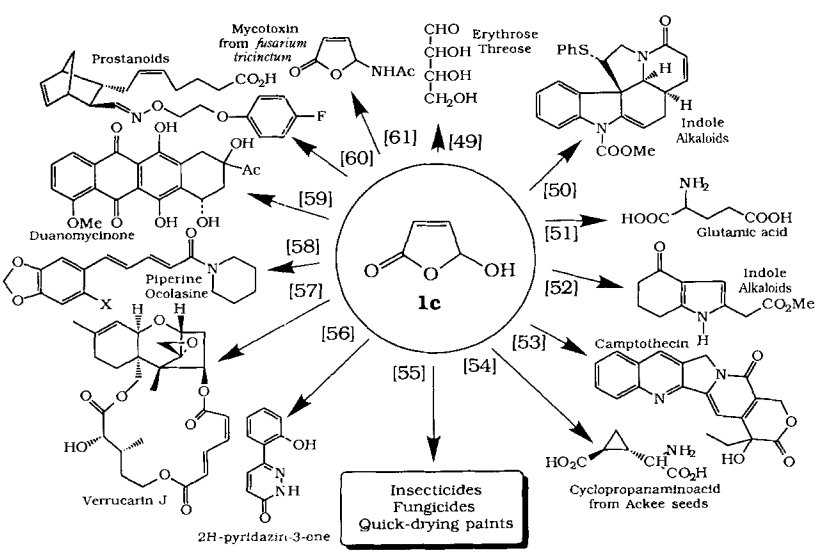
The third test reaction was the dye-sensitized photooxidation of furfural (**8**) with oxygen to give the 5-hydroxyfuranone **1c** in alcoholic solution (Scheme 4). This reaction was first described

Scheme 4. Photooxidation of **8**, a renewable raw material, to **1c** (sometimes referred to as pseudoacid or maleic aldehyde acid).

by Schenck.[44] In it, the sensitizing light is absorbed from the visible spectral range. By an inter-system crossing step, the sensitization of the oxygen takes place from the triplet state of the sensitizer. Singlet oxygen is the result. Furfural (**8**), which is produced industrially by the action of mineral acids on materials such as oat husks, corn cobs, rice husks, groundnut shells, and reeds, can be replaced for the synthesis of **1c** by furfuryl alcohol[44b] or 2-furancarboxylic acid.[44b, 45] Both are produced from **8**. Because of the high temperatures during working up, Schenck could only isolate the 5-methoxy or 5-ethoxy analogues (**1d**), depending on the alcoholic solvent used. It was later shown that by operating below about 40 °C in the working up procedure, **1c** is the only reaction product.[46]

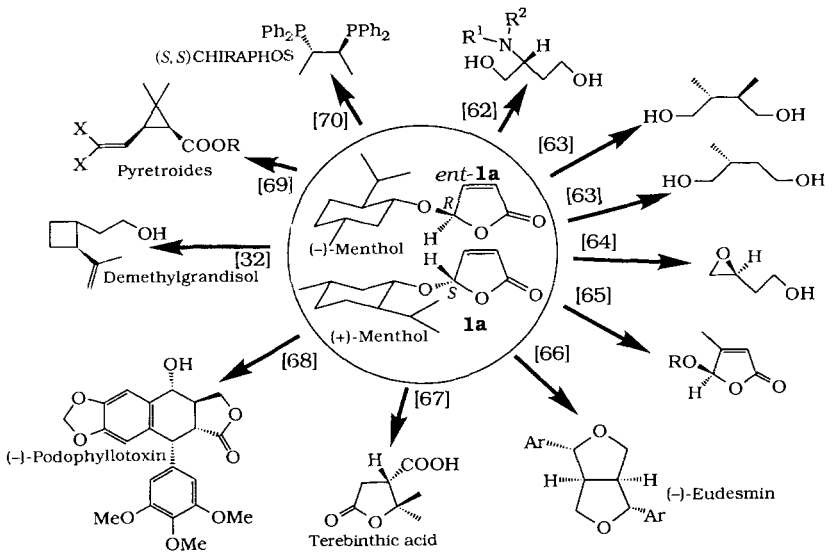
The use of **1c** as a C_4 building block in the synthesis of a large number of natural and synthetic substances has been described, and is summarized in Scheme 5. Because of the easy accessibility of the diastereomerically pure 5-menthyloxyfuranones **1a** and *ent*-**1a**,[47] these have recently been used for synthesizing C_4 building blocks or directly as chiral building blocks (Scheme 6).[48] The two furanones **1a** and *ent*-**1a** can be obtained in high yield by the condensation of the furanone **1c** with (+)- or (−)-menthol followed by crystallization from *n*-hexane[47] and thermal or proton-catalyzed epimerization.[63b, 64]

Rose Bengal (**10**) and methylene blue (**11**) are used as sensitizers for the solar dye-sensitized photooxidation of **8** (Fig. 17). Rose Bengal[71] has its absorption maximum at 555 nm. Only light up to a maximum wavelength of 600 nm is used. The absorption yield η_{abs} based on the quantity of irradiating photons of wavelength ≥ 700 nm is 0.63. Rose Bengal in ethanol as solvent has the highest singlet oxygen quantum yield (0.86) of all the sensitizers so far used for this purpose.[71a, 72] The combination of these two factors results in a solar sensitizing efficiency of 0.54 for Rose Bengal.



Methylene blue (**11**) has its absorption maximum at 685 nm. It can be electronically excited by light of wavelength up to 720 nm, so that, using the solar chemical threshold wavelength as the reference point, an absorption yield of 1.07 results. With methylene blue, the singlet oxygen quantum yield depends very much on the reaction conditions,[73] and has a value of about 0.35 for photooxidation in ethanol. This results in a solar sensitization efficiency of 0.37.

The photooxidative conversion of **8** into the 5-hydroxyfuranone **1c** proceeds to only a small extent directly. Under the reaction conditions, furfuraldiethylacetal (**12**) is formed, which reacts considerably more rapidly with singlet oxygen. Since the formation of **12** is catalyzed under the reaction conditions, the course of the reaction is autocatalytic. The kinetics of the photooxidation of **8** are summarized in Figure 18.



With a starting concentration of 1.1 mol L^{-1} **8** and a 97% conversion, a singlet oxygen utilization of 65% follows from the kinetics of the photooxidation. The reaction proceeds via the furfuraldiethylacetal intermediate to the extent of 80%.

In the two experimental phases on the PSA a total of 16 experiments were carried out, using just over 40 kg furfural **8**. The results of these experiments are illustrated by five examples, which are summarized in Table 2. The course of Experiment A is shown in Figure 19, and that of Experiment E in Figure 20.

Experiment A (Fig. 19) was carried out over 14 days. However, a period of bad weather meant that direct solar irradiation was only available for three days (Fig. 19). Even so, the radiation was interrupted on all these three

Scheme 5. Reaction "star" showing uses of **1c** in synthesis with literature references.

Scheme 6. Reaction "star" showing uses of **1a** and *ent*-**1a** in synthesis with literature references.

days by the movement of clouds. Under these conditions, the reaction behaved remarkably robustly. The reaction starting materials can be left in the loop during bad weather without harm until direct solar radiation reappears.

An ideal experimental run is shown in the example of Experiment E in Figure 20. This indicates that with clear weather, and hence the best solar irradiation, the experiment can be completed shortly after midday after only five and a half hours irradiation.

Methylene blue (**11**) is clearly preferable to Rose Bengal (**10**) as a sensitizer for the photooxidation of **8**. This is at first surprising as the solar sensitization efficiency of **10** is 0.54, which compares with 0.37 for **11**. The weakly acidic reaction conditions, which also favor the formation of furfuralacetal, have a detrimental effect on the extinction values and singlet oxygen quantum yields of **10**, which is a dianion. This is convincingly demonstrated by comparing Experiments B and C in Table 2. In Experiment C, twice the amount of starting material is converted with an almost equal irradiation time and almost identical irradiation conditions. Furthermore, in Experiment B, the amount of sensitizer needed is extremely high, first because of the effect on the extinction properties of **10**, and second because of the

[a] furfuralacetal **12**. [b] Addition of 5 mL conc. HCl (furfural **8**/HCl = 625/1).

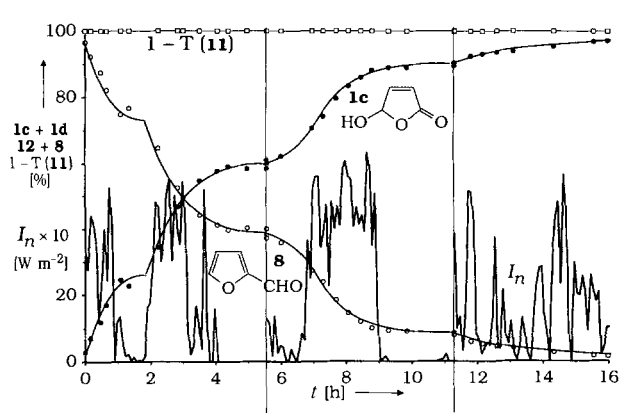

Fig. 19. In Experiment A, irradiation was carried out on three days (see Table 2). The following are given in percentages: starting materials (decreasing with time) (**8** + **12**, GC analysis), product (increasing with time) (**1c** + **1d**, GC analysis) and the absorbance (1 – T) by the sensitizer in the absorption tube (diameter of absorption tube: 5.6 cm, on the basis of an extinction measurement of 695 in a 1 cm cell). The direct solar radiation is also shown. The experimental days are separated by vertical lines.

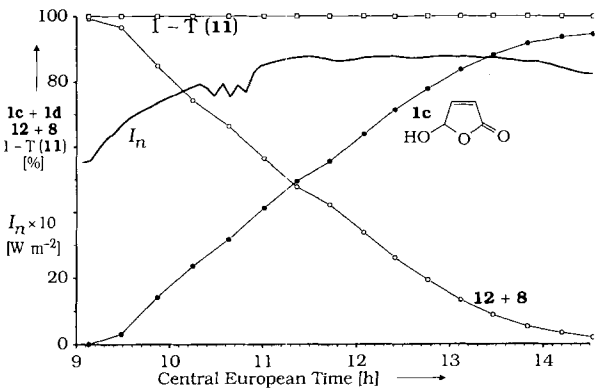

Fig. 20. In experiment E (see Table 2) the time (Central European Time) is shown on the x axis (see also legend to Fig. 19). At this time of the year, the sun is at its zenith at about 13:00 h. Between entering and leaving the irradiation tube, the reaction solution, flowing at 45 L min^{-1} was heated 3 K (maximum daily ambient temperature: 25 °C).

lower stability of **10** towards UV light compared with **11**. The sensitizer stability can be considerably improved by the exclusion of UV radiation by suitable choice of the mirror and the type of glass. Singlet oxygen sensitizers represent a considerable opportunity for optimization, not only from the point of view of stability, but more so because of the possibility for matching to the solar spectral radiation, while at the same time obtaining the highest possible quantum yields.

The photooxidation of **12**[74] proceeds with a higher rate constant k_{ox2} (see Fig. 18); thus the singlet oxygen utilization is higher. This substance was therefore used as the starting material in Experiment D. The reaction also shows the highest solar photon yield (17.7%) compared with the other reactions recorded in Table 2. A higher solar photon yield would be expected from the higher oxidation rate constant k_{ox2}. The appearance of clouds immediately after the start of the reaction led to extensive decomposition of **12** due the acetal formation equilibrium, leading to a reduction in the rate of the photooxidation reaction. A possible alternative to the use of **12** as the starting material to improve the efficiency is to accelerate attainment of the acetalization equilibrium by adding protons. This was investigated in Experiment E by adding a little hydrochloric acid. After only five and a half hours irradiation under the best irradiation conditions the experiment could be ended after the starting material (37.6 mol) had undergone 98.1% conversion. The overall solar photon yield was 16.3%. The selectivity is somewhat less than in the case of the photooxidation of **8** without acid addition, and the reaction is no longer so robust. A sufficiently high conversion, enabling the photoreaction to be ended, should be achieved after one day of irradiation.

Before making a conclusive comparison of the solar photon yields achieved, some further comments should be made about Experiments A and C. In Experiment A, because of the low maximum irradiation and the frequent cloud problems, the reaction mainly took place via **12**. Also, because of the extent of cloud cover, the molar solar irradiation could not be calculated with the same accuracy as would have been possible on a day of uninterrupted irradiation. Experiment C delivered the highest conversion figure (99.7%). The photon yields given in Table 2 are based on the conversions obtained in the respective reactions. In Experiment C, at a conversion of 98%, which is more interesting for comparison purposes, the solar photon yield was 11.6%. However, because of the high reaction rate in the absorber tube due to the high irradiation rate, there was an oxygen deficiency due to insufficient turbulence in the region of highest light absorption, although a more than sufficient total amount of oxygen was being passed through the absorber tube. After this experiment, in the second experimental phase, the problem of inadequate saturation by oxygen was solved by installing a mixing element in the middle of the absorber tube. The concentrated sunlight can lead to such high reaction rates that the demand for dissolved oxygen is a limiting parameter. The possibilities for solving the problem by the techniques used (increasing the pressure and the intensity of mixing the gas phase with the solution) have limits, imposed partly by the quenching properties of the singlet oxygen and partly by light scattering.

Comparisons of solar photon yields in Table 2 show that the increased cost of production of **12** is not justified, since the efficiency can also be much improved by adding protons to **8** in ethanol. It is prudent to limit the conversion to 97%. Higher conversions lead to a considerable reduction in the utilization of the solar photon stream.

The photon balance of the solar photooxidation of **8** is determined by the photoreactor efficiency (0.62), the solar sensitization efficiency (methylene blue **11**: 0.37), and the singlet oxygen utilization of the photooxidation (0.65). In practice, it was possible to obtain solar photon yields of 16%. This figure agrees with the separately determined values of the three efficiency factors mentioned. The photoreactor efficiency can be increased from 0.62 to 0.80 for the SOLARIS reactor by matching to the requirements of the singlet oxygen reaction. The need to optimize the sensitizer and the possibilities for influencing the kinetics of the photoreaction have already been discussed in some detail.

The photooxidation of **8** with artificial light from lamps gives an overall efficiency of 4.5%. In this calculation, the following efficiencies are assumed: electricity production: 30%, light production: 30%, photoreactor efficiency: 90%, singlet oxygen quantum yield: 86% (Rose Bengal **10** with artificial light optimally matched to the absorption of the sensitizer), and utilization of the singlet oxygen: 65% (as stated above). Caution must be used when comparing the figures, since a pure photon balance takes place with the sun, whereas with artificial light a mixture of energetic (including light production) and photon balances must be considered, but the advantage of the solar production route is still nevertheless apparent. This is even more the case if one considers that the optimum figures for the artificial light route have been used, whereas the solar reaction path is capable of further considerable improvement.

As well as the solar photon yield, the heat balance is also essential for the operation and design of solar photochemical reactors. Considerable amounts of energy are associated with the stream of photons. In the photochemical production of fine chemicals, the main aim is to produce complex chemical structures. The contribution of the reaction enthalpy to the heat balance can be neglected to a first approximation compared with the amount of energy absorbed for electronic excitation. The radiation absorbed by the photochemical system is completely thermalized, and must be removed from the system by cooling.

The relevant data obtained from the SOLARIS reactor is fundamentally of two different kinds. By the design of the SOLARIS reactor the light above the long wave absorption limit of the photochemical system and before the start of IR absorption (especially by the solvent) passes through the absorber tube essentially without absorption. The SOLARIS reactor is not completely thermally insulated. The experiments took place at a time of year with moderate outside temperatures, so that the convective thermal currents were mainly small.

The photooxidation of **8** is strongly exothermic, so that in this case the reaction enthalpy must be included in the heat balance. In the solar experiments, the extent of cooling required was 8 kWh kg^{-1} **1c**. If a solar reactor is insulated and the solar photon yield is optimized, the cooling can be reduced.

6. Conclusions

The sun provides a small but continuous photon radiation density. This must be concentrated to obtain high space-time yields in photochemical processes, enabling the photoreactor itself to be kept small. The choice of location, height above sea level, and geographical latitude is important. Photons with a wavelength of above 300 nm arrive at the earth's surface from the sun. For acetone-sensitized [2 + 2] photocycloaddition, which absorbs light only up to a wavelength of 330 nm, the basic feasibility has been indicated (Section 5.2.2). Improvements are both necessary and possible. On the other hand, the amount of solar radiation in the range below 330 nm is so small that artificial light sources are preferable in these cases even if the solar reactor is optimized. For photoreactions that absorb the complete solar UV radiation, as shown for the Paternò–Büchi reaction of phenyl glyoxylate **5** (Section 5.2.3., Fig. 15), improvements to the solar reactor by concentrating the light with line focusing parabolic troughs enable satisfactory space-time yields to be obtained. The attractiveness of concentrated sunlight of this wavelength range has also been demonstrated by the experiments in the solar reactor of the MPI in Mülheim (Section 5.1.). Here, the development of the more highly concentrating solar reactor concept (Section 5) is of particular interest.

Investigations of the singlet oxygen reaction in the SOLARIS reactor have demonstrated a realizable technology for the reactions which can utilize all visible sunlight. The solar photoreactors in which the sunlight is concentrated with parabolic trough collectors (described above) lend themselves to technically simple design. Unlike solar technology, which must inevitably be discontinuous because of the day/night rhythm, artificial lamps enable operation to be continuous. However, as well as the poor energy balance of artificial light exemplified by the photooxidation of furfural (**8**), there are other disadvantages. The intensity of photon flux from these lamps is limited, so that the scope for scaling up is limited compared with solar technology. Problems of cooling the lamps, the deposition of coatings on both sides of the glass window between the cooling water and the lamp, and the limited life span of lamps are avoided when the sun is used. Also, at least for singlet oxygen reactions, the proximity of the potentially explosive reaction mixture to the hot lamps means that high safety standards are required.

7. Industrial Photochemical Processes

The photochemical processes used in industry have been documented in a number of reviews,[20, 75] although it is noticeable that there has been a cessation of developments after over 20 years. These processes can be divided into free radical chain reactions (photochlorination, sulfochlorination, and sulfoxidation) with quantum yields considerably greater than 1 and photoreactions with quantum yields less than 1 (photonitrosylation, photooxidation, and photoelectrocyclic reactions). Following the decline in chlorine chemistry, a reduction in the industrial importance of photochlorination, sulfochlorination, and photonitrosylation is likely. The synthesis of vitamin D is a photoelectrocyclic reaction that is highly wavelength-selective and therefore unsuitable for the polychromatic solar spectrum. Of the photochemical processes currently in operation, the sensitized *cis/trans* isomerization included in the vitamin A acetate synthesis and the photooxidation processes are of interest. Photooxidation is at present mainly used in the synthesis of odoriferous substances (rose oxide, nerol oxide, desoxide, terpineol, myrtenol).[76] Dioxetanes (the disodium salt of spiro[adamanan-2,3′-(4-methoxy-4-(3-phosphonooxyphenyl)-1,2-dioxetane)] = AMPPD) are of increasing importance for chemiluminescence assays[77] in clinical chemical diagnostics, although the amounts required can be produced in laboratory irradiation apparatus.

To conclude, Figure 21 gives the available data for the singlet oxygen reaction in industrial processes together with the data from the experiments in the SOLARIS reactor.

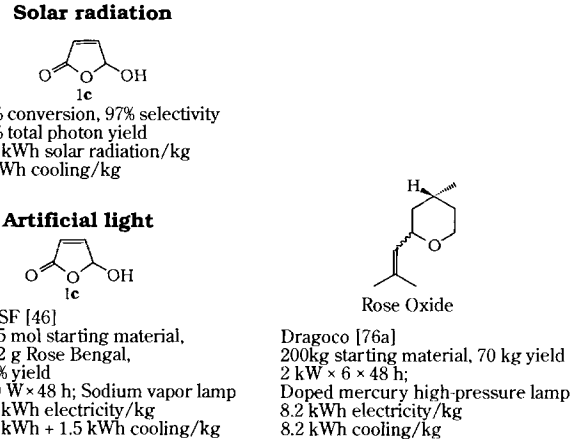

Fig. 21. Comparison of data for industrial and solar singlet oxygen reactions. The data for the production of rose oxide are applicable and are therefore listed. Cooling is performed either with a process cooler or by cooling water.

8. Future Outlook

The fundamental processes and techniques used to enable solar photochemical fine chemical synthesis to make a contribution to a "chemical technology of the future" have been described. In view of the generally low level of industrial interest in preparative photochemistry, there is still a long way to go. It is especially necessary to open up and adapt the photochemical synthesis potential for solar application in particular cases.

However, there is at the same time the option of going along this route in an economically and ecologically appropriate manner, closely matched to solar reaction conditions and local circumstances (see Fig. 1). For this, both "know-how" and especially "know-where" are required.

"Photochemical syntheses utilizing sunlight are not in general, and especially on an industrial scale, suitable for use in Europe or in the northern part of America, where sunlight is unreliable and often unavailable....." [9c]

An encouraging success for solar thermal chemistry was the very recent production of fullerene.[78] The high proportion of UV light in the electric arc processes used hitherto leads to partial decomposition of the fullerene.[78a] Highly concentrated solar radiation, up to 20000 suns and above,[78d] enables high temperatures to be achieved with a considerably lower proportion of UV, leading to a significant increase in the yield of fullerene and hopefully to an industrially attractive process.

A very important technical difference between thermal and photon solar chemistry is the degree of concentration of the solar radiation. In the first case, the extremely high concentration is the most significant advantage, but for photochemistry, which involves radiation concentration which is two orders of magnitude less, high space-time yields are obtained, and the limits of thermal control of the reaction system are reached. Here, photochemistry shows parallels to the photosynthesis model in which light energy is transferred from the chlorophyll-antenna complexes to the reaction center chlorophyll, thus using ultimately comparable degrees of energy concentration.

The SOLARIS reactor used here, together with the entire plant, was dismantled on November 18, 1992, by the DLR Köln on the PSA (Almeria) immediately after the final experiment. It is to be re-erected in Köln Porz.

Our thanks are due to Dipl.-Chem. P. Esser and Dipl.-Chem. I. Wöhrle for their support in the solar experiments, and also to Mr. Esser for contributions to the elucidation of the kinetics of the photooxygenation of furfural in the course of his work for his Diploma. We also thank Mrs. D. Gilliam for carrying out many experiments in preparation for the solar experiments, as well as Dr. N. Hoffmann (now at CNRS, VRA 459, Reims), Dr. H. Buschmann (now with Grünenthal GmbH, Aachen), and Dr. P. Jütten (now at the Hans Knöll Institut, Jena) for many discussions, and Dipl.-Ing. G. Schneider (now with EVT Stuttgart), Dr. M. Becker, and Dr. K. H. Funken, MD-ET DLR Köln for technical construction, and especially Mr. Schneider for the construction of the SOLARIS reactor. The SOLARIS experiment was cordially received by the PSA, Almeria, and was widely supported. We also thank the following, and the many other people whom they represent: W. Grasse and M. Sánchez (Directors of the PSA), J. A. Rodriguez and J. Hansen (Chief Engineers), and J. Blanco and S. Malato (detoxification loop—responsible engineer and chemist). Prof. Dr. H. Leismann (EHICS, Strasbourg) is thanked for determining the reflectivity of the aluminum foil and quantum yields. The construction of the SOLARIS loop and the first experimental phase (17 October 1991–15 February 1992) was financed by the DLR Köln through the Bundesministerium für Forschung und Technologie within the framework of the SOTA (SOLAR test center, Almeria) program. We also thank Dr. R. Hopp, Dr. W. Kuhn, and Dr. R. Pelzer (Haarmann & Reimer) for their support by supplying equipment and chemicals in the second experimental phase. Prof. Dr. G. O. Schenck is thanked for preparing Figure 2, and Prof. Dr. M. Demuth for information for Section 5.1. and for producing Figure 7. We are also obliged to the Fonds der Chemischen Industrie, to the Land Nordrhein-Westfalen (AG Solar NRW), as well as to Prof. Dr. K.-H. Büchel and Dr. W. Draber (Bayer AG). We also thank Mrs. I. Voss for her help in the preparation of the manuscript.

[23] The degree of concentration is defined as the increase in the energy flow density (here the direct radiation of the sun) passing through an aperture of given area (see ref. [2a]). For parabolic trough collectors, a good representation of the light concentration is given by the ratio of the width of the parabolic mirror to the inside diameter of the absorber tube multiplied by the photoreactor efficiency.

[30] The reflective material was aluminum foil formed by vapor deposition on Hostaflon, the back surface of which was sealed to polyester film and fixed by adhesive to a carrier structure. The reflectivity of the the foil at a half aperture angle of 43.6 mrad and a wavelength of 600 nm was 79%. The half aperture angle is given by the geometry of the mirror and absorber tube. Scattered light within this half aperture angle still impinges on the inside diameter of the absorber tube and hence on the reaction solution.

Thermal and Optical Switching of Iron(II) Complexes

Philipp Gütlich,* Andreas Hauser, and Hartmut Spiering

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

Transition metal chemistry contains a class of complex compounds for which the spin state of the central atom changes from high spin to low spin when the temperature is lowered. This is accompanied by changes of the magnetic and optical properties that make the thermally induced spin transition (also called spin crossover) easy to follow. The phenomenon is found in the solid state as well as in solution. Amongst this class, iron(II) spin crossover compounds are distinguished for their great variety of spin transition behavior; it can be anything from gradual to abrupt, stepwise, or with hysteresis effects. Many examples have been thoroughly studied by Mössbauer and optical spectroscopy, measurements of the magnetic susceptibilities and the heat capacities, as well as crystal structure analysis. Cooperative interactions between the complex molecules can be satisfactorily explained from changes in the elastic properties during the spin transition, that is, from changes in molecular structure and volume. Our investigations of iron(II) spin crossover compounds have shown that green light will switch the low spin state to the high spin state, which then can have a virtually unlimited lifetime at low temperatures (this phenomenom is termed light-induced excited spin state trapping—acronym: LIESST). Red light will switch the metastable high spin state back to the low spin state. We have elucidated the mechanism of the LIESST effect and studied the deactivation kinetics in detail. It is now well understood within the theoretical context of radiationless transitions. Applications of the LIESST effect in optical information technology can be envisaged.

1. Introduction

Thermally induced spin crossovers, that is, changes of the spin multiplicity within one and the same transition metal complex, are among the most fascinating "games" electrons play in the coordination chemistry of 3d elements with electron configuarations d^4 to d^7 (and d^8 when molecular symmetry is lower than O_h). This spin crossover phenomenon (less commonly called magnetic crossover, spin equilibrium, or spin isomerism) was discovered more than sixty years ago by Cambi et al. For iron(III) tris(dithiocarbamate)s,[1–4] they observed electronic states[5, 6] with occupations strongly dependent on temperature. It took more than thirty years for the first iron(II) complex with a temperature-dependent $^5T_{2g}(O_h) \rightleftharpoons {}^1A_{1g}(O_h)$ spin transition, $[Fe(phen)_2(NCS)_2]$ (phen = 1,10-phenanthroline), to be discovered.[7] This marked the start of very active research on the spin crossover phenomenon found in the solid state as well as in solution. Even at this early stage of spin crossover research it was apparent that the phenomenon is found very often in complexes of iron(II), iron(III), and cobalt(II), but also occasionally in those of nickel(II), cobalt(III), and manganese(III). The first thermal spin crossover in chromium(II) compounds was reported in 1989.[8] The unusual temperature dependence of the magnetic properties observed in cluster compounds such as Nb_6I_{11} and HNb_6I_{11} is also caused—so one assumes—by the spin crossover phenomenon.

The field has been covered in a series of review articles emphasizing different aspects. The first comprehensive articles[10–12] treated all spin crossover compounds known at the time and even then emphasized the distinct influence of the chemical environment, such as the particular ligand sphere. Towards the end of the sixties, a preference for investigations of the thermal high spin (HS) to low spin (LS) transition [(HS$\rightleftharpoons$LS] in octahedral iron(II) complexes developed,[13–23] probably because ^{57}Fe Mössbauer spectroscopy was such an extraordinary tool for following the spin transition as a function of temperature, pressure, time, concentration, and other variables of the system. Because the relaxation times of the Fe^{2+} (HS) and Fe^{2+} (LS) spin states are much longer (at least below 300 K) than the time resolution of the Mössbauer method (10^{-7} s), their resonance lines usually appear sharp and well resolved with characteristic Mössbauer parameters.[24] On the contrary, for the HS ($^6A_{1g}$) $\rightleftharpoons$ LS ($^2T_{2g}$) spin transition in iron(III) complexes, fluc-

tuation rates are greater by several orders of magnitude . Thus, the relaxation times of the HS and LS states often approach the size of the Mössbauer time window, and consequently, we find strong broadening of the resonance lines, or even time-averaged spectra. This greatly complicates data evaluation and makes the pure HS and LS states hard to distinguish.

Apart from Mössbauer spectroscopy, at least half a dozen other methods are applied in spin crossover investigations. The magnetic susceptibilities ($\chi(T) = \gamma_{HS}\chi_{HS} + (1-\gamma_{HS})\chi_{LS}$) of solid spin crossover compounds (measured with a Faraday balance, a Foner type magnetometer, or a SQUID magnetometer), and of liquids (measured with Evans's NMR method) is a function of the temperature-dependent fractions of HS (γ_{HS}) and LS ($\gamma_{LS} = 1-\gamma_{HS}$) molecules. If χ_{HS} and χ_{LS} are known, $\gamma_{HS}(T)$ can be determined from these values and used as an ordering parameter for the spin transition as a function of temperature. The spin transition curve $\gamma_{HS}(T)$ obtained this way (and also from the integrals of the HS and LS absorption bands from optical spectra and, for solid spin crossover compounds, from those of the HS and LS Mössbauer resonance lines as well) can adopt very different forms. Cooperative interactions between the complex molecules have a crucial influence on the different spin transition functions $\gamma_{HS}(T)$ in the solid, whereas interactions between spin-changing molecules are virtually insignificant in the liquid phase. Therefore, the simple Boltzmann law always describes $\gamma_{HS}(T)$ in liquids. In the liquid phase, for instance in d^6 spin crossover compounds, the distribution over the different spin states contains the simple degeneracy of the $^1A_{1g}$ state as well as the 15-fold degeneracy of the $^5T_{2g}$ state. For solids, such a Boltzmann behavior of $\gamma_{HS}(T)$ is rather the exception.

Another valuable source of information are the temperature-dependent IR spectra. There is a clear increase in the central ion–ligand stretching frequency in the FIR range from approximately 250 cm^{-1} for the iron(II) HS state to approximately 400 cm^{-1} for the iron(II) LS state.[25, 26] The N–C stretching modes around 2000 cm^{-1} are a sensitive probe for many iron(II) spin crossover systems with NCS or NCSe ligands coordinating through nitrogen atoms, because going from the HS to the LS state shifts the band by about 40 cm^{-1} towards higher frequencies (see the review in ref. [18]). The IR spectroscopic data indicate a distinct increase in the metal–ligand bond strength on one hand, and of the N–C bond in the NCS or NCSe ligands on the other, upon transition from the HS to the LS state. The explanation becomes clear from the electronic rearrangement associated with the spin transition in an octahedral ligand field: $t_{2g}^4 e_g^2 (^5T_{2g}) \rightleftharpoons t_{2g}^6 (^1A_{1g})$. Looking at the MO scheme for octahedral complexes,[6, 27] we see that the e_g orbitals occupied in the HS state are antibonding in character. The increase in bond strength upon transition to the LS state is then jointly effected by their depopulation and the concomitant population of the t_{2g}

P. Gütlich

A. Hauser

H. Spiering

Philipp Gütlich studied Chemistry at the Technische Hochschule Darmstadt. After obtaining his doctorate (in Physical Chemistry/Nuclear Chemistry with K. H. Lieser) in 1963, he worked at the Nuclear Research Center Saclay/Paris and subsequently at Brookhaven National Laboratory/USA, where his research led him into the field of Mössbauer spectroscopy for the first time. After his return in 1966 he further diversified his experience into the field of theoretical chemistry at Uppsala and Oxford. In 1969 he completed his habilitation at the TH Darmstadt with a thesis on the application of Mössbauer spectroscopy in chemistry. He accepted the chair of Anorganische und Analytische Chemie at the University of Mainz in 1975. His main research interests are spectroscopy on transition metal compounds (problems of electronic structure, magnetism, phase change, and photochemistry) and application of Mössbauer and electronic spectroscopy (Auger, ESCA) to problems in technology. P. Gütlich received the Research Award of the Japanese Society for the Promotion of Science (JSPS) in 1989 and in 1993 together with O. Kahn (Paris) the Forschungspreis der Max-Planck-Gesellschaft.

Andreas Hauser, born in 1955 in Bern, Switzerland studied Chemistry at the University of Bern and obtained his doctorate under the supervision of H. U. Güdel in 1983. From 1984 to 1987 he worked as postdoctorate fellow at the Research School of the Australian National University in Canberra with J. Ferguson and thereafter as Wissenschaftlicher Mitarbeiter at the University of Mainz with P. Gütlich. There he completed his habilitation with a thesis on the photophysical properties of Fe^{II} coordination compounds. Since 1992 he has been Oberassistent at the Institut für Anorganische und Physikalische Chemie der Universität Bern. His research interests are photochemical and photophysical properties of transition metal compounds.

Hartmut Spiering, born in 1943 in Bad Wildungen, Germany, received his Doctorate in Physics at the University of Münster in 1978 under the supervision of H. Wegener and his habilitation at the University of Erlangen-Nürnberg for contributions to the methodology and application of Mössbauer spectroscopy. Since 1978 he has been Wissenschaftlicher Mitarbeiter at the University of Mainz in the research group of P. Gütlich.

orbitals. This in turn increases the $d_\pi - p_\pi$ backbonding towards the ligand. In complexes containing NCS and similar ligands together with arene ligands, backbonding to the aromatic ligand is dominant. This is accompanied by a partial depopulation of the antibonding π^*(N–C) orbitals to compensate the charge deficit at the central ion caused by the backbonding. As a consequence, the frequency of the N–C stretching mode increases.

Of course we have to expect that such striking changes in the metal–ligand bond strength will cause bond shortening. Indeed, temperature-dependent single crystal X-ray structure analyses of many iron(II) spin crossover compounds show that the Fe–N bond lengths shorten by about 20 pm when going from the HS to the LS state,[28] which corresponds to approximately 10% of the bond length or up to 5% of the unit cell volume. This must have its effect on the phonon system and the elastic properties of the lattice. This provides the driving force for the cooperative interactions which decisively influence the spin transition mechanism in the solid (see Section 3.4.1). Crystal structure analyses above and below the critical spin transition temperature $T_{1/2}(\gamma_{HS} = 0.5)$ also detect whether a change in the crystal structure (that is, in the space group) is associated with the spin transition, as well as the ever present changes in the bond lengths. Experience shows that gradual (continuous) spin transitions normally proceed without structural changes. Abrupt (discontinuous) spin transitions, however, are often associated with structural changes, which are frequently also accompanied by hysteresis effects of the $\gamma_{HS}(T)$ curve between falling and rising temperatures. Though the reverse reasoning is quite common in solid state research (namely that hysteresis effects during a phase change are indicative of an associated structural change), recent evidence proves it to be invalid (at least for spin transitions in the solid).[29–31] For those cases where a spin transition is associated with a structural change, the question about the original cause and the ensuing effect arises. From what we know today, both possibilities can be realized. A change of spins in the electronic ground state can be caused by a thermally induced lattice distortion, but a thermally induced spin transition can also deform the lattice. The possibility of observing lattice and molecular changes of the structure directly at the spin transition makes the various diffraction methods with X-rays, neutrons, and more recently also synchrotron radiation (including EXAFS[32, 33]) so eminently valuable for spin crossover research on solids, be they in the form of single crystals or powders (see refs. [28, 34–36]).

Amongst the plethora of physical methods for the investigation of spin crossover phenomena, calorimetric measurements are also well established. They show the spin transition and enable determination of the transition enthalpy and entropy, which, for the example of iron(II) spin crossover compounds, are $\Delta H = H_{HS} - H_{LS} \approx 6-15\ kJ\,mol^{-1}$ and $\Delta S = S_{HS} - S_{LS} \approx 40-65\ J\,K^{-1}\,mol^{-1}$ at spin transition temperatures around 130 K.[28] From C_p measurements on $[Fe(phen)_2(NCS)_2]$ and $[Fe(phen)_2(NCSe)_2]$, Sorai and Seki[37] concluded twenty years ago that the driving force behind the spin transition is the considerable entropy increase on going from the LS to the HS state. This is true for all spin crossover complexes, irrespective of the central ion. According to Sorai and Seki, the electronic (magnetic) contribution to the total measured gain in entropy of $\Delta S \approx 50\ J\,K^{-1}\,mol^{-1}$ is about 30%: $\Delta S_{mag} = R[\ln(2S+1)_{HS} - \ln(2S+1)_{LS}] = 13.4\ J\,K^{-1}\,mol^{-1}$. For complexes with a symmetry lower than O_h (such as C_{2v} in the case under discussion), the orbital contribution is insignificant. The major part of the remaining 70% of the entropy change stems roughly equally from contributions from intramolecular stretching modes and intramolecular deformation modes; only a comparatively small fraction is supposed to be attributable to changes in intermolecular vibrational modes. The authors conclude from the dominant share of the total entropy gain from the vibrational changes that long-range interactions from coupling between the electronic states and the phonon system must play an important role in the cooperative spin transition in the solid.

Over many years a good number of research groups[38–54] have worked on how the spin transition in the solid proceeds in detail, in particular on understanding the mechanism of the cooperative interactions and developing a theoretical model. Such a model should be formulated generally enough to include and account for all the experimental observations. In Section 3.4.1 the model of elastic interactions[40–44] developed in our group will be treated in depth.

Kinetic investigations of liquids and solids are especially enlightening. Relaxation rates have been measured for spin crossover systems which were perturbed from equilibrium by temperature jump, ultrasound, or irradiation with light, and for systems decaying from long-lived metastable states after thermal or optical excitation (see review articles in refs. [28] and [55]). ^{57}Fe Mössbauer spectroscopy adds to this variety of methods. Relaxation rates k around $10^7\ s^{-1}$ and related activation parameters can be determined from line shape analyses of relaxation-broadened Mössbauer absorption lines.[56–59] A special variant of Mössbauer spectroscopy is time-differential coincidence spectroscopy.[60] Here, the ^{57}Co(EC)^{57}Fe nuclear decay (EC = electron capture) in ^{57}Co-doped complexes is used as an "intrinsic clock" for a time scale from approximately 5–500 ns on one hand, and as an "intrinsic light source" for the creation of excited electron states on the other. These states then relax back to the ground state by intersystem crossing (ISC) processes along that very time scale.[61–63]

Contributions towards a better understanding of spin crossover processes have come from kinetic measurements supplying detailed data on lifetimes and activation parameters, from equilibrium measurements supplying thermodynamic data, and from spectroscopic investigations and quantum chemical calculations supplying molecular orbital and ligand field diagrams. Our own efforts serendipitously led us to the discovery of the LIESST effect in iron(II) spin crossover compounds in 1984.[64–66] Buhks et al.[67] have published a theoretical paper that led the way to understanding spin crossover dynamics. It was later applied to the interpretation of the HS → LS relaxation after light excitation (LIESST) in the solid by Hauser[68] (see Section 5.2).

Now that the essential aspects of spin crossover research have been sketched, we shall present the most important results and insights from our own spin crossover and LIESST research on solid iron(II) complexes. As our particular goal has for years been to apply a multitude of physical methods to a few suitable examples in order to gain an in-depth view and to learn as much as possible about the whys and wherefores of spin crossover and

LIESST, the emphasis will be on picolylamine and tetrazole complexes. We shall start the second section with some considerations on ligand field theory to clarify the conditions for thermally induced spin crossover. A discussion of the chemical and physical influences on spin crossover behavior in the solid follows. The section ends with a description of the structural changes associated with the spin transition. Model views based on elastic interactions developed from there will be the subject of Section 3, together with the thermodynamics of the spin transition. Sections 4 and 5 are dedicated to the LIESST effect and to kinetic investigations of the processes associated with it. The article ends with some concluding remarks on possible applications of spin crossover and the LIESST effect.

2. Thermal Spin Transitions in Iron(II) Complexes

2.1. Ligand Field Considerations—Theory

Iron(II) is a transition metal ion with six d electrons. In a complex where iron(II) is coordinated by six ligands, that is, in an octahedral ligand field (LF), the ^{2S+1}L terms of the free ion will be split according to the Tanabe–Sugano diagram,[69] as shown in Figure 1. The parameter along the x axis is the LF

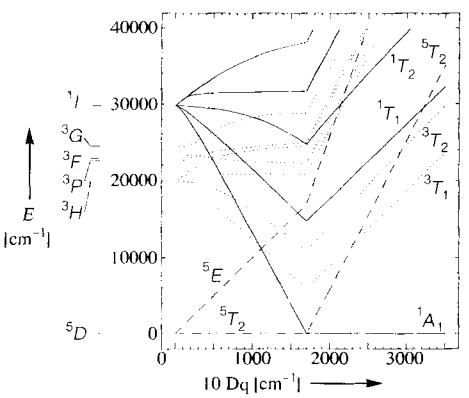

Fig. 1. Tanabe–Sugano diagram for an octahedral d^6 complex, calculated with the Racah parameters [6] of the free iron(II) ion according to Tanabe and Sugano [69].

strength expressed as 10 Dq, a measure for the influence of the ligands on the d electrons of the central ion.

Iron(II) complexes with ligands that exert only a weak influence on the d electrons of the central iron (for example, the paramagnetic $[Fe(H_2O)_6]^{2+}$ complex) have a HS $^5T_{2g}$ state as the ground state, stemming from the ^5D ground state of the free ion. With increasing ligand field strength, however, the LS $^1A_1$ state, based on the ^1I term of the free ion, is quickly lowered in energy; consequently, from a critical LF strength Δ_{crit} onward, it becomes the ground state of the complex. This is, for example, the case for the diamagnetic $[Fe(CN)_6]^{4-}$ complex.

For a proper appreciation of the importance of the crossover point at Δ_{crit} and the phenomenon of thermal spin transition, it is not sufficient to discuss the Tanabe–Sugano diagram alone, since it gives only the energies of the electronic excited states with respect to the energies of the corresponding ground state. The ligand field strength is not only determined by the properties of the ligand; it is also a strong function of the metal–ligand distance. For neutral ligands[6] Equation (1) holds in which μ

$$10\,Dq \approx \mu / r^6 \tag{1}$$

is the dipole moment of the ligand and r the metal–ligand distance. For a given ligand, 10 Dq(r) can be determined experimentally at the equilibrium distance r_0 of the corresponding ground state, that is, for the metal–ligand bond length. 10 Dq(r) can then be estimated for any r from the simple relation in Equation (2).

$$10\,Dq(r) = 10\,Dq(r_o)\left(\frac{r_o}{r}\right)^6 \tag{2}$$

For each ground state, LS or HS, we can apply a potential with the metal–ligand distance r (or the totally symmetric normal coordinate $Q = Q_{a_1}$) as the configuration coordinate. Now the electronic energies of the excited states can be calculated as a function of r, with 10 Dq(r) from Equation (2) and the Tanabe–Sugano diagram. One has to keep in mind that, contrary to 10 Dq, electron–electron interactions (that is, the Racah parameters B and C) depend only weakly on r. A natural consequence of this calculation is that for the other ligand field states the potential wells are shifted vertically as well as horizontally with respect to the reference state.

In the first place we are now interested in the $^5T_2$ potential well, which is always shifted towards a greater metal–ligand distance than that of the $^1A_1$ state, irrespective of the ligand (Fig. 2). This is understandable, since the $^5T_2$ state is based on

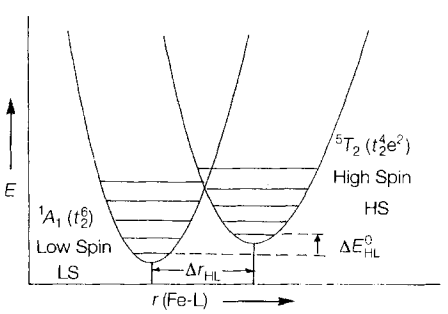

Fig. 2. Schematic representation of the potential wells for the $^1A_1$ and the $^5T_2$ states of an iron(II) spin crossover complex. The condition for a thermal spin transition is $\Delta E^0_{HL} \approx k_B T$. The nuclear coordinate is r(Fe–L).

the $(t_2^4e^2)$ configuration with two of the six d electrons in antibonding e orbitals, whereas the $^1A_1$ state of the (t_2^6) configuration has all six d electrons in the mainly nonbonding t_2 orbitals.

The relative vertical shift of the two potential wells, on the other hand, depends very much on the specific properties of the ligands. For complexes with suitable ligands, the difference in the zero point energies for the two states, $\Delta E^0_{HL} = E^0_{HS} - E^0_{LS}$, can fall within the range of thermal energies. In that case, only the $^1A_1$ state as the ground state is occupied at low temperatures. At higher temperatures, however, thermal occupation of the $^5T_2$ state occurs. Because the $^5T_2$ state is 15-fold degenerate and has a higher vibrational density of states, this entropy-driven thermal spin transition is almost quantitative.

What exactly does the energy term crossover point Δ_{crit} in the Tanabe–Sugano diagram signify? We can now safely identify it with the intercept of the two potentials in the configuration-coordinate diagram (Fig. 2). This point, however, can never correspond to an equilibrium configuration of the ground state, which means that iron(II) complexes at an equilibrium distance and LF strengths around Δ_{crit} are nonexistent in the ground state. Consequently, we always have $10\,Dq^{HS} < \Delta_{crit} < 10\,Dq^{LS}$ for spin crossover compounds, because there is the dependence of 10 Dq on r and the large difference $\Delta r_{HL} = r_{HS} - r_{LS}$ between the equilibrium distances.

Iron(II) spin crossover compounds mainly have sixfold nitrogen coordination. Typical values for r_{LS} range between about 1.96 and 2.00 Å; those for r_{HS} lie between about 2.16 and 2.20 Å and are typically longer by approximately 0.16–0.22 Å.[29, 70–72] From Equation (2) we derive Equation (3).

$$\frac{10\,Dq^{LS}}{10\,Dq^{HS}} = \left(\frac{r_{HS}}{r_{LS}}\right)^6 \approx 1.74 \qquad (3)$$

From the condition that ΔE_{HL} for a spin crossover complex must be of the order of thermal energies, we can define ranges for $10\,Dq^{LS}$ and $10\,Dq^{HS}$ where HS, LS, and spin crossover complexes can be expected. The range where we can expect spin

$10Dq^{HS} < 11\,000\ cm^{-1}$	HS complex
$10Dq^{HS} \approx 11\,500-12\,500\ cm^{-1}$ $10Dq^{LS} \approx 19\,00-21\,000\ cm^{-1}$	Spin crossover complex
$10Dq^{LS}$	$> 21\,500\ cm^{-1}$ LS complex

Scheme 1.

crossover complexes is very narrow. Minor changes in the ligands and also in the second coordination shell can shift the thermal spin transition to very different temperatures or even suppress it entirely.

In the foregoing considerations we have up to now (deliberately) not mentioned the "spin pairing energy" P, widely used in the literature, and its comparison with 10 Dq. The common argument that the difference between the average spin pairing energy P and 10 Dq must be of the same order as thermal energies for spin crossover complexes is too simple a notion to be correct, because the change in bond lengths during the spin transition is not taken into account. It is true that both quantities depend on r, but whereas the LF strength decreases from $10\,Dq^{LS}$ to $10\,Dq^{HS}$ by a factor of approximately 1.74 for the thermal spin transition, the average spin pairing energy changes only by about the same order as the nephelauxetic effect.[6]

2.2. Spin Transition Behavior in the Solid

While thermal spin transitions in liquids are always gradual (that is, the spin transition function $\gamma_{HS}(T)$ obeys a simple Boltzmann law), and spin transition curves of that type do exist in solids as well, the $\gamma_{HS}(T)$ curves generally look very different because of long-range cooperative interactions (Fig. 3). Accord-

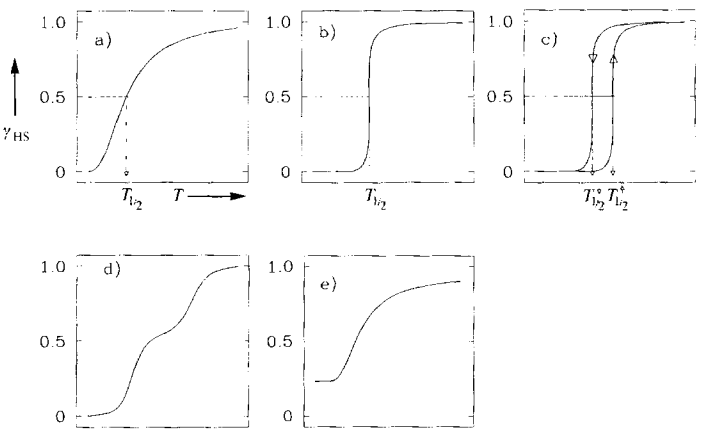

Fig. 3. Schematic representation of the spin transition types a–e (see text). $\gamma_{HS}(T)$ represents the fraction of complex molecules in the high spin state ($\gamma_{HS}(T_{1/2}) = 0.5$). In each case the temperature axis is plotted on the x axis and γ_{HS} on the y axis.

ing to the $\gamma_{HS}(T)$ curve shapes, spin transitions in solids can be classified as follows:

a) Spin transitions covering a wide temperature range (up to several hundred degrees Kelvin), called "gradual" (Fig. 3a).
b) Spin transitions changing from one "phase" to another within only a few ($\leq$10 K) Kelvin, called "steep" or "abrupt" (Fig. 3b).
c) Spin transitions showing hysteresis effects (Fig. 3c).
d) Spin transitions with two discernible steps (gradual or steep), and a step or a plateau along the $\gamma_{HS}(T)$ curve (Fig. 3d).

A distinction is quite often made between continuous and discontinuous spin transitions. From our point of view, types a), b), and d) would be continuous, and only type c) would have to be called discontinuous. In many cases, more so for continuous than for discontinuous transitions, an HS residual is observed at low temperatures ($\geq$4 K); that is, the $\gamma_{HS}(T)$ function does not approach zero, but rather a plateau (Fig. 3e). Dislocations and defects in the lattice are held responsible for this behavior (see Section 2.4.3).

Normally, continuous spin transitions in the solid are not accompanied by crystallographic changes, which means that the HS lattice above $T_{1/2}$ ($\gamma_{HS} = 0.5$) and the LS lattice below $T_{1/2}$ have the same space group.[34] Discontinuous spin transitions mostly entail crystallographic changes; refs. [21] and [34] contain many examples. Yet there are exceptions. Wiehl et al.[29] have, by variable-temperature single-crystal X-ray analyses, for the first time ascertained that a spin transition with hysteresis effects but without a change in the space group occurs in $[Fe(2\text{-pic})_3]Br_2 \cdot EtOH$ (2-pic = 2-(aminomethyl)pyridine). Gallois et al.[31] have described another example. These authors found the same space group for $[Fe(phen)_2(NCS)_2]$ (phen = 1,10-phenanthroline) above and below $T_{1/2} \approx 175$ K, even though the spin transition does exhibit hysteresis effects.[73]

For many years in spin crossover research there was a common notion that spin transitions in a solid were determined by the interplay of temperature-dependent lattice effects. Lattices contract with decreasing temperature. Metal–ligand distances thus shorten, which was associated with an increasing ligand field potential.[6] For cases where hysteresis effects in the $\gamma_{HS}(T)$

curve were observed, one expected an accompanying structural change of the lattice. Along these lines, the observation of spin transitions with hysteresis effects in the $\gamma_{HS}(T)$ curve, but without a change in the crystal structure as just described for two examples, was a great surprise. It demonstrated that spin transitions can have lives of their own. Today we know that the regular thermal lattice contraction with falling temperature does not play a decisive part in the spin transition phenomenon.

In light of Everett's theorems,[74–76] hysteresis effects during discontinuous spin transitions in some spin crossover systems have been thoroughly investigated.[21, 34, 77, 78] Everett assumes that domain formation among complex molecules with predominantly like spin plays an important role in the mechanism of discontinuous phase transitions. He has suggested that experimental verification of independent whole-domain conversion during a phase transition should be possible by scanning inner loops inside the primary hysteresis loop. The condition for this, according to his fourth theorem, is that the inner loops have the same form and area, no matter where the starting temperature on the boundary loop is chosen. For $[Fe(bt)_2(NCS)_2]$ (bt = 2,2′-bi-2-dihydrothiazole), whole-domain conversion could be confirmed.[78] The study has also established that for mechanically crushed (milled) material, the shapes and the areas of the inner loops are no longer the same. The conclusion is that long-range order in the unperturbed crystal is significantly damaged by the grinding procedure, and that the domain size is drastically reduced. The Everett model does not allow estimation of the actual size of the domains.

A spin transition in two steps, that is, with a plateau or a discontinuity near $T_{1/2}(\gamma_{HS} = 0.5)$, is a phenomenon first discovered in 1982 during investigations on $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$.[79] Figure 4 shows $\gamma_{HS}(T)$ for this system. The transition is of the

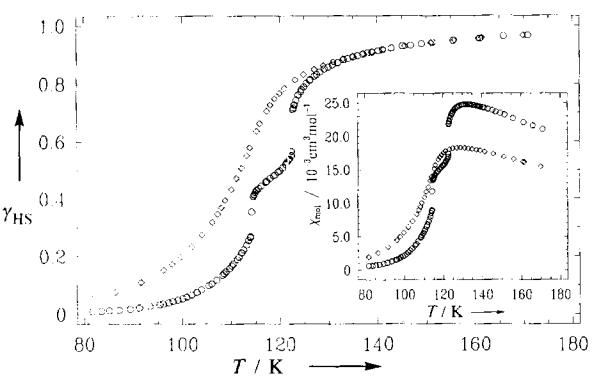

Fig. 4. Temperature dependence of the HS fraction $\gamma_{HS}(T)$ in $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (○) and $[Fe_{0.73}Zn_{0.27}(2\text{-pic})_3]Cl_2 \cdot EtOH$ (◇) (from refs. [80, 81]).

continuous type; there is no change in the crystal structure with the spin transition. The Mössbauer spectra, however, show abrupt changes of the quadrupole splitting with temperature around the discontinuity, both for the HS and the LS state. This indicates that the discontinuity has to be regarded as somehow related to lattice changes, especially to changes in the close vicinity of the complexed central iron(II) ion. Incidently, the discontinuity is sensitive to chemical and physical changes (see also Sections 2.3 and 2.4). Our search for a sound explanation for this stepwise spin transition has only lately been rewarded with further insights.[80, 81] We have performed microcalorimetric measurements on a single crystal (approximately 20 mg) of $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$. Earlier, Kaji and Sorai[83] had already measured the temperature dependence of the heat capacitiy of this compound with an adiabatic calorimeter (sample weight approximately 15 g); the discontinuous spin transition there was mirrored by two sharp peaks at 114 and 122 K (Fig. 5). Using a newly constructed microcalorimeter,[84] we have succeeded in reproducing the $C_p(T)$ curve of this compound with a single crystal of only about a thousandth of the weight (20 mg), with similar accuracy (Fig. 5). Included in Figure 5 are measure-

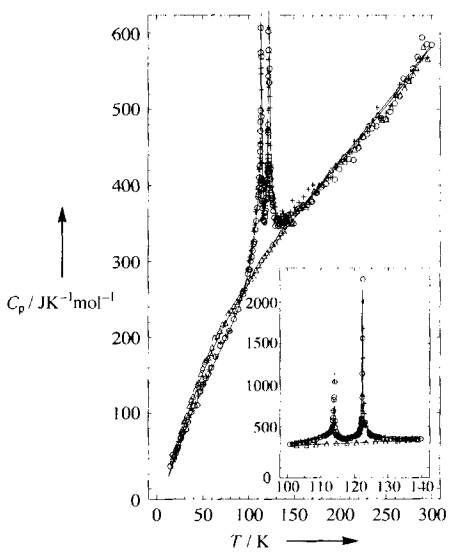

Fig. 5. Molar heat capacity C_p of $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (○ and +) and $[Zn(2\text{-pic})_3]Cl_2 \cdot EtOH$ (△), measured on single crystals weighing approximately 20 mg in a newly constructed microcalorimeter [80]. The solid curve represents the measurements of Kaji and Sorai [83] performed with 15 g of polycrystalline material in a Nernst type calorimeter. The inset shows the enlarged area around the spin transition.

ments for the corresponding zinc complex, where a spin transition is not possible for the Zn^{2+} (d^{10}) ion, and no peak appears in the $C_p(T)$ curve. However, the lattice properties are very similar to those of the iron(II) HS complex, as the data show. For the iron complex, the mixing entropy, calculated from the $C_p(T)$ values near the discontinuity, is significantly lower than mixing entropy values calculated on the assumption of a statistical distribution between HS and LS molecules.[80, 81] An obvious explanation is that certain ordering phenomena must take place among the HS and LS molecules. The fact that cooperative interactions again play a special role in this spin crossover system is expressed in the disappearance[85] of the discontinuity in $\gamma_{HS}(T)$ on going from the pure $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ to the Fe_xZn_{1-x} mixed crystal (see Fig. 4). The measured $C_p(T)$ curve for this metal-diluted complex exhibits but one peak.[81]

Kambara[52] was the first to succeed in simulating a stepwise spin transition. Assumption of a sublattice structure for the HS and LS complexes leads to steplike behavior in $\gamma_{HS}(T)$. The sublattices originate from a quasi antiferromagnetic interaction between the complexes, where HS–LS pairs are preferred on the equipoints of a layered structure. Real et al.[53] also

explain the steplike transition they observed in the binuclear $[Fe(bt)(NCS)_2]_2bpym$ (bpym = 2,2'-bipyrimidine) complex by assuming an energetically favored mixed HS–LS or LS–HS state (that is, by antiferromagnetic interaction). These findings point to short-range quasi antiferromagnetic interactions as the source of steplike spin transitions.

2.3. Chemical Influences on the Spin Transition in a Solid

2.3.1. The Influence of Ligand Exchange and Substitution at a Coordinated Ligand in Iron(II)–Phenanthroline Complexes

The spin transition function $\gamma_{HS}(T)$ can be subjected to manifold chemical alterations of the spin crossover system. As representatives of the numerous iron(II) complexes, let us pick out the phenanthroline complexes. We shall see how, for example, the total exchange of a phen ligand for two NCS or NCSe groups on one hand, and substitution at the phen ligand on the other, influences the magnetic properties of the iron(II) central ion (see ref. [18] for a more comprehensive review of the field).

The LS character of the $[Fe(phen)_3]X_2$ complex (irrespective of the anion X^-) with a $^1A_1$ ground state down to very low temperatures ($\geq$4K) is well-known. If we now replace one of the three bidentate phen ligands by two *cis* NCS groups coordinating through N, the LF will be markedly weakened. The resulting $[Fe(phen)_2(NCS)_2]$ complex behaves purely HS at room temperature. The $\Delta E^0_{HL} \approx k_B T$ condition (see Fig. 2) for thermal spin crossover is met. Cooling to about 185 K produces a discontinuous spin transition into the LS($^1A_1$) state. The ^{57}Fe Mössbauer spectra in Figure 6 are an eye-catching demonstration of the abrupt crossover from the HS into the LS state within a narrow temperature interval of only some degrees Kelvin around 180 K. The transition has an associated hysteresis of $\Delta T = 0.2$ K,[73] but no associated change in the crystal structure.[31] The ligand exchange effect in the related bipyridyl complexes of iron(II) is very similar.[86]

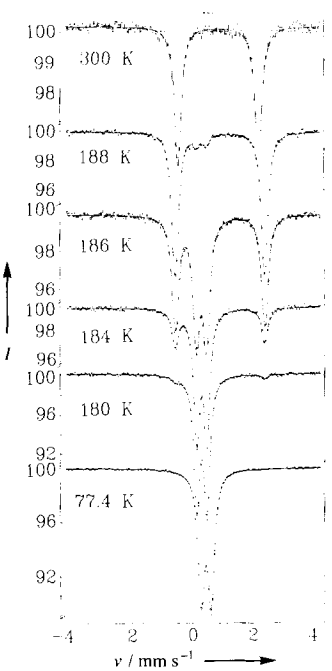

Fig. 6. ^{57}Fe Mössbauer spectra of $[Fe(phen)_2(NCS)_2]$ as a function of temperature (from ref. [18]). The ordinate in each case is the relative transmission I and the abscissa the relative velocity v between source and absorber.

A more subtle way to influence the LF strength at the central ion than changing the ligand entirely is substitution at the coordinated ligand. We shall illustrate this for the group of $[Fe(2\text{-}Y\text{-}phen)_3]X_2$ complexes.[18] On exchange of H for CH_3 groups at the 2-position (or 9-position) of the 1,10-phenanthroline ligand, the previously diamagnetic iron(II) complex becomes strongly paramagnetic ($^5T_2$ ground state).[87] This substitution overcompensates the stronger $\sigma(L \rightarrow M)$ donor effect of the methyl group (a consequence of its higher inductivity relative to that of the H atom) by increased steric hindrance. It causes an elongation of the neighboring Fe–N bond, and consequently a weakening of the ligand field strength.[6] Cooling the system brings about a spin transition to the $^1A_1$ ground state,[88–90] while the nature of the uncoordinated anion X determines whether the spin transition curve is shifted towards higher or lower temperatures. A thermal spin transition is still observed in the complex with $Y = CH_3O$ as a substituent.[91] Indeed, the transition temperature is notably higher than for the 2-CH_3-phen complex, which implies that the ligand field strength is somewhat greater for the CH_3O-phen complex than for the unsubstituted phen complex. Finally, the 2-Cl-phen complex is strictly HS across the entire temperature range. This compound no longer has a thermal spin transition and stays in the $^5T_2$ ground state down to 4K.[92, 93] The same is true for the iron(II) complex with 2,9-$(CH_3)_2$-phen as a ligand, apparently because the two methyl groups at the 2- and 9-positions are sterically more demanding. If we look at the $[Fe(2\text{-}Y\text{-}phen)_3]X_2$ complexes, the paramagnetic properties (for which γ_{HS} is a measure at a given temperature) increase along the $Y = H < CH_3O < CH_3 < Cl$ series. The series is not simply correlated with the bulkiness of the substituent, because the concurrent presence of the electronic effect with its influence on the basicity of the coordinating N atom superposes the steric effect. This reasoning could be corroborated from CNDO/2–MO calculations.[94]

A change of substituents at positions not adjacent to the N atom in the phen molecule does not alter the spin state of the corresponding $[FeL_3]X_2$ complexes relative to the unsubstituted $[Fe(phen)_3]X_2$ complexes. LS($^1A_1$) remains the stable ground state at all temperatures.[18, 95]

Many other examples of modifications of the magnetic properties of iron(II) in $[FeN_6]$ complexes after changing substituents have been reported.[16, 96–106] The effects of chemical changes in the ligand sphere extend from a more or less distinct $\gamma_{HS}(T)$ shift towards higher or lower temperatures (with the possibility of an additional change in the transition slope) to complete suppression of the spin transition (enabling only the HS state or the LS state to be observed at all temperatures). The widespread opinion that "custom-tuning" of the ligand field strength for thermal spin crossover is possible by taking advantage of steric and electronic effects combined with a suitable choice of ligands rather applies to spin crossover in solution. In the solid we have the additional influence of cooperative interactions, which make custom-tuning more difficult or even uncontrollable.

2.3.2. The Influence of Metal Dilution (Formation of Mixed Crystals)

Our scrutiny of $[Fe_xM_{1-x}(2\text{-pic})_3]X_2 \cdot sol$ systems corroborated the assumption that cooperative interactions play a key role in thermal spin crossover behavior. We have studied how the spin crossover behavior is influenced by metal dilution (M = Zn, Co, Mn), anion exchange (X = Cl, Br), exchange of the solvent molecule (sol = C_2H_5OH, CH_3OH, H_2O, $2H_2O$), and finally the H/D isotope effect.

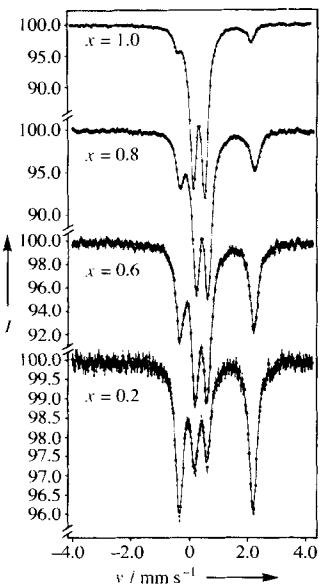

Fig. 7. ^{57}Fe Mössbauer spectra of $[Fe_xZn_{1-x}(2\text{-pic})_3]Cl_2 \cdot EtOH$ at $T = 101$ K.

Using ^{57}Fe Mössbauer spectroscopy we could show that for mixed crystals of $[Fe_xM_{1-x}(2\text{-pic})_3]Cl_2 \cdot EtOH$, with an unchanged crystal structure for all concentrations $0 \leq x \leq 1$, the $\gamma_{HS}(T)$ curve becomes more gradual as the iron concentration decreases. Concurrently, the spin transition temperature $T_{1/2}$ is shifted towards lower temperatures.[107-109] Decreasing iron content thus stabilizes the HS($^5T_2$) state, as can be clearly seen from the Mössbauer spectra in Figure 7 and the plot of $\gamma_{HS}(T)$ versus x in Figure 8. These experiments also revealed that spin crossover is a primary, entropy-driven, intramolecular phenomenon, not requiring interactions between neighboring iron complexes. Even in a highly diluted system ($x = 0.0009$), where the iron complexes are separated by as much as 50 Å and more, we find spin crossover behavior.

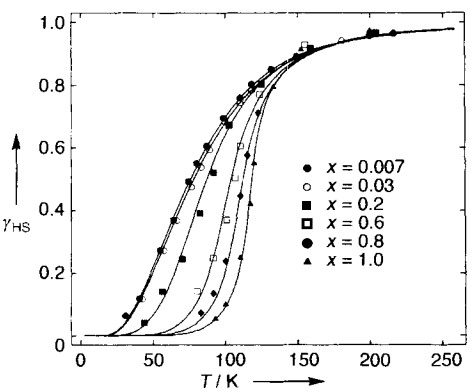

Fig. 8. Temperature dependence of the HS fraction $\gamma_{HS}(T)$, determined from the ^{57}Fe Mössbauer spectra of $[Fe_xZn_{1-x}(2\text{-pic})_3]Cl_2 \cdot EtOH$ for different concentrations x (from ref. [40]).

Figure 9 shows $\gamma_{HS}(T)$ curves of the highly diluted $[Fe(2\text{-pic})_3]^{2+}$ complex in different matrices and in liquid solutions. The similarity of the transition curves is striking; they seem only to be shifted with respect to the transition temperature—transitions in liquid solutions have the highest temperatures. The potential implication that only the energy gap ΔE^0_{HL} between the HS and LS states of the complex (see Fig. 2) is modified by the different matrices will lead to a more quantitative description in Section 3.1.

This conspicuous effect of metal dilution demonstrates that cooperative interactions must be involved in spin transitions in the solid. They are purely mechanical in nature. The key factor is a change in volume of the complexes, translated into a decrease of 3–5% of the crystal volume during the HS → LS transition. Our first efforts to use this concept as a basis for a better understanding of the thermal spin transition in solids led to a model which has "image pressure", lattice expansion and elastic interactions as characteristic features.[40, 41, 43, 44] In fact, it could satisfactorily reproduce experimental results from metal dilution experiments on $[Fe_xM_{1-x}(2\text{-pic})_3]Cl_2 \cdot EtOH$ (M = Zn, Co). More on this model will be reported in Section 3.

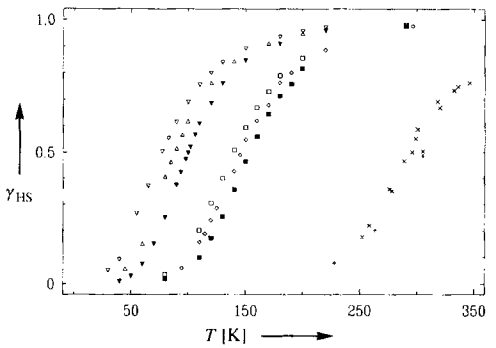

Fig. 9. Temperature dependence of the HS fraction $\gamma_{HS}(T)$ of the highly dilute $[Fe(2\text{-pic})_3]^{2+}$ complex in different lattices and in liquid solutions. ▽ $[Fe_{0.007}Zn_{0.993}(2\text{-pic})_3]Cl_2 \cdot EtOH$; △ $[Fe_{0.02}Co_{0.98}(2\text{-pic})_3]Cl_2 \cdot EtOH$; ▼ $[Fe_{0.03}Zn_{0.97}(2\text{-pic-}ND_2)_3]Cl_2 \cdot EtOD$; □ $[Fe_{0.02}Zn_{0.98}(2\text{-pic})_3]Cl_2 \cdot MeOH$; ◇ $[Fe_{0.01}Co_{0.99}(2\text{-pic})_3]Cl_2 \cdot MeOH$; ■ $[Fe_{0.01}Zn_{0.99}(2\text{-pic-}ND_2)_3]Cl_2 \cdot MeOD$; × $[Fe(2\text{-pic})_3]^{2+}$ complex in acetonitrile/water; + $[Fe(2\text{-pic})_3]^{2+}$ complex in methanol/water. (Solution data taken from ref. [110]).

Metal dilution experiments on other spin crossover systems such as $[Fe_xM_{1-x}(phen)_2(NCS)_2]$ (M = Mn, Co, Zn)[111] led to very similar insights as for the pic system: the $\gamma_{HS}(T)$ curve became more gradual as the iron concentration decreased, and the spin transition temperature $T_{1/2}$ was simultaneously shifted towards lower temperatures. Thus, decreasing iron content again stabilized the HS state.

2.3.3. *The Influence of Noncoordinating Anions*

Crystalline spin crossover compounds that are uncharged contain the anions necessary for electric neutrality coordinated directly at the metal center. An example is $[Fe(phen)_2(NCS)_2]$. It is obvious that in such a case the NCS^- ion is a direct codeterminant of the ligand field strength at the Fe^{2+} center. An exchange of NCS^- for anions exerting a much weaker (for example, halogens) or much stronger (for example, CN^-) LF would suppress the spin transition, and the resulting complexes would have temperature-independent HS or LS character, respectively.

In ionic lattices with cationic spin crossover complex components and uncoordinated counterions on lattice points remote from the metal center (for which we have many examples), the anion can nonetheless exercise a strong influence on spin crossover behavior. The reason is again cooperative interaction. Renovitch and Baker, Jr.[112] observed that the transition characteristics of the thermal spin transition in $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ depends strongly on the nature of the anion X (Cl^-, Br^-, or I^-). More detailed investigations on the chloride and the bromide[29, 79] have yielded the spin transition curves $\gamma_{HS}(T)$ shown in Figure 10. A discontinuous step is evident for the chloride and a weaker step with an additional hysteresis

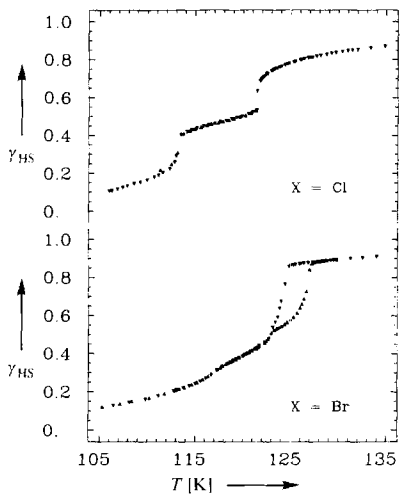

Fig. 10. Temperature dependence of the HS fraction $\gamma_{HS}(T)$ in the spin transition system $[Fe(2\text{-pic})_3]X_2 \cdot EtOH$ (X = Cl, Br) (from refs. [29, 79]).

effect for the bromide. The space group of the chloride is $P2_1/c$; that of the bromide is $P2_1/n$.[29] In both cases the space group remains unchanged during the spin transition.

2.3.4. The Influence of Uncoordinated Solvent Molecules

When a spin crossover compound is crystallized from certain solvents, solvent molecules are often incorporated into the lattice. They are located outside the ligand sphere, that is, not coordinated to the metal center. Just as uncoordinated anions can strongly influence spin crossover behavior as described in Section 3.3, one would expect an equally strong effect of uncoordinated solvent molecules on the spin transition.[16–18, 21, 22] We have investigated $[Fe(2\text{-pic})_3]Cl_2 \cdot sol$ complexes where sol = C_2H_5OH, CH_3OH, H_2O, and $2H_2O$ in detail and determined the $\gamma_{HS}(T)$ functions of the solvates using ^{57}Fe Mössbauer spectroscopy.[1–3, 114] The spin transition is continuous in the EtOH ($T_{1/2} = 121$ K) and the MeOH adduct ($T_{1/2} = 121$ K). For the monohydrate it is discontinuous with an unusually broad hysteresis loop ($\Delta T = T_{1/2}^{\uparrow} - T_{1/2}^{\downarrow} \approx 90$ K). For the dihydrate, finally, the spin transition is totally suppressed (the system adopts the $LS(^1A_1)$ state across the full temperature range). So the transition temperature (and likewise the energy gap ΔE_{HL}^0) increases along the solvent series $C_2H_5OH < CH_3OH < H_2O < 2H_2O$. The crystal structures of the solvates are different; the space groups are $P2_1/c$ (monoclinic, $Z = 4$) for the EtOH compound,[29, 82, 115] *Pbca* (orthorhombic, $Z = 8$) for the MeOH compound,[71, 116] and $P\bar{1}$ (triclinic, $Z = 2$) for the dihydrate.[116] For the monohydrate the structure is unknown. Both the EtOH and the MeOH adduct of the cationic $[Fe(2\text{-pic})_3]^{2+}$ complex have the same ligand arrangement (symmetry), which is meridional (C_{2v}), whereas the facial isomer (threefold symmetry) is adopted in the dihydrate. This difference is probably the reason why the thermal spin crossover behavior of the EtOH adduct resembles that of the MeOH adduct (the $\gamma_{HS}(T)$ curves are very similar), but deviates from that of the dihydrate, where the magnetic properties differ markedly. Here apparently, a stronger ligand field causes temperature-independent LS behavior. Distinct differences have also been found for the bridging hydrogen bonds in the EtOH and the MeOH compound on one hand, and for the dihydrate on the other. In the alcohol adducts, the $[Fe(2\text{-pic})_3]^{2+}$ complex ions are connected by $NH \cdots Cl \cdots NH$ contacts, and the alcohol molecule is joined to the Cl^- counterion through a $Cl \cdots HO$ hydrogen bond.[29, 71] In the dihydrate, however, the water molecules are bound directly to the $[Fe(2\text{-pic})_3]^{2+}$ complex. Apparently this leads to the facial isomer,[116] and we have to assume that the hydrogen bonds are actively involved in the spin crossover transition. To test this hypothesis at least qualitatively, we have carried out experiments with deuterated and ^{15}N isotope-substituted $[Fe(2\text{-pic})_3]Cl_2 \cdot sol$ complexes (see next section).

2.3.5. Isotope Effects

From Mössbauer experiments on the deuterated $[Fe(2\text{-pic})_3]Cl_2 \cdot sol$ (sol = C_2H_5OD, CH_3OD) systems, the LS state appeared to be stabilized by deuteration.[114] The spin transition curves $\gamma_{HS}(T)$ were of the same general shape as those for the nondeuterated solvates, but the transition temperatures $T_{1/2}$ were both shifted by about 15 K towards higher temperatures. This quite noticeable effect was first interpreted in terms of a widening of the energy gap ΔE_{HL}^0 between the lowest vibronic levels of the LS and the HS state, because deuteration had increased the reduced mass. Since this deuteration experiment uses C_2H_5OD and CH_3OD as solvents in the preparation of the complexes, the acidic amino group protons of the picolylamine ligand are also exchanged. Consequently the deuteration effect can have its origin in the $NH \cdots Cl$ as well as in the $Cl \cdots HOR$ hydrogen bonds. Presumably the influence of the NH hydrogen bond dominates, because the NH/OH ratio in the lattice is 3:1. Moreover, the NH positions form an integral part of the "path" between two neighboring complexes and can thus act as "communication links". They are likely to have a much stronger influence on elastic interactions than the solvent molecules have, which are just attached across OH groups much like pendulums. This view is supported by very thorough and precise H/D and $^{14}N/^{15}N$ isotope-exchange experiments on $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$.[19, 117] In these experiments Köppen[117] observed the first steplike spin transition anomaly in nondeuterated $[Fe(2\text{-pic})_3]Cl_2 \cdot C_2H_5OH$ using very precise Mössbauer measurements. His measurements on the $[Fe(2\text{-pic})_3]Cl_2 \cdot C_2H_5OD$ com-

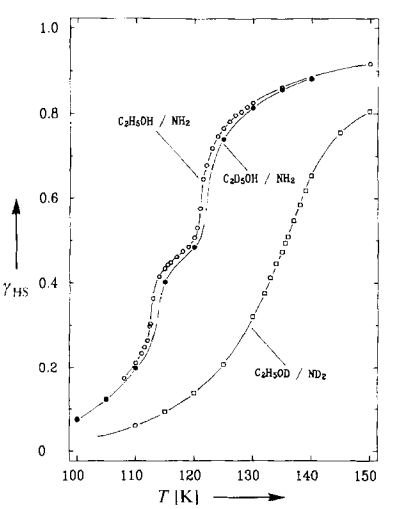

Fig. 11. Temperature dependence of the HS fraction to $\gamma_{HS}(T)$, determined from ^{57}Fe Mössbauer spectra for $[Fe(2\text{-pic})_3]Cl_2 \cdot C_2H_5OH$ in C_2H_5OH/NH_2 (not deuterated), C_2D_5OH/NH_2 (deuterated alkyl group of the ethane molecule), and C_2H_5OD/ND_2 (deuterated hydroxyl and amino groups) (from refs. [19, 117]).

pound in which exclusively the H atom of the alkyl group was exchanged yielded the same steplike $\gamma_{HS}(T)$ curve, but slightly shifted towards higher temperatures (Fig. 11). This H/D effect is clearly weaker than in the C_2H_5OD/ND_2 system, where the spin transition occurs at about 15 K higher without anomaly. This is probably also because the H/D exchange positions are direct links in the hydrogen bond chain for the C_2H_5OD/ND_2 system, whereas they are just dangling on the sides in the C_2D_5OH/NH_2 system. It also speaks for the importance of the H bonds involved in the cooperative interactions between the spin-changing metal centers. Studies of $^{14}N/^{15}N$ exchange in the NH_2 group of the picolyl ligand in $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ led to similar results. Here too, the steplike spin transition curve retains its shape and is just shifted slightly towards higher temperatures (Fig. 12). Again the $^{15}NH_2$ position is a direct link in the

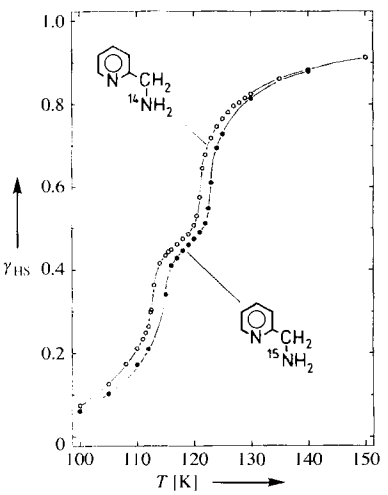

Fig. 12. Influence of $^{14}N/^{15}N$ exchange in the NH_2 group of the picolylamine ligand in $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ on the HS fraction $\gamma_{HS}(T)$, determined from the ^{57}Fe Mössbauer spectra, as a function of temperature (from refs. [19, 117]).

hydrogen bond and influences the spin crossover behavior. The fact that the effect is much smaller than the one in the C_2H_5OD/ND_2 system stems from a much smaller change in the reduced mass.

H/D exchanges at the 3,4,5-positions of the pyridyl ring in the $[Fe(2\text{-pic-py}D_3)_3]Cl_2 \cdot EtOH$ complex[117] have resulted in slight shifts towards higher temperatures, as expected for a mass increase from the above argument.[114] Here again the effects are minor because deuteration does not take place in the hydrogen bond. Upon deuteration of the CH_2 group in the 2-pic ligand of $[Fe(2\text{-pic-}CD_2)_3]Cl_2 \cdot EtOH$, Köppen[117] observed a similar, very minor shift of $\gamma_{HS}(T)$, but towards lower temperatures, which corresponds to a stabilization of the HS state (Fig. 13). Again deuteration took place outside the communication link; nevertheless this small shift of $\gamma_{HS}(T)$ towards lower temperatures is inconsistent with the expected effect from a mass increase.[114]

2.4. Physical Influences on the Spin Transition in Solids

From the very start, the aim of gaining a deeper insight into the spin crossover phenomenon and finally to understand its mechanism has stimulated research groups to look at the physical influences on thermal spin crossover in the solid. Experiments varying the pressure are obvious, but the influences of an external magnetic field and of changes in the crystal quality have been investigated as well. The attentive reader will have already noticed in our description of chemical influences on the spin crossover behavior (Section 2.3) that in one or other instance the true nature of this influence is a physical one, which is inherently associated with the chemical change on the system. Metal dilution, for example, creates the so-called image pressure, which can be positive or negative depending on the volume difference between the HS or LS iron(II) complex and the corresponding complex molecule in the host lattice. In Section 3.4 we shall demonstrate that the influence of this image pressure on neighboring HS or LS molecules is equivalent to an external pressure. In a way, the isotope effects treated in Section 2.3.5 should also be counted as physical influences, since these subtle changes on the system by a slight change of the reduced mass chiefly modify the phonon system and the elastic properties.

2.4.1. The Influence of Pressure

Because the complex molecules are bigger in the HS state than in the LS state (a general result from crystal structure analyses), we expect that increasing the pressure will favor the LS($^1A_1$) state; that is, at elevated pressure the spin transition will occur

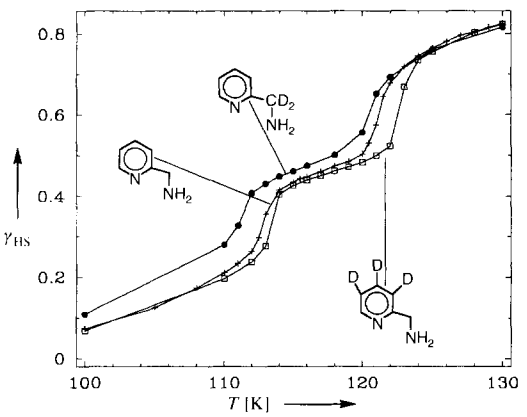

Fig. 13. Comparison of the HS fractions $\gamma_{HS}(T)$ for $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (+), $[Fe(2\text{-pic-py}D_3)_3]Cl_2 \cdot EtOH$ (□), and $[Fe(2\text{-pic}CD_2)_3]Cl_2 \cdot EtOH$ (●) as a function of temperature (from ref. [117]).

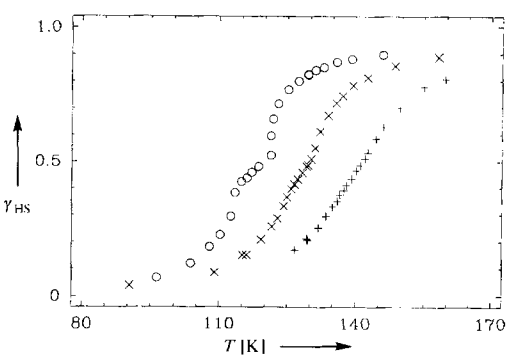

Fig. 14. The spin transition curve $\gamma_{HS}(T)$ for $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ at ambient pressure (○), 600 bar (×), and 1350 bar (+), determined from the area under the HS doublet in the Mössbauer spectra (from ref. [85]).

at higher temperatures than at ambient pressure. Experiments varying the pressure on iron(II) spin crossover complexes in the solid have always confirmed this.[118-126]

Our variable-pressure and variable-temperature Mössbauer experiments on $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ have shown that the $\gamma_{HS}(T)$ curve is shifted towards higher temperatures with increasing pressure, and that the step in it is progressively suppressed[85] (Fig. 14). In this study we have also determined the change in the unit cell volume associated with the spin transition, namely $\Delta V = V_{HS} - V_{LS} = 55.2$ Å^3, well in accord with the value of 62 Å^3 determined by X-ray analysis.[127] Metal dilution, as described in Section 2.3.2, has the same effect as applying external pressure. Incorporation of $[Fe(2\text{-pic})_3]^{2+}$ ions into a similar host lattice with bigger $[Zn(2\text{-pic})_3]^{2+}$ ions creates a negative image pressure, which stabilizes the HS state and shifts the $\gamma_{HS}(T)$ curve to lower temperatures with increasing Zn dilution (see Fig. 8). Simultaneously the step in $\gamma_{HS}(T)$ vanishes[85] (see Fig. 4). The influence of metal dilution on the spin transition behavior in the $[Fe_xMn_{1-x}(phen)_2(NCS)_2]$ system has been interpreted in the same way.[111] From ^{57}Fe Mössbauer spectra it was established that spin transition temperatures decrease with increasing metal dilution in mixed crystals in which the ionic radii $r(Mn^{2+}) > r(Fe^{2+}_{HS})$.

Pressures up to 1500 bar at temperatures around $T_{1/2}$ apparently changed the Lamb–Mössbauer factor f significantly.[123] The $f(p,T)$ behavior could be described by the Debye model.

Spin transition dynamics have been investigated as a function of pressure in liquids as well as in solids.[128] Adler et al.[57] have confirmed an increased HS → LS relaxation rate under pressure using line shape analysis of Mössbauer spectra and Blume's relaxation model.

2.4.2. The Influence of a Magnetic Field

Since different spin states have different magnetic properties, we expect magnetic fields to affect the spin transition curve. The magnitude of this effect is easily estimated.[129] In a first order approximation, $T_{1/2}$ changes as described by Equation (4),

$$\Delta T_{1/2} = \left[\frac{E^m_{HS} - E^m_{LS}}{S_{HS} - S_{LS}}\right]_{T_{1/2}} \quad \text{with} \quad E^m_j = -\chi_j B^2 \tag{4}$$

where S is the entropy at $T_{1/2}$. The temperature-independent susceptibility of the LS($^1A_1$) state ($\chi_{LS} \approx 10^{-4}$ cm^3 mol^{-1}) is approximately two orders of magnitude smaller than $\chi_{HS}(T) = \mu^2_{eff}/3k_BT = 5.2\ \mu_B$. Thus the change in the transition temperature is but the ratio between the differences in the magnetic energies ΔE^m_{HL} and the entropies ΔS_{HL} of the HS and LS states. For steep discontinuities, $\Delta S(T_{1/2})$ is obtained with good accuracy from the specific heat curve $C_p(T)$. For a typical value of $\Delta S(T_{1/2})$ of 50 J K^{-1} mol^{-1} in a field of 5 Tesla, the shift $\Delta T_{1/2}$ is -0.1 K. This is a very small value and difficult to verify experimentally. The only example where a very steep transition has been measured in different magnetic fields (1 and 5 Tesla) is $[Fe(phen)_2(NCS)_2]$.[129] For the stronger field the data yielded a shift of the spin transition curve of -0.11 ± 0.04 K, in good agreement with the estimate given above.

A theoretical study by Sasaki and Kambara[46] on spin transitions in magnetic fields is based on a model incorporating a cooperative Jahn–Teller interaction. Because only minor effects are to be expected for small fields (see above), these authors consider strong magnetic fields up to 100 Tesla. They present a comprehensive calculation of the HS state in a $^5T_2$ space ligand field approximation and predict a strong dependence of the spin transition on the magnetic field, due to stabilization of the high spin state. These calculations have so far eluded experimental verification.

2.4.3. The Influence of Sample Preparation

The spin transition behavior is considerably influenced by the quality of the crystalline material resulting from different preparative procedures. This observation suggested that additional post-preparative treatments, for example ball-milling or crushing in a mortar, should have a similar effect. Haddad et al.[132] were the first to observe significantly larger proportions of residual HS state (evident from a plateau in $\gamma_{HS}(T)$) and a less steep spin transition curve with increasing degree of milling. We have detected similar effects with the iron(II) complexes $[Fe(phen)_2(NCS)_2]$ and $[Fe(bipy)_2(NCS)_2]$ (bipy = 2,2′-bipyridyl):[73] with increasing grinding time in a ball mill, the very narrow hysteresis loop widens and flattens, and finally joins the low-temperature plateau at higher $\gamma_{HS}(T)$ values. Such grinding effects have also been observed for cobalt(II) spin crossover complexes.[133] From X-ray powder diffraction and electron microscopy studies we know that these effects are mainly caused by crystal defects introduced during sample preparation by milling or by rapid precipitation. They have less to do with particle size.

A particle size effect is, however, assumed by Wei and Jean[134] to explain their findings with Mössbauer spectroscopy on spin crossover compounds on supporting materials such as MgO, SiO_2, and activated charcoal. They observed a distinct (and in part also steep) increase of the HS fraction (at constant temperature) with increasing loads of spin crossover compound. The nature of the supporting material exerts less influence.

The application of spin crossover compounds in Langmuir–Blodgett (LB) films may be regarded as another special way of sample treatment. A French research group has introduced long-chain substituents (C_{17} and C_{18}) into the *o*-phenanthroline molecule, and after complexation with iron(II) (complex type $[FeL_2(NCS)_2]$), has obtained a Langmuir–Blodgett-compatible spin crossover system supported on CaF_2 or quartz.[135, 136] Thermal spin crossover was monitored with IR spectroscopy by following changes at the NCS^- ligand. $\gamma_{HS}(T)$ is much more gradual than for the initial complex $[Fe(phen)_2(NCS)_2]$: $T_{1/2}$ is about 260 K and the hysteresis width is approximately 4 K.

2.5. Structural Changes as a Consequence of Molecular Reorganization upon Spin Transition

Differences in the metal–ligand bond lengths between HS and LS state not only lead to a change in shape of the spin crossover molecule, but also cause lattice deformations, which in turn can entail crystallographic changes of the structure. The increase of the HS state population of the complexes with increasing temperature is more the cause than the effect of the

lattice deformation. This fact has for long been veiled by experimental observations that spin crossovers with hysteresis effects are accompanied by structural phase transitions. The variation of the lattice parameters with temperature seemed to adjust to the equilibrium between the smaller LS and the bigger HS complexes. This point of view was challenged until the discovery of a spin crossover with a temperature hysteresis but without a crystallographic change in structure.[29]

Lattice expansion with increasing fractions of HS molecules had been observed for many examples by variable-temperature X-ray studies of lattice parameters.[34] It finally emerged that the lattice volume is proportional to the fraction of HS molecules with a high degree of accuracy.[127] The total increase in volume $V(T)-V_{LS}(T_0)$ (relative to the unit cell volume in the LS state at a reference temperature T_0) is the sum of the linear volume increase due to lattice expansion, $V_{LS}\alpha_V(T-T_0)$ (α_V is the linear expansion coefficient), and the volume increase due to the spin transition, $\Delta V_{HL}\gamma_{HS}(T)$ [Equation (5)].

$$V(T) = V_{LS}(T_0) + V_{LS}\alpha_V(T-T_0) + \Delta V_{HL}\gamma_{HS}(T) \quad (5)$$

As the volume difference $\Delta V = V_{HS}-V_{LS}$ between the HS and LS unit cells is temperature independent, we can neglect the small differences between the expansion coefficients α_V of the pure HS and LS lattices. This first example of a spin crossover with a temperature hysteresis without a crystallographic change of structure[29] is especially convincing, because the anomalous spin transition in $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ with a step in the $\gamma_{HS}(T)$ curve is exactly mirrored (that is, with the same step) in the temperature dependence of the unit cell volume V and the lattice parameters a, b, and c themselves (Fig. 15). The influence of the spin transition on the lattice is also clearly demonstrated by crystal structure investigations on the $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole) spin crossover complex.[137] Irrespective of an overall volume decrease, certain distances in the lattice may well increase and thus cause a lattice deformation. This deformation can be adequately described by two tensors, an expansion tensor $\boldsymbol{\alpha}$ and a temperature-independent tensor $\boldsymbol{\varepsilon}$. An arbitrary lattice point with the vector $\boldsymbol{X}(T)$ at temperature T is related to the vector $\boldsymbol{X}(T_0)$ at temperature T_0 according to Equation (6).

$$\boldsymbol{X}(T) = [1 + \boldsymbol{X}(T-T_0) + \boldsymbol{\varepsilon}\gamma_{HS}(T)]\boldsymbol{X}(T_0) \quad (6)$$

Equation (5) is a special case of this equation with $\alpha_V = \text{trace}\,\boldsymbol{\alpha}$ and $\Delta V_{HL}/V_{LS} = \text{trace}\,\boldsymbol{\varepsilon}$. The curves in Figure 15 have been calculated with the experimental values for the HS fraction $\gamma_{HS}(T)$ from Figure 11. Table 1 lists the tensor components in the principal axes coordinate system and the orientation of the principal axes relative to the crystal axes for three similar compounds with different solvent molecules (EtOH and MeOH) and anions (Cl^- and Br^-). The deformation tensors $\boldsymbol{\varepsilon}$ and $\boldsymbol{\alpha}$ are very different; even their traces can differ by a factor of 2. The complex molecules might be pictured in the lattice as dilatation (LS → HS transition) centers which force a deformation onto the lattice. Evidently, different relative orientations of the anisotropic centers in the unit cell lead to different deformation tensors in the lattice, as a result of averaging. As the isotropic part of the dilatation centers (the volume increase δV_{HL} of a single complex molecule) is independent of the orientation, at first sight the traces of the tensors would be expected to be equal for all three examples. For the orthorhombic structure of $[Fe(2\text{-pic})_3]Cl_2 \cdot MeOH$ (space group *Pbca*) and the monoclinic structure of $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (space group $P2_1/c$[115]) this is true. For the bromide, however, which has the same space group as the chloride/EtOH compound, the $\boldsymbol{\varepsilon}$ trace is more than twice as large. This seeming contradiction only resolves after the elastic properties of the compounds are also taken into account, for the elastic properties are the key factor for the macroscopic changes in volume.[138] We shall look at this in detail in Section 3.4.

Table 1. The components of the thermal expansion $\boldsymbol{\alpha}$ and the deformation tensor $\boldsymbol{\varepsilon}^{HL}$ as a result of the HS → LS transition referred to the principal axes system [a].

	$[Fe(2\text{-pic})_3]X_2 \cdot sol$		
$X_2 \cdot sol =$	$Cl_2 \cdot MeOH$	$Cl_2 \cdot EtOH$	$Br_2 \cdot EtOH$
α_1	0.85	1.86	1.54
α_2	0.33	0.31	0.53
α_3	0.64	−0.31	−0.30
Tr (α)	1.82	1.86	1.77
$\delta(\alpha)$	–	107	97
ε_1	0.18	2.93	4.45
ε_2	1.43	1.57	1.03
ε_3	0.83	−2.07	−0.19
Tr(ε)	2.44	2.43	5.29
$\delta(\varepsilon)$	–	14	−1

[a] The crystal systems for the similar compounds $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ and $[Fe(2\text{-pic})_3]Br_2 \cdot EtOH$ are monoclinic, and the crystallographic a axis forms an angle of δ with the x axis of the principal axes system (a anticlockwise with respect to x). In the orthorhombic system of $[Fe(2\text{-pic})_3]Cl_2 \cdot MeOH$ the principal axes (x,y,z) are parallel to the crystallographic axes (a,b,c). The units are: δ [ ], ε_i [10^{-2}], α_i [$10^{-4}K^{-1}$].

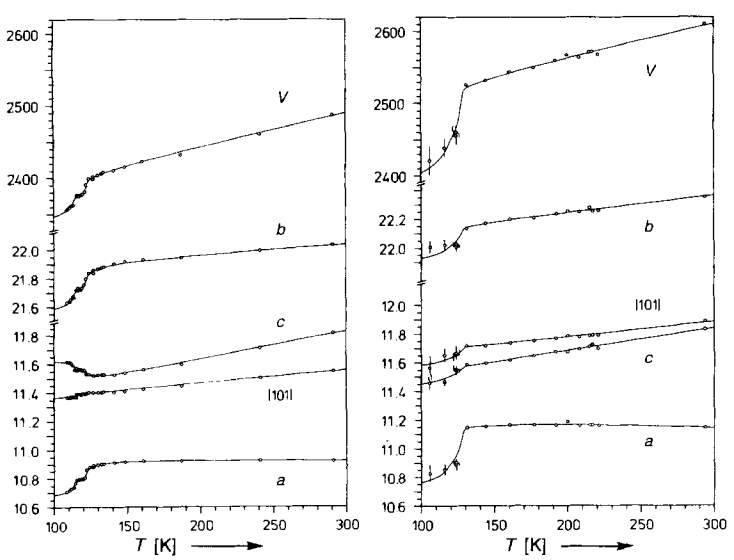

Fig. 15. Temperature dependence of the unit cell volume V [Å] and of the lengths of four vectors ($\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, $|\boldsymbol{a}+\boldsymbol{c}|$) in the monoclinic crystal system (space group $P2_1/c$ with $Z = 4$) for $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ (left) and $[Fe(2\text{-pic})_3]Br_2 \cdot EtOH$ (right). The solid curves were calculated from the observed values for the HS fraction $\gamma_{HS}(T)$. For the hystersis effect in the Br^- system, $\gamma_{HS}(T^{\downarrow})$ was plotted from values obtained on decreasing the temperature (from ref. [29]).

3. Thermodynamics of Spin Transition Complexes

3.1. Dilute Mixed Crystal Systems

All highly dilute spin crossover complexes in which the concentration of Fe ions in lattice positions of Zn, Co, or Mn ions is 1–2% and less show very simple transition behavior. Their spin transitions are gradual and occur over a wider temperature range than the gradual spin transitions in undiluted Fe compounds. The difference can be attributed to a cooperative interaction between the HS and LS complexes, which is mostly suppressed in the very dilute systems. The population of the energy levels in the isolated complexes is then described by the Boltzmann law, which determines the thermodynamic spin equilibrium. If $Z_{HS}(T)$ and $Z_{LS}(T)$ are the densities of state of the HS and LS fractions, the HS fraction of the spin transition curve is given by Equation (7).

$$\gamma_{HS}(T) = Z_{HS}(T)/[Z_{HS}(T) + Z_{LS}(T)] \quad (7)$$

Because the volume of the complex has increased and its shape changed, part of the energy difference between the lowest HS and LS states of the complex is elastic energy. This fraction can be changed experimentally by incorporating the same complex into host lattices with different elasticity constants. Then the free energy per complex molecule $\Delta f_{HL} = f_{HS} - f_{LS}$ in two different host lattices should only differ by a constant energy contribution. The difference $\Delta f_{HL}(T)$ follows from the HS part with $f_i = -k_B T \ln Z_i$ [Eq. (8)].

$$\Delta f_{HL}(T) = -k_B T \cdot \ln[\gamma_{HS}(T)/(1-\gamma_{HS}(T))] \quad (8)$$

The simple shifting of the $\Delta f_{HL}(T)$ curves has been tested for the picolylamine complex $[Fe(2\text{-pic})_3]^{2+}$ (Fig. 16). The complex (with EtOH and MeOH as solvent molecules, in two cases also deuterated) was dissolved in solid Zn and Co compounds, and above 230 K in two liquid solvents. Figure 16 shows Δf_{HL} for all transitions. The shifts Δ' are relative to the transition of $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ with the lowest transition temperature. Clearly, the curves do not intersect, but are just shifted along the temperature axis. The solid lines, which are not fitted curves but freehand guides, all have identical shapes.

The interpretation of the shift Δ' is evident. If we disregard the influence of the polar solvent on the ligand field strength, we have free complexes that do not interact in the liquid solutions. There is no elastic energy to overcome on going from the HS to the LS state (work against ambient pressure is minimal and can be neglected). Upon incorporation into a crystal lattice, the complete set of energy levels of the HS state is shifted downward by $\Delta = \Delta'(\text{solution}) - \Delta'(\text{lattice})$, relative to the LS state. At ambient temperature the solution in this case[110] contains about the same number of HS and LS complex molecules. Because the HS complex molecules, along with the solvent molecules, fit best into the available structures, a HS crystal precipitates. So the lattice stabilizes the HS state by Δ (downward shift by Δ). Viewed from the LS state, the change in structure to convert into the LS ground state involves expenditure of elastic energy (of Δ), with the result that the HS state is already populated thermally at a lower temperature. It should be mentioned that the opposite case of a destabilization of the lattice HS state relative to the solution HS state has also been observed.[106]

Because a transition from the LS state to the HS state entails a volume increase, the LS state is stabilized by $\Delta = p\delta v_{HL}$ when an increasing external pressure p is applied. The term δv_{HL} is the volume change of the host crystal per complex molecule. Figure 17 shows Δf_{HL} at ambient pressure and at $p = 1350$ bar for

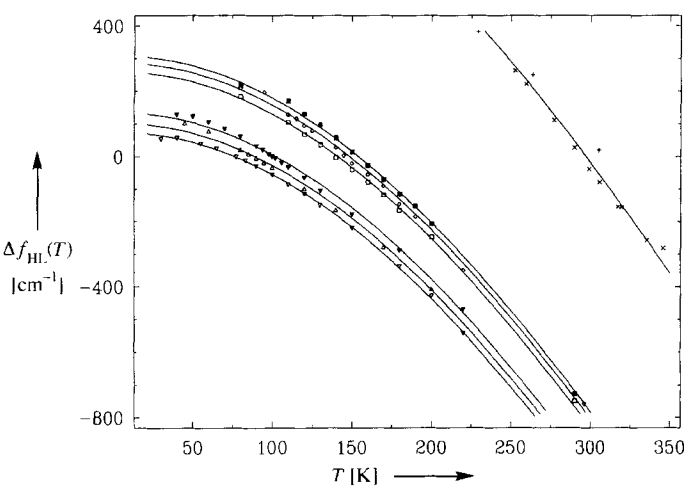

Fig. 16. The difference between the free energies $\Delta f_{HL}(T) = f_{HS}(T) - f_{LS}(T)$ of the highly dilute $[Fe(2\text{-pic})_3]^{2+}$ complexes in the HS and LS state in different lattices and in liquid solution. The values are derived from the spin equilibrium. ▽ $[Fe_{0.007}Zn_{0.993}(2\text{-pic})_3]Cl_2 \cdot EtOH$; △ $[Fe_{0.02}Co_{0.98}(2\text{-pic})_3]Cl_2 \cdot EtOH$ ($\Delta' = 20$ cm^{-1}); ▼ $[Fe_{0.03}Zn_{0.97}(2\text{-pic-ND}_2)_3]Cl_2 \cdot EtOD$ ($\Delta' = 86$ cm^{-1}); □ $[Fe_{0.02}Zn_{0.98}(2\text{-pic})_3]Cl_2 \cdot MeOH$ ($\Delta' = 225$ cm^{-1}); ◇ $[Fe_{0.01}Co_{0.99}(2\text{-pic})_3]Cl_2 \cdot MeOH$ ($\Delta' = 243$ cm^{-1}); ■ $[Fe_{0.01}Zn_{0.99}(2\text{-pic-ND}_2)_3]Cl_2 \cdot MeOD$ ($\Delta' = 282$ cm^{-1}); × $[Fe(2\text{-pic})_3]^{2+}$ complex in acetonitrile/water; + $[Fe(2\text{-pic})_3]^{2+}$ complex in methanol/water ($\Delta' \approx 800$ cm^{-1}). Observed values for the solutions are taken from ref.[110]. The curves (not fitted, just freehand viewing guides) are essentially parallel with a shift Δ' along the y axis.

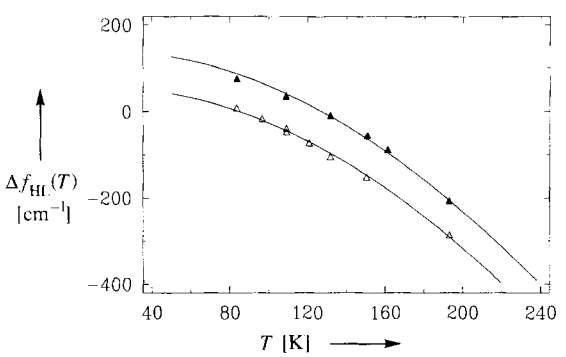

Fig. 17. The difference between the free energies $\Delta f_{HL}(T)$ of the highly dilute ($x = 0.03$) $[Fe(2\text{-pic})_3]^{2+}$ complex in the lattice of $[Zn(2\text{-pic-ND}_2)_3]Cl_2 \cdot EtOD$ at ambient pressure (△) and at $p = 1350$ bar (▲). Under an external pressure the free enthalpy is higher by $\Delta = 80$ cm^{-1} (from ref.[85]).

the compound $[Fe_{0.03}Zn_{0.97}(2\text{-pic-ND}_2)_3]Cl_2 \cdot EtOD$. The LS state stabilization of $\Delta = 80$ cm^{-1} corresponds to a volume increase of $\delta v_{HL} = 11.9$ Å^3, well within experimental error of a value of 12.3 Å^3 from variable-temperature X-ray measurements on the all-iron compound.[123]

Measurement of the spin equilibrium under pressure gives an impression of the internal pressure on the spin crossover complex molecule when the spin state changes in the crystal. A

simple consideration ($\Delta = -\frac{1}{2}p_{HL}\delta v_{HL}$) shows that a negative pressure of more than -25 kbar acts on the complex molecule to stabilize the HS state by $\Delta = 800\ cm^{-1}$. The assumption is that the essential deformation work is performed by the volume change, not by the change in shape. The latter would require a treatment of the full strain tensor instead of using merely the pressure (trace of the tensor). It will be shown in Section 3.4.1 that the isotropic part is 10–20%, so only pressures between -2.5 and -5 kbar actually act on the $[Fe(2\text{-pic})_3]^{2+}$ complexes, and the 80–90% of the elastic energy is due to the anisotropic strain in the crystal.

3.2. Concentrated Mixed Crystal Compounds

In concentrated systems (in particular, in mixed crystals with Fe concentrations of $0 \ll x \leq 1$), we have in any case an elastic interaction due to changes in shape and volume that is a function of the fraction $\gamma_{HS}(T)$ of the complexes in the HS state and entails a deviation from the Boltzmann type population. The simplest approach for the calculation of the free energy per complex molecule, f_x, is to consider a mixed crystal system of HS, LS, and M complexes (M = Zn, Co, etc.) [Eq. (9)].

$$f_x = x[\gamma_{HS}.f_{HS} + (1-\gamma_{HS})f_{LS} - Ts_{mix}(\gamma_{HS})] + (1-x)f_{Zn} + x\,w(\gamma_{HS}, x, T) + f_G \quad (9)$$

Here $w(\gamma_{HS}, x, T)$ is the interaction energy per Fe complex molecule and f_G is the free energy of the residual lattice, taken as independent of γ_{HS}. The mixing entropy between HS and LS molecules is $s_{mix} = -k_B[\gamma_{HS}\ln\gamma_{HS} + (1-\gamma_{HS})\ln(1-\gamma_{HS})]$, and contributions to the mixing entropy independent of γ_{HS} have been omitted. Because the interaction energy per complex molecule must vanish at infinite dilution ($w(\gamma_{HS}, x \to 0, T) \to 0$), the equilibrium condition $\partial f_x/\partial\gamma_{HS} = 0$ yields the Boltzmann type population given in Equation (7) for $x \to 0$.

From the temperature dependence of the spin equilibrium of a mixed crystal series (for example, the deuterated compounds $[Fe_xZn_{1-x}(2\text{-pic-}ND_2)_3]Cl_2\cdot EtOD$), we obtain an expression for w. Equation 10 follows from the equilibrium condition $\partial f_x/\partial\gamma_{HS} = 0$.

$$(\partial w/\partial\gamma_{HS})_T = -k_B T\cdot\ln[\gamma_{HS}(T)/(1-\gamma_{HS}(T)] - \Delta f_{HL} \quad (10)$$

The partial derivative $(\partial w/\partial\gamma_{HS})_T$ as a function of T and x can be calculated from the values of $\Delta f_{HL}(T)$ obtained from the transition curve for highly dilute lattices (see Fig. 16) and the experimental data for $\gamma_{HS}(T)$[139, 140] at concentration x. We have interpreted the temperature-independent energy difference of $\Delta f_{HL}(T)$ in the different lattices as an elastic energy difference. We now assume that the interaction between the complexes ($x > 0$) is chiefly elastic in nature as well, and their temperature dependence also negligible. We further assume that correlations between the HS excitations in the crystal are unimportant. Then w should be a function of γ_{HS} alone and should not explicitly depend on T. In Figure 18 we have therefore plotted the derivatives of w for several concentrations x over γ_{HS}. As a good approximation $\partial w/\partial\gamma_{HS}$ is a linear function: $\partial w/\partial\gamma_{HS} = \Delta - 2\Gamma\gamma_{HS}$. Figure 19 shows that both constants, Δ and Γ, are also proportional to the concentration: $\Delta(x)/x = 273\ cm^{-1}$ and $\Gamma(x)/x = 152\ cm^{-1}$.

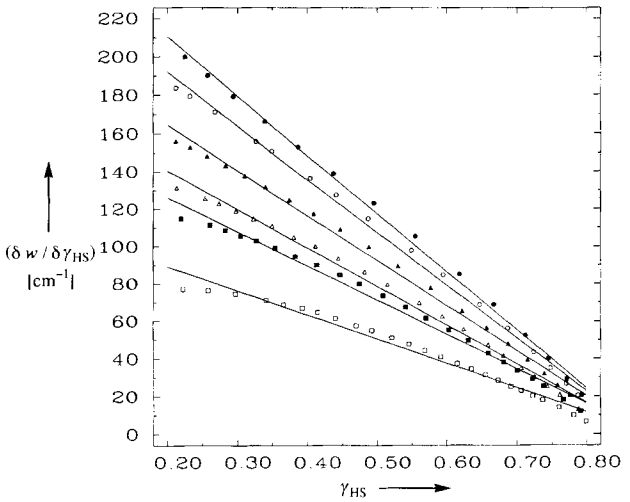

Fig. 18. The partial derivative $\delta w/\delta\gamma_{HS}$ as a function of γ_{HS} for different Fe concentrations x in $[Fe_xZn_{1-x}(2\text{-pic-}ND_2)_3]Cl_2\cdot EtOD$) with linear regression lines (from refs. [139, 140]). ●: $x = 1.00$; ○: $x = 0.91$; ▲: $x = 0.78$; △: $x = 0.68$; ■: $x = 0.60$; □: $x = 0.46$.

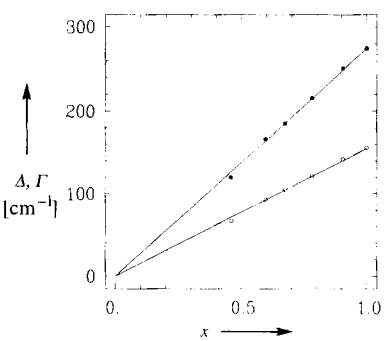

Fig. 19. $\Gamma(x) = 152\ cm^{-1}\cdot x$ (●) and $\Delta(x) = 273\ cm^{-1}\cdot x$ (○) as linear functions of the Fe concentration x. The linear regression lines were made to pass through the origin, so that the condition $w(x = 0) = 0$ is met (from ref. [140]).

This means that w fulfills the simplest possible phenomenological formulation, the Bragg–Williams approximation for a binary mixture with interaction between the components [Eq. 11]. The formal integration constant, which can only possibly be dependent on T and x, is included into the lattice contribution $f_G(x,T)$ or thought of as contained in this term from the start.

$$w(\gamma_{HS}, x) = \Delta(x)\gamma_{HS} - \Gamma(x)\gamma_{HS}^2 \quad (11)$$

The linear dependence of $\partial w/\partial\gamma_{HS}$ on x as well as on γ_{HS} was first discovered for the nondeuterated mixed crystal series[40] and later also verified for other mixed crystals.[41, 42, 81] However, a closer look reveals slight curvature in the line through the data points, especially towards large and small γ_{HS} values. At the end of Section 3 we shall present arguments to explain deviations from linearity. First we shall demonstrate that the free energy calculated from Equation (9) agrees well with observations from calorimetric results.

3.3. Specific Heat

The expression for free energy in Equation (9) was deduced solely from observations of the spin equilibrium $\gamma_{HS}(T)$. For an interacting system it is of the simplest imaginable form and was derived by different authors who used the expression in this or an equivalent formulation to parameterize the $\gamma_{HS}(T)$ curves.[28, 49] In Equation (9) one assumes that the different contributions (the HS/LS system and the corresponding lattice into which the Fe complex molecules are embedded) are additive. An interaction, also in the simplest approximation, is only considered in the HS/LS system.

This approach for the free energy was tested with calorimetric data. For these measurements we have chosen the $[Fe_xZn_{1-x}(2\text{-pic-}ND_2)_3]Cl_2 \cdot EtOD$ mixed crystal system, which has no structural (or other) order–disorder transition apart from the spin transition. In Figure 20 the specific molar heat is plotted for Fe

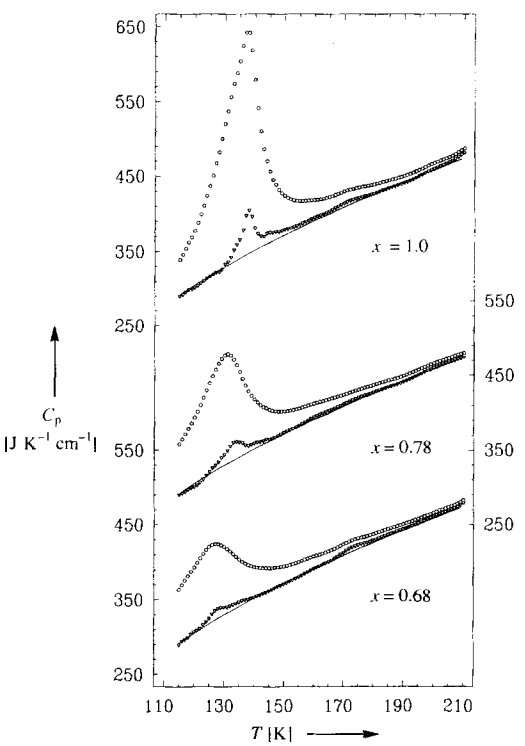

Fig. 20. The molar specific heats C_p of the mixed crystals $[Fe_xZn_{1-x}(2\text{-pic-}ND_2)_3]Cl_2 \cdot EtOD$ for three concentrations x as observed (○), and after subtraction of the specific heat due to the spin transition (▽). The subtracted fraction was calculated with the phenomenological approach for the free energy according to Equation (9). The solid smooth curves are extrapolations in the peak areas and averages of the data points beyond them. They are identified (see text) with the specific heats of a hypothetical, purely LS state lattice (from ref.[140]). The right hand axis refers to $x = 0.78$.

concentrations $x = 1.0$, 0.78, 0.68 for $T = 100$–200 K.[139, 140] As expected, the peak areas decrease with decreasing Fe concentrations and their maxima shift towards lower temperatures, equivalent to the transition curves $\gamma_{HS}(T)$ (see Fig. 8). As a consequence of the free energy expression we used, the specific heat C_p ($= -T\,\partial f_x/\partial_T{}^2$) is the sum of three terms [Eq. (12)].

$$C_p = x C_p^{HL} + x C_p^{LS} + (1-x) C_p^{Zn} \qquad (12)$$

$C_p^{LS}(T)$ and $C_p^{Zn}(T)$ is the specific heat of the pure LS and Zn lattices. $C_p^{LS}(T)$ is unknown in the transition area and at higher temperatures, and not accessible from direct measurements. Even though no suitable low-temperature calorimeter was available for measurements on the Fe complexes in the LS state, the free energy expression from Equation (9) could be tested by comparisons between members of the mixed crystal series. We subtract the measured $C_p^{Zn}(T)$ values (weighted by $(1-x/x)$) and the fraction $C_p^{HL}(T)$ (calculated from the $\gamma_{HS}(T)$-dependent terms of the free energy) from the observed values $C_p(T)/x$. This gives us the ▽ data points in Figure 20. Except for a small area around $T_{1/2}$, they are equal for all Fe concentrations and rise monotonously, as expected for $C_p^{LS}(T)$. The solid line is an extrapolation for $T = 125$–160 K, and the average of the ▽ data points outside this temperature interval. The small peak above this smoothed assumed function is only approximately 5% of the measured peak above the same $C_p^{LS}(T)$ curve. The thermodynamics of the gradual spin transition in question is thus very adequately described by the free energy expression from Equation (9), derived solely from the $\gamma_{HS}(T)$ curves.

3.4. Interpretation of the Interaction Term

3.4.1. Elastic Interaction

We have already stressed several times that the elastic interactions between the spin-changing complex molecules certainly play an important if not decisive role in the HS–LS transition. This section will show that the parameters $\Delta(x)$ and $\Gamma(x)$ in the interaction term for a mixed crystal series can be well understood if the elastic interaction is considered.

We use a simplified picture of the crystal, so that we can apply the theory of elasticity and derive quantitative expressions. The HS, LS, and M complex molecules are considered defects in their own crystal lattice into which they fit more or less well. The crystal lattice itself is seen as a homogeneous medium with certain elastic properties. Even for that simple model there is no adequate treatment in the literature. Therefore, as a further simplification, the elastic medium is assumed to be isotropic, so that it can be characterized by just two constants, the elastic (bulk) modulus K and the Poisson ratio σ.

Let us first look at the isotropic part of the defects only. A stress-free volume v_0 shall be reserved for a lattice site in the homogeneous medium. This volume can be occupied by volumes v_{HS}, v_{LS}, and v_M from a metal-diluted mixed crystal of the $[Fe_xZn_{1-x}(2\text{-pic})_3]X_2 \cdot sol$ type. They can be smaller or larger than v_0, and for the following simple consideration are assumed to be incompressible: When a volume v_α (α = HS, LS, M) is put into the medium (volume V), a stress field is built up, because the volumes v_{HS}, v_{LS}, and v_M are different from v_0. This stress field has an elastic energy [Eq. (13)].[138]

$$E = \tfrac{1}{2}K(\gamma_0-1)(v_\alpha-v_0)^2/v_0 - \tfrac{1}{2}K\gamma_0(\gamma_0-1)(v_\alpha-v_0)^2/V \qquad (13)$$

The Eshelby constant γ_0 is related to the Poisson ratio σ as follows: $0 \le \gamma_0 = 3(1-\sigma)/(1+\sigma) \le 3$. The second term in Equation (13) is very small since V/v_0 is of the order of Avogadro's number. It vanishes in an infinite medium, so the elastic energy

for an isolated complex in the lattice is given by the first term only. In a liquid solution, the inner degrees of freedom of the complex alone are active, and to these the difference in the elastic energies between the HS and the LS state during spin transition are added for the highly dilute mixed crystal. In this simple picture the energy difference between transitions in mixed crystals (see Fig. 16) is traced back to the differences in K, γ_0, and v_0. We shall not discuss this energy difference in the following.

In the finite crystal, an interaction between the defects gives rise to the second term. It is caused by the image pressure of the defect in a finite crystal. The crystal volume V changes upon incorporation of v_x on the v_0 site by more than just $v_x - v_0$, namely by δv_x [Eq. (14)].[138]

$$\delta v_x = \gamma_0(v_x - v_0) \tag{14}$$

This additional volume change $\delta v_x - (v_x - v_0) = (\gamma_0 - 1)(v_x - v_0)$ is formally attributed to a pressure $p_i = -K(\gamma_0 - 1)(v_x - v_0)/V$, and the second term in Equation (13) ($\frac{1}{2} p_i \delta v_x$) can be interpreted as volume work against that pressure.[138] Of course, the term "pressure" applies only for defects centered in a sphere, otherwise the stress field is no longer homogeneous. Eshelby, however, could show that δv_x remains valid irrespective of the form of V and the location of the defect. A homogeneous distribution of defects results in a homogeneous stress field, so again we can speak of a "pressure". The pressure is positive when ions with $v_x < v_0$ are incorporated and negative when bigger volumes are embedded. This effect can be used for the creation of positive or negative pressures by replacing atoms in the crystal with smaller or larger foreign atoms. The term "chemical pressure" is therefore also in use. Although small for a single defect, for one mole of defects it adds up to a finite entity which acts on all defects. For N defects in a crystal we obtain E_{total} according to Equation (15).

$$E_{\text{total}} = \tfrac{1}{2} K(\gamma_0 - 1) \sum_{i=1}^{N} (v_i - v_0)^2 / v_0 - \tfrac{1}{2} K \gamma_0 (\gamma_0 - 1) \left[\sum_{i=1}^{N} (v_i - v_0) \right]^2 / V \tag{15}$$

If we express the fraction x and γ_{HS} according to Equation (16) and consider the γ_{HS}-dependent terms in the elastic

$$\frac{1}{N} \sum_{i=1}^{N} (v_i - v_0) = x[\gamma_{\text{HS}}(v_{\text{HS}} - v_0) + (1 - \gamma_{\text{HS}})(v_{\text{LS}} - v_0)] + (1 - x)(v_{\text{M}} - v_0) \tag{16}$$

energy, we obtain an interpretation of $\Delta(x)$ and $\Gamma(x)$ within the phenomenological approach for the free energy [Eq. (17)].[140]

$$\Gamma(x) = x \tfrac{1}{2} K \gamma_0 (\gamma_0 - 1)(v_{\text{HS}} - v_{\text{LS}})^2 / v_c \tag{17a}$$

$$\Delta(x) = x K \gamma_0 (\gamma_0 - 1)(v_{\text{HS}} - v_{\text{LS}})(v_{\text{M}} - v_{\text{LS}}) / v_c \tag{17b}$$

The expression $v_c = V/\text{N}$ gives the volume per complex molecule. We see that Δ and Γ depend linearly on x, as is observed, and that all parameters can be experimentally determined. Note that v_0 is absent from the formulas. Thus, $\gamma_0(v_{\text{HS}} - v_{\text{LS}})/v_c$ is the relative volume increase on going from the LS to the HS state, that is, the trace of the ε tensor $\varepsilon_s^{\text{HL}}$ from a variable-temperature structure determination. We obtain $\varepsilon_s^{\text{ML}} = \gamma_0(v_{\text{M}} - v_{\text{LS}})/v_c$ from a comparison of the unit cell volumes of the metal compound and the Fe compound in the LS state. K and γ_0 are accessible as elasticity constants.

It should be stressed that for this type of interaction the Bragg–Williams approach is a very good approximation, since for the spherical part of the elastic interaction in an isotropic medium there is no direct, short-range interaction that could give rise to correlations between the HS and LS states. The image pressure is ubiquitous and effectively extends to infinity. The slowly changing anisotropic stress fields stemming from the location of the defects within V and its shape do not lead to short-range correlations.

If we use typical values (from X-ray structure analyses) for K ($= 10^{10}$ Pascal) and γ_0 ($= 1.5$; $\sigma = 1/3$) along with $\delta v_{\text{HL}} = 12\ \text{Å}^3$ and $v_c \approx 600\ \text{Å}^3$, we obtain $\Gamma = 20\ \text{cm}^{-1}$ for the interaction constant, which is merely 13% of the value of Γ in the free energy in the $[\text{Fe(2-pic-ND}_2)_3]\text{Cl}_2 \cdot \text{EtOD}$ system.[140] It is remarkable that the ratio $\Delta/\Gamma = 2\varepsilon_s^{\text{ML}}/\varepsilon_s^{\text{HL}}$ corresponds very well to the experimental value. The unit cell volumes of the M = Zn compound and the HS compound are almost equal. For example, at room temperature in the nondeuterated compound $[\text{M(2-pic)}_3]\text{Cl}_2 \cdot \text{EtOH}$, Mikami et al.[72] found 2485 Å^3 for the M = Fe(HS) compound and 2482 Å^3 for the Zn compound, whereas the difference between the HS and LS states is 57 Å^3. This predicts that $\Delta/\Gamma \approx 2$, in good agreement with the value of $273\ \text{cm}^{-1}/152\ \text{cm}^{-1} = 1.8$ obtained from the free energies. This correspondence apparently is the result of similar ionic radii for Zn^{2+} and Fe^{2+}(HS).

For both cases of mixed crystals $[\text{Fe}_x\text{Co}_{1-x}\text{(2-pic)}_3]\text{Cl}_2 \cdot \text{sol}$ (sol = EtOH and MeOH),[42] the ratio Δ/Γ is smaller than for the Zn compounds with the same solvent (Δ/Γ(EtOH) = 1.46[41] and Δ/Γ(MeOH) = 1.30 for Co and Δ/Γ(EtOH) = 1.58[44] and Δ/Γ(MeOH) = 1.60 for Zn), in accordance with the smaller Co^{2+} radius and the smaller unit cell volume, which was determined as 2467 Å^3 for $[\text{Co(2-pic)}_3]\text{Cl}_2 \cdot \text{EtOH}$ at room temperature. As we expected, the energy shift $\Delta(x)$ depends only on the chemical pressure of the substituted ions, whereas the interaction constant Γ is determined only by the density of the spin-changing Fe ions. Even though the ratio of the constants and the trends in size and concentration of the substituted ions are predicted quite well, the volume dilatation cannot explain the magnitude of the absolute values. It seemed reasonable to generalize the approach from the theory of elasticity for anisotropic defects, and thus, presumably, to keep these correct trends. This problem was treated in two articles,[43, 44] and the results are briefly summarized in the following.

The problem of anisotropic lattice deformation still has a relatively simple solution if the crystal (the homogeneous medium) has the shape of a sphere. An additional term, formed from the components of the trace-free tensor $\varepsilon_d^i = \varepsilon^i - \varepsilon_s^i/3 \cdot 1_3$ (i = HL, ML; 1_3 is the 3×3 unit matrix), is added to Δ and Γ. If $\varepsilon_{d,m}$ denotes the spherical components ($M = -2, -1, \ldots, 2$), Δ and Γ are defined by Equations (18).[43]

$$\Delta(x) = x K v_c (\gamma_0 - 1)/\gamma_0 \left[\varepsilon_S^{HL} \varepsilon_S^{ML} + \frac{3}{10}(2\gamma_0 + 1) \sum_m \varepsilon_{d,m}^{HL*} \varepsilon_{d,m}^{ML} \right] \quad (18a)$$

$$\Gamma(x) = x \frac{1}{2} K v_c (\gamma_0 - 1)/\gamma_0 \left[\left(\varepsilon_S^{HL} \right)^2 + \frac{3}{10}(2\gamma_0 + 1) \sum_m \varepsilon_{d,m}^{HL*} \varepsilon_{d,m}^{HL} \right] \quad (18b)$$

The proportionality to the concentration is, of course, retained. The extension of Equations (17a) and (17b) are contained in the second additive terms within the square brackets. The similar form of the expressions for Δ and Γ ensures that the ratio will still be close to 2. In Figure 21 the isotropic part (curve A) and the sum of the isotropic and anisotropic part (curve B) are plotted as a function of Γ/K versus γ_0 for the ε^{HL} tensors of two compounds.

As a new feature, the direct elastic interactions of the defects are treated in a third term, which vanishes for isotropic defects. This interaction energy can only be dealt with by numeric summation, since it depends on the relative positions and orientations of the defects in the single crystal. From X-ray crystal structure analysis we obtain the temperature-dependent average of the ε tensors belonging to the defects on the equipoints in the unit cell. For symmetrically equivalent lattice sites the corresponding ε tensors ε_i^{HL}(local) (the index i runs over all n positions in the unit cell) are distinguished only by their orientation. Under favorable conditions, namely if the average in crystals from different structures is formed in different ways, we can determine the local tensor ε_i^{HL} at the i-th equipoint. The necessary assumption is that the complex creates the same stress fields on transition from the HS to the LS state. This is true if their elastic properties are the same. The isotropic fraction $\delta v_{HL} = \gamma_0 (v_{HS} - v_{LS})$ is the same in different lattices (the complexes themselves are assumed to be incompressible, so $(v_{HS} - v_{LS})$ is independent of their environment) if γ_0 has the same value in both media. The data for the two spin crossover compounds in Figure 21 known so far do not contradict these requirements. They have exactly the same volume expansion δv_{HL}, so that at least an effective γ_0 must be the same for both compounds. They have different crystal structures with monoclinic (EtOH, $n = 4$) and orthorhombic (MeOH, $n = 8$) symmetry, well suited for the determination of all five ε tensor components belonging to the $[Fe(2\text{-pic})_3]^{2+}$ complex.[44] Whereas their isotropic components in the image pressure interaction are equal (ε_s is the same), the anisotropic contribution to the image pressure (curve B in Fig. 21) is much smaller for the MeOH system than for the EtOH system. This is a consequence of the different averaging over different equivalent orientations of the ε tensor in the two crystals.

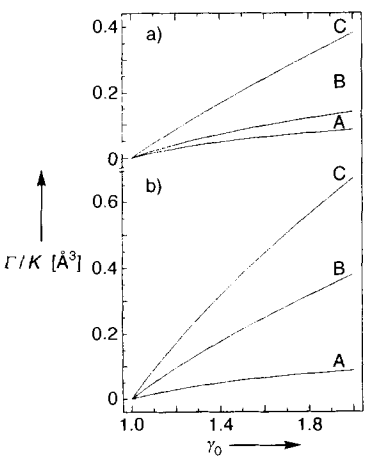

Fig. 21. The interaction constant Γ divided by the elastic (bulk) modulus K plotted versus the Eshelby constant γ_0 for two compounds $[Fe(2\text{-pic})_3]Cl_2 \cdot$sol: a) sol = MeOH and b) sol = EtOH. Γ/K was calculated from the deformation tensors ε^{HL} of the two compounds. The three curves for each compound show the different contributions included in the calculation. Curves A take into account only the isotropic part of the deformation tensor. Curves B include the interaction from the anisotropic image pressure. Curves C represent the total elastic interaction including the direct interaction between the HS complexes in a medium with a spherical shape (from ref. [44]).

A numerical summation of the direct interaction with the local tensor has been carried out over a sphere of radius 600 Å^3 (approximately). It can be shown analytically that further summation towards the edge of the macroscopic crystal will not yield any additional contribution as long as the microscopic sphere is contained in the macroscopic one. No special treatment was given to the interaction of the edge atoms in the crystal. In Figure 21 the C curves represent the sum over all elastic interactions. Especially for the MeOH compound (Fig. 21a), the direct interaction is the dominant part.

Applying the rigorous assumption of equal elastic constants K and γ_0 without any presupposition about the absolute values of the compressibility K, we now use the experimental values of $\Gamma^{MeOH} = 98\ cm^{-1}$ and $\Gamma^{EtOH} = 175\ cm^{-1}$ and their ratio ($\Gamma^{MeOH}/\Gamma^{EtOH} = 0.56$) to fix $\gamma_0 = 1.53$ at a point where the quotient of the theoretical curves in Figure 21 reaches the same ratio. At this point we have $\Gamma^{EtOH}/K = 0.43$ Å^3 and $K = 0.86 \times 10^{10}\ Nm^{-2}$, a value we can safely regard as typical for organometallic compounds of that kind.

In summary we conclude that a full description of the interaction term in the phenomenological approach for the free energy of a spin crossover compound can be derived from the microscopic elastic interaction between the HS and the LS complexes. Even though the simplified model of an isotropic elastic medium with a spherical shape does not allow exact quantitative comparisons with observed data, there is no question that the magnitude of the elastic contribution is of the same order as the experimental values. Any additional contribution is either small or a part of other contributions of which the sum must again be small.

3.4.2. Other Models

Two contributions to the interaction problem from the literature deserve some discussion. Zimmermann and König[141] have treated the phonon component in the interaction. They derive a phonon contribution of $bNk_B\theta(\Delta\theta/\theta)^2$, stemming from a change in the Debye temperature θ of the lattice upon transition from the LS to the HS state. It can be understood as follows. While the crystal volume increases as the HS fraction increases, the Debye temperature decreases because of the anharmonicity of the oscillator potentials. Consequently, the phonons acquire a higher density of states, and the free energy is lowered accordingly, not only as a result of the lower frequencies but, more crucially, of an increase in vibrational entropy. The nonlinear relationship between θ and γ_{HS} on one hand and the free energy of the Debye crystal on the other yields a $-bNk_B\theta(\Delta\theta/\theta)^2$ term as the coefficient of γ_{HS}^2 in a potential series

for γ_{HS}. This term is estimated at $-40\ cm^{-1}$ by the authors; this estimate is much too big for two reasons. The first is that the decrease in the vibrational frequencies on increasing the volume does not affect the intramolecular frequencies, with the result that only the Debye temperature θ for the long-wave acoustic branch related to the sonic speed and the elastic (bulk) modulus must be included. It is about 50 K. The change in the intramolecular frequencies is already accounted for in the difference of the free energies for the highly dilute systems. It contributes nothing to the interaction. By the same argument, N cannot be taken as the number of atoms in the complex, but rather is equal to 1, because the complex in the Debye model must be treated as a single entity. The high-temperature approximation for the constant $b \approx 3T/\theta$ holds in the transition range $T > 100$ K. The Grüneisen formula $\theta_{HS} = \theta_{LS}(V_{HS}/V_{LS})^{-\gamma_G}$ can be used to obtain an estimate for $\Delta\theta/\theta$ of 0.1 ($\gamma_G = 3$). The phonon contribution is therefore smaller than $3\ cm^{-1}$ and can still be neglected within the scope of the present discussion.

The theory of the second contribution was developed by Kambara,[38, 142, 143] who, within the framework of crystal field theory, regards the cooperative Jahn–Teller coupling of the 3d electrons to the molecular deformation as the cause for the HS → LS transition. In the first articles only the isotropic part (A_1 mode) was treated.[142, 143] Later the model was expanded to include the E_g mode. The change of vibrational modes, which proved to be significant, is not taken into account. Aside from the general shortcomings of crystal field theory, only direct elastic interactions are considered in this approach and the substantial part of the image pressure is entirely neglected. For the A_1 deformation (which in an isotropic medium entails no direct interaction) this means that only small corrections can play a role because of the anisotropy of the medium. The anisotropic Jahn–Teller interaction of the $^5T_{2g}$ HS state is certainly small, if significant at all. From its temperature-dependent quadrupole splitting we have proof that the T_{2g} triplet is already completely split in a highly dilute mixed crystal containing only a few Fe complexes.[144] The splitting, depending on the HS fraction γ_{HS}, barely changes for the pure Fe compound. This means that any deformation of the complex during the spin transition is independent of x and γ_{HS}, and that additional deformations due to the cooperative Jahn–Teller effect must be small. Even though, at first sight, the approach of Kambara seems to be an elegant one, because it contains the inner elasticity of the complexes, it obviously accounts only for rather small contributions. The parameters in his model cannot be translated into meaningful quantities which could be related to observed values of the deformation tensor and the changes in Fe–N bond lengths. Kambara himself has not tried such a verification.

4. Light-Induced Spin Transitions

Iron(II) coordination compounds have had a comparatively miserable standing compared to other transition metal complexes with respect to the investigation of their photophysical and photochemical properties. The primary reason was that they do not have optically excited states with long lifetimes as the latter do. Their low-energy LF states are generally associated with radiationless relaxations back to the ground state through a series of intersystem crossing (ISC) and internal conversion (IC) steps on a subnanosecond time scale.

After Decurtins et al.[64, 65] discovered the phenomenon of light-induced $^1A_1(LS) \rightarrow {}^5T_2(HS)$ transitions in iron(II) spin crossover compounds at temperatures far below the thermal spin transition temperature while investigating the spin transition in $[Fe(ptz)_6](BF_4)_2$ by optical spectroscopy, it became clear that iron(II) coordination compounds can also have photophysical properties worthy of attention. A two-step mechanism of ISC's with $\Delta S = 1$ each was postulated for the light-induced spin transition leading from the original $^1T_1$ excited LF state via a low-energy $^3T_1$ state to the final $^5T_2$ state. Because of the large difference in bond lengths associated with the transition from the LS to the HS state,[36, 72, 82] the energy barrier between the two states is big enough to "freeze" the system in the HS state at low temperatures. The phenomenon of the light-induced spin transition was therefore termed "light induced excited spin state trapping", in short LIESST.

Further work subsequently established the existence of the light-induced reverse transition (reverse-LIESST effect), and finally, evidence for the proposed mechanism with the $^3T_1$ state as an intermediate was discovered.[145, 146]

4.1. The $[Fe(ptz)_6](BF_4)_2$ Spin Crossover System

4.1.1. Thermal Spin Transition

The thermal spin transition in $[Fe(ptz)_6](BF_4)_2$ was first investigated by Franke et al.[100] and Müller et al.[78] by means of magnetic susceptibility measurements. In the concentrated solid the transition from the diamagnetic LS state to the strongly paramagnetic HS state involves a crystallographic first-order phase transition with a hysteresis effect of about 7 K ($T_c^{\uparrow} = 135$ K, $T_c^{\downarrow} = 128$ K) and a change in Fe–N bond lengths of $\Delta r_{HL} \approx 0.18$ Å.

Not only do the magnetic properties change with the spin transition, so does the color: $[Fe(ptz)_6](BF_4)_2$ in the LS state at 20 K is deep purple, whereas in the HS state at 293 K it is colorless. The corresponding single crystal absorption spectra with the direction of light propagation along the crystallographic c axis are shown in Figures 22a and 22b. The exctinction coefficients of the bands in the NIR and visible regions are within the range typical for spin-allowed LF transitions. According to the Tanabe–Sugano diagram in Figure 1, the one band in the room temperature spectrum at $\bar{\nu} = 11\,760\ cm^{-1}$ can be assigned without difficulty to the $^5T_2 \rightarrow {}^5E$ transition, and the two bands in the low-temperature spectrum at $\bar{\nu} = 18\,210$ and $26\,400\ cm^{-1}$ to the $^1A_1 \rightarrow {}^1T_1$ and $^1A_1 \rightarrow {}^1T_2$ transitions. The LF strengths for the HS and the LS state are given by Equations 19.[147]

$$10\,Dq^{HS} = E(^5E) - E(^5T_2) = 11\,760\ cm^{-1} \quad (19a)$$

$$10\,Dq^{LS} = E(^1T) - E(^1A_1) + (E(^1T_2) - E(^1T_1))/4 = 20\,550\ cm^{-1} \quad (19b)$$

Thus $10Dq^{LS}/10Dq^{HS} = 1.75$ and very close to the estimated value from Equation (3) (see Section 2.1).

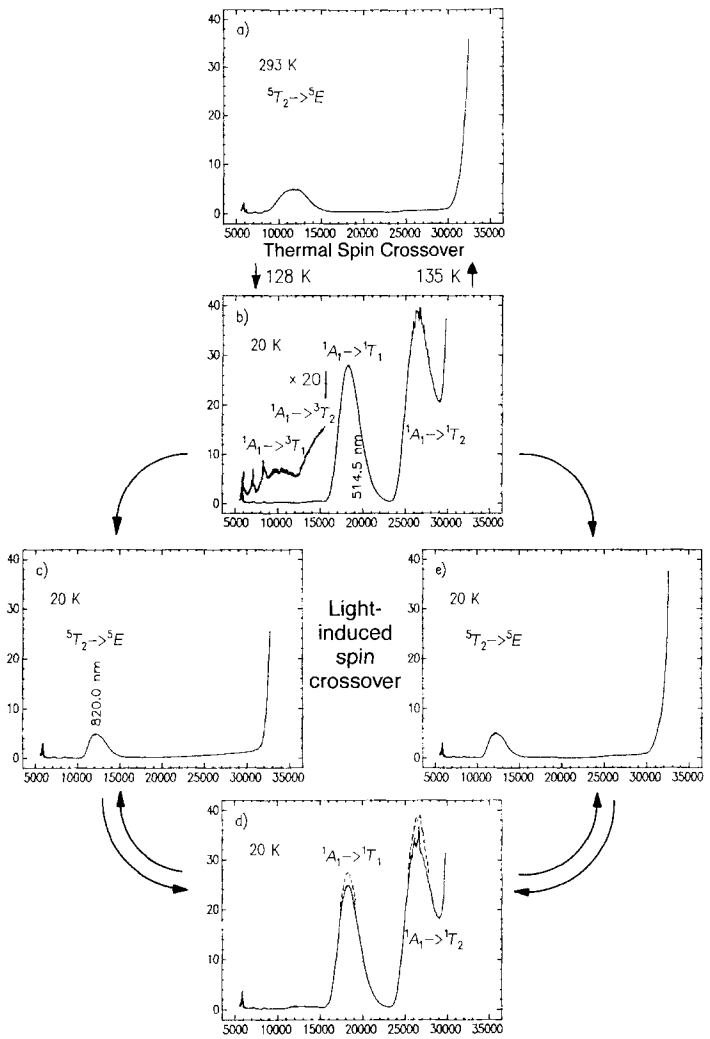

Fig. 22. Single crystal absorption spectra with the light propagating along the crystallographic c axis of $[Fe(ptz)_6](BF_4)_2$ in the range of the d–d transitions at a) 293 K and b) 20 K; c) after irradiation at 514.5 nm (20 K), d) after subsequent irradiation at 820 nm (20 K), e) after irradiation at 980 nm (20 K) (from ref.[146]). See text for an explanation of the overlay in b). In each case ε [L mol^{-1} cm^{-1}] is plotted along the y axis and $\tilde{\nu}$ [cm^{-1}] along the x axis.

The LS or HS fraction as a function of temperature can be determined from the explicit temperature dependence of the band intensity, for example for the $^1A_1 \rightarrow {}^1T_1$ band. The resulting transition curve for the thermal spin transition in $[Fe(ptz)_6](BF_4)_2$ with the well-known hysteresis is shown in Figure 23. It matches the curve obtained from susceptibility measurements well.[81, 100, 148]

The absorption spectra at 20 and 293 K of a mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$) and those of the concentrated material are identical.[145] This implies that a complete thermal spin transition occurs also in the mixed crystal. The transition curve (see Fig. 23), however, is gradual with a transition temperature $T_{1/2} \approx 95$ K and without hysteresis because only minor elastic interactions are left at such a low Fe concentration.

By sufficiently rapid cooling, however, the first-order crystallographic phase transition in $[Fe(ptz)_6](BF_4)_2$ can be suppressed.[149] But also in the crystallographic high-temperature phase (space group $R\bar{3}$[100]) the thermal spin transition is complete. The corresponding transition curve with $T_{1/2} \approx 125$ K is

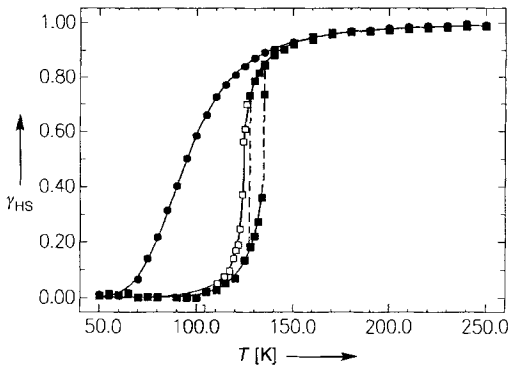

Fig. 23. The thermal spin transitions in $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$, •) and $[Fe(ptz)_6](BF_4)_2$ (■) with a crystallographic phase transition and in the supercooled high-temperature phase (□), determined from the temperature dependence of the $^1A_1 \rightarrow {}^1T_1$ absorption band. The solid line for the dilute system (•) was calculated for the model of a unimolecular, temperature-dependent LS⇌HS equilibrium: $\Delta G_{HL} = \Delta H_{HL} - T\Delta S_{HL} = -k_B T \ln K$ with $\Delta H_{HL} = 462$ cm^{-1} and $\Delta S_{HL} = 4.9$ cm^{-1} K^{-1}. The critical temperatures for the concentrated system are $T_c^{\downarrow} = 135$ K and $T_c^{\downarrow} = 128$ K (from ref.[146]). The solid line connecting the points for the supercooled high-temperature phase was calculated with an interaction constant $\Gamma = 170$ cm^{-1}.

included in Figure 23. Still the transition is much steeper than for the isostructural mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$. Following the thermodynamic considerations outlined in Section 3, it can be reproduced with an interaction constant Γ of about 170 cm^{-1}.[68, 80] Characteristically, the high-temperature spin transition curves of the concentrated and the dilute systems are parallel, because the volumes v_{Zn} of the Zn complex and v_{HS} of the Fe complex in the HS state are approximately equal.[137]

According to Figure 24 there are several triplet states additional to the higher excited quintet and singlet states. Spin for-

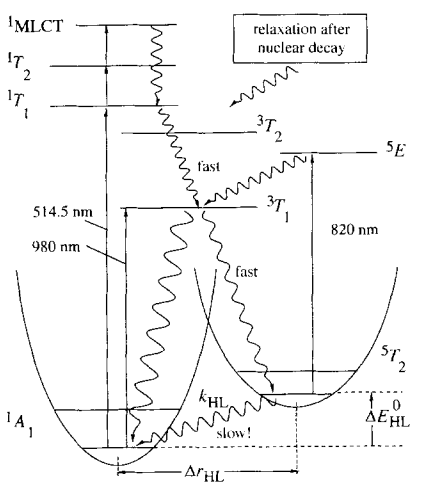

Fig. 24. Schematic representation of the excited higher LF states of a d^6 complex for LF strengths in the spin crossover range. Spin allowed d–d transitions are denoted by straight arrows. The scheme fully illustrates the complete mechanism of LIESST and reverse-LIESST.

bidden singlet → triplet transitions will not only be very weak but also as broad as the spin-allowed ones, since these triplet states are not based on the t_2^6 configuration like the $^1A_1$ ground state.

Indeed, a close inspection of the $[Fe(ptz)_6](BF_4)_2$ absorption spectrum at 20 K (see overlay in Fig. 22b) reveals two very weak and broad bands on the low energy side of the $^1A_1 \rightarrow {}^1T_1$ band. One is at $\tilde{\nu} = 10280\ cm^{-1}$ and the other (as a shoulder on the rising slope of the $^1A_1 \rightarrow {}^1T_1$ band) at $\tilde{\nu} \approx 14300\ cm^{-1}$, and they can be assigned to the spin forbidden $^1A_1 \rightarrow {}^3T_1$ and $^1A_1 \rightarrow {}^3T_2$ transitions.

4.1.2. Light-Induced Excited Spin State Trapping (LIESST)

Irradiation into the $^1A_1 \rightarrow {}^1T_1$ band of a $[Fe(ptz)_6](BF_4)_2$ crystal with the 514.5 nm line of an Ar^+ laser at temperatures below about 50 K completely bleaches the crystal within a short time. The absorption spectrum after irradiation again shows the $^5T_2 \rightarrow {}^5E$ band typical of the HS state in the NIR region, but the LS bands in the visible spectrum have disappeared (compare Figs. 22b and 22c). Consequently a complete light-induced LS → HS conversion has taken place. The absorption maximum of the $^5T_2 \rightarrow {}^5E$ band now is at $\tilde{\nu} = 12200\ cm^{-1}$, slightly blue-shifted from the 293 K value, exactly as expected for an LF transition upon cooling. At 20 K $10Dq^{HS}$ is thus $12000\ cm^{-1}$. At this temperature the HS state is a metastable one that virtually has an infinite lifetime. Only at temperatures above about 50 K does a noticeable thermal relaxation back to the LS state set in.

Figure 24 shows schematically the two-step ISC mechanism, postulated by Decurtins et al.,[65] with $\Delta S = 1$ for each step from the originally excited $^1T_1$ state via the $^3T_1$ state to the $^5T_2$ state. Because the energy level of the $^3T_1$ state is lower not only than the $^1T_1$ state but, for the spin crossover systems, also than the ^5E state, a light-induced reverse transition seems feasible. And indeed, if in a second step the colorless crystal is now irradiated in the band maximum of the $^5T_2 \rightarrow {}^5E$ transition at 820 nm with light from a Ti-sapphire laser while the temperature is kept at 20 K, its orginal red color soon returns. Figure 22d shows that effectively a light-induced reverse transition (reverse-LIESST) has occurred. However, the reverse transition is not quite complete. Even after repeated irradiation a saturation value for the LS fraction of only $\gamma_{LS} \approx 0.9$ is reached. The most straightforward explanation is that the LS species has a weak absorption band overlapping with the quintet band in such a way that this absorption in turn entails another light-induced LS → HS transition. Indeed the two spin-forbidden transitions of the LS species, the $^1A_1 \rightarrow {}^3T_1$ and the $^1A_1 \rightarrow {}^3T_2$ transitions, overlap with the $^5T_2 \rightarrow {}^5E$ transition (see Figs. 22a and 22b). Although the minimum between the two spin-forbidden transitions is just at 820 nm, the absorption does not quite return to zero.

The maximum of the $^1A_1 \rightarrow {}^3T_1$ band at $10280\ cm^{-1}$ (980 nm) is just to the low-energy side of the $^5T_2 \rightarrow {}^5E$ band. The crystal (with a normal LS spectrum at 20 K) can now be irradiated with a narrow band around 980 nm from a Ti-sapphire laser, and again a complete light-induced LS → HS conversion results (see Fig. 22e). This proves 1) that the two weak bands do not arise from impurities, and therefore their assignment to the spin-forbidden transitions is justified, and 2) that the mechanism for LIESST with the $^3T_1$ state as an intermediate state as shown in Figure 24 is correct.

LIESST and reverse-LIESST can also be followed quantitatively,[145] and the quantum yields of the ISC processes of the LIESST and reverse-LIESST mechanism can be determined.[146] Those for the first step, the $^1T_1 \rightarrow {}^3T_1$ transition for LIESST and the $^5E \rightarrow {}^3T_1$ transition for reverse-LIESST, are close to unity. The branching ratio from the $^3T_1$ state either into the $^1A_1$ ground state or the metastable $^5T_2$ state is about 1:4. The lower limit for the relaxation rate constants for the ISC processes (with the exception of the $^5T_2 \rightarrow {}^1A_1$ relaxation) is $10^9\ s^{-1}$, because up to now no transient populations of an intermediate state on the nanosecond time scale could be found with pulsed laser experiments.[150-152]

The $^5T_2 \rightarrow {}^1A_1$ relaxation, however, is very slow at low temperatures; in $[Fe(ptz)_6](BF_4)_2$ its metastable state at 10 K has a lifetime of roughly 40 days. Only above about 50 K does a noticeable thermal relaxation begin to set in. There, strong cooperative interactions are conspicuous in the concentrated solid (see Section 5).

4.2. The $[Fe(mtz)_6](BF_4)_2$ Spin Crossover System

In principle, by analogy with reverse-LIESST, it should also be possible to trigger a light-induced HS → LS conversion by irradiation in the NIR region for the case $\Delta E^0_{HL} < 0$ (that is, for stable HS complexes). For this, the minimum of the ^5E potential well must, at any rate, lie energetically above the well for the $^3T_1$ state, which is only the case for complexes whose LF strengths are not significantly below $10Dq^{HS}$ for a spin crossover compound.

Such a HS → LS conversion was first realised for the methyl-substituted compound $[Fe(mtz)_6](BF_4)_2$ (mtz = 1-methyltetrazole).[153] In this system the $[Fe(mtz)_6]^{2+}$ complexes are distributed over two nonequivalent lattice sites.[36] Complexes on the lattice site denoted as A show a thermal spin transition with a transition temperature $T_{1/2} \approx 75$ K. For those on the lattice site denoted as B, however, a doublet with a large quadrupole splitting characteristic of an HS state is observed in the Mössbauer spectrum even at low temperatures (see Fig. 25a). This means

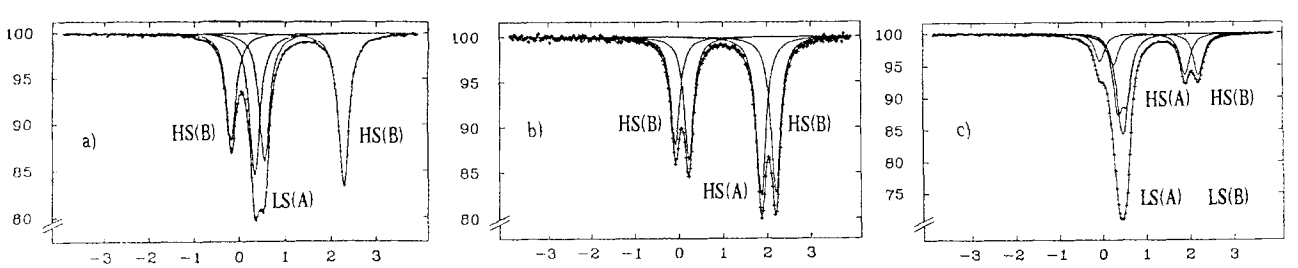

Fig. 25. Mössbauer spectra of $[Fe(mtz)_6](BF_4)_2$: a) at 20 K, b) at 20 K after irradiation in the visible range (300-600 nm), c) at 20 K after irradiation in the NIR region (700-1000 nm) (adapted from ref.[153]). The relative transmission is plotted along the ordinate and the relative velocity v [$mm\,s^{-1}$] between source and absorber along the abscissa.

that the HS state is the ground state on lattice site B and thus $\Delta E^0_{HL} < 0$.

The complex molecules on lattice site A show a LIESST behavior analogous to the one in $[Fe(ptz)_6](BF_4)_2$. Irradition in the visible region at 20 K causes a complete LS(A) → HS(A) conversion, whereas, as expected, the complexes on lattice site B remain unaffected (Fig. 25b). The light-induced HS state on lattice site A at 20 K has a lifetime similar to that in $[Fe(ptz)_6](BF_4)_2$, and likewise the HS(A) → LS(A) relaxation sets in at temperatures above about 50 K. Irradiation in the NIR region for the lattice site A as well as for the lattice site B results in a steady-state distribution with $\gamma_{LS}(A) \approx \gamma_{LS}(B) \approx 0.65$, just like in $[Fe(ptz)_6](BF_4)_2$ (Fig. 25c). However, for the lattice site B the light-induced HS(B) → (LS(B) conversion corresponds to the population of a metastable LS state. This state now has a very long lifetime at 20 K. Here the LS(B) → HS(B) relaxation does not set in until above about 50 K.

4.3. LIESST in Other Iron(II) Spin Crossover Systems

Since the discovery of LIESST in $[Fe(ptz)_6](BF_4)_2$, light-induced metastable HS states could be produced in a great number of Fe(II) spin crossover complexes. Not only in concentrated materials such as $[Fe(pic)_3]X_2 \cdot sol$ (X = Cl, Br; sol = MeOH, EtOH,[65] $[Fe(phen)_2(NCS)_2]$,[66] $[Fe(2\text{-mephen})_3](ClO_4)_2$ (mephen = methylphenanthroline),[154] and others,[155–157] but also in the dilute mixed-crystal systems $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$,[146] $[M_{1-x}Fe_x(pic)_3]Cl_2 \cdot sol$ (M = Mn, Zn; sol = MeOH, EtOH,[152, 158] and $[Zn_{1-x}Fe_x(mepy)_3(tren)](PF_6)_2$ (mepy = methylpyridine, tren = tris(2-aminoethyl)amine),[152] and even in spin crossover complexes embedded in polymer foils,[159] among others in the $[Fe(2\text{-mephen})_3]^{2+}$ complex in polyvinylalcohol (PVA).[160] In the systems just mentioned the lifetimes of the metastable HS states at low temperatures range from 10^1 to 10^5 seconds.

In most of these systems, however, the d–d bands of the LS species are hidden by low-energy, intense metal–ligand charge-transfer (MLCT) bands. The MLCT bands for the LS state are much more intense than those for the HS state, because the shorter metal–ligand bond lengths in the LS state result in stronger overlap between metal and ligand orbitals.

4.3.1. The $[Fe\{(mepy)_3(tren)\}]^{2+}$ Complex

The thermal spin transition of iron(II) complexes with hexadentate ligands of the $\{(mepy)_y(py)_{3-y}(tren)\}$ ($y = 0$–3) type was first investigated by Hoselton et al.[70] by means of magnetic susceptibility measurements. In the $[Fe\{(mepy)_y(py)_{3-y}(tren)\}](PF_6)_2$ series, the thermal spin transition is gradual even in the concentrated solid. The transition temperature $T_{1/2}$ increases from about 215 K for $y = 3$ through about 290 K for $y = 2$ to about 380 K for $y = 1$. The complex with $y = 0$ remains in the LS state up to about 400 K. The increasing stabilization with the increasing number of methyl groups at the pyridyl rings is due to the associated mutual steric interaction of the Me groups, which favors the longer Fe–N distance in the HS state.

Optical spectroscopy with these complexes is only possible for highly dilute systems, because the MLCT band in the LS state is very intense. Figure 26a shows the single crystal absorption spectra of the dilute mixed crystal $[Zn_{1-x}Fe_x\{(mepy)_3(tren)\}](PF_6)_2$ ($x \approx 0.0003$) at temperatures between 15 and 325 K. The transition is gradual and the transition temperature $T_{1/2} \approx 210$ K is virtually equal to the one in the concentrated compound $[Fe\{(mepy)_3(tren)\}](PF_6)_2$.

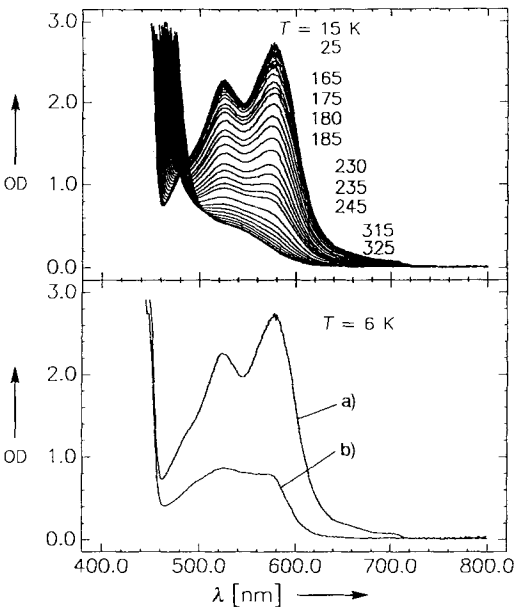

Fig. 26. Single-crystal absorption spectra of $[Zn_{1-x}Fe_x\{(mepy)_3(tren)\}](PF_6)_2$ ($x \approx 0.0003$). Top: at different temperatures in thermal equilibrium; bottom: at 6 K before and immediately after an irradiation with 514.5 nm (from ref.[152]). OD = optical density.

In Figure 26b, in addition to the normal low-temperature spectrum of $[Zn_{1-x}Fe_x\{(mepy)_3(tren)\}](PF_6)_2$, the spectrum immediately after irradiation with light at 514.5 nm is depicted. A comparison with Figure 26a shows that irradiating into the MLCT band causes a light-induced LS → HS conversion as well. The lifetime τ of the light-induced HS state is about 10 s at 6 K, much shorter than for $[Fe(ptz)_6](BF_4)_2$, and it decreases rapidly with increasing temperature.

4.3.2. The $[Fe(2\text{-mephen})_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ Complexes

The $[Fe(2\text{-mephen})_3]^{2+}$ complex is a spin crossover complex in the solid (as $[Fe(2\text{-mephen})_3](ClO_4)_2$[88]) as well as embedded in polymer matrices.[160] The thermal spin transition is gradual in both cases, and the transition temperature $T_{1/2}$ is about 140 K. LIESST also occurs in this iron(II) spin crossover complex in both forms (in the concentrated solid for $[Fe(2\text{-mephen})_3]X_2$ (X = ClO_4, BPh_4)[154] and in various polymer matrices[160]) by irradiating into the MLCT band in the visible region.

The electronic structure of the $[Fe(2\text{-mephen})_3]^{2+}$ complex cannot be very different from that of the $[Fe(phen)_3]^{2+}$ or the $[Fe(bipy)_3]^{2+}$ complex. Although the latter two complexes are typical LS complexes, the HS state (longer Fe–N bond lengths) in the $[Fe(2\text{-mephen})_3]^{2+}$ complex is just stabilized enough with

respect to the LS state, by virtue of the steric interaction of the methyl groups, to turn the compound into a spin crossover complex. Conversely, the conditions in $[Fe(phen)_3]^{2+}$ and the $[Fe(bipy)_3]^{2+}$ complexes cannot be very different from those for spin crossover systems with $\Delta E^0 \approx 2500-3500\ cm^{-1}$.

Already several years before the LIESST effect was discovered, Ensling et al.[161] and Grimm et al.[162] had noted anomalous HS states additional to the LS state in the Mössbauer emission spectra of $[^{57}Co/Co(phen)_3](ClO_4)_2 \cdot 2H_2O$ at low temperatures. As possible explanations they considered either some radiation damage on one of the ligands, or a transient population of the $^5T_2$ state after nuclear decay of the ^{57}Co atom. Figure 27 depicts the time-integrated Mössbauer emission spectra of $[^{57}Co/Co(phen)_3](ClO_4)_2 \cdot 2H_2O$ at 40 (top) and at 172 K (bottom). The spectrum at 172 K with an only weakly split doublet shows an isomer shift and a quadrupole splitting characteristic for the LS state and also observable in the Mössbauer absorption spectrum of $[^{57}Co/Co(phen)_3](ClO_4)_2$. In the emission spectrum at 40 K beside the LS doublet and signals characteristic of iron(III), which is an "aliovalent" charge state as a consequence of nuclear decay, are two doublets with a large quadrupole splitting and isomer shifts characteristic for HS states. One of these doublets, denoted HS1 in the spectrum, has Mössbauer parameters very similar to those of the light-induced state in $[Fe(2\text{-mephen})_3](BPh_4)_2$.[154] The assignment of this HS1 state to the $^5T_2$ state in an otherwise unperturbed $[^{57}Fe(phen)_3]^{2+}$ complex seems appropriate. Grimm et al.[162] determined the lifetime of that state by time-differential Mössbauer emission spectroscopy (TDMS) to be about 390 ns at 10 K, about 205 ns at 47 K, and about 100 ns at 100 K.

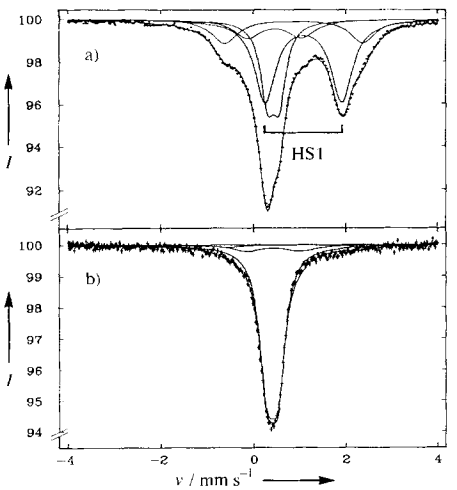

Fig. 27. Mössbauer emission spectra of $[^{57}Co/Co(phen)_3](ClO_4)_2 \cdot 2H_2O$ at a) 40 K and b) 172 K (adapted from ref.[62]). I [%] represents the relative transmission.

The question now is the following: is a light-induced transient population of a HS state also possible in a LS complex, and, if yes, is the nuclear decay-induced transient HS state the same as the light-induced HS state? It is true that Street et al.[163] and Creutz et al.[164] (in an experiment with a pulsed picosecond laser) found a transient state with a liftime $\tau \approx 0.71$ ns for $[Fe(phen)_3]^{2+}$ in solution. However, their assigments included a low-lying ^{3}MLCT state as well as $^1T_1$ and $^3T_1$ states, and they also did not exclude a $^5T_2$ state. For $[Fe(phen)_3]^{2+}$ embedded in a Nafion matrix on the other hand, the lifetime of the light-induced state is about 190 ns at an effective temperature of ≈ 50 K.[165] This lifetime is indeed in accord with the one determined from time-differential Mössbauer spectroscopy, and we can conclude that also in LS compounds the same HS state as in spin crossover compounds is populated after irradiation and after nuclear decay, but its lifetime τ is considerably shorter. Also, in complete agreement with the observations from LIESST experiments, much longer lifetimes of the HS state populated after nuclear decay were observed in the Mössbauer emission spectra of ^{57}Co-doped iron(II) spin crossover complexes.[166-170] By analogy, we call this effect NIESST, meaning nuclear decay-induced excited spin state trapping. The phenomenon has so far only been observed on the ^{57}Co-doped complexes just mentioned. Here the radioactive ^{57}Co atom functions as an intramolecular "quasi light source"—its decay supplies the excitation energy—and the ^{57}Fe daughter atom functions as an intrinsic clock in the time-differential Mössbauer emission spectroscopy experiments.[61, 62, 171]

5. The HS → LS Relaxation in Iron(II) Complexes

During the past years many studies have been performed on the dynamics of the HS → LS relaxation, especially for iron(II) spin crossover compounds in solution and at ambient temperatures.[128, 150, 172-178] Different experimental methods were used to determine the rate constants k_{HL} of the HS → LS relaxation. After the studies of McGarvey and Lawthers,[150] however, pulsed laser excitation has become the most common technique. In solution only a limited temperature range is accessible and $\ln[k_{HL}]$ versus $1/T$ plots (Arrhenius plots) usually resulted in straight lines. The results have accordingly been discussed in terms of semiclassical absolute rate theory. Experimental activation energies E^a for most of the iron(II) spin crossover complexes under study were found to be between $1000-1500\ cm^{-1}$ with preexponential factors A of $10^7-10^9\ s^{-1}$. Thus, values for k_{HL} in solution and at ambient temperatures are typically of the order of $10^6-10^8\ s^{-1}$.

For some iron(II) spin crossover complexes, the HS → LS relaxation rates and activation parameters determined with line shape analysis of Mössbauer spectra[42, 56-59] in the solid state around room temperature were similar to those in solution. This technique, however, is restricted to systems with transition temperatures $T_{1/2}$ around room temperature, because at temperatures where the rate constants k_{HL} fit into the Mössbauer time window of $10^6\ s^{-1} \leq k_{HL} \leq 10^8\ s^{-1}$, HS and LS species must be simultaneously present in sufficient concentrations.

With the discovery of LIESST and the elucidation of the mechanism of light-induced population of metastable HS states, new possibilites to study HS → LS relaxation in the solid and at low temperatures were opened.

The classical energy barrier E^c between the HS and LS potential wells is $2500-3000\ cm^{-1}$ for iron(II) spin crossover compounds with a small zero point energy difference ΔE^0_{HL}. Accordingly, for all iron(II) spin crossover compounds $k_{HL}(T \rightarrow 0)$ should approach zero at low temperatures. That this is not so

already became apparent from the low-temperature lifetimes τ mentioned in Section 4: the approximate value of τ is between 10^6 s ($k_{HL} \approx 10^{-6}$ s^{-1}) for the $[Fe(ptz)_6](BF_4)_2$ system and 10 s ($k_{HL} \approx 10^{-1}$ s^{-1}) for the $[Zn_{1-x}Fe_x\{(mepy)_3(tren)\}](PF_6)_2$ system. Xie and Hendrickson[151] have investigated the temperature dependence of the HS → LS relaxation rate constant $k_{HL}(T)$ in the $[Fe\{(mepy)_2(py)(tren)\}](PF_6)_2$ spin crossover system embedded in polystyrene sulfonate (PSS), using pulsed laser excitation. The value of approximately 10^4 s^{-1} they found for $k_{HL}(T \rightarrow 0)$ is somewhat larger than in the systems just mentioned, and also displayed a marked deviation from classical behavior: above about 100 K the HS → LS relaxation is thermally activated with activation parameters in the normal range, but below about 80 K k_{HL} is more or less temperature independent. This is typical for a tunneling process. Analogous behavior was found for the $[Fe(pic)_3]^{2+}$ complex in the metal-diluted mixed crystal $[Zn_{1-x}Fe_x(pic)_3]Cl_2 \cdot MeOH$ ($k_{HL}(T \rightarrow 0) \approx 10^{-1}$ s^{-1}) already mentioned,[58, 158] and even for the LS complex $[Fe(bipy)_3]^{2+}$ in the diluted mixed crystal $[Zn_{1-x}Fe_x(bipy)_3](PF_6)_2$ ($k_{HL}(T \rightarrow 0) \approx 10^{-6}$ s^{-1}).[165]

Thus the question arises which parameters govern the lifetime of the metastable HS state in such a way that in one extreme low-temperature tunneling rates $k_{HL}(T \rightarrow 0)$ of less than 10^{-6} s^{-1} and in the other more than 10^6 s^{-1} result. It is obvious that classical concepts for the understanding of the HS → LS relaxation process must fail. Already several years ago, Buhks et al.[67] pointed out that HS → LS relaxation is in all probability a highly nonadiabatic process.

5.1. The HS → LS Relaxation in Dilute Mixed-Crystal Systems

For a systematic determination of the HS → LS relaxation rate constants $k_{HL}(T)$ as a function of temperature, the Fe(II) spin crossover complexes $[Fe(ptz)_6]^{2+}$, $[Fe(pic)_3]^{2+}$, $[Fe\{(mepy)_y(py)_{3-y}(tren)\}]^{2+}$ ($y = 1-3$), and the LS complexes $[Fe\{(py)_3(tren)\}]^{2+}$ and $[Fe(bipy)_3]^{2+}$ from the diluted mixed-crystal systems $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$), $[M_{1-x}Fe_x(pic)_3]Cl_2 \cdot sol$ (M = Mn, Zn; sol = MeOH, EtOH; $x \approx 0.0003$), $[Zn_{1-x}Fe_x\{(mepy)_y(py)_{3-y}(tren)\}](PF_6)_2$ ($y = 0-3$; $x \approx 0.0003$), and $[Zn_{1-x}Fe_x(bipy)_3](PF_6)_2$ ($x \approx 0.0001$) were considered.

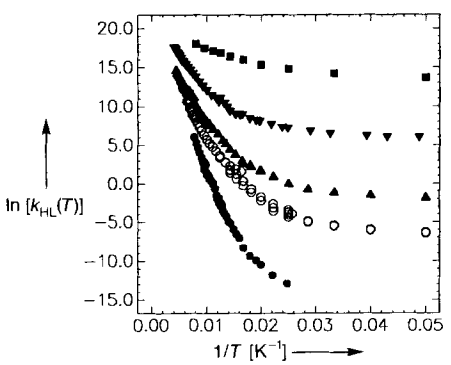

Fig. 28. Observed HS → LS relaxation rates as $\ln[k_{HL}(T)]$ versus $1/T$ plotted for $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ●, $[Mn_{1-x}Fe_x(pic)_6]Cl_2 \cdot MeOH$ ○, $[Zn_{1-x}Fe_x\{(mepy)_3(tren)\}](PF_6)_2$ ▲, $[Zn_{1-x}Fe_x\{(py)_3(tren)\}](PF_6)_2$ ▼, and $[Zn_{1-x}Fe_x(bpy)_3](PF_6)_2$ ■ (from ref. [152]).

HS → LS relaxation curves after light-induced population of the metastable HS state were recorded on single crystals in transient transmission. Single exponential relaxation curves are found for these diluted systems for all cases.

Figure 28 shows the resulting HS → LS relaxation rate constants plotted as $\ln[k_{HL}(T)]$ versus $1/T$ for selected compounds. Though the relaxation process is thermally activated at elevated temperatures, there is a strong deviation from simple Arrhenius behavior towards a more or less temperature-independent relaxation rate for temperatures below about 100 K. Such a behavior is typical for a low-temperature tunneling process. In Table 2 the experimental low-temperature tunneling rate constants $k_{HL}(T \rightarrow 0)$ and the activation energy E^a with the preexponential factor A from the thermally activated region above about 100 K according to the Arrhenius law (20) are listed.

$$k_{HL}(T) = Ae^{-E^a/k_BT} \quad (20)$$

Also included in Table 2 are the transition temperatures $T_{1/2}$ for the thermal spin transition. The thermal transitions are all gradual and not accompanied by crystallographic phase transitions, since in this context we have only investigated dilute systems.

Table 2. Transition temperature $T_{1/2}$, activation energy E^a at high temperature, preexponential factor A, and low-temperature tunneling rate $k_{HL}(T \rightarrow 0)$ (determined at $T \approx 10$ K) for some iron(II) coordination compounds. The reduced energy gap p has been estimated from the exponential relation between $k_{HL}(T \rightarrow 0)$ and p (inverse energy gap law).

	$T_{1/2}$ [K]	E^a [cm^{-1}]	A [s^{-1}]	p	$k_{HL}(T \rightarrow 0)$ [s^{-1}]

5.2. Nonadiabatic Multiphonon Relaxation

As already mentioned, classical concepts cannot explain the observed temperature dependence of the HS → LS relaxation rate constant. Several years ago Buhks et al.[67] suggested applying the theory of radiationless transitions based on Fermi's golden rule[179] to spin crossover dynamics. In this theory, HS → LS relaxation is described as a nonadiabatic process occurring between two distinct spin states in different nuclear configurations, where the electronic energy of the initial state is spontaneously transformed into vibrational energy of the final state. The simplest model for treating this problem is the "Single Configurational Coordinate" (SCC) model, in which the reac-

tion coordinate parallel to a certain nuclear coordinate is considered (Fig. 29). Since the nuclear configurations of the LS and

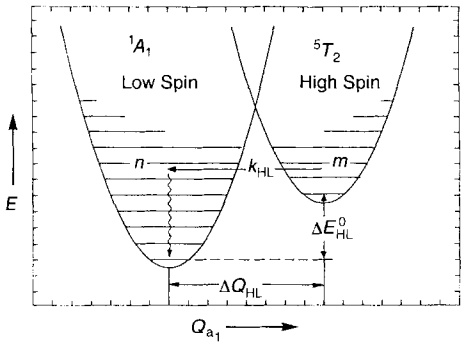

Fig. 29. Potential wells for the HS and LS states of Fe(II) in octahedral coordination along the totally symmetric normal coordinate Q with $\Delta Q_{HL} = \sqrt{6}\Delta r_{HL}$. In the simple SCC model, harmonic potentials with equal force constants are used.

the HS state differ predominantly in the metal–ligand distance $\Delta r_{HL} \approx 0.16-0.22$ Å, the reaction coordinate will be approximately equivalent to the totally symmetric normal coordinate with $\Delta Q_{HL} = \sqrt{6}\Delta r_{HL}$.[180]

If Fermi's golden rule and the Condon approximation are considered, the radiationless HS → LS relaxation rate constant in the SCC model is given by Equation (21),[179, 181] where β_{HL}

$$k_{HL}(T) = \frac{2\pi}{\hbar^2\omega}\beta_{HL}^2 F_p(T) \tag{21}$$

denotes the electronic matrix element, $\hbar\omega$ the oscillation frequency of the totally symmetric stretching mode, and $F_p(T)$ the thermally averaged Franck–Condon factor over the m vibrational levels of the initial state. The spin–orbit transition operator $\hat{H}_{SO}$[179] is the transition operator for ISC processes between distinct spin states that can be described by Born–Oppenheimer functions. For the HS → LS relaxation in iron(II) centers with $\Delta S = 2$, the $^5T_2$ and the $^1A_1$ states can only be mixed by higher order spin–orbit coupling. This gives an estimate for the electronic matrix element [Eq. (22)].[67]

$$\beta_{HL} = \langle\Phi_{LS}|\hat{H}_{so}|\Phi_{HS}\rangle \approx -150\,\mathrm{cm}^{-1} \tag{22}$$

If the potentials of the initial and the final states are approximated as harmonic potentials with equal force constants f and vibrational frequencies $\hbar\omega$, the thermally averaged Franck–Condon factor is given by Equation (23),[181] where the sum-

$$F_p(T) = \frac{\sum_m |\langle\chi_{m+p}|\chi_m\rangle|^2 e^{-m\hbar\omega/k_BT}}{\sum_m e^{-m\hbar\omega/k_BT}} \tag{23}$$

mation is over all vibrational levels m of the initial state, and the reduced energy gap p is defined by Equation (24).

$$p = \Delta E^0_{HL}/\hbar\omega \tag{24}$$

The energy gap p is a measure of the vertical displacement of the two potential wells relative to each other. From the point of view of energy conservation, only the transition from the m-th vibrational level of the initial state to the n-th vibrational level of the final state is allowed under the limiting condition (25).

$$n = m + p \tag{25}$$

In the SCC model the Franck–Condon factors $|\langle\chi_n|\chi_m\rangle|^2$ can be easily evaluated by using harmonic potentials and equal force constants.[182] For $T \to 0$, for example, F_p simplifies to Equation (26a) where S [Eq. (26b)] is the Huang–Rhys factor,

$$F_p(T \to 0) = |\langle\chi_p|\chi_o\rangle|^2 = \frac{S^p e^{-S}}{p!} \tag{26a}$$

$$S = \tfrac{1}{2} f\Delta Q_{HL}^2/\hbar\omega \tag{26b}$$

a measure for the horizontal displacement of the two potential wells relative to each other. With $\Delta Q_{HL} = \sqrt{6}\Delta r_{HL} \approx 0.5$ Å, a mean force constant f of 2×10^5 dyn cm^{-1}, and a typical vibrational energy $\hbar\omega$ of between 200 and 300 cm^{-1}, a value for S of between 40 and 50 can be estimated.[159]

For iron(II) complexes with a coordination sphere of six nitrogen atoms, the changes in bond length Δr_{HL}, the force constant f, and the vibrational energy $\hbar\omega$ (and therefore the Huang–Rhys factor S as well) will be restricted to a fairly narrow range. What can vary widely between two compounds, however, is ΔE^0_{HL} and thus the reduced energy gap p. Figure 30a shows a

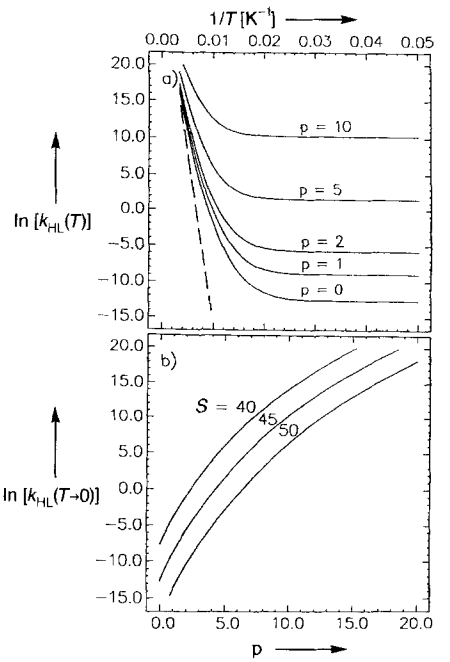

Fig. 30. a) Plots of $\ln[k_{HL}(T)]$ versus $1/T$ calculated from the simple SCC model with $S = 45$, $\hbar\omega = 250$ cm^{-1}, and the reduced energy gap p as a parameter. The dashed line represents the classical energy barrier $E^c = \hbar\omega S/4$ for small values of p. b) The low-temperature tunneling rate calculated with $\hbar\omega = 250$ cm^{-1} and $S = 40$, 45, 50, plotted as $\ln[k_{HL}(T \to 0)]$ versus p.

plot of $\ln[k_{HL}(T)]$ (calculated with $S = 45$ and $\hbar\omega = 250$ cm^{-1}) versus $1/T$, for different values of the reduced energy gap parameter p. The characteristic features of the curves reveal a temperature-independent tunneling rate at low temperatures

and a thermally activated relaxation process at higher temperatures. As can be seen from Figure 30b, the low-temperature tunneling rates $k_{HL}(T \rightarrow 0)$ thus calculated become very small for small reduced energy gaps p and increase exponentially with increasing p, which is termed the "inverse energy gap law" in the strong vibronic coupling limit $S \gg p$. The expected activation energies at elevated temperatures on the other hand decrease with increasing p. Even for $p = 0$ they are smaller than the classical energy barrier $E^c = S\hbar\omega/4$ (about 2500–3000 cm^{-1}). Consequently, the thermally activated relaxation is not triggered across the classical energy barrier either. It, too, must be interpreted as a nonadiabatic tunneling process from a thermally activated vibrational level of the HS state.

Clearly the $\ln[k_{HL}]$ versus $1/T$ curves calculated with the simple SCC model show the same general behavior as the experimental ones with an only weak temperature dependence for temperatures below about 80 K and a thermally activated regime above about 100 K. In the following, an increase of $k_{HL}(T \rightarrow 0)$ over as many as twelve orders of magnitude from approximately 5×10^{-7} s^{-1} for the $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ spin crossover system to 6×10^5 s^{-1} for the $[Zn_{1-x}Fe_x(bipy)_3](PF_6)_2$ LS system in the strong vibronic coupling limit $S \gg p$ of the SCC model is predicted as an inverse energy gap law.

Although $T_{1/2}$ of the thermal spin transition is but a crude measure of the energy gap ΔE^0_{HL} (and thus for p), the experimentally observed low-temperature tunneling rates do indeed increase dramatically with increasing $T_{1/2}$ (Fig. 31). For a more

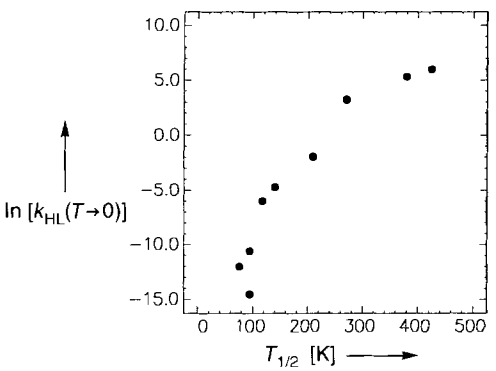

Fig. 31. Observed low-temperature tunneling rates plotted as $\ln[k_{HL}(T \rightarrow 0)]$ versus the transition temperature $T_{1/2}$ (from ref.[183]).

quantitative verification of the inverse energy gap law, the reduced energy gaps p of the investigated systems would have to be known. Unfortunately, ΔE^0_{HL} and therefore p are very difficult to determine experimentally.

For the three mixed-crystal compounds with a spin transition temperature $T_{1/2} < 100$ K in Table 2, $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$, $[Mn_{1-x}Fe_x(pic)_3]Cl_2 \cdot EtOH$, and $[Zn_{1-x}Fe_x(pic)_3]Cl_2 \cdot EtOH$, a value of $p \leq 1$ is certainly reasonable, and for the $[Mn_{1-x}Fe_x(pic)_3]Cl_2 \cdot MeOH$ system with $T_{1/2} \approx 120$ K, $p \approx 1-2$ is appropriate. The observed low-temperature tunneling rates $k_{HL}(T \rightarrow 0)$ for the four compounds all lie within the range predicted by the simple SCC model around $S \approx 45$. For the $[Zn_{1-x}Fe_x(bipy)_3](PF_6)_2$ LS system, with a $\Delta E^0_{HL} \approx 2500-3500$ cm^{-1} not too far away from a spin crossover system, p is definitely greater than 10. For such a value of p we do indeed expect $k_{HL}(T \rightarrow 0)$ to be more than ten orders of magnitude larger than in the systems just mentioned. This leads us to the conclusion that the Huang–Rhys factor estimate of $S \approx 45$ is quite realistic, and we can assign the values of p listed in Table 2 for the reduced energy gap to the other compounds.

It would be presumptuous to expect a more quantitative agreement of the experimental $\ln[k_{HL}(T)]$ versus $1/T$ curves with the curves calculated on the basis of the SCC model with harmonic potentials and equal force constants, in view of the crude assumptions made. Although the model does predict a thermally activated HS → LS relaxation at elevated temperatures with an activation energy smaller than the classical energy barrier between the potential wells, the passage from the thermally activated process to the low-temperature tunneling process is much more gradual in the experimental curves than in the calculated ones. The symmetry of the investigated iron(II) complexes is in all cases lower than O_h, so that generally we must have more than just one totally symmetric normal coordinate. Especially for the $[Fe(pic)_3]^{2+}$ complex, where one half of the coordinating nitrogen atoms belong to NH_2 groups and the other half to pyridyl rings, at least two vibrational modes with rather different frequencies must be active. This may well be the cause of this much more gradual transition. Also, the observed activation energies in the high temperature regime are still lower than those calculated from the simple SCC model. Taking anharmonic terms in the potentials into account would correct the values in the right direction. The influence of anharmonic terms becomes noticeable only at higher temperatures in the strong coupling limit and does not entail a shift in the rates by several orders of magnitude, in contrast to the case of weak or intermediate vibronic coupling.[184]

In the SCC model, coupling to low-frequency phonons is generally neglected. The low-frequency phonons just provide a heat bath for energy dissipation and implicitly ensure energy conservation should there be an energy mismatch between the vibrational levels of the HS and the LS state. In reality this is certainly the case. At high temperatures, where the low-frequency phonons are mostly thermalized, the simplified approach of the SCC model is justified. At low temperatures, however, the coupling to the low-frequency phonons would have to be explicitly taken into account, for these phonons are the ones responsible for the fact that the experimental relaxation rates at low temperatures are not quite as temperature independent as the SCC model calculations predict.[158, 185]

What about other spin crossover systems, say for example those of iron(III) with a $^6A_1 \rightarrow {}^2T_2$ transition, or those of cobalt(II) with a $^2E \rightarrow {}^4T_1$ transition? At ambient temperatures, for iron(III) and cobalt(II) spin crossover complexes, HS → LS relaxation rates of around 10^7 to 10^{10} s^{-1} have been determined in solution.[55] Lawthers and McGarvey[186] were successful in using the pulsed laser excitation technique even for iron(III) systems. So at least for iron(III) systems a LIESST-like process does exist, and, in principle, the same type of temperature dependence of the HS → LS relaxation rates as with the iron(II) systems should be observed. The low-temperature tunneling rates for iron(III) and cobalt(II), however, are expected to be several orders of magnitude larger than for iron(II) spin crossover compounds, because Δr_{HL} and therefore S of the for-

mer are smaller. For iron(III) compounds, typical values for Δr_{HL} are 0.1 Å,[187] giving an S of about 17. Buhks et al.[67] have calculated an electronic matrix element of $\beta_{HL} \approx 50\ cm^{-1}$ for iron(III). From this a value for the low-temperature tunneling rate $k_{HL}(T \rightarrow 0)$ for small reduced energy gaps p of $10^5 - 10^7\ s^{-1}$ can be estimated. For iron(III) spin crossover compounds, a LIESST effect in the true sense can thus not be expected. For the cobalt(II) systems, the estimations are difficult to perform, since the ^2E state is generally susceptible to strong Jahn–Teller interactions and the SCC model here becomes a rather bad approximation. However, also for cobalt(II) no LIESST effect in the real sense can be expected.

5.3. Cooperative Effects on the HS → LS Relaxation in $[Fe(ptz)_6](BF_4)_2$

In Section 4.1 in the discussion on photophysical properties of the $[Fe(ptz)_6](BF_4)_2$ spin crossover compound, we pointed to the cooperative effects found also in this concentrated material, which, among other things, influence the thermal spin transition.

In the dilute mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$), single exponential HS → LS relaxation curves, just like those of all mixed-crystal systems treated in Section 5.1, are observed.[188] The cooperative effects in concentrated materials, however, give rise to strong deviations from first-order kinetics.[66, 188] This will be the subject of the following discussion.

5.3.1. Experimental Results

Figure 32 shows the $^1A_1 \rightarrow {}^1T_1$ band of concentrated $[Fe(ptz)_6](BF_4)_2$ at 57.0 K, recorded at time intervals of 120 s following the light-induced LS → HS conversion. Figure 33

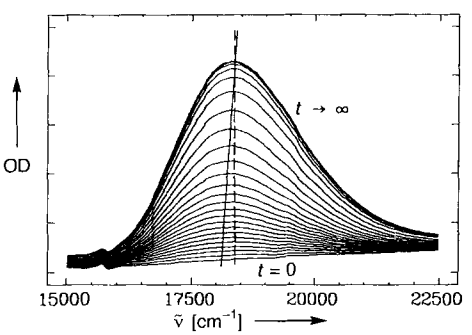

Fig. 32. Time dependence of the $^1A_1 \rightarrow {}^1T_1$ band in $[Fe(ptz)_6](BF_4)_2$ at 57.0 K after a complete light-induced LS → HS conversion. The spectra were recorded with time intervals of 120 s (from ref. [189]).

shows the HS → LS relaxation curves (as $\gamma_{LS}(t)$) in the supercooled crystallographic high-temperature phase at different temperatures between 50 and 60 K, obtained from the relative optical density at the band maximum as a function of time.

The deviation from single exponential behavior is obvious. The sigmoidal curve shape must be interpreted as a self-acceleration of the HS → LS relaxation with increasing proportions of LS γ_{LS}. The acceleration stems from the buildup of an internal

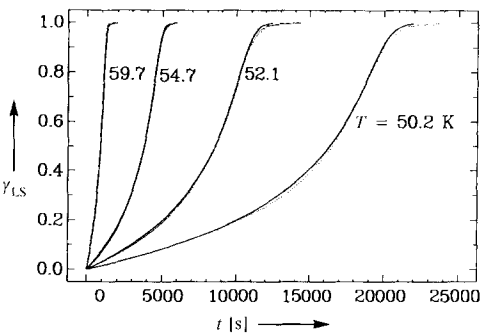

Fig. 33. Complete HS → LS relaxation curves for $[Fe(ptz)_6](BF_4)_2$ in the crystallographic high-temperature phase. (···) experimental values, (—) curve fits with Equation (28) for $k_{HL}(\gamma_{LS})$ (from ref. [189]).

pressure (image pressure) with increasing LS proportions, which in turn is caused by the volume change $\Delta V_{HL} = V_{HS} - V_{LS}$ of the complexes associated with the spin transition (see Sec-

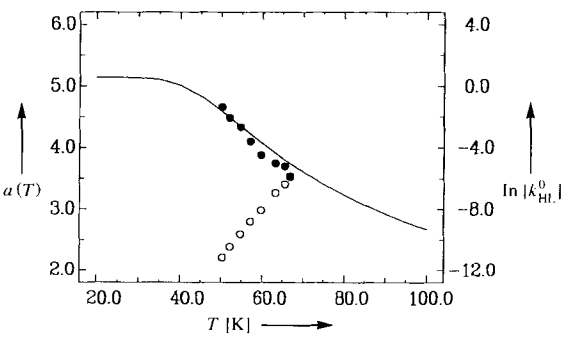

Fig. 34. $a(T)$ and $\ln[k^0_{HL}(T)]$ from the curve fit in Figure 33 for $[Fe(ptz)_6](BF_4)_2$. ●: observed $a(T)$; — —: calculated $a(T)$, see text; ○: $\ln[k^0_{HL}(T)]$ (from ref. [189]).

tion 3.4.1). The relaxation rate is a function of this pressure and therefore also a function of the LS proportion γ_{LS}. The differential equation (27) still holds, but now k_{HL} is no longer a constant,

$$\frac{d\gamma_{LS}}{dt} = k_{HL}(1 - \gamma_{LS}) \tag{27}$$

but itself a function of the LS proportion γ_{LS}. Nevertheless, the relaxation curves can be well described empirically on applying a phenomenological approach [Eq. (28)] for the $k_{HL}(\gamma_{LS})$ depen-

$$k_{HL}(\gamma_{LS}, T) = k^0_{HL}(T) \cdot e^{a(T)\gamma_{LS}} \tag{28}$$

dence. Included in Figure 33 are the HS → LS relaxation curves calculated with this phenomenological approach, and the agreement with the experimental curves is very good indeed. Figure 34 shows the values for $\Delta k^0_{HL}(T)$ and $a(T)$ obtained from a numerical curve fit. Within experimental error, $\Delta k^0_{HL}(T)$ is equal to the HS → LS relaxation rate $k_{HL}(T)$ of the exponential decay of the HS state in the dilute mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ with $x \approx 0.1$ (see Fig. 28). This is not surprising, since V_{Zn} and V_{HS}, as we have already mentioned, are about equal and therefore, at the beginning of the relaxation process, the internal pressure in pure $[Fe(ptz)_6](BF_4)_2$ is about the same size as that in the dilute mixed crystal.

A careful analysis of the position of the $^1A_1 \rightarrow {}^1T_1$ band reveals that the band maximum is shifted towards higher energy on relaxation.[189] Figure 35 shows this shift, which is linear in

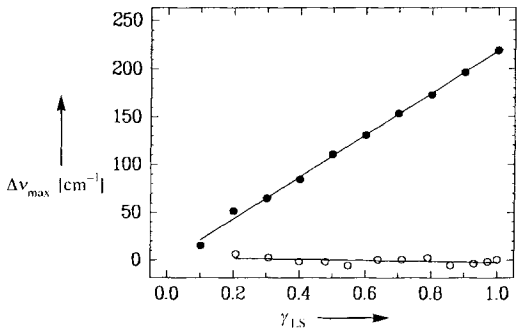

Fig. 35. Shift of the $^1A_1 \rightarrow {}^1T_1$ band maximum for $[Fe(ptz)_6](BF_4)_2$ at 57.0 K relative to the band maximum extrapolated to $\nu_{max}(\gamma_{LS} = 0) = 18000\ cm^{-1}$ as a function of the LS fraction γ_{LS}. •: observed; : linear regression with slope $\Delta\nu_0 = 219(4)\ cm^{-1}$. o: data for the dilute mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$) for comparison (from. ref.[190]).

γ_{LS}, for the relaxation curve at 57.0 K. No such shift can be observed in the mixed crystal $[Zn_{1-x}Fe_x(ptz)_6](BF_4)_2$ ($x \approx 0.1$). According to the Tanabe–Sugano diagram (see Fig. 1), the shift for the concentrated system corresponds to an increase of the ligand field strength of the LS species by $\delta 10Dq^{LS}$ on relaxation [Eq. (29) where $\Delta\nu_{max} = 219(4)\ cm^{-1}$ is the slope of the linear

$$\delta 10Dq^{LS}(\gamma_{LS}) = 10Dq^{LS}(\gamma_{LS}) - 10Dq^{LS}(\gamma_{LS} = 0) = \Delta\nu_{max}\gamma_{LS} \quad (29)$$

regression in Figure 35]. Relative to average values for $10Dq^{LS}$ and $10Dq^{HS}$ of about 20550 and 12200 cm^{-1}, respectively (see Section 4), the value for $\Delta\nu_{max}$ is small.

5.3.2. Discussion Based on the SCC Model

As already mentioned, the increase of the relaxation rate at a given temperature ($a = 4.5$ at $T = 55$ K) is attributed to an increase of the internal pressure on relaxation. This increase effects a horizontal as well as a vertical displacement of the potential wells for the initial state and the final state relative to each other, as shown schematically in Figure 36. The zero point energy difference ΔE^0_{HL} and the change in bond length Δr_{HL} become a function of γ_{LS}. Naturally, therefore, the parameters in Equation (23) for the thermal average of the Franck–Condon factor $F_p(T)$ (the Huang–Rhys factor S and the reduced energy gap p) also become functions of γ_{LS} in the concentrated material.

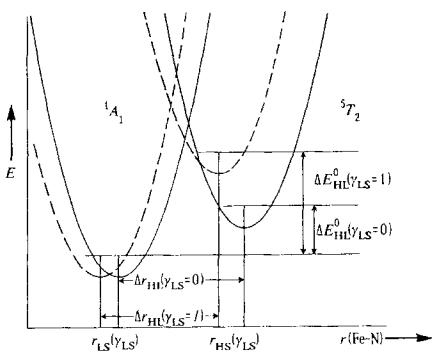

Fig. 36. Potential wells of HS and LS states, schematically illustrating relative horizontal and vertical shifts due to the build-up of an internal pressure during relaxation.

The change of the bond length differences $\delta\Delta r_{HL}(\gamma_{LS})$ on relaxation can be estimated from the $1/r^6$ dependence of the ligand field strength. $\delta\Delta r_{HL}$ between the start and the end of the relaxation process is approximately 2×10^{-3} Å, much smaller than $\Delta r_{HL} \approx 0.18$ Å. The resulting change of the Huang–Rhys factor on relaxation, $\delta S(\gamma_{LS})$, will also be much smaller than the average Huang–Rhys factor S itself. Thus, a linear dependence of $\delta S(\gamma_{LS})$ follows according to Equation (30).[189] An average value of $S \approx 45$ gives $a_s \approx -1$.

$$\delta S(\gamma_{LS}) := S(\gamma_{LS}) - S(\gamma_{LS} = 0) \approx 2\frac{\delta\Delta r_{HL}(\gamma_{LS})}{\Delta r_{HL}} S := a_s\gamma_{LS} \quad (30)$$

In principle, $10Dq^{LS}$ determines only the electronic energy of the excited states at the equilibrium distance of the LS state according to the Tanabe–Sugano diagram in Figure 1. Clack and Smith[191] used INDO-SCF-MO calculations to show the linear relationship with slope 1 between $10Dq^{LS}$ and the zero point energy difference ΔE^0_{HL} between the HS and the LS state. Consequently, Equation (31) is valid for the change of the zero point energy difference $\delta\Delta E^0_{HL}(\gamma_{LS})$ on relaxation. This corresponds to a total change of the zero point energy difference of $\Delta\nu_{max} = 219\ cm^{-1}$ on relaxation. Therefore, following the definition in Equation (24), the change of the reduced energy gap $\delta p(\gamma_{LS})$ is given in Equation (32). Since $\Delta\nu_{max}$ is of the order of $\hbar\omega$, a_p becomes approximately 1.

$$\delta\Delta E^0_{HL}(\gamma_{LS}) := \Delta E^0_{HL}(\gamma_{LS}) - \Delta E^0_{HL}(\gamma_{LS} = 0) \approx \delta 10Dq^{LS}(\gamma_{LS}) = \Delta\nu_{max}\gamma_{LS} \quad (31)$$

$$\delta p(\gamma_{LS}) := p(\gamma_{LS}) - p(\gamma_{LS} = 0) \approx \frac{\delta\Delta E^0_{HL}(\gamma_{LS})}{\hbar\omega} = \frac{\Delta\nu_{max}}{\hbar\omega} \cdot \gamma_{LS} := a_p\gamma_{LS} \quad (32)$$

Using $\delta p(\gamma_{LS})$ and $\delta S(\gamma_{LS})$, we can calculate the γ_{LS} dependence of the thermal Franck–Condon factor average $F_p(T)$ according to Equation (23). With some approximations Equation (33a) follows, in particular for the low-temperature tunneling rate in the strong vibronic coupling limit.[189] For S an average value

$$k_{HL}(\gamma_{LS}, T \rightarrow 0) \approx k_{HL}(\gamma_{LS} = 0,\ T \rightarrow 0) \cdot e^{a(T \rightarrow 0)\gamma_{LS}} \quad (33a)$$

$$a(T \rightarrow 0) = a_p \ln S - a_s \approx 5 \quad (33b)$$

of 45 was used and values of 1 and -1 as estimated above for a_p and a_s, respectively. The first term in Equation (33b), $a_p \ln S$, accounts for the increase of ΔE^0_{HL} on relaxation, in accord with the inverse energy gap law as treated in Section 5.2. The second term, a_s, results if the change in Δr_{HL} is taken into account as well.

One can now show numerically that this form is still valid for $T > 0$. The resulting curve for $a(T)$ is accordingly included in

Figure 34. Below about 50 K, in the low-temperature tunneling regime, $a(T)$ is temperature independent. Above this temperature, however, $a(T)$ decreases with $1/T$, well in accord even with the absolute values of the experimental observations. The cooperative effects of the HS → LS relaxation in $[Fe(ptz)_6](BF_4)_2$ can thus be explained in a way consistent with quantum mechanics by a simple SCC model of nonadiabatic multiphonon relaxation, which takes the spectroscopically observed displacements between the potential wells of the initial state and the final state into account.

Spiering et al.[40] (see Section 3) have treated the elastic interactions during spin transitions in solids as a continuous model, without stipulating in detail how the elastic energies are distributed. In the crystallographic high-temperature phase of $[Fe(ptz)_6](BF_4)_2$, a good part of this energy is apparently absorbed by the metal–ligand bonds. That this happens in a uniform way is quite understandable, since the inversion center of the high-symmetry space group must be retained in the complex.

5.3.3. Comparison with the Lattice Expansion Model

To finish our discussion, we shall now relate the thermodynamic treatment of the spin transition based on the lattice expansion model from Section 3 to the cooperative effects on HS → LS relaxation. Following the lines of thought of Adler et al.,[58, 59] we shall employ the semiclassical absolute rate theory. For $[Fe(ptz)_6](BF_4)_2$ with a low-temperature tunneling rate of $\Delta k^0_{HL}(T \rightarrow 0)$ of less than $10^{-6}\ s^{-1}$, the HS → LS relaxation in the temperature range under discussion is already a thermally activated process, as evidenced by rates of 10^{-4}–$10^{-2}\ s^{-1}$. According to absolute rate theory[174, 192] Equation (34) is applic-

$$k_{HL} = \frac{k_B T}{h} \kappa e^{-(\Delta H^{\ddagger}_{HL} - T\Delta S^{\ddagger}_{HL})/k_B T} \tag{34}$$

able, where $\Delta H^{\ddagger}_{HL}$ and $\Delta S^{\ddagger}_{HL}$ denote enthalpies and entropies of activation, and κ is a measure of the probability for an ISC process in the transitory state. We do not expect a strong dependence on the LS fraction for $\Delta S^{\ddagger}_{HL}$. It is rather $\Delta H^{\ddagger}_{HL}$ which shows a γ_{LS} dependence through the change in the elastic energy of the transition state $\Delta^{\ddagger}_E$ during the course of the relaxation [Eq. (35)].

$$\Delta H^{\ddagger}_{HL}(\gamma_{LS}) = H^{\ddagger}_{HL}(\gamma_{LS} = 0) + \Delta^{\ddagger}_E(\gamma_{LS}) \tag{35}$$

Here, $\Delta H^{\ddagger}_{HL}(\gamma_{LS} = 0)$ is the activation enthalpy at the beginning of the HS → LS relaxation. By analogy with the difference in the elastic energies between HS and LS state [see Equation (15)], the change $\Delta^{\ddagger}_E$ in the elastic energy of the transition state as a result of the changing internal pressure during relaxation, is given by Equation (36), where v_{HS} and v_{LS} are the

$$\Delta^{\ddagger}_E = -\frac{K(\gamma_0 - 1)\gamma_0}{v_c}(v_{HS} - v_{LS})(v_{HS} - v^{\ddagger})\gamma_{LS} = -2\Gamma q^{\ddagger}\gamma_{LS} \tag{36a}$$

$$q^{\ddagger} = \frac{v_{HS} - v^{\ddagger}}{v_{HS} - v_{LS}} \tag{36b}$$

volumes of the complex in the HS and LS states, and $v^{\ddagger}$ the volume of the activated complex. We neglect the concentration $\gamma^{\ddagger}$ of activated complex, since it is much smaller than 1. Having the linear γ_{LS} dependence of $\Delta^{\ddagger}_E$ in the thermally activated regime, we can now identify $a(T)$ with $\Delta^{\ddagger}_E$ by comparing Equations (34) and (28) according to Equation (37).

$$a(T) = 2\Gamma q^{\ddagger}/k_B T \tag{37}$$

As already mentioned and depicted in Figure 34, $a(T)$ obeys a $1/T$ dependence quite well, from which a value of about 164(6) cm^{-1} for $2\Gamma q^{\ddagger}$ results.

As the reaction coordinate is chiefly determined by the totally symmetric stretching mode, the volume $v^{\ddagger}$ of the activated complex must lie between the volumes v_{HS} and v_{LS}. Even though the force constants for the HS and LS states are not exactly equal, the classical intersection between the two potential wells is not too far from the median between r_{HS} and r_{LS}. Indeed, we obtain an approximate value of 0.5 for $q^{\ddagger}$ using the value of 170 cm^{-1} for Γ, the interaction constant, as it was determined from the thermal spin transition. We see that for the $[Fe(ptz)_6](BF_4)_2$ system in the crystallographic high-temperature phase with its high symmetry, the reaction coordinate is really well described by the totally symmetric stretching vibration.

6. Conclusion and Outlook

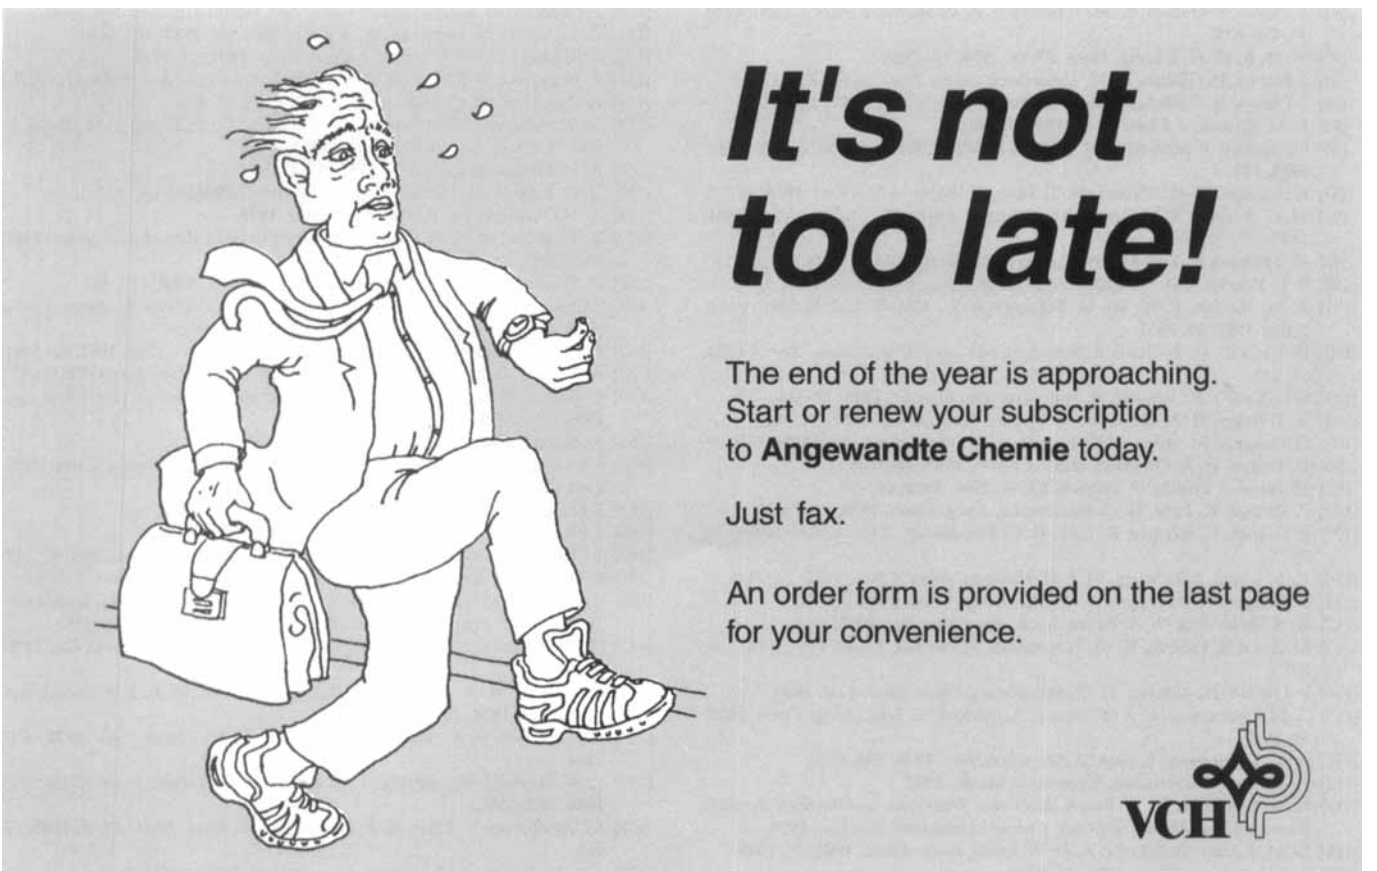
Though more than sixty years have passed since the discovery of thermal spin crossover for iron(III) complex compounds, it was not until the discovery of the phenomenon for iron(II) complexes during the sixties that a more exhaustive line of spin crossover research began to flourish. The reason is primarily that on one hand a large variety of different spin transition curves were observed in the solid, and on the other, solid state scientists had recourse to an excellent microscopic method for the investigation of the electronic structure of iron complexes after the Mössbauer effect was discovered. In addition, magnetic susceptibility studies, electron excitation and vibrational spectroscopy, crystal structure analysis, and calorimetry have yielded a host of data enabling us today to understand the essential aspects of thermal spin crossover and the relaxation of the metastable spin state created by irradiation (LIESST effect) in the solid as well as in the liquid state. Thus we have learned that the spin transition behavior can be drastically affected by changes in the ligand system, exchange of noncoordinating anions or solvent molecules in the solid, and by metal dilution. The same holds for changes in physical parameters such as pressure, magnetic environment, and crystal quality. All this allows us to change the ligand field strength at the metal center and to shift the spin transition curve along the temperature scale.

For more than two decades of spin crossover research, our interest has been almost exclusively directed towards the solid, because the spin transition types may vary so much in the solid, supplemented by the fact that spin transition behavior can be deliberately adjusted in solutions (by changing the steric and electronic influence of the ligand system), but such predictions in the solid were impossible. Already at an early stage of spin crossover research had it become clear that spin transitions in

the solid are accompanied by cooperative interactions which, additional to the immediate local (steric and electronic) influences on the complex, are responsible for the variety of spin transition types. Our main object was to clarify the nature of these interactions. The model we developed on the basis of elasticity theory, with the enormous volume changes and the associated changes in the elastic energies during the spin transitions under consideration, has significantly promoted our understanding of the interaction mechanism.

The discovery that iron(II) spin crossover compounds can also be switched between their different spin states by irradiation with light of different wavelengths (LIESST effect, where the metastable states can have extraordinarily long lifetimes) came as a surprise. Iron(II) coordination compounds had not been very prominent in photochemistry and had not attracted any special attention because they lack luminescent properties. From intensive studies of the kinetics of the radiationless decay of the LIESST state we have learned that the deviation of the decay curves from an exponential law can be well understood on the basis of the model of elastic interactions. The temperature dependence of the relaxation times (tunneling at lower temperatures and observance of the Arrhenius law at higher temperatures) is in accord with the theory of radiationless transitions.

The possibility of switching between two phases with very different optical and magnetic properties (as is the case with the LIESST effect) immediately suggests potential applications in optical information technology. Another objective of our studies was to sound out these possibilities. From our systematic investigation of the decay kinetics one must conclude that long-term storage using the LIESST effect is only possible at sufficiently low temperatures below 80 K. From our observations, optical switches using spin crossover/LIESST compounds with an LS state just still stable around room temperature seem conceivable, because the intersystem crossing processes involved in the decay mechanism are very fast (the reciprocals of the rate constants are in the subnanosecond range), they have high quantum yields ($LS \rightarrow HS \approx 1$), and the metastable HS states have lifetimes in the nanosecond range. The large differences between the refractive indices in the HS and the LS states of iron(II) complex compounds gives rise to their photodiffractive properties, which could be exploited especially with holographic methods.[190]



Special thanks are due to all collaborators (graduate and doctorate students, postdoctorate fellows) for their enthusiasm for the spin crossover and LIESST research presented in this article. Their names are cited in the references section. Thanks are also due to the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, the Fonds der Chemischen Industrie, the Volkswagen Stiftung, and the Materialwissenschaftliches Forschungszentrum der Universität Mainz for financial support. A. Hauser is grateful to the Schweizerische Nationalfonds for scholarships and research funds.

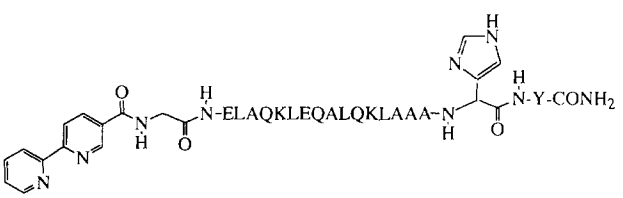
Designer Proteins: On the Art of Synthesizing De Novo Metalloproteins**

Heinz-Bernhard Kraatz*

Dedicated to Professor P. Michael Boorman



Contemporary research in chemistry often crosses the lines that previously divided the classical disciplines of chemistry and biology. Coordination chemistry has certainly been one of the areas of chemistry that has spanned the old boundaries. An inclusive definition of what constitutes coordination chemistry is emerging which requires "only that distinct molecular species be formed by the binding interaction."[1] The modeling of active sites of metalloenzymes has always been a great stimulus to coordination chemists. An excellent example for this is the "nitrogenase problem", which has played a pivotal role in the rapid development of the coordination chemistry of molybdenum and sulfur-based ligands. Recent advances in the de novo design of nonnatural proteins have allowed the combination of classical coordination chemistry and protein biochemistry. The main idea of the design is to reduce the highly complex naturally occurring proteins to the minimum structural features necessary for a certain function. The model protein is prepared by standard synthetic methodologies, and can be used to evaluate the structural assumptions that led to its design and thereby lead to an understanding of the intricate interplay between protein structure and function. Current research in this area following this approach has led to the successful design of a range of artificial proteins.[2]

Two major routes to the structural design of a de novo protein can be distinguished: a) the synthesis of a larger peptide with subdomains of known secondary structure, which will adopt a particular tertiary structure, and b) the design of smaller peptide subunits of known secondary structure and their assembly on a template to yield the final protein of a particular tertiary structure, such as desribed by Mutter et al.[3] The construction of specific and topologically predetermined protein structures from smaller amphiphilic peptide precursors by simple self-assembly is hampered by the tendency of peptides to establish an equilibrium between monomers and aggregates in aqueous solution. This makes controlling the number of participating peptides and their relative stereochemistry a formidable task indeed.

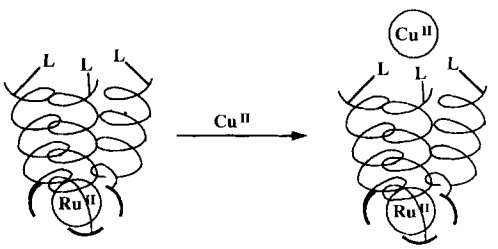
An important step forward in this area has been made by Ghadiri et al. with a metal ion mediated self-assembly process[4] in the spirit of the new inclusive definition of coordination chemistry. The coordination of chemically modified peptides to a metal center through a ligating group leads to the formation of a metal–peptide complex, thereby allowing control of the stereochemistry of the complex and the number of peptide subunits participating in the final de novo protein. To a large extent, the art of successfully applying this strategy lies in the choice of the metal center and the chemical modification of a specific peptide. This surprisingly simple approach has been applied to the synthesis of several helical metalloproteins with well-defined stereochemistry such as **1** (py = pyridine)[4a] and **2**.[4c]

trans-[$RuCl_2$(py-peptide)$_4$] **1**
cis-[$Ru(NH_3)_4$(His-peptide)$_2$]$^{3+}$ **2**

This idea has now been refined to such an extent that it has been possible to synthesize a Ru^{II} metalloprotein with a well-defined metal-binding site.[5] This was achieved with peptide **3**,

3

which has two potential metal-binding sites—an N-terminal bipyridine group (bpy) and an imidazole nitrogen atom of a histidine residue close to the C-terminus of **3**—and should favor a helical structure. Incorporation of the bpy functionality at the N-terminus of each peptide allowed direction of the self-assembly of three peptides with a Ru^{II} ion as a template to form a three-helix bundle protein. Kinetically inert **4** is produced exclusively. Since the three peptide subunits are in close proximity, short-range intramolecular hydrophobic interactions amongst



fac-[Ru^{II}(bpy-peptide)$_3$]$^{2+}$ **4**

the three metal-bound peptides exceed intermolecular interactions, which thereby facilitates the formation of the overall helical tertiary structure of **4** (circular dichroism) (CD) spectrum: $\theta_{222} = -23000\,^{\circ}cm^2dmol^{-1}$). UV/VIS spectroscopy ($\lambda_{max}$ = 289 and 475 nm), electrospray mass spectrometry (found: M = 6887 ± 2; calcd.: M = 6887), and gel permeation chromatogra-

phy all provide unequivocal evidence for the identity of **4**. It is important to point out that because of this helical arrangement, the three His18-residues close to the C-termini of each of the three peptide subunits are close together, thereby forming an effective metal binding site. Coordination of Cu^{2+} to this binding site does not significantly alter the structure of the protein, which indicates the presence of this binding site after the self-assembly of **4** (CD spectrum: $\theta_{222} = -24000^\circ cm^2 dmol^{-1}$). Based on the marked decrease in the fluorescence emission of the adjacent tyrosine chromophore and analysis of the EPR ($g_{\|} = 2.27$ and $A_{\|} = 173\ cm^{-1} \times 10^4$) and UV/VIS ($\lambda_{max} = 375$ (charge transfer) and 495 nm) spectra, Ghadiri and Case[5] demonstrated that a Cu^{II} ion is able to bind to this metal-binding site and leads to the formation of the $Ru^{II}Cu^{II}$ protein **5** (Scheme 1).

4 **5**

Scheme 1.

Relevant in this context are the recent reports of the design and syntheses of cytochrome (cyt) models by Diederich et al.[6] based on polyether–amide dendrites encapsulating a central Zn porphyin core, and the approach by DeGrado et al. for the synthesis of artificial proteins.[7] In DeGrado's approach, several peptides have been synthesized consisting of two identical 31-residue helical subunits linked by a disulfide bridge. The peptides contain histidine residues which allow the coordination of Fe^{II} heme through two *trans* imidazole groups. The peptides accociate to dimeric four-helix bundle structures. Model protein **7** was designed from two identical subunits **6**, which each possess two histidine units (His10 and His24), to mimic the cyt b subunit of cyt bc_1. Compound **7** has two possible heme binding sites per peptide (based on two histidine residues) and an estimated separation between the Fe atoms of about 20 Å. Due to dimerization of the model protein **7**, addition of Fe^{II} heme leads to the incorporation of four redox centers at the four predetermined binding sites of the protein dimer. CD spectroscopy also confirms in this case that well-defined binding sites are present prior to heme coordination ($\theta_{222} = -26000^\circ cm^2 dmol^{-1}$). As expected the heme–protein complex exhibits a rhombic EPR spectrum ($g_z = 2.89$, $g_y = 2.24$, $g_x = 1.54$) confirming the coordination of low-spin Fe^{2+} through two *trans* imidazole groups.

6 **7** **8**

These are only two examples indicating the scope of this emerging area of research at the interface of protein chemistry and coordination chemistry. The synthesis of metal-binding metalloproteins and the introduction of redox-active metal centers into artificial proteins by self-assembly processes is surely only the beginning. One can certainly think of extending this approach to the incorporation of substrate-binding enzymatic functions, as already demonstrated by Sasaki and Kaiser,[8] and photosensitive metal centers in proteins which can then act as light-harvesting analogues of the photosystem of green plants.

Novel Copper Nitrosyl Complexes: Contributions to the Understanding of Dissimilatory, Copper-Containing Nitrite Reductases

Bruce A. Averill*

Denitrification is the dissimilatory reduction of nitrogen-oxide species to gaseous products by bacteria, and occupies a central position in the global nitrogen cycle. As shown in Figure 1,

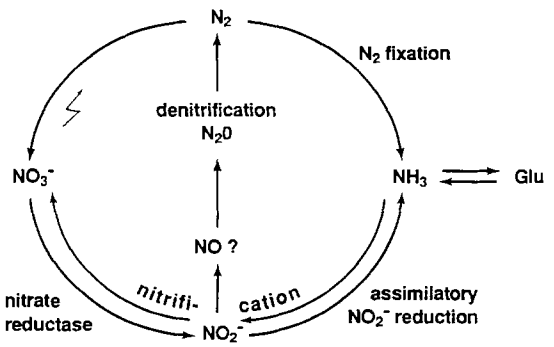

Fig. 1. A schematic of the reactions involved in inorganic nitrogen metabolism, showing the central position of the denitrification pathway.

denitrification provides the only route for recycling fixed nitrogen back into the atmosphere. In addition, denitrification is a major source of NO and N_2O, which play an significant role in ozone layer destruction and global warming. Denitrification is also important in bioremediation efforts and cycling of nutrients in aquifers and rock formations beneath the soil. Finally, NO, named the 1992 "Molecule of the Year" by *Science*, is a key chemical signal in a wide variety of processes. Consequently, microbial systems that evolve or consume NO are of substantial interest as potential models for the mammalian system, and the possible effects of NO generated by enteric or pathogenic bacteria remain an unexplored but potentially important area of research.

The pathway of denitrification has been the object of controversy for the past 10–15 years, with the focus of attention on the route from nitrite to nitrous oxide, and whether nitric oxide is an obligatory intermediate. As a result of recent contributions, it is now clear that, at least in most denitrifiers most of the time, reduction of NO_2 produces NO that is subsequently reduced to N_2O in a separate enzymatic step (Fig. 2).[1–3] The controversy was exacerbated by the existence of two distinct types of dissimilatory nitrite reductase, containing either two hemes or two copper per protein monomer, which exhibit significantly different chemistry.[4] These enzymes appear to operate on the same basic principles (one chromophore in the active site, either heme d_1 or Type 2 (non-blue) copper, plus one electron transfer site, either heme c or an unusual green variant of a Type 1 (blue) copper center, respectively).[5, 6] The heme enzymes produce almost exclusively NO from NO_2^-, but the copper enzymes are capable of producing significant amounts of N_2O from NO_2^- in the presence of NO.[7]

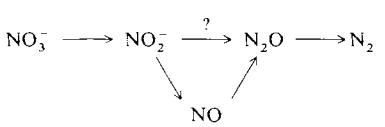

Fig. 2. The pathway of denitrification.

The existence and properties of well-defined model complexes have been central to an understanding of the structure and reactivity of many metalloenzymes and metalloproteins, including cytochrome P450, hemoglobin, hemerythrin, and iron-sulfur proteins.[8] In the case of the heme cd_1 nitrite reductases, ample synthetic precedents exist for interaction of NO with both Fe^{II}- and Fe^{III}-porphyrin complexes, and it seems clear that the enzymes operate by a mechanism involving protonation and dehydration of bound nitrite to give a Fe^{II}-heme-nitrosyl (Fe^{II}-NO^+) intermediate[9] that rapidly decomposes to NO and the Fe^{III}-heme by an internal electron transfer reaction. Until recently, however, model complexes for copper-containing nitrite reductases were notable solely by their absence; no structurally characterized copper-nitric oxide complexes were reported. Preliminary mechanistic studies on one copper nitrite reductase were interpreted as suggesting a mechanism similar to that utilized by the heme cd_1 enzymes, with a copper nitrosyl (possibly Cu^+-NO^+) species as an intermediate[10] (Fig. 3). In retrospect, the evidence originally reported for such a species is not particularly convincing, due largely to the lack of any model complexes for comparison.

The situation regarding models for copper enzymes has improved dramatically in the last three years, however, with reports by Karlin et al. and Tolman et al. of the synthesis of binuclear[11]

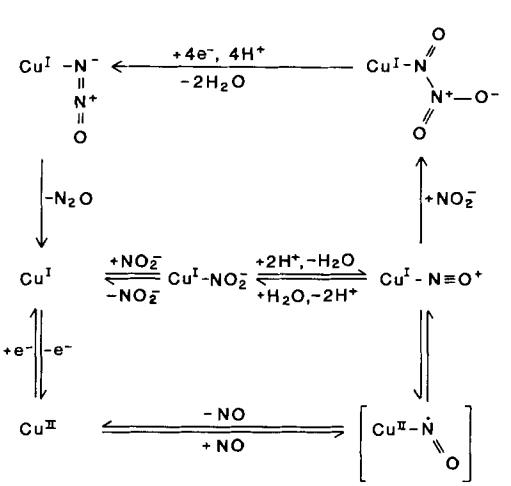

Fig. 3. Proposed mechanism for reactions of copper-containing nitrite reductases; (lower portion) reaction occurring at low levels of NO; (upper portion) possible reactions occurring in the presence of NO.

[*] Prof. B. A. Averill

and mononuclear[12] copper–NO complexes, respectively; Tolman et al. also synthesized a series of Cu^{II}[13, 14] and Cu^{I}[15, 16] nitrite complexes. These complexes have provided structurally characterized benchmarks for comparison of corresponding properties with appropriate forms of the enzymes. The work by Tolman et al. is particularly significant due to the use of the biologically relevant hydrotris(pyrazolyl)borate and 1,4,7-triazacyclononane (tacn) ligands. These tridentate ligands provide nitrogen ligation that closely resembles that formed by three imidazole ligands in the pseudotetrahedral coordination sphere of the active site of the *Achromobacter cycloclastes* nitrite reductase determined in an elegant structural study by Adman et al.[17] As a result of the synthetic work, we now have available a variety of structurally characterized model complexes with biologically relevant ligands, including both monomeric Cu^{II}–NO_2^- and Cu^{I}–NO_2^- and dimeric Cu^{I}–Cu^{I} and Cu^{I}–Cu^{II} complexes with bridging NO_2^- ligands, as well as Cu–NO complexes[12] in which the electron distribution is not quite so readily assessed. The monomeric Cu^{I}–NO_2^- complex,[16] in which nitrite is N-coordinated, and the Cu–NO[12] complexes are of particular significance, since they are the first structurally defined model systems that approximate the structures of the enzyme–substrate or enzyme–product complexes in copper-containing nitrite reductases.

Perhaps most importantly, these synthetic complexes have now been utilized to provide the first *functional* models for the chemistry occurring on the copper nitrite reductases. The copper enzymes are unique in being able to incorporate nitrogen from nitric oxide into nitrous oxide, although whether the reaction involves coupling of nitric oxide with nitrite or with a second molecule of nitric oxide derived from nitrite remains unclear.[6] In the two lovely pieces of work that have appeared recently, Tolman et al. have synthesized complexes that are able to mimic certain aspects of the reactivity of the copper enzymes. Thus, the complex $[(i\mathrm{Pr}_3\mathrm{TACN})\mathrm{Cu}(\mathrm{NO}_2)]$, containing nitrite coordinated to Cu^{I} through nitrogen, reacts smoothly with two equivalents of acid to give NO quantitatively,[16] presumably via a Cu^{I}–NO^+ intermediate similar to that originally proposed for the copper nitrite reductases.[10] Further, Tolman et al. have shown that Cu^{I} complexes with appropriately functionalized hydrotris(pyrazolyl)borate ligands react with NO to produce N_2O and the Cu^{II}–NO_2^- complexes in a novel disproportionation reaction.[14] Initial kinetics studies clearly show that the reaction is first order in the Cu complex, ruling out a pathway involving a dimeric intermediate. Remaining possibilities include coupling of NOs in a dinitrosyl copper complex and direct coupling of coordinated NO with free NO to produce coordinated N_2O_2 as an intermediate (Fig. 4). The reaction evidently occurs at one metal center, making it highly relevant to the enzyme-mediated reactions, which almost certainly occur at a monocopper active site. In passing, the above reactions also provide the first well-characterized model system for disproportionation of NO in heterogeneous reactions catalyzed by copper-containing systems.

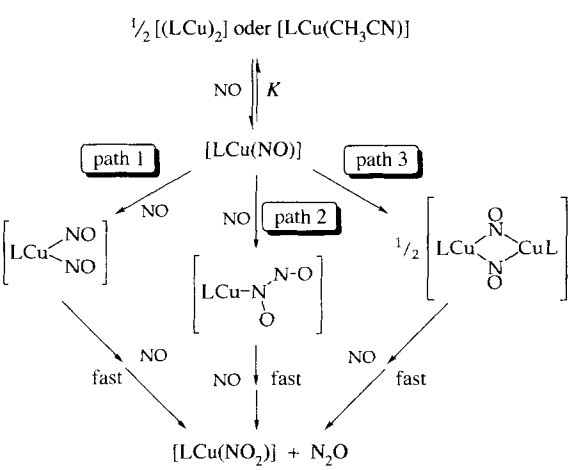

Fig. 4. Possible mechanisms for copper-mediated disproportionation of NO [14]. L = substituted tris(pyrazolyl)hydridoborate.

In only three years, we have thus come from an absence of any well-characterized copper nitrite or nitric oxide systems to having at our disposal a battery of structurally characterized compounds and a preliminary understanding of relevant reaction chemistry. By any standards, this constitutes remarkable progress.

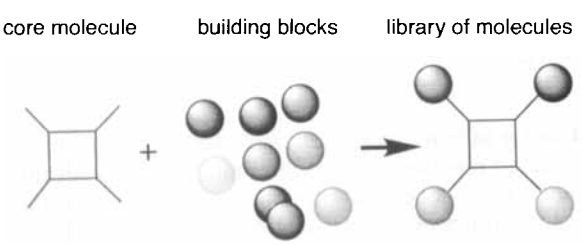
A Novel Procedure for the Synthesis of Libraries Containing Small Organic Molecules**

Thomas Carell, Edward A. Wintner,
A. Bashir-Hashemi,* Julius Rebek, Jr.*

The traditional approach to finding an active pharmacological compound requires the synthesis of individual compounds and the evaluation of their biological activity. Hundreds of compounds are typically synthesized and screened before a substance with significant activity is identified which then serves as a lead structure for the development of potent drug candidates. The time-consuming process of finding a lead compound can be accelerated by synthesizing, instead of single compounds, mixtures (libraries) of potentially biologically active molecules. The libraries generated may each contain a vast number of different molecules. Modern screening and isolation procedures offer the means to identify and isolate compounds from a library which fulfill specific biological requirements.[1] To alleviate the difficulties in preparing and handling large mixtures of compounds, strategies have been developed in which libraries of linear peptides on a solid support are synthesized and screened for promising lead compounds.[2] While this method offers the possibility of preparing complex libraries, lead structures discovered from peptides linked to a support have certain disadvantages. Because of their intrinsic conformational flexibility, peptide lead compounds still require extensive modifications before a suitable drug candidate can be proposed. In addition, the conformation of the immobilized peptide may be significantly affected by its solid support, such that the measured biological response does not reflect the activity of the free compound in solution.

In order to overcome these problems, we investigated the synthesis and screening of chemical libraries of small, semirigid compounds free in solution. We explored the reaction between a rigid core molecule (Fig. 1) possessing multiple reactive functional groups and a mixture of small reactive organic molecules (building blocks). Each building block contains one complementary functional group able to form a covalent bond with the core molecule.



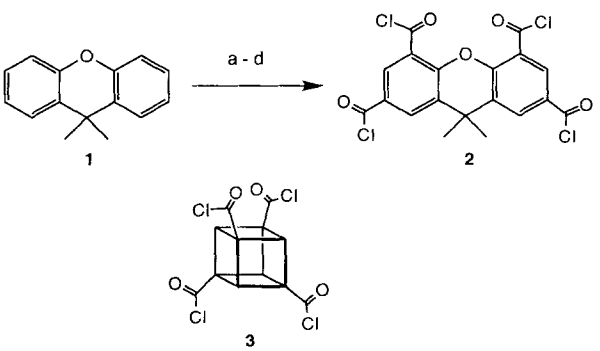


Fig. 1. Schematic representation of the generation of a library of small organic molecules.

In this approach, the spatial arrangement of the reactive groups on the core molecule defines the overall structure of the molecules in the library. By attaching the building blocks on the scaffold at random, every possible combination of building blocks can theoretically be generated. A variety of core molecules can be combined with a variety of building blocks in order to obtain nearly limitless libraries of conformationally restricted molecules. We chose as core molecules 9,9-dimethylxanthene-2,4,5,7-tetracarboxylic acid tetrachloride (**2**) and cubane-1,3,5,7-tetracarboxylic acid tetrachloride (**3**).[3] Attached building blocks are presented on the xanthene core molecule **2** in an overall disklike structure; on the cubane core molecule **3** the building blocks have a more spherical arrangement. The synthesis of the xanthene core molecule **2** was achieved in four steps starting from 9,9-dimethylxanthene (**1**) (Scheme 1).

Scheme 1. Cubane **3** and synthesis of xanthene derivative **2**. a) Br_2, cat. Fe powder, CH_2Cl_2, 2 h at 20 °C, 4 h at reflux, 93%; b) CuCN, *N*-methyl-2-pyrrolidine, 2 h, reflux, HNO_3 (20%), 10 h, reflux, 98%; c) NaOH, water, 14 h, reflux, 98%; d) PCl_5, benzene, 12 h, reflux, 68% [4].

Appropriate building blocks were selected after evaluation of numerous reactions between **2** and various individual amines. The products of these reactions were characterized and their HPLC properties examined for later experiments estimating library diversity (vide infra). Twenty-one amines, predominantly L-amino acid derivatives and small heterocycles (Scheme 2, Set 1), were chosen as building blocks for the generation of libraries; comparable reactivity towards the core molecule carboxylic acid chloride groups was the main criteria for tool selection. Additional functional groups on the amines were protected to define the regiochemistry between the building blocks and the core molecule, and to obtain initial libraries with good solubility in organic solvents.[5] The libraries were constructed by condensing one equivalent of a given tetracarboxylic acid tetrachloride core molecule in dichloromethane with four amine equivalents of a mixture of amines in dichloromethane. This approach minimizes competition effects between the amines for acid chloride groups and therefore should result in the synthesis of libraries with maximum diversity. The libraries thus generated

Set 2
L-alanine *tert*-butyl ester, N^{ω}-4-methoxy-2,3,6-trimethylbenzenesulfonyl-L-arginine, L-asparagine *tert*-butyl ester, O^4-*tert*-butyl-L-aspartic acid *tert*-butyl ester, *S*-trityl-L-cysteine, O^5-*tert*-butyl-L-glutamic acid *tert*-butyl ester, glycine methyl ester, N^{im}-trityl-L-histidine, L-isoleucine *tert*-butyl ester, L-leucine *tert*-butyl ester, N^{ε}-Boc-L-lysine methyl ester, L-methionine methyl ester, L-phenylalanine *tert*-butyl ester, L-proline *tert*-butyl ester, O-*tert*-butyl-L-serine *tert*-butyl ester, O-*tert*-butyl-L-threonine methyl ester, L-tryptophane methyl ester, O-*tert*-butyl-L-tyrosine methyl ester, L-valine *tert*-butyl ester

Scheme 2. Amines (building blocks) used for the synthesis of libraries. Trityl = triphenylmethyl, Boc = *tert*-butoxycarbonyl. The amides marked with a star were synthesized by reaction of the fluorenylmethoxycarbonyl (FMOC) protected amino acid with *p*-methoxybenzylamine, benzylamine, *n*-propylamine, or cyclohexylamine and subsequent cleavage of the FMOC group [4.5].

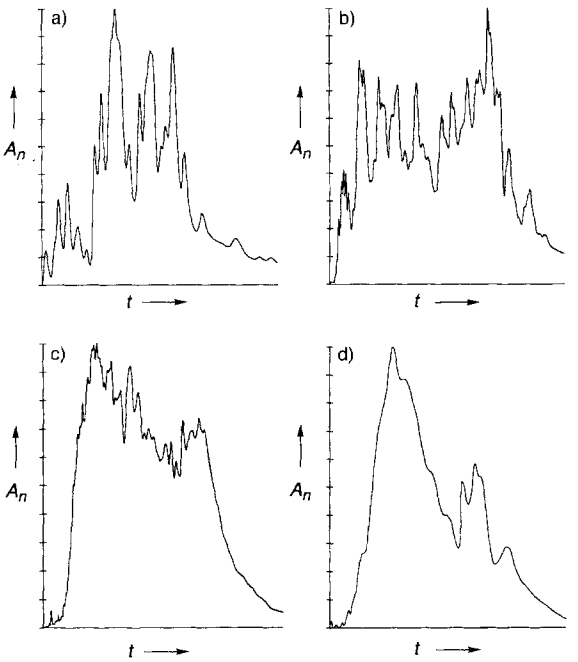

Fig. 2. Analytical HPLC traces (normalized) obtained from libraries of theoretically 136 (a), 1225 (b), 10440 (c), and 97461 compounds (d) [8]. The libraries were constructed with the **2** and 4, 7, 12, or all 21 of the amines listed in Scheme 2, Set 1.

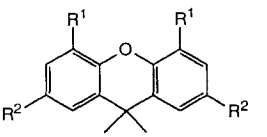

were purified by washing the dichloromethane solution with citric acid and sodium hydrogen carbonate solution to remove any unreacted starting material. By using the xanthene core molecule **2** and 4, 7, 12, or all 21 of the primary amines listed in Scheme 2, Set 1, libraries with increasing complexity were constructed containing theoretically 136, 1225, 10440, and 97461 different compounds, respectively.[6]

Corresponding reactions with the cubane core molecule **3** gave mixtures of fewer compounds (36, 245, 1860, and 16611, respectively), because the diversity of the libraries decreases with increasing symmetry of the core molecule. Even though the reaction products are complex mixtures of different compounds, the described procedure yielded powders which could be conveniently handled. More problematic was the clean conversion of these lipophilic libraries to their water-soluble forms; only the deprotected, water-soluble compounds were useful for later drug screening.

Hydrazinolysis or hydroxyl aminolysis of the methyl esters of the libraries gave the corresponding hydrazides and hydroxyl amides. Subsequent deprotection of the amino acid side chains with a mixture of trifluoroacetic acid, water, phenol, thioanisol, and ethanedithiol (82.5:5:5:5:2.5, reagent K)[7] yielded oils which were only slightly water-soluble. However, deprotection of the libraries constructed with 19 *tert*-butyl ester protected building blocks (Scheme 2, Set 2) with reagent K (4 h, room temperature) and subsequent treatment with diethyl ether/*n*-hexane afforded the libraries in the form of white powders with excellent solubility in water/dimethylsulfoxide (9:1).

We were not only interested in the synthesis of these libraries, but also in the determination of the variety of the compounds present in the libraries. In order to qualitatively determine library diversity, the mixtures containing theoretically 136, 1225, 10440, and 97461 compounds were evaluated by HPLC. The increasingly complex libraries featured increasingly complex HPLC traces (Fig. 2). In the chromatograms of lesser diversity (Fig. 2a, b) multiple peaks are readily observed in the spectra. The chromatogram of theoretically 97461 different compounds, however, contains no well-resolved peaks and tends towards a smooth curve. This is in agreement with the assumption of a much greater variety of compounds in the libraries constructed with 12 and 21 building blocks.

In order to investigate if our reactions between an acid chloride and a mixture of amine building blocks produce the statistical number of compounds expected, we synthesized and investigated smaller representative libraries. The readily accessible xanthenedicarboxylic acid dichloride **4** was used as a truncated core molecule for this purpose (Scheme 3).

2, $R^1 = R^2 = COCl$

a - c

4, $R^1 = COCl$, $R^2 = COOBz$

Scheme 3. Synthesis of **4**. a) Benzyl alcohol, pyridine, 2 h, 20 °C, 75%; b) HBr, CH_2Cl_2, 3 h, 0 °C, 72%; c) $(COCl)_2$, cat. DMF, CH_2Cl_2, 3 h, reflux, 97% [4].

With **4** and a mixture of ten selected building blocks from Scheme 2, Set 2, a representative library containing theoretically 55 compounds was synthesized such that each compound in the library had a distinct molecular weight.[6] This model library was then analyzed for the presence of all theoretically predicted molecules.

An HPLC trace of the library was similar to that obtained from the library with 136 compounds described above. The presence of roughly 40 peaks in the chromatogram hinted that indeed most of the desired compounds were present in the mixture. The model library was then subjected to plasma desorption or fast atom bombardment (FAB) mass spectrometry directly or after separation into various fractions by preparative HPLC.[8] The mass spectra contained nearly exclusively signals in the mass range expected for the molecules in the library, and little fragmentation was observed. In a detailed mass spectroscopic investigation of the 55-compound model library, 75% (42) of

the expected molecular ion peaks were observed, which confirms that a sizable fraction of the theoretically expected 55 compounds are present in the mixture. Further investigation of several representative water-soluble libraries with electrospray mass spectrometry and HPLC mass spectrometry are in progress to fully quantify the diversity of the model libraries.[9] However, the results presented here alone indicate that large and well-defined libraries of small organic molecules with a conformationally restricted, drug-related structure can be generated by condensing a core molecule with a set of primary amines.

In order to determine whether single compounds with interesting biological properties can be obtained from our libraries, we synthesized and screened several highly diverse mixtures using the cubanetetracarboxylic acid tetrachloride **3**, the xanthenetetracarboxylic acid tetrachloride **2**, and the 19 building blocks listed in Scheme 2, Set 2. After deprotection with reagent K and precipitation of the libraries from ether/*n*-hexane, the obtained white powders were screened in a modified trypsin assay for their ability to inhibit the trypsin-catalyzed cleavage of an amide bond.[10, 11] By employing a procedure described in the following communication,[11] we were able to extract from this mixture—in only four weeks of work—a molecule able to inhibit the trypsin-catalyzed reaction. The selection strategy enabled us to rapidly isolate from libraries of tens of thousands of compounds a single compound with the desired biological properties.[10, 11]

Experimental Procedure

General description of the synthesis of diverse libraries: Xanthene-2,4,5,7-tetracarboxylic acid tetrachloride **2** (100 mg, 0.217 mmol), a given mixture of amines (0.88 mmol total), and 5 mL of dichloromethane under argon were treated with 1 mL of triethylamine. The reaction mixture was stirred under argon for 3 h, then diluted with dichloromethane (50 mL) and washed with 1 M citric acid solution (2 × 75 mL) and with saturated sodium hydrogen carbonate solution (1 × 100 mL). The organic phase was dried over $MgSO_4$ and concentrated to afford a tan oil, which formed a tan foam in vacuo. The protecting groups were removed by stirring with reagent K [7] at room temperature for 4 h (reagent K: trifluoroacetic acid, water, phenol, thioanisol, and ethanedithiol 82.5:5:5:5:2.5). The solution was concentrated in vacuo and the libraries precipitated by adding cold diethyl ether and *n*-hexane. The white precipitate was filtered off, washed five times with cold diethyl ether, and dried in vacuo.

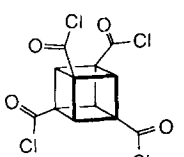
A Solution-Phase Screening Procedure for the Isolation of Active Compounds from a Library of Molecules**



Thomas Carell, Edward A. Wintner, and Julius Rebek, Jr.*

In the preceding communication[1] we described an approach to molecular diversity that produces structurally biased libraries of small molecules in solution. As these libraries are synthesized as complex mixtures, this approach runs counter to the traditional teachings of synthetic organic chemistry in which single compounds of high purity are the goal. Because the new approach uses neither coding schemes[2] nor spatially isolated molecules,[3] conventional methods for screening and amplification are not applicable.[4] Accordingly, we have developed a solution-phase selection procedure for use with these mixtures, and we report here our initial findings.

All of the libraries were constructed by following a two-step procedure.[1] In the first step, a core molecule such as xanthene tetracarboxylic acid tetrachloride **1** or cubane tetracarboxylic acid tetrachloride **2** was condensed with a mixture of 19 protect-

1

2

ed L-amino acids designated as building blocks.[5] The diversity of compounds obtained in this reaction is determined by the number of building blocks used and by the symmetry of the core molecule. With 19 building blocks and xanthene **1**, 65 341 different variants are theoretically produced. By using cubane **2** with its higher symmetry, only 11 191 possible compounds are generated from the same set of building blocks. In the second step, the generated libraries were treated with a trifluoroacetic acid based reagent to remove acid-labile protection groups present on certain building blocks. After precipitation with diethyl ether/*n*-hexane, the mixtures were obtained in the form of white powders with sufficient solubility in a 9:1 mixture of water/dimethylsulfoxide (DMSO) for enzymatic studies.[1]

[**] This work was supported by the National Institutes of Health, the Alexander von Humboldt Foundation (Feodor-Lynen fellowship to T. C.), and the National Science Foundation (predoctoral fellowship to E. A. W.). We thank Prof. J. Stubbe for advice regarding the enzyme assay and Dr. A. J. Sutherland for corroborating several assay experiments.

The screening procedure was based on a trypsin assay as performed by Houghten et al. on peptide mixtures.[6] Our goal was to identify a compound within the library able to inhibit the trypsin-catalyzed hydrolysis of the amide bond in N^{α}-benzoyl-D,L-arginine-*p*-nitroanilide (BAPA). In the assays, the activity of the inhibitor was correlated inversely to the rate of *p*-nitroaniline released by the enzyme. The results of adding various libraries to the trypsin assay are shown in Figure 1.

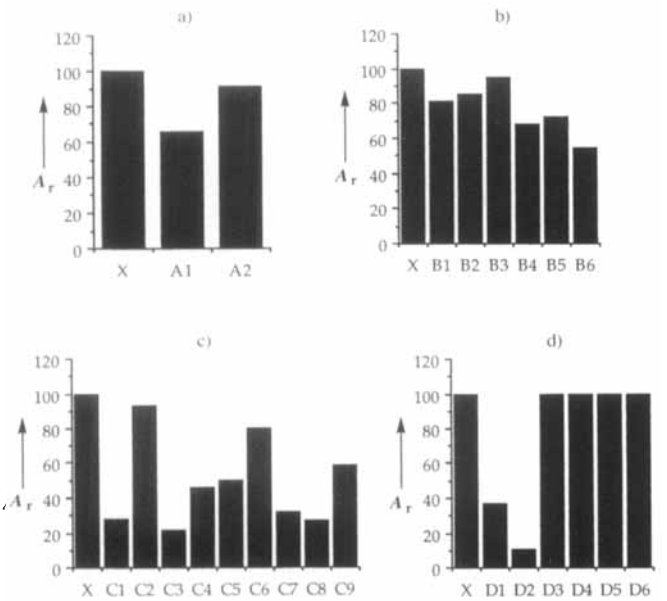

Fig. 1. Trypsin activity A_r in the presence of added libraries relative to that of a blank (X, $A_r = 100\%$) containing no added library material. Each bar represents average trypsin activity for four measurements. a) Trypsin activity [%] with the initial libraries A1 and A2 (in each case 2.5 mg in 50 mL of DMSO) constructed from the core molecules **1** and **2**, respectively, and 19 amino acid building blocks [1,5]. b) Trypsin activity [%] with the six sublibraries B1–B6 (in each case 2.5 mg in 50 mL of DMSO) constructed from core molecule **1** and 15 of the 19 amino acid building blocks (without *S*-Trt-Cys). B1: group G1 omitted; B2: group G2 omitted; B3: group G3 omitted; B4: group G4 omitted. B5: group G5 omitted. B6: Group G6 omitted. Groups G1–G6 are listed in Table 1. c) Trypsin activity [%] with the nine sublibraries C1–C9 (in each case 1.5 mg in 50 mL of DMSO) constructed from the core molecule **1** and eight of the nine building blocks from the amino acids in groups G1–G3 (Table 1). C1: Arg omitted; C2: Lys omitted; C3: His omitted; C4: Leu omitted; C5: Ile omitted; C6: Pro omitted; C7: Gly omitted; C8: Ala omitted; C9: Val omitted. d) Trypsin activity [%] with the six sublibraries D1–D6 (in each case 0.5 mg in 50 mL of DMSO). For a description of their compositions see text and Table 2.

Plot a in Figure 1 depicts the screening results obtained from the initial libraries (A1 and A2) generated from the core molecules **1** and **2** and the 19 protected amino acids.[5] Even though both libraries were constructed with the same set of building blocks, only library A1 caused a significant reduction of trypsin activity (approximately 30%). The fact that library A2, based on the cubane core molecule **2**, does not interfere substantially with enzyme reaction (activity 91%) suggests that merely the presence of certain functional groups is not enough to produce a trypsin inhibitor. Rather, the orientation and arrangement of these functional groups with respect to each other and the (relatively rigid) core molecule are also important.

In order to determine which of the 19 building blocks are essential for an active xanthene library, three further screening procedures were carried out.

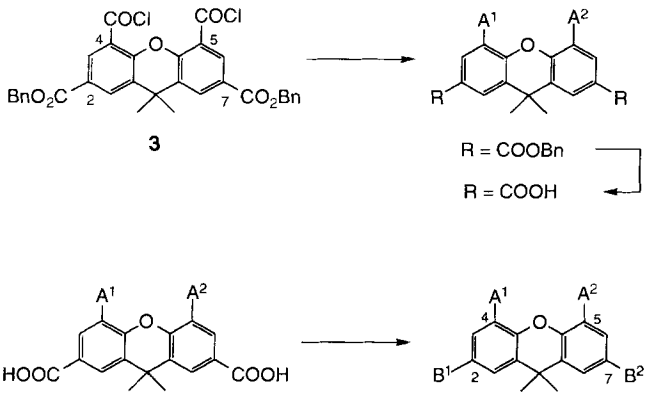
The first experiment was developed to reduce the number of potentially active building blocks from 19 to 9. We divided the building blocks (without *S*-Trt-Cys) into six groups, G1–G6 (Table 1). Each group contained three building blocks with related side chains. Six sublibraries B1–B6 were then synthesized by using the xanthene core molecule **1** and five of the six building block groups G1–G6. The screening results from each sublibrary (plot b, Fig. 1) indicate that when certain amino acid groups were omitted from the set of 19, the ability of the library to inhibit the trypsin reaction was reduced. By ranking the activity of each sublibrary, the importance of the omitted group of amino acids could be ascertained. Sublibraries B1–B3, which do not contain the amino acids in groups G1–G3, showed highest trypsin activity. Therefore the nine amino acids in groups G1–G3 showed the greatest inhibitory activity in the context of the xanthene skeleton. Only these nine amino acids were examined in the second screening step.

Table 1. The building blocks in groups G1–G6; see [5] for protecting groups used.

G1	G2	G3	G4	G5	G6
Gly	Leu	Arg	Ser	Phe	Glu
Ala	Ile	Lys	Thr	Tyr	Asp
Val	Pro	His	Met	Trp	Asn

The second experiment reduced the number of potentially active building blocks from nine to five. Nine sublibraries (C1–C9) of eight building blocks each were synthesized with sequential omission of one of the nine protected amino acids. The screening results obtained from these nine sublibraries (plot c, Fig. 1) indicate that the sublibraries created without the building blocks N^{ε}-Boc-Lys-OMe, Leu-O*t*Bu, Ile-O*t*Bu, Pro-O*t*Bu, or Val-O*t*Bu (C2, C4, C5, C6, and C9, respectively) resulted in very high trypsin activities; they did not contain potent trypsin inhibitors. These five building blocks were therefore deduced to be the substituents predominantly responsible for the generation of inhibitors.

In the third round of screening, sublibraries were generated from the xanthene core molecule and mixtures of three or four of the five building blocks N^{ε}-Boc-Lys-OMe, Leu-O*t*Bu, Ile-O*t*Bu, Pro-O*t*Bu, and Val-O*t*Bu. Trypsin assays with these sublibraries confirmed the results of plot c, and showed that the highest inhibitory activity resulted from a library constructed of **1** and N^{ε}-Boc-Lys-OMe, Ile-O*t*Bu, Pro-O*t*Bu, and Val-O*t*Bu. Omission of any one of these four building blocks gave libraries with significantly reduced inhibitory activity.[7]



We were aided by the fact that with each round of screening, the sublibraries became less complex. The relative concentration of each compound increases as sublibraries become smaller, and since only active sublibraries are selected, the net effect is an "amplification" of the concentration of active compound(s) relative to inactive compounds. As activities of successive screening rounds become more pronounced, the sublibraries become ever easier to assay.

Thus, after only three rounds of screening, we were left with the 12 structural isomers of the Lys-Ile-Pro-Val-xanthene derivative. To determine the structure of the most potent molecule among the isomers, six more sublibraries (D1–D6, Table 2) were generated following the two-step synthetic procedure outlined schematically in Scheme 1.

For each sublibrary, the dibenzyl ester protected xanthene dicarboxylic acid dichloride **3**[1] was first reacted with only two of the four building blocks N^{ε}-Boc-Lys-OMe, Ile-O*t*Bu, Pro-O*t*Bu, Val-O*t*Bu. Debenzylation by hydrogenation of the resulting three-compound mixtures (H_2; 10% Pd/C; ethyl acetate/ethanol 9:1) followed by reaction with the other two building

Table 2. List of the amino acids attached to xanthene positions 4 and 5 (A^1, A^2), and positions 2 and 7 (B^1, B^2) in the generation of sub-libraries D1–D6.

Sublibrary	A^1,A^2	B^1,B^2

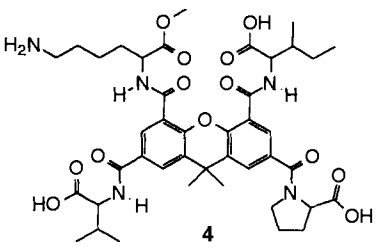
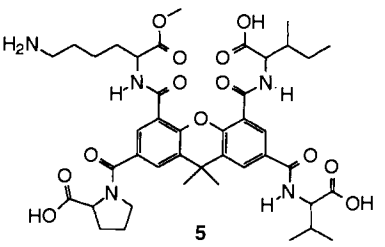


Scheme 1. Synthesis of the sublibraries D1–D6 (see Table 2 for A^1, A^2, B^1, B^2).



blocks (1*H*-benzotriazol-1-olato-*O*)tris(*N*-methylmethanaminato)phosphorus hexafluorophosphate (BOP), dimethylformamide (DMF), triethylamine (TEA) gave in each case a mixture of ten compounds. After cleavage of the acid-labile protection groups, the six sublibraries D1–D6 were obtained, each with a unique distribution of products. The amino acids and their positions on the core molecule are listed in Table 2.

The screening results obtained from these sublibraries (plot d, Fig. 1) indicate that only those mixtures in which the 4- and 5-positions were substituted with Lys/Val or Lys/Ile combinations contained inhibitory compounds (sublibraries D1 and D2, respectively). The most active mixture was D2; D1 was slightly less active. In contrast, sublibrary D3, which contained only compounds in which the 4- and 5-positions were substituted with Lys/Pro, showed no inhibitory activity. All three sublibraries in which the Lys building block was attached at positions 2 or 7 were inactive as well (sublibraries D4–D6). These results narrowed down the most potent inhibitor to **4** and **5**.

Compounds **4** and **5** were synthesized, and their activities were determined.[9] Despite their structural similarities, compound **4** is significantly more active than its structural isomer **5**. Compound **4** is a competitive inhibitor for trypsin ($K_i = 9 \pm 2 \times 10^{-6}$ M). Further investigations are underway to clarify the interaction of **4** with trypsin.

It must be noted that compound **4** is clearly not the only inhibitory compound present in the original library A1. The described screening procedure guided us to a set of structurally related molecules of which **4** was the most potent inhibitor. But this set may or may not include the most effective inhibitor from the given library with 19 building blocks. We are currently examining libraries in which certain substituents of **4** remain constant while others are "randomized" with various sets of the original 19 building blocks. This should allow us to jump from one set of active compounds to the next. By using this strategy we hope to determine the effectiveness of our present screening procedure in selecting the most potent inhibitor from the 65341 compounds in library A1.

Nevertheless, by applying our simple iterative screening procedure, we were able to isolate the single compound **4**, a nonlinear peptide inhibitor with a micromolar inhibition of trypsin, from a complex library of small organic molecules in solution in a few weeks. This result suggests that the synthesis and screening of molecular libraries from a core molecule and a variety of building blocks[1] is a useful means of exploring the structural landscape of small molecules and can complement the existing repertoire of methodologies for finding suitable lead compounds for pharmaceuticals. Furthermore, while this study used readily available protected L-amino acids and only two types of core molecules, any nucleophile leading to products of reasonable hydrolytic stability can be used with these or other core molecules. The potential variety of new libraries offered by this method is clearly limitless.

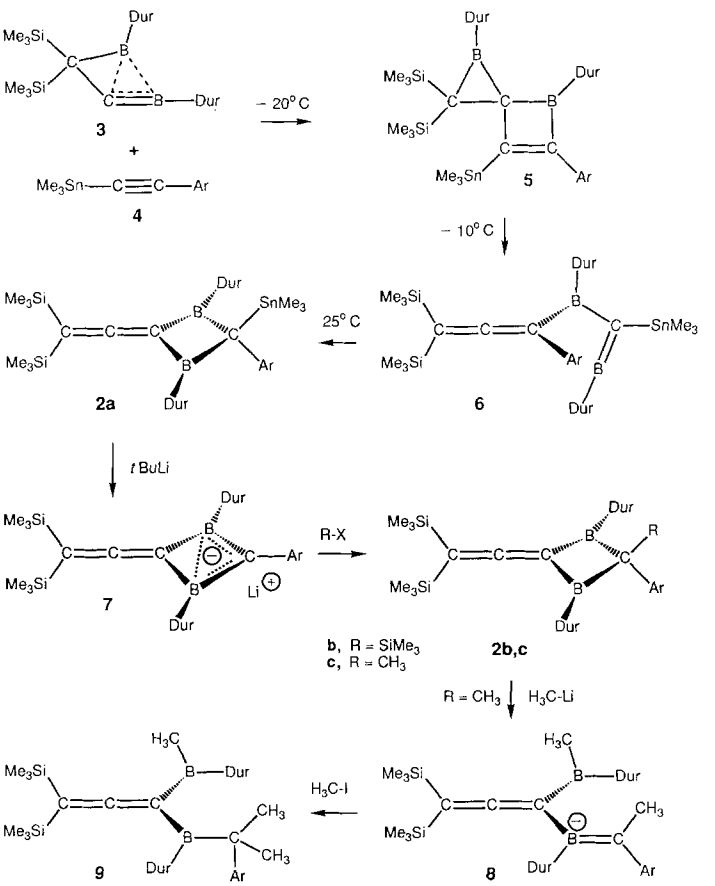
[9] Both compounds were fully characterized. A detailed description of their synthesis and characterization will be described elsewhere. Compound **3** was reacted first with N^{ε}-Boc-Lys-OMe and Ile-O*t*Bu (at positions 4 and 5), and the compound in which A^1 = Lys and A^2 = Ile was isolated through chromatography. Subsequent debenzylation and reaction of the resulting dicarboxylic acid with Pro-O*t*Bu and Val-O*t*Bu (at positions 2 and 7) gave four compounds from which the two isomers (A^1 = Lys, A^2 = Ile, B^1 = Val, B^2 = Pro and A^1 = Lys, A^2 = Ile, B^1 = Pro, B^2 = Val) were obtained individually by chromatography. Deprotection with trifluoroacetic acid and purification by reversed-phase preparative HPLC gave **4** and **5** as white powders. All analytical data (NMR, COSY, NOE, MS) are in agreement with the proposed structures. Initial experiments indicate that **4** is a specific trypsin inhibitor; **4** does not inhibit the activity of thrombin, a related serine protease, to any noticeable extent.

Nonclassical Stabilization of Planar Allenes: Low Rotational Barriers for Allene Double Bonds**



Dirk Steiner, Heinz-Jürgen Winkler, Sigrid Wočadlo, Stefan Fau, Werner Massa, Gernot Frenking, and Armin Berndt*

According to MP2/4-31G calculations of Schleyer et al.,[1] the orthogonal allene $\mathbf{1}_o$ is 11.6 kcal mol^{-1} higher in energy than the planar allene $\mathbf{1}_p$, which is misleadingly described by the classical formula $\mathbf{1}_p^*$. Polarization of the C–C double bonds adjacent to the boron atoms leads to the stabilization of the negative charge in the 2π-electron arene diboriranide[2] (resonance structure $\mathbf{1}_o'$). The positive charge of the formal vinyl cation can, however, only be stabilized through C–B hyperconjugation with the strained C–B σ bonds[2, 3] of the three-membered ring after

rotation around the polarized double bond. Optimum stabilization is achieved in planar $\mathbf{1}_p'$. These nonclassical interactions in $\mathbf{1}_p$ are adequately described by 3c–2e bonds.[2] We report here on the classical orthogonal allenes $\mathbf{2}_o$, which are related to **1** and have remarkably low barriers to rotation around C–C double bonds. This can be explained by the formation of planar, nonclassical allenes $\mathbf{2}_p$ in the transition state, which are stabilized as described above; the 2π-electron arene diboriranide in **1** has now been replaced by the 2π-electron arene homodiboriranide[4] in **2**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The methyleneborane **3** (Dur = 2,3,5,6-tetramethylphenyl, Ar = 3,5-di-*tert*-butylphenyl)[2] added to alkyne **4** at −20 °C to form **5**, which isomerized at −10 °C to **6**.[5] Rearrangement of **6** at 25 °C gave the allene **2a**. The aryl group, which was linked to an allene C atom in **6**, is now bound to the C atom between both B atoms in **2a**. The allene **2a** could be transformed by tin/lithium exchange with *t*BuLi to the lithium compound **7**, which gave the allenes **2b** and **2c** on treatment with chlorotrimethylsilane (X = Cl) and methyl iodide (X = I), respectively. The 1,1-diborylallene **9** was prepared for the purpose of comparison from **2c** via **8** by treatment with methyllithium and then methyl iodide. The structures of **2a**–**c**, **5**, **6**, and **9** were deduced from their NMR spectra (Table 1); those of **2a** and **2c** were confirmed by crystal structure analysis (Fig. 1, Table 2).[6]

The signal at $\delta = 85$ in the ^{11}B NMR spectrum of **9** lies in the region associated with boron atoms that are not in conjugation with π donors: due to mutual steric hindrance, the boryl substituents are twisted in such a way that the empty p orbitals of the boron atoms cannot interact with the π electrons of the allene. The signal at $\delta = 74$ in the ^{11}B NMR spectrum of **2c** indicates π delocalization as shown in **2′$_o$**; this is also reflected in the relatively long C2–C3 bond and in the shortened C2–B1 and C2–B2 bonds with respect to **2a** (see Table 2). The π delocalization corresponding to **2′$_o$** is less important in **2a** because C–Sn hyperconjugation reduces the electron deficiency at the boron atoms. This results in a long C1–Sn bond (224 compared with 212–214 pm for the Sn–CH_3 bonds), small B-C-Sn and Sn-C-C(aryl) angles, short C1–B1 and C1–B2 bonds, and shielding of the boron atoms ($\delta(^{11}B) = 63$). The geminal trimethylsilyl groups in **2a**–**c** give rise to two signals in the ^{1}H NMR spectrum only below 300, 263, and 173 K, respectively. These signals broaden at higher temperatures and coalesce at

Table 1. Selected physical data for compounds **2a**–**c**, **5**, **6**, and **9**.

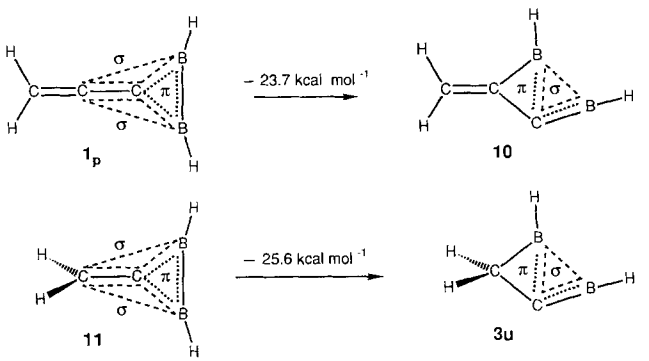
315, 273, and 183 K, respectively. The activation energies for exchange were calculated to be 14.5 (**2a**), 12.6 (**2b**), and 8.6 (**2c**) kcal mol^{-1}, as determined by the temperature of coalescence and the difference in the chemical shifts at slow exchange.

The low barriers (rotation around the C–C double bond of an allene usually requires 46–47 kcal mol^{-1}[7]) and their dependence on the substituent at C1 can be explained when one assumes that exchange takes place by rotation around the C–CB_2 bond. The transition-state conformations are therefore planar allenes $\mathbf{2}_p$. Their negative charge is stabilized by $\pi-\pi$ delocalization towards homodiboriranides $\mathbf{2}'_p$, and their positive charge through $\sigma-\pi$ delocalization of the C(sp^2)–B σ bonds of the homodiboriranide rings as shown in $\mathbf{2}_p$. The Me_3Sn and Me_3Si substituents in **2a** and **2b** lower the electron deficiency of the boron atoms through C–Sn and C–Si hyperconjugation. The π delocalization as shown in $\mathbf{2}'_p$ as well as the subsequent σ delocalization as shown in $\mathbf{2}_p$ are therefore less important. The energies of the transition-state conformations of **2a** and **2b** are thus higher than that of **2c**.



Our explanation for the low exchange barriers is supported by MP2/6-31G* calculations[8] for the model allene **2u**: The nonclassical planar allene $\mathbf{2u}_p$ is only 6.2 kcal mol^{-1} (MP2/6-31G* + ZPE[8]) higher in energy than the classical orthogonal

$\mathbf{2u}_o$. This difference in energy is consistent with the exchange barrier of 8.6 kcal mol^{-1} determined for **2c**. The strong homoaromatic π delocalization in the transition state $\mathbf{2u}_p$ is reflected in a short calculated B···B distance of 185.7 pm ($\mathbf{2u}_o$: 198.2 pm);[10] the strong C–B hyperconjugation results in a short bond length for the polarized C–CB_2 bond (130.9 pm), which is even shorter than the weakly polarized C–CB_2 bond of $\mathbf{2u}_o$ (132.0 pm). Similarly, a very short B–B bond (147.2 pm; 158.7 pm in $\mathbf{1}_o$) and a slightly shorter C–CB_2 bond (129.7 pm; 130.9 pm in $\mathbf{1}_o$) have been calculated for $\mathbf{1}_p$.[1] The influence of the silyl substituents on the rotational barrier is low: the energy difference between the orthogonal and planar forms of allene **2u** without silyl groups is 9.1 kcal mol^{-1} (MP2/6-31G* + ZPE[8]).

The energy difference between the orthogonal and planar allenes is approximately 37 kcal mol^{-1} less for **2c** than for alkyl-substituted allenes (46–47 kcal mol^{-1}[7]). Replacement of the homoaromaticity in **2** by the aromaticity in the diboriranide **1** should further stabilize the planar form and give rise to allenes with planar ground states. However, calculations at the MP2/6-31G* level show that the structure $\mathbf{1}_p$ is not a minimum on the potential hypersurface. The Hesse matrix has a negative eigenvalue, which indicates that $\mathbf{1}_p$ is a transition state. A geometrical optimization without symmetry constraints gives the minimum energy structure **10**, which is 23.7 kcal mol^{-1} more stable than $\mathbf{1}_p$ at the MP2/6-31G* level.

Thus, planar allenes are just as unlikely to be prepared by this route as the analogous orthogonal alkenes with the basic unit

11. The latter is 25.6 kcal mol^{-1} (MP2/6-31G*) higher in energy than the corresponding methyleneborane **3u**.[2, 11]

[5] The structure of **6** (Me_3Sn group linked to the carbon atom adjacent to the dicoordinated boron atom) follows clearly from the small ^{13}C, ^{119}Sn coupling constant of 46.5 Hz and the shielding of the C atom in the C–B double bond ($\delta(^{13}C) = 78$), which is characteristic of stannylmethyleneboranes (the corresponding compound with Me_3Sn instead of the aryl group shows values of $\delta(^{13}C) = 75.3$ and $^1J(^{13}C, ^{119}Sn) = 66$ Hz [2].

[6] Crystal structure analysis: yellow crystals of **2a** · 0.5 *n*-C_6H_{14} and **2c** were measured on a four-circle diffractometer (CAD4 Enraf-Nonius) at –80 °C and at room temperature (**2c**) with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). **2a**: $C_{47}H_{74}B_2Si_2Sn \cdot 0.5\,C_6H_{14}$, crystal dimensions $0.3 \times 0.25 \times 0.2$ mm^3, monoclinic, space group $P2_1/n$, $Z = 4$, $a = 1326.5(1)$, $b = 947.4(1)$, $c = 4207.0(4)$ pm, $\beta = 91.99(1)°$, $V = 5283.9 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.104$ g cm^{-3}; 7220 measured reflections up to $2\theta = 110°$ (ω scans), of which 6609 were independent. 4877 reflections with $F_o > 3\sigma(F_o)$, after Lorentz and polarization correction, were used for further calculations, no absorption correction ($\mu = 4.479$ mm^{-1}). The structure was solved with direct methods and refined with full matrix against the F_o data. The H atoms were included in the calculation riding on their bonding partners, partially on calculated positions and with common isotropic temperature factors refined in groups. For the rest of the atoms, anisotropic temperature factors were used. $R = 0.062$, $wR = 0.040$ ($w = 1/\sigma^2(F_o)$), maximum residual electron density 0.66 e Å^{-3}. – **2c**: $C_{45}H_{68}B_2Si_2$, crystal dimensions $0.4 \times 0.3 \times 0.15$ mm, monoclinic, space group $P2_1/n$, $Z = 4$, $a = 1399.3(3)$, $b = 2001.6(4)$, $c = 1666.7(3)$ pm, $\beta = 95.80(3)°$, $V = 4644.0 \times 10^{-30}$ m^3, $\rho_{calcd} = 0.982$ g cm^{-3}; 4353 measured reflections up to $2\theta = 94°$ (ω scans), of which 4166 were independent. 4165 reflections, after Lorentz and polarization correction, were used for further calculations; the structure was solved and refined as for **2a**. The refinement against the F_o^2 data (SHELXL-93) was complicated by disorder in the *tert*-butyl groups at C32 and C34; a "split atom model" description led to a $wR_2 = 0.225$, corresponding to a conventional $R = 0.076$ for 1759 reflections with $I > 2\sigma(I)$, and a maximum residual electron density of 0.27 e Å^3. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-58377.

[7] The rotational barrier for the C–C double bond in 1,3-dimethyl- and 1,3-di-*tert*-butylallene were determined to be 46.17 and 46.91 kcal mol^{-1}, respectively: W. R. Roth, G. Ruf, P. W. Ford, *Chem. Ber.* **1974**, *107*, 48–52.

[8] The calculations were performed with the programs Gaussian 92 [9a] and TURBOMOLE [9b]. The geometries were optimized at the HF/6-31G* and MP2/6-31G* levels. The equillibrium structures were calculated as minima ($i = 0$) or transition states ($i = 1$) at the HF/6-31G* level. The zero-point vibration corrections (ZPE) were scaled with a factor of 0.89 at the HF/6-31G* level.

[9] a) Gaussian 92, Revision A: M. J. Frisch, G. W. Trucks, M. Head-Gordon, P. M. W. Gill, M. W. Wong, J. B. Foresman, H. B. Schlegel, K. Raghavachari, M. A. Robb, J. S. Binkley, C. Gonzalez, R. Martin, D. J. Fox, D. J. DeFrees, J. Baker, J. J. P. Stewart, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1992**; b) TURBOMOLE: R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, *162*, 165–169.

[10] The ring folding angle at the B–B diagonal is 32.3° in $2u_p$ and 31.3° in $2u_o$; the barriers to ring inversion of the folded four-membered ring are calculated as 4.5 kcal mol^{-1} for $2u_o$ and 5.5 kcal mol^{-1} for $2u_p$ and thus are significantly smaller than for a homodiboriranide without strong C–B hyperconjugation (7.9 kcal mol^{-1} [4]).

Synthesis of Sulfonamido-Pseudopeptides: New Chiral Unnatural Oligomers

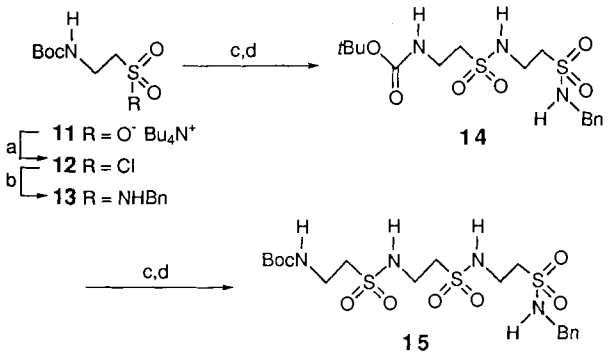
Cesare Gennari,* Barbara Salom, Donatella Potenza, and Anthony Williams

Although many research groups have devoted their efforts during the past two decades to the replacement of the scissile peptide bond with mimetic groups,[1] relatively little is known about pseudopeptides characterized by the presence of the sulfonamide bond.[2] This modification creates a peptide bond surrogate with significant changes in polarity, H-bonding capability, and acid–base character (RSO_2NHR', $pK_a = 10–11$). Furthermore, the sulfonamide bond should show enhanced metabolic stability and structural similarity to the tetrahedral transition state involved in the amide bond enzymatic hydrolysis.[2a–c] This makes sulfonamidopeptides promising candidates in the development of protease inhibitors and new drugs.[3] The oligomers and the polymers should also be interesting molecular scaffolds, with specific pseudopeptide backbone conformations based on the hydrogen-bonding network.

Unfortunately α-aminosulfonamides are known to be unstable and to immediately decompose by fragmentation.[4] We have synthesized chiral vinylogous aminosulfonic acids (γ-amino-α,β-unsaturated) from natural α-amino acids, developed a straightforward protection–deprotection–coupling chemistry for the sulfonamide bond, and synthesized sulfonamido-pseudopeptides by an iterative process (Scheme 1).

N-Boc α-aminoaldehydes **1** (Boc = *tert*-butoxycarbonyl) were obtained from naturally occurring α-amino acids.[5] Wittig–Horner reaction with methyl- or ethyldiethylphosphoryl methanesulfonate **2** (R = Me, Et[6, 7a]) and *n*BuLi at −78 °C gave the corresponding α,β-unsaturated sulfonates **3** in good yield (75–85%) and complete *E* stereoselectivity.[6c] Cleavage of the methyl (ethyl) ester was effected by treatment of sulfonates **3** with nBu_4NI in refluxing acetone (100%).[7a, 8] This deprotection offers several advantages over related reactions leading to different sulfonate salts (e.g., Na^+, NH_4^+, $NHEt_3^+$)[7b–d]: a) the nBu_4N^+ salts **4** are easily handleable and soluble in organic solvents; b) they are the most suitable starting material for the next step. The activation step required an extensive search for appropriate reagents and conditions. After screening several different methods, we found that SO_2Cl_2/PPh_3 in dichloromethane[8] gives the corresponding sulfonyl chlorides **5** cleanly and in high yield (85–90%) as stable compounds which can be purified by chromatography, while other protocols (e.g., triphosgene/cat. dimethylformamide (DMF)/CH_2Cl_2,[9] $PCl_5/CHCl_3$[10]) were less efficient. The sulfonyl chlorides **5** were coupled with the amine salts **6** (CH_2Cl_2/1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)/cat. 4-dimethylaminopyridine (DMAP)) to give the dimers **7**. Although the coupling step is unoptimized and needs further improvement, the dimers **7** were obtained in a reasonable yield (55–65%). Amine hydrochlorides **6** were prepared from *N*-Boc derivatives **3** by treatment with 3 M HCl in MeOH (room temperature, 3 h) followed by solvent removal (100%). The process can be further iterated to give trimers (e.g., **9**, 60%) and tetramers (e.g., **10**, 60%; R = Et, R^1 = Me, R^2 = *i*Pr, $R^3 = CH_2Ph$, $R^4 = CH_2CHMe_2$).

Scheme 1. Synthesis of sulfonamido-pseudopeptides from *N*-Boc α-aminoaldehydes. a) $(EtO)_2PO-CH_2SO_3R$ **2**, *n*BuLi, THF, −78 °C, 30 min, 75–85%. b) Bu_4NI, acetone, reflux, 10–16 h, 100%. c) SO_2Cl_2, Ph_3P, CH_2Cl_2, 3 Å molecular sieves, 0 → 25 °C, 3 h, 85–90%. d) CH_2Cl_2, DBU, cat. DMAP, 25 °C, 18 h, 55–65%. e) 3 M HCl in MeOH, 0 → 25 °C, 3 h, 100%.



The stereochemical integrity was checked a) by α-methoxy-α-trifluoromethyl(phenyl)acetic acid (MTPA) derivatization[11] of hydrochlorides **6** and NMR analysis (^1H, ^{13}C, ^{19}F),[12] and b) by ^{13}C NMR analysis of dimers **7**.[13] The sulfonamide bond is formed from the sulfonyl chloride and the amine by a nucleophilic substitution at the four-coordinate sulfur.[14a] The alternative sequence involving an elimination–addition reaction via an achiral unsaturated sulfene,[14b] is not likely to occur as it would lead to a mixture of two diastereomeric dimers.[13]

Similar activation and coupling chemistry proved effective also for the synthesis of sulfonamido-pseudopeptides based on β-aminosulfonamides, which, unlike α-aminosulfonamides, are

known to be stable[2a-e, 4a] (Scheme 2). Saturated γ-aminosulfonic acids are also available, by the conjugate reduction of unsaturated sulfonate esters **3** with $Li(sBu)_3BH$ in THF (70–80%).[15]

Scheme 2. Sulfonamido-pseudopeptides derived from taurine. a) CH_2Cl_2, cat. DMF, triphosgene, 25 °C, 30 min. b) CH_2Cl_2, $PhCH_2NH_2$, DBU, 0 → 25 °C, 15 h (a + b = 82%). c) TFA/CH_2Cl_2 (1:1), 0 °C, 20 min, 100%. d) **12**, CH_2Cl_2, DBU, 0 → 25 °C, 15 h, 55–65%.

We have investigated the conformational preferences of the oligomers in chloroform by variable-temperature ^1H NMR spectroscopy,[16] FTIR spectroscopy,[16] and NOE experiments (NOE = nuclear Overhauser effect). The experimental results were complemented by computer modeling studies,[17] and show a strong preference for β-aminosulfonic derivatives (e.g., **14**) to form a twelve-membered ring and for γ-aminosulfonic derivatives (e.g., **9** and **16**) to form a fourteen-membered ring by intramolecular hydrogen bonding (dashed line, Scheme 3).[18] The folding ability deserves some comments: 1. The N–H–O angles are more linear in twelve- and fourteen-membered rings, thus strengthening the hydrogen bonds; 2. intramolecular hydrogen bonds between the nearest neighbor amide-type groups in the oligomer backbone (i.e., leading to smaller rings) are unfavorable.[16e] This is clearly inferred by the analysis of **14**-type monomers which show little six- or eight-membered ring hydrogen bonding, and of **16**-type monomers which show practically no seven- or nine-membered ring hydrogen bonding.

Scheme 3. ^1H NMR ($CDCl_3$, 10^{-3} M, room temperature) and FTIR ($CHCl_3$, 10^{-3} M, room temperature) spectroscopic studies of sulfonamido-pseudopeptides.

A few particularly relevant data regarding **9** and **16** are worth mentioning: *strong* NOE at the SO_2N-*H* involved in the hydrogen bonding upon irradiation of the *t*Bu of the Boc group (room temperature, 5×10^{-3} M solution in $CDCl_3$), shift to lower frequencies of both the $\nu_{C=O}$ (−30 and −25 cm^{-1}, respectively) and the ν_{N-H} (−138 cm^{-1}, for both) involved in the hydrogen bonding (room temperature, 1×10^{-3} M solution in $CHCl_3$), shift to lower field ($\Delta\delta$ = 1.2–1.5) for signal of the hydrogen involved in the hydrogen bonding (room temperature, 1×10^{-3} M solution in $CDCl_3$).

In summary, we have developed a straightforward approach for the iterative synthesis of sulfonamido-pseudopeptides based on chiral vinylogous aminosulfonic acids (γ-amino-α,β-unsaturated). The functionalization of the α,β-double bond and the extension of this chemistry to solid–phase synthesis are currently under investigation as well as the biological properties and folding patterns of this new array of chiral unnatural polymers.

Experimental Procedure

Coupling Procedure: Sulfonyl chloride **5** (0.525 mmol) was dissolved in CH_2Cl_2 (4.0 mL), and a solution of hydrochloride salt **6** or **8** (0.35 mmol) in CH_2Cl_2 (2.0 mL) containing DBU (0.052 mL, 0.35 mmol) and DMAP (8.4 mg, 0.070 mmol) was added in one portion. After the addition, more DBU (0.078 mL, 0.525 mmol) in CH_2Cl_2 (1.0 mL) was slowly added during 3 h. More sulfonyl chloride (0.175 mmol) was added, and the mixture was stirred overnight at room temperature, then diluted with CH_2Cl_2 and treated with pH7 phosphate buffer (2.0 mL). The aqueous phase was extracted with CH_2Cl_2, and the combined organic extracts were dried (Na_2SO_4) and evaporated. The crude product was purified by flash chromatography (*n*-hexane/EtOAc, ca. 1:1) to give the desired oligomer **7**, **9**, **10** in 55–65% yield. All compounds had correct C,H,N,S-analyses.

Tetramer **10** (R = Et, R^1 = Me, R^2 = *i*Pr, R^3 = CH_2Ph, R^4 = CH_2CHMe_2): The crude product was purified by flash chromatography (*n*-hexane/EtOAc, 60:40) to give the desired tetramer (60%). ^1H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 0.92 (6H, t, Me_2CHCH_2, J = 6.9 Hz), 0.96 (3H, d, CH_3CHC, J = 6.5 Hz), 0.97 (3H, d, CH_3CHC, J = 6.8 Hz), 1.32 (2H, m, $CHCH_2C$), 1.35 (3H, d, CH_3CHN, J = 6.9 Hz), 1.39 (3H, t, $CH_3CH_2OSO_2$, J = 7.0 Hz), 1.43 (9H, s, $[CH_3]_3C$), 1.65 (1H, m, Me_2CHCH_2), 1.90 (1H, m, Me_2CHC), 2.77 (1H, dd, CHHPh, J = 13.9, J = 8.4 Hz), 3.03 (1H, dd, CHHPh, J = 13.9, J = 5.3 Hz), 3.90 (1H, m, Me_2CHCHN), 4.15–4.32 (5H, m, CH_3CHN, $PhCH_2CHN$, *i*BuC*H*N, $CH_3CH_2OSO_2$, J = 7.0 Hz), 4.39 (1H, d, *i*BuCHN*H*, J = 7.7 Hz), 4.52 (1H, d, $PhCH_2CHNH$, J = 5.5 Hz), 4.96 (1H, d, *i*PrCHN*H*, J = 8.2 Hz), 5.39 (1H, d, MeCHN*H*, J = 7.0 Hz), 5.91 (1H, d, BnCHCH=C*H*, J = 15.0 Hz), 6.35 (1H, d, CH=C*H*, J = 14.6 Hz), 6.42 (1H, d, CH=C*H*, J = 14.0 Hz), 6.44 (1H, d, *i*PrCHCH=C*H*, J = 14.8 Hz), 6.53 (1H, dd, MeCHC*H*=CH, J = 14.7, J = 5.9 Hz), 6.59 (1H, dd, BnCHC*H*=CH, J = 15.0, J = 5.1 Hz), 6.63 (1H, dd, CHC*H*=CH, J = 15.1, J = 6.4 Hz), 6.74 (1H, dd, *i*PrCHC*H*=CH, J = 14.8, J = 6.8 Hz), 7.18 (2H, d, Ar-H), 7.30 (1H, t, Ar-H), 7.35 (2H, t, Ar-H); ^{13}C NMR (DEPT, $CDCl_3$, 25 °C): δ = 14.85 (CH_3), 18.20 (CH_3), 18.63 (CH_3), 21.21 (CH_3), 21.66 (CH_3), 22.83 (CH_3), 24.58 (CH), 28.24 ($[CH_3]_3$), 32.39 (CH), 40.37 (CH_2), 43.14 (CH_2), 49.03 (CHN), 49.57 (CHN), 55.21 (CHN), 59.56 (CHN), 67.27 (OCH_2), 126.62 (CH=), 127.24 (CH=), 128.31 (CH=), 128.55 (CH=), 128.81 (CH=), 129.71 (CH=), 129.77 (CH=), 130.33 (CH=), 131.90 (CH=), 132.10 (CH=), 143.48 (CH=), 144.26 (CH=), 146.36 (CH=).

Localization of Electrons in Intermetallic Phases Containing Aluminum**

Ulrich Häussermann, Steffen Wengert, Patrick Hofmann, Andreas Savin, Ove Jepsen, and Reinhard Nesper*

Dedicated to Professor Ewald Wicke on the occasion of his 80th birthday

Intermetallic phases and Zintl phases are important classes of compounds in inorganic chemistry which were for a long time considered as unusual. These compounds formed from metals, or from metals and semi-metals, possess a very large combinatorial potential, only a very small part of which has been investigated to date. Both classes demonstrate enormously varied, yet differing, aspects of structural chemistry, which are to some extent very complex. Unfortunately, the understanding of most of these structures causes great difficulties, in particular with regard to a description of their chemical bonding. These difficulties have already been reported in detail in this journal.[1]

The electron localization function (ELF) has developed into a useful tool for the interpretation of the chemical bond.[2] The ELF is particularly attractive for crystalline materials, because it is not wave vector dependent and, like electron density, is only a function of the three positional coordinates (x,y,z). Originally derived from the Hartree–Fock pair density for electrons with the same spin by Becke and Edgecombe,[3] it is a measure of the probability of finding an electron in the surroundings of another electron with the same spin. The ELF is normalized so that its dimensionless values lie between zero and one. Large values correspond to a high localization and mean that for an electron with a particular spin, located at (x,y,z), no other electron with the same spin is to be found in the vicinity. Such a situation may also be interpreted as meaning that an electron pair with α,β spin is localized in the region around (x,y,z).[4] This interesting result, that the probability of finding an electron pair is dependent on the location, is based entirely on the Fermi correlation. The Coulomb correlation, which opposes the formation of an electron pair, is not taken into consideration in the calculation of the ELF. High ELF values have indeed been found for those regions which correspond to bonds, lone pairs of electrons, and electron shells.

The term localization, in the sense of the ELF, describes thus the tendency of formation of electron pairs at a position (x,y,z), whereas the electron density $\rho(x,y,z)$ is the probability density for an electron in an arbitrary spin state at this position. The value ELF = 0.5 represents the situation in an homogeneous electron gas, a model system without atomic cores, which serves as a reference. The deviations from this value are caused by the presence of the atomic cores, that is, by the formation of a structure. As a result of these, domains of high localization are

formed, for example, in bonds, and domains of low localization, for example, between the electron shells in atoms.

In the meantime, the ELF has also been calculated by using density matrices from density functional methods[5] and even by using those from semiempirical calculations.[6] Strictly speaking, the interpretation given above does not hold for these procedures. In spite of this, the results correspond to a great extent, and we would like therefore to use our interpretation, independent of the method of calculation employed.[7]

Both the electron density and the ELF values are shown in the two-dimensional graphical representation. The electron densities are displayed as point densities and the corresponding ELF values coded in the form of a color scale, similar to that used in a map. High ELF values (ca. 0.8–1.0) are colored white; the series descends through brown and yellow to green for middle ELF values (ca. 0.5); blue and violet then indicating the lower end of the scale.[8]

The abrupt transition within the third period from the metallic bond in aluminum to the covalent bond in silicon can take place in a stepwise manner in intermetallic compounds and Zintl phases containing aluminum. This will be demonstrated using the series $Al \rightarrow CaAl_2 \rightarrow SrAl_2 \rightarrow BaAl_4 \rightarrow CaAl_2Si_2 \rightarrow Si$ as an example.[9]

The structure of elemental aluminum is a cubic close packed arrangement (fcc, Fig. 1a). Each Al atom has twelve nearest

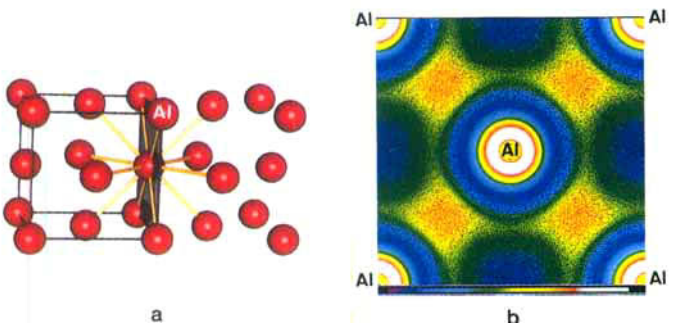

Fig. 1. a) Section from the fcc structure of aluminum showing the (100) plane and connecting lines to the twelve nearest neighbors (yellow). The edges of the unit cell are indicated by black lines in all structure diagrams. b) Electron density ρ (density of points) and ELF (color) for the (100) plane in Al. The ELF color scale is shown at the lower edge of the picture (see text). The electron shells of the cores cannot be entirely resolved in these diagrams, especially those of the heavier elements.

neighbors at a distance of 286.3 pm which form a cuboctahedral coordination. The ELF was calculated for the (100) plane (Fig. 1b). Clearly, the brown areas of highest localization can be recognized between nearest neighboring nuclei and the blue regions of lowest localization in the empty octahedral holes of the structure. The difference between the electron densities at these positions is approximately 100%, the ELF values, however, vary between 0.21 and 0.62, and clearly show that an electron-gas-like localization, which may perhaps have been expected, does not exist in elemental aluminum.

$CaAl_2$ crystallizes in the $MgCu_2$ structure (Fig. 2a) and thus belongs to the cubic Laves phases. All the Al atoms are symmetry-equivalent and connected to give a three-dimensional network of corner-sharing tetrahedra. Thus, each Al atom has six equivalent nearest neighbors at a distance of 284.2 pm. The Ca partial structure is diamond-like. If the twelve Al atoms at a distance of 333.2 pm are taken into consideration, the coordination polyhedron for Ca is a Friauf polyhedron (coordination number 16). The (110) plane contains zigzag chains of Ca atoms and bisects the Al_4 tetrahedra (cf. Fig. 2a). Regions with high ELF values are not only to be found between Al cores, but also extend between Al and Ca cores. The maximum ELF values are 0.74 (Fig. 2b). All tetrahedral faces lie in the (111) planes and

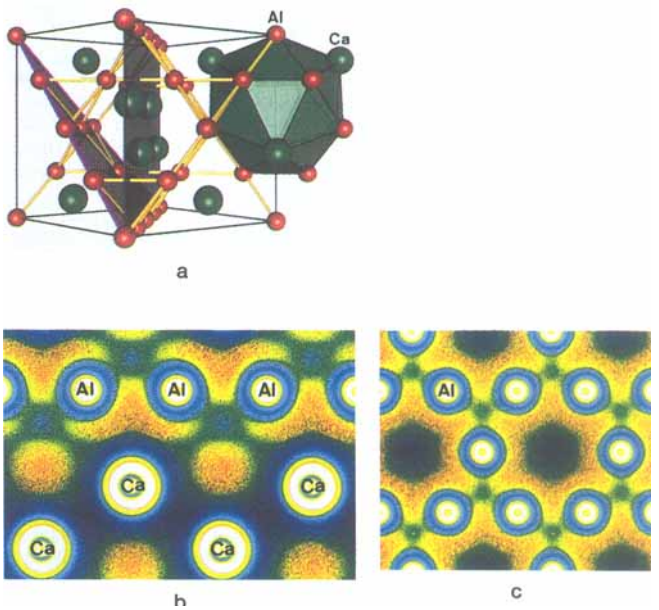

Fig. 2. a) Section from the cubic $CaAl_2$ structure (Ca: green; Al: red; edges of the Al_4 tetrahedra: yellow; coordination polyhedra of Ca: green) showing the (111) (violet border) and (110) planes (black border). b) ρ and ELF for the (110) plane in $CaAl_2$. c) ρ and ELF for the (111) plane in $CaAl_2$.

the corresponding Al atoms form the Kagomé net, a connection pattern comprising equal numbers of triangles and hexagons (3636 net, Fig. 2c). In the tetrahedral faces, green regions of electron-gas-like behavior is found. The localization in the middle of the hexagons is the lowest for the valence region (ELF = 0.115). The ELF values in $CaAl_2$ are admittedly higher than in metallic Al, they are, however, too small for usual covalent bonds. The structure of the localization pattern resembles that of banana bonds.

Figure 3a shows the $SrAl_2$ structure ($CeCu_2$ type) in which the Al atoms form slightly puckered nets of hexagonal rings stacked in the [100] direction. The Al–Al distances in the net are 278.6 and 279.9 pm. Longer bonds (293.0 pm) connect these nets through chains of four-membered rings which follow the [010] direction. All in all, the Al coordination polyhedron is a slightly distorted trigonal pyramid. The Sr atoms are located between the nets of six-membered rings and are coordinated by twelve Al atoms. The (040) plane cuts perpendicularly through the stacked nets of hexagonal rings. The Sr atoms, one sort of Al–Al bond in the nets (279.9 pm), and the long bonds connecting the nets all lie in this plane. The electron density distribution and the ELF for this plane are shown in Figure 3b. White regions can be distinguished between the Al cores, that is, regions of high ELF, which indicate a bonding electron pair. Figure 3c shows the localization behavior in one of the four-membered Al rings. In contrast to $CaAl_2$ (Fig. 2), the areas of highest localization in $SrAl_2$, with maximum ELF values of around 0.88, are entirely due to the Al partial structure, which can be described as a covalent network.

In the $BaAl_4$ structure, one sort of Al atom, which may be described as basal, forms a quadratic net with large Al–Al

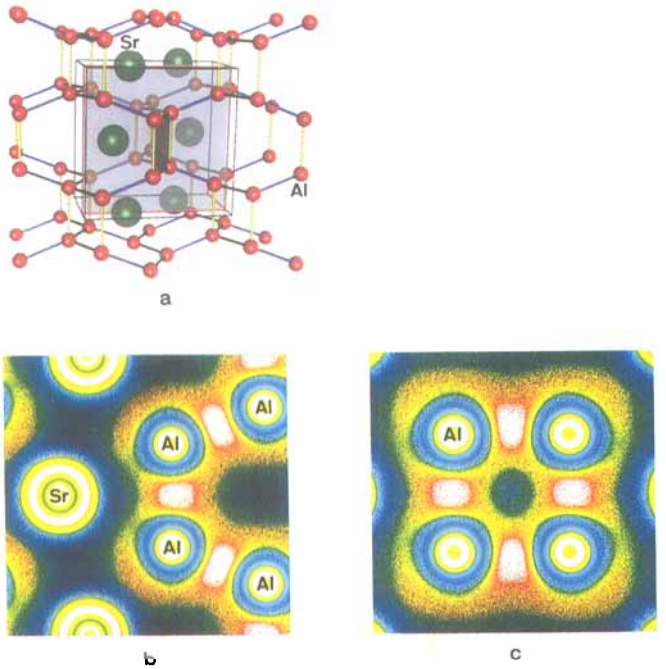

Fig. 3. a) Section from the $SrAl_2$ structure (Sr: green; Al: red). The Al–Al bonds forming the nets of hexagonal rings are colored blue and those connecting the nets yellow. The (040) plane is colored violet. Additionally, a four-membered Al ring from one of the chains of four-membered rings in the [010] direction is shaded for emphasis. b) ρ and ELF for the (040) plane in $SrAl_2$. c) ρ and ELF for a four-membered Al ring in $SrAl_2$.

distances of 321.0 pm (Fig. 4a). The squares are alternately capped from above and below by the second sort of Al atom, the apical ones, to form pyramids. In addition, these apical Al atoms connect the pyramid layers so that the tips of neighboring

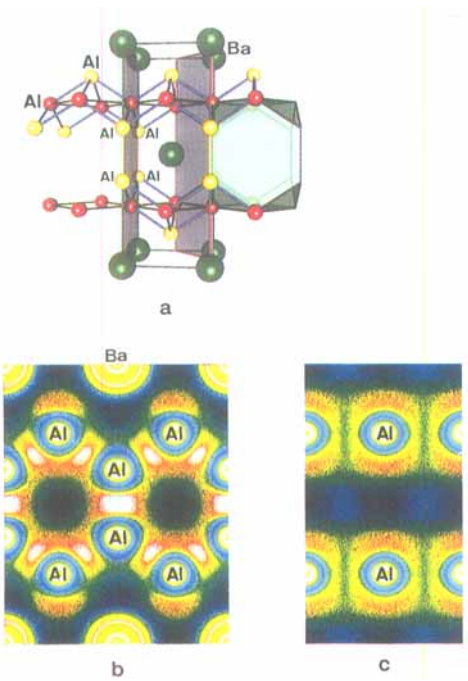

Fig. 4. a) Section from the $BaAl_4$ structure (Ba: green; apical Al: yellow; basal Al: red; coordination polyhedron of Ba: green). The (220) plane (red-violet border) contains the distances between the basal Al atoms (black rods), the (110) plane contains the bonds between the basal and the apical Al atoms (blue rods), and those between the apical Al atoms (yellow rods). b) ρ and ELF for the (100) plane in $BaAl_4$ (2 unit cells). c) ρ and ELF for the (220) plane in $BaAl_4$ (2 unit cells).

layers lie directly above one another. Each of the Ba atoms is situated in one of the large cavities between the layers and is coordinated by 16 Al atoms. The bonding in the Al framework was interpreted as follows:[10] The distance of 278.4 pm between the apical Al atoms represents a two-electron, two-center (2e–2c) bond; 6e–5c bonds are found between the apical and the basal Al atoms, although the distance is somewhat shorter (272.5 pm). The two types of bonds lie in the (100) plane, for which the electron density distribution and ELF are shown in Figure 4b and can be distinctly differentiated in this case. The larger white regions, with a maximum ELF value of 0.93 between the apical Al atoms, correspond to the electron pairs of the 2e–2c bonds. The smaller white regions between the apical and the basal Al atoms are attributed to multicenter bonds (highest localization value ca. = 0.85). The long Al–Al distances of the quadratic net lie in the (220) plane. The ELF runs through a minimum between these atoms, which can clearly be recognized by the green areas between the basal Al atoms, and which excludes the possibility of a bonding interaction (Fig. 4c). It is this conclusion which allows for the formulation of the 6e–5c bond as such.

Figure 5a shows the structure of $CaAl_2Si_2$. Al atoms and Si atoms form puckered double layers of hexagonal rings. Al and Si atoms are alternately arranged in a net of hexagonal rings at distances of 248.9 pm. The longer Al–Si bonds of 257.2 pm

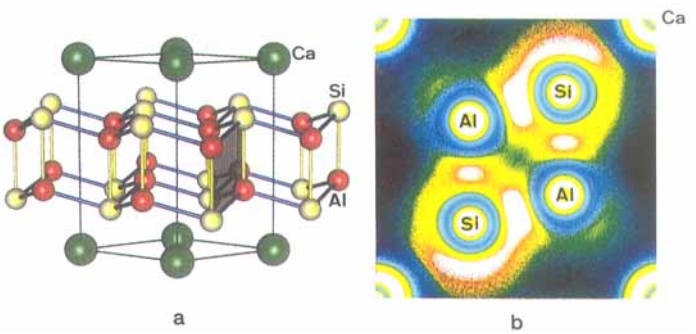

Fig. 5. a) Section from the hexagonal $CaAl_2Si_2$ structure (Ca: green; Al: red; Si: yellow). The short Al–Si distances in a layer of hexagonal rings are colored blue-violet, the long distances connecting the layers colored yellow. The central building block of the double layer, the oblique Al_2Si_2 four-membered ring, is shaded for emphasis. b) ρ and ELF for the (120) plane in $CaAl_2Si_2$. The section shows the Ca nuclei in the corners and an Al_2Si_2 four-membered ring.

connect to form a double layer. The Si atoms in a double layer always occupy the peripheral positions and are rather strangely coordinated by four Al atoms, somewhat resembling an umbrella, whereas the Al atoms are surrounded tetrahedrally by four Si atoms. The Ca atoms are located between the double layers in the middle of two six-membered rings. The (120) plane contains the central building unit of the double layer, an Al_2Si_2 four-membered ring with one long and three short Al–Si bonds. The ELF permits the recognition of a lone electron pair on the Si atom (maximum ELF value = 0.86 for this region). The highest localization values in the valence area of this compound (ca. 0.91), however, are found along the short Si–Al bond (Fig. 5b). This bond, like the longer Si–Al bond connecting the layers, is clearly polarized in the direction of the somewhat more electronegative Si atoms, the maximum ELF value lying at 0.84. The semi shell-shaped distribution of the high ELF values around Si indicates an intermediate state between the purely covalent and ionic situations represented by the formulas

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2020-2071 $ 10.00+.25/0

$Ca^{2+}(Al^{3+})_2(Si^{4-})_2$ and $Ca^{2+}(4b)[AlSi]^{2-}$.[*] A bonding interaction between Al atoms, as had been assumed in the literature,[11] cannot be recognized.

Silicon in the diamond structure (Fig. 6a) does of course have extended regions of high localization between the nuclei, where the bonding electron pairs are situated. Figure 6b shows the (110) plane. The large differences in the electron densities in the valence region are quite remarkable. Very little electron density (black areas) is found between the zigzag chains in comparison to that located in the regions between the cores, where the highest localization values (ELF = 0.95) are found.

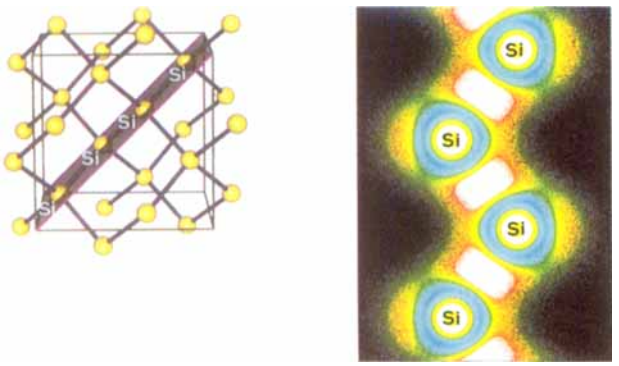

Fig. 6. a) Diamond structure showing the (110) plane. b) ρ and ELF for the (110) plane in α-Si.

Structures with large differences in electron density in the valence regions are normally divided into covalent and ionic structures. In contrast, intermetallic phases have a more uniform density distribution. In spite of this, our ELF results demonstrate that both bonding electron pairs and lone pairs do occur in these compounds, just as in the covalent and ionic structures which are understood in terms of the valence rules. For those compounds in which the chemical bond is described as a metallic bond (fcc Al and $CaAl_2$), the occurrence of numerous ELF maxima (with respect to the number of valence electrons in the unit cell) is characteristic; however, the absolute value of these does not usually exceed 0.75. The number and the position of these maxima can vary to a great extent within a simple structural type.[14] In structures with localized multicentered bonds (6e–5c bond within Al_5 pyramids in $BaAl_4$), the maximum ELF values lie above 0.8 in the regions of these bonds. For bonding electron pairs, maximum ELF values of about 0.9 are to be expected, whereas for lone pairs somewhat smaller values are found.

This relationship is further clarified in the Figures 7a–7d, in which the electron density (dotted line) and the ELF (full line) along symmetrical bonds are plotted in a one-dimensional representation. The shell structure of the cores is easily discernible. Figure 7a shows the Al–Al bond in fcc aluminum and Figure 7b the 2e–2c bond between the apical Al atoms in $BaAl_4$. The electron density difference in the middle of the bond amounts to only about 20%, but the ELF shows impressively the difference between the chemical bonds for the two Al pairs. The course of the ELF along the 2e–2c Al–Al bond is the same as that for the Si–Si bond in α-Si (Fig. 7c). The electron density in the middle of the Si–Si bond, however, is more than twice as

[*] $(4b)[AlSi]^{2-}$ refers to a four-bonded framework made of Si and Al in which each atom is assigned four valence electrons.

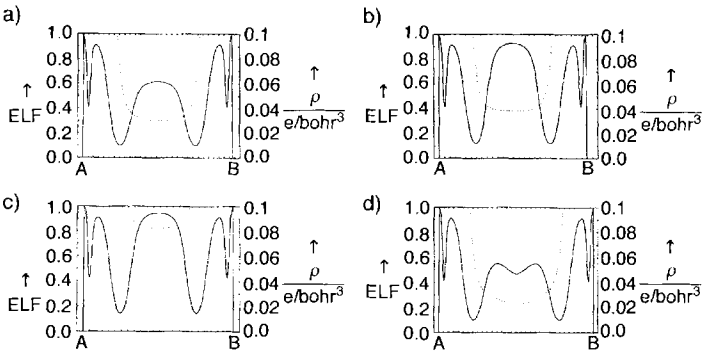

Fig. 7. ρ (dotted line) and ELF (full line) a) along the Al–Al bond in fcc aluminum, b) along the 2e-2c bond between the apical Al atoms in $BaAl_4$, c) along the Si–Si bond in α-Si, d) along the distance between basal atoms in $BaAl_4$. The atoms involved in a particular bond are labeled A and B accordingly.

large as that in the Al–Al bond. Finally, the situation for the large distance between the basal Al atoms in the $BaAl_4$ structure is shown in Figure 7d. The ELF minimum observed between these cores clearly shows the nonbonding character.

This discussion sheds new light on the problem of the interpretation of bond lengths in intermetallic phases: In $BaAl_4$, for example, the Al–Al distance, which is attributed to the 6e–5c bond, is about 6 pm shorter than the 2e–2c bond—contrary to expectations when bond lengths and bond orders are correlated with one another! Similarly, a bond order of around one has to be attributed to the Al–Al distance of 293 pm in $SrAl_2$, although this distance is considerably larger than the Al–Al distance in the metal (286.3 pm) with a bond order of 0.25. In our opinion, a simple relationship between bond length and bond strength[12] or bond order[13] does not exist in the compounds discussed here. In contrast, the ELF can be of decisive assistance in the classification of the diverse interatomic vectors in intermetallic compounds.

New approaches for a more quantitative interpretation of ELF results are being made by using a topological analysis of the ELF (x,y,z) scalar field. The unequivocal attribution of the numbers of electrons to the ELF maxima, described as localization attractors,[15] as well as the possibility of defining a scale of ionic character[16] must be mentioned at this point.

Unequivocal Partitioning of Crystal Structures, Exemplified by Intermetallic Phases Containing Aluminum**

Ulrich Häussermann, Steffen Wengert, and Reinhard Nesper*

Dedicated to Professor Ewald Wicke on the occasion of his 80th birthday

Crystal chemical parameters, such as partial volumes,[1] partial charges,[2] bond strengths,[3] and coordination numbers[4] have long been successfully employed in crystal structure analysis to understand and to interpret structures. There have always been attempts to define such incremental parameters as unequivocally as possible. In this context, the partitioning of space in a crystal structure into domains of its building blocks[***][5] is a useful approach and delivers important information about the parameters mentioned above.

Using the ordering of spheres of equal size as an example, Niggli introduced the concept of the "Wirkungsbereich" as far back as 1927.[5] According to his definition, the Wirkungsbereich of a sphere comprises all points in space whose distances from the sphere are smaller than those to all other spheres. The simplest polyhedron marking this domain is constructed with perpendicular planes at the midpoints of the lines connecting neighboring spheres. When the hypothetical spheres, that is, the atoms or ions, have different radii, the connecting lines can be divided according to the ratio of the radii. In many cases this procedure does, however, lead to polyhedra that are not totally space-filling. The construction procedure developed by Fischer, Koch, and Hellner yields better results.[6] Here, the division of the connecting lines between neighboring spheres by means of the exponential plane construction guarantees that no gaps occur in the partitioning of space and always leads to a convex polyhedron for every occupied point position of the crystal structure. However, this method too is still dependent on the choice of radii for the spheres, that is, on the definition of atomic or ionic radii.[7]

According to Bader,[8] a clear partitioning of the three-dimensional space into atomic domains can be achieved by the analysis of the scalar field, the electron density $\rho(x,y,z)$, and the gradient $\Delta\rho(x,y,z)$. The (3,−1) saddle points[9] of the electron density play an important role here. The sum of all the trajectories[10] that end on these saddle points form surfaces in three-dimensional space, which define the atomic boundary. In crystalline structures, these surfaces form closed polyhedra around the atomic nuclei. The polyhedra fill the volume of the unit cell completely[*] and thus provide the best definition for atomic domains. In addition, the faces of the polyhedra fulfill the conditions for a vanishing density flow, that is, $\Delta\rho(x,y,z)\vec{n}(x,y,z) = 0$ for all points (x,y,z) on these faces, where $\vec{n}(x,y,z)$ is the unit vector perpendicular to the face.

The use of the scalar field, electron localization function (ELF),[11] also leads to an unequivocal partitioning of three-dimensional space. We will designate the resulting fragments as domains of electrons and atomic cores. The regions of space occupied by bonding electrons or lone pairs are examples of domains of valence electrons. Their centers correspond to the local ELF maxima ((3,−3) points) in the valence region. The positions of the nuclei also correspond to local maxima defined by the first electron shell. The other electron shells of the core are, however, not resolved, and the ELF minimum of the outermost filled shell is thus used to specify the domain of an atomic core. The sum of these domains once again fills the unit cell completely.

The boundaries of the domains can be used as limits of integration for the following volume integrals:

a) Volume of domain A: $V_A = \int_{V_A} dV$

b) Number of electrons in this domain A: $N_A = \int_{V_A} \rho(x,y,z)dV$

The volume and the corresponding number of electrons are important characteristic parameters of such a domain or Wirkungsbereich. In addition, the net charge of an atom can be calculated from the corresponding number of electrons of an atomic domain.[12]

There is of course a close relationship between the volume of an atomic domain and the number of electrons. This was recognized by Biltz as far back as 1934.[1] The analysis of the empirically determined domain volumes (volume increments) in a large number of compounds showed that these volumes depend to a large extent on the environment, that is, on the bonding character of the atoms in the structure. In addition to such local influences, Biltz was also able to confirm relationships between the core potentials and the volume requirement of the corresponding valence electrons. This allowed him to define volume increments for three main classes of compounds.

Based on Bader's definition of the domain of an atom, interesting relationships between chemical bonding, volume, and number of electrons can be clearly quantified. This is especially true for changes in these quantities with the formation of a compound. The domain of electrons based on the ELF can be used for the analysis of chemical bonding. Moreover, the volumes and the shapes of both types of domains contain important chemical information relevant to the structure. Based on the example of the series Al, $CaAl_2$, $SrAl_2$, $BaAl_4$, $CaAl_2Si_2$, and Si in which a transition from metallic to covalent bonding occurs,[13] these distinct possibilities of spatial partitioning will be described.[14]

Figure 1a (top) shows the contour diagram of the electron density for face-centerd cubic (fcc) aluminum in the (100) plane. The (3,−1) saddle points lie exactly at the midpoint between neighboring nuclei. The trajectories defining the atomic domains begin at the local density minima of the octahedral holes (edges of the unit cell) and end at the (3,−1) saddle points. In

The sectional planes of all the contour diagrams are shown in the drawings of the structures in ref. [13].

this simple case, they correspond exactly to the boundaries of the geometrical domain. In the three-dimensional picture, a cubooctahedron is formed as a convex polyhedron enclosing the atomic domain. Its vertices are the octahedral and tetrahedral holes of this structure (cf. Fig. 2a).

The ELF for the (100) plane is shown in Figure 1a, bottom. The maxima of this function occur between the atomic cores and, of course, in the region of the electron shells. Three critical points lie on every line connecting an octahedral hole and an atomic nucleus: the octahedral hole itself is a local ELF minimum; a (3,−1) saddle point follows, and finally, a further local minimum occurs at the boundary between the core and valence regions. Three trajectories emanate from these minima. One ends at the above-mentioned (3,−1) saddle point and forms, together with the trajectory starting from the octahedral hole, the boundary between the domains of the metallic bond in fcc aluminum. The other two trajectories end at (3,−1) saddle points on the line connecting two neighboring Al atoms. They virtually form a quarter circle and, together with symmetry-

equivalent trajectories, the boundary of the domain of the atomic core. A domain of the metallic bond is shown in Figure 2b. It can be seen that the complete ensemble of polyhedra representing the electronic domains also contains all the edges of the atomic domains.

α-Si in the diamond structure is also a simple, yet interesting example. The contour diagrams of the electron density and ELF (Fig. 1b) were calculated for the (110) plane. The domains of the Si atoms are defined by curved trajectories. The three-dimensional picture (Fig. 2d) shows a so-called saddle polyhedron. Its straight edges form an adamantane-like cage. However, the polyhedron faces are curved and correspond to the D^* minimal surface.[16] This saddle polyhedron was described by P. Pearce as the diamond saddle polyhedron (Fig. 2f).[15] The result of a simple geometrical domain construction is of course a convex polyhedron with flat faces. Its edges can be seen in Figure 2g. The domains of the Si–Si bonding electron pairs are defined exclusively by flat surfaces in this case (Fig. 2e). As in fcc Al, these polyhedra also contain the edges of the atomic domains. In both cases the common edges form the labyrinth network of a periodic minimal surface: the D^* surface in Si and the FF^*_{2x}-FP_2 surface in Al.[16] Labyrinth nets describe the tunnel system of a periodic minimal surface.[17] Whether or not the common trajectories generally have this relationship to periodic minimum surfaces has yet to be investigated in detail. In the binary compound $CaAl_2$ (Fig. 1d, 1e, and 2c), which like α-Si crystallizes in the space group $Fd\bar{3}m$, the Ca atoms lie on nodes of the labyrinth net of the D^* surface formed from these special trajectories.[*]

In Figures 1c, 1g, and 1f, the contour diagrams of the electron density distribution and ELF values are shown for high-symmetry planes of the compounds $SrAl_2$, $BaAl_4$, and $CaAl_2Si_2$, respectively. The domains of the electrons in $BaAl_4$ and $SrAl_2$ correspond to the different Al–Al bonds. In addition to the domains for the Al–Si bonds in $CaAl_2Si_2$, another one for the Si lone pair is observed, which is symmetrically coordinated by three Ca atoms (cf. Fig. 5 in ref. [13]).

The results of the volume integrations are summarized in Tables 1 and 2.[18] In the compounds $CaAl_2$ (Fig. 2a in ref. [13]) and $SrAl_2$ (Fig. 3a in ref. [13]), the extent of the charge transfer from the atoms of the alkaline earth metal to the more electronegative Al atoms is approximately the same; Ca and Sr have a positive net charge of $q \approx 1$. This means that a conclusion regarding the electron localization in the Al partial structure, as described in the simple Zintl–Klemm concept for semiconductors, may not necessarily be drawn from the effective charge transfer. Three electronic domains occur in $SrAl_2$ corresponding to the three different Al–Al bonds (Table 2). Electron numbers greater than 2 ($N_{val} = 2.13$) were assigned to the bonds with a length of 279.9 pm in the slightly puckered net of six-membered rings. This indicates the presence of a π-bonding component. In contrast, the domain of the long Al–Al bonds connecting the layers contains only 1.6 electrons. On the whole, relatively high localization values are observed (ELF_{max} is larger than 0.88 in all three cases; cf. Fig. 1c, bottom). In contrast, the localization in the electronic domains in $CaAl_2$ is distinctly weaker ($ELF_{max} = 0.739$; cf. Fig. 1d and 1e, bottom) in spite of the equally large charge transfer M → Al.

From a purely stoichiometric point of view, one would expect the larger charge transfer for MAl_4 in the series MAl_2, MAl_4. This is, however, not the case: in $BaAl_4$ (Fig. 4a in ref. [13]) the positive net charge on Ba is only 0.67 (Table 1). The Al atoms form a net of square pyramids. In the ternary variants of this structure type, the more electronegative atoms are usually found at the apical positions. In the binary $BaAl_4$, however, the apical Al atoms have a positive net charge of 0.43, while the basal Al

[*] The labyrinth net of the D^* surface in $CaAl_2$ is shifted by 1/8,1/8,1/8 relative to the position in α-Si.

Table 1. Classification of the atomic domains.

Compound	Domain	n [a]	V [b]	V_{elem} [c]	N_{val} [b]	q [d]

[a] n is the frequency of a domain in the unit cell. [b] V is the corresponding volume (in 10^6 pm^3) and N_{val} the corresponding number of valence electrons. The sums of the volumes for the domains and the numbers of electrons (Σ lines) are compared with the volumes and the total numbers of valence electrons in the unit cells (in parentheses). The deviations are less than 1% [18]. [c] V_{elem} is the atomic volume (in 10^6 pm^3) taken from the elemntal structure. [d] q is the net charge of a particular atom [12].

Table 2. Classification of the electronic domains.

Compound	Domain	n	ELF_{max} [a]	V [b]	N_{val} [b]	N_{val}/V [c]
fcc-Al	Al-Al (286.3 pm)	24	0.620	2.51	0.50	0.20

	Σ			161.0 (160.0)	32.2 (32.0)	

[a] ELF_{max} is the largest ELF value in a domain. [b] V is the volume of a domain (in 10^6 pm^3) and N_{val} the corresponding number of valence electrons. Here, the sum of the numbers of electrons in the domains is always smaller than the total number of electrons in the unit cells. The deviation can be as large as 3% [18]. [c] N_{val}/V is the average electronic density (in e10^{-6} pm^{-3}) in a particular domain.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2020-2075 $ 10.00+.25/0

atoms have a clear negative polarization ($q = -0.75$). This admittedly contradicts the net charge calculated from the population analysis in ref. [19] (but, see [12]); however, the number of electrons for the two electronic domains agree excellently with the results of the analysis of chemical bonding in ref. [19]: a two-electron, two-center (2e2c) bond connects the apical Al atoms (bond length 278.4 pm), whereas apical and basal Al atoms (Al–Al distance 272.5 pm) are bound through a 6e5c bond (this corresponds to 1.5 electrons per domain). The electron numbers attributed to the two electronic domains are 2.05 and 1.45, respectively.

In $CaAl_2Si_2$ (Fig. 5a in ref. [13]), the atoms of the alkaline earth metal have a higher oxidation state than in the binary aluminides ($q = 1.23$, Table 1). The polarization of the Al atoms is also distinctly positive ($q = 1.54$), although the difference in the electronegativity between Al and Si is small. A high net charge of -2.18 is observed for Si. The domain of the Si lone pair contains almost exactly two electrons ($N_{val} = 1.96$) and has, in agreement with the Gillespie–Nyholm rules, the largest volume of all electronic domains in this structure (Table 2). The short Al–Si distance of 248.9 pm within the puckered layer of six-membered rings and the longer distance between layers are not consistent with a 2e2c bond ($N_{val} = 1.67$ and 1.00, respectively). A total of six electrons are found distributed among four topological contacts.

For the positively polarized atoms of the alkaline earth metal, the volumes of the domains are between 2 and 2.5 times smaller than the atomic volumes in the elemental structures (cf. V and V_{elem} in Table 1). This reflects the well-known volume contraction observed in the formation of these compounds from their elements, since the increase in volume for the domain of the negatively polarized components only lies between 46% (Al in $CaAl_2$) and 74% (Si in $CaAl_2Si_2$). It would be interesting to determine just how far the electronegative component in intermetallic phases and Zintl phases can be reduced and what domain volumes result from this process. It seems important to us that well-defined effective charge transfer can also be considerable in intermetallic phases. The atomic domains of the alkaline earth metals basically resemble polarized spheres, and their shape is therefore still similar to that typical of ions.

Keith, *Angew. Chem.* **1994**, *106*, 647; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 620 (this very good recent review gives a clear introduction to the quantum mechanical definition of an atom and of a functional group in a molecule; this definition is also the basis for the calculation of expectation values for such subsystems.)
[9] Saddle points are among the critical points for which $\nabla\rho(x,y,z) = 0$. Four types of critical points can occur. They are classified by the eigenvalues of the matrix of the second derivative. A (3,−3) point is a local maximum. Although, strictly speaking, $\nabla\rho(x,y,z)$ is not defined at the nuclear positions, the nuclear positions behave topologically like (3,−3) points. (3, +1) and (3,−1) points are saddle points. A (3,−1) point often occurs between neighboring nuclei and is therefore also described as a bond critical point. (3, + 3) points are local minima.
[10] Trajectories are lines along the gradient vector that indicate the direction from one point in space to another. Here, they run orthogonally to the lines of equal density. In crystalline structures they begin and end at critical points. All points in space, with the exception of the critical points, can only be traversed by a single trajectory.

[12] The net charge q_A of an atom A is the difference between the nuclear charge Z_A and the number of electrons N_A. The use of N_A as defined in the text for the determination of the net charge has the advantage that this definition is unambiguous. In contrast, the calculation of the net charge from quantum mechanical population analyses is dependent on the choice of definition for the parameter N_A, on the one hand, and of the basis set on the other. These factors can have a significant effect on the resulting net charge.

[18] The volume integrals were only calculated approximately: The volume of the domain A: $V_A \approx \sum_{i \in V_A} \Delta V_i$; corresponding number of electrons: $N_A \approx \sum_{i \in V_A} \rho_i \Delta V_i$. The index i refers to a grid point (x,y,z) at which ρ and ELF were calculated. The chosen grid-point density usually gave a ΔV_i of about 5×10^{-4} Å^3. The grid points i were subsequently attributed to a domain A by means of a simple algorithm. If a grid point happened to fall on the border between two domains, its volumes were divided among these according to the trajectory course. The sum of the volumes of the domains should give the volume of the unit cell. The deviations lie below 1% (see Table 1 and 2). Only the valence electron density was used in the calculation of the number of electrons in a particular atomic domain. This is because the contribution from the core functions cannot be determined by means of this simple method due to the large change near the nucleus. The sum of the number of electrons obtained by this method gives, to a good approximation, the total number of valence electrons in the unit cell (Table 1). Whether or not the numbers of electrons for the electronic domains also add up to the total number of valence electrons in the unit cell still has to be investigated in more detail. This seems to be the case for the structures of elemental Al and Si, whereas distinct deviations occur for the other compounds. One reason for this is probably the strong dependence of the core volumes of the alkaline earth metals on the size of the muffin-tin spheres. These volumes are possibly incorrect, in which case the adjacent electronic domains will also be affected.

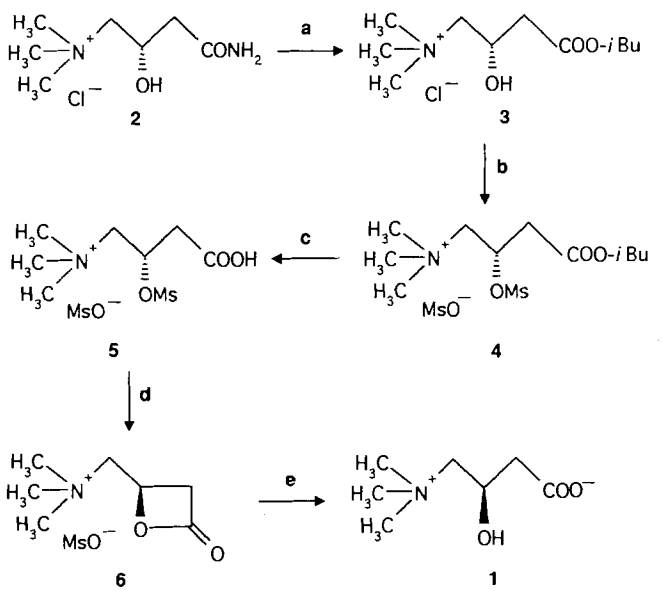
Totally Enantioselective Inversion of Configuration of (*S*)-(+)-Carnitine Derivatives



Ida Bernabei, Roberto Castagnani, Francesco De Angelis, Paolo De Witt Scalfaro, Fabio Giannessi,* Domenico Misiti, Sandra Muck, Nazareno Scafetta, and Maria Ornella Tinti

The importance of configuration in biologically active compounds,[1] which is emphasized by the strict rules governing the use of chiral compounds in medicinal applications, forces pharmaceutical companies to develop chiral drugs as single enantiomers.[2] In the case of carnitine, the "chirotechnological" problem has always been of concern, since only the (*R*)-(−) enantiomer **1** is biologically active[3] and is involved in fatty acid metabolism,[4] while the (*S*) isomer is a competitive inhibitor of the (*R*) isomer.[5]

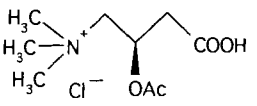
Industrially, the (*R*) isomer is produced economically and on a multiton scale by traditional fractional crystallization of the diastereoisomeric salt of racemic carnitinamide with D-canforic acid.[6] The obvious drawbacks of this procedure are the cost of production, storage or disposal costs for half the starting material, and the resulting chemical pollution. Chemical racemization of the undesired isomer, which would have allowed recrystallization of the resulting racemate, was not successful.[7] Dehydration followed by microbiological stereospecific rehydration of the double bond[8] is not feasible on an industrial scale. Also, asymmetric synthetic processes require large amounts of relatively costly starting materials, reagents, or catalysts.[9]



We report here on a straightforward and high-yielding route to (*R*)-(−)-carnitine (**1**) starting from the enantiomerically pure (*S*)-(+)-carnitinamide (**2**) (Scheme 1), which is formed as the undesired by-product during the production of the active enantiomer.[6]

Scheme 1. Asymmetric synthesis of (*R*)-(−)carnitine (**1**) from enantiomerically pure (*S*)-(+)-carnitinamide (**2**). a) *i*BuOH, HCl gas, reflux (90%); b) methanesulfonic anhydride (3 equiv), 80 °C, 24 h (99%); c) 2 M HCl, 55 °C, 20 h (90%); d) $NaHCO_3$ (1 equiv), RT, 20 h; e) $NaHCO_3$ (1 equiv), RT, 20 h, (99% over two steps; >99% *ee*). Ms = methanesulfonyl.

The key step is the totally enantioselective inversion of the stereogenic center, which is accomplished through the intermediacy of the (*R*) β-lactone **6**. We devised this β-lactone route after the classical Mitsunobu reaction[10] failed. We tentatively propose that this failure is caused by the intrinsic instability of the reaction intermediate owing to the high concentration of charge at the trimethylammonium moiety. Our strategy exploits the merits of the methanesulfonate **5**, namely, the electrophilicity of the β carbon atom and the nucleophilicity of the carboxylic function: this permits a strict stereochemical control of the reaction, which proceeds with hydroxyl group activation.[11]

The methanesulfonate **5** was obtained from the (*S*)-(+)-carnitinamide chloride **2** by standard reactions: sulfonylation was achieved by treatment of **3** with an excess of methanesulfonic anhydride in acetonitrile or, preferentially, by fusion of the reagent mixture at 80 °C.[12] Ester hydrolysis under acidic conditions yielded **5**. Treatment of **5** with one equivalent of $NaHCO_3$ in water at room temperature for 20 h gave the carnitine lactone **6** ($[\alpha]_D = -24.7$ ($c = 1$, MeOH)), which could not be crystallized.[13] Saponification with a second equivalent of $NaHCO_3$ gave the expected (*R*)-(−)-carnitine (**1**) (>99% *ee*) in quantitative yield.[14] The sign of the specific rotation of **6** suggests the (*R*) configuration for the β carbon atom—by analogy with the well-established configuration of acetyl-(*R*)-carnitine **7** ($[\alpha]_D = -27.3$ ($c = 1$, MeOH)). The total yield of the reaction sequence was 80%.

7

The stereochemical course of the reaction clearly indicates that the two key steps, formation of lactone **6** and its hydrolysis, must be totally stereoselective. Since the starting material **5** has an (*S*) and the lactone **6** an (*R*) configuration, the latter must have been formed with inversion of configuration at the stereogenic center. The trimethylammonium moiety probably favors the intramolecular approach of the carboxylate group, which leads to ring closure. Nucleophilic attack of the hydroxide ion at the acyl carbon atom results in totally regioselective ring opening of the β-lactone ring to give optically pure (*R*)-(−)-carnitine,[15] as expected for oxygen–acyl bond fission in a slightly basic medium.[11]

The β-lactone **6** and its enantiomer appear to open a general route to stereochemically controlled preparations of carnitine analogues and derivatives. Also, replacement of the mesylation reagents with other reagents might yield synthetically useful compounds with different active functional groups.

Experimental Procedure

3: A stirred suspension of **2** (10 g, 0.05 mol) in isobutyl alcohol (50 mL) was cooled at 4 °C and saturated with HCl gas. The reaction mixture was refluxed for 1 h and then filtered whilst still hot to remove NH_4Cl. The filtrate was concentrated under vacuum, and the residue was taken up twice into isobutyl alcohol (2 × 50 mL) and concentrated to dryness. The residue was triturated with acetone to give, after filtration, **3** (11.6 g, 90%). M.p. 150 °C (decomp.); $[\alpha]_D = +15.0$ ($c = 1$ in H_2O); ^1H NMR (300 MHz, D_2O, 25 °C): $\delta = 4.7$ (m, 1H), 4.0–3.9 (m, 2H), 3.5 (m, 2H), 3.2 (s, 9H), 2.7 (m, 2H), 2.0–1.9 (m, 1H), 0.9 (d, $^3J = 7$ Hz, 6H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1730 (C=O); MS (FAB): *m/z*: 218 [*M*$^+$]; correct C, H, N, Cl analysis for $C_{11}H_{24}ClNO_3$

4: A mixture of **3** (2.5 g, 0.01 mol) and methanesulfonic anhydride (5.2 g, 0.03 mol) was heated at 80 °C for 24 h. The mixture was taken up into CH_2Cl_2 (20 mL), and the product was precipitated with Et_2O. This procedure was repeated three times in order to thoroughly eliminate the residual anhydride to give **4** (3.9 g, 99%). M.p. 137–140 °C (decomp.); $[\alpha]_D = +24.7$ ($c = 1$ in H_2O); ^1H NMR (300 MHz, D_2O, 25 °C): $\delta = 5.5$ (m, 1H), 3.9–3.8 (m, 3H), 3.6 (dd, $^2J = 16$ Hz, $^3J = 1.3$ Hz, 1H), 3.2 (s, 3H), 3.1 (s, 9H), 3.0 (m, 2H), 2.7 (s, 3H), 1.8 (m, 1H), 0.8 (d, $^3J = 7$ Hz, 6H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1731 (C=O), 1341, 1200 (CH_3SO_3); MS (FAB): *m/z*: 296 [*M*$^+$]; correct C, H, N, S analysis for $C_{13}H_{29}NO_6S_2$

5: A solution of **4** (3.9 g, 0.01 mol) in HCl (2 N, 65 mL) was heated at 50 °C for 20 h. The solution was then concentrated to dryness under vacuum, and the residue was triturated with acetone to give, after filtration, pure **5** (3.3 g, 90%). M.p. 148–150 °C (decomp.); $[\alpha]_D = +22.0$ ($c = 1$ in H_2O); ^1H NMR (300 MHz, D_2O, 25 °C): $\delta = 5.5$ (m, 1H), 3.9 (dd, $^2J = 16$ Hz, $^3J = 10.6$ Hz, 1H), 3.6 (dd, $^2J = 16$ Hz, $^3J = 1.3$ Hz, 1H), 3.2 (s, 3H), 3.1 (s, 9H), 2.9 (m, 2H), 2.7 (s, 3H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1713 (C=O), 1332, 1200 (CH_3SO_3); MS (FAB): *m/z*: 240 [*M*$^+$]; correct C, H, N analysis for $C_9H_{21}NO_8S_2$

1: $NaHCO_3$ (375.5 mg, 4.47 mmol) was added to a solution of **5** (1.5 g, 4.47 mmol) in H_2O (25 mL), and the solution was allowed to stand at room temperature for 20 h with stirring. Additional $NaHCO_3$ (375.5 mg, 4.47 mmol) was added and the solution was stirred at room temperature for 24 h. The solution was then transferred into Amberlite IRA-402 (20 g, OH-form), and eluted with deionized water till pH = 7. The collected eluate was concentrated (10 mL) and transferred onto Amberlite IRC-50 (20 g), and **1** was eluted completely. Evaporation under vacuum gave **1** in practically quantitative yield (720 mg, >99%).

6: A solution of **5** (1.5 g, 4.47 mmol) in H_2O was transferred onto Amberlite IRA-402 (30 g, activated as HCO_3^-) at 5 °C and eluted with cold water (5 °C). The eluate was allowed to stand for 4 h at room temperature to give, after water evaporation under vacuum, a crude product, which was taken up into CH_3CN and filtered. The filtrate was evaporated to dryness to give **6** (0.855 g, 80%) as a white solid. M.p. 160 °C (decomp.); $[\alpha]_D = -24.7$ ($c = 1$ in MeOH); ^1H NMR (300 MHz, D_2O, 25 °C): $\delta = 5.35–5.25$ (m, 1H), 3.98–3.89 (m, 3H), 3.54–3.46 (dd, $^2J = 16.8$ Hz,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2020-2077 $ 10.00+.25/0

^3J = 4.8 Hz, 1 H), 3.26 (s, 9 H), 2.81 (s, 3 H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1835 (C=O); MS (FAB): m/z: 144 [M^+]; correct C, H, N analysis for $C_8H_{17}NO_5S$.

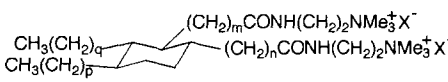
Assembly Properties of Bolaamphiphiles from Dimeric Acids**



Pilar Bosch,* José L. Parra, and Alfonso de la Maza

Self-organization is an important feature of many biologically relevant molecules.[1] One of the most interesting questions which arises is whether it is possible to develop new materials that simulate natural supramolecular systems whose function is determined by their three-dimensional self-assembly.[2] Newkome et al. have described the synthesis of some compounds called arborols or dendrimers which form automorphogenic suprastructures possessing helical or ribbonlike morphologies.[3] We sought to demonstrate that the concept of supramolecular self-assembly can be extended to other organic compounds having a cyclohexane structure substituted with different ionic side groups and counterions.

Several bolaamphiphiles were prepared from an inexpensive mixture of α,ω-dicarboxylic acids (dimeric acid, versadyme),[4] which were obtained by thermal Diels–Alder cyclization of methyl-(10*E*,12*E*)-linoleate (from tall oil). Tetrasubstituted cyclohexane derivatives were obtained. The dianionic bolaamphiphile DAS **1** was synthesized by reduction of the dimeric acids with $LiAlH_4$ followed by reaction with chlorosulfonic acid and addition of Na_2CO_3. The resulting disulfate was obtained with an overall yield of 65%. Activation of the acid groups of the dimeric acids with thionyl chloride and reaction with *N*,*N*-dimethylethylenediamine followed by quaternization yielded DAC-I **2** (81%). Ion exchange on Dowex resin gave the cationic acid amides, DAC-Cl **3** and DAC-CO_3 **4** with yields of 88 and 86%, respectively. All the bolaamphiphiles gave satisfactory spectra (IR, ^{1}H NMR, FAB-MS) and elemental analysis.[5]

DAC-I **2**, X=I; DAC-Cl **3**, X=Cl; DAC-CO_3 **4**, X=HCO_3

m + n + p + q = 26
m, n = 7–10
p, q = 3–6

The aggregation behavior was studied directly by transmission electron microscopy (TEM) and image analysis.[6] A buffer solution containing the bolaamphiphiles 0.5% (weight per volume) was sonicated for 15 min at 55 °C. When the internal volume of the sonicated samples was measured by dye encapsulation (carboxyfluorescein and pyranine) no closed vesicles formed. Sonicated samples were stained (1% uranyl acetate) for TEM imaging and then digitalized for image analysis. Depending on the TEM magnification, 1 pixel corresponds to 0.123, 0.246, 0.328, and 0.579 nm (DAC-Cl, DAS, DAC-CO_3, and DAC-I, respectively; Fig. 1).

Some rodlike structures with internal organization may be recognized for the anionic species DAS **1** in Figure 1. Cationic species form multilamellar arrangements whose specific features depend on the counterion. Thus, with the bicarbonate counterion (DAC-CO_3) a complex multilayer structure resembling a fingerprint is seen. In the case of chloride counterion the arrangement is less well defined. The presence of iodide counterion leads to the formation of more complex multilamellar aggregates (Fig. 1).

It seems that both the ionic character of the synthesized bolaamphiphiles and the counterions of the cationic compounds rule out the three-dimensional arrangement of such molecules. However, as described by Okahata et al.[6] the aggregate morphology of ionic dialkyl amphiphiles is relatively insensitive to the chemical structure, and vesicles and lamellae are the most common morphologies. In sharp contrast, the morphology of the aggregates formed by polyoxyethylene glyceryl α,α'-diethers

Blavia and A. del Giorgio for the TEM measurements and image analysis, respectively, and G. von Knorring for his expert technical assistance.

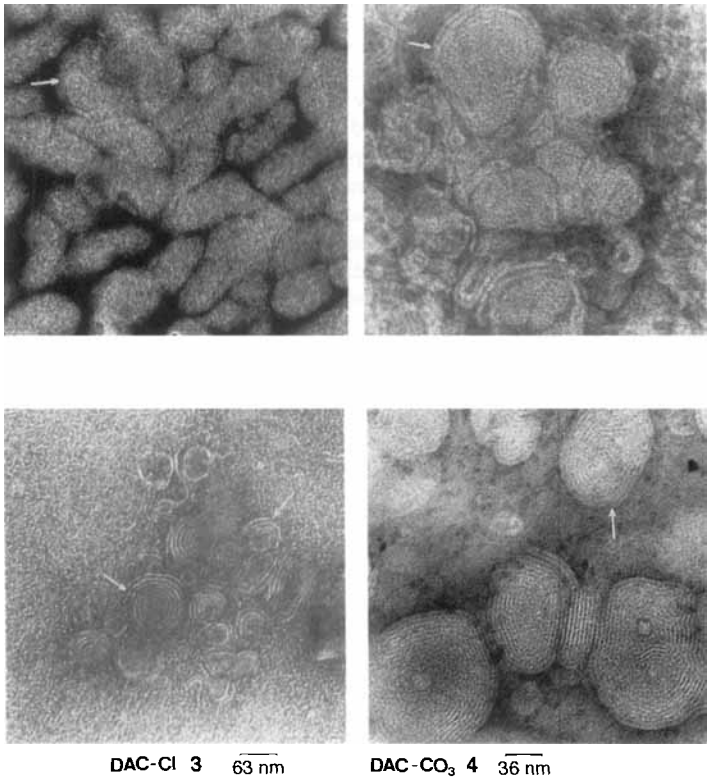

Fig. 1. TEM microphotographs of **1**–**4**. The white arrows point to the beginning of the three-dimensional open multilamellar structure.

($2C_n$-gl-xG) varies remarkably with their chemical structures.[7]

To obtain further information on some characteristics of self-assembly we determined the periods or the average distance of the pattern ordering in each lamellar structure by analysis of the TEM images. Two approaches were used: a) Fourier transformation (FT) and b) profile of direct measurements from digitalized TEM pictures (Fig. 2). The good correlation of the results obtained by the two methods is shown in Table 1. The largest period was found for DAC-I.

From physico-chemical studies we know that critical micelle concentrations (CMC) for DAS, DAC-I, DAC-Cl, and DAC-CO_3 are 1420, 20, 2600, and 300 ppm, respectively.[5] The areas for these bolaamphiphiles measured with a Langmuir film balance are 100, 116, 62, and 78 Å^2, respectively.[5] The most striking results are the lowest CMC value (20 ppm) and the highest area per molecule (116 Å) obtained for DAC-I. The peculiar three-dimensional arrangement of **2** and its lamellar period of 10 nm, the largest in the series, cannot be explained by the small difference between the van der Waals diameters of chloride (4.2 Å) and iodide (4.6 Å). An alternative explanation could be that a macrocycle of approximately 18 atoms is formed by hydrogen bonding between the two amide groups of both chains containing ionic head groups (Fig. 3). Thus, the chaotropic character[8] of the iodide anion closely bound to the trimethylammonium head group may prevent the formation of such a macrocycle. As a consequence, a more extended arrangement of the molecule with a greater surface area at the liquid–air interface would result. In addition, a more hydrophobic bolaamphiphile would have a lower CMC value. With the other counterions not having chaotropic characteristics the macrocyclic molecular arrangement could be maintained, and consequently a smaller surface area would be occupied by the bolaamphiphile molecule. Moreover, the macrocycle formation could account for the periods measured for the lamellae of the bolaamphiphiles (Table 1).

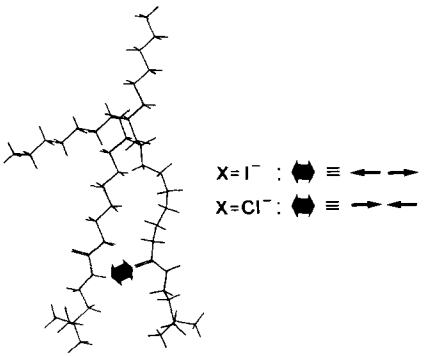

Fig. 3. Energy-minimized structure shows the formation of a macrocycle from the cationic bolaamphiphiles **2**–**4** through hydrogen bonds between the carbonyl O atom and the amide NH group. When X = I, the counterion disturbs the binding interaction by increasing the N–O distance.

It is noteworthy that bolaamphiphiles form multilamellar aggregates at low concentrations. The morphology of these stable aggregates depends on the bolaamphiphile's ionic groups and nature of the counterion.

Photodecomposition of 10-Diazo-2-hexadecylanthrone on Graphite Studied by Scanning Tunneling Microscopy

Roland Heinz, Andreas Stabel, Jürgen P. Rabe,*
Gerhard Wegner, Frans C. De Schryver,*
David Corens, Wim Dehaen, and Carsten Süling

Diazoanthrone has long been used in photoresists,[1] and the structure and spectroscopic properties of some *p*-benzoquinonediazides including 10-diazoanthrone have been discussed recently.[2] The excited state properties of this compound and the nature of the reaction products generated upon irradiation in solution have been studied in detail.[3] Other researchers have shown that a wide variety of organic compounds can be deposited from solution as two-dimensional (2D) crystals on the basal plane of highly oriented pyrolytic graphite (HOPG) and imaged in situ by scanning tunneling microscopy (STM) at the solid–fluid interface.[4] Until now photochemically unreactive organic molecules have been studied by STM; light-induced transformations in a thin liquid film have previously not been examined by this high-resolution technique. We report here on the first such STM study of the phototransformation of 10-diazo-2-hexadecylanthrone (**1**) to 2-hexadecyl-9,10-anthraquinone (**2**) [Eq. (a)].

1 **2** (a)

An oxygen-saturated 0.05 M solution (3 mL) of diazoanthrone **1** in 1,2,4-trichlorobenzene (Aldrich 99.9 + %) was irradiated for 24 h in a 1 cm quartz tube with a cold light source (Schott, KL 1500, light power 1.3 W). Since the solvent chosen has no easily abstractable hydrogen atoms, undesirable side reactions such as insertion into a C–H bond should be eliminated. The solution was saturated with oxygen to optimize the conversion of **1** into **2**. UV spectra were recorded before and after irradiation to confirm the transformation of **1** (starting material, $\lambda_{max} = 418$ nm) to anthraquinone **2** (photoproduct, $\lambda_{max} = 340$ nm). Compound **2** was also synthesized independently and characterized by UV spectroscopy.

Two-dimensional crystals precipitated from the above-mentioned solutions of **1** and of **2** and were analyzed with a scanning tunneling microscope constructed in our institute which allows imaging in situ at solid–liquid interfaces.[5] A droplet of a solution of **1** or **2** in 1,2,4-trichlorobenzene was applied to a vertically oriented piece of HOPG to form a thin liquid film (Fig. 1 top). The thickness of the liquid film in the vicinity of the STM tip is less than 20 μm (Fig. 1 bottom). The photoreaction was then studied in situ at the graphite–solution interface. An optical multimode PMMA fiber (diameter 1 mm) was used for irradiation (Fig. 1 top). The light intensity was approximately 5 $mWcm^{-2}$ at the graphite surface. The temperature of the graphite was measured in situ with a Pt 100 thermoresistor fixed at one side (Fig. 1 top). The temperature was simultaneously measured at the surface and at the side of the piece of graphite in a control experiment to exclude a nonnegligible temperature gradient. In another control experiment photochemically unreactive monolayers were imaged with and without illumination, and no difference was observed.

The STM images were obtained in constant height mode under ambient conditions (scan rate 0.3 Hz per image, positive tip bias). They were recorded on a videotape in real time and digitized later. Data as recorded without digital image processing are displayed in the figures. The tunneling tips were electrochemically etched (2 N KOH + 6 N NaCN) from a 0.25 mm Pt/Ir (80:20) wire. Every tip was then calibrated in situ by imaging the hexagonal graphite lattice ($a = 246$ pm).

Physisorption of diazoanthrone **1** and of anthraquinone **2** from 1,2,4-trichlorobenzene on HOPG leads to well-ordered 2D

crystallites. As shown in Figures 2 and 3 the lamellar spacing of these crystallites differs by approximately 50%. The larger interlamellar distances (Fig. 3) can be observed only in case of the anthraquinone. This has been verified by imaging the independently synthesized anthraquinone **2**. Therefore the observation of the large structure can be regarded as a direct proof for the presence of the photoproduct. Table 1 summarizes the structural data of the 2D crystals of **1** and **2**. The respective models presented in Figures 4 and 5 are compatible with the STM images. However, the experimental images are only averaged images of systems that exhibit fast molecular dynamics on timescales not accessible to STM.

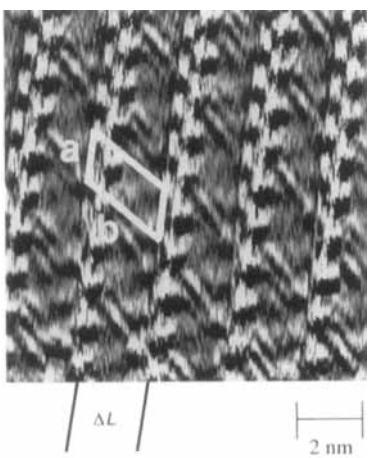

Fig. 2. STM image of a 2D crystal of diazoanthrone **1** on HOPG at submolecular resolution ($V_{tip} = 0.5$ V; $I = 3$ nA).

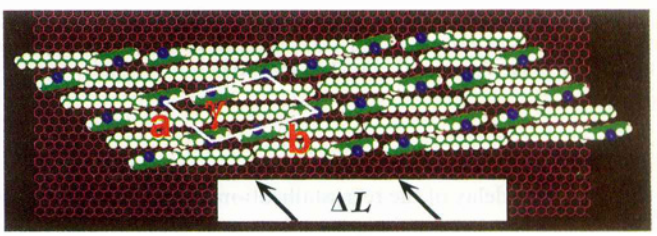

Fig. 4. Molecular model of diazoanthrone **1** on HOPG.

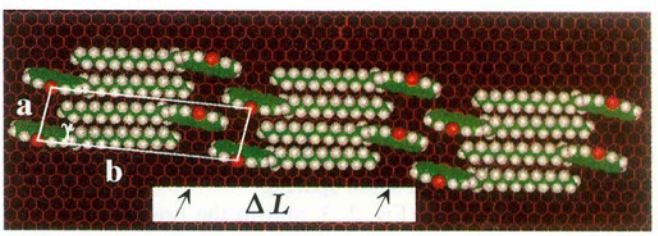

Fig. 5. Molecular model of anthraquinone **2** on HOPG.

The light-induced transformation of diazoanthrone **1** to anthraquinone **2** in trichlorobenzene can be followed in situ by STM. At the beginning a stable 2D crystal of **1** was observed. When one of its domain boundaries (Fig. 6a) was irradiated, the dissolution of the highly ordered molecular pattern was observed, starting at the domain boundary (Fig. 6b–d). When the irradiation was stopped, the highly ordered pattern reappeared and recrystallization of the molecules occurred (Fig. 6e, f). The dissolution–recrystallization cycle shown in Figure 6 was repeated several times within one hour. The time delay of the dissolution after irradiation had started *decreased*

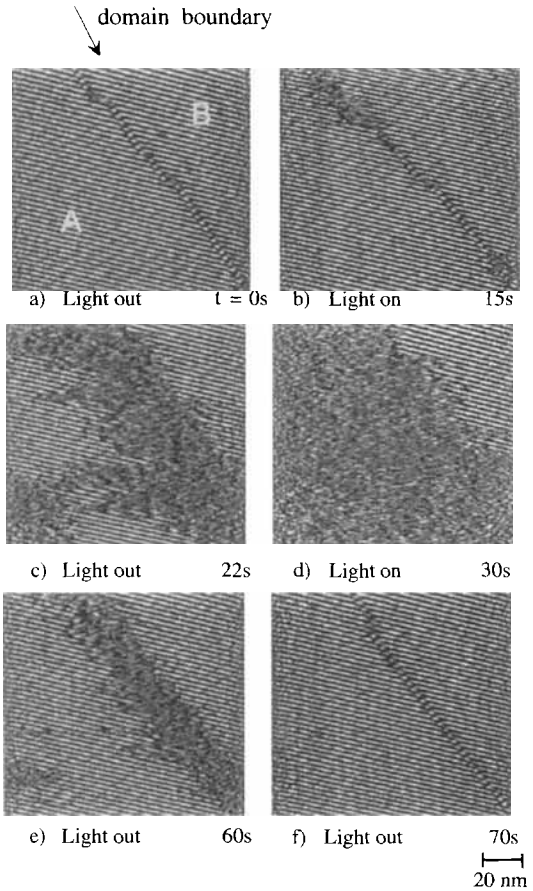

Fig. 6. Light-induced dissolution–recrystallisation cycle of diazoanthrone crystals on the basal plane of graphite ($V_{tip} = 0.3$ V; $I = 1$ nA).

from 30 s initially to approximately 5 s after six cycles. In contrast, the time delay of the recrystallization after irradiation had been halted *increased* in the same experiment from less than 30 s to several minutes. The irradiation had no influence on the temperature of the surface to within 0.1 °C. The starting material and the photoproduct could not be imaged simultaneously on the graphite surface. After complete conversion of **1** (irradiation for several hours) only the product **2** was observed. For the absorption of the 2D crystals with the large lamellar spacing (product) to take place, a large excess of the product with respect to the starting material is necessary. Even imaging of a solution of a 90/10 mixture of **2** and **1** resulted only in the lamellar structures with small spacing.

In the STM images (Fig. 2, 3, and 6) the bright rows (high tunneling current) are attributed to the aromatic moiety of the molecules and the darker rows (low tunneling current) to the alkyl chains. The use of STM as a tool to monitor the ex situ photoreaction was simplified by the large structural differences in the 2D crystals of the diazoanthrone and the anthraquinone. From in situ calibration with the help of the underlying graphite lattice and analysis of the Moiré pattern in the lamellae,[6] the structural parameters of the 2D crystals were evaluated with a high degree of accuracy. From these data we conclude that the alkyl chains are oriented parallel to one of the three main axes of the graphite. Domain boundaries as shown in Figure 6 are common in highly ordered 2D crystals and can be regarded as one of their intrinsic properties.[7]

In our in situ experiments no change of the surface temperature was observed. Therefore the dissolution and recrystallization process at the domain boundaries of the crystals of **1** (Fig. 6) can only be photoinduced. Physisorbed 2D crystallites at a liquid–solid interface are in equilibrium with the supernatant solution.[8] In our experiments the dynamics of molecular processes are too fast to be recorded by STM. Therefore the observed dynamics must be the result of a shift in the overall equilibrium between the solution and the 2D crystals. When the system is irradiated, the equilibrium is disturbed and the 2D crystals on the graphite surface dissolve. The domain boundaries represent thermodynamically favored sites for the dissolution process (Fig. 6b–d). These observations suggest the following explanation for the dissolution–recrystallizaton cycles: The system consists of two different phases. At the onset of the process phase a is represented by the 2D crystallite of **1**, which is covered by several less-ordered layers of **1**[9] with a total thickness of several nanometers. Phase b is the supernatant solution. Provided that the thickness of phase b is less than 20 μm (see Fig. 1b) and based on Beer's law ($c_0 = 0.05$ M, $\varepsilon = 10^{-4}$ mol cm^{-1} at λ_{max}), 90% of the incoming light is absorbed by phase b, which results in a depletion of diazoanthrone in phase b. However, the concentration of **1** in phase a is approximately 100 times higher than in phase b. As a consequence, the residual light intensity depletes phase a more strongly than phase b, and the 2D crystal in phase a starts to dissolve. When irradiation is stopped, the system relaxes and the 2D crystal is reformed. Phase b serves as a reservoir to provide the starting material **1**. During every dissolution–recrystallization cycle the absolute concentration in phase b decreases. This leads to a decrease in the time delay of the dissolution and an increase in the time delay of the relaxation process.

Experimental Procedure

1: Tosyl azide (0.523 g, 2.7 mmol) and piperidine (0.226 g, 22.7 mmol) were added to a suspension of 2-hexadecylanthrone (1 g, 2.4 mmol) in ethanol (30 mL). The mixture was stirred ca. 12 h at room temperature, concentrated, and chromatographed on silica gel with chloroform/hexane (1:1) as the eluent. Compound **1** was obtained in 47% (500 mg) yield; m.p. 64–65 °C (methanol); IR (KBr): $\tilde{\nu} = 2055$ (C=N$_2$), 1636 (C=O); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 0.90$ (t, 3H), 1.25 (m, 26H), 1.65 (m, 2H), 2.70 (t, 2H), 7.27 (d, $J_o = 8$ Hz, 1H), 7.34 (d, $J_o = 8$ Hz, 1H), 7.40 (td, $J_o = 8$ Hz, $J_m = 2$ Hz, 1H), 7.53 (dd, $J_o = 8$ Hz, $J_m = 2$ Hz, 1H), 7.69 (td, $J_o = 8$ Hz, $J_m = 2$ Hz, 1H), 8.37 (d, $J_m = 2$ Hz, 1H), 8.55 (dt, $J_o = 8$ Hz, $J_m = 2$ Hz, $J_p = 1$ Hz, 1H); ^{13}C NMR ($CDCl_3$): $\delta = 14.1$, 22.7, 29.2, 29.3, 29.5, 29.6, 29.7, 30.9, 31.4, 31.9, 35.6, 64.5 (C=N$_2$), 120.6, 125.1, 127.0, 127.7, 128.3, 128.3, 128.4, 129.0, 129.9, 132.7, 133.7, 140.4, 180.1 (C=O); MS (CI): *m/z* (%): 445 (1, MH^+), 417 (16, $MH^+ - N_2$).

2: A suspension of 2-hexadecylanthrone (0.5 g, 1.2 mmol) in glacial acetic acid (20 mL) was added to a stirred suspension of chromium trioxide (0.5 g, 5 mmol) in glacial acetic acid (20 mL) at 10 °C. After 30 min of stirring at 0 °C and 2 h at room temperature, the mixture was poured into ice water (200 mL), extracted with CH_2Cl_2 (3 × 100 mL) and washed with water (2 × 100 mL). The combined extracts were dried ($MgSO_4$), the solvent was evaporated, and the crude product was chromatographed on silica gel with $CHCl_3$/hexane (3:1) as the eluent. Compound **2** was obtained in 75% yield (400 mg), m.p. 102–103 °C (hexane; ref. [10]: 100–103 °C); IR (KBr): $\tilde{\nu} = 1673$ (C = O); ^{1}H NMR (400 MHz): $\delta = 0.9$ (t, 3H), 1.25 (m, 26H), 1.65 (m, 2H), 2.75 (t, 2H), 7.60 (dd, 1H), 8 (m, 2H), 8.11 (d, 1H), 8.22 (d, 1H), 8.30 (m, 2H); MS (CI): *m/z* (%): 432 (29%, $M^{\cdot+}$), 222 (18, $M^{\cdot+}$-$C_{15}H_{31}$) 43 (100, $C_3H_7^+$).

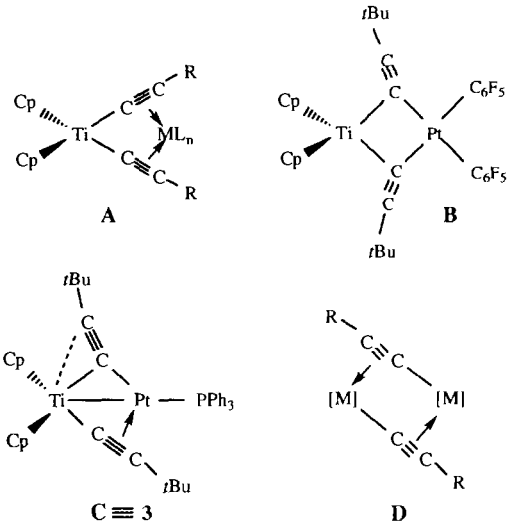
$[Cp_2Ti(C{\equiv}CtBu)_2]$ as an Alkynyl Transfer Reagent: Synthesis and Characterization of the Asymmetrically Bridged Heterodimetallic Complex $[Cp_2Ti(C{\equiv}CtBu)_2Pt(PPh_3)]\cdot 0.5\,THF$**

Jesús R. Berenguer, Juan Forniés,* Elena Lalinde,* and Antonio Martín

Since the report that $[Ni(CO)_4]$ reacts with $[Cp_2Ti(C{\equiv}CPh)_2]$ to give the side-on bridged chelate complex $[\{Cp_2Ti(C{\equiv}CPh)_2\}Ni(CO)]$,[1] a series of titanocene derivatives have been described in which a further metal ion is coordinated by alkynyl ligands:

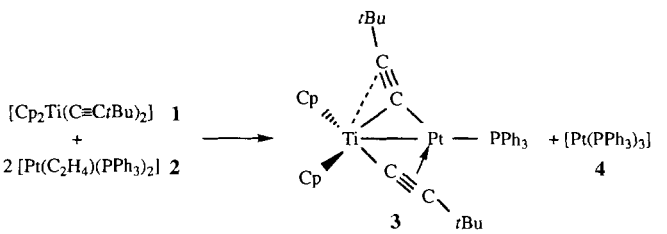
$[\{Cp_2Ti(C{\equiv}CPh)_2\}Pt(PR_3)]$[2] $[\{Cp'_2Ti(C{\equiv}CSiMe_3)_2\}FeCl_2]$[3]



$[\{Cp'_2Ti(C{\equiv}CSiMe_3)_2\}CuCl]$[3]

$[Cp'_2Ti(C{\equiv}CSiMe_3)_2AgX]$ (X = Cl, CN, SCN, NO_2, ClO_4)[4]

$[\{Cp'_2Ti(C{\equiv}CPh)_2\}M(CO)]$ (M = Co,[5] Ni;[6] Cp′ = $C_5H_4SiMe_3$)



$[\{\eta^5\text{-}C_5HMe_4)Ti(C{\equiv}CSiMe_3)_2\}Mg(thf)Cl)]$[7]

All of these complexes display a "tweezer" structure (Scheme 1, **A**) in which the alkynyl groups act as two-electron ligands. Recently we reported on the synthesis of $[Cp_2Ti(\mu\text{-}\eta^1\text{-}C{\equiv}CtBu)_2Pt(C_6F_5)_2]$, an unusual complex in which the two $\mu\text{-}\eta^1\text{-}C{\equiv}CtBu$ ligands bridge both metal centers[8] (Scheme 1, **B**). Usually, only complexes of type **A** or **B** are obtained from reactions of $[Cp_2Ti(C{\equiv}CR)_2]$ with transition metal compounds; in no case has an alkynyl transfer been observed. In this paper we report on the synthesis of $[Cp_2Ti(C{\equiv}CtBu)_2Pt(PPh_3)]$ (**3**), a complex having an unusual asymmetric structure of type **C** (Scheme 1), the formation of which necessarily implies an alkynyl transfer from titanium to platinum.

Scheme 1.

The reaction of the alkynyl complex $[Cp_2Ti(C{\equiv}CtBu)_2]$ (**1**) with $[Pt(C_2H_4)(PPh_3)_2]$ (**2**) in tetrahydrofuran (THF) afforded a deep orange-red solution, from which moderately air-stable, red crystals of **3** were isolated. In addition, $[Pt(PPh_3)_3]$ (**4**) was obtained, which indicates that the PPh_3 liberated when **3** forms is in competition with titanium complex **1** for reaction with **2**. For that reason, **3** was obtained in better yield (55%) when the reaction was carried out with a Ti/Pt molar ratio of 1:2.

The elemental analysis and mass spectrum of **3** are in accord with this formulation. The well-resolved ^{31}P NMR spectrum of **3** indicates that it is a diamagnetic compound. It exhibits a single resonance (δ = 42.0) with a ^{195}Pt satellite pattern corresponding to the presence of a $PtPPh_3$ group. The IR spectrum of **3** exhibits a single, medium-intensity $\nu(C{\equiv}C)$ band (2003 cm^{-1}) at lower wavenumbers than the corresponding vibration in **1** (2061 cm^{-1}), which is consistent with the π coordination of the alkynyl group with an adjacent metal atom.[9] However, this band is much higher in energy than those observed for complexes of type **A**. For instance, $\nu(C{\equiv}C)$ for complexes $[\{Cp_2Ti(C{\equiv}CPh)_2\}PtL]$ (L = tertiary phosphane) with stoichiometries similar to that of **3** occurs at about 1800 cm^{-1}.[2] This suggests that the alkyne ligands in **3** have a different coordination mode.

A single-crystal X-ray diffraction study of **3** (Fig. 1)[10] clearly reveals that it is not a titanocene "tweezer" compound of type **A** but has an unsymmetrical structure (type **C**). The core of the molecule (Pt, Ti, C1, C2, C7, and C8) is planar (mean deviation 0.025 Å), and the phosphorus atom is also located in this plane (deviation 0.029 Å). Although each alkynyl group is π-bonded to a metal center, the strength of this interaction is very different in each case. The coordination of the platinum

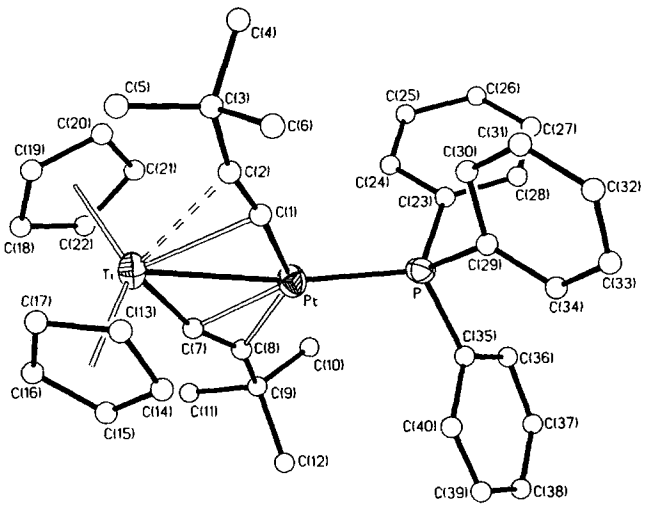

Fig. 1. Crystal structure of **3**·0.5THF. Selected bond lengths [Å] and angles [°]: Ti-C1 2.435(14), Ti-C2 2.795(14), Ti-C7 2.102(14), Pt-C1 1.990(13), Pt-C7 2.054(13), Pt-C8 2.191(15), C1-C2 1.197(19), C7-C8 1.236(19), Pt-P 2.247(3), Pt-Ti 2.789(3); Pt-C1-C2 171.4(13), Ti-C7-C8 163.8(12), C1-C2-C3 165.7(16), C7-C8-C9 147.8(15), Ti-C1-Pt 77.4(5), Ti-C7-Pt 84.3(5), C1-Ti-C7 91.3(5), C1-Pt-C7 107.0(6), C1-Pt-P 108.6(4), C1-Pt-C8 140.6(5), C8-Pt-P 110.7(4).

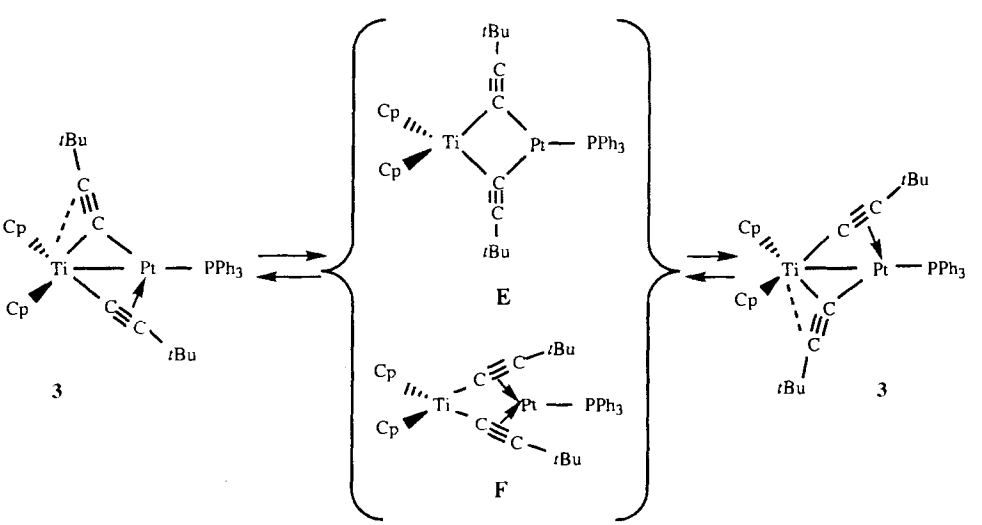
atom to the alkynyl moiety is almost symmetrical with very short Pt–C bond lengths (Pt–C7 = 2.054(13) Å and Pt–C8 = 2.191(15) Å), which suggests a very strong interaction of the platinum center with C7 and C8. As a result the alkyne skeleton is very distorted [Ti-C7-C8 163.8(12)°, C7-C8-C9 147.8(15)°]. The Ti–alkynyl side-on interaction is much weaker, as reflected by the Ti–C bond lengths (Ti–C1 = 2.435(14) Å and Ti–C2 = 2.795(14) Å) which are longer than the Pt–C distances and very different from each other. This suggests that this bond has predominately σ character. However, the Ti–C1 distance is longer than that in **B** (2.240(10), 2.257(10) Å).[8] In **B** the alkyne skeleton displays a very small distortion [Pt-C1-C2 171.4(13)° and C1-C2-C3 165.7(16)°]. It is noteworthy that although alkynyl ligands interact differently with the metal centers, the C≡C bonds have practically the same lengths. The Ti–Pt distance in **3** (2.789(3) Å) is shorter than that found in **B** (2.831(2) Å)[8] and compares well with the distances found in other Pt–Ti complexes for which dative Pt → Ti interactions have been suggested.[12] This short Pt–Ti distance and the diamagnetism of **3** suggest the existence of a Pt–Ti bond. The narrow Ti-C-Pt angles (77.4(5), 84.3(5)°) could be taken as further evidence of this Pt–Ti bond. However, in this kind of complex neither the magnetic properties, nor the intermetallic distances provide, per se, enough evidence to conclude whether a metal–metal bond actually exists.[13] Diamagnetism could be due to spin pairing through the bridging ligands, and short metal–metal distances can be enforced by the bridging ligands.



The structure of complex **3** in the solid state is not reflected in solution. The ^{1}H NMR spectrum of **3** shows that the two *tert*-butyl groups are equivalent at room temperature. This could be the result of a dynamic process involving a fast intramolecular σ migration of the C≡C*t*Bu ligands between the metal centers (Scheme 2). Such dynamic processes have been invoked for other polynuclear complexes with bridging alkyne ligands.[9, 14] Unfortunately, the dynamic process cannot be stopped even at the lowest temperature attainable (CD_2Cl_2, −92 °C). Under these conditions the signal due to the *t*Bu groups is very broad. The ^{13}C NMR spectrum is even less informative since the signals due to *t*Bu groups appear as narrow singlets through the entire temperature range. In addition, the only observed low-field signal (δ = 178.4), which was assigned to one of the alkyne C atoms, disappears at low temperatures.

The unusual behavior of $[Cp_2Ti(C{\equiv}C\,tBu)_2]$ (**1**) towards $[Pt(C_2H_4)(PPh_3)_2]$ (**2**) in acting as an alkynyl transfer reagent is especially surprising since $[Cp_2Ti(C{\equiv}CPh)_2]$ acts only as a chelating ligand in reactions with $[Pt(C_2H_4)_2(PPh_3)]$[2] and **2**.[15] Although in a few cases other bis(alkynyl) complexes have proved to be alkynyl transfer reagents (e.g., $[Cp'_2Zr(C{\equiv}CR)_2]$ in its reaction with $[Cp_2Zr(C_4H_6)]$[14] and *cis*-$[Pt(C_6F_5)_2(C{\equiv}CR)_2]^{2-}$ in its reaction with *cis*-$[Pt(C_6F_5)_2(thf)_2]$[9]), the resulting dinuclear complexes display a symmetrical doubly bridging μ-$\eta^{1:2}$-alkynyl system (Scheme 1, **D**). The formation of **3** can be formally considered as the result of the oxidative addition of a Ti^{IV}–C bond to a Pt^0 substrate to give a dinuclear Ti^{III}–Pt^I compound. Finally, the very different nature of the metal centers and their oxidation states can be the reason for the very different kinds of alkynyl–metal π interactions in **3**.

Our results clearly suggest that the electronic effects and/or steric demands of the alkynyl substituents affect the bonding features of the alkynyl ligands in these doubly bridged alkyne complexes.

Experimental Procedure

3: To a yellow solution of **1** [16] (32.5 mg, 0.10 mmol) in 6 mL of dry THF (distilled under N_2 from Na/benzophenone) under N_2 was added **2** [17] (143 mg, 0.20 mmol). The resulting red solution was concentrated to dryness, and the residue was treated with Et_2O (2 mL) and *n*-hexane (4 mL). The insoluble $[Pt(PPh_3)_3]$ (identified by its elemental analysis and IR spectrum, 60 mg, 64% yield) was removed by filtration, and the dark-red solution was concentrated and kept in the refrigerator for roughly 15 h. The dark-red solid obtained (**3**, 42 mg, 55% yield) was filtered and washed with cold *n*-hexane. IR (Nujol, polyethylene plates): ν = 2003 (m) cm^{-1}, ν(C≡C); ^{1}H NMR (300 MHz, CD_2Cl_2, 25 °C, $SiMe_4$): δ = 7.51 (m, Ph), 7.29 (m, Ph), 5.57 (s, Cp), 3.74 (m, THF), 1.84 (m, THF), 1.04 (s, *t*Bu); (−92 °C): δ = 7.46 (m, Ph),

Scheme 2.

7.3 (m, Ph), 5.6 (s, Cp), 3.62 (m, THF), 1.78 (m, THF), 1.05 (br.s, *t*Bu); ^{13}C NMR (25 °C): $\delta = 138.6$ (d, C_{ipso}, Ph; $^1J(P,^{13}C) = 44.3$ Hz, $^2J(^{195}Pt,^{13}C) = 30.2$ Hz), 134.8 (d, C_{ortho}, Ph, $^2J(P,^{13}C) = 13.4$ Hz, $^3J(^{195}Pt,^{13}C) = 25.5$ Hz), 129.6 (d, C_{para}, Ph, $^4J(P,^{13}C) = 2$ Hz), 128.1 (d, C_{meta}, Ph, $^3J(P,^{13}C) = 10.1$ Hz), 105.1 (s, Cp), 77.8 (s, $C(CH_3)_3$), 68.1 (s, THF), 32.6 (s, $C(CH_3)_3$), 26 (s, THF); (−92 °C): $\delta = 136.3$ (d, C_{ipso}, Ph, $^1J(P,^{13}C) = 45$ Hz), 133.7 (d, C_{ortho}, Ph, $^2J(P,^{13}C) = 13.4$ Hz), 129.1 (s, C_{para}, Ph), 127.4 (d, C_{meta}, Ph, $^3J(P,^{13}C) = 9.4$ Hz), 104 (s, Cp), 77.5 (s, $C(CH_3)_3$), 67.4 (s, THF), 31.4 (s, $C(CH_3)_3$), 25.1 (s, THF); $^{31}P\{^1H\}$ NMR ($CDCl_3$, 85% H_3PO_4, 25 °C): $\delta = 42.0$ ($^1J(^{195}Pt, P) = 4577$ Hz); EIMS: m/z (%) = 799 (47) [$M^+ + H$], 535 (46) [$M^+ - PPh_3$], 453 (100) [$PtPPh_3$]$^+$.

[10] Crystal data for **3**: $C_{42}H_{47}O_{0.5}PPtTi$, $M_r = 833.8$, monoclinic, space group $C2/c$, $a = 21.674(4)$, $b = 9.343(2)$, $c = 36.425(7)$ Å, $\beta = 92.23(3)°$, $V = 7370(3)$ Å^3, $Z = 8$, $\rho_{calc.} = 1.50$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 40.8$ cm^{-1}, $F(000) = 3344$, $T = 293$ K, crystal dimensions $0.13 \times 0.38 \times 0.63$ mm. Crystallographic data were collected by Crystallytics Co. (Lincoln, Nebraska) on a Nicolet (Siemens) Autodiffractometer, $3 < 2\theta < 46°$ (ω scan); 5081 independent reflections, 2741 with $F > 4\sigma(F)$ were observed and used for structure refinement (program system SHELXTL-PLUS [11]). Cell constants were refined from 30 reflections (including Friedel pairs) with $15 < 2\theta < 30°$. An absorption correction based on Ψ scans was applied. Six standard reflections were measured every 300 reflections but showed no decay. The structure was solved by direct methods and refined on $|F_0|$ to $R = R' = 0.043$ for 397 variables (weighting scheme $\omega^{-1} = \sigma^2(F_0) + 0.0004F_0^2$), highest shift/error 0.001. Goodness of fit 1.13. All non-hydrogen atoms, except those of the solvent molecule were refined anisotropically. All hydrogen atoms were included in calculated positions and refined as riding atoms (C–H 0.96 Å and $U = 0.1065$ Å^3). A difference map following convergence showed no peaks higher than 1 e Å^{-3} (maximum/minimum difference density 0.76/−1.12 e Å^{-3}). Further details of the crystal structure investigation are available on request from the Director of Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[15] The reaction of **2** (0.216 g, 0.29 mmol) and $[Cp_2Ti(C{\equiv}CPh)_2]$ (0.11 g, 0.29 mmol) in THF gave a mixture of products. The first fraction obtained by crystallization from THF/hexane was a yellow solid (0.045 g). The ^{31}P NMR spectrum indicates this to be a mixture of complexes. The second fraction, an orange microcrystalline product (0.1 g, 41% yield) was identified by elemental analysis, mass spectrum, and IR and NMR spectra as the previously reported $[Cp_2Ti(C{\equiv}CPh)_2Pt(PPh_3)]$ [2].

Optically Active Reference Compounds for Environmental Analysis Obtained by Preparative Enantioselective Gas Chromatography**

Wilfried A. König,* Ingo H. Hardt, Bärbel Gehrcke, Detlev H. Hochmuth, Heinrich Hühnerfuss, Bernd Pfaffenberger, and Gerhard Rimkus

Dedicated to Professor Hansjörg Sinn on the occasion of his 65th birthday

The distribution and behavior of toxicologically relevant xenobiotics in the environment is of increasing scientific interest. Chiral, biologically active compounds whose enantiomers produce fundamentally different effects and whose *biological* degradation is, as a rule, enantioselective are of particular importance in this context. These properties have been observed in "cyclodiene" insecticides[1] and, more recently, in chiral α-1,2,3,4,5,6-hexachlorocyclohexane (α-HCH),[2] the enantiomers of which are selectively accumulated in living organisms. Using gas chromatography on modified cyclodextrins (CDs), we have been able to separate a number of polychlorinated hydrocarbons (PCHs) into their enantiomers: heptachlor and *cis*- and *trans*-chlordane, which were used as insecticides for decades; their metabolites *cis*-heptachlor epoxide and oxychlordane;[3] the atropisomeric polychlorinated biphenyls (PCBs);[4] and bromocyclen[5] (Fig. 1). Other groups have also used enantiose-

lective gas chromatography in the analysis of PCHs isolated from different compartments of the environment, and, in several cases, they have shown that these compounds are metabolized enantioselectively.[6]

Optically active samples of these compounds have already been obtained by enantioselective dehydrochlorination, separation of the enantiomers by liquid chromatography (α-HCH[7, 8]), and enantioselective synthesis (heptachlor, heptachlor epoxide, *cis*- and *trans*-chlordane[1, 9]); however, enantiomerically pure (or enriched) reference substances, which can be used in gas chromatography to determine the sequence of elution of enantiomers, are not commercially available. Using preparative gas chromatography columns with modified CDs as the chiral stationary phase, we have now succeeded in separating the enantiomers of a selection of PCHs on a milligram scale and with enantiomeric excesses of between 42 and over 99% (Fig. 2, Table 1).[12]

So far, preparative separations on columns packed with CDs have only been described for the highly volatile inhalation anesthetics enflurane[13] and isoflurane,[14] which have separation factors $\alpha > 2$ on capillary columns.[15] In the examples reported here, the separation factors are between 1.02 (e.g., heptachlor, *trans*-heptachlor epoxide, bromocyclen) and 1.10 (α-HCH). Although the quantity of sample injected in each *individual* run ranged from 2 to 7 mg, satisfactory to very high enantiomeric purity (with yields of 20–90% for each enantiomer) was obtained by fractionation. In each case, the enantiomers were characterized by measurement of optical rotation; the order of elution of the enantiomers can thus be determined for any CD derivative.[16]

Table 1. Isolated yield and enantiomeric excess (*ee*) obtained in the preparative resolution of the enantiomers of chiral xenobiotics by gas chromatography on cyclodextrin (CD) derivatives. In each case, the racemate (ca. 2 mg) in acetone (ca. 20 mL) was injected at an injector temperature of 200 °C; the total weight of sample was ca. 20 mg.

Compound	Yield [mg]	*ee* [%]	CD derivative

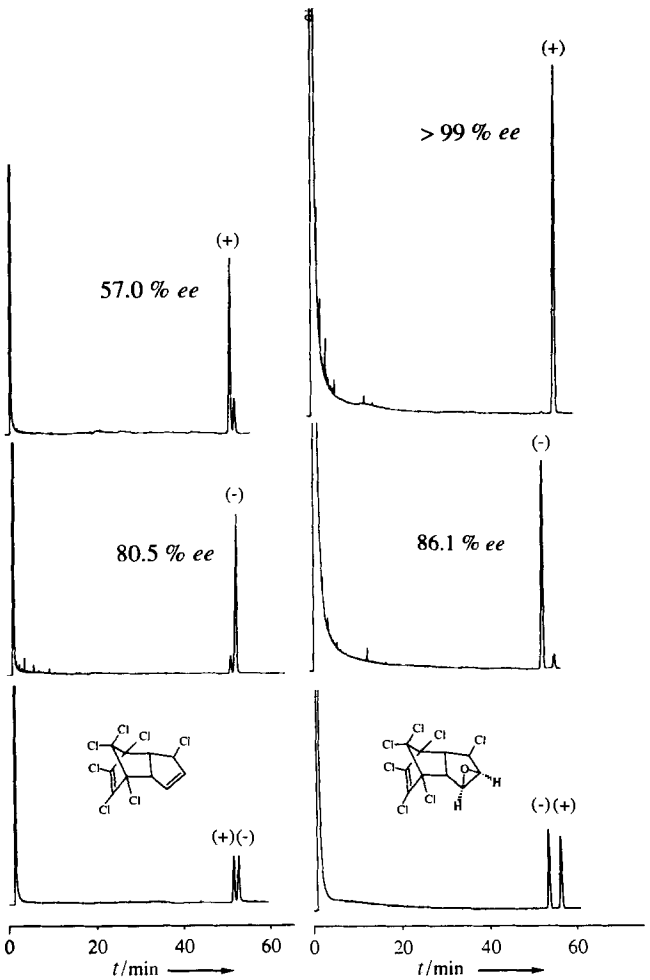

Fig. 2. Determination of the enantiomeric purity of heptachlor (left) by enantioselective gas chromatography on a "fused silica" capillary column (25 m) containing heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin in polysiloxane OV 1701 (20%) at 130 °C and of *cis*-heptachlor epoxide (right) on a "fused silica" capillary column (25 m) containing heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin in polysiloxane OV 1701 (20%) at 160 °C; injector temperature 200 °C, detector temperature 250 °C; carrier gas, hydrogen.

The toxic compounds mentioned above are ubiquitous and are highly persistent contaminants in the environment; they are accumulated in the adipose tissue of higher organisms. Sea gull eggs, liver of roe deer and hare, and different seal organs were examined; the ratio of enantiomers for the metabolites *cis*-heptachlor epoxide and oxychlordane deviated significantly from 1.0 in all cases (Table 2). It is not only noticeable that the selectivity of metabolism differs greatly from one organism to the next, but also that the (+)-enantiomers are enriched in sea gull eggs and

Table 2. Enantiomer ratio (+/−, determined by gas chromatography) of *cis*-heptachlor epoxide and oxychlordane in various samples of sea gull eggs, hare liver, roe-deer liver (from Schleswig-Holstein), and adipose tissue from seals (from Iceland).

Sample	*cis*-Heptachlor epoxide	Oxychlordane
Sea gull egg, 1	-	2.3
Sea gull egg, 2	-	2.1
Sea gull egg, 3	-	1.8
Sea gull egg, 4	2.7	1.5
Sea gull egg, 5	1.6	1.5
Hare liver, 1	3.3	1.1
Hare liver, 2	2.5	1.0
Hare liver, 3	3.7	1.3
Hare liver, 4	2.6	1.3
Hare liver, 5	3.2	1.5
Roe-deer liver, 1	1	9
Roe-deer liver, 2	2	12
Roe-deer liver, 3	6	14
Roe-deer liver, 4	7	17
Roe-deer liver, 5	9	12
Seal, 1 (adipose tissue)	0.14	0.66
Seal, 2 (adipose tissue)	0.18	0.54
Seal, 1 (liver)	0.06	0.57
Seal, 2 (liver)	0.05	0.45
Seal, 1 (brain)	0.11	0.57
Seal, 2 (brain)	-	0.48

in the liver of roe deer and hare, whereas the (−)-enantiomers predominate in the adipose tissue of seals. Bromocyclen, which is used in Europe to counter parasitic infestations of pets and has been found in fresh water fish, in some cases, in surprisingly high concentrations of $>1\ mg\,kg^{-1}$, is also metabolized enantioselectively.[5] The ratio of enantiomers (peak area ratio of (+)-enantiomer/(−)-enantiomer) lies between 1.25 and 1.06.

The toxicological implications of these findings are not yet clear; however, the results show that the enzymatic degradation of the xenobiotics dicussed here is possible for at least one enantiomer. Degradation of both enantiomers may also be occurring at different rates. Enantioselective gas chromatography has not only proven to be a sensitive and selective analytical method for distinguishing between enzymatic and non-enzymatic degradation of chiral toxic compounds, but can also be used for the virtually complete preparative-scale resolution of enantiomers with low separation factors.

The Versatility of the Azido Ligand: Linkage of Ni^{II} Centers to Form a Chain with One End-to-End and Three End-On Bridges in Alternation**

Joan Ribas,* Montserrat Monfort, Barindra Kumar Ghosh, and Xavier Solans

In recent years several groups have investigated the correlation between magnetic and structural properties of μ-azido-nickel(II) complexes.[1, 2] We are now working systematically in this field[3–5] and have prepared two types of systems whose structures depend on the amino ligand employed (Scheme 1).

Scheme 1. Possible coordination modes for azido ligands.

The bridging ligand with its end-to-end (EE) coordination mode affords antiferromagnetic (AF) dinuclear[3a] and one-dimensional (1D) systems.[3b–e] End-on (EO) coordination is observed in some dinuclear,[4a, b] one tetranuclear,[4c] and several one-dimensional polymeric ferromagnetic (F) compounds.[4b] A new unexpected two-dimensional (2D) complex (Fig. 1) with both EE and EO bridges has also been characterized[5] and displays overall AF behavior with canting phenomenon at low temperatures. This variation in coordination modes, EE and EO, causes different magnetic couplings which appear to be general for the metal ions Cu^{II},[6] Mn^{II},[7] Mn^{III},[8] and Co^{II}.[9]

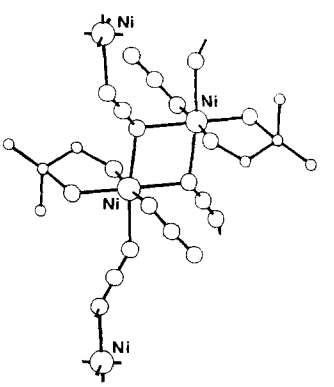

Fig. 1. Schematic representation of the structure of the 2D complex $[Ni(N_3)_2(dmpd)]_n$ (dmpd = 2,2-dimethylpropane-1,3-diamine), showing the different kinds of azido coordination: EO, EE, and terminal [5].

In continuation of our investigations we considered that the 2D system presents one terminal azido ligand on each Ni^{II} atom (Fig. 1), and it should thus be possible to have three EO bridges. We report here on the synthesis and characterization of $[Ni(N_3)_2(tmeda)]_n$ (tmeda = *N,N,N′,N′*-tetramethylethylenediamine), a novel compound in which the Ni^{II} centers are linked alternately by one EE and three EO bridges to form a chain (Fig. 2).[10] Each Ni^{II} center completes its distorted octahedral coordination by binding to one bidentate tmeda lig-

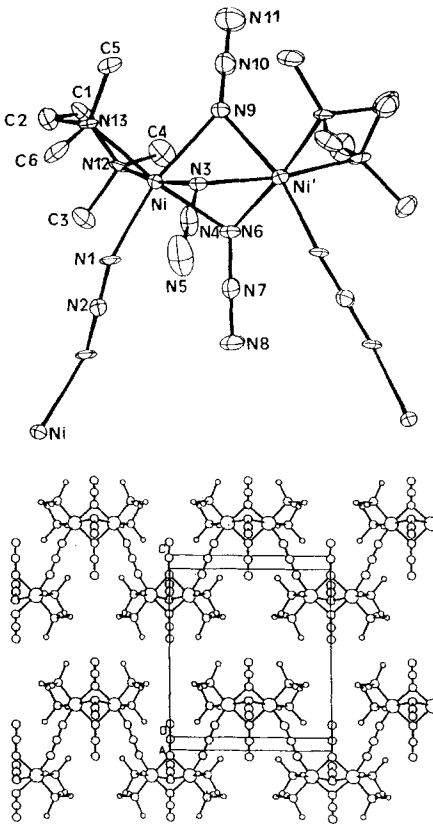

Fig. 2. Top: Crystal structure of $[Ni(N_3)_2(tmeda)]_n$. Selected bond lengths [Å] and angles [°] (standard deviation in parentheses): Ni-N1 2.062(4), Ni-N3 2.120(3), Ni-N6 2.139(5), Ni-N9 2.160(6), Ni-Ni' 2.8692(7), Ni-N12 2.132(3), Ni-N13 2.150(3); N1-Ni-N3 91.9(2), N1-Ni-N6 92.8(2), N3-Ni-N6 83.79(14), N1-Ni-N9 166.6(2), N3-Ni-N9 77.3(2), N6-Ni-N9 78.3(3), N2-N1-Ni 138.0(2), N1-N2-N1(ii) 180.0, Ni-N3-Ni' 85.16(13), Ni-N6-Ni' 84.3(2), Ni-N9-Ni' 83.2(3). Bottom: Arrangement in the crystal.

and. The most important features are the Ni-N-Ni angles. The average value in the EO bridge is 84.2°, which is the lowest value for any metal atom;[2-9] in the EE bridge the Ni-N-N angle is 138° with a Ni-N_3-Ni dihedral angle of 0°. These angles are relevant to the discussion of magnetic properties.

Variable-temperature solid-state magnetic susceptibility studies have been performed on a powder sample from 290 to 4 K. Overall antiferromagnetic interaction is evident from the magnetic behavior (Fig. 3). The χ_M value increases when the temperature decreases; reaches a maximum near 47 K, and then decreases as the temperature approaches 4 K. To explain the magnetic behavior we must assume two J values (alternating chain): J_1 for EE coordination and J_2 for EO coordination, where J_1 must be negative[3] (AF) and J_2 could be negative (AF) or positive (F) because of the low Ni-N-Ni angle. We have fitted the data with the Borrás formula[11a] for an antiferromagnetic, alternating $S = 1$ chain and with the standard formula[12] for a dinuclear Ni^{II} unit (i.e., assuming $J_2 = 0$). The parameters of the best fit and their reliability factors (R) are $J_1 = -31.8 \pm 0.3\ cm^{-1}$, $J_2 = -6.9 \pm 0.2\ cm^{-1}$, $g = 2.35$, and $R = 1.5 \times 10^{-4}$ for the alternating chain, and $J_1 = -29.3 \pm 0.5\ cm^{-1}$, $g = 2.26$, and $R = 6.6 \times 10^{-3}$ for a dinuclear unit (Fig. 3). The following values were obtained for the maximum susceptibility: 0.01141 (experimental), 0.01160 (alternating chain), and 0.01192 $cm^3\ mol^{-1}$ (dinuclear unit). In both cases the experimental value in this zone is lower than the theoretical, and the difference is even greater for the dinuclear model. This clearly indicates antiferromagnetic coupling in both parts of the chain

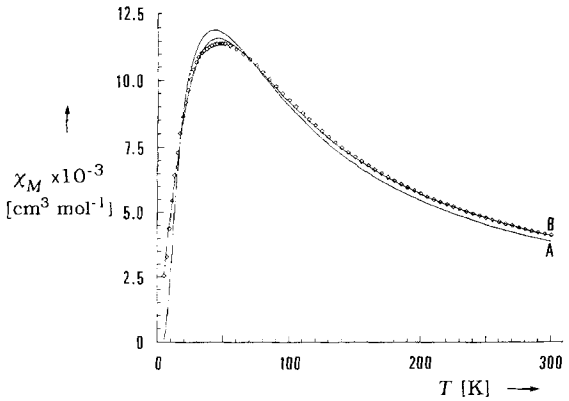

Fig. 3. Plots of χ_M (◇) versus T for $[Ni(N_3)_2(tmeda)]_n$. Solid lines correspond to the best fitting curves for dinuclear Ni^{II} complexes (A) and for an AF alternating chain (B).

(both J_1 and J_2 are negative). There is no formula in the literature for an $S = 1$, ferromagnetic-antiferromagnetic alternating chain, but according to the reported formula for an $S = 1/2$ system,[11b] the maximum should be higher than that for the dinuclear unit.

Our previous studies on 1D Ni^{II} complexes with EE coordination show that for a Ni-N-N angle of 138° and a Ni-N_3-Ni dihedral angle of 0° the J_1 value should be close to $-40\ cm^{-1}$.[3d,e] However, the behavior of the $Ni(N_3)_3Ni$ core is very difficult to predict. Indeed, all Ni^{II} complexes reported so far with EO bridge(s) are ferromagnetically coupled[2,4] with Ni-N-Ni angle(s) close to 103°. For similar Cu^{II} complexes Kahn et al. explained the ferromagnetic behavior by accidental orthogonality[13] and with the results of ab initio calculations on model systems,[14] which led to the theory of spin polarization. Accidental orthogonality appears for Cu-N-Cu angles close to 103°.[13] For the analogous Ni^{II} complexes the Ni-N-Ni angle ranges from 100 to 105°. Consequently, it is not surprising that all of these complexes are ferromagnetically coupled. In our case, the angle is 84° (average), the smallest yet reported for an azidometal complex.[15] This is also most likely the main reason for the net negative value of J_2 (AF) found in the experimental fitting.

In conclusion we state that the Ni^{II} complex described here is a further example in which the change of the nonbridging ligand (dmpd → tmeda) dramatically affects the coordination mode of the μ-azido ligand and, of course, the nature of magnetic interaction propagated through the bridge. We are currently attempting to elucidate the nature and magnitude of the interactions between two types of nickel centers of this novel system where the Ni-N-Ni angle of EO bridge ranges from 105° to 80°.

Experimental Procedure

A solution of tmeda (0.3 g 2 mmol) in MeCN (10 mL) was added dropwise to a stirred aqueous solution (25 mL) of $Ni(ClO_4)_2 \cdot 6\ H_2O$ (0.74 g, 2 mmol). After filtration, a solution of NaN_3 (0.26 g, 4 mmol) in water (10 mL) was added slowly. Within a few minutes a bit of greenish-white solid precipitated which was filtered off and discarded. Slow evaporation of the clear dark green solution for one week at room temperature provided X-ray quality green monocrystals (yield 0.42 g, 80%).

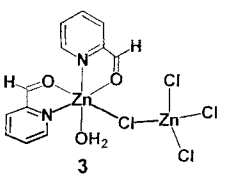
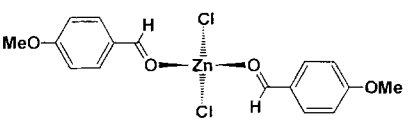
On the Nature of Zinc Chloride–Aldehyde Interactions**

Bodo Müller, Michael Ruf, and Heinrich Vahrenkamp*



Among the large number of organic reactions that involve aldehydes as starting compounds or products, many are catalyzed by simple metal salts, $ZnCl_2$ being the most prominent co-reagent for carbonyl conversions.[1] This should imply that the coordination chemistry of aldehydes or the reactivity of aldehydes in the ligand sphere of complexes are attractive objects of study. However, the inherently low donor strength of aldehydes has limited the types of well-characterized metal–aldehyde complexes to some organometallic species of the inert heavy transition metals[2] and to classical chelate complexes like those of salicylic aldehyde.[3] The number of known adducts of metal halides with simple aldehydes[4] or aldehyde solvates of metal salts[5] is surprisingly small, and to our knowledge only one such complex[6] has been structurally characterized.[7]

We became interested in this type of compound through our work on the bioinorganic chemistry of zinc, specifically by attempts to model the active site of the zinc enzyme alcohol dehydrogenase. The immediate coordination sphere of the metal in this enzyme is S_2NZn-substrate,[9] and the closest approach to its static nature was achieved by Bochmann et al., who isolated complexes $[Zn(SeR)_2 \cdot R'CHO]_2$ ($R = C_6H_2tBu_3$, $R' =$ aromatic group) and determined the structure for $R' = p\text{-}C_6H_4OMe$.[10] In addition to working on this problem by preparing cysteine–zinc–(O donor) complexes we carried out a general screening of the donor/acceptor relations between simple zinc salts and monofunctional aldehydes. Here we report our findings for the zinc chloride system.



For aliphatic aldehydes, condensations and polymerizations seem to be preferred over coordination in the presence of $ZnCl_2$. But by dissolving anhydrous zinc chloride in a 100-fold excess of benzaldehyde and crystallizing by diffusion of petroleum ether into the solution, the compound [$ZnCl_2$ · benzaldehyde] (**1**) is obtained as colorless crystals.[11] Similarly, from *p*-methoxybenzaldehyde (anisaldehyde) the colorless 1:2 complex [$ZnCl_2$ · 2 anisaldehyde] (**2**) is formed. Reacting the potentially chelating aldehyde pyridine-2-carbaldehyde (L) in stoichiometric amounts with zinc chloride and one half equivalent of water in ether, a product with yet another stoichiometry, $[L_2Zn_2Cl_4 \cdot H_2O]$ (**3**), is precpitated as colorless crystals.

1

3

2

In **1**, **2**, and **3** the aldehyde ν(CO) bands in the IR spectrum at 1682, 1677, and 1663 cm^{-1}, respectively, are shifted by 20–50 cm^{-1} to lower wavenumbers, indicating coordination of the aldehydes through their oxygen atoms.[4, 5] Similarly the ^{1}H NMR signals in acetone of the aldehyde protons for **1** ($\delta = 10.02$), **2** ($\delta = 9.91$), and **3** ($\delta = 10.27$) respond to the complexation by low-field shifts of $\Delta\delta = 0.1–0.2$.

The crystals of **1** were not suitable for a structure detemination. The solubility of **1**, however, indicates the presence of a molecular species which, in accordance with Bochmann's selenolate complex,[10] may be formulated as a chloride-bridged dimer. The structure of **2** was obtained crystallographically.[12] Figure 1 shows one molecule of **2**, which to our knowledge is the first structurally characterized transition metal halide complex of a simple aldehyde. Complex **2** is a quite normal tetrahedral zinc complex with all bond lengths and angles at zinc within the

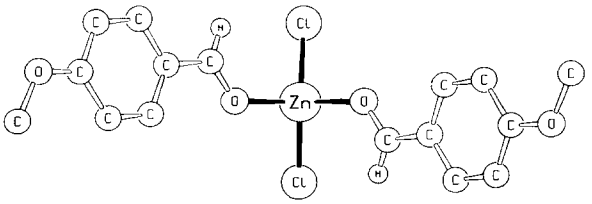

Fig. 1. Molecular structure of **2**. Selected bond lengths [pm] and angles [°]: Zn-Cl 219.8(1), Zn-O 202.0(4); O-Zn-O 100.2(2), Cl-Zn-Cl 130.0(1), Cl-Zn-O 105.0(1) and 106.5(1), Zn-O-C 127.3(4).

standard range, except for a slight increase of the Cl-Zn-Cl angle. Thus, there are no bonding features supporting the argument that such complexes should be difficult to obtain. This in turn means that unusual steric hindrance or the presence of special chalcogenolate ligands[10] are not prerequisites for their isolability. However, care must be taken in handling the compounds, since they are extremely hygroscopic. The structure (also obtained crystallographically) of **3**, which initially resulted from accidental access of water, underlines this.

The comparison of **1**, **2**, and **3** points to the subtleties governing the coordination behavior of the three aldehydes. In solid **1** the aldehyde donor seems to be unable to compete with a Zn–Cl unit for a coordination position on zinc despite the large excess of the aldehyde in solution. In **2** the *p*-methoxy substituent on the phenyl ring has sufficiently increased the donor capacity of the aldehyde to enable this. Complex **3** shows yet another way of balancing the donor abilities of the aldehyde and chloro ligands: one zinc ion binds both chelating aldehydes, the second one is only coordinated by chloro ligands.

These findings underline the ambiguity about the mode of coordination of the aldehydes, which is due to their low donor capacity. This in turn means that mechanistic implications about metal salt mediated organic reactions of aldehydes[1, 13] may have an equally high degree of ambiguity.

Cyanide–Isocyanide Isomerism in CN-Bridged Organometallic Complexes**

Nianyong Zhu and Heinrich Vahrenkamp*

Bridged dinuclear complexes are a prime object of studies for mixed valence and electron transfer.[1] Among these complexes those with cyanide bridges have often been mentioned because of their obvious relation with Prussian Blue.[2] The actual number of studies of their redox and mixed-valence behavior, however, is still rather small.[3]

We have started a systematic preparative, structural, and electrochemical investigation of cyanide-bridged complexes, in search of "organometallic Prussian Blue".[4] Such complexes are amazingly easy to prepare, since almost any organometallic complex with cyanide ligands (neutral or anionic) can be used as a ligand itself for another organometallic unit, thereby establishing the CN links. Furthermore the oligonuclear species obtained this way seem to be highly inert towards M–CN–M′ → M–NC–M′ isomerizations, which are a common fate of classical complexes with CN links, leading to the thermodynamically preferred isomers.[2, 5] This behavior has allowed us to prepare and characterize for the first time stable pairs of organometallic species with cyanide/isocyanide isomerism, that is species which exist in the M(μ-CN)M′ as well as in the M(μ-NC)M′ forms.[6]

Here we report on two such pairs which relate to complexes that we have described before. The first pair, **1a** and **1b**, can be

$[Cp(CO)_2Fe(\mu\text{-}CN)Mn(CO)_2Cp]$ **1a** $[Cp(CO)_2Fe(\mu\text{-}NC)Mn(CO)_2Cp]$ **1b**

derived from the pseudosymmetrical anion $[Cp(CO)_2Mn(\mu\text{-}CN)Mn(CO)_2Cp]^-$.[4] Replacing one neutral $Cp(CO)_2Mn$ fragment on the left- or right-hand side of this complex by an isoelectronic cationic $Cp(CO)_2Fe$ fragment results in the pair of isomers **1**. Chemically this is achieved by either reacting $[Cp(CO)_2FeCN]$ in THF with $[(thf)Mn(CO)_2Cp]$ to give **1a** or $[Cp(CO)_2Fe(thf)]BF_4$ in CH_2Cl_2 with $Na[Cp(CO)_2Mn\text{-}CN]$ to give **1b**. Recrystallization from CH_2Cl_2/petroleum ether provides **1a** and **1b** in 25 and 45% yield, respectively.

Complexes **1a** (orange-red) and **1b** (red) can be distinguished by their colors, as evidenced by their absorptions in the visible range showing a broad featureless band extending from the UV for **1a** and one exhibiting a weak maximum at 495 nm for **1b**. The differences in their ν_{CO} bands and ^1H NMR spectra are very small.[9] However, the CN stretching frequency for **1b** (2100 cm^{-1}) is 50 cm^{-1} lower than that for **1a**, which means that for this pair of isomers the different electronic situations are not accommodated by the M–CO units but by the bridging CN ligand. The redox behavior of **1a** and **1b**[9] reflects the orientation of the bridging CN by a difference of 0.24 V in the $E_{1/2}$(ox) values.

The second pair of isomers completes a series of compounds starting with **2a** and $[\mathbf{2a}]^+$.[10] While **2a** was obtained from $Na[Cr(CO)_5CN]$ and [BrFe(dppe)Cp] (dppe = 1,2-bis(diphenylphosphano)ethane),[10] **2b** was prepared from $[(CO)_5Cr(thf)]$

$[(CO)_5Cr(\mu\text{-}CN)Fe(dppe)Cp]$ **2a** $[(CO)_5Cr(\mu\text{-}NC)Fe(dppe)Cp]$ **2b**

and [Cp(dppe)FeCN] in THF and recrystallized from CH_2Cl_2/petroleum ether in 62% yield. Both isomers of **2**, just like those of **1**, cannot be interconverted thermally up to their decomposition points around 150 °C. **2a** (red) and **2b** (yellow) differ clearly in their colors and in their optical absorption maxima (472 nm for **2a** and 402 nm for **2b**). This time the δ(Cp) and ν(CN) values[9] are quite similar, and the electronic difference is mostly reflected in the CO vibrations.[9] Specifically the A_1^1 band of the $Cr(CO)_5$ group which corresponds to the CO vibration *trans* to CN is about 30 cm^{-1} higher for **2a** (1898 cm^{-1}) than for **2b**. This might be expected because N-bonded CN is a weaker π acceptor than C-bonded CN. A comparison of **2b** with $[(CO)_5CrNCMe]$ (A_1^1 bands at 1869 and 1930 cm^{-1}, respectively) reveals clearly that the "ligand" [Cp(dppe)FeCN] in **2b** is extremely electron-rich. Irrespective of this, the HOMOs of **2a** and **2b** seem to be lower in energy than those of **1a** and **1b**, since both complexes **2** are about 0.2 V more difficult to oxidize than their counterparts **1**.[9]

The structure determinations of **2a** and **2b**[11, 12] reveal that it is almost impossible to distinguish the compounds in the solid state. The crystals are isomorphous (but clearly distinguished by their colors), and both structures can be presented by one drawing (Fig. 1). The bonding parameters are all normal. The differences between **2a** and **2b** are almost insignificant, but the trends in the Cr-CN-Fe backbones are as expected. Thus, the M–N distances are longer than the corresponding M–C distances because of weaker M–N vs. M–C backbonding, and the Fe–C bond in **2b** is the shortest of the M–(CN) bonds because the electron-rich iron unit has the most backbonding to offer, while the C–N bond length shows very little variation. The largest difference between **2a** and **2b** lies in the deviations from linearity at the bridging C and N atoms. We consider this bending of the molecules to result from packing forces. Isomorphism, a similar bending, and the near-to-identity of all bonding parameters were also observed for the pair of complexes $[(NH_3)_5Co(\mu\text{-}L)Co(CN)_5]$ (L = CN, NC).[8]

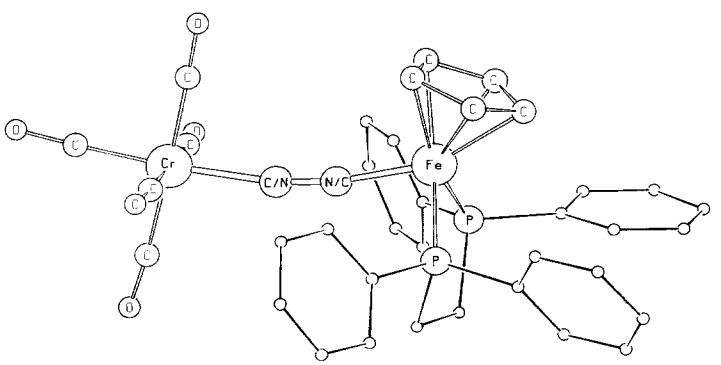

Fig. 1. Molecular geometry of **2a** and **2b**. Pertinent distances [pm] and angles [°] (values for **2b** in square brackets): Cr-C/Cr-N 206.4(5) [208.6(3)], C-N 115.8(7) [115.1(5)], Fe-N/Fe-C 193.5(4) [189.7(4)], Cr-C(CO *trans*) 183.8(6) [184.4(5)], Cr-C(CO *cis*, average) 188.6(6) [189.5(5)], Fe-P (average) 220.2(1) [218.5(1)]; Cr-C(N)-N(C) 170.7(4) [165.1(3)], Fe-N(C)-C(N) 169.8(4) [174.3(4)].

The spectroscopic and structural similarity within the pair of isomers **2a** and **2b**, which may be explained by their delocalized nature, extends itself to their cationic species. The molecular structure of the cation in [**2b**] $[BF_4]$[10] is again most similar to that of **2a** and **2b**, and a detailed investigation has revealed that the radical ion $\mathbf{2b}^+$ possesses a high degree of charge delocalization.[10]

The physical properties of the isomers and their tolerance of a change in the electron count underline the ability of the cyanide ligand to act as a mediator and transducer of electronic effects. The position of the ν(CN) vibration in the IR spectrum[9] and preliminary extended-Hückel MO calculations[13] indicate that the bridging cyanide ligand can respond to the donor/acceptor properties of both organometallic units by variation of its electronic situation without altering its bond length, just as has been observed for many solid-state metal-cyanide compounds.[14] Thus, it does not seem to be utterly unrealistic to search for "organometallic Prussian Blue".

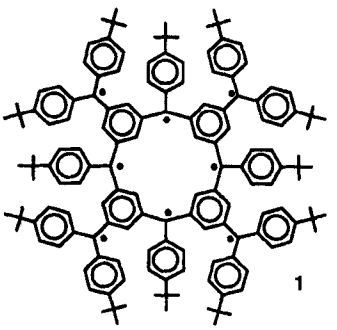
Calixarene-Based Macrocyclic Nonet ($S = 4$) Octaradical and its Acyclic Sextet ($S = 5/2$) Pentaradical Analogue**

Andrzej Rajca,* Suchada Rajca, and Raghavakaimal Padmakumar



Very high-spin organic molecules are of current interest in relation to fundamental aspects of bonding and novel approaches to materials.[1] Synthesis of mesoscopic-size and well-defined high-spin organic molecules is one of the ultimate goals in the area of organic magnetism.[2, 3] The organic molecule with the

[**] This research was supported by the National Science Foundation (CHE-9203918). Mass spectral determinations were performed by the Midwest Center for Mass Spectrometry with partial support by the National Science Foundation (DIR-9017262). We thank Professor S. H. Liou for access to a SQUID magnetometer.

highest spin quantum number S is the nonacarbene ($S = 9$) prepared by Iwamura et al.[4] So far, strong ferromagnetic coupling could be maintained in molecules with up to around ten carbene or radical sites.[4, 5] Dendritic polyradicals with up to 31 radical sites were reported to possess lower than expected spin values. It was suggested that one of the possible reasons for the interruption of the spin coupling was the presence of defects, which were defined as failure to generate a radical site.[2] In acyclic spin-coupled structures, such as typical organic high-spin molecules, even a single defect may interrupt or weaken the only available pathway for spin coupling.[6, 7] This is in contrast to inorganic clusters or extended networks,[8] where an alternative pathway (to that containing the defect) is possible, as long as the number of defects is moderate.

We now report on two macrocyclic high-spin organic molecules, the calix[4]arene-based nonet ($S = 4$) octaradical **1** and its acyclic analogue **2**.[9] Both polyradicals are designed to minimize the potential impact of defects on spin coupling (conjugation): in **1** cyclic connectivity and in **2** the number of terminal sites was maximized. Spin coupling in the above polyradicals is interrupted when a defect divides the spin system into at least two uncoupled spin systems with lower spin. Because the minimum requirements for such interruptions (namely, *more than one* defect at the four-site calix[4]arene ring in **1** and one defect at the solitary central site in **2**) are quite stringent, we expect to obtain high-spin polyradicals with negligible amounts of low spin ($S = 1/2$, 1, etc.) contaminants.

Scheme 1. Synthesis of the polyethers: A: 1) *n*BuLi/ether, 2) 4,4'-di-*tert*-butylbenzophenone; B: NaH/THF, MeI; C: 1) *t*BuLi/ether, 2) methyl 4-*tert*-butylbenzoate; D: 1) *t*BuLi/THF, 2) 1-(4-*tert*-butylbenzoyl)pyrrolidine; E: 1) **6**/*t*BuLi/THF, 2) **7**; F: 1) *n*BuLi/THF, 2) 4,4'-di-*tert*-butylbenzophenone; G: 1) **9**/Na/K in THF or ether, 2) MeOD; H: 1) **12**/Li in THF, 2) MeOD.

First, polyethers **9** and **12** were synthesized (Scheme 1). In the key step, the assembly of calix[4]arene ring, a single isomer of **8** was isolated in approximately 20% yield.[10] The characteristic features of the ^{1}H NMR spectrum of **8** are: one signal for the hydroxyl groups, four for the methoxy groups (2/2/1/1), and seven for the *t*Bu groups (2/2/2/2/2/1/1); the symmetry in **8** is corroborated by the ^{13}C NMR spectrum. NMR spectroscopic investigations confirmed the fact that the two equivalent hydroxyl groups were replaced with two equivalent methoxy groups in the conversion of **8** to **9**.[10]

Treatment of octaether **9** with Na/K alloy in THF or diethyl ether and of pentaether **12** with Li metal in THF for 2–4 days gave solutions of the corresponding carbopolyanions. This was confirmed by the quenching products **10** and **13** obtained with deuterated methanol. Addition of one equivalent (or a small excess) of iodine to the carbopolyanions in THF at 180 K gave polyradicals **1** and **2**, respectively.[5] When a solution of **1** in THF/2-MeTHF was allowed to react with an excess of Na/K alloy at low temperature and then quenched with methanol, nondeuterated isotopomers of **10** were obtained; this suggests that the macrocyclic ring is intact in **1**.

The $\Delta m_s = 1$ regions of the electron spin resonance (ESR) spectra for **1** and **2** in THF or THF/2-MeTHF (10^{-4}–10^{-3} M) at 77 K are not sufficiently resolved to permit a meaningful spectral fit for these sterically congested polyradicals.[12a] A weak $\Delta m_s = 2$ signal is observed for **1** but not for **2** at 77 K; this is what one would qualitatively expect for such polyradicals with integral ($S = 4$) and half-integral ($S = 5/2$) spin quantum numbers.[12b] The product of the intensity I of the $\Delta m_s = 2$ signal for **1** and temperature T is constant in the range $T = 20$–80 K.

The bulk magnetization (M) of solutions of **1** and **2** in THF (8×10^{-4}–1×10^{-2} M) were measured as a function of magnetic field H (0–5.5 Tesla) at $T = 2$, 3, 5, and 10 K and as a function of temperature ($T = 2$–35 K) at $H = 1.0$ and 0.5 Tesla. The sample consisted of a band of a frozen polyradical solution (ca. 4 mm high) wedged between two bands of pure frozen solvent (ca. 60 mm high) in a 4 mm OD flame-sealed quartz tube. Such a sample does not allow for measurement of the amount of thermally unstable polyradical, but gives an adequate signal in the Quantum Design SQUID magnetometer and guarantees almost complete cancellation of the diamagnetic contribution to M.[2, 5] An adequate correction for diamagnetism was made for **1**. This was verified by comparing the plot of MT vs T ($T = 2$–35 K) with that of IT vs T ($T = 20$–80 K), where I is the $\Delta m_s = 2$ ESR-signal intensity for **1**. For the most dilute solutions, the data for M vs H/T were fitted to a Brillouin function with variable S and magnetization at saturation M_{sat}.[13] The coincidence of the plots for $T = 2$, 3, 5, and 10 K is consistent with the absence of intermolecular magnetic interactions in the dilute solution. In the concentrated solutions, the curves for M vs H/T at different temperatures do not overlap, and intermolecular antiferromagnetic interactions are accounted for with a mean-field parameter θ ($\theta < 0$, $|\theta| \leq 0.1$), that is, H/T is replaced with $H/(T - \theta)$.[14] The standard errors of the parame-

ters for the fits at each temperature are $<1\%$; discrepancies between the parameters for different temperatures and samples are $<5\%$, and the parameter dependence for S and M_{sat} ranges from around 0.3 at $T = 2$ K to around 0.8 at $T = 5$ K.[15] The values for S obtained from fitting are 3.8 and 2.3 for **1** and **2**, respectively (Fig. 1). In the absence of defects, high-spin polyradicals **1** and **2** with all unpaired electrons coupled ferromagnetically would be expected to have $S = 4.0$ and 2.5, respectively.[16]

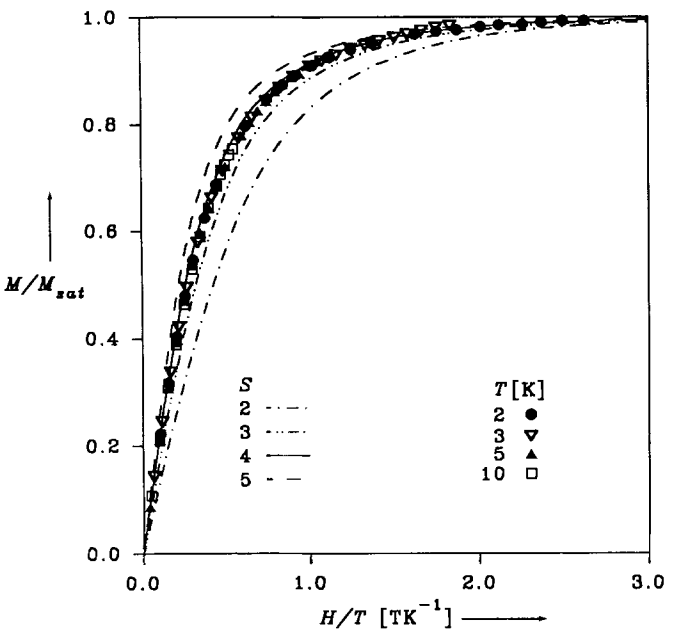

Fig. 1. Magnetization studies of **1** (8.5×10^{-4} M in THF) performed with a SQUID magnetometer. The plots of M/M_{sat} vs H/T are shown. The fit to a Brillouin function with variable S gives $S = 3.8$. The solid line corresponds to the Brillouin function with $S = 4$.

The magnetization data establishes that **1** and **2** have nonet ($S = 4$) and sextet ($S = 5/2$) ground states, respectively. The strength of the ferromagnetic coupling in **1** may be judged by the lack of a detectable thermal population of the low-spin excited states up to $T = 35$ K (or 80 K), as determined by either SQUID magnetometry or ESR spectroscopy. The magnetization data for **1** are drastically different from those for polyradicals with a comparable or larger number of sites, such as star-branched hepta- and decaradicals and their dendritic homologues.[2] For the latter, magnetization data could not be fitted to a single Brillouin function and the average values for S (between the low and high field values) were well below the theoretical values expected for high-spin systems without defects.

In summary, macrocyclic polyradical **1** with nonet ($S = 4$) ground state was prepared. This compound may provide a first step towards addressing the problem of defects in molecules with large numbers of interacting radical sites.

[10] a) Compounds **3**–**9**, **11** and **12**, have adequate ^{1}H NMR, ^{13}C NMR, and FABMS data. The IR spectra for compounds **3**–**9** confirm the presence of the OH and C–O groups. C/H analyses (**3**, **5**, **6**, and **9**) or high resolution FABMS (**4**) are satisfactory. b) Calix[4]arene **8**: M.p. 132–133 °C, FAB-MS (*ortho*-nitrophenyl octyl ether matrix), cluster: *m/z* (peak height) for $(M - OH)^+$: 2196.3(3.5), 2197.3(5), 2198.3(4.5), 2199.3(2.5); for $(M - OCH_3)^+$: 2182.3(7), 2183.3(10), 2184.3(8.5), 2185.3(5); calcd for $(M - OCH_3)^+$, $C_{159}H_{185}O_7$: 2182.41(5.5), 2183.42(10), 2184.42(9), 2185.42(5). ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta = 7.45$–6.50 (m, 60H), 2.821 (s, 2H, exchange with D_2O), 2.654 (s, 6H), 2.629 (s, 6H), 2.519 (s, 3H), 2.225 (s, 3H), 1.258 (s, 18H), 1.239 (s, 9H), 1.203 (s, 9H), 1.185 (s, 18H), 1.175 (s, 18H), 1.163 (s, 18H), 1.127 (s, 18H). ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 20 °C): $\delta = 150.0$–138.0 (20 signals), 130.0–124.0 (14 overlapping signals), 87.39, 86.97, 86.77, 86.62, 82.43, 52.40, 52.11, 51.87, 51.78, 35.0–31.0 (8 overlapping signals). IR (ZnSe): $\tilde{\nu} = 3500\ cm^{-1}$ (OH). – Calix[4]arene **9**: M.p. 166–167 °C, calcd for $C_{160}H_{192}O_8$: C 85.67, H 8.63%; found: C 86.05, H 8.88%. FAB-MS (ON-POE), cluster: *m/z* (peak height) for $(M - OCH_3)^+$: 2209.6(4), 2210.5(7), 2211.4(10), 2212.4(8), 2213.4(5); calcd for $(M - OCH_3)^+$, $C_{159}H_{189}O_7$: 2210.44(5.5), 2211.45(10), 2212.45(9), 2213.45(5). ^{1}H NMR: $\delta = 7.30$ 6.80 (m, 60H), 2.654 (s, 6H), 2.641 (s, 6H), 2.601 (s, 6H), 2.560 (s, 3H), 2.445 (s, 3H), 1.208, 1.181, 1.165 (s, 108H). ^{13}C{^{1}H} NMR: $\delta = 150.0$ 140.0 (19 overlapping signals), 129.0–124.0 (16 overlapping signals), 87.24, 87.15, 87.13, 86.84, 86.78, 52.18, 52.03, 52.00, 51.98, 51.93, 35.0–31.0 (5 overlapping signals). IR: OH not detected.

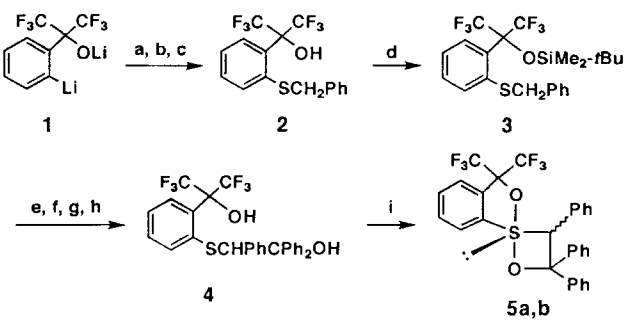
[11] Compounds **10** and **13** have adequate ^{1}H NMR and FABMS spectra; one of the isomers of **10** was separated. Reaction of **9** with Li in THF gave complex reaction mixtures; the FAB mass spectrum suggests incorporation of THF-like fragments.

[12] a) With the exception of one heptaradical ($S = 7/2$, ref. [5]), all polyarylmethyl polyradicals with $S > 2$ have unresolved dipolar couplings in their ESR spectra. b) One of the differences between the integral and half-integral spin systems is the presence in the former of an intense center peak in the $\Delta m_S = 2$ region: A. Rajca, S. Utamapanya, *J. Am. Chem. Soc.* **1993**, *115*, 2396.

[13] R. L. Carlin, *Magnetochemistry*, Springer, Berlin, **1986**, p. 14–18.

[14] A. Bino, D. C. Johnston, D. P. Goshorn, T. R. Halbert, E. I. Stiefel, *Science* **1988**, *241*, 1479.

[15] The reliability of the M vs H/T fits is indicated by low parameter dependence [dependence = 1 – (variance of the parameter, other parameters constant)/(variance of the parameter, other parameters changing)]. For example, application of a standard technique (ESR signal intensity vs temperature in the 15–90 K range) to a favorable case of diradical with $J/k = -20$ K gives a two-parameter fit with dependence of 0.6.



[16] One of the referees suggested fitting the magnetization data for **1** to a mixture of the polyradicals with $S = 4$ (defect-free **1**) and $S = 3.5$ (**1** with one defect), which would correspond to a simplified version of the procedure in ref. [2]. For a sample with $S = 3.83 \pm 0.03$, such fitting gives 66% ±10% octaradical with $S = 4$.

Synthesis, Structure, and Thermolysis of a Tetracoordinate 1,2λ⁴-Oxathietane**

Takayuki Kawashima,* Fumihiko Ohno, and Renji Okazaki*

The reaction of sulfur ylides with carbonyl compounds, known as the Corey–Chaykovsky reaction,[1] gives oxiranes. In sharp contrast, phosphorus ylides afford olefins regioselectively in the Wittig reaction.[2] In our research on oxetanes bearing high-coordinate main group elements at the position adjacent to the O atom, we have synthesized pentacoordinate 1,2-oxaphosphetanes, 1,2-oxasiletanides, and 1,2-oxastannetanides, in other words intermediates of the Wittig, Peterson, and tin-Peterson reactions, respectively.[3] We recently found that in contrast to other oxetanes 1,2-oxaselenetanes yield neither olefins nor oxiranes on heating.[4] This unique result prompted us to examine the reactivity of a tetracoordinate 1,2λ⁴-oxathietane,[5] a novel type of sulfurane.[6] We now report on the synthesis, crystal structure, and thermolysis of **5a**, the first tetracoordinate 1,2λ⁴-oxathietane.

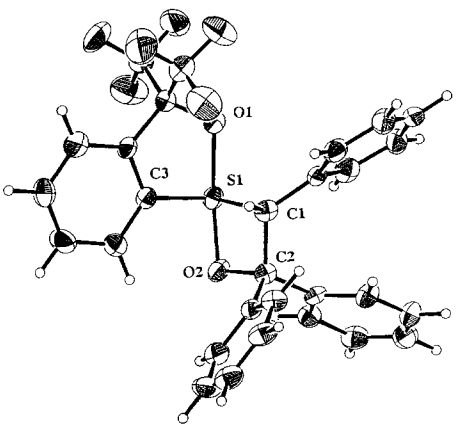
Sequential treatment of dilithio derivative **1**[7] with elemental sulfur, benzyl bromide, and aqueous NH_4Cl gave benzyl sulfide **2** (86%) (Scheme 1). Protection of the hydroxyl group of **2**

Scheme 1. a) S_8, THF, 0 °C; room temperature (RT), ca. 15 h; b) $PhCH_2Br$, 0 °C; RT, 3 h; c) aq NH_4Cl; d) tBuMe$_2$SiOTf, Et_3N, CH_2Cl_2, 0 °C; RT, 20 h; e) 2 equiv LDA, THF, −78 °C, 5 min; f) $Ph_2C{=}O$, THF, −78 °C, 15 min; g) aq NH_4Cl; h) 2 equiv nBu$_4$NF, THF, 0 °C, 30 min; i) 1.2 equiv Br_2, 2.4 equiv Et_3N, CCl_4, 0 °C; RT, ca. 15 h.

with a *tert*-butyldimethylsilyl group (88%), deprotonation with lithium diisopropylamide (LDA) followed by reaction with benzophenone (95%), and desilylation with nBu$_4$NF (95%) gave the β-hydroxyalkyl sulfide **4**. Oxidative cyclization of **4** with Br_2 afforded **5a** (37%) with recovery of **4** (26%). Interestingly, the phenyl group at the 3-position is important for the isolation of 1,2-oxathietane;[8] in contrast, phenyl groups typically destabilize oxetanes having Group 14 and 15 elements and accelerate olefin formation.

In the ^{1}H NMR spectrum of **5a** a downfield shift ($\delta = 8.50$–8.53) for the *ortho* proton of the "Martin ligand" was observed, which is one of the features of compounds with a trigonal-bipyramidal (TBP) structure.[3a, b, d, 6b, c, e] In the ^{19}F NMR spectrum of **5a** two quartets were observed at $\delta_F = -76.0$ and -76.7 (^4J(F,F) = 8.1 Hz) owing to the chirality of the S atom.

The X-ray crystallographic analysis of **5a** indicates that it has a structure very similar to that of oxaselenetane **6** and that the phenyl group at the 3-position is *cis* to the lone pair of sulfur atom (Fig. 1).[9] The two oxygen atoms occupy apical positions,



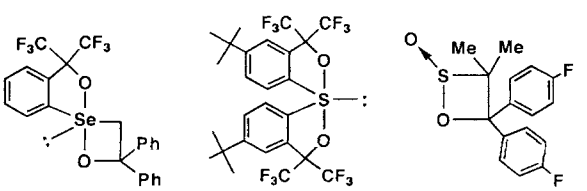


Fig. 1. Crystal structure of **5a** (ORTEP). Selected bond lengths [Å], bond angles [°], and torsion angles [°]: S1-O1 1.863(5), S1-O2 1.764(5), S1-C1 1.837(8), S1-C3 1.801(7), C1-C2 1.574(9), C2-O2 1.448(8); O1-S1-O2 167.4(3), O1-S1-C3 86.1(3), C1-S1-O2 77.2(3), S1-C1-C2 89.4(4), C1-C2-O2 96.0(5), S1-O2-C2 96.6(4); O2-S1-C1-C2 6.2(4), S1-C1-C2-O2 −7.5(5).

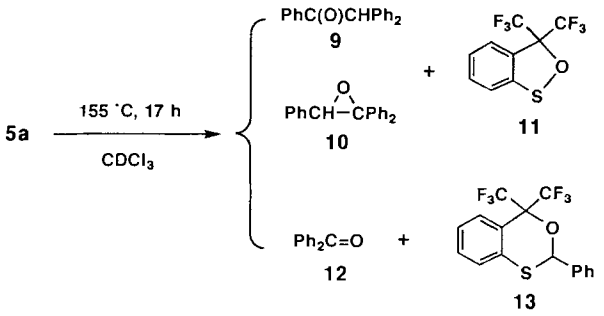
while two carbon atoms and a lone pair occupy equatorial positions. The bond angle O1-S1-O2 deviates from 180° by 12.6(3)°. The S1–O1 bond (1.863(5) Å) is as long as the S–O bond of sulfurane **7** (1.832(5) Å),[6b] but the S1–O2 bond (1.764(5) Å) is significantly shorter, a characteristic feature of TBP structures with electronically different apical groups.[3a, 4, 6c, e] However, both bonds are much longer than the S–O bond of β-sultine **8** (1.667(4) Å).[5a] The torsion angle S1-C1-C2-O2 (−7.5(5)°) is



smaller than that of **8** (S-C-C-O 14.7°), indicating that the four-membered ring is almost planar; this is another a common structural feature of such oxetanes.[3, 4]

Thermolysis of **5a** was monitored by ^{19}F NMR spectroscopy (Scheme 2). The signals due to **5b** appeared soon after the reaction started, and the ratio (**5a**:**5b**) was constant (95:5) after 1 h. Finally cyclic sulfenate **11** (52%) and cyclic thioacetal **13** (31%) were formed as fluorine-containing compounds. The formation of a trace of oxirane **10** was confirmed by ^{1}H NMR spectroscopy. HPLC separation (column: JAIGEL 1H + 2H, Japan Analytical Industry) gave phenyl-migrated ketone **9** (47%) and benzophenone (**12**) (33%) along with **13** (31%), but **11** could not be isolated. As in the case of the oxaselenetane, thermolysis of oxathietane **5a** did not give an olefin. This indi-

[**] This work was supported in part by a Kurata Research Grant (T. K.) and a Grant-in-Aid for Scientific Research (B) (No. 04553062, T.K.) from the Ministry of Education, Science and Culture (Japan). We thank Dr. N. Tokitoh of the University of Tokyo for the determination of the X-ray structure of **5a**. We also thank Shin-Etsu Chemical, Central Glass, and Tosoh Akzo Co. Ltd. for gifts of silyl chlorides, hexafluorocumyl alcohol, and alkyllithium compounds, respectively.

Scheme 2.

cates that the bond energy of a chalcogen–oxygen double bond, even a sulfur–oxygen bond, is not sufficient for a Wittig-type reaction. Betaine **A** formed by heterolysis of the S–O bond leads to reactions such as C–S bond cleavage with phenyl migration (**9**[10] and **11**) and elimination of a ketone (**12** and **B**) (Scheme 3).

Scheme 3. Proposed mechanism for the thermolysis of **5a**.

Epimerization and fragmentation back to the starting ketone have never been observed for such hypervalent oxetanes.[11] It can be interpreted that **5** and/or betaine **A** is in equilibrium with ketone **12** and sulfonium ylide **B**, the latter of which undergoes Pummerer-type rearrangement to give **13** (Scheme 3). The presence of an oxirane in the reaction mixture suggests that a 1,2λ⁴-oxathietane may be an intermediate in the Corey–Chaykovsky reaction.

Experimental Procedure

A stock solution of bromine in CCl_4 (0.17 M, 3.1 mL, 1.2 equiv) was added to a solution of **4** [12] (238 mg, 0.43 mmol) and Et_3N (0.15 mL, 1.04 mmol) in CCl_4 (15 mL) at 0 °C. The mixture was allowed to warm to room temperature and stirred for about 15 h. The precipitate was filtered off with a glass filter, and the filtrate was concentrated in vacuo. The ^{19}F NMR spectrum of the residue showed two sets of two quartets due to diastereomers **5a** and **5b** (4:1). Purification by flash chromatography (SiO_2, hexane/CH_2Cl_2 (2:1)) gave **5a** (88 mg, 37%) and recovered **4** (62 mg, 26%), but **5b** could not be isolated. An analytically pure sample was obtained as colorless plates by recrystallization from ether–hexane, and single crystals for X-ray analysis were grown in the same solvent. **5a**: M.p. = 151.0–154.0 °C (decomp); Correct elemental analysis; high-resolution MS (70 eV): calcd. for $C_{23}H_{15}F_6O_2S$ (M^+ − Ph): *m/z* 469.0697, found: 469.0688; ^1H NMR (500.1 MHz, $CDCl_3$, 27 °C, TMS): δ = 6.73 (s, 1H), 7.04 (d, ^3J(H,H) = 7.4 Hz, 2H), 7.12–7.25 (m, 9H), 7.30 (t, ^3J(H,H) = 7.8 Hz, 2H), 7.40–7.42 (m, 2H), 7.56–7.60 (m, 2H), 7.62 (br, 1H), 8.50–8.53 (m, 1H); $^{13}C\{^1H\}$ NMR (125.8 MHz, $CDCl_3$, 27 °C, TMS): δ = 80.41 (s), 83.93 (sept, ^2J(C,F) = 31 Hz), 94.21 (s), 122.12 (q, ^1J(C,F) = 288 Hz), 122.49 (q, ^1J(C,F) = 288 Hz), 125.07 (s), 126.03 (br s), 127.06 (s), 127.09 (s), 127.10 (s), 127.67 (s), 127.87 (s), 128.35 (s), 128.81 (s), 130.54 (s), 130.83 (s), 131.57 (s), 131.59 (s), 132.33 (s), 132.49 (s), 138.54 (s), 142.73 (s), 148.19 (s); ^{19}F NMR (253.8 MHz, $CDCl_3$, 27 °C, $FCCl_3$): δ = −76.0 (q, ^4J(C,F) = 8.1 Hz), −76.7 (q, ^4J(C,F) = 8.1 Hz).

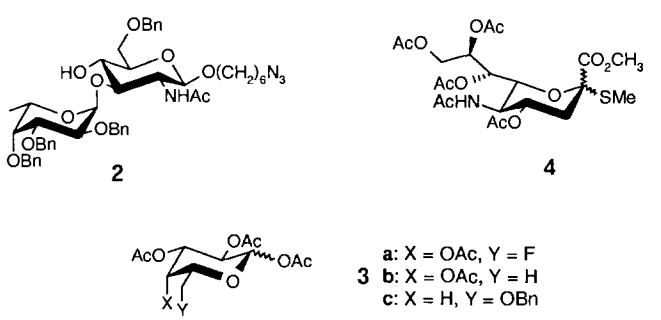
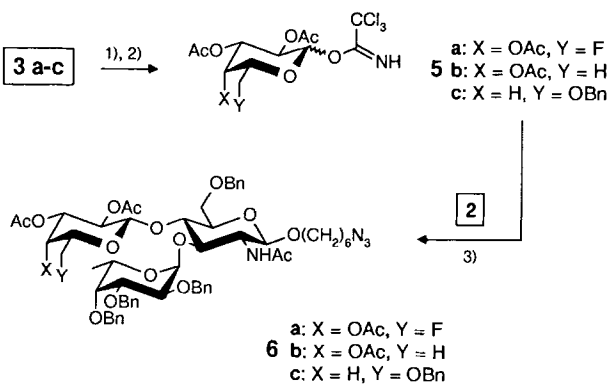
Synthesis of Deoxy Sialyl Lewis^x Analogues, Potential Selectin Antagonists**



Wilhelm Stahl,* Ulrich Sprengard, Gerhard Kretzschmar, and Horst Kunz

The cell surface receptors E-, P-, and L-selectins[1] play a key role in the adhesion of leukocytes to endothelial cells and their subsequent invasion into tissue, a critical process at the onset of inflammatory diseases. The ligands of these receptors are sialyl Lewis^x (α-Neu5Ac-(2-3)-β-D-Gal-(1-4)-[α-L-Fuc-(1-3)]-β-Glc-NAc **1**) and related structures,[2] which are found on the cell surface as terminal carbohydrate sections of the glycoproteins and glycolipids. The controlled blocking of the carbohydrate–selectin binding is a new therapeutic approach[3] to battling inflammatory diseases.

1: X = Y = OH

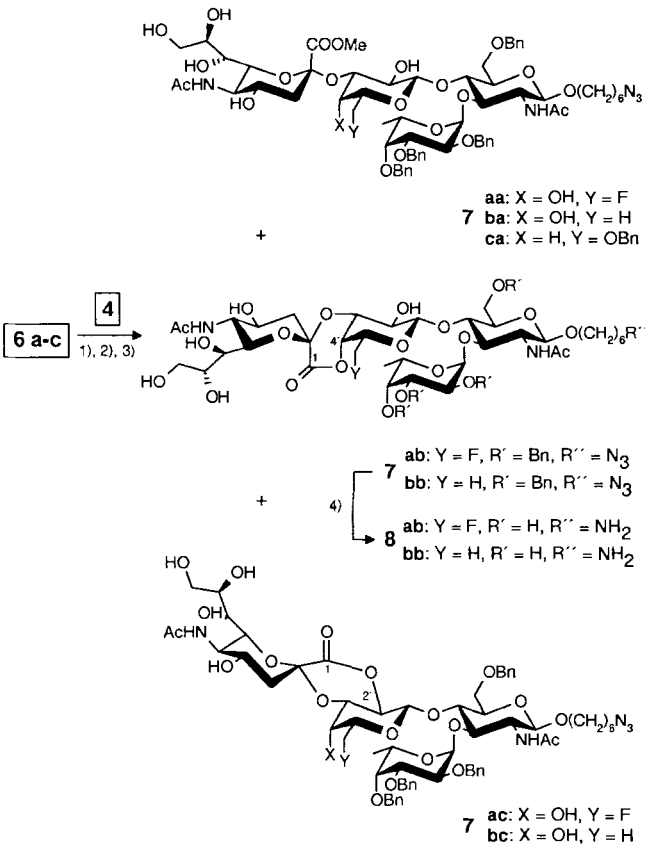


Sialyl Lewis^x derivatives with modified fucose,[4] neuraminic acid,[4, 5] and glucosamine residues[6] were synthesized both chemically and enzymatically for investigations of the structure–activity relationship. Based on the biological properties of these derivatives, conclusions were drawn on which structural elements are essential for the binding to selectins. In this context we describe the synthesis of deoxy analogues of sialyl Lewis^x with modified galactose units starting from intermediates **2**,[7] **3a–c**, and **4**[8] (Scheme 1).

Scheme 1.

Various strategies have been employed for the chemical preparation of sialyl Lewis^x.[9] The linear saccharide synthesis has several advantages over the convergent route: two reaction steps (blocking and deblocking of the anomeric center of galactose) are side-stepped, and the difficult purification of the *O*-acetyl-protected intermediates containing neuraminic acid, which are formed in the convergent synthesis,[7] is avoided.

The trichloroacetimidate method was applied for the construction of the stereoselective linkage of disaccharide **2** with the galactose derivative(s) (Scheme 2).[10] The acetyl protecting



Scheme 2. 1) 1.5 equiv hydrazine acetate, DMF, 0 °C → room temperature, **a**: 68%, **b**: 71%, **c**: 82%; 2) trichloroacetonitrile, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), CH_2Cl_2, **5a**: 99%, **5b**: 83%, **5c**: 93%; 3) **2**, $BF_3 \cdot OEt_2$, 3 Å molecular sieves, CH_2Cl_2, **6a**: 73% (3 equiv **5a**), **6b**: 45% (1.7 equiv **5b**), **6c** 74% (2.2 equiv **5d**).

group at the anomeric center of **3a–c** was cleaved with hydrazine acetate, and subsequent reaction with trichloroacetonitrile provided the corresponding trichloroacetimidates. Derivatives **5a**, **5b**, and **5c** were obtained in yields of 67, 59, and 76% for the two steps. Glycosidic linkage of the disaccharide acceptor **2** with donors **5a–c** in the presence of the promotor boron trifluoride–ether furnished trisaccharide **6a**[11] (3 equiv **5a**) in 73%, **6b** (1.7 equiv **5b**) in 45%, and **6c** (2.2 equiv **5c**) in 74% yield.[12] In each case the β-glycoside was obtained as the exclusive linkage product. The donor reactivity of imidates **5a** and **5c** toward the disaccharide receptor is comparable to that of the corresponding galactosylimidate;[7] the yields obtained under the same reaction conditions were similar.

Thioglycoside **4** served as the neuraminic acid donor in the sialylation. The *O*-acetyl groups of trisaccharides **6a–c** were cleaved to yield the appropriate acceptors.[13] These trisaccharides reacted with **4** in dichloromethane/acetonitrile in the presence of the promotors methylsulfenyl bromide (MST) and silver trifluoromethanesulfonate[14] between −70 and −40 °C to give the corresponding tetrasaccharides (Scheme 3). The laborious chromatographic purifiction of the reaction products can be simplified by first removing the acetyl protecting groups of the crude product of the sialylation reaction. Then unreacted **4** and related side products can be separated easily, and unreacted trisaccharide is recovered. In this way the reaction of **6a** afforded equal amounts of the methyl ester **7aa** and the 1-4′-lactone **7ab**[15] with a combined yield of 53% (over three steps). Only traces of the 1-2′-lactone **7ac** were isolated. **6b** was converted into **7bb**[15] with a yield of 48% over three steps, and only minimal amounts of **7ba** and **7bc** were isolated. Under the conditions described **6c** was converted into **7ca** exclusively in 9% overall yield (over three steps). This sialylation provided solely α-glycosides.

Scheme 3. 1) MeOH/NaOMe, **a**: 99%, **b**: 97%, **c**: 91%; 2) 2 equiv. **4**, MSB/AgOTf (1 equiv./2 equiv.), 3 Å molecular sieves, CH_2Cl_2/CH_3CN, $-70 \rightarrow -40\,^{\circ}C$; 3) MeOH/NaOMe, **7aa** 27%, **7ab**: 26%, **7ba**: 49%, **7ca**: 9%; 4) Pd, HCOOH, MeOH, **8ab** 43%, **8bb** 56%.

The benzyl ethers were cleaved by hydrogenolysis (Pd, methanol/formic acid); subsequent saponification of the ester or lactone with NaOH led to acids **9a**, **9b**, and **9c** in overall yields of 43, 56, and 58% (over two steps) (Scheme 4).

Scheme 4. 1) Pd, HCOOH, MeOH; 2) H_2O, NaOH; H_3O^+, **9a** 43%, **9b** 56%, **9c** 58%.

The efficient synthesis of sialyl Lewis^x described here has fewer steps than previously reported syntheses. In addition, the combination of thioglycoside **4** and the promotors methylsulfenylbromide and silver trifluoromethanesulfonate, which was used for the first time, proved to be an effective sialylation reagent.[9, 16] The reaction of two equivalents of donor **4** with one equivalent of acceptors **6a,b** gave exclusively the corresponding α-sialoglycosides in yields of 50–55%. The unreacted acceptor was recovered almost completely. Comparison with the corresponding Lewis^x derivative[7] as the acceptor shows that the modification in the galactose 6-position hardly affects the reactivity relative to that of **4**, since reaction under the same conditions gave almost the same yields. In contrast, the acceptor reactivity of the 4-deoxy derivative **6c** is permanently altered and can be attributed in part to the change in the electron density on the 3-hydroxyl group. The significantly reduced yield can be explained by the mismatched reactivity of the donor and acceptor. Remarkably, the 2′-lactone also does not form when the 4′-hydroxyl group is not present.

The O-glycosidically linked aminohexanol in **9a–c** allows attachment to a support.[17] Alternatively, this may be achieved by N-glycosidic linkage to the reducing end of the *N*-acetylglucosamine, for example, with the side-chain carboxyl group of aspartic acid.[18] Such compounds could be used to test the recently postulated multivalence theory for the interaction of E-selectin and sialyl Lewis^x.[19]

Preliminary investigations on the binding of **9a–c** to E-selectin[20] indicate that the native sialyl Lewis^x binds more strongly than analogues **9a–c**.[21] These results are a further contribution to the understanding of the interaction of sialyl Lewis^x with selectin receptors and to the development of therapeutically useful antagonists.

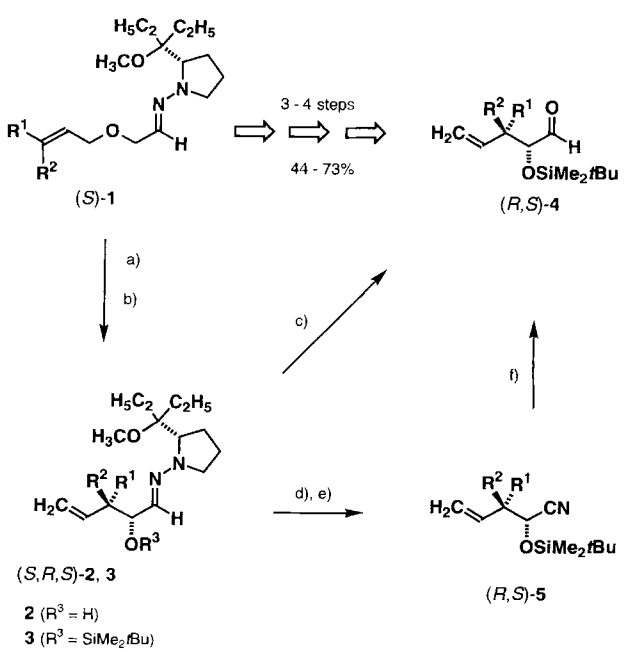
[2,3] Sigmatropic Wittig Rearrangement of Chiral Allyloxyacetaldehyde Hydrazones in the Diastereo- and Enantioselective Synthesis of Protected, γ,δ-Unsaturated α-Hydroxyaldehydes and Cyanohydrins**



Dieter Enders,* Dirk Backhaus, and Jan Runsink

In the last twenty years the [2,3] sigmatropic Wittig rearrangement has become an important tool for the stereoselective formation of C–C bonds.[1, 2] The asymmetric version of the [2,3] sigmatropic Wittig rearrangement of chiral allyl ethers **A**-H, proceeding with chirality transfer, has found many applications in the field of natural product synthesis.[3] Asymmetric inductions with retention of the directing center have been achieved not only with substituents in the allyl part of the molecule,[4] but also with chiral auxiliaries G* in the anionic moiety **A** such as esters,[5] amides,[6] oxazolines,[7] and a η^6-arene-Cr(CO)$_3$ complex.[8] By appropriate variation of the group G* in **A** (in the form of a chiral hydrazone **B**), it should be possible to prepare protected α-hydroxyaldehydes (X = CHO) and cyanohydrins (X = CN) **C** stereoselectively. Both classes of compounds are of great interest due to their synthetic potential: Protected chiral α-hydroxyaldehydes are commonly used in the synthesis of natural products and pharmaceuticals,[9] and cyanohydrins can be easily converted to α-hydroxycarboxylic acids,[10] esters,[11] ketones,[12] aldehydes,[13] β-hydroxyamines[10b, 10c, 12] as well as α-amino acids[14] without racemization.[14c]

We report now the *syn* diastereo- and enantioselective synthesis of protected γ,δ-unsaturated α-hydroxyaldehydes (X = CHO) and cyanohydrins (X = CN) **C** from allyloxyacetaldehyde hydrazones **B**. The [2,3] sigmatropic Wittig rearrangement of the metalated hydrazone is the key step in the synthesis. After protection of the hydroxy function and oxidative cleavage of the auxiliary, either the aldehyde or the nitrile group can be formed selectively.

The metalation of the (*E*)-configurated (*S*)-1-amino-2-(1-ethyl-1-methoxypropyl)pyrrolidine (SAEP) hydrazones[15, 16] (*S*)-**1** with lithium diisopropylamide (LDA) in tetrahydrofuran/hexamethylphosphoric triamide (THF/HMPA) at −78 °C delivers the α-hydroxyhydrazones (*S,R,S*)-**2** with good *syn*/*anti* diastereoselectivity (87–95% *syn*) and with high asymmetric induction (81–92% *de*) (Scheme 1).[17] After purification by

column chromatography the products of the rearrangement (*S,R,S*)-**2** are obtained in good yields (72–91%) as pale yellow liquids. Silylation of the hydroxy function with *tert*-butyldimethylsilyl chloride (TBDMSCl) in dimethylformamide (DMF)[18] leads, after chromatographic purification on deactivated silica gel, to the hydrazones (*S,R,S*)-**3** in unchanged isomer ratios and almost quantitative yields. The diastereomeric excess can be increased to >98% by using high-pressure liquid chromatography (HPLC), and for the hydrazone **3a** the *anti* isomer can also be separated in this way. The proportion of the predominant isomer can also be increased at the α-hydroxyhydrazone (*S,R,S*)-**2** stage by column chromatography or by HPLC. Ozonolysis of the protected rearrangement products (*S,R,S*)-**3** at −78 °C yields, after flash chromatography on Florisil, the silylated α-hydroxyaldehydes (*R,S*)-**4** in moderate to high yields (55–84%). With smaller R^1 groups the yield is lower (Table 1) because in these cases the double bond is also ozonolyzed. Additionally, a partial epimerization occurs during the hydrazone cleavage with ozone, such that the *ee* values of aldehydes **4** are 4–12% lower than the *de* values of the starting hydrazones **3**.

The protected cyanohydrins (*R,S*)-**5** are accessible in good yield (86–95%) by cleavage of the auxiliary with magnesium monoperoxyphthalate (MMPP).[19] As an alternative to ozonolysis, reduction with diisobutylaluminum hydride (DIBAH) yields the aldehydes (*R,S*)-**4**. This two-step method of cleaving the hydrazones leads to better overall yields of aldehydes than the direct ozonolysis (Table 1). Furthermore, since this method causes minimal racemization, the aldehydes **4** can be obtained with enantiomeric excesses of 94–97%.

The diastereomeric excesses of the hydrazones **2** and **3** were measured by ^{13}C NMR spectroscopy, while the enantiomeric excesses of the aldehydes **4** were determined by ^1H NMR spectroscopy, using the chiral cosolvent (−)-(*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol, by comparison with the spectra of the corresponding racemate. The racemates were prepared analogously by [2,3] sigmatropic Wittig rearrangement of the corresponding *N,N*-dimethylhydrazones.

The absolute configurations of the aldehydes **4** were determined by derivatization and comparison of optical rotation. The α-methoxyphenylacetate esters (*R*)-**6a** and (*S*)-**6a** were prepared from the aldehyde **4a** in a four-step synthesis (Scheme 2). Measurement of the nuclear Overhauser effect showed that the relative configuration within the tetrahydrofuran ring of the major isomer[20] is 2,3-*cis*, 3,4-*trans*. The absolute configuration[21] follows from the ^1H NMR signals which are shifted to high field by the diamagnetic effect of the phenyl groups. As indicated in the structure (*S*)-**6a**, the aldehyde **4a** can be assigned the configuration *syn*-(2*R*,3*S*). The *syn* selectivity of the [2,3] Wittig rearrangement of the azaenolate of hydrazone (*S*)-**1**

Scheme 2. Derivatization of the aldehyde **4a** for the determination of the absolute configuration. The differences in the ^1H NMR shifts of (*S*)-**6a** and (*R*)-**6a** ($\Delta\delta = \delta(S) - \delta(R)$) at 500 MHz are given: a) $NaBH_4$, MeOH, 0 °C, 1 h; b) I_2, $NaHCO_3$, Et_2O/H_2O (5/2), room temperature, H_2O, 18 h; c) MeOH, HCl, 0 °C, 1 h; d) (*S*)- or (*R*)-α-methoxyphenylacetic acid, 4-dimethyaminopyridine (DMAP), dicyclohexylcarbodiimide (DCC), CH_2Cl_2, room temperature, 18 h, column chromatography (silica gel, ether/petroleum ether 1/4).

corresponds to selectivities found for other enolates,[1,4–6] for which several transition state models have been suggested.[22] The derivatization of the aldehyde **4a** (57% *de*)[17] (Scheme 2, a)–c)) by esterification with (*R*)-(−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride (MTPACl) leads to the corresponding Mosher ester. The absolute configuration of the major isomer was confirmed by NMR spectroscopic investigations (modified Mosher method[23]). A comparison of the optical rotation of the 3-methylpent-4-ene-1,2-diol ($[\alpha_D^{20} = -40.4$ ($c = 0.85$ in $CHCl_3$))—prepared by reduction of aldehyde **4a** (*de* = 96%) with sodium borohydride and subsequent cleavage of the silyl protecting group with methanol/HCl—with the literature value[24] confirms the configuration as (2*R*,3*S*).

The configuration of the aldehyde **4b** was determined as (2*R*) by transformation to the (*R*)- and (*S*)-α-methoxyphenylacetate ester. The absolute configurations of aldehydes **4c**–**4e** were assigned based on the assumption of the same reaction pathway.

The asymmetric [2,3] sigmatropic Wittig rearrangement of SAEP hydrazones described here provides access to protected γ,δ-unsaturated α-hydroxyaldehydes and cyanohydrins with variable substitution in the β-position. The double bond, aldehyde, cyano, hydroxy, and cyanohydrin functionalities in these products should allow their use in the preparation of optically active building blocks in the synthesis of natural products and pharmaceuticals.

Experimental Procedure

α-Hydroxyhydrazones **2**: *n*-butyllithium (1.6 mL of a 1.6 M solution in *n*-hexane) was added dropwise to diisopropylamine (2.7 mmol) in anhydrous THF (2 mL) at 0 °C under argon. After 15 min the solvents were removed under vacuum and the residue taken up in THF (5 mL). After addition of HMPA (1 mL) the solution was cooled to −78 °C and the hydrazone (*S*)-**1** (1 mmol), dissolved in THF (1 mL), was added dropwise. After 22 h at −78 °C (for **2b** 6 h at −78 °C, then 15 min at 0 °C) the solution was hydrolyzed by addition of saturated NH_4Cl solution (20 mL). The organic phase was washed twice with water, and the aqueous phase washed several times with ether. The combined organic phases were dried over $MgSO_4$ and the

solvents removed. The residue was purified by flash chromatography (silica gel, ether/petroleum ether 1/2).

Silylation of the hydroxy function: The hydrazone **2** (1 mmol) was dissolved in DMF (5 mL), treated with TBDMSCl (2.4 mmol) and imidazole (3 mmol), and stirred at room temperature for 5–20 h. At the end of the reaction (monitored by thin-layer chromatography) petroleum ether was added, the reaction mixture washed with water and dried over $MgSO_4$. After removal of the solvent the residue was purified by column chromatography (silica gel, ether/petroleum ether 1/40, 2.5% triethylamine). The major isomer can be enriched by HPLC (preprepared column silica gel 7 μ, length 250 mm, ether/petroleum ether 3/97 to 5/95).

Ozonolysis of the hydrazone **3** to the aldehyde **4**: The hydrazone (1 mmol) was dissolved in petroleum ether (ca. 40 mL) and cooled to −78 °C. Ozone was passed through the reaction solution. During the reaction the ozonolysis was interrupted by passing argon through the solution to allow the reacton to be followed by TLC. At the end of the reaction (120–180 s) the reaction mixture was allowed to warm to 0 °C under an argon stream. The solution was concentrated and the crude product purified by flash chromatography (Florisil, ether/petroleum ether 1/40 to 1/60).

Cleavage of the hydrazone **3** to give the nitrile **5**: The hydrazone (2 mmol) was dissolved in methanol (40 mL), cooled to 0 °C and MMPP·$6H_2O$ (5 mmol) added. After the end of the reaction (monitored by thin-layer chromatography, 30–90 min) ether and saturated $NaHCO_3$ were added, and the aqueous phase extracted with ether three times. The combined organic phases were washed several times with saturated NaCl solution, dried over $MgSO_4$, and the solvent removed on a rotary evaporator. The crude product was purified by column chromatography (silica gel, ether/petroleum ether 1/40).

Reduction of the nitrile **5** to the aldehyde **4**: The reaction was carried out as described in reference [13], and the crude product purified by column chromatography (Florisil, ether/petroleum ether 1/40) [25].

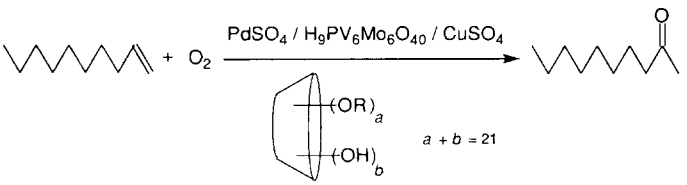
Wacker Oxidation of 1-Decene to 2-Decanone in the Presence of a Chemically Modified Cyclodextrin System: A Happy Union of Host–Guest Chemistry and Homogeneous Catalysis**



Eric Monflier, Emilie Blouet, Yolande Barbaux, and André Mortreux*

The oxidation of olefins to ketones catalyzed by palladium/copper or palladium/heteropolyacid systems, which is generally known as the Wacker process, has been the subject of several studies.[1] Because of their insolubility in water, higher α-olefins require the presence of polar organic solvent to be oxidized

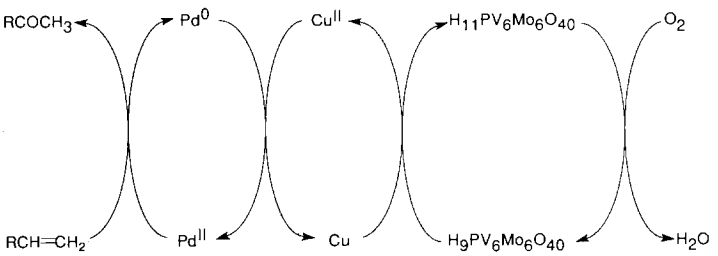
efficiently.[2] Recently, Alper et al. reported the oxidation of higher olefins in a two phase system in the presence of cyclodextrins.[3] Nevertheless, even in the presence of cyclodextrins or polar organic solvents, the oxidations proceeded at moderate rates and with poor yields and selectivities. We report here on the high-yield oxidation (up to 98%) of 1-decene to 2-decanone with $PdSO_4/H_9PV_6Mo_6O_{40}/CuSO_4/O_2$ and chemically modified cyclodextrins in a two-phase system (Scheme 1).

Scheme 1. Catalytic oxidation of 1-decene to 2-decanone. A schematic representation of the β-cyclodextrin is shown; R = CH_3, $CH_2CH(OH)CH_3$.

The results obtained with various catalytic systems are shown in Table 1. β-Cyclodextrin (β-CD), a cyclic oligosaccharide composed of seven glucopyranose units (Scheme 2),[4] was used



Scheme 2. Schematic representations of β-cyclodextrin.

as the inverse-phase transfer catalyst.[5] The palladium(II)/copper(II)/β-cyclodextrin system gave 2-decanone, but the yields (38%) and selectivities (49%) were low (Table 1, entry 1). However, in the presence of catalytic amounts of the heteropolyacid $H_9PV_6Mo_6O_{40}$, 2-decanone was obtained in a good yield (58%) and selectivity (80%) (Table 1, entry 6). In this case, the isomerization of 1-decene to give 2-, 3-, 4-, and 5-decenes was considerably reduced. It is noteworthy that addition of copper sulfate to the palladium/heteropolyacid system increased the selectivity (Table 1, entries 4 and 6).

These results can be rationalized if one considers that copper sulfate or the heteropolyacid alone reoxidize palladium(0) to palladium(II) species less efficiently than the copper sulfate/heteropolyacid couple. Indeed, faster reoxidation reduces the concentration of the palladium(0) and palladium hydride species, which are responsible for isomerization,[6] and isomerization is thus suppressed. The oxidation of such palladium species has already been described.[2c, 7a, 8]

The efficiency of our binary system can be explained by the stabilization of the heteropolyacid by copper(II) and/or the replacement of the two-step reversible electron transfer with three steps of lower activation energy (Scheme 3). This system shows similarities with biochemical processes in which oxidation becomes very mild when redox couples with progressively lower redox potentials interact. Similar systems have been described by Bäckvall[7] and Vasilevskis.[2c]

Scheme 3. Redox cycles involved in the oxidation of Pd^0.

In our two-phase system, the $PdSO_4/H_9PV_6Mo_6O_{40}/CuSO_4$ combination was the most efficient. The transfer of material between organic and aqueous phases is brought about by the cyclodextrin (CD).[5] The CD, which has a hydrophobic host cavity, can form an inclusion complex with an organic molecule and transport it into the aqueous phase. The efficiency of transfer depends on the solubility of the CD in water; this can be modified by functionalization with hydrophilic or lipophilic groups.[4] To our knowledge, the use such chemically modified CDs in biphasic reactions catalyzed by transition-metal complexes has not yet been studied. We were therefore interested in investigating the influence of such functionalized CDs on the transfer of material.

The yields and selectivities obtained in the oxidation of 1-decene to 2-decanone in the presence of various modified CDs are shown in Table 2. The extent of conversion of 1-decene strongly depended on the magnitude of the angular aperture in the CD (Table 2, entries 1–3). The optimal size for the cavity is reached in β-CD (entry 3). A larger aperture, such as in γ-CD,[4] resulted in a drastic decrease in the extent of 1-decene conver-

sion; however, a smaller aperture, such as in α-CD,[4] gave only a small decrease. These results indicate molecular recognition based on reversible interactions between the CD host cavity and 1-decene.[4]

The yields obtained with CDs modified by polar or nonpolar groups are given in entries 3 to 7 (Table 2). Unexpectedly, 2-decanone was obtained in very high yield (98%) with methylated β-CD (Table 2, entry 4). The 2-hydroxypropyl-β-CDs with different degrees of substitution also gave 2-decanone in high yields (Table 2, entries 6 and 7).

We believe that the most important factor influencing these results is the degree of solubility of the CDs in water. The acylated β-CD is totally insoluble in water and cannot transfer 1-decene into the aqueous phase; the 2-hydroxypropyl-β-CD is more soluble and can therefore transfer 1-decene more readily. The fact that the highest conversion was obtained with methylated β-CD could be explained by its high solubility both in water and the organic layer. Another possible explanation is the lower stability of the host–guest complexes; this would facilitate the dissociation–association reactions between the organic compounds and CD (Scheme 4, steps a) and c)).[9] These properties of the methylated β-CD probably increase exchange at the phase boundary. The surprising selectivity could be due to the ability of β-CD to cause preorientation of 1-decene in the host cavity. The interactions between CD, 1-decene, palladium, and heteropolyacid will not be discussed here. Inclusion complexes between CD and transition-metal complexes have already been reported.[10]

At the present time, we are investigating the formation of inclusion complexes and the use of these modified CDs in other reactions. This preliminary study suggests that modified CDs will become important for reactions catalyzed by transition-metal complexes in aqueous–organic two-phase systems.

Scheme 4. Formation and dissociation of the inclusion complexes of a modified β-cyclodextrin with 1-decene (a) and 2-decanone (c), and the oxidation of 1-decene with Pd^{II} (b).

Experimental Procedure

In a typical experiment, $PdSO_4 \cdot 2H_2O$ (0.206 g, 0.86 mmol), $CuSO_4$ (1.64 g, 10 mmol), $H_9PV_6Mo_6O_{40}$ (8 mmol, synthesized according to ref. [11]), and 2,6-dimethyl-β-CD (1.3 g, 1 mmol) were introduced with water (30 mL, 1.66 mol) and 1-decene (7.6 mL, 40 mmol) into a 250 mL flask. Oxygen was bubbled through the solution ($p = 1$ bar), which was vigorously stirred at 80 °C for 6 h. The solution was then cooled, and the organic layer was analyzed by GLC with undecane as internal standard. Products were identified by comparing the retention times and spectral properties with those of authentic samples.

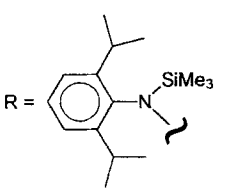
Soluble Organic Derivatives of Aluminosilicates with $Al_2Si_2O_4$ and $Al_4Si_2O_6$ Frameworks**



Mavis L. Montero, Isabel Usón, and Herbert W. Roesky*

Dedicated to Professor Klaus Möckel on the occasion of his 65th birthday

Although aluminosilicates are widely found in nature and have achieved great practical and commercial significance as zeolites, there are few soluble organic derivatives of these compounds.[1] Feher et al.[2] have described an $AlSi_7$ aluminosilasesquioxane; however, this is not very suitable for the construction of zeolites by the sol-gel process, because the Si–C bonds are almost inert towards hydrolysis. The aim of our investigations was therefore the synthesis of soluble organic derivatives of aluminosilicates, containing good leaving groups on the silicon and aluminum atoms. In an attempt to achieve this goal we treated the silanetriol **1**[3] with $HAliBu_2$ (**2**). Depending on the stoichiometry and the temperature of the reaction the organic derivatives **3** and **4** were obtained.

1 **2** **3**

Compound **3** was formed by the addition of **1** to a solution of **2** in THF at −78 °C. In this way the starting material **1** does not condense. Isobutane and hydrogen are formed in the reaction. Compound **3** is very soluble in common organic solvents, and single crystals can be obtained from *n*-hexane. The structure of **3** (Fig. 1) contains an eight-membered $Al_2Si_2O_4$ ring with bridging oxygen atoms. The ring has a chair conformation; the O(2) and O(2A) atoms lie 0.38 Å above the plane formed by the other six atoms (deviation 0.03 Å). The same structural unit is found in the mineral gismondine[4] $(CaAl_2Si_2O_8(H_2O)_4)_n$ in which, however, the condensed eight-membered $Al_2Si_2O_4$ rings exist in both the chair and boat conformations. The coordination at the aluminum atoms in **3** is distorted tetrahedral with bond angles of 99.4(2) to 116.2(2)°. The Al–O bond lengths within the ring (average 1.72 Å) are in very good agreement with the corresponding lengths in gismondine (1.75 Å). As expected the Al–O bonds to the coordinating THF molecules are longer (1.879(5) Å). The silicon atoms have likewise a distorted tetrahedral environment with bond angles of 106.2(2) to 113.6(2)°.

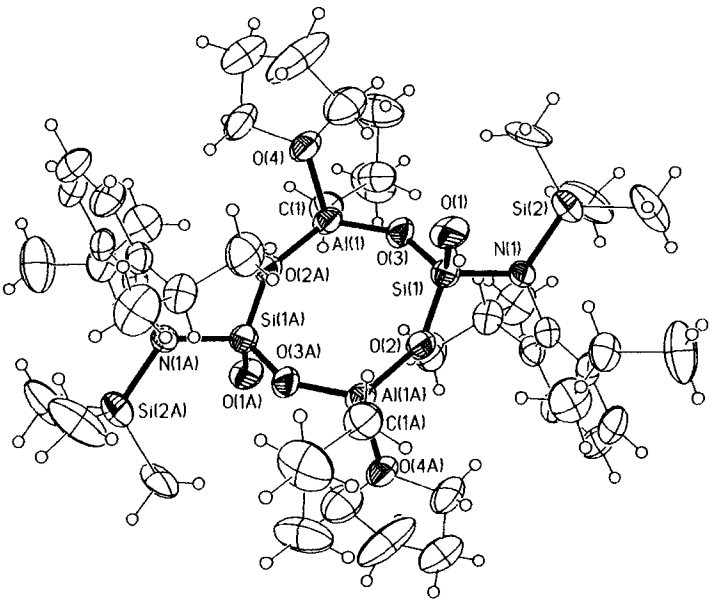

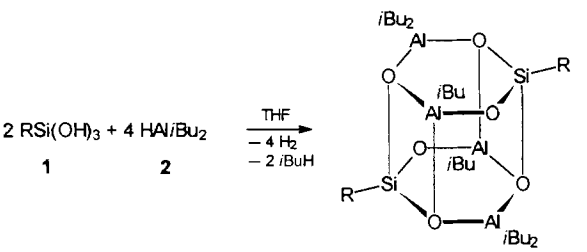

Fig. 1. Crystal structure of **3**. Selected bond lengths [Å] and angles [°]: Al(1)-O(2) 1.717(4), Al(1)-O(3) 1.718(4), Al(1)-O(4) 1.879(5), Al(1)-C(1) 1.945(7), Si(1)-O(2) 1.598(4), Si(1)-O(3) 1.590(4), Si(1)-O(1) 1.813(5), Si(1)-N(1) 1.735(5); O(2)-Al(1)-O(3) 116.1(2), O(3)-Al(1)-O(4) 99.4(2), O(3)-Al(1)-C(1) 116.2(3), O(2)-Al(1)-O(4) 100.2(2), O(2)-Al(1)-C(1) 113.1(3), O(4)-Al(1)-C(1) 109.3(3), O(2)-Si(1)-O(3) 113.6(2); O(2)-Si(1)-N(1) 108.9(2), O(3)-Si(1)-N(1) 111.1(2), O(2)-Si(1)-O(1) 109.8(2), O(3)-Si(1)-O(1) 106.2(2), O(1)-Si(1)-N(1) 107.0(2).

The average length of the endocyclic Si–O bonds (1.59 Å) is in good agreement with that in gismondine, whereas the exocyclic Si–O bonds are significantly longer (Si–OH 1.813(5) Å).[5] The OH stretch at 3413 cm^{-1} in the IR spectrum is characteristic for **3**.

1 **2** **4**

The reaction of **1** with **2** in the molar ratio 1:2 yields compound **4** as a colorless crystalline solid. The results of the crystal structure analysis of **4** (Fig. 2) show that the $Al_4Si_2O_6$ framework is built up of two four-membered $AlSiO_2$ and four six-membered Al_2SiO_3 rings, and can be described as a bitruncated distorted octahedron.[5]

The $Al_4Si_2O_6$ framework in **4** can be derived from the $Al_2Si_2O_4$ ring in **3** by the additional coordination of two aluminum atoms (Al(1), Al(1A)), which are bound to the hydroxy group at one silicon atom and to the two oxido bridging ligands at the other silicon atom in **3**. In order to make this coordination possible the eight-membered ring must be folded. In the resulting cage the coordination geometry of the six metal atoms deviates more strongly from tetrahedral geometry than in **3** (bond angles of 80.0–125.2° at the aluminum atoms and of 91.4–115.3° at the silicon atoms). The distances to the μ_2-oxygen atoms are almost as large as those in **3** and gismondine[4] (Al(1)–O(3)) 1.745(2), Si(1)–O(3) 1.598(2) Å), whereas the

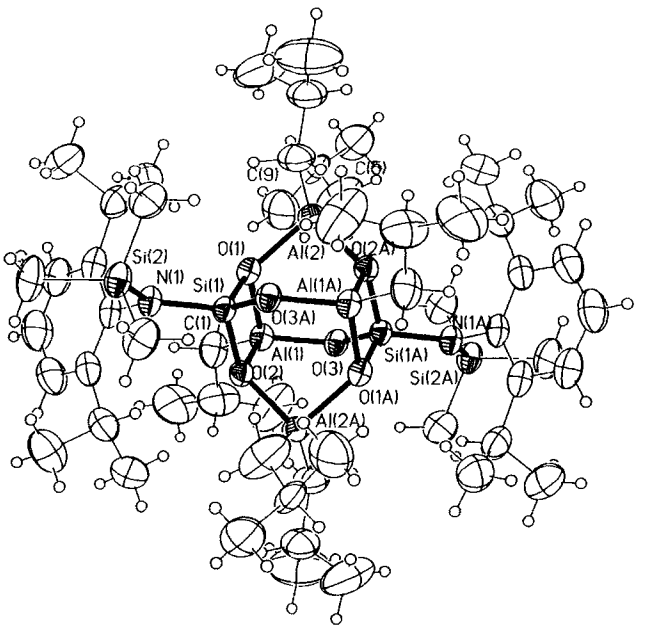

Fig. 2. Crystal structure of **4**. Selected bond lengths [Å] and angles [°]: Al(1)-O(2) 1.869(2), Al(1)-O(3) 1.745(2), Al(1)-O(1) 1.878(2), Al(1)-C(1) 1.933(3), Al(2)-O(1) 1.879(2), Al(2)-O(2) 1.882(2), Al(2)-C(5) 1.938(4), Al(2)-C(9) 1.976(3), Si(1)-O(3) 1.598(2), Si(1)-O(2) 1.680(2), Si(1)-O(1) 1.685(2), Si(1)-N(1) 1.688(2); O(3)-Al(1)-O(2) 103.54(9), O(3)-Al(1)-O(1) 104.09(9), O(2)-Al(1)-O(1) 79.98(9), O(3)-Al(1)-C(1) 123.4(1), O(2)-Al(1)-C(1) 118.5(1), O(1)-Al(1)-C(1) 118.4(1), O(1)-Al(2)-O(2) 95.33(9), O(1)-Al(2)-C(5) 111.1(2), O(2)-Al(2)-C(5) 106.5(2), O(1)-Al(2)-C(9) 110.1(1), O(2)-Al(2)-C(9) 103.9(1), C(5)-Al(2)-C(9) 125.2(2), O(3)-Si(1)-O(2) 110.3(1), O(2)-Si(1)-O(1) 91.4(1), O(3)-Si(1)-O(1) 110.5(1), O(3)-Si(1)-N(1) 112.8(1), O(2)-Si(1)-N(1) 114.7(1), O(1)-Si(1)-N(1) 115.3(1).

bonds to the μ_3-oxygen atoms are significantly longer (average Al–O 1.87, Si–O 1.69 Å).

The four silicon, the two nitrogen, two aluminum (Al(1), Al(1A)) and two oxygen atoms (O(3), O(3A)) lie in a plane (deviation 0.006 Å), which is perpendicular (89.8°) to the plane (deviation 0.006 Å) of the atoms Al(2), Al(2A), O(1), O(1A), O(2), and O(2A).

The compounds **3** and **4** should be particularly promising starting materials for the synthesis of new zeolites under mild conditions by sol-gel processes, because both the Si–N and the Al–C bonds can be readily cleaved hydrolytically.

Experimental Procedure

3: A solution of **1** (1.63 g, 5.00 mmol) in THF (30 mL) was added dropwise at −78 °C to a solution of $HAliBu_2$ (0.71 g, 5.00 mmol) in *n*-hexane/THF (5 mL, 20 mL) and stirred. The mixture was then allowed to warm to room temperature and volatiles were removed under vacuum. The residue was crystallized from *n*-hexane (30 mL) and **3** (3.85 g, 80%) was obtained. M.p. 178 °C; ^{1}H NMR (250 MHz, [D$_6$]DMSO, TMS): $\delta = -0.27$ (d, 2H, ^3J(H,H) = 6.5 Hz, $CH_2CH(CH_3)_2$), 0.03 (s, 9H, $Si(CH_3)_3$), 0.70 (m, 1H, $CH_2CH(CH_3)_2$), 0.81 (d, 6H, ^3J(H,H) = 6.5 Hz, $CH_2CH(CH_3)_2$), 1.06 (d, 6H, ^3J(H,H) = 6.9 Hz, $CH(CH_3)_2$), 1.13 (d, 6H, ^3J(H,H) = 6.9 Hz, $CH(CH_3)_2$), 1.77 (m, 4H, THF), 3.60 (m, 4H, THF), 3.85 (m, 2H, $CH(CH_3)_2$), 4.56 (s, 1H, OH), 6.80 (m, 3H, H_{arom}); ^{29}Si NMR (50 MHz, [D$_6$]DMSO, TMS): $\delta = -77.0$ ($SiO_2(OH)$), 1.27 ($Si(CH_3)_3$); IR (KBr, Nujol): $\tilde{\nu}$[cm^{-1}] = 3413, 1438, 1363, 1248, 1063, 963, 803, 685, 417; MS (EI): *m/z* (%): 234(20) [$Al_2Si_2O_6N_2^+$], 161 (100) [$C_{12}H_{17}^+$]; correct elemental analysis.

4: A solution of **2** (0.95 g, 6.70 mmol) was placed in *n*-hexane (35 mL) and THF (25 mL). A solution of **1** (1.10 g, 3.35 mmol) in THF (25 mL) was added dropwise to this at −78 °C over an hour. The mixture was allowed to warm to room temperature and subsequently heated to reflux for 3 h. Thereafter it was cooled to room temperature and the volatile components as well as the solvent were removed under vacuum. A white solid remained, which was dissolved in *n*-hexane (20 mL). On cooling this solution (−21 °C) **4** (1.12 g, 61%) was obtained as a white, microcrystalline solid. M.p. > 200 °C (decomp.); ^{1}H NMR (250 MHz, C_6D_6, TMS): $\delta = -0.43$ (d, 2H, ^3J(H,H) = 6.6 Hz, $CH_2CH(CH_3)_2$), 0.30 (s, 9H, $Si(CH_3)_3$), 0.50 (d, 4H, ^3J(H,H) = 6.6 Hz, $CH_2CH(CH_3)_2$), 0.87 (m, 3H, $CH_2CH(CH_3)_2$), 1.05 (d, 6H, ^3J(H,H) = 6.5 Hz, $(CH(CH_3)_2)$), 1.19–1.27 (m, 3H, $CH_2CH(CH_3)_2$), 1.42 (d, 6H, ^3J(H,H) = 6.5 Hz, $(CH(CH_3)_2)$), 3.61 (m, 2H, $CH(CH_3)_2$), 7.03 (m, 3H, H_{arom}); ^{29}Si NMR (79 MHz, C_6D_6, TMS): $\delta = -65.3(SiO_3)$, 12.5 ($Si(CH_3)_3$); IR (KBr, Nujol): $\tilde{\nu}$[cm^{-1}] = 1246, 1186, 1053, 915, 801, 684, 599, 483; MS(EI): *m/z* (%): 1041 (100) [$M^+ - CH_2CH(CH_3)_2$]; correct elemental analysis.

NiO/CaO-Catalyzed Formation of Syngas by Coupled Exothermic Oxidative Conversion and Endothermic CO_2 and Steam Reforming of Methane

Vasant R. Choudhary,* Amarjeet M. Rajput, and Bathula Prabhakar

The safe, energy-efficient conversion of methane to syngas (with a H_2/CO ratio close to 2.0 for methanol and Fischer–Tropsch synthesis) with high conversion, selectivity, and yield is of great practical importance. In this way natural gas can be used effectively by its conversion to more valuable and/or easily transportable products.[1] Presently, syngas is produced from methane mostly by catalytic steam reforming,[2, 3] which suffers

[*] Dr. V. R. Choudhary, A. M. Rajput, Dr. B. Prabhakar
Chemical Engineering Division, National Chemical Laboratory
Pune 411008 (India)
Telefax: Int. code +(212)330233/334761

from several limitations such as a very high energy requirement, a high H_2/CO product ratio not suitable for methanol and Fischer–Tropsch synthesis, and poor selectivity for CO. Many research groups have attempted to convert methane to syngas without external energy by the catalytic partial oxidation of methane.[4–10] Although this conversion is mildly exothermic, a small decrease in CO selectivity (due to the total combustion of methane, which is highly exothermic) results in a large increase in the reaction temperature. In addition, a high methane conversion coupled with high space velocity (reaction rate per unit volume) leads to production of a large amount of heat in a small catalyst zone. Since it is very difficult to remove the reaction heat from the reactor, particularly for a large-scale operation, the process becomes very hazardous and/or difficult to control. We have overcome the limitations of the endo- and exothermic methane-to-syngas conversion processes and report here on the coupling of the two reactions, which are carried out simultaneously over the same catalyst (NiO/CaO) to produce syngas with a H_2/CO ratio close to 2.0. A very high conversion of methane is achieved at high space velocities and hence, with high productivity, energy efficiency, and safety. Our results show that by manipulating the process conditions (particularly the reaction temperature and CH_4/O_2, CH_4/CO_2, and CH_4/H_2O ratios in feed) the coupled process can be made mildly exothermic, nearly thermoneutral, or mildly endothermic. Thus little or no external energy is required, and this coupled process may be adapted for operation in a simple adiabatic reactor, which has several added advantages.

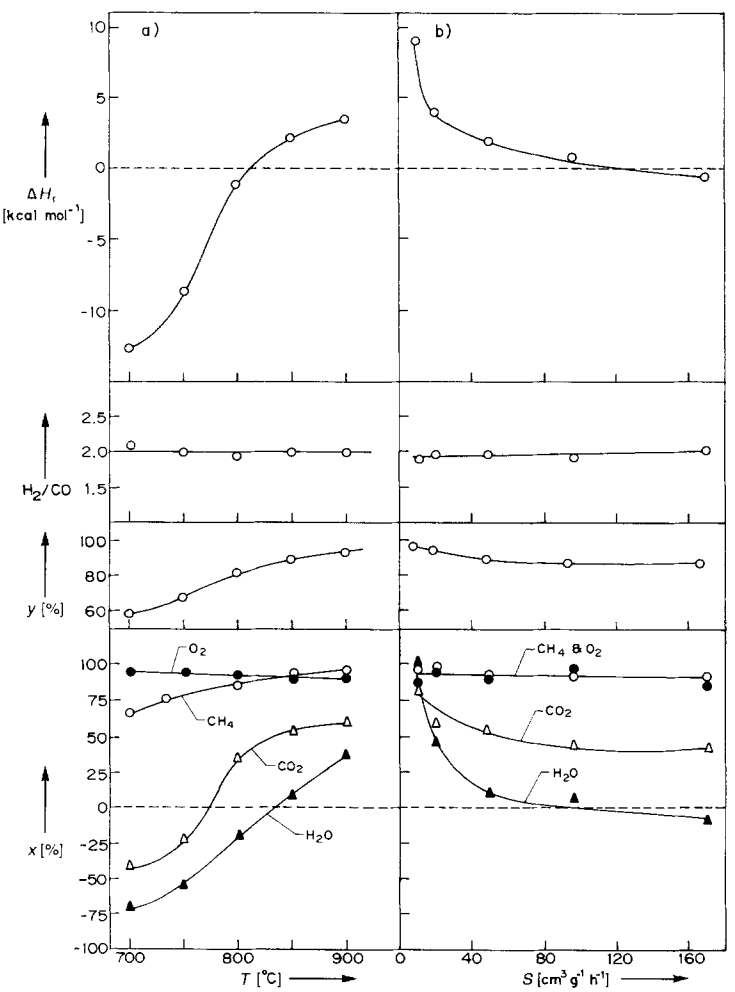

Fig. 1. Influence of a) reaction temperature T and b) space velocity S on the coupled process. x = conversion, y = CO yield or conversion of CH_4 and CO_2 to CO, ΔH_r = heat of reaction. a) $S = 48300\ cm^3 g^{-1} h^{-1}$, $CH_4/O_2 = 2.1$, $CH_4/CO_2 = 10$, $CH_4/H_2O = 10$; b) $T = 850\ ^\circ C$, $CH_4/O_2 = 2.1$, $CH_4/CO_2 = 10$, $CH_4/H_2O = 10$.

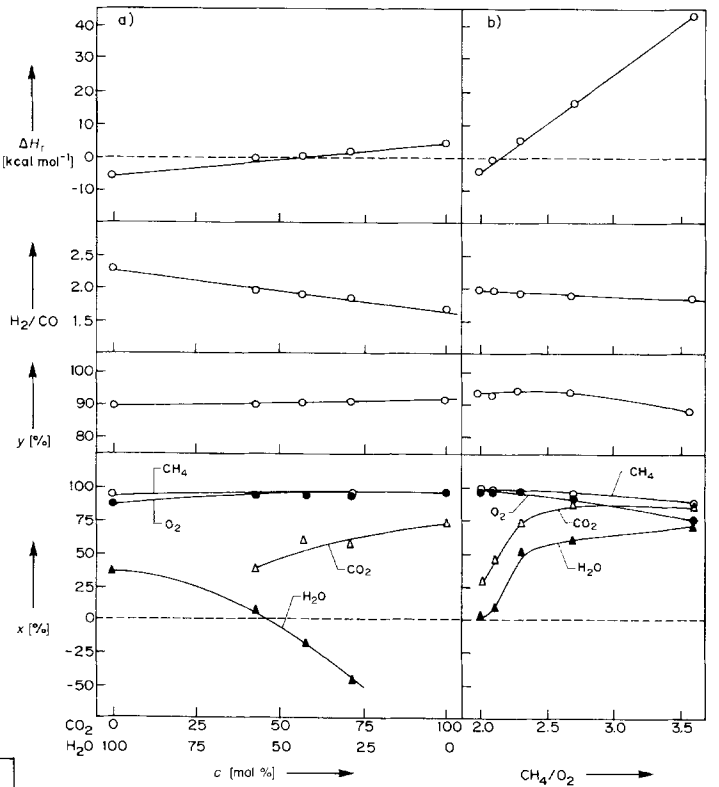

Fig. 2. Influence of a) relative concentration c of CO_2 and H_2O and b) CH_4/O_2 ratio in feed on the coupled process. x = conversion, y = CO yield or conversion of CH_4 and CO_2 to CO, ΔH_r = heat of reaction, S = space velocity. a) $T = 850\ ^\circ C$, $CH_4/O_2 = 2.1$, $CH_4/[O_2 + \frac{1}{2}(CO_2 + H_2O)] = 1.77$, $S = 47500\ cm^3 g^{-1} h^{-1}$; b) $T = 850\ ^\circ C$, $CO_2/H_2O = 1.0$, $CH_4/[O_2 + \frac{1}{2}(CO_2 + H_2O)] = 1.83$, $S = 48200\ cm^3 g^{-1} h^{-1}$.

Our results on the coupling of the two reactions under different process conditions are summarized in Figures 1 and 2. The negative conversions of CO_2 and H_2O indicate that these reactants are formed in the coupled process. The net heat of the reaction (ΔH_r) is estimated by subtracting the heat of formation (at the reaction temperature) of the components in feed from that of the components present in the product stream.

High methane conversions (above 90%) and a H_2/CO ratio close to 2.0 at high space velocities (hence with high CO productivity) are possible by adjusting the process conditions, particularly the reaction temperature and the CH_4/O_2 and $CH_4/(H_2O + CO_2)$ ratios in the feed. The H_2/CO ratio can be decreased or increased by increasing or decreasing, respectively, the CO_2/H_2O ratio in the feed. The coupled process occurs in a most energy-efficient and safe manner with the requirement of little or no external energy because the heat produced in the exothermic reactions is used for the endothermic reactions occurring simultaneously. The following exothermic and endothermic reactions occur in the coupled process (at 700–900 °C).

Exothermic Reactions

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2 + 5.2\ kcal\,mol^{-1} \quad (1)$$

$$CH_4 + 2O_2 \longrightarrow CO_2 + 2H_2O + 191.5\ kcal\,mol^{-1} \quad (2)$$

$$CO + H_2O \longrightarrow CO_2 + H_2 + 8.0\ kcal\,mol^{-1} \quad (3)$$

(water–gas shift reaction)

Endothermic Reactions

$$CH_4 + CO_2 \longrightarrow 2CO + 2H_2 - 62.2\ kcal\,mol^{-1} \quad (4)$$

$$CH_4 + H_2O \longrightarrow CO + 3H_2 - 54.2\ kcal\,mol^{-1} \quad (5)$$

The influence of various process parameters on the conversion of methane, O_2, CO_2, and H_2O, and on the H_2/CO ratio and the net heat of reaction (ΔH_r) in the coupled process is as follows:

1. When the temperature is increased the conversion of methane, CO_2, and H_2O increases but that of O_2 decreases (Fig. 1a); the H_2/CO product ratio is not changed, and the heat of reaction increases (i.e. exothermicity or endothermicity of the process decreases or increases, respectively).

2. Owing to the increase in the space velocity (Fig. 1b), the conversion of CO_2 and H_2O decreases but that of methane and O_2 is affected only to a very small extent. The H_2/CO ratio is not affected. However, the net heat of reactions is decreased.

3. With the increase in the concentration of CO_2 relative to that of H_2O in the feed (Fig. 2a), the conversion of CO_2 increases but that of H_2O decreases. The conversion of CH_4 and O_2 is almost unaffected. The H_2/CO ratio decreases and the heat of reaction increases. The desired H_2/CO ratio can be obtained by manipulating the relative concentrations of CO_2 and H_2O in the feed.

4. When the CH_4/O_2 ratio in the feed is increased (Fig. 2b), the conversion of CH_4 and O_2 decreases but that of CO_2 and H_2O increases; the H_2/CO ratio decreases and the net heat of reaction increases.

In general, when the reaction temperature and the CH_4/O_2 ratio are increased, the exothermicity of the process decreases (or the endothermicity of the process increases). When the space velocity is increased, the exothermicity increases because of the occurance of exothermic and endothermic reactions to different extents. Owing to the very low net heat of the reaction and consequently a low adiabatic temperature change, it may be possible to operate the coupled process adiabatically. A simple packed-bed reactor could be used which has much lower capital and process operation costs. However, for the adiabatic operation, the catalyst bed would probably no longer be isothermal.

Experimental Procedure

The NiO/CaO catalyst (Ni/Ca = 3.0) was prepared from a thick paste of thoroughly mixed, finely ground nickel nitrate, calcium hydroxide, and deionized water. The paste was dried and heated in air at 600 °C for 4 h. The solid was powdered, pressed without a binding agent, crushed to particles of 22–30 mesh, and calcined in air at 930 °C for 4 h. The catalytic oxidative conversion and CO_2 and steam reforming reactions were carried out at atmospheric pressure by continuously passing a mixture of pure methane, O_2, CO_2, and steam at different temperatures, feed ratios, and gas hourly space velocities (GHSV, measured at 0 °C and 1 atm) in a quartz microreactor (i.d.: 10 mm) containing about 0.2–1.0 g catalyst (pretreated at 930 °C for 1 h in a flow of moisture-free N_2). The reaction temperature was measured with a Chromel-Alumel thermocouple located in the catalyst bed. The water from the product stream was condensed at 0 °C. The feed and products were analyzed by an on-line gas chromatography. The C, H and O balances were within 4% error.

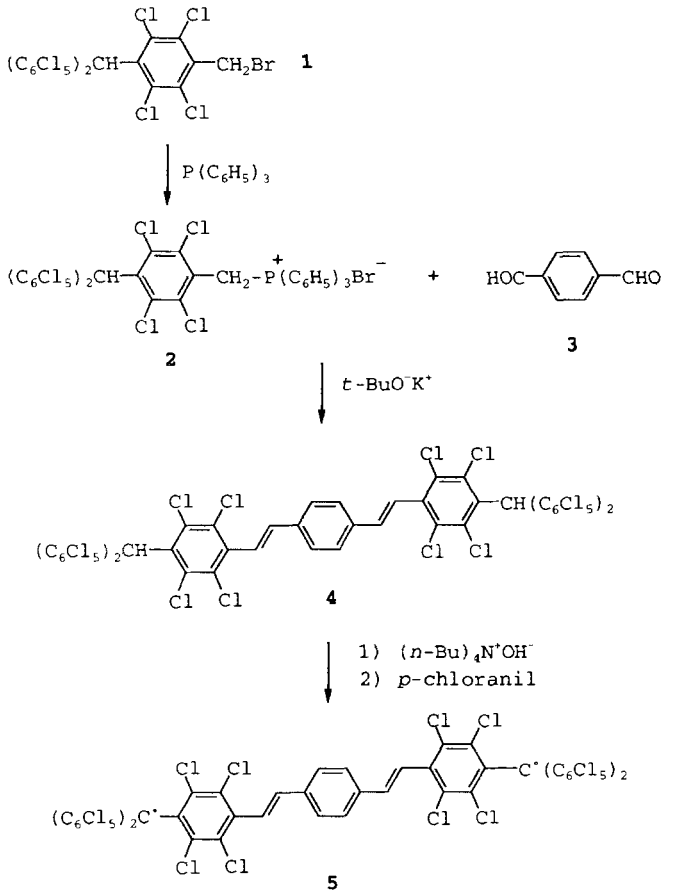
Purely Organic Mixed-Valence Molecules with Nanometric Dimensions Showing Long-Range Electron Transfer. Synthesis, and Optical and EPR Studies of a Radical Anion Derived from a Bis(triarylmethyl)Diradical**

Jacques Bonvoisin,* Jean-Pierre Launay, Concepció Rovira, and Jaume Veciana*



In the area of molecular electronics one of the big challenges is to design and produce molecular wires at least 100 Å long. So far these types of structures have been obtained only by lithography.[1] A molecular wire is composed of at least two redox sites linked by a bridge. One of the major purposes of this bridge is to mediate the transfer of electrons from one site to the other. Rules for the prediction and control of the electron propagation in these compounds would be particularly important. Although many organometallic compounds of this type are known, only few purely organic, mixed-valence compounds have been synthesized and studied up to now[2] owing to their high instability.

Polychlorinated triphenylmethyl radicals typically have high thermal and chemical stability. These electroactive species give, either chemically or electrochemically, the corresponding anions and cations, which are also quite stable species.[3] Thus it seemed interesting to prepare and study symmetrical molecules consisting of two of these radicals linked with different types of bridges. These diradicals could be converted by partial reduction or oxidation to the corresponding radical anions or radical cations. The resulting mixed valence species could therefore display interesting long-range electron transfer phenomena. At the same time this kind of symmetrical diradical could permit the study of the influence of the oxidation state of each redox site in the molecule on the electron transfer.

We report here on our study of the radical anion derived from **5**. This diradical contains two perchlorotriphenylmethyl radical units linked by an all-*trans* *p*-divinylbenzene bridge, which produces a nominal separation between redox centers of about 18.9 Å. This distance between the two methyl carbon atoms was determined with a CPK model and is practically independent of

rotations about the single bonds of the divinylbenzene bridge. The related monoradical **7** was also prepared for comparison purposes.

The diradical **5** was synthesized from **1**[4] via **2** and **4**. **5** is a brown, microcrystalline, air-stable solid. The related monoradical **7** was prepared analogously from **2** and **6**, and shows physicochemical properties similar to those of **5**.[5]

The anions of **5** and **7** were prepared electrochemically in solution. The most important spectroscopic and electrochemical data for the compounds examined are listed in Table 1.

In a detailed magnetic study of diradical **5** based on EPR and magnetic susceptibility measurements in the temperature range of 4–300 K[6] a very weak magnetic interaction on the EPR timescale was observed between the two unpaired electrons over the entire temperature range. The estimated limits for the *intramolecular exchange coupling constant*, J^{intra}, of diradical **5** are $15\ cm^{-1} \gg J^{intra}/hc \gg 10^{-3}\ cm^{-1}$, as ascertained from EPR and magnetic susceptibility measurements.[7] Furthermore, the EPR spectrum of diradical **5** in a frozen rigid medium at 100 K shows that the average interspin separation is about 14 Å. This distance is somewhat smaller than the nominal separation of 18.9 Å between the two methyl carbon atoms where most of the spin density is localized. This result is in agreement with a certain degree of electronic conjugation in the π system of the molecule, owing to the *para* connectivity of the divinylbenzene bridge. Thus the effective separation of the redox sites in **5** is less than that determined with the CPK model.

The electrochemical properties of **5** are in accord with the weak electronic interaction present in this diradical. The cyclic voltammogram of this diradical shows a unique and reversible two-electron reduction wave (Table 1), which was unambiguously confirmed by coulometry to occur at a constant potential of −0.4 V (versus the standard calomel electrode (SCE)). The reduction of **5** was also followed by UV/VIS-NIR spectroscopy. During the reduction the sharp band at 386 nm characteristic of **5** decreases and disappears completely, while the band at 339 nm does not change at all (Fig. 1). At the same time two new broad, intense bands at 522 and 606 nm grow in, which correspond to the continuous formation of the dianion **5**$^{2-}$. Finally, a weak, broad band centered at 1400 nm increases and then decreases during the reduction. This behavior corresponds to

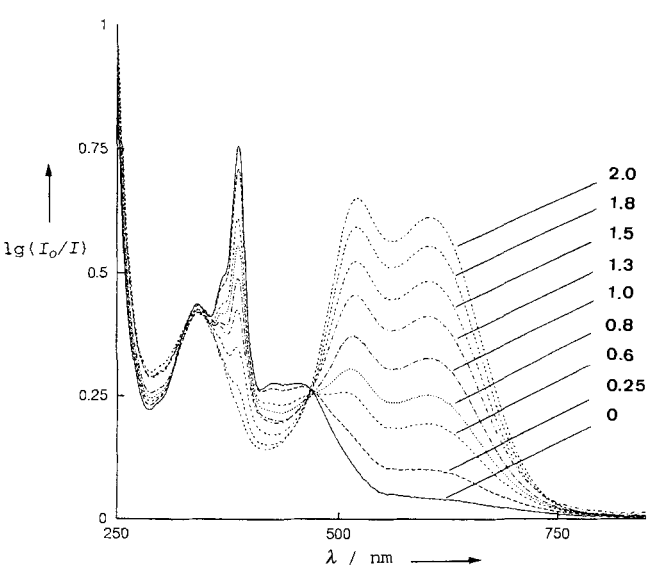

Fig. 1. Evolution of the electronic spectrum in the UV/VIS region in the course of the reduction of **5**. The number of added electrons is given on each spectrum.

that expected for an intermediate species showing intramolecular electron transfer (intervalence transition).[8]

This assignment was confirmed by theoretical calculations following the method employed by Nelsen et al.[9] The energy of an intervalence transition comes from two contributions, λ_{in} and λ_{out}, which correspond to the rearrangements of the internal medium (the molecule) and the outside medium, respectively. The internal Marcus term (λ_{in}) can be obtained by a suitable quantum chemical calculation.[9] Applying this method to $(C_6Cl_5)_3C^{\cdot}$ and using Dewar's semiempirical AM1 method,[10] provides a value of 4.93 kcal mol^{-1} for λ_{in}.[11] The outer shell term (λ_{out}) can be estimated with Equation (a).

$$\lambda_{out} = 332.4\ g(r,d)\ \gamma\ [\text{kcal mol}^{-1}] \qquad \text{(a)}$$

Equation (a) uses a dielectric continuum model with the geometrical parameter $g(r,d)$. The latter is calculated from r, the effective radius of the localized charge, which is represented as a sphere centered at the carbon atom in our case, and R, the distance between the centers of the carbon atoms [Eq. (b)]. γ is

$$g(r,d) = 1/r - 1/R \qquad \text{(b)}$$

the Marcus solvent parameter, which is 0.380 for CH_2Cl_2. With r = 5.4 Å, from the X-ray structure of the perchlorotriphenylmethyl radical,[12] and R = 14 Å (or 18.9 Å) as the distance between the redox sites, one obtains λ_{out} = 14.37 kcal mol^{-1} (or 16.70 kcal mol^{-1}) and finally λ = 19.30 kcal mol^{-1} (or 21.63 kcal mol^{-1}), that is, 0.837 eV (or 0.938 eV), in fairly good agreement with the experimental value of 0.787 eV (see below). Interestingly, λ_{in} provides a noteworthy contribution here, whereas in the related case of partly oxidized tertiary aromatic amines[13] this term was almost negligible relative to λ_{out}.

In order to experimentally determine the effective electronic coupling V_{ab} (in cm^{-1}) between the redox sites of **5** we can use the Hush equation (c). Here R is the effective separation of

$$V_{ab} = [2.05 \times 10^{-2} \sqrt{\varepsilon_{max}\, \bar{\nu}_{max}\, \Delta\bar{\nu}_{1/2}}]\, R^{-1} \qquad \text{(c)}$$

the redox sites (in Å), ε_{max} is the maximum extinction coefficient (in M^{-1} cm^{-1}), $\bar{\nu}_{max}$ is the transition energy, and $\Delta\bar{\nu}_{1/2}$ is the full width at half height (both in cm^{-1}) of the intervalence absorption band. The variation of this absorption band versus the average reduction state can be used to determine the comproportionation constants K_c according to Equation (d).[8]

$$K_C = [\mathbf{5}^{\cdot -}]^2/[\mathbf{5}][\mathbf{5}^{2-}] \qquad \text{(d)}$$

In the present case, K_c is 7. This value is employed in Equation (e) for the calculation of the corrected spectra (Fig. 2).

$$\varepsilon_{\cdot -} = [(2 + \sqrt{K_c})/\sqrt{K_c}]\varepsilon_{\cdot -\,(app)} - (\varepsilon_{\cdot\cdot} + \varepsilon_{2-})/\sqrt{K_c} \qquad \text{(e)}$$

$\varepsilon_{\cdot -}$ and $\varepsilon_{\cdot -\,(app)}$ are the true and the apparent extinction coefficients of the radical anion $\mathbf{5}^{\cdot -}$, and $\varepsilon_{\cdot\cdot}$ and ε_{2-} are the extinction coefficients of diradical **5** and dianion $\mathbf{5}^{2-}$, respectively.

Band deconvolution of the corrected spectrum of $\mathbf{5}^{\cdot -}$ was performed, assuming Gaussian profiles, in order to separate the intervalence band from bands of the nearby radical and/or anion chromophore. This deconvolution procedure has already been described elsewhere,[8] and has the advantage of giving a better estimate of the Marcus λ value. The following parameters for the intervalence absorption band gave satisfactory agreement with the experimental data: $\bar{\nu}_{max}$ = 6349 cm^{-1}

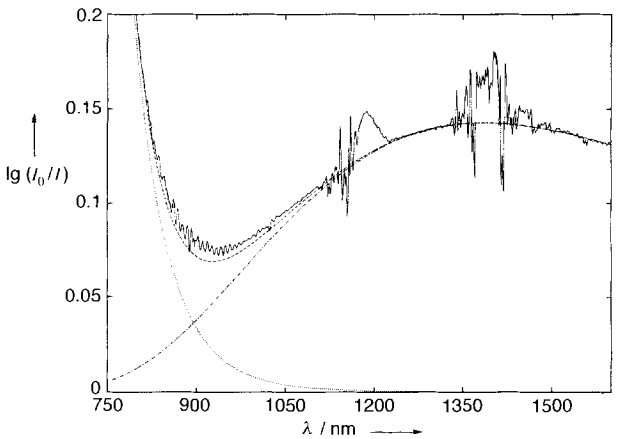

Fig. 2. Corrected electronic spectra for $\mathbf{5}^{\cdot -}$: — experimental spectrum; ---- simulated spectrum (sum of the intervalence transition band - - - - - - and the radical and/or anion chromophore transition band · · · ·). The two bands at 1200 and 1350 nm are artifacts due to solvent absorption.

(i.e. $\lambda = E_{opt}$ = 0.787 eV), $\Delta\bar{\nu}_{1/2}$ = 2940 cm^{-1}, and ε_{max} = 677 M^{-1} cm^{-1}. Finally, application of these parameters to Equation (c) provides the effective electronic coupling for $\mathbf{5}^{\cdot -}$. When 14 Å is used as the effective separation of the redox sites, V_{ab} is 167 cm^{-1} (0.021 eV). For R = 18.9 Å, V_{ab} = 122 cm^{-1} (0.015 eV) is obtained. This method has already been successfully employed to determine the V_{ab} parameter for several mixed-valence dinuclear ruthenium compounds.[8]

The electron transfer in $\mathbf{5}^{\cdot -}$ was also studied by EPR spectroscopy. The EPR spectrum of $\mathbf{5}^{\cdot -}$ at 200 K displays two symmetrical lines (Fig. 3a) with an ^{1}H hyperfine coupling constant very close to that of monoradical $\mathbf{7}^{\cdot}$ (Table 1). This result clearly demonstrates that at this temperature the unpaired electron of radical anion $\mathbf{5}^{\cdot -}$ is localized on the EPR timescale on one stilbene-like moiety only. When the temperature is increased, a new central line gradually emerges between the two initial ones. This evolution is consistent with the increase of the electron jump rate on going from 200 K (the slow-exchange limit) to 300 K (the fast-exchange limit) due to a thermally activated electron transfer between the two equivalent redox sites. The EPR spectra of $\mathbf{5}^{\cdot -}$ at various temperatures were fairly well simulated by using the parameters given in the Table 1 and the program of Heinzer.[14] The best fit was made by varying the rate constant k_{th} for the thermally activated electron transfer between the two equivalent sites. The experimental and simulated EPR spectra are compared in Figure 3; the simulation parameters are also included. The resulting k_{th} values give a linear Eyring plot [$\ln(k_{th}/T)$ vs $1/T$] with a correlation coefficient of 0.998. From the slope of this plot we have calculated a value for the barrier to the thermal electron transfer, $\Delta H^{\ddagger}$, of 2.69 kcal mol^{-1} K^{-1} (0.117 eV).

According to Hush theory, the energy of the intervalence transfer absorption band, E_{opt}, corresponds to the energy for the vertical electron transfer between the sites. In the limit of a vanishingly small electronic interaction, the barrier to the thermal electron transfer is then predicted to be one-quarter of E_{opt}, because of the usual parabolic shape of energy wells [Eq. (f)].

$$E_{opt} = 4\Delta H^{\ddagger} \qquad \text{(f)}$$

The difference between one-quarter of the experimental optical electron transfer energy (0.787 eV/4 = 0.197 eV) and the thermal electron transfer energy (0.117 eV) should be the effective electronic coupling, which in this case is 0.08 eV, a markedly higher value than that found experimentally with Equation (c)

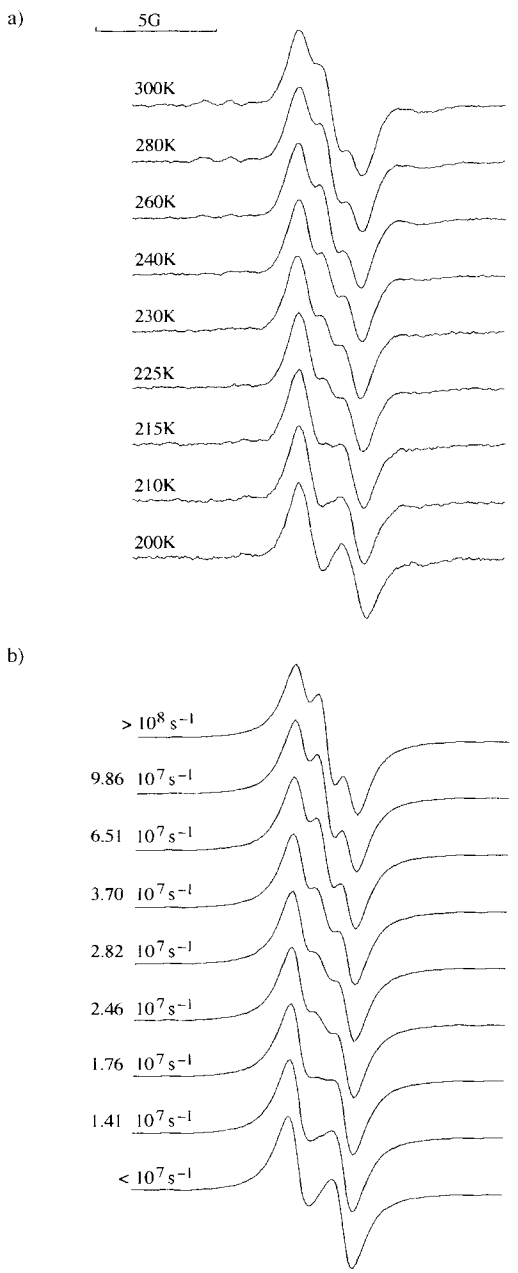

Fig. 3. Experimental (a) and simulated (b) EPR spectra of $5^{\bullet-}$ at different temperatures in CH_2Cl_2 with 0.1 M of nBu_4NPF_6. Spectra recorded at the very end of the reduction process. At this stage, the major species present in the solution is the EPR-silent dianion 5^{2-}. Most of the observed EPR signal is due to radical anion $5^{\bullet-}$, since for statistical reasons diradical **5** must have a negligible concentration. The simulated spectra were performed using a^1H (1 H) = 1.90 G, $\Delta H_{1/2}$ = 0.85 G, and the electron exchange rate constant given on each spectrum.

(0.015 to 0.02 eV). This discrepancy could come from the use of Equation (c) to calculate V_{ab}, which may not be correct for organic compounds. The separation R between the redox sites, which is employed in Equation (c), is not perfectly defined, because in the ground state the wavefunction of the electron is not fully localized on the radical carbon atom, but has important extensions on the adjacent phenyl rings. This has already been pointed out by Nelsen et al.[2a] and also by two of us[13] for organic nitrogen compounds. Alternatively, the discrepancy may result from nuclear tunneling effects, which may lead to an apparent lowering of the thermal activation barrier in organic compounds.[15a]

We have proved that $5^{\bullet-}$ displays an intervalence transition and have determined the thermal electron transfer energy. The radical anion is one of the rare examples for which optical and thermal electron transfer can be observed and correlated. The only other system for which such studies have been reported appeared very recently.[15b]

Polynuclear Lanthanide Complexes: Formation of a Selenium-Centered Sm_6 Complex, $[\{(C_5Me_5)Sm\}_6Se_{11}]$**

William J. Evans,* Gerd W. Rabe, Mohammad A. Ansari, and Joseph W. Ziller

We have been exploring the utility of the organosamarium complexes $[(C_5Me_5)_2Sm(thf)_2]$[1] and $[(C_5Me_5)_2Sm]$[2] in the assembly of unusual polyelement anions involving the main group elements. $[(C_5Me_5)_2Sm]$ complexes containing $(Bi_2)^{2-}$, $(Sb_3)^{3-}$, and $(Se_3)^{2-}$ ions have been obtained from $BiPh_3$,[3] $SbnBu_3$,[4] and elemental selenium.[5] The chemistry of Group 16 elements has proven to be complicated, since several series of compounds can form depending upon reaction conditions and the stoichiometries of the reagents. For example, for E = S, Se, Te two classes of complexes, $[\{(C_5Me_5)_2Sm(thf)\}_2(\mu\text{-}E)]$ and $[\{(C_5Me_5)_2Sm\}_2(\mu\text{-}\eta^1\text{:}\eta^3\text{-}Se_3)(thf)]$ have been fully identified and can be interconverted.[5, 6] $(E_2)^{2-}$ complexes are also accessible in this system, as exemplified by the synthesis of $[\{(C_5Me_5)_2Sm\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}Te_2)]$.[5, 7] Other complexes were observed in the $(C_5Me_5)_2Sm/E$ system, but until now were not identifiable.

We report here a new product from this reaction system, $[\{(C_5Me_5)Sm\}_6Se_{11}]$ (**1**), the first representative of a new class of polynuclear lanthanide complexes. Since complex **1** contains seventeen samarium and selenium atoms, it may be of interest for preparation of dilute semiconducting materials containing lanthanide metals and chalcogenides, an area which has recently seen considerable activity.[8–12] Complex **1** also appears to be unique among chalcogen compounds. Although numerous transition metal/chalcogenide clusters stabilized with substituted phosphanes, thiols, or organic ligands are known,[13] none have the structure found in **1**.

Complex **1** is reproducibly obtained from NMR samples of $[\{(C_5Me_5)_2Sm\}_2(\mu\text{-}\eta^1\text{:}\eta^3\text{-}Se_3)(thf)]$ (**2**)[5] in toluene at ambient temperature over three to seven days in a nitrogen-containing glovebox. Single crystals with the same unit cell parameters were obtained from three different samples of **2** in toluene, but crystals were not obtained from benzene. Attempts to synthesize S and Te analogues by this method have been so far unsuccessful. The low solubility of **1** in solvents with which it does not react has hampered characterization by NMR spectroscopy, but **1** could be definitively identified by X-ray crystallography (Fig. 1).[14]

The six $(C_5Me_5)Sm$ units in **1** describe an octahedron distorted in one plane such that the only Sm-Se-Sm angles which are not close to the expected 90° and 180° values are the 74.6(1)° Sm(1)-Se(6)-Sm(3) and 105.4(1)° Sm(1′)-Se(6)-Sm(3) angles (and their inversion-symmetry equivalents). The $Sm-C(C_5Me_5)$ distances (2.679 Å average) clearly indicate the presence of Sm^{III}, since no $Sm^{II}-C(C_5Me_5)$ distance less than 2.79(1) Å has been reported.[15, 16]

The eleven Se atoms in **1** can be divided into three sets. There are four pairs of selenium atoms, Se(1)–Se(2), Se(4)–Se(5), and their inversion equivalents, which have Se–Se distances of 2.376(2) and 2.361(2) Å. These distances are similar to those found in other structures containing $(Se_2)^{2-}$ ions.[17] In each of these pairs, one selenium atom, Se(1) and Se(5), is 2.869(2) to 2.880(2) Å from two samarium atoms. These distances are longer than the 2.782(1) and 2.779(1) Å Sm–Se distances in $[\{(C_5Me_5)_2Sm(thf)\}_2(\mu\text{-}Se)]$,[5] but shorter than the 2.917(1) to 3.007(1) Å distances in $[\{(C_5Me_5)_2Sm\}_2(\mu\text{-}\eta^1\text{:}\eta^3\text{-}Se_3)(thf)]$.[5] The other selenium atoms in each pair Se(2) and Se(4), are oriented toward three samarium atoms at longer distances, 2.989(2) to 3.308(2) Å.

The second type of selenium in **1** is the unique central Se(6) which is located 3.123(1) to 3.186(1) Å from the six samarium atoms. The third type of selenium in **1**, Se(3) (and its inversion equivalent), is located 2.859(2) to 2.951(2) Å from three samarium atoms. Se(6), Se(3), and Se(3′) must bear a −4 charge to make up the difference between the four $(Se_2)^{2-}$ ions and the six $[(C_5Me_5)Sm]^{2+}$ units. A $(Se_3)^{4-}$ ion has never been identified in the past to our knowledge, but it is isoelectronic with the known $(I_3)^-$ ion.[18, 19] The 2.749(2) Å Se(3)–Se(6) distance is consis-

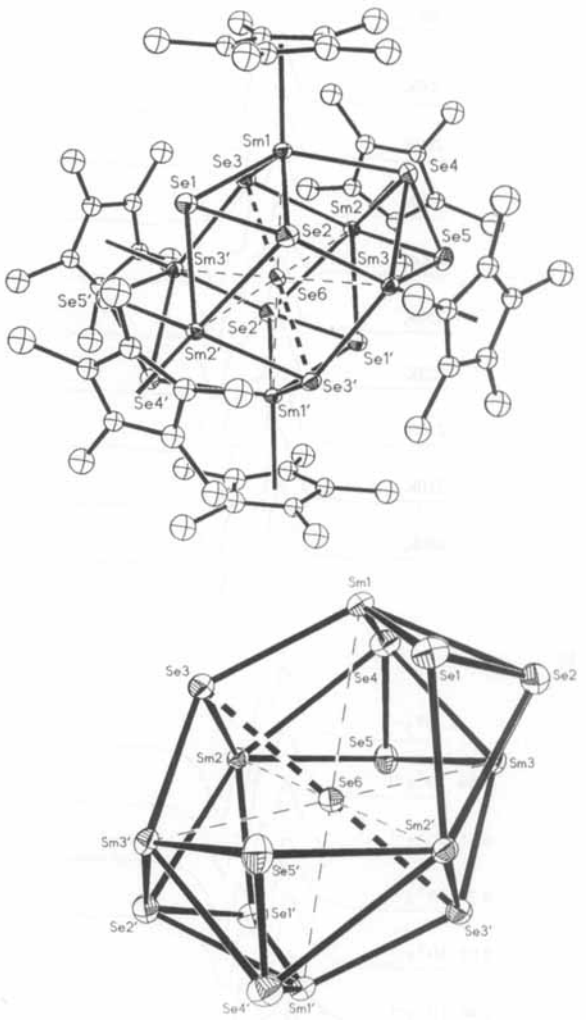

Fig. 1. Top: Molecular structure of **1**. Bottom: Structure of the central Sm_6Se_{11} core of **1**. tent with a $(Se_3)^{4-}$ ion: it is longer than the 2.37 Å average single bond length in $(Se_2)^{2-}$ species, just as the 2.901(1) and 2.904(1) Å I–I distances[19] in symmetrical $(I_3)^-$ are longer than the 2.70 Å single bond length in I_2.[20] Precedence for chalcogen–chalcogen distances longer than typical single bonds is found in the $(Te_7)^{4-}$ ion.[21, 22]

It is unlikely that hexanuclear **1** is unique in lanthanide chemistry. The closest organolanthanide complexes in the literature are the oxo-centered square-pyramidal systems $[(C_5H_5)_5Ln_5(OMe)_8O]$ (Ln = Y[23], Gd[24]) and the capped butterfly fluoride complex $[(C_5Me_5)_6Yb_5F_9]$.[25] The mechanism of formation of **1** and related species is under investigation.

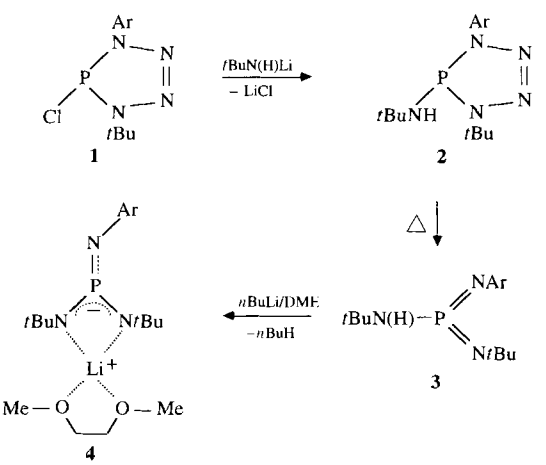
Monomeric Tris(imino)metaphosphates**

Edgar Niecke,* Matthias Frost, Martin Nieger, Volker von der Gönna, Alexander Ruban, and Wolfgang W. Schoeller



Dedicated to Professor Nils Wiberg on the occasion of his 60th birthday

The existence of monomeric metaphophosphate (**I**) in the gas phase[1] and in the matrix[2] is well-documented. Furthermore, **I** is discussed as a component of mechanistic processes in a series of phosphorylation reactions in solution.[3] Theoretical studies on **I** as well as on anions of the general type $[PXYZ]^-$ (X,Y,Z = O, S, CH_2) reveal the unusual electronic behavior of such species;[4] to date only one representative of the type **III** has been isolated and structurally characterized in the form of its lithium salt.[5, 6] We report here on the synthesis and structure of the lithium salts of tris(imino)metaphosphates (**II**), which exist either as lithium complexes[7] or as "separated ions" depending on their substituents.

I II III

The reaction of the chlorodihydrotetrazaphosphole **1**[8] (Ar = 2,4,6-tri-*tert*-butylphenyl) with lithium *tert*-butyl amide affords the amine **2**, which can be converted thermally with elimination of N_2 into the aminobis(imino)phosphorane **3**. Subsequent metalation with *n*-butyllithium in 1,2-dimethoxyethane (DME) leads to the lithium complex **4** of the

tris(imino)metaphosphate. The free anion in **7** can be obtained from the bromobis(imino)phosphorane **5**[9] by Br/NHAr exchange to give **6** followed by metalation in THF.

The composition and constitution of the precursors **2**, **3**, and **6** can be obtained from the high-resolution mass spectrum (molecular ion) and the results of multinuclear NMR measurements. The structures of the lithium tris(imino)metaphosphates **4** and **7** were elucidated by X-ray crystal structure analyses.[10] Figure 1 shows the structure of the lithium complex **4**. The

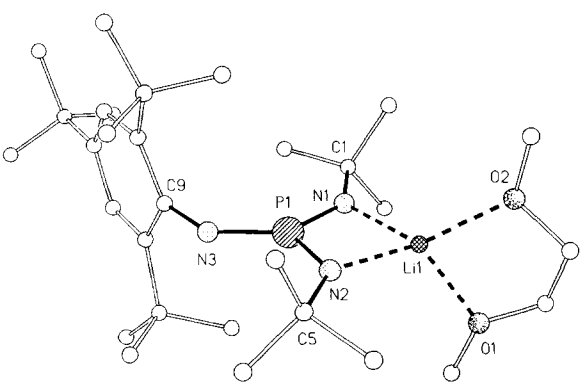

Fig. 1. Crystal structure of **4**. Selected bond lengths [pm] and angles [°]: P1-N1 155.4(2), P1-N2 156.7(2), P1-N3 154.3(2), N1-Li1 202.1(5), N2-Li1 197.9(5); N1-P1-N2 105.3(1), N2-P1-N3 121.1(1), N1-P1-N3 133.6(1), P1-N1-Li1 88.4(2), P1-N2-Li1 89.6(2), N1-Li1-N2 76.6(2), P1-N1-C1 139.7(2), P1-N2-C5 131.1(2), P1-N3-C9 131.9(2).

phosphorus atom resides in a trigonal-planar environment. The carbon atoms of the substituents linked with the nitrogen atoms also lie in this plane; of these the two *tert*-butyl groups at N1 and N2 have an *exo*/*exo* arrangement. The formation of two N–Li bonds (197.9 and 202.1 pm) as well as a relatively small N1-P1-N2 angle at phosphorus (105.3°) is associated with this conformation. A similar bonding situation is shown by 1,3-diaza-2-phosphaallyllithium complexes.[14] The P–N distances (154.3–156.7 pm) in **4** are significantly longer than those in the corresponding substituted bis(imino)phosphoranes.[15]

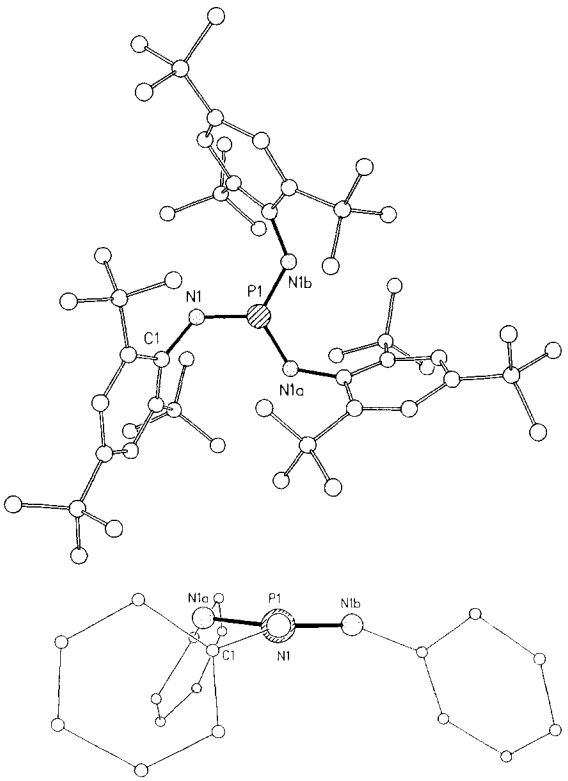

Fig. 2. Top: Crystal structure of the anion of **7**. Selected bond lengths [pm] and angles [°]: P1–N1 156.5(5), N1–C1 140.9(10); N1-P1-N1 119.9(1), C1-N1-P1 126.7(5). Bottom: Simplified representation showing the pyramidalization of the imine nitrogen atom.

In contrast to the metaphosphate unit in **4**, that in **7** is uncoordinated (Fig. 2). The shortest distance between the lithium atom tetrahedrally coordinated by four solvent molecules (THF) and the nitrogen atom N1 is 722 pm. The anion has C_3 symmetry; that is, the three imino groups are equivalent. The aryl substituents are arranged propellor-like around the central PN_3 framework (angle between the PN_3 and the aryl plane is 66°). The twist about the P–N bond is remarkable when compared to that in **4** and that in the sulfur triimide isoelectronic to **7**;[16] the *ipso* carbon atoms of the aryl groups each project 41 pm below the PN_3 plane (angle between the N–C vector and the PN_3 plane is 17.5°).

In order to establish whether the reduction in symmetry of **7** is an inherent property of the tris(imino)metaphosphate ion or is attributed to the steric effects in the crystal, quantum chemical calculations were carried out on the parent compound $[P(=NH)_3]^-$.[17] The most stable structure has C_{3h} symmetry (RHF/6-31 + G(d,p) optimized, P–N 156.2 pm, ∢ N 111.6°). A structural isomer with two hydrogen atoms in an *exo*/*exo* conformation (C_s symmetry), as occurs in the lithium complex **4**, is 3.4 kcal mol^{-1} higher in energy (HP + SD (tq) 6-31G(d,p) + zero-point vibration correction). Furthermore, the quantum chemical calculations showed that in metaphosphates of the type PX_3^- (X = SiH_2, PH, CH_2, S, NH, O) the tendency toward a reduction of symmetry (pyramidalization at phosphorus and/or twist of the π system) decreases with increasing electronegativity of the ligands X.[18] Since the geometry at the imine nitrogen atom in **7** deviates from that predicted by theory, it is assumed that van der Waals interactions between the solvent ligands of the cation and the sterically demanding substituents on the nitrogen atoms of the anion lead to the twisting about the P–N bond.

Experimental Procedure

2: A solution of **1** (4.25 g, 10 mmol) in diethyl ether (30 mL) was treated with the equimolar quantity of lithium *tert*-butyl amide at −30 °C. After the mixture had been warmed to 20 °C, the solvent was removed under vacuum, the resulting lithium chloride filtered, and the yellow residue taken up in *n*-hexane (10 mL). Compound **2** crystallized as fine needles at −30 °C. Yield: 3.45 g (72%), m.p. 83–85 °C (decomp.); ^{31}P NMR ($CDCl_3$): $\delta = 32.1$; ^{1}H NMR ($CDCl_3$): $\delta = 7.39$ (s, *m*-CH), 2.85 (d, $J = 4.7$ Hz, NH), 1.54 (s), 1.42 (s), 1.28 (s), 1.21 (s), 0.93 (d, $J = 0.9$ Hz, each *t*Bu); MS (40 eV): *m/z* (%): 433 (12) [$M^+ - N_2$], 418 (41) [$M^+ - N_2 - CH_3$], 362 (100) [(*t*BuN(H)P=NAr)$^+$]

3: **2** (3 g, 6.5 mmol) was dissolved in absolute DME (20 mL) and stirred for 2 h under reflux. At the beginning of the reaction a violent evolution of nitrogen was observed. After the solution had been concentrated and cooled to −30 °C, the aminobis(imino)phosphorane **3** was isolated as a fine crystalline white solid. Yield: 2.3 g (81%), m.p. 95–98 °C; ^{31}P NMR ($CDCl_3$): $\delta = 39.5$; ^{1}H NMR ($CDCl_3$): $\delta = 7.30$ (s, *m*-CH), 1.82 (d, $J = 3.8$ Hz, NH), 1.50 (s, *o*-C(CH_3)$_3$), 1.36 (d, $J = 7.2$ Hz, N(H)C(CH_3)$_3$), 1.27 (s, *p*-C(CH_3)$_3$), 1.15 (s, NC(CH_3)$_3$); MS (40 eV): *m/z* (%): 433 (21) [M^+], 362 (100) [(*t*BuN(H)P=NAr)$^+$].

4: *n*BuLi (2.9 mL, 1.6 M in *n*-hexane) was slowly added dropwise to a solution of the bis(imino)phosphorane **3** (2.0 g, 4.6 mmol) in DME (20 mL) at −60 °C. After complete addition the mixture was stirred for 1 h. The solution was then concentrated to half the volume. Compound **4** precipitated at −30 °C within two weeks in the form of yellow, prismatic crystals. Yield 0.9 g (37%).

6: **5** (2.0 g, 3.8 mmol) was dissolved in THF (50 mL) and treated with lithium 2,4,6-tri-*tert*-butylphenyl amide (1.1 g, 3.8 mmol). The solution was stirred overnight, subsequently all volatile components were removed under vacuum. The residue was taken up in toluene (30 mL), and the lithium amide which had been formed was removed by filtration. The product **6** precipitated from the concentrated solution in the form of pale yellow needlelike crystals. Yield: 2.4 g (84%), m.p. 167–169 °C (decomp.); ^{31}P NMR (C_6D_6/THF, 25 °C): $\delta = 22.1$.

7: **6** (1.00 g, 1.2 mmol) was dissolved in THF (70 mL) and treated with *n*-butyllithium (0.76 mL, 1.6 M in *n*-hexane). This resulted in the spontaneous precipitation of **7** as an amorphous solid. The product was obtained in crystalline form by redissolving the precipitate at 60 °C, followed by slow cooling (10 °C per h) to room temperature. Yield: 0.9 g (90%), m.p. 92–93 °C (decomp.); ^{31}P NMR (C_6D_6/THF): $\delta = 41.3$; ^{1}H NMR (C_6D_6/DME): $\delta = 7.44$ (s, 6H), 1.68 (s, 54 H), 1.40 (s, 27 H).

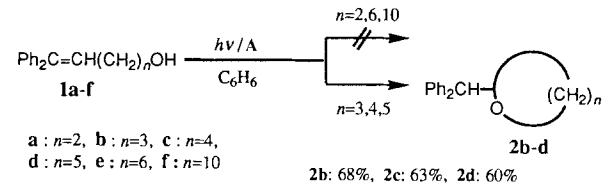
Intramolecular Photocyclization of ω,ω-Diphenyl-(ω − 1)-alken-1-ols by an Exciplex Quenching Mechanism**

Kazuhiko Mizuno,* Toshiyuki Tamai, Toshinori Nishiyama, Kyoko Tani, Mayumi Sawasaki, and Yoshio Otsuji

Photochemical polar addition of nucleophiles to alkenes can be achieved by photoinduced electron transfer.[1–6] This photoreaction often proceeds via radical cations of alkenes, which are generated by photoinduced electron transfer from the alkene to an electron acceptor; this reaction is generally very efficient in polar media such as acetonitrile. Recently, we found that the efficiency of the photoaddition of alcohols to arylalkenes sensitized by 9,10-anthracenedicarbonitrile **A** depends markedly on the structure of the alkenes and the nature of the solvents.[5] The photoaddition of methanol to 1,1-diphenylpropene occurs more efficiently in less polar aromatic solvents such as benzene and toluene than in acetonitrile. We now report the regio- and stereoselective intramolecular photoaddition of ω,ω-diphenyl-(ω-1)-alkenols in the presence of **A**.[7] One step in this photoreaction is the quenching of the **A**–arylalkene exciplex by the terminal OH group present in the alkenol.



Irradiation of a solution of 6,6-diphenyl-5-hexenol (**1c**, 0.2 mmol) and a catalytic amount of **A** (0.04 mmol) in benzene through an aqueous $CuSO_4$–NH_3 filter solution ($\lambda > 400$ nm) gave 2-(diphenylmethyl)tetrahydropyran (**2c**) in 63% yield (isolated product).[8] The intramolecular photocyclization of **1c** occurred efficiently in aromatic solvents such as benzene and

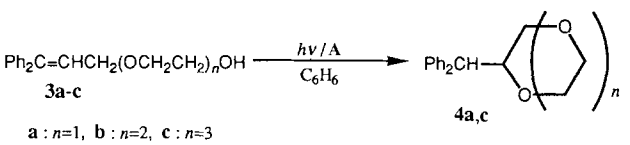
[**] This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan. We thank Dr. Y. Masaki, Dr. C. Pac, and Prof. S. Yanagida, Osaka University, for measurements of fluorescence lifetimes of 9,10-anthracenedicarbonitrile.



toluene and in halogenated solvents such as dichloromethane but less efficiently in acetonitrile, propionitrile, and ethyl acetate.[9]

The photoreactions of **1b** and **1d** under similar conditions gave the corresponding cyclized products **2b** and **2d** in good yields. In contrast **1a** and **1e–f**, which have shorter or longer methylene chains between the carbon–carbon double bond and the OH group, did not give any cyclized products. In the photoreactions of more flexible alkenes **3a–c**, only **3a** afforded the 1,4-dioxane **4a** in low yield.[10] The photocyclization of 3-substituted 6,6-diphenyl-5-hexenols **5a–c**[11] in benzene was

stereoselective and gave the *cis* and *trans* 4-substituted 2-(diphenylmethyl)tetrahydropyrans **6a–c** and **7a–c**, respectively, in about a 4:1 ratio.[8] The *cis*/*trans* isomer ratios were little affected by the reaction temperature, solvent, and substituents.[12] The quantum yields for the formation of the cyclized products **2**, **6**, and **7** in benzene were five to ten times higher than those in acetonitrile.

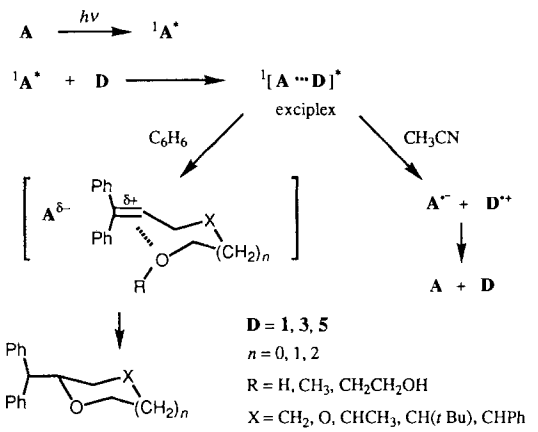
The fluorescence of 9,10-anthracenedicarbonitrile **A** in acetonitrile was efficiently quenched by all the arylalkenes at nearly diffusion-controlled rates; the rate constants for the fluorescence quenching were in the range of 3.3×10^8–1.3×10^{10} $M^{-1} s^{-1}$ ($\tau_{A,air} = 16.1$ ns in acetonitrile and 15.2 ns in benzene). However, the Stern–Volmer constants K_{sv} in benzene were much smaller than those in acetonitrile (Table 1). For **1a**, **1f**, and 1,1-diphenylpropene (**8a**), the K_{sv} values were much smaller than that of 9-ethylidenefluorene (**9**),[5, 13] although the oxidation potentials of these alkenes are almost the same. The fluorescence lifetime of **A** in benzene in the presence of methanol (1 M) was almost the same as that in the absence of methanol ($\tau_{air,C_6H_6} = 15.2$ ns, $\tau_{air,C_6H_6/CH_3OH} = 14.9$ ns). However, the K_{sv} value for **1f** in the presence of methanol was four times greater than that in neat benzene and almost the same as those for **1b**, **c**

Table 1. Stern–Volmer constants for the fluorescence quenching of **A** in various solvents and oxidation potentials of arylalkenes and other compounds.



Alkene	$E^{ox}_{p/2}$ [a] [V]	K_{sv} [b] [M^{-1}] C_6H_6	C_6H_6/MeOH [c]	MeCN

9	1.06	47	49	106

[a] Oxidation potentials (V vs. $Ag/AgClO_4$) were determined by cyclic voltammetry: Pt electrode, Bu_4NClO_4 (0.1 M) in CH_3CN. [b] Stern–Volmer constants for the fluorescence quenching of **A** in three solvents: [A] = 1×10^{-4} M. [c] In C_6H_6 in the presence of CH_3OH (1 M).

and the ether **1g**. Furthermore, weak emissions from the **A**/**8a**, **b** exciplexes and the **A**/**1g** exciplex were observed in benzene at longer wavelengths than the emission from $^1A^*$.[14]

We propose the exciplex quenching mechanism shown in Scheme 1 for the 9,10-anthracenedicarbonitrile (**A**) sensitized intramolecular photoaddition of **1a–f**. In benzene, a reversible

Scheme 1. Exciplex quenching mechanism for the **A**-sensitized intramolecular photocyclization of ω,ω-diphenyl-($\omega-1$)-alkenols.

exciplex[15] is formed between the **A** in the excited singlet state and the diphenylalkene moiety of the ω-hydroxyalkene. This exciplex is quenched by the OH group within the molecule.[16, 17] For **1b–d**, exciplex quenching leads to the five- to seven-membered transition state structures that are favorable for the formation of cyclized products. Exciplexes of the hydroxy ethers **3b**, **c** are not quenched by the OH group, but by the oxygen atom of the oxyethylene group. Therefore, **3b**, **c** have relatively large K_{sv} values, although the photoreaction of **3b**, **c**

gives hardly any cyclized products.[18] The intramolecular photoreaction is extremely efficient compared to the intermolecular photoaddition. In fact, the intramolecular photoaddition occurs smoothly even at high concentrations of the alkenes ([**1b**] = 0.001 - 0.1 M).

Photoinduced electron transfer in acetonitrile is known to occur rapidly to produce radical ions. However, in our system, the radical cations, probably solvent-separated radical cations, are less reactive toward alcohols. Solvent-separated radical ions will be inactivated by rapid back electron-transfer.[19] In fact, the addition of $Mg(ClO_4)_2$ to the reaction systems suppresses the formation of cyclized products.[19]

[7] This work was presented in part at the United States/Japan seminar, "New Aspects of Molecular Photochemistry in Photoconversion", Tsukuba, Japan, April 13–17, 1992.

[8] The cyclized products were characterized by their ^{1}H NMR, ^{13}C NMR, and two-dimensional COSY and NOESY spectra. **2c**: ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.24–1.33 (m, 1H; 3eq-H), 1.40–1.58 (m, 4H; 4-H, 5-H), 1.76–1.79 (m, 1H; 3ax-H), 3.38–3.47 (m, 1H; 6ax-H), 3.88 (d, J = 9.26 Hz, 1H; 7-H), 3.95–3.96 (m, 1H; 6eq-H), 4.00–4.02 (m, 1H; 2-H), 7.13–7.35 (m, 10H); IR (KBr): ν = 1091 cm^{-1}; MS (70 eV): m/z: 252 (M^+). – **6c**: ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.39–1.53 (m, 1H; 3eq-H), 1.67–1.84 (m, 3H; 3ax-H, 5-H), 2.70–2.82 (m, 1H; 4-H), 3.51–3.73 (m, 1H; 6eq-H), 3.95 (d, J = 9.40 Hz, 1H; 7-H), 4.09–4.16 (m, 2H; 2-H, 6ax-H), 7.13–7.35 (m, 15H); IR (KBr): ν = 1100, 1042 cm^{-1}; MS (70 eV); High-resolution MS of M^+: 328.1936 (calcd $C_{24}H_{24}O$: 328.1827). – **7c**: ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.68–1.78 (m, 1H; 3eq-H), 1.87–1.98 (m, 3H; 3ax-H, 5-H), 3.13–3.25 (m, 1H; 4-H), 3.63–3.71 (m, 1H; 6eq-H), 3.78–3.88 (m, 1H; 6ax-H), 4.38 (d, J = 9.40 Hz, 1H; 7-H), 4.55–4.63 (m, 1H; 2-H), 7.14–7.36 (m, 15H); IR (KBr): ν = 1125, 1084 cm^{-1}; MS (70 eV): High-resolution MS of M^+: 328.1817 (calcd $C_{24}H_{24}O$: 328.1827).

[9] Relative quantum yields for the formation of **2c** in various solvents: 0.70 (C_6H_6), 0.72 (PhMe), 0.22 ($MeCO_2Et$), 1.0 (CH_2Cl_2), 0.07 (EtCN), 0.06 (MeCN).

[10] The phenanthrene–1,4-benzenedicarbonitrile sensitized photoreaction of **3a–c** in acetonitrile gave **4a–c** (yields: 13% for **4a**, 6% for **4b**, 9% for **4c**). These reactions probably proceed via the radical cations of **3a–c** [3].

[11] **5c**: ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.76–1.98(m, 2H), 2.39–2.47 (m, 2H), 2.80–2.90 (m, 1H), 3.37–3.52 (m, 2H), 5.96 (t, J = 7.45 Hz, 1H), 7.01–7.37 (m, 15H); IR (film): ν = 3400 cm^{-1}; MS (70 eV): high-resolution MS of M^+: 328.1842 (calcd $C_{24}H_{24}O$: 328.1827).

[12] Product ratios of **6a–c**/**7a–c** in different solvents: **6a**/**7a** = 83:17 (CCl_4), 82:18 (C_6H_6), 80:20 (CH_2Cl_2), 80:20 (C_2H_5Br), 84:26 (MeCN); **6b**/**7b** = 72:28 (CCl_4), 71:29 (C_6H_6), 75:25 (CH_2Cl_2), 81:19 (EtBr), 79:21 (MeCN); **6c**/**7c** = >98:>2 (CCl_4), 83:17 (C_6H_6), 80:20 (CH_2Cl_2), 78:22 (EtBr), 83:17 (MeCN). Ratios at different temperatures: **6a**/**7a** = 79:21 (–20 °C, CH_2Cl_2), 73:27 (50 °C, CH_2Cl_2), 72:28 (70 °C, CH_2Cl_2), 85:15 (–60 °C, C_6H_5Me), 78:22 (10 °C, C_6H_5Me), 73:27 (80 °C, C_6H_5Me), 72:28 (150 °C, C_6H_5Me).

[13] The fluorescence of ^{1}**A*** was efficiently quenched by **9**, probably as a result of the sandwich-type π-π interaction.

[14] The exciplex emissions were quenched by adding methanol to the benzene solutions.

[15] Although **1a**, **1f**, and **8a** have oxidation potentials similar to those of **1b–e** and **9**, their K_{sv} values are relatively small (Table 1). The formation of reversible exciplexes is postulated based on these results. See D. A. Labianca, G. N. Taylor, G. S. Hammond, *J. Am. Chem. Soc.* **1972**, *94*, 3679.

[16] R. A. Caldwell, L. Smith, *J. Am. Chem. Soc.* **1974**, *96*, 2994; D. Creed, R. A. Caldwell, *ibid.* **1974**, *96*, 7369; D. Creed, R. A. Caldwell, H. Ohta, D. C. DeMacro, *ibid.* **1977**, *99*, 277; C. Pac, H. Sakurai, *Chem. Lett.* **1976**, 1067; T. Majima, C. Pac, H. Sakurai, *Bull Chem. Soc. Jpn.* **1978**, *51*, 1811.

[17] The **A**-sensitized photoaddition of methanol to 1,1-diphenylethene (DPE) in acetonitrile is inefficient [5]; the phenanthrene–1,4-benzenedicarbonitrile sensitized photoaddition in acetonitrile is efficient [3]. The π complex [(phenanthrene–DPE)$^{\cdot+}$], which has a longer lifetime than the solvent-separated radical cation of DPE, has been proposed as a key intermediate by Pac et al. [3]. In the **A**-sensitized intramolecular photocyclization in benzene, the solvent may act as a π donor to stabilize the radical cation of ω-hydroxyalkenes. K. Mizuno, K. Nakanishi, Y. Otsuji, *Chem. Lett.* **1988**, 1833. See also ref. [19].

[18] It is notable here that the large K_{sv} values do not necessarily lead to the efficient formation of the cyclized products. For **3a**, an intramolecular hydrogen bond may be formed between the OH groups and the oxygen atom of the oxyethylene group, and hence the exciplex is quenched less efficiently.

Electrifying Reading!

Structure of Electrified Interfaces. Edited by *J. Lipkowski* and *P. N. Ross*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 406 pp., hardcover DM 196.00, $ 125.00.—ISBN 3-527-28787-6/0-89573-787-6

This book, edited by two well recognized electrochemists, is the second volume in a new series appearing in the specialist electrochemical literature. Compared with the many other series in this field, some of which have continued for many years, this new one aims to win the reader over by setting out different objectives. Instead of collecting together in one volume a rather haphazard collection of reviews on mostly unrelated electrochemical topics, here the editors aim to offer articles by experts on a single general theme of special importance. Aspects specific to particular methods or to the authors' own research are to be relegated to the background. In the first volume of this new series, which dealt with the adsorption of molecules on metal electrodes, these aims were not fully achieved. In contrast the impression from the chapter titles in this second volume is of a treatment that is not dominated by methods. As the title of the volume indicates, the emphasis is on a general consideration of all types of phase boundaries under the influence of electric fields, which of course includes both solid–liquid and solid–gas interfaces. The fact that in nearly every case the solid phase is a metal, despite the growing interest in semiconductor electrodes, is an indication of the large difference that still exists with regard to the state of knowledge and development of general models. On the other hand, numerous studies in the area of vacuum physics are mentioned.

In the first chapter M. van Hove gives a thoroughly systematic description of the surface crystallography at metal–gas interfaces. After a lucid introduction to the standard nomenclature and a brief description of some important methods of investigation, the author discusses typical examples of surface reconstruction and adsorption. In Chapter 2, P. N. Ross extends the above treatment to solid–liquid interfaces. Here there is slightly more emphasis on experimental aspects, as in this case the surface crystallography is often studied by ex-situ methods. The critical process of transfering the sample is discussed in detail. The examples are confined to systems that are thoroughly understood, namely metallic and ionic adsorbates and surface structural changes that depend on the electrode potential. In Chapter 3 surface reconstruction is discussed very methodically for many different electrochemical systems by D. M. Kolb. However, the experimental results described are so many and varied and are covered in such detail that this sometimes threatens to obscure the essentials. The surface crystallography existing in vacuum becomes modified on contact with a condensed phase, and then depends on many other parameters and is by no means always stable. However, any expectations that this might open up new methods in electrocatalysis are dampened by sober considerations. The interaction with the reactands, which are usually strongly adsorbed, destroys the reconstruction and with it any catalytically active surface properties that it conferred. In the fourth chapter M. P. Soriaga discusses molecular adsorption at single crystal surfaces. At first glance it might seem that this contribution rightfully belongs instead to the first volume of the series, but its presence here is fully justified by the emphasis on structural aspects of the adsorbate, with only a brief treatment of the experimental procedure and of the relationship to results obtained for metal–gas interfaces. The author concludes by correctly pointing out that the theoretical treatment and modeling of interactions between electrodes and adsorbed molecules has up to now received insufficient attention in relation to its practical importance. In Chapter 5, G. Pirug and H. P. Bonzel discuss the influence of coadsorbed alkali metals on the interactions at a metal–water interface, on the basis of intensive experimental studies of the metal–vapor boundary. Whereas most previous interpretations by electrochemists have been based on the strong adsorption of various anions, this article emphasizes the special role of cations in the double layer. The authors rightly point out that on this topic there is still insufficient interaction between vacuum physics and electrochemistry.

In the sixth chapter W. Schmickler considers the metal–electrolyte phase boundary from the standpoint of theoretical physics. The author discusses all the main aspects of developing models and illustrates these by examples involving the specific adsorption of simple ions. Continuing this topic in the following chapter, K. Heinziger reports on molecular dynamics studies of water molecules at phase boundaries. Experiments on solid–vapor interfaces have confirmed these calculations, encouraging the author to believe (hopefully correctly) that the method can soon be applied successfully to phase boundaries of importance in electrochemistry. In Chapter 8, Z. Borkowska and U. Stimming discuss the effects of anions in forming structures within the electrochemical double layer, based on studies of electrochemical phase boundaries in a hydrated perchloric acid over a wide range of temperatures. Regrettably, however, it is not clear how these studies can contribute to a better understanding of structured electrochemical double layers. In the last (very long) chapter, F. T. Wagner discusses methods and results in the simulation of electrochemical double layers in ultra-high vacuum (UHV), a technique introduced by J. K. Sass. This article goes far beyond the ground covered in Chapter 5 (Pirug and Bonzel); the critical reader may feel that it might have better to leave out the shorter of these two chapters, or to relate it more appropriately to Chapter 9. After briefly introducing some important physical concepts for discussing phase boundaries, Wagner takes a

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

critical look at some common prejudices about the validity of carrying over results from UHV studies into electrochemistry and refutes them. Although a comprehensive theoretical model of the double layer in UHV is still only a dream, the extensive knowledge gained from UHV studies has proved very useful in the interpretation of spectroelectrochemical results. The growing importance of spectroscopic methods in electrochemistry makes it certain that modeling of the double layer in UHV will continue to play an important role in the future.

The visual quality of the text and figures comes up to one's highest expectations. Each article is followed by a bibliography, though these vary considerably in comprehensiveness. Even many very recent papers that appeared only shortly before the manuscript deadline are included, but happily there are few references to unpublished work, making it easy for the interested reader to explore further. The short index is a useful aid to finding specific topics in the articles. The book will be of great value to the readership envisaged by the editors, namely advanced students and scientists with interests in the chemistry and physics of phase boundaries involving electric fields. The book is an essential addition to every relevant departmental library, but owing to the high price, understandable in view of the high standard of production and the limited potential readership, it is less likely to find its way onto readers' private bookshelves.

Nobel Laureates in Chemistry, 1901–1992. Edited by *L. K. James*. American Chemical Society, Washington, DC, 1993. 814 pp., hardcover $ 69.95/paperback $ 34.95.—ISBN 0-8412-2459-5/0-8412-2690-3

Nobel prizes have a special fascination like that of Oscars or Olympic medals, with a public appeal which is widely promoted, despite the pretence to scorn hero worship as a relic of feudalism. We need our role models. It is the personalities rather than the circumstances that seem to be important in making things happen. The fuss and the jostling for the limelight in the competition for Nobel prizes may appear unseemly, but probably only to those who have no real prospect of success in that game. For the observer of current events, Nobel prize awards represent the ultimate in top-class research. The public looks on spellbound, enjoys the spectacle of the rather comical eggheads in their remote world winning the lottery, and returns to everyday business. But an emotional response of this kind encourages the public to open its purse to fund research, as people then feel that they have been involved and have shared in the results, especially when the laurel wreaths indirectly enhance the standing of their own region.

This latest volume in the American Chemical Society's *History of Modern Chemical Sciences* series also aims to harness that response and thereby reach a wider and younger audience, and by revealing the roots of the towering and ever more exciting tree of chemical knowledge to inform and encourage readers to emulate these models. What could be better for that purpose than brief portraits of the Nobel prizewinners, describing their origins, education, and achievements, and finally their rewards of recognition? These are inspiring success stories with a dash of anecdote, rarely a progress from Cinderella to queen, but often from stable-lad to winner of races.

Why have the Nobel prizes come to be so highly esteemed? It is because the choice of winners from the large range of candidates has, on the whole, been based on decisions that were generally accepted. Right from the start this was a difficult task calling for many compromises, because although the possibilities to be considered were initially few and manageable, a great many suggestions and arguments were received. The Nobel Committee has taken great care in laying down standards, in justifying these, and in keeping to them—a fact which must always be acknowledged despite the fashionable trend to criticize. Its decisions command a level of trust resting on a quality that has now been maintained for nearly a hundred years.

At the turn of the century when Alfred Nobel, to ease his conscience which was weighed down by dynamite, donated his wealth to set up the foundation, most people were convinced that there was light at the end of the tunnel of progress (although he himself may already have had doubts). The attitude of innocent dilettantist euphoria had given way to a serious, science-driven industrialization, and the successes of the chemical and physics-based industries and of medicine, in both therapy and theory, had given people still unused to such ideas an appreciation of the possibilities of applied research. The association of names of individual scientists with results of research in fields such as dyes, medicines, vaccines, X-rays, and atomic and cosmic forces was just at the limit of understanding of lay people. Information and emotion were supplied by the press, and competition by the spirit of empire—the best performances of the year and of a lifetime were rewarded. There was a widespread feeling of satisfaction that we had evidently come quite a long way.

Since then the Nobel prizes have been awarded on almost ninety occasions (the sequence was not completely stopped even during wars, despite the fact that these did not leave even the Swedish peacefulness entirely undisturbed). The list of over a hundred prizewinners is impressive enough in itself—the first recipients: J. H. van't Hoff, E. Fischer, S. Arrhenius, and the youngest ones at the time: E. J. Corey, R. R. Ernst, R. A. Marcus—it is also interesting that both the beginning and the end of the current list illustrate the close interaction that has always existed between the molecular and biological sciences. But even these few names are enough to show how, since the beginning around 1900, the emphasis in research of Nobel prize quality has moved from Europe to North America, catalyzed by the large forced exodus of talent during the 1930s, now seen with hindsight by those not involved as a blessing. The shift of interest from organic and physical chemistry to biochemistry and from single molecules to the clusters and macromolecules of interacting aggregates also reflects the prevailing trend. As well as rewarding individual achievements, in other cases a lifetime's work was honored. To reinforce this point, one's sense of justice is reassured by the recognition not only of a timely piece of research but also of a breakthrough in concepts or in the introduction of new (perhaps easier) methods, often involving systems several orders of magnitude smaller. The fact that the self-made man has become rarer, while success depends more on origins and background, illustrates the increasing trend to professionalization. It also follows from this that the Nobel prizes will remain the preserve of the highly industrialized nations unless special help is given. Thus it is a pointless exercise to identify "family pedigrees" in which Nobel prizes breed more Nobel prizes. Although that is true (sometimes even with regard to multiplication of families), it is not the Nobel prizes and their aura but the research group and its ambience that generate a tradition of success and eventually gain recognition in Stockholm.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2020-2118 $ 10.00+.25/0

The way in which the Nobel prize system was set up under the old guard, who had so many irons in the fire, seems to have been rather haphazard. The specialization of modern times may make it easier to identify a particular achievement with one, or perhaps two, names, but there are so many! This too is a result of overall trends.

These biographies, with a mixture of broad perspectives and sidelong glances, of facts and traditions, written with expert knowledge but regrettably often in a rather colorless style, together paint a picture that is full of valuable information. Using small brush-strokes it shows how each Nobel laureate became involved in his or her field of work, how the environment and the thirst for knowledge interacted and formed each other, and how the route to the Nobel prize often seems in retrospect to have been laid down in advance in a unique and direct way—at least in these accounts, which undoubtedly have as one of their aims to motivate students, in the hope that they will not only learn about science and history but will themselves generate more.

Most of the laureates' biographies in this well produced and stoutly bound book are compressed into about ten pages and accompanied by a contemporary photograph from the archives of the Nobel foundation. A clear and consistent structure is used throughout, in which upbringing and education are followed by scientific achievements and honors, and in many cases by a short "moral of the story" which can be distilled from that particular life. It is a book for relaxation and bedtime reading—but certainly not for the evening of life, rather for the young, even though the style is a little dull. But anyway, young people are very sensible nowadays.

Leaving No Stone Unturned: Pathways in Organometallic Chemistry. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *F. G. A. Stone.* American Chemical Society, Washington, DC, 1993. XXIV, 240 pp., hardcover $ 24.95.—ISBN 0-8412-1826-9

"Research in chemistry has enabled me and my wife to establish an extensive but nevertheless tightly knit network of human relations with other chemists, and in many cases with their families also. This network, the excitement of discovery, and the game of making new compounds, are probably the main factors for the word 'retirement' not being found in my vocabulary. One is singularly fortunate if one is able to focus for most of one's waking hours on a type of work that grows into a hobby, while at the same time opportunities occur for social contact with colleagues of many different nationalities and ethnic backgrounds, all having in common an interest in investigating new fields." (p. 202).

This statement by Gordon Stone, a universally well-liked "chemist's chemist" and "experimentalist's experimenter" with a "green thumb" for synthesis, summarizes his multiple loves—for chemistry, research, teaching, family, students, and colleagues. In the words of a former student, "He cares for the whole of the individual, just as he cares for the whole of chemistry." (p. xxi). Stone's dedication is evident: "My students never need to make an appointment. I am like a pastor who looks after his parishioners." (p. xxi). Another characteristic trait is his modesty. He sums up his achievements with the disarming pronouncement: "I have been lucky to do what I liked" (p. xix). He begins his volume in Jeff Seeman's popular series with a paean to the rapidly expanding field of organometallic chemistry and then explains: "a collection of autobiographies by active practitioners of organic chemistry would be incomplete without a contribution from an organometallic chemist, and this is my main justification for writing this book." (p. 4).

Francis Gordon Albert Stone (he never uses his full name) was born in Exeter, southwest England in 1925, the only child of Sidney Charles Stone, a British civil servant, and his wife Florence. His parents wanted him to become an accountant, but he decided on a career in chemistry, his best subject at the Exeter school. However, he was rejected by London University because the grades on his final examinations at Exeter were unsatisfactory (the letter of rejection is reproduced on p. 10). Undeterred, he spent a year at Medway Technical College at Gillingham to improve his knowledge of chemistry and applied to three colleges at Cambridge University on the basis of these same "unsatisfactory" examination grades. Accepted by all three, in 1945 he entered Christ's College, Cambridge, the first in his family to attend a university. He graduated in 1948 with first class honors. Always one to see the positive side of any event in his life and never one to rationalize his shortcomings, Stone remarks: "The lesson I learned from my rejection by London University was to have faith in one's own ability and not to be easily rebuffed by the actions of others." (p. 11).

Stone received his Ph.D. degree for his research on boron hydrides supervised by Harry Emeléus in 1951, whereupon he spent two years as a Fulbright postdoctoral scholar at the University of Southern California with Anton B. Burg, from whom he learned that "success in chemistry is most likely to result from careful experimentation and especially hard work." (p. 17). He also received "superb training in the manipulation of compounds in the absence of air..., which ...proved invaluable when [he] took up research in organometallic chemistry." (p. 18).

In 1954 Stone met Judith Hislop of Sydney, Australia, whom he subsequently married and to whom his book is dedicated. The couple later had three sons—James, Peter, and Derek. That same year he joined Eugene G. Rochow's group at Harvard University as a postdoctoral assistant. Several months later he became an instructor and began his first independent research (on boron compounds) with William A. G. Graham and Herbert D. Kaesz, the first of a long series of graduate students, who figure prominently on almost every page of the book. When future (1973) Nobel chemistry laureate Geoffrey Wilkinson left Harvard for Imperial College, London in 1956, Stone was appointed to the vacant assistant professorship, which included the teaching of a graduate course in advanced inorganic chemistry. In preparing his lectures from the original literature he found that the most exciting articles involved the synthesis of transition metal compounds with organic ligands, the field in which Wilkinson had specialized. In 1958 R. Bruce King and Tom A. Manuel became the first of his numerous graduate students to work on organometallic compounds.

In 1962 Stone returned to Great Britain to join the staff of Queen Mary College of the University of London, where he remained for only ten months. In 1963 he moved to Bristol University to become the first occupant of a newly established chair of inorganic chemistry. During his 27 years at Bristol he never took a sabbatical leave because he is "a firm believer in the need for research supervisors to be on hand to remove as far as possible any real or imagined impediments placed in the way of the work being done by their young colleagues." (p. 117). Here, as well as continuing his research on synthetic organometallic chemistry with undiminished interest, he served on a number of important but time-consuming govern-

ment committees, work to which he devotes an entire chapter. The British University Grants Committee appointed him chairman of its chemistry review panel. The results of his review of teaching and research in chemistry and their funding at British universities, published as *University Chemistry: The Way Forward* (1988), became known as "the Stone Report" (he modestly neglects to mention this fact).

In 1990 Stone reached the mandatory retirement age of 65 and moved to Baylor University to continue his research under the auspices of the Robert A. Welch Foundation. Typically concerned with his students, he now accepts only postdoctoral fellows because he thinks that he might become too old to supervise graduate students during what he considers an excessively long time required to complete the doctoral program in the United States. By retaining their home in England as well as maintaining one in Waco, the Stones are able to avoid both the British winter and the Texas summer.

Stone began his research on organometallic compounds at a time when the subject was just beginning to attract wide interest. Consequently, he and his students are responsible for many of the fundamental discoveries in the field, including cyclooctatetraenyl, cycloheptatrienyl, allyl, and fluorocarbon complexes of transition metals, species with silicon–ruthenium bonds, iron–tin compounds, many metal cluster compounds, including those with bridging alkylidyne ligands, pentalene complexes, metallacarboranes, low-valent platinum compounds such as $[Pt(C_2H_4)_3]$, complexes with heteronuclear metal–metal bonds, including bonds bridged by alkylidene or alkylidyne groups, and most recently (in Texas), alkylidyne(carborane)-metal species. He also pioneered the use of instruments in characterizing these new compounds.

The consummate synthetic chemist, Stone devotes his penultimate chapter to answering the question "Why Make New Compounds?" He maintains not only that "in the domain of organometallic chemistry those engaged in synthesis have usually been far ahead of predictions made by theoretical chemists" (p. 107) but also that "predictions from theoretical chemists can sometimes impede preparative work." (p. 107). He further believes that "research projects at the undergraduate level serve the useful purpose of stressing that chemistry is an intensely practical subject and that theory is driven by experiment and not, as often presented, the other way around." (p. 198). Yet he pays tribute to theory in his acknowledgement of his use of 1981 Nobel chemistry laureate Roald Hoffmann's "isolobal model". In a holograph letter of July 17, 1992 (p. xxiii) congratulating Stone on receiving an honorary degree from his home university, Exeter, Hoffmann writes: "What has always impressed me is how you could know ahead of time what the theoreticians would later come up with! So while I benefitted from your popularization of the isolobal analogy as a synthetic tool, I know full well that *you* didn't need that analogy at all, that you know deeply and surely, what it took me and others, in our round about way, years to find."

Synthetic organometallic chemistry is an intensely competitive field, a fact of which Stone is well aware: "Just as an actor is judged by his most recent performance, so organometallic chemists are judged by their most recent work." (p. 105). However, he is supremely sensitive to the feelings of his students and coworkers, which remain his primary concern. For example, whenever a breakthrough occurred in his laboratory, he would encourage other members of his group to place their own projects on hold and help with the new experimental work, but he would "leave no doubt in the mind of any member of the group that each individual's contribution will not be forgotten." (p. 139). He also states that "it's very hard to work in my group and not get a publication as a result" (p. xxi)..." in order to make the coauthor's curriculum vitae look reasonable for the next job application." (p. 182). But his concern with his students extends long after they have worked with him. He details their achievements and awards and follows their careers as conscientiously as his own. Most of the book's 61 illustrations are informal snapshots of Stone with students or colleagues taken at home or during his extensive travels. Scrupulous in assigning credit, he admits: "My co-workers have suggested many original projects for research that I would not have conceived myself." (p. 197).

This engaging autobiography of a warm, personable human being, one of the giants of organometallic chemistry, should interest not only researchers in the field but also chemists and historians of chemistry in general.

The Kinetics of Heterogeneous Electron Transfer Reactions in Polar Solvents

William Ronald Fawcett* and Marcin Opallo

Data for heterogeneous electron transfer reactions obtained in the last ten years have been examined within the context of contemporary theory. Special attention is focused on systems for which rate constants and activation parameters are available as functions of solvent and of temperature. The role of reactant structure in determining the kinetic parameters is also considered. Double layer effects both at unmodified and modified electrodes are discussed in detail. Experimental techniques, especially those suited to measuring fast reactions, are also outlined.

1. Introduction

Since the early 1980s there has been a great increase in interest in medium effects for electron transfer (ET) reactions. This revival was spurred by the appearance of several theoretical papers[1-4] that predicted the existence of dynamic solvent effects in the kinetics of ET. The first experimental evidence for such a dynamic effect in a heterogeneous ET reaction, presented by Kapturkiewicz and Behr,[5] was quickly followed by a report describing similar effects for a homogeneous ET reaction.[6] Since then a significant body of experimental evidence for solvent and other medium effects has been gathered in the literature. These experiments have focused on three areas, namely, homogeneous self-exchange ET, heterogeneous ET, and time-resolved fluorescence spectroscopy involving intramolecular ET. At the same time, significant advances have been made in the theoretical description of ET processes.

Several recent reviews have focused on the development of the theory of this elementary reaction and its application to experimental results.[7-9] Heitele[9] has examined in a particularly lucid and useful manner the theory of dynamic solvent effects in ET. On the experimental side, Barbara and Jarzeba[10] have reviewed experimental results in time-resolved fluorescence spectroscopy. Weaver[11] has discussed data for homogeneous ET reactions, especially those obtained in his laboratory.

The subject of the present review is heterogeneous ET. The discussion is limited to simple reactions, that is, those in which both oxidized and reduced forms remain in solution, only one electron is transferred, and no chemical bonds are broken or formed. Since the original work of Kapturkiewicz and Behr[5] on dynamic solvent effects, a large number of related studies have appeared in the literature. Our goal is to examine these results within the context of contemporary theoretical development and to show their relationship to other experiments describing medium effects in ET. No attempt is made here to discuss theory in detail since this has already been done.[7-9] However, a few aspects of theory that were not considered in previous reviews and that are particularly relevant to the analysis of experimental data are considered. As well as presenting the important results obtained, we also discuss advances in experimental techniques. It is important to emphasize that the improved understanding of the role of the medium in ET has been due in great part to the fact that faster processes in condensed media can now be followed experimentally with precision. Finally, it should be pointed out that heterogeneous ET is usually studied in the presence of an inert electrolyte to improve solution conductivity and maintain diffusion as a means of mass transfer. As a result, the medium for the ET reaction involves not only the solvent, but also the ions of the electrolyte that form the double layer at the electrode. Double layer effects play an important role in heterogeneous ET and are also considered in this review.

2. Theory

2.1. Estimation of the Activation Parameters

One of the important problems considered in recent years is improvement of the estimation of the Gibbs energy of activation ΔG^* and related kinetic parameters. ΔG^* is traditionally regarded as composed of two parts, the inner sphere contribution ΔG^*_{is} and the outer sphere contribution ΔG^*_{os}.[12] Estimation of the former requires a description of the changes in bond lengths and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2131 $ 10.00+.25/0

angles that accompany the activation process, and is often based on the appropriate spectroscopic data.[13] The outer sphere component, which accounts for the work done to reorganize the solvent environment around the reactant has usually been calculated by using a model based on the Born theory of ionic solvation.[12, 13] In the case of the simple heterogeneous ET reaction [Eq. (1)] this contribution is given by Equation (2),

$$A + e \rightarrow B \tag{1}$$

$$\Delta G_{os}^{*} = \frac{N_0 e_0^2}{32\pi\varepsilon_0}\left(\frac{1}{r_A} - \frac{1}{r_c}\right)\left(\frac{1}{\varepsilon_{op}} - \frac{1}{\varepsilon_s}\right) \tag{2}$$

where N_0 is the Avogadro constant, e_0 the fundamental electronic charge, r_A the radius of the reactant A represented as a sphere, r_c the distance from its image in the electrode, ε_{op} the optical relative permittivity of the solvent and ε_s the corresponding static value (measured at very low frequencies at which the molecules are able to reorient to the changing electric field), and ε_0 the permittivity of free space. An important point in application of this relationship is the value of r_A, since most reactants are not spherical. This aspect is considered in more detail in Section 6. In determining ΔG_{os}^{*} in recent work, the distance r_c has usually been assumed to be effectively infinity, the stabilizing effect of any image formed in the electrode being neglected. Certainly, in cases where in the ET reaction the reactant and product do not interact with the electrode itself, r_c is equal to $2r_A + 2d_i$ where d_i is the thickness of the layer of solvent molecules and closest approaching counterions, that is, between the reactant and the geometrical electrode/solution interface. Thus, r_c corresponds at least to three molecular diameters; that is, it is of the order of six times r_A. Moreover, the efficiency with which the image is formed in the electrode can be questioned in the light of the spatial dispersion of the solvent dielectric permittivity and electric field penetration into the metal electrode.[14, 15] Kornyshev et al.[14, 15] applied the nonlocal electrostatic treatment to the estimation of ΔG_{os}^{*} for both heterogeneous and homogeneous ET reactions, and concluded that this quantity actually increases as the reaction site moves closer to the electrode, instead of decreasing as predicted by Equation (2). However, the sharp boundary model used in these calculations[15] can be criticized, because it is not applicable in regions where the dielectric properties of the system are changing markedly over short distances, such as near a reactant at the reaction site in the double layer. Nevertheless, a comparison of activation enthalpies for the same reaction under homogeneous and heterogeneous conditions (see Section 5, Table 3) suggests the r_c is sufficiently large that $1/r_c$ can be neglected in the calculation of ΔG_{os}^{*} for the heterogeneous process. This assumption is made in the following discussion.

The estimation of ΔG_{os}^{*} has been further improved by the use of nonprimitive models for ionic solvation, especially the mean spherical approximation (MSA).[16, 17] On the basis of the hypothetical two-step charging process associated with thermal electron transfer described by Marcus,[18] ΔG_{os}^{*} can be regarded as the difference between the Gibbs solvation energies of the reacting system at optical frequencies and at static frequency. This can be seen when Equation (2) is rewritten as Equation (3),

$$\Delta G_{os}^{*} = -\frac{N_0 e_0^2}{32\pi\varepsilon_0 r_A}\left(1 - \frac{1}{\varepsilon_{op}}\right) + \frac{N_0 e_0^2}{32\pi\varepsilon_0 r_A}\left(1 - \frac{1}{\varepsilon_s}\right) \tag{3}$$

a form that clearly shows the relationship of the Marcus model to the Born continuum model for ionic solvation. Following earlier work of Wolynes,[19] McManis and Weaver[20] wrote expression (4) for ΔG_{os}^{*} in the MSA, where r_s is the radius of a solvent molecule represented as a sphere, and λ_{op} and λ_s are polarization parameters calculated from ε_{op} and ε_s [Eq. (5), (6)].

$$\Delta G_{os}^{*} = -\frac{N_0 e_0^2}{32\pi\varepsilon_0}\left[\left(1 - \frac{1}{\varepsilon_{op}}\right)\frac{1}{(r_A + r_s/\lambda_{op})} - \left(1 - \frac{1}{\varepsilon_s}\right)\frac{1}{(r_A + r_s/\lambda_s)}\right] \tag{4}$$

$$16\varepsilon_{op} = \lambda_{op}^2(1 + \lambda_{op})^4 \tag{5}$$

$$16\varepsilon_s = \lambda_s^2(1 + \lambda_s)^4 \tag{6}$$

When applied to ion solvation at static frequencies,[21] the parameter λ_s accounts for the polarizability, softness, and nonsphericity of the solvent molecule, which is otherwise represented as a hard sphere with a central point dipole. For polar solvents, the value of λ_s is in the range of 2.0 to 2.9,[22] so the MSA estimate of the static contribution to ΔG_{os}^{*} is considerably smaller than the Born estimate. In the case of the high frequency solvation, λ_{op} is close to unity; the optical contribution to ΔG_{os}^{*} is thus also greatly reduced from the continuum value. However, it is doubtful whether the MSA model developed for a system of hard spheres with point charges and point dipoles at static frequencies[19–22] can be applied at optical frequencies

W. Ronald Fawcett was born in Chatham, Ontario, Canada in 1939. He studied physics and chemistry at the University of Toronto, obtaining a Ph.D. in physical chemistry in 1964 under the direction of Professor M. J. Dignam. He then spent two years in the laboratory of Professor Roger Parsons at the University of Bristol as a NATO post-doctoral fellow. In 1966 he returned to Canada to join the faculty of the Chemistry Department at the University of Guelph, obtaining the rank of Professor in 1977. In 1984, he moved to the University of California at Davis. His research interests include theoretical and experimental studies of double layer structure and its role in the kinetics of interfacial reactions. Much of his experimental work is associated with the electrochemistry of nonaqueous solvents and has included the use of these systems in high energy density batteries and the production of semiconductors based on metal chalcogenides.

where there is no orientational contribution to dipolar polarization.[23] Thus, the McManis–Weaver (MW) model[20] can be questioned within the context of the MSA.

A quite different approach to applying the MSA to estimation of ΔG^{*}_{os} was taken by Fawcett and Blum (FB).[23] Firstly, they assumed that the optical contribution is given to a good approximation by the Born estimate. Secondly, the polarization parameter at static frequencies was obtained from the Gibbs solvation energies of simple monoatomic, monovalent ions rather than from Equation (6). As a result, Equation (7) gives the expression

$$\Delta G^{*}_{os} = -\frac{N_0 e_0^2}{32\pi\varepsilon_0}\left[\left(1-\frac{1}{\varepsilon_{op}}\right)\frac{1}{r_A}-\left(1-\frac{1}{\varepsilon_s}\right)\frac{1}{(r_A+r_s/\lambda_i)}\right] \quad (7)$$

for ΔG^{*}_{os}, where the parameter λ_i depends on whether the ion is a cation or an anion, but not on its size. Stated otherwise, the FB model predicts that the Gibbs activation energy to form a monovalent cation from a neutral molecule by electrooxidation is different from that to form a monovalent anion from the same reactant by electroreduction, all other system parameters remaining the same. This follows from the experimental observation that the extent of solvation of cations and anions of the same radius in a given solvent is not the same.[24]

Two other activation parameters, the enthalpy ΔH^{*}_{os} and entropy of activation ΔS^{*}_{os}, may be determined from the temperature coefficient of the Gibbs energy. From Equation (3), estimation of ΔS^{*}_{os} on the basis of the Born model requires knowledge of the temperature coefficients $d\varepsilon_s/dT$ and $d\varepsilon_{op}/dT$, which are available for all polar solvents used in electrochemical studies.[24, 25] In the case of the MW model the temperature coefficients $d\lambda_s/dT$ and $d\lambda_{op}/dT$ are also needed. These may be obtained from the experimental coefficients $d\varepsilon_s/dT$ and $d\varepsilon_{op}/dT$ after differentiating Equations (5) and (6) with respect to temperature.[22] Finally, the temperature coefficient $d\lambda_i/dT$ is required in the FB model. These quantities were extracted from experimental solvation entropy data for the alkali metal cations and halide anions.[22] Once ΔS^{*}_{os} has been obtained, the activation enthalpy ΔH^{*}_{os} can be found by adding $T\Delta S^{*}_{os}$ to ΔG^{*}_{os}.

Values of ΔG^{*}_{os} and ΔH^{*}_{os} determined from the models described here in twelve polar solvents are collated in Table 1. The reactant size parameter r_A was set equal to 0.37 nm, a value appropriate for the metallocenes,[26] whose ET kinetics have been studied extensively both homogeneously and heterogeneously.[11] ΔG^{*}_{os} and ΔH^{*}_{os} differ by only a few kJ mol^{-1} at the most, and in the MSA model the difference is negligible for most solvents. However, the assumption made regarding the high frequency contribution and the method of estimating the polarization parameter at low frequencies affect the values based on the MSA considerably. ΔG^{*}_{os} estimated from the MW model is about 90% of that obtained by the continuum Marcus model, but the FB model provides estimates of ΔG^{*}_{os} only 62% of the Marcus estimate for a reaction involving cations, and 80% for a reaction involving anions. These differences are significant, and the quality of the models should be able to be verified experimentally.

The major problem with the MSA approach is that a proper estimate of ion–dipole interactions at high frequencies has yet to be made. Some support for the FB assumption comes from the finding that the MSA estimates of the dielectric properties of a polar solvent at optical frequencies agree well with those based on classical models.[27] However, the separate problem of ion–dipole interactions at high frequencies needs to be addressed as well.

2.2. Estimation of the Pre-Exponential Factor

Much has been written already about the pre-exponential factor in the rate constant for ET especially with respect to dynamic solvent effects.[1–4, 7, 9, 11] The discussion here is limited to aspects that relate to heterogeneous ET and to appropriate expressions for the rate constant. In the transition state theory formalism,[13] the standard heterogeneous rate constant is usually written as in Equation (8), where κ is the electronic trans-

$$k_s = \kappa K_p \nu_n \exp(-\Delta G^{*}/RT) \quad (8)$$

mission coefficient, K_p the encounter pre-equilibrium constant, and ν_n the nuclear barrier-crossing frequency. κ is unity for an adiabatic reaction and falls below unity as the extent of diabaticity increases. The extent of diabaticity is connected with the degree of interaction between the free energy surfaces for the reactant and product, and is determined by the electronic matrix coupling element H_{ab}.[13] The value of H_{ab} can also affect the

Table 1. Gibbs energy and enthalpy of activation for a simple heterogeneous electron transfer reaction in selected polar solvents according to the Marcus [12], McManis–Weaver (MW) [20], and Fawcett-Blum (FB) models [23]. The reactant radius is assumed to be 0.37 nm and the imaging distance, ∞. The units for ΔG^{*}_{os} and ΔH^{*}_{os} are kJ mol^{-1}. Oxidations to cations are indicated by (+/0) and reduction to anions by (0/−).

Solvent	Marcus model		MSA (MW)		MSA (FB)			
	ΔG^{*}_{os}	ΔH^{*}_{os}	ΔG^{*}_{os}	ΔH^{*}_{os}	$\Delta G^{*}_{os}(+/0)$	$\Delta H^{*}_{os}(+/0)$	$\Delta G^{*}_{os}(0/-)$	$\Delta H^{*}_{os}(0/-)$
acetone (AC)	23.3	20.8	20.1	20.8	15.3	14.0	18.4	18.2
acetonitrile (AN)	24.8	21.2	22.5	21.8	16.1	14.4	20.3	19.3
butyronitrile (BuN)	22.5	20.3	19.3	19.8	14.3	13.9	17.6	18.0
benzonitrile (BzN)	18.3	16.5	16.5	17.1	9.5	9.0	13.6	14.0
dimethylacetamide (DMA)	21.5	18.3	19.6	20.2	13.9	11.9	16.1	15.3
dimethylformamide (DMF)	21.7	19.2	19.8	20.4	14.0	12.9	16.8	17.6
dimethylsulfoxide (DMSO)	20.5	18.1	19.5	18.7	12.7	12.3	16.1	16.7
hexamethylphosphoramide (HMPA)	20.5	19.5	17.7	20.5	13.1	13.4	14.9	16.4
methanol (MeOH)	25.2	23.2	23.0	24.1	16.9	16.3	22.4	20.9
nitrobenzene (NB)	18.2	16.8	17.0	18.7	8.9	8.8	13.9	14.8
nitromethane (NM)	23.3	20.3	21.4	21.2	14.1	12.8	19.0	18.4
propylenecarbonate (PC)	22.5	19.7	21.3	21.0	13.7	12.9	17.8	17.3

nuclear barrier-crossing frequency ν_n: when H_{ab} is large and the barrier rounded, ν_n falls below its value for small values of H_{ab}.[4, 28] Simple relationships connecting these quantities are given by the Landau–Zener model[13] according to which the electron tunneling frequency ν_e is given by Equation (9), where N_0 is Avogadro's constant and h Planck's constant. The electronic transmission coefficient is then given by Equation (10).

$$\nu_e = \frac{2H_{ab}^2}{N_0 h}\left(\frac{4\pi^3}{\Delta G^*/RT}\right)^{1/2} \tag{9}$$

$$\kappa = \frac{2[1 - \exp(-\nu_e/2\nu_n)]}{2 - \exp(-\nu_e/2\nu_n)} \tag{10}$$

When $\nu_e \gg \nu_n$, $\kappa = 1$, and the reaction is adiabatic. However, when $\nu_e \ll \nu_n$, the expression for κ is given by Equation (11), and

$$\kappa = \nu_e/\nu_n \tag{11}$$

electron tunneling controls the magnitude of the pre-exponential factor. This diabatic limit occurs in cases where the extent of interaction between the reactant and electrode is minimized, for instance, in the presence of a blocking film on the electrode. In this case both H_{ab} and ν_e are small, and κ is given by Equation (11). Obviously, the structure of the electrode/solution interface plays an important role in determining these quantities.

The encounter pre-equilibrium constant K_p has been defined within the context of the encounter pre-equilibrium model for heterogeneous ET reactions[29] and contains the terms describing double layer and steric effects. In the absence of steric interactions, K_p is approximately 60 pm for a spherical reactant.[29] Thus, after correction for double layer effects, the upper limit for the product κK_p is about 60 pm. Lower values can be due to steric effects or departure from reaction adiabaticity. Because of the very approximate nature of the models used to estimate κ and K_p individually, it is preferable to cite only the product κK_p obtained from an analysis of experimental data.[30]

The component ν_n of the pre-exponential factor depends on vibrational modes within the reactant and the solvent to an extent which is contingent upon the relative importance of the inner and outer sphere contributions to the activation barrier. When the reaction is adiabatic and the inner sphere contribution to ΔG^* is small, this frequency is given by Equation (12),[1–4] where τ_L is the longitudinal solvent relaxation time. For Debye solvents in the continuum approximation, τ_L is given by Equation (13),[31] where ε_∞ is the high-frequency relative solvent permittivity and τ_D the Debye relaxation time. Values of τ_L have been collected for a large number of polar solvents[32] whose behavior is well approximated by the Debye model. The pre-exponential factor is thus predicted to depend on the solvent's dielectric relaxation properties, parameters which are quite different in origin to those which determine the Gibbs activation energy barrier.

$$\nu_n = \tau_L^{-1}\left(\frac{\Delta G^*}{4\pi RT}\right)^{1/2} \tag{12}$$

$$\tau_L = \frac{\varepsilon_\infty \tau_D}{\varepsilon_s} \tag{13}$$

When the inner sphere activation barrier is large, or the reaction adiabaticity is weak, the dependence of the pre-exponential factor on solvent is weakened. A convenient, approximate way of writing ν_n is then Equation (14),[33] where ν_{is} is the frequency

$$\nu_n = \nu_{is}^{1-\theta}\tau_L^{-\theta} \tag{14}$$

associated with an intramolecular vibration. Combining Equations (8) and (14), the standard rate constant may be expressed as in Equation (15). The factor A contains all the contributions

$$k_s = A\tau_L^{-\theta}\exp(-\Delta G^*/RT) \tag{15}$$

to the pre-exponential factor that to a first approximation do not depend on the solvent, and θ is a fraction between 0 and 1. This way of expressing the solvent dependence was first given by McGuire and McLendon[34] and is especially convenient for discussing the experimentally observed solvent dependence. It is also suggested by the theoretical analysis presented by Nadler and Marcus.[35] An unattractive feature of Equation (15) is that the factor A has fractional dimensions of time when θ is a fraction.[33]

The nuclear barrier-crossing frequency determined from known values of ν_{is} and τ_L is of the order of 10^{12} to 10^{14} s^{-1}. As a result, the upper limit for the pre-exponential factor for heterogeneous ET is approximately 6000 $cm\,s^{-1}$. For a reaction with a Gibbs energy barrier of 20 $kJ\,mol^{-1}$, this corresponds to a standard rate constant of 2 $cm\,s^{-1}$ at 25 °C, which is shown to be of the correct order of magnitude by kinetic data collected to date.

Some mention should be made of solvents that do not follow the simple Debye model. Most solvents exhibit multiple relaxation when the frequency dependence of the dielectric permittivity is examined over a sufficiently wide range.[36] Estimation of τ_L is more complex for these systems,[37] but can be made on the basis of the work of Hynes.[28] Solvents for which non-Debye behavior is important are the alcohols and protic amides.[36] In these systems in which τ_L is a function of time,[37] the value observed at very short times (high-frequency limit) are relevant to the type of reaction considered here. Thus, when the relaxation modes at higher frequencies are considered in the estimation of τ_L for alcohols, the kinetic data obtained in these solvents fall into line with those obtained in simpler solvents.[33]

As a note of caution, it should be remembered that the Debye model on which the estimation of τ_L is based is a continuum model and therefore does not recognize the unique properties of the solvent in the vicinity of the reactant. Thus, the local value of τ_L may be quite different from that obtained from the Debye parameters [Eq. (13)]. However, since the majority of systems studied to date display clear correlations between $\ln k_s$ and $\ln \tau_L$, a simple relation apparently exists between the actual local relaxation time and that estimated by the Debye model. This problem can be elucidated by using ultrafast spectroscopic relaxation techniques, and work in that direction has been initiated.[10]

Finally, it should be noted that the above discussion has been made within the context of Marcus theory, which, strictly speaking, was developed for adiabatic reactions.[12] Electronic effects are included in this model heuristically by way of the electronic transmission coefficient κ. An alternative approach is that of

Dogonadze,[38] which is based on a quantum mechanical description of a manifold of potential energy surfaces. The quantum mechanical approach was recently extended by Schmickler,[39] and its relationship to relevant experimental observations discussed in detail.

3. New Developments In Experimental Methods

To test the predictions made by contemporary theory, the standard rate constants for fast heterogeneous ET reactions must be determined. Efforts in this direction have most often involved ultramicroelectrodes.[40-42] The current flowing in the electrochemical cell when microelectrodes are the working electrode is typically 100 to 1000 times smaller than that at a conventional dropping mercury electrode, so problems due to iR drop and capacitative current are greatly reduced. Ultramicroelectrodes are often metal wires with diameters of the order of microns which are sealed in glass so that a disc is exposed to the electrolyte solution. Electrode materials include platinum, gold, and carbon, and must be carefully polished before each experiment. The gold disc electrode may be modified to a mercury hemisphere by electrodeposition of mercury,[43, 44] or by exposing the gold disc to a pool of highly purified mercury for a short time.[45] Attempts have also been made to fabricate electrodes of nanometer dimensions, called nanodes.[46] However, the area of the conducting material exposed to the solution is extremely difficult to define due to problems in sealing glass to metal rods of such small diameter.[47] As a result interpretation of current–voltage data with a view to obtaining kinetic information is impossible.[47, 48]

The most popular technique for determining kinetic parameters using ultramicroelectrodes has been cyclic voltammetry with fast scan rates.[42, 49, 50] However, extraction of the kinetic information is not straightforward and requires careful analysis of the effects of any uncompensated iR drop.[51]

Another technique introduced recently by Baranski[43, 44, 52-54] is high-frequency a.c. admittance voltammetry at ultramicroelectrodes. By working at higher frequencies, linear mass-transfer conditions are maintained at the working electrode. Moreover, the resistance of the system, and interfacial capacitance are monitored directly in the experiment, which enables any problems with the state of the electrode/solution interface to be easily recognized. Baranski[54] has carried out a detailed analysis of the possible errors in these experiments and shown how the frequency range may be optimized for a kinetic study given the electrode area, solution resistance, and double layer capacity. These experiments involve a fairly simple extension of well-known admittance methods[55, 56] and are easily performed at frequencies up to 100 kHz. As a result, rate constants can be measured up to 10 $cm\,s^{-1}$ with reasonable precision.[44, 45, 53, 57] Bard et al.[58-61] demonstrated that scanning electrochemical microscopy can determine fast ET kinetics precisely. In such an experiment, a ultramicroelectrode of micrometer dimensions, which is normally used to probe the surface of a substrate very close to it, acts as a working electrode, and the reactant is dissolved in the small volume of solution between the ultramicroelectrode and the closely positioned substrate. They have shown that mass transfer conditions are such that fast ET kinetics can be measured in both aqueous[58, 59] and highly resistive nonaqueous media.[60, 61] Results from these experiments for the electrooxidation of ferrocene in acetonitrile[59] and the electroreduction of buckminsterfullerene in benzonitrile[61] agree well with data obtained earlier using high-frequency admittance methods.[53, 57]

Osteryoung et al.[62, 63] described a short time pulse voltammetric technique for studying fast heterogeneous reactions at ultramicroelectrodes. In the normal pulse mode, the electrode potential is stepped to a potential where a faradaic process occurs and held at the final potential for a fixed time of the order of microseconds while the resulting current transient is recorded.[62] The kinetic information is obtained from the faradaic current measured towards the end of the pulse. The electrode is held at each potential for some milliseconds, so that the effects of mass transfer near the electrode are obliterated by diffusion before the next pulse is applied. This technique was recently applied to determining standard rate constants for ferrocene and anthracene in acetonitrile and dichloromethane.[63]

Mahlendorf and Heinze[64] recently used impedance spectroscopy to study fast electron transfer reactions at a Pt electrode of conventional size in highly resistive non-aqueous media. Their method of data analysis differs significantly from that of Baranski[44, 54] and requires the extraction of five parameters by nonlinear regression. They obtained a standard rate constant for the oxidation of ferrocene in dichloromethane slightly smaller than that found by admittance techniques at ultramicroelectrodes[53] when one corrects for a higher experimental temperature (293 K). These authors[64] were unsuccessful in obtaining kinetic data in acetonitrile.

Some feeling for the experimental problems in determining rate constants for fast heterogeneous reactions can be obtained by comparing data reported recently by various laboratories for the kinetics of electrooxidation of ferrocene in acetonitrile (Table 2). Acetonitrile is a solvent of low viscosity with a short longitudinal relaxation time (about 0.2 ps), and ferrocene is a reactant with a low inner sphere reorganization energy. These factors combine to make ET rapid in this system. Examination of the data summarized in Table 2 reveals an unacceptably large range for rate constants reported during the last seven years from 2×10^{-2} to 220 s^{-1}, that is, by four orders of magnitude!

Table 2. Standard rate constants k_s for the electrooxidation of ferrocene at a platinum electrode in acetonitrile from recent experimental studies.

Method	k_s [$cm\,s^{-1}$]	Electrolyte [a]	T [K]	Ref.
fast-scan cyclic voltammetry	1.1	0.5 M $TBABF_4$	[b]	[65]
slow linear sweep voltammetry	0.09	0.1 M TBAP	298	[66]
fast-scan cyclic voltammetry	0.95 ± 0.44	0.6 M TBAP	[b]	[49]
fast-scan cyclic voltammetry	2.2 ± 0.8	0.5 M TEAP	294	[50]
slow linear sweep voltammetry	220 ± 120	0.3 M TBAP	[b]	[46]
high-frequency admittance	2.6 ± 0.3	0.1 M TBAP	285	[53]
cyclic voltammetry	0.0194	0.1 M $LiClO_4$	298	[67]
short time pulse voltammetry	1.2 ± 0.3	0.5 M $TBAPF_6$	298	[63]
scanning electrochemical microscopy	3.8 ± 0.8	0.52 M $TBABF_4$	[b]	[60]

[a] TEAP = tetraethylammonium perchlorate, TBAP = tetrabutylammonium perchlorate, $TBABF_4$ = tetrabutylammonium tetrafluoroborate, $TBAPF_4$ = tetrabutylammonium hexafluorophosphate. [b] Room temperature.

If the two low results[66, 67] and the high result[46] are removed, a much more acceptable range, from 1 to 4 $cm\,s^{-1}$, is found. Differences in electrolyte nature and concentration, and in temperature cause some of the observed scatter in the remaining data. The very high result by Penner et al.[46] is almost certainly due to problems in defining the area of the electrode exposed to the solution when electrodes of diameters significantly less than 1 μm are used.[47, 48, 60] The same comment can be applied to the low result of Russell et al.,[66] who used a ring microelectrode. The low result reported by Abbott et al.[67] at an electrode of conventional dimensions is attributed to uncompensated iR drop. The results obtained by fast-scan cyclic voltammetry at ultramicroelectrodes[49, 50, 65] fall somewhat below the most recent result by Mirkin et al.,[60] probably as a result of some uncompensated iR drop[51] and effects due to nonlinear diffusion.[60, 68] The rate constant estimated from the data of Baranski et al.[53] on the basis of available temperature coefficient data[53, 69, 70] is 3.8 $cm\,s^{-1}$ at 298 K. Thus, the standard rate constants determined for this reaction by scanning electrochemical microscopy and high frequency admittance agree within experimental error. The recent result of Karpinski and Osteryoung[63] is somewhat smaller for reasons that are difficult to assess, but that also may be related to uncompensated iR drop.

The above results demonstrate that one must exercise great care in the measurement of fast ET kinetics. However, experimental techniques are now available which can provide precise data for rapid reactions. This means that important theoretical questions can be examined on the light of reliable experimental data.

4. Effects of the Solvent

The major focus of experimental work during the last ten years has been to understand the role of the solvent.[71, 72] The clear dynamic solvent effect, which is especially pronounced when the inner sphere reorganizational energy is small, is most easily demonstrated by a double logarithmic plot of the standard rate constant measured in various solvents against the solvent's longitudinal relaxation time. Data for the electrooxidation of ferrocene[53] and 1,4-diaminobenzene[73] are shown in Figure 1. Quite good linear relationships are obtained; the slope for the 1,4-diaminobenzene system is less than that for the ferrocene system. The scatter observed is attributed to the fact that the variation in ΔG_{os}^{*} with solvent is ignored in making such a plot. The exact relationship between $\ln k_s$ and $\ln \tau_L$ [Eq. (16)] is derived from Equation (15). The variation in $\ln \tau_L$ obtained

$$\ln k_s = \ln A - \theta \ln \tau_L - \Delta G_{is}^{*}/RT - \Delta G_{os}^{*}/RT \qquad (16)$$

from many systems[5, 45, 53, 69, 73–79] is significantly greater than variation in $\Delta G_{os}^{*}/RT$ for a typical selection of polar solvents. In early work[5] it was also pointed out that a correlation exists with the logarithm of the solvent's viscosity.

Considerable discussion has centered on the separation of the solvent effect due to the pre-exponential factor from that due to the Gibbs energy barrier.[11, 31, 33, 40] If both τ_L and ΔG_{os}^{*} are known, the parameters A and θ are easily determined by using linear regression techniques. In most cases ΔG_{os}^{*} is either unknown or difficult to estimate. However, the Marcus model[12] predicts that it is proportional to the solvent's Pekar factor $\gamma = 1/\varepsilon_{op} - 1/\varepsilon_s$. An approximate linear relationship between ΔG_{os}^{*} and γ is also found when the former quantity is estimated with the FB model.[22] Thus, Equation (16) can be written in an approximate form [Eq. (17)], where K is a solvent independent

$$\ln k_s \approx K - \theta \ln \tau_L - g\gamma \qquad (17)$$

constant and g the proportionality constant relating ΔG_{os}^{*} to γ. The parameters θ, g, and K can be determined from a two-parameter regression with $\ln \tau_L$ and the Pekar factor γ as independent variables.[30] Such an analysis requires that $\ln \tau_L$ and γ are not correlated to one another, and that data are available in at least four of solvents. This analysis has been applied successfully to kinetic data for several heterogeneous ET reactions[30, 45, 77] and is especially useful in obtaining an estimate of θ. Weaver[11] has strongly criticized this method of analysis, pointing out that there is a weak correlation between $\ln \tau_L$ and γ. As illustration, a very weak correlation is present for the group of 15 polar solvents considered in Figure 2 ($r = 0.733$): γ becomes smaller as the value of $\ln \tau_L$ increases. Obviously, any rigorous statistical analysis must take this into consideration,

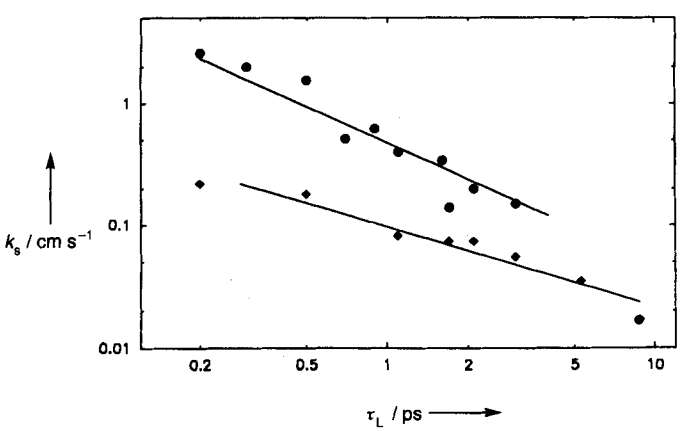

Fig. 1. Double logarithmic plots of the standard rate constant for the electrooxidation of ferrocene (●) [53] and 1,4-diaminobenzene (♦) [73] obtained in aprotic solvents against the longitudinal relaxation time of the solvent.

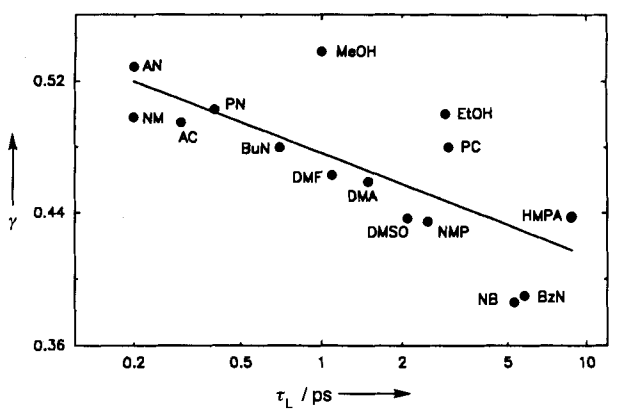

Fig. 2. Plot of the Pekar factor γ for a polar solvent against the logarithm of its longitudinal relaxation time τ_L. The abbreviations for the solvents are given in Table 1 except for ethanol (EtOH), *N*-methylpyrrolidone (NMP) and propionitrile (PN).

but the degree of correlation seen for the 15 solvents chosen would not preclude an analysis of kinetic data obtained, provided the level of experimental error in the standard heterogeneous ET rate constant is low. Therefore, experimental studies of solvent effects must be designed with careful consideration of the degree of correlation between $\ln \tau_L$ and the Pekar factor γ. For example, Phelps et al.[80] recently reported a study of solvent effects on the electrooxidation of several sesquibicyclic hydrazines in the seven polar solvents acetone, acetonitrile, nitromethane, dimethylformamide, dimethylsulfoxide, nitrobenzene, and methanol. The correlation between $\ln \tau_L$ and γ is more important for this group of solvents ($r = 0.895$); consequently, since there is no hope of separating the contributions from the pre-exponential factor and the activation barrier on the basis of Equation (17), less objective methods must be used to assess these data. A more careful selection of solvents used would have allowed firmer conclusions to be made about the role of the solvent for these systems.

In other techniques for analyzing the solvent effect, one of the solvent-dependent terms is assumed to be known, the observed rate constant is corrected for it, and then the other solvent effect is examined with respect to the corrected rate constant.[11] For instance, if one assumes values for ΔG^*_{os}, Equation (16) may be rearranged [Eq. (18)], so that a plot of the left hand side against

$$\ln k_s + \Delta G^*_{os}/RT = \ln A - \Delta G^*_{is}/RT - \theta \ln \tau_L \qquad (18)$$

$\ln \tau_L$ should yield θ. This procedure was followed in two recent studies[80, 81] with the continuum estimates of ΔG^*_{os} [Eq. (2)] and $r_c \rightarrow \infty$. As these values of ΔG^*_{os} are almost certainly high by at least RT and perhaps by as much as 4 RT (depending on the nature of the reaction), the analyses are of doubtful value. A more interesting method of estimating ΔG^*_{os} uses the optical energies for intramolecular ET in the bis(ferrocenyl)acetylene cation and related compounds.[11, 82, 83] The energy associated with transfer of one electron from one ferrocene group to the other across the acetylene bridge is assumed to be directly related to ΔG^*_{os} for homogeneous ET between ferrocene and the ferrocenium cation in a given solvent. The estimates of ΔG^*_{os} from these data are approximately 85% of those obtained by the continuum model and therefore closer to results from the MSA (Table 1). They have mainly been employed in the analysis of data for homogeneous ET with metallocenes.[11] This method of estimating ΔG^*_{os} is considered in more detail in Section 6.

A method applied to perfectly adiabatic reactions ($\theta = 1$) made use of Equations (2) and (12), so that the standard rate constant was corrected for solvent dependence of the pre-exponential factor.[84, 85] (In ref. [85] the method was incorrectly applied to some reactions that are not perfectly adiabatic ($\theta < 1$).) This method is not of great interest now, because a large body of evidence indicates that Equation (2) overestimates the value of ΔG^*_{os} (see Section 2.1).

Some mention should be made of the model for solvent effects on rate constants for heterogeneous ET reactions proposed by Abbott et al.[67] on the basis of data for the oxidation of ferrocene in 16 nonaqueous solvents. These authors ignored the possible dependence of the pre-exponential factor of the rate constant on solvent relaxation, and attributed solvent dependence to variation in ΔG^* with solvent basicity, acidity, polarity, and polarizability. Indeed, the thermodynamic properties in ion solvation can be related to solvent basicity for cations and solvent acidity for anions,[134] but ion solvation at optical frequencies was not considered in the models that they discuss. Considering the poor quality of most correlations reported by Abbott et al.[67] and the probability that their kinetic data are strongly influenced by iR drop, the conclusions reached in their study are difficult to accept.

The general picture that has emerged recently is that the solvent contribution to the pre-exponential factor can vary over a wide range of values of θ. On examination of the available data,[33] we showed that the magnitude of θ was connected to the magnitude of the rate constant observed in a given solvent: as the reaction becomes slower, θ decreases (see Fig. 1). This is attributed to a larger contribution to the activation barrier from internal vibrational modes, and/or weak reaction adiabaticity. When θ is sufficiently small a linear correlation can be observed between the logarithm of the standard rate constant and the Pekar factor γ, as noted by Weaver et al.[86] for the tri(hexafluoroacetylacetonato)ruthenium(III) system.

In conclusion, although many studies of solvent effects have now been carried out, and the presence of a dynamic effect has been clearly established, the role of the solvent cannot be assessed on the basis of these data alone. This is chiefly because no good method of estimating the activation barrier exists except for the simplest systems. One way around this problem is to determine the activation enthalpy for the reaction by studying the temperature dependence of the heterogeneous rate constant. These experiments are considered in the following section.

5. The Experimental Activation Enthalpy

The temperature dependence of the standard rate constant for heterogeneous ET is particularly useful if available in different polar solvents, and also for both the homogeneous and heterogeneous reaction. The expression for the experimental activation enthalpy [Eq. (19)] is derived from Equation (15). ΔH^*_{is} is

$$\Delta H^*_{ex} = -R \frac{\partial \ln k_s}{\partial (1/T)} = \Delta H^*_{is} + \Delta H^*_{os} + \theta \Delta H_L \qquad (19)$$

the inner sphere activation enthalpy, and ΔH_L the enthalpy arising from the temperature dependence of the longitudinal relaxation time. ΔH_L is related to the temperature dependence of the Debye relaxation time τ_D, and the high-frequency and static dielectric constants ε_∞ and ε_s [Eq. (13)]. Values of the temperature coefficients of τ_D and ε_s are available for most polar solvents,[87] and that for ε_∞ can be estimated from the temperature coefficient of the refractive index of the solvent.[88] ΔH_L is not insignificant and varies from about 4 kJ mol^{-1} for solvents in which ET is fast to $\sim$13 kJ mol^{-1} for solvents in which ET is slow.

Solvent-dependent ΔH^*_{ex} data have been collected for a number of heterogeneous ET reactions including the electroreduction of the cobaltacenium cation,[69] cobaltocene,[88] the acetylacetonato complexes of Mn^{III} and Fe^{III},[77] benzophenone,[45] and a manganese(III) porphyrin.[79] Data are also available for

the electrooxidation of ferrocene[53, 70] and tetrathiofulvalene.[78] In general, ΔH_{ex}^{*} increases with increasing solvent viscosity, as predicted by the ΔH_L term in Equation (19). The most interesting system from the point of view of heterogeneous ET is cobaltacene, because this molecule may be both oxidized to a cation and reduced to an anion. On the basis of the FB model the activation parameters for these reactions should not be the same, in contradiction to the predictions of the Marcus model. As activation enthalpy data are additionally available for the homogeneous ET between the cobaltacenium cation and the cobaltocene molecule,[89] this system is chosen here for more detailed examination.

The available data for the redox reactions of cobaltocene are summarized in Table 3. Where comparisons can be made, ΔH_{ex}^{*}

Table 3. Experimental activation enthalpy ΔH_{ex}^{*} for various redox reactions of cobaltacene in several aprotic solvents and the longitudinal relaxation enthalpy ΔH_L for the solvent. Oxidations to cations are indicated by (+/0) and reduction to anions by (0/−).

Solvent	ΔH_L [kJ mol^{-1}]	ΔH_{ex}^{*} [kJ mol^{-1}]		
		homogeneous (+/0) [89]	heterogeneous (+/0) [69]	heterogeneous (0/−) [88]
AC	3.7	18.4	20.9	-
AN	5.6	18.0	18.8	24.4
BuN	6.5	-		24.6
BzN	11.9	19.7	-	-
DMA	8.0	-	-	24.6
DMF	6.9	-	20.9	-
DMSO	10.7	20.1	23.0	25.1
HMPA	11.5	23.4	-	-
PC	13.4	-	-	28.0

for the homogeneous oxidation reaction is smaller than that for the corresponding heterogeneous reaction. Furthermore, ΔH_{ex}^{*} for the heterogeneous reduction reaction is larger than that for the oxidation reaction.[88] The experimental results are often smaller than the continuum estimates of ΔH_{os}^{*} (see Table 1). Since both the inner sphere activation enthalpy and the longitudinal relaxation enthalpy contribute to ΔH_{ex}^{*}, these data strongly confirm that the continuum estimates of ΔH_{os}^{*} are too large. One method of testing the models considered here is to plot $\Delta H_{ex}^{*} - \Delta H_{os}^{*}$ against ΔH_L and to obtain θ from the slope and ΔH_{is}^{*} from the intercept.[88] These plots using the FB estimates of ΔH_{os}^{*} are shown in Figure 3 for both the homogeneous and heterogeneous data. Reasonable linear plots are obtained for both cases, the slope being larger for the homogeneous data. The FB model seems to overestimate the activation parameters for the homogeneous case, perhaps because the two reactants are close to one another in the transition state. This conclusion is supported by the observation that the intercept which gives ΔH_{is}^{*} is significantly smaller than independent estimates of this quantity (2.1 kJ mol^{-1} [89]). When the same analysis is applied to the heterogeneous data, very striking results are obtained with the FB model: the data for the electroreduction of cobaltacene lie on the same line as those for the electrooxidation of the same molecule. These results support the proposition that differences in the solvation of cations and anions at static frequencies must be considered in estimating the activation parameters for ET reactions.[23]

Comparison of ΔH_{ex}^{*} for homogeneous and heterogeneous reactions of other systems demonstrates different features. In

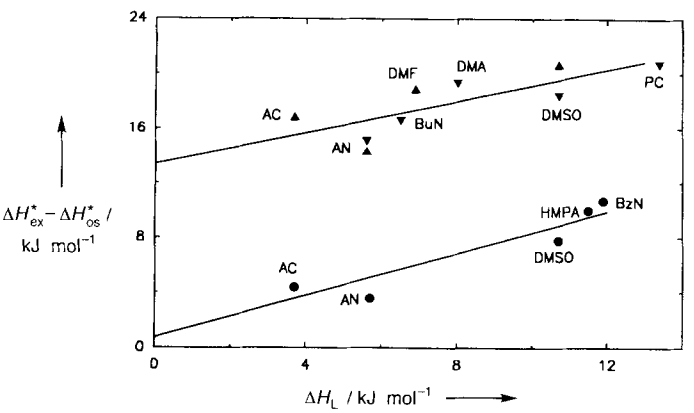

Fig. 3. Plot of the difference between the experimental activation enthalpy (ΔH_{ex}^{*}) and the outer sphere contribution according to the FB model (ΔH_{os}^{*}) for redox reactions with cobaltacene against the activation enthalpy for longitudinal relaxation ΔH_L. The homogeneous reaction is the oxidation of cobaltacene (●) and the heterogeneous reaction both oxidation (▲) and reduction (▼). The solid lines were obtained by linear regression using all the homogeneous or heterogeneous data (▲ and ▼). The ordinate for the heterogeneous data has been shifted vertically by 10 kJ mol^{-1} for clarity. The abbreviations for the solvents are given in Table 1.

the case of 1,4-diaminobenzene, the values of ΔH_{ex}^{*} determined for the heterogeneous reaction in acetonitrile and dimethylformamide[90] are much larger than the corresponding quantities for the homogeneous reaction.[91] This is certainly partly due to the dynamic solvent effect in the heterogeneous reaction,[73] which is absent from the homogeneous system.[30, 92] A more detailed analysis is not possible because data are available for only two solvents. Similar comments apply to the tetrathiafulvalene system.[78]

Particularly interesting results were described recently by Mu and Schultz,[79] who demonstrated both by means of rate constants and activation enthalpies for the reduction of a Mn^{III} porphyrin complex in six aprotic solvents that a dynamic solvent effect operates in a system with a quite large inner reorganization energy ($\Delta G_{is}^{*} = \Delta H_{is}^{*} \approx 16$ kJ mol^{-1}). These results suggest that factors other than those usually considered[1-4, 9, 11, 28] are important in determining the degree of reaction adiabaticity and hence the magnitude of the dynamic solvent effect. The reactant in this study is clearly nonspherical, and the authors estimated the effective radius from diffusion coefficient data. However, their values for ΔG_{os}^{*} and ΔH_{os}^{*} were based on the continuum model and therefore are probably too large. As a result, θ calculated from the solvent effect at 25 °C was different from that obtained from the activation enthalpy data.[79] When these quantities are deduced from the FB model, the values of θ (approximately 0.7) from the two analyses agree.

The temperature dependence of the standard rate constant in a series of polar solvents gives an additional powerful tool for examining the nature of the ET step. Under these circumstances the degree of reaction adiabaticity can be assessed provided an estimate of the effective radius of the reactant can be made. This subject is discussed in the following section.

6. Effects of the Reactant

The data available in the literature demonstrates that the standard rate constant in a given solvent varies by four orders of magnitude with the nature of the reactant.[33] Much of this

change is usually associated with variation in ΔG_{is}^{*} within the group of reactants considered, but some is also due to changes in ΔG_{os}^{*}. To gauge the ΔG_{os}^{*} contribution, an estimate of the effective radius of the reactant is needed. For this reason, much experimental effort has been directed at the metallocenes, which are simple from the point of view that they can be represented to a good approximation as spheres,[26] and buckminsterfullerene, whose heterogeneous ET kinetics have been studied more recently.[57, 61, 93] Quite good values of ΔG_{os}^{*} and ΔH_{os}^{*} were derived for buckminsterfullerene from the FB model when the effective reactant radius was assumed to be equal to the crystallographic radius (360 pm) plus the van der Waals radius of carbon (70 pm).[93]

However, most reactants are not spherical, and other methods must be used to deal with the shape of the molecule and the charge distribution within it. In early work Peover and Powell[94] studied the kinetics of electroreduction of nitrocompounds. As the charge on the anion radical formed became more delocalized, say on a benzene ring, the rate of reaction increased. A similar effect was observed in the electroreduction of a series of quinones in which the standard rate constant increased with the increasing number of benzene rings in the series benzoquinone < naphthoquinone < anthraquinone.[95]

Fawcett and Kharkats[96] extended the model proposed by Peover and Powell[94] to take into account volume correction terms when the reactant is represented as two contiguous conducting spheres. The expression for the effective radius r_e (neglecting the effect of images) is then given in Equation (20) where $F(r_x, r_i)$ is defined according to Equation (21). Here f_1

$$r_e = \left[\frac{f_1^2}{a} + \frac{f_2^2}{b} + 2\frac{f_1 f_2}{c} - f_1^2 F(c, b) - f_2^2 F(c, a)\right]^{-1} \quad (20)$$

$$F(r_x, r_i) = \frac{r_x}{2(r_x^2 - r_i^2)}\left[\frac{r_i}{r_x} - \left(1 - \frac{r_i^2}{r_x^2}\right)\ln\frac{r_x + r_i}{(r_x^2 - r_i^2)^{1/2}}\right] \quad (21)$$

and f_2 are the fractions of the total charge on spheres 1 and 2, a is the radius of sphere 1, b the radius of sphere 2, and c the distance between the centers of the spheres. For contiguous spheres, $c = a + b$. The first three terms represent the effect of the charges on the spheres irrespective of the fact that part of the solvation sheath of a given sphere is excluded by the proximity of the other sphere. The fourth and fifth terms account for the effects of the finite volume of each sphere. The excluded volume terms result in an increase in the effective radius of the reactant, and consequently in a decrease in ΔG_{os}^{*}. The effect is small if the radii of the two spheres are equal, but increases in importance as the relative sizes of the spheres change.[96] The effective radius can be used in the MSA model to obtain an improved estimate of ΔG_{os}^{*}, for example, by replacing r_A in Equation (7) by r_e.

Fawcett and Fedurco[45] recently extended the above model to the benzophenone system, which was represented as three contiguous spheres each in contact with two others. Two equally large spheres enclosed each of the phenyl rings and a smaller sphere surrounded the carbonyl group. In this case the excluded volume effect is more important. When the diameters of the contiguous spheres are defined by the structure of the molecule, such a model probably underestimates the extent of the solvation because of the chosen spherical shape for each part of the molecule. A better representation would involve contiguous ellipsoids, each extending somewhat further beyond the extreme parts of the molecule. However, a model with ellipsoids would involve more adjustable parameters and therefore would be less easily justifiable by experiment.

The excluded volume effect can also be used to explain the fact that the activation enthalpy for the homogeneous ET of the cobaltacenium (+/0) system is slightly smaller than that for it heterogeneous ET (see Table 3). According to Kharkats,[97] ΔG_{os}^{*} for homogeneous transfer of one electron between a spherical reactant of radius a to another of radius b is given within the context of Marcus continuum theory by Equation (22), in which r_e is defined by Equation (23) and the quantities c and $F(r_x, r_i)$

$$\Delta G_{os}^{*} = \frac{N_0 e_0^2}{16\pi\varepsilon_0 r_e}\left(\frac{1}{\varepsilon_{op}} - \frac{1}{\varepsilon_s}\right) \quad (22)$$

$$r_e = \left[\frac{1}{a} + \frac{1}{b} - \frac{2}{c} - F(c, a) - F(c, b)\right]^{-1} \quad (23)$$

have the same meaning as in Equation (20). When the spheres have equal radii and are in contact, ΔG_{os}^{*} is 6% smaller than when the excluded volume terms are ignored. This correction can also be made to yield the corresponding relationship for the MSA [Eq. (24)].

$$\Delta G_{os}^{*} = -\frac{N_0 e_0^2}{16\pi\varepsilon_0}\left[\left(1 - \frac{1}{\varepsilon_{op}}\right)\frac{1}{r_e} - \left(1 - \frac{1}{\varepsilon_s}\right)\frac{1}{(r_e + r_i/\lambda_i)}\right] \quad (24)$$

A different approach to dealing with the effects of molecular shape has been used by Grampp et al.[78, 91, 92, 98] In their work, the molecule is represented as an ellipsoid with semiaxes a, b, and c. This approach has been applied especially to data for homogeneous self-exchange reactions of organic molecules such as 1,4-diaminobenzene and its derivatives, tetracyanoethylene, tetracyano-*p*-quinonedimethane, and tetrathiofulvalene,[98] but also to heterogeneous ET reactions.[78] Such a description of the system requires more parameters than a model based on two continguous spheres. When applied to a diabatic system with data available both as a function of solvent and temperature,[91, 92] a detailed assessment of the mutual orientation of the reactants in the transition state is possible.[98] To date this approach has been limited to the Marcus continuum model for ΔG_{os}^{*}, but it could be easily extended to a nonprimitive model such as the MSA.

It should be emphasized that the above models have treated the reacting system as a conductor. There may be circumstances when such an assumption is not appropriate as discussed by German and Kuznetsov.[99, 100] These authors have considered the effects of polarizability on the estimation of ΔG_{os}^{*}, and developed models in which the reactant is represented as a dielectric cavity of given shape with embedded point charges. Hupp et al.[101] have shown that a dielectric cavity model is successful in accounting for the solvent dependence of optical intervalence charge-transfer absorption bands for symmetrical mixed-valence compounds. Charge transfer within the species $[(NH_3)_5Ru^{III}(4,4'\text{-bipyridine})\text{-}Ru^{II}(NH_3)_5]^{5+}$ was treated as dipole inversion within a low dielectric cavity; the length of the dipole (0.51 nm) was calculated from intervalence Stark effect measurements.[102] In contrast, a model based on conducting

spheres separated by a fixed distance [Eq. (22)] did not give a reasonable description of the same data. These authors obtained their spectroscopic data in very dilute solutions, thereby avoiding the effects of ion pairing on the spectral features. If the model based on two conducting spheres is valid, the absorption frequency observed in various solvents should be linear in the solvents' Pekar factor γ, and its slope will be determined by the geometrical parameters for the system [Eq. (23)]. Although this plot is linear,[101] the slope is much less than expected on the basis of reasonable values for the size parameters. A similar result is obtained for the bis(ferrocenyl)acetylene cation.[11, 82, 83] The analysis carried out by Hupp et al.[101] is quite important, because it suggests that a redox couple connected through a nonconducting bridge is not a good model for estimating the Gibbs activation energy for the homogeneous ET of the same redox couple.

Other compounds for which interesting structural effects on ET are seen are metalloporphyrins[79, 134–137] and oligodecker sandwich compounds.[138] An important question in metalloporphyrin redox chemistry is whether ET takes place at the metal ion or the porphyrin ring. Mu and Schultz[135] showed that the porphyrin-centered oxidation of Mn^{III} tetraphenylporphyrin chloride is much faster than the metal-centered reduction of the same compound. This observation was attributed to the much larger effective radius of the reactant and correspondingly smaller ΔG_{os}^{*} in the oxidation reaction in which the charge density is distributed over the porphyrin ring. Anxolabéhère et al.[136] concluded from kinetic data for the reduction of some tetraphenylporphyrin complexes and related compounds of more complex structure in DMF that solvent reorganization plays an important role in these fast heterogeneous ET reactions. Fawcett et al.[137] examined the redox chemistry of a stable (isoporphyrinato)zinc complex. The kinetic parameters they measured and their comparison with those for (octaethylporphyrinato)zinc suggest that ET takes place at the ring rather than the central metal ion. Interpretation of these data is greatly facilitated when activation parameters are measured.[79, 137]

Michels and Schmickler[138] have reported a study of heterogeneous ET with oligodecker sandwich compounds. These molecules are derived from metallocenes with 2,3-dihydro-1,3-diborol as a bridging ligand, for example 1,3,4,5-tetraethyl-2-methyl-1,3-diborolylbis(cyclopentadienyl)iron (BlFc). Many of these molecules can be both oxidized and reduced, and undergo some degree of inner sphere reorganization.[138] In the case of the BlFc, the rate constant for the oxidation process was 20 times larger than that for reduction at an Au electrode in dichloromethane. The activation enthalpies were 13.5 and 18.3 kJ mol^{-1} for the oxidation and reduction steps, respectively. These results suggest that inner sphere reorganization is not important for BlFc and support the general conclusion of the FB model that ΔG_{os}^{*} should be smaller for the formation of a cation by oxidation of a molecule than for the formation of an anion. Further studies of these systems would be interesting in the light of this question and others discussed in this review.

In summary, considerable progress has been made in recent years to develop reliable methods of estimating the effective size of the reactant in heterogeneous ET. As the theory of ion solvation progresses to develop nonprimitive models of nonspherical ions our understanding of the role of reactant shape in determining ET parameters will improve.

7. Double Layer Effects

Most recent studies of heterogeneous ET have involved redox couples in which the most highly charged species is a monovalent cation or anion. Often, an organic or organometallic molecule is selected to minimize double layer effects and effects due to ion pairing in the bulk of the electrolyte solution. Consequently, much less attention has been paid to redox couples of transition metal complexes with higher charge, although the structural effects in such systems are much easier to describe.

The choice of electrolyte is also important in establishing electrostatic conditions at the electrode/solution interface. In organic solutions, the electrolyte is most often a tetraalkylammonium (TAA^+) salt with a hard anion such as perchlorate, tetrafluoroborate or hexafluorophosphate. These salts are chosen to avoid ion pairing, which occurs with smaller ions, or problems with ionic adsorption on the electrode. For example, the anion radicals formed from nitro compounds strongly associate with alkali metal cations.[103, 104]

In addition, the presence of halide ions in the electrolyte makes it very difficult to interpret kinetic data obtained positive of the potential of zero charge, because these ions are strongly adsorbed on polarizable metals from all known polar solvents.[105] TAA^+ ions also adsorb on the electrode, but the nature of the adsorption appears to be more electrostatic rather than chemical, and solvophobicity plays a role. These ions also form aggregates with some anion radicals; notable examples are the strong ion associates found between C_{60}^{-} and C_{60}^{2-} anions and TAA^+ cations.[57]

When heterogeneous ET occurs at potentials negative of the point of zero charge in the presence of TAA^+ ions, the standard rate constant decreases with increasing size of the alkyl group,[106–113] though the activation enthalpy is relatively independent of cation size.[45, 106, 108, 112, 113] Moreover, the relative magnitudes of the inhibitory effect increases as the electrode potential is made more negative.[111] These observations can be rationalized if it is assumed that the TAA^+ ions are adsorbed on the electrode to form a monolayer whose thickness and extent depend on the size of the ion and electrode potential.[111–113] On the basis of capacity data we proposed[113] that the alkyl arms of these ions are bent when the chain contains more than three carbon atoms with the result that the distance of closest approach of the central nitrogen atom is approximately constant for the larger ions. This model can explain the decrease in standard rate constant as electron tunneling through a layer of TAA^+ ions.[114–116] Since the activation enthalpy depends only on the solvent and not on the size of the TAA^+ ion, ET must take place outside the adsorbed ionic layer in a region where reactant and product are still interacting chiefly with surrounding solvent molecules.[111, 113]

Other recent work on electron tunneling through barrier films has involved self-assembled monolayers. Miller et al.[117, 118] used ω-hydroxythiols to form a self-assembled monolayer on a gold electrode. The thiol functionality at one end of the hydrocarbon chain reacts with gold to form a mercaptide, thereby anchoring the molecule to the surface. Interactions between water and the hydroxy groups at the other end of the molecule make the monolayer compact. These authors[117, 118] showed that electron tunneling is the main mechanism for ET to a redox

system outside the monolayer in solution. By varying the chain length of the molecule forming the self-assembled monolayer they demonstrated that the tunneling current depends exponentially on film thickness. This corresponds to an exponential decrease in the electronic transmission coefficient κ in Equation (8).[115, 116]

Chidsey[119] used a self-assembled monolayer on gold with an electroactive terminal group on a fraction of the anchored groups to study ET through films of varying thickness. The electroactive terminal group was ferrocene, which is oxidized to the ferrocenium cation by fast ET. The monolayer consisting of hydrocarbon chains with 15 CH_2 groups slowed the reaction down sufficiently for collection of ET kinetic data over a voltage range of almost 2 V. Analysis of the dependence of the rate constant on potential provided evidence that the Gibbs activation energy is indeed a quadratic function of potential as predicted by Marcus theory.[12] Chidsey estimated the experimental value of ΔG^* for the ferrocene/ferrocenium system in water to be 20.5 kJ mol^{-1}. This result is significantly lower than the estimate of ΔG^*_{os} in water by continuum theory (25.8 kJ mol^{-1}). The FB model yields 17.4 kJ mol^{-1} for the same quantity. As a small contribution from inner sphere reorganization must be added (about 1 kJ mol^{-1}), the experimental result is very close to the value predicted by the MSA.

In a similar study by Finklea and Hanshew,[120] the redox group was pentaammine(pyridine)ruthenium$^{3+/2+}$. The experimental value for ΔG^* varied somewhat with the length of the hydrocarbon chain and presence or absence of spacer chains in the self-assembled monolayer. The role of the low dielectric monolayer in determining ΔG^*_{os} thus seems to change in the systems studied. Their results also support the conclusion that ΔG^*_{os} is overestimated by the continuum model [Eq. (2)].

Smith and White[121] have discussed double layer effects on both the thermodynamic and kinetic properties of a self-assembled monolayer modified with a redox couple. Since the redox couple is not present in the bulk of the solution, the equilibrium potential for the surface-attached redox couple depends on the local (micro) potentials at their oxidized and reduced forms when these are significantly different from the average potential in the bulk of the solution. These authors[121] determined an average potential ϕ^p in the plane through the centers of the redox species from measurable thermodynamic quantities, and showed that when this potential is used to approximate the local potential, a reasonable description of the variation in equilibrium potential of the redox couple with dielectric properties of the interface is possible. Furthermore, the effect of the charge associated with the redox couple on the shape of the current-voltage curve in linear sweep voltammetry depends on the dielectric properties of the interfacial region, their potential dependence, and the potential of zero charge. The calculations were performed according to the classical Frumkin theory[122, 123] for double layer effects in electrode kinetics. Creager and Weber[124] extended this work by considering double layer effects on the current–time transients in potential step experiments involving a self-assembled monolayer modified with a redox couple.

The Frumkin equation for the logarithm of the forward rate constant of the redox couple [see Eq. (1)], corrected for the double layer is usually written as Equation (25) where k_f is the

$$\ln k_f + z_A f\phi^d = \ln k_s + \alpha_a f(\phi^d - E - E_s) \quad (25)$$

forward rate constant, ϕ^d the average potential drop across the diffuse layer, z_A the charge on the reactant, E the electrode potential, E_s the standard electrode potential, α_a the apparent transfer coefficient, and $f = F/RT$. The transfer coefficient is termed apparent, because the actual potential experienced by the reactant may differ from ϕ^d for a variety of reasons, which are generally termed discreteness-of-charge effects.[125–127] These effects are most noticeable when discrete charges are fixed at a dielectric discontinuity in the system[128] such as the electrode/solution interface for an unmodified electrode, or the hydrocarbon/solution interface in the systems studied by Chidsey[119] and Finklea and Hanshew.[120] The local potential at an anchored redox system Ψ^p may differ significantly from the average value in the plane through their centers (ϕ^p). When this is true, the potential drop ϕ^d in Equation (25) should be replaced by the local potential Ψ^p.[127]

Becka and Miller[129] studied double layer effects at uncharged self-assembled monolayers and showed that the kinetics of heterogeneous ET at the monolayer/solution interface depends both on the charge on the reactant and the composition of the monolayer. The reduction of $[Fe(CN)_6]^{3-}$ at a ω-hydroxyldodecanethiol monolayer was considerably faster than at a dodecanethiol monolayer at potentials negative of the potential of zero charge. The authors attributed the difference to the fact that the self-assembled monolayer terminated with the hydroxy group is less hydrophobic, and the reactant can approach closer to the insulating film. In the case of $[Fe(bipyridine)CN_4]^-$, the opposite effect, namely, a faster reaction at the methyl-terminated monolayer, is observed. This reactant is more hydrophobic and bears a smaller charge. These results can also be partly attributed to discreteness-of-charge effects. Because of the large change in dielectric constant from a low value in the oil-like monolayer (about 2) to a high value in the aqueous solution (about 78), the reactant experiences strong repulsion at the monolayer/solution boundary. The electrostatic effect[128] is much more important for the polyvalent $[Fe(CN)_6]^{3-}$ ion.

Discreteness-of-charge effects have also been discussed for heterogeneous ET reactions at mercury electrodes in the presence of specifically adsorbed nonreacting ions.[130–133] Three of the systems studied[131–133] involved transition metal complexes in which the metal ion is reduced from the +3 to +2 oxidation state in the presence of specifically adsorbed anions. By carrying out these experiments at constant ionic strength, and examining the changes in the corrected logarithm of the rate constant ($y = \ln k_f + z_A f\phi^d$) with adsorbed charge density σ_a at constant potential drop across the inner layer ($E - E_s - \phi^d$), the electrostatic effects of the adsorbed ions with a minimum in change in other double layer properties can be examined [see Eq. (25)]. Because the adsorbed ions are located at the metal/solution interface, their electrostatic accelerating effect is significantly reduced by the shielding effect of the metal. If the simple Frumkin equation were correct, the kinetic parameter y would be independent of ($E - E_s - \phi^d$) for changes in the surface coverage by adsorbed anions. In the case of $[Co(NH_3)F]^{2+}$, y decreases with increasing σ_a as qualitatively expected on the basis of the discreteness-of-charge effect.[133] However, when an anion such as tetrathionate is reduced in the presence of adsorbed

iodide anions, the decelerating effect of the adsorbed charge is overestimated when discreteness-of-charge effects are ignored, and the value of y increases with increasing σ_a.[130] Further analysis of these data[130–133] led to a more detailed description of the double layer effect including the location of the reaction site with respect to adsorbed ions and counterions.

Double layer effects can be quite important in heterogeneous ET reactions especially when the reactants are highly charged. Analysis of these effects requires interfacial thermodynamic data for the electrolyte system under investigation. The lack of these data has often prevented attempts to examine the double layer effect in more detail. However, modern experimental techniques, especially those based on impedance, provide these data relatively easily. Double layer effects at self-assembled monolayers, which are excellent systems for testing in more detail the theories which have been in the literature for some time, are just beginning to be investigated.

8. Conclusions

Studies of solvent effects for heterogeneous ET reactions have done much to increase the understanding of fundamental aspects of this elementary chemical reaction. This is especially true when kinetic data are obtained both as a function of solvent and of temperature so that the variation in activation enthalpy may also be examined. Studies of the redox reactions of the metallocenes[44, 53, 69, 70, 74, 88, 89, 110] have been especially important because the reactants are relatively spherical in shape and undergo very small internal reorganization on ET.

There is strong evidence from recent experimental work that the activation parameters for outer sphere reorganization are overestimated by the original Marcus formulation.[12] This is not at all surprising, since it is well-known from equilibrium solvation data for simple ions that the Born model gives unrealistically high values of the Gibbs energy and enthalpy of solvation. The most important feature of any improvement on the Born model is that it recognizes the differences in the solvation of cations and anions. The rate constant for formation of a cation from a molecule is expected to be faster than that for formation of an anion, all other factors remaining the same, as in the case of cobaltacene[88, 110] and related compounds.[138] This prediction should be examined for other molecules for which these reactions can be carried out.

Heterogeneous ET can be understood in at least as much detail as homogeneous ET. Although double layer effects must be considered, their importance can be reduced by careful choice of the electrolyte. Homogeneous ET kinetics has the additional complication that the reactants may assume a particular configuration with respect to one another in the transition state.[98] Such steric effects need to be examined in more detail, but they should be simpler in the heterogeneous ET reaction where the electrical field due to the charge on the electrode plays an important role.[106] Changes in the nature of the steric effect with the type of ET reaction may be the cause of the differences in the relative ordering of rate constants for various metallocenes seen in the homogeneous and heterogeneous regimes.[11]

Self-assembled monolayers with anchored redox groups[119, 120] have provided an interesting new way of studying heterogeneous ET. In these systems, the environment of the redox reaction is entirely different from that at the electrode/solution interface. Thus, the comparison of data obtained in the two systems will provide valuable information on the role of environmental effects in heterogeneous ET.

In conclusion, the understanding of ET has advanced considerably during the last decade. Though it has provided a fruitful area for both theoretical and experimental work, many problems remain to be solved, and research in this field will continue to present a challenge.

Recent work from this laboratory discussed in this review was supported by the Office of Naval Research, Washington, and by the National Science Foundation, Washington (Grant No. CHE 9008171).

Otto Roelen, Pioneer in Industrial Homogeneous Catalysis

Boy Cornils,* Wolfgang A. Herrmann, and Manfred Rasch

Dedicated to Wolfgang Hilger on the occasion of his 65th birthday

Otto Roelen discovered the oxo synthesis (hydroformylation) in 1938, and despite all the problems created by the war years he was able to explore successfully the fundamental aspects related to its application up to the point of building the first plant. At the same time he laid the groundwork for industrial utilization of homogeneous organometallic catalysts. Almost simultaneously, his contemporary, Walter Hieber, was investigating the basic chemistry of the same catalysts, but with no knowledge whatsoever of their potential application. Hydroformylation today constitutes one of the most important industrial examples of a homogeneous catalytic process.

A unique opportunity for academic and industrial chemists to engage in a goal-oriented collaborative effort with respect to an important new synthetic method was missed in this case, however—missed less as a consequence of events of the day than because of the differing mentalities of two difficult personalities. In less turbulent times these two unpredictable individuals might well have collaborated. A number of contemporary documents published here for the first time, supplemented by Allied reports related to "hidden reparations," provide interesting insights into the nature of this particular discovery and its subsequent course of development.

1. The Researcher and the Man: University, Research Institute, and Industry

"...that Herr dipl. Ing. Roelen has been educated both theoretically and practically to such an extent that he would represent no obstacle to further progress in the work being conducted there. To all intents and purposes, R. carried out his thesis work completely independently, indeed very reliably, and with an equivalent amount of diligence. The only thing I might criticize is his tendency to theorize, but this is probably only a result of the fact that R. did an unbelievable amount of both work and reading. With respect to his knowledge, R. is far above the average for other doctoral candidates."[**]

This brief report accurately describing the distinguishing characteristics of its subject was written by Prof. Alexander Gutbier of the Laboratory for Inorganic Chemistry and Inorganic Chemical Technology at the Technische Hochschule Stuttgart and accompanied Otto Roelen on June 26, 1922 when he arrived at the Kaiser-Wilhelm-Institut für Kohlenforschung (KWI) in Mülheim an der Ruhr, where he would begin work under the supervision of Prof. Franz Fischer, Director of the Institute, and Fischer's Section Leader, Dr. Hans Tropsch, in the general area of hydrocarbon synthesis.[1]

Although Otto Roelen was himself born in Mülheim on March 22, 1897, and as a high school student witnessed the official dedication of the KWI on July 27, 1914, his future career was in no sense as predestined as it might appear in retrospect. Roelen attended the Königliche Realgymnasium (Royal High School) in his hometown, where he was awarded a wartime diploma on August 4, 1914. He did not immediately volunteer for military service, however, choosing instead to serve a six-month internship at the nearby blast furnace and foundry works of the Friedrich Wilhelms-Hütte before registering as a chemistry student at the Technische Hochschule München. He was one of only 21 students there between 1914 and 1918, and must have taken the introductory chemistry course taught by Wilhelm Manchot (cf. Section 3.1). Roelen was finally drafted in July of 1915, and participated as an artillerist in the battles in Flanders, where he was wounded in 1917. At that time he held the rank of artillery mate with the 2nd Marine Artillery Division of the 2nd Heavy Corps Artillery Regiment.[2] Subsequent to his injury he was no longer considered fit for active duty, and was employed as a "chemical technician" at the Royal Submarine Shipyard in Wilhelmshaven, where he was stationed when the war ended. By his own report he had joined a local Workers' and Soldiers'

Council ("Arbeiter- und Soldatenrat"),[3] but nothing is known regarding the reasons for his apparent participation in the Council Movement, and there is in fact no independent documentation of this involvement. Indeed, it seems quite inconsistent with his later attitudes, and he was never again active in politics. His alleged membership in the Wilhelmshaven Workers' and Soldiers' Council may simply have served as a protective shield during the British "denazification" process, in which Roelen was classified as presenting "no objection," and he never mentioned the matter again.

By the winter semester of 1918/19 Roelen had already resumed his chemical studies at the Technische Hochschule Stuttgart, where after six semesters, in March 1922, he was awarded a degree.[4] This was followed by an internship in the iron and steel industry, spent in the research laboratories of Hoesch in Dortmund. He was apparently unable there to find a suitable topic for a doctoral dissertation, however, and for this reason omitted all reference to the experience in his later résumés. On the other hand, Hoesch did make explicit mention of Roelen's work in the context of the 50th anniversary of its research division.[5] It was evidently during the course of this internship in Dortmund that Roelen contacted the director of the KWI regarding the possibility of pursuing doctoral work at the Institute. In response to the positive evaluation from Prof. Gutbier cited above, Franz Fischer sent the following note to Otto Roelen:[6]

> "Herr Professor Gutbier has written to me and expressed the opinion that you would be in a position to carry out scientifically worthwhile doctoral studies in one of our areas of research. I am therefore prepared to accept you as a doctoral candidate, and I request that you meet with me so I can discuss with you both the topic and the literature that will be an essential part of your preparation."

Since 1921 the KWI had been engaged in intensive investigations in the area of gas synthesis, with the goal of producing liquid hydrocarbons. One of the reasons for this activity was the fact that Rhineland-Westphalian heavy industries, a source of financial support for the Institute, were interested in finding ways of utilizing their excess coke-oven off-gases.[7b] Fischer and Tropsch were studying as one possible starting point the catalytic preparation of "Synthol," a mixture of liquid hydrocarbon- and oxygen-containing oils described in prewar patents issued to BASF,[8] and derived from the reaction of carbon monoxide with hydrogen under high pressure. Much of the ini-

B. Cornils

M. Rasch

W. A. Herrmann

Boy Cornils was born in Bremen in 1938. His chemical studies led to a doctoral degree in industrial chemistry (Technische Universität Hannover, 1964). He started his career at the Ruhrchemie AG (Oberhausen) and became head of research and development (including development of biphasic hydroformylation), before moving to Hoechst AG (Frankfurt) in 1984. His responsibilites have ranged from research to management. He is the author of several publications on such topics as homogeneous and heterogeneous catalysis, fluorine chemistry, syntheses involving carbon monoxide, organometallic compounds, aspects of chemical engineering, specialty chemicals, and coal gasification, and holds a number of patents.

Wolfgang A. Herrmann was born in 1948 in Kelheim/Donau (Bavaria). After studying chemistry (Diplom at the Technische Universität München) and completing a research thesis with E. O. Fischer in 1971, he obtained his doctorate in 1973 on a topic dealing with organometallic stereochemistry under H. Brunner at the Universität Regensburg. From 1975–1976 he carried out research with P. S. Skell at the Pennsylvania State University, and in 1978 completed his habilitation with a thesis entitled "Organometallic Syntheses with Diazoalkanes." He was appointed professor at the Universität Regensburg (1979), and full professor at the Universität Frankfurt (1982). In 1985 he accepted a chair at the Technische Universität München as the successor to E. O. Fischer. His area of research is synthetic and catalytic chemistry, primarily in organometallic chemistry. He is the author of 350 publications, and holds 30 patents. His work has frequently been the subject of special recognition, including the German–French Alexander-von-Humboldt Prize (1988), the Otto-Bayer Prize (1990), and the Max-Planck Research Prize (1991). He is a member of the Akademie der Wissenschaften und der Literatur zu Mainz (1990), and received an honorary doctorate from the University of Lyon (1990).

Manfred Rasch was born in 1955 in Dortmund and studied history and mathematics at the Ruhr-Universität Bochum with the goal of teaching in a "Gymnasium." He spent the years 1984–86 as a teaching intern and was subsequently appointed to the academic staff at the Max-Planck-Institut für Kohlenforschung at Mülheim an der Ruhr where the Director, Prof. Wilke, charged him until 1992 with the responsibility of conducting research on the history of the Institute. He received his doctorate at Bochum in 1989, and a teaching position at the same institution in 1990. Since 1992 he has been head of the archives at the Thyssen AG in Duisburg. In addition to four monographs he is credited with fifty other publications related to the history of chemistry, science, and technology as well as the application of computer techniques to archival work.

tial work was directed toward mechanistic aspects of the process (the "formate theory"). Nevertheless, Fischer and his co-workers failed to develop a satisfactory scientific explanation of the synthesis, remarking simply in their first publication:[9]

> "We wish therefore to conclude this section regarding the theory of Synthol formation by noting that for the time being we are giving first priority, relative to other possible explanations, to the notion of synthesis through carbon monoxide addition to alcohols, albeit without claiming that we have definitely proven this to be the mechanism."

In their explanation of the course of the reaction leading to Synthol, Fischer and Tropsch assumed that methane and formaldehyde arose as intermediates, which is the reason why Fischer et al. (including the young doctoral candidate Otto Roelen; cf. Fig. 1) carried out an extensive series of experiments related to

Fig. 1. Otto Roelen (third from left) at the Technische Hochschule in Stuttgart, Inorganic Laboratory, 1922.

methane combustion and the formation and decomposition of formaldehyde.[10] Despite these efforts, Fischer and his coworkers never succeeded in detecting more than traces of the presumed intermediates.[7]

Roelen had completed the experimental part of his work before the institute's summer holidays began, and even though his doctorate had not yet been officially granted he decided to move on immediately to the Technische Hochschule Berlin-Charlottenburg, where in August 1923 he joined the research group of Prof. Hans T. Bucherer. He remained in Berlin until March 1924, transcribing during this period his dissertation entitled "I: Über die katalytische Zersetzung des Formaldehyds bei höheren Temperaturen. II: Über die teilweise Verbrennung von Methan zu Formaldehyd mit Luft" (I: Concerning the Catalytic Decomposition of Formaldehyde at Higher Temperatures. II: Concerning the Partial Combustion of Methane to Formaldehyde with Air), which was evaluated very favorably by Bucherer:[11]

> "The efforts of Dr. Roelen merit special recognition; he has tried to extract the greatest possible measure of scientific benefit from the investigations he initiated, based on his own reflection and careful observations. I have no doubt that he will develop into a successful and exceptionally able scientific colleague, and wish him from my heart all the best for his long-term future."

Bucherer was not the only one who regarded Otto Roelen as an "exceptionally able" chemist; the same was true of the chemistry faculty at the TH Stuttgart, which on the basis of his work and especially his performance in the oral examination rewarded him with the grade "very good." Prof. W. Küster, Roelen's adviser in Stuttgart, thereby exceeded Franz Fischer's recommendation, which attested to work that had been conducted "with diligence, care, and understanding," and Roelen's "full engagement in the theoretical aspects as well, in the course of which he developed his own independent views. On the basis of the results, which represent a considerable advance over prior knowledge, as well as the way in which Herr Roelen mastered the problems that developed," Fischer nevertheless proposed only a grade of "good."[12] This may have been one reason why Roelen did not apply for a position at the KWI immediately upon receiving his doctorate, although the letter of appreciation he sent to Fischer provides no evidence of ill will between them. Another possible reason could be that Roelen was interested in seeking independent appraisal of his research results. Thus, his dissertation concluded with the following paragraph, appended quite self-confidently to the bibliography:[13]

> "The partial combustion of methane to formaldehyde represents a special case in the broad context of gas-phase reactions, one which holds out promise for extensive development and rich reward from the standpoint of both science and industry. It is my intention to occupy myself further with these matters, especially the combustion of methane."

Otto Roelen's thoughts even as he worked on his doctorate apparently were not simply those of a chemist, but of a businessman as well. On June 10, 1924, he applied for a patent on a "Verfahren zur Durchführung der teilweisen Verbrennung von Methan zu Formaldehyd" (Process for Accomplishing the Partial Combustion of Methane to Formaldehyde).[14] Objections were raised to this patent, however, and it was not actually issued until April 2, 1930. Since it did not even then produce any financial benefits for Roelen, he abandoned his patent rights in the very same year.[15] On October 15, 1924, he again took up research at the KWI for Kohlenforschung, this time as a regular member of the scientific staff.

Although Otto Roelen was often described as having a "tendency to theorize," he lacked the publication record that even in those days was essential to a successful scientist. Thus, during the period 1924/25 he was a co-author with Tropsch of three articles, all based on his dissertation, but the only independent publication he was permitted to release was a literature summary under the title "Über die Verbrennung von Methan zur Formaldehyd" (Concerning the Combustion of Methane to Formaldehyde).[16] This lack of publications cannot be attributed exclusively to the hierarchical structure of the Institute, which reserved the right of first publication to the Director, because after 1927 Roelen served as head of the Institute's pilot-plant facilities, with the rank of group leader. In comparison with other group leaders

his publication record continued to be meager, and was confined almost exclusively to lectures. Roelen was much more interested in technical issues, of which there were many, because the Director of the Institute envisioned in-house development of the KWI-discovered Fischer–Tropsch (FT) process all the way to technical maturity. In the years that followed, and even during his time as an industrial chemist, Roelen's list of publications included considerably more patents than other forms of communication.

Otto Roelen was one of those involved in the initial discovery of the FT synthesis. During his lifetime he regarded his personal role in this discovery as having been quite significant, although the chemical world generally was more inclined to recognize his contributions to industrial applications of the process.[17] One of his contributions, according to his own testimony, was preparation of the technically relevant catalysts. But in the second published report on the FT process by Fischer and Tropsch, Roelen is accorded only a note of appreciation—and even that in conjunction with references to the work of others as well.[18]

There is no doubt that Otto Roelen played an important part in the technical development of the FT synthesis. In 1927 he assumed responsibility for the pilot plant, which was especially appropriate, since a love for theorizing was accompanied throughout his life by an interest in practical and technical questions viewed from the perspective of an industrial chemist. Many important innovations associated with industrial implementation of the FT synthesis are attributable to Roelen, including his "independent temperature controller for a gas-fired oven" and a "sulfur determination apparatus" that he developed jointly with his assistant Walter Feißt, a device which was subsequently produced under license by a glassblower in Essen.[19] Tropsch left the institute in the summer of 1928, and in 1929 Fischer–Tropsch activities at the pilot-plant facility were merged with those in the laboratory and placed under Otto Roelen's direct supervision. Thereafter his role in the further development of the FT process was second only to that of Franz Fischer, who expressed his confidence in Roelen to the outside world in the following communication dated March 10, 1931:[20]

> "With the departure of Dr. Fuchs, our oldest and most senior chemist, Dr. Roelen, head of the development department, assumes the duties of proxy for the Director with respect to general management of the Institute."

Meanwhile, Roelen and his co-workers in the previously mentioned FT pilot facility (built in 1926) had been working on gas purification (a constant and virulent problem throughout the development of the FT process). Other important issues they addressed included the arrangement of the reactors ("catalyst ovens," "Kontaktofen" in German; by 1934, 38 different modifications had been tested), reactor cooling, and temperature measurement. These experiments are exceptionally well documented, since all the scientific personnel of the Institute were required to submit weekly reports to the Director. Many of the often hand-written reports have in the meantime disappeared, as have Roelen's originals. But in this context he was quite cautious: all Roelen's reports were typed, which permitted him to retain a carbon copy for his personal records. The latter have since become a part of the archives of the Max-Planck-Institut für Kohlenforschung, where they constitute an interesting source of information on technical refinement of the FT synthesis.[21]

Although activities at the KWI pilot plant were centered most directly on industrial development of the FT synthesis, interesting scientific results were acquired as well. Thus, Roelen discovered in July 1930 that the optimal stoichiometric ratio for $CO:H_2$ was 1:2.[22] The pilot-plant staff also attempted for the first time in November 1930 to run the FT reaction in the liquid phase as an elegant approach to solving the problem of adequate cooling. Temperature control was indeed achieved, but the typical catalysts of that period resulted in a rate of reaction too low to be practical.[23]

It was not until the National Socialists seized political power that industrial-scale implementation of the FT reaction promised to become a reality. A general license for the process was assigned to Ruhrchemie AG in Oberhausen-Holten on October 27, 1934. Quite independently of ongoing licensing negotiations with Franz Fischer, Ruhrchemie began construction of its own pilot plant, and acquired from the Institute the services of Otto Roelen to supervise the work. Roelen was apparently glad to leave the institute, which had been unable to offer him a permanent position. He had also frequently come into conflict with the authoritarian director as a result of his own unorthodox interpretation of his responsibility for keeping fixed hours—a situation that eventually caused problems at Ruhrchemie as well. The agreement Roelen reached with Ruhrchemie on October 23, 1934, read as follows:[24]

> "In the pilot plant we have constructed for the preparation of gasoline according to the Fischer–Tropsch process, you [Otto Roelen] will assume responsibility for managing the fine purification as well as the actual synthesis itself, including preparation of the purifying material and the catalysts, and for managing the laboratory... You also have the right and the responsibility to examine the rest of the pilot plant and offer suggestions regarding its operation in the interest of efficient organization."

In order to adapt existing FT technology to industrial practice, Roelen found himself engaged in problems of gas desulfurization, catalyst preparation and formulation, and the economically important issue of catalyst regeneration. Without the innovations introduced by Roelen and his co-workers Feißt and Heckel it would have been necessary soon to abandon the host of FT facilities so quickly set up during the mid-1930s, because at first no method could be found for regenerating the cobalt catalysts. Roelen and Walter Feißt ultimately succeeded in developing a catalyst preparation method in which the interfering impurities were removed by prior precipitation. This process[25] and Roelen's basic patent for the standard magnesium-containing FT catalyst[26] were implemented at all the FT plants prior to 1945, and even after 1945 at the Chemische Werke Bergkamen. Many of Roelen's other discoveries were incorporated after World War II into the South African Sasol facilities, constructed under license from Lurgi/Ruhrchemie.

Otto Roelen thus served as "chief chemist" for the general licenser, and as a result of the contractually assured exchange of expertise among the various FT plants he was also among the best-informed practitioners in the field. Nevertheless, neither he

nor Helmut Pichler, his successor in the Mülheim research group, was assigned responsibility for the "Reichsamtsversuche" (Official Government Investigations), a set of comparative evaluations of various FT catalysts conducted at the Fischer–Tropsch plant in Schwarzheide. This function was instead assumed by Herbert Kölbel from the FT producer Gewerkschaft Rheinpreußen. Roelen was apparently overburdened with other work, and also considered an interested party because of his own catalyst-development activities. Moreover, in 1941 he began developing a process for the methanization of carbon monoxide, on the basis of which a first "gas station" (in the literal sense) was erected in Essen, to be followed by similar facilities at the Opel works in Rüsselsheim and, after World War II, in Bochum at the Carolinenglück mine, in Düsseldorf, and at Röhm & Haas in Darmstadt.[27]

When the war ended, Roelen was in Gebhardshagen near Salzgitter, and at first he managed to avoid questioning by Allied specialists (cf. Section 2.2) by moving out to the farm of some friends, where he recuperated from an illness. When he finally returned to Oberhausen in 1945, British military authorities had already learned of his importance and the information he possessed. On November 4, 1945, the British Ministry of Fuel and Power ordered his transfer to Wimbledon:[28]

> "From the Investigations of the Field Teams in Germany and from examinations of captured documents it seemed probable that Dr. Otto Roelen had a more complete knowledge of the research side of the Fischer–Tropsch process than any other person in Germany... Among his own achievements were the development of the fine-purification process and the discovery of the 'Oxo' reaction."

Upon returning from England Roelen engaged initially in literature work for Ruhrchemie AG and the military government, pursuing no chemical research whatsoever. Roelen described the FT synthesis from a historical point of view in the first postwar edition of *Ullmanns Enzyklopädie der Technischen Chemie*. This led to a quarrel with his former colleague at the KWI, Helmut Pichler, because Roelen's contribution covered only the "medium-pressure fixed-bed synthesis" as one variant on the FT process, not the "Fischer–Pichler medium-pressure synthesis" (an expression occasionally utilized by Franz Fischer), which Pichler wished to see treated.[31] After 1949 Roelen became Assistant Head, and on October 1, 1955, once again Head of the Ruhrchemie Research Laboratories and Executive Secretary of the company. He officially retired on March 31, 1962.[29]

In the years after his retirement Otto Roelen not only enjoyed the respect of the scientific community but was also honored with a number of awards, including the 1963 Adolf-von-Baeyer Medal from the Gesellschaft Deutscher Chemiker (GDCh) and the Normann Medal of the Deutsche Gesellschaft für Fettwissenschaft (DGF) (cf. Fig. 2).[29] In 1983 on the occasion of his 86th birthday, and in recognition of his accomplishments in fundamental processes of coal and petroleum chemistry, he was awarded an honorary doctorate from the Technische Hochschule Aachen. As early as the end of 1944 he was nominated by the Ruhrchemie AG for the Dr.-Fritz-Todt prize. However, since at that time the oxo synthesis had not yet achieved any industrial significance, the responsible authorities declined to present him with the award, an outcome for which he had every reason to be grateful in the postwar years.[30]

Fig. 2. Otto Roelen (left) in 1963 at the presentation of the Normann Medal by the DGF.

Apart from this, Roelen's retirement years were devoted to his numerous hobbies. Many of these he had taken up earlier, as is evident from a close scrutiny of his publications and his personal papers from his years at the KWI and Ruhrchemie. He eventually found the leisure necessary to prepare comprehensive articles describing his contributions to the oxo[32] and Fischer–Tropsch[17, 22] syntheses, in which he laid considerable stress on those aspects relevant to the history of chemistry. All three papers are exceedingly informative, because he was able to write them not only as one of the direct participants, but also with perspective acquired after four decades, analogous to G. Schiemann's situation as he looked back over the field of fluorine chemistry (cf. Fig. 3).

Fig. 3. Friendly exchange between two chemists for whom reactions were named: G. Schiemann (1899–1967, the Schiemann reaction for fluorination of arenes) and O. Roelen (1897–1993) in conversation at the bowling alley ("Kegelbahn") of the Ruhrchemie AG; photo taken July 23, 1964.

Another important issue for Roelen was his personal health, with which he conducted systematic experiments. It was this period of experimentation that led to an article entitled "Behandlung der Luftwege mit angereicherten Meersalz-Aerosolen" (Treatment of the Respiratory Tract with Enriched Sea-Salt

Aerosols),[33] in which he provided experimental details regarding what was apparently a very positive set of experiences, extending even to the question of the most appropriate materials for constructing an inhaler. Roelen was particularly intensively engaged with questions of the relationship between nourishment and one's state of health, occasionally displaying the zeal of a true missionary. This led to a number of short manuscripts[34, 35] as well as papers and personal experiments on the subject of allergens.[36]

Roelen shared with the great chemist William Crookes (1832–1919), inventor of the crookes tube for investigating cathode rays, an inclination toward questions that would typically be regarded as the exclusive domain of parapsychology.[37] Whereas Crookes pursued the occult and nurtured a "familiar relationship with 'materialized personalities'," Otto Roelen spent his time in the "shadow world between the known and the unknown,"[37] searching for quantifiable experimental verification of oscillation phenomena, whose "objectification" he felt always on the verge of achieving until a stroke in 1981 prevented him from pursuing further experimental work and applying his recently acquired extensive knowledge of electronics and semiconductors. His typewritten manuscript on questions relevant to oscillation[38] describes his experiments in detail, with photographic documentation of his experimental setup and an account of results he acquired in the 3.18-cm wavelength range. But it also conveys his singular conviction that "oscillatory perception," like color blindness, is confined to only a minority of sensitized individuals. In sharp contrast to his attitudes in many other respects, he concluded the 1980 typescript with the resigned observation: "Much that is observed for the first time remains inexplicable..."

But his greatest academic obsession during retirement was a lively interest in historical and didactic problems related to research, probably stimulated in part by his excellent insight into his own discovery of the oxo synthesis and his deep disappointment for having failed to recognize the true nature of the catalysis involved (Section 3.2). A study by Roelen dated as early as 1968 and entitled "Emotik—Von den Überzeugungen und ihren heimlichen Herrschern"[39] ("Emotik"—Convictions and Their Secret Masters) explores the contrasts between opinions and convictions, considering their rational and emotional content as well as their treatment by natural scientists in light of the methodological skepticism expressed by Descartes. The motif of "semantic deception" on the part of nonscientists appears at a very early date as well; indeed, it is little wonder that in his circle of friends he came to be known as an evangelist on behalf of C. P. Snow,[40] who began in 1959 to call attention to fundamental incompatibilities between the pronouncements and worldviews of scientists and those of humanists ("The Two Cultures,"[41] still referred to euphemistically as "literate circles"). Roelen concluded in 1968 that

> "this cultural dilemma... exposed by Snow is so alarming precisely because those with a humanistic education—who persist in their denial, ignorance, and misunderstanding of the achievements of science—are the very ones occupying the seats of power."

The symptoms and consequences of this cultural dilemma can be formulated earnestly,[42, 43] satirically,[44] or in a martial spirit, the latter illustrated by Roelen's 1983 response to the question of how scientific discoveries come about:[45]

> "A further example of the way research is hampered by the spirit of the times is presented by the attack on science and technology... The demand is made that scientific research... should assume a set of moral obligations, and subject itself to social planning. This has been very clearly expressed, for example, in concepts developed at the former Max-Planck-Institut in Starnberg for the culmination of the sciences.
>
> "Such demands are advanced by people who have never engaged in experimental research, and who are able to maintain their positions only by semantic blurring and factual errors...."

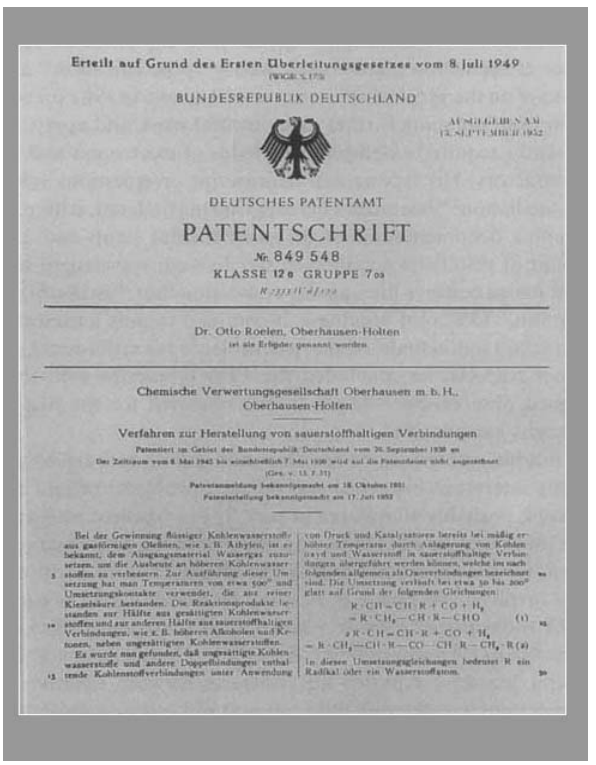
2. His Greatest Achievement: The Oxo Synthesis

2.1. History of the Discovery

It was in 1934 that Roelen moved to the Ruhrchemie AG, and it marked a turning point in his life. Adolf Hitler's Third Reich was aiming its sights quite openly and single-mindedly toward military conflict with Germany's neighbors. Military preparations quickly involved the chemical industry, including Ruhrchemie, whose fertilizer business had become increasingly unprofitable following collapse of the international cartel negotiations coupled with the compulsory cartel and international trade restrictions imposed by the German nitrogen syndicate and aggressive quota politics on the part of the I. G. Farbenindustrie (I. G.) conglomerate.[46] All of this had affected Ruhrchemie in one way or another.

One possibility for escaping the desolate economic situation called for broadening the company's product spectrum, which led to efforts directed toward coal chemistry (methanization, methane cracking to yield benzene or acetylene), as well as an increase in activity at the Chemische Fabrik Holten GmbH, which had been established in 1929. The latter originated as a joint venture operated by Ruhrchemie AG and the Th. Goldschmidt AG in Essen for preparing glycol from ethylene isolated from coke-oven gas. Even as the plant was being built, the market leader in this sector, I. G. Farben, insisted on becoming involved financially in the new operation and playing a significant role in marketing, demands that were in fact met. This serves as yet another example of the way I. G. insinuated itself into the plans of outside concerns, just as it had in the disputes related to fertilizers. Persistent interference of this type was one of the constant factors over a period of many years that marked the tense relationship linking Ruhrchemie and Otto Roelen himself with I. G. Farben and its chemists. Attempts are still being made to this day by I. G. apologists to rewrite history in such a way as to gloss over the picture of this domineering, no-holds-barred monopolizer.[46]

One potentially promising foothold for Ruhrchemie was the Fischer–Tropsch synthesis (cf. Section 1). Following preliminary negotiations and attempts by I. G. to limit competition with its own fuel production based on coal hydrogenation, Ruhrchemie acquired the rights to the FT process as general licensee, which entailed the obligation to pursue development of the tech-



nology to the point of constructing a demonstration facility and a pilot plant capable of producing 5000 t/a.[47]

Otto Roelen was thus fully aware of what awaited him as he, his colleague Dr. Feißt, and his chief technician Hanisch made the move in 1934 from the KWI in Mülheim to the Ruhrchemie works in nearby Holten, a suburb of the city of Oberhausen. And he was also well prepared. As head of the FT demonstration facility at the KWI he was effectively predestined to undertake this assignment and assume the responsibility for Fischer–Tropsch development efforts at Ruhrchemie. The Ruhrchemie organizational plan during the period 1934–1945 as presented in BIOS Report 447[28] indicates that Roelen's FT research activities were initially transferred from Ruhrchemie itself to the sister corporation Ruhrbenzin,[47] and then back again to Ruhrchemie. This plan also documents a deliberate policy (for reasons of secrecy) of mutual isolation of all the various research facilities, a policy basically consistent with Roelen's own temperament, but which nonetheless hindered the constructive exchange of ideas. Even BIOS Report 447 contains disparaging remarks with regard to this organizational structure.[28]

The emphasis in Roelen's work with Ruhrchemie was still on the continued development of the FT synthesis in 1938, when seven FT plants were either already in operation or on the verge of starting production. The general licenser was compelled to deal with a great many questions during the construction and early operational phases of these new facilities, most of which became the responsibility of Roelen's department—often without preliminary screening or prioritization. This work load was augmented by the obligation to certify all FT catalyst charges and the additional burden of a laborious and time-consuming search for a substitute for cobalt, a strategically important and exceedingly costly metal that served as the basis for FT catalysts. The latter problem was made all the more troublesome by the fact that it necessarily entailed very prolonged test cycles. One particularly urgent aspect of FT studies at that time concerned attempts to recycle "gasol" hydrocarbons (C_2–C_4 compounds, including olefins and especially ethylene)[48] as a way of incorporating them into higher hydrocarbons. In contrast to later research on "selective FT synthesis,"[49] ethylene was completely useless for gasoline synthesis. Based on agreements between the licensees, and as part of an official exchange of information, attempts were to be made to ascertain whether and to what extent it was feasible to incorporate lower olefins into the product through recycling, and whether NH_3 might also be suitable for inclusion in a "growing FT chain."

At the end of 1937 in the course of these investigations Roelen discovered the aldehyde synthesis that was later to bear his name (the Roelen reaction, hydroformylation, oxo synthesis). The actual discovery was a direct consequence of problems encountered with two atmospheric-pressure FT ovens, one of which had been charged with ethylene and the other with ammonia, ovens that were connected for waste-disposal purposes by a common off-gas pipe (for complete details see ref. [32]). In the course of this particular experiment a white residue accumulated in the piping, the odor of which was reminiscent of aldehyde–ammonia compounds (specifically the aldimine derived from ammonia and propionaldehyde, where the latter had arisen from the reaction of ethylene with synthesis gas). This observation set Roelen on the trail of the oxo synthesis. Experiments designed to establish optimal reactions conditions and the overall potential of the reaction were resumed on July 26, 1938, as soon as the appropriate pressure equipment had been acquired. Intensive investigations followed, and by September 20, 1938, the first patent application on the oxo synthesis was filed. Finally on June 17, 1952, a patent was issued with the number 849 548[50] (Fig. 4) covering the following claims:

"Procedure for the preparation of oxygen-containing compounds in which unsaturated hydrocarbons (e.g., olefinic hydrocarbons) are treated at elevated pressure and temperatures up to approximately 200 °C with water gas or other gas mixtures containing carbon monoxide and hydrogen."

KLASSE 12 o GRUPPE 7 02

Dr. Otto Roelen, Oberhausen-Holten

Chemische Verwertungsgesellschaft Oberhausen m. b. H., Oberhausen-Holten

Verfahren zur Herstellung von sauerstoffhaltigen Verbindungen

Fig. 4. Facsimile of the first oxo patent from 1938/1952 [50].

In a retrospective paper describing the discovery of the oxo synthesis, prepared in 1977 and entitled "Beitrag zur Psychologie der naturwissenschaftlichen Forschung" (Contribution to the Psychology of Scientific Research), Roelen provided a lengthy case history of this exceptional chapter "in the larger context of the catalytic reduction of carbon monoxide."[32] (Incidentally, the description he furnished in 1946 for BIOS Report 447[28] is identical in content.) Roelen includes in this case history experiments undertaken at BASF in 1913, in which higher hydrocarbons and oxygen-containing compounds were first formed catalytically from CO and H_2 at elevated pressures.[8] Fischer and Tropsch (later Roelen as well) used these experiments as their starting point in 1922 and thereafter at what was then the KWI

(today the Max-Planck-Institut) in Mülheim when they utilized iron catalysts to prepare "Synthol," a mixture of oxygen-containing compounds. These later experiments were conducted at quite high pressures. The more active the catalyst, the lower the required pressure, and the more the nature of the product shifted in the direction of hydrocarbons, an observation that led ultimately to discovery of the atmospheric-pressure Fischer–Tropsch synthesis (cf. Section 1).[51, 52]

Quite independently of Fischer's experiments, Smith, Hawk, and Golden[53] at the United States Bureau of Mines had also attempted to introduce ethylene into the reactant stream in an atmospheric-pressure FT reaction over a cobalt catalyst. With the exception of high pressure, all the essential conditions were thus established for the subsequently discovered oxo synthesis. (FIAT Report No. 1000 actually describes parenthetically —and quite incorrectly— the paper by Smith et al. as the "first publication of the basic Oxo reaction,"[54] presumably in reaction to claims of success arising out of the Third Reich.) Smith, Hawk, and Golden did indeed obtain some aldehydes and alcohols, but they interpreted them explicitly to be intermediates produced in the course of the FT reaction. Roelen formulated the matter rather more logically when he asserted that[32]

> "the cited Americans did indeed carry out the aldehyde synthesis in 1930, but they did not discover it. Their presuppositions with respect to the reaction mechanism prevented them from recognizing that a second, independent reaction was involved. This intellectual inhibition was confirmed for the author orally in the course of a later visit."

Intellectual inhibitions and presuppositions regarding the nature of the catalysis played a role in the later history of the oxo synthesis as well (cf. Section 3.2). Thus, because of the "general impression of the experts that oxygen-containing by-products of the FT synthesis were inevitably and inseparably related to the mechanism of hydrocarbon synthesis,"[32] an independent synthesis of oxygen-containing products was never even considered. This is confirmed by widespread acceptance of the Synthol (I. G. Farbenindustrie[55]) and Oxyl (Ruhrchemie AG[48, 56, 57]) syntheses as variants of the FT synthesis.

Thus, in 1937/38 Roelen's real intellectual accomplishment in analyzing the operational disruption described above was freeing himself from any preconception about oxygen-containing compounds and their inevitable appearance as intermediates in a normal FT hydrocarbon synthesis. Perhaps most important, the absence of a typical series of compounds with increasing molecular mass led him to suspect the existence of an independent synthesis of propionaldehyde [Eq. (a)] and diethyl ketone based on ethylene that had been introduced into the

$$H_2C{=}CH_2 + CO + H_2 \xrightarrow{cat.} H_3C{-}CH_2{-}CHO \qquad (a)$$

reaction mixture.[32] He concluded that such a reaction, if it occurred, must be dependent on pressure, and that propionaldehyde formation would be favored by an increase in pressure. The first high-pressure oxo reaction (243 °C/100 bar) was conducted on July 26, 1938, and it confirmed Roelen's suspicions. Subsequent process optimization for the oxo reaction involved parameters clearly outside the range appropriate for an FT reaction, including relatively low temperature and high CO/H_2 pressure. Shortly thereafter studies were initiated on possible applications of the new synthesis, and patent protection was sought as outlined previously.

The term "oxo" as applied to this reaction was coined by the Ruhrchemie patent department, and was intended to suggest a general reaction for the synthesis of both aldehydes *and* ketones (i.e., oxo compounds), although it was later established that this flexibility is limited to ethylene. The "invention" itself was noteworthy from one additional standpoint: a German patent was never actually issued until July 1952, and then on the basis of the Patent Transition Law ("Patentüberleitungsgesetz") of the Federal Republic of Germany, whereas French, Italian, and American versions appeared (but attracted little notice) during World War II.[58, 59] The war itself had the effect of depriving Roelen of the international monetary fruits of his discovery, because all foreign patent rights assigned to Germans were confiscated after the war. As a result Roelen and Ruhrchemie received royalty payments only from the German oxo facilities operated by BASF and Hüls, not from the much larger foreign producers.

It should be noted in passing that the discovery of the oxo synthesis is still controversial; experience has shown that successful children are frequently claimed by multiple fathers. In discussing the matter, Roelen always emphasized the fact, underscored in his retrospective description of the discovery, that the definitive experiments were carried out at his own risk, and that their further pursuit was against the express wishes of company management:[32]

> "Thereafter experiments on the effect of synthesis-gas supplements were abandoned at the instruction of the management."

That was in December 1937; based on the considerations described above, Roelen modified the experimental protocol between January and June of 1938 in such a way that it was possible for a first successful high-pressure experiment to be carried out on July 26, 1938.

As usual, management saw things in a somewhat different light. In the "Minutes of a Presidial and Executive Board Meeting of the Ruhrchemie and Ruhrbenzin Aktiengesellschaft on February 6, 1940"[60] remarks on the subject of fatty alcohols by F. Martin, at that time Chairman of the Board of both Ruhrchemie and Ruhrbenzin,[61] are recorded as follows:

> "Martin sketched out the history of the development of the process for preparing aldehydes and fatty alcohols. Concerns related to the disposal of relatively large quantities of gasols derived from fuel synthesis, materials with only a limited potential for exploitation, had induced him to direct Dr. Roelen to undertake experiments into the possibility of utilizing these gases for further reaction with water gas. It was found that the olefins could in fact be converted into straight-chain and isoaldehydes ... ."

Martin told the same story during the first round of questioning by C. C. Hall's CIOS team, who reported as follows: "In the gasol fraction, they had large amounts of propene and butene for which they had no use, so Martin instructed his chemists to find some more use for these compounds."[124]

In other words, the Executive Board had its own interpretation, at least with respect to causation in the history of the discovery. It is safe to assume that Otto Roelen was not aware of the corresponding minutes, which during the war were declared to be "confidential" (and that he never saw them after the war since he was not a member of the Executive Board). Thus, it is all the more noteworthy that he continued to insist on the role played by successful insubordination—not the last time, incidentally, that insubordination was to have a place in Ruhrchemie's history of the oxo synthesis.

2.2. The Industrial Oxo Synthesis during the Early Years

The oxo synthesis was an excellent match for the raw materials accessible to the Ruhrchemie AG, which had Fischer–Tropsch facilities as a source of olefins, experience in catalyst preparation, and water-gas generators (cf. Figs. 5 and 6[124]). The oxo synthesis was also well suited to the war-oriented economic politics of the National Socialists, so much so that it quickly attracted the greedy attention of others. The first entry dealing with Roelen's discoveries in the minutes of the Executive Board of Ruhrchemie is the above-cited account by Martin regarding the history of the matter.[60] The record continues as follows:

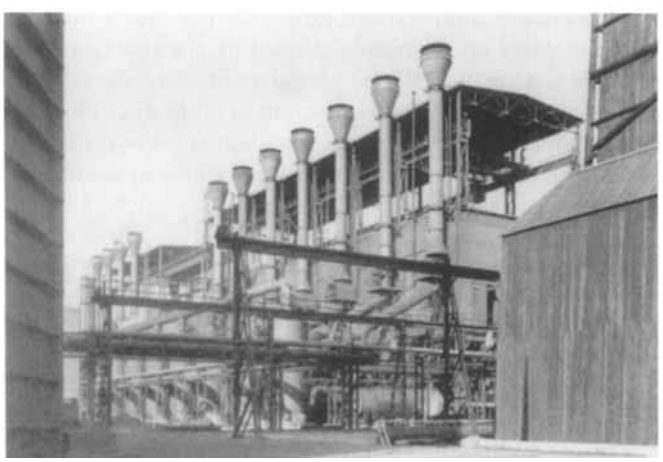

Fig. 5. The eleven water-gas generators used to supply the Fischer–Tropsch facilities at Ruhrchemie (1941).

Fig. 6. Atmospheric-pressure Fischer–Tropsch reactor at the Ruhrchemie plant (left), with the vessel used for introducing a catalyst charge (1942).

> "At the instigation of the government it is now likely that together with I. G. and Henkel we will construct a synthesis facility with a capacity of 120000 t/a in Upper Silesia ... It is further anticipated that Ruhrchemie's share of the investment will somehow take the form of a licensing agreement ... Martin noted in addition that prior to approaching Henkel and I. G. it would also be advisable to confer with Goldschmidt ... ."

Ruhrchemie and I. G. then jointly established the Chemische Verwertungsgesellschaft Oberhausen mbH, a corporation that assumed all rights related to the oxo process and was prepared to grant licenses. The nature of further interaction with Henkel and I. G. was spelled out in detail in a meeting of the Executive Board on July 4, 1940.[62] Another company, the Oxogesellschaft mbH, controlled equally by Ruhrchemie, Henkel, and I. G.,[63] was expected to erect a 15000 t/a facility for the production of synthetic fatty alcohols, whereby

> "further processing of crude intermediates to finished products by the company itself [i.e., Ruhrchemie; clarification by the authors] is out of the question, since in accordance with the government's wishes facilities belonging to Henkel and I. G. have been set aside for this purpose."

The extent to which "the government's wishes" were actually a reflection of influential guidance of I. G. can only be a matter of speculation today. Interestingly, this joint venture between Ruhrchemie and I. G. was later interpreted as Ruhrchemie's admission of parallel discovery of the oxo synthesis by I. G.:[64]

> "Comme, d'autre part, l'I. G. Farbenindustrie de Ludwigshafen avait elle aussi trouvé indépendamment cette réaction, un accord est intervenu entre la Ruhr-Chemie et l'I. G."[*]

This interpretation, which is contradicted by the facts, is presumably related to a similarly incorrect report issued by the U.S. Naval Technical Mission in Europe;[138] there is no proof to substantiate it, and it has found no backers despite efforts in that direction. For example, the oxo synthesis as defined above has sometimes (not surprisingly) been attributed to Reppe, as a special case of the "... general group of reactions between olefins, carbon monoxide and additional compounds such as ... and H_2 ..."[54] investigated and claimed by him, and it has occasionally been peddled as such by Reppe and his disciples.[65] Interestingly, BIOS Reports 273 and 355, which are dedicated more directly to Reppe, do make mention of the oxo synthesis (indeed, with $[Ni(CO)_4]$ as catalyst!) but without naming Otto Roelen.[119]

[*] "Since I. G. Farbenindustrie also discovered this reaction independently, an agreement was arranged between Ruhrchemie and I. G."

Although Board Member Kost (General Director of the Ruhrchemie Shareholders, Gewerkschaft Rheinpreussen) correctly noted during the meeting of the Executive Board that the planned venture "was not consistent with the concept that led to the formation of Ruhrchemie and Ruhrbenzin"—namely the production of chemicals independently of I. G.[47]—his opposition proved futile. Kost nevertheless ensured that his reservations would be expressed very clearly in the minutes:[62]

> "Today's events are another example of I. G.'s efforts to buy up the primary products of the Fischer synthesis and thereby prevent the companies [e.g., Ruhrchemie; clarification by the authors] from participating in the profits derived from finishing."

In this way Ruhrchemie AG was once again prevented from gaining direct access to the market.

On November 13, 1940, the Executive Board of Ruhrchemie resolved to construct a facility for producing 7000 t/a of fatty alcohols; Henkel was to assume Ruhrchemie's portion of the construction costs.[66] A year later the oxo facility was under construction,[67] after Oxogesellschaft mbH[63] on February 28, 1941, issued a construction order to Ruhrchemie on behalf of its three partners (Ruhrchemie, BASF, and Henkel) to establish a "facility in which ca. 10000 t/a of olefins with a chain length of C_{11}–C_{17} are to be converted by the oxo process into fatty alcohols or fatty acids"[68]—and thus into detergents. Because the relevant minutes of the meeting of the Executive Board are no longer available (presumably as a consequence of the war), it is impossible to reconstruct a complete chronology of this first commercial application of the oxo synthesis (cf. Figs. 7 and 8). It is

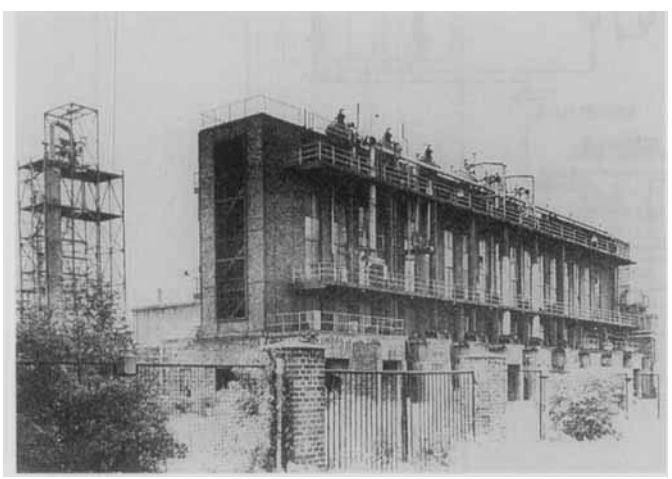

Fig. 7. Ruhrchemie oxo facility, shown under construction (1943).

clear, however, that with the exception of tests related to some of the components, the facility itself was never in operation during the war years,[124] perhaps in part because I. G. was able, upon payment of licensing fees, to test the available Ruhrchemie know-how directly in its own pilot facilities. With up to 100 tons per month of its own oxoalcohols produced in this way, I. G. had little further interest in a plant not under its direct control.[54] The Chemische Verwertungsgesellschaft Oberhausen mbH, charged with "the exploitation of chemical processes [and] the projection of facilities for licensees . . .",[69] was not dissolved until 1973,[70] serving into the 1950s as patent applicant on behalf of both Ruhrchemie and BASF with respect to inventions relevant to the oxo process.

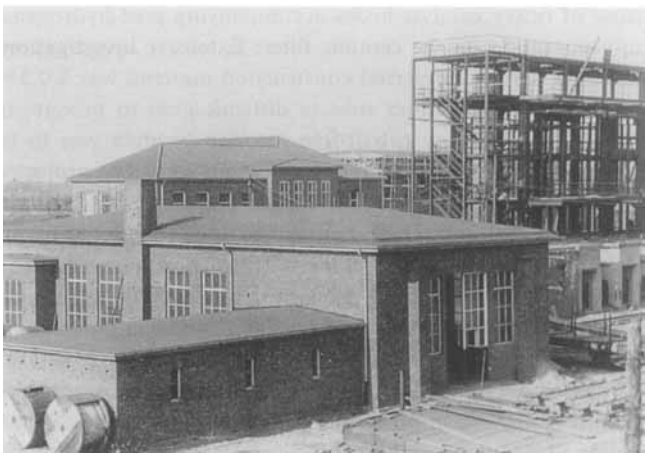

Fig. 8. Distillation facilities and administration building of the Oxo GmbH.

FIAT Report 1000[54] provides a wealth of interesting information (which would otherwise have been lost) regarding the development of the oxo process during the war. Otto Roelen's attention in Oberhausen-Holten was concentrated on the preparation of higher fatty alcohols intended for conversion into detergents and soaps.[124] I. G. had no access to FT olefins, and therefore devoted its efforts exclusively to the utilization of lower olefins (C_5–C_{10}) and the production of plasticizers of the palatinol type, as well as the further utilization of lower aldehydes (e.g., in perfumes; cf. references to Reppe in ref. [28]).

Ruhrchemie's first oxo facility consisted of a "prefractionator" for the starting olefins, oxo and hydrogenation stages, a filtration system, and final distillation towers (cf. also refs. [54, 71]). The FIAT report actually contains the first use of the English expression "to oxonate," intended as a counterpart to the German "oxieren";[72] the latter was an unfortunate piece of terminology invented by the Ruhrchemie patent department, which only later replaced it by the more correct "Hydroformylierung"[73] (hydroformylation) and the alternatives "Roelen Synthesis" (proposed by Hall in 1946[74]) and "Roelen Reaction (Adkins, 1948[75]). Nevertheless, the term "oxieren" continues to be part of the technical vocabulary at oxo facilities operated by BASF and Ruhrchemie; even semiotic heresy can prove to be surprisingly persistent!

The flow sheet reproduced in Figure 9 provides details concerning the first oxo facility constructed by Ruhrchemie in Holten. The reaction was to be carried out in batch mode at 135 °C and a pressure of 200 bar. Plans called for using a standard FT catalyst consisting of cobalt, thorium oxide, magnesium oxide, and kieselguhr in a 100:5:8:200 ratio, to be introduced as a suspension (slurry) that would subsequently be ground together with the olefin. After transfer to a second reactor and purging of the gas, crude oxo product was to be hydrogenated in a single phase over the same catalyst, leading to the desired fatty alcohols. Preliminary experiments indicated a probable catalyst consumption of roughly 300 kg per day, primarily be-

cause of heavy catalyst losses accompanying post-hydrogenation separation on the ceramic filter. Extensive investigations indicated that the preferred construction material was 3/0.5% chromium–molybdenum steel, a difficult item to procure in those days. The now cobalt-free reaction product was to be fractionally distilled in a final purification step. The projected average yield was 80%; 20% of the starting olefin was expected to be converted into a high-boiling fraction (referred to by the CIOS team as "thick oils," a literal translation of the German "Dicköle"[124]), consisting primarily of aldols. It was thought that these could be largely hydrogenated to the corresponding alcohols (including 2-ethylhexanol[124]).

In keeping with the "oxo agreement" that had been concluded with Ruhrchemie, other oxo pilot plants were to be established at I. G. plants in Leuna, Ludwigshafen, and Oppau. Instead of Roelen's batch procedure these plants were designed for continuous fixed-bed and slurry processes; carrier-free cobalt catalysts (e.g., cobalt naphthenate or acetate) were added subsequently to make up for cobalt losses (for details on the equipment and the corresponding engineering see ref. [54]). A remarkable number of the engineering and equipment features found in the Oberhausen and I. G. facilities were incorporated into later industrial oxo plants, including the cooling systems (liquid or gas), gas circulation schemes, grinding and introduction of suspended catalysts, pressure filtration of the pyrophoric catalysts, pumped transport of suspended catalysts, and carbonyl generators.

The first oxo facility constructed under license was destined for the explosives manufacturer Bombrini–Parodi–Delfino in Colleferro/Rome. Plans called for the conversion of ethylene into 25–30 tons per month of propionaldehyde, which was then to be reacted with formaldehyde to give trimethylolethane (TME, 2-hydroxymethyl-2-methyl-1,3-propanediol), a potential substitute for the important explosives intermediate pentaerythritol. This facility was designed for continuous production with a suspended catalyst (FT catalyst, suspended in diesel oil), but by the time the war ended only the corresponding reactor had been sent from Holten to Italy.[54] Experiments related to the conversion of propionaldehyde to TME had been entrusted to G. Natta, among others,[76] which explains Natta's early familiarity with the oxo synthesis (and his acquaintance with the Chairman of the Board of Ruhrchemie, F. Martin[77]).

The work in Holten and at the I. G. plants led not only to valuable engineering data, it also shed light on a number of fundamental chemical principles,[28, 48, 54, 57, 71] some of which were later "rediscovered" by others. This is the case, for example,

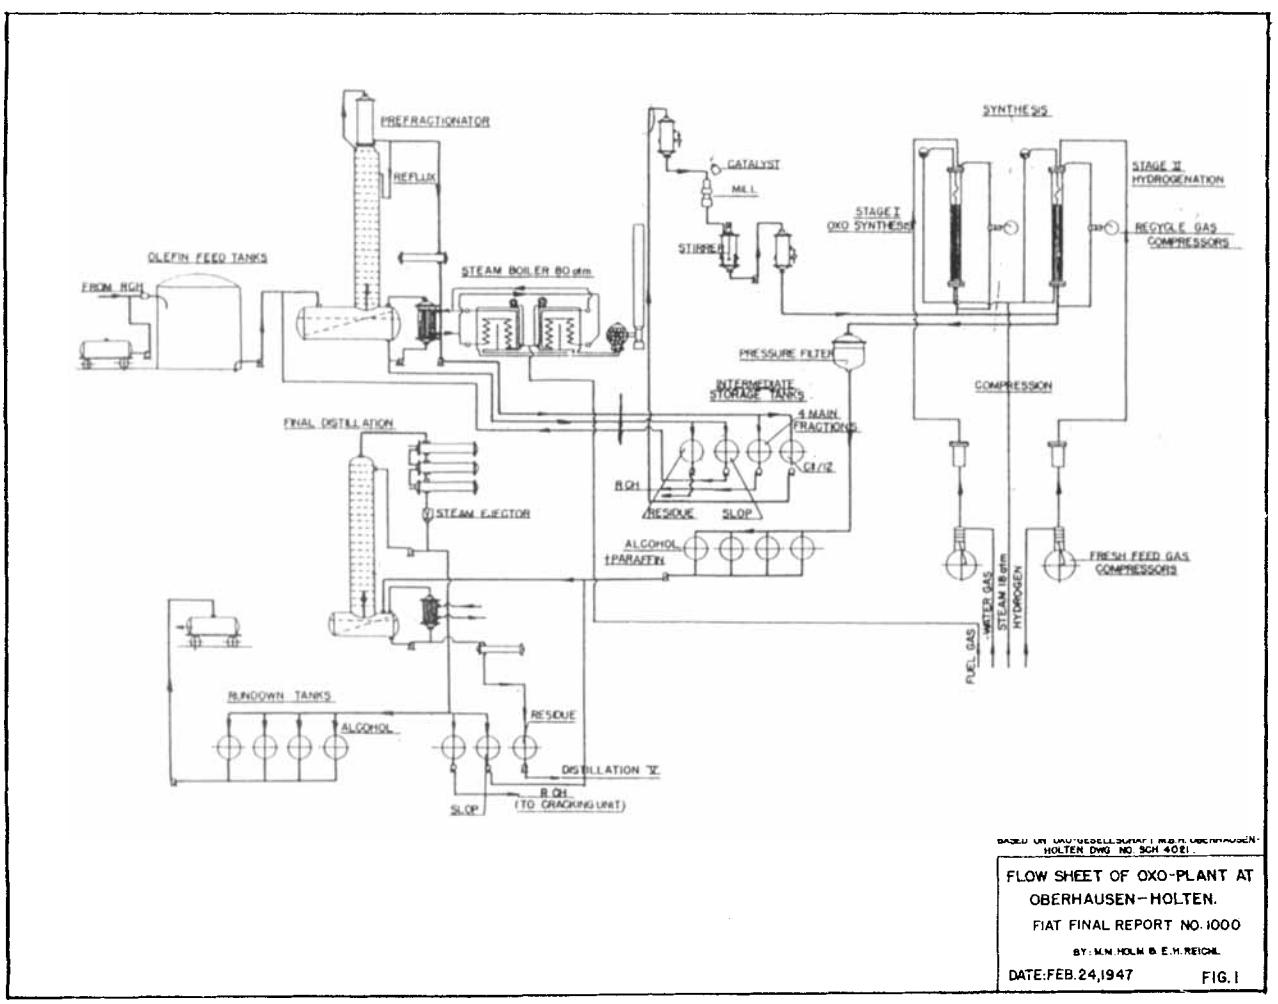

Fig. 9. Schematic diagram (flow sheet) of the oxo facility at Holten (Fig. 1 in ref. [54]).

with what has come to be known as "Keuleman's rule,"[78] according to which steric and electronic factors ensure that hydroformylation of isobutene will produce almost exclusively 3-methylbutanal, a phenomenon already observed by both I. G. and BASF[79] as well as Roelen himself,[80, 81] and communicated in the FIAT report[54] (cf. also ref. [64]).

The reports of the Allied commissions of inquiry (e.g., BIOS, CIOS, and FIAT) make unusually fascinating reading even today.[82] These special units consisting of outstanding specialists from science and industry followed on the heels of the troops. Their assignment was to provide the respective countries (and, less explicitly, individual firms) with information on German scientific and technological progress during the war years, as well as insight into the current level of German know-how. It is also important to recognize in this context that at least the American FIAT teams—consisting of 6000 experts assigned exclusively to an investigation of the German chemical industry—were granted extraordinarily comprehensive powers, including the right (in the true spirit of the late James Bond) "to remove, arrest, and intern individual Germans."[82, 122, 123]

The discrepancy between official instructions from the government and personal obligations to individual firms made it easier for many of those questioned to limit the amount of information they provided, and in some cases even to introduce obstacles. A striking example is Otto Roelen's behavior with respect to the Farragher Report on Fischer–Tropsch research at Ruhrchemie, prepared in 1947 by Warren F. Farragher (who had already served as co-author of the CIOS report covering the entire Oberhausen facility[57]). Farragher was employed by the Houdry Process Corp. in Philadelphia. His report was to be based on testimony from various German experts, and was allegedly for the United States Government.[122] Otto Roelen had given the impression that he was quite willing to provide information during his questioning from November 1945 to September 1946 as a civil intern in Wimbledon, although he himself always regarded this period as one of defamatory "imprisonment" (cf. Fig. 10).[48] With respect to Farragher's demands, however, he was utterly intractable. The events leading up to the report were described by Roelen in the preface to his own account as follows:[83]

> "As former head of the research laboratory I was assigned the task of preparing a report on Ruhrchemie. Owing to my imprisonment in London, I was a very familiar figure at the relevant British office in Düsseldorf. There I learned that the Farragher operation was in no sense being conducted under orders from the occupation forces, but amounted instead to a private effort on behalf of American industry. In view of this situation I did indeed undertake and in fact complete the requested Ruhrchemie report, but in spite of an anticipated and delivered scolding, I did not submit it punctually. As a result, Mr. Farragher returned to the United States with eight Fischer–Tropsch reports..., but not with one from Ruhrchemie... For this reason the contents of the Ruhrchemie report have remained largely unknown."

Moreover, Ruhrchemie refused even at a later date to permit *cost-free* distribution of the report, and after the currency reform (1948) it enlisted the Economics Ministry of the State of North Rhine-Westphalia in support of its position relative to Farragher when the latter returned to Europe in 1950/51.[47] Only through Roelen's preface, cited above, did the whole process—described with revealing openness by Gimbel[82] as well—become fully understandable (cf. Fig. 11).

Fig. 10. Otto Roelen as a civil intern at the Beltane School, Wimbledon, 1945/46.

Fig. 11. Otto Roelen in Oberhausen at the time the Farragher Report was prepared (1947), shown here with his legendary briefcase.

The opinions reflected in the Allied reports with respect to new and, from their perspective, previously unknown developments such as the oxo synthesis were somewhat mixed. The reports remain a fundamentally sound source of insight into the state of technology in 1945 (albeit with occasional ambiguities as a result of misunderstandings). The quality of the information is of course a function of the competence of the particular investigators involved. Thus, reports on the oxo synthesis are quite varied, depending on whether they were prepared by the two-man teams Hasche/Boundy[71] and Withers/West,[48] or one of the groups associated with Farragher,[57] Hall,[28] or Holm[54] (cf. Fig. 12). Some of the inquisitors made liberal use

Fig. 12. Discussion of the FIAT Reports at the Martin family's garden house in Mülheim-Uhlenhorst, April 1947 [from the left: Rosendahl, Weinrotter (KWI Mülheim), Gehrke, Martin, Roelen (all three from the Ruhrchemie AG), Koch (KWI)]; photo taken by Mr. Atwell, FIAT].

of information from the interviews in their own publications, adding critical commentary on the historical development of the oxo reaction—from the British perspective, for example—and showing no hesitancy when it came to value judgments (cf. Hall,[74, 124] for example, who published a somewhat embellished version of his CIOS reports[57]). All the reports are tainted with at least a whiff of industrial espionage—quite understandably, given the history of the Third Reich; this was regarded by the British, for example, as a form of "hidden reparations" and compensation "... not only in direct damage, but in loss of time for research and re-equipment ... ."[123] The expropriation of all foreign patent rights, which was very painful and also financially devastating for the victims (including Otto Roelen), had deprived both the discoverers and their companies of the fruits of their labor. The following opening comment from the reports is thus especially moving to read:[71]

> "This report is issued with the warning that, if the subject matter should be protected by British Patents or Patent applications, this publication cannot be held to give any protection against action for infringement."

This statement was rarely extended by "and/or US Patents,"[84] and never adapted to cover patent rights of the other victorious powers—clear indication in whose interest the interrogations were actually conducted. It is therefore not surprising that oxo facilities in the United States benefited.[85] Contemporary press reports announcing the opening of new plants often ignored the country of origin for the process, and almost never mentioned the name Roelen. France was in this respect an exception. Oxo developments there were greatly influenced by a former Ruhrchemie employee, Lemke, who had worked in Oberhausen from 1941 until 1945.[86]

Economic data in the Allied reports is also interesting. During his interrogation Otto Roelen expressed himself in very vague terms:[87]

> "Finally Roelen said that he did not know if the oxo-process would be an economic proposition in peace time, but it was possible that it would, since Germany had to import large quantities of natural oils for production of soap and detergents."

Economic calculations, presumably based on a merger of the National Socialist wartime and self-sustaining economic projections with those drawn up by the Military High Command (and therefore not very reliable), estimated for the preparation of 100 kg of fatty alcohols a cost of 78 Reichsmark (RM) (for the Oberhausen facility, with a capacity of 12000 t/a[57, 124]); the cost under continuous operation was expected to fall to ca. 60 RM per 100 kg, assuming an olefin price of 45 RM per 100 kg. For comparison, the cost of primary FT product was estimated at roughly 24 RM per 100 kg (Bergkamen facility, 1944[74]).

A few additional comments are in order with respect to the subsequent history of the first oxo plant, that at Oberhausen-Holten. Activity here during the war was limited to the testing of a few of the individual components, and orderly production was never achieved. The facility was damaged during the final months of the war, but not so severely that its resurrection would have been impossible, or possible only at unreasonable cost.[124] Thus, the struggle to retain the oxo plant, along with an attempt to prevent demolition of the largely destroyed FT facility, was a life-and-death matter for Ruhrchemie in the immediate postwar years. It was argued for example, that the oxo plant was needed to guarantee the hygiene and health of an undernourished population, which was living under a threat of epidemics and hence in need of a reliable source of soap and cleansing agents based on synthetic fatty alcohols. In other attempts to stall demolition of the oxo facility Ruhrchemie accepted a foreign partner (the Sunlicht subsidiary of Unilever) in the Oxo GmbH, and worked on negotiation of a contract with the British concern Balduin, which (because it belonged to the Allies) might have offered some protection in the interest of acquiring detergent alcohols for its own purposes from the oxo facility.[47]

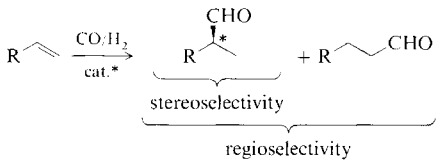
Nothing helped, however. By 1950, one of the two production lines of the oxo plant had been dismantled (Fig. 13)—only to be reconstructed at considerable expense starting in 1951. Never

Fig. 13. Dismantling of the Ruhrchemie facilities under the protection of the British Occupation Forces; the banner reads "Dismantlers, now begin your work!" [120].

theless, it soon became apparent that regular supply of starting olefins from the kogasin fraction of FT products or pyrolysis of FT waxes could not be assured, owing to the uncertain future of German FT facilities. As a result, a total of only about 3000 t of C_{10}–C_{18} oxo product was produced during the period 1953–1955.

The situation was further complicated by the fact that the original facility had become technically obsolete, and scientific information and technical experience gained in the meantime at the license-free production plants in the United States made it apparent that an oxo process based on the technical specifications of the original Ruhrchemie facility was unlikely to be successful. Synthetic detergent alcohols at that time were also not in a position to compete qualitatively with the natural alternatives. Moreover, an excellent supply of short- and medium-chain olefins was available (from cracking plants, or polymer olefins, C_6 to C_{12}), and interest had grown in producing the corresponding aldehydes resulting from the first step of the oxo synthesis (whereas the original oxo facility had been designed to produce higher detergent alcohols in a single step). Perhaps most important, so much had been learned about the mechanism of the oxo reaction that promising development potential was not apparent for the Ruhrchemie technology, based as it was on batch-slurry operation with a Fischer–Tropsch catalyst (cf. Section 3.2). Given a loss of interest on the part of Henkel, BASF (which in the early postwar years, like Ruhrchemie, continued to file patent applications on the oxo process through the Chemische Verwertungsgesellschaft mbH) drew the appropriate consequences as well, and abandoned its joint partnership with Ruhrchemie AG[88] in order to pursue its own interests—with payment of appropriate license fees. As matters developed, work began in 1958 on the perfection of a second "Ruhrchemie oxo process," culminating in a production capacity of roughly 335000 t/a. The new process attracted the interest of many licensees, and at its peak constituted the basis for over 20% of the newly erected oxo plants throughout the world. This success story was due in large measure to efforts of the Ruhrchemie engineering department, but Otto Roelen's research again played an important role.[89]

Several observations dating back to the war years were clearly suggestive of the true nature of the catalysis (homogeneous), the catalytically active species (tetracarbonylhydridocobalt), and at least parts of the reaction mechanism. The initially inexplicable and troublesome loss of cobalt through soluble cobalt compounds,[28] the pyrophoric nature of the catalyst,[54] and the elegant utilization of cobalt carbonyl for catalytic purposes[28, 54] might all have served as starting points for early speculation on the reaction mechanism, had such speculation not been hampered by specific mental blocks (cf. Section 3.2).



2.3. The Significance and Status of the Oxo Synthesis Today

The oxo synthesis has long been, and remains even now, an important industrial process; indeed, from a quantitative standpoint among catalytic organometallic processes it is second only to the Ziegler process for the manufacture of polyethylene and polypropylene. World capacity is currently ca. 6×10^6 t/a. Without going into detail on the present state of development with respect to the major oxo producers, we can still predict that three developments will determine the future significance of the oxo synthesis:

- As the literature indicates, continuing intense research and development in the area of hydroformylation is directed toward innovative applications of homogeneous catalysis, including regio- and stereoselective transformations of suitable starting materials.
- Oxo facilities in the highly industrialized countries will in the future be characterized largely by "highly sophisticated" applications involving regioselective hydroformylation, to be followed in due course by stereoselective reactions leading to unique and valuable products (i.e., special intermediates, formed perhaps enantioselectively), all in conjunction with tailored catalysts.
- World demand for "classical" oxo products (plasticizer and detergent alcohols) will increasingly be met by oxo facilities in less developed countries with access to the necessary resources (raw materials and labor). Many years of free-wheeling licensing politics, coupled with a high degree of automation that has reduced the demand for skilled personnel, now makes it possible for third-world countries (counter to Biblical prophecy) to harvest the fruits of development from fields they did not themselves sow, contributing "only" the essential inexpensive raw materials. Moreover, as the standard of living rises in these countries, so too will demand for certain oxo products that have increasingly become subjects of concern in countries with a higher level of "ecological awareness" (e.g., phthalate plasticizers).

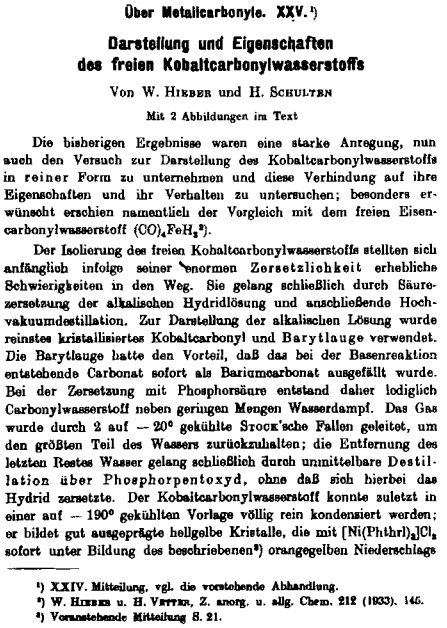
In this respect the oxo synthesis will follow a trend already apparent in chemistry generally: highly industrialized countries will devote their oxo facilities to Roelen reactions and follow-up steps leading to such highly specialized, "ecologically accept-

able" oxo compounds as pharmaceuticals and crop-protection agents. Consistent with this classical scenario, research and development will prepare the way by perfecting an improved line of catalysts. The improvements themselves will be fundamental in nature, encompassing both regioselectivity and stereoselective control over the course of the reaction [Eq. (b)].

(b)

3. Lost Opportunities

3.1. Hieber's Pioneering Work in the Area of Metal Carbonyls



Our current vantage point makes it clear that in the very year the oxo synthesis was discovered the time was ripe for a synergism to develop between the brilliant research efforts of Otto Roelen and Walter Hieber (1895–1976). Had this come to pass, both mechanistic understanding and industrial development of the hydroformylation reaction would have benefited enormously.

Walter Hieber, born on December 18, 1895, in Waldhausen (Württemberg) a son of the pastor and later Minister of Education Johannes Hieber, earned his doctorate in 1919 at the University of Tübingen under the supervision of the coordination chemist Rudolf F. Weinland. Habilitation followed at the University of Würzburg in July 1924. The first theme Hieber addressed in his habilitation thesis blazed the trail for his later work on the chemistry of carbon monoxide complexes: "It is not permissible to regard secondary valence simply as a residual valence or a fragmented main valence." Following a brief guest appearance in Jena, Hieber held professorships at the Universities of Heidelberg (until 1932) and Stuttgart before moving in 1935 at the age of 39 to the Technische Hochschule München as the successor to Geheimrat (Privy Councilor) Wilhelm Manchot (1869–1945). Hieber served in Munich as Professor and Director of the Inorganic Chemical Institute until his retirement in 1964. His predecessor, Manchot, was himself active and quite successful in the field of metal carbonyls (e.g., $[Au(CO)Cl]$, $[Os(CO)_3Cl_2]$), which was then still in its infancy, and it was for this reason that the young Hieber's brilliant work on reactions of this class of compounds came to Manchot's attention.[125, 126] Since 1927 Hieber had been trying to establish the extent to which carbon monoxide in metal complexes could be replaced by amines as a way of characterizing the metal carbonyls $[M(CO)_x]$ in the form of "elemental complexes." During the course of a set of experiments with pentacarbonyliron, suggested to him by Alwin Mittasch of BASF,[103, 125, 127] Hieber quickly recognized the principle that came to be known as valence disproportionation.[128] Nonoxidizing acids were used to protonate the readily accessible carbonylmetalates—anions with the formula $[M(CO)_n]^{m-}$ containing metal atoms in negative (!) oxidation states—to give a completely new class of "carbonyl hydrides" of the transition metals. The first spectacular example was "iron carbonyl hydride" with the formula $[H_2Fe(CO)_4]$, a colorless, clear, light- and temperature-sensitive, volatile substance, the isolation and manipulation of which required the experimental skills of a master.[129] Whereas its discoverers immediately assigned the correct structural formula to the compound, including bonding between the metal and atomic hydrogen, other authors were still ruminating many years later over the isomeric "hydrocarbonyls," with structures involving -COH ligands.[54]

In his continuing search for meaningful bonding interpretations Hieber formulated the H_2Fe group in $[H_2Fe(CO)_4]$ as a "pseudonickel atom" (essentially an isoelectronic substitution). This simple idea led him to the conclusion that a "cobalt carbonyl hydride" with the formula $[HCo(CO)_4]$ should also be possible; this compound would effectively complete the series $[Fe(CO)_5]$, $[H_2Fe(CO)_4]$, **$[HCo(CO)_4]$**, and $[Ni(CO)_4]$. While still in Heidelberg (1932) he in fact succeeded in demonstrating the existence of this highly volatile compound by the acid decomposition of amine-containing cobalt carbonyls.[130] The substance proved to be much less stable and even more reactive than the analogous iron compound. At this point Hieber was suddenly confronted with competition from America: Coleman and Blanchard of the Massachusetts Institute of Technology, completely unaware of Hieber's publications (all of which had been in German), reported in a paper submitted July 28, 1935, the reaction of $K[Co(CO)_4]$ with HCl, from which they isolated "a light yellow crystalline solid which melts at $-33\,^{\circ}C$ to a sulfur yellow liquid."[131] Although these authors had clearly recognized the acidic character of $[HCo(CO)_4]$, "the other experiments related to cobalt carbonyl hydride reported by the cited authors were conducted so inexactly, and the results were so imprecise, that one can dispense with discussing them further, especially since they have for some time been largely superseded by our own investigations."[132] Nevertheless, Hieber received from the American authors "a letter expressly acknowledging our priority in the discovery of the metal carbonyl hydrides."[132] Indeed, manuscripts received by journal editors from Hieber in 1932[130] and on February 9, 1936,[99] clearly do establish this priority.

The synthesis and properties of $[HCo(CO)_4]$ are described very precisely in two masterpieces of experimental work carried out in collaboration with H. Schulten (Fig. 14).[132, 133] The compound was prepared by means of the recently discovered "base reaction" (now commonly referred to in textbooks as the "Hieber base reaction") of the cobalt carbonyl $[Co_2(CO)_8]$ with barium hydroxide in a high-vacuum apparatus.[132] The melting point was determined "with a pentane thermometer calibrated by the Imperial Physical-Technical Facility, Berlin" and reported as $-26.2\,^{\circ}C$:[132] Swabian precision in every detail!

Although Walter Hieber published 200 additional experimental papers on metal carbonyls, those dealing with the carbonyl hydrides are regarded as the most original. They are also the most important if one includes in this category the "high-pressure direct syntheses" of metal carbonyls, developed for this category of substances. Hieber together with H. Schulten and R. Marin achieved a total synthesis of $[HCo(CO)_4]$ starting with cobalt powder and synthesis gas in 1938.[101, 102] Depending on the pressure and temperature, the major product of the reaction was either $[Co_2(CO)_8]$ or $[HCo(CO)_4]$. This particular piece of work—fundamentally important with respect to hydroformyla-

Über Metallcarbonyle. XXV.[1]

Darstellung und Eigenschaften des freien Kobaltcarbonylwasserstoffs

Von W. Hieber und H. Schulten

Mit 2 Abbildungen im Text

Die bisherigen Ergebnisse waren eine starke Anregung, nun auch den Versuch zur Darstellung des Kobaltcarbonylwasserstoffs in reiner Form zu unternehmen und diese Verbindung auf ihre Eigenschaften und ihr Verhalten zu untersuchen; besonders erwünscht erschien namentlich der Vergleich mit dem freien Eisencarbonylwasserstoff $(CO)_4FeH_2$[2]).

Der Isolierung des freien Kobaltcarbonylwasserstoffs stellten sich anfänglich infolge seiner enormen Zersetzlichkeit erhebliche Schwierigkeiten in den Weg. Sie gelang schließlich durch Säurezersetzung der alkalischen Hydridlösung und anschließende Hochvakuumdestillation. Zur Darstellung der alkalischen Lösung wurde reinstes kristallisiertes Kobaltcarbonyl und Barytlauge verwendet. Die Barytlauge hatte den Vorteil, daß das bei der Basenreaktion entstehende Carbonat sofort als Bariumcarbonat ausgefällt wurde. Bei der Zersetzung mit Phosphorsäure entstand daher lediglich Carbonylwasserstoff neben geringen Mengen Wasserdampf. Das Gas wurde durch 2 auf −20° gekühlte Stock'sche Fallen geleitet, um den größten Teil des Wassers zurückzuhalten; die Entfernung des letzten Restes Wasser gelang schließlich durch unmittelbare Destillation über Phosphorpentoxyd, ohne daß sich hierbei das Hydrid zersetzte. Der Kobaltcarbonylwasserstoff konnte zuletzt in einer auf −190° gekühlten Vorlage völlig rein kondensiert werden; er bildet gut ausgeprägte hellgelbe Kristalle, die mit $[Ni(Phthrl)_2]Cl_2$ sofort unter Bildung des beschriebenen[2]) orangegelben Niederschlags

tion as well—was submitted for publication on November 24, 1938,[101] very soon after Otto Roelen filed the first oxo patent application.[50] The relevance of Hieber's pioneering work to the reaction mechanism of hydroformylation thus becomes obvious. An article in an American journal first alluded to the possible connection ("We suggest that a hydride is the reagent effective in the synthesis"[75]), and FIAT Report 1000 also speaks of "hydrocarbonyl $Co(CO)_x(H)_y$" as the reactive species,[54] referring to information provided by Otto Roelen of Ruhrchemie and Kurt Schuster of BASF (cf. Section 3.2).

It remains one of the ironies in the history of science that Walter Hieber (Fig. 15) never met Otto Roelen, who was almost exactly his age. Hieber's students maintained that he never even sought such a contact. Moreover, the name Roelen is nowhere cited in any of Hieber's publications, although he frequently mentioned the "Reppe chemistry" that was also strongly influenced by his work. By contrast, Otto Roelen kept himself well informed of results from the laboratory in Munich, and shortly after the war he proved to be a friendly and interested host in Oberhausen for field-trip groups from Munich. Helmut Behrens, at that time a young instructor under Hieber[134] and later a professor in Erlangen, recalls: "In the course of a field trip to Oberhausen in the early 1950s Dr. Roelen asked me to remain an extra half day so I could discuss with him recent progress in the Munich metal carbonyl chemistry. His interest was so keen that he offered to provide me with the company car to catch up with the rest of the group."[135]

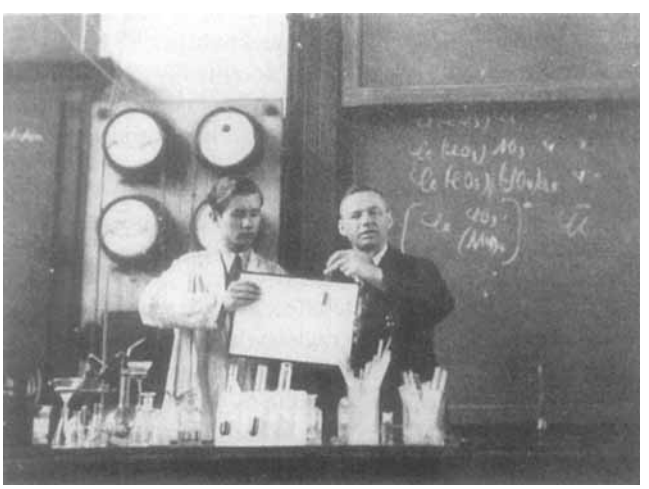

Fig. 15. Walter Hieber during one of his lectures on experimental inorganic chemistry (on the left, his assistant H. Behrens).

We have no way of knowing why Hieber never became involved in questions regarding the mechanism of hydroformylation. It is a matter he appears predestined to have tackled, given his knowledge of the catalytic substance $[HCo(CO)_4]$. Was he marked too strongly by the classical attitude of coordination chemists like Weinland? Was his interest in new complexes and an understanding of the underlying bonding theory more compelling than any effects such materials might have on organic compounds and any possible industrial applications? Was he too preoccupied with the metal carbonyl class of compounds per se? In any event, posterity is keenly aware of this loss of a unique opportunity for synergism between academic and industrial laboratories with mutually complementary expertise. It is also interesting to speculate whether such a symbiosis might have significantly hastened the next major advance: the shift from organocobalt to organorhodium catalysts for hydroformylation, which in fact began only in the 1970s.[89]

Germany remained the world leader in metal carbonyl chemistry until the end of the 1950s thanks to the tremendous success of the school surrounding Walter Hieber. As part of one of the "four-year-plan institutes" designated by the Reich Economics Ministry, Hieber's research group could depend on the requisite continuity in its research even during the period 1939–1945. Given these circumstances, three factors must be taken into account if one wishes to understand why Roelen's and Hieber's paths never intersected. First, scientific research was much more compartmentalized in those days than it is now. Research areas were "marked out" by specific individuals, and "claims"—once established (usually in the form of concluding sentences in the relevant groundbreaking papers)—were generally respected. Hieber defended his research interests in an especially dedicated way against every potential encroacher, and was thus all the more annoyed in 1954 when E. O. Brimm et al. of the Ethyl Corporation presented a report describing the preparation of $[Mn_2(CO)_{10}]$, the target of a decades-long search.[139] Hieber himself always respected the territorial claims of others. We are aware of only a single exception: the isocyanide complexes, which Friedrich Klages could legitimately have claimed for himself.[140] Second, until the groundbreaking discoveries of Ziegler and Natta, practical applications were essentially ignored by all organometallic chemists, who restricted their attention to preparative developments and an understanding of reactivity. In the academic world, catalysis was regarded as an erratic field steeped in empiricism and lacking intellectual pretensions.

Third, mechanistic thinking was not yet well established in metal complex chemistry in the days of Hieber and Roelen, and neither scientist was particularly fond of the type of speculative excursion that would have been required to formulate what we

would today regard as the relatively simple set of steps constituting the Roelen reaction [olefin–metal complexation, which Roelen already suspected, followed by transformation of the alkyl group into an acyl group, and subsequent hydride transfer; Eqs. (c) through (e)]:[89, 114]

$$RCH{=}CH_2 + [HCo(CO)_4] \longrightarrow \underset{\displaystyle HCo(CO)_4}{RCH{=}CH_2} \longrightarrow [RCH_2{-}CH_2{-}Co(CO)_4] \quad (c)$$

$$[RCH_2{-}CH_2{-}Co(CO)_4] + CO \longrightarrow [RCH_2CH_2{-}CO{-}Co(CO)_4] \quad (d)$$

$$[RCH_2CH_2{-}CO{-}Co(CO)_4] + H_2 \longrightarrow RCH_2CH_2{-}CHO + [HCo(CO)_4] \quad (e)$$

In fact, it was not until 1960 that these three homogeneous-phase reactions were sufficiently well known and understood for Heck and Breslow to derive the complete mechanism.[114] One might with a bit of restraint surmise that in today's internationally cross-linked scientific community, potential relationships between apparently independent research areas would have been recognized much more quickly. On the other hand, even now, every innovative field of research requires a certain amount of time to mature, and we must not forget that in 1938, the year hydroformylation was discovered, metal carbonyl chemistry was scarcely a decade old.

3.2. The Long Road to Understanding the Oxo Synthesis as a Case of Homogeneous Catalysis

It may seem strange that Otto Roelen, a reflective and observant investigator, did not see the nature of the catalysis involved in hydroformylation for so long—indeed, into the postwar era. However, given the circumstances of the times and Roelen's own particular way of thinking, it all becomes quite understandable. On one hand, working and living conditions during the Third Reich were hardly normal, despite an appearance of orderliness and the regime's brutally rigorous attitude toward "law and order." Researchers at that time, occupied as they were with a surplus of militarily vital projects, were a privileged lot, but they were still restricted in their movements, and subject to the same limitations and threats as other citizens living in that absolute war economy. The Ruhrchemie premises experienced a total of 1020 alarms and 27 bombings during the course of the war,[47] and this affected Otto Roelen (who lived in the immediate vicinity of the plant) just as much as it did his contemporaries. A constant sensation of not having slept enough, together with persistent threats to his very existence, were hardly conducive to pondering over mechanistic aspects of the oxo synthesis or questions related to the nature of the catalysis in the new reaction. Holm et al. expressed the matter directly in similar tones in FIAT Report 1000:[54]

> "This deficiency stems from the wartime necessity of placing the emphasis upon industrial application and development rather than on fundamental studies."

The collective harassment of "comrades" by the Nazi regime by constant warnings and threats was bound to take a toll on a loner like Otto Roelen. It prevented him from working properly, and it denied him the leisure necessary for conducting proper literature searches, as he himself later acknowledged. Symptomatic of the pressures is a Ruhrchemie in-house newsletter from that period, the content of which ranges from instructions from the "Head of the Works Committee" to threats from the "Workforce Combat Patrol Leader," culminating in "knitting for the final victory":[90]

> "Our participation in the wool collection for the army on the Eastern Front. Dr. Roelen's research laboratory is deserving of special mention. Through his initiatives it was possible to accomplish the astonishing feat of assembling 167 individual items for the army, including a large number of lined vests... ."

Moreover, notwithstanding all the apparent efficiency of the Nazis there was still a shocking level of disorganization in many employment and research activities,[91] and Roelen's involvement in too many research projects unrelated to the oxo synthesis had exceeded his capacity (cf. the report of Otto Roelen's interrogation in December 1945 at Wimbledon[28, 48]). Keeping up with the technical literature also became increasingly difficult under the weight of external factors. In the last years of the war the literature was hardly accessible at all (several of the German journals quit publishing altogether after about 1942, including *Chemische Berichte*, *Chemische Industrie*, and *Öl und Kohle*). The way research was organized generally, especially at Ruhrchemie (see above[28]), coupled with the Nazi mania with respect to secrecy, also prevented the fruitful exchange of ideas with colleagues. Moreover, in the early phases of his discovery Otto Roelen had been inclined to undertake personally as much as possible of the fundamental work of development and refinement, as well as the preparation and filing of patent applications.

Nevertheless, the most important factor, as Roelen himself later complained and elaborated in numerous conversations and several lectures on the subject of "Research Psychology,"[39, 45, 92] was a distinct mental block during the war years—probably due in part to strong preconceptions—against accepting the notion of a *new* type of catalysis. Like many of his contemporaries, Otto Roelen was fascinated by catalysis as a spectacular, modern (albeit empirical) science, but he took it for granted that catalysis generally was equivalent to "chemistry at a catalyst surface" (Kontakt), in other words that it was a *heterogeneous* phenomenon. The idea of homogeneous catalysis was admittedly not completely unknown (Mittasch and Sabatier[93] both mentioned it briefly), but it was limited conceptually to simpler and technically unspectacular reactions, and did not yet encompass the present definition[94] of a transformation in which there is

> "a molecular distribution of the catalytically active species, which is therefore highly dispersed and consequently might be present at very low concentration (into the ppm range)."

Mittasch's views had an aftereffect as well, such that homogeneous catalysis was viewed exclusively in the context of "a material 'invention of nature'," and the "material 'substrate' of all natural phenomena" (i.e., biocatalysis, according to present-day terminology). This lingering reflection of Berzelius, for whom "the concept of a catalyst was useful primarily for purposes of physiology,"[95] was acknowledged as such by Mittasch in his own writings.

For chemists in Otto Roelen's generation, catalysis in the everyday use of the term referred to *heterogeneously* catalyzed transformations associated with a series of empirical investigations: the ammonia synthesis, coal hydrogenation, hardening of fats, the Fischer–Tropsch synthesis, and other industrial-scale and forward-looking technologies. Organometallic catalysts and reactants were essentially unknown except in the case of a few special and exotic applications (e.g., the Grignard reaction, Mond process).

An additional obstacle was the firm assumption that the oxo synthesis depended on heterogeneous catalysis, which meant that any observations to the contrary tended to be dismissed. Thus, the discovery that the reaction products always contained significant amounts of cobalt was not taken as evidence suggestive of the *nonheterogeneous* nature of the reaction. Ostwald's definition of a catalyst as a "substance that alters the rate of a reaction without appearing in the final product"[96] implies that a substance that does appear in the final product might be almost anything, but certainly not a catalyst. In this sense Berzelius' simpler definition of catalysts as "substances the mere presence of which confers chemical activity not found in their absence"[95] was more useful and less misleading.

Experimental findings should at the least have led Roelen and his contemporaries to be somewhat suspicious, because the assumption of an unchanged catalyst was incompatible with the observed facts, which were also not explained by the secondary hypothesis that the reaction conditions simply resulted in partial physical dissolution of certain catalyst components. Moreover, experiments initiated during the war in an attempt to convert the oxo synthesis from a reaction based on suspension techniques to some other alternative were motivated less by a mechanistic way of looking at the reaction than by a desire to increase the effective utilization of the catalyst. Even developments like the Leuna variant, the BASF continuous process in a fixed-bed reactor,[54] and the "diaden" approach (alternate utilization of the oxo and hydrogenation chambers)[117] had their origin not in the possibility that this might be a homogeneously catalyzed reaction, but rather (as nearly as can be established today) in a desire to achieve optimal reaction or temperature control and at the same time increase productivity (cf. ref. [28]).

This is all in the face of the fact that Hieber's most crucial papers had already been published, and the important observations of the early oxo researchers had already been made. Thus, even though it seemed self-evident that a commercial (large-scale) oxo synthesis should be based on the usual catalysts from the heterogeneous FT process, it very soon became common practice to compensate for massive losses of cobalt by the introduction of additional soluble cobalt compounds.[28, 54] The effect of this material could only have been homogeneous, not heterogeneous, and it did not in any way take the place of other components of the FT catalyst; indeed, the additives were deemed responsible for an observed instability of the FT catalyst itself. Especially revealing in this context were experiments conducted by Reppe in Ludwigshafen for a continuous process in a fixed-bed reactor, which presupposed subsequent cobalt removal and separate hydrogenation of the resulting oxo aldehydes over copper–chromite catalysts.[54, 79] One other curiosity is worth noting: a "miraculous" hydroformylation achieved with metals that do not form carbonyl complexes such as calcium, magnesium, and zinc, ingredients that among other things were partially responsible for the structural composition of the classical FT catalysts.[97] The person who dreamed up this particular patent application, an American by the name of Whitman (related to the famous American poet?) mentions in the general section of his application in a very pointed and convincing way that the use of volatile carbonyl complexes actually does nothing but cause problems, and it might therefore be better to add elements of atomic number 12–30, which do not form carbonyl complexes. At least Otto Roelen's own patent[59] was properly cited in this case; the same could not always be said for other authors.[98]

Given the ubiquitous presence of cobalt carbonyls in all the various streams of the oxo reaction– reactants, off-gas, and gas and liquid recycle systems –and in the product itself, Roelen was led to postulate quite early that volatile "cobalt hydrocarbonyls," described by Hieber in 1934,[99] were the truly active oxo catalysts. This conclusion was influenced by the fact that active oxo catalyst could be prepared starting with a wide range of cobalt compounds,[28] as well as by the experimental observation that cobalt,[99–102] but not the oxo-inactive nickel,[54] formed a hydridocarbonyl (hydride shift rule[103]). The hydroformylation of ethylene in particular was carried out at a very early date with dissolved cobalt carbonyls. The lack of consistency in Roelen's ideas regarding the mechanism of the oxo synthesis is underscored by the view he expressed as late as 1945 that the threshold temperature for carbonyl formation must lie below that for formation of cobalt carbide.[54] The possibility of stoichiometric hydroformylation[80] may also have contributed to the confusion.

Interestingly, while possible roles for dissolved carbonyls or hydridocarbonyls[64, 80, 81, 104, 105] in the oxo synthesis were subsequently discussed, Adkins and Krsek[75] were the first to describe the reaction explicitly as "nonheterogeneous," and it was Storch et al.,[121] Berty and Markó,[106] and Natta[107] who first explicitly used the descriptive term "homogeneous." A 1951 patent application by Kuhlmann, describing the catalytic application of gas-phase carbonylhydridocobalt,[108] refers to a "lack of homogeneity," but more in the sense of a lack of experimental homogeneity. A parting shot in the battle to formulate hydroformylation as a heterogeneous process ("... an assumption that even now has scattered adherents ... ," as Falbe[78] cautiously expressed it in 1967) was fired as late as 1963 by Aldridge et al.,[109] but vigorously criticized by Macho et al.[110] The generation of tetracarbonylhydridocobalt, first suspected by Otto Roelen[54] and later proposed by numerous authors,[65, 75, 81, 105, 111, 112] was finally proven by the work of I. Wender et al.[113]

Complete unanimity regarding the mechanism of hydroformylation was achieved with the appearance of a persuasive paper by Heck and Breslow.[114] Apart from early kinetic investigations by Natta et al.[76] and their subsequent conclusions regarding the kinetic order of the reaction,[77] several very divergent interpretations were proposed along the way to an unambiguous formulation of the mechanism, including addition of $[HCo(CO)_x]$ to the C–C double bond of the starting olefin followed by a transformation to a more stable hydridocarbonyl containing less CO (foreshadowing the later dualism of hydridotri- and hydridotetracarbonylcobalt), and a cyclopropyl (more precisely: cyclopropenone) structure[124] with preferen-

tial anti-Markovnikov attack of the formyl group (based on Reppe and Asinger; a summary is provided in refs. [54,65,115]). The term "π complex" for the product resulting from the addition of $[HCo(CO)_4]$ to a double bond was first suggested by Klopfer,[105] and then discussed by Roelen in connection with "crypto ions,"[111] although until 1947 he had clung to the possibility of intermediate formation of a carbide in the "genetic sequence" leading from CO to aldehydes.[104] In 1957 Asinger provided a valuable overview of current ideas on the mechanism of the oxo reaction.[115]

3.3. Pioneer of Industrial Homogeneous Catalysis

Although there has been general consensus regarding the nature of the incorporation of "cobalthydridocarbonyl" since 1949 and publication of the work of Adkins and Krsek (e.g., refs. [73, 75, 105, 111] with mechanisms based on findings by Martin[112] and Natta et al.[107, 118]), it took many years and several duels between adherents of Reppe[65] and Dupont et al.[116] before the currently accepted mechanism of the oxo reaction was firmly established. This occurred 22 years after hydroformylation was discovered, and then not as a result of efforts by the discoverer or other protagonists of the oxo synthesis, but by Heck and Breslow.[114] Nevertheless, Otto Roelen can rightfully be identified as the pioneer of modern industrial homogeneous catalysis. His discovery of hydroformylation sensitized the chemists of his day to the potential for industrial application of organometallic catalysts (ten years prior to the equally history-making work of Ziegler and Natta), and smoothed the way for an understanding of the homogeneous version of catalysis as an independent, versatile, and commercially successful method for preparing important basic chemicals and specialty products. More than that, recognition of the catalytic potential of metal coordination compounds – coupled with further stimulus from the exciting discoveries of ferrocene[136] and dibenzenechromium[137] – gave an unprecedented impetus to organometallic chemistry in the 1950s. Carbon monoxide chemistry in particular cast a bright light on this ascendancy that began with the groundbreaking work of Otto Roelen and Walter Hieber.

One is compelled to agree with Otto Roelen's later formulation of the quintessence of his personal experience, set against a background of personal prejudice:[45]

> "... fantasy and the powers of imagination can fulfill their appointed role as intellectual 'sources of raw material' only if they are allowed to develop fully and without restriction, and if nothing stands in the way of one's intellectual processing of a research field in any direction whatsoever, neither habitual patterns of thought nor preconceptions."

In his reflections on his personal failure to recognize the nature of the homogeneous catalysis underlying the oxo reaction,[45] Roelen thus paid tribute to the true meaning of his favorite author Descartes' "methodological skepticism." He was indeed the discoverer of the oxo synthesis, but not – as he had hoped – the one who unraveled its mechanism. Otto Roelen's special significance, extending into the present, is to be sought rather in the fact that as the pioneer in the first industrially successful synthesis involving organometallic catalysts he raised the level of consciousness regarding the technical relevance and broad applicability of homogeneous catalysis – in spite of every attack from aggressive "heterogenophiles."

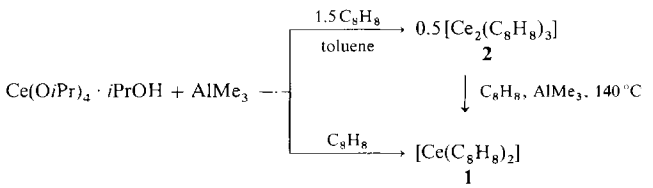
New Upswing of Organolanthanoid Research: A Very Promising Revival of Organocerium(IV) Chemistry and the First Stable Lanthanoid(II/III)–Carbene Complexes

R. Dieter Fischer*

What chance of survival has the cyclooctatetraene dianion $C_8H_8^{2-}$ in the presence of a cerium(IV) compound? Well-documented redox potentials[1] clearly suggest rapid oxidation [Eq. (a)].

$$C_8H_8^{2-} + 2Ce^{4+} \longrightarrow C_8H_8 + 2Ce^{3+} \quad (a)$$



Even UCl_4 is reduced by 1,3,5,7-(*tert*-$C_4H_9)_4C_8H_4^{2-}$ to elemental(!) uranium,[2] and in the classical synthesis of "uranocene"[3] (bis([8]annulene)uranium(IV)) [Eq. (b)] at least one

$$U^{IV}Cl_4 + 2K_2(C_8H_8) \xrightarrow[-4KCl]{THF} [U^{IV}(\eta^8\text{-}C_8H_8)_2] \quad (b)$$

intermediate uranium(III) species[4] occurs. A "targeted" synthesis of reportedly air-stable green "cerocene" (bis([8]annulene)cerium(IV)) in 1972 [Eq. (c)][5] has proved not to be

$$(C_5H_5NH)_2[Ce^{IV}Cl_6] + 2K_2(C_8H_8) \xrightarrow[-4KCl]{THF} \underset{\mathbf{1}}{[Ce^{IV}(C_8H_8)_2]} + 2(C_5H_5NH)Cl \quad (c)$$

reproducible.[6] Nevertheless, in 1976, authentic, brown-black $[Ce(C_8H_8)_2]$ (**1**)[7] was isolated in addition to the then expected[8] compound $[Ce_2(C_8H_8)_3]$ (**2**) (Scheme 1).

Scheme 1. Synthesis and reactivity of $[Ce(C_8H_8)_2]$ **1** [7].

However, the existence of bis([8]annulene)cerium(IV) could only be reliably confirmed later,[6, 9] and the first crystal structure analysis was not achieved until 1991 on the 1,1′-dimethyl derivative **6**,[10] obtained according to Equation (d).

$$\underset{\mathbf{5}\text{ (green)}}{K[Ce^{III}(CH_3C_8H_7)_2]} \xrightarrow[-Ag, KI]{AgI} \underset{\mathbf{6}\text{ (dark red)}}{[Ce^{IV}(\eta^8\text{-}CH_3C_8H_7)_2]} \quad (d)$$

Many other, very desirable investigations, however, have still not been possible chiefly because of the extreme chemical sensitivity and the poor solubility of the few so far known bis([8]annulene)cerium(IV) complexes. An unusual challenge for the experimentalist results, moreover, from detailed quantum chemical studies,[11] according to which the singlet ground state of the $[Ce(C_8H_8)_2]$ molecule mainly derives from the (valence) electron configuration $4f^1e_{2u}^3$ (and not $4f^0e_{2u}^4$). If this interesting postulate could be confirmed experimentally, it would be shown that the cerium ion in bis([8]annulene)cerium exists in the oxidation state +III and that—from a more physical point of view—there would be a close analogy between the unusual ground state of the sandwich molecule and a Kondo ion in a metal lattice.[11] Since cyclooctatetraene may form a planar dianion $C_8H_8^{2-}$ or radical anion $C_8H_8^{\cdot-}$,[12] it could belong to that category of ligands, such as 2,2′-bipyridine in particular, for which the oxidation state of the metal atom they complex cannot be clearly assigned.[13]

A fresh point of departure has now been signalized by experimental results by Edelmann et al.:[14a–c] These authors synthesized for the first time the extremely sensitive, green cerium(III) sandwich complexes **7** and **8**, which contain two- and threefold trimethylsilylated cyclooctatetraenes, respectively, and subsequently converted them in situ into the corresponding uncharged bis([8]annulene)cerium(IV) complexes **9** (deep purple oil) and **10** (deep purple crystals, m.p. 38 °C) [Eqs. (e) and (f)].

$$\underset{\mathbf{7}}{Li[Ce^{III}\{1,4\text{-}(SiMe_3)_2C_8H_6\}_2]} \xrightarrow[-Ag, LiI]{AgI} \underset{\mathbf{9}}{[Ce^{IV}\{1,4\text{-}(SiMe_3)_2C_8H_6\}_2]} \quad (e)$$

$$\underset{\mathbf{8}}{K[Ce^{III}\{1,3,6\text{-}(SiMe_3)_3C_8H_5\}_2]} \xrightarrow[-Ag, KI]{AgI} \underset{\mathbf{10}}{[Ce^{IV}\{\eta^8\text{-}1,3,6\text{-}(SiMe_3)_3C_8H_5\}_2]} \quad (f)$$

The lithium salt **7** had been described by Cloke et al. shortly before,[14d] while only Edelmann et al. succeeded in preparing

the 1,3,6-$(SiMe_3)_3C_8H_5^{2-}$ anion extending corresponding attempts by Cloke et al.

The multiply silylated sandwich complexes **9** and **10** are diamagnetic as expected and not only very soluble in nonpolar solvents such as hexane and pentane, but also briefly stable in air. The crystal structure analysis of the well-crystallizing complex **10** (Fig. 1) confirms the expected[10] sandwich structure with two almost parallel, η^8-coordinate eight-membered rings and Me_3Si substituents positioned slightly *exo*, which contribute to a notable degree of shielding of the cerium(IV) ion. The average Ce–C distance (270.4 pm) is only slightly shorter than in the bis([8]annulene)cerate(III) anion of **13** (275.3 pm; see below). The corresponding values for **6** (269.2 pm[10]) and [K(diglyme)][$Ce^{III}(C_8H_8)_2$] (273.9 pm[16]; diglyme = diethylenegylcol dimethyl ether) also lie very close to one another.

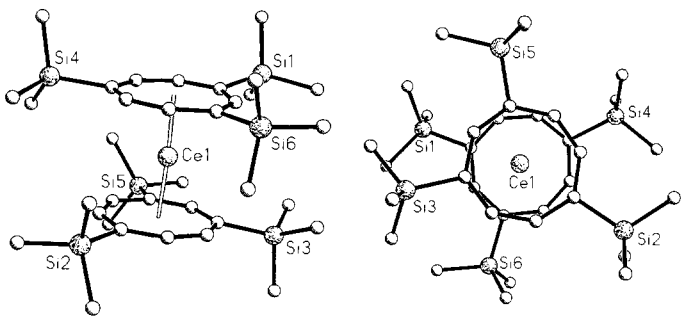

Fig. 1. Crystal structure of the complex **10** [14a]. Side view (left) and top view (right).

It should now also be possible to finally decide whether the anion $[Ce^{III}(cot')_2]^-$ (cot' = $(Me_3Si)_nC_8H_{8-n}^{2-}$ with $n = 0-3$) can in fact be reduced to the dianion $[Ce^{II}(cot')_2]^{2-}$ (cf. **4** in Scheme 1), and whether the solvent-free $[Ce_2(cot')_3]$ (cf. **2** in Scheme 1) may even be a true lanthanoid triple-decker complex. In a reaction analogous to that in Equation (b), Edelmann et al. also treated UCl_4 with $K_2[1,3,6\text{-}(SiMe_3)_3C_8H_5]$ and obtained dark green $[U^{IV}\{1,3,6\text{-}(SiMe_3)_3C_8H_5\}_2]$ (**11**), which was again stable in air for a short time.[14a–c] Perhaps even cerium(IV) compounds and $K_2[(SiMe_3)_nC_8H_{8-n}]$ ($n = 2,3$) react after all to give bis([8]annulene)cerium complexes (cf. Eq. (c))? And why couldn't the multistep mechanism for the formation of $[U^{IV}(C_8H_8)_2]$[4] (see Eq. (b)) be elucidated further with the aid of silylated ligands? The new bis([8]annulene)cerium and -uranium derivatives, which are relatively easy to handle, should also be well suited for systematic electrochemical investigations; to date only the potential of the redox pair $[Ce^{IV}(C_8H_8)_2]$/$[Ce^{III}(C_8H_8)]^-$ has been determined by cyclic voltammetry. The E^0 value is -1.28 V[4, 6] and differs significantly from that for the likewise organometallic redox pair $[Ce^{IV}(C_5H_5)_3(OiPr)]$/$[Ce^{III}(C_5H_5)_3(OiPr)]^-$ ($+0.32$ V)[15b] and especially from representative E^0 values of purely inorganic redox pairs in H_2O (pH < 7); for example $+1.61$ V.[1a]

Edelmann et al. have already carried out several reactions with **9**, **10**, and **11**, which reflect a promising and also preparatively interesting redox chemistry of their new bis([8]annulene)-metal(IV) compounds. Thus, despite the very negative E^0 value of **1**, complex **9** is readily reduced by cobaltocene (E^0 for $([Co^{II}(C_5H_5)_2]/[Co^{III}(C_5H_5)_2]^+) = -0.86$ V[17]) to give the new compound **12**,[14a] which has initially been formulated as a salt [Eq. (g)].

$$[Ce^{IV}\{1,4\text{-}(SiMe_3)_2C_8H_6\}_2] \xrightarrow[THF]{[Co^{II}(C_5H_5)_2]} [Co^{III}(C_5H_5)_2][Ce^{III}\{1,4\text{-}(SiMe_3)_2C_8H_6\}_2] \quad \text{(g)}$$

9 (purple) → **12** (green, pyrophoric)

The occurrence of two signals for the two C_5H_5 ligands in the ^1H NMR spectrum ([D_8]THF) of **12** at higher field than usual for the diamagnetic $[Co^{III}(C_5H_5)_2]^+$ ion ($\delta = 1.30$, 0.90[14a]) does, however, not rule out possible surprises with regard to the true structure of solid **12**. The genuine salt **13**,[18] which has already been characterized by crystal structure analysis, is formed from **10** [Eq. (h)] when elemental ytterbium is used as the reducing agent.

$$2[Ce^{IV}\{1,3,6\text{-}(SiMe_3)_3C_8H_5\}_2] \xrightarrow[THF]{Yb^0} [Yb^{II}(thf)_6][Ce^{III}\{1,3,6\text{-}(SiMe_3)_3C_8H_5\}_2]_2 \quad \text{(h)}$$

10 (purple) → **13** (green)

The cation of **13** loses all of its six thf ligands surprisingly easily. Interestingly, for several contact ion pairs of the type $[M^IL_x\{Ln^{III}(cot)_2\}]$ (L = ligand, Ln = lanthanoid, cot = $C_8H_8^{2-}$), an η^8 coordination of an otherwise coordinatively unsaturated alkali metal ion by one of the ring ligands[10, 19] (Fig. 2 left) has been established by X-ray crystallography; hence, an ideal tetra-decker arrangement is conceivable for the THF-free, purple product **13a**. (Fig. 2 right)[14b, c] Indeed, the

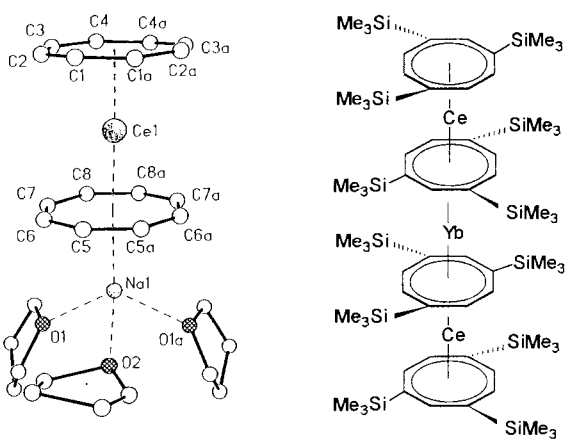

Fig. 2. Left: Crystal structure of the complex $[Na(thf)_3(\mu\text{-}C_8H_8)Ce(C_8H_8)]$ [19]. Right: Possible structure of **13a**.

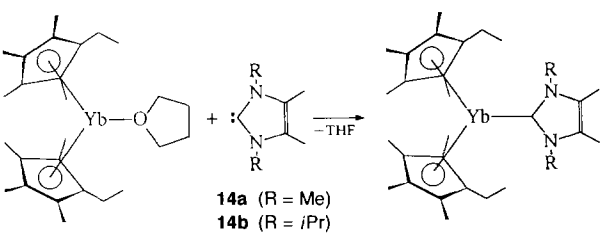
mass spectrum of **13a** shows a molecular peak with an appropriate isotopic pattern.[18] In an analogous way, reactions according to Equation (i) with Ln = Eu, Sm, Yb could, in the absence of any coordinating solvents, possibly lead to heterodimetal triple-decker compounds.

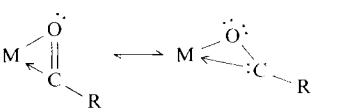


$$[Ce^{IV}(cot)_2] + [Ln^{II}(cot')] \longrightarrow [(cot')Ln^{III}(\mu\text{-}cot)Ce^{III}(cot)] \quad \text{(i)}$$

Recently, Evans et al. impressively demonstrated that organolanthanoid(II) compounds, particularly those of the type $Cp^*_2Ln^{II}L_n$ ($Cp^* = C_5Me_5$; Ln = Sm, Yb; L = ligand), offer an almost unlimited synthesis potential. This is exemplified by the reactions of $[Cp^*_2Sm]$ with some unsaturated reaction partners such as CO,[20] N_2,[21] N_2H_2,[22] alkyne,[23] mono-,[24] and polyolefins.[25] The essential driving force for these reactions is the strong reduction potential of the samarium(II) complex. Hereby, as in the case of the unexpected course of the reaction with the cycloolefin C_8H_8 [Eq. (j)],[26] samarium(III) com-

$$2[Sm^{II}Cp^*_2(thf)_2] + C_8H_8 \longrightarrow [Sm^{III}Cp^*(C_8H_8)] + [Sm^{III}Cp^*_3] \qquad (j)$$

pounds are always formed. On this background, it will be interesting to see the results of corresponding reactions with Edelmann's new bis([8]annulene)cerium/uranium compounds instead of neat C_8H_8.



The reduction potential of the homologous $[Cp^*_2Yb^{II}]$ is not quite as strong as that of $[Cp^*_2Sm^{II}]$. Thus, several conventional adducts $[Cp^*_2Yb^{II}L_n]$ ($n = 1,2$) with an unsaturated nucleophile L (e.g. alkene,[27] alkyne,[28] and even pyridine[29]) could be isolated. Several homologous imidazol-2-ylidenes **14** (Scheme 2) have now turned out to be reducible neither with $[(C_5Me_4Et)_2Yb^{II}(thf)]$ nor with $[Cp^*_2Sm^{II}(thf)]$.

Scheme 2. Synthesis of the carbene complexes **15** (R = Me) and **16** (R = *i*Pr) [32a]. The π-electron pair of each nitrogen atom is not shown.

In 1991 Arduengo et al. first reported on imidazol-2-ylidenes with particularly voluminous groups R; these were the first carbenes that could be isolated and crystallized.[30] This result catalyzed fervent activity with regard to the development of numerous complexes with Arduengo-carbenes.[31] The first stable ytterbium(II)-carbene complexes **15** and **16**, which form surprisingly readily by the replacement of a THF ligand with a carbene (Scheme 2), were characterized by Schumann et al. as Fischer-type carbene complexes without detectable metal → ligand backbonding.[32a] The black compounds are thermally very stable and diamagnetic; the crystal structure analysis of **15** reveals an apparently strong Yb → C σ-donor bond (Yb–C distance 255.2 pm, comparable to the mean Yb–N distance of 256.5 pm in $[Cp^*_2Yb^{II}(NC_5H_5)_2]$[29]), as well as coplanarity of the ylide five-membered ring with its five substituent atoms, suggesting sp^2-hybridized ring atoms. Simultaneously with Schumann et al., Arduengo and co-workers have described the corresponding Sm(II) complexes $[Cp^*_2Sm^{II}L_n]$ (L = **14a**; $n = 1$, **17**; $n = 2$, **18**).[32b] Both **18** and the so far unique lanthanoid(III)-carbene complex $[Eu^{III}(thd)_3L]$ **19** (thd = 2,2,6,6-tetramethylheptane-3,5-dionate) have already been subjected to crystal structure analyses.[32b] Considering that isocyanides have so far been the only uncharged ligands in organolanthanoid chemistry that coordinate through just one carbon atom,[33] the entry of Arduengo's carbenes into this field will clearly have a significant impact. In some contrast to the present excitement of most coordination chemists there is still controversy surrounding whether all compounds with very nucleophilic two-coordinate carbon atoms, which, however, lack the intrinsic reactivity of "classic" carbenes, should still be correctly classed as carbenes.[34] In the meantime the synthesis of homologous imidazol-2-germylenes[35] and imidazol-2-silylenes[36] has already been successfully completed, providing also a basis for the access of novel lanthanoid compounds with unusual metal-to-germanium and -silicon bonds.

Finally it should be recalled that 15 years ago Marks et al. characterized organoactinoid and lanthanoid complexes with a η^2-acyl ligand as complexes containing a Fischer-carbene ligand (Scheme 3), directly anchored through its heteroatom to the metal ion.[37] This description was based on the distinct carbene-like reactivity of the relatively loosely coordinated acyl carbon atom (the M–O distance is shorter than the M–C distance).

Scheme 3. η^2-acyl ligand with carbene-like properties [37].

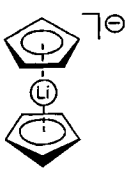
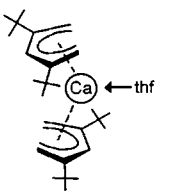
The Lithocene Anion and "Open" Calcocene—New Impulses in the Chemistry of Alkali and Alkaline Earth Metallocenes



Dietmar Stalke*

The impetus given to the field of organometallic chemistry by the discovery of bis(cyclopentadienyl)iron(II), ferrocene, is quite unique. The cyclopentadienyl anion $C_5H_5^-$ (Cp) and its substituted derivatives ($C_5H_{5-n}R_n^-$), especially the pentamethylcyclopentadienyl anion $C_5Me_5^-$ (Cp*), are the most frequently used substituents when the steric shielding of a metal center is required. While in the mid 1950s a rapid development in the synthesis of bis(cyclopentadienyl) complexes of main group and transition metal elements took place, the corresponding compounds of the alkaline earth metals have until very recently been one of the sleeping beauties of organometallic chemistry.



The s-block metals are highly electropositive, thus their complexes are mainly ionic. The highly polar nature of alkyllithium compounds and Grignard reagents forms the basis of their preparative use. Up to now compounds containing the heavier alkaline and alkaline earth metals have been almost neglected. Only recently has interest focused on, for instance, alkaline earth metal compounds as precursors to metal oxides for chemical vapour deposition (CVD) and sol-gel processes. Ideally, CVD precursors for thin films should be easy to synthesize, volatile, and free of halide or silyl groups. The sol-gel process requires starting materials that can be specifically hydrolyzed in a reproducible way. This is why the investigation of alkali and alkaline earth metallocenes is an important and advantageous goal.

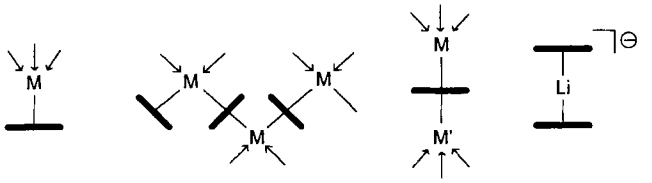
Two very recent results, the synthesis and structure determination of the simplest metallocene $[Cp_2Li]^-$ **1** and of the "open" calcocene **2** are taken to highlight a flourishing field of research.

1



2

Cyclopentadienyl Alkali Metal Complexes

The physical properties of CpLi are those of a typical salt.[1] It is almost insoluble in hydrocarbons, has a high melting point, and a low volatility. These facts had hampered the structure determination of donor-free, CpLi until now. It is mainly because of the pioneering work of Jutzi et al. that we nevertheless possess structural information on CpLi derivatives. They introduced three trimethylsilyl groups to the C_5 skeleton, and the solubility of the corresponding compound increased drastically. These silylated cyclopentadienyllithium derivatives can be crystallized with nitrogen donor bases. These derivatives are all monomeric in the solid state. The lithium atom is more or less ideally η^5-coordinated to the C_5 framework. The coordination sphere of the lithium atom is completed by mono-, bi-, or tridentate nitrogen donor bases (structure type **A**, Table 1). Examina-

Table 1. Cyclopentadienyl alkali metal complexes.

Compound [a]	Coordination type	M-$Cp_{centroid}$ [pm]	Ref.
$[(Me_3Si)_3C_5H_2Li(pmdeta)]$	**A**	198	[3a]
$[Me_3SiC_5H_4Li(tmeda)]$	**A**	193	[3b]
$[(Me_3Si)_3C_5H_2Li(quin)]$	**A**	179	[3c]
$[(Me_3Si)_3C_5H_2Li(tmeda)]$	**A**	199	[3c]
$[MeC_5H_4Li(tmeda)]$	**A**	191	[3d]
[CpLi([12]-Krone-4)]	**A**	206	[3e]
$[Cp^*Na(py)_3]$	**A**	240	[3f]
$[(C_6H_5CH_2)_5C_5K(thf)_3]$	**A**	279	[3g]
$[Me_3SiC_5H_4Li]_\infty$	**B**	197	[4a]
$[CpNa(tmeda)]_\infty$	**B**	265	[4b]
$[(MeCO)C_5H_4Na(thf)]_\infty$	**B**	253	[4c]
$[Cp^*K(py)_2]_\infty$	**B**	279	[3d]
$[Me_3SiC_5H_4K]_\infty$	**B**	278	[4d]
$[MeC_5H_4Li_2(tmeda)_2]^+$	**C**	200	[5a]
$[Li(pmdeta)][Cp_2Tl]$	**C**	225	[5b]
$[Li(pmdeta)][Cp_2SnN(SiMe_3)_2]$	**C**	225	[5c]
$[Na(pmdeta)][Cp_3Sn]$	**C**	255	[5d]
$[(isodiCp)_2Li]^-$	**D**	200	[6]
$[Cp_2Li]$	**D**	201	[7]

[a] pmdeta = $MeN(CH_2CH_2NMe_2)_2$; tmeda = $Me_2NCH_2CH_2NMe_2$; quin = $C_9H_{13}N$; thf = tetrahydrofuran; py = pyridine; isodiCp = isodicyclopentadienyl anion (= 4,5,6,7-tetrahydro-4,7-methano-1*H*-inden-1-ide).

tion of the metal ring centroid ($Cp_{centroid}$) distances is very instructive. With this experimental feature it is possible to elucidate the contribution of single structural determining parameters like charge distribution, steric requirement, radius or electronegativity of metal centers, or influence of donor bases in these polar organometallic compounds,[2] and makes it easier to understand coordination patterns.

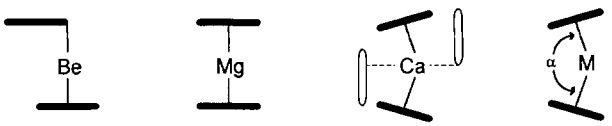
The Li–$Cp_{centroid}$ distance in substituted cyclopentadienyllithium derivatives ranges from 179[3c] to 206 pm.[3e] The more donor centers that are coordinated to the lithium atom, the less important (hence the longer) becomes the Li–Cp contact. The three silyl groups in $[(Me_3Si)_3C_5H_2Li(quin)]$[3c] increase the electron density within the ring to such an extent that the anion is particularly attractive to the lithium cation (Li–$Cp_{centroid}$ 179 pm). In this complex the lithium cation coordinates only one nitrogen donor base. In the [CpLi([12]crown-4)] complex the lithium cation is supplied electron density by four donor oxygen atoms, hence the Li–$Cp_{centroid}$ distance (206 pm) is relatively long. $[Cp^*Na(py)_3]$[3f] and $[(C_6H_5CH_2)_5C_5K(thf)_3]$[3g] are also monomers.

In the coordination type **B** two- or three-dimensional polymeric nets are built. In $[Me_3SiC_5H_4Li]_\infty$[4a] and $[Me_3SiC_5H_4K]_\infty$[4a] no further solvation of the metal is observed. It is worthy to note that the Na–$Cp_{centroid}$ distance changes from 240 pm in $[Cp^*Na(py)_3]$[3f] to 265 pm in $[CpNa(tmeda)]_\infty$.[4b] The shortest Na–$Cp_{centroid}$ contact is found in the monomer, because the sodium atom is coordinated to only one Cp* anion, rather than to two Cp anions as in the polymer. Apart from steric crowding, the fact that one positive charge has to be distributed between two negative centers certainly results in increasing distances. The K–$Cp_{centroid}$ distance, however, seems to be almost invariant against the degree of oligomerization or the presence of donor bases. In monomeric $[(C_6H_5CH_2)_5C_5K(thf)_3]$[3g] this distance is 279 pm, like that in the two-dimensional polymeric $[Cp^*K(py)_2]_\infty$,[3f] and almost unchanged from the 278 pm in unsolvated $[Me_3SiC_5H_4K]_\infty$.[4d] In the monomer the distance is probably elongated because the steric requirement of the bulky $C_5(CH_2C_6H_5)_5$ anion prevents closer contact between the metal and the C_5 framework.

The opposite case in which two positive charges have to share one negative charge has been structurally characterized as well (structure type **C**). In the cation $[MeC_5H_4Li_2(tmeda)_2]^+$, the two lithium atoms are η^5-coordinated to the single MeC_5H_4 anion. The average Li–$Cp_{centroid}$ distance of 200 pm is quite long but falls in the normal range. Only when the lithium atom competes with a significantly more electronegative element like tin or thallium for a single Cp anion (EN of Li: 1.0, of Sn and Tl: 1.8), does the Li–$Cp_{centroid}$ distance increase considerably. In $[(\eta^5\text{-Cp})Tl(\mu_2\text{-}\eta^2\text{-Cp})Li(pmdeta)]$[5b] and in $[(\eta^5\text{-Cp})(Me_3Si)_2NSn(\mu_2\text{-}\eta^5Cp)Li(pmdeta)]$[5c] the Li–$Cp_{centroid}$ distance is 225 pm. The tin and thallium atoms both claim more electron density from the Cp anion, which makes them less attractive to the lithium atom. The Na–$Cp_{centroid}$ distance to the μ_2-bridging Cp anion in $[(\eta^5\text{-Cp})_2Sn(\mu_2\text{-}\eta^5\text{-Cp})Na(pmdeta)]$[5d] of 255 pm is almost the same as the one in polymeric $[(MeCOC_5H_4Na(thf)]_\infty$.[4c]

Recently Gautheron and Paquette et al. published the synthesis and crystal structure of the $[(isodiCp)_2Li]^-$ ion in which the lithium atom lies on a center of inversion between the two Cp ligands.[6] With the structure determination and the synthesis of $[Ph_4P][Cp_2Li]$ according to Equation (a), Harder et al. achieved

$$Ph_4PCl + 2\,CpLi \longrightarrow \underset{[Ph_4P]\text{-}\mathbf{1}}{[Ph_4P][Cp_2Li]} + LiCl \qquad (a)$$



the characterization of the simplest metallocene, the lithocene anion **1**.[7] The sandwich complex **1** has almost D_{5d} symmetry; the lithium atom is found on the inversion center (coordination type **D**). The Li–$Cp_{centroid}$ distance of 201 pm is almost identical with that in the $[MeC_5H_4Li_2(tmeda)_2]^+$ ion and in the $[(isodiCp)_2Li]^-$ ion (Table 1). Apparently the competition between two Cp anions for one lithium cation (**D**) results in the same distance as the competition between two lithium cations for one Cp anion (**C**), because the absolute value of the sum of charges is the same. The distance between the rings of 402 pm is considerably longer than the interlayer distance in graphite of 335 pm; thus steric hindrance of the two five-membered rings with respect to each other can be excluded. The controversial question of whether hydrogen-out-of-plane bending occurs towards or away from the metal[8] could not be answered unequivocally for the $[Cp_2Li]$ anion from this experiment, because even at $-40\,^\circ C$ libration of the Cp rings is quite high. This is indicative of a fairly low rotational barrier of the Cp ligand about the metal. Good low-temperature neutron data would certainly be beneficial.

Harder et al. confirmed the existence of lithocene, deduced previously from conductivity measurements,[9a] NMR spectroscopic,[8d, 9b] and cryoscopic[9c] experiments, in the solid state. This success should be used as a basis for the study of the bis(cyclopentadienyl) compounds of the heavier alkali metals as well.

Alkaline Earth Metallocenes

The comparison of the lithocene anion with the isoelectronic alkaline earth metallocenes is very interesting. The isotype $[Cp_2Mg]$ has almost the same structural parameters as the $[Cp_2Li]$ anion. The $Mg-Cp_{centroid}$ distance is 198 pm.[11a] Apparently the Cp ligands (staggered) in the solid state can come closer together than in the gas phase (eclipsed) ($Mg-Cp_{centroid}$ 201 pm[11b]). This shows once again the close relationship between the elements lithium and magnesium (among other criteria the almost identical radius of Li^+ and Mg^{2+} is decisive). $[Cp_2Li]^-$ and $[Cp_2Mg]$ adopt the same coordination type in the solid state, schematically depicted as **D** (Table 1) and **F** (Table 2), which can be rationalized as a pentagonal antiprism.

Table 2. Alkaline earth metallocenes.

$[Cp_2^*Ba]$	**H**	134	299	290	131	148	[15, 16]

[a] Average values of the two η^5-coordinated rings. [b] In the complex a thf molecule is coordinated to the calcium atom at the open side. [c] Values taken from: *CRC Handbook of Chemistry and Physics*, CRC Press, Cleveland, **1973**. [d] The first value refers to a single-crystal X-ray structure determination, the second to the gas phase electron diffraction experiment.

In $[Cp_2Be]$, however, the coordination polyhedron formed is quite different. The Be^{2+} ion, which is almost half the size of the Mg^{2+} ion, is η^1/η^5-coordinated between two Cp rings (**E**). Furthermore, in the solid state,[10a] it is disordered with regard to the η^1/η^5 and η^5/η^1 position. The distance between the two Cp rings is only 331 pm, and hence falls below the interlayer distance in graphite (335 pm). The assumed increase in M–C bond length of about 33 pm because of the increase of ionic radii going from $[Cp_2Mg]$ (230 pm) to $[Cp_2Ca]$ (280 pm) is significantly exceeded[12] (Table 2). Compared to $[Cp_2Mg]$, $[Cp_2Ca]$ exhibits a completely different coordination type (**G** instead of **F**), emphasizing a well-known argument from the cyclpentadienyl alkali metal complexes: In $[Cp_2Ca]$ the posititve charge of the Ca^{2+} ion is not only shared by two η^5-bound Cp rings, but is distributed between four substituents. Apart from the two η^5-coordinated ligands there are significant Ca–C contacts to a η^3- and η^1-coordinated ring. That the M–C bond is lengthened when several Cp ligands compete for one metal is also true for the alkaline earth metallocenes. This effect is certainly not exclusively due to steric requirements. Bond lengthening is also found in the $[CpMg(pmdeta)]^+$ ion of the solvent-separated ion pair $[CpMg(pmdeta)][Cp_2Tl]$.[5b] The $Mg-Cp_{centroid}$ distance in this cation is 208 pm; in neutral $[Cp_2Mg]$ it is 198 pm.

The expected Ca–C distances of 264 pm in the solid state[13a] and 261 pm in the gas phase[13b] are only found in monomeric $[Cp_2^*Ca]$. The structure of this calcocene derivative shows a different, a priori unexpected phenomenon: the two rings are not aligned coplanar like in **F** but are bent with respect to each other ascribing a $Cp_{centroid}$-M-$Cp_{centroid}$ angle (α in Table 2) of 147 and 154° (solid state and gas phase, respectively) (**H**). On first sight this bent structure, despite the missing lone pair, is as puzzling as the coplanar rings in $[(Ph_5C_5)_2Sn:]$[14a] or in $[Cp_2^*Si:]$,[14b] in which the lone pair is assigned exclusively s character.

$[Cp_2^*Sr]$[15] and $[Cp_2^*Ba]$,[15, 16] bis(cyclopentadienyl) compounds of the heavier alkaline earth metals, also adopt bent monomeric structures of type **H**. Long-range intermolecular interactions causing packing effects, and the f-orbital bonding contribution, which might be responsible for bent structures, are to date almost ruled out. It is now assumed that ligands polarize a large positive charge (bent structures have been found, for example, in $[Cp_2^*Sm]$ and $[Cp_2^*Eu]$) and induce a dipole. This dipole can interact with negatively charged ligands more effectively.[17] Apparently holistic features like radii, charges, polarities, etc. seem to be most fruitful in structural interpretation in this area of organometallic chemistry. The estimated energy required to bend an alkaline earth metallocene by 20° is only 2–3.5 kJ mol^{-1}.[15]

The first open calcocene **2**,[18] was recently synthesized by Hanusa et al. according to Equation (b). This complex is

$$2[K(tBu_2C_5H_5)] + CaI_2 \xrightarrow{THF} \underset{\mathbf{2}}{[(tBu_2C_5H_5)_2Ca(thf)]} + 2KI \qquad (b)$$

also a bent monomer of type **H**. Because of the coordination of thf the question of whether this bend is intrinsic or induced by base coordination remains open. However, it is certain that the pentadienyl ligand is planar and π-bonded to the calcium atom. The average Ca–C distance of 276 pm is relatively long.

This is even more remarkable since transition metal pentadienyl complexes normally exhibit equally long or even shorter M–C distances than those in the related cyclopentadienyl complexes. Certainly the elongation of the Ca–C bonds in **2** is neither caused by the frequently referenced steric requirement nor by coordination by donor bases, since the distance in the sterically more crowded $[(iPr_5C_5)_2Ca]$[19a] is 264 pm and in $[(MeC_5H_4)_2Ca(dme)]$[19b] 268 pm. The acyclic pentadienyl ligand offers a wide range of bonding modes (σ, η^3, η^5) that are in principle easily interconvertible.[20] Here the Ca^{2+} center behaves like a d- or f-block metal to which acyclic penta-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2170 $ 10.00+.25/0

dienyl ligands normally bond in an η^5 coordination. In $[(Me_2C_5H_5)_2Mg(tmeda)]$, however, both pentadienyl ligands are terminally σ-bonded.[21] The Mg–C distance in this complex is 218 pm, hence significantly shorter than the corresponding distance in $[Cp_2Mg]$ of 230 pm.

The work of Hanusa et al.[22] in particular has contributed to a better understanding of the bonding in alkaline earth metallocenes. Further success in this flourishing area of research of alkali and alkaline earth metallocenes will most certainly be achieved in the near future. For instance, it is quite evident that one should also investigate the corresponding heterocyclopentadienyl complexes. The replacement of a CH group with an isoelectronic ER group (E = Si, Ge, Sn, Pb) or with E′ = N, P, As, Sb, Bi should give rise to further types of coordination. Other potent π donors like the cyclooctatetraene ligand, which has proved to be very useful especially in f-block element chemistry,[23] may be employed as well.

These opportunities indicate that there is still a lot to be discovered. This becomes more exciting and necessary, the more it becomes apparent that our knowledge for describing and predicting the coordination behavior in this class of substances is not by any means sufficient. To extend our understanding, a great deal of experimental work is still required.

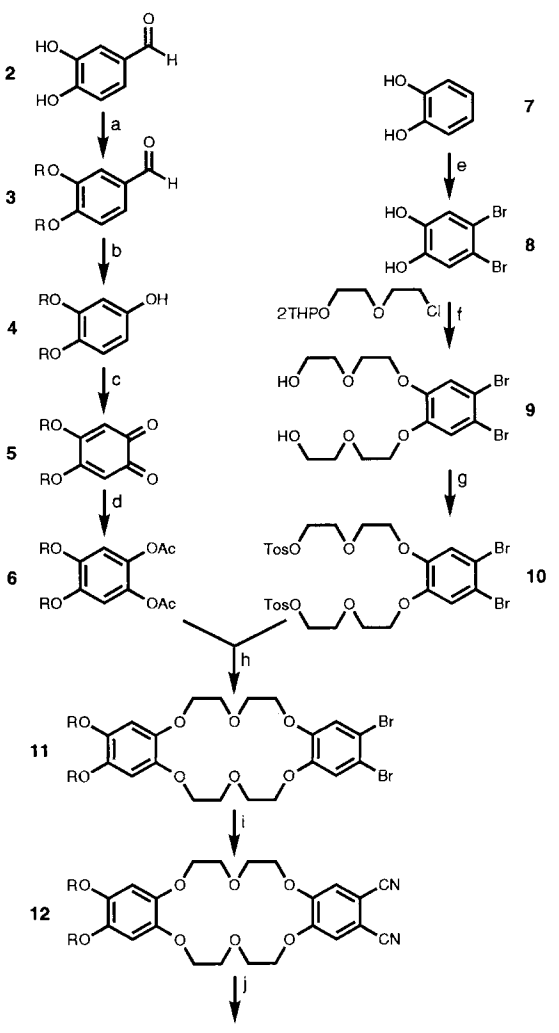
Construction of a Multiwired Molecular Cable of Micrometer Length by a Self-Assembly Process**

Cornelus F. van Nostrum, Stephen J. Picken, and Roeland J. M. Nolte*



The engineering of molecules and molecular systems that can form nanometer-sized structures is currently receiving a great deal of attention.[1-3] An interesting challenge is the construction of molecular wires and molecular channels capable of transporting electrons and ions. For example, phthalocyanines substituted with long hydrocarbon side chains have been reported to form conducting mesophases in which the molecules are stacked in columns. Electron conduction within the columns is fast, whereas it is slow between the columns.[4, 5] In previous papers we have shown that crown ether molecules can be stacked to create ion conducting channels.[6, 7] Here we describe a novel liquid-crystalline molecule (**1**) that self-assembles in

1

chloroform solution to form a molecular cable. This cable contains a central wire of stacked phthalocyanines, four molecular channels built up from stacked crown ether rings and a surrounding hydrocarbon mantle. Isolated cables with molecular thickness and a length of several micrometers can be recognized in electron microscopy images.

Phthalocyanine **1** was prepared from crown ether **12** by a cyclization reaction (see Scheme 1). The crown ether was synthesized from **11**, which in turn was assembled from the building blocks **6** and **10**. The starting compound for **6** was 3,4-dihydroxybenzaldehyde (**2**). This compound was alkylated with decyl

bromide ($\rightarrow$ **3**) and subsequently converted into 3,4-bis(decoxy)phenol (**4**) by a Baeyer–Villiger type of oxidation.[8] Treatment of the phenol with Fremy's radical[9] under phase transfer conditions yielded 4,5-bis(decoxy)-1,2-benzoquinone (**5**), which was converted into 1,2-bis(acetoxy)-4,5-bis(decoxy)benzene (**6**; for characterization see Table 1) by reduction with zinc/acetic acid/acetic anhydride. The overall yield of **6** from **2** was 38%. The synthesis of the second building block **10** was performed using more standard reactions. Catechol (**7**) was brominated and subsequently alkylated with tetrahydropyranyl-(THP)-protected diethyleneglycol monochloride to give, after in situ deprotection, compound **9**. Reaction of **9** with *p*-toluenesulfonyl chloride gave compound **10** as a highly viscous oil in 42% overall yield (Table 1). The coupling of the two fragments was carried out by first hydrolyzing **6** and subsequently treating the resulting catecholate in situ with **10**. The two bromine atoms of **11** were substituted by nitrile groups with copper cyanide in *N*,*N*-dimethylformamide (DMF). Finally, the resulting crown ether **12** was converted into phthalocyanine **1** by refluxing in *N*,*N*-dimethylaminoethanol (overall yield from **6** and **10** 13%). Compound **1** was purified by repeated recrystallization from chloroform. Spectroscopic and elemental analysis were consistent with the proposed structure (Table 1).

Table 1. Characteristic physical data of **1**, **6**, and **10**.

1: IR ($CHCl_3$): $\tilde{\nu}$ = 3294 (NH), 2925, 2853 (CH_2), 1603, 1529, 1413 (Ar), 1490, 1391, 1369, 1101 (phthalocyanine), 1280 (ArO), 1134 (COC), 1022 (NH), 863 cm^{-1} (ArH); ^1H NMR (400 MHz, $CDCl_3$, 53 °C): δ = 6.64 (s, 8H, ArH), 3.6–4.9 (m, 80H, CH_2O), 1.2–1.8 (m, 128H, CH_2), 0.89 (s, 24H, CH_3); elemental analysis: $C_{168}H_{250}N_8O_{32}.CHCl_3$: calcd C 67.36, H 8.40, N 3.72, found C 67.18, H 8.28, N 3.74%

6: IR (KBr): $\tilde{\nu}$ = 2800–3100 (CH_2, CH_3, ArH), 1760 (C = O), 1605, 1510 (Ar), 1230, 1180 cm^{-1} ($C_{Ar}O$); ^1H NMR (100 MHz, $CDCl_3$): δ = 6.68 (s, 2H, ArH), 3.94 (t, 4H, CH_2O), 2.26 (s, 6H, CH_3C = O), 1.2–1.9 (m, 32H, CH_2), 0.88 (t, 6H, CH_3); MS (CI): *m/z*: 506 [M^+]; elemental analysis: $C_{30}H_{50}O_6$: calcd C 71.11, H 9.95, found C 71.42, H 9.82%

10: IR ($CHCl_3$): $\tilde{\nu}$ = 2800–3100 (CH_2, ArH), 1350, 1170 (SO_3), 1245, 1190 ($C_{Ar}O$), 655 cm^{-1} (ArBr); ^1H NMR (100 MHz, $CDCl_3$): δ = 7.13–7.85 (m, 8H, ArH), 7.03 (s, 2H, ArH), 3.6–4.25 (m, 16H, CH_2), 2.38 (s, 6H, CH_3); MS (FAB): *m/z*: 752 [$M^+ + 1$]

Crown ether phthalocyanine **1** showed thermotropic liquid crystalline behavior as was evident from differential scanning calorimetry (DSC), polarizing microscopy, and small angle X-ray scattering (SAXS) measurements. A transition to a highly viscous, birefringent mesophase was observed at 148 °C on heating (ΔH = 130 kJ mol^{-1}). Large hysteresis was observed on cooling: the transition to the crystalline phase occurred at 105 °C. No transition to the isotropic phase was observed below the decomposition temperature of the compound (320 °C). The large number of peaks in the SAXS measurements at room temperature indicated a crystalline phase. In the mesophase at 170 °C an intense peak, corresponding to a spacing of 35.10 Å, and a very broad peak, corresponding to 4.5 Å, were visible. The former peak probably is the (100) reflection of a hexagonal columnar phase with an intercolumnar distance of 40.5 Å.

Generally, alkoxy- and crown-ether-substituted phthalocyanines are highly soluble in organic solvents. Surprisingly, **1** was only soluble in boiling chloroform and in boiling toluene. A solution of **1** (at a concentration of 7 mg mL^{-1} or more) in chloroform formed a gel on cooling. A UV/Vis spectrum of a dilute solution (11 μM) of **1** in chloroform at 50 °C showed a split Q-band at 660 and 700 nm that is typical for nonaggregated metal-free phthalocyanines. However, when this solution was cooled to room temperature a blue shift of the bands and a broadening of the signals was observed, which is characteristic of aggregated phthalocyanine species (Fig. 1).

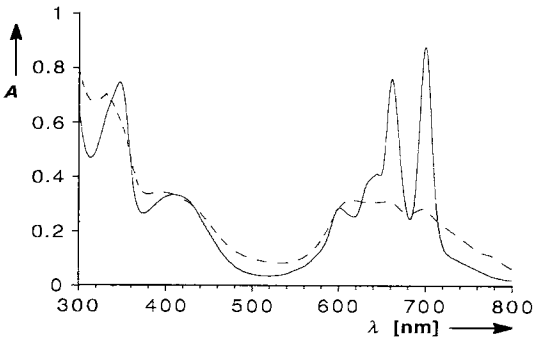

Fig. 1. UV/Vis spectra of **1** in chloroform (11 μM) at 25 °C (– – –) and 50 °C (——).

The structure of the aggregates was elucidated with the help of transmission electron microscopy (TEM). Compound **1** (7 mg) was boiled in chloroform (1 mL), and after the solution had cooled, a drop of the resulting gel was placed on a carbon-coated copper grid. After one minute the grid was blotted dry and shadowed with platinum at an angle of approximately 45°. Two representative TEM pictures are shown in Figure 2. At low magnifications fibers with a length in the order of micrometers, which form a network structure, are observed. At higher magnifications these fibers are seen to consist of bundles of single parallel strands. The thickness of these strands equals the diameter of a molecule of **1** as estimated from CPK space-filling molecular models, that is, 50–60 Å. Several isolated strands can be observed with the same diameter. At lower concentrations of **1** in chloroform, that is, below the gel-forming point, fibers are still present, but they are smaller, and no network is formed.

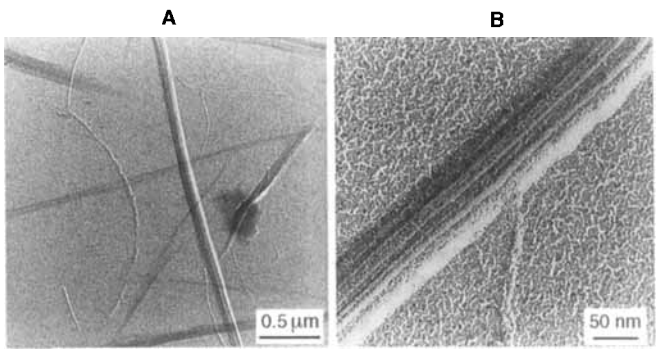

Fig. 2. Transmission electron micrographs of a gel of **1** in chloroform. A): Isolated single strands and bundles of parallel strands of **1**. B): Magnification showing individual strands of molecules **1**, which have diameters of 60 Å.

The conclusion from these experiments is that crown ether phthalocyanine **1** self-assembles into extremely long stacks of molecular thickness, which consist of more than 10^4 molecules. To the best of our knowledge, evidence for the formation of such large phthalocyanine aggregates has not been reported before. Apparently, the attractive forces between the molecules are so strong that complete solvation is prevented at room tempera-

Fig. 3. Schematic representation of the multiwired molecular cable formed by self-assembly of crown ether phthalocyanine **1**. In the mesophase the individual molecules probably rotate around their stacking axis (see ref. [10]).

ture. As shown schematically in Figure 3 a stack of molecules **1** can be considered to be a multiwired molecular cable. In view of its structural resemblance to the crown-ether-substituted phthalocyanine polymers previously studied by us,[7] it is reasonable to postulate that the molecular cable is capable of conducting ions and electrons. Apart from that, the transition of **1** from the solid state to the mesophase is probably accompanied by a change in electronic and ionic conductive properties. We are currently investigating this in detail, as well as the polymerization of the dihydroxysilicon derivative of **1** to give a polymerized molecular cable.

cannot form stable metal complexes. The goal of our research work is the synthesis of macrocycles that have only a few fluorine atoms incorporated into the cyclic structure. Upon complexation of metal ions, the fluorine should act as a "detector", since the ^{19}F NMR signals shift upon complexation.[3] The high sensitivity, combined with a large signal dispersion and the absence of a natural background make ^{19}F NMR spectroscopy an ideal tool for investigation.[4]

Recently we reported the synthesis of a partially fluorinated [2.2.2]cryptand.[5] This compound forms complexes with metal ions; however, the ^{19}F NMR signals shift only slightly upon complexation, since no direct metal–fluorine contacts are formed. Such an interaction becomes more likely if a carbon–fluorine bond is directed towards the center of the crown ether. The relatively small steric demand of the fluorine atom is not expected to interfere with the binding of metal ions; on the contrary it is hoped that formation of a σ-donor bond between fluorine and the metal ion will increase the stability of the metal complexes.

The building block used for the synthesis of the fluorine-containing macrocycles was 1,3-bis(bromomethyl)-2-fluorobenzene (**1**), which was treated with tetraethyleneglycol, ethyleneglycol, or azacrown ethers to yield fluorocrown ethers (Scheme 1).[6]

Scheme 1. a) KO*t*Bu, tetraethyleneglycol, b) KO*t*Bu, ethyleneglycol, c) Na_2CO_3, aza[9 + 3*n*]crown-(*n* + 3).

Complexes of Partially Fluorinated Macrocycles with a Metal–Fluorine σ-Donor Bond and Their Suitability as Metal Ion Indicators**

Herbert Plenio* and Ralph Diodone

Even though a rather large number of macrocyclic polyethers is known,[1] only few fluorine-containing crown ethers[2] have been reported, and in most of these all of the hydrogen atoms are substituted by fluorine. As a result of the electron-withdrawing nature of the CF_2 units, the oxygen or nitrogen atoms in these polyethers no longer exhibit Lewis basicity and therefore

[**] This work was supported by the Fonds der Chemischen Industrie. The authors thank Prof. Dr. H. Vahrenkamp for his support and Dr. E. Keller for hints in determining the crystal structure.

The macrocyclic ligands **2**–**6** were obtained in yields of 30 to 80%. In these compounds the carbon–fluorine bond is directed towards the region that is expected to be the binding site for metal ions.

The reaction of compounds **2**, **4**, **5**, and **6** with metal salts leads to the complexation of a metal ion, while at the same time the ^1H, ^{13}C, and ^{19}F NMR resonances of the ligands are shifted; in contrast, no such effects were observed for **3**. The ^{19}F NMR resonances (300 K) reported for the various metal complexes represent the averaged ^{19}F NMR signals for the metal-free and metal-containing ligands (fast exchange). The absolute values of these signal shifts are, however, only large in the ^{19}F NMR spectra, in which values up to $\Delta\delta = 8.8$ have been observed.

Figure 1 shows the differences in chemical shift ($\Delta\delta$) obtained by adding an approximately tenfold molar excess of metal salt to the fluoroxylene bis(crown ethers) **4**–**6**; however, in most cases addition of metal salt beyond a twofold excess does not markedly change the position of the signals. It was

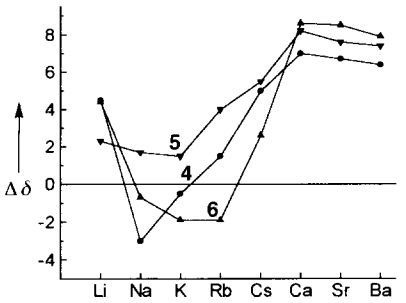

Fig. 1. Observed differences in the chemical shift for the ^{19}F NMR resonances upon complexation of the free bis(crown ethers) **4**–**6**, with Li^+, Na^+, K^+, Rb^+, Cs^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}. In case of **5**-Rb^+ two signals are observed: a very broad one and one whose position is concentration-dependent.

found that alkaline earth metal ions give rise to a larger difference in chemical shift than alkali metal ions; this behavior is most likely a result of the higher charge density of the former. However, no conclusion about the relative or absolute stabilities of the complexes can be drawn from the final values given. Selective complexation is observed when metal ions with largely differing radii compete for binding to the macrocycle. For example, addition of Li^+ or Mg^{2+} has a negligible effect on the ^{19}F NMR titration curves of **2** with Na^+ or K^+. Figure 2 depicts the results for the ^{19}F NMR titrations of fluorocrown ether **2** with solutions of various metal salts. The experimentally determined curves show that close to the equivalence point, the steep curve in the stoichiometric region becomes a straight line which asymptotically approaches the limiting value and indicates that formation of a stoichiometric 1:1 metal:ligand complex has taken place. This graph can be regarded as a calibration curve that allows the determination of the metal ion concentration if either the ligand concentration or the formation constant of the complex is known.

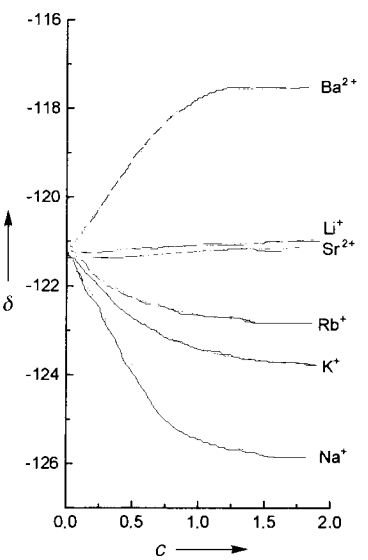

Fig. 2 Plot of the ^{19}F NMR chemical shifts of **2** as a function of added equivalents c of metal ion. The titration was carried out with solutions of the perchlorates of Li^+, Na^+, K^+, Rb^+, Sr^{2+}, and Ba^{2+} in CH_3CN.

From Figures 1 and 2 it becomes apparent that some ^{19}F NMR signals are shifted to higher field while others are shifted to lower field. Reinhoudt et al. have reported a similar phenomenon in the ^1H NMR spectra of the non-fluorinated analogues of **2**. They proposed an explanation based on the complementarity of the size of the cavity and ion.[7] Although this hypothesis succeeded in explaining the observed differences in chemical shift for the ^1H NMR resonances of the non-fluorinated analogues, such a simple explanation is not forthcoming for the compounds described herein. For the alkali metals, the "size-match" and the observed shift of the signals in the NMR spectra seem to correlate, since the absolute differences in the NMR chemical shift are largest when the metal ion fits well in the macrocycle or, alternatively, when a crown ether-sandwich complex can be formed. However, this simple model does not hold for the divalent alkaline earth metal ions.

Whereas NMR spectroscopy can provide information on the formation of metal complexes of partially fluorinated macrocycles, it is not possible to draw a more definitive conclusion regarding the nature and strength of the metal–fluorine interactions. This is also due to the fact that no scalar coupling to the fluorine was detected in the ^{19}F NMR.

In order to make more accurate statements about possible metal–fluorine contacts in the solid state, an X-ray structure analysis was performed for one of the metal complexes.[8, 9] Single crystals of **2**·$Ba(ClO_4)_2$ were obtained by diffusion of diethyl ether into a solution of the metal complex in acetonitrile. In the crystal, barium is ten-coordinate (Fig. 3) with seven short

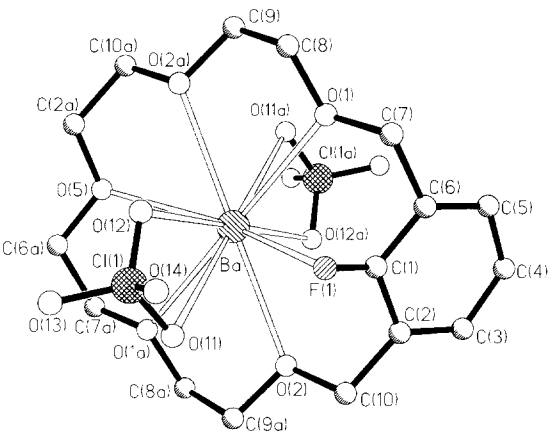

Fig. 3 Structure of **2**·$Ba(ClO_4)_2$ in the crystal. For clarity the hydrogen atoms have been omitted. Selected bond lengths [pm] and angles [°]: Ba–F(1) 279.9(8), Ba–O(1) 279.4(5), Ba–O(2) 279.5(5), Ba–O(12) 281.0(7), Ba–O(11) 301.0(6), F(1)–C(1) 134.8(10); Ba–F(1)–C(1) 80.5(5), Ba–C(1)–F(1) 72.2(5).

(279.4–281.0 pm), one medium (289.9 pm), and two long distances (301.0 pm) to the coordinating atoms. The Ba–F distance is 279.9(8) pm and is therefore in the same range as the short Ba–O distances. Short metal–fluorine distances have been reported for several metal alkoxides[10] and aryl metal compounds;[11] they are regarded to be similar to the interactions of ethers and amines with metal ions.[12] Ba–O distances of approximately 280 pm have also been observed in the structure of benzo[18]crown-6·$Ba(ClO_4)_2$ and can therefore be considered as typical.[13] The C(1)–Ba distance (289.9(8) pm) is significantly shorter than the two long Ba–O distances. This raises the question of whether the interaction of Ba^{2+} with the C(1)–F(1) bond can be classified as η^2 bonding—a similar trend towards polyhapticity has also been observed in the solid-state structures of some benzylmetal compounds.[14]

To decide whether metal–fluorine contacts make a positive contribution towards the stability of metal complexes in solution or if on the other hand steric hindrance dominates, we have carried out a simple competition experiment. In this experiment, the ^1H, ^{13}C, and ^{19}F NMR spectra of a 1:1:1 mixture of **2**, its non-fluorinated analogue, and Na^+ were recorded. We found that the complex of **2** with Na^+ is more stable by a factor of 1.5. The same trend is also reflected in the heterogeneous stability constants determined by picrate extraction.[15, 16] For the metal ions Na^+, K^+, and Cs^+ the stability constant is always larger for the fluorine-containing compound **2** than for the non-fluorinated analogue.

The short Ba–F(1) distances in **2**·$Ba(ClO_4)_2$ are indicative of a direct σ donor bond from F(1) to the metal ion. From the large chemical shifts of the ^{19}F NMR resonance it can be deduced that bonding of F(1) to cations of the alkali and alkaline earth metal ions also exists in solution.

Experimental Procedure

2: KO*t*Bu (920 mg, 8.2 mmol) and tetraethyleneglycol (688 mg, 3.6 mmol) were dissolved in toluene (100 mL) and the resulting solution was heated under reflux for 1 h. A solution of 1,3-bis(bromomethyl)-2-fluorobenzene (1000 mg, 3.6 mmol) in toluene (40 mL) was then slowly added at room temperature while vigorously stirring. Stirring at room temperature was continued for 12 h, and the solution was then heated under reflux for 2.5 h. The reaction mixture was allowed to cool to room temperature, the precipitate was filtered off, and the solvent was removed from the filtrate under vacuum. Distillation of the residue at 0.1 Torr/200 °C afforded compound **2** as a colorless oil (R_f = 0.35). Yield: 656 mg (58%). ^1H NMR (CD_3CN): δ = 3.46 (s, 8H, OCH_2), 3.50–3.59 (m, 8H, OCH_2), 4.51 (d, J = 1.1 Hz, 4H, $ArCH_2$), 7.07 (t, J = 7.5 Hz, 1H, ArH), 7.32 (t, J = 7.2 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$): δ = 67.38 (d, ^3J(C,F) = 3.5 Hz, $ArCH_2$), 69.24 (OCH_2), 70.42 (OCH_2), 70.46 (OCH_2), 70.63 (OCH_2), 123.34 (d, J(C, F) = 4.7 Hz, Ar), 125.36 (d, ^2J(C, F) = 15.1 Hz, Ar), 131.00 (d, J(C, F) = 4.8 Hz, Ar), 160.23 (^2J(C, F) = 15.1 Hz, Ar), 160.23 (d, ^1J(C, F) = 250.2 Hz, Ar). ^{19}F NMR ($CDCl_3$, $CFCl_3$): δ = −122.20 (t, J = 7.1 Hz). ^{19}F NMR (CD_3CN, $CFCl_3$): δ = −126.81 (t, J = 7.1 Hz). $C_{16}H_{23}FO_5$ (314.35) calcd (found): C 61.12 (60.43), H 7.38 (7.29).

^{19}F NMR titrations: A solution of **2** (0.95 mg, 3 μmol) in CD_3CN (0.5 mL) was titrated with the corresponding metal perchlorates (3 μmol per 0.1 mL CD_3CN). The ^{19}F NMR shifts were referenced internally to $CFCl_3$ and determined on a Bruker 200 ACF (^{19}F: 188 MHz) at 300 K. In a control experiment, the ^{19}F NMR resonance for 1,3-bis(bromomethyl)-2-fluorobenzene did not change upon addition of metal perchlorates; hence, interactions between the metal ions and $CFCl_3$ which might affect the standard can be ruled out. Differences in NMR chemical shifts when employing CD_3CN as solvent are reproducible to at least ±0.02 ppm when NMR data is collected at the same temperature and using similar concentrations of reactants. The maximum sensitivity of the measurement technique described herein (5 mm NMR tube, data collection time: 30 min, 188 MHz) allows for the detection of 0.01 μmol metal ions in 0.5 mL sample volume. This is equivalent to a metal ion concentration of 2×10^{-5} mol L^{-1}.

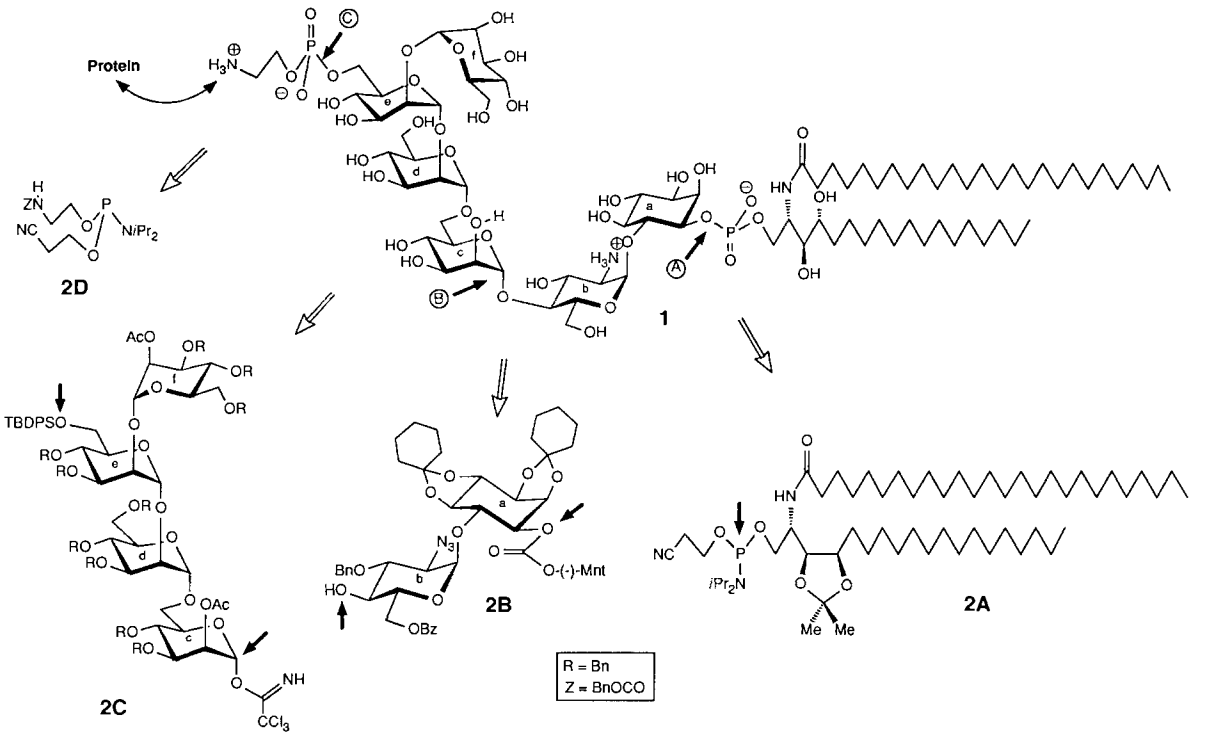
[16] Even though these heterogeneous stability constants are not precisely correlated with the Gibbs energy of complexation, they allow for a good prediction of the relative stabilities of metal complexes for structurally related systems.

Synthesis of a GPI Anchor of Yeast (*Saccharomyces cerevisiae*)**

Thomas G. Mayer, Bernd Kratzer, and Richard R. Schmidt*

Glycosylphosphatidylinositols (GPIs) are a class of naturally-occurring glycophospholipids, discovered about ten years ago, that anchor the C-termini of proteins and glycoproteins to the membrane of eukaryotic cells.[1] Analysis of the GPI anchors of *Trypanosoma brucei* variant surface glycoprotein (VSG),[1,2] murine brain Thy-1,[3] *Leishmania major* promastigate surface protease,[4] *Trypanosoma cruzi* 1G7 antigen,[5] and human erythrocyte acetylcholinesterase[6] gave the general structure shown in Scheme 1 (framed).



Scheme 1. Structure of GPI anchors.

The occurrence of additional carbohydrate (R^4–R^6) or ethanolamine phosphate (R^3) side chains is species-specific,[7] and there is a noticeable difference in membrane-anchoring lipid structures depending on species and cell type. In the case of glycerolipids (variation of R^1 and R^2), the lipids are made up of *sn*-1,2-dimyristoylglycerin in *T. brucei* VSGs,[8] *sn*-1-stearoyl-2-lysoglycerin in *T. brucei* procyclic acidic repetitive protein,[9] *sn*-1-alkyl-2-acylglycerin in bovine and human erythrocyte acetylcholinesterase[10] and human folate binding protein,[11] and *sn*-1,2-diacylglycerin in torpedo acetylcholinesterase.[12] In addition, the inositol residue can be palmitoylated. In GPI anchors of yeast (*Saccharomyces cerevisiae*), ceramides containing

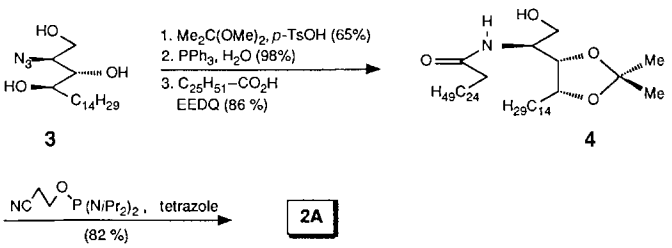

Scheme 2. Retrosynthesis of GPI anchor **1**.

phytosphingosine were also found as a membrane anchors instead of glycerolipids.[13,14] The typical structure of such a GPI anchor is shown in Scheme 2 (**1**).

The role of GPI-anchored proteins in cell–cell recognition, in interactions with bioactive factors, and as enzymes have been discussed.[1] Moreover, there are increasing indications that intracellular signal transfer triggered by insulin is caused by compounds that are structurally related to glycosylphosphatidylinositols.[15] The GPI anchor itself and its partial structures are thus gaining in significance as mediators of regulatory processes, and the chemical synthesis of structurally homogeneous GPI anchors and their derivatives is an important objective for biological investigations. The appropriate combination of lipid, phosphate, carbohydrate, and, when necessary, peptide chemistry has been successfully employed for the synthesis of partial structures[16–23] and the diacylglycerin-based GPI anchor of *Trypanosoma crucei*.[24] We report here on a versatile strategy for the first total synthesis (Scheme 2) of the ceramide-containing GPI anchor **1** of yeast (*Saccharomyces cerevisiae*).

The strategy we followed for the synthesis of **1** is convergent and versatile. The target molecule was cleaved at positions Ⓐ–Ⓒ into the fragments **2A**–**2D** (Scheme 2), which should have many applications, either directly or after structural modification (especially at O-3 or O-4 of the mannose building block c), in the synthesis of a great variety of GPI anchors. Our aim is to demonstrate the efficiency of this strategy with respect to the synthesis of the individual components and the coupling to form the target molecule. Here, the formation of the crucial glycosidic bonds is based on highly anomer-selective reactions with O-glycosyltrichloroacetimidates as glycosyl donors,[25] and phosphorylation by the phosphite amide method.[22,26] Appropriate selection of protecting groups enables their final cleavage in two simple, high-yielding reaction steps.

The ceramide component **2A**, which contains phytosphingosine as nitrogen base, was prepared starting from the readily available azide derivative **3** (Scheme 3).[27] Reaction with dimethoxypropane in the presence of *p*-toluenesulfonic acid (*p*-TsOH) as catalyst afforded the 3,4-O-protected derivative regioselectively; azide reduction according to the method used by Staudinger et al.[28] and N-acylation with cerotic acid (hexacosanic acid) in the presence of 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ) as condensation agent produced the 1-O-unprotected ceramide **4** in high yield. The desired component **2A** (Table 1) was obtained by reaction with the bifunctional phosphitylation reagent cyanoethoxybis(diisopropylamino)phosphane in the presence of tetrazole as activator.

Scheme 3. Synthesis of **2A**.

For the synthesis of the α-glucosaminyl(1-4)inositol compound **2B**, the readily available trichloroacetimidate **5**[29] and the D-*myo*-inositol derivative **6**,[22] for which a high yield synthesis has been developed,[30] were employed as starting materials (Scheme 4). The 6-O-glycosylation of the acceptor **6** with the glycosyl donor **5** in diethyl ether at room temperature with trimethylsilyl trifluoromethanesulfonate (TMSOTf) as catalyst led exclusively to formation of the α-linked product **7** in high yield. Earlier unsatisfactory α-selectivities and/or yields in the synthesis of **7**[16–21, 24] were overcome by the judicious choice of protecting groups for the starting materials and by optimizing

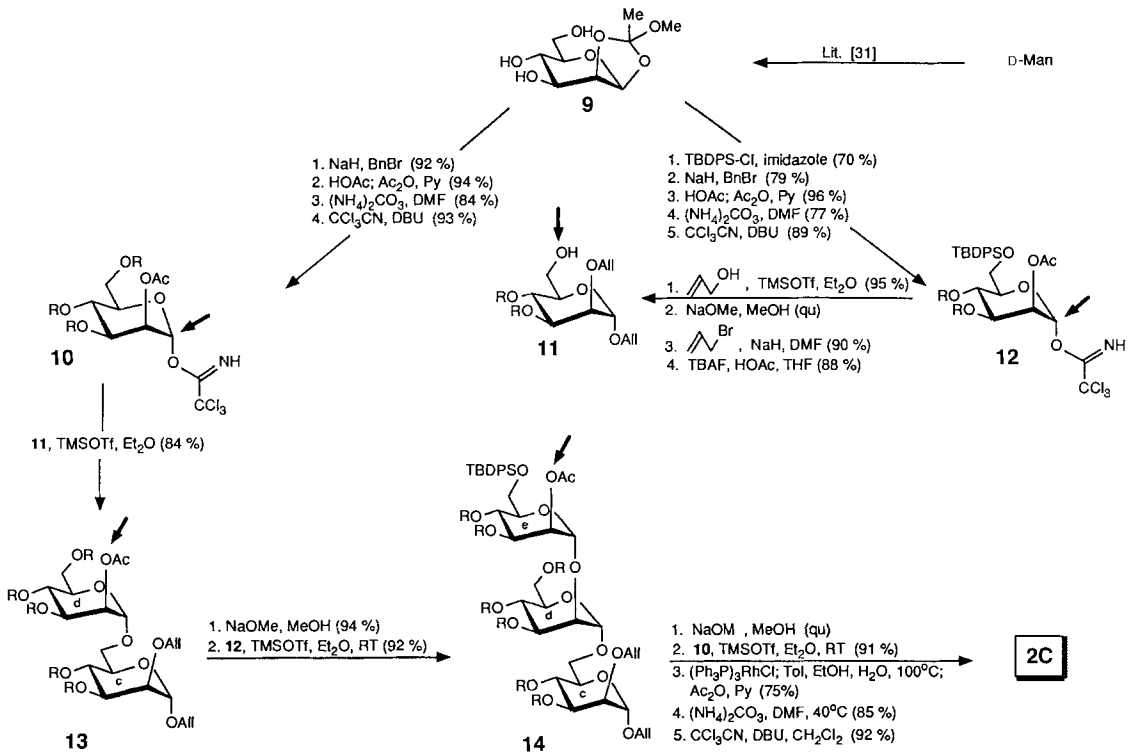
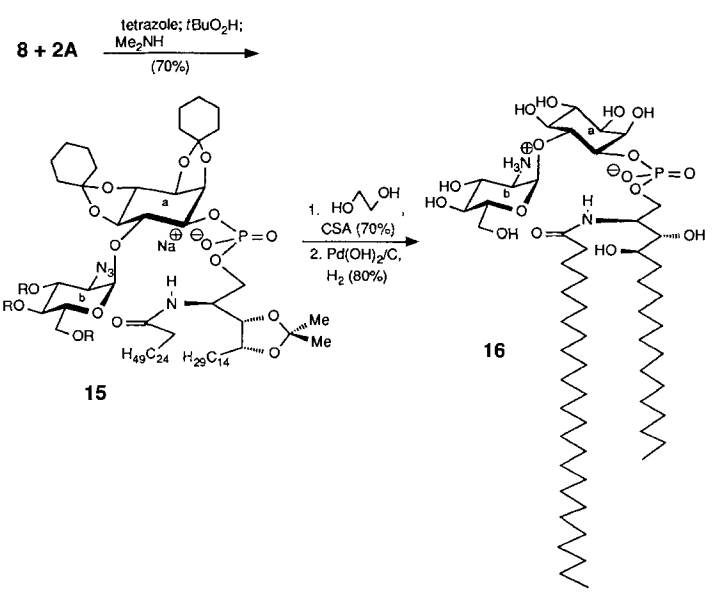


Scheme 4. Synthesis of **2B** and **8**. MS = molecular sieve, qu = quantitative, R = Ac, Mnt = menthyl.

reaction conditions. The 1a-O-unprotected compound **8** was obtained by selective cleavage of the acetyl protecting groups with NaOMe/MeOH, O-benzylation with NaH/benzyl bromide in the presence of tetra-*n*-butylammonium iodide (TBAI), and cleavage of the carbonate residue with K_2CO_3/MeOH at 40 °C. The synthesis of unit **2B** was performed by selective deacetylation of **7**. Regioselective 6b-O-benzoylation with benzoyl cyanide at −70 °C was then followed by regioselective 3b-O-benzylation with benzyl bromide in the presence of Ag_2O. The 4b-O-unprotected acceptor **2B** could thus be obtained directly from **7** in good overall yield without having to resort to complex manipulations of protecting groups. The structure of **2B** was confirmed by ^{1}H NMR data (Table 1).

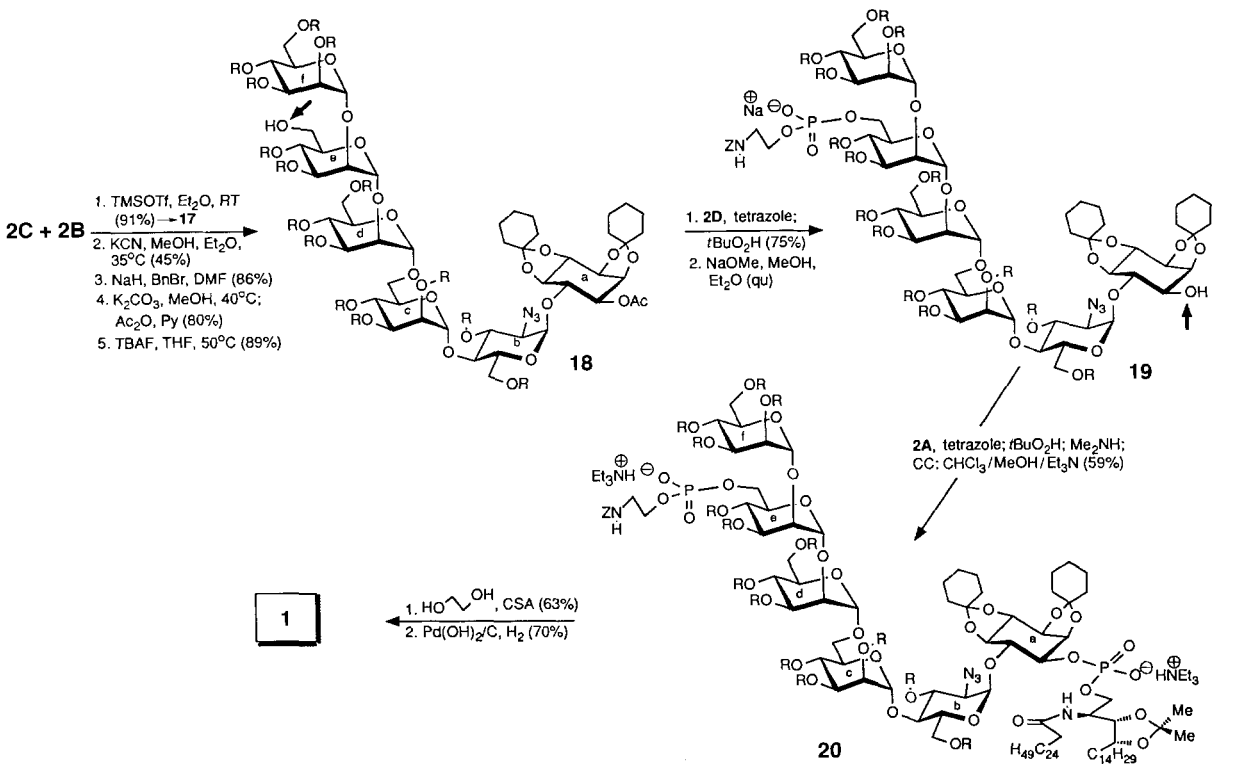
The synthesis of tetramannose unit **2C** started from the orthoester **9** (Scheme 5), which is readily available from D-mannose.[31] The synthon **10** was obtained by the following reaction sequence: benzylation with benzyl bromide/NaH, opening of the orthoester with glacial acetic acid, acetylation, selective 1-O-deacetylation with ammonium carbonate in dimethylformamide (DMF), and conversion into the trichloroacetimidate with trichloroacetonitrile, in the presence of diazabicycloundecene (DBU) as base. The 2-O-acetyl group in **10** promotes α-selective glycosylations; the pattern of protecting groups in **10** also corresponds to that required for the monomer units d and f of **2C** (see Scheme 2). The e-monomer component **12** was obtained by regioselective 6-O-silylation of **9** with *tert*-butyldiphenylsilyl chloride (TBDPS-Cl) in the presence of imidazole, benzylation, opening of the orthoester, acetylation, selective 1-O-deacetylation, and conversion into the trichloroacetimidate. The c-monomer unit of the tetrasaccharide **2C** was also prepared from **12** in a straightforward reaction sequence: the allyl-α-glycoside was generated from **12** in almost quantitative yield by reaction with allyl alcohol under standard conditions; deblocking of the 2-O-acetyl group, 2-O-allylation with allyl bromide/NaH in DMF, and removal of the 6-O-silyl group with TBAF in glacial acetic acid/THF yielded the 6-O-unprotected derivative **11**.



Reaction of the mannosyl donor **10** with acceptor **11** in diethyl ether at room temperature with TMSOTf as catalyst gave the α(1-6)-linked disaccharide **13** in good yield. Cleavage of the 2d-O-acetyl group with NaOMe/MeOH and glycosylation with the mannosyl donor **12** under the same conditions afforded the α(1-2)-α(1-6)-linked trisaccharide **14**, again in high yield. The desired α(1-2)-α(1-2)-α(1-6)-linked tetrasaccharide was obtained almost quantitatively by cleavage of the 2e-O-acetyl group and glycosylation with the mannosyl donor **10** under the conditions previously described. The 1c- and 2c-O-allyl groups were subsequently removed by treatment with the Wilkinson catalyst and hydrolysis, and the free hydroxyl groups were acetylated with acetic anhydride/pyridine. The building block **2C** was obtained by regioselective cleavage of the 1c-O-acetyl group and conversion to the trichloroacetimidate. Thus, starting from the mannose units **10**–**12**, **2C** was obtained α-specifically in high yield. The structure of **2C** was confirmed by its ^{1}H NMR spectrum (Table 1).

The N-benzyloxycarbonyl(Z)-protected aminoethylphosphite component **2D** was prepared according to published procedures.[24]

Scheme 5. Synthesis of **2C**. RT = room tempertaure, All = allyl, R = Ac.



To test the overall synthetic strategy, in which the coupling of the **2DBC** moiety with the **2A** moiety was planned as the last step, component **8** was combined with the ceramide phosphite **2A** (Scheme 6). The required phosphite diester formation was achieved by activation with tetrazole; subsequent oxidation to the phosphate with *tert*-butylhydroperoxide and cleavage of the cyanoethyl group by treatment with dimethylamine afforded the ceramide-1-phosphate derivative **15** with 70% overall yield. Camphorsulfonic acid (CSA) catalyzed the cleavage of the O-cyclohexylidene and O-isopropylidene groups in the presence of glycol. The simultaneous hydrogenolysis of the benzyl and azide groups readily yielded the GPI derivative **16**, which was characterized by NMR and mass spectroscopy (Table 1).

Scheme 6. Coupling of **8** with **2A**. R = Ac.

Encouraged by this result, we started on the synthesis of **1** (Scheme 7). The glycosyl donor **2C** was first reacted with the acceptor **2B** in ether at room temperature, in the presence of TMSOTf as catalyst (→**17**); the (1-4) linkage between these two components was thus formed α-selectively in good yield. Formation of the α-linkage was corroborated by the C,H coupling constants (INEPT): $169.51 > J_{C,H} > 177.30$ Hz. All acyl groups were subsequently removed with KCN as base, and the free hydroxyl groups were benzylated with benzyl bromide and NaH. This step was followed by cleavage of the 1a-carbonate group and by acetylation of the 1a-OH group. Only then was the 6e-OH group deprotected with TBAF in THF to yield fragment **18**, which was used for the coupling with **2D**. By activation of **2D** with tetrazole and oxidation of the condensation product with *tert*-butylhydroperoxide, the Z-protected aminoethyl phosphate residue was introduced at the 6e-O position of **18** in 75% yield. Cleavage of the cyanoethyl group and the 1a-O-acetyl group gave component **19**, which was now converted into **1** as described for the synthesis of **16**. The coupling of **19** with **2A** was performed by activation with tetrazole, oxidation, and cleavage of the cyanoethyl group with dimethylamine. The product was purified by column chromatography (CC) with $CHCl_3$/MeOH/Et_3N (100/3/1). The bis(triethylammonium) salt was isolated, and the structure confirmed by NMR (^1H, ^{31}P) and MS data (Table 1). Simultaneous cleavage of the O-isopropylidene and O-cyclohexylidene groups with glycol in the presence of CSA as catalyst followed by hydrogenolysis of the Z-group, the O-benzyl protecting groups, and the azide group yielded the target GPI anchor **1** (10 mg), which was characterized by NMR and MS data (Table 1).

The ready accessibility of all starting materials, the high regio- and diastereoselectivities, and the high yields obtained in all reaction steps as well as the facile cleavage of the protecting

Scheme 7. Total synthesis of **1**. R = Ac.

groups form an excellent basis for further successful chemical syntheses in this field.

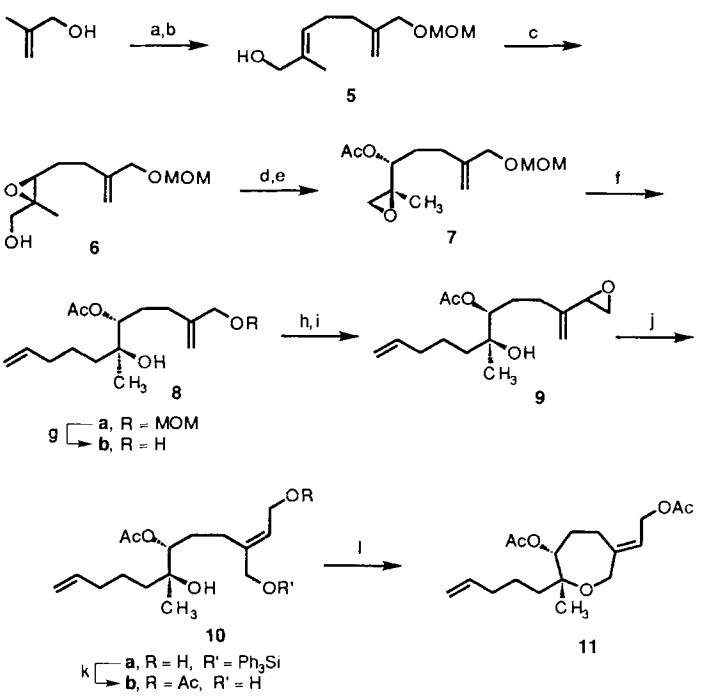
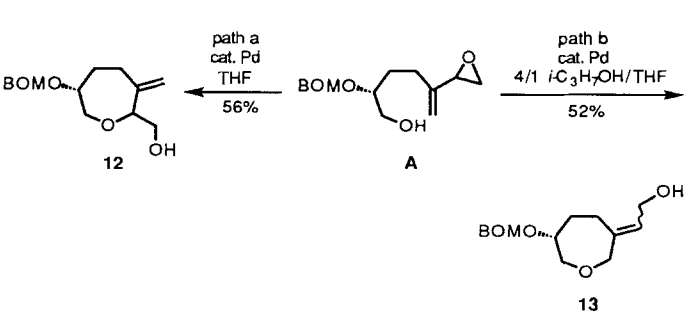
A Total Synthesis of (+)-2′*S*, 3′*R*-Zoapatanol**

Barry M. Trost,* Paul D. Greenspan, Holger Geissler, Jung H. Kim, and Nicholas Greeves



Extraction of the leaves of the Mexican zoapatle plant *Montanoa tomentosa*, which have been used as a contraceptive in folk medicine, led to isolation of a series of oxepanes **1**–**4**.[1] The

extraordinary biological activity that prompted recent speculations on the contribution of further metabolites to this activity[2] and the unusual structural motif of these diterpenoids stimulated a number of total syntheses,[3] none of which have culminated in an asymmetric synthesis. In addition to the stereocontrolled synthesis of the oxepane core, the correct introduction of the exocyclic double bond represents a significant challenge. We wish to report the first asymmetric synthesis of zoapatanol, which addresses both of these stereochemical issues.



The asymmetric synthesis of the oxepane core depends upon Sharpless epoxidation[4] of the allyl alcohol **5**, which is readily available from the dianion of methallyl alcohol as shown in Scheme 1.[5] Use of L-(+)-diethyl tartrate (DET) as chiral ligand at −40° for 12–24 h gave the epoxide **6** in 90% yield and greater than 95% *ee* (typically 96–98% *ee*) as determined by NMR spectroscopy of the Mosher esters.[6] Attempts to introduce a side chain in **6** through alkylation by Payne rearrangement[7] failed. However, a sequential protocol initiated by a titanium-promoted regioselective opening of the epoxide[8] with acetate as the nucleophile, which sets the two key stereocenters of the subsequent oxepane in 2′*S*,3′*R* configuration, followed by conversion of the diol into the epoxide **7**, successfully primed the system for introduction of the side chain.

Several attempts to bring in a side chain bearing the carbonyl group in various protected forms using cuprate chemistry gave no opening of the epoxide **7** in spite of the excellent reactivity of this epoxide towards an *n*-butylcuprate reagent. Seizing upon this dramatic difference, we examined a cuprate bearing an olefin as a carbonyl surrogate (convertible to a carbonyl function by Wacker oxidation).[9] Not surprisingly, the cuprate from 3-butenylmagnesium bromide reacted well to give the tertiary alcohol **8a**. The corresponding diol **8b**, obtained by acid hydrolysis, underwent a straightforward conversion to the requisite epoxide **9**.

Scheme 1. Synthesis of the oxepane core. a) 2.2 equiv *n*-C_4H_9Li, tetramethylethylenediamine (TMEDA), ether, $(CH_3)_2C{=}CHCH_2Br$, then methoxymethyl chloride (MOM-Cl), $(i\text{-}C_3H_7)_2NC_2H_5$, CH_2Cl_2, 92%. b) 4 mol% SeO_2, *t*-C_4H_9OOH, 10 mol% salicylic acid, CH_2Cl_2, room temperature (RT), 53%. c) *t*-C_4H_9OOH, 6 mol% L-(+)-DET, 5 mol% $Ti(OC_3H_7\text{-}i)_4$, 4 Å molecular sieve, CH_2Cl_2, −40 °C, 90%. d) HOAc, $Ti(OC_3H_7\text{-}i)_4$, CH_2Cl_2, −10 °C, then TsCl, 4-dimethylaminopyridine (DMAP), CH_2Cl_2, 0 °C, 95%. e) Amberlite IRA-400 (OH) resin, THF, 78%. f) $H_2C{=}CHCH_2CH_2MgBr$, CuI, THF, −40 °C, 91%. g) 6N HCl, CH_3OH, 50 °C, 62%. h) Dess-Martin periodinane, CH_2Cl_2, 0 °C, 84%. i) $(CH_3)_3S^+ {}^-O_3SCH_3$, NaOH, H_2O, CH_2Cl_2, RT, 85%. j) 2.5 mol% $[(dba)_3Pd_2]\cdot CHCl_3$ (dba = dibenzylidene acetone), 25 mol% $(i\text{-}C_3H_7O)_3P$, Ph_3SiOH, THF, RT, 67%. k) Ac_2O, DMAP, CH_2Cl_2, RT then CH_3CN, H_2O, KF, 70 °C, 79%. l) $(CF_3SO_2)_2O$, 2,6-lutidine, CH_2Cl_2, 74%.

Cyclization of vinyl epoxide **9** was envisioned to create the proper olefin geometry, since palladium has a bias to ionize such systems preferentially to the *syn* π-allylpalladium complex. Studies on the model compound **A** revealed an interesting dichotomy in terms of regioselectivity [Eq. (1)]. Palladium-catalyzed cyclization of **A** in THF led exclusively to **12** by proximal attack of the hydroxy nucleophile, presumably as a result of hydrogen bonding between the hydroxyl group of the nucleophile and the departing oxygen of the epoxide.[10] Interrupting such hydrogen bonding by employing an exogeneous alcohol as solvent indeed appears to reorient the reaction partners to give the desired product **13**, formed by distal attack, as the major regioisomer, in a 3:1 mixture of (*E*/*Z*) isomers. No attempt was made to optimize olefin geometry in this model. However, all attempts to effect either palladium-catalyzed, or any acid-

[**] This research was supported by fellowships for P. D. G. (NIH), H. G. (Humboldt-Stiftung), J. H. K. (Pfizer), and N. G. (Harkness Foundation). We thank the General Medical Sciences Institute of the National Institutes of Health (NIH) for generous financial aid and especially Dr. Stefan Scheiblich who performed some of our early studies. The mass spectra were recorded at the Mass Spectrometry Facility of the University of California at San Francisco, which is sponsored by the Division of Research Resources.

(including Lewis acid) or base-catalyzed cyclization of **9** to an oxepane failed, presumably as a result of the diminished nucleophilicity of a tertiary alcohol.

Intermolecular reactions with common oxygen nucleophiles and palladium catalysis also failed to give satisfactory selectivity for the S_N2' type attack. However, exposing a 1.4:1 mixture of triphenylsilanol and epoxide **9** to 2.5 mol% of $[(dba)_3Pd_2]\cdot CHCl_3$ in THF at ambient temperature gave the distal product **10a**, exclusively in the ***E*** configuration as desired.[11] On differentiation of the two primary hydroxy groups as in **10b**, this compound was converted into the triflate,[12] which spontaneously cyclized under the reaction conditions to **11**.

After the absolute and relative stereochemistry of the core had been established, elaboration of the side chain was required to complete the synthesis. As outlined in Scheme 2, Wacker oxidation proceeded well to generate the methyl ketone **14a**. At this point, exchange of the protecting groups from acetyl to *tert*-butyldimethylsilyl was performed to minimize problems of chemoselectivity. Many attempts to achieve carbonylative cross-coupling[13, 14] at low CO pressures with the vinyl triflate **15a** (formed with 2-bis(trifluorosulfonyl)amino-5-chloropyridine[15]) and a prenylstannane failed, as did similar attempts at the electronic inverse, namely, with vinylstannane (**15b**)[16] and prenyl halide. However, on increasing the CO pressure to 34 atm and adding molecular sieves to reduce protodestannylation, prenyl chloride underwent carbonylative alkylation of the vinylstannane **15b** to give a 76% yield at 80% conversion (based on recovered starting material) of the bis(silyl ether) of (+)-dehydrozoapatanol (**16**). Chemoselective conjugate reduction occurred smoothly with the Stryker reagent[17] to give (+)-zoapatanol, after desilylation[18] of **17**. The spectroscopic properties were identical to those recorded for the natural product.

Scheme 2. Introduction of the side chain. a) LiCl, $PdCl_2$, CuCl, dimethylformamide (DMF), H_2O, O_2, RT, 90%. b) K_2CO_3, CH_3OH, H_2O, 93%. c) *tert*-Butyldimethylsilyl chloride (TBDMS-Cl), imidazole, DMF, 55 °C, 85%. d) Potassium bis(trimethylsilyl)amide, 2-N(SO_2CF_3)$_2$-5-ClC_5H_3N), THF, −78 °C, 82%. e) $[(CH_3)_3Sn]_2$, 3% $[(Ph_3P)_4Pd]$, LiCl, THF, 60 °C, 82%. f) $(CH_3)_2C=CHCH_2Cl$, 34 atm CO, 10% $[(dba)_3Pd_2]\cdot CHCl_3$, 20 mol% Ph_3P, 3 Å molecular sieve, PhH, 60 °C, 76%. g) $[Ph_3PCuH]_6$, H_2O, PhH, 94%. h) HF, H_2O, CH_3CN, RT, 90%.

Besides providing the first asymmetric synthesis of this biologically fascinating system, there are several noteworthy features of this synthesis. The strategy employs three palladium-catalyzed processes: allylic alkylation, Wacker oxidation, and carbonylative cross-coupling. The regio- and diastereoselectivity of the allylic alkylation is particularly interesting. Whereas a role for the nucleophile in controlling regioselectivity is anticipated, its influence on olefin geometry is not. The fact that only the *E* product **10a** is obtained, in contrast to what happens with other oxygen nucleophiles in this systems,[19] suggests that the silanol may coordinate with the epoxide oxygen to help promote formation of the sterically and thermodynamically preferred *syn* complex. The use of the carbonylative cross-coupling at a late stage of the synthesis provides an opportunity to diverge

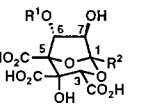
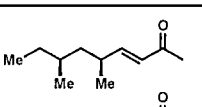
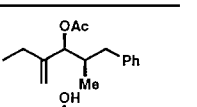
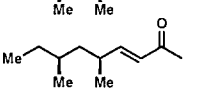
[18] As in all previous syntheses, zoapatanol is obtained as a mixture epimeric at C-6. The stereochemistry has not been rigorously established for the natural product. The diastereomers were inseparable. At 300 MHz, the ^{1}H NMR spectrum shows evidence for the presence of two diastereomers in the doubling of the signals for the protons of the C-2 and C-6 methyl groups. According to the NMR spectrum the diastereomeric ratio is 1:1.

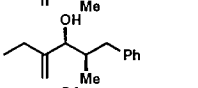


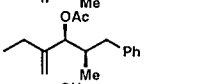
[19] Carboxylic acids reacted as nucleophiles, but were only moderately regioselective; the *E*/*Z* ratio was approximately 4.5:1.

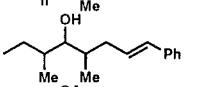


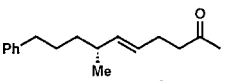


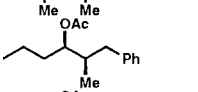


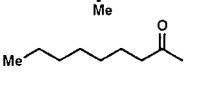


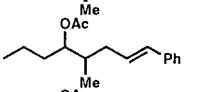


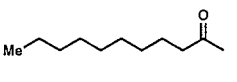


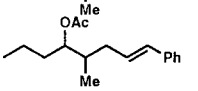












Zaragozic Acid A/Squalestatin S1: Synthetic and Retrosynthetic Studies**

Kyriacos C. Nicolaou,* Eddy W. Yue, Yoshimitsu Naniwa, Francesco De Riccardis, Alan Nadin, James E. Leresche, Susan La Greca, and Zhen Yang

In 1992, researchers at Glaxo[1] and Merck[2] independently reported the isolation and characterization of a family of structurally related natural products, which they respectively named the squalestatins and the zaragozic acids. The three squalestatins (S1, S2, and H1, **1a–c**, Table 1) and five zaragozic acids (A, B, C, D, and D_2, **1a**, **2a–d**, Table 1)[3,4] isolated so far have been shown to be potent and selective inhibitors of mammalian and fungal squalene synthase both in vivo and in vitro.[5] Consequently, they may act as therapeutically useful serum cholesterol-lowering agents, and a number of analogs have been prepared for structure–activity relationship studies.[6,7] Zaragozic acid A/squalestatin S1 also displays activity against a wide spectrum of important yeast and fungal pathogens,[1a] and is a potent inhibitor of *ras*-farnesyltransferase.[8] It has recently

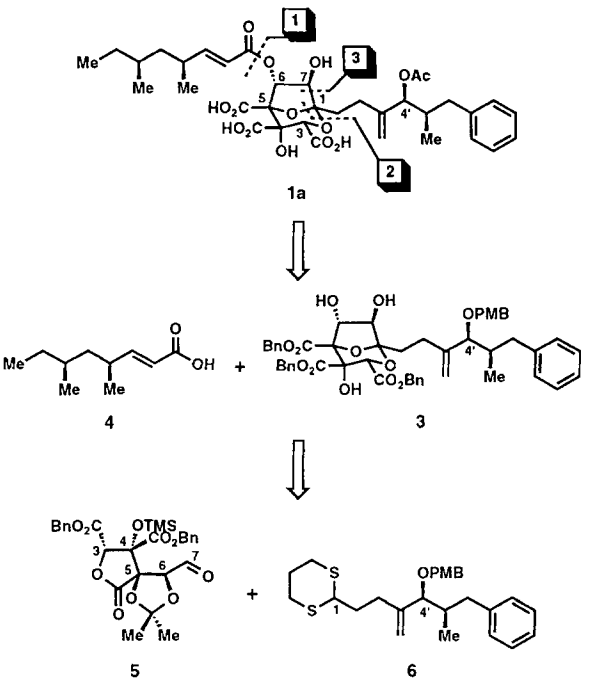
[**] We thank Dr. Kenneth E. Wilson (Merck & Co. Inc., Rahway) for a generous gift of zaragozic acid A. The work was financially supported by the National Institutes of Health, fellowships from Glaxo (E. W. Y.), Teijin Corporation, Japan (Y. N.), the Swiss National Science Foundation (J. E. L.), and by a grant from Merck, Sharp and Dohme. We thank Drs. Dee H. Huang and Gary Siuzdak of The Scripps Research Institute for NMR and mass spectroscopic assistance, respectively.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2184 $ 10.00+.25/0

been demonstrated that zaragozic acid A/squalestatin S1 has a moderately high affinity for Ca^{2+} ions, a property speculated to be the cause of its observed biological activity.[9] As a prelude to a total synthesis of zaragozic acid A/squalestatin S1, its minor congeners, and designed synthetic analogs, we initiated preliminary retrosynthetic and synthetic studies in this area.

Our strategy is shown in Figure 1. Disconnection of the C_6 ester side chain (step 1), unraveling of the C1 acetal (step 2) and cleavage of the C1–C7 bond (step 3) led to aldehyde **5**[10] and acyl anion equivalent **6**. In principle, this approach would enable the synthesis of all the zaragozic acids/squalestatins from a single key intermediate. In order to define clearly the protecting groups and the final synthetic stages, we targeted **3** as a specific late stage key intermediate and embarked on degradative studies on the natural product.

The degradation and reassembly of zaragozic acid A (**1a**) is outlined in Scheme 1.[11] Zaragozic acid A tribenzyl ester **7** was formed in almost quantitative yield by refluxing the natural product with a slight excess of *N,N*-dicyclohexyl-*O*-benzylisourea[12] in toluene. Deacetylation using the Merck[2b] conditions (3% HCl/MeOH) provided the triol **8** in good yield (51% plus 37% recovered starting material). Longer reaction times led to significant methanolysis of the C3 benzyl ester. The allylic alcohol **8** was selectively protected to give the *para*-methoxybenzyl (PMB) ether **9** (68% plus 26% recovered starting material). Hydrolysis of the α,β-unsaturated ester followed



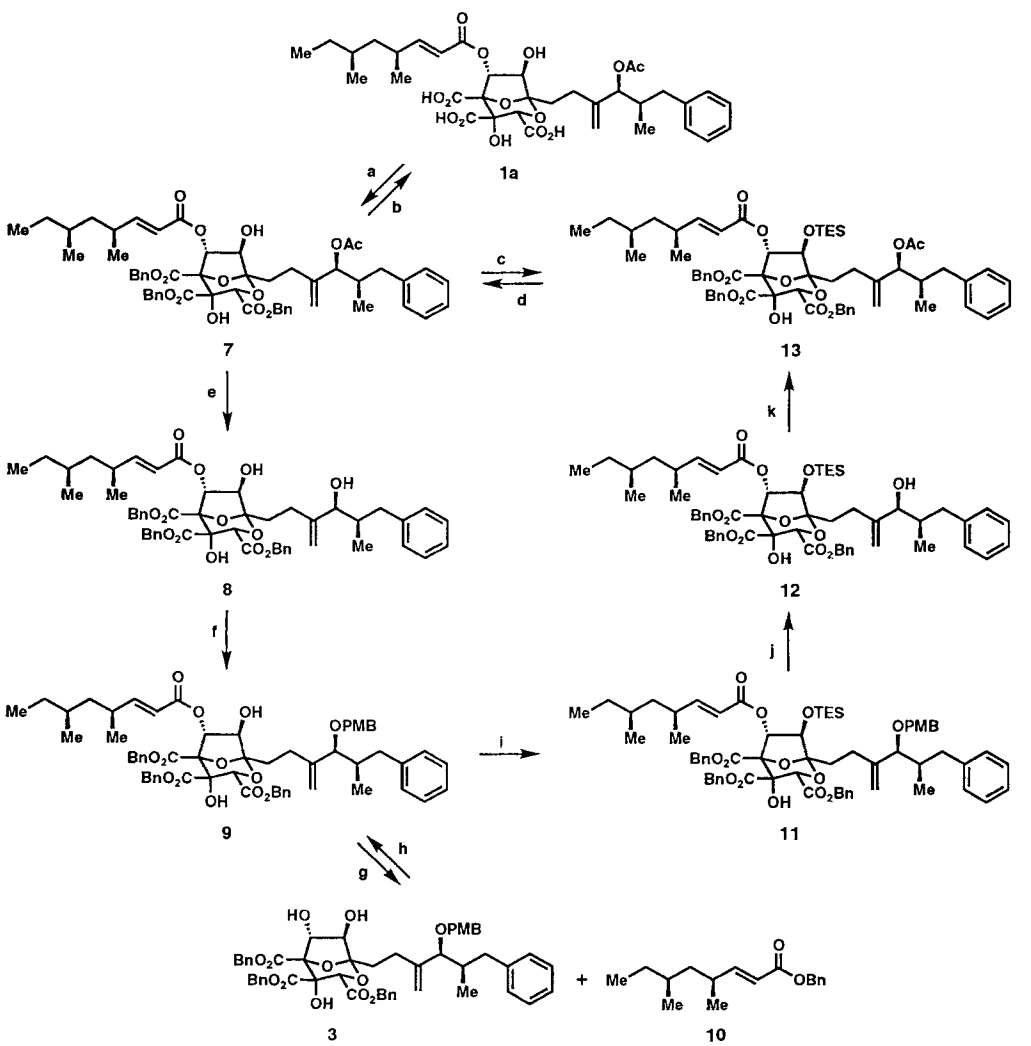


Fig. 1. Retrosynthetic analysis of zaragozic acid A/squalestatin S1 (**1a**).

Scheme 1. Retrosynthetic and synthetic studies with **1a**. a) *N,N'*-dicyclohexyl-*O*-benzylisourea (4.2 equiv), toluene, reflux, 2 h, 99%; b) 10% Pd/C (1.0 wt.equiv), 1,4-cyclohexadiene, 1,4-dioxane, 110 °C, 2 h, >70% crude, 50% after HPLC (reverse phase C18, MeOH/0.1% aqueous AcOH (4/1), flow rate 9 mL min^{-1}, retention time 13.8 min); c) TESOTf (1.1 equiv), pyridine (1.5 equiv), CH_2Cl_2, 22 °C, 10 min, 95%; d) TBAF (1.2 equiv), THF, 0 °C, 15 min, 85%; e) 3% HCl/MeOH, 0 °C, 1.5 h, 51% (plus 37% **7**); f) $Cl_3CC(OPMB)=NH$ (2.0 equiv), CSA (0.1 equiv), 22 °C, 3 h, 68% (plus 26% **8**), g) 1. LiOH (10 equiv), THF/H_2O (2/1), 22 °C, 12 h; 2. *N,N'*-dicyclohexyl-*O*-benzylisourea (4.5 equiv), toluene, reflux, 2 h, 42% **3**, 62% **10**; h) 1. **10** (1.0 equiv), LiOH (15 equiv), THF/MeOH/H_2O (2/1/1), 22 °C, 4 h; 2. **3** (1.0 equiv), EDC (1.25 equiv), DMAP (0.6 equiv), CH_2Cl_2, 22 °C, 10.5 h, 47% (3:2 mixture of the C6-acyl- (**9**) and the C7-acyl compound; plus 20% **3**); i) TESOTf (1.1 equiv), pyridine (1.5 equiv), CH_2Cl_2, 22 °C, 20 min, 79%; j) DDQ (1.2 equiv), CH_2Cl_2/H_2O (20/1), 22 °C, 1 h, 98%; k) Ac_2O (2.5 equiv), pyridine (3.0 equiv), DMAP (0.1 equiv), CH_2Cl_2, 22 °C, 4 h, 99%.
TESOTf = triethylsilyl trifluoromethanesulfonate, TBAF = tetrabutylammonium fluoride, THF = tetrahydrofuran, PMB = *para*-methoxybenzyl, CSA = (±)-10-camphorsulfonic acid, EDC = 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, DMAP = 4-dimethylaminopyridine, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2185 $ 10.00+.25/0

by workup with excess *N,N*-dicyclohexyl-*O*-benzylisourea (toluene, reflux, 2 h) cleanly gave the triol **3** (Table 2) in 42% yield and benzyl ester **10** in 62% yield.

Reconstitution of the natural product began with selective acylation of the C6 hydroxyl group of **3** with (*E*)-(4*S*,6*S*)-4,6-dimethyl-2-octenoic acid **4** to give a 3:2 mixture of C6- and C7-acylated products. However, on subsequent removal of the allylic PMB group, selective acetylation of the C4′ hydroxyl group could not be achieved, which led us to consider temporary protection of the C7 hydroxyl group with a TES ether (**9** → **11**, 79%). Removal of the PMB group from **11** with DDQ afforded **12** in 98% yield, which upon C4′ acetylation and desilylation gave the allylic acetate **7** (85% yield overall) via the intermediate **13**. Removal of the three benzyl esters by transfer hydrogenolysis[13] gave the triacid **1a** (>70% crude, 50% after HPLC), identical in all respects to an authentic sample of zaragozic acid A (**1a**).[11]

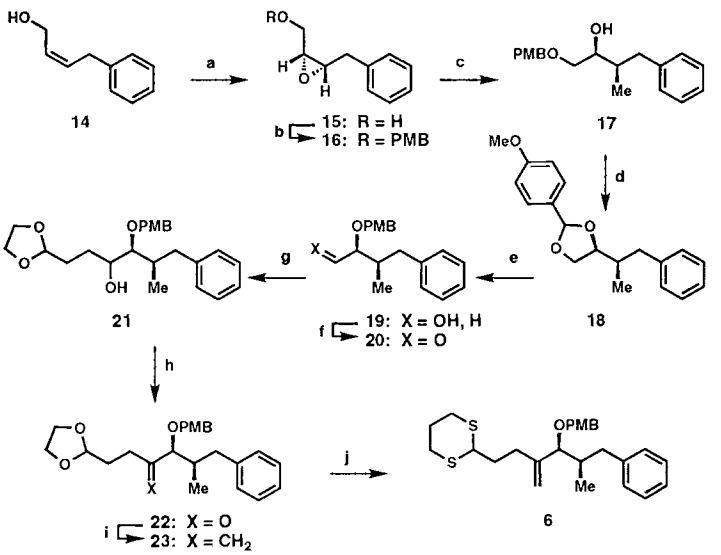

Table 2. Selected physical data for **3**, **4**, and **6**.

3: $[\alpha]_D^{22} = -20.9$ ($c = 0.55$ in $CHCl_3$); $R_f = 0.29$ (silica, ethyl acetate/petroleum ether 2/3); IR (film): $\tilde{\nu}$ = 3487, 3330, 3027, 2929, 2853, 1746, 1617, 1512, 1454, 1246, 1034 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$): δ = 7.30–7.13 (m, 20H, arom. Our retrosynthetic scheme also required a synthesis of the C1 alkyl side chain **6** and the C6 acyl side chain **4**.[14] The synthesis of **6** is outlined in Scheme 2. Sharpless asymmetric epoxidation[15] of the allylic alcohol **14** gave the epoxide in good yield and in approximately 81% *ee*.[16] Protection of the primary alcohol and regioselective opening of the epoxide ($AlMe_3$, *n*-BuLi)[17] gave the alcohol **17** as a single regioisomer (by 500 MHz ^1H NMR analysis) in 65% yield overall. Transfer of the PMB protecting group to the secondary alcohol via the PMB acetal[18] **18** followed by Swern oxidation[19] of the resulting alcohol **19** gave the aldehyde **20** in 42% overall yield. Three-carbon homologation of the aldehyde with 2-(1,3-dioxolan-2-yl)ethylmagnesium bromide gave the acetal **21** as a mixture of diastereoisomers (ratio 1:1 determined by 500 MHz ^1H NMR analysis). Oxidation with the Dess–Martin periodinane,[20] and Tebbe methylenation[21] gave the olefin **23** in 78% yield (two steps). Olefin **23** was crystalline, and a single recrystallization from cyclohexane increased the enantiomeric excess to 98% (according to ^1H NMR and ^{19}F NMR analysis of the Mosher's ester following C4′ PMB deprotection). Completion of the synthesis was achieved by transthioacetalization[22] to give the dithiane **6** (61% yield) (Table 2).

Scheme 2. Synthesis of the side chain at C1 (**6**). a) *t*BuOOH (2.0 equiv), $Ti(OiPr)_4$ (0.1 equiv), diisopropyl-D-tartrate (0.14 equiv), 4 Å molecular sieves (0.5 wt. equiv), CH_2Cl_2, −20 °C, 24 h, 84%; b) PMBCl (1.25 equiv), NaH (1.2 equiv), nBu_4NI (0.04 equiv), THF, reflux, 30 min, 73%; c) $Al(CH_3)_3$ (2.0 equiv), *n*BuLi (0.3 equiv), toluene, −20 °C, 24 h, 89%; d) DDQ (1.1 equiv), CH_2Cl_2, 4 Å molecular sieves (0.25 wt. equiv), 22 °C, 4 h, 53%; e) DIBAl-H (1.2 equiv), CH_2Cl_2, −78 °C, 2 h, 81%; f) $(COCl)_2$ (1.5 equiv), DMSO (2.0 equiv), Et_3N (4.0 equiv), CH_2Cl_2, −78 °C, 2 h, 98%; g) Mg (3.3 equiv), 2-(2-bromoethyl)-1,3-dioxolane (3.0 equiv), THF, 22 °C, 6 h, 73%; h) Dess-Martin periodinane (1.2 equiv), CH_2Cl_2, 22 °C, 20 min, 92%; i) Tebbe reagent (1.2 equiv), THF, 22 °C, 1 h, 85%; j) $iBu_2AlSCH_2CH_2CH_2SAliBu_2$ (2.0 equiv), benzene, 22 °C, 12 h, 61%. DIBAl-H = diisobutylaluminum hydride, DMSO = dimethylsulfoxide.

The C6 acyl side chain was synthesized in four steps as shown in Scheme 3. Alkylation of the hydrazone **24**[23] with commercially available (*S*)-1-iodo-2-methylbutane gave the hydrazone

Scheme 3. Synthesis of the side chain at C6 (**4**). a) 1. iPr_2NH (1.1 equiv), *n*BuLi (1.05 equiv), THF, 0 °C, 15 min; 2. **24** (1.0 equiv), 0 °C, 4 h; 3. *n*BuLi (1.05 equiv), −20 °C, 2 h; 4. (*S*)-$CH_3CH_2CH(CH_3)CH_2I$ (1.2 equiv), −100 °C → −50 °C, 1.5 h; b) O_3, CH_2Cl_2, −78 °C, 30 s; c) $Ph_3P=CHCO_2CH_3$ (1.2 equiv), CH_2Cl_2, 22 °C, 5 h, 30% overall yield from **24**; d) LiOH (3.0 equiv), $MeOH/H_2O$ (3/1), 22 °C, 3 h, 90%.

25 as a 96:4 mixture of diastereoisomers. Ozonolysis of the crude reaction mixture provided the aldehyde **26**,[24] and Wittig olefination gave the ester **27** (30% yield overall). Hydrolysis of the ester afforded, in 90% yield, acid **4** (Table 2), identical in all respects with an authentic sample.[25]

The chemistry described outlines potential final steps from a projected synthetic intermediate, details efficient and stereoselective routes to the C1 and C6 side chains, and should facilitate the total synthesis of zaragozic acid A/squalestatin S1 (**1a**), and related compounds. In the following communication,[10] we report the synthesis of the first fully functionalized core of the zaragozic acids/squalestatins.

Synthesis of the First Fully Functionalized Core of the Zaragozic Acids/Squalestatins**

Kyriacos C. Nicolaou,* Alan Nadin, James E. Leresche, Susan La Greca, Tatsuo Tsuri, Eddy W. Yue, and Zhen Yang

The zaragozic acids/squalestatins (e.g. zaragozic acid A[1]/squalestatin S1,[2] **1**) are a novel class of natural products, recently isolated from various fungal cultures by researchers at

1

Merck and Glaxo. In addition to remarkable biological activity, the majority of the zaragozic acids/squalestatins possess a novel, highly oxygenated 4,6,7-trihydroxy-2,8-dioxobicyclo-[3.2.1]-octane-3,4,5-tricarboxylic acid "core" and differ only in the nature of the alkyl side chain at C1 and the ester side chain at C6. There have recently been several reports describing the successful synthesis of models of the bicyclic core,[3] but these all lack the characteristic tricarboxylate functionality and suitable devices or strategies for synthetic elaboration to the natural

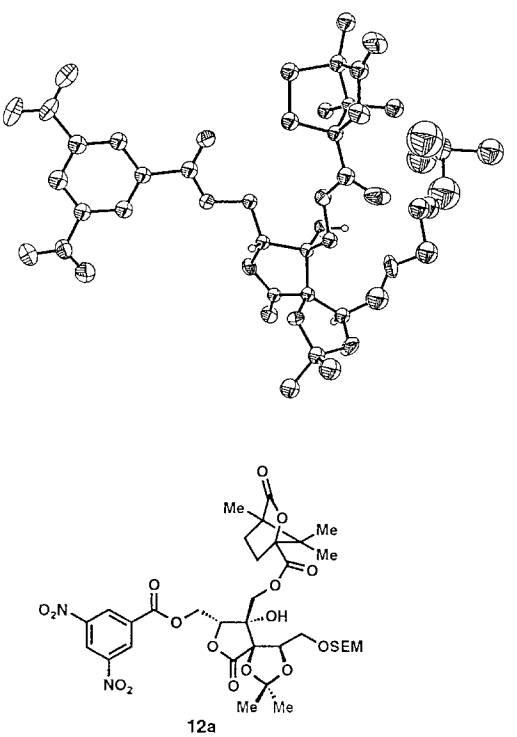
products. In the preceeding communication,[4] we disclosed a general strategy for the synthesis of the zaragozic acids/squalestatins and now wish to report a synthesis of the first fully oxidized core of the zaragozic acids/squalestatins, compounds **16a**–**18a** and their C7 epimers **16b**–**18b**. Our retrosynthetic analysis is shown in Figure 1. The key intermediate aldehyde **3** was expected to arise by a series of functional group manipulations from diene **5**, asymmetry being introduced by a Sharpless dihydroxylation.[5]

The synthesis is summarized in Scheme 1. Diene **5** was synthesized in 70% yield by a Stille coupling[6] between vinylstannane **6**[7] and vinyl iodide **7**.[8] The dihydroxylation of diene **5** was best effected by using an enriched version of AD-mix β, containing 1% $K_2OsO_2(OH)_4$ and 5% of the chiral ligand $(DHQD)_2PHAL$. Although the yield is moderate (40% based on recovered starting material), the reaction is extremely reliable and can be run conveniently on a large scale.[9] The absolute and relative configurations depicted were confirmed by X-ray crystallography of compound **12a**, esterified at C3 with 3,5-dinitrobenzoic acid, and at C4 with (−)-camphanic acid (Fig. 2).[10] Protection of the diol **8** as an acetonide and deprotection of the PMB protecting group gave the allylic alcohol **10** via intermediate **9** on spontaneous lactonization. Dihydroxylation of the allylic alcohol with OsO_4/NMO and concomitant translactonization furnished the crystalline triol **11** as a single diastereoisomer. A series of functional group interconversions as outlined in Scheme 1 gave the diester **13** in 52% overall yield from diol **12**. Completion of the synthesis of the key aldehyde **3** (Table 1) was achieved by protection of the alcohol at C4 as a TMS ether and oxidation of the alcohol at C7 with the Dess–Martin periodinane.[11] By this route, multi-gram quantities of aldehyde **3** can be synthesized in 22 steps (longest linear sequence 19 steps) from readily available starting materials.



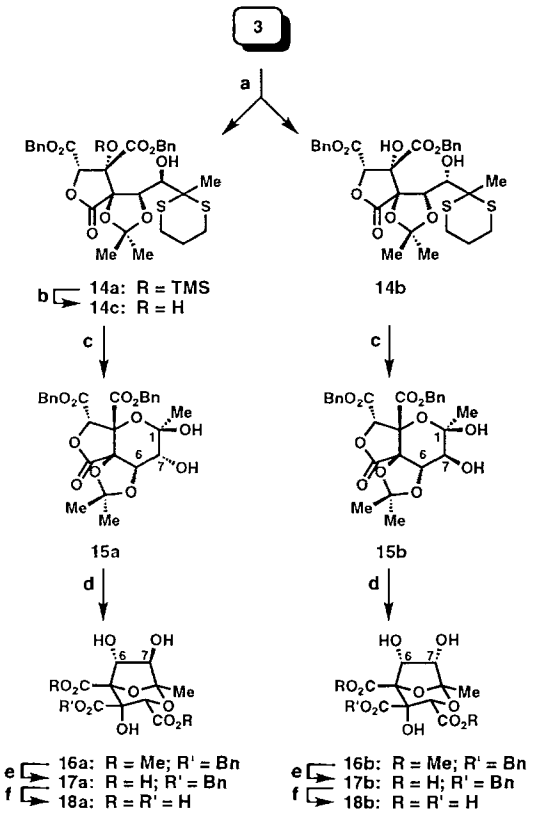


Fig. 2. ORTEP representation (top) of **12a** (bottom).

Addition of aldehyde **3** to 2-methyl-2-lithio-1,3-dithiane[12] (Scheme 2) gave the two epimeric dithianes **14a** and **14b** as major products (ratio approximately 1:1.3). Since the minor epimer **14a** retained the TMS group, chromatographic separation was facilitated.[13] Separate hydrolysis of the dithiane moiety with $Hg(ClO_4)_2/CaCO_3$ gave the lactols **15a** and **15b** as

Scheme 2. Synthesis of the zaragozic acid/squalestatin core: compounds **16a**–**18a** and their C7 epimers **16b**–**18b**. a) 1. 2-Methyl-1,3-dithiane (3.0 equiv), *n*BuLi (3.0 equiv), THF, −23 °C, 1.5 h; 2. −78 °C, 1 h, **14a** (28%) and **14b** (35%); b) 2% HCl in CH_3OH, 10 min, 25 °C, 76%; c) $Hg(ClO_4)_2$, (1.2 equiv), $CaCO_3$ (1.3 equiv), THF/H_2O (5/1), 2 h, 25 °C, **15a** (73%) and **15b** (76%); d) 2% HCl/CH_3OH, 10 h, 60 °C, **16a** (56%) and **16b** (54%); e) $LiOH \cdot H_2O$ (20 equiv), THF/H_2O (1/1), 25 °C, 19 h, >90%; f) H_2, Pd/C, CH_3OH, 25 °C, 5 h, 100%; Bn = benzyl.

single anomers in good yield. A ROESY experiment ($CDCl_3$, 298 K, mixing time 400 ms) on the major lactol diastereoisomer **15b** revealed large NOEs between (C1-Me) and H6, between H6 and H7, and between (C7-OH) and the acetonide methyl, suggesting that the stereochemistry is 1*R*,7*S* (the (1*R*,7*R*) configuration of **15a** was similarly determined). Lactols **15a** and **15b** possess the complete, fully oxygenated carbon skeleton of the zaragozic acid/squalestatin core, and it was gratifying to observe that rearrangement to the bicyclic cores, **16a** and **16b**, respectively, (a multistep process involving methanolysis of the lactol, the lactone, the acetonide, and the C3 benzyl ester, and ketalization) could be readily achieved in a single operation by warming with 2% HCl in MeOH (60 °C, 10 h).[14] The suspected 6*R*,7*S* stereochemistry of **16b** was confirmed by the coupling constant ($J_{H6,H7} = 6.3$ Hz),[15] and by NOE measurements.[16] Similarly, the 6*R*,7*R* configuration of **16a** was demonstrated by the small coupling constant ($J_{H6,H7} = 2.3$ Hz)[1, 2] and NOE measurements. Selective hydrolysis of the methyl esters of **16a** at C3 and C5 could be readily achieved with lithium hydroxide to yield the diacid **17a** in greater than 90% yield. Finally, hydrogenolysis of the benzyl ester of **17a** gave the triacid **18a** in essentially quantitative yield. A similar set of reactions converted the triester **16b** into triacid **18b**, epimeric at C7, via diacid **17b**.

16b: $R_f = 0.25$ (silica, ethyl acetate/petroleum ether 5/1); IR (Film): $\tilde{\nu}$ = 3429, 2924, 2854, 1749, 1445, 1382, 1270, 1234, 1171, 1107 cm^{-1}; ^{1}H-NMR (500 MHz, $CDCl_3$): δ = 7.47–7.38 (m, 5H, Ph), 5.39 (d, J = 11.9 Hz, 1H, PhC*H*H), 5.32 (dd, J = 6.3, 6.3 Hz, 1H, H6), 5.28 (d, J = 11.9 Hz, 1H, PhCH*H*), 4.69 (s, 1H, H3), 4.32 (dd, J = 6.3, 6.3 Hz, 1H, H7), 3.75 (s, 1H, C4-OH), 3.72 (s, 3H, C5-CO_2Me), 3.57 (s, 3H, C3-CO_2Me), 3.08 (d, J = 6.3 Hz, 1H, C6-OH), 3.03 (d, J = 6.3 Hz, 1H, C7-OH), 1.72 (s, 3H, C1-Me); ^{13}C-NMR (125 MHz, $CDCl_3$): δ = 169.1, 166.5, 166.4, 134.5, 129.1, 128.7, 128.6, 109.0, 92.4, 74.6, 73.9, 71.0, 68.7, 52.8, 52.5, 19.3; HR-MS ($C_{19}H_{22}O_{11}Na$ [(M + Na)$^+$]): calcd: 449.1060; found: 449.1065.

The described chemistry opens a flexible, efficient and enantioselective route to the fully oxidized core of the zaragozic acids/squalestatins and paves the way for a total synthesis of these novel natural products.

[7] Prepared from 2-butyne-1,4-diol by the following sequence: a) NaH (2.5 equiv), PMBCl (2.5 equiv), nBu$_4$NI (0.04 equiv), DMF, 25 °C, 8 h, 94%; b) Bu$_3$SnH (1.1 equiv), Pd(PPh$_3$)$_2$Cl$_2$ (0.015 equiv), THF, 25 °C, 17 h, 94%.

[8] Prepared by a Wittig reaction between 2-(trimethylsilyl)ethoxymethyloxyethanal and methyl iodo(triphenylphosphoranylidene)acetate (benzene, 25 °C, 24 h, 78%; the Z/E ratio is 30/1 according to the 300 MHz ^{1}H NMR analysis).

[9] The enantiomeric excess of the dihydroxylation step was determined to be approximately 78% by ^{19}F and ^{1}H NMR analysis of the Mosher's ester of allylic alcohol **10** (J. A. Dale, D. L. Dull, H. S. Mosher, *J. Org. Chem.* **1969**, *34*, 2543).

[10] Compound **12a** (m.p. 146–147 °C, heptane/ethyl acetate) was prepared from **12** by the following sequence of reactions: 1) (−)-camphanic acid chloride (3 equiv), pyridine, DMAP (0.1 equiv), 25 °C, 6 h, 73%; 2) TBAF (1.2 equiv), AcOH (2.0 equiv), THF, 0 °C, 1 h, 84%; 3) 3,5-dinitrobenzoyl chloride (3.0 equiv), pyridine, DMAP (0.1 equiv), 25 °C, 1 h, 75%. The mixture of diastereoisomers was recrystallized until only the major diastereoisomer was present (500 MHz ^{1}H NMR analysis). Crystals were then grown by slow evaporation of the solvent from a solution in hot heptane/ethyl acetate. Complete details will be reported in a full account of this work.

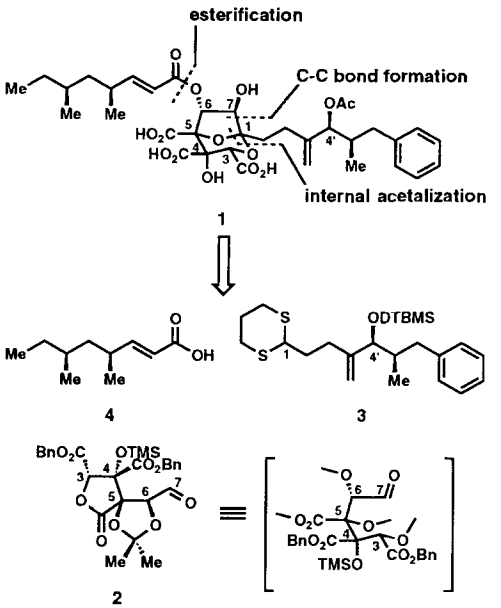
[11] a) D. B. Dess, J. C. Martin, *J. Org. Chem.* **1983**, *48*, 4155; b) *J. Am. Chem. Soc.* **1991**, *113*, 7277; c) R. E. Ireland, L. Liu, *J. Org. Chem.* **1993**, *58*, 2899.

[12] a) D. Seebach, E. J. Corey, *J. Org. Chem.* **1975**, *40*, 231. b) b) For a recent review on the synthetic uses of 1,3-dithianes see: P. C. Bulman Page, M. B. van Niel, J. C. Prodger, *Tetrahedron* **1989**, *45*, 7643.

[13] This reaction is currently somewhat capricious; variable amounts of products sometimes arise from attack at the C3 ester.

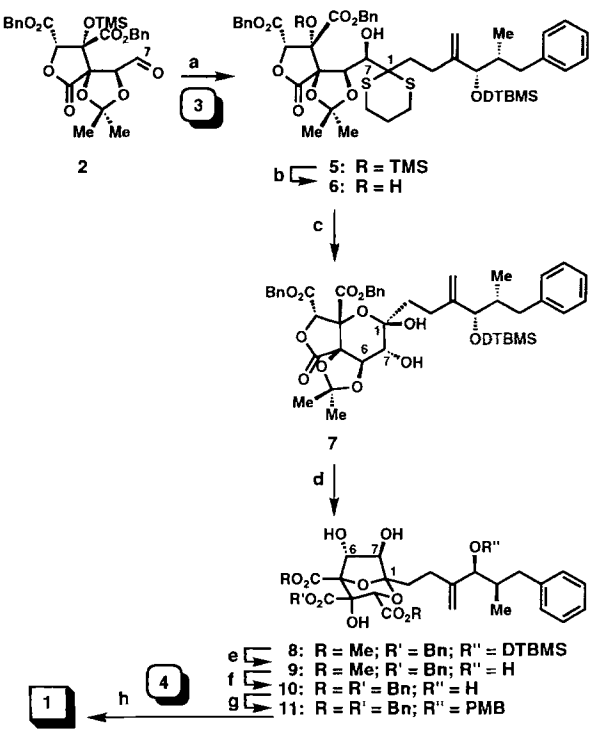
[14] The choice of these conditions was prompted by the rearrangement of a compound with a similar pattern of functional groups: E. Campbell, B. J. Newhouse, J. Bordner, E. F. Kleinman, *Tetrahedron* **1993**, *49*, 7437.

[15] A coupling constant of J(H6,H7) = 6.5 Hz for a 6*R*,7*S* core (M. G. Lester, G. M. P. Giblin, G. G. A. Inglis, P. A. Procopiou, B. C. Ross, N. S. Watson, *Tetrahedron Lett.* **1993**, *34*, 4357) and J(H6,H7) = 9.5 Hz for a (6*S*,7*R*) core (ref. [3b]) have been reported. A typical coupling constant J(H6,H7) for the naturally occurring 6*R*,7*R* core is 2 Hz (ref. [2b]).



[16] A ROESY experiment ($CDCl_3$, 298 K, mixing time 400 ms) aided assignment of all the proton resonances. Large reciprocal NOEs were observed between H3, H7, and H6. In a 1D NOE difference spectrum ($CDCl_3$, 298 K), the NOE between H3 and H7 was about 8%, and between H3 and H6 about 6%.

Total Synthesis of Zaragozic Acid A/ Squalestatin S1**



Kyriacos C. Nicolaou*, Alan Nadin, James E. Leresche, Eddy W. Yue, and Susan La Greca

In the previous two papers,[1, 2] we described our model studies directed towards a total synthesis of zaragozic acid A/squalestatin S1 (**1**). Herein we record the first total synthesis of this compound in its naturally occurring enantiomeric form by a convergent and flexible strategy applicable to the construction of all members of the class.

Our retrosynthetic strategy for the total synthesis of **1** required building blocks **2**–**4** (Scheme 1). Relying on this plan, and assured by the zaragozic acid skeletal rearrangement described in the preceding paper,[2] we embarked on the total synthesis as outlined in Scheme 2. Thus, aldehyde **2**[2] was treated with the lithio derivative of dithiane **3**[1] to afford two

Scheme 1. Retrosynthetic analysis of zaragozic acid A/squalestatin S1 (**1**).

Scheme 2. Reagents and conditions. a) **3** (1.5 equiv), nBuLi, THF, −30 °C, 1.5 h, then **2**, THF, −78 °C, 5 min, 75%; b) 2% HCl in MeOH/CH_2Cl_2 (1/1), 25 °C, 5 min, 100%; c) Hg(ClO$_4$)$_2$ (1.2 equiv), $CaCO_3$ (1.3 equiv), THF/H_2O (5/1), 25 °C, 2 h, 83%; d) 1.8% HCl in MeOH, 78 °C, 21 h, 50%; e) 49% aqueous HF/MeNO$_2$ (1/10), 0 °C, 24 h, 30%; f) LiOH·H_2O (10 equiv), THF/H_2O (2/1), 25 °C, 1 h, then *O*-benzyl-*N*,*N*′-dicyclohexylisourea (4.5 equiv), THF, 55 °C, 1.5 h, 74% (2 steps); g) CSA (0.1 equiv), $Cl_3CC(OPMB)=NH$ (1.0 equiv), CH_2Cl_2, 25 °C, 45 min, **11** (21%), **10** (37%); h) see Ref. [1]. Bn = Benzyl, CSA = (±)-10-camphorsulfonic acid, DTBMS = di-*tert*-butylmethylsilyl, PMB = *para*-methoxybenzyl, TMS = trimethylsilyl. All new compounds exhibited satisfactory spectral data (Table 1). Yields were based on spectroscopically and chromatographically homogeneous materials.

diastereoisomers, compound **5** (Table 1) and the corresponding C7 epimer (75% total yield in an approximate 1:1 ratio), which had been desilylated under the reaction conditions. Product **5** was separated from its C7 diastereoisomer by flash column chromatography, and the TMS and dithiane protecting groups were removed sequentially by standard methods to afford lactol **7** via intermediate **6** (80% overall yield).

Exposure of **7** to the rearrangement conditions (1.8% HCl in methanol at 78 °C, 24 h) led smoothly to the desired product **8** in 50% yield (Table 1). During the course of this reaction several new compounds appeared but were converted slowly into **8**, which apparently represents the thermodynamically most stable skeleton of the central region of the molecule. It should be noted that before choosing the previously reported,[3] but very rarely used, di-*tert*-butylmethylsilyl (DTBMS) protecting group for the allylic alcohol, two other groups [*para*-methoxybenzyl (PMB) and *tert*-butyldiphenylsilyl (TBDPS)] were utilized but failed to withstand the rearrangement conditions. The PMB ether suffered displacement by methanol even at ambient temperatures, and the TBDPS group was removed under the rearrangement conditions which led to the formation of spiroacetals.[4]

Proceeding with the synthesis, desilylation of **8** [49% aqueous HF/nitromethane (1/10), 0 °C, 24 h] gave the tetraol **9** in 30% yield.[5, 6] Selective alkaline hydrolysis of the two methyl esters of **9** followed by esterification with *O*-benzyl-*N*,*N*′-dicyclohexylisourea[7] (4.5 equiv, THF, 55 °C) furnished the tribenzyl ester **10** (Table 1) in 74% overall yield.

Selective protection of the allylic alcohol **10** as a PMB ether with one equivalent of *p*-methoxybenzyl trichloroacetimidate with a catalytic amount of (±)-10-camphorsulfonic acid afforded compound **11**, identical (^1H and ^{13}C NMR, IR, TLC, $[\alpha]_D$), to an authentic sample obtained by degradation from the natural product.[1] Compound **11** was converted into zaragozic acid A (**1**) by the sequence:[1] a) esterification of the C6 hydroxyl group with (*E*)-(4*S*, 6*S*)-4,6-dimethyl-2-octenoic acid (**4**); b) silylation of the C7 hydroxyl group with triethylsilyl trifluoromethanesulfonate (TESOTf); c) replacement of the PMB with an acetate group by using 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) followed by acetic anhydride treatment; and d) desilylation with fluoride ion and debenzylation of the esters by transfer hydrogenolysis.

The described chemistry demonstrates the usefulness of the asymmetric dihydroxylation reaction[2, 8] and of several substrate-controlled reactions in the synthesis of complex molecules, and shows the power of a newly discovered cascade rearrangement in the synthesis of the zaragozic acids. The convergent and flexible nature of the opened route to zaragozic acid A (**1**) makes the entire class of these natural products and their designed analogs now accessible by total synthesis.

Synthesis and Crystal Structure of the "Open" Calcocene $[(t\mathrm{Bu}_2\mathrm{C}_5\mathrm{H}_5)_2\mathrm{Ca} \cdot \mathrm{thf}]$**

Jason S. Overby and Timothy P. Hanusa*

The recent surge of activity with organometallic compounds of the heavy alkaline earth metals calcium, strontium, and barium has focused on complexes containing alkyl-substituted cyclopentadienyl ligands.[1] Much less work has been done on compounds with other anionic unsaturated ligands,[2, 3] and none of these has been structurally characterized. As an alterna-

[**] This work was supported by the Donors of the Petroleum Research Fund, administered by the American Chemical Society.

tive to the cyclopentadienyl group, the acyclic pentadienyl ligand would be among the most interesting, since this ligand exhibits a variety of bonding modes to metals (η^1, η^3, η^5) that are in principle interconvertible.[4, 5] Largely through the work of Ernst et al. pentadienyl complexes have been described for many transition elements and some f- and p-block metals.[6] We now report the synthesis and X-ray crystal structure of the first bis(pentadienyl)complex of calcium, which displays both surprising similarities to, and differences from, its transition metal analogues.

Reaction of two equivalents of K[2,4-tBu$_2$C$_5$H$_5$] with CaI$_2$ in THF at low temperature produces the yellow complex [(2,4-tBu$_2$C$_5$H$_5$)$_2$Ca · thf]. It has limited solubility in THF and only slight to trace solubility in hydrocarbons. A substantial amount (ca. 20%) of the coupled ligand (2,4,7,9-tetra-*tert*-butyl-1,3,7,9-decatetraene) is also formed in the reaction, evidence that a radical reaction competes with halide metathesis in this system.[7] The ^{1}H NMR spectrum of the calcium complex in [D$_8$]THF displays a slightly split tBu resonance and broadened resonances for the pentadienyl protons; this could be evidence for a fluxional process in solution, although solubility constraints limit the information available from the NMR spectrum.

The solid-state structure of the calcium complex was obtained by X-ray analysis on a yellow crystal slowly grown from a saturated solution of the compound in hexane.[8] The compound exists as a monomeric species with two planar η^5-pentadienyl ligands (as evidenced by the narrow range of Ca–C distances from 2.74(1)–2.81(2) Å) and a single coordinated thf molecule (Fig. 1). As such, it is the first "open metallocene" of a Group 2

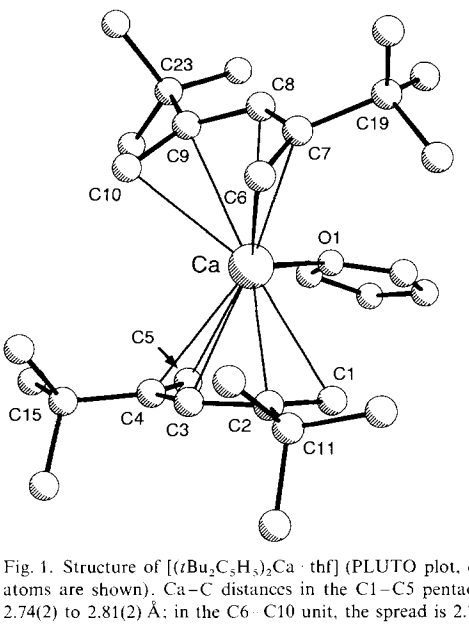

Fig. 1. Structure of [(tBu$_2$C$_5$H$_5$)$_2$Ca · thf] (PLUTO plot, only the non-hydrogen atoms are shown). Ca–C distances in the C1–C5 pentadienyl unit range from 2.74(2) to 2.81(2) Å; in the C6–C10 unit, the spread is 2.74(1) to 2.77(2) Å. The mean deviations of the pentadienyl carbon atoms from the least square planes are 0.015 Å and 0.0098 Å for C1–C5 and C6–C10, respectively. Selected distances [Å] and angles [°]: C1-C2 1.38(1), C2-C3 1.37(2), C2-C11 1.57(2), C3-C4 1.44(2), C4-C5 1.37(1), C4-C15 1.52(2), C6-C7 1.37(2), C7-C8 1.46(2), C7-C19 1.58(3), C8-C9 1.42(2), C9-C10 1.38(2), C9-C23 1.55(2); C1-C2-C3 127(1), C2-C3-C4 133(1), C3-C4-C5 125(1), C(6)-C(7)-C(8), 126(2), C7-C8-C9 128(2), C8-C9-C10 128(2).

metal, comparable to the open metallocenes of the transition metals.[5] The only other structurally characterized main-group pentadienyl complex, [(C$_7$H$_{11}$)$_2$Mg(tmeda)],[9] like the zinc pentadienyl complexes [(C$_5$H$_7$)ZnCl · tmeda] (tmeda = *N,N,N′,N′*-tetramethylethylenediamine)[10] and [(2,4-tBu$_2$C$_5$H$_5$)$_2$Zn],[6] has sigma-bonded, monohapto ligands. In this respect, the Ca^{II} center is acting like a d- or f-block metal, whose structurally characterized pentadienyl compounds usually contain pentahapto ligands.

Apart from the pentadienyl binding mode, the calcium complex displays several structural features that are distinctly untypical of transition metal pentadienyl complexes. The average Ca–C bond length of 2.76(2) Å is somewhat longer than the value observed in other formally seven-coordinate organocalcium complexes (e.g., 2.678(9) Å in [{1,3-(SiMe$_3$)$_2$C$_5$H$_3$}$_2$Ca · thf],[11, 12] and 2.67(1) Å in [{Cp*CaI · (thf)$_2$}$_2$] (Cp* = C$_5$Me$_5$)[13]). In contrast, transition metal pentadienyl complexes usually display M–C distances that are equal to, or slightly shorter than, related M–Cp distances (e.g., 2.211(2) Å in [{2,4-(CH$_3$)$_2$C$_5$H$_5$}$_2$V][14] vs. 2.280(5) Å in [Cp$_2$V][15]). The Ca–O(thf) distance of 2.439(9) Å is also moderately long for a seven-coordinate calcium center; the analogous Ca–O distances in [{1,3-(SiMe$_3$)$_2$C$_5$H$_3$}$_2$Ca · thf][11] and [{Cp*CaI · (thf)$_2$}$_2$][13] are 2.329(3) and 2.40(1) Å, respectively.

The two pentadienyl ligands adopt an almost perfect "*anti*-eclipsed" conformation: the plane containing Ca, C3, and the midpoint between C1 and C5 forms an angle of 174.4° with the plane containing Ca, C8, and the midpoint between C6 and C10. This is the first time such a wide angle has been observed in an open metallocene: typical values are near the angle of 60° for the "*gauche*-eclipsed" conformation, although twist angles up to 89.8° have been found (Fig. 2).[14] The presence of the thf ligand

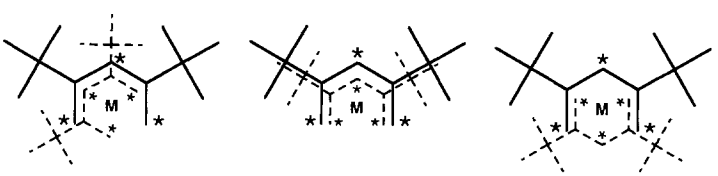

Fig. 2. Possible *gauche*-eclipsed (left), *syn*-eclipsed, and *anti*-eclipsed (right) conformations of the calcocene; the negatively charged atoms are marked with asterisks. The *anti*-eclipsed form is observed in the title complex.

complicates a straightforward analysis of the factors that may be involved, but the *anti*-eclipsed arrangement may partially reflect an attempt by the tBu$_2$C$_5$H$_5$ units to avoid unfavorable steric interactions; the closest contact between tBu groups is at 4.28 Å, which puts them outside van der Waals contact.

Although undoubtedly important, steric effects are probably not the only determinant of the pentadienyl orientation. In the calcocene [{1,3-(SiMe$_3$)$_2$C$_5$H$_3$}$_2$Ca · thf], the cyclopentadienyl ligands are twisted by only 29.2°,[11, 12] despite having two bulky trimethylsilyl groups on each ring. By virtue of a relatively small interplanar angle of 133.2°, the closest contact between SiMe$_3$ groups is 4.3 Å. The angle between the planes in the pentadienyl complex, however, is markedly larger at 146.5°. Thus it appears that the pentadienyl complex could have adopted a nearly "*syn*-eclipsed" conformation that would avoid severe steric repulsions. The *anti*-eclipsed conformation, however, places the formally charged carbon atoms of the pentadienyl ligands (1, 3, 5, 6, 8, 10) in an octahedral arrangement around the metal center; this would serve to maximize electrostatic bonding. A *gauche*-eclipsed conformation also generates an octahedral charge distribution, but the potential steric repulsions between the ligands would be much more severe.

The limited solubility provided by the tBu$_2$C$_5$H$_5$ ligand precludes its use with the larger strontium and barium centers. For

these metals, pentadienyl ligands that provide better solubility (such as $(Me_3Si)_2C_5H_5$[16]) will be needed to make their study feasible.

Experimental Procedure

$K[tBu_2C_5H_5]$ [6] (0.250 g, 1.16 mmol) and CaI_2 (0.170 g, 0.58 mmol) were mixed in THF (30 mL) under nitrogen at −78 °C. After stirring overnight at room temperature, a white precipitate and a yellow solution remained. The precipitate was removed by filtration, and the filtrate evaporated to dryness. The tan residue was washed twice with hexane to remove the tetraene by-product (ca. 20%), and then dried under vacuum, leaving $[(tBu_2C_5H_5)_2Ca \cdot thf]$ as an air-sensitive pale yellow solid (0.111 g, 41%). Anal. calcd. for $C_{30}H_{54}CaO$: C, 76.53; H, 11.56. Found: C, 67.66; H, 10.10. Although the C, H values from elemental analysis are low, the molar C:H ratio is 0.56, in agreement with the predicted value. ^1H NMR (300 MHz, [D$_8$]THF, 20 °C): $\delta = 0.11$ (s), 1.04 (s, *t*Bu), 1.09 (s, *t*Bu), 1.74 (β-C_4H_8O), 3.58 (α-C_4H_8O), 5.3–5.7 (br). The compound is insufficiently soluble in [D$_8$]THF to obtain useful ^{13}C NMR data. Attempts to sublime the compound (80–120 °C, 10^{-6} Torr) caused it to decompose. Small amounts of crystalline material were obtained by allowing a saturated hexane solution of the complex to evaporate slowly at room temperature.

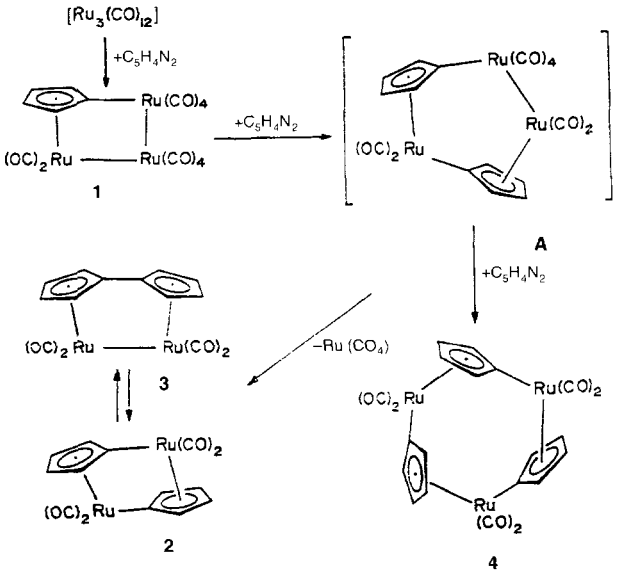
$[Ru_3(CO)_6(\eta^5:\eta^1\text{-}C_5H_4)_3]$: The First Six-Membered Ru_3C_3 Ring Formed by Insertion of C_5H_4 Units into Metal–Metal Bonds of $[Ru_3(CO)_{12}]$**

Alejandro J. Arce,* Ysaura De Sanctis, Jorge Manzur, and Mario V. Capparelli

The cyclopentadienyl ligand has played a key role in the development of organometallic chemistry,[1] and cyclopentadienyl complexes (π- or σ-bonded to a central metal atom or to two metal atoms) of many transition metals are known.[2] Many syntheses and studies of mononuclear cyclopentadienyl derivatives of group VIII transition metals have been reported, but only few polynuclear cyclopentadienyl complexes are known, and new types of interesting compounds have been recently synthesized.[3]

Mononuclear cyclopentadienyl derivatives have been of more practical value: a variety of cyclopentadienyl-containing complexes are used in a broad range of catalytic reactions,[4] though their full potential has yet not been realised. Cyclopentadienyl (C_5H_5) and cyclopentadienylidene (C_5H_4) bridges in polynuclear compounds have attracted little attention so far.[5] The use of the diazocyclopentadiene ($C_5H_4N_2$) has made the synthesis of monohalocyclopentadienyl and multiply substituted cyclopentadienyl complexes readily accessible.[6] Diazocyclopentadiene reacts with metal–metal triple bonds, as in the reaction with $[Mo_2(CO)_4Cp_2]$,[7] to afford a cyclopentadienylidene derivative $[Mo_2(CO)_3(\eta^5\text{-}Cp)_2(\mu\text{-}\eta^5:\eta^1\text{-}C_5H_4)]$ (N_2 and CO elimination). In this compound the organic ligand acts both as a terminal σ-alkyl ligand to the $[(\eta^5\text{-}Cp)Mo(CO)_2]$ fragment and as an aromatic η^5-system to the $[(\eta^5\text{-}Cp)Mo(CO)]$ unit. The overall result is a metal-bridging, six-electron-donating ligand.



When ketene ($H_2C{=}C{=}O$) reacts with $[Os_3(CO)_{10}(CH_3CN)_2]$, the C=C bond of ketene is broken to afford the compound $[Os_3(CO)_{11}(\mu\text{-}CH_2)]$.[8] The same compound can also be obtained by treating $[Os_3(CO)_{11}(CH_3CN)]$ with CH_2N_2.[9] In view of these results we tried to synthesize C_5H_4-bridged clusters from triruthenium clusters and $C_5H_4N_2$ in order to obtain μ,η^1-cyclopentadienylidene complexes such as $[Ru_3(CO)_{11}(C_5H_4)]$, which might contain the dimetallacyclopropane unit, like the product from the reaction between diazomethane and triosmium clusters. The outcome was products with a different type of bonding.

The reaction of $[Ru_3(CO)_{12}]$ with $C_5H_4N_2$ in THF under reflux gave complexes **1**, **3**, and **4** in 46, 20, and 25% yield, respectively (Scheme 1). Compounds **1** and **4** are formed with concomitant elimination of N_2 and CO and are thermally stable. All the products were characterized by ^1H NMR and IR spectroscopy, and the X-ray structures of **1** and **4** were determined.[10]

Compound **3** has been synthesized[11] by the reaction of $[Ru_3(CO)_{12}]$ and dihydrofulvalene and can be converted into compound **2** by photocleavage (sunlight) of the Ru–Ru bond in THF. Under our reaction conditions **2** also reverts thermally to **3** as described in the earlier synthesis. Compounds **2** and **4** can also

Scheme 1.

be obtained by direct reaction of **1** and diazocyclopentadiene in THF under reflux. After 20 min complete conversion was achieved. We postulate that the species formed in the early stages of the reaction is **A** (Scheme 1), an open Ru_3 compound which in the presence of diazocyclopentadiene converts readily into the new cyclotrimer **4**. To account for the formation of **3** the intermediate species **A** loses a $Ru(CO)_4$ unit to afford the cyclodimer **2**, which was confirmed by comparison of the IR and ^1H NMR spectroscopic data with those reported earlier (see *Experimental*).[11] Recently Vahrenkamp reported the insertion of a C_5H_4 unit[12] into a metal–metal bond by the reaction of $Ph_3P{=}C(CH)_4$ and $[Ru_3(CO)_{12}]$ and gave spectroscopic evidence for compound **1**.

The crystal structure analysis of compound **1**[10a] (Fig. 1) showed that it is an open Ru_3 cluster, with two metal–metal bonds, bridged by an $\eta^5{:}\eta^1$-C_5H_4 moiety, which makes **1** a

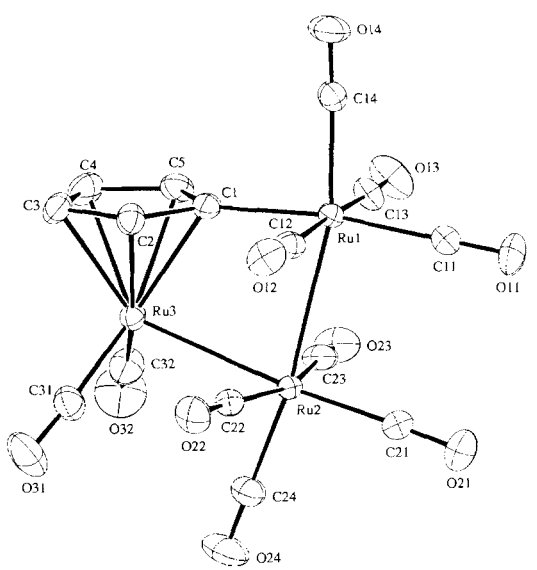

Fig. 1. Molecular structure of **1** (ORTEP plot; thermal ellipsoids represent 30% probability). Selected bond lengths [Å] and angles [°]: Ru1–Ru2, 2.9486(6), Ru2–Ru3, 2.8256(7), Ru1–C1, 2.105(6), Ru3–C1, 2.270(6), Ru3–C*n* (mean for $n = 2$–5) 2.231(7); C1–Ru1–Ru2, 76.4(2), Ru1–Ru2–Ru3, 83.56(2), Ru2–Ru3–C1, 76.8(2), Ru1–C1–Ru3, 123.1(3).

50-electron cluster. The molecule has a plane of symmetry defined by the three Ru atoms, four CO groups, and C1. (The metal atoms are within 0.003 Å of the plane, while the mean deviation for all 12 atoms defining the plane is 0.061 Å.[13]) Therefore, this crystal structure is an example of an achiral molecule crystallizing in a chiral space group.

An X-ray structure determination for **4** was needed to establish the mode of bonding. The crystallographic study[10b] (Fig. 2) revealed that this compound is a novel cyclic trimer with no metal–metal bonds, derived from the insertion of C_5H_4 units into Ru–Ru metal bonds. The $Ru(CO)_2$ units are held together by $\eta^5{:}\eta^1$-C_5H_4 ligands. The resulting Ru_3C_3 metallacycle has a twist-boat conformation, with Ru1 and C1c at 0.79 and 0.53 Å from the mean plane through Ru2, Ru3, C1a and C1b.

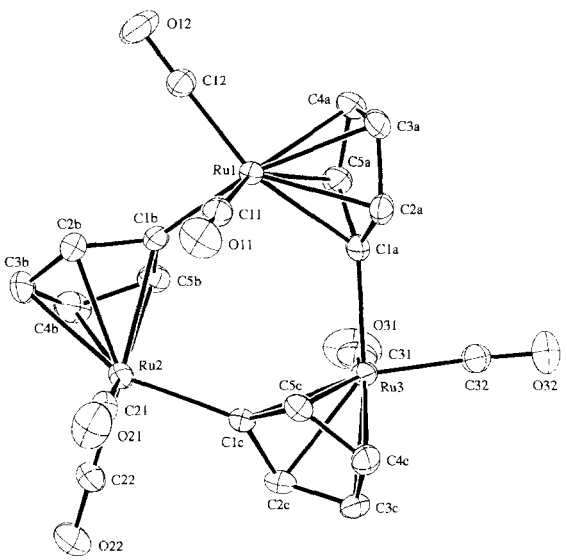

Fig. 2. Molecular structure of **4** (ORTEP plot; thermal ellipsoids represent 30% probability). Selected bond lengths [Å] and angles [°]: Ru1–C1b, 2.084(4), Ru2–C1c, 2.104(4), Ru3–C1a, 2.095(5), Ru1–C1a, 2.293(4), Ru2–C1b, 2.308(4), Ru3–C1c, 2.300(4), Ru1–C*n*a (mean for $n = 2$–5) 2.238(5), Ru2–C*n*b (mean for $n = 2$–5) 2.241(5), Ru3–C*n*c (mean for $n = 2$–5) 2.247(5); C1a–Ru1–C1b, 97.9(2), C1b–Ru2–C1c, 96.7(2), C1c–Ru3–C1a, 102.0(2), Ru1–C1a–Ru3, 129.5(2), Ru2–C1b–Ru1, 130.0(2), Ru2–C1c–Ru2, 132.1(2).

In **1** and **4** the C_5H_4 moiety is bonded to two metal atoms as a metallocyclopentadienyl, six-electron-donor ligand, rather than as a cyclopentadienylidene ligand. In both compounds the $Ru_2(\eta^5{:}\eta^1$-$C_5H_4)$ units display similar structural features: a) within each $Ru(\eta^5$-$C_5H_4)$ moiety, the Ru–C1 distance is significantly longer than the other four metal-carbon distances (0.039 Å in **1**, average of 0.058 Å in **4**); b) of the two Ru–C bonds formed by each C1 atom, the π bond involved in the η^5 coordination is significantly longer than the σ bond involved in η^1 coordination (0.165 Å in **1**, average of 0.206 Å in **4**). All the Ru–C(Cp) bond lengths are similar to those found in $[Ru_3(CO)_9(PPh_3)(C_5H_4)]$[12] and in **2**;[11] the averages of the four shorter Ru–C(Cp) distances (2.231 Å in **1**, 2.242 Å in **4**) are close to the mean of 2.236 Å compiled in ref. [14]. All the compounds described here show an $\eta^5{:}\eta^1$ coordination of the cyclopentadienyl bridge. The tendency of the cyclic ring to aromatize seems to be responsible for the preference of $\eta^5{:}\eta^1$ complexation in trinuclear clusters rather than carbene–diolefin coordination.

In conclusion we found that **4** $[Ru_3(CO)_6(\eta^5{:}\eta^1$-$C_5H_4)_3]$ is the first six-membered Ru_3C_3 ring system formed by a facile insertion of C_5H_4 units into metal–metal bonds of $[Ru_3(CO)_{12}]$. This pro-

cedure opens up the possibility for a suitable access to new ruthenium complexes with μ-η^5:η^1-C_5H_4 units as bridging ligands.

Experimental Procedure

A solution of $[Ru_3(CO)_{12}]$ (200 mg, 0.32 mmol) and freshly distilled diazocyclopentadiene [15] (40 μL, 0.5 mmol) in dried THF (40 mL) was heated at reflux under nitrogen for one hour. After evaporation of the solvent, thin-layer chromatography (SiO_2) of the orange-red residue, eluting with pentane:dichloromethane 4:1 (v:v) gave three bands. Compound **1** was recovered as pale yellow crystals from hexane in 46% yield, compound **2** as a pale yellow solid in 20% yield, and compound **4** as colorless crystals (cyclohexane) in 25% yield. On exposing a solution of compound **3** in THF to sunlight for 4 h, complete conversion to **2** was achieved (IR monitoring). **1**: IR(C_6H_{12}) $\tilde{\nu}$(CO) [cm^{-1}]: 2113w, 2066s, 2047w, 2031vs, 2001s, 1987sh, 1949w. ^1H NMR ($CDCl_3$, 300 MHz, 296 K, J in Hz): δ = 5.29 (dd, 2H, J = 1.8, 1.8), 4.39 (dd, 2H, J = 1.8, 1.8). **2**: IR(CH_2Cl_2) $\tilde{\nu}$(CO) [cm^{-1}]: 2012vs, 1960vs. ^1H NMR ($CDCl_3$, 300 MHz, 296 K, J in Hz): δ = 5.39 (dd, 4H, J = 2.0, 2.0), 4.68 (dd, 4H, J = 2.0, 2.0). **3**: IR(CH_2Cl_2) $\tilde{\nu}$(CO) [cm^{-1}]: 2019vs, 1952vs. ^1H NMR ($CDCl_3$, 300 MHz, 296 K, J in Hz): δ = 5.69 (dd, 4H, J = 1.9, 1.9), 3.95 (dd, 4H, J = 1.9, 1.9). **4**: IR(C_6H_{12}) $\tilde{\nu}$(CO) [cm^{-1}] 2017vs, 1970vs. ^1H NMR ($CDCl_3$, 300 MHz, 296 K, J in Hz): δ = 5.29 (dd, 6H, J = 2.1, 2.1), 4.95 (dd, 6H, J = 2.1, 2.1).

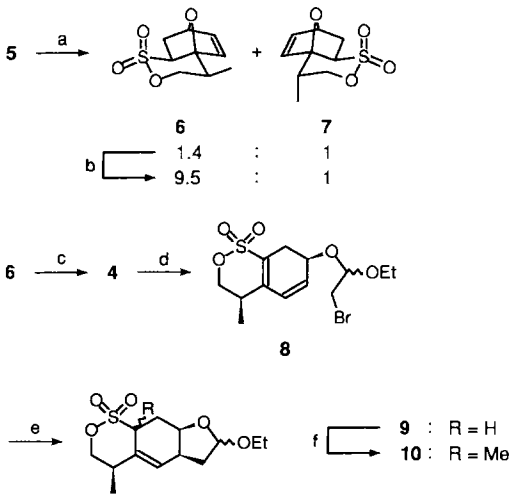
A Short and Highly Stereoselective Synthesis of the 1,10-*seco*-Eudesmanolide Ivangulin**

Peter Metz,* Jörn Stölting, Mechtild Läge, and Bernt Krebs

The bicyclic sesquiterpene lactones ivangulin (**1**),[1] eriolanin (**2**),[2] and eriolangin (**3**)[2] (Scheme 1) belong to the class of the 1,10-*seco*-eudesmanolides, the more highly oxygenated members of which, **2** and **3**, display significant antileukemic activity

Scheme 1. Retrosynthetic analysis of **1**–**3**.



in vivo. A central problem associated with the diastereoselective synthesis of **1**,[3] **2**,[4, 5] and **3**[4] is control of the relative configuration of the exocyclic stereogenic center. Based upon our studies on intramolecular Diels–Alder reactions of vinylsulfonates[6–8] and the synthetic elaboration of the resultant sultones,[7, 9, 10] we can retrosynthetically convert all three natural products to sultone **4** (Scheme 1). In **4** two of the stereogenic centers of the target molecules in a 1,5-relationship are already present with correct relative configuration; moreover, the latent primary alcohol offers the possibility of chain extension, and the endocyclic 1,3-diene activates all further positions which are substituted in the cyclohexene moiety of **1**–**3**. Sultone **4** in turn is rapidly available from furan **5**[11] using a methodology[6, 9] developed by us. Here we report an efficient synthesis of **1** by a thermodynamically controlled intramolecular Diels–Alder reaction of the vinylsulfonate of **5**, a radical cyclization of a derivative of **4**, as well as a reductive sultone cleavage.

When **5** is treated with vinylsulfonyl chloride,[13] the primarily formed, spectroscopically characterized (^1H, ^{13}C NMR) vinylsulfonate undergoes an intramolecular cycloaddition[6–8] at 0 °C (12 h) to give a 1.4:1 mixture of the two *exo*-sultones **6** and **7** (Scheme 2). An equilibration through retro-Diels–Alder reaction only takes place in refluxing toluene and eventually leads to a ratio of 9.5:1 in favor of the thermodynamically more stable diastereomer **6** with equatorial methyl group.[14] To avoid side reactions of the vinylsulfonate of **5** regenerated in the equi-

Scheme 3. a) Li, NH_3(l), THF, −60 °C (73%). b) CBr_4, Ph_3P, pyridine, 25 °C (83%). c) $NaCH(CO_2Me)_2$, dimethylformamide, hexamethylphosphoric acid triamide, 100 °C. d) PhSH, K_2CO_3, DMF, 90 °C (38% **14** from **13**). e) $Na_2Cr_2O_7$, H_2SO_4, acetone, 0 °C (83%). f) $MeOCO_2MgOMe$, DMF, 130 °C. g) CH_2O, PhNHMe, NaOAc, HOAc, H_2O, 25 °C (67% **1** from **15**, 78% **1** based on converted **15**).

librium at elevated temperature, a small amount of the radical scavenger BHT (2,6-di-*tert*-butyl-4-methylphenol) is added. After separation of the cycloadducts by chromatography[15] or recrystallization (ethyl acetate), the desired major isomer **6** is isolated in pure form. Moreover, the separated diastereomer **7**, too, is subjected to the equilibration during the next run, so that a continuous conversion into the major isomer **6** ensues. The relative configurations of **6** and **7** follow from diagnostic coupling constants in the ^{1}H NMR,[16] if a chair conformation of the δ-sultone is assumed. An X-ray diffraction analysis[17] of the minor product **7**, which yielded suitable crystals, served as unambiguous proof of the spatial orientation of the methyl group.

In the presence of tetramethylethylenediamine (TMEDA), basic ring opening[9, 10] of **6** to dienol **4** with lithium diisopropylamide (LDA) proceeds almost without disturbing dehydration to the corresponding benzene derivative. For construction of the γ-lactone of **1** in masked form, **4** is first coupled with the adduct from ethyl vinyl ether and bromine prepared in situ to give the mixed acetal **8**.[18] When **8** is cyclized with tri-*n*-butylstannane (azobis*iso*butyronitrile, toluene, reflux),[19, 20] **9** and its double bond isomer with S–C=C unit are formed in a ratio of 2:1 (84%). Complete regioselectivity in favor of **9** is achieved by a chromium(II)-induced cyclization[21] of **8**. Methylation of the allyllithium species generated from **9** with methyllithium[22] occurs only in α-position to sulfur with formation of the diastereomeric alkylation products **10**.

Due to faster protonation at the less substituted terminus of the allyllithium intermediate,[9, 10, 23] a reductive desulfurization of **10** with lithium in liquid ammonia leads with good selectivity to the tetrasubstituted olefin **11** which, after chromatographic separation[15] from **12**, is converted[24] to bromide **13** (Scheme 3). The side chain of **1** is completed by reaction of **13** with sodium dimethylmalonate followed by demethoxycarbonylation[25] of the resultant substituted malonate, and Jones oxidation[19, 21] of acetal **14** unmasks the γ-lactone **15**. For α-methylenation to ivangulin (**1**),[26] we use a two-step sequence consisting of carboxylation of **15** with methyl methoxymagnesium carbonate[27] and subsequent Mannich reaction with decarboxylation[28] which succeeds with complete chemoselectivity.[29]

Starting from 2-acetylfuran, our sultone route featuring excellent control of the relative configuration of the stereogenic center located on the side chain requires only 15 steps to the 1,10-*seco*-eudesmanolide **1**, and thus halves the number of steps needed in the previously published synthesis of this natural product.[3] Utilization of **9** for the synthesis of eriolanin (**2**) and eriolangin (**3**) is currently under investigation.

Increase in the Enantioselectivity of Asymmetric Hydrogenation in Water Influenced by Surfactants or Polymerized Micelles**

Arvind Kumar, Günther Oehme,* Jean Pierre Roque, Manuela Schwarze, and Rüdiger Selke*

The hydrogenation of sparingly soluble compounds using slightly soluble complexes of rhodium(I) biphosphanes or biphosphinic acid esters as catalysts in water can be considerably accelerated by the addition of solubilizing agents that form micelles.[1] In the asymmetric hydrogenation of methyl (*Z*)-2-*N*-acetylaminocinnamate (**1f**), the substrate exclusively used up to now, the enantioselectivity is lower in water than in other solvents (particularly alcohols) for all of the catalysts investigated in the absence of surfactants and is increased relative to the blank by the addition of amphiphilic compounds. Thus it seems important to determine whether this is only an apparent increase in enantioselectivity, caused, for example, by suppressing the influence of unspecific catalyst impurities (perhaps metallic rhodium) that reduce the selectivity, as a consequence of the considerably shorter reaction times relative to the blanks.

1

2

Our investigations into the hydrogenation of a large number of substrates (**1a**–**n**) with the catalyst **2** conclusively favor a real increase in selectivity, presumably by optimizing the conformation of the catalyst, which is concentrated on the micelle surface, in the transition state. By adding sodium dodecylsulfate (SDS) in substoichiometric amounts, the enantioselectivity of the hydrogenation of the esters **1a**–**h** increases to 96–98% *ee* (*S*)-*N*-acyl-α-amino acid ester, almost independent of the wide-ranging solubility of the substrates (Table 1). It corresponds to a sevenfold increase of the average relative enantioselectivity Q[2] over the blank in water without surfactant:

$$Q = \frac{q(\mathrm{SDS_{H_2O}})}{q(\mathrm{blank_{H_2O}})} = 7.4 \pm 1.3$$

The doubled relative enantioselectivity

$$Q' = \frac{q(\mathrm{SDS_{H_2O}})}{q(\mathrm{blank_{MeOH}})} = 2.1 \pm 0.6$$

shows that the reported enantiomeric excess in methanol (see ref. [3]) is also clearly exceeded, although the reaction rate is generally higher in methanol. The experimentally determined enantiomeric ratio—here *S*/*R*—is used as the value q.

The lower enantioselectivities of hydrogenations in methanol without surfactants also supports a real increase in selectivity caused by micelle-forming compounds in water, because, due to the high reaction rate in methanol, the explanation of an influence of less active, unspecific catalyst impurities cannot be applicable.

Strongly in favor of our postulate of a real increase in selectivity influenced by surfactants is the high Q value of 5.2 for the completely water-soluble **1n**, as here the reaction rate is also high in the blank. The increase in activity of about one order of magnitude can be explained by the solubilizing influence of the surfactant on the catalyst. For the acids **1i**–**m** and ester **1n**, no clearcut increase in the enantioselectivity over the corresponding blanks in methanol by SDS addition can be detected ($Q' = 1.2 \pm 0.3$).

[a] Solubility of **1** as the percentage of 1 mmol which dissolves in 15 mL water at 25 °C. [b] Hydrogenation conditions: 1 mmol substrate, 0.01 mmol catalyst **2**, 15 mL solvent, 25 °C, 0.1 MPa H_2. [c] Calculated using the values for % *ee* in methanol from ref. [3].

Particularly interesting was the introduction of the new precatalyst **4**, recently synthesized by our group [Eq. (a)].[4] Essential for the synthesis was the support of the hydrolysis by the electronic influence of the methoxy function of the anisylidene protective group. Only products that clearly showed lower activities in water (with similar enantioselectivity) were obtained from the analogous benzylidene compounds as a consequence of contamination by the initial chelate.[5] In contrast, due to its good solubility, the hydrogenation times in the aqueous blanks are surprisingly short with **4**, obtained from the anisylidene compound **3**. The complete conversion of the substrate **1** to the methyl ester of *N*-acetylphenylalanine in 1.5 h with a half-life $t_{1/2}$ of 33 min warranted the assumption that unspecific hydrogenations do not falsify the blank result of the enantioselectivity of 61.1 % *ee* (*S*) (Table 2). The addition of SDS also with **4** raises the selectivity considerably (94 % *ee* (*S*), $Q = 7.8$).

3 (a)

4

The reason for the influence of the amphiphile on the stereoselectivity is not easy to explain, as an influence on the conformation of the catalyst in the transition state cannot be identified spectroscopically. A change in the mechanism of the catalyst at the micelle surface is not expected. The Eyring plot obtained by varying the temperature does not display any point of inflection. Very probably the surface-active substances are effective in their micellar form, as the critical micelle concentration must be approached for the maximal increase in the activity and enantioselectivity. However, the effect can be achieved with less modifier when polymerized micelles are used. These are formed by irradiating ω-undecenyl sulfate as depicted in Equation (b) and are effective at considerably lower concentrations

$$n\ CH_2{=}CH(CH_2)_9{-}OSO_3Na \xrightarrow{\gamma\text{-irradiation}} (CH_2{-}CH(CH_2)_9{-}OSO_3Na)_n \quad (b)$$

$n = 40-60$

due to their stability. To utilize the polymer to its full effect (Fig. 1) the precatalyst is first dissolved in methanol, which is subsequently completely removed. This preformation in methanol also has a positive effect on the monomeric SDS due to the better solubility. The polymer effect here, however, does not increase the reactivity as much as in the case of acetal hydrolysis.[6]

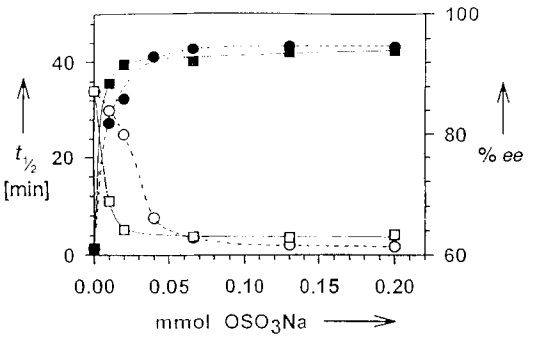

Fig. 1. Hydrogenation of 1 mmol **1f** in 15 mL H_2O in the presence of micelle-forming substances with 0.01 mmol precatalyst **4** (for conditions see Table 1). Open symbols: $t_{1/2}$; filled symbols: % *ee* (*S*); circles: SDS as micelle-forming substance; squares: polymerized micelles with OSO_3Na groups.

The function of the precatalyst **4** is determined by the axial aglycone. As we were recently able to demonstrate, induction of chirality in hydrogenation reactions decreases with an increasing number of axial substituents on the pyranose ring in analagous rhodium(I) chelate complexes of type **3**, which are protected by a benzylidene group in the 4,6-position of the carbohydrate residue.[7] Thus we have now also demonstrated this decrease in optical induction for the first of the conformatively less rigid analogues carrying an axially oriented substituent without the inflexibility imposed by the dioxane ring (Table 2). The enantioselectivity of such conformatively labile seven-membered chelates was shown to be very sensitive to the influences of a modifier.[8, 9] We conjecture that this is a key to direct optical induction over a wide range.

Experimental Procedure

The experimental procedures for the hydrogenation, the synthesis of the precatalyst **2** and the substrates, the derivatization of the hydrogenated products, and the determination of the enantioselectivity are described or referred to in ref. [3], and the synthesis of polymerized micelles in ref. [6]. With polymerized micelles the formation of the catalyst was performed in methanol. For all experiments of Figure 1 and Table 2—but not for those of Table 1—a homogenous solution was made from the precatalyst and the micelle-forming compounds under argon in methanol (5 mL) by stirring for 1 h. The solvent was then removed under vacuum, the dry residue dispersed in water (15 mL) under argon by stirring for 1 h, the substrate added, stirred for 10 min, the argon atmosphere replaced with hydrogen, and the hydrogenation started by stirring. The hydrogenated products were isolated by exhaustive extraction with dichloromethane. For the acid hydrogenation products and the ester from **1f**, the results of the determination of selectivity were additionally checked in double experiments by conversion in methanol to exclude the possibility of enantiomer enrichment during isolation. For this, the hydrogenation suspension was quantitatively evaporated to dryness, and the residue dissolved in methanol. This procedure was also applied to all experiments with the precatalyst **4**. For the enantiomeric excesses determined by gas chromatography, the standard deviation was less than ± 1 % *ee*; similar results were also obtained for the derivatized hydrogenation products of **1a**, **e**, **h**, and **i**, which were separated by HPLC. To determine the substrate solubility, a small excess of substrate was stirred in water (100 mL) at 25 °C for 1 h, the filtrate evaporated on a watch glass, dried under vacuum, and the residue weighed.

Synthesis of **5**, the glucopyranoside ligand of **3**: A solution of methyl-4,6-*O*-anisylidene-α-D-glucopyranoside (21.78 g, 32 mmol) in pyridine (20 mL) was added to Ph_2PCl (15.53 g, 70.4 mmol) in THF (100 mL) within 5 min with vigorous stirring. Pyridine hydrochloride precipitated out. The next day the solid residue was extracted four times with boiling THF until only the pyridine hydrochloride remained. The pooled solutions were subsequently reduced under vacuum to 50 mL. The target compound crystallized out at 0 °C and was obtained in a very pure form in low yield after recrystallization in anhydrous, oxygen-free toluene/triethylamine (70/30): 10.8 g (33.3%), m.p. 175–178 °C; $[\alpha]_D^{25} = +86.9$ ($c = 2$ in $CHCl_3$); ^{31}P NMR (101.2 MHz, [D_5]pyridine, 25 °C): $\delta = 113.6$ (d, $^3J(P,P) = 2.5$ Hz), 116.5 (d, $^3J(P,P) = 2.5$ Hz); ^{13}C NMR (62.8 MHz, [D_5]pyridine, 25 °C): $\delta = 54.5$, 54.8 (CH_3/α-CH_3), 62.7 (C6), 68.7 (C2,3,4,5), 99.5 (d, $^3J(C,P) = 6$ Hz; C1), 101.3 (C7) and arene-C signals; correct elemental analysis (C,H,P); MS (70 eV): *m/z* 680 ([M^+]).

Synthesis of **4**: [Rh^I(cod)(acac)] (1.55 g, 5 mmol) and **5** (3.4 g, 5 mmol) were dissolved in THF (5 mL) to afford the chelate, and 40% aqueous HBF_4 (10 mmol) added. The yellow solution turned red. After 28 h, of which 10 h were at 65 °C, the solution was filtered to remove impurities. Oxygen-free diethyl ether (40 mL) were stirred into the filtrate, and the complex separated out as an orange syrup. The remaining yellow solution was decanted, and diethyl ether (40 mL) was again added to the oil. The product **4** crystallized out: 4.3 g (89.7%); ^{31}P NMR (101.2 MHz, $CDCl_3$, 25 °C): $\delta = 132.7$ (dd, $^1J(P,Rh) = 178$, $^2J(P,P) = 27$ Hz), 137.3 (dd, $^1J(P,Rh) = 181$, $^2J(P,P) = 27$ Hz); ^{13}C NMR (62.8 MHz, $CDCl_3$, 25 °C): $\delta = 27.9$, 28.9, 30.7, 30.9 (CH_2 of cod), 55.1 (CH_3), 60.9 (C6), 68.7, 70.7, 76.2 ($^3J(C,P) = 8$ Hz), 80.8 ($^3J(C,P) = 9$ Hz) (C2,3,4,5), 98.3 (d, $^3J(C,P) = 4$ Hz; C1), 101.5, 102.2 (CH of cod), 128.5–134.6 (C-phenyl); LSI-MS (positive, matrix: sulfolane): *m/z* 773 [$M^+ - BF_4$], 665 [773 − cod].

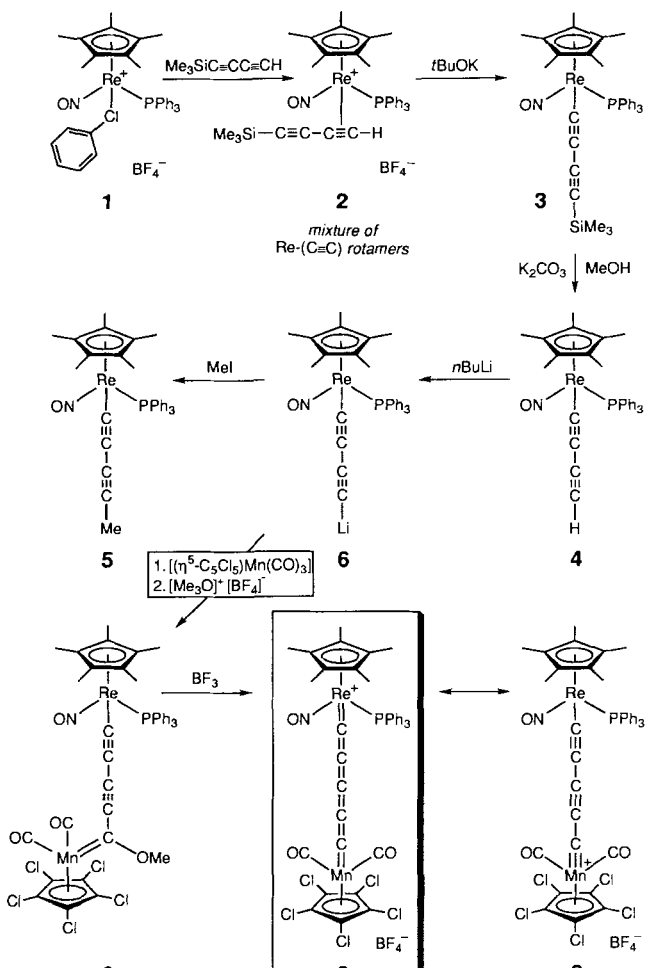
Towards One-Dimensional Carbon Wires Connecting Single Metal Centers: A Cumulenic C_5 Chain that Mediates Charge Transfer between Rhenium and Manganese Termini**

Weiging Weng, Tamás Bartik, and John A. Gladysz*



Compounds in which linear elemental carbon chains span two transition metals, [$L_nMC_xM'L'_n$], exhibit a variety of unusual physical and chemical properties.[1] However, only complexes with $x = 1-4$ have been isolated to date. We have been particularly interested in charge transfer and electron delocalization across the wire-like C_x moieties[2–4] and have sought to study such phenomena in longer-chain compounds. We reported earlier that C_3 complexes can be prepared by methoxide group ab-

straction from bimetallic Fischer carbene complexes of the formula $[L_nMC{\equiv}CC(OMe){=}M'L'_{n'}]$.[2] These are in turn accessed from $[L_nMC{\equiv}CLi]$ species, metal carbonyl complexes, and $[Me_3O]^+[BF_4]^-$. In this communication, we describe the extension of this methodology to a C_5 complex,[5] which shows several remarkable properties relative to its C_3 counterpart.

The substitution-labile chlorobenzene complex **1**[16] was treated in situ with the 1,3-diyne $HC{\equiv}C{-}C{\equiv}CSiMe_3$. Workup gave the terminal alkyne complex **2** in 95% yield (Scheme 1). Reaction of **2** and *t*BuOK gave the σ complex **3** (96% yield). Protodesilylation (K_2CO_3/CH_3OH) gave the air-stable butadiynyl complex **4** (84% yield), which melted with decomposition at 105–108 °C. Complexes **2**–**4** and other new compounds below were characterized by microanalysis, IR and NMR (^1H, ^{13}C, ^{31}P) spectroscopy (Table 1). Most features were similar to those of the monoalkynyl analogues;[7] however, the $\tilde{\nu}$(NO) values in the IR spectrum were 7–20 cm^{-1} higher, and additional bands assigned to C≡C were observed (2139–1975 cm^{-1}).

Scheme 1. Synthesis of the C_5-bridged bimetallic complex **9**.

Complex **4** was treated with 1.0 equiv of *n*BuLi in THF at −80 °C. When the reaction was monitored by ^{31}P NMR, resonances were observed at δ = 21.3 and 21.0 (70:30; **4**, δ = 21.0). One sharp resonance was obtained when the sample was warmed to 10–20 °C (δ = 21.0). Addition of MeI, either at −80 °C or room temperature, gave the 1,3-pentadiynyl complex **5** (δ = 20.9) in 95% yield, as determined by NMR and IR spectroscopy.[8] These data were taken as evidence for the formation of C_4Li complex **6**, which is possibly present as a mixture of aggregates. The deprotonation of a butadiynyl iron complex and subsequent reactions with metal halides to give $[L_nMC{\equiv}C{-}C{\equiv}CM'L'_n]$ complexes has been previously reported by Wong.[9]

We sought to elaborate **6** to a bimetallic Fischer carbene complex. Thus, $[(\eta^5\text{-}C_5H_5)Mn(CO)_3]$ and $[Me_3O]^+[BF_4]^-$ were added to **6** under various conditions; however, no evidence was found for an adduct with a $ReC{\equiv}C{-}C{\equiv}CC(OMe){=}Mn$ linkage, although the corresponding reaction of the lower homologue **7** worked well.[2] The major product was **5**. Hence, an analogous

Correct elemental analysis.

reaction was conducted with $(\eta^5\text{-}C_5Cl_5)Mn(CO)_3$,[10] which should be more conducive to nucleophile addition from the standpoints of both reaction rate and equilibrium. Workup gave the dark purple C_5OMe complex **8** (77% yield).[11] Thus, the ReC≡C–C≡CLi moiety in **6** is less basic and/or nucleophilic than the ReC≡CLi moiety in **7**, a trend often observed for organic analogues.

Toluene/hexane solutions of **8** were treated with excess BF_3 gas (Scheme 1). The C_5 complex **9** precipitated as a dark brown solid. Workup gave **9** (52% yield) that was approximately 94% pure by NMR spectroscopy. Several unusual properties of **9** became immediately apparent and have so far precluded further purification or crystallization. First, **9** is extremely light-sensitive, both in solution and the solid state. Second, **9** decomposes on the time scale of hours in the dark at room temperature; the rate apparently depends upon the concentration of **9**. In all cases, a black decomposition product formed that gave ESR signals and broad NMR signals.[12] Elemental analyses gave values for the carbon, hydrogen, and chlorine content that were within 1–5% of those calculated for **9**.

Complex **9** was characterized spectroscopically. The ^{13}C NMR spectrum showed a downfield ReC signal ($\delta = 218.4$) with a $^2J(C, P)$ value (12.5 Hz) near the range typical of $^+Re{=}C$ linkages (10.0–12.3 Hz) and smaller than that characteristic of Re–C≡ linkages (15.8–17.3 Hz).[13] Other signals assigned to the C_5 chain were observed at $\delta = 296.2$ (MnC), 119.1, 110.6, and 107.0. The $\tilde{\nu}$(NO) value (1718 cm^{-1}) in the IR spectrum was in a range diagnostic of cationic $^+Re{=}C$ compounds (1719–1698 cm^{-1}) and much higher than that characteristic of neutral Re–C≡C compounds (1653–1630 cm^{-1}). Thus, the cumulene resonance form $^+Re{=}C{=}C{=}C{=}C{=}C{=}Mn$ dominates over the alternative $Re{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}Mn^+$ (Scheme 1).[15] A very strong IR band at 1953 cm^{-1} was presumed to be associated with the cumulene fragment.

We sought to characterize the optical properties of **9**. As a prelude, the new C_3 complex **10** was prepared similarly to **9** from ReC≡CLi complex **7**. Complex **10**, and the previously reported chlorine-free analogue **11**, did not exhibit any unusual photo-

$[\{Re^*\}(CCC)Mn(CO)_2(\eta^5\text{-}C_5Cl_5)]^+\ [BF_4]^-$ **10**

$[\{Re^*\}(CCC)Mn(CO)_2(\eta^5\text{-}C_5H_5)]^+\ [BF_4]^-$ **11**

chemical or thermal reactivity.[2] Thus, the cyclopentadienyl chlorines in **9** are not an intrinsic source of instability. This implicates the carbon chain length in **11** as the key labilizing feature. Complex **10** exhibited signals in the IR ($\tilde{\nu} = 1717$(s) (NO), 1899(vs) cm^{-1} (C=C=C)) and ^{13}C NMR ($\delta = 221.1$ (d, $^2J(C, P) = 11.8$ Hz; ReC), 287.8 (s; MnC), 168.9 (s; CCC)) spectra indicative of a dominant "cumulenic" resonance form, $^+Re{=}C{=}C{=}C{=}Mn$. These results parallel those for **11**, which was also crystallographically characterized.[2]

The UV/visible spectra of **9**–**11** are compared in Figure 1. The yellow-brown solutions show very intense absorptions at 480 (**9**), 414 (**10**), and 392 (**11**) nm ($\varepsilon = 60\,500$, 49000, and 56000 $M^{-1}cm^{-1}$, respectively). Weaker bands occur at longer wavelengths (634, 554 sh, and 484 nm; $\varepsilon = 4800$, 2700, and 3700 $M^{-1}cm^{-1}$). Thus, either increased carbon chain lengths (**9** vs **10**) or electronegative chlorine substituents on the manganese cyclopentadienyl ligand (**10** vs **11**) result in absorptions at longer wavelengths. The latter trend suggests that the transitions have appreciable rhenium-to-manganese charge transfer character.

Attempts to trap **9** as a stable adduct have to date been unsuccessful. No reaction occurs with TCNE, ethylene, or SMe_2 at ambient temperature, and PMe_3 gives a complex mixture of unusual products. Nonetheless, we anticipate an array of unusual properties for this series of compounds. Further examples of complexes with C_5 and longer chains will be reported in the near future.

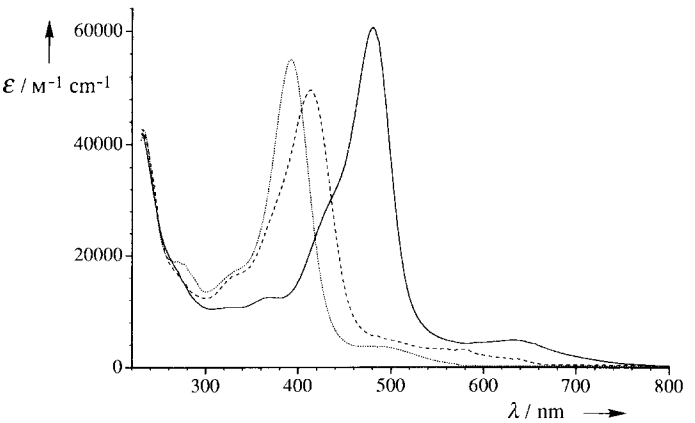

Fig. 1. UV/visible spectra of compounds **9**–**11**. (CH_2Cl_2, ambient temperature, $c = 2.3\text{-}3.9 \times 10^{-5}$ M). — **9**, ---- **10**, · · · · **11**.

Experimental Procedure

8: A Schlenk tube was charged with **4** (0.048 g, 0.072 mmol) in THF (5 mL). The mixture was cooled to −80 °C. Then *n*BuLi (36 μL, 2.3 M in hexane) was added with stirring. After 1 h, a solution of $[(\eta^5\text{-}C_5Cl_5)Mn(CO)_3]$ [10] (0.028 g, 0.075 mmol) in THF (3 mL) was added via a cannula. After 1 h, the cold bath was removed. After a further hour, the red-orange solution was transferred via a cannula to a Schlenk flask that had been charged with $[Me_3O]^+[BF_4]^-$ (0.050 g, 0.32 mmol). The mixture was cooled to −80 °C and stirred for 0.5 h. The cold bath was then removed. After 0.5 h, the sample was concentrated to ca. 2 mL, and hexane (10 mL) was added. Chromatography (N_2, Florisil; hexane → hexane/THF 1/1 (v/v)) gave a deep purple fraction. The solvent was removed under oil pump vacuum to give **8** as a dark purple powder (0.059 g, 0.056 mmol, 77%). M.p. 114–116 °C; ^1H NMR (300 MHz, C_6D_6, 25 °C, TMS): $\delta = 7.65\text{-}7.55$ (m, 6H; $3C_6H_5$), 7.12–6.95 (m, 9H; $3C_6H_5$), 3.53 (s, 3H; OCH_3), 1.55 (s, 15H; $C_5(CH_3)_5$); $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C, C_6D_6 int.): $\delta = 288.9$ (s; Mn=C), 228.2 (s; CO), 228.1 (s; CO), 167.1 (d, $J(C, P) = 14.8$ Hz; Re*C*≡C), 134.2 (d, $J(C, P) = 52.4$ Hz; *i*-Ph), 134.0 (d, $J(C, P) = 10.8$ Hz; *o*-Ph), 130.7 (s; *p*-Ph), 128.6 (d, $J(C, P) = 10.3$ Hz; *m*-Ph), 127.4, 116.3, 82.4 (3s; C≡*CC*≡*CC*=), 102.1 (s; $C_5(CH_3)_5$), 97.0 (s; C_5Cl_5), 63.3 (s; OCH_3), 9.9 (s; $C_5(CH_3)_5$); $^{31}P\{^1H\}$ NMR (121 MHz, C_6D_6, 25 °C, 85% H_3PO_4 ext.): $\delta = 20.6$ (s); IR (CH_2Cl_2/KBr): $\tilde{\nu} = 2057/2054$(m), 2046/2044(m) sh (C≡C), 1965/1962(s), 1925/1922(s) (C≡O), 1655/1657(s) cm^{-1} (NO); UV/VIS (CH_2Cl_2): λ_{max} (ε) = 264 sh (29000), 318 (19000), 376 sh (13000), 502 sh (14500.) 562 nm (21000); MS (positive ions FAB (Cs^+), 3-NBA/benzene matrix): *m/z* (%) 1053 (3) [*M*$^+$], 614 (100) [{Re}$^+$]. Correct elemental analysis.

9: This procedure was carried out in the dark. A Schlenk tube was charged with **8** (0.094 g, 0.089 mmol), toluene (10 mL), and hexane (8 mL). The mixture was cooled to −60 °C. Then BF_3 gas was bubbled through the solution for 1 min. A dark solid precipitated. The supernatant was removed with a syringe, and the solid was washed with hexane (3 × 5 mL) and dried under oil pump vacuum. The solid was extracted with CH_2Cl_2 (2 × 2 mL). The extracts were filtered through a Celite pad (1 cm). Hexane (10 mL) was added, and the dark brown precipitate was collected by filtration, washed with hexane (2 × 2 mL), and dried under oil pump vacuum to give **9** (0.051 g, 0.046 mmol, 52%). ^1H NMR (300 MHz, CD_2Cl_2, 25 °C, CD_2Cl_2 int): $\delta = 7.64\text{-}7.49$ (m, 9H; $3C_6H_5$), 7.48–7.36 (m, 6H; $3C_6H_5$), 1.95 (s, 15H; $C_5(CH_3)_5$); $^{13}C\{^1H\}$ NMR (75 MHz, CD_2Cl_2, −20 °C, CD_2Cl_2 int.): $\delta = 296.2$ (s; MnC), 220.8 (s; CO), 220.2 (s; CO), 218.4 (d, $J(C, P) = 12.5$ Hz; ReC), 133.2 (d, $J(C, P) = 10.9$ Hz; *o*-Ph), 132.4 (s; *p*-Ph), 129.5 (d, $J(C, P) = 10.6$ Hz; *m*-Ph), 119.1, 110.6, 107.0 (3s; *CCCCC*), 108.5 (s; $C_5(CH_3)_5$), 100.4 (s; C_5Cl_5), 10.0 (s; $C_5(CH_3)_5$); $^{31}P\{^1H\}$ NMR (121 MHz, CD_2Cl_2, 85% H_3PO_4 ext.): $\delta = 20.5$ (s); IR (CH_2Cl_2/KBr): $\tilde{\nu} = 2045/2042$(s), 2008/1996(s) (C≡O), 1953/1948(vs) (C=C=C=C=C), 1718/1705(s) cm^{-1} (NO); UV/VIS (CH_2Cl_2): λ_{max} (ε) = 262 (19000), 370 (12500), 442 sh (33000), 480 (60000), 634 nm (4800); MS (positive ions FAB (Cs^+), 3-NBA/CH_2Cl_2 matrix): *m/z* (%): 1022 (4) [*M*$^+$], 614 (100) [{Re}$^+$].

[11] Analogous reactions with the monochlorocyclopentadienyl complex $[(\eta^5\text{-}C_5H_4Cl)Mn(CO)_3]$ gave mixtures of **5** and a C_5OMe adduct that we could not easily purify.
[12] Isolated by precipitation with hexane or ether. Found (two independently prepared samples): C, 44.77–42.64; H, 3.54–3.17; Cl, 12.51–12.41. Calcd for precursor **9**: C, 43.33; H, 2.73; Cl, 15.99. A UV/visible spectrum showed no features at > 300 nm other than intense tailing. A FAB mass spectrum showed no peaks with m/z higher than 614 ($[\{Re^*\}^+]$). IR (CH_2Cl_2): $\tilde{\nu}$ = 1726(s) br, 2043(s), 1974(s), and weaker unresolved bands at 1850–2000 cm^{-1}; ^1H NMR (300 MHz, CD_2Cl_2, 25 °C, CD_2Cl_2 int.): δ = 7.75 (br m; C_6H_5), 1.95 (s; $C_5(CH_3)_5$); ^{31}P NMR (121 MHz, CD_2Cl_2, 25 °C, 85% H_3PO_4 ext.): δ = 22 (br s); ESR (CH_2Cl_2) (g) 2.02 (sextet, A_{iso} 97 G).
[13] Limiting values are taken from **3**–**5** and pentamethylcyclopentadienyl complexes in ref. [4a] and [8].
[14] The ^{13}C NMR chemical shifts of the ReC and CMn units are also consistent with this conclusion, although the former is intermediate between limiting model compounds, and the latter must be compared with neutral carbene and cationic carbyne complexes of the $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]$ fragment [2].

A Novel Hexamer of But$C\equiv P$: Synthesis, Structure, and Theoretical Studies**

Vinicius Caliman, Peter B. Hitchcock, John F. Nixon,* Matthias Hofmann, and Paul von Ragué Schleyer*

The organic and organometallic chemistry of phosphaalkynes ($RC\equiv P$) is developing rapidly.[1–4] The very recent report[5] by de Meijere and co-workers of the "cage" hydrocarbon $C_{12}H_{12}$ (**1**), with D_{3d} symmetry, prompts us to describe the synthesis and structure of the novel isostructural $P_6C_6tBu_6$ cage compound (**2**) that represents the largest known oligomer of the phosphaalkyne tBuC≡P.

A landmark in the chemistry of phosphaalkynes was Regitz et al.'s synthesis and structural characterization of the very stable tetraphosphacubane $P_4C_4tBu_4$ (**3**), made either thermally from tBuC≡P or more efficiently by use of the precursor complex $[Zr(\eta^5\text{-}C_5H_5)_2(P_2C_2tBu_2)]$.[6, 7] Previously[8] the related pentameric cage compound $P_5C_5tBu_5$ (**4**) was obtained readily by oxidative coupling of the 1,3-di- and 1,2,4-triphosphacyclopentadienyl ring systems **5** and **6**. The structure of pentamer **4** is closely related to that of the tetraphosphacubane, **3** as one corner C atom of the "cube" can be considered to be replaced by a triangle of CCP atoms (Fig. 1).

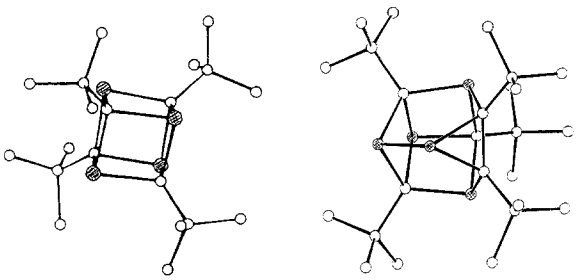

Fig. 1. Structure of **3** (left) and **4** (right) in the crystal. (○ carbon, ● phosphorus) [6–8].

Whereas the $P_3C_2tBu_2^-$ ring ion exhibits η^1- and η^5-ligating behavior towards transition metals, the corresponding $P_2C_3tBu_3^-$ ion only exhibited η^5- or η^3-ligation.[1, 9, 10] Since the structurally well characterized η^1-$P_3C_2tBu_2$ complexes typified by $[M(\eta^1\text{-}P_3C_2tBu_2)_x(PR_3)_yX_z]$ (M = Pd, Pt; X = halide; $x = 2, y = 2, z = 0$; $x = 1, y = 2, z = 1$) all contained stabilizing phosphane ligands,[11] we have now carried out a reaction of the more labile complex $[PtCl_2(cod)]$ (cod = 1,5-cyclooctadiene) with a mixture of the $P_3C_2tBu_3^-$ and $P_2C_3tBu_3^-$ ring ions in dimethoxyethane and obtained nonmetal-containing organophosphorus compounds, presumably via unstable organometallic intermediates.

The reaction product mixture was chromatographed and the known $P_5C_5tBu_5$ (**4**), $P_5C_5tBu_5H_2$ (**7**), and the new compound $P_4C_6tBu_6H_2$ (**8**), whose structure is similar to **7**, were separated and characterized by their $^{31}P\{^1H\}$ NMR spectra.[8, 12, 13] Of special interest was a fraction which yielded a colorless compound (**2**), which exhibited a parent ion in the mass spectrum at m/e = 600, indicative of a hexamer of tBuCP. The $^{31}P\{^1H\}$ NMR spectrum of **2** is very simple, consisting of two singlets of relative intensity 2:1 whose chemical shifts are characteristic of $\lambda^3\sigma^3$ P atoms (δ = 4.8 (P^A), 184.0 (P^B); relative to H_3PO_4). The simplicity of the ^1H NMR spectrum (singlets at δ = 1.64 and 1.25 of relative intensity 1:2) strongly suggests a highly symmetric cage structure.

The molecular structure of $P_6C_6tBu_6$ (**2**), which was established subsequently by a single crystal X-ray structural determination,[14] consists of a lanternlike hexameric cage containing two 3-membered CCP rings (Fig. 2). There is a close similarity between the C_{2h} symmetry exhibited by **2** and the D_{3d} symmetry of the $C_{12}H_{12}$ hydrocarbon p-[$3^2.5^6$]-octahedrane (**1**, Fig. 3, left),[5] as well as the obvious structural relationship of **2** to the D_{3d} structure computed recently for the hypothetical P_{12} molecule **9**[15] (Fig. 3, right). These results provide further strong support for previous contentions about the similarity in chemical behavior of P and CR fragments in both organic and organometallic chemistry.[1, 2, 3]

Ab initio calculations on oligomers of HCP as a model for tBuCP oligomers were performed with the Gaussian 92 program.[19] The MP2(fu)/6-21G* (fu = full, all electrons correlated) geometry of the model hexamer is in good accord with that determined for **2**. Experimental bond lengths and bond angles for $P_6C_6tBu_6$ and corresponding theoretical values for $P_6C_6H_6$ are summarized in Figure 4. Reaction energies computed at different levels for the HCP → 1/n(HCP)n (n = 2–6) reac-

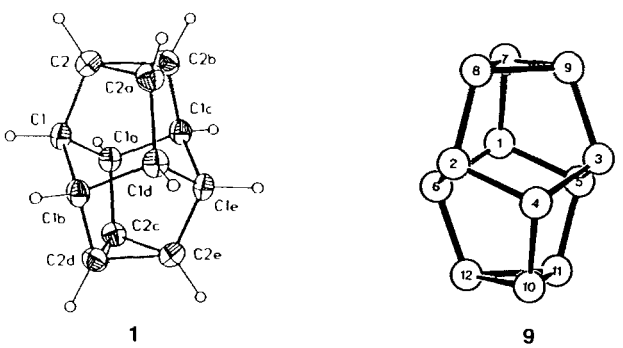

Fig. 3. Molecular structure of $C_{12}H_{12}$ **1** [5] in the crystal (left) and predicted structure of P_{12} **9** [15] (right).

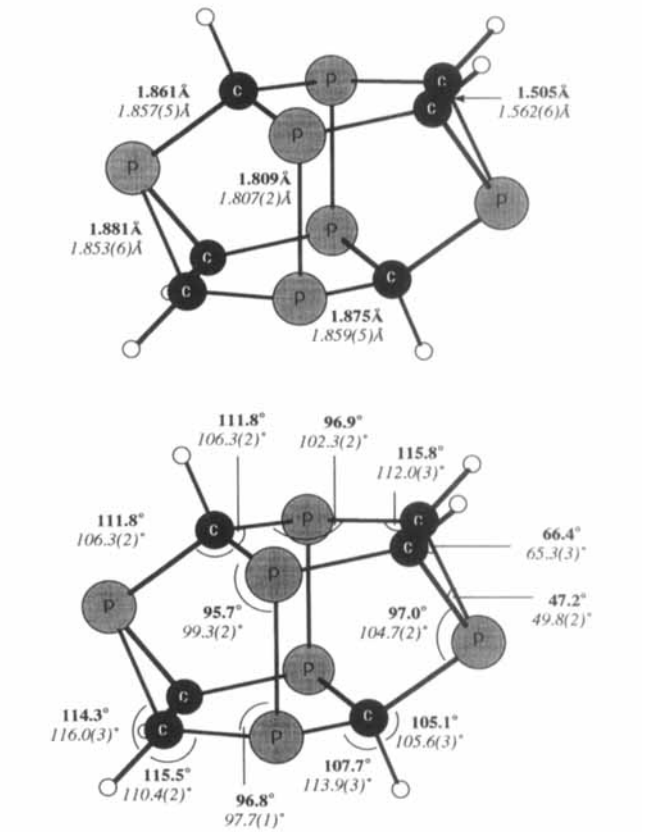

Fig. 4. Comparison of the calculated (RMP2(fu)/6-31G*-level, boldface) and the experimentally determined bond lengths and bond angles (italics) of **2**.

tions are listed in Table 1. The following molecules were chosen: $n = 2$, diphosphatetrahedrane;[20] $n = 3$, 1,2,3-triphosphabenzene;[21] $n = 4$, bishomoprismane;[22] $n = 5$, model compound similar to **4**; $n = 6$, $(HCP)_6$ model compound similar to **2**. The energies differ somewhat with the level of theory employed but interesting trends are obvious. For example, dimerization is less favorable than higher oligomerizations. Tetramers, which are well-known experimentally, are nevertheless calculated to be thermodynamically somewhat less stable than trimers. Despite this, trimers are so far only known as ligands complexed by metal fragments.[1-3, 18] Perhaps free trimers are not easily formed but react easily to give higher oligomers, whereas tetramers are formed by condensation of two dimers rather than through a trimeric stage. For $n = 2$–6, the extent of stabilization of each HCP unit by oligomerization increases with n, with the exception of $n = 3$, which suggests an extraordinary stabilization of trimers.

Just as the pentameric structure **4** can be built by replacing one edge of the tetrameric cube by a three-membered ring, the hexamer structure **2** corresponds to a cube in which two opposite edges are replaced by three-membered rings. However, while the substitution pattern of the pentamer **5** is directly analogous to the cube, this pattern is different in the hexamer **4**.

Table 1. Oligomerization energies per HCP unit for the reaction $HCP \rightarrow 1/n(HCP)_n$ in kcal mol^{-1}.

Method	ΔH(0 K) [a]				
			n		
	2 [b]	3 [c]	4 [d]	5 [e]	6 [f]

Becke3LYP/6-311G**	−6.6	−24.9	−20.5	−20.7	−24.0

[a] Energies were derived from single point calculations employing the 6-31G** basis set and MP2(fu)/6-31G* geometries, and are corrected for scaled zero-point vibrational energies obtained at HF/6-31G*. [b] See ref. [20]. [c] See ref. [21]. [d] See ref. [22]. [e] $(HCP)_5$ model for **4**. [f] $(HCP)_6$ model for **2**. [g] Enthalpy and entropy corrections are derived from scaled frequencies computed at HF/6-31G*.

A hypothetical hexamer with a structure like **2**, but like that of the known cube and pentamer, is computed to lie somewhat lower in energy (2.7 kcal mol^{-1} at Becke3LYP/6-31G**//MP2(fc)/6-31G**, see C_s in Table 2). A hexagonal prism (D_{3d}) not containing any P–P or C–C bonds (D_{3d}) was found to be disfavored by about 58 kcal mol^{-1} relative to the C_{2h} model for **2**.

Interestingly Alrichs et al.,[15] on the basis of theoretical calculations, have proposed that P_{12} (**9**) and P_{16} clusters may be new forms of phosphorus. However, because both species are thermodynamically unfavorable with respect to elemental P_4, they may need additional stabilization by ligation to suitable

transition metal–ligand fragments. On the other hand, the synthesis of the organophosphorus hexamer **2** suggests that higher oligomers of *t*BuCP may also be stable. Further studies on these types of compound, including cages, containing phosphorus (and/or arsenic), carbon, and also transition metals such as Co and Rh will be topics of future papers.

Experimental Procedure

Phosphaalkene $(Me_3Si)P{=}C(OSiMe_3)tBu$ [16,17] (10 mmol) was stirred overnight with an excess of sodium metal in 10 mL of dimethoxyethane (dme) to afford a red solution of a mixture of the anions $P_3C_2tBu_2^-$ and $P_2C_3tBu_3^-$. The solution was cooled to −30 °C, and a suspension of $[PtCl_2(cod)]$ (0.75 g, 2 mmol) in dme (15 mL) was added, and the mixture stirred for 4 h before being warmed to room temperature. After removal of solvent under vacuum, the product mixture was extracted with petroleum ether (60–80 °C), concentrated, and chromatography (silica gel petroleum ether) gave **4** (0.012 g), **7** (0.040 g), and **8** (0.057 g) (identified by their characteristic $^{31}P\{^1H\}$ NMR spectra and a single crystal X-ray diffraction study on the latter [12]), and a fraction (0.032 g) containing **2** and an as yet unidentified compound containing 4 P atoms as evidenced by its $^{31}P\{^1H\}$ NMR spectrum. Crystals of **2** (ca. 2% yield) suitable for the single crystal X-ray study were obtained by cooling the mixture of **2** and **8**. The characterization by mass spectroscopy and NMR spectroscopy were also performed on these crystals.

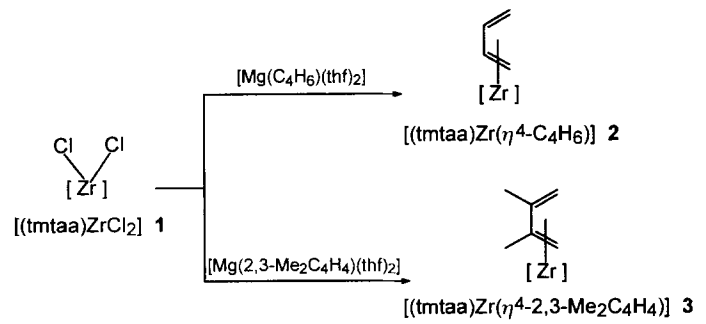
Tetraaza[14]annulenezirconium(IV) Complexes with Butadiene Ligands and their Relationship with Bis(cyclopentadienyl)zirconium(IV) Complexes**

Luca Giannini, Euro Solari, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

In recent years zirconocenes with diene ligands have become some of the most versatile organometallic building blocks. This development dates back to pioneering work by Erker et al. and Nakamura et al.[1] A significant advance in this field would arise from the use of a metal complex fragment with different steric and electronic properties from those of zirconocene. Some years ago we suggested the use of tetramethyltetraazadibenzo[14]annulene metal(IV) complex ([tmtaaM], metal = Ti, Zr, Hf, Nb) as a $[Cp_2M]$ equivalent,[2, 3] which should show some significant differences in terms of a) the number and arrangement of available coordination sites, b) the size of the cavity formed by the ligand, and hence the reactivity of the metal center toward incoming substrates, and c) the Lewis acidity at the metal center and at the ligand.



H_2tmtaa

We report here on a novel class of (butadiene)zirconium complexes. For the synthesis we employed starting materials which we recently reported in detail.[2e] *cis*-[(tmtaa)$ZrCl_2$] (**1**)[2e] was treated with $[Mg(C_4H_6)(thf)_2]$ and $[Mg(2,3\text{-}Me_2C_4H_4)(thf)_2]$ to give the corresponding butadiene complexes **2** and **3**, respectively (Scheme 1).[4]

The two complexes **2** and **3** have been isolated and characterized, and in the case of **2** an X-ray structure analysis has been carried out.[5] There are two crystallographically independent molecules (A and B) of **2** in the asymmetric unit, and four

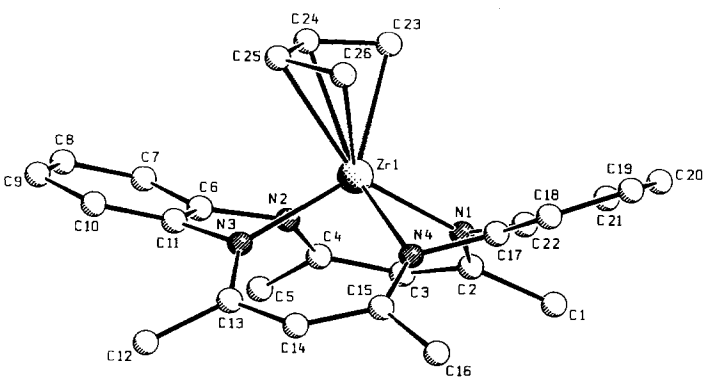
Scheme 1.

four independent solvent molecules (toluene). Figure 1 shows a Schakal view of molecule A. The [(tmtaa)Zr] moiety has the usual saddle-shape conformation, and structural parameters (values in square brackets refer to molecule B) are similar to



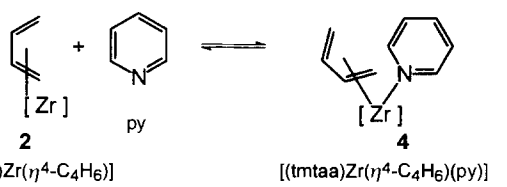


Fig. 1. Crystal structure of **2** (Schakal view of molecule A; values in square brackets refer to molecule B). Bond lengths [Å]: Zr1–N1 2.187(6) [2.185(5)], Zr1–N2 2.252(7) [2.252(6)], Zr1–N3 2.250(6) [2.248(5)], Zr1–N4 2.180(6) [2.214(6)], Zr1–C23 2.387(8) [2.407(10)], Zr1–C24 2.428(7) [2.440(11)], Zr1–C25, 2.434(8) [2.433(9)], Zr1–C26 2.399(9) [2.396(9)], C23–C24, 1.366(12) [1.394(12)], C24–C25 1.436(13) [1.397(12)], C25–C26 1.431(16) [1.418(11)]. Bond angles [°]: C25-Zr1-C26 34.4(3) [34.1(3)], C24-Zr1-C25, 34.4(3) [33.3(3)], C23-Zr1-C24, 32.9(3) [33.4(3)], N2-Zr1-N3 71.2(2) [71.4(2)], N3-Zr1-N4 80.8(2) [81.9(2)], N1-Zr1-N2 81.9(2) [81.8(2)], N1-Zr1-N4 74.6(2) [74.1(2)].

those of **1**.[2e] The zirconium atom projects above the N_4 plane by 1.046(1) Å. [1.040(1) Å]. The plane of the butadiene carbon atoms is nearly parallel to the N_4 plane; the dihedral angle is 4.4(4)° [5.7(3)°]. The η^4 coordination of the butadiene is supported by the Zr–C distances, which all fall in a very small range (Fig. 1). Such distances are, however, longer than those usually observed for Zr–C σ bonds.[6] The three C–C bond lengths within the butadiene ligand, averaged for both A and B molecules and taking the rather large standard deviations into consideration, are nearly identical. Thus, the bonding mode of the butadiene ligand in **2** can be described as π^2,η^4. The structural and spectroscopic characteristics of the $[(C_4H_6)Zr]$ moiety in **2** should be compared to those in $[Cp_2Zr]$ derivatives,[1] both in solution and in the solid state. In this context it should be noted that: a) The *cis* form is the only butadiene conformer detected in the solid state following isolation both at room temperature and at −25 °C. b) We did not observe any *cis–trans* isomerization upon heating or photolyzing either **2** or **3**. c) The assignment of the ^{1}H NMR signals for **3** is trivial, while for **2** a computer-generated simulation was necessary; the latter is in agreement with a butadiene ligand with a *cis* conformation.[7] d) The pattern of splittings of the butadiene protons in the ^{1}H NMR spectrum of **2** is temperature independent, while, in contrast, the chemical shifts depend on the temperature. The above-mentioned data emphasize the difference between the butadiene complexes **2** and **3** (π^2,η^4) and the cyclopentene (σ^2,π,η^4) complexes in the $[Cp_2Zr]$ series.[1] A variety of the bonding modes of butadiene to zirconium ranging from the π^2,η^4 to the σ^2,π,η^4 mode can be found in complexes with a set of ligands different from the bis(cyclopentadienyl) moiety.[8]

Such a major difference should be reflected in the reactivity and depends chiefly upon the number and geometry of the frontier orbitals available on the [(tmtaa)Zr] fragment[9] as opposed to those on the $[Cp_2Zr]$ one. This is revealed by the reversible binding of pyridine by **2**, which leads to complex **4** (Scheme 2).[10]

Scheme 2.

Complex **4**[11] (Fig. 2) may be isolated in the solid state with a further molecule of crystallization (pyridine). The presence of pyridine does not drastically affect the structural parameters of the $[(\eta^4\text{-}C_4H_6)Zr]$ moiety, but causes a rearrangement of the

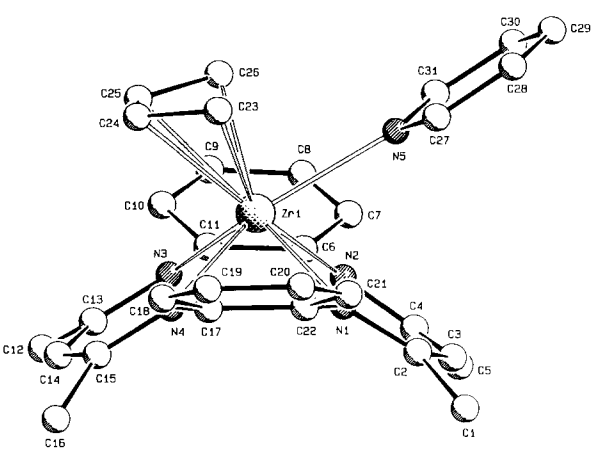

Fig. 2. Crystal structure of **4** (Schakal view). Bond lengths [Å]: Zr1–N1 2.286(3), Zr1–N2 2.301(3), Zr1–N3 2.254(3), Zr1–N4 2.270(3), Zr1–N5 2.435(3), Zr1–C23 2.383(4), Zr1–C24 2.476(4), Zr1–C25 2.491(4), Zr1–C26 2.414(3), C23–C24 1.444(5), C24–C25 1.391(6), C25–C26 1.422(5). Bond angles [°]: C25-Zr1-C26 33.6(1), C24-Zr1-C25 32.5(1), C23-Zr1-C24 34.5(1), N2-Zr1-N3 69.52(1), N3-Zr1-N4 79.2(1), N1-Zr1-N2 78.8(1), N1-Zr1-N4 68.7(1).

butadiene moiety: in comparison with complex **2**, this is rotated by about 90° with respect to the N_4 core. This is best demonstrated by the dihedral angles that the C24–C25 bond forms with the N···N lines (C24–C25 ∢ N2···N3, 91.1(3)° in complex **4** vs 1.1(5)° [0.3(5)°] in complex **2**, and C24–C25 ∢ N1···N4, 90.6(3)° in complex **4** vs 1.9(5)° [1.3(6)°] in complex **2**). The η^4 bonding mode of the butadiene ligand is slightly affected by the coordinated pyridine molecule. The Zr–C24 and Zr–C25 bond lengths are significantly longer, as

a consequence of a small shift of the butadiene ligand that allows the pyridine ligand to approach the zirconium center. Other small, but significant, differences are: a) the out-of-plane distance of the Zr center from the N_4 core [1.191(1) Å], and b) the bending of the butadiene ligand with respect to the N_4 plane [dihedral angle 11.2(2)°]. The three C–C bond lengths within the butadiene ligand range from 1.391(6)–1.444(5) Å. Such a small variation fully supports the η^4 bonding mode of the butadiene ligand as observed in complex **2**. The reaction shown in Scheme 2 can be viewed as a model for the approach of a reactive substrate to the metal center close to the butadiene ligand in the coordination sphere.

Experimental Procedure

2: **1** (11.80 g, 18.2 mmol) and $[Mg(C_4H_6)(thf)_2]$ (4.78 g, 21.5 mmol) were suspended in hexane (350 mL) at −35 °C. The mixture was allowed to warm to room temperature and stirred overnight. Volatiles were removed by evaporation in vacuo to leave an orange powder, to which toluene (450 mL) and hexane (200 mL) were added, and the mixture was stirred at room temperature for 2 h. This gave a suspension of a dark microcrystalline solid and a very fine solid in a dark brown supernatant. The mixture was heated to boiling and filtered while hot. The resulting brown solution was kept at −20 °C for 4 d to yield deep red prismatic crystals of **2**, which were collected at −20 °C. Washing this product with hexane (2 × 50 mL) at room temperature afforded solvent-free **2** as a brown microcrystalline powder (4.62 g, 52%). Anal. calcd for $C_{26}H_{28}N_4Zr$: C 64.03, H 5.79, N 11.49. Found: C 64.28, H 6.00, N 11.44. ^{1}H NMR ([D$_8$]toluene, 25 °C): δ = 7.19–7.10 (m, 8H, Ph), 5.31 (s, 2H, CH), 5.17 (m, 2H, $H_{5,6}$), 2.60 (m, 2H, $H_{3,4}$), 2.26 (s, 12H, CH_3), 0.94 (m, 2H, $H_{1,2}$). ^{1}H NMR (C_6D_6, 25 °C): δ = 7.00–6.89 (m, 8H, Ph), 5.14 (s, 2H, CH), 5.10 (m, 2H, H(5,6)), 2.54 (m, 2H, H(3,4)), 2.05 (s, 12H, CH_3), 0.91 (m, 2H, H(1,2)). ^{1}H NMR ([D$_5$]pyridine): δ = 7.30–7.03 (m, 8H, Ph), 5.56 (m, 2H, H(5,6)), 5.04 (bs, 2H, CH), 2.23 (s, 12H, CH_3), 1.20 (m, 2H, H(1,2)), 1.05 (m, 2H, H(3,4)). ^{1}H NMR ([D$_8$]THF, 25 °C): δ 7.47–7.25 (m, 8H, Ph), 5.50 (s, 2H, CH), 4.56 (m, 2H, H(5,6)), 2.53 (s, 12H, CH_3), 1.78 (m, 2H, H(3,4)), 0.21 (m, 2H, H(1,2)).

3: This complex was prepared by using a procedure analogous to that for **2** (61% yield). Anal. Calcd for $C_{28}H_{32}N_4Zr$: C 65.20, H 6.25; N 10.86. Found: C 65.01, H 6.52; N 11.00. ^{1}H NMR (C_6D_6, 25 °C): δ = 7.09–6.86 (m, 8H, Ph), 5.13 (s, 2H, CH), 2.20 (d, 2H, H(3,4)), 2.06 (s, 12H, CH_3), 1.51 (s, 6H, CH_3-butadiene), 0.77 (bd, 2H, $H_{1,2}$). ^{1}H NMR ([D$_5$]pyridine), 25 °C): δ = 7.34–7.10 (m, 8H, Ph), 4.95 (bs, 2H, CH), 2.21 (s, 12H, CH_3), 1.99 (s, 6H, CH_3-butadiene), 1.14 (d, 2H), 0.98 (d, 2H).

4: **2** (1.32 g, 2.7 mmol) was almost completely dissolved in pyridine (200 mL), the dark solution was filtered, and hexane (550 mL) was added. The resulting solution was kept at 8 °C for 24 h. This afforded large crystals of **4**·(C_5H_5N), which were collected and briefly dried in vacuo (1.13 g, 1.75 mmol, 64.8%). Anal. Calcd for $C_{36}H_{38}N_6Zr$: C 66.94, H 5.93, N 13.01. Found: C 66.91, H 5.91, N 12.95. ^{1}H NMR (C_6D_6, 25 °C): δ = 8.52 (m, 4H, pyridine), 7.00–6.87 (m, 10H, Ph + py), 6.63 (m, 4H, pyridine), 5.17 (m, 2H, H(5,6)), 5.11 (s, 2H, CH), 2.38 (m, 2H, H(3,4)), 2.05 (s, 12H, CH_3), 0.95 (m, 2H, H(1,2)). The spectrum is similar to that of pure **2** in C_6D_6; only the protons of the butadiene system and the CH group of the tmtaa ligand manifest a shift in the direction of the values observed in [D$_5$]pyridine. When complex **4** was dissolved in THF, followed by removal of volatiles in vacuo, and this procedure was repeated three times, complex **2** was obtained free of pyridine.

[5] Crystal structure analysis of **2**: $C_{26}H_{28}N_4Zr \cdot 2C_5H_8$, M = 672.0, triclinic, space group $P\bar{1}$, a = 16.319(3), b = 18.426(5), c = 12.084(3) Å, α = 104.93(2), β = 95.17(2), γ = 77.06(2)°, V = 3419.7(15) Å^3, Z = 4, ρ_{calcd} = 1.305 g cm^{-3}, $F(000)$ = 1408, $Mo_{K\alpha}$ radiation (λ = 0.71069 Å), $\mu(Mo_{K\alpha})$ = 3.47 cm^{-1}, crystal dimensions 0.16 × 0.18 × 0.24 mm. The structure was solved by the heavy atom method and anisotropically refined for all non-hydrogen atoms. One of the four independent toluene molecules of crystallization (C61–C66) was found to be statistically distributed over two positions (A and B) isotropically refined with site occupation factors of 0.5 by applying a rigid body constraint to the rings. The hydrogen atoms, except those attached to the methyl carbon atoms C37, C47, and C57, which were placed in calculated positions, were located from a difference map and introduced as fixed contributors in the last stage of refinement (U_{iso} = 0.05 and 0.10 Å^2 for those related to the complex and to three toluene molecules, respectively). The hydrogen atoms of the disordered C61–C67 toluene molecule were ignored. For 6073 unique observed reflections [$I > 2\sigma(I)$] collected at T = 123 K ($5 < 2\theta < 50°$) on a Rigaku AFC6S diffractometer and corrected for absorption the final R value was 0.056 (unit weights). All calculations were carried out with the use of SHELX-76 on an IBM AT personal computer equipped with an INMOS T800 transputer [12].

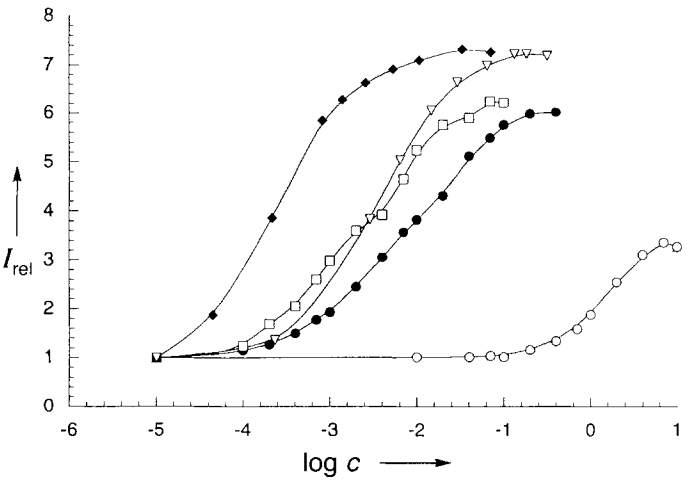
A Glucose-Selective Molecular Fluorescence Sensor**

Tony D. James, K. R. A. Samankumara Sandanayake, and Seiji Shinkai*

Photoinduced electron transfer (PET) has been employed in the design of fluorescent molecular sensors for protons and metal ions;[1] however, there are relatively few fluorescent molecular sensors for small neutral molecules. Our group[2-11] as well as others[12-17] have started to exploit the interactions of boronic acids with saccharides[18] for the development of receptor sites for saccharide detectors. Selective detection of saccharides is our aim, but to achieve this goal we must manipulate the characteristics of the boronic acid. We have found that two-point interrogation by a diboronic acid is the most expeditious approach towards the selective detection of saccharides.[4-7] The spatial disposition of the two boronic acid moieties determines which saccharide is bound preferentially. With PET sensor **1** in mind[11] and by reference to molecular models we discovered that the 9,10-diaminomethylanthracene skeleton **2** provides a perfect cleft for glucose.[19] The two inwardly facing boronic acid moieties are perfectly spaced and aligned for the 1,2- and 4,6-hydroxyl groups of glucose.

1 **2**

Synthesis of the desired boronic acid as the protected boronate ester was readily achieved (Scheme 1).[11, 20] Figure 1 shows the fluorescence intensity of **2** as a function of the concentration of the saccharides (titration curves) at pH 7.77 (33.3% methanol buffer). The stability constants are: D-glucose (log $K_a = 3.6$); D-allose (log $K_a = 2.8$); D-fructose (log $K_a = 2.5$); D-galactose (log $K_a = 2.2$) and ethyleneglycol (log $K_a = -0.20$).



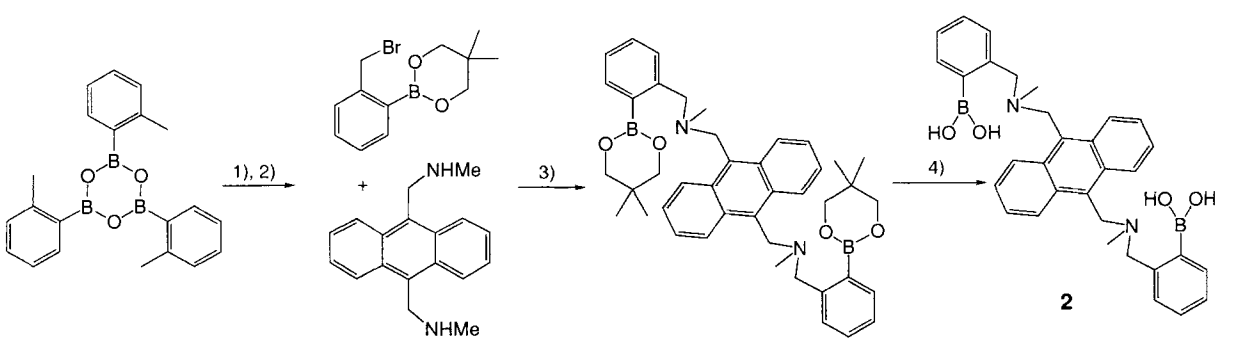


Fig. 1. Relative fluorescence intensity I_{rel} of **2** as a function of the saccharide and ethyleneglycol concentrations log c at 25 °C; 1.0×10^{-5} M of **2** in 33.3% MeOH/H_2O buffer at pH 7.77, $\lambda_{ex} = 370$ nm, $\lambda_{em} = 423$ nm. ♦ D-glucose, □ D-allose, ▽ D-fructose, ● D-galactose, ○ ethyleneglycol.

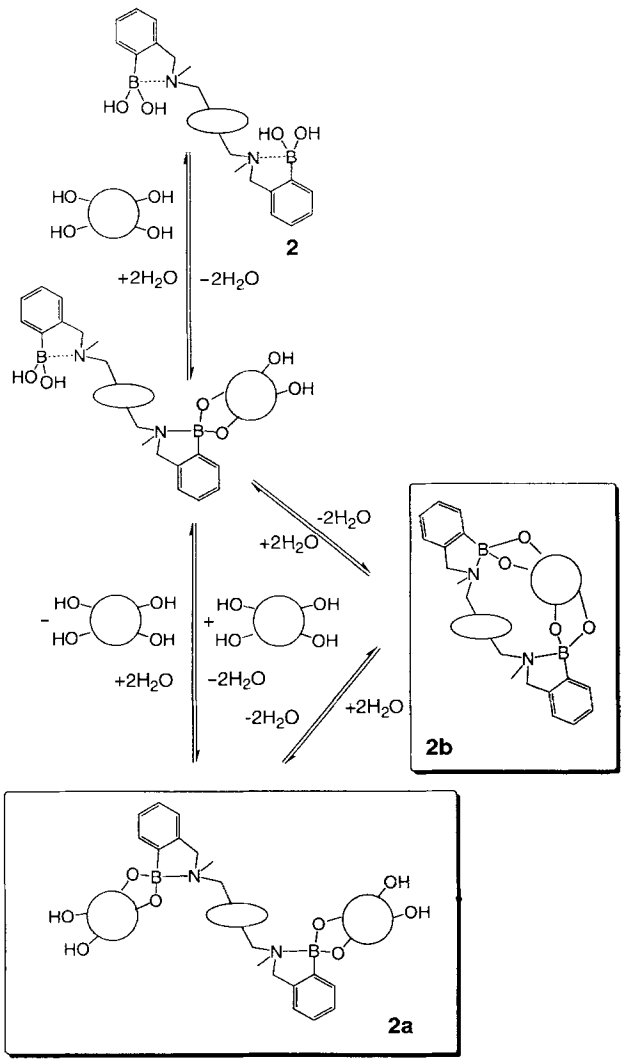
The main species involved are presented in Scheme 2. With **2** four main species exist under the experimental conditions. The fluorescent species are: **2a** (a noncyclic 2:1 complex) and **2b** (a cyclic 1:1 complex). With ethyleneglycol the fluorescent species can only be the 2:1 complex **2a**. With D-glucose the large stability is indicative of a shift in the equilibrium towards the intramolecular 1:1 complex **2b**.



The existence of the 1:1 complex **2b** with D-glucose was substantiated by ^{1}H and 2D COSY90 NMR measurements. Figure 2 shows the ^{1}H NMR spectrum of the D-glucose 1:1 complex **2b** (see Table 1). The large up-field shift of the signal of H3 ($\delta = -0.3$) is indicative of a proton pointing directly at the π electrons of anthracene. The splitting of the anthrylic and benzylic protons is also characteristic of structural rigidification in a 1:1 complex. With D-allose, D-fructose, and D-galactose no 1:1 complex could be detected in the ^{1}H NMR spectra. The secondary ion mass spectra (positive ion) of a 1:1 mixture of **2** with D-glucose, D-allose, D-fructose, and D-galactose each contained the M^+ ion of **2b**; with D-fructose this signal was weak

CH_3OH	3.30
CH_3OH	4.89
Protecting group [a]	
$(CH_3)_2C(CH_2OH)_2$	0.85
$(CH_3)_2C(CH_2OH)_2$	3.40
$(CH_3)_2C(CH_2OH)_2$	4.89

[a] The protecting group is removed under the conditions of the NMR experiment.

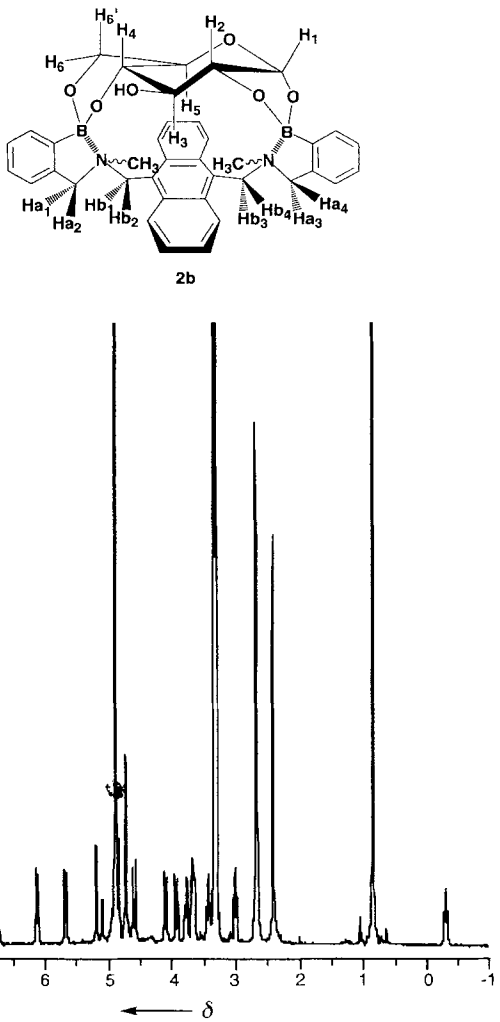

Fig. 2. ^{1}H NMR spectrum of the 1:1 complex of D-glucose and **2**. The pyranose form is depicted but the furanose form has not been ruled out.

and the spectrum also contained a signal for the M^+ ion of **2a**.

From CPK models the predicted order of stability of the 1:1 complexes **2b** are: D-glucose ≈ D-allose > D-galactose > D-fructose. D-glucose and D-allose have different configurations at C3 (H3). From the ^{1}H NMR studies of the D-glucose 1:1 complex **2b**, the C3 proton points towards the π electrons of the anthracene moiety. In the corresponding D-allose complex the C3 hydroxyl group must also be directed towards the anthracene π electrons. Since the D-allose complex (log K_a) is significantly less stable than the D-glucose complex, the π electron/hydroxyl interaction must therefore be unfavorable. The lack of correlation between the predicted and observed order for D-galactose and D-fructose is likely caused by a difference in the stability of the 2:1 complex **2a** rather than of the 1:1 complex **2b**. The mass spectral data confirms this assumption, since with D-fructose the M^+ ion of the 2:1 complex **2a** is detected, but with D-galactose only the M^+ ion of the 1:1 complex **2b** is observed.

Interestingly, the maximum fluorescence changes observed with **2** are over a concentration range suitable for the detection of physiological glucose levels. In blood three main monosaccharides are present: D-glucose (0.3–1.0 mM), D-fructose (≤0.1 mM), and D-galactose (≤0.1 mM). When D-glucose is titrated in the presence of 0.1 mM D-fructose or D-galactose, the

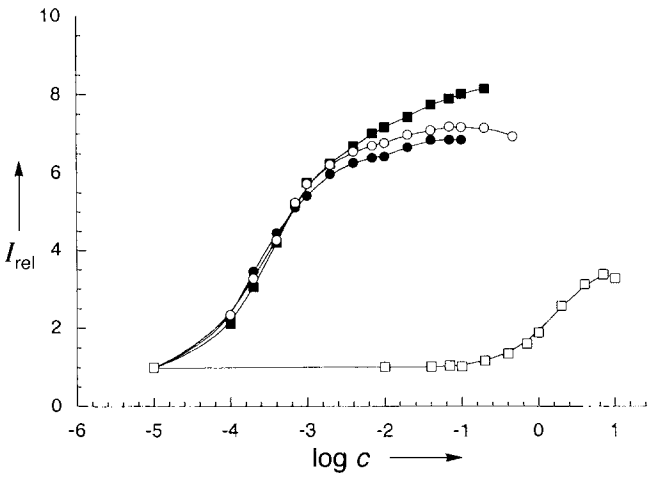

Fig. 3. Relative fluorescence intensity I_{rel} of **2** as a function of the glucose concentration log c with and without 0.1 mM D-galactose or D-fructose at 25 °C; 1.0×10^{-5} M of **2** in 33.3% MeOH/H_2O buffer at pH 7.77, $\lambda_{ex} = 370$ nm, $\lambda_{em} = 423$ nm. ● D-galactose/D-glucose, ■ D-fructose/D-glucose, ○ D-glucose, □ ethyleneglycol.

observed stability (log K_a) is the same as that obtained with D-glucose alone (Fig. 3).

In conclusion, a PET sensor has been designed that is selective for glucose. We believe that it will be possible to construct other saccharide-selective sensors if particular attention is paid to the spatial disposition of the two boronic acid moieties with respect to the hydroxyl groups of the target saccharides.

[18] From our work and that of others [2–17] it is known that the boronate ester is rapidly and reversibly formed under basic conditions. The same rapid equilibrium condition also exists in *ortho* aminoboronic acids at neutral pH [11, 16]. Non-covalent interactions are described with such terms as "recognition", "complex", and "binding constants". These terms will be used to describe the equilibrium between covalent boronate ester and free boronic acid under these conditions.

Synthesis of a Fully Unsaturated "Molecular Board"**

Matthias Löffler, Arnulf-Dieter Schlüter,* Katrin Gessler, Wolfram Saenger, Jean-Marc Toussaint, and Jean-Luc Brédas

Dedicated to Professor Henry Hall, Jr., on the occasion of his 70th birthday

Our current research is focused on the synthesis of structurally perfect, fully unsaturated double-stranded polymers.[1] These are potentially interesting as materials for application in areas such as electrical conductivity, optical nonlinearity, electroluminescence, and photovoltaics.[2–5] Unsaturated polymers of this kind should have a planar, boardlike structure, a feature which inevitably renders them insoluble. For the synthesis of insoluble and yet well-defined polymers, precursor concepts have proved very successful for those cases in which the first step is the preparation of a characterizable and processable polymer which then, in a second step, is converted into the desired polymer. Here we report the synthesis of a double-stranded Diels–Alder (DA) polymer and its polymer-analogous conversion into the unsaturated, all-carbon polymer **1** (Scheme 1). The backbone of **1** consists of a regular sequence of typical substructures of fullerenes, like the pyracylene **A** and the oligoacene **B** ($m = 2$). Polymer **1** is the second member of a new class of

1

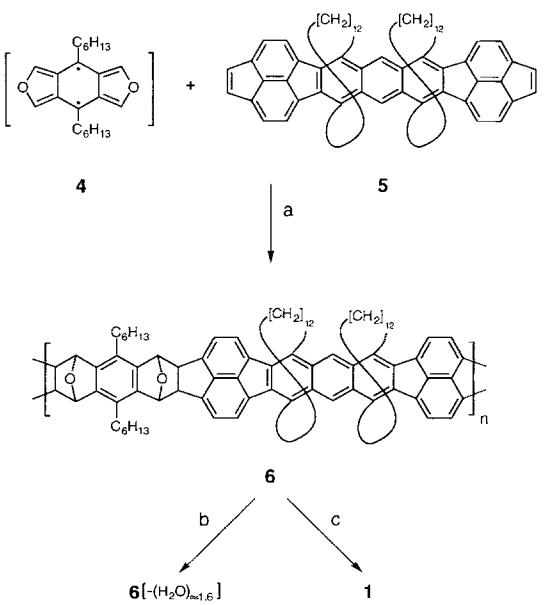
[**] This work was supported by the Bundesministerium für Forschung und Technologie, the Fonds der Chemischen Industrie, and the Deutsche Forschungsgemeinschaft. We also thank W. Lamer for the SEC measurements, O. Klein and G. Buntkowski for recording ^{13}C CP/MAS spectra, and C. Bartel for help with some of the experiments. The work in Mons was partially supported by the Belgian Government "Pole d'Attraction Interuniversitaire en Chimie Supramoléculaire at Catalyse" and the Belgian "Programme d'Impulsion en Technologie de l'Information" (contract 1T/SC/22), FNRS-FRFC, an IBM Academic Joint Study, and the Commission of European Community through the ESPRIT Basic Research Action TOPFIT Project 7282.

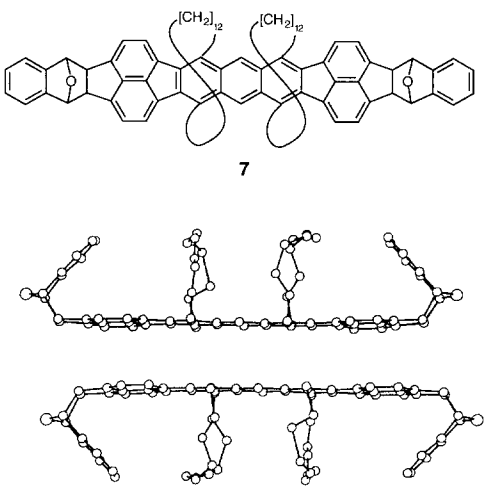
polymers composed of substructures of fullerenes.[6] It closely resembles the open-chain analogue **C** of the belt-region of C_{60}. We also discuss the results of calculations on the electronic structure of the parent compound of **1**, which bears no hexyl substituents. These calculations are aimed at providing a description of the interactions between these substructures.

The selection of the precursor polymer and the kind of chemistry needed for its conversion into the target structure resulted from the key observation that compound **2**, regardless of its actual stereochemistry (six diastereomers) can be dehydrated with *p*-toluenesulfonic acid (*p*-TsOH) to benzodifluoranthene **3** in yields of virtually 100% (Scheme 2).[7] To our knowledge,



2 **3**

Scheme 2. Dehydration of the model compound **2**.



this is the first and to date only successful way of converting precursor molecules by dehydration into polycyclic aromatic compounds, which proceeds reproducibly and cleanly. The dehydration does not seem to be catalyzed by *p*-TsOH; thus, it should be possible to control the number of water molecules removed by stoichiometry (see below). These features make a polymer with the structural subunits of **2** an ideal candidate for a polymer analogous application. We, therefore, synthesized polymer **6** and subsequently dehydrated it with *p*-TsOH.

The synthetic route to **6** involves the DA-polyaddition of the in situ prepared bisdiene **4** with the bisdienophile **5** (Scheme 3).

Scheme 3. Synthesis of the precursor polymer **6** and its conversion into polymer **1**: a) **4** (583 mg, 0.51 mmol), **5** (410 mg; 0.51 mmol), 110 °C, toluene (50 mL), 24 h, precipitation into methanol/hexane; b) **6** (24.3 mg), *p*-TsOH (5.4 mg, 1.3 equiv/repeat unit), 110 °C, toluene (15 mL), 24 h, precipitation into methanol; c) **6** (48.6 mg), *p*-TsOH (25 mg, 4.0 equiv/repeat unit), 110 °C, toluene (20 mL), 24 h, precipitation into methanol.

"Monomer" **4** has proved very versatile in countless poly-DA-additions;[11] monomer **5** deserves some comments.[8] First, **5** is bridged by flexible alkyl chains ("loops"). This should help to increase the solubility of the precursor and the target polymer. The loops, like straight alkyl chains,[9] are effective solubilizers for entropic reasons, but are also good for enthalpic reasons because they disturb the packing of "flat boards". Second, this allows one to obtain a polymer with repeating units, which already contain extended aromatic regions. Therefore only a few dehydration steps are necessary to generate large conjugated areas. As to the question of solubility, the crystal structure[10, 11] of a diastereomer of model compound **7**[8] provides an insight into how the "molecular boards" would most probably pack if alkyl loops were not present (Fig. 1). The

7

Fig. 1. Model compound **7** and its crystal structure (ORTEP).

diastereomer of **7** shown forms sandwichlike structures in which the planar regions are arranged almost on top of each other at van der Waals distance. This situation cannot occur in the polymer because of the randomness of the relative orientations of the loops.

Polymer **6** was obtained as a yellow-orange material in 85–95% yield. The molecular weight of **6**, in contrast to other DA-ladder polymers, has a pronounced effect on its solubility in common organic solvents at room temperature. The ratio of soluble, yet relatively low-molecular-weight material to insoluble but high-molecular-weight material can be adjusted by changing the conditions. For example, heating a 0.005 M mixture of the monomers **4** and **5** to 110 °C for 24 h in toluene gave a material which was completely soluble in benzene [size exclusion chromatography in THF versus polystyrene: $M_n = 5000$ ($p_n = 4-5$); $M_w = 11100$ ($P_w = 10$); $D = 2.2$]. If the same experiment was carried out at higher monomer concentration (0.135 M), the amount of soluble material was reduced to 25–30% [$M_n = 7200$ ($P_n = 6-7$); $M_w = 30200$ ($P_w = 26$); $D = 4.2$]. In this context it is important to note: a) A sample of the soluble polymer remained completely soluble if it was heated in toluene under reflux for 3 d. Cross-linking does, therefore, not seem to play a role. b) The formation of insoluble material can be prevented if dodecyl instead of hexyl chains are used as solubilizers. The determination of the structure of polymer **6** is based chiefly upon the ^1H and ^{13}C NMR spectra for the soluble and the ^{13}C CP/MAS solid-state NMR spectrum for the insol-

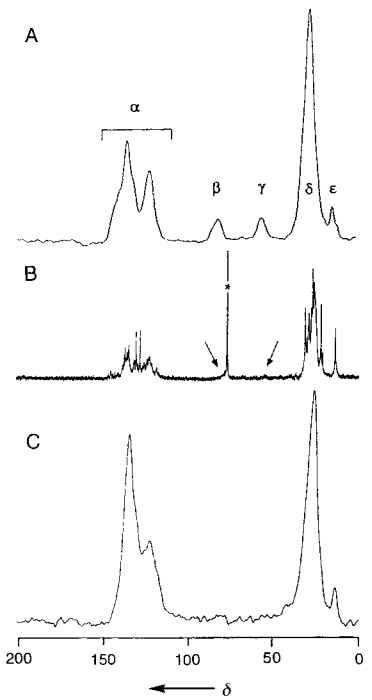


Fig. 2. ^{13}C CP/MAS NMR spectra (300 MHz) of polymers **6** (A) (α = C-arom., β = C–O, γ = H-C-C-O, $\delta = CH_2$, $\varepsilon = CH_3$) and **1** (C), and ^{13}C NMR spectrum (270 MHz, $CDCl_3$) of partially dehydrated polymer **6** (B). Signals due to residual β- and γ-C atoms and the solvent are marked with arrows and an asterisk.

uble part. The latter is shown in Figure 2 together with a signal assignment which is based on the chemical shifts of four diastereomers of model compound **2**. The ^1H NMR signals of **6** are relatively broad; therefore a detailed stereochemical (sequence) analysis was not undertaken. The C,H values from elemental analysis match the theoretical values within 0.5%. The excellent match between the UV spectra of **3** and **6** (Fig. 3) is also in accordance with the proposed structure.

In order to establish the point at which the polymer becomes insoluble, the initial dehydration studies were aimed at a partial dehydration. Preliminary experiments were done on a low-molecular-weight fraction (M_n = 5000, M_w = 10500) of **6** by heating in toluene under reflux for 24 h in the presence of 1.3 equivalents of *p*-TsOH per mole repeat unit. The dehydration was accompanied by a color change from intense orange to red. The reaction mixture remained homogeneous. A representative UV spectrum of the material obtained shows that the λ_{max} value is shifted bathochromically from 500 to 600 nm. The degree of dehydration has not yet been determined quantitatively. A comparison of the ^{13}C NMR spectrum (Fig. 2B) with that of the starting material, however, suggests that more than 80% of the oxygen bridges as well as the adjacent hydrogen atoms have been removed. Only low intensities for the signals assigned to the ether (β) and bridgehead (γ) carbon atoms are observed. The fact that the partially dehydrated materials are still soluble in common organic solvents, even though a large proportion of the kinks have been removed, underlines the effectiveness of the alkyl substituents as solubilizers. The second step involved the attempt to drive the dehydration to completion. For this the same experiments were carried out with an excess of *p*-TsOH. The material obtained in this way was only sparingly soluble. Its UV spectrum (Fig. 3) shows no further bathochromic shift, but instead a significant increase in the intensity of the long wavelength absorption bands. This is a clear indication that more water molecules have been removed from the backbone of the polymer. Furthermore, the ^{13}C CP/MAS NMR spectrum of this material (Fig. 2C), does not indicate the presence of any "residual water" in the structure. The data from elemental analysis match the calculated values within 1.0%. The soluble high-molecular-weight fractions of **6** gave comparable results.

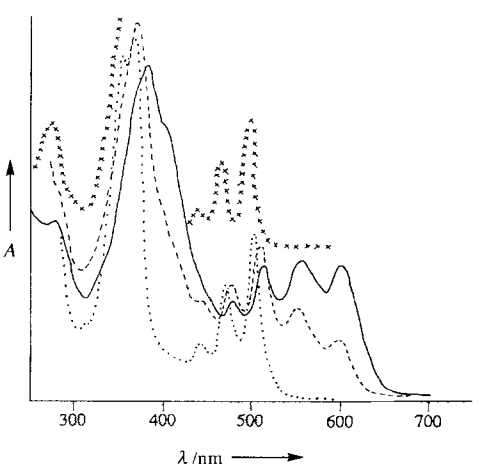

Fig. 3. UV/VIS spectra of model compound **7** in chloroform (λ_{max}(lg ε) = 497 (4700)) (crossed line) and of polymer **6** (dotted line), partially dehydrated **6** (dashed line), and fully dehydrated **1** (solid line). A = absorption (arbitrary units).

Parallel to the synthetic work, theoretical investigations were undertaken on the unsubstituted form of **1** to determine the electronic structure and to outline the origin of the band gap[4] in this polymer. The structure of the trimer was first optimized by the semiempirical AM1 technique, a method well-known for its reliable determinations of geometries on conjugated compounds.[12] Then, in a second step, the central part of the optimized trimer was used as input for band-structure calculations with the valence effective Hamiltonian (VEH) technique;[13] this method provides accurate determinations of essential electronic parameters in organic compounds, such as ionization potential, electron affinity, and band-gap values. From the optimized geometric structure of **1**, it appears that the polymer backbone can be simply envisioned as a regular succession of naphthalene and anthracene units that are linked to each other by single carbon–carbon bonds. The bond lengths and angles along the conjugated backbone obtained from the calculations are indeed almost identical to the ones optimized in discrete naphthalene and anthracene molecules. The most important electronic parameters calculated for the unsubstituted form of polymer **1** are given in Table 1 together with those obtained for naphthalene and anthracene. The calculated band gap for the polymer is 2.1 eV, a value in excellent agreement with the long wavelength absorption in the UV spectrum of the substituted polymer (Fig. 3). The bonding–antibonding electronic patterns appearing on the polymer electronic bands have been analyzed and compared to those obtained for the electronic levels of naphthalene and anthracene. It appears that the HOMO of the polymer arises from an antibonding interaction between the HOMOs of naphthalene and anthracene while the LUMO of the polymer comes from the bonding interaction between the LUMO of naphthalene and LUMO +1 of anthracene.

Table 1. VEH-calculated values of solid-state ionization potential (IP), electron affinity (EA), and energy gap (Eg) for the unsubstituted polymer **1**, naphthalene, and anthracene. Values in eV.

Compound	IP	EA	Eg
Polymer **1** [a]	4.96	−2.81	2.15
Naphthalene	6.20	−1.60	4.60
Anthracene	5.65	−2.17	3.48

[a] Parent compound without hexyl substituents.

The properties of the polymer are currently under investigation with a view to its application in the areas mentioned in the introduction.

[10] Single crystals of **7** were grown from toluene. 6565 unique reflections were collected on an Enraf-Nonius Turbo-CAD4 diffractometer with Ni-filtered $Cu_{K\alpha}$ radiation from a rotating-anode generator. ($\lambda = 1.542$, $\omega/2\theta$ scan mode, $2\theta_{max} = 120°$, nominal resolution $\lambda/2 \sin\theta_{max} = 0.89$ Å. Ψ scan absorption correction, $T = 260$ K). The data were corrected for radiation damage (12% reduction in intensity of three reference reflections). Space group triclinic, $P\bar{1}$, $Z = 2$ with two toluene per formula unit in the asymmetric unit, $a = 12.390(4)$, $b = 16.164(6)$, $c = 18.96(2)$ Å, $\alpha = 87.67(5)$, $\beta = 83.30(5)$, $\gamma = 68.66(3)°$, $V = 3514(4)$ Å^3. The structure was determined by direct methods using program SIR92 and refined with SHELX76 and SHELX93 on the basis of 3643 reflections with $|F_o| \geq 3\sigma(|F_o|)$. H atoms bonded to the aromatic C atoms were placed in their calculated positions. Two atoms in one of the aliphatic chains, C45 and C49 are twofold disordered with 0.5 occupancy. The cocrystallized toluene molecules are fully ordered. The relatively high crystallographic R factor (0.15) is associated with radiation damage of the crystal, with only 55% of the data above $3\sigma(|F_o|)$, and with the atom disorder. The extended aromatic system is virtually planar; with no atom deviating more than 0.105 Å from the weighted least-squares plane [11].
[11] Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen on quoting the depository number CSD-58461.

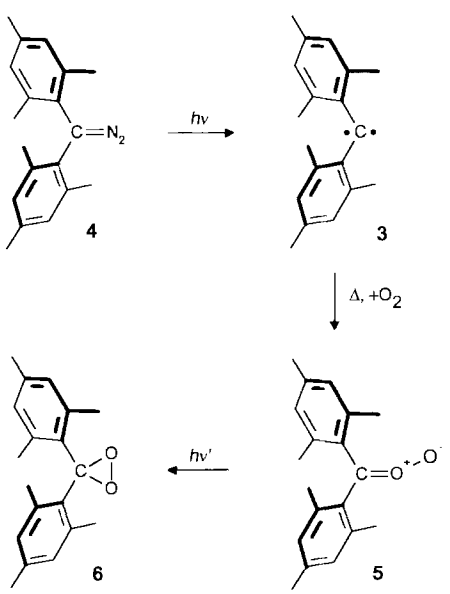
Dimesityldioxirane—A Dioxirane Stable in the Solid State**

Andreas Kirschfeld, Sengodagounder Muthusamy, and Wolfram Sander*

Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday



Since the discovery by Murray and Jeyaraman[1] in 1985 that dimethyldioxirane (**1**) can be synthesized and is stable in acetone, **1** has become an important and powerful oxidant in organic chemistry.[2–5] The only other dioxirane that has found synthetic application is methyl (trifluoromethyl)dioxirane (**2**), introduced by Curci et al.[6] Dioxiranes **1**, **2**, and a few other alkyl-substituted derivatives were synthesized by the oxidation of the corresponding ketones with Caroate,[7] a method originally developed by Edwards and Curci.[8, 9] These dioxiranes are moderately stable in solution at room temperature, but cannot be isolated as pure compounds. Two stable perfluorinated dioxiranes seem to have been synthesized by Talbott and Thompson by fluorination of the lithium salts of ketone hydrates.[10] Recently Russo and DesMarteau[11] reported the synthesis of difluorodioxirane from FCOOF and CsF/ClF. This gaseous dioxirane is stable at room temperature for several days.

1 R = CH_3
2 R = CF_3

The most general route to dioxiranes is the oxidation of diazo compounds either directly with singlet oxygen[12] or by first photochemically generating the carbenes followed by a thermal reaction with triplet oxygen.[13] Both routes lead to the highly labile carbonyl *O*-oxides as primary products, which upon irradiation into their strong UV/Vis absorptions (370–550 nm) rearrange to dioxiranes. These intense absorptions enable the identification of the carbonyl oxides by time resolved spectroscopy (laser flash photolysis, LFP) in solution at room temperature if the lifetime is of the order of μs to ms,[12, 14–17] or by matrix isolation spectroscopy at cryogenic temperatures.[13] Although carbene oxidation has been used to generate a variety of dioxiranes, this method has not yet been applied to synthesis on a preparative scale, because the solvent, the conditions of photolysis, and the temperature have to be carefully controlled to avoid carbene reactions (such as dimerization and insertion into the solvent) or secondary reactions of the dioxiranes (rearrangement to esters or reduction to ketones).

Dimesitylcarbene **3** exhibits a lifetime in solution at room temperature which is two orders of magnitude larger than that of diphenylcarbene (200 vs. 1.7 µs),[18] but the reactivity of these two carbenes towards O_2 is roughly equal.[19] Thus, although the sterically demanding substituents prevent most bimolecular chemistry, the small O_2 molecule is able to approach the carbene center almost unhindered. In an LFP study Scaiano et al. were able to generate carbonyl oxide **5** as a transient species by laser photolysis of oxygen-containing solutions of diazomethane **4**. In acetonitrile **5** shows an intense absorption band at 390 nm and a first-order decay of its intensity several orders of magnitude slower than other carbonyl oxides.[19] This makes **3** an ideal candidate for the study of the oxidation of carbenes in solution.

Here we describe the first synthesis of a dioxirane isolable at room temperature—both in solution and in pure form—by the

oxidation of a diazo compound. Dimesityldiazomethane **4** was dissolved in an oxygen-saturated mixture of $CFCl_3$ and $(CF_2Br)_2$, which formed a transparent glass[20] upon cooling to 77 K. Irradiation of this glass at 77 K into the absorption maximum of **4** (λ_{max} = 498 nm, irradiation at $\lambda > 515$ nm) produced a new species with an intense, broad absorption at 398 nm, very similar in band position and shape to that of **5**[19] (Fig. 1). After

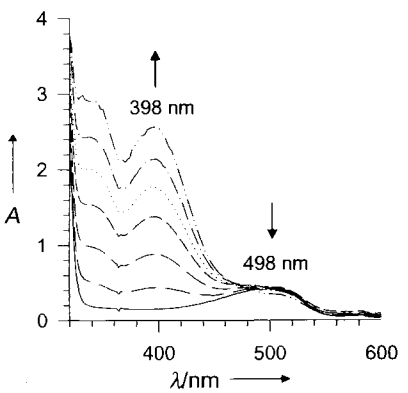

Fig. 1. UV/Vis absorption spectra obtained after irradiation of diazo compound **4** ($\lambda > 515$ nm, 77 K). Solid line: absorption spectrum of **4** before photolysis. The other spectra were recorded at 30 min intervals during photolysis.

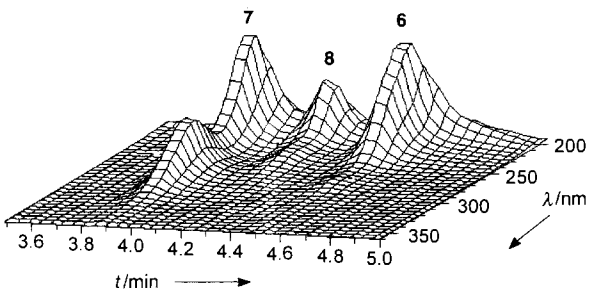
the glass was melted at 160 K and the solution warmed to 195 K (−78 °C), the yellow compound persisted for several hours, while at 243 K (−30 °C) it disappeared within several minutes. The yellow species is extremely photolabile, and rapidly disappears upon irradiation at $\lambda > 475$ nm. The absorption spectrum, the observed photochemistry, and the product analysis after warming indicate that the yellow intermediate is carbonyl oxide **5**. After warming the final reaction mixture to room temperature, the solvent was evaporated and the products were separated by reversed-phase HPLC (Fig. 2). Two of the prod-



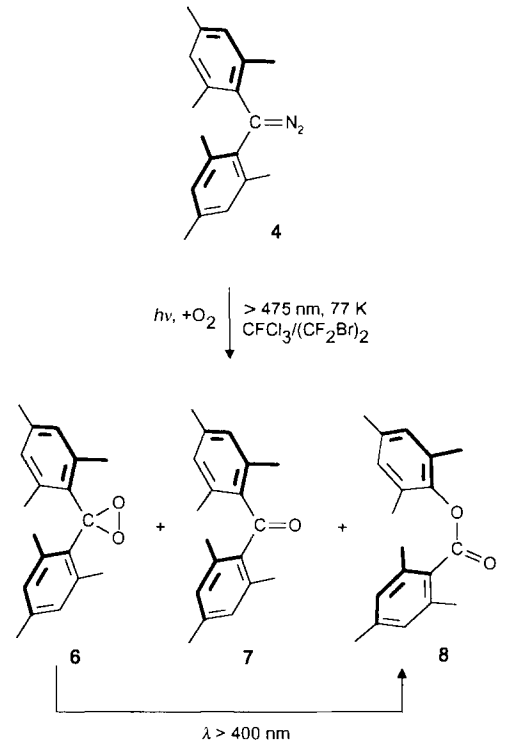


Fig. 2. HPLC separation of the reaction mixture after photolysis of **4** ($\lambda > 475$ nm, 77 K).

ucts were identified as dimesityl ketone **7** (9% yield by ^{1}H NMR) and mesityl mesitoate **8** (23% yield) by comparison with authentic material. Several minor products have not yet been identified.

The main product, which was obtained in up to 55% yield, was characterized by ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry as dimesityldioxirane (**6**). The ^{13}C NMR chemical shift of the quaternary carbon atom of the dioxirane ring was observed at $\delta = 103$, close to the value reported for **1** ($\delta = 102$).[2a, b] In solution at room temperature or as crystalline solid, dioxirane **6** slowly rearranges to yield ester **8** as the only product (in $CDCl_3$ less than 10% conversion per day). Upon irradiation with $\lambda > 400$ nm, **6** rearranges quantitatively to **8** within several minutes.

To synthesize larger quantities of **6**, the irradiation of **4** was performed in $CFCl_3$ at 183 K. The yield of dioxirane **6** was still 50% on irradiation with $\lambda > 495$ nm (30% with $\lambda > 475$ nm irradiation), and up to 10 mg of the dioxirane could be obtained in a single run. There was no significant dependence of the yield on the ratio of $CFCl_3$ and $(CF_2Br)_2$ in the solvent mixture.

In summary, we have shown that the diazo route is suitable for the synthesis of a dioxirane on a preparative scale. The mesityl groups not only stabilize **6**, but also allow observation of an intermediate, which is most likely carbonyl oxide **5**. This would be the first carbonyl oxide to be stable in solution at low temperature. We are currently exploring the chemistry of **5** and **6** and the scope of this new synthesis of dioxiranes.

Experimental Procedure

Photolyses were carried out with a Hg high-pressure arc lamp (Osram HBO 500 W in an Oriel Lamp housing with quartz optics) and suitable cut-off or interference filters. Compounds **4** [21], dimesitylketone **7** [22], and mesityl mesitoate **8** [23] were prepared and purified according to literature procedures.

Preparation of **6** in an organic glass: A solution of 2.9×10^{-3} mmol of **4** in 2 mL of a mixture of $CFCl_3$ and $(CF_2Br)_2$ (1:1 v/v) was saturated with oxygen at −20 °C for 20 min and then cooled to 77 K to form a transparent glass. After irradiation with $\lambda > 475$ nm for 3 h the mixture was warmed to room temperature, and the solvent removed under reduced pressure. The residue was dissolved in methanol and purified by HPLC (RP-18 phase with methanol as eluent).

Preparation of **6** in solution: A solution of 20 mg (0.07 mmol) of **4** in $CFCl_3$ (25 mL) was purged with oxygen at 183 K for 15 min. The mixture was irradiated with $\lambda > 495$ nm with continued oxygen purging at the same temperature. The reaction was monitored by HPLC, and **4** completely disappeared after 4 h irradiation. The solvent was removed under reduced pressure, and the dioxirane (colorless crystals) purified as described above.

M.p. 62–64 °C (dec); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.21 (s, 12H), 2.26 (s, 6H), 6.82 (s, 4H); ^{13}C NMR ($CDCl_3$): δ = 20.77 (CH_3), 21.46 (CH_3), 103.06 (C), 130.75 (CH), 131.10 (CH), 137.70 (C), 138.94 (C); MS: *m/z* (%): 300 (59, $[M + NH_4]^+$), 283 (100, $[M + H]^+$), 267 (20, $[M + H - O]^+$); IR (CCl_4): $\tilde{\nu}$ = 2923

(m), 1612 (m), 1571 (w), 1456 (m), 1295 (w), 1242 (m), 881 (m), 852 (s) cm^{-1}; UV/VIS (CH_3OH): $\lambda_{max}(\varepsilon)$ = 206 (41000), 278 nm (1700).

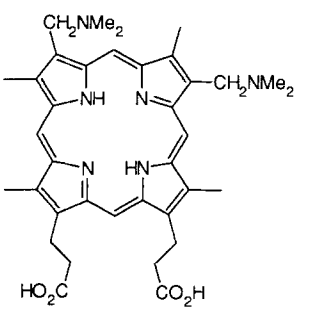
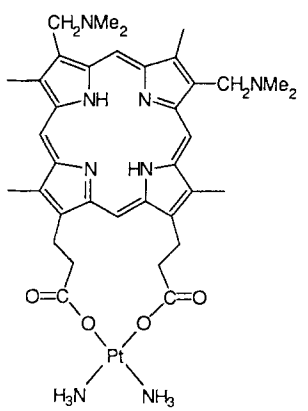
Platinum(II) Complexes with Porphyrin Ligands—Additive Cytotoxic and Photodynamic Effect**

Henri Brunner* and Herbert Obermeier



Porphyrins are used in photodynamic therapy for the treatment of tumors.[1, 2] When irradiated with light of a wavelength of about 630 nm, the porphyrins act as photosensitizers. The singlet oxygen that is formed kills the cell.[1, 3]

Porphyrins are accumulated in the tumor tissue. There are two explanations: According to the older theory the uptake occurs through low density lipoproteins (LDL), which play an important role in cholesterol metabolism. Since tumor cells show a higher LDL receptor activity than normal cells, a specific enrichment in malignant tissue results.[4] The newer theory ascribes the selectivity to the lower pH value of tumor tissue relative to normal tissue, which implies a larger proportion of neutral particles that penetrate the cell membrane in the tumor.[5, 6]



The cytostatic drugs diammine(dichloro)platinum(II) (cisplatin) and diammine(cyclobutanedicarboxylato)platinum(II) (carboplatin) have become the most important cancer chemotherapeutics during the last years.[7, 8] However, they act unspecifically and damage all rapidly growing body tissues as well as the tumor.

Making use of the enrichment of porphyrins in malignant tissue we are now trying to accumulate cytostatic platinum complexes specifically in the tumor tissue. We bind the $(NH_3)_2Pt$ moiety to the carboxylato groups of the two propionic acid side chains of porphyrins,[9] thereby obtaining systems similar to carboplatin.

Because of the carrier properties of porphyrins a specific enrichment of the cytostatic platinum complex in the tumor tissue should be achieved (drug targeting). In addition, on irradiation the porphyrins should be tumor-destructive. With the ligand/complex pair **1**/**2** as example we now prove the additivity of the two effects in cell culture experiments.

1

2

The synthesis of ligand **1** started from deuteroporphyrin dimethyl ester.[10] The two dimethylamino functions in 3- and 8-position were introduced by substitution with the "Eschenmoser salt" *N,N*-dimethylmethyleneammonium iodide.[11] After acidic ester hydrolysis ligand **1** was obtained.[12] To activate cisplatin for complexation, it was hydrolyzed with silver nitrate and chromatographed on a basic ion exchanger.[13] Diammine(diaqua)platinum(II) hydroxide was formed, which reacted with **1** in ethanol/water to give the porphyrin platinum(II) complex **2**[14].

The additivity of the cytotoxic effect of platinum and the photodynamic activity of the porphyrin in **1** and **2** were tested in vitro with the MDA-MB-231 mammatumor cell line. The seeding of the cells, the addition of the compounds, and the workup were carried out as previously described.[13, 15] During the three days of incubation of the compounds in the dark, the cell proliferation was inhibited by the platinum effect of the complex. Afterwards the cell cultures were irradiated for 20 minutes with an IR lamp that emits incoherent, red light within the wavelength range 600–800 nm. To determine the vitality of the cells the cell cultures were colored with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and the concentration of cells was obtained by measuring the optical

density in a photometer. The concentrations of ligand **1**, complex **2**, a **1**/cisplatin mixture, cisplatin, and photofrin were 10^{-5} mol L^{-1}. Photofrin, an oligomer fraction of hematoporphyrin derivative enriched to 80–90%, is at present the only phorphyrin used in clinical tests.[2]

The data of Table 1 correspond to the vitality of the cells with respect to untreated control groups, which define 100%. Ligand

Table 1. Comparison of the antitumor activity of ligand **1**, complex **2**, **1**/cisplatin mixture, cisplatin, and Photofrin in a concentration of 10^{-5} mol L^{-1} in vitro towards the MDA-MB-231 mammatumor cell line in water. The values are the average of 16 measurements, which varied by about 10–20%.

	without irradiation	with irradiation
1	>100	81
2	63	38
1/cisplatin	53	14
cisplatin	49	44
Photofrin (10 μg mL^{-1})	100	20

1 was not active without irradiation; it became tumor-destructive only on irradiation, reducing the cell proliferation to about 81%. By complexation with platinum the activity was improved. Complex **2** had cytostatic potential even without irradiation and reduced the vitality of the cells to values of approximately 63%. On irradiation the activity of the complex increased, and the cell proliferation was reduced to 38%. This demonstrates the additivity of the phototoxic effect of the porphyrin and the cytostatic effect of the platinum in the complex. Cisplatin alone and together with **1** reduced the cell proliferation to about 50%. On irradiation of the combination **1**/cisplatin the additional photodynamic effect of ligand **1** operated (reduction to 14%). Photofrin attained vitality values of 20% in a concentration of 10 μg mL^{-1}. If a molecular weight of 1000 is assumed for Photofrin, the concentration is 10^{-5} mol L^{-1}.

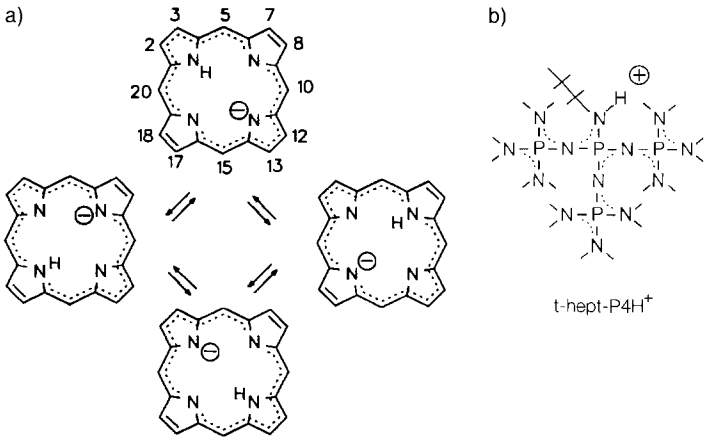
Free Acid Porphyrin and Its Conjugated Monoanion**

Jürgen Braun, Christian Hasenfratz, Reinhard Schwesinger, and Hans-Heinrich Limbach*

Porphyrin ($PorH_2$) and its derivatives are amphoteric, and the two inner protons are highly mobile between the four nitrogen atom sites (Scheme 1). This tautomerism takes place both in the



Scheme 1. The tautomerism of porphyrin $PorH_2$ according to ref. [3c,i,j].

liquid[1, 2] and in the solid state[3, 4] and has been studied from a theoretical standpoint as a model reaction for double proton transfer in polyatomic molecules.[5] The basicity of $PorH_2$, which led to the frequently used name "metal-free base porphyrin", enables a protonation by acids generating the stable dication $PorH_4^{2+}$,[1c, d] probably via a monoprotonated intermediate $PorH_3^+$. The acidity of porphyrin is manifested in the release of two protons during the formation of metalloporphyrins. However, so far the term "free acid porphyrin" has not been justified because the conjugated metal-free monoanion $PorH^-$ (Scheme 2)—judged as unstable[6]—has never been observed experimentally. This paper shows that $PorH^-$ is a stable species which can easily be generated from $PorH_2$ by reaction with very strong organic bases in aprotic medium, and can be characterized by NMR and UV/VIS spectroscopy. Moreover, it is shown that $PorH^-$ is also subject to a degenerate intramolecular tautomerism of the remaining single proton (Scheme 2a). The dynamics observed for this process shed new light on the mechanism of the porphyrin tautomerism.

Scheme 2. a) The tautomerism of the conjugated porphyrin monoanion $PorH^-$. b) Structure of the protonated phosphazene base t-hept-P4H$^+$ [9].

To avoid complications in the NMR experiments arising from ^{14}N quadrupole relaxation, ^{15}N-labeled porphyrin[7] was employed as a precursor of $PorH^-$. The choice of the base was critical. Conventional inorganic bases immediately form metalloporphyrins such as $PorM^-M^+$ or PorM;[8] neutral organic bases B are required which, on one hand, must be strong enough to remove an inner proton of $PorH_2$. On the other hand, the structure of the base should be such that fast intermolecular proton transfer between BH^+ and $PorH^-$ is slow on the NMR time scale. Higher phosphazene bases, for example, "t-hept-P4"≡1,1,1,5,5,5-hexakis(dimethylamino)-3-(1,1,2,2-tetramethylpropyl)imino-3-[tris(dimethylamino)phosphoranylidene]amino-1λ^5,3λ^5,5λ^5,-1,4-triphosphazadiene (shown in its protonated form in Scheme 2b) were suitable. The syntheses and properties of phosphazene bases have been described recently.[9]

Figure 1a depicts the superposed experimental and calculated NMR signals of the inner protons of ^{15}N-labeled porphyrin in [D$_8$]THF.[3j, 10] Because of the low solubility of $PorH_2$, the concentration was only 1 mM. As established previously,[3j] the signal of the inner protons of $PorH_2$ appears at $\delta = -3.5$ and exhibits a doublet at low temperature, arising from scalar coupling with the attached ^{15}N nucleus and indicating localized inner protons. The coupling constant is $^1J_{^1H,^{15}N} \approx 98$ Hz and decreases slightly with increasing temperature. A differential line broadening of the $^1H-^{15}N$ doublet, observed at low temperature, arises from reduced molecular mobility and interference between the $^1H-^1H$ and the $^1H-^{15}N$ dipolar interaction, as well as the chemical shift anisotropy.[11] As the temperature is increased, rotational diffusion becomes faster, and the asymmetry disappears. At the same time, a doublet–pentet transition is observed at about 250 K, arising from a fast intramolecular proton transfer between all four nitrogen atoms. The line-shape changes were calculated[10, 3h] by varying the rate constant $2k^{HH}$, which corresponds to the inverse average lifetime of a given tautomer in Scheme 1.

In the presence of phosphazene bases, the solubility of porphyrin is drastically increased. The superposed experimental and calculated high field signals of a 15 mM solution of $PorH_2$ in [D$_8$]THF in the presence of a twofold excess of t-hept-P4 are depicted in Figure 1b. Signs of $PorH_2$ can no longer be detected, but a new species is observed. At 152 K again a $^1H-^{15}N$ doublet is observed at $\delta = -2.7$ typical for an inner porphyrin proton (Fig. 1b). The scalar coupling constants $^1J_{^1H,^{15}N}$ are similar to those of the parent compound. The differential line broadening is more pronounced as the spectra were taken at lower temperatures. As the temperature is raised, the doublet–pentet transition proving a fast intramolecular tautomerism of a central porphyrin proton could be observed as in the parent compound; however, the transition occurs already around 200 K instead of 250 K, which indicates that the tautomerism of the new porphyrin species is much faster than in the parent compound. This observation can only be explained by the formation of a stable conjugated monoanion $PorH^-$. Its structure is confirmed by analyzing the signals of protons attached to the peripheral carbon atoms. At 152 K, two exchange-broadened lines arising from the methine protons 5H/20H and 10H/15H appear at $\delta = 9.79$ and 9.73 ($PorH_2$: $\delta = 10.5$[1h]). Furthermore, as expected, four exchange-broadened singlets appear at $\delta = 9.04$, 8.90, 9.15, and 8.93 for the β-pyrrole protons, which are tentatively assigned to the 7H/18H, 8H/17H, 2H/3H, and 12H/13H positions. These signals broaden and coalesce into a single line at about 200 K. In contrast, at low temperatures $PorH_2$ contributes only two β-pyrrole signals to the ^1H spectra.[1h] The NMR signals of t-hept-P4 and t-hept-P4H$^+$ were not analyzed. Subsequent NMR experiments showed that the formation of conjugated porphyrin monoanion is not restricted to the parent compound but is a common feature of substituted porphyrins, for example, tetraphenylporphyrin (TPP) and octaethylporphyrin (OEP).

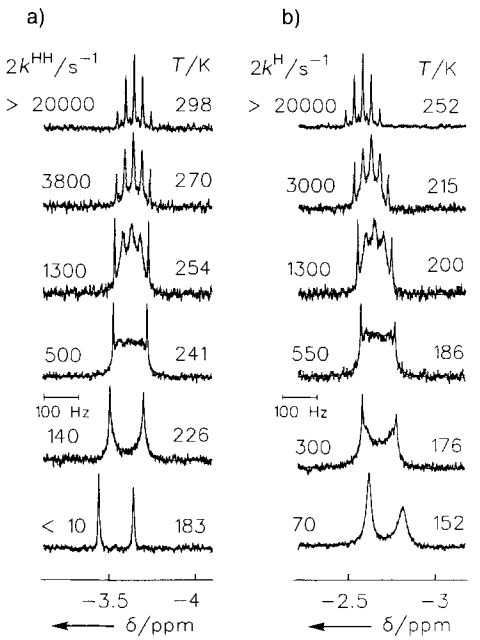

Fig. 1. Superposed experimental and calculated variable-temperature 500 MHz ^1H NMR signals of the inner protons of ^{15}N-labeled $PorH_2$ dissolved in [D$_8$]THF (a) (adapted from ref. [3j]) and $PorH^-$ (15 mM) generated by dissolving the parent compound together with a twofold excess of t-hept-P4 (b). The sample contained approximatively 34% $PorD^-$ which does not contribute to the signals. 6.5 μs 60° pulses, 9 kHz spectral width, 3.5 s repetition time, up to 3000 scans for (a) and 600 for (b) [10].

The changes in the UV/VIS and fluorescence spectra upon deprotonation of $PorH_2$ are illustrated in Figure 2. The spectra of $PorH_2$ (Figs. 2a and 2b) were previously recorded and discussed.[6, 12] The transition of lowest energy (Q_x band, $S_0 \rightarrow S_1^x$) appearing for $PorH_2$ at 615 nm is shifted in $PorH^-$ to 600 nm (Fig. 2c). The assignment to the 0-0 transition is confirmed by the fluorescence data (Fig. 2d). No evidence of a band calculated to appear at 700 nm[6] could be found, but the Soret band of $PorH_2$ at 390 nm is shifted to 420 nm in the monoanion and is more intense. In addition, major spectral changes are observed in the region between 480 and 580 nm.

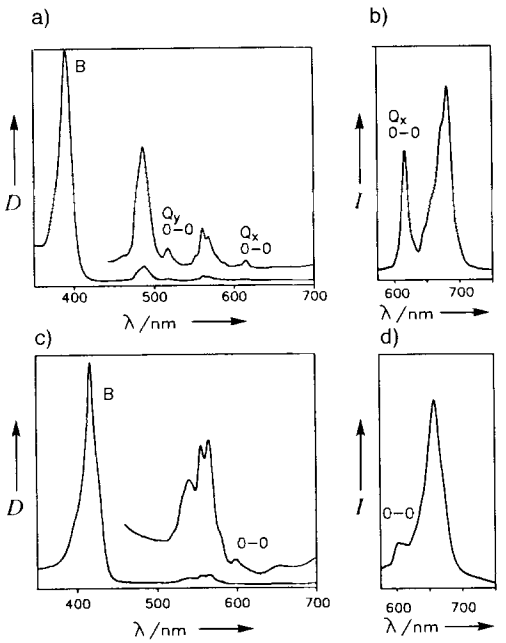

Fig. 2. a) Room temperature UV/VIS and b) fluorescence spectra of $PorH_2$ dissolved in THF, excitation wave length 570 nm. c) and d) Corresponding spectra of $PorH^-$/t-Hept-P4H$^+$ in THF. *D*: optical density; *I*: Intensity.

To estimate the pK_a of free acid porphyrin, a titration experiment of the more soluble OEP with the base t-bu-P4≡3-*tert*-butylimino-1,1,1,5,5,5-hexakis(dimethylamino)-3-[tris(dimethylamino)phosphoranylidene]amino)-1λ^5,3λ^5,5λ^5-1,4-triphosphazadiene[13] was performed. The deprotonation of OEP was followed by monitoring the Soret band shift. At concentrations of 0.01 M of t-bu-P4 in dry THF, OEP was deprotonated to approximately 85% at room temperature. From this result we extrapolate using a procedure described previously[13] an absolute pK_a value for OEP of 37 to 38 in acetonitrile. For the parent compound $PorH_2$ we expect a slightly lower value of about 35 to 36.

In conclusion, we have shown that the conjugated monoanion $PorH^-$ of porphyrin is a stable species in aprotic solvents and can easily be generated by dissolving the parent compound with an appropriate strong metal-free base. The labels "free acid porphyrin" and "free base porphyrin" are, therefore, equally justified. The tautomerism of $PorH^-$ is much faster than that of $PorH_2$. This observation can be explained by the fact that the single proton transfer in $PorH^-$ is degenerate (Scheme 2a) but leads to *cis* intermediates of higher energies in the case of $PorH_2$ (Scheme 1).[3j] The tunneling probabilities at low temperatures are, therefore, much higher for $PorH^-$ than for $PorH_2$, at comparable barrier heights. Studies of the kinetic H/D and solid state isotope effects of $PorH^-$ tautomerism, which could confirm this interpretation, are under way.

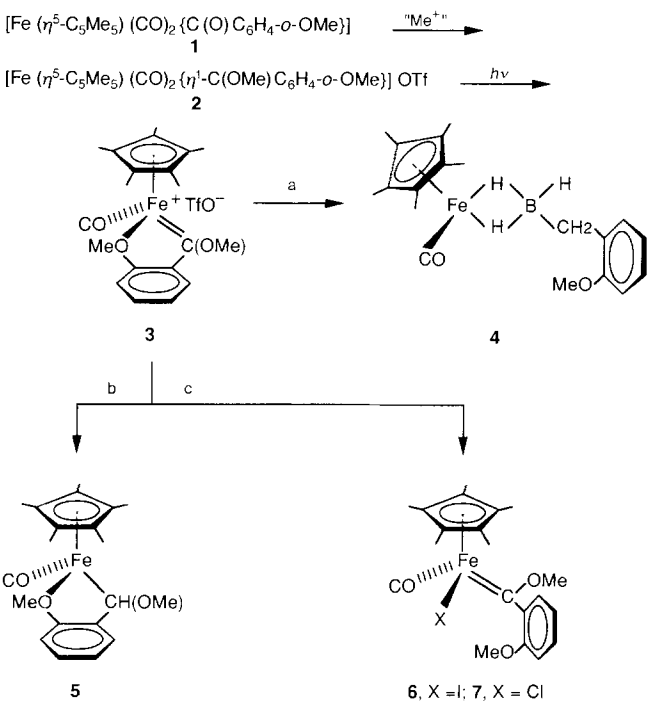
A Carbene–Iron Chelate Complex as a Source of a Ferraborane Derivative**

Sylvain Nlate, Pierre Guénot, Sourisak Sinbandhit, Loic Toupet, Claude Lapinte, and Véronique Guerchais*



Carbene complexes supplemented by a labile ligand are of interest because such ligands protect potentially vacant coordination sites for subsequent reactions.[1, 2] Moreover, migration of the incoming substrate to the carbene fragment should be promoted, since the resulting 16-electron intermediate can be stabilized by further chelation.[1] Although intramolecular reactions of carbene complexes of Group 6 transition metals have been widely developed,[1, 3] examples involving iron complexes are still scarce.[4] This led us to investigate the properties of the readily available anisyl carbene complex **3** (Tf = trifluoromethanesulfonyl), in order to examine the impact of the labile *ortho* methoxy group on the reactivity. We now report the synthesis and X-ray crystal structure of the organoborato complex **4** with an η^2-coordinated borato ligand.[5, 6]

The C,O-chelated carbene complex **3** was prepared in 76% yield by O-methylation of the corresponding acyl derivative **1**, followed by photochemically induced loss of CO and intramolecular coordination of the *ortho* methoxy group of the carbene complex **2**. Treatment of a THF solution of complex **3** at −80 °C with two equivalents of $NaBH_4$ resulted in almost quantitative formation of **4**, which was isolated as brown crystals (Scheme 1). The new compound **4** was identified on the basis of high-resolution mass spectrometry, IR and multinuclear NMR spectroscopy, elemental analysis, and crystal structure analysis.

In the ^{1}H NMR spectrum (C_6D_6), the bridging hydrogen atoms give rise to a broad pseudo-quartet at $\delta = -17.87$ (2H, $^1J(B,H) \approx 43$ Hz, whereas the terminal B–H resonates at $\delta = 6.35$ (pseudo-q, 1H); the magnitude of $^1J(B,H)$ (ca. 108 Hz) is characteristic of a B–H terminal hydrogen. The methylene group appears as a broad signal at $\delta(^1H) = 2.60$, which is transformed into a doublet of triplets ($^3J(H,BH) = 5$, $^3J(H,BH_2) = 2.5$ Hz) upon ^{11}B decoupling (55 ppm). Although positioned downfield, the boron chemical shift compares well with those reported for the η^2-hydroborato Ta complexes.[7] The nondecoupled ^{13}C NMR spectrum (C_6D_6) of **4** exhibits a triplet for the carbonyl ligand ($^2J(C,H) = 7$ Hz), which confirms the presence of two Fe–H bonding interactions. The Mössbauer spectrum shows the characteristic parameters (IS = 0.104 mm s^{-1} vs Fe, QS = 1.898 mm s^{-1}) of a diamagnetic iron(II) species;[8] the borane ligand is a three-electron donor, as required for an 18-electron count at iron(II). In agreement with the proposed structure, the mass spectrum shows ions at $m/z = 133$ (100%) for $[BH_2CHC_6H_4$-*o*-OMe$]^+$ and 232 (11%) for $[Fe(C_5Me_5)(CO)(BH_2)]^+$.

Marder (University of Waterloo, Canada) for insightful discussions. We also thank F. Varret and J. Linarès (University of Paris 6) for assistance with the Mössbauer spectra.

Scheme 1. Reactions of nucleophiles with complex **3**. a) $NaBH_4$ (2 equiv) in THF; −80 °C; b) $NaBH_4$ in THF/MeOH (9/1) or $LiBEt_3H$ (1 equiv) in THF; −80 °C; c) nBu_4NI or $(PPh_3)NCl$ in CH_2Cl_2.

The X-ray structure analysis of **4** reveals the presence of two molecules in two slightly different conformations in the asymmetric unit. The carbonyl ligand of the first molecule is disordered between two positions, and in the second molecule (Fig. 1) the carbon atoms of the C_5Me_5 ligand show a particularly large thermal coefficient. Of the atoms coordinated to the boron center, only the carbon and the bridging hydrogen atoms are located with normal B–H and B–C bond lengths.[6, 10] The terminal hydrogen atom was not found with a Fourier difference, but set in the theoretical position before the last refinements.

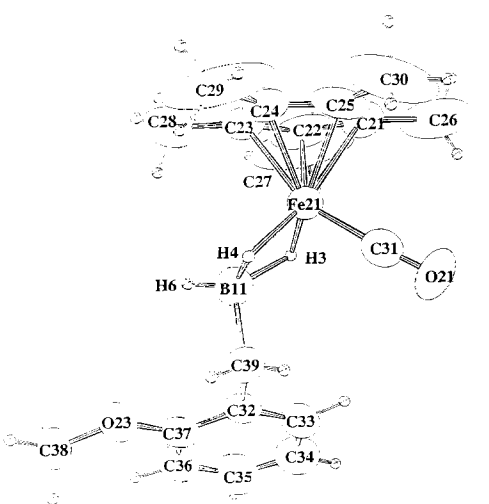

Fig. 1. Crystal structure of **4** (ORTEP diagram of the molecule with the ordered CO ligand, thermal ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: C39–B11 1.57(2), C32–C39 1.50(2), Fe21–C31 1.76(1), O21–C31 1.13(2), O23–C37 1.36(1), O23–C38 1.38(1); Fe21–C31–O21 175.(1), O23–C37–C32 118.(1), C37–O23–C38 121.(1).

Treatment of **3** with one equivalent of $LiBEt_3H$ in THF afforded the complex **5** (Scheme 1) as the single product (93% yield). According to the ^1H and ^{13}C NMR spectra, the reaction gave exclusively one diastereoisomer. Similarly, reaction of complex **3** with $NaBH_4$ in THF/MeOH (9/1) afforded **5**; under these reaction conditions, the formation of a $MeOH-BH_3$ adduct inhibits any further reduction to **4** (Scheme 1). We have found that other nucleophiles, such as halides, displace the coordinated methoxy group in **3**. Thus, reaction of **3** with nBu_4NI or $(PPh_3)_2NCl$ selectively afforded the carbene halide complexes **6** (X = I) and **7** (X = Cl), respectively, in 85% yield. This result demonstrates the high lability of the chelated *ortho* methoxy group – generally, O-demethylation is observed in the methoxycarbene, which regenerates the starting acyl complexes.[11]

Reduction of alkoxycarbene complexes $[\{Fe\}=C(OR')R]^+$ to give alkyl derivatives $[\{Fe\}-CH_2R]$ has been observed under certain reaction conditions.[4, 12] This process probably involves an alkylidene complex $[\{Fe\}=CHR]^+$ derived from acid-catalyzed elimination of the α-alkoxy group;[13] however, there is no precedence for the formation of such a complex in reductions with boranes. Reaction of the dicarbonyl complex **2** with $NaBH_4$ in pure THF afforded the η^1-benzyl derivative $[Fe(\eta^5\text{-}C_5Me_5)(CO)_2\{\eta^1\text{-}CH_2C_6H_4\text{-}o\text{-}OMe\}]$. The methylene group was formed under the same reaction conditions as those used in the synthesis of complex **4**. Formation of the borohydride complex **4** may, therefore, proceed with formal insertion of a molecule of BH_3 into an iron–carbon bond.

Related insertion reactions of boranes have been reported only for coordinatively unsaturated complexes (Rh,[14] Ta,[7] Zr[15]). The formation of **4** is probably promoted by the facile dissociation of the *ortho* methoxy group as demonstrated above. This is supported by the fact that the acetonitrile carbene complex $[Fe(\eta^5\text{-}C_5Me_5)(CO)(CH_3CN)\{C(OMe)Me\}]OTf$[16] exhibits the same behavior; the related complex $[Fe(\eta^5\text{-}C_5Me_5)(CO)\{\eta^2\text{-}H_2BH(CH_2CH_3)\}]$ is similarly obtained by $NaBH_4$ reduction.[17] Moreover, the boron ligand is readily displaced by addition of PMe_3 to compound **4**, which results in the formation of the adduct $[Me_3P-BH_2(CH_2C_6H_4\text{-}o\text{-}OMe)]$ and the hydrido complex $[Fe(\eta^5\text{-}C_5Me_5)(CO)(PMe_3)(H)]$.

Experimental Procedure

3: A CH_2Cl_2 solution (10 mL) of **2** (0.547 g, 1 mmol) was irradiated for 3 h. After removal of the solvent under vacuum, the solid was washed with ether. Crystallization from CH_2Cl_2/Et_2O gave 0.498 g (96%) of **3** as brown crystals. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.65 (m, Ar), 7.43 (m, Ar), 7.21 (m, Ar), 4.78 (s, 3H, OMe), 3.95 (s, 3H, OMe(Ar)), 1.61 (s, 15H, C_5Me_5); $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$): δ = 325.8 (=C), 213.1 (CO), 167.7, 137.2, 134.8, 125.0, 118.9, 115.9 (Ar), 95.0 (C_5Me_5), 71.4 (OMe), 69.9 (OMe(Ar)), 9.5 (C_5Me_5); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1977s (ν(CO)); elemental analysis for $C_{21}H_{23}O_6FeSF_3$: calcd C 48.66, H 4.86; found C 48.70, H 4.80%.

4: In a typical reaction, **3** (0.518 g, 1 mmol) was treated with $NaBH_4$ (0.076 g, 2 mmol) in THF (15 mL) at −80 °C. The initial brown color turned into yellow-orange at −30 °C. After evaporation of THF to dryness, the residue was extracted with pentane (2 × 10 mL). Cooling the resulting solution to −20 °C gave 0.301 g (85%) of **4** as brown microcrystals. ^1H NMR (300 MHz, C_6D_6): δ = 7.29 (dd, ^3J(H,H) = 7, ^4J(H,H) = 1.7 Hz, 1H, Ar), 7.06 (td, ^3J(H,H) = 8, ^4J(H,H) = 1.8 Hz, 1H, Ar), 6.93 (td, ^3J(H,H) = 7, ^4J(H,H) = 1 Hz, 1H, Ar), 6.65 (d, ^3J(H,H) = 8 Hz, 1H, Ar), 6.35 (br. pseudo-q, 1H, ^1J(B,H) ≈ 108 Hz, $BH_{terminal}$), 3.46 (s, 3H, OMe(Ar)), 2.60 (br.m, 2H, CH_2), 1.39 (s, 15H, C_5Me_5), −17.87 (br. pseudo-q, 2H, ^1J(B,H) ≈ 43 Hz, $B\text{-}H_{bridging}$); $^1H\{^{11}B$ (55 ppm)$\}$ NMR (C_6D_6): δ = 6.35 (br.s, $BH_{terminal}$), 2.60 (dt, ^3J(H,BH) = 5, ^3J(H,BH_3) = 2.5 Hz, CH_2) −17.87 (br.s, $BH_{bridging}$); $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$): δ = 218.8 (CO), 157.4, 134.8, 130.3, 125.3, 120.9, 110.8 (Ar), 90.8 (C_5Me_5), 55.0 (OMe(Ar)), 33.3 (br.m, BCH_2), 10.1 (C_5Me_5); $^{11}B\{^1H\}$ NMR (96.295 MHz, C_6D_6/C_6H_6, Et_2OBF_3 as external standard): δ = 55.33 (br.s); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1962s (ν(CO)); zero field Mössbauer data (298 K): IS = 0.104 mms^{-1} vs Fe, QS = 1.898 mms^{-1}; high resolution MS (70 eV): *m/z* calcd for $[M-2H]^+$ ($C_{19}H_{25}O_2{}^{11}B^{56}Fe$) 352.1297 (found 352.130), $[M-2H-CO]^+$ 324.1348 (found 324.134), $[M-3H-CO]^+$ 323.1269 (found 323.127); elemental analysis for $C_{19}H_{27}O_2BFe$: calcd C 64.45, H 7.69; found C 64.55, H 7.62%.

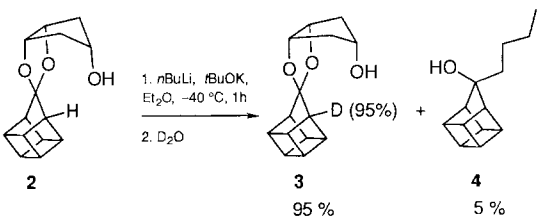
Bridgehead Functionalization of Non-Enolizable Ketones: The First Preparatively Useful Methods**

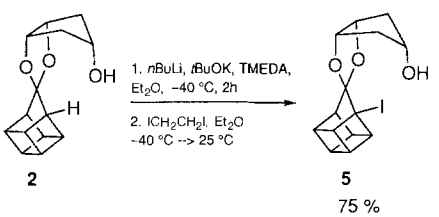
Urs P. Spitz and Philip E. Eaton*

A bridgehead hydrogen α to a carbonyl group in a small polycyclic system is not enolizable, but its acidity is enhanced inductively by the adjacent carbonyl group. Investigations here and elsewhere[1] have shown that norbornanone and other such ketones undergo efficient aldol dimerization when treated with powerful bases like lithium tetramethylpiperidide (LiTMP). However, despite intense efforts, we have been unable to trap the putative intermediate pseudo-enolates with electrophiles other than the ketone itself. Even reagents containing in situ electrophiles such as LiTMP/Me_3SiCl[2] or LiTMP/$HgCl_2$[3] fail. The inability to achieve bridgehead substitution by these or other methods presents a serious obstacle to achieving concise syntheses of cage compounds and other polycyclics.[4]



Directed metalation is well-established and of great synthetic importance for substituting aromatics,[5] cubanes,[3, 6] and cyclopropanes.[7, 8] To apply this approach to the problem of bridgehead substitution we developed the idea of using the auxiliary *cis,cis*-1,2,4-cyclopentanetriol (**1**).[9] Acetalization of bridgehead ketones with **1** would place a hydroxyl group in close proximity to one of the bridgehead hydrogen atoms (see Scheme 1), and this offers the possibility of its participation in deprotonation of this bridgehead position.

Scheme 1.



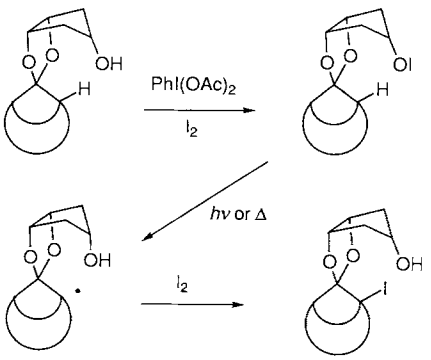
In our initial experiments we employed the homocubanone acetal **2** as the test substrate. Many attempts to metalate it failed. Usually 9-alkylhomocuban-9-ols (e.g. **4**), arising from base-induced cleavage of the acetal, were predominant products. However, reaction of **2** with *n*-butyllithium in the presence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) in ether at room temperature followed by quenching with D_2O did lead, as desired, to significant mono α-deuteriation.[10]

In the next experiments, potassium *tert*-butoxide was added to the reaction mixture: this was based on the idea that the potassium alkoxide of the auxiliary along with added alkyllithium would generate a local superbase.[11] Indeed, these conditions greatly accelerated the reaction, increased the degree of metalation (deuteriation), and reduced the interfering acetal cleavage. For example, treatment of **2** with a mixture of *n*-butyllithium (5 equiv) and potassium *tert*-butoxide (5 equiv) in ether at $-40\,^{\circ}C$ for 1 hour followed by addition of D_2O gave **3** in 95% yield with greater than 95% α-deuteriation (MS and NMR) and only about 5% cleavage [Eq. (a)].

(a)

The homocubane bridgehead metalation was turned into a useful synthetic procedure by substituting iodination for deuteriation. Transfer of the metalated reaction mixture into excess diiodoethane in ether at $-40\,^{\circ}C$ gave the iodinated acetal **5**, which could be isolated cleanly in 75% overall yield [Eq. (b)]. Hydrolysis of **5** can be expected to give 1-iodo-9-homocubanone, a cubane carboxylic acid precursor (by way of Favorskii contraction).[12]

(b)



The idea behind the design of auxiliary **1** was to position a hydroxyl group so that it might "participate" in the formation/stabilization of the desired carbanion.[13] This reasoning proved to be simplistic, which is not surprising considering the probable complexity of the carbanion superstructure.[8a] Indeed, when the hydroxyl group in acetal **2** was epimerized,[14] thus moving it further from the reaction site, metalation could still be achieved with comparable efficiency. Furthermore, some metalation (about 10% after 1 hour) occurred even when the hydroxyl group was absent, provided that TMEDA was present in the reaction mixture. Confusing the matter further, we found that the homologous acetal derived from *cis,cis*-1,2,4-cyclohexanetriol did not undergo metalation at all. Clearly, there is much yet to be learned about the real role of the auxiliary.

As useful (if puzzling) as the metalation described above will prove, it has obvious limitations: base-induced cleavage of the acetal, necessity for enhanced C-H acidity, fragility of other functionality to powerful bases, etc. Fortunately, we have found that the auxiliary approach to bridgehead functionalization can be applied in a much less limited way.

Radical reactions have been used frequently for remote C-H activation.[15] The most popular versions are the Barton and hypohalite reactions.[15, 16] As bridgehead iodo compounds are of particular utility, we focused on hypoiodites. These are readily generated in situ from alcohols[17] and decompose to oxo-radicals upon photolysis or thermolysis. Our system (Scheme 2)

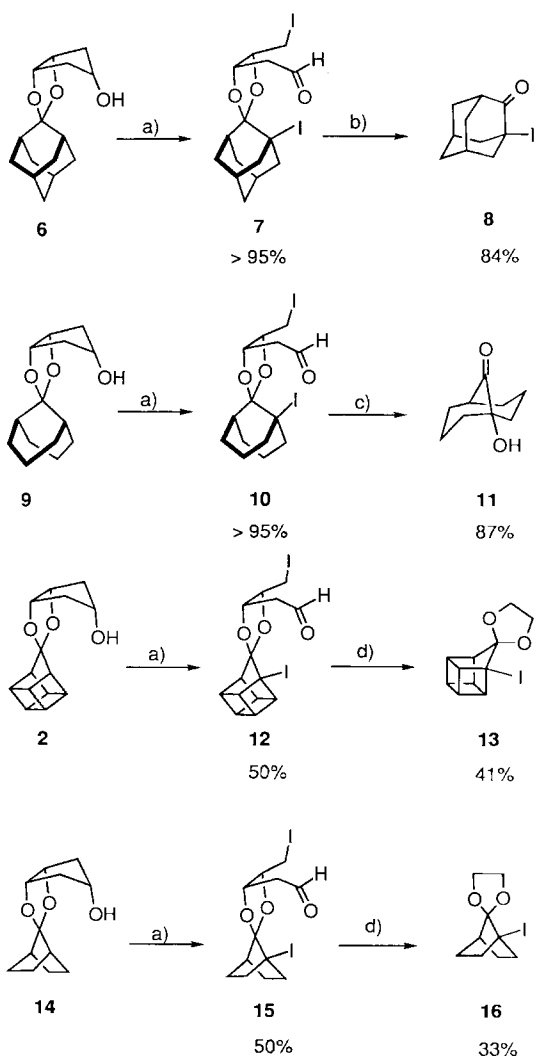
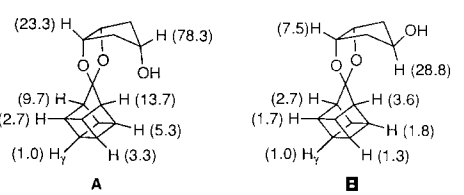
Scheme 2.



is set up to direct the oxoradical to abstract a bridgehead hydrogen.[18]

In a typical experiment, a cyclohexane solution (0.01 M) of an acetal (**2**, **6**, **9**, or **14**), iodobenzene diacetate (3 equiv), and iodine (2.5 equiv) was irradiated for 45 min with a 250 W tungsten lamp.[17] Substantial iodination at the bridgehead was observed (Scheme 3). Incidental to the desired process, cleavage of the cyclopentane ring occurred.[19] The ratio of functionalized to unfunctionalized substrates was estimated by integration of the corresponding aldehyde hydrogen NMR signals. Afterwards, the remains of the auxiliary could be removed or transformed in various ways, as illustrated.[20] Complete α-functionalization (>95%) of adamantanone and of 9-bicyclononanone was achieved. Even in the norbornanone and homocubanone systems about 50% bridgehead iodination was obtained; these are astonishingly high yields considering the notorious lack of reactivity at these sites.

In these radical reactions the mechanism of activation (direction) is much clearer than in the earlier metalations. Control experiments showed that functionalization does not occur if the 4-hydroxyl group of the auxiliary is epimerized or absent.[21]



Although much improvement is still needed, these pioneering examples open new doors in the chemistry of polycyclic compounds. We note, for example, that once bishomohexaprismandione is made, the methodology introduced here provides a way to set it up for Favorskii contraction to the long-sought hexaprismane.[22]

[8] a) For a review on metalation of non-aromatic compounds: G. W. Klumpp, *Recl. Trav. Chim. Pays-Bas* **1986**, *105*, 1. b) Directed metalation generally fails with simple cyclobutanes as they are insufficiently acidic[3b].
[9] The original procedure (F. G. Cocu, T. Posternack, *Helv. Chim. Acta* **1971**, *54*, 1676) was improved substantially, as will be reported later.
[10] The ^{1}H NMR signals in acetal **2** and its epimer[14] were assigned based on Eu(hfc)$_3$-induced chemical shifts. The shifts (see **A** and **B**) were measured relative to the *γ-anti* proton, that most removed from the hydroxyl group. As expected, the shift reagent coordinated primarily to the free hydroxyl group; the resonance of the geminal hydrogen was shifted much more than any other. The two homocubyl resonances that experienced the most downfield shift were assigned to the two bridgehead protons. Each of these appeared as a triplet integrating for 1 hydrogen. Of the two, the one with the greater downfield shift was assigned to the proton *syn* to the 5-carbon ring of the auxiliary. As expected, the shift difference was less in the epimer. After metalation/deuteriation (**2** → **3**) the signal for the homocubyl proton with the greatest downfield shift was almost completely absent; this establishes that deuteriation (and thus metalation) had occurred at the homocubyl bridgehead carbon on the same side as the hydroxyl group of the activating auxiliary.

[18] Not much is understood about the structural requirements for successful hydrogen atom abstraction from a C–H bond. Empirically, the ideal distance between the oxo radical and the C–H carbon atom is 2.5–2.7 Å [15]. In the cases at hand, this arrangement is easily achieved in the adamantane and bicyclononane systems, but is more difficult to obtain in the norbornane and homocubane systems.
[19] a) When $PhI(OAc)_2$ was the limiting reagent, some of the bridgehead-iodinated product had the auxiliary acetal intact. b) For information relevant to the acetal cleavage see: J. L. Courtneidge, J. Lusztyk, D. Pagé, *Tetrahedron Lett.* **1992**, *33*, 3053.

Toward Unified Enantioselective Chromatography with a Single Capillary Column Coated with Chirasil-Dex**

Volker Schurig,* Martin Jung, Sabine Mayer, Simona Negura, Markus Fluck, and Hansjörg Jakubetz

The simplified Golay equation (a) describes the chromatographic process in an open tubular column the walls of which

$$H = \frac{B}{u} + Cu = \frac{2D_m}{u} + f(k)\frac{d_c^2}{D_m}u \qquad \text{(a)}$$

are coated with a stationary phase.[1] It predicts that at a given inner diameter d_c the optimum efficiency (that is, the minimum plate height H_{min}) is independent of the nature of the mobile phase and that the optimum mobile phase velocity (u_{opt}) depends only on the diffusion coefficient D_m at a defined retention factor k [Eq. (b) and (c)][2] (Fig. 1). Thus, it should be possible to

$$H_{min} = 2\sqrt{BC} = d_c f_1(k) \qquad \text{(b)}$$

$$u_{opt} = \sqrt{\frac{B}{C}} = \frac{D_m}{d_c} f_2(k) \qquad \text{(c)}$$

analyze competing substrates, for example, enantiomers, on a single column with different chromatographic modes by employing a gas, a supercritical fluid, or a liquid (of different polarity, pH, or composition) as mobile phase. Here we verify this prediction for enantiomer separation on a chiral stationary phase.

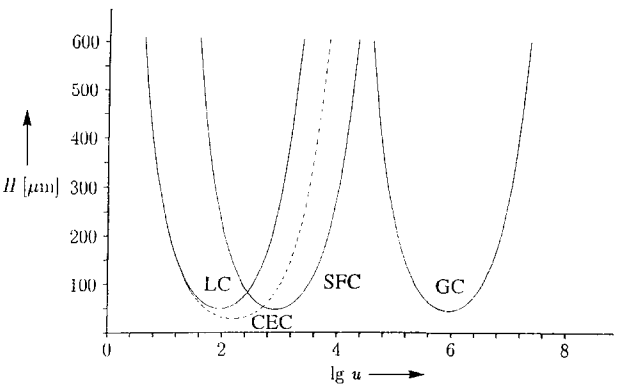
LC = liquid chromatography, CEC = capillary electrochromatography, SFC = chromatography with supercritical fluids, GC = gas chromatography.



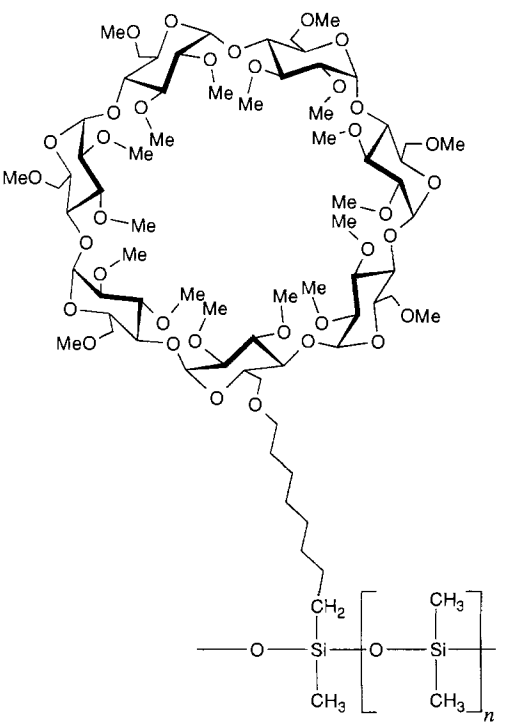


Fig. 1. Height of a theoretical plate H versus the logarithm of the velocity u [$\mu m\,s^{-1}$] of the mobile phase, according to Equation (a) for a capillary column with 50 μm i.d. $k = 5$, D_m[$\mu m^2 s^{-1}$] = 10^7 (GC), 10^4 (SFC), 10^3 (LC, CEC), $f(k)_{parabol} = (1 + 6k + 11k^2)/(96(1 + k)^2)$ [note that in CEC, H_{min} and u_{opt} are different from those of the other chromatographic techniques due to the nearly flat flow profile (dotted curve), $f(k)_{flat} = k^2/(16(1 + k)^2)$.

We previously demonstrated that Chirasil-Dex (Scheme 1)[3] can be employed as an immobilizable chiral stationary phase for enantiomer separation both in capillary GC and SFC.[4] Subsequently we found that Chirasil-Dex is even compatible with buffers in CEC. Thus, enantiomer separation on the chiral surface Chirasil-Dex has been achieved by CEC.[5]

MeO
OMe
Me
Me
Me

The feasibility of this approach is demonstrated in Figure 2.[6] Racemic hexobarbital can be separated on the same fused silica capillary column coated with Chirasil-Dex by all four current chromatographic methods irrespective of the nature of the mobile phase. As the result of the different diffusion coefficients D_m in gases and liquids (cf. caption of Fig. 1), the optimal velocity u_{opt} of the mobile phase is four orders of magnitude lower in capillary LC and CEC than that in GC (cf. Fig. 1). However, H_{min} and u_{opt} also depend on the retention factor k [Eq. (b) and (c)]. Fortunately, while k is quite large in GC and intermediate in SFC, very small values ($k < 1$) are encountered in CEC and LC notably for the first eluted enantiomer. Consequently, analysis times are not too long, and the elution bands are especially narrow for the first eluted enantiomer. However, as seen in Figure 2 (left), GC turns out to be the fastest method, in agreement with Equation (c).

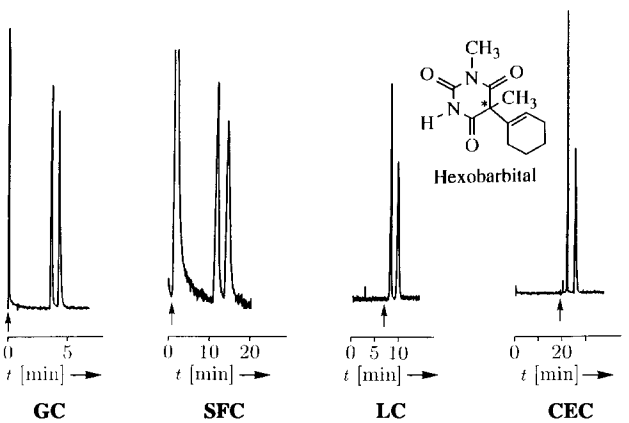

Fig. 2. Separation of hexobarbital enantiomers on a 80 cm × 50 μm (i.d.) fused silica capillary column coated with Chirasil-Dex (film thickness ≈ 0.15 μm) by GC, SFC, LC, and CEC. Conditions: GC: $T = 145\,^{\circ}C$, $p = 1.0$ bar (H_2); SFC: $\rho = 0.25\ g\,mL^{-1}$ (CO_2), $T = 60\,^{\circ}C$; LC: $p = 0.15$ bar, $T = 20\,^{\circ}C$, buffer (borate/phosphate; pH 7)/acetonitrile (90/10, v/v); CEC: $U = 30$ kV, buffer (borate/phosphate; pH 7)/acetonitrile (90/10, v/v), $T = 20\,^{\circ}C$. The arrows in the chromatograms indicate the dead time.

To the best of our knowledge LC in an open tubular column has been used here for enantiomer separation on chiral stationary phases for the first time. Significantly, a CE instrument equipped with a pressure-driven injection system can be employed for open tubular LC. Important advantages over HPLC with packed columns are low flow rates facilitating coupling techniques (LC-MS), high column permeability leading to small pressure drops, and low heat capacity. The amounts of chiral stationary phase and solvent required are minimized in open tubular CEC and LC. According to Equation (b) efficiency is further improved with smaller inner diameters d_c. One disadvantage of using short narrow-bore capillary columns is the limited sample capacity. The continuous improvement of injection techniques and (on-column) detection devices, notably in CEC and LC instrumentation, may eventually overcome these problems. Moreover, the important merit of miniaturization, namely short analysis times, leads to large, narrow peaks and thus enhances detectability.

Hitherto, the unified approach demonstrated here employed a single capillary column coated with a chiral stationary phase in different chromatographic modes. Further investigations into the use of a unified instrument design to carry out GC, SFC, and LC are in progress,[7] also in enantiomer analysis. Enantioselective open tubular LC and CEC has already been performed on the same instrument employing a pressure-driven injection system. The loss of efficiency for the first eluted enantiomer can clearly be recognized (cf. the narrow CEC peak in Fig. 2) when passing from the flat flow profile characteristic for CEC to the parabolic profile inherent to LC.

Chirasil-Dex coated on silica can also be employed for the preparative enantiomer separation of hexobarbital by HPLC. Collection of the first fraction, identified as (*R*)-(−)-hexobarbital by comparison with an authentic sample,[8] allowed the determination of the elution order of hexobarbital enantiomers on Chirasil-Dex with different mobile phases. For all five methods (capillary GC, SFC, LC, CEC, and packed HPLC) the configuration of the first eluted enantiomer is *R*-(−).

Experimental

Chirasil-Dex was synthesized and coated onto fused silica capillaries as previously described in detail [9]. The column length was 1 m and the inner diameter 50 μm. For UV detection an optical window, located at a distance of 80 cm from the injection port, was prepared by burning off about 3 mm of the polyimide outer coating. After performing CE and LC, the column was shortened to the position of the optical window (at 80 cm).

A Carlo-Erba gas chromatograph Fractovap (Fisons, Mainz, Germany) equipped with FID was used. The carrier gas was hydrogen (99.999%), and the split ratio 1:200. SFC was performed on a Carlo-Erba SFC 3000 system (Fisons, Mainz, Germany) as previously described [10]. CEC and open tubular LC were performed with the capillary electrophoresis system "PRINCE" (Bischoff, Leonberg, Germany) equipped with an on-column UV detector. The sample was injected by the pressure-driven method (40 mbar, 5 s) and detected at 220 nm. The coated column was conditioned with buffer overnight (30 kV) and was rinsed between each chromatographic run with water and methanol.

The order of measurements was CEC, LC, SFC, GC. The sequence was repeated two months later in reverse order to determine the elution order of hexobarbital enantiomers.

Primed for Success

Handbook of Enantioselective Catalysis with Transition Metal Compounds. Vol. I: Products and Catalysts, Vol. II: Ligands–References. By *H. Brunner* and *W. Zettlmeier*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 917 pp., hardcover DM 598.00.—ISBN 3-527-29068-0/1-56081-811-5

Of the many new specialist books on chemistry that continue to appear, it is rare to find one that gives an immediate impression of being an indispensable addition to the chemical literature. This two-volume handbook on enantioselective catalysis by Brunner and Zettlmeier is undoubtedly one of these exceptions, in which the authors have succeeded well in their aim of bringing some order to the jungle of chiral metal catalysts and their reactions. The work excels through being very up-to-date, through the careful collecting together of the vast amount of data (covering about 13000 reactions and 2000 ligands) and the comprehensiveness thereby achieved, and through the wealth of information that one can extract from the concisely arranged collection.

The two volumes make up an inseparable whole. Volume I covers reactions with chiral metal catalysts, while Volume II contains a comprehensive list of all the chiral ligands known up to about 1992. Each ligand has been assigned a number, so that in Volume I each catalyst can be described concisely by a combination of the metal with the ligand number.

The reactions in Volume I are arranged according to the molecular formula of the product. This is followed by the full reaction equation, in which as much information as possible has been given within a small space. The product formulas highlight the chiral centers at which chirality has been introduced through the action of the catalyst. This is especially useful in cases where the educt already contains one or more chiral centers which are not configurationally stable under the reaction conditions. Alongside the reaction arrow are shown the absolute configuration of the product and the maximum optical yield achieved with the first-named catalyst in the next column. Other catalysts that have been used for the same reaction but gave lower yields are also listed. For each reaction and each ligand all the relevant literature references are listed in Volume II in order of the year of publication, an unusual and helpful arrangement which allows one to quickly find the most recent publications.

The only criticism of this excellent handbook is that one could propose improvements that would allow even more efficient ways of retrieving the information. Firstly, in Volume II the list of ligands does not tell one where to look in Volume I to find reactions in which particular ligands are used. Secondly, since the reactions in Volume I are arranged according to the molecular formula of the product rather than according to reaction type, it would be useful to have an additional index listing the reactions contained in Volume I according to reaction types (e.g. hydrogenations, cyclopropanations, etc.). However, to have included these improvements would certainly have increased the size of the handbook beyond that which was intended, and although they would provide extra convenience for the user they would add nothing to the information content of the work.

Nevertheless, in view of the continuing exponential growth in the numbers of metal catalysts and of their reactions, the authors should be encouraged to eventually produce a version in the form of a computerized data bank with all the searching algorithms that might conceivably be useful.

To sum up, this data collection will be indispensable for every chemist who is concerned with chiral molecules. Since it is reasonably priced I feel justified in recommending not only that every departmental library should buy the book, but also that individual research laboratories should have their own copies.

Chemical Bonding. By *M. J. Winter*. 90 pp., ISBN 0-19-855694-2.—**Organometallics 1. Complexes with Transition Metal–Carbon σ-Bonds.** By *M. Bochmann*. 91 pp., ISBN 0-19-855751-5.—**Organometallics 2. Complexes with Transition Metal–Carbon π-Bonds.** By *M. Bochmann*. 89 pp., ISBN 0-19-855813-9.—**Bifunctional Compounds.** By *R. S. Ward*. 90 pp., ISBN 0-19-855808-2.—All in the series Oxford Chemistry Primers, Oxford University Press, Oxford, 1994. Paperbacks, £ 4.99 each.

The *Oxford Chemistry Primers* series, in which 24 titles have appeared up to now, aims to provide chemistry students with simple and quick introductions to specific areas of organic and inorganic chemistry. Each volume of about 90 pages contains material that would be covered in eight to ten course lectures. The emphasis on explanations and reasoning rather than on learning facts is intended to equip the student with the basic principles for understanding an area of study.

Chemical Bonding is intended for those just starting their studies. It begins with a brief historical outline in which the atomic orbital model and the Periodic System are developed very lucidly and with little mathematics. This is followed by chapters dealing with the bonding between two atoms. In Chapters 2, after a short section on the Lewis concepts of the nature of bonding, the author introduces the principle of a linear combination of atomic orbitals, with the help of molecular orbital energy level schemes and orbital diagrams. Chapter 3 is concerned with the VSEPR model, then in the final chapter the extension of the molecular orbital approach to polyatomic molecules is discussed. The excellent illustrations provid-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2225 $ 10.00+.25/0

ed throughout the volume enable the reader to gain a good appreciation of the spatial distribution of the electrons in atoms and chemical bonds. The representation of orbitals and bonds by electron density dot diagrams succeeds especially well. On the other hand it is regrettable that answers are not provided for the exercise problems included at the end of each chapter, since this means that they are not suitable for individual private study by beginners. Only a few literature references for more advanced reading are given, but these are sufficient.

Organometallics 1 and *Organometallics 2* deal with compounds containing metal–carbon σ-bonds and π-bonds respectively. The first of these volumes begins by explaining some basic concepts, then describes the chemistry of metal carbonyl, metal alkyl, and metal carbene complexes in turn. *Organometallics 2* begins by briefly repeating and extending the fundamental principles, then discusses the most important organometallic π-complexes. Basic methods of synthesis, bonding concepts, and chemical reactivities are described for each class of compounds, illustrated by appropriate examples. In each chapter the most important statements are summarized in display boxes. Where particular complexes have applications as catalysts for organic syntheses or polymerizations, or as biosensors, these are highlighted in indented paragraphs. Thus, by clearly emphasizing the essential points, the reader is given a feel for the relative importance of the material. In these two volumes also the illustrations are excellent and contribute to the clarity of presentation. The ground covered in these volumes is quite adequate for a first introduction. On the other hand the indexes (50 and 72 entries respectively) are rather scanty.

The volume *Bifunctional Compounds* offers an interesting collection of material of a kind that is unlikely to be found in conventional textbooks. It deals with the chemistry of organic compounds whose special reactive properties arise from the presence of two interacting functional groups. In addition to descriptions of the synthesis and reactions of dienes, enamines, dicarbonyl compounds, and other bifunctional compounds, there are chapters on the selective introduction of protecting groups and on cyclizations. The volume includes exercise problems (with answers), and is intended for advanced students and research chemists.

The concept underlying the *Oxford Chemistry Primers* series, whereby the teaching material is divided into small subject areas and presented individually, has the important advantage that the material is more topical and up-to-date than in conventional textbooks. New developments can be quickly incorporated, and space can also be given to aspects that are on the borders of the discipline (e.g. Volume 22: *Fractals in Chemistry*). The volumes offer a good basis for small seminars in which the work could be extended to suit individual needs. However, compared with a comprehensive textbook this teaching concept cannot give such a good overview of the whole field of organic and inorganic chemistry. Consequently the overall perspective and interconnection of the individual topics must be provided from some other source. If the volumes of this series are used as supporting reading to accompany a teaching course, the lecturers will need to link the separate topics together by providing greater depth and additional material. If this can be done effectively, the concept of a textbook of chemistry made up of units that can be combined and extended to suit individual needs could be very successful.

Scanning Tunneling Microscopy and Spectroscopy. Theory, Techniques, and Applications. Edited by *D. A. Bonnell*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 436 pp., hardcover DM 196.00, $ 125.00.—ISBN 3-527-27920-2/0-89573-786-X

It can be said straight away that this book is a must for everyone concerned with surface physics studies using high resolution microscopy and microanalysis. Although it is scarcely a decade since the invention of the scanning tunneling microscope, it has now been widely adopted in fields ranging from materials science to the biological sciences, thanks to the simplicity of the underlying concept and its remarkable ability to give direct imaging of atoms and molecules. However, apart from the short monograph by Hamann and Heitschold (Akademie Verlag, Berlin, 1992), there has hitherto been no comprehensive treatment of the subject which is also suitable for newcomers, and gives an introduction to the principles and main areas of application. Therefore this book, by a team of authors who are all actively engaged in the field, has been compiled with the needs of advanced students in the area of surface physics in mind. It will also be useful to university lecturers in physics, chemistry, and biology as a source for preparing courses. However, it is not intended to be a textbook in the conventional sense; there are many aspects that cannot yet be presented conclusively, as rapid developments are still taking place. Instead it is more of a snapshot of the knowledge that experiments have so far yielded, the theoretical understanding of which is still at a tentative stage; one such topic is the role of the conductivity of organic molecules in the generation of scanning tunneling images. According to the preface the book sets out to bridge the gap between existing monographs and specialist review articles, for the benefit of the reader who wishes to make a start in the field and is interested in the basic principles, the design of instruments, and the potential applications.

It is to the credit of the editor, Dawn Bonnell, that the individual contributions have not been simply strung together in a haphazard way; instead there is a logical structure and relationship between the chapters, which makes the work suitable as a course book. It is divided into three parts. The first part begins with a brief historical survey of the developments leading up to the invention of the scanning tunneling microscope, followed by an exposition of the basic principles: the construction of the microscope and its use, the theory of scanning tunneling microscopy, and the methods of spectroscopy. Part 2 deals with the structure of the specimen and the probe tip, the two basic elements involved in image formation. The discussion is mainly concerned with the surfaces of crystalline solids, their thermodynamic properties, and the defects of real surfaces. The preparation of the tip for scanning tunneling microscopy is then described, along with general aspects of specimen preparation. Part 3, with the title "Related Techniques and Applications", includes an introduction to scanning atomic force microscopy, probably the most important of the further developments based on the scanning probe microscopy principle. This part is completed by accounts of applications of scanning tunneling microscopy in electrochemistry and biology.

The book gives a good overview of the subject, and treats the most important experimental and theoretical aspects with appropriate thoroughness. However, the choice of applications strikes me as being rather arbitrarily restricted. Instead of the chapter on ballistic electron emission microscopy (BEEM), which should be classified as a "related technique", I would have preferred to see more space devoted

to techniques based on frictional or magnetic interactions between the probe tip and the specimen, such as nanometer-scale manipulation, optical near-field microscopy, or new developments in scanning atomic force microscopy. It is, of course, unavoidable that some restrictions must be applied in choosing the examples of applications, and how this is done must certainly depend on the preferences of the authors of the individual sections. Here the examples are in general well chosen and are representative of the whole field. It is only in the final chapter, "Biological Applications of the Scanning Probe Microscope", that I would have preferred more caution to be exercised by citing only results that are established with reasonable certainty, especially with regard to the imaging of DNA molecules, since here there is a very high risk of artefacts.

The quality of production contributes greatly to the book's readability. In a few places, however, I would have liked the figure legends to be more precise and to contain more explanation, and not all the quantities that occur in the mathematical formulas are fully explained. The extensive lists of literature references at the ends of the chapters are excellent, as also are the index and the definitions of variables and explanations of acronyms in the appendix. There are inevitably some printing errors, especially in names (Röhrer instead of Rohrer, Fostes instead of Foster, Henkl instead of Heckl, etc.), and these need to be corrected in a future edition. A German translation would help the book to reach the very wide readership that it deserves. However, the price of the present edition is too high for a student textbook.

der Universität München (FRG)

Four Books on Fullerenes

Fullerenes, a novel soluble form of carbon, have now been available in preparative quantities for about three years. The fascination aroused by these hollow spherical molecules has captivated scientists from a number of different disciplines, and many have become involved in intensive research on this class of compounds. The soccerball-shaped (or football-shaped) molecule buckminsterfullerene (C_{60}) has rapidly become one of the most thoroughly studied in all parts of the world, as is evident from the large numbers of original papers, review articles, and conference reports that have appeared since September 1990. This field of study has now developed to a stage where monographs are in order, as is shown by the recent publication of four books.

Buckminsterfullerenes. Edited by *W. E. Billups* and *M. A. Ciufolini*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 339 pp., hardcover DM 96.00.—ISBN 3-527-89608-2/1-56081-608-2

In this book of 13 chapters some of the physicists, chemists, and theoreticians who have been involved in work on fullerenes from its beginnings summarize their own research. This multiauthor approach has the advantage that the individual contributions are of a very high quality, but it does mean that some overlapping of subject matter is unavoidable. The "fullerenes era" began with the mass spectrometric investigations of the C_{60} cluster, as is very nicely described by R. F. Curl in Chapter 1. He also includes a brief account of the discovery of the "empty" fullerenes and of endohedral metallofullerenes. In Chapter 2 H. W. Kroto, one of the discoverers of the fullerenes, and his coworkers describe their research, ranging from radioastronomical and chemical studies of the cyanopolyynes, through the discovery of the spherical cluster, up to the current work on chemical modifications of the fullerenes. They also briefly discuss the preparation of fullerenes in an arc discharge and their separation, isolation, and physical properties. The impressive results obtained by the Sussex group on the halogenation of C_{60}, on the solid state properties, on the alkali metal superconductors, and on the "bucky tubes" and giant fullerenes complete this chapter, which is a miniature "fullerene story" in its own right within the book. In Chapter 3 F. Diederich and coworkers describe the methods used to isolate the various fullerenes, in a lucid presentation similar to a laboratory procedure for separation of analytical samples. The interplay between theory and experiment has proved to be especially fruitful in research on fullerenes, and in the next chapter this is well illustrated by studies to determine the structures of the higher fullerenes such as the chiral form C_{76} or on the isomerization of fullerenes. Next come two purely theoretical chapters, one by Scuseria on ab initio calculations leading to structures for C_{60}, its hydrogenated and fluorinated derivatives, giant fullerenes, and dwarf fullerenes, and the second by White and coworkers on theoretical predictions of the properties of fullerene derivatives. These chapters are also of considerable interest to preparative chemists, since the observed reactivities of the fullerenes correlate very well with the calculated geometrical and electronic structures. The next three chapters are concerned, mainly from a theoretical standpoint, with the important topic of the electronic properties of C_{60}, which leads up to the superconductivity of the alkali-metal doped fullerenes. The last four chapters are experimentally orientated; the aspects of fullerenes treated here are their endohedral gas phase chemistry, their electrochemistry, and preparative organic chemistry. After reading in this book such items as H. Schwarz's impressive results on helium inclusion complexes, or F. Wudl's very lively account of the historical development of fullerene chemistry, the newcomer to the field will already have acquired a good knowledge of the chemical properties of C_{60}.

The Fullerenes. Edited by *H. W. Kroto, J. E. Fischer* and *D. E. Cox*. Pergamon, Oxford, 1993. 314 pp., hardcover £ 29.95.—ISBN 0-08-042152-0

This monograph too has been put together on the multiauthor principle. It contains two introductory articles by the editors and 23 individual contributions by well-known researchers in the fullerenes area, which are grouped in two sections. Many of the names represented in the book reviewed above occur again here. Not surprisingly, therefore, a good many of the articles in the two books are quite similar; this is the case, for example, in the contribution by Olah's group, although the treatment here is considerably more detailed. The contents of the first part of the book are arranged in exactly the same form as has appeared in special issues of the journal *Carbon*, also published by Pergamon. The arrangement is in fact very good, as exemplified in the article "Some Well Characterized Reactivities of Buckminsterfullerene (C_{60})", by Fagan and coworkers (DuPont), which provides impressive evidence of the capabilities of this group. Like the previous one, this book covers the entire field of fullerenes research, but here the treatment is more detailed. It is therefore intended not so much for the reader seeking a general overview of fullerenes but rather for the specialist wanting more specific information. However, this does not apply to every article. For example, readers wishing to know about the discovery of the fullerene synthesis will find it well described in the first article, by Krätschmer and Huffman

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2121-2227 $ 10.00+.25/0

who made that discovery, and for those interested in the superconductivity of fullerenes the two articles by Holczer et al. and by Schlüter et al. offer a good introduction. However, on the whole the book is mainly a collection of specialist contributions. These have been put together in a way that is to some extent structured, starting with descriptions of the fullerenes then going on to deal more specifically with the chemistry and physics of fullerenes in the solid state. In a rational sequence (though one that is not always strictly followed), the articles deal in turn with the discovery of the fullerenes, mass spectrometric studies, isolation and characterization, the chemistry of fullerenes, superconductivity, and solid state properties. Despite the fact that research on fullerenes continues to progress very rapidly, with the risk that any book is already out-of-date as soon as it is published, this compilation represents the most important current knowledge covering a wide variety of topics, especially in the articles on physical and theoretical aspects.

Fullerene C_{60}. History, Physics, Nanobiology, Nanotechnology. By *D. Koruga, S. Hamerloff, J. Withers, R. Loutfy* and *M. Sundareshan*. Elsevier, Amsterdam, 1993. 380 pp., hardcover HFl 200.00.—ISBN 0-444-89833-6

This book contains poems, cartoons, and a good deal of Egyptian and Greek mythology. D. Koruga, the principal author, does not always succeed in establishing a clear connection between this material and the fivefold symmetry elements of C_{60} or the "biofullerenes". Serious research on fullerenes is at best only touched on briefly. In some cases published work that is mentioned in the text along with its authors does not appear at all in the bibliography. In one of the collages a cover picture from the journal *Science* showing C_{60} as the Molecule of the Year is needlessly combined with one of the authors' own scanning transmission micrographs. Sometimes Koruga has illustrated the text with photographs on which he appears superimposed, and a dream that he once had is classed as one of the most important events in the history of the fullerenes. The book is divided into three parts entitled "Science of Fullerenes", "From Nanobiology to Nanotechnology", and "Fullerene C_{60}: Production, Technology and Applications". The first part begins with a historical survey from the viewpoint of the authors. This is followed by a discussion of icosahedral symmetry which begins with ancient China, then sets out some general symmetry rules which are normally covered in a first-year course. Next the physical properties of C_{60} are discussed, with a strong emphasis on STM studies. The second part has scarcely anything to do with fullerenes; the topics discussed include biological molecules and slipper animalcules (Paramecium). This part ends by discussing a number of topics including the "Herz model" and the "C_{60} light machine", in which the authors establish a "pentagonal" connection between C_{60}, the birth of Christ, and the beginning of civilization. In the third part we at last learn a little about fullerene and potential applications. This book will certainly seem very strange to the non-specialist reader; for the specialist it has no value other than as a talking point.

The Fullerenes. New Horizons for the Chemistry, Physics and Astrophysics of Carbon. Edited by *H. W. Kroto* and *D. R. M. Walton*. Cambridge University Press, Cambridge, 1993. 154 pp., paperback £ 17.95.—ISBN 0-521-45917-6

In October 1992 the Royal Society held a seminar, of which H. W. Kroto was one of the organizers, entitled "A Post-Buckminsterfullerene View of the Chemistry, Physics and Astrophysics of Carbon". This little book contains reprints of 14 papers by the participants, all of whom are well known in the field, together with the main contributions to the discussion sessions following each paper. The book begins with an excellent contribution by Osawa on the relationship between the C_{60} structure and two-dimensional aromatic systems. This is of particular interest in view of the fact that the C_{60} structure was first envisaged by Osawa, as a three-dimensional "superaromatic molecule", as long ago as 1970. Since then not only Osawa's predictions, but also many of those described in the second paper by D. E. H. Jones (better known under the pseudonym Daedalus), have since been confirmed. The giant fullerenes and tubes that were postulated have since been observed experimentally. Another very exciting prediction by Daedalus that very large giant fullerenes, because of their low density at ambient temperature and pressure, should be supercritical liquids, has still to be put to the test. In the next article R. F. Curl (see the review of the first book) again reports on mass spectrometric investigations into the formation of fullerenes. The following contribution on the synthesis of fullerenes is again written by the discoverers of the method, Krätschmer and Huffman. Next there are articles on the structural systematology of the fullerenes (Fowler), the electronic properties of C_{60} (Haddon), studies of interstellar matter (Jura and Pillinger), and the reactivity of C_{60} (Taylor). Kroto and Walton then contribute a review of their classic investigations on polyynes and fullerenes, and Mackay and Terrones discuss theoretical aspects of fullerenes with negative curvatures. The book ends with a look at the common structural features of the fullerenes and geodesic domes. The compact form of this little book, the good choice of topics, and the high quality of the individual articles, which never wander off into unnecessary detail, make it well worth reading, both for interested non-specialists and for those closely involved with fullerenes.

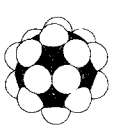
From an Insecticide to Plato's Universe—The Pagodane Route to Dodecahedranes: New Pathways and New Perspectives



Horst Prinzbach* and Klaus Weber

Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday

The original concept for the synthesis of pentagonal dodecahedranes by the conversion of structurally similar, high-energy [1.1.1.1]pagodanes relied on catalytic dehydrocyclizations. As a consequence, preparative limitations were preprogrammed. With multiple functionalization of these pagodanes, alternative cyclization methods became viable. These efficient processes allowed access to a multitude of pentagonal and nonpentagonal, carba- and heterocyclic dodecahedral skeletons with widely variable substitution patterns. Such a roundabout route provided the $(CH)_{20}$ basic framework with high efficiency, and long-lacking thermochemical data could be ascertained calorimetrically. In spite of the unusually pronounced pyramidalization of their olefinic centers, singly and doubly unsaturated dodecahedranes with isolated C=C bonds proved to be kinetically quite stable, but underwent dimerization on thermal activation. Dodecahedranes with a higher degree of unsaturation (trienes–decaenes, C_{20} fullerene?) have been found so far only in the gas phase. Higher fullerenes, including C_{60}, have been identified by mass spectrometry after exposure of halogenated dodecahedranes and pagodanes to a 248-nm excimer laser. Transannular electron delocalization has been verified for the "slender" pagodane/isopagodane and even for the "spherical" dodecahedrane cages.

Prologue

For many years the $(CH)_{20}$ hydrocarbon dodecahedrane **1**, organic chemists' transliteration of the platonic dodecahedron[1] with its historical and cultural background, which has more recently been recognized as the perhydrogenated C_{20} fullerene **2**, had the aura of a utopian object. In fact, worldwide efforts to synthesize this hydrocarbon, which is intriguing for a number of reasons, had remained unsuccessful.[2] Confronted with the task of interconnecting 20 methine units with stereochemical control through 30 C–C bonds to form twelve five-membered rings, even the Almighty apparently had given up—neither **1** nor derivatives better accessible through isoprene metabolism have ever been found in Nature. However, the "Mount Everest of alicyclic chemistry" was finally conquered, and the ascent mastered by the Paquette team at Ohio State University stands out as a landmark in organic synthesis.[3] Yet for all its elegance, this route has the intrinsic disadvantage of low flexibility. Functionalization or modification of the skeleton is only possible on the finished structure[4]—a fundamental problem given the molecular symmetry.

2

In the parallel[2] and subsequently conducted search[5] for an alternative, if possible more direct and more versatile route only our group in Freiburg has been successful thus far.[6] We have already published reviews on the concept of this "pagodane route" to dodecahedranes and on its utilization particularly for the preparation of the parent compound **1**.[7, 8] In the meantime the conceptual advantages of this route, its variability and effi-

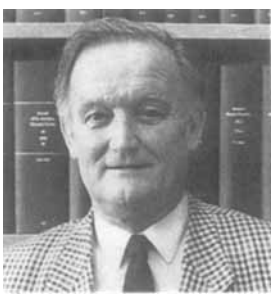
ciency, have been confirmed numerous times, and new aspects of the chemistry of these cage compounds have arisen. In order to facilitate evaluation of the type and extent of the progress we will briefly recapitulate the basic concept and previous status of the project. The reader will hopefully share in the "ups and downs" and the surroundings of a venture full of surprises, and the unceasing confrontation inevitable in a journey of this length with the necessarily high demands concerning the efficiency of each individual synthetic step.

1. The Concept



Two prominent properties of the undecacycle **1** are its high symmetry (I_h) and low energy content. The symmetry directed every synthetic approach that relied on construction of this C_{20} unit from two subunits ($C_{10} + C_{10}$, $C_{15} + C_5$).[2] The fact that **1** is the energy sink, the stabilomer,[9, 10] of the $(CH)_{20}$ family, provided incentive for Schleyer's group and others[2, 11] to attempt to rearrange energy-rich and suitably structured $C_{20}H_{20}$ isomers into **1**—as exercised with great success in "adamantane land". Even though this strategy had met with failure in various versions (or just for that reason?), such a procedure with the $C_{20}H_{20}$ pagodane **3**[12] as precursor (Route 'A', Scheme 1) was fascinating:[13] The high structural similarity of **3** to **1** is reflected in the symmetry, D_{2d} versus I_h (and also in the IUPAC names). After all, with twelve cyclopentane rings already present in **3** only two of the strained cyclobutane bonds have to be hydrogenolytically cleaved and two transannular bonds formed by dehydrogenation. Moreover, the gain in enthalpy of formation and strain energy, 40–50 kcal mol^{-1} (according to MM2 calculations), is considerable. Admittedly, one could only speculate on the course of the one-pot transformation **3** → **1** (Route 'A'), which in the end was a sequence of numerous individual steps, and on the potential intervention of kinetically "dead" intermediates. Still, it was undisputed that for steric reasons the formation of a transannular bond between the methylene groups could only be brought about after opening of the respective lateral cyclobutane bond. The controlled stepwise sequence **3** → **4** → **5** → **6** → **7** → **1** (Route 'B', Scheme 2) was the preferred alternative in the event that the "black box" variant 'A' would not be realizable. Route 'B' merged with the Paquette synthesis at the stage of secododecahedrane **7**. It should be noted that at each step in the sequence consisting of the $2\sigma \rightarrow 2\pi$ cleavage (**4**), hydrogenation (**5**, **6**), and dehydrogenation (**7**, **1**), the convexity of the molecular skeleton (d_1 in Å) increases and the lateral distance (d_2) decreases, thereby favoring lateral C–C connection. The listed enthalpies (from MM2 calculations)[14] differ markedly in absolute terms from those measured calorimetrically (see Table 1), but as with the strain energies, the trend is reliable, except with regard to the ring opening **3** → **4**. This latter step has been shown unequivocally to be endothermic;[15] the MM2 calculations underestimate in known fashion the destabilization of the diene by the transannular π,π repulsion.[13, 16] Yet, complications had to be anticipated with these "hyperstable" olefins[17] given the low exothermicity of the two hydrogenation steps—at roughly 15 kcal mol^{-1} only about half of the standard value of 30 kcal mol^{-1}—and the parallel increase in strain energy. In the original concept for Route 'B',[7, 8] cyclizations *before* the hydrogenations **4** → **8** and **5** → **9** were not formulated. Because of the considerable positive changes in enthalpy and strain under the conditions of the dehydrogenating cyclization (**7** → **1**), isolation of unsaturated dodecahedranes, predicted to be extremely reactive,[3] was not expected to be possible. Route 'C' (Scheme 3), the alternating sequence of hydrogenolysis (**10**, **7**) and formation of C–C bonds (**11**, **1**) by dehydrogenation was, a priori, only a third choice. Particularly the endothermic cyclization **10** → **11** was judged as highly

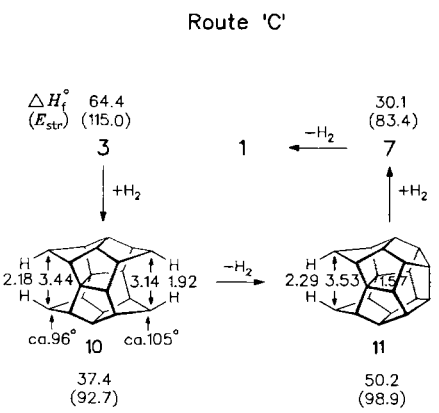
Scheme 1. Here and in all following schemes the ΔH_f° and E_{str} values (MM2) are given in kcal mol^{-1}.

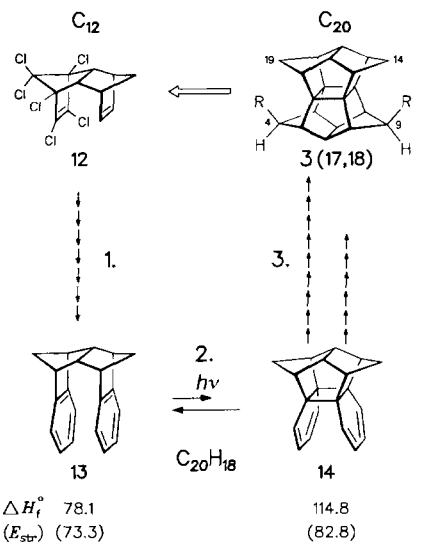
Horst Prinzbach was born in 1931 in Haslach im Kinzigtal (Black Forest, Germany). After studying chemistry in Freiburg, he obtained his doctorate there (1955, A. Lüttringhaus) and spent two years (1957–1959) as a post-doctoral fellow at Yale University, working with W. von E. Doering. He obtained his "Habilitation" at Freiburg in 1962 ("Sesquifulvalenes—A Contribution to the Chemistry of 'Nonbenzenoid Aromatics'"). In 1965 he accepted a chair of organic chemistry at the University of Lausanne (Switzerland), and in 1969 he returned to the University of Freiburg. Besides a number of other awards, Horst Prinzbach received the Adolf-von-Bayer Denkmünze of the German Chemical Society (1989). His scientific activities are centered around chemistry of "nonbenzenoid aromatics", preparative organic photochemistry, polyelectron pericyclic processes, total syntheses of aminoglycoside antibiotics, and in particular the syntheses and properties of unusual structures (including homobenzenes, pagodanes, dodecahedranes).



Scheme 2.

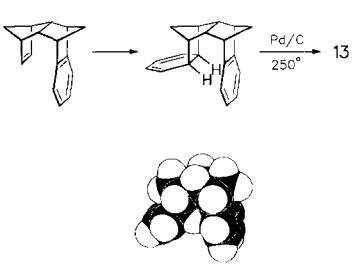
Table 1. Calculated (MM2, top line) and experimentally determined (bottom line) values for ΔH_f° and E_{str} (the latter in brackets) [kcal mol^{-1}] for pagodanes **3** and **17**, and for dodecahedranes **1** and **68**.

3	17	1	68
64.4 (115.0)	−91.7 (130.8)	22.2 (68.9)	−183.4 (64.7)
47.88 ±0.91 (95.57)	−107.33 ±0.85 (110.03)	(22.4 ±1 (61.4 ±1))	−151.80 ±0.82 (61.36)



problematic. In reality, this route was accomplished only along other methodical approaches (see Scheme 14).

Scheme 3.



2. The Basis—From Isodrin to Pagodanes

The value of our concept for the ascent to dodecahedrane **1** starting from [1.1.1.1]pagodane **3** was dependent on an acceptable "price" for **3**. This prerequisite could be fulfilled with the optimized reaction sequence subdivided in Scheme 4 into three stages. The starting material was (at the time of planning) the cheap, industrially produced C_{12} chlorohydrocarbon isodrin **12**. (In the meantime this product, permitted only for limited use as an insecticide, has become considerably more expensive.) If one considers the grand total of about 60 (or 45) changes in bonding on the way from **12** to **3** (or to the diesters **17**/**18** of primary interest), which are compressed into 14 (11) reaction steps with consequent exploitation of the given symmetry situations, the overall yield of 22–24% achieved implies a yield of over 95% for each individual functional change.[18] This route leaves no room for further optimization; it constitutes the basis of all our pertinent activities during the last few years.

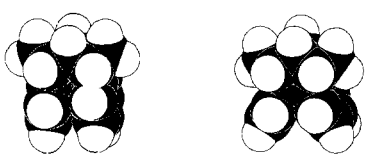
Scheme 4.

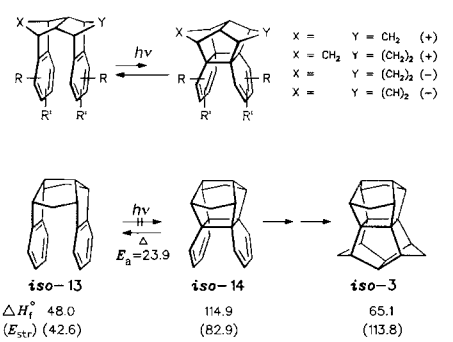
In the first stage two benzenoid rings were annulated onto **12**. The single annulation was achieved following a reliable method by Mackenzie.[19] For the second annulation, conducted analogously, an apparently trivial dehydrogenation leading to aromatization became an early stumbling block—still not completely overcome. In this reaction the hydrogen atoms deep in the opposite π electron cloud are rather inaccessible for the catalyst.

An extensive study into optimization of this dehydrogenation concluded with a protocol that prescribed heating the dihydro precursor to 250 °C with an almost tenfold amount of Pd/C. The costs, nevertheless, could be held within limits, as the catalyst remained active over several

cycles and could be reprocessed subsequently. Yields of 80% were obtained reproducibly for 16-g runs. There are good reasons to assume that the transannular π,π repulsion enforced under these extreme conditions—an indication is the pyramidalization, if only weak, of the *o,o'*-C centers—is instrumental for the subsequent photoreaction. According to X-ray structural analysis (cf. Fig. 1) the almost perfectly synperiplanar ("face-to-face") benzenoid chromophores in the annulation positions are only 3.04 Å apart.[20]

The benzo/benzo photocycloaddition **13** → **14**, the second stage, is essentially the key reaction of the concept[21]—the discovery of the formation of a four-membered ring between nonfunctionalized benzenoid rings, previously unknown in arene photochemistry, became the initial spark of the pagodane/dodecahedrane project. Neither direct irradiation of **13** with light of wavelength $\lambda > 280$ nm nor sensitized excitation produced any visible effect. However, when a dilute degassed solution of **14** was irradiated with monochromatic light at 254 nm, an equilibrium mixture of **13** and **14** (7:3) resulted. For a photoreaction of this type the lack of any competing reaction is remarkable. The explanation: The cyclohexadiene chromophores,[22] which in **14** are σ-coupled through the cyclobutane ring, call for a much more intense long-wavelength absorption which is in the range of the charge transfer (CT) absorption of **13**. At 254 nm the extinction coefficients are roughly inversely proportional to the measured equilibrium ratio. As an additional surprise, unexpected in degree and significant for the continuation of the synthesis, photoproduct **14**, a "*syn* dimeric benzene" (Fig. 1), is thermally quite stable; its half-life at 120 °C amounts to a substantial 130 min.





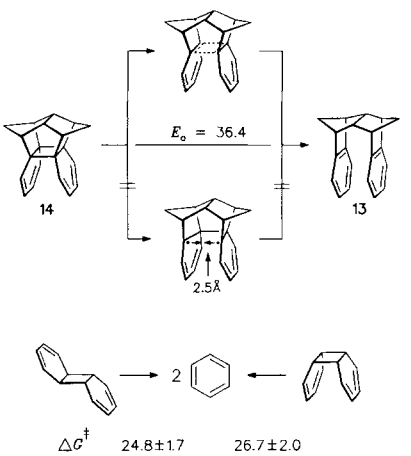


Fig. 1. Schakal plots of **13** (left) and **14** (right).

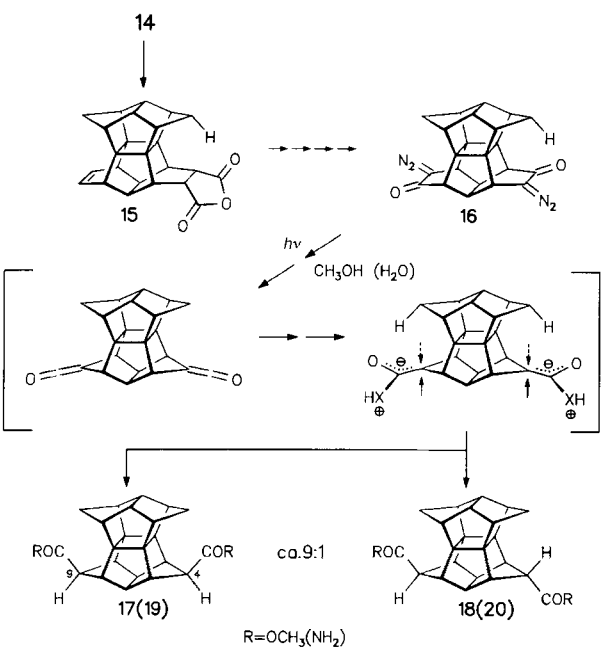
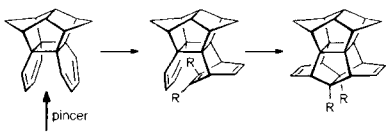


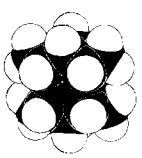
Benzo/benzo cycloadditions of the type **13** → **14** possess considerable synthetic potential. Subsequent studies including photomechanistic investigations[23] with the aim of defining the limiting conditions of this photoreaction have underlined the exceptionally favorable situation in **13** in particular with regard to transannular distance, π,π interaction, and rigidity of the skeleton.[24] The rather narrow scope of the reaction became obvious: cycloaddition occurs with various functionalizations of **13** (R,R')[25] and after homologation of one bridge (X,Y) but not after homologation of both bridges.[26] The cycloaddition *iso*-**13** → *iso*-**14** on the way to [1.1.1.1]isopagodane (*iso*-**3**) was also unrealized.[27]

The degree of kinetic stabilization conferred on **14** by its molecular corset, and quantified by kinetic data, was helpful, if not essential, for the project. For comparison, according to the work of Schröder, Oth et al.,[28] Grimme et al.,[29] Berson et al.,[30] and Yang et al.,[31] noncorseted *anti*/*syn* dimeric benzenes fragment even at room temperature. *iso*-**14**, Prepared in a roundabout way from *iso*-**13**, is also relatively labile, as the skeleton of *iso*-**14** cannot deliver comparable "kinetic protection".[33] The cleavage **14** → **13** is a special case mechanistically. Roth, Doering, et al.[33] argue that the rigidity prohibits the separation of the radical centers to the extent necessary for bond cleavage to occur by a radical pathway. Instead a concerted symmetry-forbidden [2 + 2] cycloreversion pathway via an antiaromatic four-centered transition state is followed.

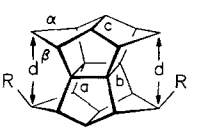
The third stage consists of converting the tricyclododecatetraene part of **14** into the lower pagodane "half" (Scheme 5) by the domino Diels–Alder addition to **14** giving **15**,[34] and ring



Scheme 5.



contraction on both sides of the [2.2.1.1]pagodane through the bis(diazoketone) intermediates (C_s- and C_2-**16**). The persistance of **14** was once again fortunate for the almost quantitative regio- and stereospecific addition yielding **15** (80 °C). A cage effect, irrelevant for the preparation of **3** but essential for the subsequent developments, dictated the stereochemical outcome of the photo-Wolff rearrangement. A roughly 9:1 mixture of

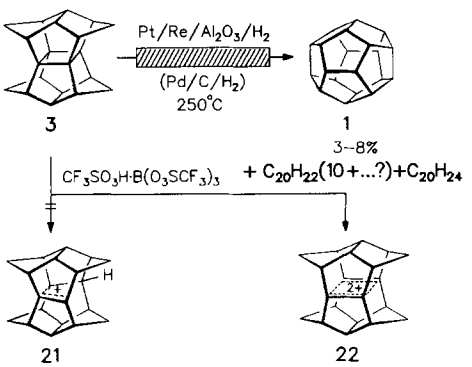


syn,syn and *syn,anti* diesters **17**/**18** (or the corresponding dicarboxylic acids) was obtained from anhydrous methanol (or moist tetrahydrofuran). The addition of methanol (water) to the ketene intermediates proceeds with obviously high (unfortunately not complete) steric control; *anti* protonation enforces the less favorable *syn* placement of the ester (acid) functions, which is energetically more "expensive" by about 7 kcal mol^{-1} (see Table 1). The base-catalyzed conversion of **17**/**18** into the thermodynamically more stable *anti,anti* diesters proceeded correspondingly slowly. The dicarboxamides **19**/**20** were produced directly by photolysis in liquid ammonia, again in a ratio of approximately 9:1.

The "pincer" addition to **14**, also of interest with regard to the directed multiple functionalization of **1**, requires "slim", rodlike dienophiles. This particular pathway dominates, for example, in the high-pressure addition of dicyanoacetylene. The cooperative [4 + 2 + 2 + 4] mechanism plausible given the spatial relationships in **14** is, however, no longer considered.[35]

In spite of their high strain pagodanes are thermally unusually stable. The waxy hydrocarbon **3** melts without decomposition at 243 °C (260 °C, high-pressure differential thermal analysis[36]) and remains unchanged up to at least 600 °C (gas phase). A defined fragmentation pattern is not evident in the electron impact mass spectrum; generally the M^+ signals are by far the most intense. The $^{13}C,H$ coupling constants for the tertiary hydrogen atoms reflect the relatively high s character caused by the strained structure. X-ray structural analyses, for example for **3**[37] and **17**[12] (Fig. 2), provide evidence for some of the trends

R = H (CO_2CH_3)



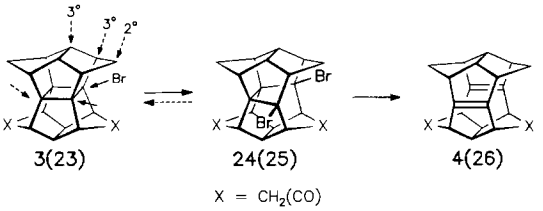
a: 1.549 (1.552) α: 96.1 (95.0)
b: 1.573 (1.589) β: 99.4 (99.5)
c: 1.589 (1.625)
d: 3.530 (3.611)

Fig. 2. Selected structural data (a–d in Å, α,β in °) for pagodanes **3** and **17**.

considered important for the chemical behavior (see Scheme 1). The "lateral" bonds in the four-membered rings (b) are significantly longer than the "frontal" ones (a); the α and β angles in the norbornane subunits deviate only slightly from those of the parent norbornane. The anticipated increase in transannular strain (Table 1) caused by the *syn* ester group is reflected by the lengthening particularly of the "ridge" bonds (c). The Schakal plot of **3** (Fig. 2, left) shows the van der Waals contact of the *syn* methylene hydrogen atoms in the half-cages as well as the shielding of the central four-membered ring from all sides by the surrounding hydrogen atoms.

3. The First Dodecahedranes—Limitations of the Dehydrocyclization Strategy

With the availability of pagodanes in decigram quantities the race appeared to be over. The catalyzed conversion **3** → **1** (Route 'A'),[11] which relied on the expertise of the Schleyer and Maier groups, ended with brilliant success and bitter disappointment simultaneously (Scheme 6). The catalysts optimized

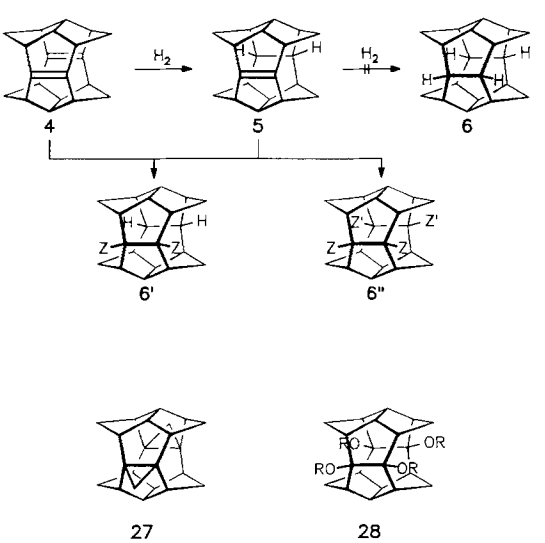


Scheme 6.

for such purposes actually did provide **1**, but the reproducible yields remained at 3–8% (besides 19–46% secopagodane **10** and additional $C_{20}H_{22}$ and $C_{20}H_{24}$ components), far below that expected and thus ruling out further preparative utilization. It could only be said that **10** was a "dead end" in this "black box" reaction (Route 'C') and not a precursor to **1**, and that **5** (**6**) was not among the by-products.[6]

According to the findings of Olah et al. pagodane **3** reacted with high selectivity in super acids,[38] successful reagents for catalytic isomerizations in "adamantane land", although **1** was not obtained as hoped. Instead two electrons were removed from the central four-membered ring of **3** to give the surprisingly persistent D_{2h}-symmetrical dication **22**,[37, 39] the unusual properties of which will be referred to later (Section 10). Even with super acids of relatively low oxidizing power, protonation of **3** as a potential entry into the isomerization cascade was outweighed by oxidation. Stabilization by homoconjugation as in the independently generated 2-secopagodyl cation **21**[39] is apparently of no help.

When secopagodane **10** was excluded as a precursor to **1** in the above "black box" reaction, bissecodiene **4** became a viable alternative. The directed preparation of **4** from **3** evolved as a serious challenge for Route 'B'. The expectation, based on the MM2 calculations (see Scheme 2), of isomerizing **3** thermally to **4**, turned out to be naive. Naphthalene was not exactly the desired goal of the gas-phase thermolysis, but its formation pointed to a mechanistically and thermochemically informative fragmentation pathway. Unfavorable oxidation potentials prohibited the isomerization via the corresponding radical cations, which would have been especially attractive as a catalytic process. The two-step procedure of bromine addition and fragmenting bromine elimination established for other small-ring propellanes (Scheme 7)[40] was the solution. Given the potential for competing processes, the sequence proceeded with surprising selectivity. The reaction of **3** with bromine, thermally slow



Scheme 7.

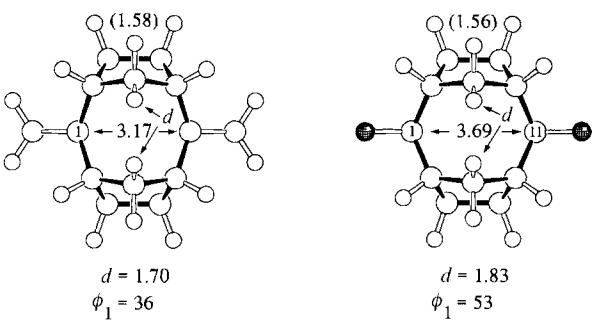
but fast under irradiation, yielded exclusively the addition product **24** (extremely prone to hydrolysis, cf. **21**!) within the short time (minutes) necessary for total conversion. Reversion back to **3** during the subsequent elimination, which is significant at lower temperature, remained minimal (< 5%) above 150 °C. It should be noted that the carbonyl groups in pagodanedione **23** reduce both the rate of conversion and the rate of hydrolysis of the intermediate **25**, but not the uniformity of the reaction leading to the dienedione **26**.

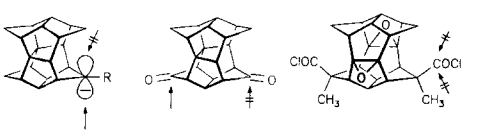
The absence of radical substitution in the course of the conversions **3(23)** → **24(25)** must be regarded as fortuitous, in view of the structural similarities of **3** to norbornane and the known radical substitution pattern of the latter.[41] In the [2.2.1.1]pagodane skeleton, as in bicyclo[2.2.2]octane, radical attack takes place preferentially at the [2.2]bridgeheads.

Because of its unusually close, nearly perfectly synperiplanar C=C bonds, bissecododecahedradiene **4** is the prototype of a per se interesting class of cage olefins (see Section 10). The through-space (TS) homoconjugation, which approaches classical π,π conjugation and is evident by UV and photoelectron spectroscopy,[42] causes **4** to be highly reactive vis-a-vis electrophilic or radical partners. The π bonds are formally part of *cis,cis*- and *trans,trans*-1,6-cyclodecadiene rings;[43] because of the C_3 spacers, the TS component of the π,π splitting of the PE bands is not adversely affected by a through-bond contribution.[44] As a consequence of the increase in strain associated with the sp^2 to sp^3 rehybridization (hyperstability), these olefins can act at best only to a limited extent as alkene components in reversible cycloadditions (potential "protective measures").

The difficulties predicted for the olefins **4** and **5** in the catalytic hydrogenation indeed dealt a fatal blow to Route 'B'. Compound **4** could still be hydrogenated to **5**—with reduction of the π,π repulsion as driving force—but the latter was a dead end. Under forcing conditions dehydrogenation (**3**, **4**) and isomerization (**10**) were detractions. Irreversible methods for saturation including cyclopropanation (e.g. **27**), epoxidation, and *cis* hydroxylation (e.g. **28**) are not subject to this limitation (Scheme 8). Multiply modified (Z,Z') derivatives (**6'**,**6"**) with shortened C,C and H,H distances across the cavity, favorable for the dehydrocyclization, became accessible. The X-ray structures of **27** and **28** (Fig. 3), as representatives of the bisseco series, underline the relation between the hybridization of the formerly olefinic centers, the convexity of the cage, and the lateral distances. With a C1–C11 distance of 3.69 Å, compound **28** is already similar to the dodecahedrane; the H ··· H distances across the cavity of 1.70–1.83 Å reveal considerable compression.[45]

Scheme 8.





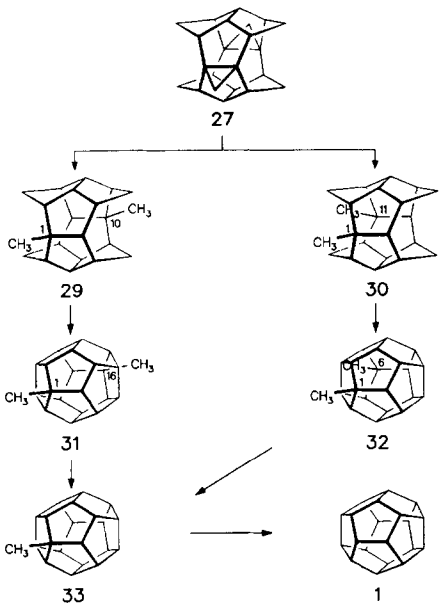


Fig. 3. Selected structural data (*d* in Å, φ in °) for bissecododecahedranes **27** (left) and **28**. R = $CH_2C_6H_5$ (right).

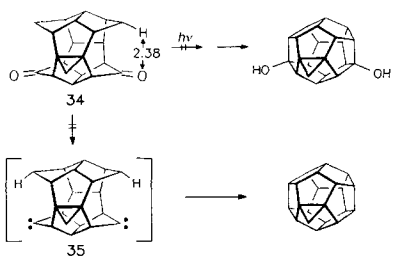
Three examples demonstrate to what extent increasing contraction of the half-cage affects the "lateral chemistry" when going from pagodanes to seco structures. Protonation (alkylation) on the open side takes place exclusively from the *anti* direction; hydrazone formation with "open" ketones is ruled out, and α-methylated *syn* acid chlorides are stable toward hydrolysis.

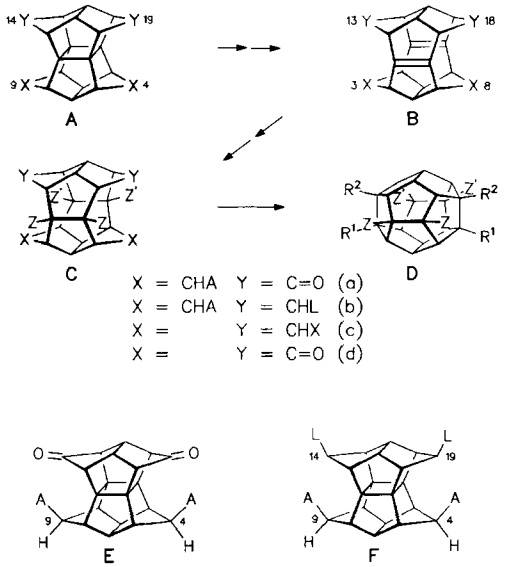


For the final dehydrocyclizations (cf. **6** → **7** → **1** in Scheme 2), mixtures of the substrate with as much as a 100-fold excess of catalyst (Pd/C) are heated up to 250 °C. It was no surprise that the cleavage of the C-Z/Z' bonds in the precursors **6'** (**6"**) and dehydrogenative olefin formation (cf. **5** → **4**) became unavoidable. One of the prominent exceptions is presented in Scheme 9. In the dehydrocyclization of the dimethyl derivatives **29**/**30**, generated by hydrogenolysis from the dicyclopropa precursor **27**, competing dehydrogenation is excluded. With 75–80% dodecahedranes **1** and **31**–**33** the overall result was excellent; however, total dealkylation to give pure **1** or separation into the individual components was only possible with considerable loss of material.[46]

As prelude to the next section a supplement: The lateral C–C bond formations implied in the strategy of Route 'B' (Scheme 2) are, in principle, variants of the widely used 1,5-cyclization in conformationally more or less fixed cyclooctanes.[47] What could be more straightforward

Scheme 9.

than to apply those proven methods to difunctionalized bissecododecahedranes such as the 4,9-diketone **26** and its derivatives, or to "dicarbenes" derived therefrom? To make a long story short, all activities in this direction ultimately came to nothing. The problems involved are exemplified with the two alternative methods given in Scheme 10. Under

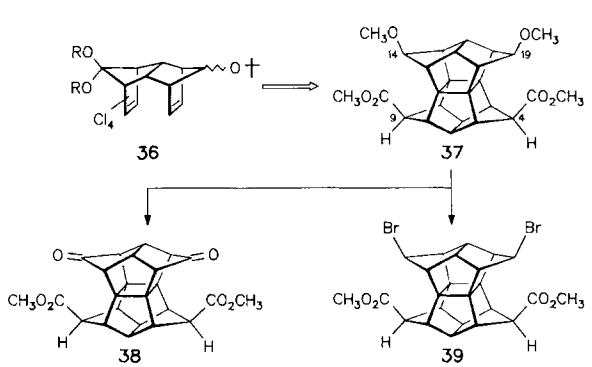


Scheme 10.

the usual excitation conditions for Norrish type II reactions the bissecocyclopropadione **34** remained unchanged; hydrogen transfer could not be induced even with the frequently more favorable solid-state irradiation, although the O–H distances were clearly below the critical limit. The Achilles' heel: the relative position of the partners in the rigid half-cage deviates significantly from that of the ideal transition state ("in-plane orbital mechanism"). In this context it should be pointed out that the homo-Norrish type photoreaction played a central role in the Paquette synthesis.[3] Carbene insertion (**35**), frequently successful especially in the polyquinane area,[48] was not applicable in these half-cages; either the carbene precursor could not be prepared or the carbene could not be liberated.

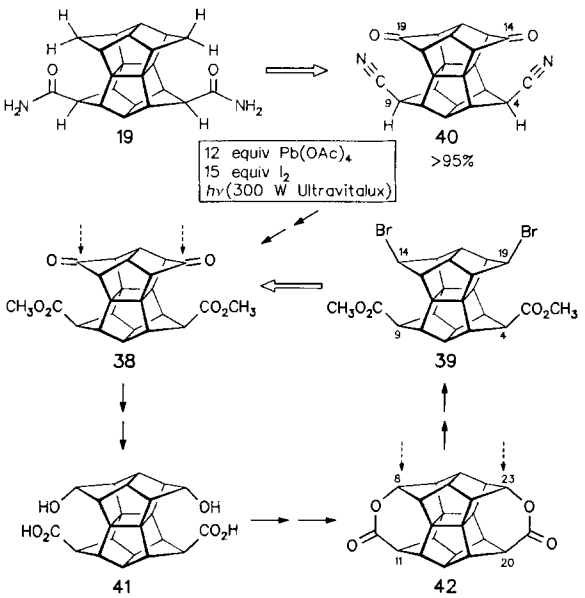
4. The Breakthrough—Dodecahedranes from 4,9,14,19-Tetrafunctionalized Pagodanes

The limitation with regard to the method of cyclization inherent to the original concept of Route 'B' should be overcome with suitably 4,9,14,19-tetrafunctionalized pagodanes (**A** in Scheme 11). "Suitable" functional groups (X, Y) are compatible with the method of opening the four-membered rings (→ **B**)



Scheme 11.

and with the saturation of the olefin (→ **C**), and permit cyclization (→ **D**) without endangering the existing substitution patterns. When these prerequisites are fulfilled, even previously blocked direct routes from unsaturated bisseco compounds leading to unsaturated dodecahedranes (**4** → **8**, **5** → **9**, Scheme 2) should become viable. Two of the alternative methods used hitherto [(a)–(d)], the aldol (Claisen) addition (a) and S_N2 substitution (b) applied to substrates of type **E** and **F**, respectively, will be dealt with here. At this point, the postulate for the activating groups A to be in the *syn* position and the leaving groups L to be in the *anti* position must be emphasized.

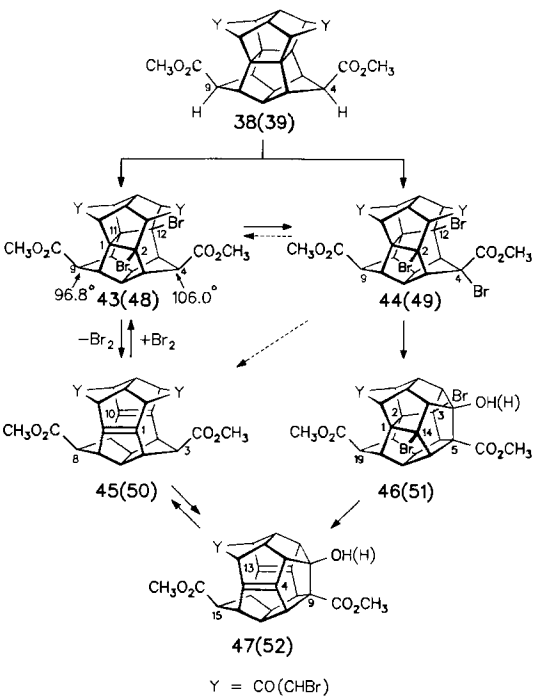


How good were the chances of functionalizing the 14(19)-methylene positions in the 4,9-disubstituted pagodanes (**17**/**19**, **23**), possibly with anchimeric assistance by the 4-*syn*,9-*syn* substituents, by using classical chemistry or biocatalysis? Or would it be better to duplicate the pagodane synthesis with a suitably modified isodrin analogue ("de novo synthesis")?

In parallel attempts the biocatalytic route was ruled out first. The expectation was, based on literature reports, that enzymatic hydroxylation could be achieved selectively for the 14(19)-positions with the directing assistance of *syn*-oriented groups such as CH_2OH, CO_2H, and $CONH_2$, which would also possibly improve the water solubility, but these hopes did not materialize.[49] Success came first with the de novo synthesis (Scheme 12).[50] The 14-*anti*,19-*anti*-dimethoxypagodane-4-

Scheme 12.

syn,9-*syn*-diester **37** (together with ca. 10% *syn,anti* isomer) was obtained from the 11,11,12-trisalkoxy-substituted isodrin analogue **36** (not exactly cheap) with roughly comparable effort but considerably lower overall yield (6.5%; ca. 84% for each of the 16 operations) along a reaction sequence that was closely patterned after the original (cf. Scheme 4). Thus, **37** provided access to ideal candidates (**E**, **F**) for the aldol (a) and the S_N2 variants (b) in Scheme 11, diketodiester **38** and 14-*anti*-19-*anti*-dibromodiester **39**, respectively. Prior to the decision whether to continue the program on this basis, the breakthrough came with the third approach (Scheme 13).[51] The



Scheme 13.

syn,syn-dicarboxamide **19** was converted into the diketodinitrile **40** by a Barton-type method in a one-pot operation. The "recipe" formulated after time-consuming optimization is detailed in Scheme 13; an almost quantitative yield was reproducible in 10-g runs. The complexity of the ketonitrile formation, the mechanistic details of which are still not clarified, was not so remarkable since oxidations ("double substitutions") by the combination of $Pb(OAc)_4$ and I_2, and photochemical conversion of iodoamides into nitriles were known from the literature.[52] The supposedly unprecedented uniformity was more amazing. After all, each of the at least 14 steps proceeding through radicals—seven for each side of the molecule—had to proceed practically quantitatively. In these half-cages steric and stereoelectronic effects cooperate apparently in an optimal fashion.

In **40** the acid-labile pagodane skeleton is deactivated to such an extent that it survived the sterically strongly retarded saponification to the dicarboxylic acid without too much damage (24 h reflux in conc. HCl/acetic acid)—as will be seen an essential measure and only possible under acid catalysis. With a total yield of 15–18% for the diketodiester **38** based on isodrin **12** (compared with 6.5% for the de novo synthesis), the aldol route had an acceptable start.[53] Obviously **38** could also serve as basis for **39** and hence for the S_N2 route. An elegant solution, which was judged to be adequate at the time, was provided by the sequence of regiospecific reduction (**41**), lactonization (**42**), and regiospecific substitution (75% yield of **39** based on **40**).[54]

The next step intended in the concept (Scheme 11) was the conversion of the tetrafunctionalized pagodanes **A** into the bissecodienes **B**, following the procedure successful with the basic skeleton and simple derivatives (Scheme 14). The accumu-

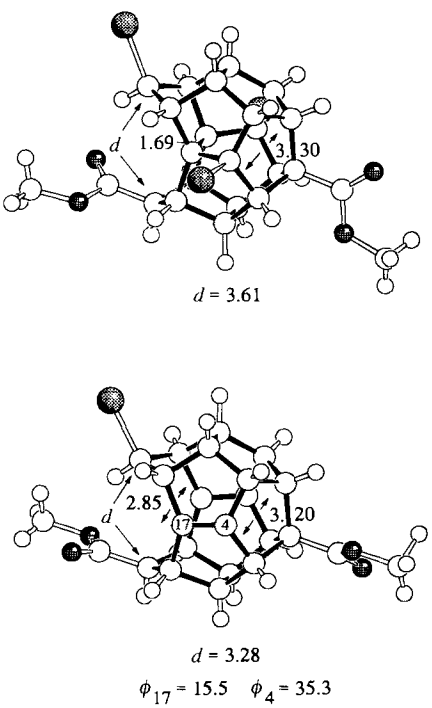
Scheme 14.

lation of functionalities in pagodanes such as **38**–**40** was not, however, without consequences, both for the photoaddition and for the fragmenting elimination of bromine; the latter was favored only above 150 °C. In fact, the addition was either completely prevented (**40**) or slowed down so much that substitution primarily at the ester-bearing positions (C-4(9)) became competitive or comparably fast. Still, the aldol intermediate **38** could be selectively photobrominated to give the tribromide **44** (92%), if only at incomplete conversion. The subsequent substitution of C-9 is markedly slower, in agreement with the smaller valence angle. The fatal blow for the use of **44** in the sequential reductive substitution and elimination (**44** → **43** → **45**) was the yield of bissecodiene **45** with at best 60%. A competing reaction partly responsible for the low yield indicated the solution, once more in the form of efficient "cage control". Under hydrogenolysis conditions (Pt, 1 atm H_2) **44** underwent quantitative transannular cyclization to yield the "isododecahedrane" **46** rather than reductive substitution to give the dibromide **43**. When in addition the 1,4-bromoelimination in **46** could be directed with high selectivity to afford the more stable and less strained secodiene **47** (90%), and when the latter opened smoothly to give **45** under alkaline work-up conditions, the problem for the aldol route was solved in a nearly perfect, though somewhat lengthy fashion.

For the "S_N2 intermediate" **39** (Y = CHBr) again the shortest pathway to the bissecodiene **52** was barred. The challenge was once more the control of the photobromination—arrest at the stage of the pentabromide **49** (>90%), after addition (**48**) and substitution on one side. The most economical exploitation of **49**, a one-pot reaction (Zn/DMF) furnishing the secododecahedradiene **52** directly by 1,4- and 1,5-bromoelimination (**49** → **50** → **52**), was only moderately efficient (close to 60% yield). As partial compensation the hydrogenolysis **49** → **48** could be accomplished completely uniformly, unlike the analogous reaction of **44**, and without affecting the other bromine substituents. As the elimination **48** → **50** proceeded without complications after the exchange of zinc by iron, the S_N2 route, too, was well served with an overall yield of at least 80% for the three-step sequence **39** → **49** → **48** → **50**.

The fragmentation patterns in the mass spectra of the secopagodanes **48**/**49**, the (bis)secododecahedradienes **50**/**52**, and the isododecahedrane **51** deserve attention with regard to the (radical) cyclization methodology listed under (c) in Scheme 11. Intensive signals for the $C_{20}H_{14}$, $C_{20}H_{12}$, and $C_{20}H_{10}$ ions, resulting from the elimination of (H)Br and $CH_3CO_2(H)$ units, are assigned to multiply unsaturated dodecahedranes originating from lateral radical recombination (cf. also Scheme 27).

Typical for the nonpentagonal isododecahedranes **46**(**51**) is that they are hybrids of pagodane and dodecahedrane "halves". In the X-ray structure of **51** (Fig. 4)[55] a correspondingly large



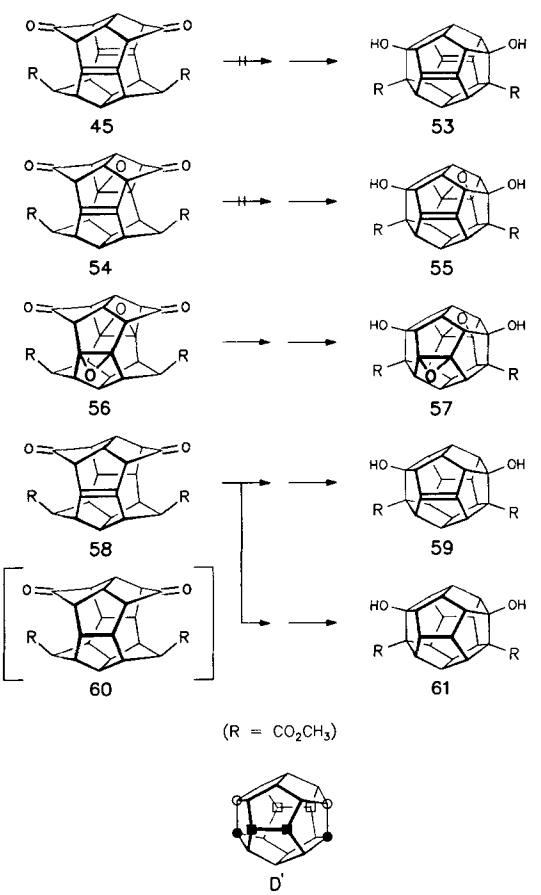


Fig. 4. Selected structural data (*d* in Å, ϕ in °) for isododecahedrane **51** (above) and secododecahedradiene **52** (below).

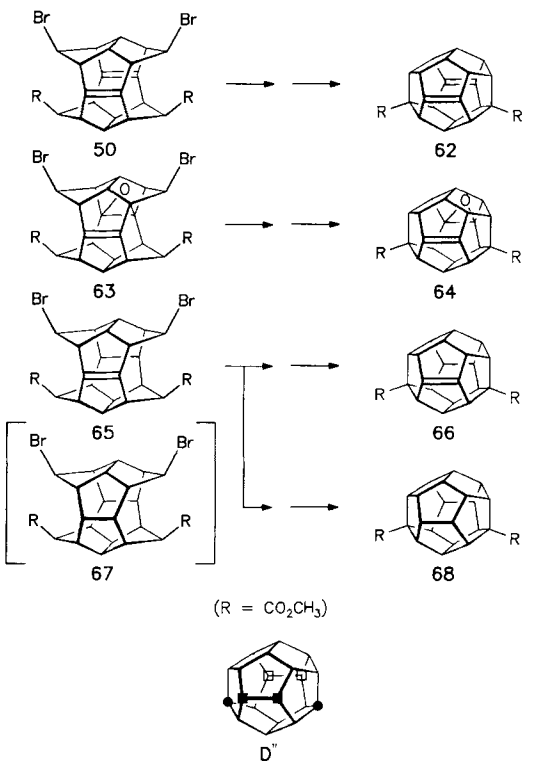
C10–C19 distance of 3.61 Å is observed (cf. 3.530 Å (3.611 Å) for **3** (**17**) in Fig. 2). The C1–C2 bond broken en route to **52** is, at 1.69 Å, one of the longest C–C single bonds measured.[56] The secododecahedradienes **47** (**52**) are hybrids of the nearly flat bissecodiene (cf. **27** in Fig. 3, **45** in Fig. 6) and the already significantly bulged 1,16-dodecahedradiene (cf. diepoxide **57** in Fig. 5 as the best model subjected hitherto to X-ray structural analysis). Correspondingly, the distances across the cavity on the "open" side of the molecule are short; the π,π distance and the pyramidalization of 35.3° on the "closed" side are large. According to "π orbital axis vector" analysis, the $(\theta_{\sigma\pi}-90)°$ value, a measure of the pyramidalization of C4(12) in the bissecodiene parent structure, surpasses that of the icosahedral C_{60} fullerene.[57]

Under the influence of their strongly electron-withdrawing functional groups (quantified inter alia by the oxidation and ionization potentials[58]) the bissecodienes **45** and **50** are easier to handle—less sensitive to oxygen and ionic or radical species. The hyperstability of the monoenes (**58**, **65**) is not affected, which provided the chance of varying the substitution pattern nearly at will en route from **B** to **C** (Z,Z'), an option not possible at the stage of the dodecahedradienes (e.g. **62**), which are no longer hyperstable. The drawback was already stated above: reversible cycloadditions, valued as potential protective measures for the highly sensitive C=C bonds of the unsaturated dodecahedranes, are not possible at this stage.



The scope and limitations of the cyclizations **C** → **D** following the aldol variant[53] are illustrated with the five examples in Scheme 15. In agreement with predictions based on calculations, only the endothermic cyclizations leading to diene **53** and eneepoxide **55** are not realized. (Attempts to conduct the reactions irreversibly had no success, probably for steric reasons.) Dodecahedranes with four (**61**), six (**59**), and eight (**57**) pairwise

Scheme 15.

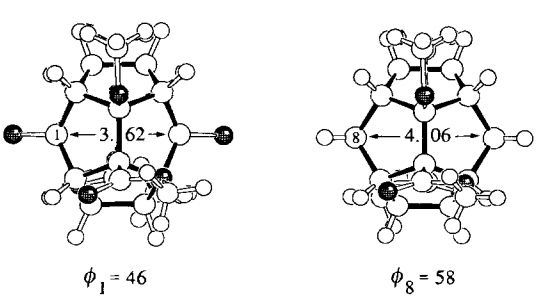
symmetrically functionalized positions (**D'**) were obtained almost quantitatively under controlled basic conditions.

The irreversible S_N2 variant (Scheme 16), as expected, allowed access to the diene **62** and to the eneepoxide **64**. Indeed the reactions were quite clean (over 90% yield), when the particular reactivity of both starting material and product was taken

Scheme 16.

into account with a phosphazene base and careful exclusion of oxygen. The saturated diester **68**, which was an important intermediate in later work (vide infra), was prepared in analogy to **61** by "hydrogenating cyclization" of the ene precursor **65**. In toto, the set of dodecahedranes (**D'**) prepared by the aldol reaction is complemented by those obtained by the S_N2 reaction (**D''**) with two (**68**), four (**66**), and six (**62**, **64**) functionalized positions.[54]

The X-ray structures of the dimethyl ethers of **57** and **61** (Fig. 5) disclose how the vicinal substituent pairs are accommodated in the crystal lattice and how strongly the dodecahedral skeleton is flattened as a result of epoxide annulation.[59]



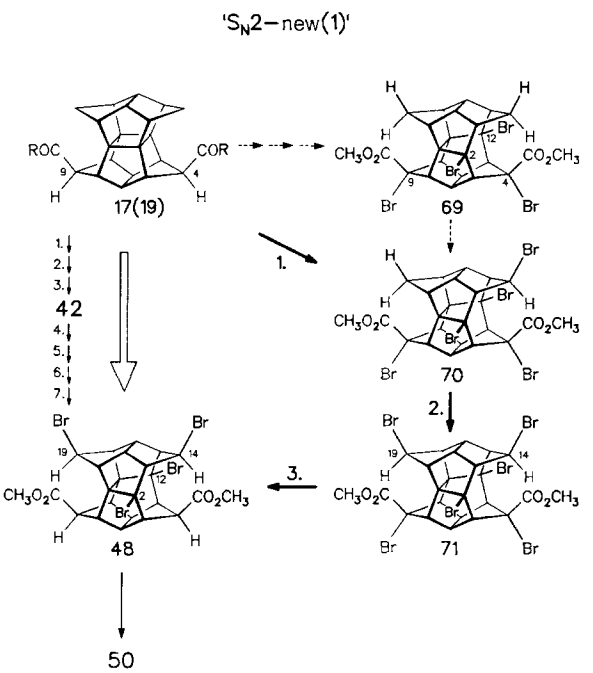


Fig. 5. Selected structural data (distance in Å, ϕ in °) for dodecahedranes **57** (left) and **61** (right) as dimethyl ethers.

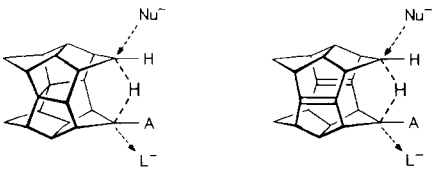
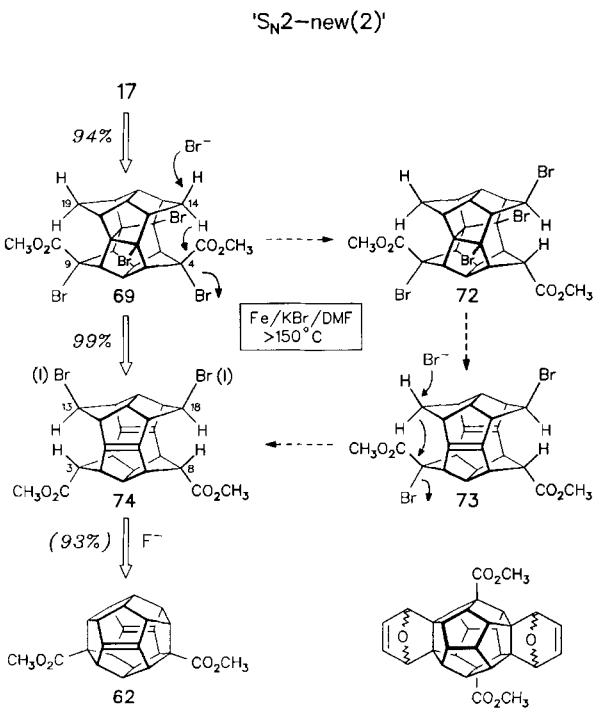
5. More Economy—The Breakthrough after the Breakthrough

For all the enthusiasm about the preparative potential of the aldol and S_N2 routes, and implicitly about the ways and means for converting the directly introduced 4,9-disubstitution (Scheme 5) into the 4,9,14,19-tetrasubstitution of the pagodane intermediates (Scheme 13), the S_N2 version in particular was very labor-intensive, and for some of the projects based thereon almost prohibitive. Impressive improvements are presented in this section.

As a shorter alternative to the S_N2 version, the route from the pagodane diester **17** to the central bissecododecahedradiene **50**, outlined in Scheme 17, by means of a straightforward sequence



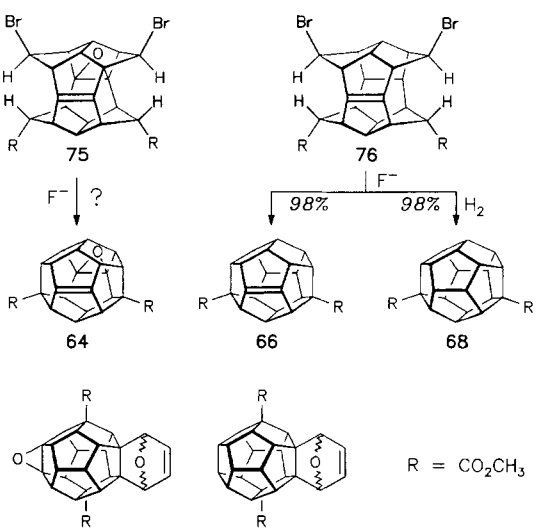
Scheme 17.



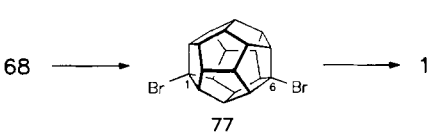
of additive/substitutive brominations and reductive/fragmentative debrominations (tetrabromide **69**, pentabromide **70**, hexabromide **71**, tetrabromide **48**) had been considered and tested very early on. For a long time, however, this approach yielded no practical results, as no satisfactory solutions could be achieved for two of the manipulations, the photobromination **70** → **71** and the second reduction of **71** (C-9)—explainably slow processes. Recently, these deficiences could be remedied by changing the light source and the medium. And since the multistep sequence from **17** to **48** was compressed into three operations (**17** → **70** → **71** → **48**)—compared with seven steps in the previous route via bislactone **42**—the time required for the preparation of the "S_N2 dodecahedranes" (Scheme 16) was reduced by two-thirds, and in addition the overall yield increased by more than one-half.[60]

"Appetite comes with eating." Isn't there an even shorter, quicker, more efficient way? Why not use hydride transfer across the cavity in the half-cages of the secopagodanes (cf. the

C4–C14 distance of 3.14 Å in **10**, Scheme 3) and the bissecododecahedranes (cf. the C3–C13 distances of 3.21–3.02 Å in **4**–**6**, Scheme 2), which are predestined for this purpose, for a directed functionalization of the methylene positions? One is reminded of the numerous literature examples of such transannular processes in eight-membered rings, in particular in those that are conformationally restricted.[47, 61] In fact, this strategy did open up new perspectives (Scheme 18).



The tetrabromide **69**, which was not isolated on the way from the pagodane diester **17** to the secopentabromide **70**, but secured almost homogeneously under controlled bromination conditions, fulfilled the requirements for the combination of hydrogen transfer and *anti* substitution on both sides along with 1,4-bromine elimination. Finally optimized as a one-pot process, the reaction of **69** with Fe/KBr in boiling dimethylformamide (DMF) gave an almost quantitative yield of the bissecodibromodiene diester **74**, the all-*anti* isomer of **50**. Control experiments confirmed the sequence of events (**72** before **73**).[60]

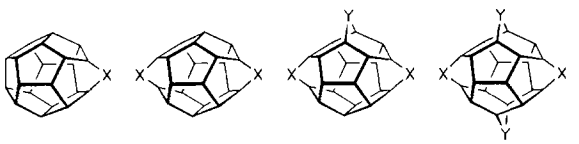


Scheme 18.

Thus, the pagodane → bissecodiene opening was condensed into two operations, and the time required for the preparation of gram quantities of **74** with an overall yield of more than 90% was reduced to a few days. Yet, this achievement had its drawbacks: the kinetic acidity of the 3-*syn*,8-*syn* hydrogen atoms in **74** is considerably less than that in **50**, since the effective steric pressure on the ester groups operative in **50** is absent (ca. 10 kcal mol^{-1} each; ca. 7 kcal mol^{-1} each in **17**, Table 1). In addition, the *syn* hydrogen atoms are rather inaccessible (cf. the problem with the dehydrogenation leading to **13**). None of the bases successful with **50** could be used for deprotonation and cyclization of **74** to give the dodecahedradiene **62**. Once again the steric situation in the seco half-cages almost led to failure. The small "naked" fluoride base recently introduced by Schwesinger[62] was the remedy. With this base, **62** could be isolated in roughly 50% yield as such or as the double furan adduct (mixture of isomers); with better leaving groups than those in **74** (13,18-diiodide) the yield could be raised to better than 90%. After epoxidation or hydrogenation of **74** to **75** and **76**, respectively, the 3(8)-*anti* analogues of **63** and **65**, the steric situation in the half-cage was even worse. The F$^-$-catalyzed cyclization (in the presence of furan) of either **75** or the diepoxide gave no uniform result (opening of epoxides through the ester enolate?); however, reaction of **76** provided a very high yield (98%) of dodecahedrene **66** in pure or protected form (Scheme 19). Note: the saturated diester **68** was obtained via **76** (**66**) with an almost quantitative yield in a one-pot operation.

Scheme 19.

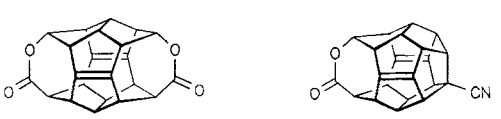
At the close of this chapter it must be emphasized that with the now much more readily available diester **68** a much more efficient access to dodecahedrane **1** was achieved. Of several alternatives explored, the sequence of Barton-type degradation to the 1,6-dibromide **77** and reduction with an overall yield of 90% fulfilled even the highest expectations (Scheme 20). The



Scheme 20.

problem to be solved was the efficient trapping of the intermediate dodecahedryl radicals in spite of strong frontal shielding.[63] Now that dodecahedrane was available by a highly efficient approach, the barrier was lowered for burning at least 0.5 g of a still most valuable material ("who wants to burn diamonds?") for a combustion calorimetric determination of the thermochemical data. The enthalpy of formation deduced for parent **1** from the corresponding values for the pagodanes **3**/**17** and dodecahedrane diester **68** in collaboration with Rüchardt/Beckhaus and Paquette confirmed the reliability of the trends derived from the force field calculations claimed at the outset (Table 1).[64] In absolute terms the MM2 values are better than the ones from ab initio calculations.[65]

6. Nonpentagonal (Hetero)Homologous Dodecahedranes



A preparative extension of the dodecahedrane synthetic scheme was aimed at the modification of the C_{20} perimeter by the insertion of functionalized carba- or heteroelements, as outlined by formulae **G**–**K**. First examples of simply expanded structures (**G**, X = CHR, C=O, N, CH^+) have been described by Paquette's group.[3]

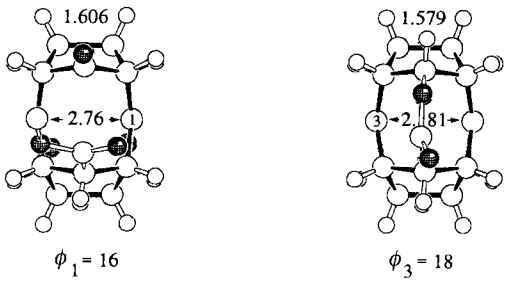
G H I K

We can only convey here some examples of a multitude of nonpentagonal, (hetero)homologous dodecahedranes that have been developed from 4,9,14,19-tetrafunctionalized pagodanes. It is understood that the increasing strain associated with exchange of [3.3.0] with [3.3.X] elements in the C_{20} perimeter is a limiting factor.

Lactone-bridged pagodanes can be converted into the homologous, nonpentagonal dodecahedradienes **78** (**H**, X = OCO) and **79** (**G**, X = OCO) by standard procedures.[66]

78 79

The X-ray structure (Fig. 6) of **78** gives a clear idea of the "flattening" of the molecular skeleton enforced by the bridges and the much greater similarity to bissecodienes (e.g. **45** as an example analyzed by X-ray structural analysis) than to pentagonal dodecahedradienes (e.g. **62**).[67] Accordingly, the behavior of compound **78** more closely resembles that of the bissecodiene. Monolactone **79** is a typical hybrid of **78** and **62** as judged



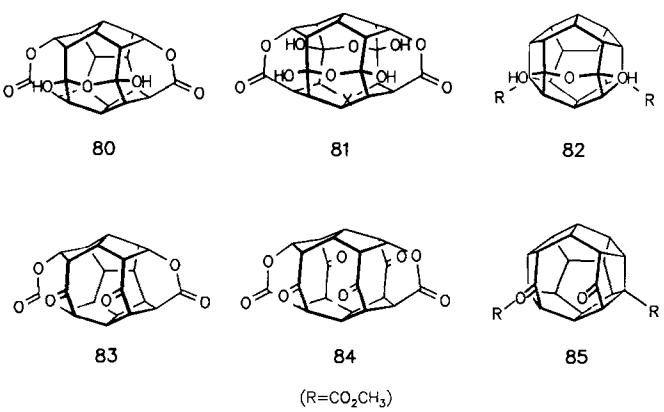


Fig. 6. Selected structural data (distance in Å, ϕ in °) for the bissecodiene **45** (left) and the nonpentagonal dodecahedradiene **78** (right).

by the criteria of olefin strain, pyramidalization, and π,π interaction.

The ether bridges in homologues **80** (**I**, X = OCO, Y = O) and **81** (**K**, X = OCO, Y = O) were installed by ozonation of the corresponding olefins (inter alia **78**). The rapid thermal loss of oxygen from the primary peroxides (Y = O–O) is also evidence for high strain in these skeletons. The same is true for the oxa-homo structure **82** (**G**, X = O) gained in analogous fashion from the dodecahedrene **66**. The α,α'-dihydroxyethers **80**–**82** are valuable precursors of the caged di- and tetraketones **83**–**85**, which have an almost parallel, unusually close alignment of carbonyl groups.[68]

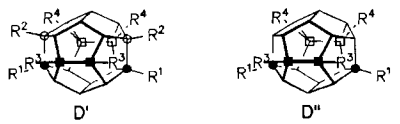
(R=CO_2CH_3)

7. Variations on the Periphery



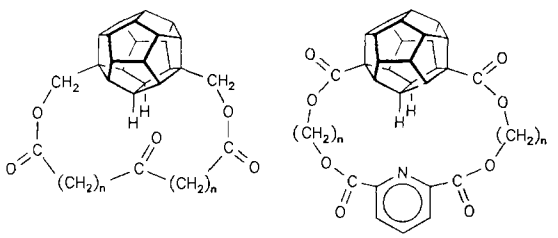
Structure **1** is nearly free of angle strain;[69] the measured strain energy of roughly 61 kcal mol^{-1} (Table 1) stems almost exclusively from interactions between the strictly eclipsed C–H bonds. How does the strain change when two (vicinal or in 1,3-positions), three, or more hydrogen atoms in **1** are replaced by OH groups or halogens?[70] Is it possible to replace all 20 hydrogen atoms?

A glance at Tables 2 and 3 is helpful for better understanding the problems and opportunities connected with positioning or changing one or more functionalities on this rigid periphery.[71] A second, vicinal OH group "costs" practically nothing, whereas the "price" for a second vicinal F, Cl, or Br substituent is about 3, 4, or 7.5 kcal mol^{-1}, respectively. The difference of 3.4 kcal mol^{-1} between 1,2- and 1,3-dibromides will be addressed below as a directing effect for selective substitution.

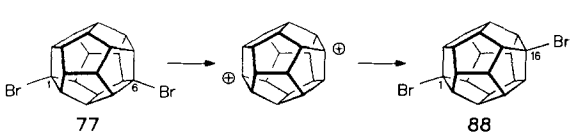
Table 2. Increase in strain energy [kcal mol^{-1}] predicted by MM2 calculations upon mono-, di-, and trisubstitution of **1** (E_{str} = 68.9 kcal mol^{-1}).

X	1	1, 2	1, 3	1, 2, 3
OH	0.07	0.12	0.10	0.17
F	3.80	6.82	7.60	9.84
Cl	1.91	5.95	3.81	10.34
Br	4.32	11.96	8.58	20.21

The substitution patterns (**D'**, **D''**) introduced directly in the aldol and S_N2 routes (Schemes 15 and 16) can be varied extensively: R^1 (R^2) by modification or degradation of the original CO_2CH_3 (OH) groups, and R^3 (R^4) via the monoenes/monoepoxides (**59**, **66**, **55**, **64**) and dienes/diepoxides (**62**, **57**), respectively.[54] Ansa derivatives should have allowed attack at hitherto inaccessible positions ("remote functionalization"), but the outcome was preparatively of no use.



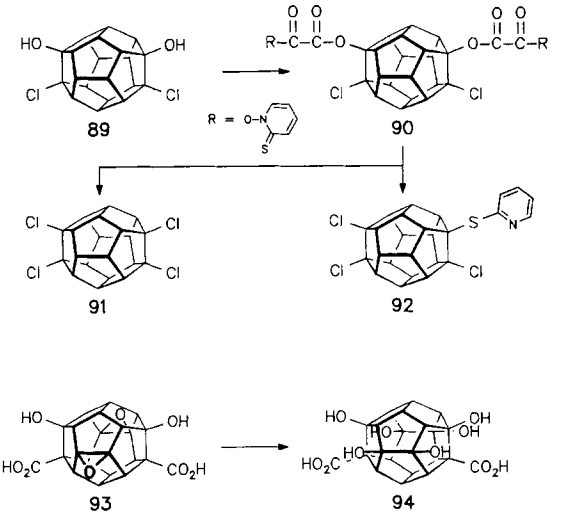
D' D''



R^1 = CO_2CH_3, CO_2H, COCl, $CONH_2$, $COCH_3$, CHO, CH_2OH, $CH_2NH_3^{\oplus}$ CH_2Cl, CH_2Br, CN, NHCOO*t*Bu, $NHCOCH_3$, $NH_3^{\oplus}$, $OCOCF_3$, F, Cl, Br, I

R^2 = OH, OCH_3, OAc, $OCOCF_3$, O–CO–CO–Cl, O–CO–CO–OCH_3, Cl

R^3, R^4 = H, Cl, Br, OH, $OCOCF_3$, O, NR, S, N_3R

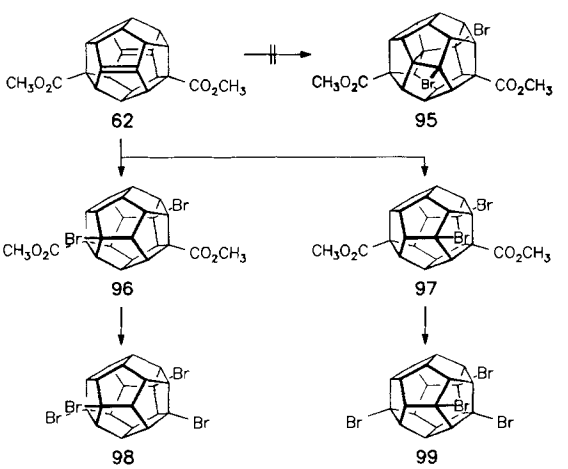


Here are some examples of the preparation of polyhalogenated (hydroxylated) dodecahedranes wanted inter alia as precursors of polyunsaturated dodecahedranes.[72] The 1,6-diester **68** was a valuable intermediate for the preparation of 1,6-dihalides by a radical or cationic route, as already shown above for the dibromide **77** (Scheme 21). Frontal hindrance in dodecahedryl radicals became only seriously detrimental in the case of the diiodide. With the known, thermodynamically controlled isomerization (**88**) in super acid media, the 1,6-dibromide **77** leads to the series of 1,16-difunctionalized derivatives.

77 88

Scheme 21.

High vicinal strain controlled the radical conversion of the dichlorodiol **89** into the tetrachloride **91** (Scheme 22). Preparation of the Barton intermediate **90** was extremely slow, and the

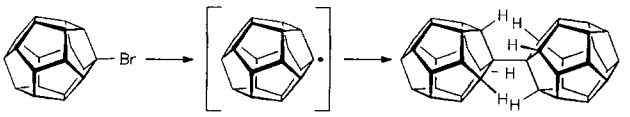


89 90 91 92 93 94

Scheme 22.

intermolecular radical recombination faced competition by the "intramolecular" recombination (**92**).[73] During ionic processes hydrogen atom migration on the molecular surface did not compete.[3, 4] Thus the vicinal diols were formed almost homogeneously by acid-catalyzed opening of the epoxides; for example **93** yielded the readily water-soluble hexahydroxydicarboxylic acid **94**.

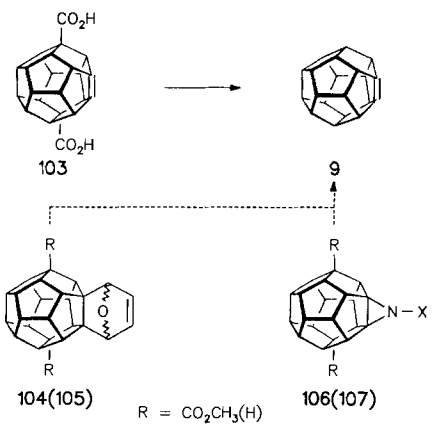
The unsaturated dodecahedranes are markedly different in their behavior toward electrophiles compared with the bisseco olefins. For example, in the double *cis*-addition of HBr to **62**, homoconjugate addition here to give the didehydrododecahedrane **95**, generally dominant for the bissecodienes (e.g. **4**, **45**, **50**), had no chance (Scheme 23). The double Barton degradation of the isolated nonvicinally substituted dibromodiesters **96**/**97** to the C_2/C_s-tetrabromides **98**/**99** was efficient.



62 95 96 97 98 99

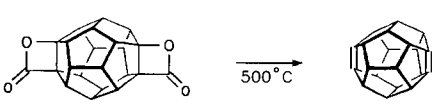
Scheme 23.

It should be stressed that the sterically demanding dimerization of two dodecahedryl radicals has not been observed in any of the numerous radical processes. When bromide **100** was subjected to suitable Wurtz coupling conditions, the presumably rigidly eclipsed didodecahedryl **102** (E_{rot} = 34.2 kcal mol^{-1},



MM2) could be generated in low yield besides **1** as major component (Scheme 24).[74] Direct characterization of the dodecahedryl radical **101** has not yet been achieved.[75]

100 101 102



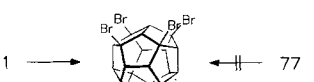
Scheme 24.

The unsaturated dodecahedranes, as π_2 components with a relatively low-lying LUMO,[76] participate readily in [4 + 2]-cycloadditions, for example with 1,3-butadiene and furan even at room temperature.[77] The perspectives in the area of annulated carba- and heterocycles have been documented on numerous occasions. Aziridines and furan adducts also act as "protected olefins" in substituent manipulations. Thus, conversion of the sensitive enedicarboxylic acid **103** into the even more sensitive parent ene **9** could be effected by double decarboxylation of the adducts with furan or tosylazide and gas-phase thermolysis of **105** or low-temperature nitrosation of **107** (X = NO) (Scheme 25).

Scheme 25.

The bis-β-lactone **108**, a doubly hetero-annulated derivative (and hence the aldol product **61**) emerged as precursor of choice for the 1,16-dodecahedradiene **8**, which is even more oxygen-sensitive than the monene **9**[78] and much desired as a model for transannular interactions (Scheme 32). The special nature of the C=C bonds to be formed (Ψ ca. 45°!) once again[79] necessitated very drastic conditions (gas-phase thermolysis, 500 °C) for the decarboxylation, which was first observed in the mass spectrum, without **8** suffering detectable damage (Scheme 26).

108 8



Scheme 26.

With the availability of **1** in gram quantities the possibilities for polyfunctionalization could be explored experimentally on a wider basis. Polya's group theoretical approach provided the insight, as shown by the data in Table 3, that this venture only made sense statistically for the $C_{20}H_{19}X$, $C_{20}H_1X_{19}$, and $C_{20}X_{20}$ compounds, even for identical functionalities (X).[71]

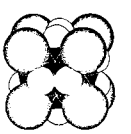


Table 3. Numbers of structural isomers (Polya).

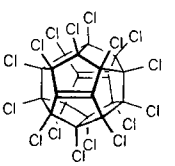
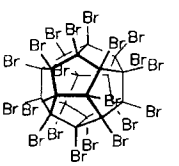
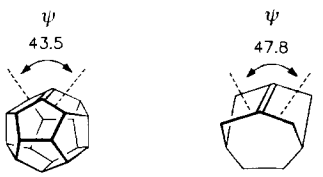


Formula	Isomers	Formula	Isomers
$C_{20}H_{19}X$	1	$C_{20}H_{14}X_6$	371
$C_{20}H_{18}X_2$	5	$C_{20}H_{13}X_7$	693
$C_{20}H_{17}X_3$	15	$C_{20}H_{12}X_8$	1135
$C_{20}H_{16}X_4$	58	$C_{20}H_{11}X_9$	1466
$C_{20}H_{15}X_5$	149	$C_{20}H_{10}X_{10}$	1648

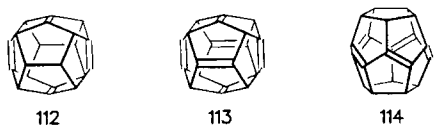
Electrophilic monosubstitution ($C_{20}H_{19}X$) and, under thermodynamic control via the 1,16-dication, selective 1,16-disubstitution ($C_{20}H_{18}X_2$) was practiced by the groups of Paquette and Olah in many cases.[4] Our investigations into the polybromination of **1** under kinetic control support a directing effect that is too weak, however, to be exploited preparatively. Under relatively mild conditions the T_d-symmetrical octabromide **109**, the only $C_{20}H_{12}Br_8$ isomer without vicinal Br substituents, was identified in admixture with lower bromides. In control experiments with the 1,6-dibromide **77**, the only one of the five $C_{20}H_{18}Br_2$ isomers that cannot proceed to **109**, no octabromide was found. The surprise: under "brutal" conditions all of the hydrogen atoms in **1** could be replaced, but "halogen balls" like **110** and **111** have extremely low solubility and can be manipulated only to a very limited extent.[63] Fluorination experiments under "brutal" conditions cause cleavage of the skeleton. Experiments in a NaF matrix (70 °C) led to $C_{20}H_2F_{18}$ (selectively) and even to $C_{20}F_{20}$.[74, 80]



109

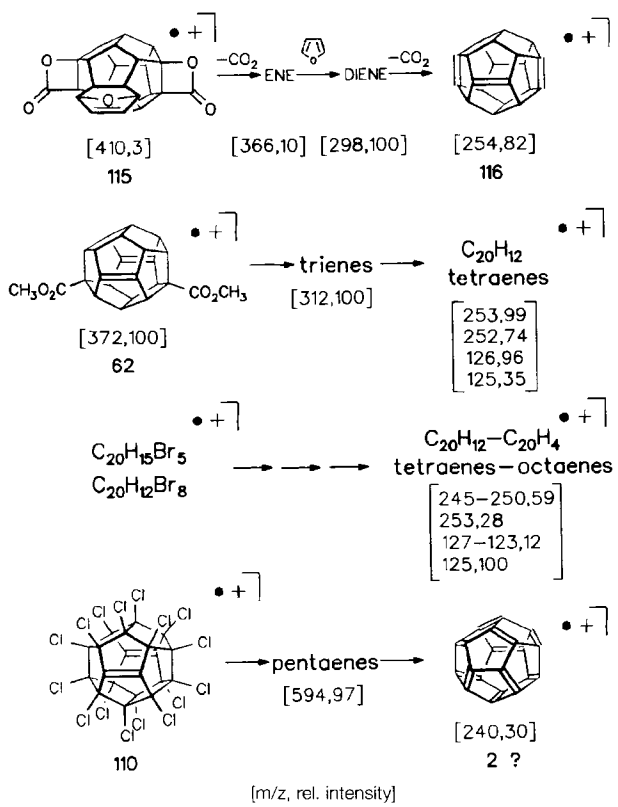


110



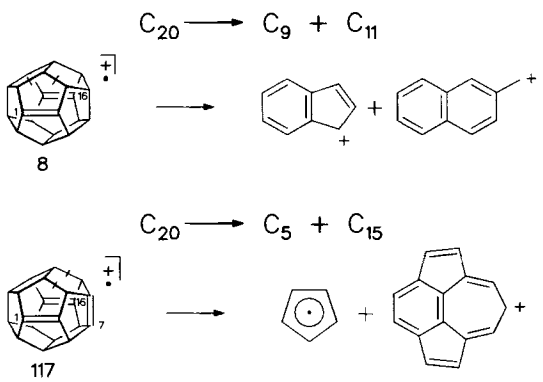
111

8. Polyunsaturated Dodecahedranes—C_{20} Fullerene?



The isolation of the unsaturated dodecahedranes (**8**, **9**, **59**, **62**, **64**, **66**) with their highly bent "diradicaloid" C=C bonds (Ψ) was quite surprising. Such a degree of kinetic stabilization as a consequence of steric shielding through four allylic hydrogen atoms was unexpected; the similarly pyramidalized bicyclo-[3.3.2.$0^{3,7}$]dec-3(7)-ene dimerized upon warming of the argon

matrix (ca. 40 K).[81] One could speculate that even polyunsaturated dodecahedranes would be isolable as long as the C=C bonds are not conjugated, for example tbe D_{2h} tetraene **112** and the T_h hexaene **113**. An exciting "inner life" is anticipated for these compounds as well as their radical cations and dications (see Section 10).[82] Conjugation of double bonds, as in [4*n* + 2]-pentaene **114**[83] or even in decaene **2**, in any case signals a considerably reduced or extremely low persistence.

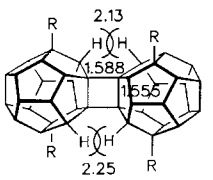


For the existence of polyunsaturated dodecahedranes in the gas phase there is in fact quite convincing MS evidence (Scheme 27).[66] The mass spectrum of **115** shows the fragmentation pattern of the functional groups and indicates that the

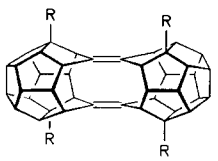
Scheme 27. The *m/z* values and the relative intensities of the signals are given in square brackets.

triene ion **116** is a relatively stable entity. In the spectrum of the diene diester **62**, (protonated) tetraene ions ($C_{20}H_{13}$, $C_{20}H_{12}$) are the dominant fragments; the intense $C_{20}H_{12}^{2+}$ signal could well be an indication of π conjugation. In the MS analysis of the bromide mixture ($C_{20}H_{15}Br_5$ to $C_{20}H_{12}Br_8$), which was prepared to find evidence of the T_d-symmetric octabromide **109**, pentaene ions prevail (*m/z* 250, *m/2z* 125, *m/3z* 83.3) besides (protonated) octaene to tetraene ions; the high intensity of the signals for the multiply charged ions is again taken as evidence for π conjugation. In the spectrum of the $C_{20}Cl_{16}$ product the assignment of the signal at *m/z* 240 to the radical cation of the C_{20} fullerene **2** is still speculative; $C_{20}Cl_{10}$ pentaenes have been substantiated by a signal at *m/z* 594.[63] The possible existence of the smallest, extremely strained fullerene has become a subject of debate following recent ab initio calculations.[84]

The fragmentation of the pagodane framework into two C_{10} halves (above 700 °C) was a thermochemically informative and mechanistically intriguing reaction.[8] Depending on the number and the positions of C=C bonds on the dodecahedrane periphery, various reaction channels for thermal fragmentation should be possible. First hints do indeed exist (Scheme 28).

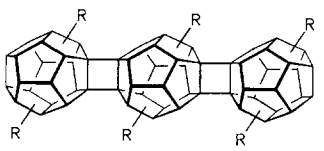


Scheme 28.

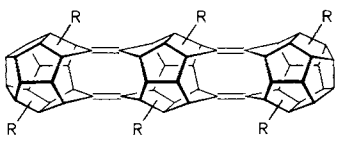


MS fragmentations of type $C_{20} \rightarrow C_9 + C_{11}$ and $C_{20} \rightarrow C_5 + C_{15}$ have been proposed for the 1,16-diene **8** and for the 1,7,16-triene **117**, respectively (but not for the 1,5,16-isomer **116**).[54]

9. From C_{20} via C_{40} to C_{60}

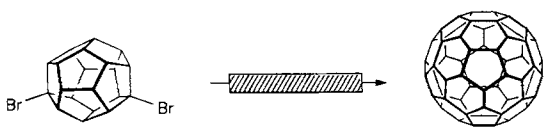


First examples show that the reluctance of unsaturated dodecahedranes to undergo [$\pi_2 + \pi_2$] or ene cycloadditions[85] could be overcome. On heating the ene diester **66** in the solid (exclusion of O_2) the sample melted at roughly 180 °C. Increasing the temperature to about 300 °C caused resolidification as a consequence of a selective [2 + 2] dimerization. For one of the two dimers (C_{2h}, C_{2v}), which was separated chromatographically (**118**, R = CO_2CH_3), X-ray structural analysis indicated that primarily lengthening of the intercage cyclobutane bonds limits the nonbonding H,H interactions.[86] The diene "tubes" **119** resulting from metathetical cyclobutane ring opening promise deeper insight into electron delocalization in organic cages (see Section 10). The one-electron oxidation wave of the octaalkylated cyclobutane **118**, measured by cyclic voltammetry (CV) (E_p = 1.60 V, **119**$^{\bullet+}$?), is irreversible and only a little higher than that of the pagodane diester **17** (1.52 V). For analogous "trimers" (**120**, **121**) diene diester **62** and ene diester **66** are the starting materials.



118

119



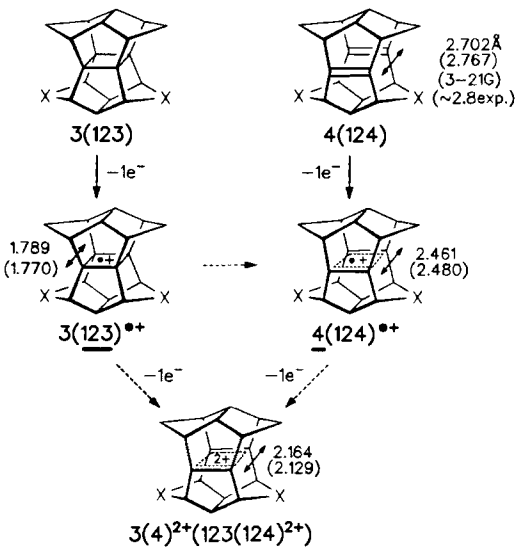
120

121

Related to these "oligomers" are the findings of a laser desorption time-of-flight mass spectroscopic study with dodecahedranes and pagodanes.[87] The prominent discovery: C_{40} "dimers" to C_{100} "pentamers" are formed from the 1,6-dibromododecahedrane **77** after desorption with a 248-nm excimer laser (Scheme 29). At higher ion velocities oligomers appear

77 122

$v \approx 650\,m\,s^{-1}$: $C_{20}H_{18} \rightarrow C_{20}H_{18}Br \rightarrow C_{40}H_{28}Br \rightarrow C_{60}H_{43} \rightarrow C_{80}H_{55} \rightarrow C_{100}H_{65}$
$v \approx 750\,m\,s^{-1}$: $C_{20}H_{18} \rightarrow C_{20}H_{18}Br \rightarrow C_{40}H_{30} \rightarrow C_{40}H_{30}Br \rightarrow C_{60}H_{45}$

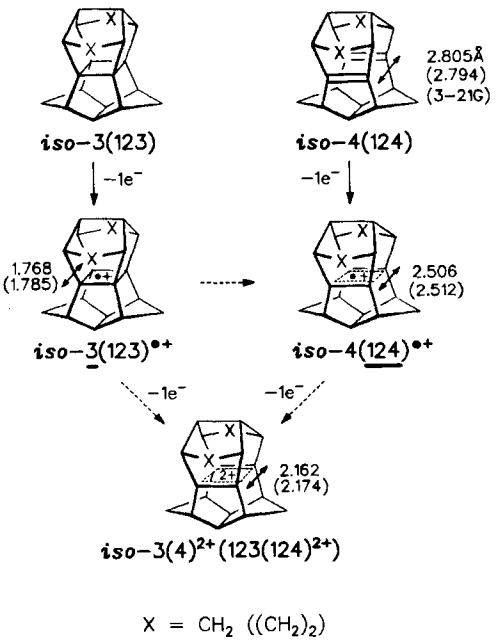


Scheme 29.

which, upon release of all hydrogen atoms and uptake of considerable kinetic energy, rearrange into pure fullerenes, preferably C_{60} (**122**). Nonbrominated substrates such as **68** and **118** give rise to practically no oligomers or fullerenes. This "mechanism" for formation of C_{60} extends the spectrum of the routes so far discussed only for non-three-dimensional sources.

10. The "Inner Life"—Electron Delocalization in Pagodane and Dodecahedrane Cages

The inclusion of guest molecules in (hydro)carbon cages, in particular **1**, was already a popular area of research before the fullerenes opened new dimensions.[88] Since the diagonal distance in **1** is 4.5 Å, a cavity about 1.5 Å across remains after subtraction of the carbon van der Waals radii. Early calculations indicated that this is sufficient for the accommodation of small ions (H^+, Li^+, Be^{2+}, Mg^{2+}) without use of excessive force.[89] Would it be possible to include even a helium atom? Experiments such as those by Saunders et al. should provide an answer.[90] What about smaller guests, for example electrons as participants in transannularly delocalized π systems?



As a reminder: the deeply colored four-center, three-electron (4c/3e) [1.1.1.1] radical cation $\mathbf{4}^{\bullet+}$,[91] which is stable for days at room temperature, and the σ-bishomoaromatic 4c/2e [1.1.1.1] dication $\mathbf{3(4)}^{2+}$ (Scheme 30) are two of the spectacular "spin-offs" of pagodane chemistry.[37, 38] Both ions can be produced

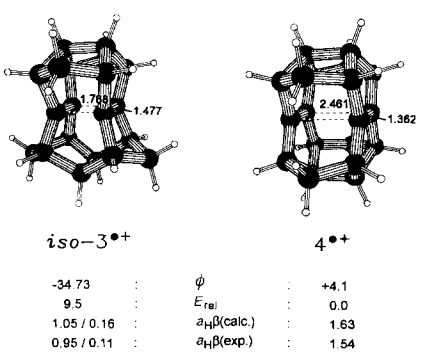
Scheme 30.

from **3** as well as from **4**. The "extended" $\mathbf{4}^{\bullet+}$ is differentiated from the "tight" $\mathbf{3}^{\bullet+}$ inter alia by the $a_{H\beta}$ coupling constants in the ESR spectrum (Fig. 7). The latter, the true [1.1.1.1] pagodane radical cation $\mathbf{3}^{\bullet+}$, is of interest as a potentially "frozen" cyclobutane radical cation[92] and could not be detected even under special ESR (20 K) and MS conditions.[93] In the very fast isomerization $\mathbf{3}^{\bullet+} \rightarrow \mathbf{4}^{\bullet+}$ the symmetry-forbidden concerted pathway is presumably avoided. Electronic and geometric factors cooperate in $\mathbf{4}^{\bullet+}$ and $\mathbf{3(4)}^{2+}$ in almost ideal fashion. The four participating "sp^2" centers are favorably oriented in a rectangular fashion, but the structure is nevertheless flexible enough to allow the shortening of the transannular distances that promote the electron delocalization; elimination of hydrogen is considerably impeded ("anti-Bredt stabilization").[94] A thermodynamically meaningful quantification of the homoconjugative stabilization in $\mathbf{4}^{\bullet+}$ is reflected in the difference $\Delta E = 0.91$ V of the (reversible) oxidation potentials for **4** (0.66 V) and the monoene **5** (1.57 V) determined by cyclic voltammetry (CV). In this context, it should be recalled that analysis of the neutral diene **4** by photoelectron spectroscopy had furnished an unusually high value of 1.90 eV for the through-space homoconjugation, quite close to classical conjugation in 1,3-butadiene (2.46 eV).[42] The [2.2.1.1] ions, the "tight" $\mathbf{123}^{\bullet+}$ (?) and $\mathbf{123(124)}^{2+}$, are considerably less persistent; hydrogen elimination is facilitated in the homologous parts of the molecules.

The relationship between the structure and the stability of these unusual ions has become clearer with the recently re-

Scheme 31.

ported [1.1.1.1]- and [2.2.1.1]isopagodanes (*iso*-**3**, *iso*-**123**, Scheme 31).[32, 95] The fixation of the four-center core of the ions of *iso*-**3** (D_{2d}) in the square geometry is a priori unlikely,[96] but opening to "extended" geometries was made difficult by the skeleton. First experimental findings are in line with these predictions.[97] In contrast to results with **3**, the radical cation of *iso*-**3** is only observed by γ-irradiation in a Freon matrix; between 20 and 140 K it has been characterized as the symmetry-reduced (C_{2v}), "tight" (cyclobutanoid) *iso*-$\mathbf{3}^{\bullet+}$ (Fig. 7). Accordingly, the CV oxidation wave of *iso*-**3** was not reversible. The situation with *iso*-**123** is totally different. The resulting radical cation is the "extended" *iso*-$\mathbf{124}^{\bullet+}$, which is about as persistent as $\mathbf{4}^{\bullet+}$; even the second CV oxidation *iso*-$\mathbf{124}^{\bullet+} \rightarrow$ *iso*-$\mathbf{123(124)}^{2+}$ is reversible. The extent that the altered geometries of the isodications affect the σ homoaromaticity was probed very recently by Olah, Prakash, and Herges. The dications generated from *iso*-**3** and *iso*-**123(124)** in SbF_5/SO_2ClF at $-78\,^{\circ}C$ are both "aromatic" (*iso*-$\mathbf{3(4)}^{2+}$ and *iso*-$\mathbf{123(124)}^{2+}$, respectively; IGLO calculations). The resulting gain in energy is probably instrumental for the lengthening of the transannular distance (ca. 1.8 Å in *iso*-$\mathbf{4}^{\bullet+}$) to about 2.2 Å as postulated for *iso*-$\mathbf{3(4)}^{2+}$.



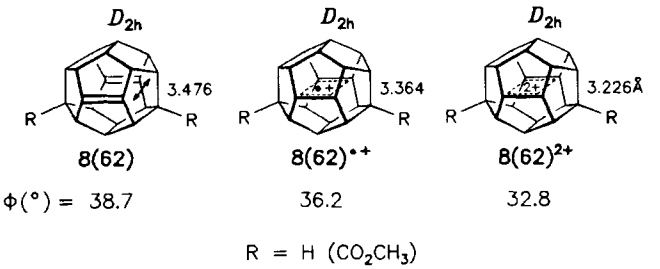


Fig. 7. Ab initio (3-21G) structures (distance in Å, ϕ in °), relative energies [kcal mol^{-1}], and coupling constants [mT] of the 4c/3e radical cations *iso*-$\mathbf{3}^{\bullet+}$ and $\mathbf{4}^{\bullet+}$.

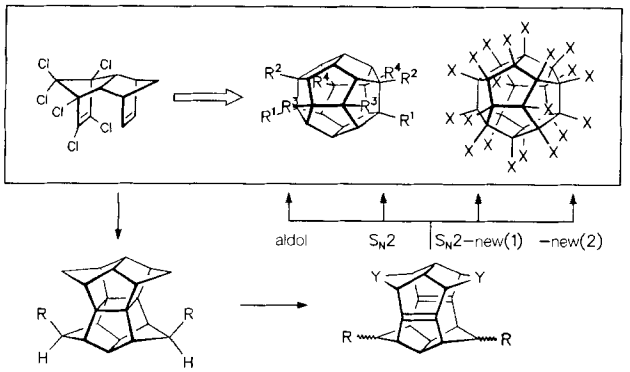
Do through-space interactions in dodecahedrane cages have a chance? In the 1,16-diene **8**, as in bissecodiene **4**, the C=C bonds have an ideal synperiplanar alignment, yet the shortest transannular π,π distance is roughly 3.5 Å (Scheme 2). In addition, as a consequence of the high pyramidalization of the olefinic centers, radial extension of the π orbitals into the cage is reduced. According to most recent calculations[98] and ESR,[99] PE,[100] and CV studies,[58] the transannular relationships in **8** and its derivatives (**62**) as well as in their ions are in principle of the same type, but they have divergent intensities (Scheme 32). In **8** the through-space homoconjugation is cut to



Scheme 32.

almost one-fifth of that in **4**, the first CV oxidation wave is no longer reversible, and the radical cation can no longer be observed in solution. Thus there was great excitement when a moss green radical cation persisted for hours after γ-irradiation of **8** in a Freon matrix (77 K) and was identified as the 4c/3e ion $\mathbf{8}^{\bullet+}$ having D_{2h} symmetry within the hyperfine timescale—in contrast to *iso*-$\mathbf{3}^{\bullet+}$ and $\mathbf{4}^{\bullet+}$ an early point on the reaction coordinate (D_{2h}) for the ethylene/ethylene$^{\bullet+}$ cycloaddition. With a π,π distance only slightly (3-21G) differing from that of the neutral molecule (on account of the higher structural rigidity) this radical cation is truly a borderline situation for homoconjugation! This would be even more true for the dication $\mathbf{8}^{2+}$, which is a no-longer-utopian shortterm target; however, ab initio calculations predict it to be more like a bis(radical cation).[37]

Epilogue

"From Isodrin to Plato's Universe"—the expectations of flexibility and efficiency for the pagodane route to dodecahedrane[4, 5] have been more than met. En route to dodecahedranes (Scheme 33) the highly optimized first section, construction of the pagodanes from isodrin (Scheme 4), could be complemented by a comparably expeditious second one, transformation of the 4,9-disubstituted pagodanes via 3,8,13,18-tetrafunctionalized bissecododecahedradienes. The productive interplay of planning, intuition, and serendipity in reactions of fascinating, if not unprecedented selectivities as a consequence of the entropic support from special cage situations has made the parent skeleton **1** as well as a vast array of multiply and even totally functionalized (unsaturated) dodecahedranes accessible with high efficiency. In the most recent version (Scheme 18) only days are required for the three-step preparation of dodecahe-

Scheme 33.

dranes from pagodanes. With increasing economy of the synthetic processes new targets can be envisaged.

To be free over years to work on projects that more than ever provoke the questions "why? for what reason? for what purpose?" is a privilege—motivation for all the people involved to seek solutions even for seemingly hopeless situations, to optimize processes, and to substitute the good with something even better. And for that there was regular occasion; the struggle for higher yields and efficiency was permanent. Were the synthetic routes per se rewarding goals of the project, unusual properties connected with the unusual structures have satisfied more extensive demands. The cage ions with their unusual bonding situations suffice as attestation. The unexpected persistence of the unsaturated dodecahedranes came as a real bonus. Have "new horizons" been revealed? This depends on the point of view of the observer.[1101] For us, dealing with these polycyclic molecular structures remains full of surprises.

Finally, reference should be made to the "Acknowledgements" of the last progress report with W.-D. Fessner.[8] *The work of the co-workers named therein (Dr. G. Lutz, Dr. H.-P. Melder, Dr. R. Pinkos, Dr. B. A. R. C. Murty, Dr. P. R. Spurr) laid the foundation for their successors (Dr. K. Scheumann, Dr. F. Wahl, Dr. K. Weber, the graduate students T. Voss, A. Weiler, M. Bertau, E. Sackers). Our work has been supported by a competent spectroscopy service (Dr. D. Hunkler, Dr. M. Keller, Dr. J. Wörth, and their co-workers), and a skillful technical staff (J. Leonhardt, M. Lutterbeck, G. Leonhardt-Lutterbeck, S. Ruf). In proven fashion Dr. L. Knothe and G. Fehrenbach helped with the manuscript. The cooperation with the colleagues C. Rüchardt/H.-D. Beckhaus (Freiburg), G. Olah/G. K. Surya Prakash (Los Angeles), H. Fritz (Basel), R. Herges (Erlangen), H.-D. Martin/B. Mayer (Düsseldorf), J. Heinze (Freiburg), G. Rihs (Basel), H. Irngartinger (Heidelberg), C. Krüger (Mülheim an der Ruhr), A. Haas/M. Lieb (Bochum) was a source of constant stimulation. This project was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. Ciba-Geigy, Basel provided decisive help with the repeated production of a precursor material on the kg scale.*

Technetium Radiopharmaceuticals— Fundamentals, Synthesis, Structure, and Development

Klaus Schwochau*

Technetium-99m radiopharmaceuticals are increasingly finding application in nuclear medicine for scintigraphic and emission tomographic imaging, morphologic description and functional testing of organs. Over 80% of the radiopharmaceuticals currently clinically used are labeled with the short-lived, metastable nuclide ^{99m}Tc, whose nuclear properties are almost optimal with regard to a low radiation exposure of the patient and an effective detection of the emitted γ quanta. $^{99m}TcO_4^-$ can be easily prepared without the use of accelerator systems through generator columns. Most of the ^{99m}Tc radiopharmaceuticals are complexes which are synthesized by reduction of $^{99m}TcO_4^-$ in the presence of suitable ligands. To achieve a high organ specificity, some understanding of the relationship between the structure of the diagnostic agent and its organ distribution is necessary. Structure analyses can be carried out on analogous compounds of the long-lived nuclide technetium-99g; these compounds are obtainable in weighable quantities. The development of new ^{99m}Tc radiopharmaceuticals is a challenge to coordination chemists. The syntheses, molecular structures, and applications of the most important ^{99m}Tc radiopharmaceuticals will be described in this review, and current directions and tendencies of the development will be shown.

1. Introduction

Radiopharmaceuticals mostly are organic or inorganic compounds with definite composition that contain a short-lived radionuclide as stoichiometric component. But also macromolecular biomolecules that are not stoichiometrically labeled with a radionuclide can be used as radiopharmaceuticals, as can chemically unbound radionuclides such as the noble gases ^{81m}Kr, ^{85}Kr, ^{27}Xe, and ^{133}Xe. Radiopharmaceuticals are used in very low concentrations and have no intentional pharmacologic effect. The aim of the diagnostic application is the detailed description of the morphologic structure of organs and, in particular, the testing of their physiological function through the accumulation of a radionuclide, whose emitted γ radiation permits the tomographic in vivo imaging of the organs. Suitable radionuclides include, for positron-emission tomography (PET) ^{11}C ($t_{1/2}$ = 20 min), ^{13}N ($t_{1/2}$ = 10 min), and ^{18}F ($t_{1/2}$ = 110 min), for single photon emission tomography (SPET) ^{99m}Tc ($t_{1/2}$ = 6 h), ^{123}I ($t_{1/2}$ = 13 h), and ^{201}Tl ($t_{1/2}$ = 73.5 h).

On average over 80% of the radiopharmaceuticals used in clinics are labeled with ^{99m}Tc, the metastable nuclear isomer of the long-lived technetium-99g in the ground state, which is obtained in weighable amounts from the fission of uranium-235 in nuclear reactors.[1, 2] ^{99m}Tc radiopharmaceuticals are used preferably because of the almost optimal nuclear properties of ^{99m}Tc as well as its convenient availability by using commercial generator columns.[3] The physical half-life of ^{99m}Tc of only 6 h and the absence of tissue-damaging corpuscular radiation[4] allow the injection of activities of more than 30 mCi (1110 MBq) with low radiation exposure of the patient.[5] The half-life is, however, long enough to carry out the labeling syntheses and the scintigraphic measurements without significant losses in activity. On the one hand, the energy of the emitted photons of 140 keV is sufficient to also study organs lying deep in the body. On the other hand, photons of this energy can be collimated with lead collimators with relatively low wall thickness and be detected effectively with NaI(Tl) scintillation counters.[6] ^{99g}Tc, the decay product of ^{99m}Tc, is a pure β-emitter with a half-life of 2.1×10^5 a and does not contribute noticeably to the radiation exposure.

For the synthesis of specific radiopharmaceuticals, the versatile chemistry of this transition element, apparent from the existence of compounds in a large number of technetium oxidation states, is an advantage. However, the labeling requires the complexing of ^{99m}Tc with suitable functional groups. Metabolizable biomolecules must always be functionalized as complexing ligands, and as a result suffer a change in their biochemical properties, especially through coordination to the central technetium atom. Consequently, the use of ^{99m}Tc complexes with ligands without biomolecular character or the use of non-complex compounds such as tetraoxotechnetate(VII) $^{99m}TcO_4^-$ was more successful to date. The development of new ^{99m}Tc radiopharmaceuticals is currently focused more on complexes whose

ligands are chosen under consideration of the expected stability, lipophilicity, charge, and structure of the radiopharmaceuticals. For specific syntheses, knowledge of the relationship between molecular structure and organ distribution is necessary. Molecular structures are, however, only analyzable on weighable technetium compounds, which are obtained by synthesis of a model radiopharmaceutical with the long-lived nuclide technetium-99g. Its structure can then determined with the standard methods used in complex chemistry. After transferring the synthesis process from the ^{99g}Tc to the ^{99m}Tc compounds, the analogous structure of the product can be confirmed by radiochromatographic techniques (HPLC, TLC) or electrophoresis.

2. Preparation of ^{99m}Tc

^{99m}Tc is available through the decay of ^{99}Mo (Fig. 1),[4] and ^{99}Mo can be obtained by irradiation of natural molybdenum or of enriched molybdenum-98 with thermal neutrons in a nuclear

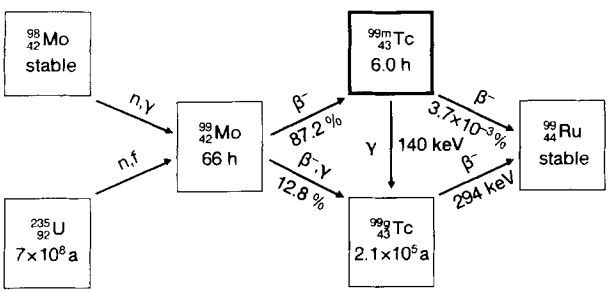

Fig. 1. Formation and decay of ^{99m}Tc and ^{99g}Tc [4].

reactor. The cross section of the reaction ^{98}Mo(n_{th},γ)^{99}Mo amounts to 0.13 barn.[7] Molybdenum trioxide, ammonium molybdate, or molybdenum metal are used as target compounds. This so-called (n,γ)-molybdenum-99 is obtained in high nuclidic purity; the specific activity, however, amounts to only a few Ci per g. In contrast, molybdenum-99 with a specific activity of more than 10^4 Ci (3.7×10^8 MBq) g^{-1} is obtainable by fission of ^{235}U with thermal neutrons in a fission yield of 6.1 atom%.[8] Natural or ^{235}U-enriched uranium in the form of metal, uranium-aluminum alloys or uranium dioxide, is used for the fission. The isolation requires many separation steps, particularly for the separation of other fission products and transuranium elements which are also formed.

The nuclide ^{99}Mo decays with a 87% probability to ^{99m}Tc, which almost quantitatively converts, by isomeric transition with a half-life of 6 h under emission of photons of the energy 140 keV, to the ground state ^{99g}Tc; the loss of photons due to internal conversion is about 10%.[9] Only 4×10^{-3}% of the decay products of ^{99m}Tc leads, under β^--emission, directly to stable ^{99}Ru.

The nuclide ^{99m}Tc is separated from ^{99}Mo mainly by column chromatography, and only for special cases by sublimation processes or solvent extraction. The development of the first chromatographically functioning ^{99m}Tc generator succeeded, as early as at the end of the 1950s, at the Brookhaven National Laboratory, USA.[10, 11] Currently acidic aluminum oxide with anion exchange properties is used as column packing material. ^{99}Mo is bound as MoO_4^{2-} at the top end of the column, whilst ^{99m}Tc can simply be eluted as negatively charged $^{99m}TcO_4^-$ with a physiological (0.15 M) sodium chloride solution. $^{99m}TcO_4^-$ is regenerated on the generator column by ^{99}Mo decay (Fig. 2).[9]

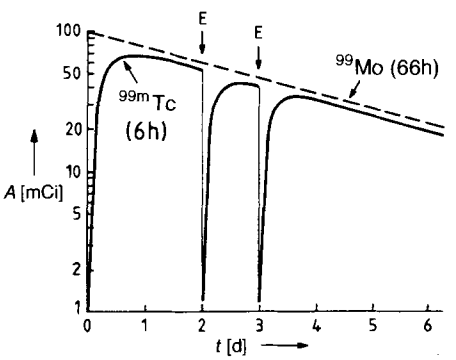

Fig. 2. Production of the ^{99m}Tc activity (A) in the system ^{99}Mo/^{99m}Tc after elution E from the generator column [9].

The ^{99m}Tc activity A_T formed after time t as a percentage of the activity A_M of the parent nuclide ^{99}Mo can be calculated according to Equation (a), where $\delta = 87.2\%$ is the branching

$$\frac{A_T}{A_M} = \delta \frac{\lambda_T}{\lambda_T - \lambda_M}(1 - e^{-(\lambda_T - \lambda_M)t}) \quad \text{(a)}$$

Klaus Schwochau is a chemist and researcher at the Institut für Chemie und Dynamik der Geosphäre of the Forschungszentrum Jülich GmbH (KFA). He obtained his doctorate in 1961 at the Universität zu Köln, habilitated in 1971 at the Technische Hochschule in Aachen, and became Professor for Inorganic Chemistry at the Technischen Hochschule in Aachen in 1977. His research activities have concentrated on the chemistry of the radioactive elements, particularly on the coordination chemistry of technetium, and for several years also on the development of new technetium radiopharmaceuticals. In addition, at the Institut für Erdöl und Organische Geochemie of the KFA, he works on problems of petroleum formation and the behavior of pollutants in the soil.

ratio, that is, the probability of the decay of ^{99}Mo into ^{99m}Tc, and $\lambda_T = 0.1155\ h^{-1}$ is the radioactive decay constant of the daughter nuclide (^{99m}Tc), and $\lambda_M = 0.0105\ h^{-1}$ is that of the mother nuclide. As an example, 24 h after elution of the generator column, the activity of ^{99m}Tc is already 88.2% of that of ^{99}Mo. The total concentration of TcO_4^- ($^{99m}Tc + {}^{99}Tc$) in the eluate is about 10^{-6}–10^{-8} M.[12] For imaging and functional testing of organs in human bodies, about 0.5–30 mCi (18.5–1110 MBq) ^{99m}Tc are needed, which corresponds to a maximum of 6 ng.

The generator eluates must be sterile and pyrogen free, and their nuclidic purity must conform to the demands of the European Pharmacopoeia. Under the assumption that ^{99m}Tc is applied within 12 h of the elution, the upper limits for ^{99m}Tc per mCi ^{99m}Tc obtained from molybdenum-99 by fission are: 1 μCi (3.7×10^4 Bq) ^{99}Mo, 50 nCi (1850 Bq) ^{103}Ru, 50 nCi (1850 Bq) ^{131}I, 100 nCi (3700 Bq) for all other γ-emitters together, 0.6 nCi (22.2 Bq) ^{89}Sr, 0.06 nCi (2.22 Bq) ^{90}Sr, and 1 pCi (3.7×10^{-2} Bq) for each α-emitter.[13]

3. Organ Imaging

The ^{99m}Tc injected into the body, depending on its chemical form and its molecular structure, concentrates in the organ to be investigated, and emits 140 keV γ-quanta which permits the imaging of the organ using planar scintigraphic or emission tomographic processes. The imaging of the spatial distribution of the radionuclide in the organ proceeds through the focusing of the gamma camera on sections or planes. The camera head moves circularly or elliptically around the patient; the rotation axis coincides with longitudinal axis of the body. Within the reconstructed layers the obtainable resolution, under favorable measurement conditions, amounts to about 7 mm. The resolution is particularly dependent on the collimator and the distance between collimator and object.[14]

The lead collimator has many, mostly parallel holes. It shields the detector from background radiation. The image resolution of the collimator improves with decreasing hole diameter and increasing length of the bore. Collimators in gamma cameras for the detection of the 140 keV γ-quanta of ^{99m}Tc have up to 40000 bores, hole diameters from 1–2 mm, and lead septa with a wall thickness of 0.25 mm.[15, 16]

The detector is a Tl-activated NaI single crystal of about 0.6 cm thickness and over 25 cm diameter.[9] Thicker crystals have, on the one hand, the disadvantage that multiple absorptions can occur, which reduce the image resolution; on the other hand, the detector sensitivity increases with growing thickness of the crystal.

4. Synthesis Procedures

For the development of ^{99m}Tc radiopharmaceuticals of definite composition and structure, the synthesis and characterization of the concipated compounds with long-lived technetium-99g which is available in weighable amounts, is indispensible. Microgram or even milligram quantities of ^{99m}Tc could hardly be handled experimentally due to the short half-life of 6 h and the enormous radioactivity; for example, 100 μg $Na^{99m}TcO_4$ already have an activity of 270 Ci (10^7 MBq). In contrast, 50 mg $Na^{99g}TcO_4$, a β^--emitter with 0.45 mCi (160 MBq), can be handled relatively easily in a well-ventilated fume cupboard, without any special radiation protection, but applying the generally accepted rules regarding radiation protection. The weak β^- radiation ($E_{max} = 0.29$ MeV) is largely shielded by the glass walls of standard laboratory vessels.[17]

Technetium occurs as a transition element of the seventh subgroup of the periodic table in the oxidation states of +7 to −1 and tends towards complex formation. Its chemical behavior is closely related to that of the homologous element rhenium because of the small differences in atomic and ionic radii.[18] Tetraoxotechnetate(VII) and tetraoxorhenate(VII) belong to the thermodynamically most stable compounds of technetium and rhenium, in contrast to tetraoxomanganate(VII). The standard electrode potential in acidic aqueous solutions amounts to only + 0.738 V for TcO_4^-/TcO_2, but +1.695 V for MnO_4^-/MnO_2. If TcO_4^- is reduced in the absence of sufficiently strong complexing ligands, the oxidation state + 4 often manifests itself through the formation of the sparingly soluble TcO_2 hydrate.[2]

The starting material for the synthesis of technetium radiopharmaceuticals is $Na^{99m}TcO_4$, which is available after elution of the generator column with physiological saline as 0.15 M aqueous NaCl solution. The concentration of $^{99m}TcO_4^-$ in the eluate is about 50–500 mCi (1.85×10^3–1.85×10^4 MBq) per 5 mL, corresponding to 2×10^{-8}–2×10^{-7} M. $^{99m}TcO_4^-$ can be used as such for thyroid and brain imaging; however, for brain imaging only then, when the blood-brain barrier (BBB) is not intact.[19] The synthesis of other ^{99m}Tc radiopharmaceuticals requires the reduction of TcO_4^- in the presence of suitable complexing ligands throughout.

A variety of reducing agents can be used for the reduction of $^{99m}TcO_4^-$. Transition metal ions such as Ti^{III}, Cr^{II}, Cu^{I}, and Fe^{II} that tend toward complex formation should be avoided, since they could compete with ^{99m}Tc for ligands. Equally unsuitable are oxalates, formates, hydroxylamine, and hydrazine, which form undesired complexes with ^{99m}Tc. One must remember that even when using the common reducing agent Sn^{II}, technetium can form heteronuclear complexes, such as the Tc-Sn-dimethylglyoxime complex $[Tc(DMG)_3(\mu\text{-}OH)SnCl_3]$ on reduction of TcO_4^- with Sn^{II} in the presence of dimethylglyoxime.[20, 21] The potentials vs. the standard hydrogen electrode of several suitable redox systems for the reduction of TcO_4^- are given in Table 1.[22]

The controlled-potential electrolytic reduction of $^{99m}TcO_4^-$ at chemically inert electrodes, for example at Hg or Pt cathodes, is also applicable. It often permits the reduction to defined oxidation states in 5–10 min and avoids the addition of reducing agents which cause impurities in the radiopharmaceutical solution.[23] The electrolytic reduction has found little application in clinical practice, since it requires more equipment.

The synthesis of the radiopharmaceutical from $^{99m}TcO_4^-$, reducing agent, and complexing ligand should preferably proceed in one step directly after elution of $^{99m}TcO_4^-$ from the generator column and must be carried out in a solvent which is suitable for intravenous injections, such as physiological sodium chloride solution. The use of ethanol additives in concentrations up to

5 vol. % is permissible. The reagents used should not be toxic and the injected solutions must be sterile and pyrogen free. ^{99m}Tc should occur predominantly in the expected complex form and molecular structure, that is the so-called radiochemical purity should exceed 90% to ensure a high organ specificity.

5. Kits

Kits are sterile and pyrogen-free reagent mixtures, which are dried by lyophilization and stored under nitrogen in ampules. These contain the substance to be labeled (complexing ligand) and generally a reducing agent, usually Sn^{II}. The kits can be purchased and stored for long periods of time. The labeling with ^{99m}Tc proceeds shortly before use of the radiopharmaceutical by addition of the ^{99m}Tc generator eluate. Table 2 shows ^{99m}Tc radiopharmaceuticals, prepared from purchasable kits, which are currently used for the scintigraphic imaging of organs.

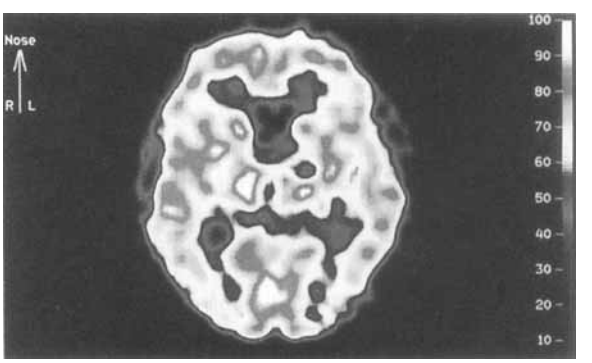
Amongst ^{99m}Tc radiopharmaceuticals for brain imaging, TcO-d,l-hexamethyl-propylene-amine oxime (TcO-d,l-HM-PAO),[25-27] TcO-*N*,*N*'-1,2-ethanediyl-bis(L-cysteine-diethyl ester(TcO-L,L-ECD),[28,29] and a boric acid adduct of technetium dimethylglyoxime TcCl(dimethylglyoxime)-(2-methyl-1-propyl)boron ($TcCl(DMG)_3$2MP)[26,30,31] (see Scheme 1) are capable of penetrating the intact blood-brain barrier due to their neutral and lipophilic character. The blood-brain barrier controls the exchange of material between blood and brain, and ensures the necessary stable environment in the brain.[32,33] Tc-diethylenetriaminepentaacetic acid,[34,35] whose molecular structure is not yet unambiguously known, Tc-glucoheptonate[36] (see Scheme 2), and sodium tetraoxotechnetate(VII)[9] can usually not pass through the blood-brain barrier, but can be used when the blood-brain barrier has been damaged, for example by tumors.

TcO-d,l-HM-PAO is formed by reduction of $^{99m}TcO_4^-$ with Sn^{II} in the presence of the ligand d,l-HM-PAO. The human brain accumulates for example 3.4–5.7% of the injected activity up to 8 h after the injection.[37] Figure 3 shows as example an emission tomogram, obtained by using ^{99m}TcO-d,l-HM-PAO, of the brain of a patient with focal blood hypoperfusion. According to structural investigations on ^{99g}Tc-d,l-HM-PAO the molecular structure of the complex is a square pyramid with the oxygen atom at the apex (Scheme 1a). Technetium in the oxidation state + 5 is located 0.68 Å above the basal plane defined by the four nitrogen atoms. The oxime-oxygen atoms form a strong intramolecular hydrogen bond. The complex carries no charge.[25]

TcO-L,L-ECD can also be prepared by reduction of $^{99m}TcO_4^-$ with Sn^{II} and subsequent complexing with the ligand. The brain takes up almost 5% of the injected activity dose within a few minutes; after an hour this falls to 4%.[29] The ^{99g}Tc complex, with a distorted square-pyramidal geometry of the donor atoms

Table 2. ^{99m}Tc Radiopharmaceuticals in kits for scintigraphic imaging of human organs [6,9,24].

Organ	^{99m}Tc-labeled substance	*A* mCi (MBq)	Application
brain	TcO-d,l-HM-PAO	7–15 (259–555)	regional blood perfusion, cerebral stroke, ischemia, dementia, epilepsy, tumors
	TcO-L,L-ECD	25–30 (925–1110)	regional blood perfusion, trauma, cerebral stroke, focal epilepsy
	$TcCl(DMG)_3$2MP		regional perfusion
	Tc-DTPA	5–20 (185–740)	blood perfusion, tumor localization
	Tc-glucoheptonate	15–20 (555–740)	blood perfusion
	sodium tetraoxotechnetate(VII)	10–20 (370–740)	blood perfusion, regional accumulation, cerebral lesions
thyroid	sodium tetraoxotechnetate(VII)	0.5–2 (18.5–74)	morphology, vascularity, function
lungs	Tc-MAA, particle size 10–40 μm	1–16 (37–600)	blood perfusion, shunt diagnosis, vessel scintigraphy
	Tc-DTPA aerosol	5.4 (200)	ventilation
heart	Tc-HEXAMIBI	10–30 (370–1110)	blood perfusion, ischemia, myocardial infarction, coronary arteries
	Tc-CDO-MeB	15 (555)	blood perfusion, coronary arteries, myocardial infarction
liver, gall	Tc-HIDA and derivatives	5–15 (185–555)	liver and gall bladder function, gall bladder infection
	Tc-sulfur colloid	1–3 (37–111)	liver morphology, tumors, abscesses
kidneys	$TcO\text{-}MAG_3$	1–20 (37–740)	nephrological and urological complaints, kidney tubuli function
	Tc-DMSA	1–5 (37–185)	function diagnosis, morphology
skeleton	Tc-MDP and derivatives	10–20 (370–740)	skeleton-scintigraphy, bone metastases, sarcoma, osteomyelitis, arthritis.



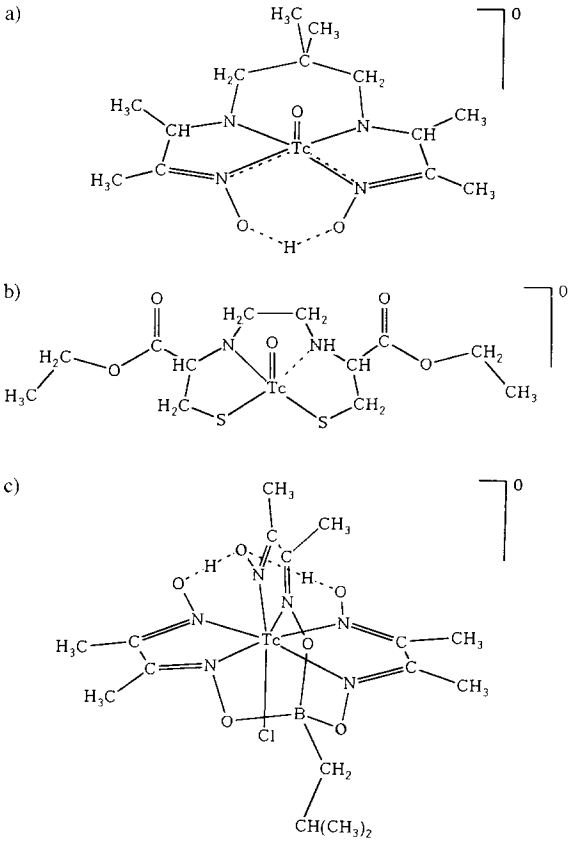


Fig. 3. Emission tomogram of the brain of a patient suffering from focal blood hypoperfusion; taken after injection of ^{99m}TcO-d,l-HM-PAO. The scale on the right-hand edge of the picture gives the count rate per 10 mm^2 [%].

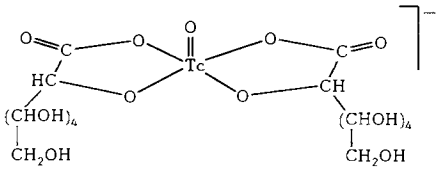


(Scheme 1 b) with the oxygen atom at the apex, and an oxidation state of + 5, has a similar structure to that of ^{99g}Tc-d,l-HM-PAO. Also the distance of the central atom from the N_2S_2 plane is similar with 0.73 Å. Since one nitrogen atom is protonated, this complex is again uncharged.[28]

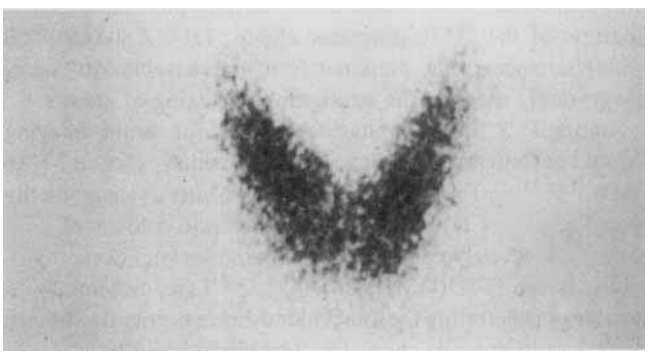
Scheme 1. Structural formulas of ^{99m}Tc radiopharmaceuticals that can pass through the blood-brain barrier: a) TcO-d,l-HM-PAO, b) TcO-L,L-ECD, c) TcCl-(DMG)$_3$2MP.

TcCl(DMG)$_3$2MP forms by reduction of $^{99m}TcO_4^-$ with $SnCl_2$ in the presence of dimethylglyoxime and 2-methylpropylboric acid. The testing of this complex for clinical applications in brain imaging does not appear to be completed yet. In the brain of baboons, the uptake 5 min after injection amounted to 2.8 % of the injected dose; the biological half-life of the decrease in activity in the brain was determined to be 86 min.[30] As shown in Scheme 1c, technetium in TcCl(DMG)$_3$2MP has the relatively rare coordination number 7, the oxidation state + 3, and is surrounded by the nitrogen atoms of three dioxime ligands and a covalently bonded chlorine atom. The boron atom resides in a tetrahedral environment, bound to three dioxime oxygen atoms and the 2-methylpropyl group. The remaining three oxygen atoms of the dioxime ligands are bound to each other through two strong hydrogen bonds. The complex is also neutral.[38]

For the synthesis of ^{99m}Tc-diethylenetriaminepentaacetic acid (Tc-DTPA), $^{99m}TcO_4^-$, after reduction with tin(II) chloride, is treated with calcium-sodium-diethylenetriaminepentaacetate. Experimental investigations indicate the anionic character of the complex and the oxidation state of + 4 for the technetium atom.[34, 35, 39, 40] Tc-glucoheptonate is obtained by reaction of a mixture of calcium glucoheptonate and $SnCl_2$ with $^{99m}TcO_4^-$. The molecular structure[36] reproduced in Scheme 2 follows from NMR and IR spectra and shows a Tc^V=O core and two five-membered glucoheptonate rings, which are bidentately bound through oxygen atoms to the technetium center. Finally, $Na^{99m}TcO_4$ is injected as generator eluate for brain imaging. It accumulates particularly in the choroid plexus (vascular plexus in the region of the brain ventricles).

Scheme 2. Structural formula of Tc-glucoheptonate, a radiopharmaceutical, which can normally not pass through the blood-brain barrier.

Sodium tetraoxotechnetate(VII) is used predominantly for thyroid imaging.[9] Similarly to iodide, perhaps due to similar ion size and charge, $^{99m}TcO_4^-$ is taken up by the thyroid, but unlike iodine it is not incorporated by thyroglobulin. The uptake of TcO_4^- amounts to about 3–4% of the injected activity 30 min after injection and decreases to 1–2% after 6 h.[41] Figure 4 shows the scintiphotograph of a normal thyroid 1 h after injection of $Na^{99m}TcO_4$.



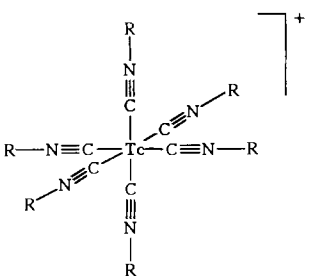


Fig. 4. Scintiphotograph of a normal thyroid; from the front, taken after injection of $Na^{99m}TcO_4$ [9], that is the thyroid lobe shown on the left-hand side of the picture corresponds to the one on the right-hand side of the body.

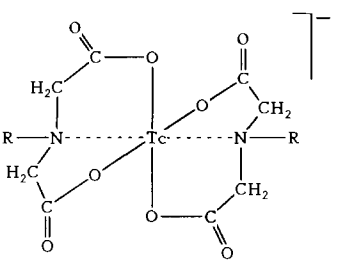
^{99m}Tc-labeled macroaggregated human serum albumin (Tc-MAA) for lung imaging is prepared by reduction of $^{99m}TcO_4^-$ with $SnCl_2$ in the presence of a human serum albumin solution. The labeling proceeds at pH 5.5, the isoelectric point of the albumin, in a yield of over 95%. It does not yet appear to be known in which oxidation state and how ^{99m}Tc is bound. The accumulation of Tc-MAA in the lung occurs because particles with a size exceeding 10 μm are held in the capillaries of the lungs. About 10^6 Tc-MAA particles per injection are applied, but the number of capillaries occluded by this, relative to the total number of lung capillaries of 2.8×10^{11}, is negligible. The biological half-life of the Tc-MAA particles in the lung amounts to 2–3 h.[9] For lung ventilation examinations, Tc-DTPA is recommended as aerosol, which is exhaled again after 8 h.

Currently, two ^{99m}Tc radiopharmaceuticals are mainly used for heart imaging (see Table 2), the cation hexakis(2-methoxy-2-methylpropyl-isonitrile)technetium(I) (Tc-HEXAMIBI) in the form of the tetrafluoroborate salt, and the neutral complex chloro{tris(cyclohexanedione dioxime)}-methylboratotechnetium(III) (Tc-CDO-MeB).

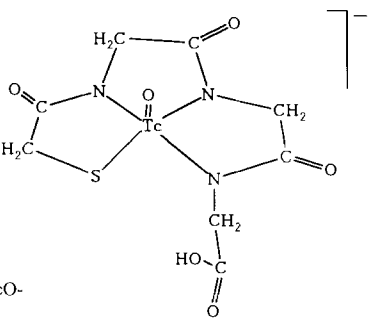
Tc-HEXAMIBI is synthesized by reduction of $^{99m}TcO_4^-$ with $Na_2S_2O_4$ in the presence of the isonitrile ligand[42] or in a kit by reaction of tetrakis(2-methoxy-2-methylpropyl-1-isonitrile)-copper(I) tetrafluoroborate with $SnCl_2$ and $^{99m}TcO_4^-$.[43] The uptake in the human heart amounts to about 1.5% of the injected activity and only decreases to 1% after 4 h. The background activity in the blood, lungs, liver, and spleen are sufficiently low.[44] The expected molecular structure for the cationic complex is given in Scheme 3. The structure of the precursor of Tc-HEXAMIBI, hexakis-(*tert*-butylisonitrile)technetium(I), has been determined by X-ray analysis.[45] Here, the Tc center is surrounded octahedrally by the isonitrile ligands; the Tc–C distance is 2.029 Å.



Scheme 3. Structural formula of Tc-HEXAMIBI. R = CH_2–$C(CH_3)_2$–OCH_3.

Tc-CDO-MeB is prepared by reaction of $^{99m}TcO_4^-$ with a mixture of 1,2-cyclohexanedione dioxime, methylboric acid, and $SnCl_2$ as reducing agent.[46] Five minutes after injection, 2.2% of the injected activity are measured in the human heart muscle, which is, however, washed out noticeably more quickly than Tc-HEXAMIBI. But, the uptake of Tc-CDO-MeB proceeds more rapidly.[47] The blood activity 15 min after the injection still amounts to 9.5% of the injected dose.[48] The molecular structure corresponds to the structure of the complex $TcCl(DMG)_3 2MP$ described in Scheme 1c.[38]

Labeled iminodiacetic acid derivatives, particularly ^{99m}Tc-*N*-(2,6-dimethylphenylcarbamoylmethyl)iminodiacetic acid (Tc-HIDA) as well as ^{99m}Tc-sulfur colloid with a particle size of about 0.1 μm, are commonly used ^{99m}Tc radiopharmaceuticals for liver and gall bladder imaging.



Tc-HIDA is obtained by reduction of $^{99m}TcO_4^-$ with $SnCl_2$ in the presence of the iminodiacetic acid derivative. Over 95% of the ^{99m}Tc is bound in the complex. The scintiphotograph can already be recorded a few minutes after injection. Scheme 4 shows the coordination of the technetium center in the HIDA complex. Two tridentate ligands chelate technetium in the oxidation state + 3 through the carboxyl-oxygen atoms and the imino-nitrogen atoms in an octahedral arrangement. The complex is uninegatively charged.[49, 50]

Scheme 4. Structural formula of Tc-HIDA.

^{99m}Tc-sulfur colloid is used for liver as well as spleen imaging. The preparation proceeds by reaction of $^{99m}TcO_4^-$ with $S_2O_3^{2-}$ in acidic solution; $^{99m}TcO_4^-$ is almost completely converted. The reaction product is mainly a mixture of $^{99m}Tc_2S_7$ and colloidal sulfur.[51] 80–85% of the colloid is accumulated in the liver, 5–10% in the spleen, and the rest in the bone marrow. Scintiphotographs can already be recorded 5–10 min after injection. The effective half-life of the colloid in the liver is almost equal to the physical half-life of ^{99m}Tc.[9]

^{99m}TcO-mercaptoacetyltriglycine (TcO-MAG_3) was developed a few years ago[52] for renal scintigraphy, particularly for testing the functioning of the renal tubuli. A kit for its preparation is now available.[53] $^{99m}TcO_4^-$ and benzoyl mercaptoacetyltriglycine are reduced in aqueous solution by $SnCl_2$, with concomitant elimination of the benzoyl protecting group. The labeling proceeds with a yield of more than 95%. A few minutes after injection, about 50% of the injected activity is taken up by the kidneys. After 30 min, more than 70% of the injected dose is found in the urine.[54, 55] In Tc-MAG_3, technetium occurs in the + 5 oxidation state and resides in a distorted square-pyramidal environment, surrounded by three nitrogen atoms and one sulfur atom in the basal plane and one oxygen atom at the apex (Scheme 5). The structure agrees with that found for ReO-mercaptoacetyltriglycerine.[56, 57]

Scheme 5. Structural formula of TcO-MAG_3.

Tc-dimercaptosuccinic acid (Tc-DMSA) has been used for kidney imaging for quite a while (Fig. 5). $^{99m}TcO_4^-$ is reduced with $SnCl_2$ for complex formation in the presence of DMSA. The binding of ^{99m}Tc is almost complete. Three hours after injection, about 50% of the activity has been taken up by the

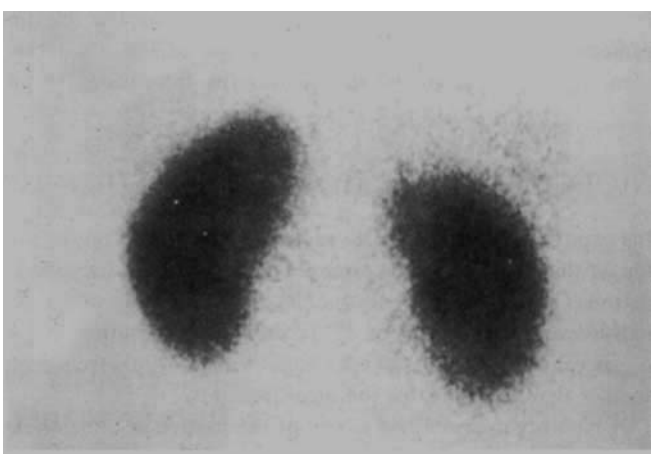


Fig. 5. Scintiphotograph of normal kidneys; from behind, taken after injection of Tc-DMSA [9], that is, the kidney shown on left-hand side of the picture corresponds to one on the left-hand side of the body.

Fig. 6. Scintiphotograph of a normal skeleton, taken after injection of Tc-MDP [9]. The injection site is labeled with an arrow.

kidneys, and 10–20% is excreted in the urine during the first 2 h. ^{99m}Tc-DMSA specifically localizes in the proximal convoluted tubule.[55] The structure of the Tc-DMSA complex has not yet been unambiguously determined.[58]

^{99m}Tc-methylene diphosphonate (Tc-MDP) has proved effective for bone imaging (Fig 6). It is formed by reduction of $^{99m}TcO_4^-$ with tin(II) chloride in the presence of sodium methylene diphosphonate. Again the conversion is almost complete. The bone scanning is performed 2–3 h after injection to reduce the background activity in the body. In 24 h 75–85% of the activity is excreted in the urine.[9] Evidently, several Tc-MDP complexes, whose compositions and structures have not been established to date, are produced under the given conditions for the preparation.[59] Derivatives of methylene diphosphonate, such as hydroxyethylidene, hydroxymethylene, and dicarboxypropane diphosphonate are also used for bone imaging after complex formation with ^{99m}Tc.

6. Development

The ^{99m}Tc radiopharmaceuticals listed in Table 2 are the result of systematic developments and accidental discoveries. None of the complexes meets the conditions of ideal radiopharmaceuticals without limitations.

In addition to the physical half-life $t_{1/2} = t_{phys}$, the biological half-life t_{bio} is of importance; the latter indicates the time after which, regardless of radioactive decay, the activity of the radiopharmaceutical in the body has decreased to one-half by biological elimination. Naturally, t_{bio} is dependent on the relevant radiopharmaceutical. The so-called effective half-life t_{eff} follows from t_{phys} and t_{bio} according to Equation (b). In consideration of

$$t_{eff} = \frac{t_{phys} \cdot t_{bio}}{t_{phys} + t_{bio}} \qquad \text{(b)}$$

the exposure of the patient to radiation, t_{eff} should not be any longer than it takes to carry out the required diagnostic investigation. The value of t_{eff} is always less than the shorter of the two half-lives t_{phys} and t_{bio}. For ^{99m}Tc radiopharmaceuticals $t_{bio} < t_{phys}$ is valid throughout, and the biological half-life is frequently smaller than desirable for the measurements.

A high organ specificity is one of the particular aims of the development of radiopharmaceuticals. The injected activity should preferably accumulate in the organ to be investigated, that is a high activity ratio of target organ to the nontarget areas of the body is desired. High activity in adjacent organs and specifically in the blood can severely obscure the target organ image, the reproduction of structural details, and the function testing quite considerably. In addition, a high organ specificity permits the reduction of the injected activity dose and consequently the exposure of the patient to radiation.

A radiopharmaceutical should not change chemically in vivo during its transport to the target organ, in other words, it should be kinetically inert. However, the metabolization of the labeled complex in the target organ can be of advantage, particularly if the functioning of the organ should be tested. The in vivo stability prior to the accumulation in the organ is a necessary precondition if information concerning the relationships between molecular structure and organ distribution is to be gained.

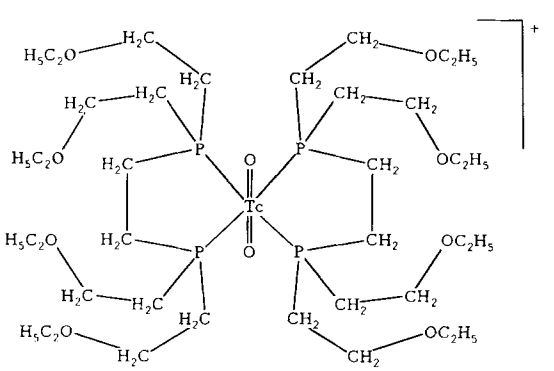
In the forefront of efforts to develop ^{99m}Tc radiopharmaceuticals are brain and heart agents.

6.1. Brain Radiopharmaceuticals

Brain radiopharmaceuticals should be capable of penetrating the intact blood-brain barrier. The barrier arises from epithelial-like tight junctions that virtually cement adjoining capillary endothelium together in the brain microvasculature.[32, 33] Lipid-soluble, uncharged molecules can pass through the blood-brain barrier by simple diffusion, as long as a concentration difference exists on both sides of the capillary wall. The lipophilicity of complexes is often quantified by the logarithm of the octanol/water partition coefficient P_{oct}. Compounds with values of log P_{oct} between 0.9 and 2.5 appear to penetrate the blood-brain barrier rather easily, whilst more strongly lipophilic substances are increasingly bound to blood components.[60] Such relations are, however, dependent on the character of the complex.[61] The permeability of the blood-brain barrier also increases, as expected, with decreasing molar mass.[62]

^{99m}Tc brain radiopharmaceuticals developed to date appear to penetrate the blood-brain barrier by simple diffusion. However, nonlipid-soluble substances, such as glucose as the most important energy source of the brain cells and essential amino acids, which can not be synthesized by the brain, must also be able to pass through the membrane of the endothelial cells. Systems in the endothelial cells are available for this special transport which make the normal osmotic diffusion of glucose and for example large neutral amino acids much easier. At least ten of these amino acids, amongst others also L-phenylalanine, penetrate the membranes of the endothelial cells by the same transport system.[32] The binding of an uncharged ^{99m}Tc complex to a large neutral amino acid could, by using this transport system of the endothelial cells, accelerate the passage of ^{99m}Tc into the brain.[63]

Apart from the diffusion of radiopharmaceuticals into the brain, the retention in the brain is of great importance for scintigraphic investigations. In particular, their rediffusion from the brain should be limited, either by binding to (in) the brain cells or through metabolization (metabolic trapping). The development of new ^{99m}Tc brain radiopharmaceuticals is concentrated on complex compounds, which not only can penetrate the blood-brain barrier in the direction of the brain, but also lose their neutral or/and lipophilic character by metabolization in



the brain, so that the diffusion out of the brain is hindered.[19, 31] For example, the relatively long retention time of TcO-L,L-ECD in the brain was explained by an increase in the polarity of this complex by hydrolysis of an ester group in the brain,[28] even though some doubt now exists about this interpretation.[31]

6.2. Heart Radiopharmaceuticals

A working hypothesis for the development of ^{99m}Tc myocardial perfusion imaging agents is the assumption that unipositively charged complexes preferably concentrate in the heart muscle tissue (myocardium).[64] The hypothesis is based on the known concentration of alkali metal ions, such as K^+, Rb^+, and Cs^+ as well as particularly Tl^+, which still used as $^{201}Tl^+$ in competition with the ^{99m}Tc radiopharmaceuticals described in Section 5 for heart imaging. However, the nuclear properties of ^{201}Tl (decay by electron capture with $t_{1/2} = 73.5$ h, maximum γ energy 167 keV for only 8.8% decay probability) and its necessary production in accelerators are disadvantageous when compared to ^{99m}Tc. It is also known that several NH_4^+ derivatives accumulate in the heart muscle.[65] Whether, in addition to K^+ ions, other simple cations such as Tl^+ concentrate in the heart muscle cells via Na^+/K^+-adenosinetriphosphatase (Na^+/K^+-ATPase) has yet to be proven. Probably, the Na^+/K^+-ATPase does not participate in the uptake of the Tc-HEXAMIBI cation.[66] Finally, it must be emphasized that the cationic character of ^{99m}Tc myocardial perfusion imaging agents is not an essential precondition with regard to the use of neutral Tc-CDO-MeB. However, it is washed out of the heart muscle tissue more rapidly than Tc-HEXAMIBI.

The lipophilicity of the diagnostic agent is also of importance for its uptake in the heart. Agent-dependent parabola-like functions between the accumulation in the myocardium and log P_{oct} were observed.[66] A reason for the decrease in the accumulation at high lipophilicity values (log $P_{oct} > 5$) will again be the binding of the agent to blood protein.

A further cationic ^{99m}Tc myocardial perfusion imaging agent was developed only recently, $^{99m}TcO_2$-bis[1,2-bis{bis(2-ethoxyethyl)phosphino}ethane]$^+$.[67, 68] Scheme 6 shows the molecular structure of this Tc^V complex. According to a crystal structure analysis of the ^{99g}Tc complex both bidentate diphosphane ligands lie in a plane; perpendicular to this plane is the linear

Scheme 6. Structural formula of the unipositively charged cation TcO_2-bis[1,2-bis{bis(2-ethoxyethyl)phosphino}ethane]$^+$.

trans-TcO_2 unit.[68] Noticeable are the eight ethoxyethyl groups of the ligands, which apparently contribute to reduce the disadvantageous background activity in the blood and in the liver, which is known from other ^{99m}Tc phosphane complexes. The uptake of the cationic complex in the heart amounts to 1.2% of the injected activity, which only decreases to 1% 2 h after injection. The synthesis proceeds by reduction of $^{99m}TcO_4^-$ with $SnCl_2$ in the presence of 1,2-bis[bis(2-ethoxyethyl)phosphino]-ethane, which is also called tetrofosmine.[68]

7. Summary and Future Prospects

^{99m}Tc radiopharmaceuticals are widely applied in nuclear medicine for planar scintigraphic and tomographic (SPET) imaging and for testing the functioning of organs such as the brain, thyroid, lungs, heart, liver, gall bladder, kidneys, and skeleton. In particular, this is due to the excellent nuclear properties of ^{99m}Tc and its easy preparation in generator columns. Composition and structure of the radiopharmaceuticals can be determined with the analogous compounds of the long-lived nuclide ^{99g}Tc which can be prepared in weighable quantities. The efforts to develop defined diagnostic agents have given new impulses to the coordination chemistry of technetium[69] and contributed significantly to the understanding of the chemistry of this radioelement. The synthesis of specially designed radiopharmaceuticals with higher organ specificity requires deeper insights into the relationship between the structure of the agent, its associated physicochemical properties, and the organ distribution. Misleading differences of distribution between the bodies of animals and man are not uncommon. Stereoselective uptake and retention of technetium radiopharmaceuticals are well known.[28, 70] The structures of several technetium radiopharmaceuticals that have been in use for several decades, such as Tc-DTPA, Tc-DMSA, and Tc-MDP, have still not been characterized.

^{99m}Tc is no physiological nuclide such as ^{11}C, which is accepted by the body and metabolized in biomolecules.[71] But, still it cannot be excluded that specially designed ^{99m}Tc labeled biomolecules are taken up by the body as analogue tracers.[63] Since long-chain fatty acids are the major energy source for the heart muscle, many attempts were made to improve the uptake and retention of ^{99m}Tc in the myocardium by binding to functionalized fatty acids. The expected accumulation was, however, not observed, not even for cationic complexes containing fatty acids.[72] Recently the complexing of ^{99}Tc/^{99m}Tc by a functionalized D-glucose, 2-amino-2-deoxy-D-glucosoxime, was successful. High accumulations in the myocardium or in the brain were not observed.[73]

In a wider sense ^{99m}Tc-labeled monoclonal antibodies, which are used in immunoscintigraphy mainly for tumor localization,[74] can also be classed as technetium radiopharmaceuticals. ^{99m}Tc can, after reduction of $^{99m}TcO_4^-$ and partial cleavage of the disulfide bridges in the antibody, be bound by the thiol groups. The indirect labeling through bifunctional ligands, such as diethylenetriaminepentaacetic acid or diaminodithiol derivatives,[75] which complex the radionuclide and concomitantly bond to the antibody, has to date been less successful and is still under development. After labeling with a radionuclide, mono-

clonal antibodies accumulate specifically in tumor tissue by binding to so-called tumor markers, such as proteins, glycoproteins, glycolipids, or polysaccharides, which are formed by tumor cells. However, unspecific binding to normal tissue can not be completely excluded. With ^{99m}Tc-labeled monoclonal antibodies it was possible to gain high contrast images 2–24 h after injection of an activity of about 27 mCi (1000 MBq). The smallest imaged lesion had a diameter of 0.6 cm.[74]

Long incubations of the labeled monoclonal antibodies in the blood can possibly be avoided by the pretargeting method, for example with the avidin-biotin system. The glycoprotein avidin disposes of four binding sites that are highly specific and have a high affinity for biotin. Very recently, by pretargeting, an image of a brain tumor was successfully obtained only 30 min after the injection of ^{99m}Tc-labeled biotin, which was bound to propylene-amine-oxime (PnAO) (cf. Scheme 1a) for complexing the ^{99m}Tc.[76] The tumor-specific monoclonal antibody bonded to avidin was injected three days earlier to localize the tumor. The affinity of avidin and biotin for each other is 5–7 orders of magnitude higher than those of antibodies for tumors.[74]

The physiological function of organs, the testing of which is the predominant aim of the application of radiopharmaceuticals, is often controlled by receptors. They are found as glycoproteins on the cell surface or as soluble proteins inside a cell and bind the associated ligands through complementary structures. Receptors exhibit high ligand affinity, specificity, stereoselectivity, and saturability. Radiopharmaceuticals bound to receptors permit insights into special physiological processes, in particular, changes in receptor concentration are thought to be related to certain disease states of an organ.[77] Many receptor-specific radiopharmaceuticals with radionuclides such as ^{11}C, ^{18}F, ^{75}Br, ^{77}Br, or ^{123}I are known. However, apparently only one receptor-binding ^{99m}Tc radiopharmaceutical is known, ^{99m}Tc-galactosyl-neoglycoalbumin (Tc-NGA),[78] which binds to the hepatocyte-specific membrane receptor (HBP) for at least 4 h.[79] Clinical tests after injection of about 5 mCi (185 MBq) Tc-NGA per patient indicate that with liver diseases such as hepatoma, cirrhosis, and liver metastases the logarithm of the HBP concentration is directly related to the reduced functional hepatocyte mass.[80]

Very recently, attempts were made to develop radiopharmaceuticals for the detection of hypoxic tissue in tumors, in the heart as well as in the brain by binding ^{99m}Tc complexes to nitroimidazole derivatives. It is known that nitroimidazole can be selectively trapped with reactive metabolites in hypoxic cells by enzymatic reduction of the nitro group in the absence of oxygen. The redox potential of the nitroimidazole derivative appears to be a measure of the intensity of the reduction and the trapping. In preliminary investigations a 2-nitroimidazole derivative was bonded through a methylene group to the neutral brain agent ^{99m}TcO-propylene-amine-oxime.[81] Animal experiments show that the labeled compound was selectively retained in hypoxic brain and heart tissue.[82, 83]

I thank Univ.-Doz. Dr. F. Fazekas, Neurologische Universitätsklinik Graz, for the gift of a copy of the tomogram shown in Figure 3. I would further like to thank Prof. Dr. Gopal B. Saha, Department of Nuclear Medicine, Clinical Foundation Cleveland, Ohio, and the Springer Verlag, Heidelberg, for permission to reproduce the Figures 4, 5, and 6. My thanks are also due to the referees of this manuscript for some stimulating comments and to Susan and Harald Poelchau for reviewing the English version.

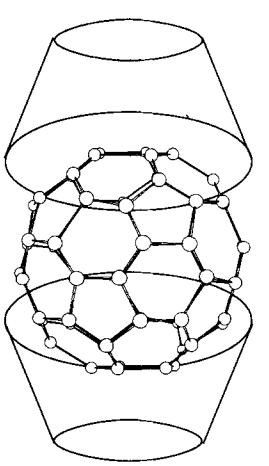
Taking Fullerenes from Large Molecules to Supramolecules

Edwin C. Constable*

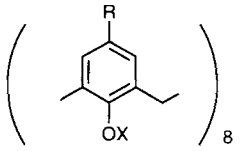


As in all forms of human endeavor, chemistry has, from time to time, especially favored topics. The early to mid-1980s were characterized by the study of high-temperature superconductors, whilst the twin themes of supramolecular chemistry and the chemistry of the new allotropes of carbon, the fullerenes, ran through the late 1980s and the 1990s. By the strict definition of Jean-Marie Lehn[1] the fullerenes and their derivatives are merely large molecules—they do not possess the intermolecular bonding interactions that characterize supramolecules. Isolated examples of fullerene-containing supramolecules have been reported,[2] but recently, a series of independent reports have appeared which have as the common theme the placement of a fullerene guest into a suitably designed host molecule. Apart from the obvious elegance of these systems, application of this supramolecular chemistry offers a facile purification method for specific fullerenes from the usual mixture present in carbon soot.

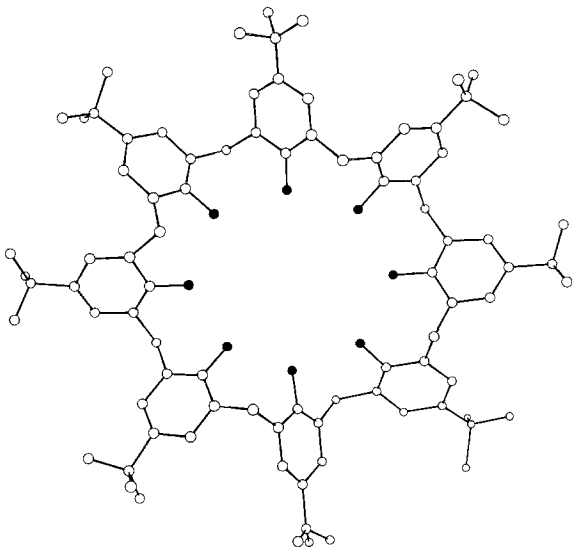
The key observation is that certain cyclic host molecules possess cavities having the correct dimensions for the inclusion of a fullerene guest. The critical observations date back to 1992 when Wennerström and co-workers described the solubilization of C_{60} in water by complexation with the host molecule γ-cyclodextrin.[3] The cyclodextrins (CDs) constitute a family of cyclic oligosaccharides prepared from starch. The commonest forms are α-CD with six glucopyranose units and a cavity diameter of 500 pm, β-CD with seven units and a cavity diameter of 650 pm, and γ-CD (**1**, Scheme 1), which contains eight sugar subunits and has a cavity 850 pm in diameter. Wennerström recognized that the cavities of α- and β-CD are too small to encapsulate a C_{60} molecule, but that γ-CD might just be large enough. Although γ-CD is a little too small to completely encapsulate C_{60}, it could form a 2:1 complex as depicted by structure **2**. Wennerström et al. then showed that when an aqueous solution of γ-CD was boiled with a solid mixture of C_{60} and C_{70}, an aqueous solution containing only a CD–C_{60} complex (> 99%) was obtained. C_{60} was not extracted when β-CD was used. Spectrophotometric and molecular modeling studies indicated the likely formation of a 2:1 CD–C_{60} complex. Extraction of the aqueous solution of the adduct with toluene yielded a pure solution of C_{60} in the organic phase. The purification of significant quantities of C_{60} by this method is probably not practical, as the limiting concentration of the γ-CD–C_{60} complex in the aqueous phase is of the order of 10^{-4} mol dm^{-3}.

Scheme 1. Two views of γ-CD **1**. In the structure on the right the oxygen atoms are shaded and the hydrogen atoms have been omitted.

Although the studies of Wennerström et al. provided the basic idea, they had not achieved the extraction of fullerenes from a liquid phase, nor had they demonstrated that it was possible to develop a preparative-scale method for the purification of C_{60} using the CD complex. The first problem was addressed by Williams and Verhoeven, who recognized that the cavity in the related host system calix[8]arene (**3**) was the correct size for a C_{60} guest (Scheme 2).[4] These authors then demonstrated that an aqueous solution of the sulfonate derivative **4** extracted only C_{60} from toluene solutions of C_{60} and C_{70} to give a yellow aqueous solution of a **4**–C_{60} complex. We will return to the structures of calix[8]arene–C_{60} adducts shortly.



2



In a paper in this journal, Yoshida and co-workers have returned to the constitution of the CD–C_{60} complex.[5] They have used the liquid-phase extraction of fullerenes from toluene to aqueous solution to confirm the selective formation of complexes of C_{60} with γ-CD. Neither the inclusion of C_{70} was observed, nor complexation with α- or β-CD was detected. When the

authors refluxed a (purple) solution of C_{60} in toluene with aqueous γ-CD, all of the C_{60} was transferred to the aqueous phase. Subsequent purification by precipitation, freeze-drying, and recrystallization gave purple crystals of a pure 2:1 γ-CD–C_{60} complex. Detailed NMR and CD spectroscopic studies have led the authors to propose the bicapped structure **2** for the 2:1 complex. Molecular modeling studies support this formulation.

The first successful *purifications* of fullerenes by host–guest chemistry were published concurrently by the groups of Atwood[6] and Shinkai[7] earlier this year. Both relied on the specificity exhibited by calix[8]arene for C_{60} to develop preparatively useful methods for the purification of fullerenes. Atwood et al. demonstrated that a one-phase reaction of toluene solutions of C_{60} with a toluene solution of calix[8]arene **5** gave a precipitate of a 1:1 **5**–C_{60} complex. When carbon soot was used, the crude product consisted of 89% C_{60} and 11% C_{70} complex. This corresponds to a 90% extraction of the C_{60} content of the soot! Two recrystallizations of the mixture of C_{60} and C_{70} complexes gave the 1:1 complex of C_{60} with a purity of >99.5%. Treatment of the residues and the mother liquors provided C_{70} fractions of 87% purity. Both groups then addressed the question of release of the fullerenes from the calix[8]arene complexes. This proved to be simplicity itself. Treatment of the 1:1 complex with chloroform (presumably in the course of attempts to obtain NMR spectra) led to the precipitation of the fullerene; the host went into solution. The efficiency of this method for the isolation of C_{60} is impressive. Atwood et al. report that they can obtain 0.28 g of pure C_{60} from 7.5 g of carbon soot, and also present preliminary findings regarding the use of calix[6]arenes for the enrichment of C_{70} fractions. Shinkai and his co-workers also describe the selectivity of calix[8]arene derivatives over calix[6]arene and calix[4]arene for the extraction of C_{60}. In their hands, 0.200 g of carbon soot containing 72 wt% of C_{60} yielded 0.102 g of 99.8% pure C_{60}. Very recently, Verhoeven et al. have described further studies on the **5**–C_{60} system.[8] The 1:1 complex was isolated as a metallic green solid from the reaction of C_{60} with **5** in carbon disulfide. The green solid decomposed to its constituents upon dissolution in chloroform. Verhoeven et al. also confirm the selective binding of C_{60} over C_{70}.

What is the nature of the bonding between the host and the fullerene guest? The primary interaction appears to be related to the π-bonding properties of the aromatic surface of the guest. However, there are conflicting interpretations with the different host systems. It is thought that C_{60} may act as a π-acid,[9] and that its binding to the γ-CD may arise from a charge transfer type of interaction involving the lone pairs on the oxygen atoms of the sugar, ether, and hydroxyl groups. This is supported by the electronic spectrum of the adduct, which is typical of a charge transfer complex. A secondary stabilizing feature is thought to be the formation of hydrogen bonds between the two γ-CD hosts.

In the case of the calix[8]arene host **5**, the primary interactions are thought to be between the CH_3 groups of the *tert*-butyl substituents and the π-cloud of the fullerene. In other words, the fullerene is acting as a π-donor! This type of CH–π interaction is well established for calixarenes[10] and might explain why the C_{60} forms a complex with a host that is a little too small for it. The guest is not deep in the cavity, but lies above it and has primary interactions with the *tert*-butyl surface. This also explains why the binding of C_{60} to calix[8]arenes lacking these *tert*-butyl substituents is very weak. Decomposition of the complex by chloroform may now be interpreted in terms of competitive hydrogen bonding between the acidic CH group of the solvent and both the fullerene and the aromatic surfaces of the calix[8]arene.[11] These aspects of the 1:1 complex of **5** and C_{60} might be relevant for the situation in solution, but it does not appear to be correct for the solid-state species. Shinkai and Atwood assume that the calix[8]arene is in a bucket-shaped conformation, although both are aware that there is a mismatch between the sizes of the host and the guest. However, calix[8]arenes are conformationally mobile and can adopt conformations in which aromatic rings point "up" or "down". In the conformation assumed by Shinkai and Atwood all of the aromatic rings point in the same direction. In detailed ^{13}C NMR studies of the 1:1 **5**:C_{60} complex, Verhoeven et al. presents compelling evidence that **5** adopts a conformation in which two of the aromatic rings are oriented in the opposite direction to the rest—the alternate-cone conformation.[8] This conformer should have a slightly larger cavity more appropriate to the C_{60} guest. We must, perhaps, await detailed crystallographic studies of these complexes to clarify the nature of the host–guest interactions in the solid state.

Why are these results exciting? There are two answers to this question. The first is transparent, and relates to the preparation of fullerenes. Host–guest chemistry offers the promise of cheap and convenient methods for the rapid isolation of highly pure fullerenes. Shinkai et al. comment that their method allows them "to obtain the gram-order of high-purity C_{60} without us-

ing any precious apparatus".[7] In these cost-conscious days, perhaps we should note Atwood's financial argument that the approach "will lead to a 50-fold reduction in the cost of production of high-purity C_{60}, noting the current Aldrich price of \$2800 per gram".[6] Perhaps a note of caution is required here. The *commercial* cost of fullerenes is probably as much dictated by limited demand and novelty as by the actual production costs. The price would undoubtedly drop if a market existed for 100 kg quantities of C_{60}! Conventional separations of fullerenes rely upon chromatography, and although the original methods based upon silica or alumina stationary phases[12] were time-consuming and inefficient, the use of activated charcoal columns allows the relatively facile separation of gram quantities of pure C_{60}.[13] For the state-of-the-art isolation of C_{60} there is probably little difference between chromatographic or extraction methods in terms of time or cost. The real question relates to the specific purification of the higher fullerenes. The Atwood extraction technique gives a hint of a future methodology, but a recent paper by Tour et al. reveals that chromatography over a silica gel/charcoal stationary phase is presently the most efficient way of isolating tangible quantities (> 1 g) of C_{70}.[14] However, the large volumes of solvents used and the relatively long separation times mean that the "extractors" may improve on this in the near future!

The second reason why this area is so thought provoking is more general. Personally, I am interested in the ramifications of these separation methods for inorganic chemistry. The fullerenes C_{60} and C_{70} are allotropes of the element carbon. Many other elements have allotropes possessing different molecular structures. One must speculate upon the possibility of using such size-based methods for the separation and purification of such homoelemental compounds. Is the rapidly developing chemistry of the fullerenes the dawn of a whole new era in the chemistry of the main group elements? For this, we will have to wait future results.

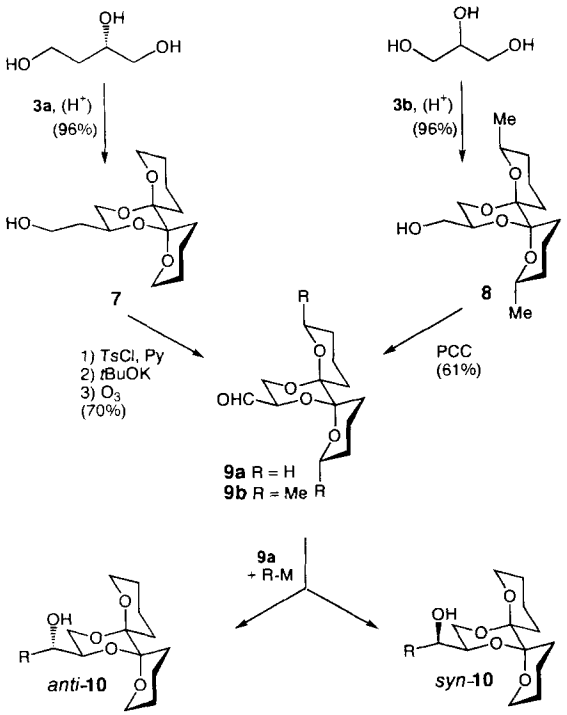
The Selective Blocking of *trans*-Diequatorial, Vicinal Diols; Applications in the Synthesis of Chiral Building Blocks and Complex Sugars

Thomas Ziegler*

For efficient chemical synthesis of complex oligosaccharides, protecting group strategies and blocking techniques are of overriding significance. It is usually unavoidable first to prepare protected smaller saccharide units that enable a directed selective formation of the glycosidic bond and sequential construction of larger saccharides. To this end all functional groups with the exception of the projected reaction center in the saccharide building block to be glycosylated (the glycosyl acceptor) must, as a rule, be protected, and only in particularly favorable cases can partially protected glycosyl acceptors be used for regioselective glycosylation. In the glycosyl donor, the saccharide building block that must be linked to the glycosyl acceptor, the protecting groups must be very precisely tuned to the planned glycosylation method. Both the reactivity of glycosyl donor and glycosyl acceptor and the anomeric selectivity of the glycosylation step is dominated by the protecting groups. The search for novel protecting group strategies is therefore as urgent for the carbohydrate chemist as the need for useful glycosylation methods.

Of the classical protecting groups of esters, ethers, and acetals that are favored in saccharide synthesis, the benzylidene and isopropylidene protecting groups have particular significance, because both open the possibility of blocking two hydroxyl functions in a monosaccharide simultaneously and selectively. As the example of methyl-α-D-galactopyranoside in Scheme 1 illustrates, benzylidene acetals can be the major product from 1,3-diols, so that in the protected galactose derivative **1** the hydroxyl functions of positions 2 and 3 are available for further reaction. In contrast, isopropylidene acetals can be selectively prepared from vicinal *cis*-diols, with the result that in the example **2** chosen here the hydroxyl functions of positions 2 and 6 remain free.[1] Although isopropylidene acetals can also be synthesized from monosaccharides with vicinal *trans*-diequatorial diols, these acetals are usually so acid-labile that they are difficult to handle and are therefore less suitable for glycosylation reactions.



In the search for acetal protecting groups for vicinal *trans*-diequatorial diols that can be selectively introduced, the research group of S. V. Ley in Cambridge, England, recently developed the dispiroketal (Dispoke)[2] and cyclohexane-1,2-diacetal (CDA) protecting groups.[3] The former can be introducted by acetalization of a diol with the readily accessible 3,3′,4,4′-tetrahydro-6,6′-bis-2*H*-pyran[4, 5] (bis-DHP, **3a**), the latter by acetalization with the just as easily obtainable 1,1,2,2,-tetramethoxycyclohexane **4**.[3] In the case of the methyl-α-D-galactopyranoside (Scheme 1), the *trans*-diequatorial hydroxyl functions of positions 2 and 3 can be highly selectively blocked as the Dispoke-protected galactoside **5a** (76%)[5] or the CDA-protected galactoside **6a** (46%)[3] in this way. Dispoke and CDA derivatives of monosaccharides are therefore useful complements to benzylidene and isopropylidene derivatives. Like the classical acetal protecting groups, the Dispoke group can be removed hydrolytically under acidic conditions, preferably by transacetalization with ethylene glycol.[5]

Scheme 1.

The exceptionally high selectivity of the Dispoke and CDA groups can be explained by a steric interaction of the neighboring spiro centers and the equatorial arrangement of the alkyl residue as well as a strong anomeric effect of the two acetal functions.[2, 3] This high selectivity is particularly impressively reflected in the reaction of (*S*)-1,2,4-butanetriol with bis-DHP (**3a**) and a catalytic amount of camphorsulphonic acid (CSA), in which the dispiroketal **7** (96%) is obtained as exclusive stereoisomer[2] (Scheme 2). In the case of the symmetric glycerine, a "desymmetrization" of glycerine can even be achieved during the Dispoke formation by the use of chiral C_2-symmetric bis-DHP derivative **3b**. Here the only product is the enantiomerically pure compound **8** (96%). The compounds **7** and **8** can be transformed into the corresponding Dispoke-protected glycerinaldehydes **9**, which not only are thermally more stable than the isopropylidene glycerinaldehyde,[2, 6] but also have a distinctly higher *anti*-selectivity in the 1,2-addition of carbon nucleophiles to the aldehyde function[2] (Table 1).

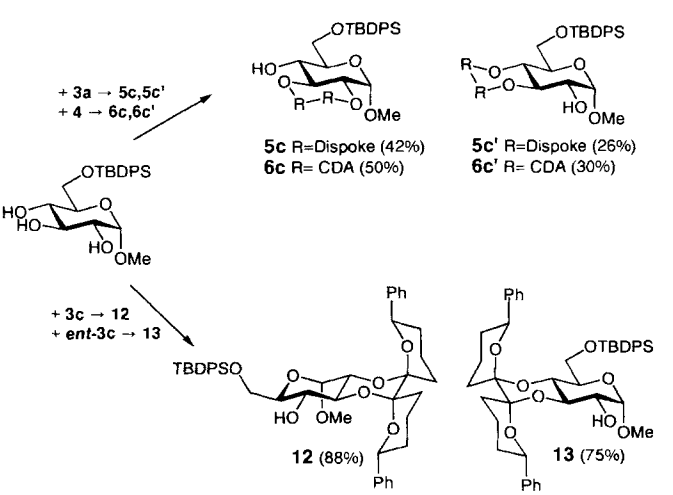
[a] THF = tetrahydrofuran. [b] Reaction of isopropylidene glycerinaldehyde with the corresponding organometallic compound.

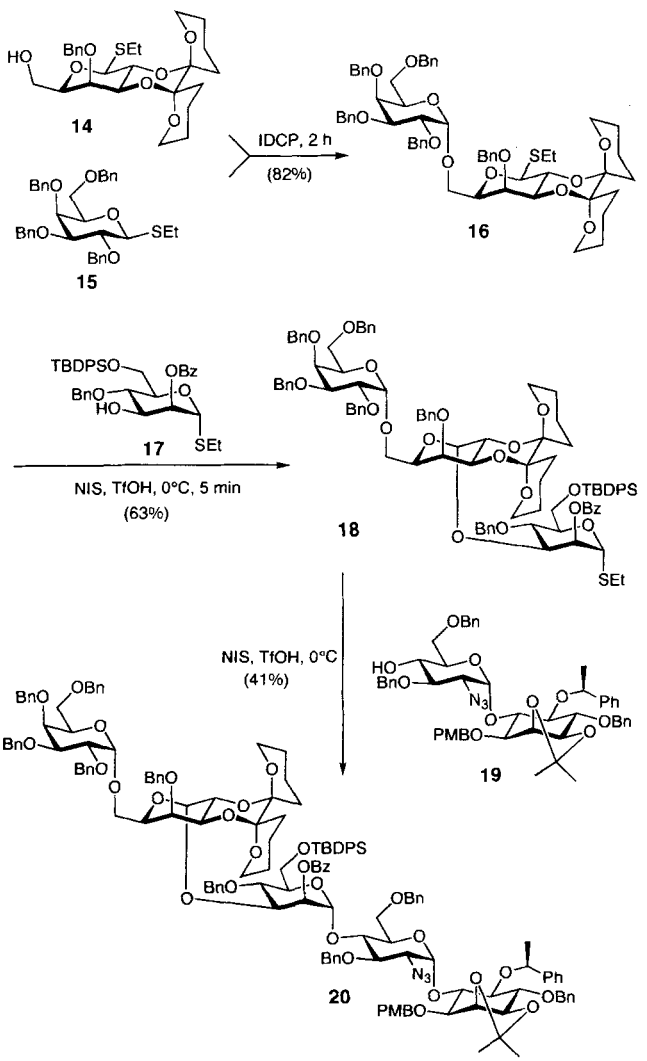
In the same way glycolic acid can be stereoselectively transformed into the Dispoke derivative **10** (61%) with enantiomerically pure **3b**.[7] Formation of the ester enolate, alkylation with methyl iodide, renewed enolate formation and treatment with benzyl bromide then give highly diastereoselectively in 51% yield the protected α-hydroxycarbonic acid derivative **11** (Scheme 3).[7] It can be predicted that the C_2-symmetric Dispoke group will rapidly become popular as auxilliary in the stereoselective synthesis of small building blocks.



Scheme 3. LDA = lithium diisopropylamide.

Besides the 2,3-protected galactosides **5a** and **6a** (Scheme 1), other monosaccharides from the *gluco*, *manno*, *rhamno*, *fuco*, *xylo*, *lyxo*, and *arabino* series can be converted into the corresponding Dispoke- and CDA-blocked derivatives **5** and **6**.[3, 8] However, the regioselectivity of the acetal formation of Dispoke derivatives can in some cases (for instance, methyl-α-L-rhamnopyranoside) lead to mixtures of the 3,4- and 2,3-derivatives **5b** and **5b'**, respectively.[8] For the CDA analogues **6**, the ratio is most often shifted so far to the side of the *trans*-diequatorially blocked compounds **6b** that a preparative application seems meaningful[3] (Scheme 4).

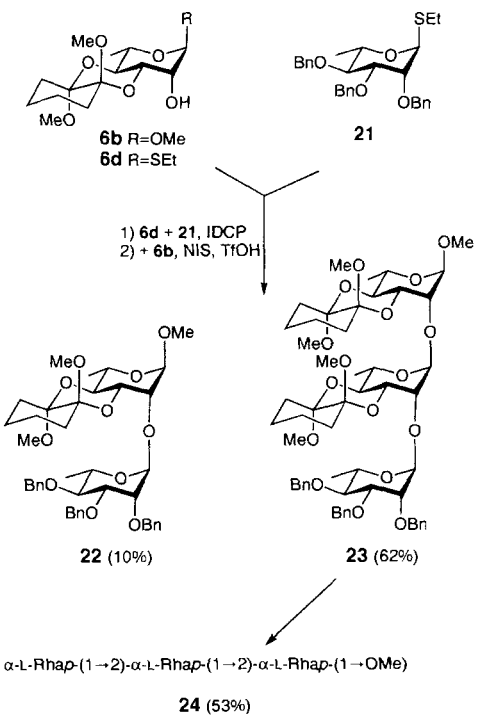
Scheme 4.



On the other hand the Dispoke and CDA protection for D-glucopyranosides presents problems, because here all secondary OH groups are *trans*-diequatorially arranged. Both with bis-DHP **3a** and with 1,1,2,2-tetramethoxycyclohexane **4**, mixtures of the 2,3- and 3,4-protected glucosides **5c**,**6c** and **5c'**,**6c'**, respectively, are obtained.[3, 8, 9] If, however, analogous to the "desymmetrization" of glycerine, phenyl-substituted, chiral bis-DHP **3c** is used, for glucose derivatives the two regioisomers **12** and **13** can be prepared in a highly selective synthesis through double diastereoselection[10] (Scheme 5).[11]

Scheme 5. TBDPS = *tert*-butyldiphenylsilyl.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2222-2273 $ 10.00+.25/0

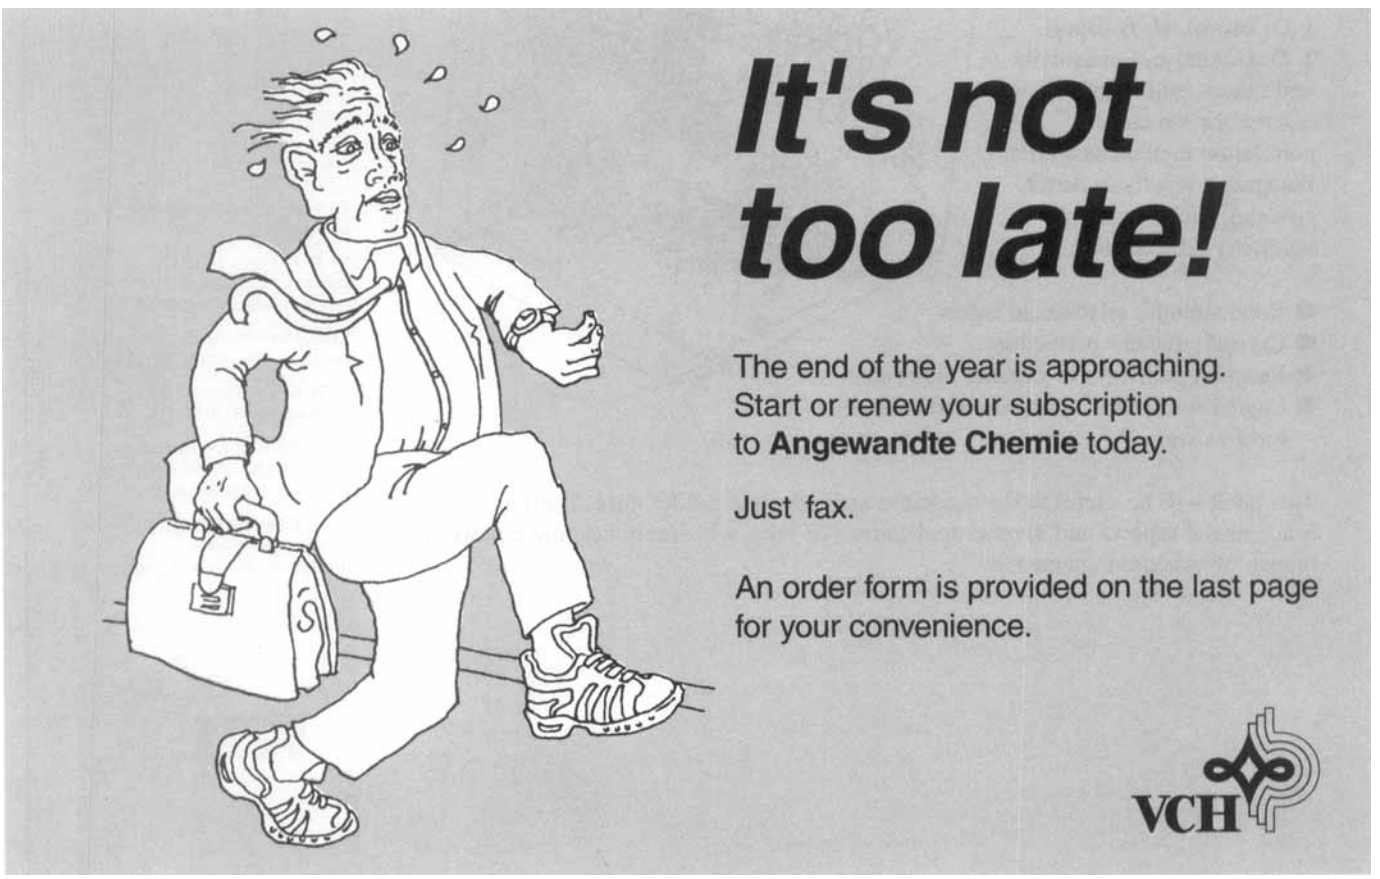


For strategies with the Dispoke or CDA protecting groups in oligosaccharide synthesis the concept of armed and disarmed glycosyl donors[1,2] is especially fruitful. According to this principle the reactivity of a glycosyl donor is diminished by deactivating protecting groups (e.g. acyl groups) or by restricting the flexibility of the pyranose ring by bridging two hydroxyl functions (e.g. acetal protecting groups). Such a disarmed donor can then function as a glycosyl acceptor and participate in a selective reaction with a reactive armed (most often benzyl-protected) glycosyl donor. The conformation-stabilizing Dispoke and CDA groups are plainly predestined to disarm a glycosyl donor. For example, the ethyl-1-thio-β-D-galactoside **14**, conformationally fixed by a Dispoke group and thus disarmed, undergoes a smooth reaction with thiogalactoside **15**—reactive as a result of benzyl protection—and the mild activator iodonium dicollidine perchlorate (IDCP) to form disaccharide **16**[13] (Scheme 6). Through the subsequent use of the more reactive activator *N*-iodosuccinimide (NIS), disaccharide **16** is armed and reacts with the 2-*O*-benzoyl-protected and thus disarmed thiomannoside **17** as glycosyl acceptor in attractive yield to afford trisaccharide **18**.

Scheme 6. TfOH = trifluoromethansulfonic acid, PMB = *para*-methoxybenzenyl.

The transformation of **18** as trisaccharide donor without further protecting group manipulation is achieved with the pseudo disaccharide acceptor **19** and NIS after prolonged reaction times. The pentasaccharide **20**, a fragment of the GPI anchor of *Trypanosoma brucei*, is thus obtained in 41% yield.[13]

Based on the concept of armed and disarmed glycosyl donors, the trisaccharide **23** can be constructed very elegantly from the two CDA-protected rhamnosides **6b** and **6d** in a one-pot reaction similar to the ciclamycin trisaccharide synthesis[14] in two steps as follows:[15] The IDCP-catalyzed condensation of armed thiorhamnoside **21** and disarmed glycosyl acceptor **6d** yields as intermediate a disaccharide that reacts immediately without further purification with the CDA derivative **6b** under NIS activation to form **23** (62%). The disaccharide **22** is also found as by-product (10%), which arises in the second glycosylation step from unconverted **21** and added **6b**. The final deblocking of saccharide **23** furnishes the *Streptococcus* antigen trisaccharide **24** (Scheme 7).



Scheme 7. Rha*p* = rhamnopyranose.

In particular, the examples given in Schemes 6 and 7 for the application of Dispoke and CDA groups in oligosaccharide synthesis demonstrate magnificently that with these novel protecting groups complex sugars can be synthesized very efficiently. The Dispoke and CDA acetals should therefore rapidly become standard practice in carbohydrate chemistry.

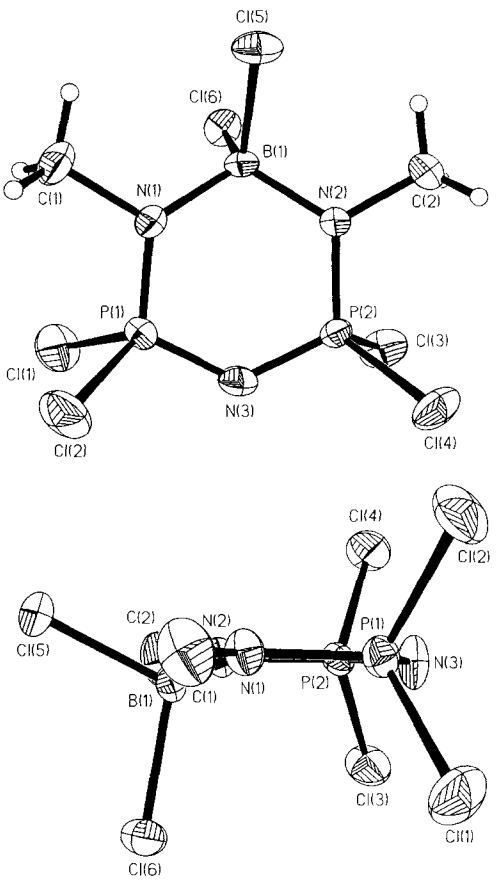
Synthesis and Structure of the First Hybrid Borazine–Phosphazene Ring**

Derek P. Gates, Ralf Ziembinski, Arnold L. Rheingold, Brian S. Haggerty, and Ian Manners*

Inorganic heterocycles have attracted considerable attention because of the interesting questions they pose with respect to structure and bonding and their function as precursors to inorganic polymers by ring-opening polymerization, and to ceramics by pyrolysis.[1–3] Borazines and cyclic phosphazenes (1,3,5,2λ^5, 4λ^5, 6λ-triazatriphosphinines) represent two of the most well-studied classes of these compounds.[4, 5] In contrast, very few examples of rings constructed from boron, nitrogen, and phosphorus atoms have been reported and none of these can be regarded as an authentic borazine–phosphazene hybrid.[6, 7]

One of the best characterized boron–nitrogen–phosphorus rings is **1**. This compound has been prepared by several routes, of which one is the reaction of $[Cl_3P{=}N{=}PCl_3][BCl_4]$ with $[MeNH_3]Cl$.[6] The boratophosphazene **1** was previously characterized spectroscopically, and a zwitterionic structure was proposed in the solid state. However, electrical conductivity measurements have provided evidence for the formation of an ion pair through chloride loss from boron in polar solvents such as nitrobenzene.[8] To clarify the nature of **1** and in view of the complete absence of any crystallographic studies of six-membered rings of this type, a single-crystal X-ray diffraction study of this species was undertaken.

Colorless crystals of **1** were obtained by cooling a solution of the compound in CH_2Cl_2 to $-30\,^{\circ}C$ over several days. Two views of the molecular structure of **1** are shown in Figure 1.[9] The BP_2N_3 ring deviates significantly from planarity and the sum of the internal angles for the ring is 711.6(6)° (expected value 720°). In particular, the boron atom in **1** is 0.39(1) Å removed from the best plane of the other five ring atoms as is clearly apparent in the side-on view of **1** in Figure 1 bottom. The P–N bonds flanking N(3) [P(1)–N(3) and P(2)–N(3)] are shorter (average, 1.547(4) Å) than those involving the methyl-substituted nitrogen atoms N(1) and N(2) [P(1)–N(1) and P(2)–N(2)] (average, 1.593(4) Å). This suggests a greater degree of π bonding in the case of the former bonds which is consistent with the presence of a positive charge on N(3). For comparison, the phosphorus–nitrogen bonds in $[Cl_3P{=}N{=}PCl_3]^+$ are 1.51–1.56 Å long.[10] Significantly, however, the P(1)–N(1) and P(2)–N(2) bonds (average, 1.593(4) Å) are similar in length to the P–N bonds in $(NPCl_2)_3$ (1.58 Å)[11] and are far shorter than a typical P–N single bond (ca. 1.78 Å).[12] This indicates that the lone pairs on N(1) and N(2) are involved in the π-bonding to the phosphorus atoms of the P(1)-N(3)-P(2) fragment. Further evidence for π-bonding is provided by the trigonal-planar rather than pyramidal environments of N(1) and N(2). In contrast to the P–N bonds, the B–N bonds have lengths (average, 1.533(5) Å) which are indicative of predominantly single bond character. For example, the accepted bond length range for a B–N single bond is about 1.58–1.59 Å, whereas B=N double bonds are generally about 1.41 Å, and in borazines, the bond length is slightly longer at about 1.43 Å.[13] Nevertheless, the skeletal B–N bonds are still significantly shorter than a typical single bond, suggesting the possibility of some degree of π character in the skeletal N-B-N moiety. This postulate is supported by a careful consideration of the environment about the boron atom B(1). Remarkably, the two boron–chlorine bonds differ significantly. The B(1)–Cl(5) bond lies approximately in the best plane of the BP_2N_3 ring and is 1.847(5) Å long which is



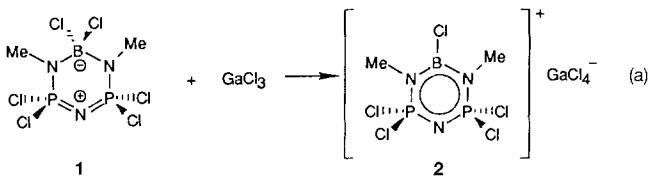


Fig. 1. Crystal structure of **1**. Selected bond lengths [Å] and angles [°]: P(1)-N(3) 1.551(4), P(2)-N(3) 1.544(4), P(1)-N(1) 1.583(4), P(2)-N(2) 1.602(4), N(1)-B(1) 1.536(6), N(2)-B(1) 1.531(5), Cl(5)-B(1) 1.847(5), Cl(6)-B(1) 1.903(4); P(1)-N(3)-P(2) 125.7(3), N(1)-P(1)-N(3) 113.9(2), N(2)-P(2)-N(3) 113.7(2), P(1)-N(1)-B(1) 122.2(3), P(2)-N(2)-B(1) 122.2(3), N(1)-B(1)-N(2) 113.9(3).

comparable to that found in cyclic chloroborane–amine adducts such as the dimeric species $(Cl_2BNMe_2)_2$ (1.830(10) Å).[14] In contrast, the B(1)–Cl(6) bond is approximately perpendicular to the best plane of the six-membered ring (Fig. 1 bottom) and is significantly elongated to 1.903(4) Å. Together with the significant shortening of the skeletal B–N bonds, this elongation suggests that Cl(6) is close to heterolytic dissociation which would generate a "borazine-like" planar environment at B(1). In view of this possibility, halide abstraction from **1** was attempted by using $GaCl_3$.

Addition of $GaCl_3$ in CH_2Cl_2 to **1** in the same solvent [Eq. (a)] gave no obvious color change. However, analysis of the

1 **2**

reaction mixture by ^{11}B NMR spectroscopy showed that **1** (δ = 5.38 (triplet)) was completely consumed and that a new product **2** with a singlet resonance at δ = 31.7 had formed. The ^{11}B NMR resonance for **2** is substantially broader than that for **1** which is consistent with the presence of a planar rather than tetrahedral environment at boron. In addition, the ^{11}B NMR chemical shift for **2** is similar to that for the borazine $(ClBNMe)_3$ (δ = 31.2).[15] The ^{31}P NMR resonance of **2** at δ = 35.5 is shifted downfield compared to the corresponding singlet resonance of **1** at δ = 28.2. The ^1H NMR spectrum of **2** shows a methyl proton resonance centered at δ = 3.36 which is shifted slightly downfield from that of **1** at δ = 3.23. Although the NMR spectroscopic data for **2** was clearly consistent with the successful abstraction of the chloride from **1** using $GaCl_3$, conclusive proof is provided by a single-crystal X-ray diffraction study.

Two alternative views of the molecular structure of **2**[16] are shown in Figure 2. The structure confirmed that a chlorine atom attached to boron in **1** had been abstracted to yield a boron–nitrogen–phosphorus cation with $[GaCl_4]^-$ as counterion. In contrast to the structure of **1**, the BNP ring in **2** is virtually planar (Fig. 2 bottom); the N(1) atom exhibits the largest deviation from the best plane (0.11(1) Å), and the sum of the internal angles for the ring is 718(1)°. There are no significant interactions between the cation and the anion; the shortest B···Cl(6) distance is 3.223(3) Å, and the shortest N(1)···Cl(9) distance is 3.980(3) Å. A clear difference between the structures of **1** and **2** is apparent in the N(2)-B-N(3) bond angle. This angle shows a substantial increase from 113.9(3)° in **1** to a value of 124.2(6)° in **2** which is consistent with a decrease in the coordination number at boron from 4 to 3. In addition, the B–N bond lengths in **2** (1.429(10) Å) are much shorter than in **1** (1.533(5) Å). This indicates a degree of π-bond character in **2** similar to that found in borazines (B–N bond length ca. 1.43 Å).[13] In contrast to the environment at boron, the bond lengths and angles in the phosphazene portion of the ring are virtually identical to those in **1**. However, the P(1)–N(2) and P(2)–N(3) bonds are longer in **2** (average, 1.624(6) Å) than the analogous bonds in **1** (average, 1.593(5) Å) which can be attributed to the greater degree of π-bonding between nitrogen and boron in the former species.

Further work is underway, aimed at gaining greater understanding of the reactivity of **1** and **2** and at investigating the potential use of these compounds as precursors to BN–PN based polymers and ceramics.

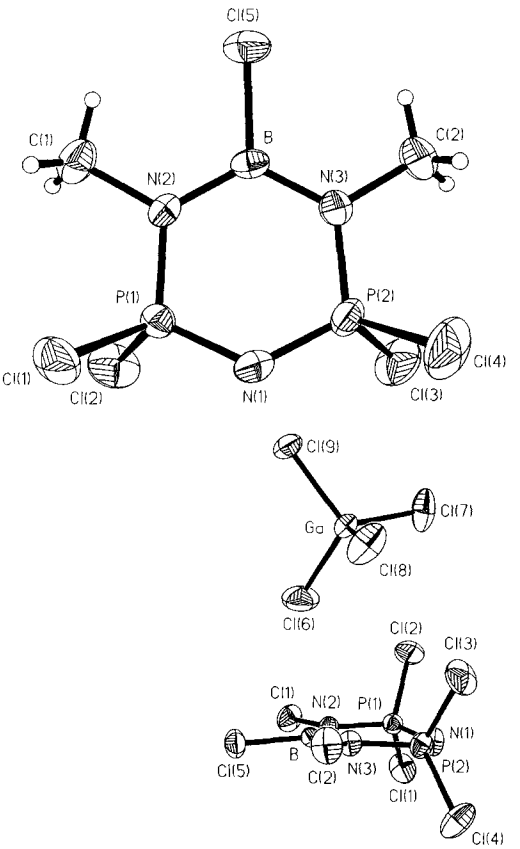

Fig. 2. Crystal structure of **2**. Selected bond lengths [Å] and angles [°]: P(1)-N(1) 1.551(7), P(2)-N(1) 1.551(6), P(1)-N(2) 1.623(6), P(2)-N(3) 1.625(7), N(2)-B 1.436(9), N(3)-B 1.422(10); P(1)-N(1)-P(2) 125.4(4), N(1)-P(1)-N(2) 112.2(3), N(1)-P(2)-N(3) 112.0(4), P(1)-N(2)-B 121.5(5), P(2)-N(3)-B 122.2(4), N(2)-B-N(3) 124.2(6).

Experimental Procedure

2: A solution of $GaCl_3$ (0.26 g, 1.5 mmol) in CH_2Cl_2 (20 mL) was added to a pale yellow solution of **1** (0.47 g, 1.4 mmol) in CH_2Cl_2 (20 mL) in an flame-dried evacuated chamber [17] at room temperature. No color change was observed in the reaction mixture after it had been stirred, but the reaction was shown to be quantitative by ^{31}P NMR. The solvent was removed in vacuo over approximately four hours by slow condensation into a flask held about 10 cm above liquid nitrogen. This yielded beige fibrous needles, which were recrystallized from CH_2Cl_2 by slow removal of solvent in vacuo. The colorless crystals obtained were washed three times with cold hexanes. Yield: 0.33 g (47%). ^{31}P NMR ($CDCl_3$; H_3PO_4 ext.), δ = 35.0; ^{11}B NMR (CH_2Cl_2/D_2O; $BF_3 \cdot OEt_2$ ext.), δ = 31.7; ^1H NMR ($CDCl_3$; TMS ext.), δ = 3.36 (m). Elemental analysis: $C_2H_6BCl_9GaN_3P_2$: calcd. C 4.50, H 1.13, N 7.87, found C 4.50, H 1.12, N 7.72.

Tetralithiated Dibenzyl(methyl)phosphane**

Martin Winkler, Martin Lutz, and Gerhard Müller*

Polar di- and polymetalated organic compounds (polycarbanions)[1] have attracted widespread interest because of their synthetic potential and the intriguing problems associated with their structure and bonding.[2] For dimetalated organic compounds, in particular, a plethora of preparative, structural, spectroscopic, and theoretical information is available. Far less is known about polar organometallic compounds containing triply[3] or higher charged carbanions. Prominent examples of tetrametalated carbon compounds are tetralithiomethane[4] and other polylithium compounds obtained by perlithiation or lithiation of alkynes, for example C_3Li_4, C_5Li_4,[5] and tetrametalated 2,4-hexadiyne and 1,8-cyclotetradecadiyne.[6] Other highly metalated organometallic compounds are tetralithiated 1,2,3,4-tetraphenyl-1,3-butadiene[7] and 1,1-dimethyl-2,3,4,5-tetraphenyl-1-silacyclopentadiene,[8] 3,3′,5,5′-tetrakis(kaliomethyl)-biphenyl,[9] 2,3-bis(α-kaliobenzyl)-1,4-dikalio-1,4-diphenylbutane,[10] polylithiated aromatic rings[11] including ferrocene,[12] and multiply charged anions derived from molecules with extended π systems[13] including fullerenes.[14] Precise structural information on most of these systems is scarce, however, because polymetalated organic compounds tend to be highly associated in the solid state thereby often preventing structure elucidation in solution as well as the growing of single crystals.

In the course of studies of the ligand properties of *ortho*-metalated benzylphosphanes towards main group metals[15] we became interested in *o,o′*-dilithiated dibenzyl(methyl)phosphane (**1**), a valuable starting material for the preparation of metal complexes of this dianionic phosphane ligand.[16] The dilithium compound **1** is conveniently prepared from bis(2-bromobenzyl)methylphosphane[17] and *n*BuLi in pentane at −20 °C in 79% yield.[18] The almost exclusive *ortho*-dilithiation is proven by reactions of **1** with D_2O and dimethyldisulfide which yield the respective *ortho*-derivatives. Monolithiation amounts to only 10% of the total product yield under these conditions. Compound **1** is only sparingly soluble in pentane as well as in aromatic solvents which prevented further characterization especially by NMR spectroscopic methods.[19]

We now found that a suspension of **1** in pentane at room temperature may be further lithiated with excess *n*BuLi in the presence of *N,N,N′,N′*-tetramethylethylenediamine (tmeda) to give the pentane-soluble red tetralithium compound **2** in 50% yield. In addition to the *ortho*-carbon atoms, in **2** also the α-carbon atoms of dibenzyl(methyl)phosphane are deprotonated. Thus, the organolithium complex **2** contains a surprisingly small quadruply charged carbanion formally comprising not less than five lone pairs of electrons. The tetralithiation was again proven by hydrolysis of **2** with D_2O. In addition, **2** was also characterized by an X-ray structure determination,[20] which also yielded valuable insight into the origin of the stability of this highly charged carbanion.

2

In the solid state **2** is a dimer with crystallographically imposed centrosymmetry (Fig. 1). The deprotonation of the *ortho*-carbon atoms of the phenyl rings (C2, C9) clearly follows from their coordination to lithium atoms, while that of the α-carbon atoms C7 and C14 is evident from their planar geometry (H

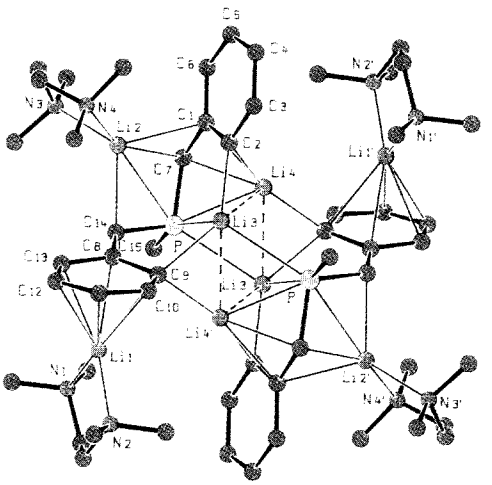

Fig. 1. Structure of the dimer of **2** in the crystal (SCHAKAL plot; atoms with arbitrary radii; H atoms omitted for clarity; primed atoms are related to those without a prime by a crystallographic center of inversion; the central rhombus of lithium atoms is indicated by the red dashed lines). Important distances [Å] and angles [°]: Li2-P 2.79(1), Li2-C1, 2.42(2), Li2-C7 2.35(1), Li2-C14 2.25(1), Li3-P 2.70(1), Li3-P' 2.73(1), Li3-C2 2.12(1), Li3-C9 2.19(2), Li4-P 2.50(2), Li4-C2 2.15(2), Li4-C1 2.26(2), Li4-C7 2.27(2), Li4-C9' 2.14(2), P-C7 1.796(7), P-C14 1.775(7), P-C15 1.821(8), C1-C7 1.45(1), C8-C14 1.42(1), Li3···Li4 2.62(2), Li3···Li4' 2.51(2); C7-P-C14 109.1(3), C7-P-C15 99.0(4), C14-P-C15 103.8(4), C1-C2-C3 115.1(6), C8-C9-C10 115.6(7), C2-C1-C7 120.1(6), C9-C8-C14 123.3(7), P-C7-C1 121.0(5), P-C14-C8 126.4(5), Li4-Li3-Li4' 102.7(5), Li3-Li4-Li3' 77.3(5). Torsion angles [°]: C2-C1-C7-P 9.9(9), C9-C8-C14-P 8(1).

atoms located). Dimer formation is brought about by four bridging lithium atoms (Li3, Li4, Li3', Li4') arranged in a planar, almost perfectly equilateral rhombus (Fig. 1). Due to the bridging nature of these four lithium atoms each of the carbanions forms close contacts to not less than six lithium cations. Five of them (Li2, Li3, Li4, Li3', Li4') are arranged in close proximity to the carbanionoid centers (α- and *ortho*-C atoms), the *ipso*-phenyl atoms, and the phosphorus atom. In particular, Li2 is bonded in η^4 fashion to the nonplanar fragment comprising C1, C7, P, C14. The bridging atom Li3 connects both *ortho*-carbon atoms and the phosphorus atom of one ligand with the phosphorus atom of the second, while Li4 is η^4 π bonded to the fragment comprising C2, C1, C7, P and in addition to the *ortho*-C atom C9'. As a clear consequence of the good steric shielding of most of the anion by these five lithium atoms, the Li1 atom is η^6 π bonded to the least shielded phenyl ring C8–C13 (Li–C 2.32(1)–2.54(1) Å).[21] Due to the coordinative unsaturation of the Li1 and Li2 centers by carbanion contacts, only these are further complexed by tmeda molecules. The bonding pattern of Li2 and particularly those of Li3 and Li4 are without precedent. They involve Li–C distances between 2.12(1) and 2.42(2) Å, while the Li–P distances are between 2.50(2) and 2.79(1) Å, a range commonly observed in many complexes of lithium with anionic phosphanes, however.[22] The latter deserves special mention since the (phosphane) P atom in addition to three covalently bonded C atoms is coordinated to not less than four Li atoms, which likewise has no precedent in the literature.

In addition to the electrostatic stabilization of the tetracarbanion in **2** by tight ion pairing with six Li^+ counterions, further stabilization of the anion is gained from extensive delocalization of the negative charges as well as from the at least partial onium character of the phosphorus center brought about by the large number of Li^+ contacts. The first effect is particularly evident from the almost perfect planarity of both benzylic fragments P-CH-C_6H_4 and the short bonds C1–C7 (1.45(1) Å) and C8–C14 (1.42(1) Å). The latter effect, which has long been known to be the dominating stabilizing factor for the carbanionoid centers in phosphorus ylides,[23] is reflected in the slightly shortened bonds between phosphorus and the benzylic carbon atoms (P–C7 1.796(7), P–C14 1.775(7) Å). Finally, the intraring bond angles at the metalated phenyl carbon atoms C2 and C9 deserve comment. From a variety of metal aryl structures they are well known to be characteristically smaller than the sp^2 standard.[24] This is believed to be due to the concentration of the negative charge at this carbon atom in an orbital with increased s-character, thus leaving more p-character for the bonds to the neighboring carbon atoms with consequent reduction in bond angle. With 115.1(6)° and 115.6(7)° at C2 and C9, respectively, the effect is noticeably smaller in **2** than in prototypal phenyllithium structures, where a range of 111.2–114.6° is usually encountered.[24, 25] We take this as a further indication of the superior charge delocalization in the tetracarbanion in **2**.

Synthesis and structure of **2** strongly indicate that benzylphosphanes and benzylphosphonium cations should be particularly well suited as starting materials for the formation of highly charged carbanions by multiple lithiation.

Experimental Procedure

All experiments were carried out under rigorous exclusion of atmospheric oxygen and moisture. Solvents were dried according to established procedures and redestilled immediately prior to use. NMR: Jeol JNM GX 400(^{13}C, ^{31}P, ^{7}Li), Bruker WM 250 (^{1}H).

1: Bis(2-bromobenzyl)methylphosphane (2.33 g, 6.0 mmol) was suspended in pentane (50 mL) to which diethyl ether (0.3 mL) was added. After the mixture had been cooled to −40 °C *n*BuLi (9 mL, 18 mmol, 2 M solution in pentane) was added dropwise. The reaction mixture was allowed to warm to −20 °C and stirred for 4 h. A slightly yellow precipitate formed which was filtered off, washed with pentane (50 mL) and dried in vacuo. Yield: 1.15 g (4.8 mmol, 79%) of **1**.

Reaction of **1** with D_2O: **1** (0.55 g, 2.4 mmol) was suspended in pentane (25 mL) and D_2O (1.5 mL) was added. After the mixture had been stirred for a short while both phases became colorless and clear. The phases were separated and the pentane phase washed twice with H_2O. The pentane was removed in vacuo and the residue dissolved in $CDCl_3$ for the NMR measurements. The ^{1}H and ^{31}P NMR spectra are virtually identical with those of $(C_6H_5CH_2)_2PCH_3$ [17b]. $^{13}C\{^{1}H\}$NMR (105.3 MHz, 25 °C, TMS ext.) of (*o*-D-$C_6H_4CH_2)_2PCH_3$: δ = 10.56 (d, ^{1}J(P,C) = 18.5 Hz, CH_3), 36.47 (d, ^{1}J(P,C) = 16 Hz, CH_2), 125.69 (s, C-4), 128.20/128.32 (s, C-3/5), 128.73 (dt, ^{1}J(D,C) = 24, ^{3}J(P,C) = 5.6 Hz, C-2), 129.05 (d, ^{3}J(P,C) = 4.9 Hz, C-6), 137.60 (d, ^{2}J(P,C) = 4.9 Hz, C-1).

Reaction of **1** with MeSSMe: **1** (0.55 g, 2.4 mmol) was suspended in pentane (25 mL) and MeSSMe (1 mL, 1.1 g, 11 mmol) was added dropwise whereupon the reaction mixture warmed up slightly. The pentane phase was washed three times with H_2O (1.5 mL), the pentane was removed in vacuo, and the residue characterized by NMR in $CDCl_3$. According to the PCH_3 to SCH_3 ratio in the ^{1}H NMR, the reaction product consists of a 9:1 mixture of di- and monosubstitution products. NMR data of (*o*-MeS-$C_6H_4CH_2)_2PCH_3$: ^{31}P NMR (161.83 MHz, 25 °C, 85% H_3PO_4 ext.): δ = −28.6, s. ^{1}H NMR (250 MHz, R.T., TMS ext.): δ = 1.03 (d, ^{2}J(P,H) = 3.6 Hz, PCH_3), 2.44 (s, SCH_3), 2.91 (d, $^{2}J(H_A,H_B)$ = 13.4 Hz, CH_2), 3.11 (d, CH_2), 7.05–7.26 (m, Ph). $^{13}C\{^{1}H\}$NMR (105.3 MHz, 25 °C, TMS ext.): δ = 11.33 (d, ^{1}J(P,C) = 18.5 Hz, PCH_3), 16.28 (s, SCH_3), 34.75 (d, ^{1}J(P,C) = 17.2 Hz, CH_2), 124.80 (s, C-4), 126.10 (s, C-3), 126.50 (s, C-5), 129.65 (d, ^{2}J(P,C) = 7.4 Hz, C-1), 136.46 (d, ^{3}J(P,C) = 6.1 Hz, C-6), 137.36 (d, ^{3}J(P,C) = 2.5 Hz, C-2).

Synthesis of **2** by dilithiation of **1**: As described above, bis(2-bromobenzyl)methylphoshane (2.1 g, 5.4 mmol) was treated at −10 °C in pentane (50 mL) to which diethyl ether (0.3 mL) was added with *n*BuLi (6 mL, 15 mmol, 2.5 M solution in hexane). The yellow precipitate formed after 2.5 h was filtered off, washed with pentane (15 mL), and resuspended in pentane (40 mL). At room temperature more *n*BuLi (6 mL, 15 mmol, 2.5 M solution in hexane) was added dropwise, followed by tmeda (1 mL, 0.77 g, 6.6 mmol). A clear red solution formed which was stirred for 1.5 h after which a red solid slowly precipitated. Further tmeda (1 mL, 0.77 g, 6.6 mmol) was added and the mixture was stored at −25 °C overnight. The precipitate was filtered off. Yield: 1.3 g (2.7 mmol, 49.7%) of **2**. ^{31}P NMR (161.83 MHz, 25 °C, 85% H_3PO_4 ext.): $\delta(C_6D_6)$ = −49.5, br. s. ^{7}Li NMR (155.37 MHz, 1 M LiCl/H_2O ext.): δ (52 °C, C_6D_6) = −0.30, s; δ (0 °C, [D_8]toluene) = −1.37, br. s; −0.66, br. s; 1.43, br. s; 1.99, br. s.

Reaction of **2** with D_2O: **2** (1.3 g, 2.7 mmol) was dissolved in pentane (25 mL) and D_2O (2.0 mL) was added. The phases were separated and the pentane phase washed twice with H_2O (5 mL). The pentane was removed in vacuo and the remaining oil dissolved in $CDCl_3$ for the NMR measurements. The ^{31}P NMR spectrum is virtually identical with that of $(C_6H_5CH_2)_2PCH_3$ [17b]. ^{1}H NMR (250 MHz, 25 °C, TMS ext.) of (*o*-D-$C_6H_4CHD)_2PCH_3$: δ = 0.87 (d, ^{2}J(P,H) = 3.4 Hz), 2.6 (br. s,

CHD), 2.8 (br. s, CHD), 7.10–7.16 (m, Ph), 7.20–7.27 (m, Ph). $^{13}C\{^1H\}$ NMR (105.3 MHz, R.T., TMS ext.): $\delta = 10.4$ (d, $^1J(P,C) = 18.3$ Hz, CH_3), 36.0 ("q" = dt, $^1J(P,C) \approx {}^1J(C,D) = 19$ Hz, CHD), 125.7 (s, C-4), 128.2/128.3 (s, C-3/5), 128.73 (dt, $^1J(D,C) = 27.0$, $^3J(P,C) = 6.0$ Hz, C-2), 129.0 (d, $^3J(P,C) = 5.5$ Hz, C-6), 137.6 (d, $^2J(P,C) = 4.9$ Hz, C-1).

[1] Highly polar organometallics, especially those of the alkaline metals, are commonly referred to as "carbanions". This oversimplified view has long been criticized as organometallic compounds never contain isolated carbanions neither in the solid state nor in solution. For a recent discussion of the subject see: C. Lambert, P. von R. Schleyer, *Angew. Chem.* **1994**, *106*, 1187; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1129.

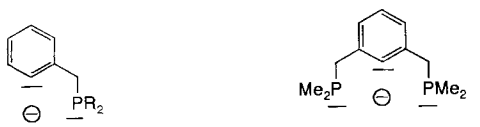
Phosphane Coordination to Magnesium: Synthesis and Structure of Bis[*ortho,ortho'*-bis{(dimethylphosphino)-methyl}phenyl]magnesium**

Andreas Pape, Martin Lutz, and Gerhard Müller*



Coordination of phosphanes to organomagnesium species has only been demonstrated in solution as yet. As could be shown by ^{25}Mg NMR spectroscopy, $[Cp_2Mg]$ is complexed by PMe_3 and $Me_2PCH_2CH_2PMe_2$ in solution; however, isolation of definite adducts is ruled out by the ease of dissociation of the complexes.[1] In contrast to phosphanes, phosphides such as $PHPh^-$ are noticeably better complexing agents to magnesium, which permitted the isolation and structural characterization of [(tmeda)Mg(PHPh)$_2$] (tmeda = *N,N,N',N'*-tetramethylethylenediamine), a molecular complex with magnesium–phosphorus bonds.[2]

In previous work we showed that *ortho*-metalated benzylphosphanes **A** (R = Ph, Me)[3] are valuable bidentate (C, P) chelating ligands due to the intramolecular phosphorus complexation favored by the phosphane donor site held in close spacial proximity to the carbanionoid function.[4] This complexation potential is particularly evident from the ease of formation of stable complexes with a large number of main group metals

[**] This work was supported by the Fonds der Chemischen Industrie and the State of Baden-Württemberg (Forschungsschwerpunkt "Metallzentrierte Substrattransformationen"; fellowship to A.P.). We are grateful to Prof. Dr. L. M. Venanzi, ETH Zürich, for valuable suggestions concerning the synthesis of **1**.

known to be notoriously weak phosphorus acceptors.[5] In an effort to extend these studies to the potentially tridentate (P,C,P) ligand **B**, we were initially interested in its lithium complex as a convenient starting material for the preparation of other main group element complexes.[6] We report here on its synthesis and structure, as well as its use for the preparation of a stable diarylmagnesium complex containing magnesium-coordinated phosphano groups which could be fully characterized structurally both in solution and in the solid state.

A **B**

The organolithium compound $[\{Li[o,o'\text{-}(Me_2PCH_2)_2C_6H_3]\}_2]$ (**2**) was prepared in 77% yield from the corresponding bromide **1**[7] by metal–halogen exchange with *n*BuLi in pentane at

1 **2**

3

223 K in the presence of 5% tmeda. The structure of **2** in the solid state, as revealed by an X-ray structure determination,[8] shows the presence of two crystallographically independent dimers with approximate *222* (D_2) symmetry (Fig. 1). In both dimers the lithium atoms bridge the metalated carbon atoms of the two phenyl rings that are almost perpendicular to the central planar Li-C-Li-C four-membered ring.[9] In addition to the two carbanionoid carbon atoms, the strongly distorted tetrahedral coordination sphere of each lithium is completed by two phosphorus atoms of the *o*-CH_2PMe_2 substituents of the ligands. Each Li atom is coordinated to one phosphano function of each ligand; thus the ligand **B** in **2** acts in a tridentate (P,C,P) fashion to two different Li atoms. The organolithium compound **2** strongly resembles the structure proposed for the lithium complex of the corresponding nitrogen ligand[4b] which was verified for dimeric 2,3,5,6-tetrakis[(dimethylamino)methyl]phenyllithium.[10] However, the Li–N bonds (2.109(3) Å) in the latter are significantly shorter than the Li–P bonds in **2**.[11] The dimeric nature of **2** largely persists in toluene at least up to room temperature, as revealed by NMR spectroscopy.[12] At 193 K the structure is static and the ^{7}Li NMR (triplet, $^1J(^7Li,^{31}P)$ = 44 Hz) and ^{31}P NMR spectra (quartet) clearly indicate the coordination of the lithium centers by two phosphorus atoms. At room temperature the dimer is fluxional as indicated by the coupling of the ^{7}Li nucleus to all four ^{31}P nuclei (quintet,

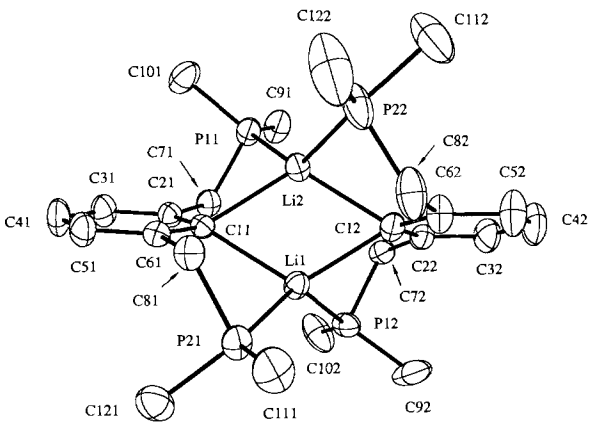

Fig. 1. Molecular structure of one of the two crystallographically independent dimers in the crystals of **2** and atomic numbering scheme adopted (ORTEP plot, displacement ellipsoides at the 50% probability level, H atoms omitted for clarity). Important bond lengths [Å] and angles [°] for both dimers: Li1-C11 2.252(4)/2.229(4), Li1-C12 2.257(4)/2.225(4), Li2-C11 2.249(4)/2.290(4), Li2-C12 2.258(4)/2.262(4), Li1-P21 2.668(3)/2.544(4), Li1-P12 2.667(3)/2.513(4), Li2-P11 2.668(4)/2.550(4), Li2-P22 2.627(4)/2.586(4); C11-Li1-C12 115.5(2)/117.4(2), C11-Li2-C12 115.6(2)/113.4(2), Li1-C11-Li2 64.6(1)/64.3(1), Li1-C12-Li2 64.3(1)/64.8(1). Dihedral angles [°]: C11, C21, C31, C41, C51, C61/Li1, C11, Li2, C12 79.9/69.3; C12, C22, C32, C42, C52, C62/Li1, C11, Li2, C12 79.6/71.5; C11, C21, C31, C41, C51, C61/C12, C22, C32, C42, C52, C62 21.2/39.3.

$^1J(^7Li,^{31}P)$ = 21 Hz), while each ^{31}P nucleus, on the other hand, couples to both ^{7}Li nuclei (septet). A $\Delta G^{\neq}$ of about 50 kJ mol^{-1} is estimated from the coalescence temperatures.

The reaction of **2** with anhydrous $MgCl_2$ in Et_2O/THF at 203 K affords the arylmagnesium compound **3** in 90% yield. The superior thermal stability of **3** follows from decomposition only at temperatures above 473 K. In the solid state[13] the central magnesium atom in **3** is six-coordinate with an approximately octahedral coordination geometry, consisting of two carbon atoms *trans* to each other (C1-Mg-C1′ 178.10(8)°) and all four phosphorus atoms of the two ligands occupying the remainder of the coordination sites (Fig. 2).[14] Thus, both lig-

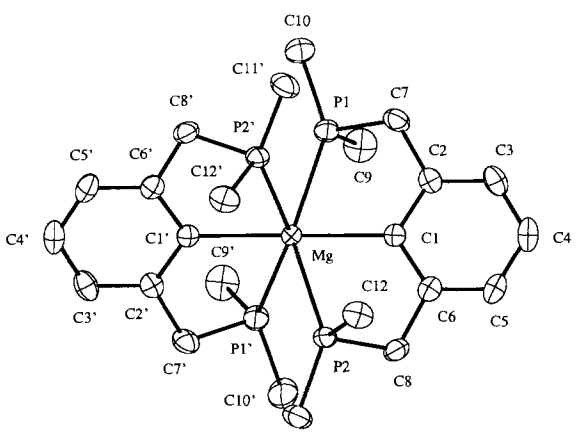

Fig. 2. Solid-state molecular structure of **3** and atomic numbering scheme adopted. (Primed atoms are related to those without a prime by a crystallographic twofold axis which is approximately perpendicular to the paper plane and passes through the Mg atom). Important bond lengths [Å] and angles [°]: Mg-C1 2.216(1), Mg-P1 2.770(1), Mg-P2 2.761(1), C1-C2 1.413(2), C1-C6 1.410(2), C2-C7 1.516(2), C6-C8 1.517(2), P1-C7 1.831(2), P2-C8 1.835(2); C1-Mg-C1′ 178.10(8), P1-Mg-P2 148.98(1) P1-Mg-P2′ 86.96(2) P1-Mg-P1′ 103.84(3), C1-Mg-P1 74.75(4), C1-Mg-P2 74.30(4), C1-Mg-P1′ 106.47(4), C1-Mg-P2′ 104.42(4), Mg-P1-C7 92.36(6), Mg-P2-C8 92.80(6), P1-C7-C2 111.5(1), P2-C8-C6 110.3(1), C7-C2-C1 119.2(1), C8-C6-C1 119.3(1), C2-C1-Mg 122.4(1), C6-C1-Mg 122.5(1), C2-C1-C6 115.1(1). ands act as tridentate (P,C,P) ligands to the same central Mg atom. The entire molecule has crystallographic *2* (C_2) symmetry. As imposed by the ligand shape, the two phosphorus atoms of one ligand likewise are arranged *trans* to each other at the magnesium center, but noticeable deviations from the ideal angles in an octahedron result from the formation of four chelating five-membered rings upon complexation of magnesium. In particular, the *trans* angles P1-Mg-P2 amount to only 148.98(1)°. The Mg–P bond lengths, for which there is no precedent in the literature, are 2.761(1) and 2.770(1) Å. They are at the upper limit of the range commonly observed for phosphorus dative bonds to the diagonally related lithium,[15] although it should be kept in mind that the coordination numbers of the metal atom in lithium phosphane complexes are generally smaller than in **3**, that is, shorter bonds result. The only molecular Mg–P bond lengths determined so far are those in [(tmeda)Mg(PHPh)$_2$] (2.587(5), 2.592(5) Å).[2, 16] The observed bond length shortening with respect to **3** is paralleled when going from lithium phoshane complexes[15] to lithium phosphide complexes.[17] The accomodation of the exceedingly long Mg–P bonds in the five-membered chelate rings is only made possible by pronounced envelope conformations of the latter (see Fig. 2) which, as a consequence, lead to a remarkably small dihedral angle of only 38.6° between the phenyl rings. The best comparison is probably the analogous Mg complex of the bis-methoxymethyl ligand [*o*,*o*′-(MeOCH$_2$)$_2$C$_6$H$_3$]$^-$ for which the dihedral angle (75.3°) is much closer to a perpendicular arrangement.[4e] The Mg–C bonds in **3** (2.216(1) Å) are at the upper end of Mg–C(phenyl) bond lengths in octahedral magnesium complexes.[4d, 18] In the complex of the bis(methoxymethyl)ligand they are 2.093(4) and 2.105(4) Å.[4e]

In toluene **3** apparently maintains its molecular structure. Apart from line broadening effects no significant change in the ^{1}H and ^{31}P NMR spectra is observed on cooling to 183 K. Particularly informative is the room temperature ^{13}C NMR signal of the *ipso*-C atom C1 at $\delta = 174.5$ (Fig. 3). Analysis of the complex multiplet (AX_2X_2' spin system) not only allows the extraction of the coupling constants (with relative signs) with the ^{31}P nuclei of both ligands (^2J(C,P) = +50, ^2J(C,P′) = +19 Hz) but also that between the ^{31}P nuclei of the different ligands (^2J(P,P′) = ±38 Hz), strongly indicating that also in solution all four phosphano groups are magnesium-coordinated.

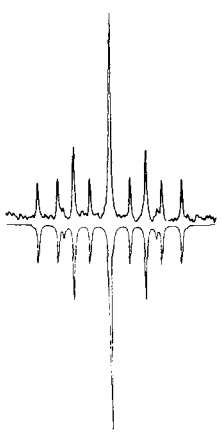

Fig. 3. ^{13}C NMR signal of the *ipso*-C atom C1 in **3** at room temperature. Upper trace: experimental spectrum; lower trace: simulated spectrum (LAOCN-5 [19]).

In summary, we could show that in spite of the inherent weakness of P–Mg dative bonds, magnesium complexation by phosphanes may be achieved if geometrically favorable anionic phosphanes are employed. The fact that in **3** the magnesium atom is complexed by all four phosphano groups of the two ligands is a direct consequence of the geometrically favorable five-membered chelate ring formation brought about by the ligand system **B**. For the synthesis of further main group element complexes of **B** the new organometallic compounds **2** and **3** should be ideal starting materials, a potential which we are currently exploring.

Experimental Procedure

All experiments were carried out under rigorous exclusion of atmospheric oxygen and moisture. Solvents were dried according to established procedures and redestilled immediately prior to use. NMR: Jeol JNM GX 400 (^{13}C: 100.53 MHz, ^{31}P: 161.83 MHz, ^{7}Li: 155.57 MHz), Bruker AC 250 (^{1}H).

2: To a suspension of **1** (8.9 g, 29 mmol) in *n*-pentane (50 mL), was added tmeda (1.4 mmol). At 223 K *n*BuLi (14.5 mL, 29 mmol, 2 M solution in pentane) was added dropwise under stirring. The phosphane dissolved and **2** started to precipitate. The mixture was stirred for 1 h and the temperature was allowed to warm to 258 K. The solid was filtered off at room temperature and washed twice with pentane (25 mL) and dried under reduced pressure. Single crystals suitable for X-ray diffraction were obtained from toluene/pentane. Yield: 5.2 g (11 mmol; 77%) of **2**. Slightly yellow, pyrophoric crystals, m.p. 403 K (decomp). Analysis for $C_{24}H_{38}Li_2P_4$ (464.344): calcd: C 62.08, H 8.25; found: C 60.64, H 8.26. ^{31}P{^{1}H}NMR ([D$_8$]toluene, 298 K, 85% H_3PO_4 ext.): $\delta = -41.8$ (sept., ^1J(P,Li) = 21 Hz), δ (193 K) = −40.5 (quart., ^1J(P,Li) = 44 Hz), $T_{coal.} = 253 \pm 5$ K, $\Delta G^{\neq} = 52$ kJ mol^{-1}. ^{7}Li NMR ([D$_8$]toluene, 293 K, 1 M LiBr/THF ext.): $\delta = 3.1$ (quint., ^1J(P,Li) = 21 Hz), δ (193 K) = 3.2 (t, ^1J(P,Li) = 44 Hz), $T_{coal.} = 233 \pm 5$ K, $\Delta G^{\neq} = 48$ kJ mol^{-1}. ^{1}H NMR (C_6D_6, 293 K, TMS int.): $\delta = 0.81$ (br. s, 12H; CH_3), 3.02 (br. s, 4H; CH_2), 6.99 (d, ^3J(H,H) = 7.3 Hz, 2H; H-3,5), 7.26 (t, ^3J(H,H) = 7.3 Hz, 1H; H-4), δ ([D$_8$]toluene, 213 K) = 0.73 (br. d, ^2J(P,H) = 3.8 Hz, 12H: CH_3), 2.34 (dd, ^2J(H$_A$,H$_B$) = 11.8, ^2J(P,H) = 9.6 Hz, 2H; CH_2), 3.39 (d, ^2J(H$_A$,H$_B$) = 11.8 Hz, 2H; CH_2), 7.01 7.35 (m, 3H; Ph), $T_{coal.} = 268 \pm 5$ K, $\Delta G^{\neq} = 51$ kJ mol^{-1}. ^{13}C{^{1}H}NMR ([D$_8$]toluene, 293 K, TMS int.): $\delta = 12.1$ (m, CH_3), 46.8 (m, CH_2), 123.9, m, 125.9 s, (C-3,4,5), 151.8 (m, C-2,6), 183.0 (m, C-1), δ (223 K) = 11.1 (s, C_AH_3), 12.8 (s, C_BH_3), 46.1 (s, CH_2).

3: To a solution of **2** (5.2 g, 11 mmol) in Et_2O (50 mL), a solution of anhydrous $MgCl_2$ (10 mmol) in THF (50 mL) was added dropwise under stirring at 203 K. The reaction mixture was allowed to warm to room temperature and the solvents were removed under reduced pressure. The remaining solid was dissolved at 313 K in toluene, the LiCl was filtered off, and the solution was cooled to 277 K whereupon large colorless crystals of **3** · toluene started to precipitate. Yield: 5.8 g (20 mmol; 90%) of **3**. Colorless, highly air-sensitive crystals, m.p. > 473 K (decomp). Analysis for $C_{24}H_{38}Mg_2P_4 \cdot C_7H_8$ (566.92): calcd: C 65.68, H 8.18; found: C 63.91, H 8.22. Crystals suitable for X-ray diffraction were grown in the same way from benzene and were found to be **3** · benzene. ^{31}P{^{1}H}NMR (C_6D_6/[D$_8$]toluene, 293/223 K, 85% H_3PO_4 ext.): $\delta = -51.3$, s. ^{1}H (C_6D_6/[D$_8$]toluene, 293/183 K, TMS int.): $\delta = 0.81$ (s, 12H; CH_3), 2.94 (br. s, 4H; CH_2), 7.00 7.27 (m, 3H; H-3,4,5). ^{13}C{^{1}H}NMR ([D$_8$]toluene, 293 K, TMS int.): $\delta = 11.4$ (s, CH_3), 43.4 (7 signals, 2:2:3:5:3:2:2, 1–3 Hz; CH_2), 125.1 (5 signals, 4:5:15:5:4, ca. 2 Hz; C-3,5), 125.4 (s, C-4), 146.6 (5 signals, 2:3:9:3:2, ca. 2 Hz; C-2,6), 174.5 (9 signals, 4:5:8:4:22:4:8:5:4, ca. 20 Hz; C-1, see text).

[8] Crystal structure data of **2**: Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, graphite monochromator, $T = 183(2)$ K, $C_{24}H_{38}Li_2P_4$, $M_r = 464.344$, triclinic, space group $P\bar{1}$ (No. 2), $a = 9.648(2)$, $b = 15.316(4)$, $c = 20.081(6)$ Å, $\alpha = 103.22(2)$, $\beta = 99.19(2)$, $\gamma = 91.04(2)°$, $V = 2847(1)$ Å^3, $Z = 4$ dimers, $\rho_{calcd} = 1.083$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 2.7$ cm^{-1}, $F(000) = 992$. The integrated intensities of a total of 13677 reflections were measured, 12908 of which were unique ($R_{int} = 0.023$, $((\sin\vartheta)/\lambda)_{max} = 0.647$ Å^{-1}, hkl range $+12$, ± 19, ± 25, $\vartheta/2\vartheta$ scans, $\Delta\omega = 0.9 + 0.35 \tan\vartheta$). Lorentz-polarization corrections were applied, those for intensity decay (-1.6%) and absorption were not considered necessary. The structure was solved by automated Patterson methods (SHELXS-86). All 75 H atoms except one were located in difference syntheses, the latter was calculated in idealized geometrical position. In the final refinement cycles they were included as fixed atom contributions ($U_{iso} = 0.05$ Å^2), while all other atoms were refined with anisotropic displacement parameters. Refinement was done on F_o^2 and all unique data were used except two structure factors which were excluded due to their abnormally negative value. Refinement of 541 parameters converged at $R(F)/wR(F^2) = 0.082/0.118$, GOOF = 1.012, $w = 1/[\sigma^2(F_o^2) + (0.0563 \cdot P)^2 + 1.19 \cdot P]$ with $P = [\max(F_o^2, 0) + 2F_c^2]/3$ (SHELXL-93). The final difference map was featureless with $\Delta\rho_{fin}(max/min) = +0.31/-0.35$ e Å^{-3}.

[9] It should be noted that deviations from a strictly perpendicular arrangement of the bridging phenyl rings with respect to the central M, C, M, C ring have also been observed to a varying degree in the classic dimeric structures of Al_2Ph_6 and $[(tmeda)LiPh]_2$: J. F. Malone, W. S. McDonald, *J. Chem. Soc. Chem. Commun.* **1967**, 444; D. Thoennes, E. Weiss, *Chem. Ber.* **1978**, *111*, 3157.

[10] A. A. H. van der Zeijden, G. van Koten, *Recl. Trav. Chemi. Pays-Bas* **1988**, *107*, 431; W. J. J. Smeets, A. L. Spek, A. A. H. van der Zeijden, G. van Koten, *Acta Crystallogr. Sect. C* **1987**, *43*, 1429.

[11] The Li–P bond lengths in **2** differ significantly in the two crystallographically independent dimers (see caption to Fig. 1). This is a consequence of a noticeably different dihedral angle between the two phenyl rings in each dimer (dimer 1: 21.2°; dimer 2: 39.3°). Given the known inherent weakness of P–Li dative bonds, conformational differences of this type should be easily feasible energetically even in **2**, where they are accompanied by bond length differences, and are almost certainly caused by the crystalline environment of the molecules. Drastic differences in bond lengths between chemically equivalent bonds clearly caused by the crystalline environment are rare and we are not aware of any other example with differences as large as those in **2**.

[12] Cryoscopic molecular weight determinations of **2** in benzene at 278 K (several concentrations) consistently indicated an average molecular weight of about 1.6 monomers. Apart from systematic errors resulting from the extreme air and moisture sensitivity of **2**, this may be caused be increasing amounts of monomers being present in solution at higher temperatures.

[13] Crystal structure data of **3**: $T = 183(2)$ K, $C_{24}H_{38}MgP_4 \cdot C_6H_6$, $M_r = 552.885$, monoclinic, space group $C2/c$ (No. 15), $a = 13.320(2)$, $b = 12.661(2)$, $c = 19.764(6)$ Å, $\beta = 106.86(1)°$, $V = 3190(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.151$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 2.7$ cm^{-1}, $F(000) = 1184$. 7553 measured reflections, 3617 of which were unique ($R_{int} = 0.028$, $((\sin\vartheta)/\lambda)_{max} = 0.647$ Å^{-1}, hkl range ± 17, $+16$, ± 25, $\vartheta/2\vartheta$ scans, $\Delta\omega = 0.9 + 0.35 \tan\vartheta$). Lorentz-polarization but no absorption correction. Direct methods (SHELXS-86), all H atoms located. Refinement of 247 parameters on all unique F_o^2 converged at $R(F)/wR(F^2) = 0.056/0.081$, GOOF = 0.993, $w = 1/[\sigma^2(F_o^2) + (0.0432 \cdot P)^2 + 1.16 \cdot P]$ with $P = [\max(F_o^2, 0) + 2F_c^2]/3$ (SHELXL-93). $\Delta\rho_{fin}$ (max/min) $= +0.25/-0.22$ e Å^{-3}. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-58455.

[14] A similar structure has been proposed for the Mg complex of the analogous nitrogen ligand [4e].

[15] Li–P distances in the hitherto crystallographically examined cases generally range between 2.5 and 2.65 Å, but longer bonds have also been observed: H. H. Karsch, G. Grauvogl, P. Mikulcik, P. Bissinger, G. Müller, *J. Organomet. Chem.* **1994**, *465*, 65; H. H. Karsch, G. Baumgartner, S. Gamper, J. Lachmann, G. Müller, *Chem. Ber.* **1992**, *125*, 1333; H. H. Karsch, K. Zellner, S. Self-Assembly and Structure of a 3 × 3 Inorganic Grid from Nine Silver Ions and Six Ligand Components**

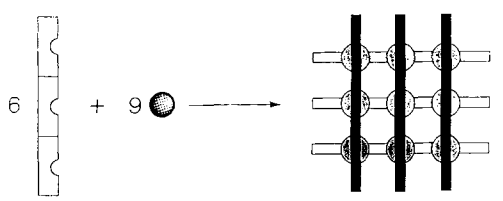
Paul N. W. Baxter, Jean-Marie Lehn,* Jean Fischer, and Marie-Thérèse Youinou

Self-assembly of noncovalent architectures from "programmed" components has become a central theme of supramolecular chemistry in recent years.[1, 2] In particular, inorganic superstructures are spontaneously generated from suitably designed ligands and selected metal ions that "read" the binding sites according to their coordination algorithm. We have described the self-assembly of several types of entities, such as, double[1, 3, 4] and triple[5] helical complexes (termed helicates) as well as circular,[6] capped,[7] and cylindrical[6] multicomponent inorganic architectures.

Furthermore, the ordering of metal ions and organic partners into defined arrays presents intriguing prospects for the development of electroionic devices for information storage. To this end, the controlled generation of novel types of two- and three-dimensional arrays of metal ions is of direct interest.

Along these lines, rigid, linear polytopic ligands containing bidentate chelating sites might be able to self-assemble into square-matrix arrays of metal centers with ions of tetrahedral coordination geometry. Thus, an n-topic ligand would form an $n \times n$ inorganic grid ($[n \times n]$G) based on n^2 metal ions and $2n$ ligand components. This is illustrated schematically in Figure 1



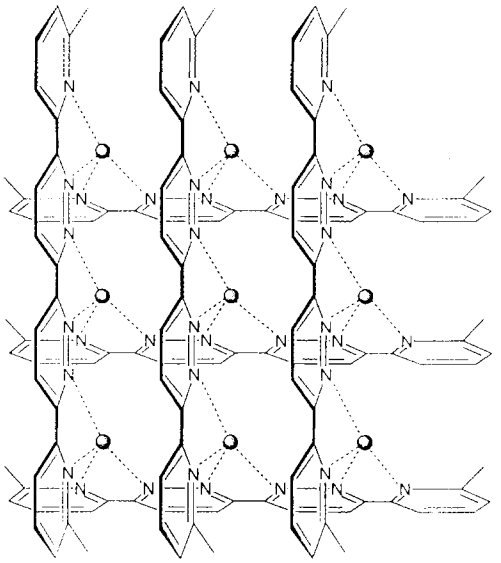


Fig. 1. Schematic representation of the formation of a 3 × 3 inorganic supramolecular grid from six tritopic linear ligands and nine metal ions.

for $n = 3$. We now describe the self-assembly of the inorganic 3×3 grid **1** consisting of an array of nine silver(I) metal ions and six tritopic ligands **2**. The corresponding ditopic ligand 3,6-bis(2-pyridyl)pyridazine has been found to assemble into a 2×2 square complex built from four ligands and four copper(I) ions[8a] and has also been introduced into macrobicyclic structures forming dinuclear cryptates.[8b]

1: $[Ag_9L_6]^{9+}$ (L = **2**)

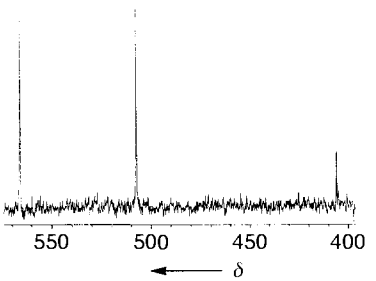
2 **3** **4** X = OCH_3 **5**

6 X = Cl

The ligand 6,6′-bis[2-(6-methylpyridyl)]-3,3′-bipyridazine **2** was prepared in the following way: A toluene solution of 3-chloro-6-methoxypyridazine **3** (1 equiv) and 2-methyl-6-trimethylstannylpyridine (1.3 equiv) was refluxed in the presence of a catalytic amount of $Pd(PPh_3)_4$ for 20 h.[9a] Chromatographic workup of the reaction mixture gave **4** in 83–90% yield (m.p. = 61–62 °C). The latter was demethylated by gentle reflux in excess 33% HBr/CH_3COOH for 48 h to afford **5** in 92% yield (m.p. 228–229 °C). Subsequent chlorination of **5** upon heating with excess $POCl_3$ led to **6** in 98% yield (m.p. = 148–149 °C). Finally, coupling of **6** (1 equiv) in the presence of the reduced nickel catalyst (generated from a mixture nBu_4NI (1 equiv), zinc powder (1 equiv), and $[NiBr_2(PPh_3)_2]$ (0.3 equiv))[9b] in dimethylformamide at 55 °C gave compound **2** in 80% yield (m.p. = 307–308 °C). The overall yield of **2** from **3** was 63%.

The complex of ligand **2** with silver ions was prepared quantitatively from **2** and $AgCF_3SO_3$ in a ratio of 1:1.5 in the following manner: To 0.051 g (0.15 mmol) of **2** and 0.058 g (0.226 mmol) of silver triflate (Aldrich, 99%) was added nitromethane (5 mL). The mixture was sonicated for 1 min. The cloudy yellow suspension was then stirred for 12 h at room temperature. During the first hour of stirring, all suspended solid dissolved to give a clear yellow solution. The solvent was then removed under reduced pressure to yield a bright yellow powder. This was briefly sonicated in benzene, then isolated by filtration under vacuum, further washed with benzene, and pumped dry. Drying under high vacuum (25 °C/5×10^{-7} Torr) for 2 days gave the product in 99% yield.

The substance thus obtained was characterized by microanalysis,[10] ^1H, ^{13}C and ^{109}Ag NMR spectroscopy, and X-ray crystallography. The NMR spectral data, in particular, are consistent with a complex having the 3×3 gridlike structure **1**. The ^1H NMR spectrum shows two sets of signals in a 2:1 ratio corresponding to ligand **2** in two different environments. The ^{109}Ag NMR spectrum was especially informative. A structure such as **1** is expected to give three resonances in 4:4:1 ratios for the silver ions located at the corners, the midpoints of the edges, and the center of the 3×3 grid, respectively. This was indeed found to be the case (Fig. 2).



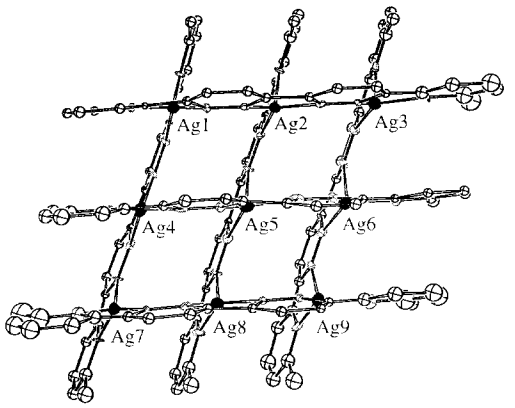


Fig. 2. ^{109}Ag NMR spectrum of complex $[Ag_9L_6](CF_3SO_3)_9$ (L = **2**) at 18.620 MHz in $[D_3]$nitromethane; chemical shifts (from left to right) = 566.06, 507.56, and 406.13 with respect to a 2 M solution of $AgNO_3$ in D_2O.

The complex was crystallized from nitromethane, and its structure was determined by X-ray crystallography.[11] This indicates that the complex contains $[Ag_9L_6]^{9+}$ ions **7** (L = **2**; Fig. 3, top), uncoordinated triflate anions, and solvent molecules. The overall arrangement in **7** is that of a 3×3 grid of nine Ag^I ions; the diamond-type shape results from deformation of the regular square represented in **1**. The grid consists of a distorted rhombus with a dihedral angle of about 72° between the mean planes of the ligands and an average Ag···Ag distance of approximately 3.72(3) Å. All silver ions are in a distorted tetrahedral environment with the same average dihedral angle of about 72(3)° between the N-Ag-N planes of the two chelating subunits at each Ag^I site. The Ag1, Ag3, Ag7, and Ag9 ions lie at the vertices and almost in a single plane (Ag1–Ag3 = 7.403(4), Ag1–Ag7 = 7.529(4), Ag3–Ag9 = 7.432(4), and Ag7–Ag9 = 7.418(4) Å; inner angles Ag3-Ag1-Ag7 = 107.04(5) and Ag1-Ag3-Ag9 = 72.81(4)°). A second set of four silver ions is inserted into the first rhombus; these form a twisted quasi-rectangle (Ag2–Ag4 = Ag6–Ag8 = 6.026(4), Ag4–Ag8 = 4.367(4), and Ag2–Ag6 = 4.444(4) Å; inner angles Ag4-Ag2-Ag6 = 90.58(6), Ag2-Ag4-Ag8 = 88.20(6), Ag2-Ag6-Ag8 = 87.54(6), and Ag4-Ag8-Ag6 = 91.37(6)°). The center is occupied by the ninth silver Ag5. The nine silver ions define a slightly warped saddle-type surface: Ag5 is located in the mean plane of the silver ions; the pairs Ag2/Ag8 and Ag4/Ag6 lie respectively about 0.25 Å above and below this plane, and Ag3/Ag7 and

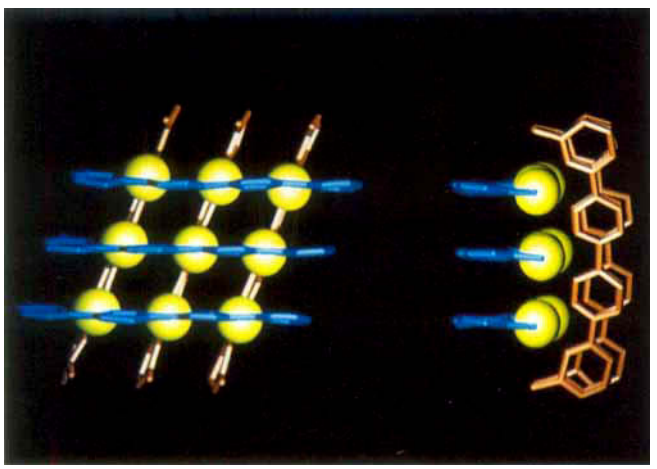

Fig. 3. Cystal structure of the self-assembled 3×3 inorganic grid **7** ($[Ag_9L_6]^{9+}$, L = **2**). Top: ORTEP representation. Bottom: computer representation showing the top view (left) and the side view (right).

Ag1/Ag9 are respectively about 0.06 Å above and below. The central Ag5 ion is coordinated to four pyridazine (pz) nitrogen atoms (mean Ag–N = 2.437 Å); the silver ions lying at the vertices of the rhombus (Ag1, Ag3, Ag7, and Ag9) are each bound to two pyridine (py) and two pyridazine nitrogen atoms (mean Ag–N = 2.323 Å); the median silver ions (Ag2, Ag4, Ag6, and Ag8) interact with one pyridine and three pyridazine nitrogen atoms (mean Ag–N = 2.342 Å).

The six ligands **2** are divided into two sets of three, one of which is above and the other below the mean plane formed by the nine silver ions. Although each bidentate chelate ring formed with a silver ion is planar, within each ligand there is a significant twisting from planarity, with a maximum deviation of 16.3(4)°. The average distance between the mean planes of two neighboring ligand units is about 3.74(8) Å, that is, somewhat larger than that expected for van der Waals contacts (ca. 3.4 Å). The slight bending seen for the ligand in the complex (Fig. 3, bottom right) may be, at least in part, a consequence of the geometry of the pyridazine ring, which is not a regular hexagon.

The chemical shifts of the ^{109}Ag NMR spectrum are expected to depend on both the nature of the nitrogen binding sites and the number of neighboring Ag^I ions. Thus, the signals from left to right in Figure 2 may be assigned as follows [Ag (position) (number of vicinal Ag atoms) (nitrogen sites)]: Ag (vertex) (2) (py_2pz_2), Ag (edge) (3) ($pypz_3$), and Ag (center) (4) (pz_4).

The generation of the $[3 \times 3]$G **7** represents the spontaneous and correct assembly of a closed inorganic superstructure from a total of fifteen components, six ligands, and nine metal ions. It displays the three basic levels of operation of a programed supramolecular system: recognition, orientation, and termination;[1, 6] geometric, thermodynamic, and entropic factors play a role. The analysis of the effects that influence the generation of **7** will benefit from the extension of the present work to other grid systems.

The self-assembly of complex **7** opens the way to a whole family of polynuclear inorganic $m \times n$ grids, which represent a new facet in the controlled arrangement of metal ions into specific arrays and patterns. Square- and rectangular-type arrangements would result from systems with ligands containing the same ($m = n$) or different ($m \neq n$) number of binding sites, respectively. Grids based on octahedral metal centers and on ligands containing binding subunits of terpyridine type may also be envisaged.[16]

Finally, one should note the analogy of such gridlike structures with grids based on quantum dots[17] that are of great interest in microelectronics. The grid structures discussed above consist of *ion dots* of yet smaller size than quantum dots and do not necessitate microfabrication, but rather form spontaneously by self-assembly. Such architectures may represent multistate, digital supramolecular chips for information storage in and retrieval from these inscribed patterns, which could be addressed by means of light or electrically. The different states could in principle result either from different local features at a given x, y coordinate, in an ion dot fashion, or from specific overall optical or oxidation levels. The extension into three dimensions, with stacks of grids leading to layered arrays, may be envisaged.

[11] X-ray structure analysis of $1 \cdot (CF_3SO_3)_9 \cdot (CH_3NO_2)_5 \cdot (CH_3OH) \cdot (H_2O)_7$ ($C_{135}H_{129}N_{41}O_{43}F_{27}S_9Ag_9$): $M = 4818.1$, yellow crystals, monoclinic, $a = 28.579(4)$, $b = 22.450(2)$, $c = 31.494(3)$ Å, $\beta = 116.35(2)°$, $V = 18107.4$ Å^3, $Z = 4$, $\rho_{calcd} = 1.767$, $F_{000} = 9584$, $\mu = 11.516$ cm^{-1}, space group $P2_1/n$. A suitable crystal of $1 \cdot (CF_3SO_3)_9 \cdot (CH_3NO_2)_5 \cdot (CH_3OH) \cdot (H_2O)_7$ ($500 \times 420 \times 400$ μm^3), obtained by slow evaporation of nitromethane, was selected in Paratone-N oil (Exxon) and mounted on the end of a glass fiber. 34284 reflexions were collected on a CAD4-F diffractometer at −100 °C with $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å, graphite monochromator), $\theta/2\theta$ scans, variable speed, scan width = 2.10 + 0.34 tg(θ)°, $2° < \theta < 25°$. Three standard reflections measured every hour during the data collection period showed a decay in intensity of 13%; corrected with a linear, time-dependent function. The raw data were converted to intensities and corrected for Lorentz and polarization factors. Absorption corrections calculated from the psi scans of 4 reflections were applied. Finally, 12897 reflections with $I > 3\sigma(I)$ were used to determine and refine the structure. The positions of the nine Ag atoms were found by direct methods. The rest of the nonhydrogen atoms were located in successive difference Fourier maps. Due to high thermal motion, the O and F atoms of 3 out of 9 triflate anions were not well resolved. Up to this stage, the Molen program

[12] on a Vax computer was used for all calculations. To take advantage of noncrystallographic symmetry introduced by chemically identical moities, the structure was refined with the SHELX-93 software package [13] (F^2 refinements). The 12 pyridazines, the 12 methylpyridines, the 9 triflate anions, and the 5 nitromethane molecules were refined as identical, rigid groups (σ of equivalent bond lengths: 0.03 Å); the geometries were taken from ref. [8], [8], [14], and [15], respectively. The pyridazine and methylpyridine groups were restrained to be planar within 0.2 Å. These restraints reduced the number of variables in the refinement to 624; this takes into account the poor observed data/measured data ratio and hence the low diffraction power of the crystals. All hydrogen atoms were omitted. Final $R(F) = 0.109$. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

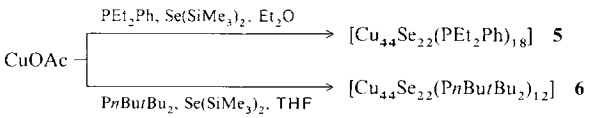
$[Cu_{44}Se_{22}(PEt_2Ph)_{18}]$ and $[Cu_{44}Se_{22}(PnButBu_2)_{12}]$: Synthesis and Structure of Two Copper Clusters with Isomeric Cu–Se Frameworks**

Stefanie Dehnen and Dieter Fenske*

Dedicated to Professor Larry Dahl on the occasion of his 65th birthday

We recently reported on new sulfur- and selenium-bridged copper clusters, synthesized by the reaction of copper(I) acetate with tertiary phosphanes and $E(SiMe_3)_2$ (E = S, Se). The molecular structures of the resulting clusters **1**–**3**, and **4** (see Scheme 1) containing 12 and 20 copper atoms, respectively, were characterized by X-ray crystal structure analysis.



Scheme 1.

In analogous reactions of $E(SiMe_3)_2$ with CuCl instead of CuOAc as starting material, so far only selenium-bridged copper clusters could be synthesized,[2] which, however, exhibit considerably larger $[Cu_2Se]_n$ cluster frameworks. Examples include the compounds $[Cu_{30}Se_{15}(PiPr_3)_{12}]$, $[Cu_{70}Se_{35}(PEt_3)_{22}]$, and $[Cu_{146}Se_{73}(PPh_3)_{30}]$.[2]

Evidently, the anion of the copper(I) compound used influences the formation of the cluster; thus, it was possible to isolate previously unknown smaller clusters as well as sulfur-bridged copper clusters in a crystalline form. Compounds **1**–**4** may possibly be considered as intermediates in the formation of larger cluster compounds.[1, 2]

In a further attempt to prepare corresponding intermediates of larger copper clusters, we treated CuOAc with $Se(SiMe_3)_2$ in the presence of PEt_2Ph or $PnButBu_2$ in diethyl ether and THF, respectively (Scheme 2). In this way we isolated the compounds

Scheme 2.

5 and **6** in high yields (80–85%) (Scheme 2), and these were characterized by X-ray structure analysis.[3] There are no indications that other clusters are formed in the reactions.

The structure of **5** in the crystal is shown in Figure 1 top. Significant differences in the structure of **5** can be seen in comparison to those of other known selenium-bridged copper clusters with 36 and more copper atoms. Unlike in $[C_{70}Se_{35}(PEt_2Ph)_{23}]$ and $[Cu_{146}Se_{73}(PPh_3)_{30}]$,[2] whose structures can be derived from a hexagonal closest packing of Se atoms, and where the copper atoms fill the holes, a rather shell-like cluster framework is observed for **5**, similar to that found for smaller ligand-clad $[Cu_2Se]_n$ clusters.[2]

The core of the cluster has at most C_s symmetry even when the carbon atoms and slight distortions are neglected. The mirror plane passes through the atoms Se 9, Cu 7, and Cu 13. A possible threefoldness (D_{3h} symmetry) with a rotation axis through Se 1 and Se 22 is ruled out by a "defect" in the copper framework that occurs instead of an additional copper atom between the atoms Cu 17, Cu 30, Cu 31, and Cu 41. In this way, however, the composition $Cu_{44}Se_{22}$ corresponding to $[Cu_2E]_n$ (E = S, Se) is guaranteed, which applies for almost all known sulfur- or selenium-bridged copper clusters.

The selenium framework in **5** (Fig. 2 top) can be described as a deltohedron consisting of 20 selenium atoms (Se 1–Se 7, Se 9–Se 14, and Se 16–Se 22), which contains two additional selenium atoms in the center (Se 8 and Se 15). No bonding interactions exist between the selenium atoms (Se–Se distances 381.8–450.8 pm).

The polyhedron is formed by two hexagonal antiprisms (Se 2–Se 14 and Se 9–Se 21) linked through a hexagonal face; the free hexagonal faces are each capped by an additional Se atom (Se 1 and Se 22). If the corners of the polyhedron are joined, one obtains 36 almost equilateral triangles on the surface of the polyhedron.

Of the 44 copper atoms, 18 are situated just above and 18 just below the triangles of the selenium deltohedron.

The 18 copper atoms (Cu 1–Cu 18) that are arranged above the surface of the chalcogen polyhedron bear the 18 PEt_2Ph groups, which shield the Cu–Se core of the cluster of **5** with an almost closed ligand shell. These copper atoms—with the exception of Cu 6, Cu 10, and Cu 17, for which in each case one neighboring selenium atom is significantly further away from the metal atom than the other two—are coordinated tetrahedrally by three selenium atoms and one phosphorus atom. In contrast, the 18 Cu atoms, which are located just below the selenium triangles, form no Cu–P bonds and are—like Cu 6, Cu 10, and Cu 17—aproximately trigonal-planar coordinated. The remaining eight Cu atoms (Cu 37–Cu 44) are found inside the cluster, and form two trigonal prisms linked through a triangular face (Cu 40, Cu 41, Cu 42). In these prisms one corner remains unoc-

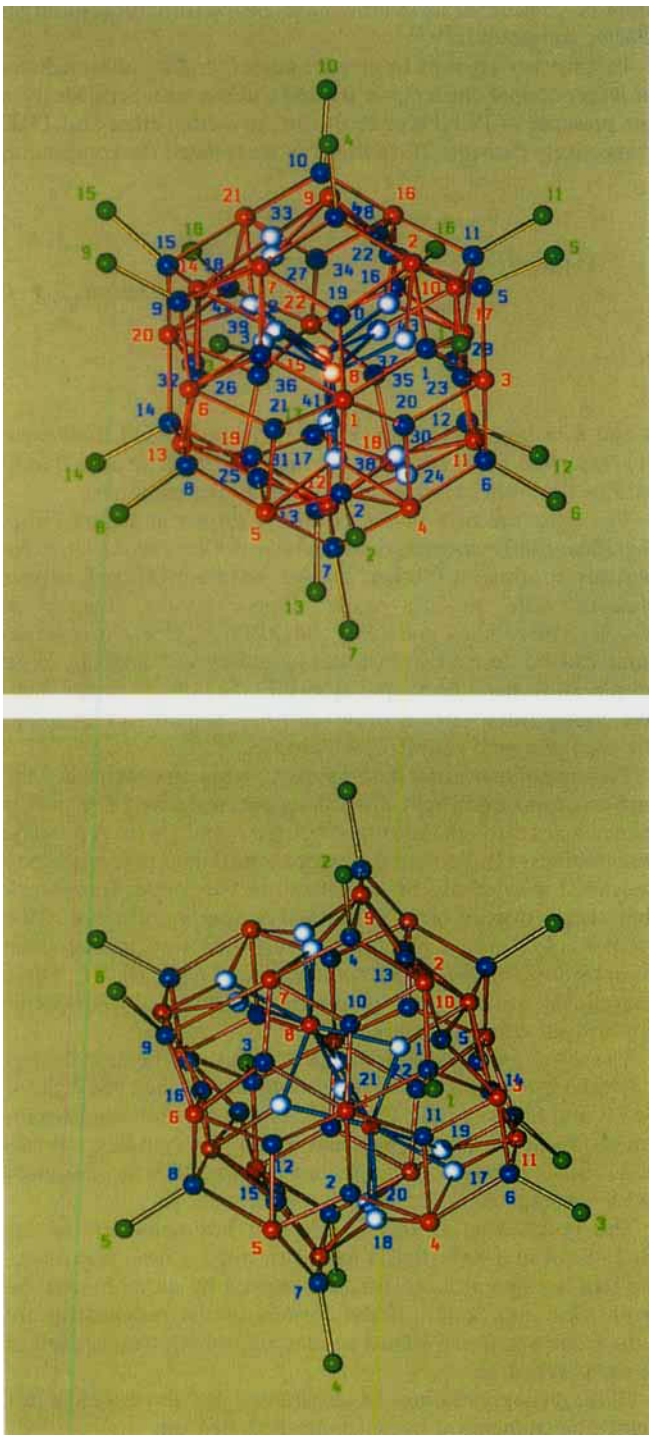

Fig. 1. Structures of **5** (top) and **6** (bottom) in the crystal (drawn without organic groups): Cu: blue, Se: red, P: green; for clarity all the atoms shown have been assigned color-coded numbers which correspond to the appropriate elements. Bond lengths and Cu–Cu distances [pm] (error ±0.8 pm): **5**: Cu–Se (tetrahedral environment) 244.3–293.7, Cu–Se (trigonal-planar environment) 235.1–273.8, Cu–P 220.3–223.9, Cu–Cu 251.1–293.9. **6**: Cu–Se (tetrahedral environment) 240.9–278.5, Cu–Se (trigonal-planar environment) 231.7–289.9, Cu–P 224–227.6, Cu–Cu 250.7–299.8.

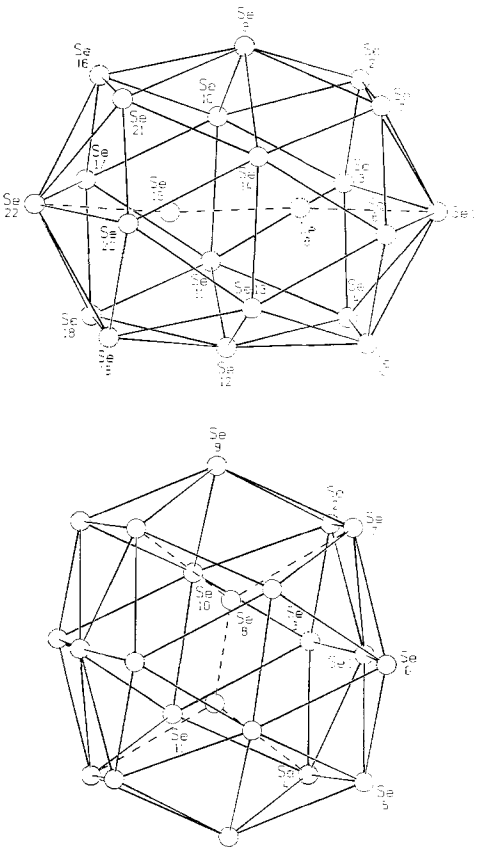

Fig. 2. The Se_{22} framework in **5** (top) and **6** (bottom); the lines drawn between the Se atoms do not represent bonds. For clarity only selected lines are shown between selenium atoms in the center of the cluster and selenium atoms on the surface of the polyhedron. Se–Se distances [pm] (error ±0.9 pm): **5**: 381.8–450.8, **6**: 341.2–462.4.

cupied – the previously mentioned "defect" in the cluster framework. The selenium atoms Se8 and Se15 sit in the center of the two prisms. Through bonding to these selenium atoms and to two further selenium atoms of the selenium polyhedron, the copper atoms Cu40, Cu41, and Cu42 likewise achieve near trigonal-planar coordination. The inner Cu_8Se_2 structural fragment is highlighted in Figure 1 top by lighter colored spheres, together with four additional copper atoms of the cluster periphery that belong to a $Cu_{12}Se_2$ unit that differs considerably from the corresponding one in **6**.

Despite the fact that the cluster core has the same composition with 44 copper and 22 selenium atoms, the structure of **6** in the crystal (Fig. 1 bottom) differs considerably from that of **5**; thus, the Cu–Se frameworks of both compounds may be considered isomeric. Unlike **5**, **6** has an inversion center. If the carbon atoms and the slight distortions of the Cu-Se-P framework are neglected, **6** has approximate C_{4h} symmetry; the fourfold axis runs through the atoms Se8 and Se8′.

Particularly apparent in this comparison is the different number and arrangement of the phosphane ligands in the cluster periphery, a fact which can be attributed to the differing spatial requirements of the various organic groups attached to the phosphorus atoms in **5** (PEt_2Ph) and **6** ($PnButBu_2$); Tolman's cone angles amount to 136.3° for PEt_2Ph and 165.3° for $PnButBu_2$.[4] Consequently, in **6** there is only room for 12 phosphane ligands on the cluster surface for the shielding of the Cu–Su core.

This difference in the ligand shell, and thus in the number of copper atoms that coordinate above the surface of the deltohedron to selenium atoms seems decisive for a structural change in the cluster core: the six additional copper atoms without Cu–P bonds in **6** (Cu2, Cu3, Cu5 and inverted positions) move into the Cu–Se core below the surface of the cluster. Furthermore, four of the eight copper atoms that form an inner Cu_8Se_2 unit in **5** (cf. Fig. 1 top) are forced outwards until they lie just below

the periphery; thus 12 Cu–P units are located just above and 28 copper atoms just below the surface of the Se deltohedron.

The copper structure in **6**, which could be considered as a reorganized version of that in **5**, is accompanied by a strong distortion of the selenium polyhedron shown in Figure 2 bottom. The nonbonding Se–Se distances are 341.2–462.4 pm.

As in **5**, the polyhedron is obtained by linking two hexagonal antiprisms together through a hexagonal face and by capping the two free hexagonal faces with an additional selenium atom (Se1 and Se1′) each. However, the hexagons are distorted to such an extent that they are no longer planar. The polyhedron can no longer be described as a deltohedron built up from 36 equilateral triangles, a circumstance which is already apparent by the fact that in **6** 40 copper atoms (instead of 36 in **5**) are arranged on the Se_{26} surface. Of these 40 metal atoms, 32 are μ_3-coordinated to 32 Se_3 triangles. The copper atoms bound to phosphorus —with the exception of Cu4 and Cu7—like those in **5** are almost tetrahedrally coordinated, whereas those without a Cu–P bond reside in a trigonal-planar environment, surrounded by three selenium atoms. Cu4 and Cu7, also located in a near trigonal-planar environment, are coordinated by two selenium atoms and one phosphorus atom. The remaining eight copper atoms (Cu17, Cu18, Cu19, Cu20, and inverted positions) have to share a Se_3 face as coordination site pairwise; thus, these four triangles are greatly extended and can be better described as two Se_4 rectangular faces (Se4, Se7, Se9, Se11, and inverted positions). The metal atoms last mentioned act as μ_2-bridges along the sides of the nearly square Se_4 rectangles. By bonding to Se8 or Se8′, they also achieve nearly trigonal-planar coordination.

As a result of this change, the structure of the central $Cu_{12}Se_2$ unit, whose atoms are highlighted by lighter colored spheres in Figure 1 bottom, is completely different from that of the corresponding Cu–Se fragment in **5**. This $Cu_{12}Se_2$ unit in **6**, which occurs along the fourfold axis of the molecule—perpendicular to the orientation of the analogous structure fragment in **5**, could be interpreted as a segment from a chain of *trans*-corner-sharing octahedra.

The structure-determining influence of tertiary phosphanes on $[Cu_2Se]_n$ clusters has previously been shown by ab initio calculations with PH_3 as model ligand.[1] This result is underlined by the experimental findings here. The noticeable similarities in the molecular structures of **5** and **6**, despite significant differences, suggest the possibility that in fact the number and the steric demand of the phosphane ligands can eventually lead to a reorganization of the cluster framework, after the energetically most favorable basic structure of the copper–selenium cluster of a certain composition favored under the reaction conditions has been formed.

How can the influence of the phosphane shell transfer its effect to the inside of the cluster? Whether, for example, electronic effects through the change in the total number of valence electrons (872 VE in **5** and 860 VE in **6**) or the desire of the copper and selenium atoms to achieve particular coordination numbers are decisive, is still not certain. It can also not be ruled out that the phosphane ligands control the arrangement of copper and selenium atoms from the beginning of the growth of the cluster, until their influence then gives way to other structure-determining influences at increasing cluster sizes.

The compositions of **5** and **6** suggest the presence of a Cu_{44}^{44+} framework and 22 Se^{2-} ligands in both cases. Consequently the oxidation state +1 (d^{10} configuration) can be assigned to all the copper atoms; thus, these compounds can be placed in the series containing most of the known sulfur- and selenium-bridged copper clusters,[1, 2] which is also in agreement with bond theory. Hence, bonding interactions between the copper atoms can be neglected. The distances between the copper atoms (Cu4–Cu37 251.1 pm to Cu5–Cu23 293.9 pm in **5**; Cu3–Cu12 250.7 pm to Cu2–Cu15 299.8 pm in **6**) also support this assumption; the Cu–Cu interactions are at best considered as dispersion interactions.[1] The coherence of the cluster framework is therefore essentially based on the bridging of the metal atoms by the selenido ligands.

If the structure of **5** is studied with regard to the question of whether this cluster might possibly be an intermediate in the formation of larger clusters such as $[Cu_{70}Se_{35}(PEt_2Ph)_{23}]$,[2] it becomes clear that the two molecular structures are not topologically related to each other. Instead of the arrangement of selenium atoms in hexagonal A-B-A layers between layers of copper atoms, an ellipsoid-shaped deltohedron of selenium atoms is formed in **5**. Also the fact that no crystals of the cluster $[Cu_{70}Se_{35}(PEt_2Ph)_{23}]$ were obtained in the reaction carried out for the synthesis of **5** indicates that the two compounds are formed independently from each other. Thus, it is clearly evident that the influence of the anion of the copper salt not only has an effect on the rate of cluster formation, but also on the actual formation mechanism.

It is conceivable that the copper–selenium clusters isolated so far[1, 2] constitute PR_3-stabilized (R = organic group) sections from structures in the formation of copper(I) selenide; finally, for the largest characterized clusters $[Cu_{70}Se_{35}(PEt_2Ph)_{23}]$ and $[Cu_{146}Se_{73}(PPh_3)_{30}]$ a relationship has been found to the known structure of β-Cu_2Se.[2]

Experimental Procedure

All steps for the preparations of **5** and **6** were carried out under a nitrogen atmosphere and in dry solvents.

5: $PEtPh_2$ (1.61 mL, 6 mmol) was added to a suspension of CuOAc (0.37 g, 3 mmol) in diethyl ether (25 mL), which resulted in the dissolution of the CuOAc. The reaction mixture was cooled to −78 °C and treated with $Se(SiMe_3)_2$ (0.37 mL, 1.5 mmol). The solution was allowed to warm to −20 °C over 8 d, during which time it turned red and dark red rhombuses of **5** crystallized out (yield 85%).

6: $PnBuiBu_2$ (0.75 mL, 3 mmol) was added to a suspension of CuOAc (0.37 g, 3 mmol) in diethyl ether (25 mL), which resulted in the dissolution of the CuOAc. The reaction mixture was cooled to −78 °C and treated with $Se(SiMe_3)_2$ (0.37 mL, 1.5 mmol). The solution was allowed to warm to −20 °C over 20 d, during which time it turned red brown and black rhombuses of **5** crystallized out (yield 80%).

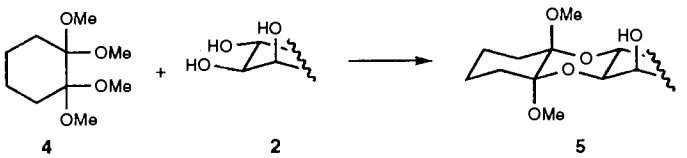
Cyclohexane-1,2-diacetals (CDA): A New Protecting Group for Vicinal Diols in Carbohydrates

Steven V. Ley,* Henning W. M. Priepke, and Stuart L. Warriner

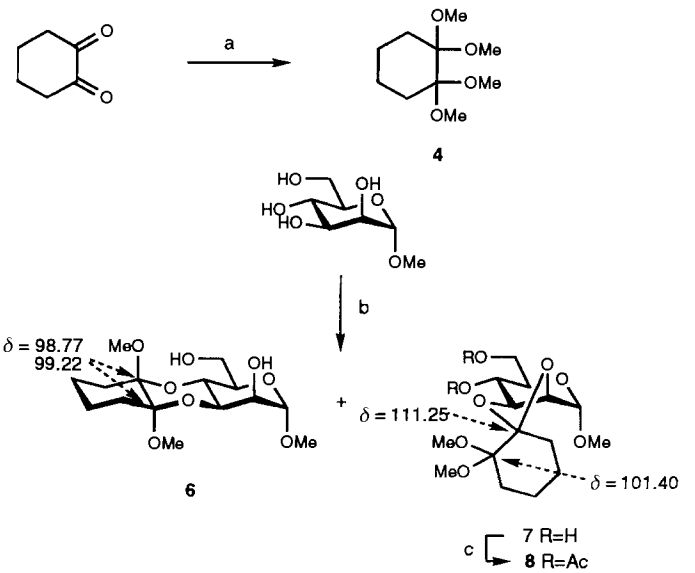


Recently we introduced the dispiroketal protecting group (Dispoke) as a selective protective group for diequatorial 1,2-diol units in carbohydrates (Scheme 1).[1, 2] The regio- and diastereoselectivity of the reaction of 3,3',4,4'-tetrahydro-6,6'-bi-2*H*-pyran (bis-DHP, **1**) with pyranosides such as **2** arises

Scheme 1. Only the relevant portion of the pyranoside is shown.

from the stabilizing influence of the four anomeric effects in the resulting dispiroketal **3** and the equatorial arrangement of all four alkyl substituents of the central 1,4-dioxane unit. Although we observed the exclusive formation of only one isomer with many carbohydrates, the results with important *manno*-type sugars were less satisfactory. The low yields and the lack of regioselectivity were attributed to the low solubility of these compounds in chloroform and the instability of **1** when heated over prolonged periods of time.[3]

To develop the general concept further, we considered the use of 1,1,2,2-tetramethoxycyclohexane (**4**) as a new alternative reagent for carbohydrate protection (Scheme 2). Reaction of **4**



Scheme 2. Only the relevant portion of the pyranoside is shown.

with **2** should furnish selectively the cyclohexane-1,2-diacetal **5** where all the regulatory elements mentioned above should govern the outcome of the reaction. In the product **5** both methoxy groups should be oriented in the axial position to obtain the maximum anomeric stabilization, while all four sterically demanding alkyl substituents should be placed in the favored equatorial positions. To overcome the solubility problem we chose methanol, a solvent frequently used for acetalizations of carbohydrates.[4] With this solvent the diacetal **5** should be formed under thermodynamically controlled conditions.

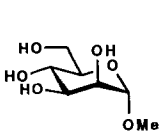
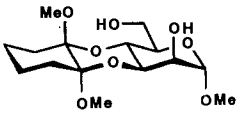
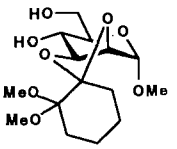
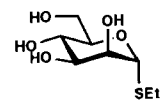
[**] Cyclohexane-1,2-diacetals in Synthesis, Part 1. We are grateful to Dr. P. Raithby, Cambridge, for the X-ray structure determination and Dr. M. Thompson, SmithKline Beecham, for helpful discussions. This work was supported by Schering Agrochemicals Ltd (Schering Fellowship of Bio-Organic Chemistry for H.W.M.P.), SmithKline Beecham (Research Studentship for S.L.W.), Pfizer Central Research, and the BP Research Endowment.

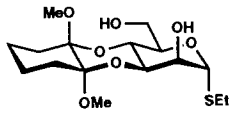
The required 1,1,2,2-tetramethoxycyclohexane (**4**) was readily obtained in 75% yield from inexpensive 1,2-cyclohexanedione by reaction with trimethyl orthoformate in methanol containing a few drops of conc. H_2SO_4 (Scheme 3). In the initial

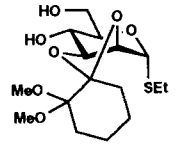


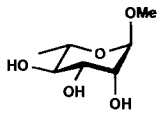


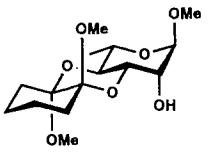


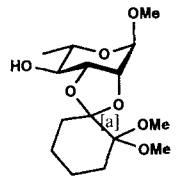


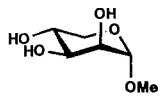


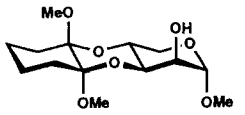


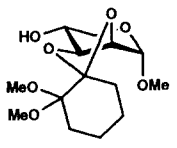


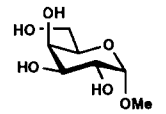


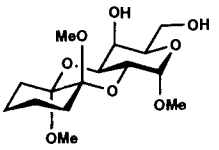


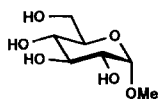


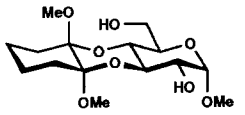


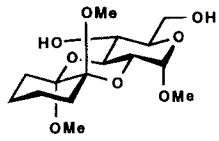












Scheme 3. Synthesis of **4** and protection of methyl α-D-mannoside: a) MeOH, $CH(OMe)_3$, cat. H_2SO_4, reflux, 75%; b) **4**, MeOH, $CH(OMe)_3$, reflux, cat. CSA, 48% **6** and 11% **7**; c) Ac_2O, pyridine, 97%.

experiment methyl α-D-mannoside was investigated, as this substrate failed to react under the standard dispoke reaction conditions (bis-DHP **1**, $CHCl_3$, (±)-camphorsulfonic acid (CSA)).[2] By using 1.4 equivalents of **4** in boiling methanol with a trace of trimethyl orthoformate and a catalytic amount of CSA, the acetalization reaction proceeded smoothly to give the 3,4-protected sugar **6** as the major reaction product in 48% yield. Purification of **6** was achieved by recrystallization from diethyl ether, and its structure was unambiguously assigned by X-ray crystallography.[5] Protection of the *cis*-2,3-diol unit occurred only to a minor extent. Interestingly the major side product[6] was the 1,3-dioxolane **7**. Its structure was deduced from the significant downfield shift of the signal of one of the acetal carbons in the ^{13}C NMR spectra ($\delta = 111.25$ and 101.40 in **7** vs. 98.77 and 99.22 in **6**).[7] To confirm the assigned structure, **7** was converted into the acetate **8**, which showed the expected downfield shift for the H-4 signal (H-4: $\delta = 4.41$ in **7**, $\delta = 5.02$ in **8**). Moreover its ^1H NMR spectra is very similar ($\Delta\delta < 0.03$, $\Delta J < 0.6$ Hz) to that of the isopropylidene analogue.[8]

To improve the yield of **6** the dioxolane **7** was treated in boiling methanol with a trace of CSA. After four days **6** was obtained in 35% yield and recovered **7** in 16% yield. This result suggests that the acetalization reaction is reversible and that the isomer ratio is governed by thermodynamic control under the prolonged reaction time.

Next, we converted other pyranosides into the corresponding diacetals. Table 1 summarizes these results and compares them with the related dispoke protection.[1, 2, 9, 10] We were able to transform ethyl 1-thio-α-D-mannopyranoside in good selectivity and yield into the crystalline 3,4-protected adduct **9** and small amounts of its isomer **10**. Methyl α-L-rhamnopyranoside, which gave a disappointing 3:2 mixture with dispoke protection,[1] was also converted in high yield into diacetal **11**. Again the 3,4-protected derivative **11** could be easily separated from re-

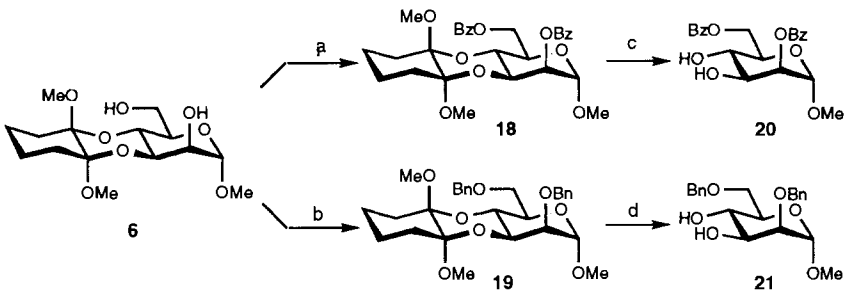
[a] Contaminated with minor amounts of other isomers. [b] Other minor products were formed but not readily identified. [c] A multitude of products were evident but were not isolated. [d] An inseparable mixture of **16** and **17** was obtained.



gioisomers by a combination of chromatography and crystallization. With methyl α-D-lyxopyranoside we obtained the 3,4-adduct **13** in 45% yield along with dioxolane **14** in 11% yield. This is the only case in the series of sugars with an axially oriented 2-hydroxyl group where bis-DHP **1** gives better selectivity and yield than diacetal **4**.[1]

Next, we tried to protect methyl α-D-galactopyranoside which could be converted regioselectively by the dispoke methodology.[2] Disappointingly, we could see many more side products by thin-layer chromatography than usual. This may have resulted from epimerization at the anomeric center. However, we were able to isolate the *trans*-protected adduct **15** in 46% yield, although here the separation from other isomers was rather difficult. The use of other solvents (acetonitrile, dimethylformamide, $CHCl_3$) neither improved the yield nor the selectivity of the reaction. We observed the same difficulties for the corresponding arabino- and fucopyranosides.[11] Apparently CDA protection is superior in the *manno*-configurated pyranosides, while dispoke protection is the method of choice for sugars having the *galacto* ring configuration. The methods are therefore complementary.

We also converted methyl α-D-glucopyranoside into an inseparable 3:5 mixture of the corresponding 3,4- and 2,3-protected sugars **16** and **17** in 80% yield. Although we could not improve the selectivity for either of the two *trans* diol units, the yield was higher compared to the dispoke protection.[9]

The usefulness of a protecting group is highly dependent on the ease with which it is removed at the end of a synthetic sequence. Therefore the compatibility of the CDA unit was investigated with some protection/deprotection conditions. We

could easily convert **6** in high yield into the corresponding dibenzoate **18** or the dibenzyl ether **19** using standard conditions (Scheme 4). Finally, removal of the CDA moiety was achieved by treatment with aqueous trifluoroacetic acid (TFA). A 19:1 TFA:H_2O mixture removed the cyclohexane diacetal group of **18** in 20 min to furnish **20** in 96% yield,[12] while a 4:6 TFA:H_2O mixture smoothly converted **19** into **21** in 16 h.

Scheme 4. Derivatization and deprotection of **6**. a) BzCl, pyridine, 94%; b) NaH, DMF, BnBr, nBu$_4$NI, 78%; c) TFA/H_2O 19:1, 20 min, 96%; d) TFA/H_2O 4:6, 16 h, 86%.

The new CDA methodology is a versatile procedure for the protection of diequatorial 1,2-diols especially in *manno*-type sugars where regioselective introduction of 3,4-protection is rather difficult. For rhamnosides this was, until now, only accessible by a four-step sequence.[13] Furthermore, the CDA unit induces a conformational rigidity into the sugar ring which, by analogy to our findings with dispoke derivatives,[14] should modify the reactivity of a potential glycosyl donor leaving group. The behavior of CDA-protected sugars in glycosylations is described in the following paper.[15]

Experimental Procedure

1,1,2,2-tetramethoxycyclohexane (**4**): Conc. sulfuric acid (8 drops) was added to a stirred solution of 1,2-cyclohexanedione (11.2 g, 0.10 mmol) in methanol (15 mL) and trimethyl orthoformate (30 mL). The resulting black solution was refluxed for 16 h and then neutralized with sodium bicarbonate (ca. 1 g). After evaporation of the solvent, the crude material was purified by column chromatography on silica gel (Merck 9385) to furnish **4** as colorless liquid (15.3 g, 75%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.31–1.48 (m, 4H), 1.60–1.75 (m, 4H), 3.32 (s, 12H); ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 21.67, 30.61, 49.25, 102.07.

Typical acetalization: Preparation of **6** and **7**: CSA (308 mg, 1.33 mmol) was added to a stirred solution of methyl α-D-mannopyranoside (3.46 g, 17.8 mmol), **4** (4.60 g, 24.4 mmol) and trimethyl orthoformate (2.0 mL) in dry methanol (25 mL), and the mixture was heated under reflux for 16 h. After neutralization with $NaHCO_3$ (ca. 0.5 g), the solvent was removed in vacuo, and the crude material was purified by column chromatography on silica gel (Merck 9385) to furnish **7** (666 mg, 11%) as an off-white foam and slightly impure **6**, which was further purified by slow crystallization from diethyl ether to give clean **6** (2.83 g, 48%). **6**: $[\alpha]_D^{25}$ = +191 (c = 0.94, $CHCl_3$); m.p. 168 °C (Et_2O); ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.29–1.43 (m, 2H), 1.45–1.55 (m, 2H), 1.62–1.82 (m, 4H), 2.25 (br. t, J = 5.8 Hz, 1H), 2.89 (s, 1H), 3.20 (s, 3H), 3.21 (s, 3H), 3.35 (s, 3H), 3.72–3.86 (m, 3H), 3.92 (br. s, 1H), 4.14 (dd, J = 10.6, 2.9 Hz, 1H), 4.25 (dd, J = 2 × 10.0 Hz, 1H), 4.72 (d, J = 0.9 Hz, 1H); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 21.35 (2 ×), 27.00 (2 ×), 46.79, 46.93, 54.88, 61.41, 63.88, 65.84, 68.83, 70.05, 70.72, 98.77, 99.22, 101.21. **7**: $[\alpha]_D^{25}$ = +19.8 (c = 0.89, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.37–1.87 (m, 8H), 2.17 (br t, J = 6.2 Hz, 1H), 2.74 (d, J = 5.0 Hz, 1H), 3.27 (s, 3H), 3.32 (s, 3H), 3.40 (s, 3H), 3.64 (ddd, J = 8.4, J = 2 × 4.2 Hz, 1H), 3.72 (ddd, J = 8.3, 6.5, 5.3 Hz, 1H), 3.80–3.86 (m, 2H), 4.30 (dd, J = 2 × 6.4 Hz, 1H), 4.41 (d, J = 6.3 Hz, 1H), 4.88 (s, 1H); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 21.59, 22.89, 30.71, 35.68, 49.13, 49.98, 55.23, 62.89, 69.56, 70.17, 78.37, 98.92, 101.40, 111.25.

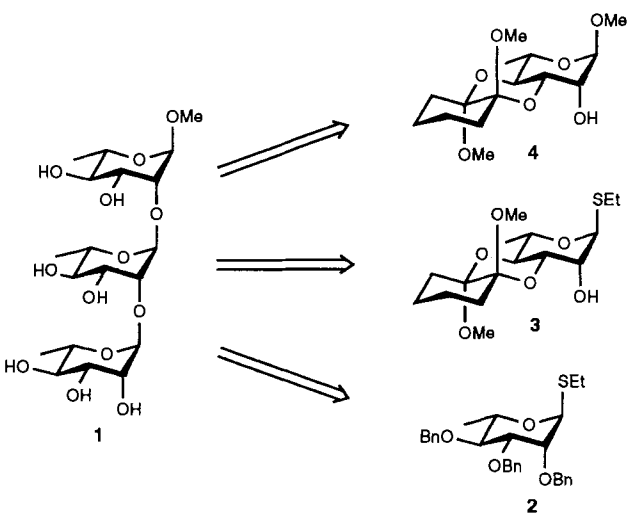
A Facile One-Pot Synthesis of a Trisaccharide Unit from the Common Polysaccharide Antigen of Group B *Streptococci* Using Cyclohexane-1,2-diacetal (CDA) Protected Rhamnosides**

Steven V. Ley* and Henning W. M. Priepke

In the previous paper[1] we introduced the use of cyclohexane-1,2-diacetals (CDA) in a new one-step procedure for the regioselective protection of the 3,4-hydroxyl groups of rhamnosides and mannosides. We will show here that the CDA protecting group is also able to tune the reactivity of a glycosyl donor in glycosylation reactions.



The important armed/disarmed concept introduced by Fraser-Reid et al. has proven to be a powerful tool in the concise preparation of complex oligosaccharides.[2] It relies upon the fact that the reactivity of a glycosyl donor can be regulated by the flanking protecting group at C-2 owing to stereoelectronic effects (e.g., ether = armed, ester = disarmed). According to Fraser-Reid et al.,[3] a sugar can be also considered to be disarmed in glycosylation reactions when a cyclic acetal group is attached to the pyranose ring. In this case, the formation of the intermediate cyclic oxocarbenium ion is more difficult because the required ring flattening in the pyranose ring is inhibited by the annulated acetal function.

[**] Cyclohexane-1,2-diacetals in Synthesis, Part 2. This work was supported by Schering Agrochemicals Ltd (Schering Fellowship in Bio-Organic Chemistry for H.W.M.P.), Pfizer Central Research, and the BP Research Endowment. Part 1: [1].

Recently,[4] we demonstrated that dispiroketal (dispoke) protected sugars exhibit a third level of reactivity in glycosylation reactions which we called "semidisarmed", as their reactivity lies between fully armed and fully disarmed sugars. We therefore expected a similar tuning of reactivity with CDA-protected pyranosides. We report here on the synthesis of methyl α-L-(1 → 2)-trirhamnoside **1**, a common substructure and the immunodominant epitope of the group-specific polysaccharide of group B *Streptococci*.[5] As this organism is responsible for bacterial meningitis in newborn infants, the synthesis of **1** and various analogues has attracted the interest of several research groups.[6]

For the synthesis of **1** we would require monosaccharide building blocks **2**, **3** and **4** (Scheme 1). The terminal unit at the

nonreducing end should be the fully armed glycosyl donor **2**. The central part, the diprotected ethyl 1-thio-α-L-rhamnopyranoside **3**, should ideally act either as acceptor or as donor under carefully selected reaction conditions without any functional group interconversion. It should be possible to selectively activate the S-ethyl group of fully armed **2** in presence of the disarmed sugar **3**, which should be easily reacted later with the methyl glycoside **4**.

The precursor for **2** and **3** was the ethyl 1-thio-α-L-rhamnopyranoside **5**, which was prepared from α-L-rhamnose by a known three-step procedure (Scheme 2).[7a, b] Perbenzylation of **5** furnished **2** in 94% yield.[7a, c] Conversion of **5** into **3** with 1,1,2,2-tetramethoxycyclohexane was achieved in 55% yield using our standard CDA protection conditions.[1, 8] The preparation of **4** has already been described.[1] The monosaccharides **3** and **4** were therefore each prepared from the corresponding glycosides in one-step procedures, shortening the usual four-step route to 3,4-diprotected rhamnose units dramatically.[6a, 7]

With all monosaccharides in hand, we first investigated a stepwise approach to the synthesis of **1**. The choice for the activation of the armed donor **2** was the mild thiosugar activator iodonium dicollidine perchlorate (IDCP)[9] to guarantee the selective reaction of the S-ethyl group of the fully armed donor **2** in presence of the semidisarmed acceptor **3**. Indeed, under these reaction conditions the only glycosidation product obtained was the disaccharide **6**, which was isolated exclusively as the α anomer. No homocoupling of **3** was detected. Obviously CDA protection efficiently deactivates the attached sugar moiety relative to a fully armed glycosyl donor. Further reaction of disaccharide **6** with acceptor **4** by use of the more potent activator trifluoromethanesulfonic acid/*N*-iodosuccinimide (TfOH/NIS)[10] yielded the trisaccharide **7** in 72% yield,[11] again exclusively as the α anomer.

As we could perform two successive glycosylations without any functional group interconversions, it was possible to develop a one-pot synthesis of **7**.[12] According to Fraser-Reid et al. the selective activation of a fully armed *O*-pentenyl glycosyl donor in the presence of a disarmed *O*-pentenyl acceptor is possible even if the potent promoter TfOH/NIS is used.[2a]

We therefore investigated a one-pot conversion to the trisaccharide **7** by using TfOH/NIS for both glycosylation steps (Scheme 3). After activation of a mixture of armed **2** and disarmed **3** with TfOH/NIS, analysis by thin-layer chromatography revealed that disaccharide **6** was the sole reaction product. Only traces of unreacted glycosyl donor **2** remained. After addition of the second acceptor **4** the disaccharide **6** could be activated by addition of NIS and small portions of TfOH to afford the trisaccharide **7** in an excellent overall yield of 62%. To our knowledge this is the first example where the armed/disarmed concept has been applied for a one-pot synthesis of a trisaccharide. It is also noteworthy that nearly stoichiometric amounts of the three monosaccharide units could be used. Disaccharide **8** was isolated as a side-product from addition of unreacted **2** to an excess of the second acceptor **4**. The target trisaccharide **1** was obtained in 53% overall yield by heating **7** with AcOH/

Scheme 3. One-pot synthesis of **7** and deprotection to **1**. a) NIS, cat. TfOH, DCE:Et_2O 1:1, 4 Å molecular sieves, 0 °C; b) AcOH:H_2O 2:1, 100 °C, 2 h; c) H_2, Pd/C, EtOH:AcOH 20:1.

H_2O 2:1 at 100 °C to remove the acetals, followed by debenzylation and chromatography on Sephadex G-15.[13]

The CDA protecting group has proved to be especially useful since it converts the attached sugars into disarmed bifunctional glycosyl donor/acceptor "hermaphrodites". Deprotection of CDA units is possible under mild conditions, and the number of steps for the synthesis of **1** is therefore considerably reduced.

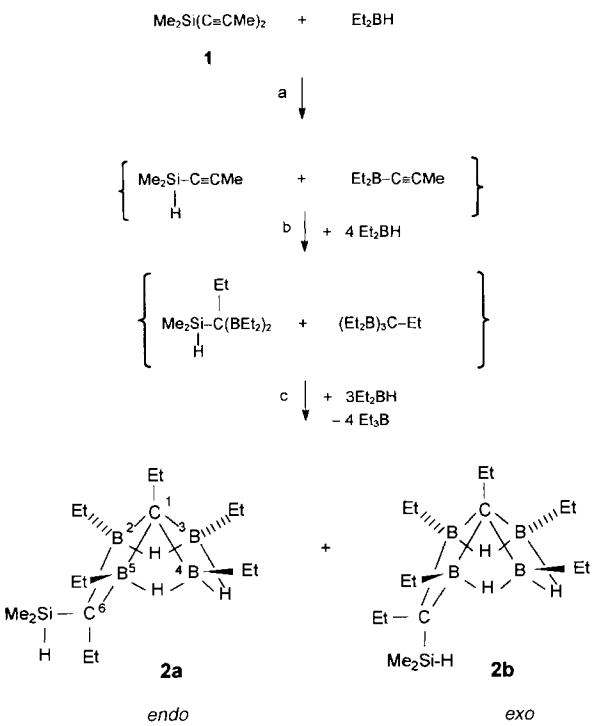
[13] The physical data of **1** is in accord with the published data [6a].

1-Carba-*arachno*-pentaboranes(10) from Dimethyldi(1-propynyl)silane and Ethyldiboranes(6)**



Roland Köster, Günter Seidel, and Bernd Wrackmeyer*

For 1-alkynyltrimethylsilanes $Si-C_{alkynyl}$ bond cleavage with the formation of Me_3SiH competes with C≡C hydroboration[1] if alkyldiboranes(6) [e.g. $(Et_2BH)_2$, but not, however, (9-H-9-BBN)$_2$] are present in excess during the reaction. Thus, the experimentally determined hydride number[2] for dimethyldi(1-propynyl)silane (**1**) is not 4, but rather 4.7; in other words additional hydride is consumed by $Si-C_{alkynyl}$ bond cleavage. We have now studied the reaction of **1** with ethyldiboranes(6) ("Et_2BH"[3, 4]), which proceeds by $Si-C_{alkynyl}$ bond cleavage and exhaustive C≡C hydroboration (Scheme 1). From this reaction we obtained the novel 1-carba-*arachno*-pentaboranes(10) **2** (molecular formula $C_{16}H_{40}B_4Si$, M = 304 g mol^{-1}) in 61% yield and 92% purity without optimization.

The requisite large excess of Et_2BH (undiluted and Lewis base free, in contrast to other normal hydroboration agents) has at least three different functions, and is therefore referred to as a "hydride bath" rather than the comparatively unspecific description of excess hydride. Initially, the $Si-C_{alkynyl}$ bond cleavage, necessary for the formation of **2**[1, 5] is predominant in the hydride bath. This leads to dimethyl(1-propynyl)silane and diethyl(1-propynyl)borane (Scheme 1, step a), which, after BEt/BH exchange, are presumably held together in the hydride bath by BHB bridges. The excess of Et_2BH thereby accounts also for the rapid and complete hydroboration of all the unsaturated C≡C bonds (step b). The third function of the excess Et_2BH present consists of the concluding B–H-catalyzed elimination of Et_3B[6] (step c). The ^{11}B NMR spectrum of the reaction solution proves that the two stereoisomers **2a** and **2b** form spontaneously under these conditions.

The structures proposed for the BHB-containing isomers **2a** and **2b**, formed in a ratio of 55:45, are supported experimentally

by the hydroboration of 1-decene, which converts **2a, b** completely into trialkylboranes only above 120 °C, followed by the oxidative determination of twelve B–C bonds with Me_3NO.[7] The low reactivity towards 1-decene distinguishes **2** from alkyldiboranes(6). The degradation of **2** through alcoholysis yields a hydride content which can be used to calculate the number of B–H–B and Si–H bonds present. Deuteration with Et_2BD leads to the D_3 derivative (according to MS data), and in the IR spectrum the strikingly high intensity of the (BHB, SiH) bands for **2a** and **2b** around 2100 cm^{-1} is sharply reduced. In the presence of γ-picoline, **2a** and **2b** remain unchanged, and hence do not form N–B addition compounds, in contrast to alkyldiboranes(6).

The structures of **2a** and **2b** are verified by their NMR data.[8] The $\delta(^{11}B)$ values (**2a,b**: 14.9, −12.1; 13.5, −12.1) alone rule out the possibility of "simple" alkyldiboranes(6) with BH_2B bridges.[9] The appearance of Me_2SiH signals in the ^1H and ^{29}Si NMR spectra is consistent only with Si–C bond cleavage (see Scheme 1, step a). Starting from each Me_2SiH group in **2a** and **2b**, the structures of the isomers may be "unraveled" by using numerous NMR techniques. The routine applications 2D $^1H/^1H$ COSY, 2D $^{13}C/^1H$ HETCOR, and 2D $^{29}Si/^1H$ HETCOR at room temperature were conducted to confirm the linkage of the respective nuclei through the coupling constants ($^3J(^1H,^1H)$, $^1J(^{13}C,^1H)$, $^2J(^{13}C,^1H)$, $^1J(^{29}Si,^1H)$, $^2J(^{29}Si,^1H)$, and $^3J(^{29}Si,^1H)$). In addition 2D $^{13}C/^1H$ HETCOR experiments, based on $^1J(^{13}C,^1H)$ and $^2J(^{13}C,^1H)$, were carried out at low temperature. This allowed the ^{13}C NMR signals of BCH_2, C^1, and C^6, which are broad at room temperature, to be assigned to their respective ^1H NMR signals. Of the 1D NMR techniques used, special mention should be given to $^{13}C/^{13}C$ INADEQUATE measurements [$^1J(^{13}C,^{13}C)$ coupling constants], selective $^1H\{^{11}B\}$ double resonance experiments (assignment of the ^1H and ^{11}B NMR signals), $^1H/^1H$ NOE difference spectra (determination of the spatial proximity of the B^2/B^5 Et and C(Et)$SiMe_2H$ groups), and the ^{13}C-*J*-modulated NMR spectra measured at −60 °C. The latter experiment permits the undisturbed observation of the resonance signals due to the quaternary carbon atoms C^1 and C^6, which at room temperature are very broad and of low intensity. The $^{13}C^6$ resonance signal may be clearly distinguished from that of $^{13}C^1$ owing to the ^{29}Si satellite signals, which can only be easily observed in this way. The results of these experiments leads conclusively to the number and sequence of the B–H, B–C, C–H, C–C, Si–H, and Si–C bonds. Of note is the low-frequency position of the $^{13}C^6$ NMR signals (**2a**: −6.8; **2b**: −13.2). The $^{13}C^1$ resonance signals are likewise at low frequency (**2a**: 10.3, **2b**: 6.2), which is characteristic for an apical carbon atom.[10] The comparatively large[11] coupling constant $^1J(^{13}C^1,^{13}C_{Et}) = 45.1$ Hz is in agreement with an increase in s-electron density in the C^1-C_{Et} hybrid orbital, which is expected owing to the formal sp hybridization of this carbon atom. For **2a** and **2b**, analysis of the 500 MHz ^1H NMR spectrum in the region of the B-ethyl and C-ethyl groups reveals an additional structural element, a mirror plane passing through C^1 and C^6. Thus, an A_2M_3 spin system is present for both the C^1 and C^6-ethyl groups, whereas an ABM_3 spin system results for each of the B-ethyl groups.

The 1-carba-*arachno*-pentaborane type, isoelectronic with *arachno*-pentaborane(11), has already been proposed for **3** as one of the numerous products of the lithium metal dehalogenation of Et_2O-BF_3/Et_3B mixtures in THF.[12] The existence of the parent species CB_4H_{10} was presumed based on mass spectrometric data and an incompletely described IR-spectrum.[13] The CB_4-carborane **4** with μ-C_2 bridges between the atoms B^2 and B^5 can now be prepared in a quite different manner.[14] NMR data[15, 16] and MO calculations[17] support the assumption that the repeatedly discussed $C_3B_4H_{12}$ product obtained from tetraborane(10) and propyne does not have the proposed structure **5**,[15] but rather the 1-carba-*arachno*-pentaborane(10) structure **6**. With their stability and obviously high ease of formation, 1-carba-*arachno*-pentaboranes(10) must therefore be taken into consideration upon future investigations of multiply C-borylated organic compounds. All derivatives to date contain a μ-C_1 or μ-C_2 bridge between B^2 and B^5. The multiply borylated carbon atom incorporated into a BH-rich system is forced into the highly coordinated apical position in **2**–**4** and **6**,

which would otherwise be avoided for *nido* or *arachno* clusters containing boron and carbon atoms.[18]

The results reported here indicate that the hydroboration of metal-substituted 1-alkynes holds a far greater synthetic potential than was previously assumed. This is based not only on the known regioselective directing effect of organometallic substituents,[19] but also on the lability of certain heteroatom-substituted carbon compounds.[1, 20]

Experimental Procedure

endo/exo-**2a,b**: **1** (6.04 g, 44.3 mmol) was added dropwise at room temperature over 4 h to Et_2BH [3.4] (35.9 g, 387.7 mmol hydride) [64.2 MHz-^{11}B NMR: δ = 87 (ca. 52% Et_3B), 28.5 (ca. 24% $Et_2BH_2BEt_2$), 14, −12 (1:1, ca. 24% **2a,b**)]. Ethene was introduced at 50–55 °C to convert excess hydride into Et_3B [$\delta(^{11}B)$ = 87.0 (ca. 78%), 14, −12 (ca. 22%)], after which most of the Et_3B was removed under vacuum (10^{-1}–0.001 Torr). Distillation (0.001 Torr; bath temperature ≤ 95 °C) of the clear, colorless liquid [$\delta(^{11}B)$ = 87 (ca. 13%), 14, −12 (ca. 87%)] gave, after an initial fraction (0.61 g), 0.93 g of a highly viscous residue, and a main fraction of 9.0 g of which 8.26 g was **2a,b** (61%) with b.p. 96–100 °C (0.001 Torr, bath temperature ≤ 130 °C). **2a,b**: IR ($CDCl_3$): $\tilde{\nu}$ = 2097 cm^{-1} (vs, BHB, SiH); EI-MS (70 eV): *m/z*: 304 (M^+, 11% rel. int.), 261 (18), 162 (50), 133 (B_3 fragment, 100), 93 (B_2 fragment), 47), 59 (17), 41 (22).

Reaction of **2a,b** with Me_3NO [7]: Reaction of **2a,b** (0.304 g, 1 mmol) with anhydrous Me_3NO (excess) in boiling toluene gave a mixture of $B(OR)_3$ and $[(RO)_2B]_2O$ ($\delta(^{11}B)$ = 18.2): found 11.4% B_C; calcd 14.22% B_C for $B(OR)_3$ (formed from **2a,b**); after prior treatment with 1-decene at 135 °C to prevent the formation of $[(RO)_2B]_2O$: found 13.68% B_C.

Reaction of **2a,b** with 2-ethylhexanol: At room temperature **2a,b** remained unchanged (^{11}B NMR). Slow elimination of H_2 began at ca. 50 °C with the formation of R_2BO ($\delta(^{11}B)$ = 55.0) and RBO_2 compounds ($\delta(^{11}B)$ = 31.0); above 140 °C **2a,b** was no longer detected by ^{11}B NMR spectroscopy; found 3.7 mmol H_2 (92.5%) per mmol **2a,b**.

Reaction of **2a,b** with $(Et_2BD)_2$: After warming with excess Et_2BD for 40 min at ca. 130 °C: IR: $\tilde{\nu}$ = 2490 (BH), 2100 (SiH), 1565 (BH_2B), 1465 cm^{-1} (BDB); MS: *m/z*: 304 (no D, ca. 17%), 305 (1D, ca. 26%), 306 (2D, ca. 31%), 307 (3D, ca. 26%).

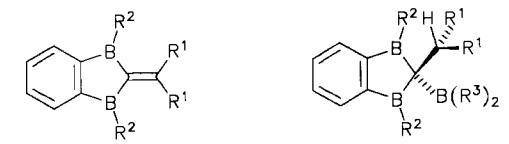
1-Alkyl-2,5-(*ortho*-phenylene)-1-carbapentaborane(10)**

Bernd Gangnus, Harald Stock, Walter Siebert,* Matthias Hofmann, and Paul von Ragué Schleyer*



Dedicated to Professor Egon Uhlig on the occasion of his 65th birthday

We recently reported on the synthesis of 2,3,5-tricarba-*nido*-hexaboranes by double hydroboration of 1,4-dibora-1,4-dihydropentafulvenes and 4,5-bis(isopropylidene)-1,3-diborolanes with diethylborane under elimination of triethylborane.[1, 2] The analogous reaction of the benzoannelated pentafulvenes **1a** with $HBCl_2 \cdot Et_2O$ and that of **1b**[3] with $(Et_2BH)_2$ leads only to **2a** and **2b**, respectively, since the C=C bond of the benzene ring between the boron atoms in **2a,b** is not hydroborated. Cl/H exchange in **2a** by using LiH or by reaction of **1c**[4] with $BH_3 \cdot THF$ should lead to the formation of **2c** as an intermediate, which we expected to rearrange to the *nido*-carborane **3a**. We report here on the unexpected formation of the 1-carbapentaboranes **4**.

The reaction of **2a** with LiH does not afford a defined product;[4] however, **1a,d** surprisingly react with excess $LiBH_4$ to give deprotonated **4a,b**, whose protonation with $HBF_4 \cdot Et_2O$ yielded the carboranes **4a,b**. According to the results of GC-MS, **4** is formed in more than 80% yield; the isolated yield of

sublimed **4a** is 36%. The constitution of **4a** is deduced from the spectroscopic data, and it is supported by the results of combined ab initio/IGLO/NMR calculations.[5] The broad ^{13}C NMR signal of the apical C atom at $\delta = 12$ is characteristic; likewise the *ipso*-carbon atoms of the benzene ring give a broad signal, whose chemical shift (**4a,b**: $\delta = 145$, 147) rules out that these atoms take part in the framework of the cluster.

Two doublets with different coupling constants occur in the ^{11}B NMR spectrum of **4a**. The couplings with the bridging hydrogen atoms are not resolved. Two signals were also observed for the deprotonated 1-carbapentaborane, which was obtained by treatment of **4a** with NaH or BuLi. Noteworthy is the low-field shift of a signal by about 5 ppm ($-5.7 \rightarrow -0.5$). The ^1H NMR spectrum of **4a** shows an AA'BB' pattern in the aromatic region as well as a septet and a doublet for the isopropyl group. In the $^1H\{^{11}B\}$ NMR spectrum, four signals appear for hydrogen atoms attached to boron. The two low-field signals were assigned to terminal hydrogen atoms, the other two signals to bridging hydrogen atoms. The IR spectrum showed three broad bands in the region of terminal BH stretching frequencies (see Experimental Procedure).

The parent compound of **4**, 1-carba-*arachno*-pentaborane(10) CB_4H_{10}, was described as unstable and could not be fully characterized.[6] The formation of a CB_4 carborane was assumed in the mixture of reaction products from $Li/Et_2O \cdot BF_3/Et_3B$ in THF;[7] two 1-carba-*arachno*-pentaboranes(10) could be obtained in 61% yield by the reaction of $Me_2Si(C{\equiv}CMe)_2$ with $[Et_2BH]_2$.[8] Their spectroscopic data are in agreement with those for **4a**,**b**.

Table 1. Calculated and experimental chemical shifts for carbapentaboranes(10).

Bridge between B2 and B5	R at C1	$\delta(^{13}C1)$	$\delta(^{11}B2,5)$	$\delta(^{11}B3,4)$	Method

[a] Compound **4a**. [b] Compound **4b**.

The calculated chemical shifts for derivatives of carbapentaborane(10) are given in Table 1. In addition to IGLO(DZ)[9] calculations, GIAO/tzpdz calculations at SCF and MP2 level[5b,10] can also be performed on the simplest model for the title compounds (ethylene bridge and hydrogen as substituent at C1). In all cases the calculated $\delta^{11}B$ values are in good agreement with those obtained experimentally. In contrast, the calculations on the simpler model compounds for the apical C1 atom each yield a high-field shift. Only calculations on **4a** itself can reproduce the unusual NMR signal of the apical C atom satisfactorily, and thus support the structure shown in Figure 1.

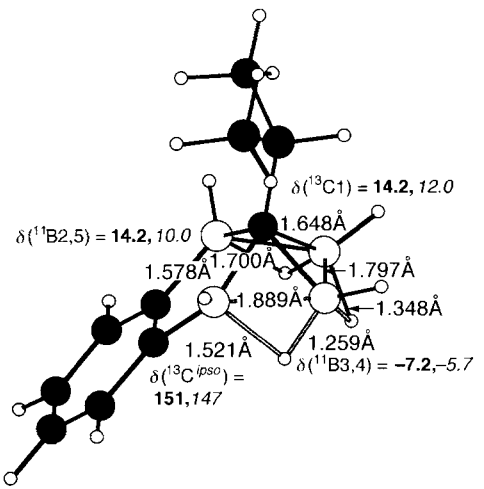

Fig. 1. The geometry (C_s) of **4a** optimized by BLYP/6-341G* calculations as well as its chemical shifts (printed in boldface) calculated with IGLO(DZ), and the measured data (printed in italics).

1-Carbapentaboranes **4** therefore show the peculiarity that the C atom occupies the most highly coordinated position in the *arachno* cluster.

Experimental Procedure

4a: THF (20 mL) was added to a suspension of **1a** (1.36 g, 6.1 mmol) [3] in pentane (10 mL) at −78 °C, the resulting suspension of **1a**·2THF was added in portions over a 30 min period to a solution of $LiBH_4$ (0.53 g, 24.3 mmol) in THF (20 mL) at −78 °C. Subsequently the mixture was stirred at 20 °C for 2 h, and then $HBF_4 \cdot Et_2O$ (1.98 g, 12.2 mmol) was added dropwise at −40 °C. After the evolution of H_2 had finished, the mixture was heated to 20 °C and the solvents were removed at 1 Torr. The oily yellow residue was treated with hexane (50 mL), filtered, and after removal of the solvent at 1 Torr, the residue was sublimed at 40 °C/10^{-3} Torr. Yield: 0.4 g (36%), m.p. 47 °C. ^1H NMR (200 MHz, $CDCl_3$): $\delta = -0.7$ (br, s, 1H), 0.98 (d, 6H, $^3J(H,H) = 6.9$ Hz), 1.97 (sept, 1H, $^3J(H,H) = 6.9$ Hz), 2.1 (br, s, 2H), 3.3 (br, q, 2H, $^1J(B,H) = 106$ Hz), 4.1 (br, q, 2H, $^1J(B,H) = 145$ Hz), 7.30 (m, 2H), 7.53 (m, 2H). ^{11}B NMR (64.2 MHz, $CDCl_3$): $\delta = -5.7$ (d, 2B, $^1J(B,H) = 145$ Hz), 10.0 (d, 2B, $^1J(B,H) = 106$ Hz). ^{13}C NMR (50.3 MHz, $CDCl_3$, 240 K): $\delta = 12$ (C1), 24.5 (CH_3), 30.9 (CH), 129.6 (C_{ar}), 131.5 (C_{ar}), 147 (*ipso*-C). IR (hexane): $\tilde{\nu}_{BH}$ [cm^{-1}] = 2502 s, 2576 m, 2594 m. EI MS: *m/z* (%): 182 (M^+, 88), 181 ($M^+ - H$, 100), 165 ($M^+ - CH_3 - 2H$, 10), 137 ($M^+ - C_3H_7 - 2H$, 33), 125 ($C_nH_4CB_3H_4^+$, 57).

4b: The synthesis was achieved analogously to that for **4a**, starting from **1d** [4], yield 45%, b.p. 55 °C/10^{-2} Torr. ^{11}B NMR ($CDCl_3$): $\delta = 9.7$ (d, 2B, $^1J(B,H) = 112$ Hz), −5.1 (d, 2B, $^1J(B,H) = 136$ Hz). ^{13}C NMR ($CDCl_3$): $\delta = 14$ (C1), 28.7 (CH_2), 37.0 (CH_2), 44.0 (CH), 129.2 (C_{ar}), 131.2 (C_{ar}), 147 (*ipso*-C).

Deprotonated **4a**: To a solution of **4a** (0.36 g, 2 mmol) in THF (15 mL) at −78 °C, was added a suspension of NaH (48 mg, 2 mmol) in THF (10 mL), or *n*BuLi (0.8 mL of a 2.5 M solution in *n*-hexane) was added by syringe. The mixture was stirred at −78 °C for 2 h, subsequently warmed to 20 °C, and the solvent was removed under vacuum. The resulting anion shows the following signals in the ^{11}B NMR spectrum ([D_8]THF): $\delta = 9.9$ (s, 2B), −0.5 (s, 2B).

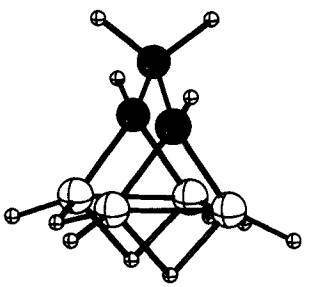
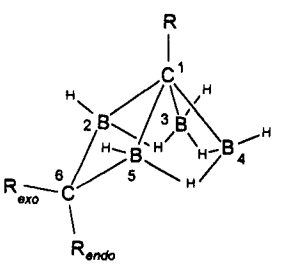
The Structures of Alkyl Derivatives of *arachno*-1-CB_4H_{10} from Reactions of B_4H_{10} with Alkynes**



Mark A. Fox, Robert Greatrex,* Matthias Hofmann, and Paul von Ragué Schleyer*

This work was inspired by early investigations of Grimes et al. in the late 1960s,[1] in which derivatives of the *nido* carboranes CB_5H_9, $C_2B_4H_8$, and $C_3B_3H_7$ were synthesized by the reaction of B_4H_{10} with alkynes at temperatures in the range 25–50 °C. The formation of compounds such as 2,3- and 2,4-Me_2-2,3,4-$C_3B_3H_5$ and 4-Me-2-CB_5H_8 from the reaction of B_4H_{10} with HC≡CH was particularly noteworthy because it indicated that C–C bond cleavage was taking place under very mild conditions and in the absence of metal catalysts. As the mechanisms of these reactions are still not understood, we have been searching for intermediates that might lead to new insights. The "hot–cold" reaction of MeC≡CH with B_4H_{10}, which yielded an unstable species with the composition $C_3B_4H_{12}$ but with an unknown structure, exemplifies the complexities of such chemistry.[2]

1



On the basis of NMR data and the relationship to the *closo*-$[B_{10}H_{10}]^{2-}$ structure, the $C_3B_4H_{12}$ product had been assigned the tricarba-*hypho*-heptaborane structure **1** with an intact (albeit H-rearranged) C_3H_4 moiety.[2] However, this proposal was not supported by subsequent ab initio computations. Optimization of starting geometries corresponding to **1** led to the quadruply bridged form of $CH_2(CH(BH_2)_2)_2$ **2** (Fig. 1), but this was excluded from consideration by both the high symmetry (C_{2v}) and the computed (IGLO) NMR chemical shifts.

2

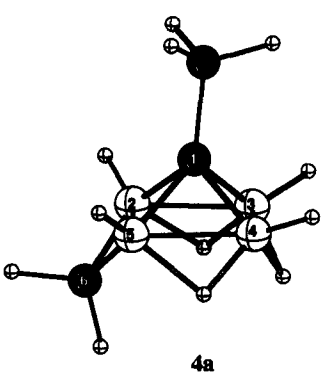


Fig. 1. Calculated structure of **2**. Selected distances [Å]: C-C 1.522, B-C 1.567, B-B with C bridge 1.830, B-B without C bridge 2.274.

We studied the gas-phase reaction at 70 °C of B_4H_{10} with the alkynes HC≡CH, MeC≡CH, EtC≡CH, and MeC≡CMe, and found that analogous compounds were formed in all except the first of these four systems. The unstable compound with a molecular ion at *m/z* 106 from the B_4H_{10}/EtC≡CH reaction gave a ^1H NMR spectrum which was similar to that of $C_3B_4H_{12}$,[2,3] except that an ethyl group was clearly indicated in the former. The evidence suggested strongly that this compound was *arachno*-$EtC_2B_4H_9$ and that $C_3B_4H_{12}$ was in fact the methyl analogue, despite the fact that no peak of relative intensity 3 had been observed in the $^1H\{^{11}B\}$ spectrum of the latter. We examined structures of *arachno*-$MeC_2B_4H_9$ with intact CH_3CCH_2 moieties generated by ab initio calculations, but these did not fit the experimental NMR data of $C_3B_4H_{12}$. We then considered structural alternatives with separated CH_3C and CH_2 units, in other words those which might have been formed by Grimes's C≡C bond cleavage reactions. The first trials employing the combined ab initio/IGLO/NMR method,[4] which we have found to give very good agreement with experimental data on known carboranes,[5] yielded highly gratifying results with the parent (but experimentally unknown) *arachno* $C_2B_4H_{10}$ system **3**. puted chemical shifts in remarkably good agreement with the experimental NMR data (Table 1). The MP2(fc)/6-31G* energy of **4a** is 150.6 kJ mol^{-1} lower than that of **2**. These data establish the structure as **4a** securely. This compound is the smallest known *arachno* carborane and the first carborane derivative related to *arachno*-B_5H_{11}.

Table 1. Experimental [a] and IGLO(DZ)-calculated [b] ^{11}B, ^{13}C, and ^1H NMR chemical shifts for *arachno*-2,5-μ-CH_2-1-CB_4H_8 derivatives [8].

[g] Ethyl group *exo* to cluster, and methyl fragment of ethyl group *anti* to CH vector.

The structures of the compounds from the B_4H_{10}/EtC≡CH and B_4H_{10}/MeC≡CMe reactions (**5a** and **6a**, respectively) were also established by the ab initio/IGLO/NMR method, and similar calculations were carried out for the three isomers (**4b**, **5b**, and **6b**) whose presence in minor amount was indicated in the NMR spectra of the derivatives **4a**, **5a**, and **6a**, respectively. The ratio of the two isomers (**a**:**b**) was found to be 6:1 for **4**, 30:1 for **5**, and 4:1 for **6**. Geometries were optimized at the MP2(fc)/6-31G* level,[6] and chemical shifts were computed with the IGLO method.[7] Relative MP2(fc)/6-31G* energies were corrected for zero vibrational energies at HF/6-31G* scaled by 0.89. These computational results helped to confirm the various products as 1-Me-carborane **4a**, *endo*-Me-carborane **4b**, 1-Et-carborane **5a**, *exo*-Et-carborane **5b**, 1-Me-*endo*-Me-carborane **6a**, and 1-Me-*exo*-Me-carborane **6b**. Consistent with experimental findings, **4a** was computed to be 8.0 kJ mol^{-1} lower in energy than isomer **4b**, which in turn was 2.9 kJ mol^{-1} more stable than the unobserved *exo* isomer (R_{exo} = Me). For **5a**, the two conformations of the ethyl group had nearly the same energy and both gave acceptable agreement with the experimental data. **6b** was found to be 1.6 kJ mol^{-1} higher in energy than **6a**. **5b** is likely to be the *exo* ethyl isomer of **5a**. Various conformers with an *endo* ethyl group were found to have an energy higher by about 5 kJ mol^{-1} and the computed B(3,4) chemical shifts showed poorer agreement with the experimental value. The B(2,5) resonance was obscured by peaks from the major isomer **5a**.[8]

Structures related to **3**–**6** were first proposed by Köster et al. in 1968 for products derived from dehalogenation reactions[9] and for derivatives of the unknown phosphorus-bridged parent borane 2,5-μ-$(PH_2)B_5H_8$,[10] which is isoelectronic with *arachno*-2,5-μ-CH_2-1-CB_4H_8. Very recently, Wrackmeyer et al. have prepared polysubstituted derivatives akin to **3**–**6** and Köster's proposals by reactions of dialkylboranes with dialkynylsilanes.[11] Siebert et al. describe an analogous system with an *ortho*-phenylene bridge instead of the $CHR_{exo/endo}$ moieties in **3**–**6**.[12]

It is now well established that B_4H_{10} decomposes at room temperature and above, initially to form the nonisolable intermediate $\{B_4H_8\}$ and dihydrogen.[13] In the formation of the *arachno* $C_2B_4H_{10}$ derivatives it appears that $\{B_4H_8\}$ fuses with the alkyne, cleaves the C–C triple bond, and transfers one of its hydrogen atoms to the carbon atom of the bridging methylene group. The result is an intriguing snapshot of the cleavage of a C–C triple bond by a borane.

Experimental Procedure

In a typical reaction, a mixture of 0.67 mmol of B_4H_{10} and 0.67 mmol of MeC≡CH was heated in a reaction vessel (1 L) at 70 °C. The reaction was monitored by bleeding the mixture continuously into a Kratos MS30 mass spectrometer coupled to an MSS data system. When the alkyne had disappeared (after ca. 0.4 h) the reaction was quenched by pumping the mixture into a U-trap surrounded by liquid nitrogen. This process was repeated twenty times, and the combined products were then separated on a high-vacuum low-temperature fractionation column [14]. The species leaving the column were monitored by mass spectrometry, and the desired product (in this case **4a**) was collected. A small amount of 2-Me-2,3-$C_2B_4H_7$, identified by its NMR spectra [15], was always present as a minor impurity [3] and could not be removed by repeated fractionation of **4a**. The analogous procedure with EtC≡CH and MeC≡CMe in place of MeC≡CH gave **5a** and **6a**, respectively; the compounds 2-Et-2,3-$C_2B_4H_7$ and 2,3-Me_2-2,3-$C_2B_4H_6$ [16], respectively, were present as minor impurities. NMR spectra were recorded at ca. 230 K. Experimental chemical shifts are given for the minor isomers only for peaks which are well resolved from those of the major isomer.

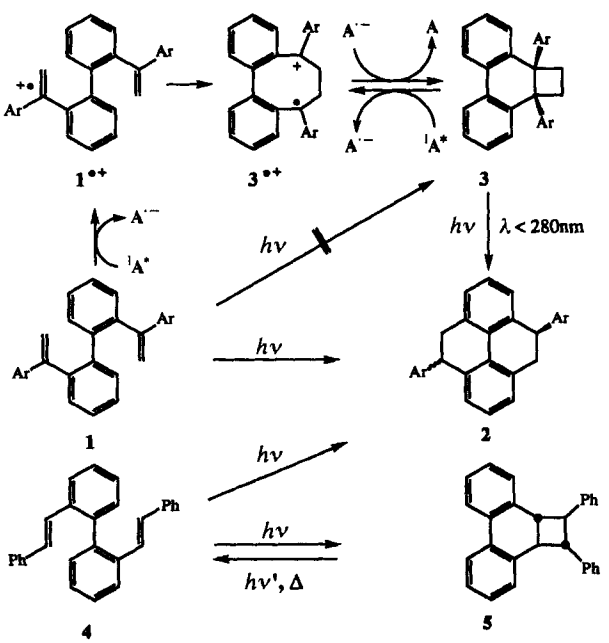
Intramolecular [2 + 2] Cycloadditions of 2,2′-Bis(1-arylvinyl)-Substituted Biphenyls Induced by Photo Electron Transfer**



Oliver Sadlek, Klaus Gollnick, Kurt Polborn, and Axel G. Griesbeck*

The *intermolecular* [2 + 2] cyclodimerization of 1,1-diphenylethylene under photo electron transfer (PET) conditions[1] has already been studied in detail.[2] In the absence of oxygen it affords, after electron transfer to the electronically excited acceptor (mainly 9,10-anthracenedicarbonitrile **A**), a 1,2-radical cation that, after formation of the 1,1,4,4-tetraphenyl-substituted 1,4-radical cation and back electron transfer, reacts further to 1,1,2,2-tetraphenylcyclobutane and other products. The intermediate 1,4-radical cations are trapped by oxygen in a radical chain reaction to form 1,2-dioxanes in high yield.[3] We report here on corresponding *intramolecular* reactions.

[+++] Crystal structure analysis
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

In order to use a substrate comparable to that studied in the intermolecular reaction, we chose the 2,2-bis(1-arylvinyl)-substituted biphenyls **1**.[4] They are particularly interesting, because their first excited singlet states react further to form the tetrahydropyrenes **2**; that is, they follow an independent reaction pathway. According to Padwa et al.,[5] no trace of the potentially photolabile [2 + 2] cyclization product **3a** can be observed even after short irradiation of **1a** (for direct excitation, $\lambda = 360$ nm). This is remarkable, because the direct irradiation of the positional isomer 2,2′-distyrylbiphenyl **4** primarily affords a strained, *trans*-fused cyclobutaphenanthrene (**5**), which on further irradiation (at shorter wavelengths of $\lambda = 300$ nm, or on thermolysis) reacts irreversibly to form the pyrene derivative **2a**. It is thus in a photochemically induced equilibrium with the starting material.[6] As a stilbene derivative, **4** behaves "reasonably", but in the long run the high ring strain of **5** takes its toll.

To achieve an intramolecular [2 + 2] cycloaddition with the coupled 1,1-diarylethylenes **1a–c** as well, the irradiation (excitation wavelength $\lambda_{exc} > 375$ nm) of **1** in acetonitrile (5×10^{-2} M) was performed in the presence of **A** (2×10^{-4} M). In all these cases, over 95% of the *cis*-1,2,2*a*,10*b*-tetrahydro-2*a*,10*b*-diarylcyclobuta[*l*]phenanthrene **3a–c** was formed (Scheme 1). These

Scheme 1. Photochemical transformation of 2,2′-bis(arylvinyl)-substituted biphenylene. **a**: Ar = Ph, **b**: Ar = *p*-MrPh, **c**: Ar = *p*-MeOPh; DCA = 9,10-dicyanoanthracene.

compounds were isolated analytically pure in good yields (Table 1). Surprisingly, this reaction was also possible with solutions containing higher concentrations of **1** and in the presence of lithium perchlorate. Under both these sets of conditions, the formation of *intermolecular* dimerization products should be favored, in one case because of simple concentration effects and in the other because of a special salt effect that leads to a prolonged lifetime for the radical cation.[7] This course is taken by, for instance, the photodimerization of stilbene to tetraphenylcyclobutane under comparable conditions with a quantum yield of $\Phi = 0.33$.[8] That nevertheless under the given conditions only **3** is obtained emphasizes the high tendency toward irreversible formation of the radical cation $\mathbf{3}^{\bullet+}$ from the precursor radical cation $\mathbf{1}^{\bullet+}$.

Table 1. Oxidation potentials, free energies of reaction, and calculated and experimentally determined electron transfer rate constants for **1a–c**.

Cmpd.	E_{ox} [a]	ΔG_{ET} [b]	k_{ET} [c]	k_q [d]	Yield of **3** [%] [e]
1a	1.28	−17.75	1.40	0.97	73
1b	1.23	−18.91	1.41	0.95	68
1c	1.18	−22.19	1.44	1.47	81

[a] In V, versus the saturated calomel electrode (SCE), irreversible, 10^{-1} M nBu$_4$ClO$_4$ in acetonitrile; sweep rate: 0.2 V min^{-1}. [b] In kcal mol^{-1} with $E_{red}(\mathbf{A}) = -0.91$ V, $E_s(\mathbf{A}) = 2.90$ eV [10]. [c] $M^{-1}s^{-1} \times 10^{10}$, calculated according to ref. [11]. [d] $M^{-1}s^{-1} \times 10^{10}$. Stern-Volmer kinetics with 10^{-5} M **A** in acetonitrile; substrate concentration: 10^{-3}–10^{-2} M, $R = 0.996 \pm 0.002$. [e] After crystallization from ethanol; samples for analytical studies were chromatograped (SiO_2, petroleum ether/ethyl acetate 10:1).

The high reactivity of the starting compounds in the presence of ^{1}**A*** is reflected in the oxidation potentials of **1a–c**. They are smaller by about 0.5 V (for **1a**) to 0.1 V (for **1c**) than those of the comparable 1,1-diarylethylenes;[9] the electron transfer should thus be almost diffusion-controlled in all cases (Table 1). The oxidation potential of **1a** is particularly strongly decreased and even approaches that of 1,1-dianisylethylene. The experimentally determined fluorescence quenching constants agree well with the rate constants calculated according to the Rehm–Weller equations.[11] Since the irradiation in the presence of typical triplet sensitizer like rose bengal ($E_T = 39.6$ kcal mol^{-1}, $\Phi_T = 0.76$[12]) does not cause a change in the starting compounds **1a–c**, an energy transfer mechanism both by ^{3}**A** ($E_T = 38.3$ kcal mol^{-1}, $\Phi_T > 0.02$[13]) and by ^{1}**A** (for which **2** must be formed) can be ruled out.

Under the reactions conditions radical cations with longer lifetimes should be trapped by triplet oxygen or by the superoxide anion.[3] On irradiation of **1a** under oxygen, however, only **3a** could be isolated, whereas analogous treatment of the substrates **1b,c** yielded a variety of nonidentifiable oxidation products. When the conversion was low, predominantly the [2 + 2] cyclization products **3b,c** were detected by spectroscopy, though with increasing duration of the irradiation the proportion of these compounds decreased. The same product composition was also found when the primary products of the electron transfer reaction (**3a–c**) were irradiated under oxygen in the presence of **A**. Apparently, as a result of the low oxidation potentials, an **A**-induced electron transfer with reformation of the intermediate **3**$^{\bullet+}$ is possible, in particular for the compounds **3b** and **c** ($E_{ox} = 1.58$ and 1.48 V respectively). Direct photochemical excitation ($\lambda_{exc} > 280$ nm) converts the PET products **3a,b** quantitatively into the pyrenes **2a,b**,[14] possibly via the biaryls **1**, though only **1b** could be detected. Addition of **A** to an irradiated solution of **3** suppresses the formation of **2**.

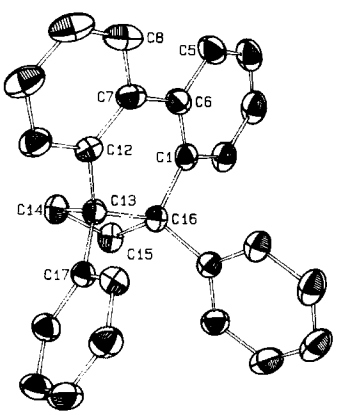

Fig. 1. Structure of **3a** in the crystal (ORTEP). Selected distances [pm] and angles [°]: C1-C6 139.5(2), C6-C7 (148.6(2), C13-C14 155.5(2), C13-C16 159.3(2), C13-C17 152.9(2); C5-C6-C7-C8 −5.56(8), C12-C13-C16-C1 −22.05 (6), C16-C13-C14-C15 19.07(8).

In the cyclization of **1** initiated by the photo electron transfer process described here, the products **3** are formed with high *cis* diastereoselectivity in all cases. For compound **3a** the structure was confirmed by a crystal structure analysis[15] (Fig. 1); from the similar NMR data[16] for **3b** and **3c**, we postulate a *cis* configuration for these substances, too. This high stereoselectivity for the (reversible) cyclization of the radical cation **3**$^{\bullet+}$ after reduction by the **A** radical anion can be explained in two ways: a) The configuration is already fixed by the one-electron two-center bond in the redical cation **3**$^{\bullet+}$, or b) the intermediate formed after electron back transfer, which has a dibenzocycloocta-1,3,5-triene structure, undergoes a (thermal) disrotatory ring closure. Because the latter reaction is expected to be very fast, the two alternatives cannot be distinguished at present.

We could thus show that for the 2,2′-bis(1-arylvinyl)-substituted biphenyls **1** the intramolecular PET-induced cycloisomerization is an efficient method for the highly stereoselective synthesis of cyclobutaphenanthrenes **3**, which are not accessible by the classical photochemical route.

Further details are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.
[16] At room temperature the rotation about the C(cyclobutane)–aryl bond is hindered: the signals of the *o,o′* and *m,m′* carbon atoms have different chemical shifts in the ^{13}C NMR spectrum ($\Delta\delta$ for the *m,m′* C atoms in **3a** is 5.5, in **3c** 4.4); the rotation about the biaryl axis (according to the crystal structure analysis the twist angle of **3a** is 5.6°) requires a lower activation energy (six signals for the phenanthrene C atoms). At + 60 °C the signals for the *o,o′* and *m,m′* carbon atoms of **3a** coalesce.

Biomimetic Phosphonylation and Phosphorylation of Glycoses and Deoxynucleosides**

Svetomir B. Tzokov, Ivan T. Devedjiev, Emilia K. Bratovanova, and Dimiter D. Petkov*

While DNA is nearly inert, RNA is rapidly hydrolyzed in mildly basic solutions. Todd et al.[1] attributed the high reactivity of phosphodiester bonds in RNA to the "nucleophilic catalysis" by the neighboring 2'-hydroxyl group; the hydrolysis proceeds via the 2',3'-cyclic phosphate intermediate **1** [Eq. (a)].

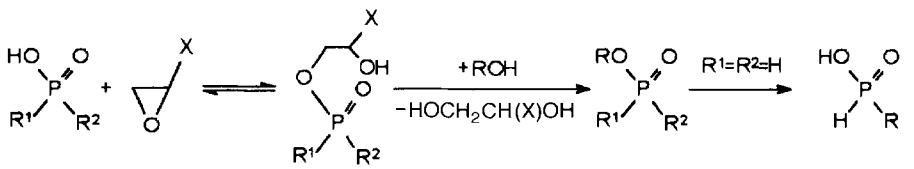
(a)

1

Alkyl esters of glycerol phosphate react similarly.[2] The ribonuclease A catalyzed hydrolysis also takes advantage of this mechanism.[3] The reverse reaction of the first step of reaction (a) (transesterification) has also been observed, and by this process both simple alkyl phosphates of nucleosides and dinucleoside monophosphates have been obtained enzymically[4, 5] and chemically.[6] The importance of the vicinal hydroxyl group at the cleavage site in the Tetrahymena ribozyme reaction has been underlined recently.[7]

The growing interest in oligonucleotides and oligosaccharides and their use in antisense technology[8] and glycobiology[9] has stimulated the development of methods for the large-scale synthesis of chemically and chirally pure sugar phosphates.[10–12] Here we report a one-pot reaction for the efficient and specific phosphonylation and phosphorylation of glycoses and deoxynucleosides, which is analogous to the biochemical reactions.

Recently Devedjiev et al.[13, 14] showed that phosphinic acid **2** ($R^1 = R^2 = H$), epoxides, and aliphatic alcohols reacted via intermediates 2-hydroxyalkyl phosphinate **3** and probably alkyl phosphinate **4** to give alkyl phosphonic acids **5** in nearly quantitative yields [Eq. (b)]. As in the biochemical reaction (a), the presence of the vicinal hydroxyl group in **3** is crucial, since 2-deoxyalkyl phosphinates do not react.[14] We have tentatively assumed that if alkyl phosphinate **4** is an intermediate, the reaction of the other phosphorus oxo acids (phosphonic acid **2** ($R^1 = OH$, $R^2 = H$) and phosphoric acid **2** ($R^1 = R^2 = OH$)) must stop at **4**, since the rearrangement **4** ⇌ **5** is possible with alkyl phosphinate ($R^1 = R^2 = H$) only.[11, 12]



Actually, when phosphonic or phosphoric acid reacts with an alcohol (D-glucose or thymidine) and an epoxide (propylene oxide or epichlorohydrin) in anhydrous organic solvent (dioxane or pyridine), only alkyl phosphonates **4** ($R^1 = H$, $R^2 = OH$) or alkyl phosphates **4** ($R^1 = R^2 = OH$) are isolated (Table 1). The crude yields are nearly quantitative. Characteristically the reaction with D-glucose is regio- and stereospecific, affording one of the five possible constitutional isomers and the α-anomer only. This is not the case with thymidine, since protection of the 5'-hydroxyl group is required to obtain thymidine 3'-phosphonate or 3'-phosphate (Table 1).

The chemical process (b) is a condensation reaction, in which the easily available epoxides serve as the condensation agent. This esterification provides the phosphorus oxo acids with a structural feature (hydroxyl group adjacent to the esterified hydroxyl group) known from biochemical studies[1–5, 7] to make available a specific reaction pathway of low activation energy. Such reactions imitating the pathway and/or results of the biochemical reactions have been called biomimetic by Breslow.[15]

In contrast to the biochemical reaction (a), the β-hydroxyl group leaves as 1,2-diol in the biomimetic reaction (b). This suggests that the route via the cyclic phosphate is not the only mechanistic pathway for hydrolysis and aminolysis of β-hydroxyesters of phosphonic and phosphoric acids. Instead of acting as a nucleophilic catalyst, the vicinal hydroxyl group could function as a general acid catalyst, as in the case of ribozymic reactions.[16]

The regio- and stereospecificity in the reaction with D-glucose (only the α-anomer is isolated, Table 1) is not surprising when one considers the kinetic anomeric effect in the reaction of glycopyranoses.[17] A lack of regiospecificity is observed with thymidine; both the 5'- and 3'-hydroxyl groups are subject to reaction (b). This feature, however, makes it possible to use the reaction in oligonucleotide synthesis after selective hydroxyl group protection. Indeed, 5'-dimethoxytritylation afforded DMT-thymidine 3'-H-phosphonate (Table 1), a building block for the efficient and rapid preparation of oligonucleotides.[11] Protected derivatives of deoxyadenosine, deoxyguanosine, and deoxycytidine react similarly.

The biomimetic reaction described here is remarkably versatile and will benefit DNA and carbohydrate synthesis. It provides easy access to sugar phosphonates and phosphates under mild conditions and in good overall yields without elaborate protective group manipulations.

Experimental Procedure

General procedure for phosphonylation/phosphorylation: Equimolar amounts (0.02 mol) of crystalline phosphonic or phosphoric acid, glucose or nucleoside, and propylene oxide or epichlorohydrin were dissolved in 20 mL of pyridine (dried over KOH). After an initial weakly exothermic period (30 min), the reaction mixture was stirred for 1 h at 40 C and then concentrated to dryness. In the case of the glycosyl

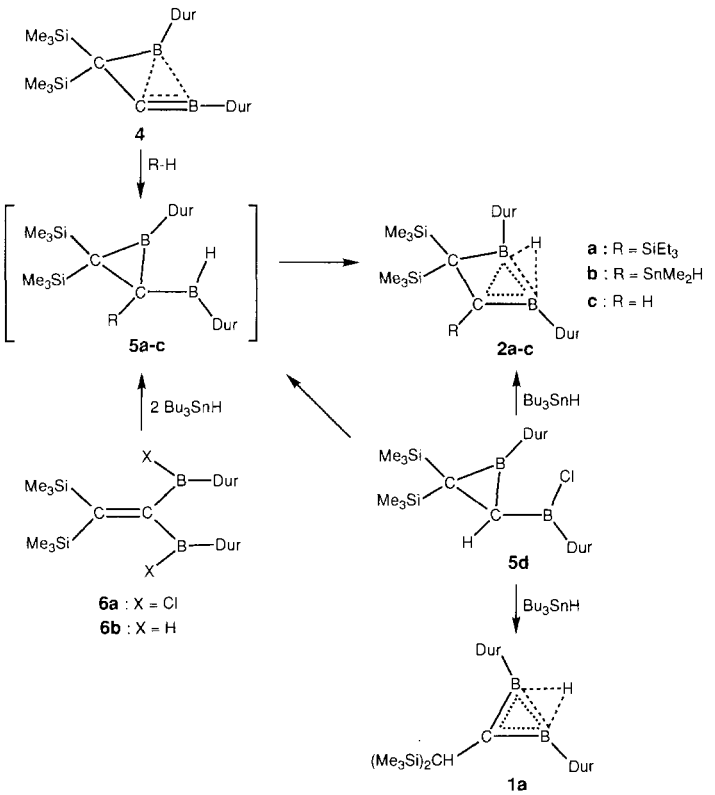
Nonclassical 1,2-Diboretanes and 1,2-Diborolanes**

Dirk Steiner, Christian Balzereit, Heinz-Jürgen Winkler, Nicolaos Stamatis, Matthias Hofmann, Paul von Ragué Schleyer, Werner Massa, and Armin Berndt*

Diborirane is 50.8 kcal mol^{-1} [1b] more stable in the tautomeric H-bridged arrangement **1u**[***] (B–H–B diborirane)[1, 2] than in the classical structure **1u***.[3] Here we show that nonclassical structures, **2** (B–H–B homodiborirane) and **3** (B–H–B dihomodiborirane), are also favored for the homologous 1,2-diboretanes and 1,2-diborolanes when the boron atoms are electron-deficient. Known 1,2-diboretanes[4] and 1,2-diborolanes[5] have dialkylamino substituents (R = Do = donor) at the boron atoms; hence, the boron atoms are no longer electron-deficient and—as usual[6]—the classical structures **2*** and **3*** are favored.



The nonclassical 1,2-diboretanes **2a,b** (Dur = 2,3,5,6-tetramethylphenyl) were obtained by addition of triethylsilane or dimethylstannane, respectively, to methyleneborane **4**.[2b] The borylboriranes **5a,b** are probable intermediates, but eluded detection by NMR spectroscopy even when a mixture of the reactants was kept below −40 °C. Compound **2c** as well as **1a**[2b] were formed in the reaction of borylborirane **5d**[7] and tributylstannane. However, **2c** could be obtained in quantitative yield by reaction of **6a**[2b] with tributylstannane. In this reaction, **6b** is probably formed as the initial product, which then undergoes intramolecular hydroboration to yield **5c**.

[***] The letter "u" is used for the unsubstituted basic structure of a compound class, and an asterisk indicates the (nonexistent but more familiar) classical forms of the nonclassical compounds.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2222-2303 $ 10.00+.25/0

The NMR data of **2a–c** (Table 1) suggested that these compounds are H-bridged 1,2-diboretanes. In order to test this hypothesis, chemical shifts for the parent compound **2u** were computed (GIAO-MP2/tzp[8, 9]). The impressive correlation between calculated and experimentally measured chemical shifts (Table 2) supported the presence of the nonclassical structure,

Table 1. Selected physical data for compounds **1a** and **2a–c**.

1a: colorless needles, m.p. 175 °C, yield 50–80%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = -0.01$ (s, 18H, $Si(CH_3)_3$), 1.85 (s, 1H, $CHSi_2$), 2.24, 2.29 (2 × s, each 6H, *o*- and *m*-CH_3), 6.97 (s, 2H, *p*-H)- 7.34 (br.s, 1H, BHB); ^{13}C NMR (125 MHz, $CDCl_3$, – 30 °C): $\delta = 0.1$ (q, 6C, $Si(CH_3)_3$), 20.1, 20.4, (2 × q, each 4C, *o*- and *m*-CH_3), 20.5 (d, 1C, $CHSi_2$), 131.7 (d, 2C, *p*-C), 133.3 (s, 4C, *m*-C), 133.6 (br. s, 2C, *i*-C), 136.9 (s, 4C, *o*-C), 140.3 (br. s, 1C, CB_2); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 23$.

2a: colorless crystals, m.p. 168 °C (decomp.), yield 78%. – ^{1}H NMR (500 MHz, $CDCl_3$, – 30 °C): $\delta = -0.10, 0.16$ (2 × s, each 9H, $Si(CH_3)_3$), 0.73–0.96 (m, total of 15H, $Si(CH_2CH_3)_3$), 1.94 (br.), 2.13 (br.), 2.17, 2.25, 2.29, 2.46, 2.54 (br.) (7 × s, total of 24H, *o*- and *m*-CH_3), 4.30 (br. s, 1H, BHB), 6.96, 7.05 (2 × s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, – 30 °C): $\delta = 2.7$, 3.2 (2 × q, each 3C, $Si(CH_3)_3$), 6.6 (t, 3C, $Si(CH_2CH_3)_3$), 8.9 (q, 3C, $Si(CH_2CH_3)_3$), 19.7 (br.), 20.4, 20.5, 20.6, 21.8 (br.), 22.9 (6 × q, total of 8C, *o*- and *m*-CH_3), 32.1 (s, 1C, CSi_2), 68.2 (s, 1C, CB_2), 130.8, 133.7 (2 × d, each 1C, *p*-C), 132.4, 132.7, 133.1 (br.), 133.6 (br.), 137.1, 138.6, 139.2 (br.), 139.8 (br.) (8 × s, each 1C, *o*- and *m*-C), 133.5, 137.0 (2 × br. s, each 1C, *i*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 3$, 48.

2b: colorless crystals, m.p. 143 °C (decomp.), yield 71%. – ^{1}H NMR (500 MHz, $CDCl_3$, – 30 °C): $\delta = -0.14$, 0.17 (2 × s, each 9H, $Si(CH_3)_3$), 0.44, 0.71 (2 × s, each 3H, $Sn(CH_3)_2$), 2.09, 2.15, 2.19, 2.25, 2.52 (5 × s, total of 24H, *o*- and *m*-CH_3), 4.41 (br. s, 1H, BHB), 5.29 (s, 1H, SnH), 6.95, 7.10 (2 × s, each 1H, *p*-H- Dur); ^{13}C NMR (125 MHz, $CDCl_3$, – 30 °C): $\delta = 1.2$, 4.5 (2 × q, each 1C, $Sn(CH_3)_2$, 1.5, 1.8 (2 × q, each 3C, $Si(CH_3)_3$), 20.4, 20.5, 20.7 (3 × q, total of 8C, *o*- and *m*-CH_3), 35.0 (s, 1C, CSi_2), 73.9 (s, 1C, CB_2), 130.7, 135.6 (2 × br. s, each 1C, *i*-C), 131.7, 134.8 (2 × d, each 1C, *p*-C), 132.9, 133.7, 136.9, 139.1, 140.9 (5 × s, total of 8C, *o*- and *m*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 2$, 48; ^{119}Sn NMR (149 MHz, $CDCl_3$, – 30 °C): $\delta = 57.3$ ($J(^{119}Sn,H) = 2216$ Hz).

2c: colorless crystals, m.p. 150–152 °C, yield quantitative by NMR spectroscopy. ^{1}H NMR (500 MHz, $CDCl_3$, – 30 °C): $\delta = -0.01, 0.27$ (2 × s, each 9H, $SiCH_3$), 2.02 (br.), 2.10, 2.32 (br.), 2.38, 2.67, 2.83 (br.) (6 × s, total of 24H, *o*- and *m*-CH_3), 3.34 (br., 1H, BHB), 3.98 (d, 1H, CHB, $^3J(H, H) = 13.5$ Hz), 7.07, 7.20 (2 × s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, – 30 °C): $\delta = -0.3$, 0.5 (each 3C, $SiCH_3$), 18.0, 19.4 (br., each 1C, *o*- and *m*-CH_3), 18.8, 20.1, 20.2, 20.5, 20.6 (total of 6C, *o*- and *m*-CH_3), 30.6 (1C, CSi_2), 73.8 (1C, $J(^{13}C,H) = 166$ Hz, CHB), 131.2, 134.6 (each 1C, *i*-C), 131.6, 134.3 (each 1C, *p*-C), 132.0, 132.6, 132.9, 138.1, 139.0, 140.4, 141.2 (total of 8C, *o*- and *m*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 5$, 44.

Table 2. Comparison of experimental and calculated data for **2a–c**, **2u**, and **2d**.

	2a	**2b**	**2c**	**2u**	**2d**
$\delta(^{11}B1)$	3	2	5	– 2.6	–
$\delta(^{11}B2)$	48	48	44	+ 43.5	–
$\delta(^{13}C3)$	68.2	73.9	73.8	+ 71.2

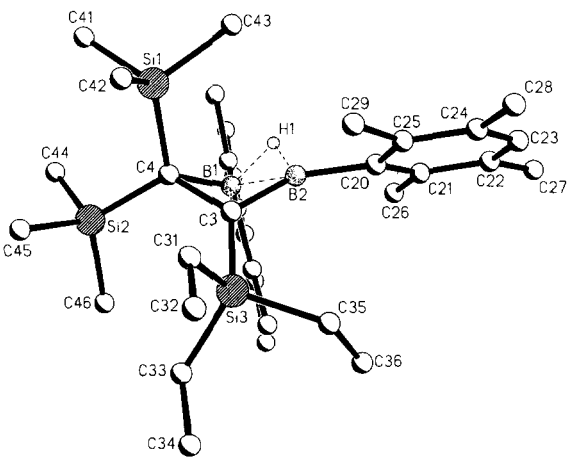
B2-B1-C3-C4 [°]	133.7(2)	–	–	140.3	141.0

which was finally confirmed by a single-crystal X-ray structure analysis. Figure 1 shows the crystal structure of **2a**.[10]



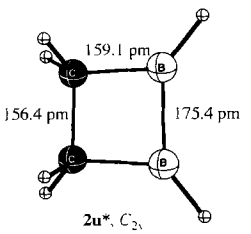


Fig. 1. Crystal structure of **2a**.

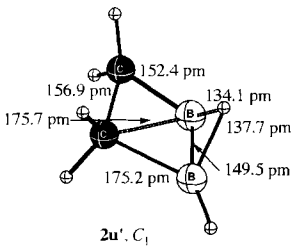
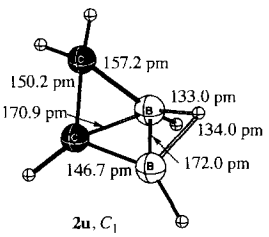


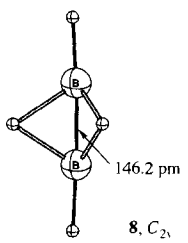
When the substituent effects are taken into account, the geometry of **2a** agrees well with that calculated for **2u** (Table 2): the duryl substituents decrease the electron-deficiency of the boron atoms and thus the nonclassical interactions; the sterically demanding trialkylsilyl groups at C3 and C4 are most likely responsible for the lengthening of the C3–C4 bond (158.9 vs. 150.0 pm in **2u**) and the increased folding along the B1–C3 bond (46.3 vs 39.7° in **2u**). An NBO analysis[11] (NBO = natural bond orbital) provided the following results regarding the electronic structure of **2u**: The methylene group is bonded in a classical fashion. The CB_2 framework is held together by a 2c–2e bond (between the C–B pair that is not C-bridged) and two 3c–2e bonds (BHB and BCB). In isomer **2u'**, which is less stable by 26.1 kcal mol^{-1} (MP2(fc)/6-31G*), the two boron atoms are joined by two 3-center bonds (BHB and BCB) and, in addition, by a classical 2-center bond. The carbon atom, now also as a CH_2 group, is bonded to the boron atoms only by a nonclassical 3c–2e bond. These bonding arrangements are reflected in the distances between atoms: The partial double bond character of B2–C3 manifests itself in the short bond lengths (**2a**: 147.2, **2u**: 146.7 pm), and the long B–B distance (**2a**: 179.9, **2u**: 172.0 pm) corresponds to that in diborane(6) **7** with

two bridging hydrogen atoms.[12, 13] The less stable isomer **2u'** has a large B2–C3 distance of 175.2 pm and a small B–B distance of 149.5 pm, reminiscent of the nonclassical diborane(4) **8**.[12, 14] The classical **2u*** is not an energy minimum, but rather a transition state.



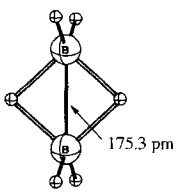
2u*, C_{2v}

E_{rel} = 34.5 kcal mol^{-1}



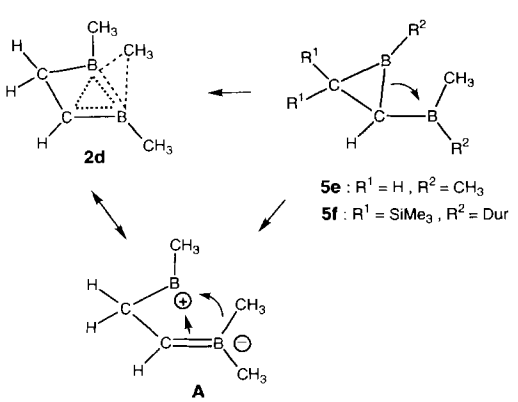
2u', C_1

E_{rel} = 26.1 kcal mol^{-1}



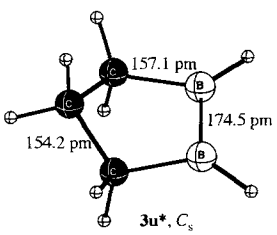
2u, C_1

E_{rel} = 0.0 kcal mol^{-1}



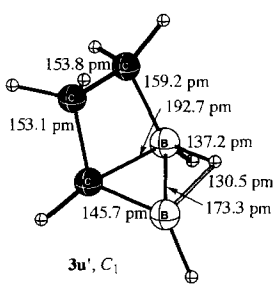
8, C_{2v}

7, D_{2h}



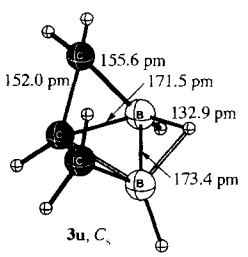
The geometry of the H-bridged 1,2-diboretanes differs only slightly from that of methyl-bridged **2d**. The latter geometry was obtained by performing calculations on borylborirane **5e**.[7] The electronic structure of the nonclassical 1,2-diboretane **2** can therefore be described in terms of a strong α-agostic type interaction[2b] between the electron-deficient boryl boron atom and the neighboring strained C–B bond of the three-membered ring in **5**. It is this interaction that gives rise to the 3c–2e bond between B1, B2, and C3. The boron atom of the three-membered ring thus has an increased positive charge (cf., resonance structure **A**) and participates in a β-agostic interaction[2b, 15]

with a σ bond of the boryl substituent (B–CH_3 for **5e**, B–H for **5a–c**) and thereby forms the second 3c–2e bond.



We were able to show the presence of a weak α-agostic interaction of the same type (C–B hyperconjugation) in the boryl borirane **5f**.[7] Due to the sterically demanding duryl substituents in **5f**, strong interactions of the type that transform **5e** to **2d** are obviously not possible here. However, when the methyl group at the boryl boron atom is replaced by an H atom, the duryl groups are no longer effective in preventing nonclassical interactions.

Calculations predict that for 1,2-diborolane the nonclassical structure **3u'** is stabilized by only 2.5 kcal mol^{-1} and the B-H-B dihomo structure **3u** by 18.9 kcal mol^{-1} relative to the classical structure **3u*** (MP2(fc)/6-31G* + 0.93ZPE).



3u*, C_s

E_{rel} = 18.9 kcal mol^{-1}

3u', C_1

E_{rel} = 16.4 kcal mol^{-1}

3u, C_s

E_{rel} = 0.0 kcal mol^{-1}

Experimentally and theoretically derived data both show that a nonclassical, H-bridged homodiborirane structure is favored for those 1,2-diboretanes in which the boron atoms are not bonded to strongly electron-donating groups. Based on calculations, an analogous dihomodiborirane structure can be expected for 1,2-diborolanes.

A 1,3-Diboratabenzene**

Christian Balzereit, Heinz-Jürgen Winkler, Werner Massa, and Armin Berndt*

While derivatives of 1,2- and 1,4-diboratabenzenes **1** and **2** are known,[1, 2] those of 1,3-diboratabenzene **3** have only been obtained as π complexes **4** with transition metals (M = Co, Fe).[3, 4] We report here on the first dilithium compound **3a** of a 1,3-diboratabenzene dianion.

When the tetracarbahexaborane **5** was reduced by lithium in tetrahydrofuran (THF), **3a** was obtained as the only product. The oxidation back to **5** was achieved by heating **3a** in boiling 1,2-dibromoethane. Analogous direct redox transformations are not known for the two- and three-dimensional arenes[5] **6** and **7** (R = alkyl),[6] which are isoelectronic with **3a** and **5**, respectively.

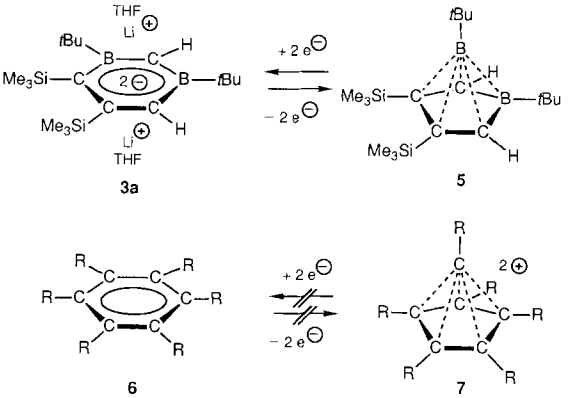

Figure 1 shows the crystal structure of **3a**.[7] The lithium ions, which are each coordinated to one molecule of THF, are positioned above and below the center of the almost planar six-membered ring (maximum deviation from best plane 6.1(4) pm; distances between plane and lithium cations 170.3 (Li1) and 166.6 pm (Li2)). A similar arrangement has been observed for the lithium ions coordinated to tetramethylethylenediamine (TMEDA) in the 1,2-diboratabenzene **1a**.[1] However, the structure of **3a** shows a disorder that can be described by an alternative arrangement of the molecule obtained by an exchange of the *t*Bu–B3 and Me$_3$Si–C5 units. Figure 1 and the geometric descriptions refer to the major conformation (59%). The steric strain between the trimethylsilyl and *tert*-butyl groups positioned *ortho* to one another is relieved by distorsion of the angles at B3 and C5 and by changes in the torsional angles around the bonds B3–C4 and C4–C5. The Li···B distances, which are not affected by the disorder, are distinctly shorter (227.7 and 232.9 pm) than those in **1a** (247.1 and 255.3 pm). The C–B1 bonds in the ring are comparable in length (151.5 and 152.5 pm) to those in **1a** (150.5 pm); the remaining bond lengths in the ring cannot be discussed because of the observed disorder.

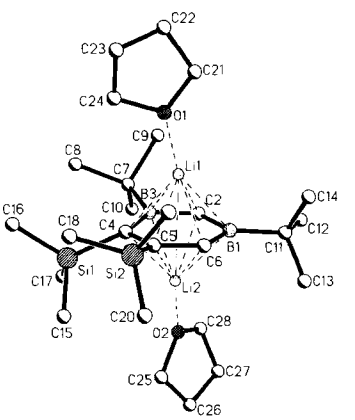

Fig. 1. Crystal structure of **3a**. Selected distances which that are not affected by the disorder of Si2 and C7 [pm] and angles [°]: B1–C2 152.5(6), B1–C6 151.5(6), Li1–B1 232.9(8), Li2–B1 227.7(8), Li1–C2 222.1(8), Li2–C2 223.7(8), Li1–C6 221.9(8), Li2–C6 221.9(8), Li1–C4 233.6(8), Li2–C4 218.6(8); C2-B3-C7 110.9(3), C7-B3-C4 125.3(3), C6-C5-Si2 109.9(3), Si2-C5-C4 127.0(3); C7-B3-C4-Si1 37.0(5), Si1-C4-C5-Si2 −38.9(5).

The signals in the ^{11}B NMR spectrum of **3a** (Table 1, $\delta = 40$ and 46) are in the range characteristic for tricoordinate boron atoms bearing negative π charge[8] (cf., $\delta = 37.5$ in **8**[9]). The

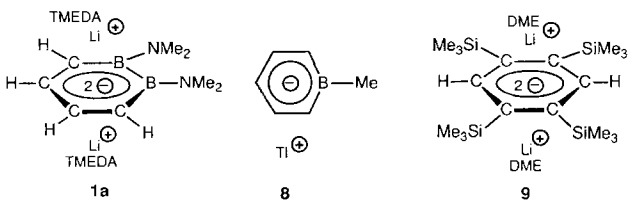
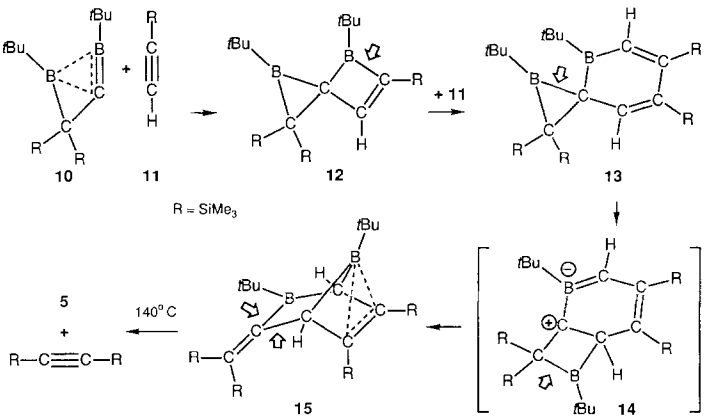
Table 1. Selected physical data for **3a**, **5**, **12**, **13**, and **15**.

3a: colorless crystals, m.p. 179–183 °C, yield: quantitative by NMR spectroscopy, isolated 60%. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.48, 0.57 (2 × s, each 9H, $SiMe_3$), 1.46, 1.58 (2 × s, each 9H, *t*Bu), 6.51, 6.95 (2 × s, each 1H, BCH); ^{1}H NMR (500 MHz, $CDCl_3$, −30 °C): δ = 0.20, 0.21 (2 × s, each 9H, $SiMe_3$), 0.95, 1.05 (2 × s, each 9H, *t*Bu), 5.88, 6.57 (2 × s, each 1H, BCH); ^{13}C NMR (75 MHz, C_6D_6, 25 °C): δ = 4.8, 8.3 (2 × q, each 3C, $SiMe_3$), 32.8, 35.1 (2 × q, each 3C, *t*Bu), 115.9 (br.d, 1C, B_2CH, ^1J(C,H) = 120 Hz), 118.0 (br.s, 1C, SiCB), 123.8 (br.d, 1C, BCH, ^1J(C,H) = 136 Hz), 160.9 (s, 1C, CSi); ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): δ = 4.0, 7.4 (each 3C, $SiMe_3$), 20.8, 24.4 (each 1C, CMe_3), 32.0, 34.2 (each 3C, *t*Bu), 114.1 (br., 1C, B_2CH), 117.0 (1C, SiCB), 122.8 (1C, BCH), 160.2 (1C, CSi); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 40, 46.



5: yellow crystals, m.p. 138 °C, quantitative yield. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.35 (s, 18H, $SiMe_3$), 0.72, 1.11 (2 × s, each 9H, *t*Bu), 4.67 (s, 2H, CHB); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 1.3 (q, 6C, $SiMe_3$), 31.1, 33.3 (2 × q, each 3C, *t*Bu), 95.3 (br.d, 2C, CHB, ^1J(C,H) = 159 Hz), 115.4 (s, 2C, CSi); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = −42, 28.

12: yellow oil, quantitative yield by NMR spectroscopy. ^{1}H NMR (400 MHz, $CDCl_3$, −40 °C): δ = 0.05, 0.07, 0.14 (3 × s, each 9H, $SiMe_3$), 0.94, 1.10 (2 × s, each 9H, *t*Bu), 7.42 (s, 1H, sp^2-CH); ^{13}C NMR (100 MHz, $CDCl_3$, −30 °C): δ = −0.2, 2.4, 3.7 (3 × q, each 3C, $SiMe_3$), 20.4, 23.5 (2 × br.s, each 1C, CMe_3), 27.8, 30.1 (2 × q, each 3C, *t*Bu), 29.4 (s, 1C, CSi_2), 53.6 (br.s, 1C, CB_2), 153.3 (d, 1C, CH of the four-membered ring, ^1J(C,H) = 168 Hz), 185.7 (s, 1C, CSi of the four-membered ring); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 45, ca. 80.



13: ^{1}H NMR (400 MHz, $CDCl_3$, 5 °C): δ = 0.09, 0.21, 0.31, 0.32 (4 × s, each 9H, $SiMe_3$), 0.92, 1.00 (2 × s, each 9H, *t*Bu), 6.40, 7.31 (2 × s, each 1H, sp^2-CH); ^{13}C NMR (100 MHz, $CDCl_3$, 0 °C): δ = 2.0, 2.2, 5.5, 5.8 (each 3C, $SiMe_3$), 30.3, 30.35 (each 3C, *t*Bu), 41.4 (1C, CSi_2), 65.7 (br., 1C, CB_2), 137.3, 155.3 (each 1C, sp^2-CSi), 145.6, 146.5 (each 1C, sp^2-CH); ^{11}B NMR (96 MHz, pentane, 25 °C): δ = 70, 79.

15: yellow crystals, m.p. 120 °C (transformation into **5**), 90% yield. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.00, 0.26, 0.32, 0.36 (4 × s, each 9H, $SiMe_3$), 0.83, 1.12 (2 × s, each 9H, *t*Bu), 3.00, 3.56 (2 × s, each 1H, BCH); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 1.4, 1.7, 2.7, 3.2 (4 × q, each 3C, $SiMe_3$), ca. 15, ca. 25 (2 × very br.s, each 1C, CMe_3), 30.4, 31.8 (2 × q, each 3C, *t*Bu), 53.7, 60.1 (2 × br.d, each 1C, CHB, ^1J(C,H) = 146 and 145 Hz, respectively); 135.2 (s, 1C, CSi_2), 145.8, 149.1 (2 × br.s, each 1C, sp^2-CSi), 181.4 (very br.s, 1C, sp^2-CB); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = −9, 67.

ring carbon atoms in **3a** (δ(^{13}C, 125 MHz, −30 °C) = 114.1 (C2), 117.0 (C6), 122.8 (C4), and 160.2 (C5)) are more strongly deshielded than in **1a** (δ(^{13}C) = 104.6 and 108.5); in the latter, less negative charge can be taken by the boron atoms because of the amino substituents. The position of the signal in the ^{7}Li NMR spectrum of **3a** (δ = −5.8) is comparable to that in the spectrum of the 6π arene cyclopentadienyllithium (δ(^{6}Li) = −6.3;[10] cf., however, δ(^{7}Li) = +10.7 for the 8π-electron system **9**[11], DME = 1,2-dimethoxyethane). Even after addition of [12]crown-4, the contact ion pair in **3a** is not disrupted (δ(^{7}Li) = −5.2).

The carborane **5** was obtained as follows: Reaction of the methyleneborane **10**[12] with trimethylsilylacetylene **11** yielded the bicyclic compound **15**. The diboraspiro compounds **12** and **13**[13] were unambiguously characterized as intermediates by NMR spectroscopy in solution (the bonds that are broken are designated with an arrow in each case). The spontaneous transformation of **13** into **15** probably occurs via the σ complex **14** resulting from an intramolecular electrophilic substitution of **13**.[14] After the opening of the Si_2C–B bond in **14**, attack of the

exocyclic boron atom at the sp^2 carbon atom bearing a hydrogen atom produces **15**.

The crystal structure (Fig. 2) shows **15** to have the rare[15, 16] dihomoborirene structure; this can also be deduced from the

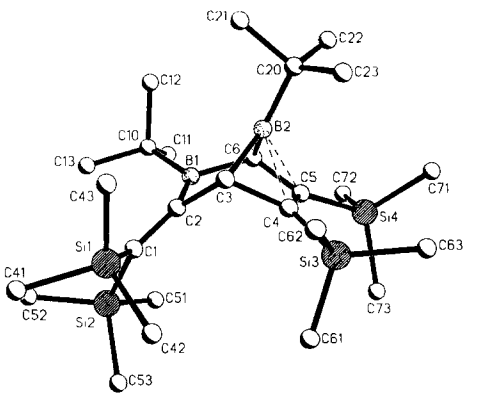


Fig. 2. Crystal structure of **15**. Selected distances [pm] and angles [°]: C1–C2 136.3(7), B1–C2 152.0(8), B1–C6 159.7(8), B2–C4 187.2(9), B2–C5 188.0(9), C4–C5 137.5(7); B1-C2-C1 134.0(6), C1-C2-C3 125.2(5), B1-C2-C3 100.7(5), C2-B1-C6 109.5(5), B2-C3-C4 72.8(4), B2-C6-C5 72.7(4), B2-C3-C2 112.4(5), B2-C6-B1 98.8(5), C4-C5-Si4 130.8(5), C5-C4-Si3 132.0(4); Si3-C4-C5-Si4 0.4(9), C3-C2-C1-Si1 19.5(8), C3-C2-C1-Si2 −150.1(5), B1-C2-C1-Si1 −157.3(5), B1-C2-C1-Si2 33.1(9)

shielding of the boron atom (δ(^{11}B) = −9) interacting with the SiC–CSi double bond. When heated to 140 °C, **15** was transformed quantitatively to **5** with elimination of bis(trimethylsilyl)acetylene. The structure of **5** follows from the positions of the signals in its ^{11}B NMR spectrum (δ = 28 and −42), which are characteristic for tetracarbahexaboranes.[17]

[7] Crystal structure analyses: colorless crystals of **3a** and **15** were investigated on a four-circle diffractometer (CAD4, Enraf-Nonius) at −80 °C with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). **3a**: $C_{18}H_{38}B_2Li_2Si_2 \cdot 2THF$, crystal dimensions $0.6 \times 0.3 \times 0.2$ mm³, monoclinic, space group $P2_1/c$, $Z = 4$, $a = 972.2(2)$, $b = 1173.5(2)$, $c = 2890.7(6)$ pm, $\beta = 98.45(3)°$, $V_{EZ} = 3262.1 \times 10^{-30}$ m³, $\rho_{calcd} = 0.998$ g cm⁻³; 3994 measured reflections in the range up to $2\theta = 110°$ (ω scans), 3903 of which were independent and were used for the further calculations after Lorentz and polarization correction; no absorption correction ($\mu = 11.0$ cm⁻¹). The structure was solved by direct methods and refined against the F_o^2 data with full matrix. A disorder showing up in the difference Fourier syntheses was accounted for by a "split atom model" where a C5–$SiMe_3$ group superposes the B3–*t*Bu unit at B3 and, vice versa, a B3–*t*Bu group superposes the C5–$SiMe_3$ unit at C5. Due to these superpositions, geometric restraints of the B–C (160 pm) and Si–C (187 pm) bond length were used during refinement, and the temperature factors of atoms approaching each other were defined to be equal. In this way good convergence and a maximal residual electron density 0.35 e Å⁻³ were achieved. The distribution of the alternative arrangements of the molecules was determined to be 59.3(4) and 40.7%. The H atoms were localized in part by difference Fourier syntheses; the others were calculated; they were included in the calculation riding on their bonding partners and with isotropic temperature factors common by groups. Anisotropic temperature factors were used for all the remaining atoms except C7; $wR_2 = 0.2066$ (SHELX 93 program), corresponding to $R = 0.069$ for 2951 reflections with $F_o > 4\sigma(F_o)$, maximal residual electron density 0.33 e Å⁻³. - **15**: $C_{26}H_{56}B_2Si_4$, crystal dimensions $0.7 \times 0.3 \times 0.2$ mm³, monoclinic, space group $P2_1/n$, $Z = 4$, $a = 928.9(2)$, $b = 1655.2(3)$, $c = 2154.4(4)$ pm, $\beta = 92.80(3)°$, $V_{EZ} = 3308.5 \times 10^{-30}$ m³, $\rho_{calcd} = 1.009$ g cm⁻³; 4461 reflections in the range up to $2\theta = 110°$ (ω scans), 4157 of which were independent. 4154 reflections were used for further calculations after Lorentz and polarization correction; the structure solution and refinement as for **3a** led to $wR_2 = 0.1955$, corresponding to $R = 0.064$ for 2123 reflections with $F_o > 4\sigma(F_o)$, and a maximal residual electron density of 0.34 e Å⁻³. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-58435.

[13] In **13**, the trimethylsilyl groups are bound to neighboring carbon atoms as in **15**. This can be deduced from long range coupling constants $^3J(^{13}C,H)$ of 9 and 11 Hz for the sp^2-C atoms in **13** that bear no protons. The 1,3-arrangement of the $SiMe_3$ groups has been established by a crystal structure analysis for a derivative of **13** with duryl groups instead of *tert*-butyl groups [14].

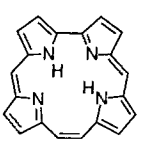
Corrphycene: A New Porphyrin Isomer**



Jonathan L. Sessler,* Eric A. Brucker, Steven J. Weghorn, Michael Kisters, Martin Schäfer, Johann Lex, and Emanuel Vogel*

Dedicated to Sir Derek Barton on the occasion of his 75th birthday

The porphyrins, represented by the general structure **1**, [18]-porphyrin-(1.1.1.1),[1] have developed into a subject of interdisciplinary research par excellence, in part because of their importance in the fields of chemistry, biology, and medicine. Indeed, the perennial interest engendered by these tetrapyrrolic macrocycles had already, in the 1960s, inspired Woodward[2] and Johnson[3] to expand the scope of porphyrin chemistry through the design and synthesis of structural variants of porphyrins (e.g., sapphyrins and corroles). In pursuing this goal, they were guided by the [18]annulene model of the porphyrin electronic structure, a model which emphasizes the presence of an 18 π electron conjugation pathway in the molecule. During the last few years, thanks in large measure to progress in preparative methods—biomimetic cyclizations,[4] reductive couplings[5] (McMurry Reaction) etc.—the number of new porphyrinoid macrocycles, from which a variety of practical applications might be expected, has increased dramatically.

1

2

3

In spite of the above interest, the simple concept of reorganizing the basic building blocks of the porphyrins—four pyrrole moieties and four methine units—to form tetrapyrrolic structural isomers of porphyrin was first realized only in 1986 with the synthesis of the porphycene **2**[6]—[18]porphyrin-(2.0.2.0). Since **2** was shown by a wide range of spectroscopic, structural, and metal complexation studies to have a porphyrinoid nature,[7] the question inevitably arose as to whether other isomers of porphyrin might also exist. A theoretical analysis based on electronic structure of all conceivable isomers containing an N_4 coordination site and [18]annulene conjugation, carried out by Waluk and Michl in 1991,[8] gave credence to the supposition that porphyrin isomers other than **2** might also prove to be porphyrin-like. In fact, a close correspondence between many of these putative structures and the known isomers **1** and **2** was implied, particularly in the case of [18]porphyrin-(2.1.0.1)[9] (**3**) and [18]porphyrin-(2.1.1.0).[10–12] According to later semiempirical calculations (carried out with the MOPAC series of

[**] This work was supported by the National Science Foundation (Grant CHE 9122161), the Alexander von Humboldt Foundation (J. L. S.) and the Deutsche Forschungsgemeinschaft (E. V.). The authors thank Dr. N. Jux, Dr. L. Neumann, and Mr. R. Deponte for useful advice concerning some aspects of the corrphycene synthesis.

programs[13]), both of these isomers have a planar ring framework and are only slightly strained. In the case of isomer **3**, these theoretical predictions have been confirmed by experiment; this was done by the synthesis and subsequent study of its tetramethyl-tetraethyl ("etio") derivative **9**. Because compound **9** (and its parent system **3**) combines structural elements of both corrole (direct bipyrrolic linkage) and porphycene (acene fragment C···CH···CH=C) within the same overall framework, the trivial name corrphycene is suggested for this new class of porphyrin-like tetrapyrrolic macrocycles.

The choice of **9** as the target molecule instead of the presumably more soluble octaethyl derivative was prompted by a desire to minimize the steric interactions arising from the inner alkyl groups of the bipyrrole unit, since such interactions could, it was thought, lead to noticeable deformations of the ring framework.[6d] On a different level, in planning an approach to the synthesis of **9** (Scheme 1), it was helpful to realize that the decisive synthetic step, one analogous to the reductive coupling of the bipyrrole dialdehyde with titanium tetrachloride/zinc used in the synthesis of porphycene,[6a] might best proceed via an as yet unknown open-chain, diformyl tetrapyrrolic intermediate. Thus, in terms of strategy, the synthesis of **9** would consist of first preparing the α,ω-dialdehyde **8**, and then coupling it under reductive conditions to generate a tetrahydrocorrphycene intermediate. This latter species, in accord with what is observed in the case of the porphyrinogens, would be expected to undergo facile oxidation to give the corresponding aromatic species **9**.

Scheme 1. The reaction **4** + **5** → **6**: *p*-Toluenesulfonic acid monohydrate, isopropanol, reflux, 10 h (55%); **6** → **7**: H_2, Pd/C, THF, triethylamine, 3 h (dicarboxylic acid not isolated); **7** → **8**: $HC(OEt)_3$, trifluoroacetic acid, −20 °C, 30 min (**6** → **8**: 85%); **8** → **9**: a) Zn/CuCl, $TiCl_4$, THF, 0 °C, 30 min; b) $FeCl_3$, 2 h (3%).

The known tetrapyrrolic α,ω-dibenzyl ester **6**,[14] available from the *para*-toluenesulfonic acid catalyzed condensation of the α-unsubstituted bipyrrole **4** with the acetoxymethyl-activated pyrrole **5**, was used for the preparation of **8**. Debenzylation to the diacid **7** was achieved by treating **6** with hydrogen in the presence of 10% palladium on charcoal in tetrahydrofuran. After removal of the solvent, intermediate **7** was subjected to a Clezy formylation[15] (triethyl orthoformate and trifluoroacetic acid) at −20 °C. In this transformation the product (dialdehyde **8**) was isolated as an amorphous, blue solid (yield 85%) by the slow addition of a 2:1 mixture of water and acetone to the reaction medium. Since this compound was pure (as judged by ^{1}H NMR spectroscopy), a recrystallization step (which might have led to a reduction in yield, Table 1) was not employed. Rather, intermediate **8** was carried on directly to the final reductive coupling step. Here, the best results were achieved if the reaction was not conducted under the usual conditions for porphycene synthesis (THF at reflux), but rather at 0 °C in THF followed by treatment with aqueous $FeCl_3$ solution to complete the necessary tetrahydrocorrphycene-to-corrphycene oxidation process. After chromatographic purification on silica gel with a mixture of dichloromethane and toluene (1/1) saturated with NH_3 as the eluent and subsequent recrystallization from dichloromethane/hexanes (1/1), **9** was finally obtained as fine violet needles with a melting point of 270–272 °C (yield 3%).

Table 1. Selected physical data for the new compounds. ^{1}H NMR: 300 MHz, $CDCl_3$; ^{13}C NMR: 75.5 MHz, $CDCl_3$; IR: CsI; MS: EI, 70 eV.

8: M.p. 188–190 °C (crude product); ^{1}H NMR: δ = 11.19 (br. s; NH), 10.29 (br. s; NH), 8.49 (s; CHO), 3.80, 2.53, 2.46, 2.02, 1.99, 1.15, 1.05; ^{13}C NMR: δ = 175.56, 138.40, 132.79, 128.50, 124.41, 122.03, 121.69, 121.13, 113.98, 22.35, 18.05, 17.02, 16.02, 15.46, 10.75, 8.70; IR: $\tilde{\nu}$ = 3300, 2962, 2928, 1617, 1560, 1498, 1377, 1309, 1276, 1154, 1116, 1085, 1062 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 272 (24400), 308 (32200), 589 nm (2200); MS: *m/z* (%): 514 (100) [M^+]; high-resolution MS (FAB): $C_{32}H_{42}N_4O_2$, calcd 514.330777, found 514.328389.

9: M.p. 270–272 °C (dichloromethane/hexanes); ^{1}H NMR: δ = 9.89 (s, 2H; H-9,20), 9.87 (s, 2H; H-14,15), 3.98 (q, 4H; H-11a,18a), 3.95 (q, 4H; H-2a,7a), 3.63 (s, 6H; H-3a,6a), 3.53 (s, 6H; H-12a,17a), 1.81 (t, 6H; H-2b,7b), 1.80 (t, 6H; H-11b,18b), −2.08 (br. s, 2H; NH); ^{13}C NMR: δ = 145.15, 144.62, 142.57, 142.11, 140.01, 139.19, 135.54, 129.26, 109.39, 102.68, 20.92, 20.60, 18.61, 18.48, 15.58, 12.80; IR: $\tilde{\nu}$ = 3274, 2961, 2929, 2867, 1594, 1467, 1448, 1207, 1057, 995, 847, 762 cm^{-1}; UV/Vis (benzene): λ_{max} (ε) = 415 (139400), 511 (13700), 540 (3800), 577 (5600), 584 (4300), 632 nm (1900); MS: *m/z* (%): 478 (100) [M^+], 239 (21) [M^{2+}]; high-resolution MS (FAB): $C_{32}H_{39}N_4$ [$(M+H)^+$], calcd 479.317473, found 479.319015; correct elemental analysis.

11: M.p. 283–285 °C (dichloromethane/hexanes); ^{1}H NMR: δ = 9.65 (s, 2H; H-9,20), 9.54 (s, 2H; H-14,15), 3.88 (q, 4H; H-11a,18a), 3.80 (q, 4H; H-2a,7a), 3.51 (s, 6H; H-3a,6a), 3.43 (s, 6H; H-12a,17a), 1.72 (t, 6H; H-11b,18b), 1.51 (t, 6H; H-2b,7b); ^{13}C NMR: δ = 150.27, 144.52 143.44, 143.24, 141.26, 137.43, 134.46, 129.19, 106.41, 100.06, 20.33, 19.52, 17.98, 17.78, 14.34, 12.61; IR: $\tilde{\nu}$ = 2959, 2927, 2866, 1734, 1465, 1445, 1282, 1258, 1154, 1132, 1121, 1057, 879, 797 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 251 (15300), 277 (9700), 330 (8600), 396 (106400), 434 (31200), 455 (20100), 547 (6400), 619 nm (5200); MS: *m/z* (%): 534 (100) [M^+], 267 (23) [M^{2+}]; high-resolution MS (FAB): $C_{32}H_{36}N_4Ni$, calcd 534.229345, found 534.228709; correct elemental analysis.

The spectra provide strong evidence that the corrphycene **9** is in fact a bona fide aromatic porphyrinoid compound. The chemical shifts observed in the room temperature ^{1}H NMR spectrum (300 MHz, $CDCl_3$), for instance, correspond fully to those expected for a porphyrin-like system; the protons of the C_{20} perimeter resonate at relatively low field (two singlets, relative intensity 1:1 at δ = 9.89 and 9.87), while those of the interior (that is, N-bound pyrrolic) protons appear at relatively high field (broad singlet at δ = −2.08) (Fig. 1). Remarkably, the signals of the perimeter protons of **9**, etioporphyrin I (**1a**), and also etioporphycene (**2a**)[6d] resonate at almost the same frequency (δ = 10.08 and 9.52, for the latter two systems, respectively). Further, the simplicity of the ^{1}H NMR spectrum for **9** implies a formal equivalence of the two halves of the molecule (effective C_{2v}, C_s, or C_2 molecular symmetry; that is, frameworks that are planar, bowl-shaped, or twisted, respectively). This equivalence can be explained as follows: Either the molecule is a corrphycene tautomer with symmetrically arranged imino protons, or it is the actual species **9** with N-bound protons that undergo rapid tautomerization on the NMR time scale. The observation that the NH signal is split into two signals of equal intensity at lower temperatures leads us to favor the latter

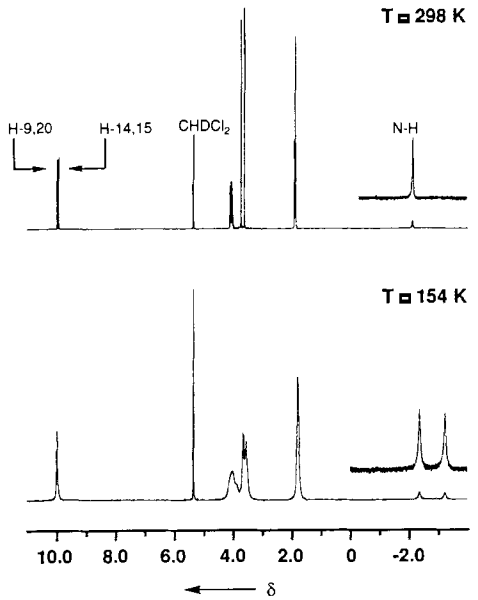

Fig. 1. ^{1}H NMR spectra (300 MHz; CD_2Cl_2/CF_2Br_2 with the addition of Al_2O_3 to guarantee anhydrous conditions) of **9** at 298 K (top) and 154 K (bottom).

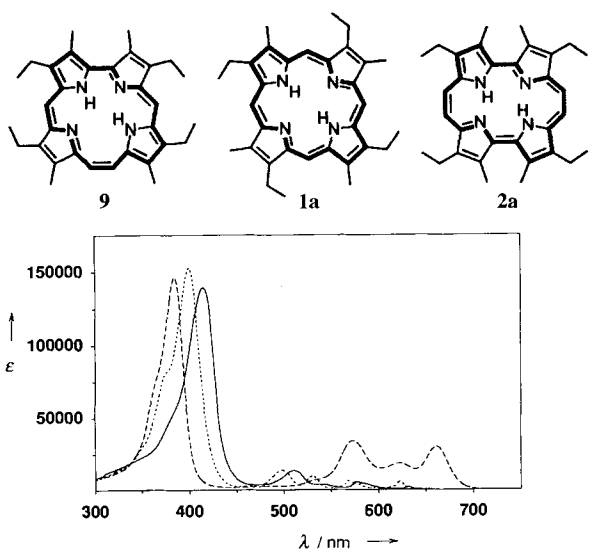
assignment. From the coalescence temperature of the NH signals (185 K) a free energy of activation $\Delta G^{\neq}$ of 8.3 kcal mol^{-1} can be calculated (corresponding values for porphyrins are on the order of 10–15 kcal mol^{-1}[16b]). The ^{13}C NMR spectrum (75.5 MHz, $CDCl_3$) at room temperature is consistent with the ^{1}H NMR spectrum in terms of the symmetry of **9**. However, solubility problems and other dynamic processes involving the alkyl groups preclude a more detailed interpretation of the low-temperature ^{13}C NMR spectrum. Thus, the tentative conclusion of a planar or near-planar overall ring structure for **9** rests at present only on its ^{1}H NMR spectrum, specifically the chemical shift values recorded for the perimeter and N-bound protons.[17]

The UV/Vis spectrum (benzene) of **9** (Fig. 2) reveals a pronounced Soret-type band at $\lambda = 415$ nm ($\varepsilon = 139400$), that is slightly red-shifted relative to that of the corresponding etioporphyrin. It also reveals five Q-like transitions at $\lambda(\varepsilon) = 511$ (13700), 540 (3800), 577 (5600), 584 (4300), and 632 nm (1900).



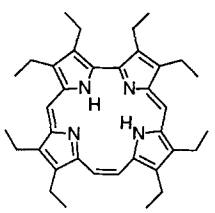


Fig. 2. UV/Vis spectra (benzene) of etiocorrphycene **9** (—), etioporphyrin I **1a** (·····) and etioporphycene **2a** (----) (in each case the 18π conjugation system appears in bold type).

In the IR spectrum of **9**, an N–H stretching vibration is found at 3274 cm^{-1}. The straightforward detection of this mode is in contrast to what is observed in the case of porphycenes; in these systems the relevant N–H strectching mode is IR-nonobservable due to the presence of strong internal N–H···N hydrogen bonds. However, the IR spectral behavior of corrphycene **9** is directly analogous to that of the porphyrins for which ν_{N-H} values on the order of 3300–3360 cm^{-1} are routinely recorded.[18]

The mass spectrum of **9** (EI, 70 eV) revealed the presence of the expected molecular ion (m/z 478) as the base peak, as well as a further prominent peak corresponding to the doubly charged molecular ion (m/z 239, 23%).

Crystal disorder precluded a direct X-ray structure analysis of **9**. Fortunately, however, these problems of crystal disorder were not observed in the case of the octaethylcorrphycene analogue **10**, a compound obtained by a synthesis similar to that described above[19] (Fig 3). In the solid state, octaethylcorrphycene[20] **10** has an approximate C_2 molecular symmetry, that stems, in part, from the conformations of the ethyl groups. The ring framework of **10** is nearly planar (the maximum deviation of the C and N atoms from the mean plane of the ring is ±0.082 Å), in line with the theoretical predictions for that of parent **3**. The planarity of the former compound was observed in spite of possible destabilizing van der Waals repulsions that might have arisen from the ethyl groups in the 3 and 6 positions. However, as is true for octaethylporphycene,[6d] these ethyl groups and the steric interactions they engender do cause a stretching of the C4–C5 bond (from 1.397 Å in porphycene[6a] to 1.423 Å in the present instance). They also induce a contraction of the N1-C4-C5 and C4-C5-N2 angles (to 114.0° compared to those in octaethylporphycene of 118.5°). As a consequence, the pyrrole rings affected are more precisely directed towards the center of the molecule in corrphycene than they are in porphycene. Actually, with regard to the C=CH–CH=C structural unit, there is a further noteworthy difference between **10** and the structurally characterized porphycenes. Specifically, relative to those of the porphycenes the C13-C14-C15 and C14-C15-C16 angles are widened by no less than 6–7° (to about 138°); nevertheless, compound **10**, like its porphycene analogues, exhibits equivalent bond lengths in this unit. Thus this bond equivalence feature may serve as a good criterion for judging aromaticity in these kinds of molecules.

10

The N-bound hydrogen atoms of **10** were localized unequivocally in the X-ray structure. These atoms were found together (that is, *cis* to one another) on the two pyrrole moieties of the bipyrrole unit. The X-ray diffraction analysis of **10** thus reveals a striking dichotomy between the NH tautomerism deduced in solution and the structure observed in the solid state (note: the room temperature and low temperature ^{1}H NMR spectra of **10** correspond to those of **9**). Nonetheless, the observed "*cis*"-like localization of the N-bound hydrogen atoms in the solid state agrees with the observed structural parameters for the pyrrole rings of the bipyrrole moiety as well as those of the other two pyrrolic entities in **10**, at least as compared to those of the corresponding subunits in porphyrins (pyrrole and pyrrolenine,

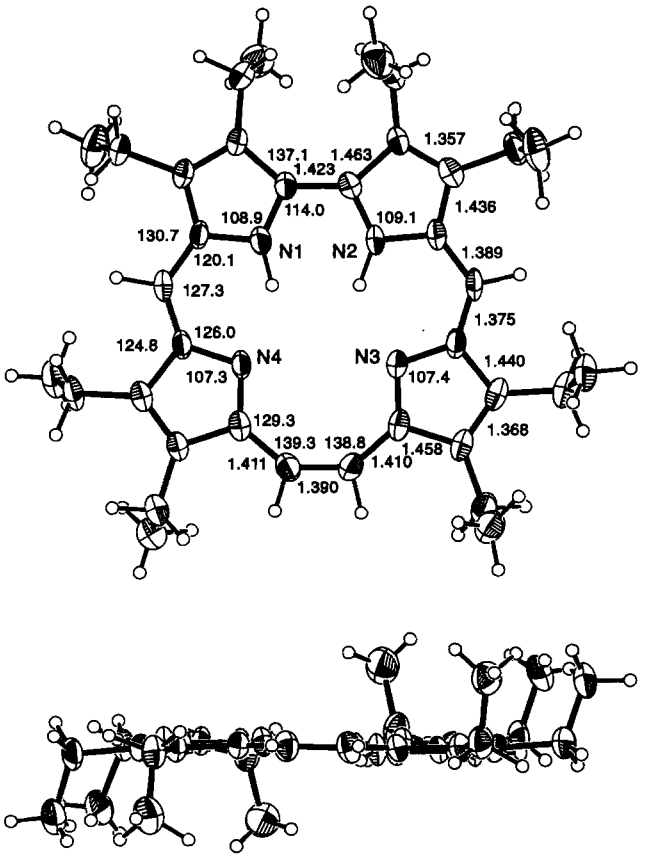

Fig. 3. Crystal structure of octaethylcorrphycene **10** (top: top view; bottom: side view). Ellipsoids are drawn at the 40% probability level. Selected bond lengths [Å] and angles [ ] (standard deviation approximately 0.006 Å and 0.3°): N1···N2 2.539 A, N1···N4 2.799 Å, N3···N4 3.447 Å.

respectively). Interestingly, while the four nitrogen atoms of the coordination core in porphyrin and porphycene form a square and a rectangle, respectively, their arrangement in **10** defines a well-characterized trapezoid. Thus, the strong internal N-H···N hydrogen bonds, typical for porphycenes, do not exist in **10**, because the N1–N4 and N2–N3 distances are relatively large.

In spite of seemingly unfavorable N_4 core geometry present in **10**, the corrphycenes act as astonishingly good porphyrin-like ligands. Indeed, corrphycenates of Ni^{II}, Cu^{II}, Zn^{II}, and Fe^{II} have already been isolated. For instance, heating **9** with nickel(II) acetate tetrahydrate in dimethylformamide produces the stable divalent nickel complex **11**, which, after conventional workup and recrystallization from dichloromethane/hexanes (1/1), is obtained as violet needles (m.p. 283–285 °C, yield 75%). The ^{1}H NMR and the UV/Vis spectra of **11** are modulated relative to those of the free ligand in ways that parallel the changes observed in the course of the same metalation process in porphyrins.

Currently work is focused on exploring further the coordination chemistry of corrphycene and on carrying out more detailed comparisons between this compound and its isomeric analogues, porphyrin, porphycene, and hemiporphycene.[10, 11] Research on the chemistry of porphyrin isomers has received an added stimulus from the recent papers of Furuta et al.[21] and Latos-Grażýnski et al.,[22] who described a new type of porphyrin isomer, the "inverted porphyrins", a class of molecules that is distinguished by its unusual metal coordination chemistry.[23] Indeed, this work, in conjunction with that reported here, leads us to suggest that the coordination chemistry of tetrapyrrolic aromatic macrocycles might well be richer than had been previously conceived.

Experimental Procedure

8: Owing to the photolability of intermediates, the reaction sequence **6** → **8** was carried out in light-protected glassware. Dibenzyl ester **6** [14] (7.25 g, 10 mmol) and 10% palladium on charcoal (3 g) were stirred in absolute tetrahydrofuran (750 mL) under a hydrogen atmosphere for 3 h. The catalyst was then filtered off, and the solvent removed under vacuum. The remaining solid, diacid **7**, was treated with triethyl orthoformate (33.5 mL, 0.2 mol), and the mixture cooled to −20 °C; to this stirred mixture was then added trifluoroacetic acid (50 mL, 0.65 mol) over a period of 15 min (here the reagent order could also be reversed). To complete the reaction, the mixture was stirred for a further 15 min at −20 °C and then 30 min at room temperature. All the operations described were carried out under an inert atmosphere (argon). Finally, the product was precipitated by addition over 30 min of a mixture of 300 mL water and 150 mL acetone. After filtration, washing with water, and drying, the dialdehyde **8** was obtained as an amorphous blue powder. M.p. 188–190 °C (crude product); yield 5.66 g (85%). Compound **8** so obtained is pure as judged by ^{1}H NMR spectroscopy, and was therefore used directly in the ensuing reductive coupling step.

9: Under argon, zinc dust (50.4 g, 0.8 mol) and copper(I) chloride (9.9 g, 0.1 mol) were added to 1.2 L of absolute tetrahydrofuran. Titanium tetrachloride (46.2 mL, 0.42 mol) was added dropwise, and the resulting mixture was heated at reflux for 1 h. Thereafter, it was cooled to 0 °C, and a solution, also at 0 °C, of **8** (3.08 g, 6 mmol) in tetrahydrofuran (1.5 L) was added over a period of 30 min. The solution was stirred for a further 5 min before being hydrolyzed by the addition of concentrated aqueous ammonia (0.5 L). The resulting organic phase was then washed with saturated sodium chloride solution until neutral. To complete the oxidation, this solution was then stirred for 2 h with a 5% aqueous iron(III) chloride solution (300 mL) and then worked up in the conventional manner. After chromatography on silica gel (column: 5 × 50 cm) with dichloromethane/toluene (1/1) as the eluent (the eluent was saturated with NH_3 gas to suppress the protonation of product on the column), **9** was obtained as a major mobile fraction. Recrystallization from dichloromethane/hexanes (1/1) provided etiocorrphycene as fine violet needles. M.p. 270–272 °C; yield 98.2 mg (3.0%).

11: Compound **9** (48 mg, 0.1 mmol) and nickel acetate tetrahydrate (90 mg, 0.5 mmol) were heated at reflux in dimethylformamide (10 mL) for 1 h. The solution was then treated with 100 mL dichloromethane, washed twice with water (2 × 100 mL), and worked up as usual. Chromatography on silica gel (column: 1 × 10 cm) with hexanes/dichloromethane (3/1) and recrystallization from dichloromethane/hexanes (1/1) yielded the nickel complex **11** as violet needles. M.p. 283–285 °C; yield 40 mg (75%). Stability (Buchler [24]). II.

[9] The numbering of the systematic name of **3** deviates from that used in the text. Systematic name for the given structure of **3**: 21,22,23,24-tetraazapentacyclo-[16.2.1.1^{2,5}.1^{7,10}.1^{13,16}]tetracosa-1(20),2(21),3,5,7,9,11,13(23),14,16,18-undecene.

[10] [18]Porphyrins-(2.1.1.0), in the form of the nickel complexes of two regioisomeric triphenylcarboxyethyl derivatives, were first obtained by H. J. Callot et al. They were isolated as unexpected rearrangement products from a demetalation–metalation sequence involving homoporphyrins. A free-base porphyrin-(2.1.1.0), liberated from the corresponding nickel complex by the addition of concentrated sulfuric acid, proved to be a porphyrin-like aromatic compound. The structure of [18]porphyrin-(2.1.1.0) is midway between that of **1** and **2**. This prompted the authors to propose the name "hemiporphycene" for this new porphyrin isomer: H. J. Callot, B. Metz, T. Tschamber (unpublished). We are very grateful to Professor Callot for allowing us to view a draft of his manuscript.

[11] The synthetic principle involved in the preparation of the isocorroles (E. Vogel, Y. Hellwig, B. Binsack, J. Lex, unpublished) and corrphycenes—reductive carbonyl coupling of the corresponding α,ω-dialdehydes—was successfully applied to the preparation of hemiporphycenes. Thus, the α,ω-dialdehyde **12**, obtained in crude form, was converted into the octaethylhemiporphycene **13**

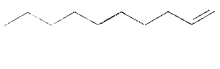
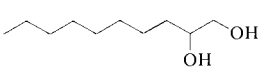
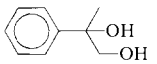
Practical and Rapid Vicinal Hydroxylation of Alkenes by Catalytic Ruthenium Tetraoxide**

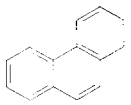
Tony K. M. Shing,* Vincent W.-F. Tai, and Eric K. W. Tam

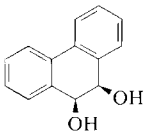
The use of ruthenium tetraoxide as an oxidant for organic functional group transformations has been well recognized.[1] In 1981, the Sharpless group reported[2] an improved procedure for the cleavage of alkenes and oxidation of a range of functional groups with a catalytic amount of ruthenium tetraoxide and a stoichiometric amount (>2 equiv) of sodium metaperiodate in a two-phase solvent system (CCl_4, CH_3CN,[3] H_2O in a ratio of 2:2:3). This experimental protocol has since been employed for the oxidative fission of alkenes[2, 4] and diols,[5] and for the oxidation of primary alcohols,[6] and phenyl,[2, 7] furan,[8] and thiophene[8a] rings to carboxylic acids, of ethers to esters,[2, 9] of acetylenes to 1,2-diketones,[10] and of cyclic sulfites to cyclic sulfates.[11] However, the dihydroxylation[12] of olefins with RuO_4 has not been achieved in acceptable yields.[13] As an extension of Sharpless's work, we report here the first practical and rapid synthesis of vicinal *cis*-diols from alkenes with catalytic RuO_4.

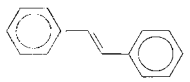


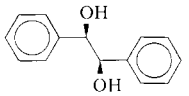


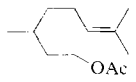


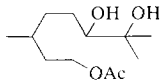


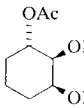


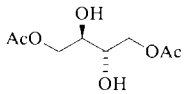


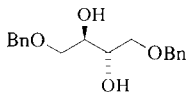


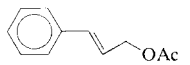


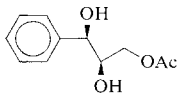


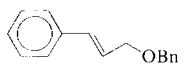


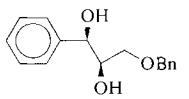


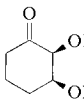


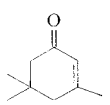


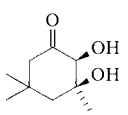


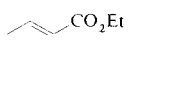


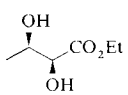


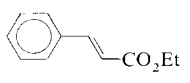


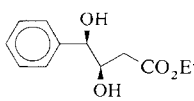












We found that when the reaction was conducted in a two-phase solvent system of ethyl acetate, acetonitrile, and water in a ratio of 3:3:1 in the presence of 0.07 molequiv of $RuCl_3 \cdot 3H_2O$ and 1.5 molequiv of $NaIO_4$ and at 0 °C, very rapid (within minutes) dihydroxylation of alkenes occurred in good yields. Our results shown in Table 1 indicate that this procedure works well with a wide range of alkenes. Simple olefins (entries 1–4) are particularly reactive, and the reactions were complete within 30 s. The C–C double bonds in allyl acetates and allyl benzyl ethers, as well as in α,β-unsaturated ketones and esters, all underwent facile *cis*-dihydroxylations within minutes. It appears that electron-withdrawing groups in conjugation with or adjacent to the C–C double bond tend to slow down the reaction a bit, but still these vicinal hydroxylations are very rapid and hence could be regarded as "flash dihydroxylations". It is noteworthy that the diastereoselectivity of the dihydroxylation of cyclohexenyl acetate (entry 8) was found to be roughly 10:1 in favor of the *anti* product. More examples of the diastereoselectivity of the flash dihydroxylation are being studied.

One limitation of this method is that if the resulting diol is highly soluble in water (entry 13), the yield of the reaction is poor, probably because of the concomitant oxidative cleavage

of the diol in the aqueous layer by $NaIO_4$. This is also reflected in the results in entries 15 and 16; the lower yield of the former case is believed to be due to the higher solubility of the resultant diol in water. We are currently investigating an alternative co-oxidant to substitute for $NaIO_4$.

Since RuO_4 is both less toxic and less expensive than OsO_4, the present flash *cis*-dihydroxylation protocol should become an attractive alternative for the syntheses of vicinal diols.

Experimental Procedure

To a vigorously stirred solution of the alkene (1.0 mmol) in EtOAc/CH_3CN (6 mL each) at 0 °C (ice bath) was added a solution of $RuCl_3 \cdot 3H_2O$ (0.07 mmol) and $NaIO_4$ (1.5 mmol) in distilled water (2 mL). The two-phase mixture was stirred vigorously for 3 min and quenched with a saturated aqueous solution of $Na_2S_2O_3$ (10 mL). The aqueous phase was separated and extracted with EtOAc (3 × 15 mL). The combined extracts were dried ($MgSO_4$) and filtered. Concentration of the filtrate followed by flash chromatography afforded the diol.

Self-Assembly of a Dimeric Porphyrin Host**

Christopher A. Hunter* and Luke D. Sarson

Biological receptors are often composed of multicomponent assemblies of flexible molecules which organize themselves into well-defined three-dimensional structures. The binding sites thus generated can show a very high substrate complementary.[1] Viruses are one of the most spectacular examples, where a single nucleic acid strand is recognized by an assembly of thousands of proteins.[2] The underlying principle, self-assem-

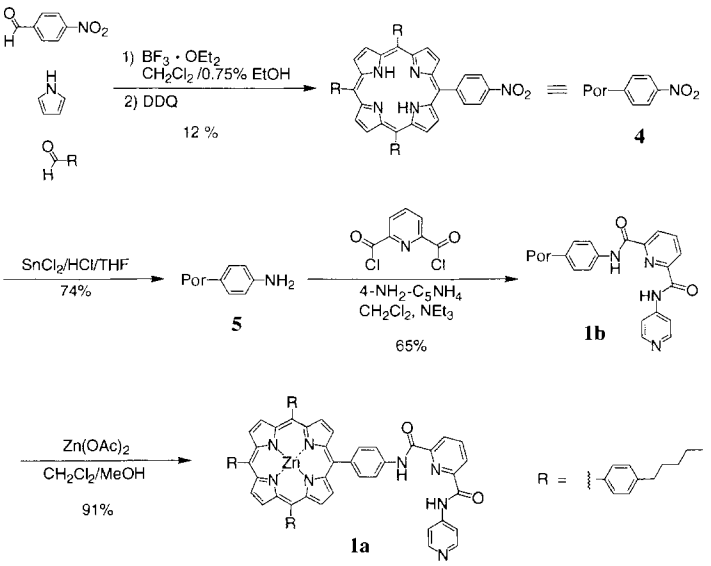
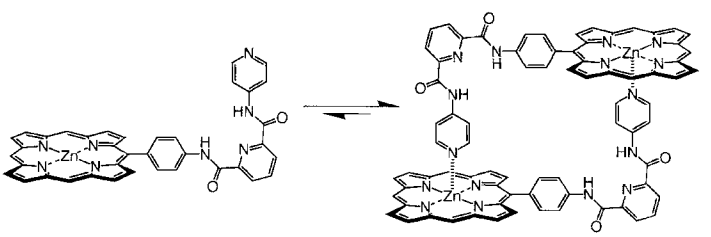
bly, has only recently begun to be exploited by chemists in the design of synthetic molecular receptors.[3] We describe here the use of metalloporphyrin coordination chemistry to direct the self-assembly of a very stable cyclic porphyrin dimer which recognizes derivatives of terephthalic acid through hydrogen-bonding interactions.

The coordination of a pyridine ligand to a zinc porphyrin is an ideal interaction for the study of noncovalent self-assembly.[4, 5] Since the association constant for the interaction is roughly $10^3\ M^{-1}$, the complexes are reasonably stable. Complexation can be detected by a range of spectroscopic techniques allowing self-assembly to be monitored across a wide range of concentrations. Finally, the properties of the assemblies can be readily tuned by chemical synthesis.[6]

The metal centers in zinc porphyrins such as **1a** and **2** are five-coordinate and can coordinate one pyridine ligand such as **3** perpendicular to the plane of the porphyrin. Therefore a self-assembled dimer can be generated if a pyridine ligand is covalently attached to a zinc porphyrin, oriented at 90° to the plane of the porphyrin. Molecular modeling suggested that this could be achieved by using a 2,6-pyridine-dicarboxamide to connect the porphyrin and the pyridine.[7] This linker has internal hydrogen bonds which reduce the 120° angle expected for *meta*-substituted arenes to approximately 96° (Scheme 1).[8]



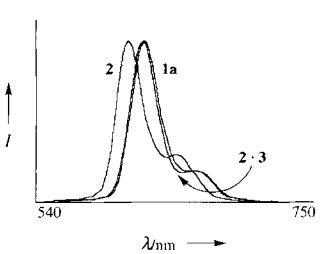


Scheme 1. The arms of a 2,6-pyridinedicarboxamide derivative are oriented approximately perpendicular to one another.

The synthesis of **1a** is outlined in Scheme 2. Results from a range of spectroscopic measurements all indicate that **1a** exists exclusively as a self-assembled dimer at concentrations between 10^{-7} and 10^{-2} M in chlorinated organic solvents at room temperature (Scheme 3). The ^{1}H NMR and UV/VIS absorption and emission spectra of **1a** are essentially concentration independent in this range and differ significantly from the corresponding spectra of **2** (see e.g. Fig. 1). The ^{1}H NMR signals due to the pyridine protons are shifted upfield, which suggests that they lie over the face of the porphyrin ring and are affected by the porphyrin ring current. The maxima in the UV/VIS absorption and emission maxima are both red-shifted. In fact, the spectra of **1a** closely resemble the spectra of the reference complex **2** · **3** (see e.g. Fig. 1), which implies that **1a** is fully bound across this concentration range. Vapor pressure osmometry gave an average molecular weight of 2233 ± 79 g mol^{-1} for **1a** in $CHCl_3$ solution at 37 °C. This corresponds to 1.98 ± 0.07 molecules of **1a** per assembly.[9]

Scheme 2. Synthesis of zinc porphyrin complex **1a**. DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

Scheme 3. Self-assembly of the dimer of **1a**. The 4-pentylphenyl substituents on the *meso* positions of the porphyrin are omitted for clarity.



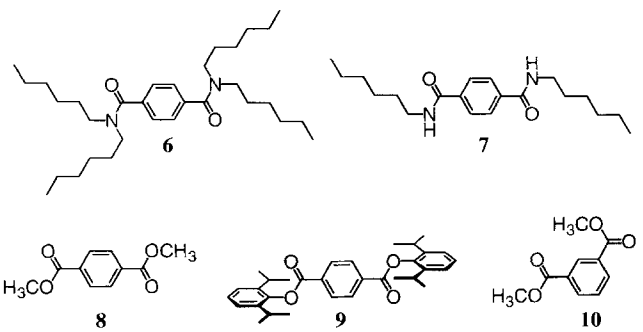


Fig. 1. UV/VIS emission spectra of **1a**, **2**, and the complex **2** · **3** (CH_2Cl_2, $c = 10^{-6}$ M).

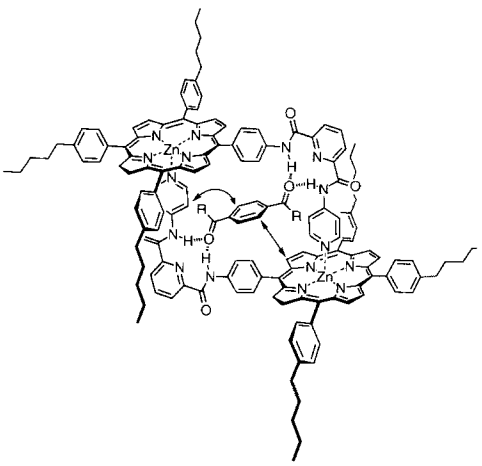
At concentrations below 10^{-7} M, the UV/VIS emission spectra of **1a** becomes concentration dependent, but at low concentrations the signals become less intense and disappear into the noise. The association constant is therefore difficult to determine with any degree of accuracy but is at least $10^8\ M^{-1}$ in CH_2Cl_2. This indicates a remarkable degree of cooperativity in the self-assembly process, given that the corresponding association constant for the reference complex **2** · **3** is $5.6 \times 10^3\ M^{-1}$ in CH_2Cl_2. The orientation of the two recognition sites and the rigidity of the linking group ensure that **1a** is almost perfectly self-complementary and so self-assembles very efficiently.

Self-assembly of the dimer of **1a** generates a macrocyclic complex containing a spacious cavity with inwardly directed hydrogen-bond recognition sites. The recognition properties of the dimer were investigated by ^{1}H NMR titration with substrates **6**–**10** in $CDCl_3$ (Table 1). The dimer of **1a** selectively



binds terephthalic acid derivatives that can form a hydrogen bond with each of the four amide groups directed into the cavity (Scheme 4). Amides **6** and **7** are bound more strongly than the ester **8**, possibly because of the greater basicity of the amide oxygens. Increasing steric bulk around the carbonyl group as in **9** inhibits complexation. Isophthalic acid derivatives such as **10** are bound only weakly, as the distance between the carbonyl groups is too short for the simultaneous formation of hydrogen bonds to the amide groups at both ends of the cavity. Complexation can be observed with the free base porphyrin **1b**, but the association constants are more than an order of magnitude less than those measured for **1a**.

Table 1. Association constants [M^{-1}] determined by titration in $CDCl_3$ followed by ^{1}H NMR spectroscopy. Errors are ±10%.

[a] Owing to the low solubility of 7 these association constants cannot be determined accurately.

The structure in Scheme 4 is supported by the observed complexation-induced changes in chemical shifts in the ^{1}H NMR spectra. The signals due to the amide protons in **1a** are shifted downfield on complexation, indicating that they are involved in hydrogen-bonding interactions with the carbonyl groups of the

Scheme 4. The dimer of **1a** recognizes terephthalic acid derivatives by hydrogen-bonding to the carbonyl oxygens. Intermolecular NOEs observed for the complex $(\mathbf{1a})_2 \cdot \mathbf{8}$ are indicated with arrows. R = $NH(CH_2)_5CH_3$.

guest. The signals of the guest are shifted upfield on complexation, suggesting that the guest molecule is positioned over the porphyrin plane and is affected by the porphyrin ring current. NOEs observed in a two-dimensional ^{1}H NMR NOESY spectrum confirm that the guests are complexed inside the cavity rather than on the outside face of one of the porphyrins (Scheme 4).

We have demonstrated a powerful new approach to the construction of functionalized macrocycles with cavities suitable for selective molecular recognition. Since the self-assembly is under thermodynamic control, the macrocyclization is quantitative, which offers significant advantages over the formation of macrocycles through covalent bonds.[1] Owing to the high degree of cooperativity between the interaction sites, **1a** exists as the fully assembled dimer at all concentrations examined. In addition, the rich photochemistry of the porphyrin units may confer interesting photochemical properties on such assemblies.

Experimental Procedure

4: 4-Nitrobenzaldehyde (4.97 g, 32.85 mmol) and 4-pentylbenzaldehyde (10.1 g, 57.2 mmol) were dissolved in 9 L of dry CH_2Cl_2 containing 58.5 mL of dry ethanol and freshly distilled pyrrole (6.25 mL, 90 mmol). The solution was purged with N_2 for 10 min. Then $BF_3 \cdot OEt_2$ (5.1 mL, 40.6 mmol) was added, and the solution was stirred for 90 min. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (20.5 g, 90 mmol) was added, and the solution was stirred for 90 min. NEt_3 (12.6 mL, 90 mmol) was added, and the solution was concentrated to dryness on a rotary evaporator. The resulting solid was placed on a glass sinter and washed with 20 L of CH_3OH. The porphyrin products were purified by repeated column chromatography (florisil then silica gel, $CHCl_3$/petroleum ether). Recrystallization from $CHCl_3/CH_3OH$ gave **4** as a purple solid. Yield 2.3 g (12%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.92 (2H, d), 8.88 (4H, s), 8.73 (2H, d), 8.63 (2H, d), 8.40 (2H, d), 8.12 (6H, d), 7.56 (6H, d), 2.96 (6H, t), 1.93 (6H, quint.), 1.54 (12H, m), 1.04 (9H, t), −2.75 (2H, s); FAB-MS: *m/z* 869 [M^+]. UV/VIS (CH_2Cl_2): λ_{max} [nm] = 421, 518, 554, 593, 649.

5: To a solution of **4** (0.63 g, 0.73 mmol) in 30 mL of THF was added $SnCl_2 \cdot 2H_2O$ (1.45 g, 6.5 mmol) in 25 mL of concd HCl. The mixture was vigorously stirred in a preheated oil bath (65–70 °C) and then cautiously made basic with concd NH_3. 100 mL of $CHCl_3$ was added, and the mixture was stirred for 30 min. The organic layer was put aside, and the aqueous layer was extracted into $CHCl_3$ three times. The combined organic phases were filtered, washed once with dilute NH_3, three times with H_2O, and concentrated to dryness (70 °C, 1 Torr). The residue was purified by column chromatography (silica gel, $CHCl_3$). Recrystallization from $CHCl_3/CH_3OH$ gave **5** as a purple solid. Yield 0.45 g (74%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.91 (2H, d), 8.87 (4H, s), 8.87 (2H, d), 8.11 (6H, d), 7.99 (2H, d), 7.53 (6H, d), 7.05 (2H, d), 2.95 (6H, t), 1.92 (6H, quint.), 1.53 (12H, m), 1.04 (9H, t), −2.75 (2H, s); FAB-MS: *m/z*: 840 [M^+]. UV/VIS (CH_2Cl_2): λ_{max} [nm] = 422, 519, 557, 594, 650.

1b: To a solution of **5** (94 mg, 0.112 mmol), 4-aminopyridine (242 mg, 2.58 mmol) and dry NEt_3 (0.38 mL, 2.73 mmol) in 100 mL of dry CH_2Cl_2 was added over

20 min a solution of pyridine-2,6-dicarbonyl dichloride (275 mg, 1.35 mmol) in 50 mL of dry CH_2Cl_2. After 20 h of stirring the mixture was washed with 1 M HCl twice, then 1 M KOH, and H_2O before it was dried over Na_2SO_4. Column chromatography (silica gel, CH_2Cl_2/CH_3OH) followed by recrystallization from $CHCl_3$/petroleum ether gave **1b** as a purple solid. Yield 77 mg (65%). ^1H NMR (400 MHz, $CDCl_3$): δ = 9.77 (1H, s), 9.70 (1H, s), 8.90 (2H, d), 8.88 (2H, d), 8.87 (4H, d), 8.69 (1H, d), 8.67 (2H, d), 8.60 (1H, d), 8.31 (2H, d), 8.28 (1H, t), 8.18 (2H, d), 8.12 (6H, d), 7.80 (2H, d), 7.56 (6H, d), 2.95 (6H, t), 1.93 (6H, quint.), 1.53 (12H, m), 1.02 (9H, t), −2.75 (2H, s). FAB-MS: *m/z* 1065.4 [M^+]. UV/VIS (CH_2Cl_2): λ_{max} [nm] = 421, 518, 554, 593, 649.

1a: A solution of **1b** (77 mg, 0.072 mmol) and $Zn(OAc)_2$ (135 mg, 0.616 mmol) in 10 mL of CH_2Cl_2/CH_3OH was stirred for 60 min. Column chromatography (basic alumina, CH_2Cl_2/CH_3OH) followed by recrystallization from CH_2Cl_2/petroleum ether gave **1a** as a purple solid. Yield 74 mg (91%). ^1H NMR (400 MHz, $CDCl_3$): δ = 9.28 (1H, s), 8.93 (2H, d), 8.88 (2H, d), 8.87 (2H, d), 8.78 (2H, d), 8.76 (1H, s), 8.45 (2H, d), 8.20 (2H, d), 8.19 (2H, br.), 8.18 (2H, d), 8.15 (1H, d), 8.05 (4H, d), 8.01 (1H, t), 7.57 (2H, d), 7.51 (4H, d), 5.97 (2H, d), 3.00 (2H, t), 2.93 (4H, t), 2.49 (2H, br.), 1.94 (2H, quint.), 1.92 (4H, quint.), 1.53 (12H, m), 1.04 (3H, t), 1.02 (6H, t). FAB-MS: *m/z* 1127 [M^+]. UV/VIS (CH_2Cl_2): λ_{max} [nm] = 431, 565, 606.

Synthesis and Structure of the First Stable Germaneselone**

Tsuyoshi Matsumoto, Norihiro Tokitoh, and Renji Okazaki*

Recently much attention has been paid to the chemistry of compounds containing multiple bonds with Group 14 elements.[1] Species with double bonds between germanium and Group 16 elements are congeners of carbonyl compounds and are of current interest because of their unusual structure and reactivity. We recently reported[2] the synthesis and crystal structure of the first germanethione Tbt(Tip)Ge=S (**1**), which is kinetically stabilized by virtue of the two sterically bulky protecting groups, namely, 2,4,6-tris[bis(trimethylsilyl)methyl]-phenyl (Tbt[3]) and 2,4,6-tris(isopropy)phenyl (Tip). In contrast to germanethiones, which have been reported in the literature,[4] very little is known about germaneselones (species containing a germanium–selenium double bond).[5] We report here on the synthesis, structure, and reactivity of the first stable diaryl germaneselone Tbt(Tip)Ge=Se (**4b**).

1,2,3,4,5-Tetraselenagermolanes (**2a**, Ar = Mes; **2b**, Ar = Tip)[6] were treated with 3 equiv of triphenylphosphine in hexane (Scheme 1). In the case of **2a**, only 1,3,2,4-diselenadigermetane **3**, a dimerization product of the intermediate Tbt(Mes)Ge=Se (**4a**), was obtained along with a quantitative amount of triphenylphosphine selenide. A similar dimerization reaction was also previously observed for mesityl-substituted germanethione Tbt(Mes)Ge=S.[7]

Scheme 1. a) hexane/Δ; b) dimerization.

By contrast, the reaction of **2b**, which bears bulkier groups on the germanium atom, gave a red solution. After filtration of precipitated triphenylphosphine selenide under argon, the red solution was concentrated to give almost pure germaneselone **4b** as red crystals. Germaneselone **4b** was extremely sensitive to oxygen and moisture, but it was thermally quite stable under inert atmosphere.

The X-ray structure analysis[8] of **4b** reveals that the two bulky groups effectively prevent the oligomerization of the germanium–selenium bond; **4b** is monomeric in the solid state (Fig. 1). The sum of the bond angles around the germanium atom is 359.3°; this indicates that a trigonal planar geometry is adopted by the Ge=Se unit. It is also notable that the Ge–Se bond length (2.180(2) Å) is approximately 10% less than that reported for typical Ge–Se single bonds;[6a, 9] this result agrees well with the calculated value.[10] There seems no significant conjugation between the two aryl groups and the Ge–Se double bond in the solid state: the dihedral angles between the aryl planes and the plane containing Ge(1), Se(1), C(1), and C(10) atoms are 38.85° for the Tbt group and 70.13° for the Tip group.

Germaneselone **4b** gave satisfactory spectral and analytical data. The ^{77}Se NMR spectrum shows one singlet (at δ = 940.6) at much lower field than is typical for compounds containing a Ge–Se single bond (e.g., the ^{77}Se NMR signal for $(H_3Ge)_2Se$ is observed at δ = −612 relative to $(H_3C)_2Se$).[11] On the other hand, most of dialkyl selenoketones give rise to signals in the range δ = 1600–2200.[12] Germaneselone **4b** shows a character-

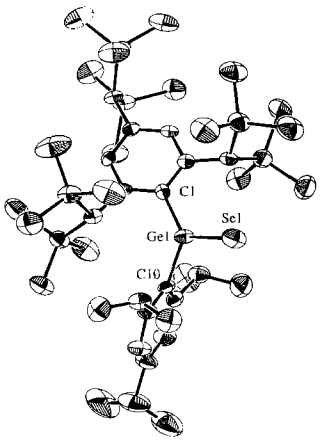
[**] This work was supported by the Ministry of Education, Science, and Culture, Japan (grant no. 05236102). We are grateful to Dr. Y. Furukawa, The University of Tokyo, and Mr. K. Kawauchi, JEOL, for the measurement of the FT Raman spectrum of **4b**. We also thank ASAI Germanium Research Institute, Shin-etsu, and Tosoh Akzo for the generous gifts of tetrachlorogermane, chlorosilanes, and alkyllithiums, respectively.



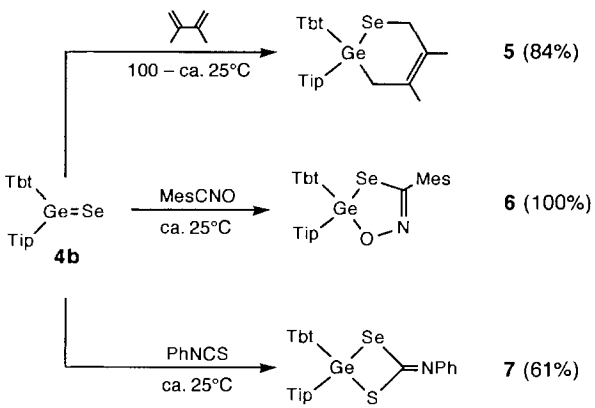


Fig. 1. ORTEP plot of the crystal structure of **4b** with thermal ellipsoids at the 30% probability level. Selected bond lengths [Å] and bond angles [°]: Ge1-Se1 2.180(2), Ge1-C1 1.932(9), Ge1-C10 1.945(9); Se1-Ge1-C1 126.4(3), Se1-Ge1-C10 113.8(3), C1-Ge1-C10 119.1(4).

istic strong Raman band at 382 cm^{-1} corresponding to the stretching frequency of the Ge=Se unit; the energy of this vibration is less than that for germanethione **1** (521 cm^{-1}). In the electronic spectrum, an absorption maximum attributed to the n–π* transition of the Ge=Se bond appears at 519 nm ($\varepsilon = 140$); this band is red-shifted compared to that in germanethione **1** (450 nm). A similar effect is observed in the corresponding carbon analogues (thioketone vs selenoketone).[13]

Reaction of **4b** with 2,3-dimethyl-1,3-butadiene in hexane in a sealed tube at 100 °C gave [4 + 2] cycloadduct **5** in 84% yield. Similarly, **4b** readily reacted with mesitonitrile oxide and phenyl isothiocyanate to produce [3 + 2] and [2 + 2] cycloadducts **6** and **7**, respectively. These results indicate that the germaneselone has double-bond character similar to that observed in its selenoketone carbon analogue.[13b, 14]

The thermal behavior of the [4 + 2] cycloadduct **5** should be noted: When a hexane solution of **5** was heated at 50 °C, the color of the solution changed from colorless to red. The fact that this change was reversible and that the thermally induced reaction (50 °C) of **5** in the presence of mesitonitrile oxide gave **6** (90%) shows that **5** undergoes facile retro-Diels–Alder reaction. Hence, **5** may be regarded as a useful, stable source of germaneselone **4b**.

Experimental Procedure

4b: An orange solution of **2b** (500 mg, 0.436 mmol) and triphenylphosphine (340 mg, 1.30 mmol) in hexane (3 mL) was refluxed for 2 h under an argon atmosphere. The solution turned red, and triphenylphosphine selenide was precipitated quantitatively with cooling to room temperature. After filtration of the selenide under argon, the residual red solution was concentrated in a glovebox filled with argon to give pure germaneselone **4b** (392 mg, 99% yield) as red crystals; m.p. 191–194 °C; ^{1}H NMR (500 MHz, C_6D_6, 27 °C, TMS): δ = 0.148 (s, 18H), 0.177 (s, 18H), 0.247 (s, 18H), 1.19 (d, ^3J(H,H) = 6.9 Hz, 6H), 1.34 (d, ^3J(H,H) = 6.9 Hz, 6H), 1.46 (d, ^3J(H,H) = 6.9 Hz, 6H), 1.49 (s, 1H), 2.73 (sept, ^3J(H,H) = 6.9 Hz, 1H), 3.40 (br.s, 1H), 3.41 (sept, ^3J(H,H) = 6.9 Hz, 2H), 3.79 (br.s, 1H), 6.51 (br.s, 1H), 6.68 (br.s, 1H), 7.05 (s, 2H); ^{13}C NMR (125 MHz, C_6D_6, 27 °C, TMS): δ = 1.11 (q), 1.37 (q), 1.67 (q), 22.28 (q), 24.09 (q × 2), 27.39 (d), 29.08 (br.d × 2), 31.83 (d), 34.83 (d), 36.52 (d), 122.64 (d × 2), 124.38 (d), 128.29 (d), 144.04 (s), 147.42 (s), 149.58 (s), 150.06 (s), 150.43 (s), 151.01 (s × 2), 152.08 (s); ^{77}Se NMR (51.5 MHz, C_6D_6, 27 °C, Me_2Se): δ = 940.6; FT Raman (solid, excitation with Nd-YAG laser, 1064 nm) 382 cm^{-1}. FAB-MS: *m/z* found: 908.3455; calcd: $C_{42}H_{83}{}^{74}GeSeSi_6$: 908.3409 ($[M + H]^+$).

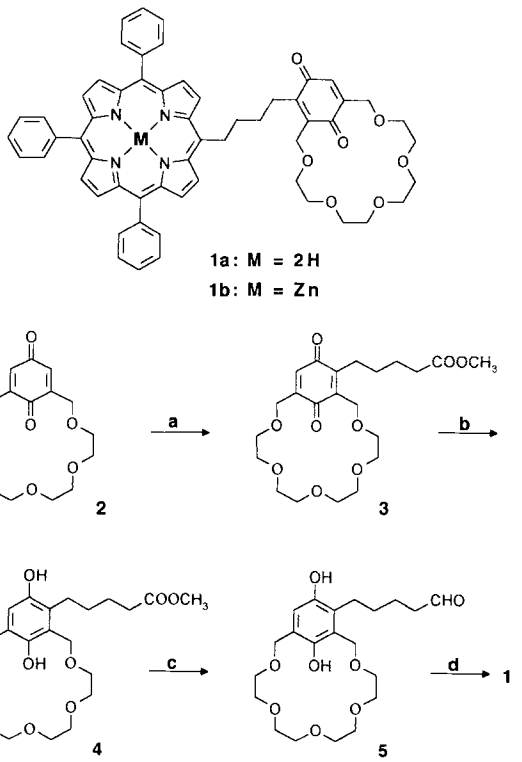
Biomimetic Model for a Photosynthetic Reaction Center: A Porphyrin with a Covalently Linked, Redox-Active Crown Ether**



Licheng Sun, Jörg von Gersdorff, Dominique Niethammer, Peizhu Tian, and Harry Kurreck*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

In the course of investigations into light-induced electron-transfer (ET) reactions occurring in the primary processes of photosynthesis, the fact that the high efficiency of charge separation depends on the structure and redox potential of the pigments and on their relative arrangement, with respect to each other and the surrounding protein matrix, has been intensively discussed.[1] Tailor-made porphyrins with covalently linked quinones (P-Q's) have been shown to be useful biomimetic models that allow a controlled variation in the parameters mentioned above.[1, 2] Attempts have recently been made to build noncovalent, supramolecular structures with stereochemically well-defined relationships between donor and acceptor, for example, by using the Watson/Crick base pairing concept.[3] Another approach employs crown ethers as photoactive macrocycles. J.-M. Lehn et al. demonstrated that irradiation of a Ag-ion-containing porphyrin–crown ether results in ET from the porphyrin to the Ag ion with subsequent ejection of elemental silver from the crown.[4] Dimerization and complexation of counterions in porphyrin–crown ethers have also been studied with optical and EPR spectroscopic methods.[5] The compounds in these studies were, however, not redox-active.

In order to be able to model two of the parameters that govern ET in P-Q's (the reduction potential of the quinone acceptor and the energy of reorganization[1]) on an otherwise unchanged substrate, we synthesized **1a**. Its acceptor fragment is similar to the recently published redox-active crown ether–quinone (CEQ).[6] The flexible $(CH_2)_4$ bridge in **1a** should allow the compound to adopt an energetically favorable and thus well-defined conformation in anisotropic media, such as, inverse micelles or liquid crystals. The role of the medium is to simulate the function of the protein matrix in the photosynthetic reaction center. The decisive steps in the synthesis are the C–C linkage of the tetramethylene fragment to the CEQ with oxidative decarboxylation (**2** → **3**),[7] the reduction of the hydroquinone ester to the aldehyde with diisobutyl aluminum hydride (DIBAL-H) (**4** → **5**),[8] and finally the formation of the porphyrin by the reaction of the aldehyde with benzaldehyde and pyrrole according to the reliable one-pot synthesis for *meso*-substituted porphyrins developed by Lindsey et al.[9] (**5** → **1a**, Scheme 1).[10]

From the literature data for the 2,6-dimethyl-substituted CEQ derivative of **2**, it was expected that the crown ethers of both the precursors and the target molecule **1a** would bind alkali metal ions such as Na^+. With EPR spectroscopy on the semiquinone derivative **1b**,[11] we were able to show that the coupling constants change relative to those in the uncomplexed crown ether after complexation with Na^+ ions. With the help of electron nuclear double resonance (ENDOR) spectroscopy, we were able to identify the Na ENDOR lines positioned around the free Na frequency as well as the proton ENDOR signals and the signs of the coupling constants (general TRIPLE resonance).[12] Figure 1 shows both ENDOR spectra.

Scheme 1. Synthesis of **1a**; reagents, conditions, and yields: a) HOOC-$(CH_2)_4COOCH_3$, $AgNO_3/(NH_4)_2S_2O_8$, CH_2Cl_2/H_2O, 25%. b) $Na_2S_2O_4$, $CHCl_3/H_2O$, room temperature, quantitative. c) 1. DIBAL-H, ether, −85 °C; 2. H_2O/SiO_2, 90%. d) 1. C_6H_5CHO, pyrrole, CH_2Cl_2, CF_3COOH, room temperature; 2. tetrachloro-*p*-benzoquinone, reflux, 2 h, 4%.

It is particularly interesting to compare the ^1H NMR spectra (500 MHz) of **1a** and **1b** (Fig. 2). Although there are almost no differences between the chemical shifts of the CEQ protons of, for example, **3** and **1a** (Fig. 2, top), the incorporation of Zn within **1a** (to form **1b**) gives rise to a significant upfield shift of the CEQ signals (Fig. 2, middle), despite the butylene spacer between the porphyrin and quinone moieties. This effect can only be explained by a folding of the CEQ towards the central Zn atom of the porphyrin, which brings the CEQ protons under the influence of the porphyrin ring current.[13] Molecular modeling calculations confirm a distinct energy minimum for the structure shown in Figure 3, bottom. The intramolecular character of this complexation is confirmed by the fact that the mixture of the free base **1a** and Zn–tetraphenylporphyrin (Zn–TPP) does not show an upfield shift of the CEQ protons (Fig. 2, bottom); therefore, an *intermolecular* complexation does not occur.

Further evidence for the CEQ folding was obtained by EPR investigation of the triplet excited state of the porphyrin. The following points should be noted:

1. The triplet state of the Zn–TPP fragment could be identified in the EPR spectrum at around 120 K in toluene with in situ irradiation; a good signal-to-noise ratio was obtained (cf. ref. [14]).
2. The triplet state of the porphyrin donor in a P-Q can only be reached photochemically if the singlet ET has been slowed down to such an extent (e.g., through cooling or use of a

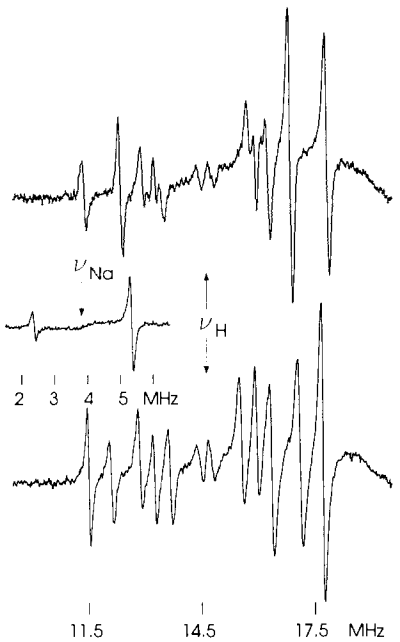

Fig. 1. ENDOR spectra of $\mathbf{1b}^{\bullet-}$ (230 K, top) and Na-$\mathbf{1b}^{\bullet-}$ (250 K, bottom) in methanol; radical formation with benzoin as reducing agent and tetrabutylammonium hydroxide as base. Formation of Na-$\mathbf{1b}^{\bullet-}$ by addition of a solution of sodium tosylate. MW power, RF power, hyperfine coupling constants (MHz $\pm$ 0.02) of $\mathbf{1b}^{\bullet-}$: 10 mW, 150 W, -6.45, $+4.52$, $+3.32$, $+2.68$, $+2.35$, $+0.34$; of Na-$\mathbf{1b}^{\bullet-}$: 15.9 mW, 300 W, -6.22, $+5.04$, $+3.51$, $+2.75$, $+1.94$, $+0.30$, 2.96 (Na). The signs were determined with general TRIPLE resonance spectroscopy for Na-$\mathbf{1b}^{\bullet-}$ and extended to the data for the radical $\mathbf{1b}^{\bullet-}$.

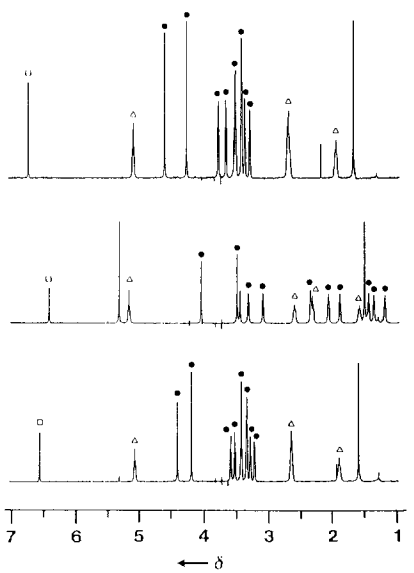

Fig. 2. High-field portion of the ^{1}H NMR spectra (500 MHz, $CDCl_3$, 25 °C, TMS) of **1a** (top), **1b** (middle), and a mixture of **1a** with Zn–TPP. Note the positions of the marked CEQ protons (□: quinone proton, △: butylene protons, ●: crown ether protons).

nonpolar solvent) that spin-orbit intersystem crossing (SOISC) can compete successfully.[15]

3. The corresponding hydroquinone derivatives of the P-Q's cannot undergo ET; the triplet state should therefore be accessible by ISC and be detectable.

For purposes of comparison, Figure 4 (top) shows the low-temperature EPR spectra in toluene of a P-Q with a butylene bridge[16] but lacking the crown ether substituent. In this case,

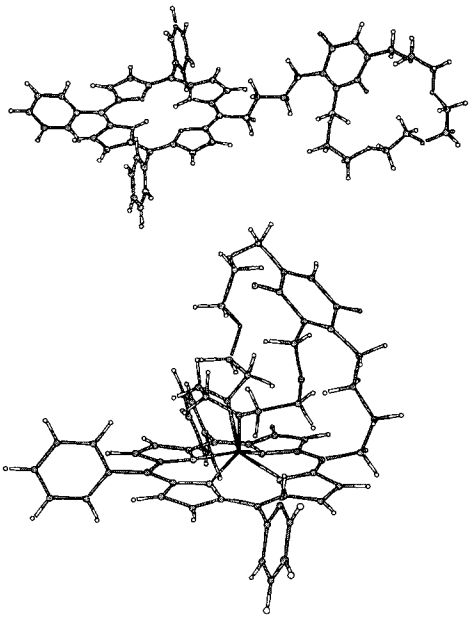

Fig. 3. Extended structure (top, **1a**) and the favored structure of **1b** after incorporation of Zn (according to the molecular modeling program Quanta 3.3). The folding of the CEQ towards the porphyrin can be seen clearly in **1b**.

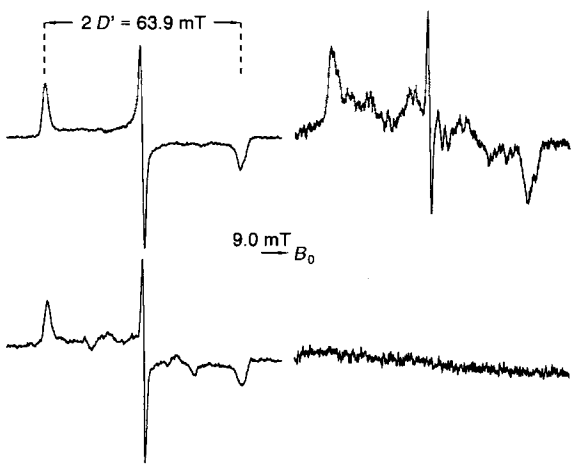

Fig. 4. Photoinduced EPR triplet spectra (measured in situ) of the porphyrin portion of porphyrin hydroquinones (left) and quinones (right). Top: analogue of **1b** lacking the crown ether substituent linked to the quinone; bottom: **1b**. Not shown here is the $\Delta m = 2$ transition ("half-field transition") characteristic of triplet systems, which was also detected. For the P-Q **1b**, a triplet excited state could not be detected under the measurement conditions used (see text).

the porphyrin triplet state can not only be identified unambiguously for the hydroquinone, but also for the P-Q itself. The signal-to-noise ratio is worse for the quinone derivative, because a certain amount of singlet ET occurs. In contrast, the crown ether shows a triplet state only for the hydroquinone; no triplet state of the porphyrin is detected for the quinone system **1b**. Presumably, in the case of **1b**, the folding of CEQ results in such spatial proximity of donor and acceptor that the singlet ET dominates even under the chosen reaction conditions; the singlet ET is, on the other hand, no longer effective at low temperatures for the P-Q without the crown ether because of the greater distance between donor and acceptor.

Finally, the UV/VIS spectrum of **1a** shows systems of bands characteristic of porphyrins, while the intramolecular complexation at the central atom of **1b** results in extensive shifts in the positions of the maxima of up to 10 nm.[17]

It may be assumed that the structural changes after incorporation of Zn have a profound influence on the ET properties of these P-Q's. Time-resolved optical and EPR measurements as well as studies of the redox potentials are underway, and compounds of type **1a** with rigid cyclohexylene bridges are under investigation.

[11] EPR, ENDOR, and TRIPLE resonance spectra were measured on a Bruker EPR spectrometer (ER 220D, ER 200D); the ER 220D was equipped with a Bruker ENDOR resonator ER 200 ENB and with an NMR additional unit, which was built within the group. For details concerning the equipment see, for example, H. Kurreck, P. Tian, H. Dieks, J. von Gersdorff, H. Newman, H. Schubert, T. Stabingis, A. Wiehe, J. Sobek, *Appl. Magn. Reson.* **1994**, *6*, 17. The photoexcited states were generated by in situ irradiation through a slit in the EPR resonator with a 1000 W Hg–Xe lamp (Oriel) with a 570 nm cut-off filter (Schott) (EPR microwave power, 5 mW; field modulation, 5 μT).
[12] Whereas the nature of the nucleus can only be deduced indirectly from an EPR spectrum, for example, through the coupling pattern, ENDOR spectroscopy—and in this respect the close relationship to NMR spectroscopy is clear—allows the unambiguous identification of the magnetic nucleus by determination of the free nucleus frequency: cf., H. Kurreck, B. Kirste, W. Lubitz, *Angew. Chem.* **1984**, *96*, 171; *Angew. Chem. Int. Ed. Engl.* **1984**, *23*, 173; *Electron Nuclear Double Resonance Spectroscopy of Radicals in Solution*, VCH, New York, **1988**.
[13] Folding of this type in a pyropheophytine anthraquinone was also observed recently by NMR spectroscopy; the corresponding upfield shifts are smaller by several orders of magnitude than the ones for **1b**: cf., A. Y. Tauber, R. K. Kostiainen, P. H. Hynninen, *Tetrahedron* **1994**, *50*, 4723.

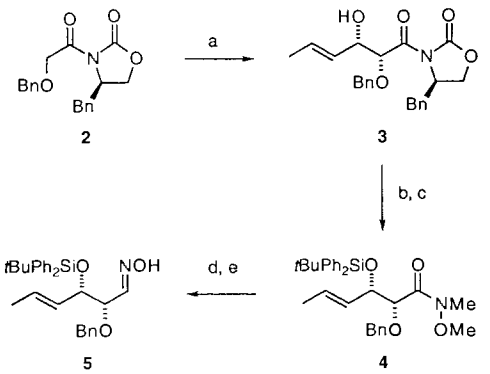
An Enantioselective Synthesis of Deoxynojirimycin**

Andrew J. Rudge, Ian Collins, Andrew B. Holmes,* and Raymond Baker

Deoxynojirimycin (**1**) and its derivatives have attracted much interest as synthetic targets owing to their potent glycosidase and related biological activity. The majority of syntheses of this molecule have utilized starting materials from the chiral pool, in particular, the carbohydrates glucose and sorbose.[1] Routes employing other chiral pool sources such as glutamic acid,[2] *myo*-inositol,[3] diethyl tartrate,[4] and serine[5] as building blocks to introduce at least one stereocenter have also been reported. To our knowledge, with the exception of the elegant use of aldolases,[6] and the intermolecular nitrone dipolar cycloaddition approach of Vasella et al.,[7] no asymmetric syntheses using induced diastereoselectivity from a chiral auxiliary have been published. We report a novel synthesis of this important azasugar in which the key step is an intramolecular nitrone cycloaddition[8] to assemble the piperidine ring. Other important features are the use of an enantioselective aldol reaction[9] to introduce two of the three ring oxygen substituents, a highly regio- and stereoselective dehydration of a secondary alcohol with the Martin sulfurane reagent,[10] and the stereoselective reduction of an ozonide with diisobutylaluminum hydride (DIBAL-H).



1

The imide **2**, prepared by acylation of the phenylalanine-derived oxazolidinone[11] with benzyloxyacetyl chloride,[12] underwent a diastereoselective aldol reaction[13a,b] with crotonaldehyde to give the *syn* product **3** in good yield (Scheme 1). The use of freshly distilled dibutylboron triflate (Bu_2BOTf) was found to be essential for the reproducibility of this reaction.[11] Formation of the Weinreb amide,[14] followed by silylation of the crude secondary alcohol gave the fully protected diol **4**. The oxazolidinone auxiliary was easily recovered under these condi-

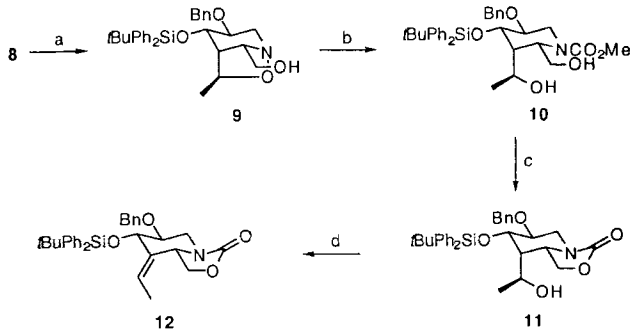
We thank Pfizer Central Research (Sandwich) for financial support and The Royal Society for the award of a Royal Society Leverhulme Senior Research Fellowship (to A. B. H.). We thank Prof. S. V. Ley for drawing our attention to the Martin sulfurane.

Scheme 1. Synthesis of the oxime **5** using an enantioselective aldol reaction. a) Bu_2BOTf, NEt_3, -78 °C, in toluene, then crotonaldehyde -78 °C to ca. 20 °C (90%); b) MeNH(OMe)·HCl, $AlMe_3$, CH_2Cl_2, ca. 20 °C; c) $tBuPh_2SiCl$, imidazole, *N*,*N*-dimethylformamide (DMF), ca. 20 °C (90% from **3**); d) DIBAL-H, toluene, -78 °C; e) NH_2OH·HCl, NaOAc, EtOH–H_2O, ca. 20 °C (93% from **4**).



tions. Conversion to the oxime **5**, isolated as a 4:1 mixture of isomers, was then achieved by reduction with DIBAL-H and condensation with hydroxylamine hydrochloride.

Reduction of the oxime **5** with $NaCNBH_3$ under acidic conditions furnished a hydroxylamine intermediate, which upon reaction with the aldehyde **6**[15] afforded the nitrone **7** in good yield (Scheme 2). Cycloaddition in refluxing benzene yielded the isoxazolidine **8**. The predominance of this product results from the preferred all-equatorial disposition of both ether substituents on the developing six-membered ring, which folds in a chairlike transition state structure. This contrasts strongly with the marked preference for formation of the axial product in the cycloaddition of analogues of **7** carrying only a single allylic ether substituent.[17] The kinetic preference for a six-membered ring over a seven-membered ring during carbon–carbon bond formation, which is thought to precede carbon–oxygen bond formation in nitrone dipolar cycloadditions, secures the correct regioselectivity.[18]

Scheme 2. Intramolecular cycloaddition of the nitrone **7**. a) $NaCNBH_3$, MeOH, pH 4, ca. 20 °C, then aldehyde **6**, CH_2Cl_2, ca. 20 °C (80%); b) Benzene, reflux (72%).
