

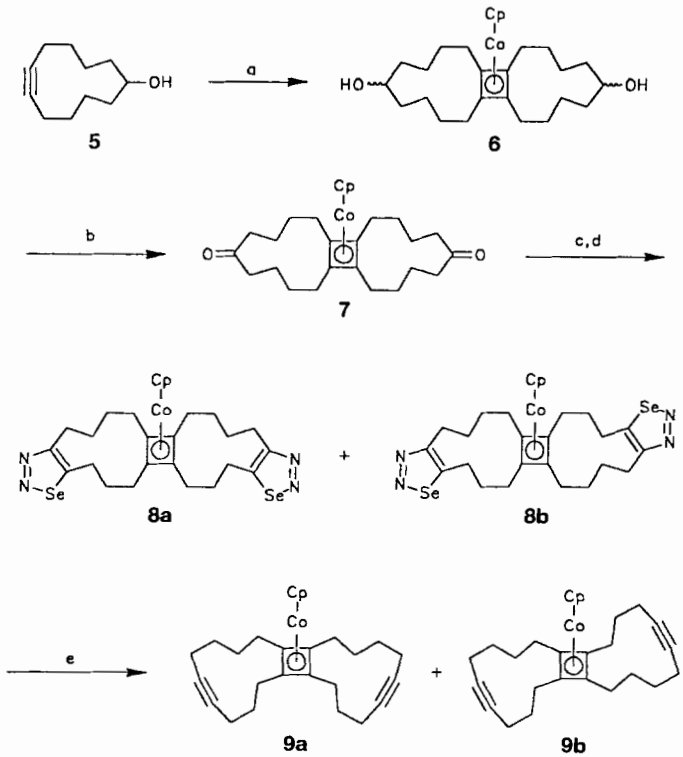
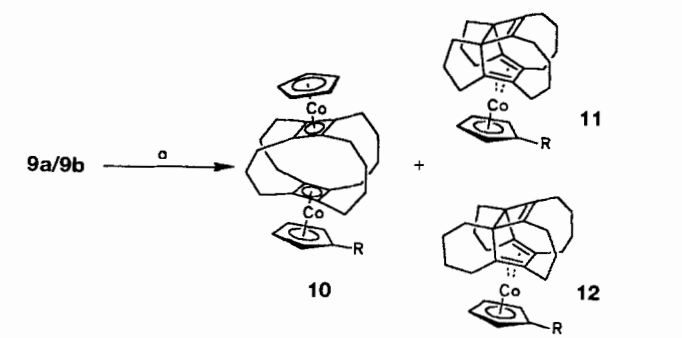


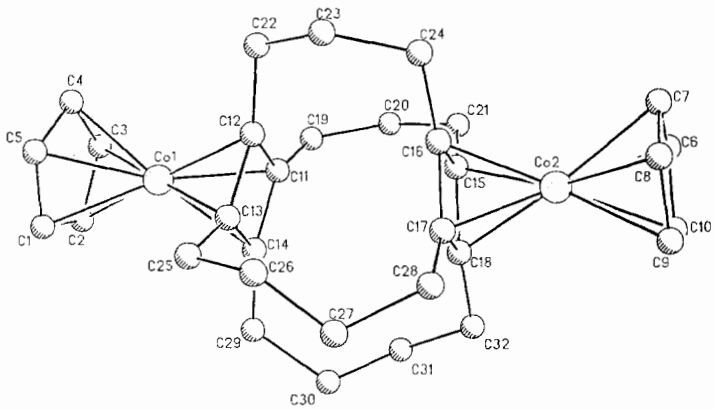


Scheme 2. a) [CpCo(cod)], decalin, 155 °C, 4 d; b) Oppenauer oxidation, acetone/toluene, $Al(OiPr)_3$, 20 h under reflux; c) semicarbazide · HOAc, ethanol, 30 min under reflux; d) SeO_2, HOAc, 40 °C, 4 h; e) *n*BuLi, THF, −40 °C.

Scheme 3 shows that heating the mixture of **9a**/**9b** with [CpCo(CO)$_2$] leads to three products in a 2:1:1 ratio and 75% yield: the superphane **10a** and the two fourfold bridged bicyclo[4.2.0]octa-2-4-7-triene complexes **11a** and **12a**.[10] X-ray studies on single crystals of **10a**[11] (Fig. 1) and **12a**[12] confirm the given structures.

Scheme 3. **10a**–**12a**, R = H; **10b**–**12b**, R = $SiMe_3$. a) R = H: [CpCo(CO)$_2$], cyclooctane, 5 h under reflux; R = $SiMe_3$: [$(Me_3SiC_5H_4)$Co(cod)], cyclooctane, 14 h under reflux.

The superphane **10a** is the first cyclobutadiene superphane containing different chain lengths in one molecule. Heating **9a**/**9b** with [$(Me_3SiC_5H_4)$Co(cod)] yielded, besides the anticipated "mixed" superphane **10b**, the bicyclo[4.2.0]octa-2,4,7-diene complexes **11b** and **12b** (Scheme 3). Thus, "labeling" of one Cp ring with the $SiMe_3$ group shows that during the formation of **11** and **12** the CpCo unit of **9a**/**9b** is removed. This observation was unexpected because CpCo-complexed cyclobutadienes are usually very inert towards the reaction with further triple



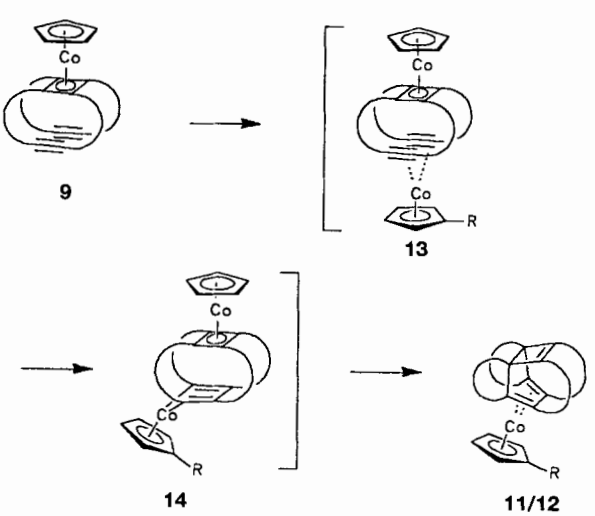


Fig. 1. Crystal structure of **10a** (H atoms omitted). Distances between the cyclobutadiene units [Å]: C11-C15 3.00, C12-C16 3.00, C13-C17 3.37, C14-C18 3.36. Micrometer-Scale Lateral Structuring of Organic Thiolate Layers through Self-Organization**

Claus Duschl,* Martha Liley, and Horst Vogel

Self-assembly techniques for the formation of ultrathin films based on sulfur-containing compounds show great potential for the modification of surfaces.[1,2] Films thus produced are remarkably free from defects and are highly stable and therefore very promising for technical applications. With these films, very precise control of chemical properties and thicknesses is possible, but it is difficult to control lateral properties, such as distribution of species in layers containing more than one component.[3–6] In contrast, Langmuir–Blodgett (LB) techniques produce ultrathin films in which a relatively high degree of lateral structuring is possible:[7–10] phase state and molecular density can be controlled, and two-dimensional domain structures in the plane of the film can be induced either by phase separation, or, in a mixed monolayer, by de-mixing. However, LB films are much less robust and generally exhibit a much higher defect density than layers prepared with self-assembly techniques. Using an amphiphilic disulfide, which can be spread as a Langmuir monolayer and which binds covalently to gold, it is possible to form ultrathin films which combine the advantages of these two techniques. The films produced are covalently attached to the surface, and therefore robust, and it is also possible to introduce two-dimensional structures with contrasting surface properties into the films. Unlike lithographic methods, this technique imposes no theoretical lower limit on the size of the lateral structures produced.

The generation of a laterally structured thiolate layer is depicted schematically in Figure 1 left. A mixture of palmitic acid and a lipid containing sulfur (thiolipid) is spread on the water/air interface of a Langmuir trough. On compression, the floating monolayer de-mixes and regularly distributed domains, containing predominantly fatty acid, are formed. Their size and shape depend on the self-organizing properties of the monolayer and its manipulation on the Langmuir trough. The film is transferred to a gold substrate where the thiolipids bind covalently to the gold surface. The physisorbed fatty acid is washed away to leave do-

mains of bare gold. A thiol monolayer is formed in these regions through a subsequent self-assembly step to give surface properties which contrast with those of the areas covered by the thiolipids. Here we present an example illustrating the potential of this new technique. Multilayers of ω-mercaptocarboxylic acid copper complex are formed according to the procedure of Evans et al.[11] (Fig. 1C left). This generates little "plateaux" on a molecular scale.

The structure formation is characterized by optical techniques. The lateral distribution of different phases of a monolayer floating on a water surface is studied by using fluorescence microscopy.[12–14] Small amounts of fluorophore-labeled lipids, which show different solubilities in different phases, are used to provide contrast between the phases. This technique allows optimization of the size and distribution of the patterns. Surface plasmon spectroscopy[15] and surface plasmon microscopy[16] are ideally suited for characterization of thin films on gold surfaces. They allow both the determination of the optical thickness of the films and the visualization of small variations in lateral optical thickness. Surface plasmon modes carry evanescent electromagnetic fields which probe the optical properties in the vicinity of a metal/dielectric interface. The sharp resonance which is observed in a reflected intensity vs. angle of incidence scan serves as a contrast mechanism for a surface plasmon microscope.

The fatty acid/thiolipid mixture is spread on the water surface from a chloroform solution. The thiolipid bis[8-(1,2-dipalmitoyl-*sn*-glycero-3-phosphoryl) 3,6-dioxaoctyl] disulfide)[17] consists of two phospholipid molecules, each attached to a hydrophilic spacer, and joined by a disulfide bond at the ends of the spacers. In addition to forming stable self-assembly monolayers on gold, the thiolipid also forms very stable Langmuir films at the air/water interface due to its amphiphilic nature. After the chloroform has evaporated, the film is compressed until a lateral pressure has been reached which lies a few $mN\,m^{-1}$ above the phase transition of the system. Figure 1A right is a fluorescence micrograph of such a mixed monolayer at the water/air interface. The film is a mixture of palmitic acid and thiolipid with, in addition, 1 mol% of the fluorescence probe *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine (NBD-PE). The size and shape of the condensed domains in the monolayer are identical to those obtained in pure palmitic acid monolayers (results not shown), and the area occupied by the domains (at a given surface pressure) varies with the content of palmitic acid. We therefore conclude that the domains contain predominantly palmitic acid. The average size and number of domains per unit

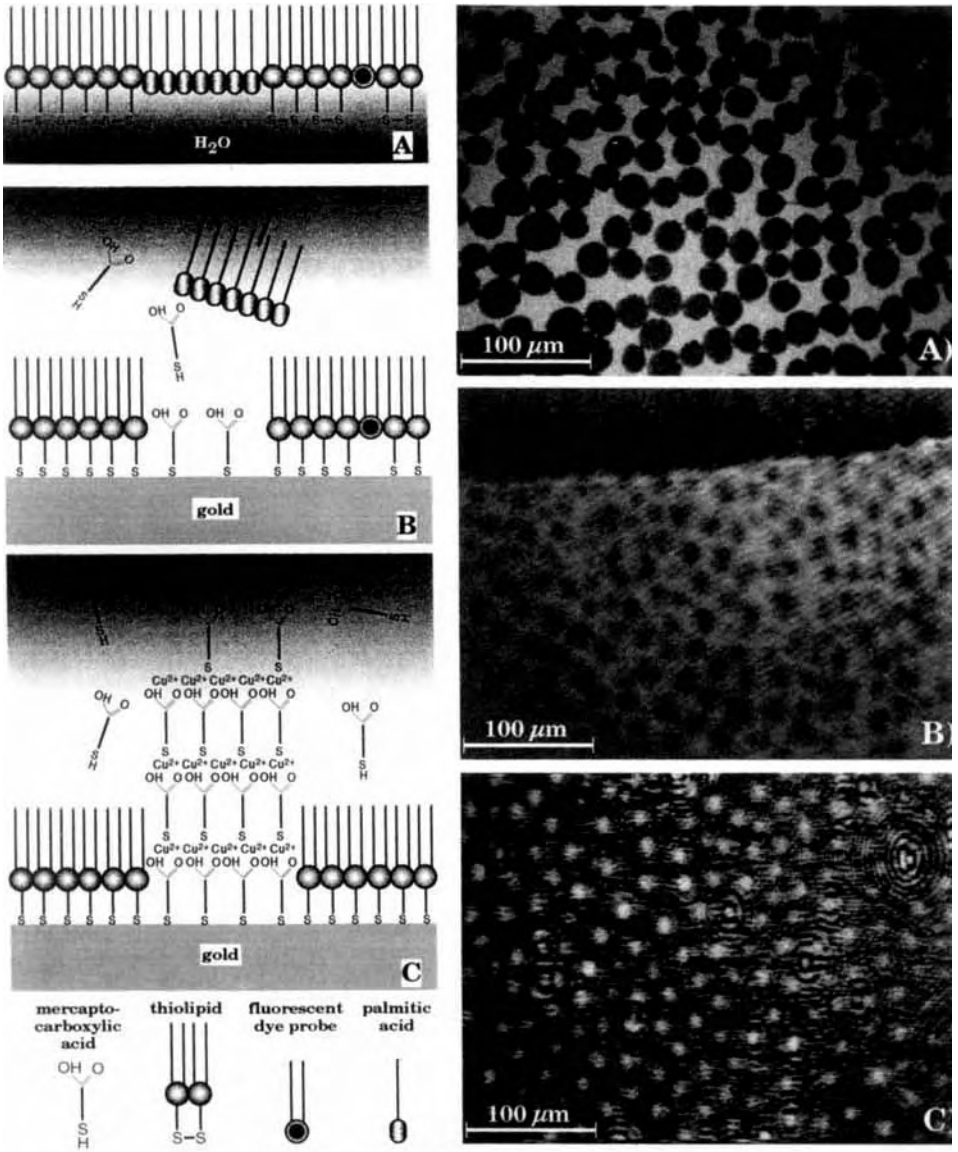

Fig. 1. Left: Generation of a laterally structured thiolate layer. Fig. 1A left shows a Langmuir film consisting of a mixture of palmitic acid and thiolipid at the water/air interface. In Fig. 1B left the Langmuir monolayer has been transferred to a gold surface by the LB technique [1]. After LB transfer the gold surface is washed in an appropriate solvent. The physisorbed palmitic acid domains are removed from the surface, while the thiolipid is not removed. Organic thiol molecules present in the solvent chemisorb to the newly exposed gold areas to form self-assembled monolayers. Fig. 1C left shows the formation of ω-mercaptocarboxylic acid copper complex multilayers on the carboxylic acid surface. Multilayers only form in those areas initially covered by the palmitic acid domains. Right: Experimental results which correspond to those steps presented in Fig. 1 left. A right: Fluorescence micrograph of a Langmuir monolayer consisting of palmitic acid and thiolipid (4:1 molar ratio) as well as 1 mol% NBD-PE. The fluorescence NBD-PE is sequeezed out of the condensed domains into the fluid phase, which therefore appears bright. B right: surface plasmon micrograph of a structured thiolipid film (3:1 palmitic acid/thiolipid ratio of the Langmuir layer) which has been transferred to a gold surface and then washed with ethanol and hexane. The horizontal line near the top of the picture is the limit of LB transfer: the dark area above this line is bare gold. Below, the surface has been covered with the LB film. The angle of incidence ($\theta = 31.95°$) of the laser beam has been tuned so that bare gold appears dark in the image, while adsorbed layers on the surface result in brighter areas. The dark domains in the lower part of the figure are bare gold. C right: Surface plasmon micrograph of a structured film (3:1 palmitic acid/thiolipid ratio of the transferred layer) on gold taken at $\theta = 32.45°$. After washing, multilayers of the copper complex of ω = mercaptoundecanoic acid were formed in the domains which appear bright due to their greater thickness.

area are determined by the mixing ratio, the surface pressure, the subphase temperature, and the ionic strength. By manipulating these parameters the structures formed can be controlled to a high degree.

A freshly prepared (by vapor deposition), and thus hydrophilic, gold substrate is quickly dipped through the Langmuir film into the water, and then slowly drawn out (at a speed of 1 $\mu m\,s^{-1}$). As the substrate is drawn out through the film, the hydrophilic head groups of the monolayer come into contact with the gold surface and adsorb. After this LB transfer, the gold surface is washed in ethanol and hexane. This removes the physisorbed palmitic acid from the surface, while the thiolipid, which binds covalently to the gold, is not removed.[18]

Control experiments using surface plasmon resonance to measure LB layers consisting only of thiolipid show that a few percent of the thiolipid are removed when the same washing procedure is applied.[19] Examining the surface plasmon micrograph (Fig. 1B right) of a mixed monolayer, transferred by the LB technique to a gold substrate and then rinsed in organic solvents, confirms that during compression of the film on the water surface, de-mixing has taken place. Analyzing the local surface plasmon resonance by using the gray values of a sequence of micrographs taken at different angles,[20] shows that the dark domains in the lower part of Figure 1B right are bare gold patches. Their size and distribution correlate well with the domains of the floating monolayer. The stability of the structures has been checked in air, in water, and in ethanol. No change could be detected either in the lateral structure or in the thickness of the films over three days.

Next, the sample is immersed in an ethanolic solution of ω-mercaptoundecanoic acid, $HS(CH_2)_{10}COOH$, for 8 hours. Measurements of the local resonance minima clearly show the formation of a monolayer on those parts of the surface which are not covered by thiolipid. No increase in the thickness of the thiolipid-covered areas could be detected. To form a second thiol layer, we first immersed the sample in an aqueous solution of $Cu(ClO_4)_2$.[21] Monitoring of the angle of surface plasmon resonance in situ revealed a just detectable shift ($\approx 0.02^\circ$), caused by adsorption of copper ions to those parts of the surface where the carboxylic groups are exposed. Subsequent immersion in $HS(CH_2)_{10}COOH$ solution led to an increase in the thickness of 12–14 Å indicating formation of a second ω-mercaptocarboxylic acid monolayer[22] via a sulfur–copper complex. Alternate immersion in copper and ω-mercaptoundecanoic acid solutions results in multilayer formation in the domains only. We formed five layers, to give a surface where multilayers of ω-mercaptocarboxylic acid copper complex extend out of the surrounding thiolipid monolayer (Fig. 1C right). Analyzing the local angles of resonance, we find that the plateaux have a thickness of 50 Å (with refractive index $n = 1.45$) which is slightly less than that expected for five layers of mercaptoundecanoic acid.

This approach to the generation of selectively addressable structures is very general: in this paper we have described a chemical method for addressing the structures. Biochemical experiments using antibodies which selectively bind to antigens immobilized in the domains are in progress. The morphology of the structures can also be manipulated, for example, by using the procedure of Spratte et al.[23] to produce stripes. Experiments in our research group show the suitability of this technique for the structuring of thiolate layers. In principle, since the structures are formed by self-organization on the water surface, there is no lower limit on the size of the patterns that can be created. The method described here does not damage the delicate gold surface: a fact which is important for the application of such novel surface-sensitive methods as the use of evanescent light[24] or scanning probe[25] techniques. The exact nature of the structures on the gold surface (sharpness of domain boundaries, extent of de-mixing, etc.) is currently under investigation. Atomic force microscopy studies are already in progress, and Raman microscopy and imaging secondary ion mass spectrometry will also be applied.

[18] A slightly different procedure for the LB transfer involves first dipping the gold substrate into the water subphase of the film balance, and subsequently spreading and compressing the palmitic acid/thiolipid mixture on the water surface. The LB films produced by this procedure are not detectably different from the films produced as described in the text. However, the method described in the text exposes the fresh gold substrate to the laboratory atmosphere for a shorter time, thus minimizing contamination of the surface.
[19] No removal is observed on washing thiolipid films formed by self-assembly. This may indicate contamination of the gold surface in the laboratory atmosphere. Such surface contaminants are displaced by thiolates during the self-assembly process, but are probably not displaced during LB transfer of a film.

[21] Multilayers of the copper complex of ω-mercaptoundecanoic acid were formed in the domains by using a modified procedure of Evans et al. [11], in which the $Cu(ClO_4)_2$ is dissolved in Millipore water, instead of ethanol. The sample was immersed for five min in the aqueous solution containing the copper ions. We obtained very similar results when we used cupric acetate monohydrate instead of cupric perchlorate. The thickness increase on immersion in the ω-mercaptoundecanoic acid solution was slightly greater after exposure to acetate ions. This is probably due to the increased deprotonation of the carboxylic acid in the more basic acetate solution.

A New Method for the Synthesis of Heterometallic Complexes: Syntheses and Structures of $[(PhCH_2CH_2NLi)_3Sb(thf)]_2$ and $[Sb_3(cyN)_4(NMe_2)_2]Li$**

Andrew J. Edwards, Michael A. Paver, Paul R. Raithby, Moira-Ann Rennie, Christopher A. Russell, and Dominic S. Wright*

Recently we embarked on a reinvestigation of the use of $(NMe_2)_{3-x}ECl_x$ (E = As, Sb, Bi; $x = 0-2$) as metallating reagents in the syntheses of group 15 heteroatom complexes (containing N, P, O, S, etc.). None of the antimony complexes previously prepared in this manner had been characterized by single-crystal X-ray analysis or by NMR spectroscopy.[1, 2] It was with surprise that we observed Me_2NH, produced as a gaseous by-product in these reactions, as a stable ligand in the dimers $[(Me_2NH)Cl_2Sb(\mu\text{-}OEt)]_2$ and $[(Me_2NH)ClSb(\mu\text{-}t\text{BuN})]_2$ both in the solid state and in solution.[3] We report here our investigations on the metalation of primary amines by different metals ("mixed-metalation") as a method for the syntheses of heterometallic complexes containing amidoantimony anions. The heterometallic complexes **1** and **2** were synthesized by the metalation reactions of the neutral amidolithium complex $[PhCH_2CH_2N(H)Li]_n$ and of the antimony anion complex $Li[Sb(cyNH)_4]^-$, respectively, with $Sb(NMe_2)_3$ [Eq. (a) and (b), respectively]. Complex **1** has an $Sb_2N_6Li_6$ cage structure in the solid state and is the first structurally characterized example of an $[Sb(NR)_3]^{3-}$ trianion complex. In **2**, which is the first structurally characterized polynuclear amidoantimony anion complex, an Sb_3N_6Li "deck-chair" core is present.

$$\tfrac{3}{n}[PhCH_2CH_2N(H)Li]_n + Sb(NMe_2)_3 \xrightarrow{THF/C_6H_5CH_3} \underset{\mathbf{2}}{[(PhCH_2CH_2NLi)_3Sb(thf)]_2} + 3\,Me_2NH \quad (a)$$

$$2\,Sb(NMe_2)_3 + Li^+[Sb(cyNH)_4]^- \xrightarrow{THF/C_6H_5CH_3} \underset{\mathbf{2}}{[Sb_3(Ncy)_4(Me_2N)_2]Li} + 4\,Me_2NH \quad (b)$$

A low-temperature X-ray crystallographic study of **1**[4] shows it to be a fourteen-membered polyhedral cage $[(PhCH_2CH_2NLi)_3Sb(thf)]_2$ (Fig. 1). The structure can be regarded as being constructed from a hexameric amidolithium fragment, $(PhCH_2CH_2NLi)_6$,[5] bicapped at the open Li_3N_3 faces by two Sb atoms. Although $[\{^iPr_3Si)AsLi\}_3GetBu]_2$[6] and $[(RNLi)_3SiR']_2$ (R = Me_3Si, R' = Me, *t*Bu, Ph;[7] R = *t*Bu, R' = Ph;[8] R = Me, R' = *t*Bu[9]) have similar cores to **1**, none of these compounds are solvated by Lewis base donor molecules and all the Li atoms have identical environments. In the core of **1** four of the six Li centers are involved in agostic *ortho* C(-H)···Li interactions with the phenyl rings of adjacent $PhCH_2CH_2$ groups. These groups bend towards Li, straddling

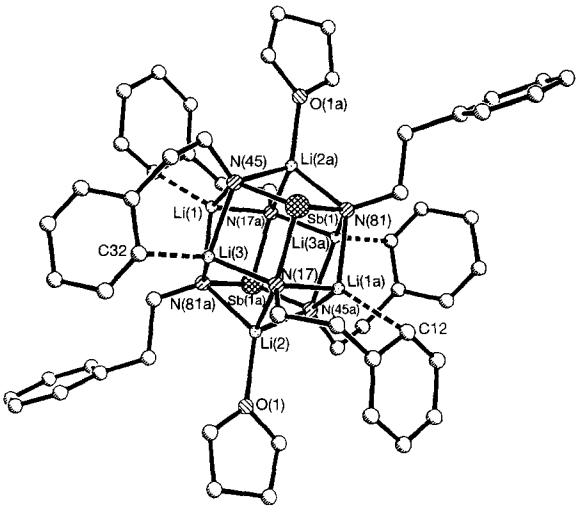

Fig. 1. Crystal structure of **1**. Selected bond lengths [Å] and bond angles [°]: Sb(1)-N(17) 2.070(3), Sb(1)-N(81) 2.059(3), Sb(1)-N(45) 2.059(3), Li(1a)-N(17) 2.035(7), Li(1a)-N(81) 2.116(8), Li(1a)-N(45a) 2.000(8), Li(2a)-N(81) 2.156(8), Li(2a)-N(45) 2.157(8), Li(2a)-N(17a) 2.137(8), Li(3)-N(17) 2.055(7), Li(3)-N(45) 2.093(7), Li(3)-N(81a) 1.988(7), Li(1a)···C(12) 2.505(8), Li(3)···C(32) 2.418(8), Li(2a)-O(1) 1.954(8); N-Sb-N 94.5 (mean).

the core N–Li bonds, and form loosely linked C_4NLi six-membered rings. These agostic C···Li distances (av. 2.472 Å) are of lengths intermediate between those observed in various organolithium compounds,[10] (e.g., the distance between tetramers in $(MeLi)_4$ 2.37 Å[11]) and those observed in certain amidolithium complexes (e.g., shortest *ortho* (C-H)···Li 2.70 Å in the trimeric amidolithium complex $[(PhCH_2)_2NLi]_3$[12]). For the remaining two Li centers of **1**, the agostic interactions are disrupted by the solvation of the metal centers by thf ligands. The result is that the pendant $PhCH_2CH_2$ groups lean away from the cage core and can no longer contact Li.

The geometry of the $Sb_2N_6Li_6$ core of **1** appears to be dictated both by the constraints imposed in accommodating the two capping Sb centers and by the inequivalent (agostic and THF) interactions of the Li^+ cations. In contrast to the largely symmetrical, pyramidal $[(PhCH_2CH_2N)_3Sb]^{3-}$ ions (av. N-Sb-N 94.5°, av. Sb–N 2.063 Å), the central Li_6N_6 fragment of **1** is highly distorted (Li–N range 1.998(7)–2.157(8) Å). The longest Li–N distances are made with the four-coordinate THF-solvated Li centers (av. 2.150 Å) and the shortest are made with the remaining coordinatively unsaturated Li centers (av. 2.050 Å).

A low-temperature X-ray crystal structure analysis of **2** shows it to have an Sb_3N_6Li ("deck-chair") core of two "back-to-back" distorted cubic fragments sharing a common face (Fig. 2).[4] Four μ-Ncy ligands link the central four-coordinate Sb center to the two terminal three-coordinate Sb atoms. Additionally, two of these μ-Ncy bridges and the NMe_2 groups attached to the terminal Sb atoms are coordinated to a Li^+ ion. Complex **2** can be regarded as an ion-pair of the trinuclear amidoantimony anion $[Me_2NSb(\mu\text{-}Ncy)_2Sb(\mu\text{-}Ncy)_2SbNMe_2]^-$ and Li^+.

Unsurprisingly, the geometry of the central Sb(2) atom, which is isoelectronic with (10 e^-) SF_4, is pseudo-square-based pyramidal. However, although the Sb(2)–N bond lengths are arranged almost symmetrically (two "short" (Sb(2)–N(11,41) av. 2.120 Å) and two "long" bonds (Sb(2)–N(21,31) av. 2.230 Å), there are large angular distortions about this center (N-Sb(2)-N range 73.8° to 150.3°). The two terminal three-coordinate Sb centers (Sb(1) and Sb(3)) are each bound to one NMe_2 and to two

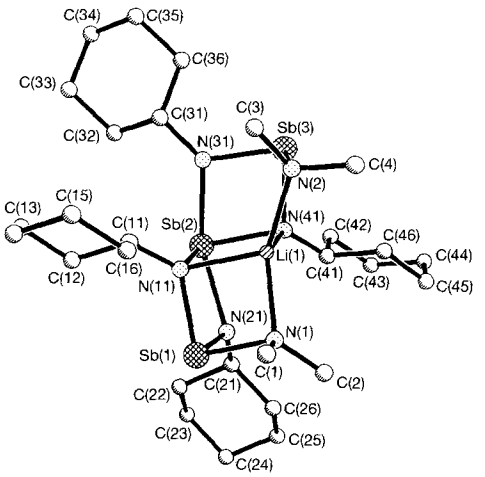

Fig. 2. The molecular structure of **2**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Sb(2)-N(11) 2.128, Sb(2)-N(41) 2.112, Sb(2)-N(31) 2.237, Sb(2)-N(21) 2.224, Sb(1)-N(21) 1.986, Sb(1)-N(11) 2.059, Sb(1)-N(1) 2.156, Sb(3)-N(31) 1.990, Sb(3)-N(41) 2.039, Sb(3)-N(2) 2.155, Li(1)-N(2) 2.074, Li(1)-N(1) 2.085, Li(1)-N(11) 2.128, Li(1)-N(41) 2.156; N(31)-Sb(2)-N(41) 73.8, N(31)-Sb(2)-N(11) 86.6, N(41)-Sb(2)-N(21) 84.1, N(41)-Sb(2)-N(11) 92.5, N(11)-Sb(2)-N(21) 74.6, N(31)-Sb(2)-N(21) 150.3, N(11)-Sb(1)-N(21) 81.4, N(11)-Sb(1)-N(1) 87.0, N(21)-Sb(1)-N(1) 96.0, N(31)-Sb(3)-N(2), 97.3, N(31)-Sb(3)-N(41) 80.9, N(2)-Sb(3)-N(41) 88.3, N(2)-Li(1)-N(11) 120.0, N(2)-Li(1)-N(41) 87.4, N(11)-Li(1)-N(41) 91.3, N(2)-Li(1)-N(1) 143.6, N(1)-Li(1)-N(11) 87.1, N(1)-Li(1)-N(41) 117.9.

μ-Ncy groups. These Sb centers both adopt similar, though not identical, distorted pyramidal geometries (N-Sb(1,3)-N range 80.9–97.3°). The Sb–(μ-Ncy) bond lengths at these Sb centers (av. 2.019 Å) are shorter than both the corresponding Sb(2)–(μ-Ncy) bonds (av. 2.175 Å) and the Sb–N bonds made with the terminal NMe_2 groups (av. 2.156 Å).

The Li^+ ion of **2** is captured by the pendant Me_2N groups (av. Li(1)–N(1,2) 2.080 Å) and by two of the Sb-attached μ-Ncy ligands (Li(1)–N(11,41) av. 2.142 Å). Although a four-coordinate geometry is typical for Li^+ ions,[5, 10] the coordination sphere of the Li center in **2** is exceptionally distorted (N-Li-N 87.1–143.6°). The angular distortions present within the core of **2** (particularly at Sb(2)) presumably partly arise from the strain induced by the coordination of this Li^+ ion to the anion of **2**. Although there are a variety of Sb[13–15] and other[16] p-block metal–amido cage complexes with structural features related to **2**, this complex is the first structurally characterized example of a compound containing a polynuclear amidoantimony anion.

Apart from the structural interest of **1** and **2**, this study highlights that $Sb(NMe_2)_3$ can be used as a metalating reagent for the synthesis of new anionic amidoheterometallic complexes. Both **1** and **2**, which are sources of $[Sb(NR)_3]^{3-}$ and $[Me_2N_2Sb_3(NR)_4]^-$ ions, respectively, are potential ligands for other main group and transition metals. We are currently preparing a range of such ligands and are investigating their coordination chemistry.

Experimental Procedure

1: A solution of 2-phenylethylamine (0.94 mL, 7.5 mmol) in THF (10 mL) was treated with *n*BuLi (4.69 mL, 7.5 mmol, 1.6 M in hexanes) at 0 °C. Heating the mixture to reflux and stirring (5 min) gave an intense red solution which was subsequently reduced to dryness under vacuum. Addition of toluene (20 mL) produced an orange solution. This was cooled to −78 °C and $Sb(NMe_2)_3$ (0.64 g, 2.5 mmol) was added. Gentle warming (60 °C) followed by stirring (1 h) gave a yellow solution and some decomposition. This solution was filtered through Celite and reduction of the filtrate under vacuum (ca. half volume) precipitated a yellow solid which was heated back into solution. Storage (5 °C, 24 h) gave yellow crystalline blocks of **1**. Isolation of **1** under vacuum resulted in loss of THF solvation. The crystal structure of the complex was obtained by mounting the crystals directly from solution so that THF solvation was maintained. The following data were obtained on the unsolvated powder after isolation; yield 0.25 g (20%, first batch); m.p. gradually darkens >90 °C to black solid, no melting below 300 °C; IR (Nujol), $\tilde{\nu}_{max}$ [cm^{-1}] = ca. 3070 (w, C-H (aryl)); ^1H NMR (C_6D_6, +25 °C, 250 MHz): δ = 7.2–7.0 (m, 5H, Ph), 2.70 (m, 2H, $-CH_2-$), 2.47 (m, 2H, $-CH_2-$); correct (C,H,N) analysis.

2: A solution of cyclohexylamine (0.99 g, 10 mmol) in THF (10 mL) was treated with *n*BuLi (6.25 mL, 10 mmol, 1.6 M in hexanes) at 0 °C. Addition of $SbCl_3$ (0.57 g, 2.5 mmol) followed by stirring at 30 °C (15 min) yielded a yellow solution. This was evaporated to dryness and the product separated from the LiCl by extraction from toluene (10 mL) and filtration. The yellow solution of $(cyNH)_4Sb^-Li^+$ in toluene (10 mL) was cooled to −78 °C and $(Me_2N)_3Sb$ added (1.27 g, 5 mmol). The reaction mixture was stirred at 60 °C (3 h) and subsequently at room temperature (16 h). During this time a faint yellow precipitate had developed and reduction of the mixture under vacuum yielded a mass of yellow solid which redissolved upon warming. Storage (10 °C, 24 h) produced yellow crystalline rods of **2**. First batch yield 0.67 g (32%), melting point 195–197 °C: ^1H NMR (25 °C, 250 MHz, [D_5]pyridine: δ = 3.34 (s, 12H, Me_2N), 0.5–2.5 (br.m, 44H, cyN); correct (C,H,N) analysis.

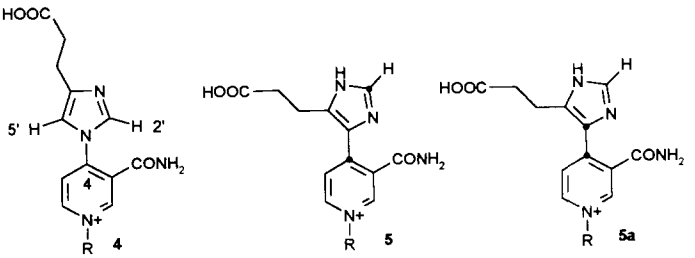
On the Mechanism of the Urocanase Reaction: Confirmation of the Structure of the NAD^+-Inhibitor Adduct by Direct ^{13}C-^{13}C Coupling**

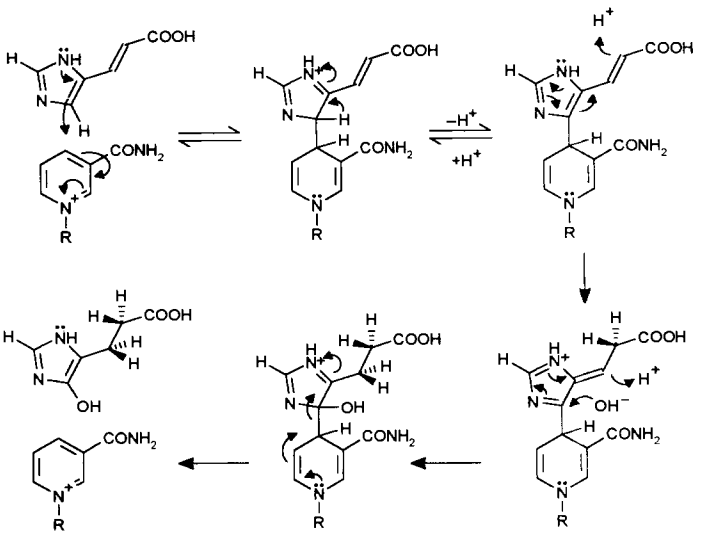
Carsten Schubert, Ymin Zhao, Jung-Hyn Shin, and János Rétey*

Dedicated to Professor Joachim Knappe on the occasion of his 65th birthday



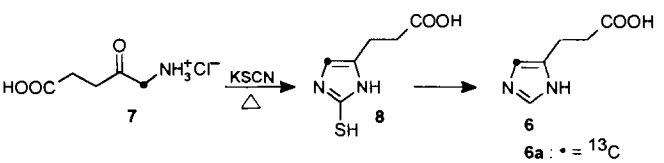
In oxidoreductases nicotinamide adenine nucleotide (NAD^+) functions as a redox reagent. In the urocanase reaction it plays a different and as yet unique role as electrophile (Scheme 1).

Scheme 1. Steric course of the urocanase reaction. The solvent protons are added to the *Re* positions of the side chains.



Urocanase (E.C. 4.2.1.49) occurs in most cells and catalyzes the second step in the degradation of histidine. In this process a water molecule is added to urocanic acid (**1**) in an unusual manner. In particular, the addition of an OH^- ion to the electron-rich imidazole nucleus seems to be chemically implausible. In overcoming this obstacle the tightly bound NAD^+ plays a crucial role. Using the competitive inhibitor imidazole propionic acid (**6**), an NAD^+-inhibitor adduct could be trapped by rearomatization of the dihydropyridine ring and then isolated. In the first postulated[1] structure **4**, the attachment of NAD^+ to the inhibitor was supposed to occur at the N1′ atom of the imidazole moiety (Scheme 2).

The assumption[1,2] that also urocanic acid forms the analogous covalent adduct in the initial step was supported convincingly by UV spectroscopy. This led to the proposal of a



Scheme 2. Proposed structures for the NAD^+-imidazole propionate adduct (^{13}C-labeling indicated by filled circles). R = ADP-ribosyl.

reaction mechanism[3] which, however, did not solve the aforementioned chemical problem. Moreover, in the ^1H NMR spectrum of the adduct one of the signals for the imidazole protons was lacking. This was explained by a spontaneous exchange of the 2′-H atoms with solvent deuterium.[1] By specific ^{13}C-labeling of the 2′(imidazole) and 4 (nicotinamide) positions Klepp et al.[4] postulated structure **5** which was consistent with all experimental data and permitted the formulation of a plausible mechanism for the urocanase reaction (Scheme 3).

Scheme 3. Proposed mechanism for the urocanase reaction. R = ADP-ribosyl.

A definitive proof for structure **5** was provided by detection of direct ^{13}C-^{13}C coupling in the doubly ^{13}C-labeled adduct **5a**. Here we describe the synthesis of the [5′-^{13}C] imidazole propionic acid **6a** as well as the isolation and NMR spectroscopic characterization of the adduct **5a** enzymatically formed therefrom. The known 5-amino [5-^{13}C] levulinic acid · HCl **7** seemed to be a suitable precursor of **6a**. Starting from Cu^I [^{13}C]N (99% ^{13}C)[6] and methyl 3-chloroformylpropionate, **7** was prepared according to the method of Pfaltz et al.[5] The ring closure to

imidazole thiol **8** was accomplished by condensation of **7** with KSCN.[7] Subsequent oxidation with $Fe_2(SO_4)_3$[8] and ion-exchange chromatography (Dowex 50 W × 4, H^+-form) afforded

Spraul, Bruker Analytische Meßtechnik GmbH, Rheinstetten/Karlsruhe for the 600 MHz H NMR spectrum, Dr. H. Röttele for the ^{13}C NMR spectrum of the adduct, Dr. M. Lenz for the urocanase overproducing *E. coli* strain, and Ms. J. Herman for her assistance in numerous enzyme isolations.

the desired product **6a** (Table 1). [4-^{13}C]Nicotinic acid (99% ^{13}C) was prepared by using the method of Oberfrank et al.[9] and biosynthetically incorporated into urocanase.[4] The cultivation of *Pseudomonas putida* nic II (a nicotinate auxotrophic mutant), the isolation of the labeled enzyme, and the enzymatic formation of the NAD$^+$-imidazole propionate adduct were carried out as described by Klepp et al.[4] 250 mg (2.03 μmol) ^{13}C-labeled urocanase and 48 mg (300 μmol) [5′-^{13}C]imidazole propionic acid · HCl were used.

Table 1. Spectroscopic data of compounds **5a** and **6a**. NMR spectra in D_2O, sodium 3-trimethylsilyl-[$^2H_4$]propionate as reference for ^{1}H, external dioxane as reference ($\delta = 68.0$) for ^{13}C NMR spectra. The water signal in the ^{1}H NMR spectra was suppressed by pre-saturation. A, I, and P refer to the corresponding positions in adenine, imidazole, and pyridinium rings, α and β for the positions in the propionic acid side chain.

5a: ^{1}H NMR (600 MHz; D_2O, pD = 9.0): $\delta = 8.88$ (d, ^3J(H2,^{13}C4) = 5.4 Hz, 1H, P2), 8.78 (t, ^3J(H6,^{13}C4) = 6.2 Hz, ^3J(H6,H5) = 6.8 Hz, 1H, P6), 8.33 (s, 1H, A8), 8.01 (s, 1H, A2), 7.93 (dd, ^3J(H5,^{13}C5′) = 6.7 Hz, ^3J(H5,H6) = 6.8 Hz, 1H, P5), 7.61 (d, ^3J(H2′,^{13}C5′ = 9.5 Hz, 1H, I2′); ^{1}H NMR (400 MHz; D_2O, pD = 9.0): $\delta = 3.05$ (dt, ^3J (β-H, α-H) = 7.0 Hz, ^3J(^{1}H,^{13}C) ≈ 2 Hz, 2H, β-H), 2.47 (t, ^3J(α-H, β-H) = 7.0 Hz, 2H, α-H); ^{13}C NMR (100 MHz; D_2O, pD = 8.0, ca. 320 μg): $\delta = 130.12$ (d, ^1J (^{13}C5′,^{13}C′4) ≈ 70 Hz, 1C, C5′), 151.12 (d, ^1J(^{13}C4, ^{13}C5′) = 70 Hz, 1C, C4).

6a: ^{1}H NMR (400 MHz; D_2O, pD = 4.6): $\delta = 2.60$ (t, ^3J(α-H, β-H) = 7.3 Hz, 2H, α-H), 2.96 (dtr, ^3J (β-H, α-H) = 7.3 Hz, ^3J (^{1}H,^{13}C) = 4.4 Hz, 2H, β-H), 7.20 (dd, ^1J(^{1}H,^{13}C) = 200.3 Hz, ^4J = 1.3 Hz, 1H, H5′), 8.55 (dd, ^3J = 5.4 Hz, ^4J = 1.4 Hz, 1H, H2′); ^{13}C NMR (100 MHz; D_2O, pD = 3.9): $\delta = 20.99$ (β-C), 34.80 (α-C), 116.44 (C5′), 133.85 (C2′), 133.69 (C4′), 179.25 (COOH); MS (70 eV): *m/z*: 141.14 [M^+].

In the ^{13}C NMR spectrum (Table 1) of the partially purified doubly labeled adduct **5a** (Fig. 1) two doublets at $\delta = 130.1$ and 155.1 with a coupling constant of 70 Hz are discernible, which

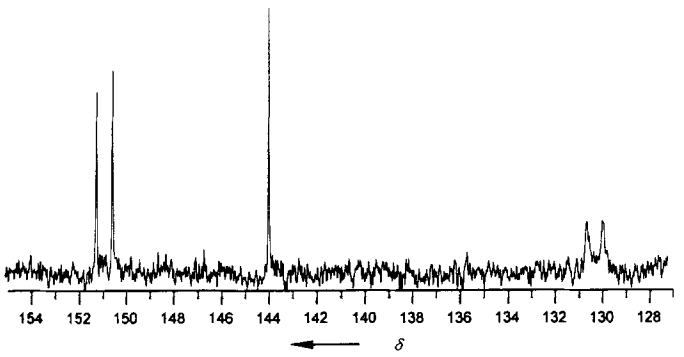

Fig. 1. Low-field portion of the ^{13}C NMR spectrum of the [4-^{13}C]NAD$^+$-[5′-^{13}C] imidazole propionate adduct **5a**.

is consistent with a direct ^{13}C-^{13}C coupling. The singlet at $\delta = 144.0$ arises from unreacted [4-^{13}C]NAD$^+$. In the low-field portion of the ^{1}H NMR spectrum of **5a** (Fig. 2; Table 1) most of the signals are identical with those of the adduct **5** formed from [4-^{13}C] NAD$^+$ and [2′-^{13}C] imidazole propionate.[4] One detects an additional coupling of $^3J = 6.7$ Hz in the 5-H signal ($\delta = 7.93$) of the nicotinamide ring (vicinal coupling with the 5′-^{13}C atom of the imidazole nucleus), and the 2′-H signal (doublet; $\delta = 7.61$) of the imidazole shows also a vicinal coupling constant of $^3J = 9.5$ Hz, instead of the direct one of $^1J = 212$ Hz in the spectrum of **5**.[4] An additional vicinal ^{1}H-^{13}C coupling is discernible also in the signal of the β-methylene

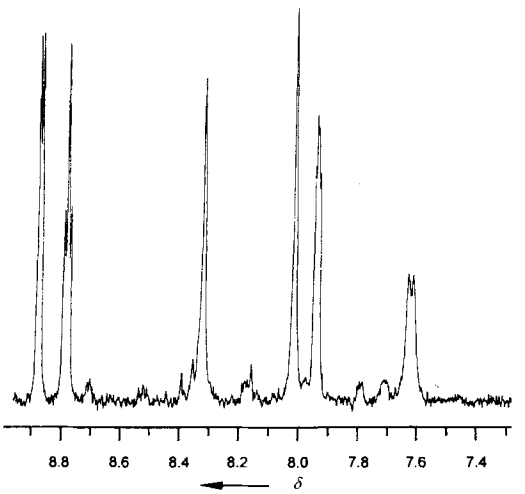

Fig. 2. Low-field portion of the ^{1}H NMR spectrum of the [4-^{13}C]NAD$^+$-[5′-^{13}C] imidazole propionate adduct **5a**.

group of the side chain of the imidazole propionic acid portion of the adduct **5a** (not shown).

All these findings support structure **5** proposed by Klepp et al. [4] for the isolated NAD$^+$-imidazole propionate adduct. In this light the mechanism of the urocanase reaction outlined in Scheme 3 seems to be even more likely.

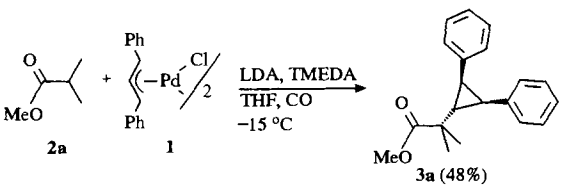
Cyclopropanes by Nucleophilic Attack of Mono- and Diaryl-Substituted (η^3-Allyl)palladium Complexes: Aryl Effect and Stereochemistry**

Andreas R. Otte, Andreas Wilde, and H. M. R. Hoffmann*



The reaction of (η^3-allyl)palladium complexes with stabilized carbon nucleophiles has matured into a major process for the formation of carbon–carbon bonds.[1] More recently the (η^3-1,3-diphenylallyl)palladium complex **1** has been investigated in

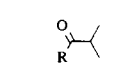
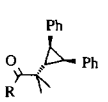
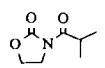
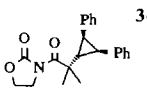
[**] This work was supported by Deutsche Forschungsgemeinschaft and by Fonds der Chemischen Industrie (PhD fellowship for A. W.). We thank Erhard Barho for experimental contributions and Degussa AG for their generous gift of palladium salts.

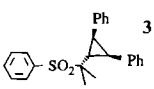
great detail with respect to asymmetric allylic alkylation, and experimental conditions have been established for high asymmetric induction by using a wide variety of bidentate ligands (P/P, N/P, N/N, N/S).[2]

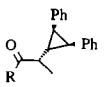


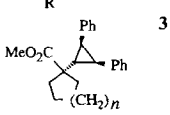


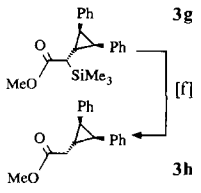












We now show that a slight change of nucleophile and ligand alters the product type decisively from that of allylic alkylation to (substituted) cyclopropane, by attack of the nucleophile at the *central* carbon of the allyl ligand. Thus, complex **1** reacted in the presence of the bidentate N/N ligand tmeda (N,N,N′,N′-tetramethylethylenediamine) with the lithium enolate of ester **2a** to give trisubstituted cyclopropane **3a** (Scheme 1). This cyclopropanation reaction is not limited to deprotonated esters, also deprotonated acid amides, modified Evans enolates (cf. **2c**), ketones, and sulfones afforded corresponding three-membered rings. Bulky tertiary carbanions were especially useful and reacted more satisfactorily than secondary carbanions (Table 1). The silylated nucleophile from methyl trimethylsilylacetate **2g** allows the indirect introduction of an unsubstituted acetic acid moiety after desilylation (**3g** → **3h**).

The monophenylated (η^3-1-phenylallyl)palladium complex **4** gave disubstituted cyclopropanes in good yields (Scheme 2, Table 2). However, attempts to transform simple alkyl-substituted (η^3-allyl)palladium complexes into cyclopropanes were not promising. For example, the (η^3-butenyl)palladium complex reacted with α-branched ester enolates, but not with other nucleophiles. Furthermore, introduction of a second methyl group as in the (η^3-1,3-dimethylallyl)palladium complex **6** provided no cyclopropanes at all, even when using experimental conditions optimum for converting the parent (η^3-allyl)palladium complex into cyclopropanes.[3]

In contrast, introduction of a single phenyl group as in the (η^3-1-methyl-3-phenylallyl)palladium complex **7**, afforded cyclopropanation products in good yields (Scheme 3). Apparently, the phenyl substituent facilitates cyclopropanation (aryl effect) for reasons which are not completely clear at present.

6 **7** **8** (82%)

Scheme 3.

The cyclopropanation was also applied to β-lactams, which are of potential interest in medicinal chemistry. Again, preparation of the mixed 1-methyl-2-phenylcyclopropane derivative with complex **7** was feasible (Scheme 4). Regarding the stereochemis-

Scheme 4. [a] Mixture of diastereomers (not separable by column chromatography).

try, the phenyl groups, which are *W*-configurated in the η^3-allyl complex **1**, are *cis* to each other in the products and therefore, potentially repel each other. The incoming nucleophile is *trans* to the two phenyl groups. Similarly, the *W*-configurated η^3-allyl complex **7** furnishes cyclopropane derivatives **8** (Scheme 3) and **11** (Scheme 4), in which the methyl and phenyl groups are *cis* to each other. Thus, in all reactions studied the formation of substituted cyclopropane is clearly disrotatory (13 examples).[4]

In summary, nucleophilic cyclopropanation of (η^3-allyl)palladium complexes is facilitated by terminal phenyl groups relative to methyl groups in the allyl ligand (aryl effect). The cyclopropanes are built up stereoselectively, and a quarternary carbon center[5] exocyclic to the three-membered ring is installed with ease.

Experimental Procedure

Tetrahydrofuran was distilled over sodium/benzophenone under nitrogen. (η^3-Allyl)palladium complexes were prepared from allyl alcohols or allyl chlorides by the method of Bosnich et al. [2a].

General procedure for generating carbanions: To a solution of lithium diisopropylamide (LDA) (1.1 mmol) or potassium bis(trimethylsilyl)amide (KHMDS) (1.66 mL, 1.1 mmol, 15% in toluene) in dry THF (5 mL) under nitrogen was added the protonated nucleophile (1.1 mmol) at −78 °C. After the solution had been stirred for 10 min it was warmed up to 0 °C and 10 min later recooled to −78 °C. If LDA was used as a base, TMEDA (0.17 mL, 1.1 mmol) was added, and the resulting solution was stirred until required.

Cyclopropanation: The dimeric (η^3-allyl)palladium chloride complex (0.275 mmol) in dry THF (5 mL) was placed in an oven-dried flask under nitrogen. The solution was cooled to −78 °C and TMEDA (0.17 mL) was added. After warming the mixture to the temperature given in the Tables, the carbanion solution (see above) was added dropwise through a double-tipped needle. Attachment of a CO balloon caused the reaction mixture to turn black and palladium to precipitate. After stirring for 30 min and warming to room temperature, the solvent was evaporated in vacuo and diethyl ether (50 mL) was added. The mixture was filtered and the filtrate washed with water. The aqueous layer was re-extracted with diethyl ether and the combined organic layers were washed with brine (20 mL), dried with $MgSO_4$, and concentrated. The resulting oil was purified by flash chromatography (silica gel, cyclohexane/diethyl ether, 5:1) to give the product as a colorless oil or solid.

Spectroscopic data of **3a**: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 7.02 (m, 10H, H_{arom}), 3.72 (s, 3H, OCH_3), 2.45 (d, J = 6 Hz, 2H, PhC*H*), 2.09 (t, J = 6 Hz, 1H, cyclopropyl CH), 1.29 (s, 6H, $(CH_3)_2C$); ^{13}C NMR ($CDCl_3$, 50 MHz, APT(Attached Proton Test) technique: primary and tertiary carbons give negative (↓) signals, secondary and quarternary carbons give positive (↑) signals: δ = 177.78↑, 137.84↑, 128.96↓, 127.73↓, 125.73↓, 51.91↓, 41.71↑, 33.49↓, 27.41↓, 23.48↓.

$[(terpy)Ru^{III}\{2,6\text{-}(Me_2NCH_2)C_6H_2\text{-}C_6H_2\text{-}2,6\text{-}(CH_2NMe_2)\}Ru^{III}(terpy)](CuCl_2)_4$ **2**-4$CuCl_2$

Scheme 1. Bis(dimethylaminomethyl)aryl Ru^{II} complexes. nbd = norbornadiene.

has as striking structural feature a perfectly planar 4,4′-biphenyldiyl bridge connecting the two Ru^{III} centers. Moreover, the mixed-valence complex $\mathbf{2}^{3+}$ displays strong electronic communication between the two metal centers.[3]

Complex **1**-Cl is an air-stable and water-soluble complex. Its reaction with three equivalents of $CuCl_2$ in dry and O_2-free MeOH, led to the green complex **2**-4$CuCl_2$ in good yield (60%) together with a minor deep red product (<10%), which was identified as **3**-PF_6 [Eq. (a)]. Complex **2**-4$CuCl_2$ is slightly soluble in CH_2Cl_2 but has a good solubility in polar solvents like MeCN, MeOH, or H_2O. Analytical data (^1H NMR, FAB-MS, and cyclic voltammetry (CV)) suggested that not only oxidation of the Ru^{II} center in **1** to Ru^{III} had occurred but also that $\mathbf{2}^{4+}$ is a diruthenium species formed by coupling of two units of $\mathbf{1}^+$.

The formation of **2**-4$CuCl_2$ by oxidation of **1**-Cl is unexpected in view of our early findings that oxidation of the arylnickel(II) complex $[Ni^{II}\{2,6\text{-}(Me_2NCH_2)_2C_6H_3\}X]$ (X = Cl, Br) with dihalogens or copper(II) halides results in quantitative formation of the trivalent arylnickel complex $[Ni^{III}\{2,6\text{-}(Me_2NCH_2)_2\text{-}C_6H_3\}X_2]$. Thus, in the latter reaction a clean one-electron oxidation of the nickel center occurs,[1] whereas the reaction of $\mathbf{1}^+$ with Cu^{II} leads to oxidation of both the ruthenium(II) center and the aryl ring. Formally the formation of $\mathbf{2}^{4+}$ can be seen as an oxidation of the C4–H bond. Obviously in the course of this process, besides C–C coupling, also competing ligand-transfer oxidation of the mononuclear ruthenium(III) intermediate with $CuCl_2$ takes place leading to formation of the 4-Cl derivative $\mathbf{3}^+$.

An X-ray structure determination[4] established that $\mathbf{2}^{4+}$ is indeed a binuclear complex containing a perfectly planar 4,4′-biphenyldiyl unit which connects the two octahedrally coordinated ruthenium centers through C1 and C1′, respectively. A PLUTON view is presented in Figure 1. Each ruthenium center

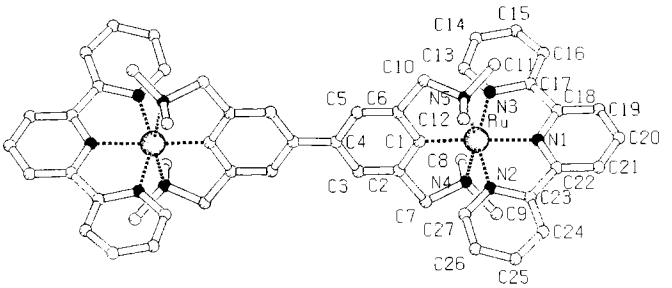

Fig. 1. PLUTON plot of the solid-state structure of **2**-4$CuCl_2$. The $CuCl_2^-$ ions, diethyl ether molecules (solvent of crystallization), and hydrogen atoms are omitted for clarity. Relevant bond lengths [Å], bond angles [°] and dihedral angles [°] are included in the text.

is coordinated by the three nitrogen atoms of a terpy and by three atoms of the *N,C,N′* bis-chelating pincer-pincer ligands. Both ruthenium atoms have a formal oxidation state of +3 leading to a cationic charge of +4 for the organometallic part, which is counterbalanced by the presence of four $CuCl_2^-$ ions in the unit cell.[4] The Ru···Ru intermetallic distance is 10.829(2) Å. A comparison of the various C–C bond lengths in the 4,4′-biphenyldiyl moiety of $\mathbf{2}^{4+}$ shows considerable differences amounting to 0.08 Å, (C2–C3, 1.361(12) vs. C3–C4, 1.441(15) Å), whereas the central C4–C4′ bond length has the value of a substantially shortened C–C single bond (1.436(12) Å). These data clearly show that at least in the solid state the π system of the 4,4′-biphenyldiyl bridging moiety in $\mathbf{2}^{4+}$ is completely conjugated between the two Ru^{III} metal centers. The extent of this conjugation is reflected in the electrochemical data (CV) of $\mathbf{2}^{4+}$ which have been compared with those of the mononuclear complexes $\mathbf{1}^+$ and $\mathbf{3}^+$ (Table 1). Cation $\mathbf{2}^{4+}$ can be reduced to the $Ru^{II}Ru^{III}$ mixed-valence complex, $\mathbf{2}^{3+}$, and subsequently to the $Ru^{II}Ru^{II}$ complex, $\mathbf{2}^{2+}$. Highly interesting is the large value of K_c (1250) (see Table 1) calculated from the electrochemical data

Table 1. Electrochemical data of complexes **1**–**4** in MeCN.

Complex [a]	$E_{1/2}$ [V] vs. SCE				K_c [b]

which points to strongly coupled ruthenium centers. The $Ru^{II}Ru^{II}$ complex 2^{2+} could be independently synthesized from the reaction of 2^{4+} with hydrazine. The UV/VIS spectral values, λ_{max} and ε_{max}, for the mononuclear and binuclear Ru complexes are given in Table 2. The NIR spectrum of the mixed-valence $Ru^{II}Ru^{III}$ complex, 2^{3+}, obtained by in situ oxidation of the $Ru^{II}Ru^{II}$ complex with Br_2,[5] was recorded in MeCN from 900 to 2400 nm. It showed a broad, intense, intervalence charge

Table 2. UV/VIS data for the ruthenium complexes **1**–**4** in MeCN.

Complex	λ_{max} [nm] (ε[$10^4 M^{-1} cm^{-1}$])
1^+	632 (0.55), 593 (0.53), 523 (0.52), 392 (0.59), 324 (3.07), 280 (2.31), 238 (2.15)
1^{2+} [a]	574 (0.55), 331 (3.45), 269 (16.05)
2^{2+}	618 (1.58), 593 (1.67), 528 (1.81), 377 (3.72), 324 (7.30), 280 (5.95)
2^{4+}	657 (11.70), 306 (3.84), 275 (4.66), 201 (17.03)

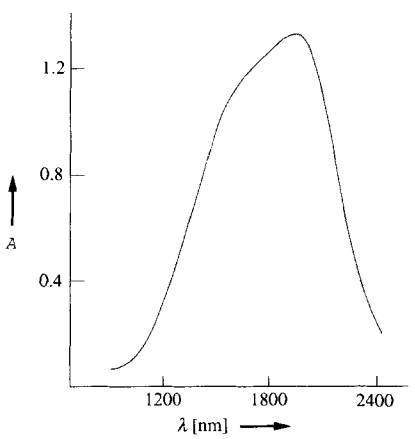
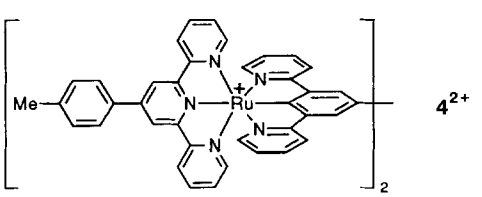
transfer (IVCT) band at 1875 nm ($\varepsilon = 33000\ M^{-1} cm^{-1}$) with a small overlapping band at 1650 nm (Fig. 2). As expected no NIR band was found for the $Ru^{II}Ru^{II}$ and $Ru^{III}Ru^{III}$ species.





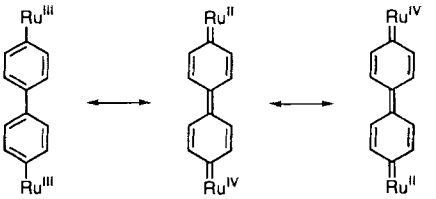


Fig. 2. NIR spectrum of complex 2^{3+} in the intervalence charge transfer region.

Recently, we reported a similar C–C coupling in the metalation reaction of the potentially terdentate N-C-N ligand 1,3-di(2-pyridyl)benzene (dpb-H) with $[Ru(tterpy)]^{3+}$ in the presence of oxygen and silver.[6] In the course of that reaction likewise not only a carbon–ruthenium but also a carbon–carbon bond was formed which led to 4^{2+}-$2PF_6$. The electrochemical and relevant spectroscopic data of 4^{n+} have been included in Tables 1 and 2. A comparison of these data and the structural features of 4^{n+} with those of 2^{p+} leads to the following results.

Binuclear 2^{3+} is among the strongest coupled diruthenium species ($K_c = 1250$, NIR band at 1875 nm, $\varepsilon = 33000\ M^{-1} cm^{-1}$) in spite of a large intermetallic distance ($Ru^{III} \cdots Ru^{III}$ separation of 10.829(2) Å; this distance is 11.009(2) Å in 4^{2+}). The dihedral angle between the phenyl rings in the 4,4′-biphenyldiyl moiety is practically 0° *in* 2^{4+} (vs. 22.2(7)° *in* 4^{2+}). The Ru^{III}-4,4′-biphenyldiyl-Ru^{III} central unit of 2^{4+} (Ru–C is 1.901(8) Å vs. 1.96(2) Å in 4^{2+}) can be envisaged as a diamagnetic formally Ru^{II}–Ru^{IV} conjugated polyene system (cf. ^1H NMR spectra and the double bond character of C4–C4′), as illustrated in Scheme 2. In 4^{2+}

Scheme 2. Limiting forms for the Ru^{III}-4,4′-biphenyldiyl-Ru^{III} system of 2^{4+}.

C4–C4′ is 1.51(1) Å with normal aromatic C–C distances in each ring. By changing the CH_2NMe_2 chelating groups of 2^{3+} for 2-pyridyl units as in 4^{3+}, the electronic communication between the metal centers is decreased ($K_c = 600$, NIR band at 1620 nm, $\varepsilon = 26000\ M^{-1} cm^{-1}$).

These results indicate that the amount of electron communication between the ruthenium centers may be modified by varying the electron-donating ability of the bridging ligand. The degree of twist between the two phenyl groups of the 4,4′-biphenyldiyl bridge should also be able to govern the extent of coupling. Further studies are directed to systems with larger and controllable torsion angles which would lead to tunable rates of electron transport through the molecule. Such systems may be useful building blocks for novel molecular switches.

Experimental Procedure

A suspension of complex **1**-Cl (0.20 g, 0.35 mmol) and $CuCl_2$ (0.13 g, 1.0 mmol) in MeOH (6 mL) was stirred at room temperature for 17 h to give a copper-colored solid and a deep red solution. The solvent was removed in vacuo and the residue dissolved in MeCN, to give a green solution which was subjected to chromatographic separation over a silica column with N_2 pressure. Elution with a solution of $MeCN/H_2O$/saturated KNO_3, (6/3/1 in volume) afforded a purple-blue band followed by a red one. The column was then eluted with a 5/5/1 mixture of the previous solvents to afford a major green band. The following workup was then applied to all three fractions: the solutions were concentrated to 1/3 in vacuo, an excess of NH_4PF_6 in solution in H_2O was added and the precipitate that formed was filtered off and washed with H_2O and Et_2O. The red fraction gave a deep red solid identified as complex **3**-PF_6 (0.04 g) and the green band gave a bronze-colored solid. The latter was dissolved in MeCN (2–3 mL), and the solution was added to CH_2Cl_2 (5 mL) and toluene (5–8 mL) to give the micro-crystalline red complex 2^{4+} (170 mg, 60%) with PF_6^- as counteranion.

Elemental analysis for **2**-$4PF_6$ + CH_2Cl_2 C 38.54, H 3.53, N 8.17 %; found C 38.88, H 3.76, N 7.98%. ^1H NMR (300 MHz, CD_3CN and some $N_2H_4 \cdot H_2O$, 25 °C TMS): $\delta(2^{2+})$ = 8.64 (d, ^3J(H,H) = 8.0, 4H), 8.49 (d, ^3J(H,H) = 7.8, 4H), 8.30 (d, ^3J(H,H) = 4.9, 4H), 7.98 (m, 6H), 7.68 (s, 4H), 7.50 (m, 4H), 3.75 (s, 8H; CH_2), 1.25 (s, 12H; NMe_2); δ(**3**-PF_6) = 8.60 (d, ^3J(H,H) = 8.0, 2H), 8.45, 8.19 (2m, 4H), 7.98 (t, ^3J(H,H) = 8.0, 1H), 7.91, 7.43 (2m, 4H), 7.24 (s, 2H), 3.60 (s, 4H; CH_2), 1.18 (s, 12H; NMe_2); FAB-MS (nitrobenzyl alcohol matrix): *m/z* (2^{2+}): 1195.0, (1195 for (**2**-PF_6)$^+$); *m/z* (3^{2+}): 705.0, (705.0 for (**3**-PF_6)$^+$).

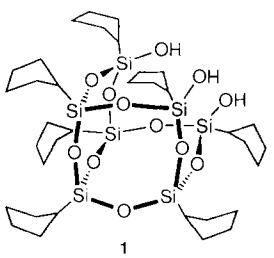
[4] **2**-4$CuCl_2$ was crystallized without chromatographic purification, (see Experimental Procedure). Crystals suitable for the X-ray structure analysis were obtained from $MeOH/CH_2Cl_2$ layered with Et_2O. Crystal data for **2**-4$CuCl_2 \cdot 2Et_2O$. $M_r = 867.65$, dark crystal ($0.20 \times 0.20 \times 0.25$ mm), monoclinic, space group $P2_1/c$ with $a = 12.1907(19)$, $b = 18.115(3)$, $c = 18.9597(17)$ Å, $\beta = 125.01(1)°$, $V = 3429.3(10)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.680$ g cm^{-3}, $F(000) = 1752$, $\mu(Mo_{K\alpha}) = 20.1$ cm^{-1}, 17010 reflections measured, 7877 independent ($1.7 < \theta < 27.5°$, $\omega/2\theta$ scan, $\Delta\omega = (1.28 + 0.35\tan\theta)°$), $T = 150$ K, $Mo_{K\alpha}$ radiation, graphite monochromator, $\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4T rotating anode diffractometer. Data were corrected for Lorentz and polarization effects and for a linear decay of 3%. An empirical absorption correction was applied (DIFABS, correction range 0.819–1.277). The structure was solved by automated Patterson methods and subsequent difference Fourier techniques (DIRDIF-92). Refinement on F was carried out by full-matrix least squares techniques (SHELX76); final R value 0.0588, $wR = 0.0559$, $w = 1/[s^2(F) + 0.000114F^2]$, $S = 1.537$ for 399 parameters and 4379 reflections with $I > 2.5\sigma(I)$. Hydrogen atoms were included in the refinement on calculated positions (C–H = 0.98 Å) riding on their carrier atoms. All non-hydrogen atoms were refined with anisotropic thermal parameters; the hydrogen atoms were refined with two common isotropic thermal parameters. Weights were introduced in the final refinement cycles. A final difference Fourier showed no residual density outside -0.83 and 0.85 eÅ^{-3} (near Ru). Further details of the structure determination, including atomic coordinates, bond lengths and angles, thermal parameters, and a thermal motion ellipsoid plot are available on request from the Director of the Cambridge Crystallographic Data centre, 12 Union Road, Cambridge CB2 1EZ (UK) on quoting the full journal citation.



[5] Br_2 was gradually added to the solution while monitoring the NIR band. Its maximum intensity was reached at a Br_2 to Ru_2 ratio of 1:2 and it had disappeared completely at a 1:1 stoichiometry.

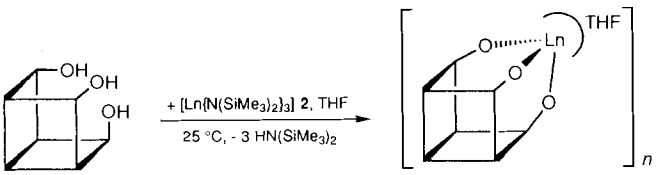
Molecular Siloxane Complexes of Rare Earth Metals—Model Systems for Silicate-Supported Catalysts?**



Wolfgang A. Herrmann,* Reiner Anwander, Veronique Dufaud, and Wolfgang Scherer

The preparation of realistic models of heterogeneous, SiO_2-supported transition metal catalysts eluded chemists for many years.[1] However, partially condensed oligosesquisiloxanes have lately proved to be reasonable model systems.[2] Since lanthanoid-doped zeolite catalysts are of considerable technical importance,[3] we have introduced oligosesquisiloxanes such as $[(c\text{-}C_5H_9)Si]_7O_9(OH)_3$ **1** as molecular models in the chemistry of the rare earth metals.[4]

1

We chose yttrium and neodymium as representatives of the lanthanoids. The metal complexes **3a**, **b** were obtained in quantitative yields according to the silylamide route given in Scheme 1. The course of the reaction was monitored by the

1

3a, Ln = Nd
3b, Ln = Y
$n = 1,2$

Scheme 1. Each corner of the formula representation corresponds to a cyclopentylsilicon group; oxygen atoms are found midway between the connected corners.

liberation of the silylamine (GC/MS analysis). **3a**, **b** are readily soluble in all organic solvents, even *n*-pentane, and were characterized by elemental analysis and IR spectroscopy (no ν(SiO–H) bands at ca. 3230 cm^{-1} typical of the starting material). Investigations by mass spectrometry (no signals < 300 °C) suggest dimeric structures in the solid state ($n = 2$) as found in the Al^{III} and Ti^{III} complexes.[2a, b] Whilst the ^1H, ^{13}C, and ^{29}Si NMR spectra could not be conclusively interpreted, the ^{89}Y NMR spectrum contains a single signal which indicates the presence of a well-defined compound and only one chemical environment of the Y atom. The shift of $\delta = 196.9$ is typical of lanthanoid siloxides (cf. $[Y(OSiMe_2tBu)_3(THF)_3]$, $\delta = 266.6$[5]). Attempts at recrystallization from common solvents such as THF, hexane, and benzene produced crystals that were amorphous by X-ray crystallography. However, with triphenylphosphane oxide as an auxiliary ligand, **3b** reacted to give the adduct **4** as single crystals.[6] Figure 1 shows the structure of the binuclear complex **4**.

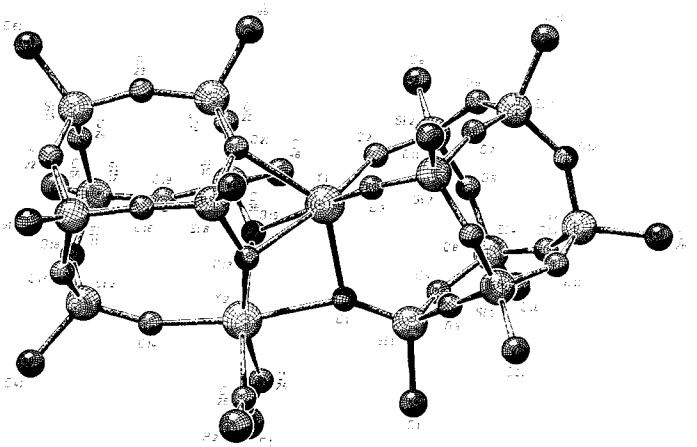


Fig. 1. Model of the molecular structure of **4** in the solid state (SHAKAL representation). To simplify the drawing, the cyclopentyl groups and the four solvent molecules are not completely represented. Selected bond lengths [Å] and angles [°]: Y1-O1 2.239(9), Y1-O2 2.119(7), Y1-O3 2.123(9), Y1-O13 2.422(7), Y1-O15 2.391(8), Y1-O21 2.509(9), Y2-O1 2.384(7), Y2-O13 2.25(1), Y2-O14 2.117(8), Y2-O15 2.255(8), Y2-O25 2.296(8), Y2-O26 2.26(1); Y1-O1-Y2 91.3(3); Y1-O13-Y2 90.0(4), Y1-O15-Y2 90.7(3), Y1-O21-Si8 92.9(4), Y1-O21-Si14 115.4(4), Si14-O21-Si8 141.1(5), Y2-O26-P1 157.0(6), Y2-O25-P2 153.3(6).

Both yttrium atoms have six-fold coordination. In contrast, the addition of the same phosphane oxide auxiliary ligand to the corresponding aluminum complex causes a *cleavage* of the dimer originally present.[2a]

[**] Lanthanoid Complexes, Part 7. This work was supported by Osram GmbH and the Alexander-von-Humboldt-Stiftung. We thank Dipl.-Chem. F.-R. Klingan for recording the NMR spectra. – Part 6: W. A. Herrmann, R. Anwander, W. Scherer, F. C. Munck, *J. Organomet. Chem.* **1993**, *462*, 163.

Furthermore, because of the considerable increase in the radius of the metal ion, as well as the increased oxophilicity of the metal compared to all other metal complexes containing this type of ligand, three bridging SiO units link the two metal centers (unsymmetrically). One of the yttrium atoms (Y1) achieves coordinative saturation by coordination to an oxygen atom in the ligand framework (O21; Fig. 2). This type of framework

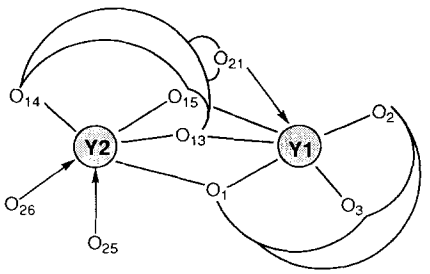

Fig. 2. Simplified representation of the coordination spheres of the yttrium atoms to emphasize the structural features of **4**. The *framework* oxygen atom O21 acts as a donor atom and completes the coordination sphere of Y1.

coordination is unknown for any of the known metal complexes of sesquisiloxanes, not even for any of the other lanthanoid siloxane complexes.[7] The distances from the yttrium center to the terminal [2.117(8)–2.123(9) Å] and bridging oxygen atoms [2.239(9)–2.422(7) Å] lie within the expected range.[7c] The Y–(O21) distance of 2.509(9) Å corresponds to a typical donor bond (cf. 2.374(20)–2.462(21) Å in $[Y(OSiR_3)_3(THF)_3]\cdot(THF)$, $R = C_6H_5$[7c]).

The Si-O-Si bridging oxygen atoms can act as Lewis bases in zeolite systems as well.[8] The binuclear complex units **4** are loosely packed in the solid state. Four crystallographically independent solvent molecules (toluene) are located in the resulting channels. The size of these solvent channels leads to a considerable disorder of the toluene molecules and explains the facile diffusion of the solvent out of the crystals even at low temperatures.

Organometallic compounds react preferentially with partially dehydroxylated silica surfaces, that is with $[Si(OH)_n]$ centers as opposed to [SiOSi] sites, towards which they usually behave indifferently.[4d] The yttrium complex **4** shows, for the first time, the coordination of [SiOSi] sites to an extremely oxophilic, electropositive metal center. This may permit interesting analogies with the structural chemistry of metal-doped zeolites. For example, in investigations of Ga-exchanged zeolites by IR spectroscopy altered lattice vibrations are observed,[3c, 9] which should correspond to a change in the catalytic properties. Furthermore, the attachment of neutral silicones of low molecular weight such as $(RSiO_{1.5})_4$ (R = *i*Pr, *t*Bu)[10] onto coordinatively unsaturated organolanthanoid compounds indicates the possibility of supporting a catalyst following the example in Scheme 1.

Experimental Procedure

In a glovebox (M. B. Braun) amides **2** and an equimolar quantity of **1** were weighed into a 100-mL round-bottomed flask. Roughly 40 mL of THF was added by condensation under high vacuum. The mixture was stirred for 1 h at 0 °C then allowed to warm to 25 °C. In the reaction of the yttrium amide a clear solution was obtained immediately, in the reaction of the neodymium amide only after 30 h. After ca. 40 h the solvent and the liberated amine were removed under vacuum (1 mbar). The colorless or light blue residue was dried for 3 h under vacuum (10^{-3} mbar). The residues are very soluble in *n*-pentane. Quantiative yields. **3a**: Starting from 0.58 g (0.92 mmol) **2a**, 0.81 g (0.93 mmol) **1**; light blue crystals; correct C,H,Si analysis (for two THF/Nd; no N); IR: $\tilde{\nu}$[cm^{-1}] = 1246 m, 1109 vs, 1088 (sh) vs, 1049 (sh) s, 998 s, 929 m, 875 w, 846 w, 525 m, 514 m. **3b**: Starting from 0.59 g (1.04 mmol) **2b**, 0.90 g (1.03 mmol) **1**; colorless crystals; m.p. 235 °C; correct C,H,N,Si analysis (for two THF/Y; no N); IR: $\tilde{\nu}$[cm^{-1}] = 1244 m, 1111 vs, 1087 vs, 1051 (sh) s, 1009 m, 954 m, 926 m, 914 m, 886 m, 841 (sh) w, 773 w, 519 m, 506 m, 483 m, 466 w. $^{13}C\{^1H\}$ NMR (400 MHz, C_7D_8, 25 °C): δ = 22.2–30.2 (complex pattern); ^{29}Si NMR (400 MHz, C_6D_6, 25 °C): δ = −65.64, −64.61, −62.74; ^{89}Y NMR (400 MHz, C_7D_8, 25 °C): δ = 196.9.

Olympiadane**

David B. Amabilino, Peter R. Ashton, Anatoli S. Reder, Neil Spencer, and J. Fraser Stoddart*

The appearance, toward the end of last year, of a remarkable paper in a special issue of the *New Journal of Chemistry*, edited by Sauvage, has drawn attention to the fact that, as long ago as 1960,

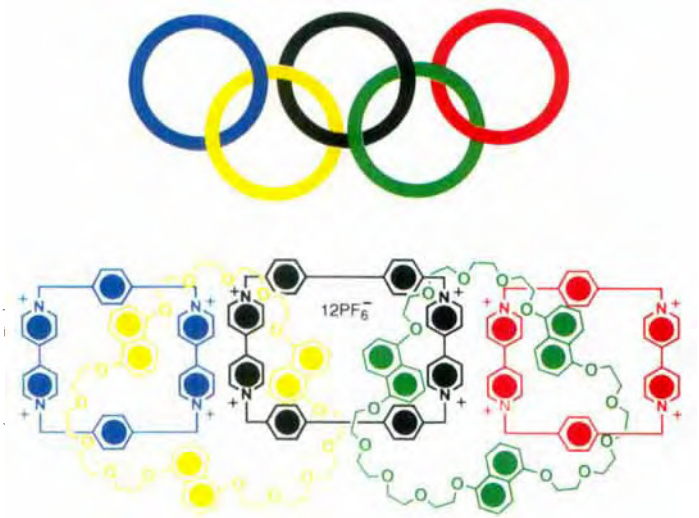
[**] This work was supported in the UK by the Science and Engineering Research Council.

van Gulick[1] had likened the well-known symbol of the International Olympics (Fig. 1 top)[2] to a pentacatenane, for which he had gone as far as to suggest the trivial name olympiadane.



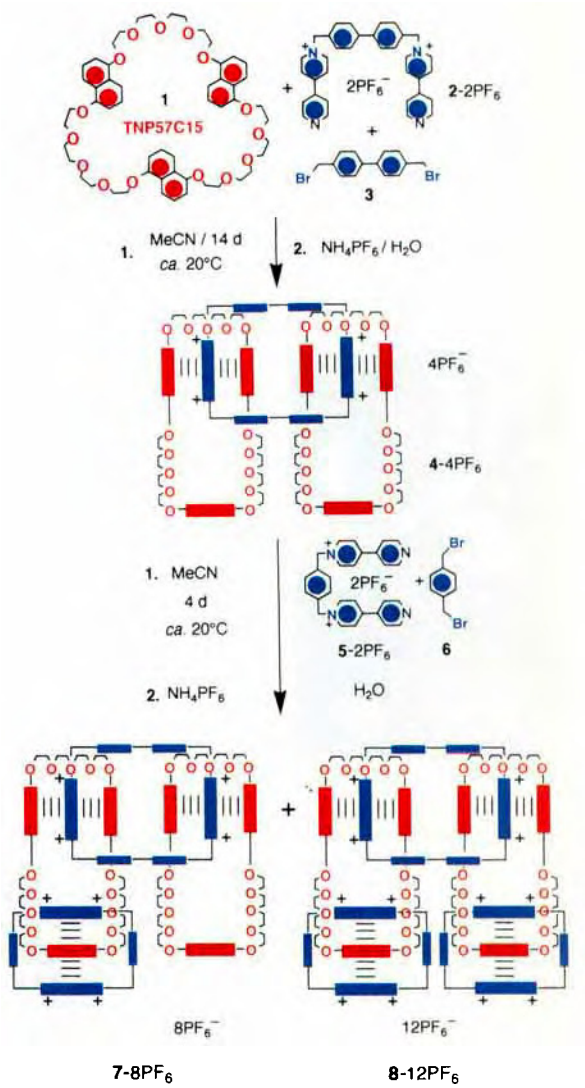


Fig. 1. The symbol of the International Olympics (top) and the structure of olympiadane (bottom).

Here, we describe the self-assembly (Scheme 1) and the characterization (Figs. 4–6) of the first molecular compound consisting of a *linear* array[3] of *five* interlocked rings. We propose to call this [5]catenane (Fig. 1 bottom) olympiadane.

Our first efforts[4] at making a [5]catenane culminated in a two-step self-assembly route (Fig. 2), which produced a [4]catenane and a whiff (< 0.5%) of a [5]catenane, which was only characterized by mass spectrometry. The reason for the reluctance of the [4]catenane to accept the addition of a fifth ring is enigmatic. Perhaps its templated formation is hindered by a negative intramolecular allosteric effect. Whatever the reason, it was clear that we needed to modify the recognition characteristics of the macrocyclic ether component. Since derivatives of 1,5-dihydroxynaphthalene are bound[5] within the receptor site of cyclobis(paraquat-*p*-phenylene) much more strongly than the analogous hydroquinone derivatives, we decided to replace the hydroquinone residues in the "failed" tris-*p*-phenylene[51]crown-15 with 1,5-dioxynaphthalene units. Here, we describe how this modification improves dramatically the templating features of the macrocyclic polyether component and enables the two-step self-assembly, *at ambient temperature and atmospheric pressure*, of a [5]catenane, which has been characterized conclusively by mass spectrometry (LSI-MS) and variable-temperature ^{1}H NMR (400 MHz) spectroscopy.

The trisnaphtho[57]crown-15 TNP57C15 **1** was prepared using a procedure[6] similar to that employed previously[4] in the preparation of tris-*p*-phenylene[51]crown-15. Reaction of **1** with two equivalents of 1,1′-[1,4-phenylenebis(methylene)]bis-4,4′-bipyridinium bis(hexafluorophosphate) (**5**-2 PF_6) and 1,4-bis(bromomethyl)benzene (**6**) in dimethylformamide (DMF) at ambient temperature and atmospheric pressure afforded[7] a [3]catenane as well as a [2]catenane, an outcome which boded well for the self-assembly of a [5]catenane under the same conditions. Next,

Scheme 1. The two-step template-directed synthesis of, firstly, the [3]catenane **4**-4 PF_6 from **1**, **2**-2 PF_6, and **3**, and secondly, the [4]catenane **7**-8 PF_6 and the [5]catenane **8**-12 PF_6 from **4**-4 PF_6, **5**-2 PF_6, and **6**. The chemical cartoons are defined as follows: *p*-phenylene rings: small blue rectangles; bipyridinium units: large blue rectangles; 1,5-dioxynaphthalene rings: red rectangles.

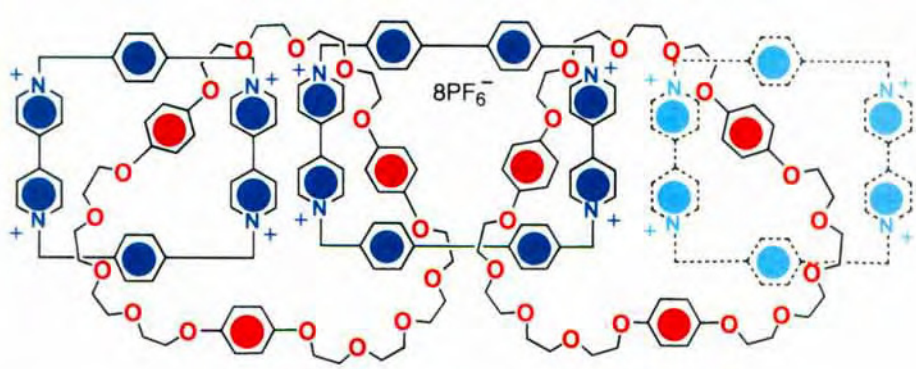

Fig. 2. The structure of the [4]catenane (solid-line drawing) comprising two tris-*p*-phenylene[51]crown-15 macrocycles, and the cyclophanes, cyclobis(paraquat-*p*-phenylene) and cyclobis(paraquat-4,4′-biphenylene). The [5]catenane (solid- plus dotted-line drawing) contains an additional cyclobis(paraquat-*p*-phenylene) macrocycle.

treatment of **2**-2PF_6 with equimolar amounts of **3** in the presence of an excess of **1** afforded[8] the [3]catenane **4**-4PF_6 (Scheme 1), albeit in a rather low yield.[9] The [3]catenane was then treated with an excess of **5**-2PF_6 and **6** at ambient temperature and atmospheric pressure. After just four days, the reaction mixture was subjected to column chromatography on silica gel, yielding, after counterion exchange, the unchanged [3]catenane **4**-4PF_6 (45%), the intermediate [4]catenane **7**-8PF_6 (31%), and the [5]catenane **8**-12PF_6 (5%), all beautiful violet-colored compounds (Fig. 3).

Fig. 3. The violet bands of the [4]catenane **7**-8PF_6 and the [5]catenane **8**-12PF_6 after column chromatography of the reaction mixture with MeOH/2M NH_4Cl(aq)/$MeNO_2$ (7:2:1) on silica gel for 24 h. Note that the unchanged [3]catenane **4**-4PF_6 has already been eluted from the column and is contained in the two conical flasks.

The positive-ion FAB[10] and LSI mass spectra[11] of **4**-4PF_6, **7**-8PF_6, and **8**-12PF_6 show similar fragmentation patterns to those previously reported[4] for the analagous [3]-, [4]-, and [5]catenanes, self-assembled from the appropriate components with tris-*p*-phenylene[51]crown-15 as the template. In addition to the sequential loss of PF_6^- ions, there is also a stepwise loss (Scheme 2) of macrocycles from the parent catenanes. Figure 4

Scheme 2. Fragmentation sequence in the LSI mass spectrum of **8**-12PF_6. The large red rectangle represents the macrocyclic polyether **1**, the small blue rectangle, cyclobis(paraquat-*p*-phenylene) tetrakis(hexafluorophosphate), and the large blue rectangle, cyclobis-(paraquat-4,4′-biphenylene) tetrakis(hexafluorophosphate). The masses given correspond to the peaks observed in the mass spectrum of **8**-12PF_6.

shows the high-mass region of the positive-ion LSI mass spectrum of **8**-12PF_6. A comparison of the theoretical and observed isotopic distributions in the $[M - 2PF_6]^+$ ion of **8**-12PF_6 is shown in Figure 5. By the use of peak matching at high resolution, and

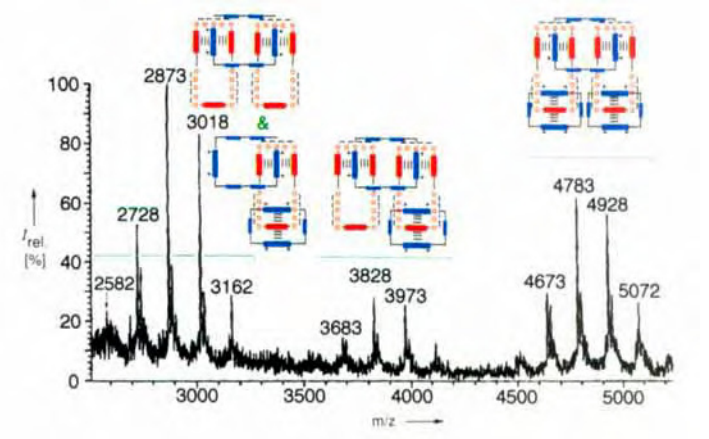

Fig. 4. The high-mass region of the positive-ion LSI mass spectrum of **8**-12PF_6, showing the sequential loss of hexafluorophosphate counterions, as well as the stepwise loss of the two smaller tetracationic cyclophanes and one of the macrocyclic polyethers.

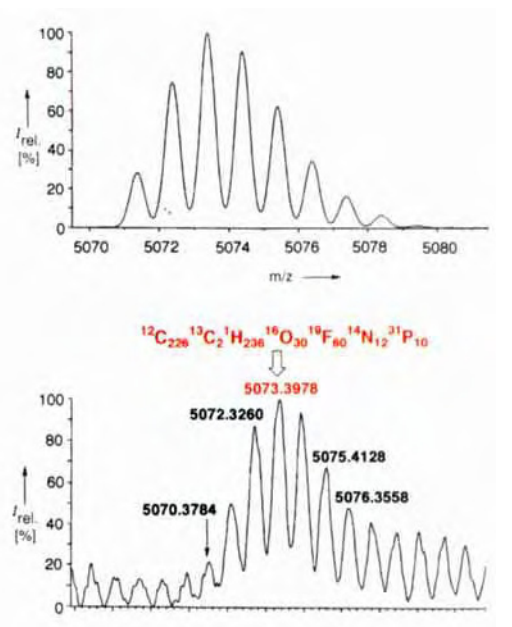

Fig. 5. A comparison of the theoretical isotopic distribution (top) for the $[M - 2PF_6]^+$ ion of the [5]catenane **8**-12PF_6 and its high-resolution LSI mass spectrum (bottom).

with CsI as a reference, the most abundant peak of this ion, which corresponds to $^{12}C_{226}{}^{13}C_2{}^{1}H_{236}{}^{16}O_{30}{}^{19}F_{60}{}^{14}N_{12}{}^{31}P_{10}$, was observed at *m/z* 5073.3978, a value that is within 5 ppm of the calculated mass.

The structure[12] of the [5]catenane **8**-12PF_6 was confirmed by variable-temperature ^1H NMR spectroscopy.[13] At ambient temperature, the 400 MHz ^1H NMR spectrum of **8**-12PF_6 recorded in CD_3CN shows well-resolved resonances at $\delta = 5.53$, 6.79, 7.72, 7.95, and 8.58 arising from the protons associated with the cyclobis(paraquat-4,4′-biphenylene) component, while all the other resonances are broadened by exchange processes. When the solution is warmed to 70 °C (Fig. 6), the four resonances for the nonequivalent protons in the two cyclobis(paraquat-*p*-phenylene) components become well resolved at $\delta =$ 5.68, 7.17, 7.94, and 8.58 as a result of relatively rapid movements and reorientations of the naphthalene rings in the macrocyclic polyether components out of and into the receptive cavities of these two smaller cyclophanes. Despite this observation, the reso-

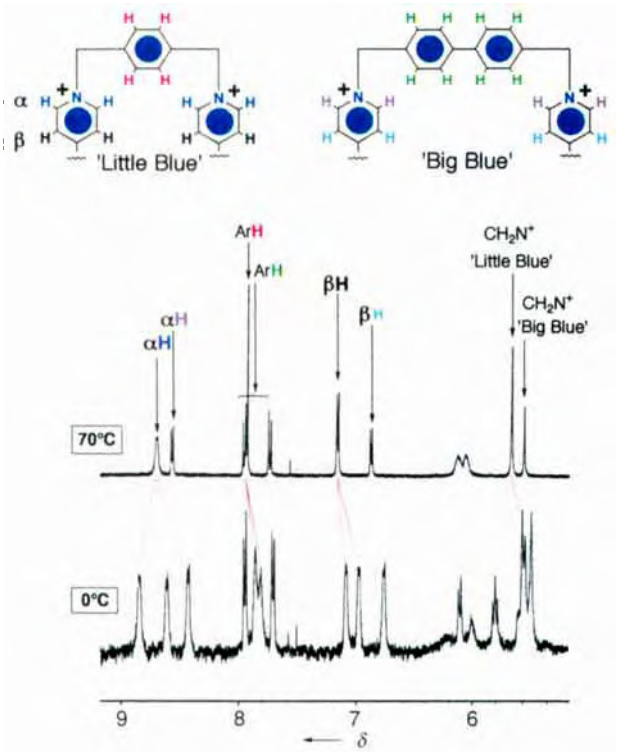

Fig. 6. The partial ^{1}H NMR spectra (400 MHz, CD_3CN) of the [5]catenane **8**-8 PF_6 recorded at 70 °C and 0 °C. The assignments of all the well-resolved signals at 0 °C have been confirmed by a two-dimensional homonuclear shift correlation experiment (COSY45). The spectrum obtained at 70 °C reflects the averaged D_{2h} symmetry of the molecule.

nances arising from the protons attached to the naphthalene rings remain broadened on account of the presumably larger limiting chemical shift differences associated with their resonances compared to those of the cyclophanes. Cooling the solution down to 0 °C results in a spectrum, wherein two sets of resonances are observed for each set of equivalent protons in the cyclobis(paraquat-*p*-phenylene) component. This doubling of the number of signals for the smaller cyclophanes is a result of the locally C_{2h}-symmetric 1,5-dioxynaphthalene units, which reside in their cavities and impose lower symmetries upon them. The "freezing" of the 1,5-dioxynaphthalene units inside the smaller cyclophanes is indicated by the emergence of resonances in the ^{1}H NMR spectrum at $\delta = 2.10$ (broad doublet for H-4/8), 5.82 (triplet for H-3/7), and 6.10 (doublet for H-2/6) arising from the naphthalene protons. The signals for the remaining two 1,5-dioxynaphthalene units in the polyether components remain broad, as these groups presumably oscillate between the interior and exterior of the larger tetracationic cyclophane. A $\Delta G_c^{\neq}$-value of 14.5 kcal mol^{-1} ($\pm$ 0.2 kcal mol^{-1}), corresponding to the reorganization of the smaller cyclophanes with respect to the included 1,5-dioxynaphthalene units, can be calculated[14] from the k_c-value of 369 s^{-1} at the coalescence temperature (T_c = + 37 °C) for the doublets centered on $\delta = 8.42$ and 8.84 (0 °C, $\Delta\nu$ = 166 Hz), which arise from the α-CH protons of the smaller cyclophane. A similar treatment of the coalescing doublets centered on $\delta = 6.97$ and 7.07 ($\Delta\nu = 41$ Hz) for the β-CH protons in the smaller cyclophanes affords a $\Delta G_c^{\neq}$-value of 14.7 kcal mol^{-1} ($\pm$0.2 kcal mol^{-1}) from a k_c of 92 s^{-1} at + 23 °C. This common free energy barrier of approximately 14.6 kcal mol^{-1} can be regarded as the one to be surmounted for the bound 1,5-dioxynaphthalene unit to be dislodged[15] from the centers of the smaller cyclophanes. The [3]catenane **4**-4 PF_6 and the [4]catenane **7**-8 PF_6 display similar multiple temperature dependencies in their ^{1}H NMR spectra.

The self-assembly[16] of olympiadane from eight components in two steps has been made possible as a result of programming sufficient molecular recognition into the constituent molecular components.[17] Reaching olympiadane—a structure some four nanometers in length when fully contracted—is symbolic in relation to developing the concept of self-assembly in chemical synthesis. When we can self-assemble a *high molecular weight, monodisperse* polymer, for example a polycatenane,[18] with *maximum efficiency*, *complete selectivity*, and *prescribed "information" content*, then the molecular self-assembly procedure will be a finely tuned and honed one. That is our ultimate goal.

Experimental Procedure

1: A solution of 1,5-bis[2-[2-[2-(1-naphthoxy-5-hydroxy)ethoxy]ethoxy]ethoxy]naphthalene (2.03 g, 2.55 mmol) in dry DMF (100 mL) was added to a stirred suspension of Cs_2CO_3 (19.39 g, 61.05 mmol) and CsOTs (1.98 g, 6.88 mmol) in dry DMF (200 mL) under nitrogen, and the temperature raised to 50 °C. After 1 h a solution of the tetraethyleneglycol bistosylate (1.39 g, 2.77 mmol) in dry DMF (100 mL) was then added during 1 h, and the temperature raised to 80 °C. Stirring and heating were continued for 4 d. The reaction mixture was then filtered, and the residue washed with DMF (100 mL) and EtOAc (100 mL). The solvent was removed under vacuum, and the residue was partitioned between CH_2Cl_2 (700 mL) and H_2O (250 mL). The CH_2Cl_2 phase was extracted once more with H_2O (250 mL), after which the organic solution was dried ($MgSO_4$) and concentrated under vacuum to afford a residue which was purified by column chromatography [SiO_2: CH_2Cl_2/EtOAc (9:1)] to yield **1** as a white solid (0.99 g, 40%, m.p. 81–83 °C); positive-ion FAB-MS: m/z = 954 for $[M]^+$; ^{1}H NMR ($CDCl_3$): $\delta = 3.64$–3.74 (m, 24H), 3.89 (t, J = 5 Hz, 12H), 4.17 (t, J = 5 Hz, 12H), 6.72 (d, J = 8.5 Hz, 6H), 7.28 (t, J = 8.5 Hz, 6H), 7.84 (d, J = 8.5 Hz, 6H); ^{13}C NMR ($CDCl_3$): δ = 68.0, 69.8, 70.8, 71.1, 105.7, 114.6, 125.1, 126.8, 154.4. When the same reaction procedure was repeated with 1,11-bis(1-naphthoxy-5-hydroxy)-3,6,9-trioxaundecane and 1,5-bis[2-[2-[2-(toluene-*p*-sulfonyl)-ethoxy]ethoxy]ethoxy]ethoxy]naphthalene as starting materials, a 35% yield of **1** was obtained.

4-4 PF_6: **2**-2 PF_6 (340 mg, 0.44 mmol), **3** (152 mg, 0.45 mmol), and **1** (1.023 g, 1.07 mmol) were combined as solids, and a dry mixture of MeCN (22 mL), DMF (1 mL), and CH_2Cl_2 (1 mL) was added. The suspension was allowed to stir at ambient temperature for 10 d, whereupon it was filtered, and the solvent was removed in vacuo yielding a purple solid. Column chromatography [SiO_2: MeOH/2 M NH_4Cl(aq)/$MeNO_2$ (7:2:1)], concentration in vacuo of the eluent containing the product, followed by solubilization of the residue in an H_2O/Me_2CO mixture, and precipitation by addition of aqueous NH_4PF_6 solution afforded **4**-4 PF_6 as a violet solid (83 mg, 6%, m.p. 109–111 °C) after filtration; positive-ion FAB-MS: m/z = 3016, 2871, 2062, 1917, and 1772 for $[M - PF_6]^+$, $[M - 2PF_6]^+$, $[M - 1 - PF_6]^+$, $[M - 1 - 2PF_6]^+$, and $[M - 1 - 3PF_6]^+$, respectively; ^{1}H NMR (CD_3CN): $\delta = 3.69$–3.74 (m, 48H), 3.75–3.81 (m, 24H), 3.82–3.88 (m, 24H), 5.51 (s, 8H), 6.21–6.42 (m, 24H), 6.50–6.64 (m, 20H), 7.65 (d, J_{AB} = 8 Hz, 8H), 7.88 (d, J_{AB} = 8 Hz, 8H), 8.42 (d, J = 7 Hz, 8H); ^{13}C NMR (CD_3COCD_3): δ = 65.6, 68.5, 70.5, 71.4, 71.5, 105.8, 114.2, 125.4, 125.9, 126.4, 128.7, 131.2, 134.5, 141.5, 144.7, 145.0, 154.0. See also ref. [9].

8-12 PF_6: **5**-2 PF_6 (58.4 mg, 0.083 mmol), **6** (24.2 mg, 0.092 mmol), and **4**-4 PF_6 (62.9 mg, 0.020 mmol) were dissolved in dry DMF (6 mL), and the solution was stirred for 2 d at room temperature and atmospheric pressure. Then, further quantities of **5**-2 PF_6 (60.2 mg, 0.085 mmol) and **6** (25.5 mg, 0.096 mmol) were added to the reaction mixture, which was stirred for an extra 2 d. The reaction was worked up as described above for **4**-8 PF_6, except that column chromatography was performed using a gradient elution [SiO_2: MeOH/2 M NH_4Cl(aq)/$MeNO_2$ (7:2:1) initially, increased slowly to 2 M NH_4Cl(aq)/DMF/MeOH/$MeNO_2$ (12:10:7:1)]. Counterions were exchanged by repeated precipitation from aqueous NH_4PF_6/Me_2CO mixtures, followed by thorough washing with water to remove all traces of ammonium salts. **4**-4 PF_6 was recovered from the column and was purified by crystallization from CH_2Cl_2/Et_2O (28.2 mg, 45%). Pure **7**-8 PF_6 was isolated as a violet solid (26.3 mg, 31%, m.p. > 250 °C); UV/VIS (MeCN, 25 °C): λ_{max} (charge transfer) = 531 nm, ε = 2190 mol^{-1} dm^3 cm^{-1}; LSI-MS: m/z = 4118, 3973, 3828, 3699, and 3554 for $[M - PF_6]^+$, $[M - 2PF_6]^+$, $[M - 3PF_6]^+$, $[M - 4PF_6]^+$, and $[M - 5PF_6]^+$, respectively; ^{1}H NMR (CD_3CN, 70 °C): $\delta = 3.60$–4.00 (m, 96H), 5.55 (s, 8H), 5.68 (s, 8H), 6.00–6.20 (br. m, 18H), 6.32 (d, J = 8 Hz, 6H), 6.47 (d, J = 8 Hz, 6H), 6.61 (t, J = 8 Hz, 6H), 6.70–6.85 (br. m, 8H), 7.16–7.20 (m, 8H), 7.70 (d, J_{AB} = 8 Hz, 8H), 7.92–7.99 (m, 16H), 8.45–8.55 (m, 8H), 8.68–8.76 (m, 8H). Pure **8**-12 PF_6 was isolated as a violet solid (5.1 mg, 5%, m.p. > 250 °C); UV/VIS (MeCN, 25 °C): λ_{max} (charge transfer) = 534 nm, ε = 2640 mol^{-1} dm^3 cm^{-1}; LSI-MS: m/z = 5072, 4928, 4783, and 4673 for $[M - 2PF_6]^+$, $[M - 3PF_6]^+$, $[M - 4PF_6]^+$, and $[M - 5PF_6]^+$, respectively; ^{1}H NMR (CD_3CN, 70 °C): $\delta = 3.60$–4.10 (m, 96H), 5.58 (s, 8H), 5.68 (s, 16H), 5.95–6.25 (br. m, 24H), 6.89 (d, J = 7 Hz, 8H), 7.17 (d, J = 7 Hz, 16H), 7.75 (d,

J_{AB} = 8 Hz, 8H), 7.94 (s, 16H), 7.97 (d, J_{AB} = 8 Hz, 8H), 8.73 (d, J = 7 Hz, 8H), 8.58 (d, J = 7 Hz, 16H). (The remaining 12H belong to one set of protons attached to the naphthalene rings. The resonances of these protons are broadened into the baseline by exchange processes.)

[1] The trivial name olympiadane has been proposed for the pentacatenane which resembles the symbol of the International Olympics. See N. van Gulick, *New J. Chem.* **1993**, *17*, 619 and the preface to this paper by D. M. Walba on p. 618. The special issue (Ed.: J.-P. Sauvage) of the *New Journal of Chemistry* published in October/November 1993 on "Topology in Molecular Chemistry" contains many excellent papers relating to catenanes.

[2] It has been pointed out (A. Nickon, E. F. Silversmith, *Organic Chemistry: The Name Game*, Pergamon, New York, **1987**, p. 160) that the coat of arms of the Ciba Foundation displays a [5]catenane with its rings portrayed slightly differently than the symbol of the International Olympics. It is noted that although "neither of these concatenated emblems has chemical significance"... "both symbols promote universal brotherhood among the five continents—the former in athletics and the latter in education and knowledge."

[3] A single macrocyclization afforded a series of catenanes containing three, four, five, six, and seven rings, in which one large ring was encircled by two, three, four, five and six small rings, respectively. The structure of these catenanes is different from the linear ones described in this communication. See C. O. Dietrich-Buchecker, J. Guilhem, A.-K. Khémiss, J.-P. Kintzinger, C. Pascard, J.-P. Sauvage, *Angew. Chem.* **1987**, *99*, 711; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 661; J.-P. Sauvage, *Acc. Chem. Res.* **1990**, *23*, 319; F. Bitsch, C. O. Dietrich-Buchecker, A.-K. Khémiss, J.-P. Sauvage, A. Van Dorsselaer, *J. Am. Chem. Soc.* **1991**, *113*, 4023; C. Dietrich-Buchecker, J.-P. Sauvage, *Bull. Soc. Chim. Fr.* **1992**, *129*, 113. Most recently, three rings have been templated around a bicyclic core. See C. O. Dietrich-Buchecker, B. Frommberger, I. Lüer, J.-P. Sauvage, F. Vögtle, *Angew. Chem.* **1993**, *105*, 1526; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1434.

[7] D. B. Amabilino, J. F. Stoddart, unpublished results.

[8] A minor product of this reaction was shown to be the [2]catenane comprising a cyclobis(paraquat-4,4'-biphenylene)cyclophane and *one* macrocycle **1**. The compound was isolated as a purple solid (2%, m.p. 159–161 °C); positive-ion FAB-MS: m/z = 2062, 1916, and 1770 for $[M - PF_6]^+$, $[M - 2PF_6]^+$, and $[M - 3PF_6]^+$, respectively; ^{1}H NMR (CD_3CN): δ = 3.72–3.76 (m, 24H), 3.81–3.86 (m, 12H), 3.97–4.02 (m, 12H), 5.69 (s, 8H), 6.43–6.53 (m, 12H), 6.78 (t, J = 8 Hz, 6H), 7.51 (d, J = 6.5 Hz, 8H), 7.56 (d, J_{AB} = 8 Hz, 8H), 7.64 (d, J_{AB} = 8 Hz, 8H), 8.75 (d, J = 6.5 Hz, 8H); ^{13}C NMR (CD_3CN): δ = 65.7, 68.7, 70.3, 71.2, 71.4, 106.4, 114.0, 126.5, 126.6, 126.7, 128.8, 130.7, 134.3, 141.6, 145.5, 147.4, 154.2.

[9] The low solubility of **1** in acetonitrile makes the self-assembly procedure leading to the [3]catenane difficult to perform in an efficient manner.

[10] FAB-MS (Fast Atom Bombardment Mass Spectrometry) for **4**-4PF_6 was carried out on a Kratos MS80RF mass spectrometer (accelerating voltage, 3 kV; resolution, 1000) coupled to a DS90 data system and off-line Sun Workstation for processing the raw data experiments. The atom gun was an adapted saddle-field source (Ion Tech Limited) operated at ca. 8 keV and a tube current of ca. 2 mA. Krypton was used to provide a primary beam of atoms, and the samples were dissolved in a small volume of 3-nitrobenzyl alcohol which had previously been coated onto a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

[11] For samples **7**-8PF_6 and **8**-12PF_6 LSI-MS (Liquid Secondary Ion Mass Spectrometry) was carried out on a Kratos Concept 1H mass spectrometer (accelerating voltage, 8 kV; resolution, 1000) coupled to a Sun Sparc Station with Mach3 software. The samples were dissolved in acetone, and a small volume (1–2 μL) was added to the 3-nitrobenzyl alcohol matrix. Spectra were recorded in the positive-ion mode at a scan speed of 5 s per decade. We gratefully acknowledge the assistance of Kratos Analytical, and in particular Dr. M. Kimber, Dr. H. Wight, and Dr. J. Moncur, in the collection of the mass spectra for these compounds.

[12] Apart from the linear sequence of macrocycles, several different topological isomers could be formed in the reaction that self-assembles the [5]catenane **8**-12PF_6. In particular, we may consider the possibility that an isomeric [5]catenane is formed where two cyclobis(paraquat-*p*-phenylene) rings clip onto *one* and the same component **1**. Further, it is possible that the same clipping procedure could occur simultaneously on the other ring **1**, yielding both a [6]- and a [7]catenane. There is preliminary evidence that, under appropriate conditions, these products are indeed formed. Alternatively, a cyclic dimer of the tetracationic cyclophane may also form, threading through macrocycles **1** in the [3]catenane, so as to create a cyclic [4]catenane. All these and other possibilities can be discounted on the basis of the spectroscopic data obtained for **8**-12PF_6.

[13] The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX400 spectrometer operating at 400.13 MHz and at 100.63 MHz, respectively. All chemical shifts are referenced by means of the residual CHD_2COCHD_2 or CHD_2CN signals to Me_4Si.

[14] The values of k_c were obtained (I. O. Sutherland, *Annu. Rep. NMR Spectrosc.* **1971**, *4*, 71) from the limiting chemical shift differences for exchanging signals by using the approximate expression $k_c = \pi(\Delta\nu)/(2)^{1/2}$. Rate constants were employed, along with the observed coalescence temperatures of the doublets for the α-CH and β-CH protons (attached to the smaller tetracationic cyclophanes in **8**-12PF_6), to calculate the $\Delta G_c^{\ddagger}$-values at the coalescence temperatures using the Eyring equation.

[15] In a highly ordered [2]catenane, in which the crown ether component (DNP38C10) incorporates two 1,5-dioxynaphthalene units, two processes corresponding to movement of the cyclic polyether through cyclobis(paraquat-*p*-phenylene) were observed: one where the included naphthalene ring is displaced, reorients itself, and then enters the cavity once again ($\Delta G_c^{\ddagger}$ = 15.8 kcal mol^{-1}), and the other where the crown ether circumrotates through the cavity of the tetracationic cyclophane ($\Delta G_c^{\ddagger}$ = 17.2 kcal mol^{-1}). $[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]$, a New Phosphorus-Bridged Copper Cluster**

Dieter Fenske* and Werner Holstein

Cluster complexes can be synthesized by treating halogeno(phosphane) transition metal complexes with silylated phosphanes.[1] For example, reactions of silylphosphanes R_2PSiMe_3 or $RP(SiMe_3)_2$ (R = organic group) with MCl and $M'Cl_2$ (M = Cu, Ag; M' = Zn, Cd) in the presence of phosphane ligands PR_3 result in a large number of cluster complexes that contain bridging phosphido and phosphinidene ligands.[2] Several examples are summarized in Scheme 1. The steric bulk of the organic groups at the bridging P atoms has a stabilizing effect on the framework of the cluster; however, this also prevents the formation of larger units.

$[Cu_4Cl(PPh_2)_3(PnPrPh_2)_3][Cu_4(PPh_2)_4(HPPh_2)_4]$
$[Cu_{18}(PPh)_4(PPh_2)_{10}(PHPh_2)_3][Cu_{13}Cl_6(PMe_2)_9]^{2-}$
$[Cu_5(PPh_2)_5(PR_3)_3]$(R = Ph,Me)$[Cu_{12}(PPh)_6(PR_2)_6]$(R = Ph, Tolyl)
$[Cu_{14}Cl_2(PPh)_6(PMe_3)_8][Cu_{14}Cl_2(PPH)_6(PEt_3)_6]$
$[Ag_4(PPh_2)_4(PMe_3)_4][Ag_6(PPh_2)_6(tBu_3)_2]$
$[M_4Cl_4(PPh_2)_4(PnPr_3)_2]$(M = Zn,Cd)

Scheme 1.

We have now investigated analogous reactions of CuCl in the presence of phosphanes PR_3 with $P(SiMe_3)_3$. If these reactions are carried out in THF, with the exception of PEt_3 which gave

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 195) and the Fonds der Chemischen Industrie.

crystalline **1**,[3] no crystalline compounds could be isolated from the resulting black solutions. In the reaction (a) the components must be used in the ratio $CuCl:PEt_3:P(SiMe_3)_3$ 1:0.5:0.6, since otherwise also in this case no crystalline products can be isolated. Compound **1** forms black crystals which are sparingly soluble in organic solvents and which react with water under decomposition.

$$CuCl \xrightarrow[PEt_3]{P(SiMe_3)_3} \underset{\mathbf{1}}{[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]} \qquad (a)$$

No signals appear in the ^{31}P NMR spectrum of the reaction mixture at room temperature which could be assigned to **1**; only the resonance signals of the starting materials are observed. Even at low temperatures only very broad ^{31}P NMR signals result from solutions of **1**. The IR spectrum likewise provides very little information. Therefore in order to determine the molecular structure an X-ray crystal structure analysis was carried out.[4]

A description of the structure is problematic, like those of the recently prepared Cu–Se[5] and Cu–Te clusters.[6] The reason for this is that no small cluster building blocks are recognizable from which the complete structure might be constructed. Remarkable is, however, that in **1** (without PEt_3 ligand) a Cu:P ratio of roughly 3:1 is present. Thus, it appears appropriate to discuss the structure of **1** in terms of its relationship to and similarities with that of Cu_3P.[7]

In the structure of Cu_3P a stacking order of Cu and P atoms is observed which could also be described as an arrangement of two differently composed layers. As a result the P^{3-} ions have the high coordination number eleven. In principle, this structure is based on a trigonal Cu_6 prism centered by P^{3-} ions; the faces of the prism are occupied by additional Cu^+ ions. The coordination numbers for the Cu^+ ions vary, namely 12 (8 Cu + 4 P; 9 Cu + 3 P) and 13 (9 Cu + 4 P).

A fragment of the Cu_3P structure occurs in **1** which has an unusual structure. The cluster core is sterically shielded by 18 PEt_3 ligands (P19–P27) and six μ_2-$P(SiMe_3)_2$ groups (P16–P18) (Fig. 1). Thus, the C atoms of the ethyl groups are strongly disordered.

The substituent-free P^{3-} ligands (P1–P15) show four forms of coordination: the P atoms at the cluster periphery act as μ_6 ligands (P5, P6, P8, and P13); P1, P3, P4, P7, P9–P12, and P15 function as μ_7 ligands. Similarly high coordination numbers as those observed in Cu_3P are only found for the four P atoms (P14, P14A, P2, P2A) in the center of the cluster, which are bound to nine and ten Cu atoms, respectively.

In **1** the Cu–P contacts differ in length: they are 216.5–255.6 to the substituent-free P atoms, 221.1–227.4 to the $P(SiMe_3)_2$ groups, and 217.9–224.0 pm to the PEt_3 groups. These values are significantly smaller than those of the Cu–P bonds in Cu_3P (236.7–257.5 pm); however, they can be compared to those of phosphane-substituted Cu clusters. If it assumed that P^{3-} and $P(SiMe_3)_2^-$ ligands occur, the Cu atoms in **1** attain the formal oxidation number 1 + (d^{10} configuration). The shortest distances between these Cu atoms are 240.3–279.8 pm; the corresponding values in Cu_3P are similar (262.8–277.5 pm). Ab initio calculations on smaller Cu complexes[8] show that bonding Cu–Cu interactions can be excluded if the Cu–Cu distances lie in this range. The reason for the relatively short Cu–Cu contacts in **1** could be dispersion interactions,[9] like those which occur in PR_3-stabilized Cu_2Se clusters.

The relationship of the structure of **1** to the Cu_3P type arises from the arrangement of the P^{3-} ions, which form an ABC order of layers. Nonbonding contacts between the P^{3-} ions are assigned to distances between 374 and 484 pm. The deviations from the average planes within these layers are ±38.2 pm (layer A, C) and ±61.8 pm (layer B). With the exception of P19, P21, and P25, the P atoms of the PEt_3 and $P(SiMe_3)_2$ ligands also lie within these layers. The layers show a network structure of corner-sharing rhombuses. The short and the long face-diagonals are each linked with one another in such a way that a section of a two-dimensional network results, which is indexed according to the Schläfli system as a 3^2434 net.[10] If these rhombuses are rotated by an angle of about 10° towards one another in the plane, hexagonal layers of P atoms are formed. Thus, the phosphorus framework in **1** can be considered as a distorted section of hexagonal packing.

The Cu atoms are inserted in different ways in this network. Fifty-two Cu atoms are inserted into the P layers, in which they are surrounded by two P atoms (Cu1–Cu4, Cu7, Cu10, Cu12, Cu14–Cu16, Cu18, Cu21, Cu24, Cu27, Cu30, Cu32, Cu35, Cu37, Cu40, Cu47, Cu48—this arrangement leads to slightly bent P-Cu-P angles of 152–168°) or by three P atoms (Cu5, Cu9, Cu19, Cu33, Cu44—this arrangement leads to a trigonal planar structure). Between the layers there are 44 Cu atoms, which are surrounded by P atoms either in a trigonal planar

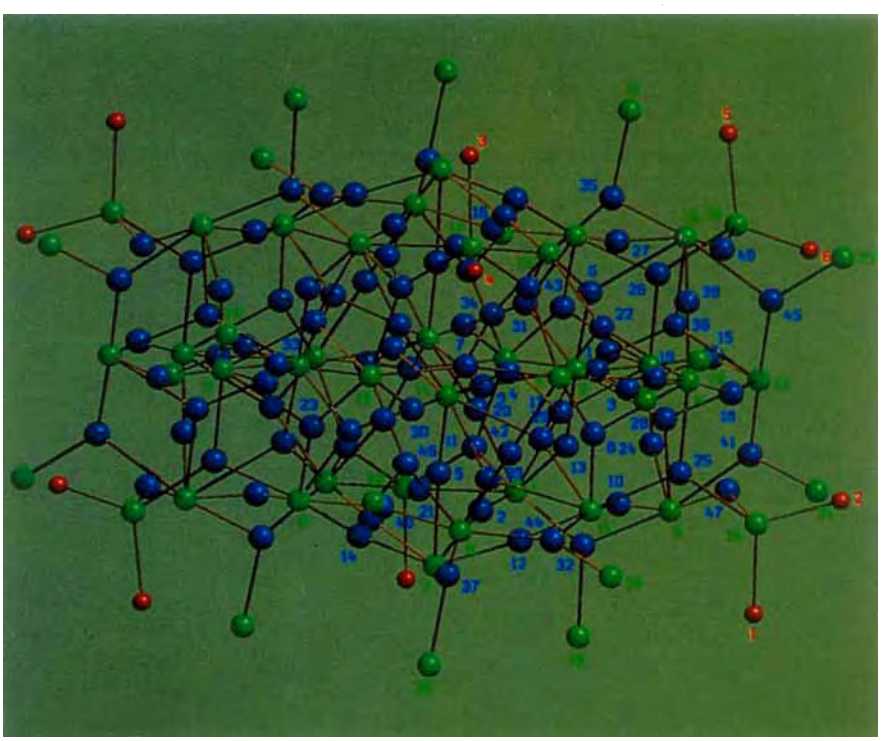

Fig. 1. Molecular structure of **1** in the crystal (without C atoms). For clarity no Cu–Cu contacts are drawn. The Cu atoms are blue, the P atoms green, and the Si atoms red. All atoms shown have been assigned color-coded numbers which correspond to the appropriate elements. In the figure only one set of symmetrically equivalent atoms is labeled (substituent-free P atoms: 1–15; $P(SiMe_3)_2$ groups: 16–18; PEt_3 ligands: 19–27).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1212-1291 $ 10.00+.25/0

fashion (Cu17, Cu22, Cu23, Cu25, Cu26, Cu28, Cu36, Cu38, Cu41, Cu42, Cu45, Cu46) or in a distorted tetrahedral fashion (Cu6, Cu8, Cu11, Cu13, Cu20, Cu29, Cu31, Cu34, Cu39, Cu43).

Overall the structure of **1** can be considered as an intermediate in the formation of the Cu_3P structure. The course of events which take place during the growth of such a cluster cannot be described at present. NMR investigations show that CuCl–phosphane complexes are partly dissociated in solution and that an equilibrium exists between coordinated and free phosphane.[11] In contrast, the coordination of $P(SiMe_3)_3$ to Cu atoms is irreversible due to the elimination of $SiMe_3Cl$. The growth of the cluster is limited by the solubility of the units formed, since when cluster units become too insoluble they precipitate. The favorable position of the participating complex equilibria seems particularly important. If the stoichiometry of the reactants is changed and the PEt_3 contribution is increased, the formation of **1** can no longer be observed. From this point of view **1** is only an intermediate.

Attempts to use the reactive centers of **1** (the six μ_2-$P(SiMe_3)_2$ ligands) for the construction of larger units have been unsuccessful so far. The main reason is the poor solubility of **1**. Compound **1** decomposed on treatment with nonmetal halides such as PCl_3, $RPCl_2$, and R_2PCl; the cluster also did not react with additional CuCl.

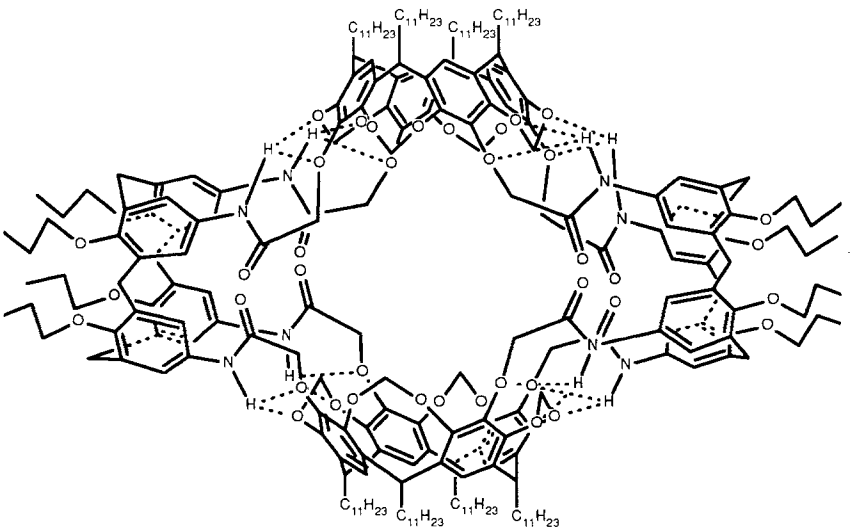
An Organic Molecule with a Rigid Cavity of Nanosize Dimensions

Peter Timmerman, Willem Verboom, Frank C. J. M. van Veggel, Willem P. van Hoorn, and David N. Reinhoudt*



The rapidly expanding field of supramolecular chemistry[1–3] has revealed a number of useful building blocks for the synthesis of artificial receptor molecules, for example calixarenes,[4] cyclodextrins,[5] and resorcinol-based cavitands.[6] Nature constructs an almost infinite number of macromolecular receptors by the systematic combination of a limited number of building blocks. We are currently exploring an analogous approach for the synthesis of host molecules by the combination of simple rigid building blocks.[7] Recently, this method has resulted in the synthesis of several new receptor molecules with unique complexation properties.[8–11] These molecules possess small cavities suitable for the complexation of alkali metal cations, anions, or small organic molecules. The synthesis of receptor molecules with large cavities generally meets with the problem that such cavities collapse because of the inherent flexibility of large organic molecules. Recently, a few examples of receptor molecules with large, relatively open, rigid cavities were reported by Sanders et al.[12] in which rigid planar components (porphyrins and cholic acid derivatives) were linked by single covalent bonds.

In this paper we describe a new approach to receptor molecules with large cavities by the combination of building blocks which already possess a cavity, namely calix[4]arenes and resorcinol-based cavitands. The assembly of four such units in a cyclic array provides a convergent route for the synthesis of holand **1**,[13] an extremely rigid host molecule in which the cavities of the four components form a shielded hole of nanosize dimensions.

As part of our work on the synthesis of selectively functionalized resorcinol-based cavitands,[14] we studied the reaction between cavitand **2**[15] and upper rim 1,2-functionalized calix[4]arene **3**. Compound **3** was prepared in 72% overall yield by reduction of the corresponding 1,2-dinitro compound[16] and subsequent reaction with two equivalents of α-chloroacetyl chloride. When this reaction was performed in $CH_3CN/Cs_2CO_3/KI$ (ratio **2**/**3** 1:1), we isolated compound **4a** (20% yield), in which the calix[4]arene moiety is coupled in a 1,2 fashion, that is to two neighboring arene rings of **2** with the *endo* stereochemistry, together with 32% of the *exo* isomer **4b**.[17] In addition to these 1:1 adducts small amounts of the three possible isomeric 2:1 products **5a–c** were formed. Products in which the calix moiety is coupled in a 1,3 (distal) fashion to the cavitand could not be detected. When **2** was treated with two equivalents of **3** only the 2:1 addition products were isolated in an almost statistical ratio of *endo-endo* (**5a**, shown), *endo-exo* (**5b**), and *exo-exo* (**5c**) in a total yield of 64%.[18]

Apparently in this reaction there is a slight preference for the formation of the *exo* 1:1 product. The formation of the *endo* 1:1 product is favored by the introduction of functional groups at the calix[4]arene fragment that favorably interact with the cavitand moiety in the transition state. Reaction of a 1:1 mixture of **2** and calix[4]arene **6**,[19] in which two nitro groups have been introduced, exclusively gave the *endo* 1:1 isomer **7** together with small amounts of the 2:1 products **8a** (*endo-endo*) and **8b** (*endo-*

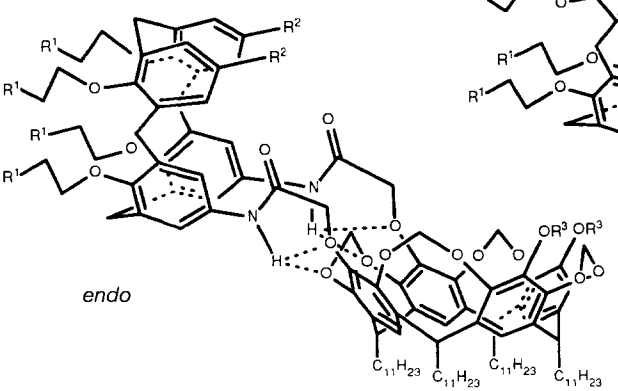
1

exo). Because of its instability **7** was isolated, after silylation of its free hydroxyl groups,[20] as **9** in 41% yield. The nitro groups in **9** could easily be reduced to amino groups by using Raney Ni/hydrazine.[16] The subsequent reaction with α-chloroacetyl chloride led to the bis(2-chloroacetamide) derivative **10** in quantitative yield. Compound **10** was dissolved in dimethylformamide (DMF; 5 mM) and desilylated with CsF at 80 °C; the solution was subsequently stirred for 48 hours in the presence of Cs_2CO_3 and KI to give two reaction products. The more polar product (isolated in 27% yield) is the calix[4]arene-based carcerand **11** with one molecule of DMF inside its interior. The presence of this permanent guest molecule is evident from both FAB mass spectrometry ($m/z = 2126$ (100%) $[M + DMF + Na^+]$) and ^1H NMR spectroscopy (two different singlets for the two methyl groups of DMF at $\delta = 0.66$ and -0.86.[21])



The second product (isolated in 26% yield) is the desired holand **1**. This compound could also be synthesized in 35% yield by dropwise addition of an equimolar solution of **12**[22] and **2** in DMF to a suspension of Cs_2CO_3 and KI in DMF. The FAB mass spectrum proves the formation of the 2:2 structure ($m/z = 4084$ (100%) $[M + Na^+]$) and the ^1H NMR spectrum (Fig. 1) reflects the high degree of symmetry expected for **1**. For its size, the molecule is extremely rigid: The calix[4]arene and cavitand moieties,

11

which are intrinsically rigid, are connected by two highly organized spacers. This becomes evident when the ^{1}H NMR spectra of compounds **3** and **5a** are compared with that of **1**. The signals of the aromatic protons *ortho* to the amide in **3** differ only by 0.08 ppm in chemical shift as a result of almost free rotation around the C(arene)–N bond. However, in **5a** the $\Delta\delta$ value is much greater because two of these calixarene moieties are coupled with the cavitand. The 0.85 ppm chemical shift difference is illustrative for the rigidity in the amide spacers of **5a**. In holand **1** the mobility of the calixarene fragments is further reduced to give a $\Delta\delta$ value of 1.0. The rigidity of the structure of **1** is even better exemplified when the chemical shift difference between the two methylene protons in the spacer in **3** and **5a** is compared with that in **1**. Whereas these protons in **3** give a singlet, this splits in **5a** to show an AB system with $\Delta\delta = 0.4$.

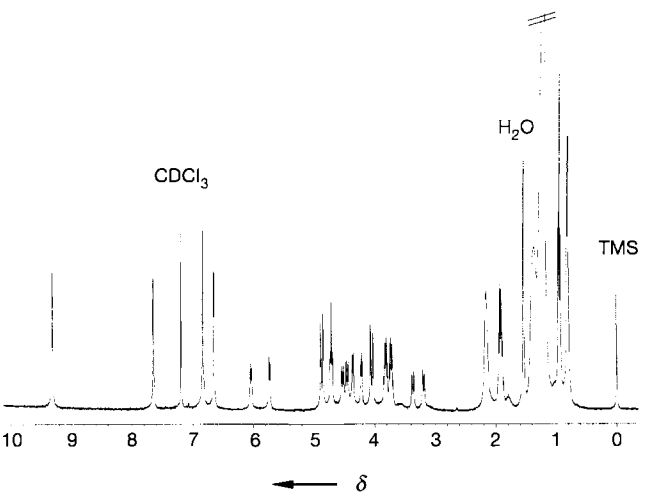

Fig. 1. ^{1}H NMR spectrum (400 MHz) of **1** in $CDCl_3$ at room temperature.

The motion of the calixarene fragments still present in **5a** mainly takes place by rotation around the O–CH_2 bond in the spacer. When this motion is finally frozen completely in **1** the $\Delta\delta$ value between the two AB doublets is 0.85. The above mentioned rigidity of **1** is partly a result of the three-center hydrogen bonds between the amide hydrogen atoms, the oxygen atoms in the spacer itself, and the oxygen atoms in the methylenedioxy bridges. These bonds are indicated in **1** with dashed lines.[23]

When compound **10** was used at a higher concentration (11 mM), the yields decreased from 27 (**11**) and 26% (**1**) to 12 (**11**) and 12% (**1**), respectively. Apparently, polymerization predominates at this concentration.

Holand **1** contains a cavity of nanosize dimensions. According to CPK models, the axes are about 1.5 and 2.0 nm long. The calculated internal volume is approximately 1.0 nm^3 (1000 $Å^3$). Figure 2 represents a picture of the energy-minimized structure

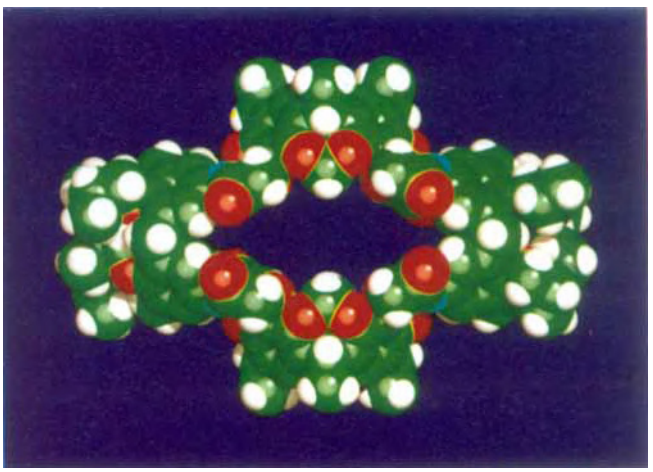

Fig. 2. Energy-minimized structure of holand **1** (undecyl chains have been replaced by methyl chains for simplicity).

of **1**. This minimized structure was subjected to a 50 ps dynamics simulation at 300 K in a $CHCl_3$ box with 46 Å edges. During this simulation four chloroform molecules entered the cavity and stayed there for the rest of the simulation without changing the shape of the cavity. This supports likewise the rigid structure of **1**. The organization of the amide spacers was clearly observed in this simulation. Although the hydrogen bonds were sometimes broken, they reformed after a short period of time. Rotation around the C(arene)–N bond was not observed.

Holand **1** is expected to have unique complexation properties. The size of the cavity permits complexation of host molecules which themselves are good complexing agents. Such complexation studies are currently under investigation.

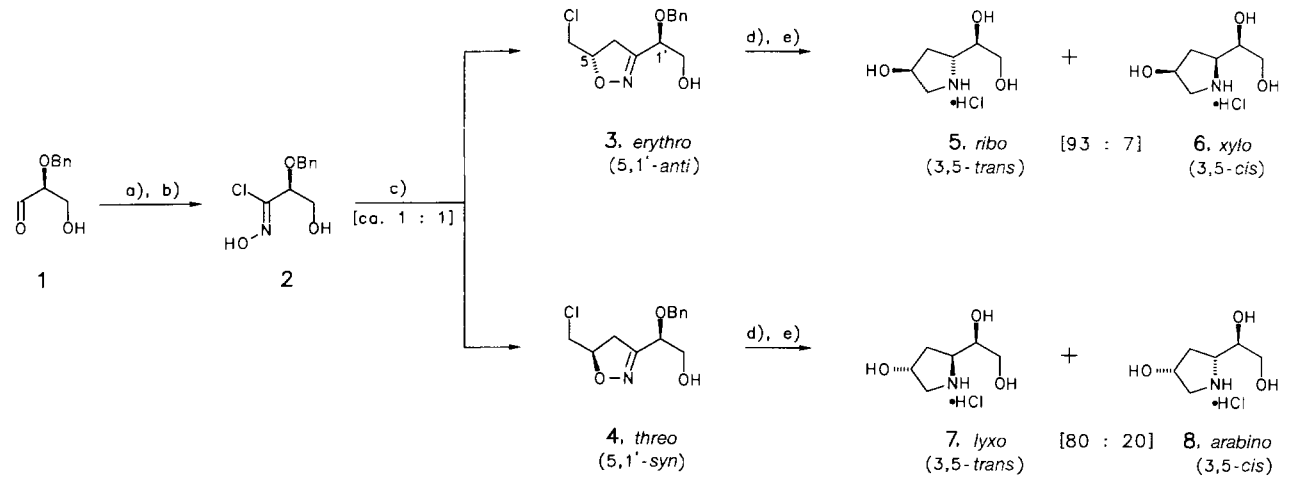
[15] This compound was prepared as described in: J. C. Sherman, C. B. Knobler, D. J. Cram, *J. Am. Chem. Soc.* **1991**, *113*, 2194–2204.
[16] J.-D. van Loon, J. F. Heida, W. Verboom, D. N. Reinhoudt, *Recl. Trav. Chim. Pays-Bas* **1992**, *111*, 353–359.
[17] The configuration was determined by using NOE spectroscopy. In a compound very similar to **5c** in which the undecyl chains have been replaced by methyl chains, a short-distance contact was observed between the protons of the unsubstituted aromatic rings and the protons of the methyl groups, indicating that this compound adopts the *exo* configuration. The configurations of all the other compounds could be easily determined by comparing their ^{1}H NMR spectra with that of **5c**.
[18] Compounds **5a–c** have large hydrophobic surfaces and show selective complexation of several corticosteroids in $CDCl_3$ solutions. These results will be described elsewhere.
[19] P. Timmerman, W. Verboom, D. N. Reinhoudt, A. Arduini, S. Grandi, A. R. Sicuri, A. Pochini, R. Ungaro, *Synthesis*, **1994**, 185–189.
[20] The crude reaction mixture was first subjected to a silylation reaction with 20 equiv of *tert*-butyldimethylsilyl chloride, 20 equiv of NEt_3, and a catalytic amount of dimethylaminopyridine in CH_2Cl_2 for 24 h at room temperature, because of the instability of **7** on silica gel.
[21] This incarceration of solvent molecules has been frequently observed by Cram, see ref. [15] and also: a) D. J. Cram, S. Karbach, Y. H. Kim, L. Baczynskyj, K. Marti, R. M. Sampson, G. W. Kalleymeyn, *J. Am. Chem. Soc.* **1988**, *110*, 2554–2560; b) J. C. Sherman, D. J. Cram, *ibid.* **1989**, *111*, 4527–4528; c) J. A. Bryant, M. T. Blanda, M. Vincenti, D. J. Cram, *J. Chem. Soc. Chem. Commun.* **1990**, 1403–1405. The stability of **7** was determined by an exchange experiment in [D$_7$]DMF at 100 °C for 1 h. No exchange of DMF was observed at this temperature. Further work on these carcerands will be described elsewhere.
[22] Compound **12** was obtained from **8a** in quantitative yield in a similar way as **10** was prepared starting from **9**.
[23] Evidence for these hydrogen bonds was obtained from a quantitative NOE analysis performed with **5a** in which the distance between the aromatic protons *ortho* to the amide and the outer methylene proton was determined to be 2.5 Å and the distance between the amide protons and the outer methylene proton was determined to be 2.8 Å.

A New Synthesis of 1,3,4-Trideoxy-1,4-iminoglycitols of Varying Chain Length by (C_3 + C_n)-Coupling of Allyl Halides with Glyconitrile Oxides**

Rudolf Müller, Thomas Leibold, Michael Pätzel, and Volker Jäger*

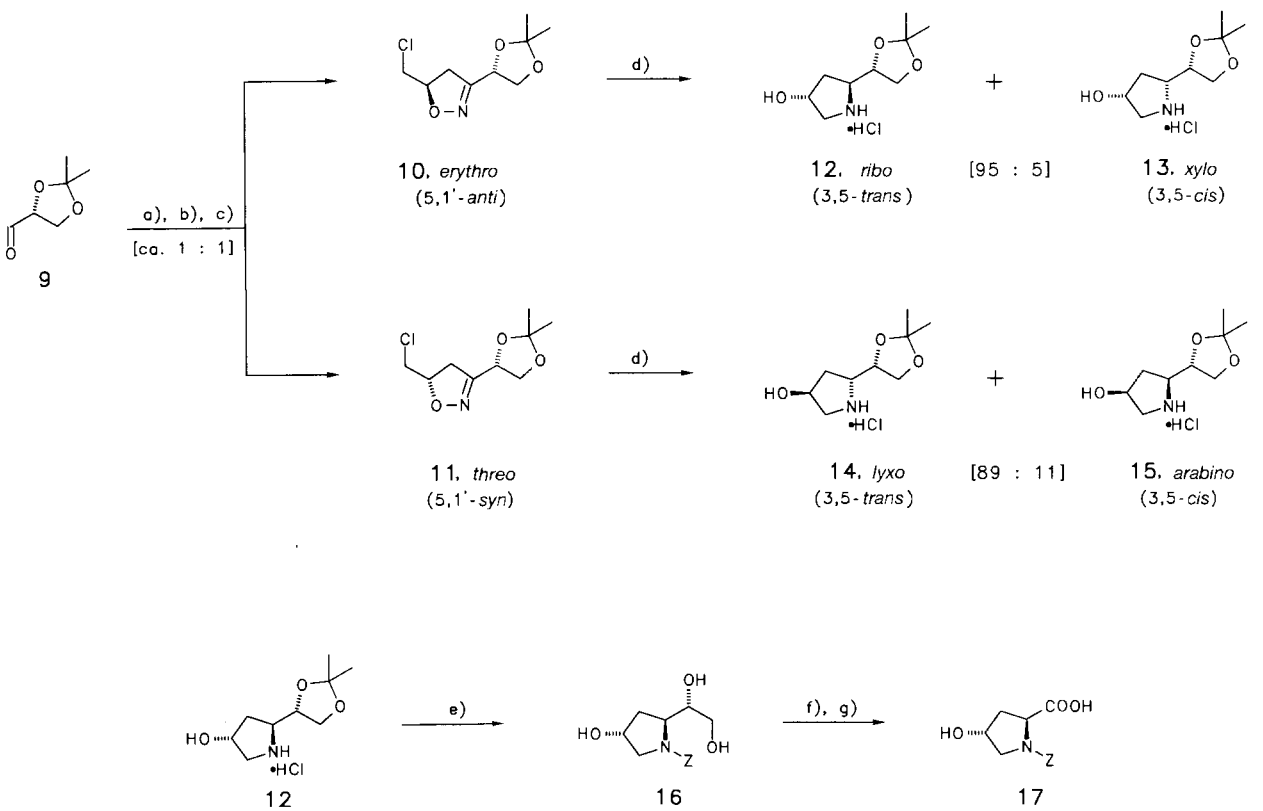
Dedicated to Professor Heinz Günther Viehe on the occasion of his 65th birthday

Iminoglycitols such as **A** have attracted attention both as target compounds and as intermediates for polyhydroxylated N-bicycles. Some of the well-known representatives of this series that often act as powerful glycosidase inhibitors are pyrrolidine derivatives such as 1,4-dideoxy-1,4-imino-L-arabinitol (LAB)[2] and -D-lyxitol,[3–5] piperidines such as deoxynojirimycin (DNJ) and DNJ derivatives or analogues,[6] as well as indolizidine derivatives of the swainsonine[7] or castanospermine type.[8] The increasing interest in simple syntheses of specific compounds and derivatives with related unnatural structures stems from their potential for pharmaceutical application: inhibition of the corresponding enzymes is often accompanied by diverse physiological effects (anti-retroviral, -bacterial, -tumoral effects; reduction of the blood-sugar level). Topographical equivalence with the corresponding glycoside[3, 6, 9] or pyranosyl cation[4, 6] generally serves as a guideline to find active products of this type. The aim of our investigations is to provide access to unnatural analogues in the pyrrolidine series—by omission of OH groups, by placing them in different positions, or by inclusion of additional ones. Recently, two routes to *cis*-dihydroxypyrrolidines, based on a nitroaldol reaction and aminopentenediol cyclizations, have been presented.[5] Here we describe a third approach to 4-hydroxypyrrolidines (1,3,4-trideoxy-1,4-iminoglycitols) for which the highly selective, catalytic hydrogenation of 5-halomethyl-4,5-dihydro-1,2-oxazoles (**B**) has been developed as a new key step (Scheme 1). This route is exemplified in detail by the sequence leading to L-*ribo*-hexitol **5** and to the diastereomers **6**–**8** (Scheme 2).



Scheme 1. Retrosynthesis of 1,4-iminoglycitols (hydroxypyrrolidines) **A** by the isoxazoline route. Y = H, R = $(CHOH)_xH$: this work; Y = OH, R = $(CHOH)_xH$: Refs. [10,19]. The hydroxypyrrolidines **A** are named as 1,4-iminoglycitols to facilitate the comparison with the structures and configurations of natural glycosidase substrates.

The glyceraldehyde **1**, available from diethyl L-(+)-tartrate,[13] was converted into the hydroxamic acid chloride **2** by oximation/chlorination.[12a] Cycloaddition of the nitrile oxide with allyl chloride according to Huisgen's in situ method[12b] gave, as expected,[14] the 5-chloromethyl-dihydro-1,2-oxazoles **3**/**4** as an approximately 1:1 mixture of diastereomers, each of which was isolated in 46% yield (in gram quantities) after chromatographic separation. Thus, an entry to two series of stereoisomers is provided (actually to four if the D-tartrate is also taken into account).



The catalytic hydrogenation of **3** and **4** in the presence of platinum on charcoal gave, in each case, the corresponding *trans*-hydroxypyrrolidine as major product. Thus, the 2-*O*-benzyl derivatives (L-*ribo*/L-*xylo*) were formed from **3** with a diastereomer ratio (*dr*) of 93:7, and the L-*lyxo*/L-*arabino*-isomers from **4** with *dr* = 80:20. The free iminoglycitols **5**/**6** and **7**/**8**, respectively, were obtained after removal of the O-protecting benzyl group with H_2/palladium on charcoal. The major isomer **5** was obtained pure in 73% yield from the mixture of **5**/**6** by crystallization (*dr* > 95:5 according to ^{1}H and ^{13}C NMR). The bromo compounds (from **2**/Et_3N and allyl bromide) corre-

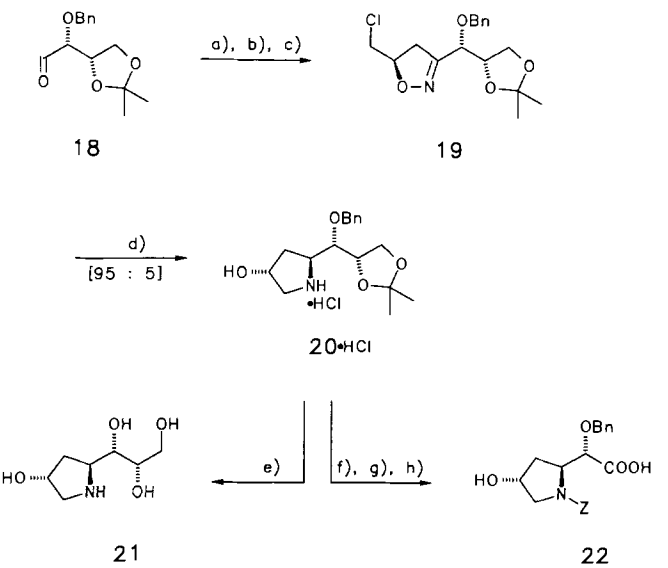
[**] Syntheses with Isoxazolines, Part 22. This work was supported by the Deutsche Akademische Austauschdienst (postdoctoral fellowship for Dr. M. Pätzel), the Bundesministerium für Forschung und Technologie (AIDS-Forschungsförderung im Bundesgesundheitsamt), the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Bayer AG, Wuppertal; we thank Frau Sabine Ebeling for experimental assistance. Part 21: [1]

Scheme 2. Synthesis of 1,3,4-trideoxy-1,4-iminohexitols **5**–**8** of the L series from 2-*O*-benzyl-L-glyceraldehydes **1** [11,18]: a) $HONH_3Cl$, Na_2CO_3, H_2O, 25 °C, 20 h; 95% oxime as (83:17) *E*/*Z* mixture, $[\alpha]_D^{20} = -62.4$ ($c = 1.51$ in EtOH); b) *N*-chlorosuccinimide (NCS), *N*,*N*-dimethylformamide (DMF), HCl (cat.), 25 °C, 1 h (cf. ref. [12]); 96% **2**, colorless oil, $[\alpha]_D^{24} = -79.7$ ($c = 0.780$ in MeOH); c) 6 equiv $ClCH_2$-CH=CH_2, Et_3N, Et_2O, 25 °C, 3 d: diastereomer ratio (*dr*) of the crude product = 50:50; medium-pressure liquid chromatography (MPLC) LiChroprep Si60, 15–25 μm, *t*BuOMe: **3**, $[\alpha]_D^{24} = -7.4$ ($c = 0.85$ in CH_2Cl_2), and **4**, $[\alpha]_D^{24} = -193$ ($c = 0.645$ in CH_2Cl_2), each 46% of colorless, analytically pure oil; d) H_2, Pt/C, MeOH, 25 °C, 24 h; yield from **3** quant. with *dr* = 93:7 (^{13}C NMR), $[\alpha]_D^{22} = +29.4$ ($c = 0.715$ in MeOH); yield from **4**: 94% with *dr* = 80:20, $[\alpha]_D^{24} = +35.9$ ($c = 0.570$ in MeOH); e) H_2, Pd/C, MeOH/conc. HCl (10:1), 25 °C, 3 d; after crystallization from MeOH 73% 5 · HCl with *dr* > 97:3, m.p. 132–133 °C, $[\alpha]_D^{24} = +26.1$ ($c = 0.640$ in H_2O), and 93% **7**/**8** (hydrochloride) with *dr* = 80:20, light yellow oil, solidified at −20 °C (m.p. 109–110 °C).

Scheme 3. Synthesis of 1,3,4-trideoxy-1,4-iminohexitols of the D series from 1,2-*O*-isopropylidene-D-glyceraldehyde **9**, and correlation with *trans*-4-hydroxy-L-proline (Z derivative) [11, 18]. a) $HONH_3Cl$, K_2CO_3, H_2O, 0 → 25 °C, 2 h; after distillation (bath temp. 100–120 °C/0.1 Torr): 70% oxime, *E*/*Z* = 60:40 (^1H NMR), $[\alpha]_D^{20} = -74.6$ ($c = 1.60$ in $CHCl_3$); b) NCS, DMF, HCl (cat.), 25 °C, 18 h (cf. ref. [12]); 77%, colorless powder, m.p. 82–83 °C; c) 5 equiv $ClCH_2$-CH=CH_2, Et_3N, Et_2O, 3 d; crude product *dr* = 50:50. MPLC (cf. Scheme 2), eluent petroleum ether/EtOAc 4:1. **10**: 33%, $[\alpha]_D^{23} = -88.7$ ($c = 1.22$ in $CHCl_3$); **11**: 37% (3.64 g for 42.5 mmol batch), $[\alpha]_D^{23} = +85.1$ ($c = 1.02$ in $CHCl_3$); both colorless oils with b.p. 130 °C/0.04 Torr; d) H_2, Pd/C, MeOH, 25 °C, 18 h; **12**/**13** in 96% yield with *dr* = 95:5; **14**/**15** in 97% yield with *dr* = 89:11; e) ClCOOBn, Ag_2O, CH_2Cl_2/MeOH (20:1), 25 °C, 4 d, filtration/hydrolysis with silica gel; 73% of **16** as ca. (2:1)-rotamer mixture, $[\alpha]_D^{20} = -53.4$ ($c = 0.500$ in MeOH); f) $NaIO_4$, H_2O/MeOH 2:1, 25 °C, 45 min, then Br_2 (2 equiv)/MeOH, 25 °C, 1 h (according to ref. [16]); 79% of *Z*-L-4-hydroxyproline methyl ester as (55:45)-rotamer mixture, $[\alpha]_D^{21} = -50.1$ ($c = 0.340$ in MeOH); g) K_2CO_3, H_2O/EtOH 5:2, 25 °C, 7 d; MPLC (LiChroprep RP 18, 15–25 μm, CH_2Cl_2/MeOH 97:3); 66% of **17**, analytically pure (55:45)-rotamer mixture (based on NMR) and according to **12** probably about 95:5 *trans*/*cis*-mixture; $[\alpha]_D^{24} = -62.1$ ($c = 0.800$ in $CHCl_3$); ref. [17]: $[\alpha]_D^{20} = -72$ ($c = 1.00$ in $CHCl_3$) for Z-*trans*-4-hydroxyproline and $[\alpha]_D^{24} = +26.3$ ($c = 1.0$ in $CHCl_3$) for Z-*cis*-4-hydroxyproline.

sponding to **3**/**4** similarly gave the 2-*O*-benzyl derivatives of **5**/**6** and **7**/**8**, respectively, in the form of hydrobromides (*dr* = 91:9 and 73:27, respectively), but with somewhat lower stereoselectivity.[11, 15]



The route to compounds of the D series—in principle open by analogous elaboration of the enantiomeric D-tartrates—was started from 2,3-isopropylidene-D-glyceraldehyde (**9**), to simultaneously check if the structure of the side chain at the 3-position would somehow affect the course of the hydrogenation (Scheme 3). The *erythro*-dihydro-1,2-oxazole (**10**, 5,1′-*anti*) was hydrogenated with platinum on charcoal, again with high selectivitity (**12**/**13** with *dr* = 85:15; from **11**: **14**/**15** with *dr* = 73:27), although palladium on charcoal was shown to be more advantageous here: with Pd the product from the reduction/cyclization, the D-*ribo*-iminohexitol (**12**), was isolated in 96% yield; it contained only about 5% of the *xylo* isomer **13**. The D-*lyxo*/D-*arabino* products **14**/**15** were obtained in a 89:11 ratio from the *threo*-dihydro-1,2-oxazole (**11**, *syn*).[11] The configuration of **12** at C 2/C 4 (D-*ribo*) was established as follows: N-protection and hydrolysis to **16**, subsequent oxidative degradation with periodate/bromine in methanol according to Lichtenthaler et al.,[16] and finally hydrolysis of the methyl ester with base gave the known reference compound *N*-Z-4-hydroxyproline (**17**, Scheme 3).[17]

These cases—and others[19]—show that the stereochemical course of the hydrogenation of dihydro-1,2-oxazoles (isoxazolines) is determined by several factors. The configuration at C 1′ plays some role (cf. reduction of the pairs **3**/**4**, **10**/**11**),[20] as do the catalyst system and the structure of the side chains in the 3- and/or 5-position. Thus, with other adducts prepared from **9**, only insignificant induction (about 60:40) was observed for dihydro-1,2-oxazoles bearing $TosOCH_2$, MeOOC, or no substituent at the 5-position (see below). Nevertheless, with the appropriate combination of all of these factors this sequence should be suitable for the formation of higher trideoxyiminoglycitols from other glyconitrile oxides.

This expectation was confirmed by the outcome of the synthesis of imino-L-*talo*-heptitol **21**, a tetrol. For this synthesis we used the C_4 building block **18**, a threose derivative, also readily available[21] in both enantiomeric forms from tartrate or 2-*O*-benzylthreitol (Scheme 4).

The cycloadduct with allyl chloride (**19**) was obtained in 31% yield after chromatographic separation (in addition to 32% of the 5-epimer); hydrogenation with Pt catalyst gave the *trans*-hydroxypyrrolidine **20** as a single stereoisomer (>95:5 according to ^{13}C NMR) and further, after removal of the protecting groups, the iminoheptitol **21** (six steps, 16% overall yield from **18**). The configuration of **20** at C4 was established at the dihydro-1,2-oxazole stage, by degradation of the previously mentioned 5-epimer of **19** (hydrolysis, cleavage with periodate, and aldehyde reduction); in this manner the D-enantiomer of **4** (*threo*) was obtained. A similar degradation to the dihydroxyhomoproline derivative **22**[22] was carried out with **20** (Scheme 4).

The results described here show that the catalytic hydrogenation of isoxazolines (4,5-dihydro-1,2-oxazoles)[20] contains yet unrecognized possibilities for stereoselective reductions and thus supplements the well-investigated "predictable" $LiAlH_4$ reduction.[20, 23] The mechanism of this transformation is not yet apparent: the catalytic reduction of 5-halomethyl-isoxazolines, such as **3**, to the hydroxypyrrolidine **5** involves four steps (N–O and C=N reduction, rotation to a conformation suitable for cyclization, and intramolecular substitution at C1 by the N atom) moreover, the sequence might be structure-dependent (*dr* of 60:40 to 95:5). A point to be stressed is that all results on catalytic reductions of isoxazolines—whether leading to amino

Scheme 4. Synthesis of 1,3,4-trideoxy-1,4-imino-L-*talo*-hepitol **20** and dihydroxy-L-homoproline **21**. a), b), c) reactions as in Scheme 2. Oxime of **18**, 84%, $[\alpha]_D^{22} = +37.1$ (*c* = 0.675, MeOH), colorless, viscous, partially solidified oil (*E*/*Z* = 80:20); hydroxamic acid chloride 84%, $[\alpha]_D^{20} = +33.8$ (*c* = 0.685 in MeOH); **19**: (31%); m.p. 93–94 °C (from Et_2O/petroleum ether), $[\alpha]_D^{20} = 6.5$ (*c* = 0.535 in CH_2Cl_2); 5-epimer (32%): m.p. 36 °C, $[\alpha]_D^{20} = +152$ (*c* = 0.485 in CH_2Cl_2); d) H_2, Pt/C, MeOH, 25 °C, 25 h (reaction followed by H_2 consumption and by thin-layer chromatography; 95% **20** · HCl with *dr* = 95:5 (^{13}C NMR), m.p. (decomp.) 142–148 °C, $[\alpha]_D^{22} = -16.4$ (*c* = 0.510 in MeOH); e) 0.7 N HCl, 25 °C, 20 h, then Pd/C, MeOH/conc. HCl (15:1), 25 °C, 4 d; 79% of **21** · HCl, m.p. 154–155 °C (from MeOH), $[\alpha]_D^{19} = -16.1$ (*c* = 0.615 in H_2O), *dr* > 97:3 (NMR); fully analogous data for the D series (via 3-*O*-benzyldiacetone-D-glucose), ref. [19]; f) Z-Cl, Ag_2O, CH_2Cl_2, 25 °C, 3 d, filtration/hydrolysis with silica gel, eluent EtOAc/MeOH (85:15), 69% of *N*-Z,5-*O*-benzyltetrol as (75:25)-rotamer mixture, $[\alpha]_D^{19} = -81.8$, *c* = 0.183 in MeOH), m.p. 59–62 °C; g) $NaIO_4$, H_2O/MeOH (2:1), 25 °C, 75 min, then Br_2/CH_3OH [16] 2 h; 80% of methyl ester, $[\alpha]_D^{19} = -89.9$ (*c* = 0.300 in MeOH); h) K_2CO_3, H_2O/EtOH (5:2), 25 °C, 7 d; 81% of **22** as (55:45)-rotamer mixture (^1H NMR); colorless oil, $[\alpha]_D^{20} = -95.3$ (*c* = 0.395 in MeOH).

alcohols or to aldols—had led to the conclusion that N–O cleavage precedes the C=N hydrogenation.[15, 20a, 23]

The possibilities of combining other glyconitrile oxides with allyl chloride in a "building block fashion", according to $(C_3 + C_n)$, is currently being examined, the objectives being to provide "higher homologues", "other ring sizes", and "bicyclic structures". The new results presented here, namely, 1) the possibility of chromatographic separation of diastereomeric isoxazolines from chiral nitrile oxides on a preparative scale (gram quantities), 2) highly selective catalytic reduction of isoxazolines with specific combinations of side chains in 3- and 5-position, and 3) assignment of configuration of 5-epimeric isoxazolines based on consistent, markedly different specific optical rotations[24] should be essential assets to attain the above and related goals.

[18] Assignment of the stereochemical series of the cycloadducts is not possible by NMR spectroscopy, but can be made consistently and safely on the basis of numerous data (optical rotation, HPLC and MPLC retention factors) [19], cf. $[\alpha]_D$ values for **3**/**4**, **10**/**11**, **19**/5-epimer in the legends to the schemes. To check the enantiomeric purity and to ascertain whether a potential racemization/epimerization takes place at the nitrile oxide stage, correlations were undertaken by degradation of isoxazolines of all three series (from **1**, **9**, and **18**). The deviation in the optical rotation of enantiomers of isoxazoline-3-carboxylic acid derivatives produced by independent routes were of the order of $\leq 5\%$. Moreover, in a series of cycloadditions with optically active olefins only two diastereoisomers were observed in the crude products; a significant racemization/epimerization at the nitrile oxide stage would have led to the appearance of two additional diastereomers. For a summary of all correlations and degradation reactions see ref. [10,19].

Simple and Versatile Synthesis of Optically Active 1,2-Amino Alcohols by Grignard Addition to *N*,*O*-Dibenzylglyceraldimine and -lactaldimine**

Thomas Franz, Matthias Hein, Ulrich Veith, Volker Jäger,* Eva-Maria Peters, Karl Peters, and Hans Georg von Schnering

Dedicated to Professor Ulrich Schmidt on the occasion of his 70th birthday

The 1,2-amino alcohol fragment **A** is found in many natural products and drugs, in particular as a central moiety of non-proteinogenic amino acids and amino polyols. Examples include statine,[1] norstatine,[2] and homostatine,[3] (see formula **B**), as well as related diamino alcohols **C**,[4a] which constitute

A **B** **C**

n = 0, 1, 2

R^1 = *i*Bu, CH_2Ph, $CH_2C_6H_{11}$

core units of peptide isosters that strongly inhibit a number of proteinases (aspartase, acetylcholine esterase, renin, pepsin, penicillopepsin, cathepsin D, HIV protease).[4b]

For the synthesis of compounds containing fragment **A**, mostly N-protected esters and aldehydes of the corresponding α-amino acids have been employed (path (a) indicated on formula **A**). This strategy imposes "natural" limitations on the choice of R^1. Until now these have rarely been overcome by devising "independent syntheses", that is, approaches not based on amino acids.

We now summarize the first part of our efforts to assemble disubstituted amino alcohols of type **A** by adding C-nucleophiles to the C=N bond of α-oxyaldehyde derivatives according to strategy (b) as outlined in **A**. Imine derivatives of 2-*O*-benzylglycerinealdehyde **1**, readily available in both enantiomeric forms,[5] were chosen as promising substrates that would allow for straightforward transformations at the other terminus. A survey of the literature up to 1990 on the addition of organometallic reagents to imines gave the following: 1) Additions to imines of enolizable aldehydes and ketones were found to be rather troublesome: "In general, these aldimines and ketimines are inert to alkyl Grignards and in their presence will

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Bundesministerium für Forschung und Technologie (Aids-Forschungsförderung im Bundesgesundheitsamt) and Bayer AG. We thank Dr. Häbich for helpful discussions and Ms. Petra Schneider for experimental help. Results of these investigations were presented in Hamburg, Germany, at the Org.-Chem. Kolloquium, November 30th, 1990, and in Oxford, Great Britain, at the 13th International Symposium "Synthesis in Organic Chemistry", Perkin Division, RSC, July 20–22, 1993.

undergo complete enolization ... in refluxing THF."[6] 2) Except for a few cases of additions of Grignard,[7] organolithium,[7a, 8] and organocopper compounds[8, 9] to enolizable imines, primarily such reactions with the less basic allyl Grignard compounds[9] were known. In the course of our investigations, additions with organolithium,[10–12] organocopper,[12, 13] and organocerium compounds[11–13] as well as additions to several types of activated imines[11, 14] were reported.

After initial, unsatisfactory attempts to add *C*-nucleophiles stereoselectively,[15] a smooth and highly stereoselective reaction in what had appeared one of the less promising cases was observed: From the reaction of **2** with isobutylmagnesium bromide in ether, the amino diol **3**/**4** was isolated after 31 h at room temperature in 68% yield (Scheme 1), with an isomer ratio greater than 9:1. The major isomer was identified as **3d** and proved optically active.

Scheme 1. Synthesis of amino alcohols from N,O-dibenzylglyceraldimines and -lactaldimines. a) H_2NBn, neutral Al_2O_3, room temperature (RT), 1 h, quantitative; b) 4 RMgX, ether, 0 °C → RT, 12 h → 3 d, 41–92%; c) 4 RMgX, THF, 0 °C → RT, 3 d, incomplete conversion; d) 2.5 RLi, ether, −78 °C → RT, 79–83%, cf. reference [11]; e) 4 RMgX/4 $CeCl_3$, 0 °C → RT, 12 h, 62–70%, cf. reference [19].

Table 1 summarizes some of the results obtained in a more systematic study of this reaction.[16] At first questions about the possibility of varying the organo-Grignard moiety and about the origin of the unexpected high reactivity of the aldimine component had to be dealt with. Next, the possibilities for changing, improving, or reversing the diastereodifferentiation in the C–C bond-forming step were to be explored.

In general these additions were carried out at room temperature with four equivalents of the Grignard reagent; they proceeded at a moderate pace and gave satisfactory to good yields of isolated amino alcohols (41–92%) throughout, with rather varying diastereomer ratios—from approximately 1:1 to greater than 95:5 (runs 1–12). Apparently this increase in reactivity and the uniform course of the reaction is related to the presence of the alkoxymagnesium halide intermediate forming from **2**. The Grignard additions to the deoxy derivative, that is, the lactaldimine **6** (prepared analogously from **5**[17]), however, led to high yields of products under the same conditions (see runs 13–20 in Table 1). Hence, we attribute the successful outcome of all these cases to prior formation of a five-membered chelate with the 2-alkoxy group, due both to the inductive effect and the coordinative ability of OR,[18] and to the Lewis basicity of the

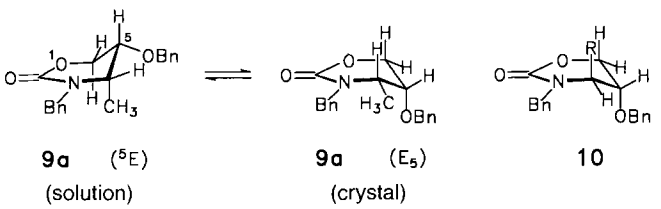
[a] Diastereomer ratio of the reaction mixture. Solvents: runs 21, 22, 27–29 in THF; others in diethyl ether. 3-MeBu = 3-methylbutyl; Cy = cyclohexyl, Ad = 1-adamantyl. [b] Crude yield, contaminated by imine **2** or **6**.

imine nitrogen atom. Further, the effect of R with respect to the 1,2-asymmetric induction is noteworthy: methyl, *tert*-butyl, adamantyl, allyl, and benzyl groups are taken up with rather low selectivity (runs 1, 7, 8, 11, 12), isopropyl and vinyl with satisfactory selectivity (approximately 4:1, runs 3, 10), and the β-branched groups, isobutyl and cyclohexylmethyl, with very good stereoselectivity (runs 4, 6). With lactaldimines, methyl and allyl groups show good inductions (run 13, 19), whereas benzyl (run 20) and other groups cause very high stereoselection. For the latter, the second diastereomer (run 16–18) could virtually not be detected by NMR analysis of the crude reaction mixtures.

The rate and stereoselectivity of the addition of RM to dibenzylglyceraldimine (**2**) was strongly dependent on the solvent and metal cation employed. Grignard additions to **2** in THF (instead of ether) proceeded much more slowly (in some cases the reaction was still incomplete after 76 h), with almost no induction (runs 21, 22). The corresponding reactions with organolithium compounds in ether again gave good yields but nearly no selectivity (runs 23–26).[11] Remarkably, on addition of $CeCl_3$[19] in THF the selectivity was reversed in favor of the adducts **4** with *erythro* (*anti*) configuration (R = alkyl, runs 27, 28). This observation was all the more surprising since related imines derived from threose had been reported to afford *xylo* (1,2-*syn*) isomers as the only products.[13] We therefore attribute the diastereomer ratios of **3**/**4** to the efficient formation of a cerium alkoxide coordinating to the N-atom, that is, the presence of a six-membered chelate with an $O^- \cdots Ce^{3+} \cdots N$ arrangement.

The amino diol products **3**/**4** were assigned the *threo* or *erythro* configuration based on analogies in ^1H and ^{13}C NMR spectro-

scopic data. The ^{13}C chemical shifts of the resonance signals from C1 to C4 showed characteristic and consistent differences even for OCH_2Ph/NCH_2Ph (of 12 data sets, only one deviation, for **3i/4i**, was observed). From run 6 the data of only one diastereomer were available; the assignment to the *threo* series was based on ^1H NMR coupling constants. Furthermore, the configuration of several adducts (run 1, 4, 5, 7, 12) was derived by analysis of ^1H NMR data of the tetrahydro-1,3-oxazin-2-ones **9**, **10** (prepared from the amino diols according to Scheme 2).[16]



3, 4 **9, 10**

Scheme 2. Im = 1-imidazolyl.

From the ^1H NMR data of the N-protected oxazinones the coupling constants $J_{4,5} = 4.4-4.9$, $J_{4,6} = 0.8-1.0$, and $J_{5,6} = 4.4-4.9$ as well as 8.0–8.9 Hz for **9**, and $J_{4,5}$ and $J_{5,6} = 2.1-2.2$ for **10** were derived. These values agree well with results obtained from 3,4,5-substituted tetrahydrooxazinones[20] and show that **9** and **10** adopt sofalike conformations in $CDCl_3$ (Fig. 1, top). The *threo* configuration of the oxazinone **9a** was proven by crystal structure analysis (Fig. 1, bottom).[21] Notably the preferred conformation of **9a** in the crystalline state has the 4-methyl group in the equatorial position.[22]

The configurations of the lactaldimine adducts **7**, **8**[16] were deduced from comparison with data of known amino alcohols and oxazolidinones as well as from the consistent pattern of their ^{13}C NMR chemical shifts. The Grignard additions to glyceraldimine **2** and lactaldimine **6** proceed without discernible racemization; this was demonstrated by ^1H NMR experiments (addition of (*R*)-trifluoroanthrylethanol[23]) to the products of runs 4 and 5, and further by comparison of the optical rotation of an oxazolidinone derivative of **7l** with the value reported in the literature.[24]

Classics in Chemistry

Chemistry Imagined. Reflections on Science. By *R. Hoffmann* and *V. Torrence*. Smithsonian Institute Press, Washington, 1993. 168 pp., hardcover $ 23.95.—ISBN 1-50698-214-4

Among the treasures kept in the Herzog August Library in Wolfenbüttel are a number of "Malerbücher" (books of the painters), each of which is a two-author work in which an important artist of the day has illustrated a literary text of his own choosing.

Chemistry Imagined is a "Malerbuch" of chemistry, in which the text is by Roald Hoffmann and the illustrations are by Vivian Torrence, a well-known American artist. For Hoffmann this book is a continuation of his efforts, previously in the form of lectures, essays, and television programs, to help laypeople to understand those aspects of the sciences, and especially of chemistry, that relate to the arts and humanities.

Just as the words "imagined" and "reflections" in the title have various meanings, so also does the book itself. It is not a book to be read straight through, but rather one to enjoy looking at, to read a little and pause, to dream and speculate—about the elements as understood by the ancient Greeks and Chinese, or the Periodic Table, the Philosophers' Stone, phlogiston, or the relationship between theory and practice or between energy and form. A recurring theme throughout many of the chapters is the "fluxional" character of chemistry, which is the science of change and instability par excellence. They contain much that is of a very personal nature, for example thoughts based on childhood recollections, and are written in a style that is perhaps best described as bright and relaxed. No knowledge of chemistry is assumed, although the author is not immune from lapses into technical jargon and over-specialization.

Or could that perhaps have been intentional? In the same way as the chemist experiments with structures of all kinds, here the author plays with different literary forms—the essay, poetry, text arranged to form shapes (as in the chapter on the Periodic Table mentioned above), and even dialogue (in a chapter on "Possibilities and Pragmatism" that is surprisingly reminiscent of the radio dialogues of Arno Schmidt).

The pictures by Vivian Torrence are works of art in their own right, and yet at the same time serve to illustrate the text. The use of collage in these is very appropriate for a text dealing with such a creative science as chemistry. Most of them are packed with detail and invite one to make journeys of discovery, to smile at the Greek and Roman wrestlers in a chapter on force constants, or to follow the flows of liquids in the chapter on reaction steps and processes, which gives the reader a sort of "monochrome" introduction to the language of chemistry in the form of descriptions of experiments (although this will certainly be incomprehensible to lay readers). A very readable epilogue by Lea Rosson Delong serves to extend and add depth to one's own thoughts about the pictures. (In the copy sent to me for reviewing I marked the sentences that struck me as especially pertinent comments on the pictures, only to find at the end that I had highlighted practically everything.)

In his preface Carl Sagan writes that we need more books of this kind. That is probably true. Nevertheless, I have a sneaking feeling that books such as this which aim (once more) to reach a certain section of the reading public are no longer noticed by the people for whom they are intended. How many readers will find this book? Could it be as many as those who see the "Malerbücher" mentioned above? Probably far fewer. On one side "refinement, decline, sorrow" (G. Benn), on the other, much more numerous side, more and more pictures in more and more "channels" with ever less of the text which slows down the tempo. And between the two sides hardly any communication.

Unraveling DNA. By *M. D. Frank-Kamenetskii*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 205 pp., hardcover DM 49.00, $ 25.95.—ISBN 3-527-89617-1/1-56081-617-1

The publication of a new English version of the Russian book "Samaya glavnaya molekula", which originally appeared in Moscow in the early 1980s, may seem surprising in view of the already enormous volume of literature on DNA throughout the world. However, *Unraveling DNA* is quite different from other books on the subject.

Only once before have I come across a book such as this about the information-carrying molecule that determines our lives. That was when I read, in the course of one evening and one night, Watson's book *The Double Helix*. Frank-Kamenetskii's *Unraveling DNA* too is unmistakably a very personal account of the history of DNA and its importance in our life processes, even though it comes 40 years after those events. It deals with the most fruitful period that has ever occurred in the interdisciplinary collaboration between physics, chemistry, and biology, describing the events in a way that is wide-ranging and at the same time profound, ensuring that the reader becomes captivated right from the first sentences of the preface and is held throughout by the fascination of the subject. The style is colorful and gripping, yet with consummate ease the author effectively brings together insights at very different levels, so that the descriptive quality of everyday

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Review Editor, Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

language is constantly balanced by scientific precision, resulting in a vividness and clarity that is rarely found. By using a wealth of appropriate analogies even the most difficult process concepts are clearly explained, and the direct and forceful presentation broadens and liberates the reader's outlook. The result is a work into which the author and the translator have each put their whole soul.

As one expects, the book covers nearly all the ground that is nowadays common knowledge in the scientific world: the tedious "march across the plains" that began with Miescher and Altmann and continued through several decades; the tortuous pathways that were followed and eventually led, by an unexpected route, to the summit; the conquest of the summit by the four researchers whose discovery of the "sacred structure" and its inherent dynamics released a veritable flood of creativity; the "dogmas" concerning the flow of information between DNA, RNA, and proteins, and the partial revision of these that was so significant; the great efforts to discover the key to life in the DNA code; the role of the structures and long-range order of DNA molecules in the developing understanding of the static and dynamic behavior of genes, and the effects of natural and artificial stimuli in the complex information processing of DNA, RNA, and proteins; the new insights into evolution and the emergence of contradictions with genetics, a subject then experiencing an unprecedented surge of interest; the challenges and temptations of the technology of genetic engineering that began to emerge within the wider field of biotechnology—a technology that could be seen either as offering the realization of mankind's ancient dream of achieving a godlike omnipotence, or as perhaps the ultimate folly, already previously discovered by Oppenheimer in the case of physics, of "original sin", here in its truest sense; ultrastable cybernetic systems and the threatening disruption of their rhythms; DNA in the conflict between self/non-self recognition and discrimination, between new plagues on humanity and still unfulfilled needs, between the examples of the past and visions of the future.

So much of this we already know—and yet the "unwinding" and "decoding" DNA that Frank-Kamenetskii describes here contains much that is different. In what formerly seemed to be mainly an irregular mosaic of observations, previously unnoticed relationships are now becoming apparent. Whereas formerly the observer was content to look at mountains of statistical and ephemeral data, now he delights in the many new insights that are becoming clear for the first time in an exciting and action-packed film. In order to come closer to a scientific understanding of the processes of life, our approaches to the subject should preferably take account of the complexity involved. On the other hand, science is the science of human beings. Its endeavors in the many different skills are dependent on people, and thus it is subject to development and decay. Frank-Kamenetskii's praiseworthy attempt at a novel way of informing and inspiring the reader is based on a recognition of this dependence. It is an endeavor in which one must wish the author and publishers all success; it is also to be hoped that all kinds of readers and many areas of science will benefit from authors (and translators!) following this example.

"I am the original fragrance of the earth/ I am the life of all that lives/I am the original seed of all existences/All states of being are manifested by my energy/I am unborn and my transcendental form never deteriorates/Although I appear in so many configurations/You know not my true transcendental form"—Krishna's description of himself from the Bhagavad-gita, as applied by Ramaswamy H. Sarma to represent the informational component of life, would perhaps form a suitable epilogue to this book by Maxim D. Frank-Kamenetskii on the molecule of life and its "unraveling", again reflecting the preface's theme of the wonder of life, the "transfiguration of its molecule".

Electrode Kinetics for Chemists, Chemical Engineers, and Material Scientists. By *E. Gileadi*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 597 pp., hardcover DM 189.00.—ISBN 3-527-89561-2/1-56081-561-2

After a period of twenty years during which there was a shortage of good textbooks on electrochemistry, now in rapid succession several books have appeared dealing with general and special aspects of electrochemistry, and differing in their level of treatment and intended readership. This book by Gileadi, his second on this subject, is intended as an introduction to electrochemical kinetics, and sets out to familiarize students, and also scientists from related disiplines, with the classical methods of this field. Readers are assumed to have only a basic grounding in thermodynamics and chemical kinetics, and the amount of mathematics is kept to a minimum.

The book is in two parts. The first part contains, according to the author, the minimum basic knowledge that the reader needs to understand electrode processes. The second, more advanced, part treats some special topics in greater depth. Part 1 begins with two introductory chapters in which some basic concepts of electrochemical kinetics are explained from a phenomenological standpoint: current–voltage curves, material transport, and the capacitance of the double layer. The various potentials that can apply to a phase are then defined: the electrochemical and chemical potentials, internal and external potentials, and the conventional hydrogen scale. Next there are chapters on measurement principles and cell design, the relationship between chemical and electrochemical kinetics, and some simple measurement procedures. The core of this first part consists of the chapters on the kinetics of electrode processes, which deal with all the usual topics, such as overvoltage, the Butler–Volmer equation, the transfer coefficient, and simple and more complex reactions, and discuss these in relation to hydrogen and oxygen evolution. The author takes considerable time in discussing these aspects, describes practical examples, raises various relevant questions and answers them, and presents all this material clearly and skillfully. Nevertheless, one may not always agree with his views—for example, the answer to the question of whether the permeation factor depends on the potential must be yes, at least for simple electron transfer processes. Part 1 ends by discussing simple theories of the double layer and of electrocapillarity.

The more advanced part begins with a chapter on intermediates formed in electrode reactions including, interestingly, a discussion of underpotential deposition and the adsorption of halides. The latter topic is also included under the heading "underpotential deposition", although to thus broaden the meaning of this clumsy expression could well lead to confusion here. Next come two chapters on the electrosorption of neutral molecules; the prominence given here to the now obsolete "Gileadi combined adsorption isotherm" can be excused as a touch of vanity on the part of the author. Most of the space is then devoted to measurement techniques: current and voltage transients, cyclic voltammetry, electrochemical impedance spectroscopy, and microelectrodes. Here again it is pleasing to find that the treatment of these topics is lucid and practically-orientated. The only unsatisfac-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1212-1304 $ 10.00+.25/0

tory chapter is that on impedance spectroscopy, which suffers from the author's self-imposed restriction to simple mathematics; the spectra given here cannot be understood without the relevant derivations. The book ends by discussing some examples of practical applications: batteries and fuel cells, corrosion, and electrodeposition. The review articles listed in the bibliography are mostly from the period 1970 to 1983, with only a few exceptions. That is also an indication of the state of knowledge covered by the book, which is not inappropriate for an introductory work such as this.

The book has evidently been produced in copy-ready form, and the author has made good use of modern desk-top publishing methods. The only aspects that I disliked were the inadequately small type size in the index and inaccurate positioning of the subscripts in some of the diagrams.

As can be seen from the list of contents, the subject matter is limited to classical electrochemistry, and therefore to the information obtainable from current–voltage curves. This restriction is appropriate for an introductory text, so the author should not be blamed for having omitted modern spectroscopic methods. Nevertheless, I would have liked to see the electrochemistry of semiconductors included, as it is undoubtedly within the classical domain. To summarize, however, this introduction to electrochemical kinetics is lucid and well written from a teaching standpoint, and the few shortcomings and omissions can willingly be forgiven.

Wolfgang Schmickler
Abteilung Elektrochemie

Dictionary of Trivial Names/Trivialnamen-Handbuch. Vols. 1–3. Edited by Fachinformationszentrum Chemie (FIZ Chemie), Berlin. VCH Verlagsgesellschaft, Weinheim, 1993. XIV, 2464 pp., hardcover DM 2100.00.—ISBN 3-527-29030-6

Having regard to the size of this reference work and what it claims to provide, it is at first glance very impressive and, despite the small print, easy to use. It lists 21812 compounds under eight data fields, which comes to a total of 174496 data field entries—a considerable amount of information which should be of interest to a large number of potential users. However, because of its price the number of actual purchasers will probably be much smaller than that. In any case, the high price makes it necessary to do a careful cost–benefit analysis, and that is what this review aims to provide.

The 14 pages of preliminaries in Volume 1 contain information about the contents, an introduction, and a more detailed explanation of the individual data fields and the indexes. This is followed by 1008 pages of text covering trivial names from A to H. Volume 2 (1196 pp.) covers trivial names from I to Z. Volume 3 contains an index of synonyms (60 pp.) and a reference index (200 pp.). Altogether 21812 compounds are listed, each page presenting ten compounds in miniature VDU-screen displays (5 cm × 9 cm). Each of these has fields containing the English and German trivial names, a sequential data-bank number, the structural formula with full stereochemistry, the molecular formula, the CAS Registry number, stereochemical information, and bibliographic information (a literature reference selected for maximum information about synthesis, structure, and activity). The print size of the text within the fields is uniform, about 1.5 mm, whereas the characters in the structural formulas are rarely more than 1.0 mm. Volumes 1 and 2 are each provided with a Fresnel lens that can be used as a bookmark and magnifier.

The work lists about 28000 entries (twice as many as in the German-language first edition published in the form of index cards), comprising trivial name of simple organic compound, names of natural products of known constitution, common abbreviations and acronyms for important compounds, and selected trade names of dyes, pharmaceuticals, and other industrial chemical products, together with an index of synonyms (in English), and a German–English index of names.

This reference work is intended as a resource that one can turn to for help when, for example, a compound is referred to in the literature by a trivial name with which one is unfamiliar, when one needs the correct structural formula of a compound for a publication or lecture and the trivial name is open to misunderstanding, or when one wishes to use an on-line data bank and needs search criteria such as synonyms or CAS Registry numbers. The *Dictionary of Trivial Names* is intended for use by everyone working in the areas of organic chemistry, biochemistry, or pharmaceutical chemistry, both in industry and in academic research.

After a thorough examination of this handbook (it would perhaps have been better to use the word "Handbook" instead of "Dictionary" in the English title, as on the back cover), a number of specific points occur to me:

1) Since the field containing the structural formula is of a constant size and each formula is always adjusted to fill the field so far as possible, the result is that small molecules are shown on a large scale and large molecules on a reduced scale. Consequently there is often a gross mismatch between the size of the characters and the length of the bond lines (an extreme example is acetaldehyde, where the CH_3 and CHO groups are linked by a bond 7.5 cm long!).

2) The editors have not followed the usual practice of distinguishing stereochemical descriptors from atomic symbols by means of italic type and/or brackets; also they are sometimes too far distant from the chiral center or too close to it, which can cause confusion (example: abienol).

3) The bibliographic information (which is not always in the form recommended in the *Chemical Abstracts System Source Index*) often seems very outdated (e.g., hystazarin: 1955), and sometimes cites exotic sources that are not easily accessible (e.g., hypotaurine: *Atti Accad. Naz. Lincei Cl. Sci. Fis. Mat. Nat. Rend.*). Occasionally publications in less common languages are cited (e.g., homostephanoline: *Yakugaku Zasshi*), or only a patent number is given (e.g., hetacillin: US 4321196). In such cases it would have been very useful to also include a reference to *Chemical Abstracts*.

4) In a few cases the CAS Registry number is not given, even though it is already known (e.g., inusoniolide: 129927-20-4).

5) In most cases the *Chemical Abstracts Index* name is also known, and could usefully have been included. Alongside the trivial name one would then have a name in accordance with nomenclature rules that would give the structure unambiguously and could be used for on-line searching.

6) Despite the size of the work there are, of course, some gaps here and there. Random checks showed, for example, that pseudilin and temaroten were both missing (the CAS Registry numbers of these compounds prove that they have been known for a long time). Surprisingly, some common acronyms such as AIBN, BBN, COT, and DABCO were also missing (showing that the claims made in the introduction regarding "Acronyms of Important Compounds" need to be qualified somewhat).

How serious these individual shortcomings are to be regarded is a question that potential purchasers or users must decide for themselves.

However, one must also ask at this point whether or not some works of comparable usefulness already exist. In principle the answer has to be yes—for ex-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1212-1305 $ 10.00+.25/0

ample, there are the Chemical Abstracts publications *Registry Handbook—Common Names* and the *Index Guide*. The first of these contains, in its names section, over 1 300 000 names with their CAS Registry numbers and molecular formulas, and in its numbers section over 840 000 Registry numbers with more than 1 800 000 names (including the CA Index names that are so useful for on-line searching). This work is available at a cost of $ 1070.00 (1994 price) in microfiche or microfilm form. If one is unwilling to derive the structural formula from the CA Index name, it can easily be obtained by on-line retrieval or from the usual Chemical Abstracts printed volumes (as also can the bibliographic information). The *Index Guide* contains 2248 pages listing about 250 000 entries (mainly trivial names and acronyms with their CA Index names and CAS Registry numbers, and also structural formulas for "stereoparent" compounds), as well as numerous appendices that are also useful in dealing with questions of nomenclature; in printed form it costs $ 70.00 for a single issue, or $ 190.00 for three updated issues over a five-year period (1994 prices). The facilities for structural formulas and bibliographic information mentioned above for the *Registry Handbook—Common Names* are the same in this case.

A simple calculation gives "unit costs" of about DM 0.08 per name or DM 0.10 per compound in the case of the *Dictionary of Trivial Names*. Similar calculations for the *Registry Handbook—Common Names* and for the *Index Guide* give "unit costs" of less than DM 0.01 per name or per compound. Here again the potential purchaser or user must decide whether to pay more for fewer names and compounds *with* structural formulas and a literature reference (the latter subject to the reservations mentioned earlier), or to pay less for a greater number of names and compounds, usually *without* structural formulas and *without* literature references.

The decision in favor of one or the other publication will certainly depend on the detailed needs of the user. The reviewer hopes that the comments offered here will help in making the decision.

Udo Eberhardt
Chemische Berichte Editorial Office
Weinheim (FRG)

Scanning Electron Microscopy and X-Ray Analysis. By *R. E. Lee*. Ellis Horwood/PRT Prentice Hall, Englewood Cliffs, 1993. 464 pp., hardcover $ 60.00.—ISBN 0-13-813759-5

Scanning electron microscopy (SEM) has now become well established in many areas of chemistry, materials science, physics, biology, and medicine, in situations that demand high resolution imaging of materials and specimens or chemical analysis of microscopic regions. There is already plenty of literature, including some that is very recent, treating the methods of electron microscopy at a level suitable for specialists. However, this book has been written with a different objective, namely to explain, with a minimum of mathematics but with many well-chosen drawings, figures, and diagrams, the elementary physical and technical aspects of the scanning electron microscope. The author, who has many years of practical experience in this field, has certainly succeeded in this aim.

The first five of the twelve chapters are concerned with the construction of the scanning electron microscope, the generation of the electron beam, and the principles, functioning, and aberrations of magnetic lenses. The author describes applications-related aspects with detailed illustrations, for example, images of the surface of a cathode after overheating, and also discusses recent instrumental developments such as the use of field emission sources. The following chapters deal with the interaction of electrons with matter, different types of detectors, and in considerable detail with image formation and image processing. Scattering processes, contrast mechanisms, and many other aspects of importance to the user are explained in careful detail by text and figures. The chapters on vacuum pumping and pressure measurement and on specimen preparation are equally clear and detailed. The final chapter contains a thorough and detailed description of SEM X-ray microanalysis, explaining the principles of energy-dispersive and wavelength-dispersive spectroscopy, and the artefacts that can arise in qualitative and quantitative elemental analysis. The book ends with a useful appendix which includes data on the characteristic X-ray emissions of the elements, and also a short glossary of technical terms which is especially helpful.

I can thoroughly recommend this book for newcomers to SEM methods, as it covers all the important aspects and explains them in a simple, clear, and understandable way, but without being too superficial. Technical and scientific staff working in electron microscopy laboratories will also find the book very useful, and will obtain new insights from it. *Scanning Electron Microscopy and X-Ray Analysis* is certainly a very useful addition to the literature of the SEM laboratory, and I feel sure that it will come to be regarded as essential basic reading there. Lastly I recommend the book to the interested reader who simply wants to know something about how an electron microscope works and how it is used.

Fluorinated Isocyanides—More than Ligands with Unusual Properties

Dieter Lentz*

The substitution of hydrogen by fluorine in organic compounds usually results in drastic changes in their properties. For isocyanides, for which fluorinated examples have only recently become available in preparative quantities, this substitution leads to a significantly increased reactivity and a tendency to polymerize, which, on one hand, makes their handling more difficult. On the other hand, this high reactivity makes the fluorinated isocyanides useful building blocks for the synthesis of compounds like *N*-trimethylformamide. Energetically favorable π^* orbitals bestow excellent π-acceptor properties towards low-valent transition metal complexes, especially on the ligand trifluoromethyl isocyanide. The pronounced tendency of this ligand to bridge two metal atoms enables the formation of structural types that are not accessible with other π-acceptor ligands. Thus it was possible to prepare $[(Os_3(CO)_{11}(\mu_2\text{-}CNCF_3)_2]$ (a derivative of the hypothetical $[Os(CO)_{13}]$) which may be considered as a model for an associative mechanism of ligand substitution at carbonyl clusters. In contrast to the well-studied chemistry of trifluoromethyl isocyanide, that of the few other known fluorinated isocyanides is only now receiving attention. In particular the only recently synthesized trifluorovinyl isocyanide promises a rich chemistry as a result of its difunctionality.

1. Introduction

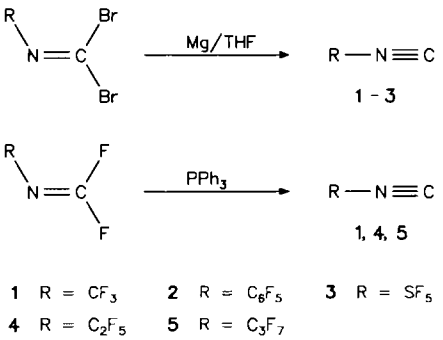
Isocyanides have been known for more than a hundred years. In 1867 Gautier[1] and Hofmann[2] recognized the nature of these compounds, which are isomeric to nitriles. Due to their repulsive odor and only limited synthetic accessibility, this class of compounds was long neglected. The synthesis of isocyanides from the corresponding formamides, developed by Ugi,[3] as well as the large number of subsequent studies of this class of compounds have demonstrated their great importance to organic synthesis.[3] The review by C. Grundmann gives a good survey of the current state of synthetic methods.[4]

Recently a number of novel isocyanides, some of which had been long sought after, have been prepared. Examples include CN–CN,[5] CN–NC,[6] NC–C≡C–NC, CN–C≡C–NC,[7] and HC≡C–NC.[8] The last species is not only of interest to chemists since it has been detected in interstellar space.[9]

The coordination chemistry of isocyanides has experienced a renaissance through the studies of Malatesta and Bonati.[10] Since then the interest in isocyanide complexes has not abated. The coordination chemistry of regular isocyanides has been summarized in several review articles.[11] The studies by Fehlhammer et al.[12] over the last few years on the coordination chemistry of functionalized isocyanides have led to remarkable compounds like $[(CO)_5Cr(CNCN)]$[13] or $[\mu_3\text{-}\{(CO)_5Cr(CN\text{–}C)\}\text{-}\{Co(CO)_3\}_3]$.[14] Multidentate isocyanides have been studied primarily with respect to their use as technetium complexes for radiological diagnostics.[15]

Fluorination of organic compounds usually leads to a drastic change in their properties,[16] particularly in the case of perfluorination. It is therefore somewhat surprising that the chemistry of fluorinated isocyanides has remained nearly unexplored for quite some time, even though the synthesis of trifluoromethyl isocyanide was first reported in 1967.[17]

2. The Synthesis of Fluorinated Isocyanides



There are currently two main preparative methods for α-fluorinated and perfluorinated isocyanides, apart from the poorly reproducible syntheses for trifluoromethyl isocyanide (**1**)[17, 18] and pentafluorophenyl isocyanide (**2**)[19] described before the onset of our work that yield by-products that are difficult to remove. Simonneaux et al. recently discovered that isocyanides that are fluorine-substituted at the β position, like 2,2,2-trifluoroethyl and 2-fluoroethyl isocyanide, can be prepared by Ugi's synthetic method.[20]

2.1. Dehalogenation of Dihalomethanimines

The synthesis of **1**,[21] **2**,[22] and sulfurpentafluoride isocyanide (**3**)[23] is best performed by α-dehalogenation of the corresponding dibromomethanimines. Magnesium in THF has proven to be the best dehalogenation agent.[21–23] The reaction of $CF_3N{=}CBr_2$ with zinc in dimethylformamide leads directly to the isocyanide **1**;[24] it has not been possible to detect an organozinc inter-

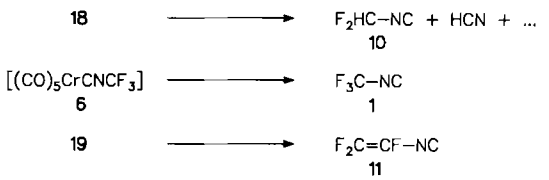
mediate. For **1** the yield is very high; for SF_5NC **3**, however, it is below 5%. The use of organolithium compounds does not improve the yields.[23] Recently Shreeve et al. reported an alternative synthesis for **1**, **4**, and **5**, utilizing the defluorination of difluoromethanimines with triphenylphosphane.[25]

2.2. Pyrolysis of Pentacarbonyl(isocyanide)chromium Complexes

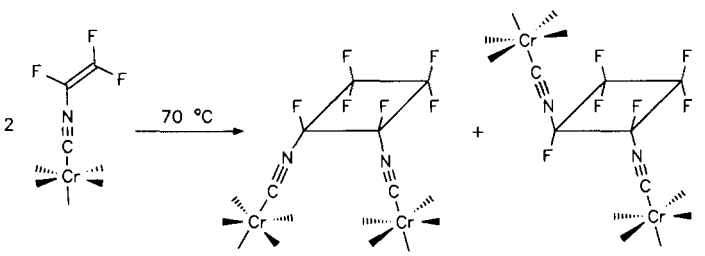


Fehlhammer et al. showed that pentacarbonyl(cyano)chromate can be alkylated by a radical pathway in the presence of diazonium salts.[26] The use of trifluoromethyl, heptafluoro-*n*-propyl, and nonafluoro-*n*-butyl iodide enabled the preparation of the corresponding isocyanide complexes $[(CO)_5Cr(CN-R)]$ (**6**–**8**) in low yields. A chlorine/fluorine exchange in pentacarbonyl(trichloromethyl isocyanide)chromium with $SbF_3/SbCl_5$ led at best to traces of the fluorinated isocyanide complex **6**.[27] The authors made no attempt to obtain the free isocyanides from these complexes.

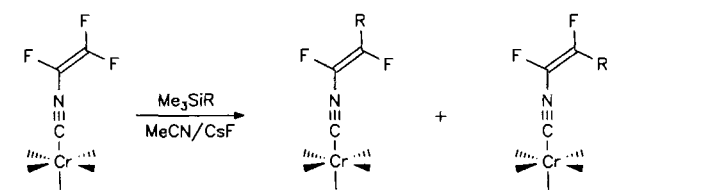
There are no suitable organic precursors for the synthesis of the intermediate members of the series methyl, fluoromethyl (**9**), difluoromethyl isocyanide (**10**), and **1**, as well as for trifluorovinyl (**11**) and fluoroethynyl isocyanide (**12**). The formation of these isocyanides on the pentacarbonylchromium fragment proved to be advantageous.

Radical alkylation yields the corresponding starting compounds **13**–**16**, which can be modified by standard methods of organic synthesis. For instance, reduction of pentacarbonyl(dichlorofluoromethyl isocyanide)chromium (**13**) by tributyltin hydride leads to the fluoromethyl isocyanide complex **17**. Chlorine/fluorine exchange with mercuric fluoride yields the difluoromethyl isocyanide complex **18**.[28] Dechlorination of the dichlorotrifluoroethyl and tetrachlorofluoroethyl isocyanide complexes with zinc enables the preparation of the halogenated vinyl isocyanide complexes **19** and **20**,[29] which were supposed to serve as precursors for **11** and **12**.

Vacuum pyrolysis of these organometallic precursors, however, meets only with limited success. While the trifluoromethyl isocyanide complex **6** only yields the free isocyanide **1**,[30] the pyrolysis of **18** is accompanied by the release of significant amounts of HCN.[31] By using microwave spectroscopy, ethynyl isocyanide (**21**) was detected as an important, albeit trace impurity. This compound was subsequently directly prepared by pyrolysis of $[(CO)_5Cr(CN-CCl=CHCl)]$.[8] This method fails completely when applied to the fluoromethyl isocyanide complex **17**.[31]

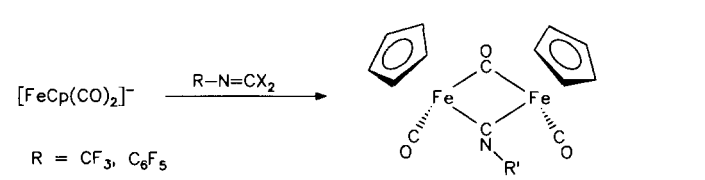


Much better results are obtained with the trifluorovinyl isocyanide complex **19**. Vacuum pyrolysis at 240 °C leads smoothly



Dieter Lentz was born in Heidelberg in 1951. After finishing his Diplom in chemistry in 1977, he completed his studies in 1979 under the direction of Professor Konrad Seppelt with a Ph.D. thesis on pentafluoroorthoselenates and -tellurates of nonmetals. From 1980 to 1986, he worked on his habilitation at the Freie Universität Berlin, studying fluorinated isocyanides and bis(fluoromethylidyne)triiron clusters. Since 1986 he has been Privatdozent in the Institute for Inorganic and Analytical Chemistry at the Freie Universität Berlin. In 1991, he was a visiting professor in the Department of Chemistry, Clemson University, South Carolina.

to free **11**.[29] It has not yet been possible to detect **12** by microwave spectroscopy during the pyrolysis of **20** or **19** at high temperatures.[32] The action of electric discharges on **2** and H_5C_6NC does also not lead to **12** or **21**.[32] F–C≡C–C≡N can, however, be prepared from F_5C_6CN in this manner and characterized by mass spectrometry (MS), and photoelectron (PE), IR, and microwave spectroscopy.[33]



The trifluorovinyl isocyanide complex **19** proved to be an ideal starting material for other fluorinated isocyanides. As a fluorinated alkene, it can undergo [2 + 2]cycloaddition as well as nucleophilic substitution reactions. When **19** is heated under ambient pressure to 70 °C, one smoothly obtains an isomeric mixture of the *cis*- and *trans*-1,2,3,3,4,4-hexafluoro-1,2-diisocyanocyclobutane complexes **22a** and **22b**.[34] This reaction provides a convenient access to fluorinated cyclic diisocyanides. If the trifluoromethylation agent $F_3CSi(CH_3)_3$[35] or the pentafluorophenylating reagent $F_5C_6Si(CH_3)_3$[36] is treated with **19** in the presence of CsF a nucleophilic attack on the β-carbon atom yields an (*E*)/(*Z*) isomeric mixture of the perfluorinated alkenyl isocyanide complexes **23a** and **23b**, respectively.[37] The use of other nucleophilic reagents should make it possible to prepare numerous fluorinated vinyl isocyanides on the pentacarbonylchromium fragment.

23a R = CF_3 **23b** R = C_6F_5

Another pathway for the synthesis of fluorinated isocyanides on a complex fragment is the reaction between the highly nucleophilic anion $[FeCp(CO)_2]^-$ and the dihalomethanimines $CF_3–N=CBr_2$ and $C_6F_5–N=CCl_2$. The expected isocyanide complexes **24** and **25** are obtained in low yields. The main product of the reaction with $C_6F_5–N=CCl_2$, however, is the interesting isocyanide complex **26**, which is formed by a further nucleophilic attack on the fluorinated aromatic ring.[38]

24 R' = CF_3 **25** R' = C_6F_5
26 R' = 4–CpFe(CO)$_2$–C_6F_4

3. Physical Properties, Spectra, and Structures

The boiling point of **1**, −80 °C, is significantly lower than that of methyl isocyanide. This is due to the much smaller dipole moment of 1.153(20) D (determined by measuring the Stark effect in the microwave spectrum[39]) than the 3.8 D for methyl isocyanide.[40] The IR spectra of all fluorinated isocyanides synthesized up to now—except of SF_5NC—exhibit ν(NC) bands between 2100 and 2150 cm^{-1}. A complete analysis of the high-resolution spectrum of **1** is still in progress, but the following assignments of fundamental vibrations appear to be correct: $\nu_1(A_1)$ 2139, $\nu_2(A_1)$ 1209, $\nu_3(A_1)$ 840, $\nu_4(A_1)$ 552, $\nu_5(E)$ 1238, $\nu_6(E)$ 620, $\nu_7(E)$ 460, and $\nu_8(E)$ 145 cm^{-1}.[41]

The gas-phase structure of trifluoromethyl isocyanide (**1**) could be determined very accurately by a combination of microwave and electron diffraction data (Table 1).[39] During the course of this work, it was noted that the quadrupole coupling constants $\chi_{aa} = 1060(30)$, $\chi_{bb} = -530(30)$, and $\chi_{cc} = -530(30)$ kHz are unusually large for isocyanides.[39] The corresponding coupling constants for methyl isocyanides are only $\chi_{aa} = 489.4(4)$, $\chi_{bb} = -244.7(4)$, and $\chi_{cc} = -244.7(4)$ kHz.[42] In addition, it was possible to examine the rotational spectra of vibrationally excited $CF_3–NC$ more closely.[43] Dreizler et al. successfully obtained and analyzed the microwave spectra of difluoromethyl isocyanide[44] and pentafluorophenyl isocyanide.[45] They also determined the quadrupole coupling constants to be $\chi_{aa} = 599.0(10)$, $\chi_{bb} = -406.5(14)$, and $\chi_{cc} = -192.6(14)$ kHz for **10**, and $\chi_{aa} = 958.(113)$, $\chi_{bb} = -794.(60)$, and $\chi_{cc} = -165.(69)$ kHz for **2**.

It proved possible to perform low-temperature crystal structure analyses of pentafluorophenyl isocyanide (**2**)[46] and trifluorovinyl isocyanide (**11**).[47] Table 1 shows a comparison with the structural data of other isocyanides. It is noteworthy that the N≡C bond lengths in the solid state are shorter than those determined in the gas phase.

PE spectroscopic data for valence[53] as well as core[54] electrons are available only for **1** and methyl isocyanide. Noteworthy is the lowering of the $n_C(A_1)$ and the $\pi_{NC}(E)$ energy levels in trifluoromethyl isocyanide by 1.3 and 2.1 eV, respectively, rela-

Table 1. C–NC and CN≡C bond lengths in isocyanides [pm].

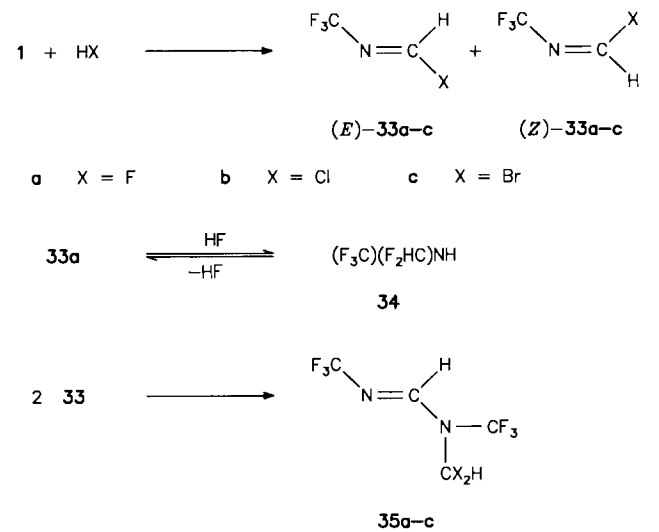
tive to methyl isocyanide. Assuming that an approximately equal $\pi-\pi^*$ splitting of the molecular orbitals occurs in both isocyanides, trifluoromethyl isocyanide possesses a LUMO that is lowered by about 2 eV. This explains the strong π-accepting behavior of trifluoromethyl isocyanide, which makes it an excellent ligand.

Ab initio calculations for the fluorinated methyl isocyanides **9**, **10**, and **1** indicate a distinct lowering of the LUMO energies with increasing degree of fluorination.[55] The lowest LUMO energy was calculated for **3**, which therefore should be a stronger π-acceptor than **1**.[55] Experimental evidence for this does not yet exist, as there are no known complexes of **3**.

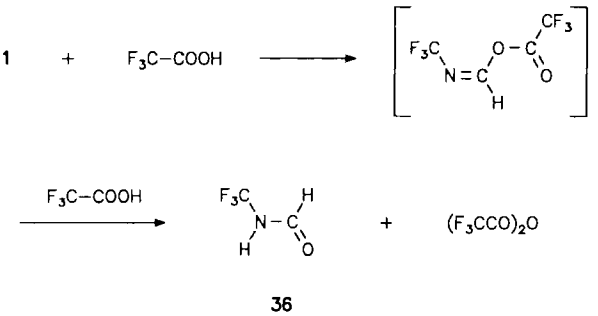
With mass spectrometry on the negatively charged ions of CF_3NC and CF_3CN the dissociation energies of the C–C and C–N bonds were determined to be 4.4 ± 0.2 eV for CF_3CN and 3.9 ± 0.2 eV for CF_3NC, and the binding enthalpies ΔH_f^{298} to be 4.8 ± 0.3 eV for CF_3CN and 4.3 ± 0.3 eV for CF_3NC.[56]

The ^{19}F, ^{13}C, and ^{14}N NMR data for trifluoromethyl isocyanide show nothing unusual.[57] Due to the low electric field gradient at the nitrogen atom, an effect that is generally observed for isocyanides, the coupling between the ^{14}N and ^{19}F nuclei can be observed [$^2J_{^{19}F,\,^{14}N}=15.5$ Hz for CF_3NC[18, 57] **1**; $^2J_{^{19}F,\,^{14}N}=13$ Hz for CHF_2NC[31] **10**; $^2J_{^{19}F,\,^{14}N}=10$ Hz for C_2F_3NC[29] **11**].



4. Fluorinated Isocyanides as Building Blocks for Synthesis

Fluorinated isocyanides are characterized by their increased reactivity relative to nonhalogenated isocyanides. This is especially evident in a very strong tendency towards polymerization. Trifluoromethyl isocyanide **1** decomposes even below its boiling point of $-80\,^\circ C$ to yield a polymer. According to Haszeldine et al. an α-polymer is formed.[18] Pentafluorophenyl isocyanide **2** decomposes rapidly above its melting point of $13\,^\circ C$;[22] trifluorovinyl isocyanide begins to decompose above $-40\,^\circ C$.[29]

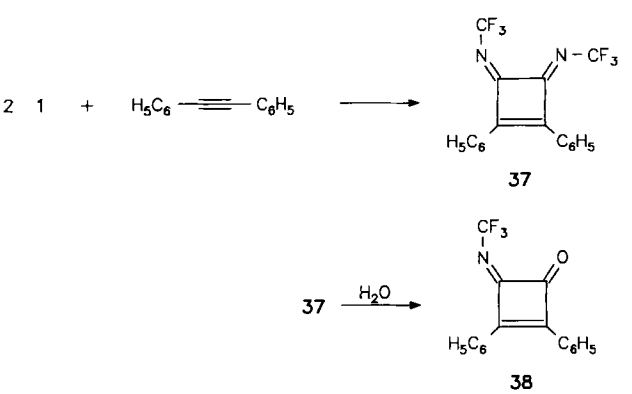


4.1. α-Additions

α-Additions have only been investigated for **1**. In a reversal of the formation of **1**, the α-addition of bromine to **1** yields dibromo-*N*-trifluoromethylmethanimine (**27**).[17] Mercuric oxide oxidizes the isocyanide to the isocyanate **28**.[18] The reaction of **1** with $(CF_3)_2NO$ leads to a mixture of CF_3-NCO, $(CF_3)_2N-O-N(CF_3)_2$, $CF_3-N=C[ON(CF_3)_2]_2$, and $CF_3-N=C[ON(CF_3)_2]-C[ON(CF_3)_2]=N-CF_3$.[58] With chlorine monofluoride, a mixture of the dihalomethanimines **29**–**31** is obtained, whereas the addition of SF_5Br leads to methanimine **32**.[59]

The addition of hydrogen halides is especially interesting, as it yields the *N*-trifluoromethylmethanimines **33**.[59] When performed with regular isocyanides, it is impossible to stop the reaction at this stage.[60] The methanimines **33** are present as mixtures of (*Z*) and (*E*) isomers; electron diffraction and NMR studies indicate that the (*E*) isomer predominates. The barriers for isomerization as well as the (*E*/*Z*) ratios depend on the substituents. Compound **33a** is capable of adding HF reversibly to give **34**.[59] Like $CF_3-N=CF_2$, the compounds **33** tend to dimerize, leading to the formation of the formamidines **35**.[59]

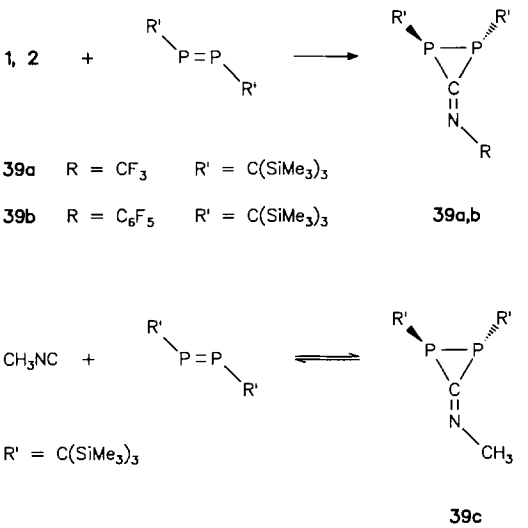
The reaction of **1** with trifluoroacetic acid enables the synthesis of *N*-trifluoromethylformamide **36**,[61] which cannot be prepared directly owing to the low stability of trifluoromethylamine.[62] The boiling point of **36** is lower than that of *N*-methylformamide. It is present as the formamide, and not in the form of the hydroxymethanimine. In contrast to *N*-methylformamide, for which 95% (*Z*) is present in the isomeric mixture, the (*E*) isomer is the thermodynamically more stable form for **36**. The isomers



36

are interconverted by a hindered rotation, for which the free enthalpy of activation, determined by dynamic NMR methods, is 62 kJ mol^{-1}.[61]

4.2. Cycloadditions



Reactions of alkynes with isocyanides lead to numerous products that depend on the substituents on both the isocyanide and the alkyne.[63] The simple [2 + 1]cycloaddition product, a cyclopropenimine,[64] is observed only in exceptional cases. The reactions generally require alkynes with either electron-donating or electron-withdrawing substituents.[63, 64] Isocyanide **1** reacts smoothly with diphenylacetylene in dilute solution to form colorless, crystalline 1,2-diphenyl-3,4-bis(trifluoromethylimino)-cyclobut-1-ene (**37**),[65] which has been completely characterized by its spectroscopic data and an X-ray crystal structure analysis. Partial hydrolysis of **37** leads to the formation of the pale yellow ketone derivative **38**. Similar reactions were also observed for 2-butyne and ethoxyacetylene.[66] Fluoroalkenes and hexafluorobutyne, however, do not react with trifluoromethyl isocyanide.[67]

37

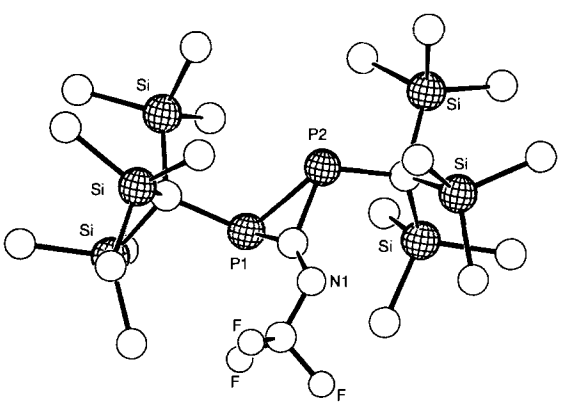
38

So far, the cycloaddition of **1** and **2** (and other isocyanides) with diphosphenes is the most thoroughly investigated reaction. Depending on the substituents on the phosphorus atoms different products are obtained. The reactions of **1** and **2** with diphosphenes containing a tris(trimethylsilyl)methyl substituent are identical. The diphosphiranimines **39a** and **39b** are formed and have been characterized by their spectroscopic data[68] and by a crystal structure analysis of **39a** (Fig. 1).[69] These products

39a,b

39c

39a and **39b** form thermally extraordinarily stable crystals that are also not sensitive to air or hydrolysis. The analogous addition of methyl isocyanide leads to the diphosphiranimine **39c**, which undergoes a reverse cycloaddition reaction at room temperature to yield the diphosphene and methyl isocyanide.



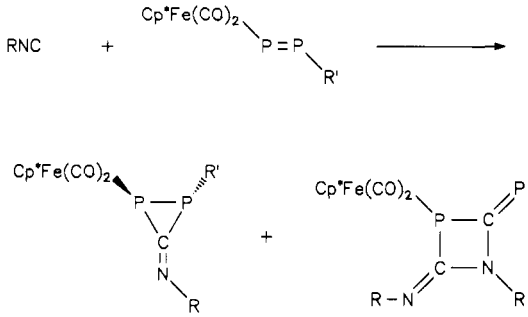


Fig. 1. Molecular structure of **39a** in the crystal.

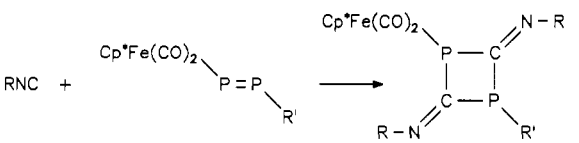
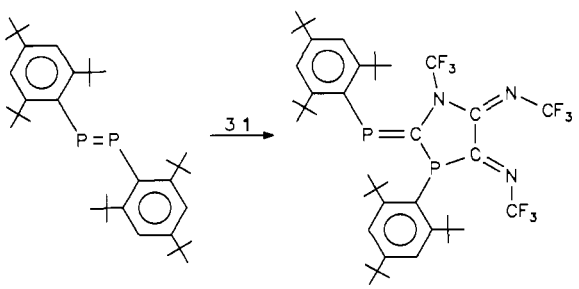


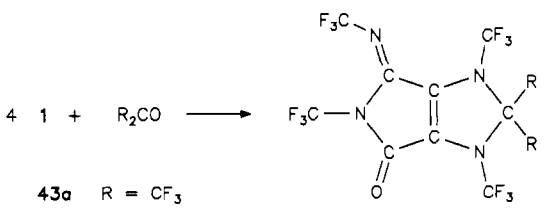
The metal-substituted diphosphenes Cp*Fe(CO)$_2$P=PR' (Cp* = C_5Me_5, R' = C[Si(CH$_2$)$_3$]$_3$) react to form the three-membered ring systems **40**.[70] In the case of the 2,4,6,-tri-*tert*-butylphenyl substituent, however, the reaction proceeds further to afford a product with the composition [Cp*Fe(CO)$_2$PPR'][RNC]$_2$ (**41**), which displays two sets of signals in the ^{31}P and ^{19}F NMR spectra. According to the spectroscopic data, **41** possesses a 1,3-azaphosphetane structure with an exocyclic P=C double bond. Regular isocyanides like *ortho*-tolyl isocyanide, however, lead to 2,4-diimino-1,3-diphosphetane derivatives, as demonstrated by a crystal structure analysis.[70]

If the diphosphene carries two 2,4,6,-tri-*tert*-butylphenyl substituents, the three-membered ring cannot be detected. Instead, the reaction with **1** leads, by an as yet unknown mechanism, to the five-membered ring system **42** with an exocyclic P=C double bond, whose structure was determined by a crystal structure analysis.[68]



40 **41**

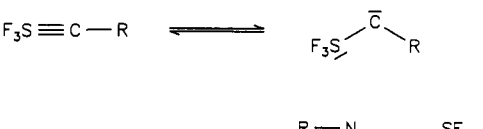
40a R = CF_3 R' = 2,4,6-tBu_3-C_6H_2
40b R = CF_3 R' = $C(SiMe_3)_3$
40c R = C_6F_5 R' = 2,4,6-tBu_3-C_6H_2
41 R = CF_3 R' = 2,4,6-tBu_3-C_6H_2



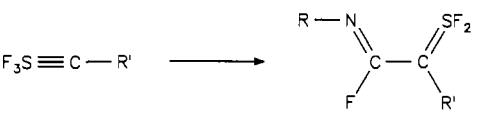
R = 2-CH_3-C_6H_4 R' = 2,4,6-tBu_3-C_6H_2

42

A similarly complicated course is taken by the reaction of hexafluoroacetone or 1,3-dichlorotetrafluoroacetone with **1**. The expected iminodioxolane is not formed,[71] but instead the hexahydropyrrolo-[3,4-d]imidazole **43** is found.[61, 72]



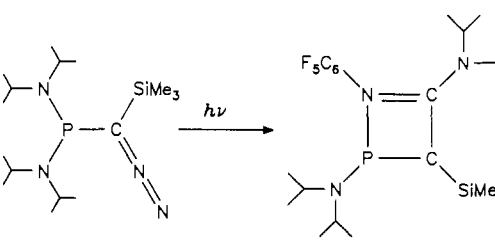
43a R = CF_3
43b R = CF_2Cl



43

4.3. Reactions with Carbenoids

According to structural studies, the alkylidynesulfurtrifluoride compounds prepared by Seppelt et al. possess an energetically low-lying excited state with a C–S single bond and a carbene-like carbon atom in addition to the ground state with a C–S triple bond.[73] This readily explains the decomposition of these compounds to yield dimers with C–C double bonds.[73] Reactions of the P–C triple bond as well as of the carbene-like carbon atom can also be observed in the compound $(iPr_2N)_2PC-SiMe_3$, prepared by Bertrand et al.[74]



Recently the first successful reactions—apart from the trivial addition of hydrogen fluoride—of alkylidynesulfurtrifluorides (possessing a C≡S triple bond or a carbene-like carbon atom) with the fluorinated isocyanides **1** and **2** have been performed. The resulting alkylidenesulfurdifluoride **44** containing conjugated double bonds could stem from a ketenimine as well as from a three-membered ring species.[73] The compounds **44** can be

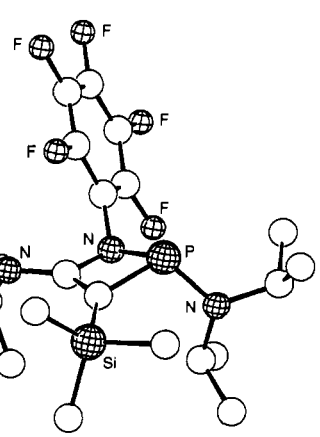
44a R = CF_3 R' = CF_3
44b R = C_6F_5 R' = CF_3
44c R = C_6F_5 R' = SF_5

44

45

three-membered ring species.[73] The compounds **44** can be present as several isomers. When the substituents are SF_5 and C_6F_5, only one isomer is observed. This enabled the first crystal structure analysis of an alkylidenesulfurdifluoride.[73]

The photochemical reaction of $(iPr_2N)_2P-C(N_2)-Si(CH_3)_3$ with C_6F_5NC (**2**) yields, by migration of the diisopropylamino group, the didehydroazaphosphetane derivative **45** (Fig. 2).[75]



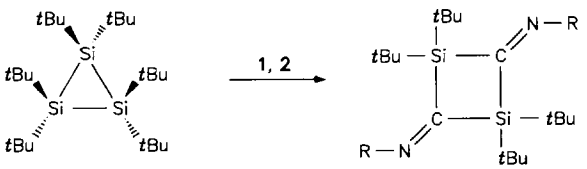


Fig. 2. Molecular structure of **45** in the crystal.

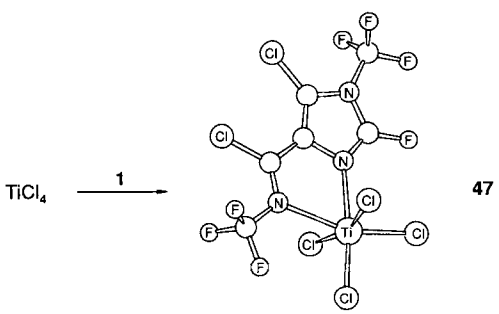
The expected primary product, a ketenimine, could again not be observed.

2,6-Dimethylphenyl isocyanide reacts with tetrakis(2,6-dimethylphenyl)disilene under the formation of a disilacyclopropanimine.[76] Although the photolysis of hexa-*tert*-butylcyclotrisilane yields a disilene, it appears that this compound does not react with isocyanides like **1** or **2**, but that the simultaneously formed silylene is the reactive species. Head-to-tail dimerization of the silaketenimine intermediates formed from the silylene leads to the observed 1,3-disilacyclobutane-2,4-diimines **46**.[77] The trifluoromethyl derivative **46a** was characterized by a crystal structure analysis.[77]

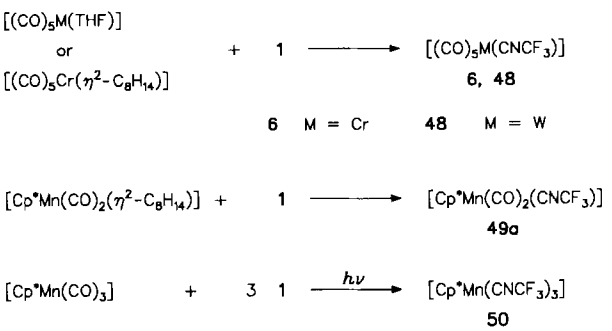


46

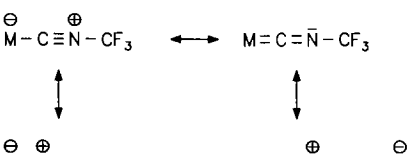
46a R = CF_3
46b R = C_6F_5

5. Fluorinated Isocyanides as Ligands in Coordination Complexes

According to results obtained from PE spectroscopy (see Section 3), trifluoromethyl isocyanide (**1**) should be a relatively weak Lewis acid; it should, however, possess rather good π-acceptor properties because of its energetically favorable π^* orbitals. Indeed, **1** does not form Lewis acid–base addition products with BF_3 or PF_5. The reaction with the stronger Lewis acid AsF_5 proceeds further, probably yielding $CF_3N{=}C(F)AsF_4$,[78] and even with titanium tetrachloride no simple trifluoromethyl isocyanide complex is formed. Instead, the linking of three CF_3NC units leads to an imidazole derivative that acts as a bidentate ligand in complex **47**.[79]



47



5.1. Mononuclear Trifluoromethyl Isocyanide Complexes and the Relative Ratio of the π-Acceptor and σ-Donor Strengths of the CF_3NC Ligands

Owing to the strong tendency of trifluoromethyl isocyanide **1** to polymerize, all syntheses must be performed at the lowest possible temperatures and at high dilution. In addition it is necessary to use reactive complex fragments, for example, those carrying readily substitutable ligands. It is frequently possible to perform ligand substitutions under photochemical conditions.

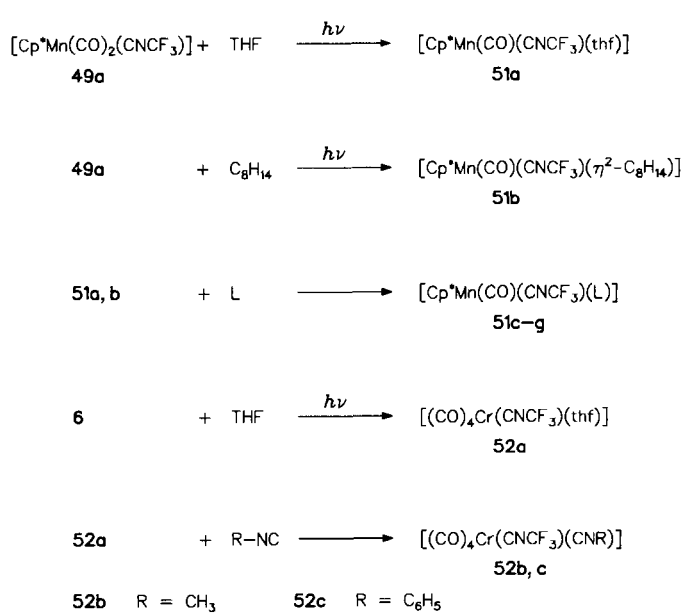
The synthesis of the first trifluoromethyl isocyanide complexes $[(CF_3NC)Cr(CO)_5]$ (**6**) and $[(CF_3NC)W(CO)_5]$ (**48**)[30] indicated

that the trifluoromethyl isocyanide ligand has a very similar, maybe even superior, ratio of π-acceptor to σ-donor strengths than CO. For instance, ^{13}C NMR spectra show the resonance of the *trans*-CO ligand at higher field than those of the *cis* ligands. This is the reverse of the effect that is observed for most other complexes containing the pentacarbonylchromium fragment—exceptions are thiocarbonyl and selenocarbonyl complexes.[80] Data from vibrational spectroscopy indicate the same trend. However, it is very difficult to analyze these data precisely, because the CO vibrations couple with those of the CN unit. Further proof is obtained from UV PE spectra of **6** and **48**. No splitting, but only a slight lowering of the "t_{2g}" level by 0.26 eV[81] relative to that of hexacarbonyl complexes is observed.[82] Results from X-ray PE spectra also confirm this trend.[54] The binding energies of the core electrons of all atoms in the trifluoromethyl isocyanide ligand in **6** and **48** are clearly lower than those found for free trifluoromethyl isocyanide. Especially notable is the decrease of the F-1s binding energy by more than 1 eV. In a valence bond description this can be explained by the participation of resonance structures with hyperconjugation. (Scheme 1).

Scheme 1.

A structural study of the chromium complex **6** in the gas phase, by electron diffraction,[83] indicates a significant bending at the isocyanide nitrogen atom to 142(4)° and a slight increase in the CN distance to 122.0(16) pm, relative to the free isocyanide.

Manganese halfsandwich complexes of the type $[Cp^*Mn(CO)_2L]$ (L = $CNCF_3$, CO, $CNCH_3$, CS) (**49a–d**),[84] $[Cp^*Mn(CO)(CNCF_3)L]$ (L = THF, η^2-C_8H_{14}, CH_3NC, C_6H_5NC, PF_3, $P(C_2H_5)_3$, $P(C_6H_5)_3$, CS) (**51**),[85] and $[\eta^6$-1,3,5-$C_6H_3(CH_3)_3]Cr(CO)(L)(CNCF_3)]$[86] (L = CO, $CNCH_3$) are much better suited for the comparison of π-acceptor and σ-donor strengths based



on vibrational spectroscopic data than the complexes **6** and **48**. The IR data of $[Cp^*Mn(CNCF_3)_3]$ (**50**) [ν(CN) = 1948, 1823 cm^{-1}] indicate unambiguously that the band between 1650 and 1850 cm^{-1} in the spectra of **49a** and **51** can be assigned to the CN valence vibration of the trifluoromethyl isocyanide ligands. In the case of the complexes **51** with donor ligands such as THF, this band is shifted to below 1700 cm^{-1}, which indicates a CN bond order in the isocyanide ligand of approximately 2. A comparison of the force constants of the CO valence vibrations of these complexes (Table 2), calculated according to the method

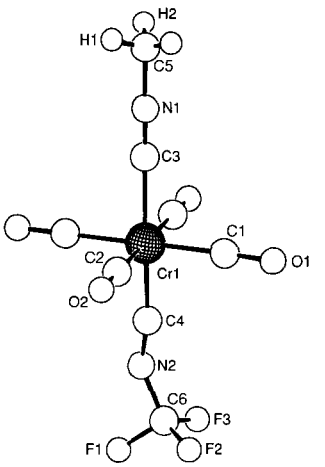
of Cotton and Kraihanzel,[87] allows an estimate of the relative ratio of π-acceptor and σ-donor strengths of the trifluoromethyl isocyanide ligand relative to other ligands. This force constant is a measure of the CO bond order and, hence, of the contribution of the CO ligands to backbonding. If the force constant is large, the CO ligands do not contribute strongly to backbonding, and therefore the other ligands' contribution must be high. This is the case for the known strong π-acceptor ligands CS and PF_3 and apparently for the trifluoromethyl isocyanide ligand as well.

Further indications for the extraordinary properties of the trifluoromethyl isocyanide ligand stem from ligand substitution reactions on **49a** and **6**.[85, 88] Only the carbonyl ligands are substituted. This enables the synthesis of **52b**, which is formed preferentially as the *trans* isomer. This particular compound in

corporates all three ligands to be compared in one molecule. Its crystal structure analysis shows that there are significant differences among the $Cr-C_{ligand}$ distances. The bond to the trifluoromethyl isocyanide ligand is 20 pm shorter than that to the methyl isocyanide ligand, and also clearly shorter than the bonds to the carbonyl ligands. A further notable difference between the two isocyanide ligands is the distinct bending of the trifluoromethyl isocyanide ligand, relative to the nearly linear methyl isocyanide ligand.[85]



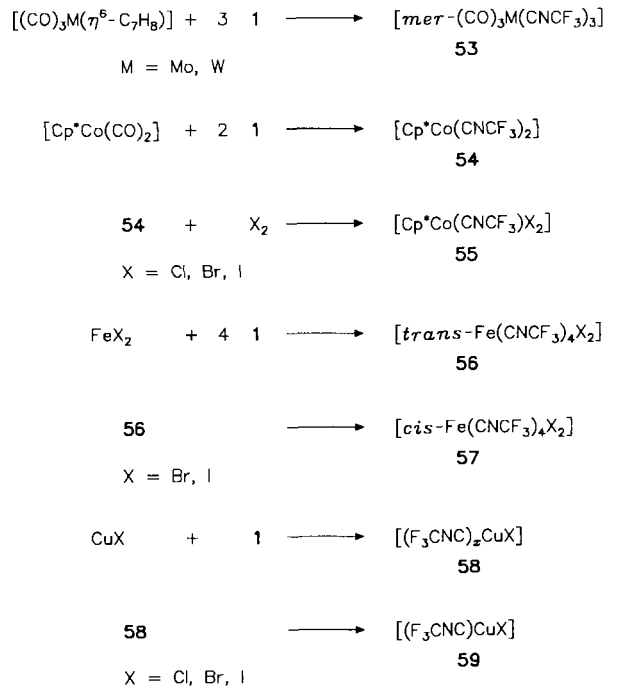


Fig. 3. Molecular structure of *trans*-**52b** in the crystal. Important distances [pm] and angles [°]: Cr1–C1 188.2(5), Cr1–C2 189.8(5), Cr1–C3 201.7(5), Cr1–C4 181.4(6), C3–N1 113.9(6), C4–N2 125.0(8), C3-N1-C5 179.7(3), C4-N1-C6 141.2(7).

According to NMR data, the molybdenum and tungsten complexes **53** are in the meridional form.[89] The exchange of carbonyl ligands in $[Cp^*Co(CO)_2]$ enables the synthesis of the halfsandwich complex **54**, which can be oxidized by halogens to give **55**.[90] The stability of these compounds decreases with increasing electronegativity of the halogen ligand. The low charge density on the metal center results in a distinct shift of the NC valence vibration to higher wavenumbers and a high-field shift of the ^{13}C resonance of the isocyanide carbon atom, in the order I < Br < Cl. According to its crystal structure, $[Cp^*Co(CNCF_3)I_2]$ crystallizes with one molecule of I_2 per complex to form chains of iodine molecules. These chains link the $[Cp^*Co(CNCF_3)]$ fragments;[91] however, the I_2 units are disordered.

The reaction of $FeBr_2$ or FeI_2 with **1** leads primarily to *trans*-**56**, which in dichloromethane slowly converts into the *cis*-isomer **57**.[92] The reaction of copper(I) halides with **1** in dichloromethane is especially interesting. In the presence of an excess of **1** the copper halide dissolves completely and forms **58**. These soluble species with an unknown number of isocyanide ligands, however, tend to liberate **1** to afford **59** in the form of small leaf-shaped crystals with a mother-of-pearl luster. These are insoluble in noncoordinating solvents, but dissolve in acetonitrile. The ^{19}F and ^{13}C NMR spectra confirm the presence of coordinated trifluoromethyl isocyanide.[93]

62

Owing to the instability of **1**, the preparation of homoleptic trifluoromethyl isocyanide complexes is difficult. The most readily performed synthesis is that of the nickel complex **60** from tetracarbonylnickel.[94] The reaction with bis(η^4-butadiene)carbonyliron leads only to moderate yields of $[Fe(CF_3NC)_5]$ (**61**) and $[Fe_2(CF_3NC)_9]$ (**64**).[95] Like $[Fe(CO)_5]$[96] and $[Fe(CNR)_5]$ (R = Et, *i*Pr, *t*Bu)[97] **61**, which presumably possesses a trigonal-bipyramidal structure, is nonrigid on the NMR time scale. After many unsuccessful attempts the synthesis of the chromium complex **62** was achieved by the reaction of trisallylchromium and **1**.[98] The structural analysis shows the expected octahedral coordination by the trifluoromethyl isocyanide ligands. In this molecule, however, there are four crystallographically distinct isocyanide ligands, which differ in the degree of bending at the isocyanide nitrogen atom. Interestingly, an isocyanide ligand with a large C-N-C bond angle is *trans* to an isocyanide ligand with a small angle.

5.2. Multinuclear Trifluoromethyl Isocyanide Complexes

As is the case for the carbonyl ligand, the trifluoromethyl isocyanide ligand should be able to act not only as terminal ligand in mononuclear complexes, but also as bridging ligand in di- or multinuclear complexes and clusters. Due to its strong π-acceptor properties, the trifluoromethyl isocyanide ligand should have an especially high preference for the bridging position, since calculation by Howell et al. indicate that strongly π-accepting ligands favor the bridging position.[99] This was also confirmed for the thiocarbonyl ligand.[100]

5.2.1. Dinuclear Trifluoromethyl Isocyanide Complexes

Dinuclear trifluoromethyl isocyanide complexes have been prepared with nickel,[94] iron,[95] molybdenum,[101] ruthenium,[102] and tungsten.[103] Bis[η^5-cyclopentadienyl-μ-(trifluoromethyl isocyanide)nickel] (**63**) is formed, like the corresponding carbonyl complex, by the reaction of tetrakis(trifluoromethyl isocyanide)nickel (**60**) with bis(η-cyclopentadienyl)nickel. According to the spectroscopic data, the two isocyanide ligands bridge the nickel atoms.

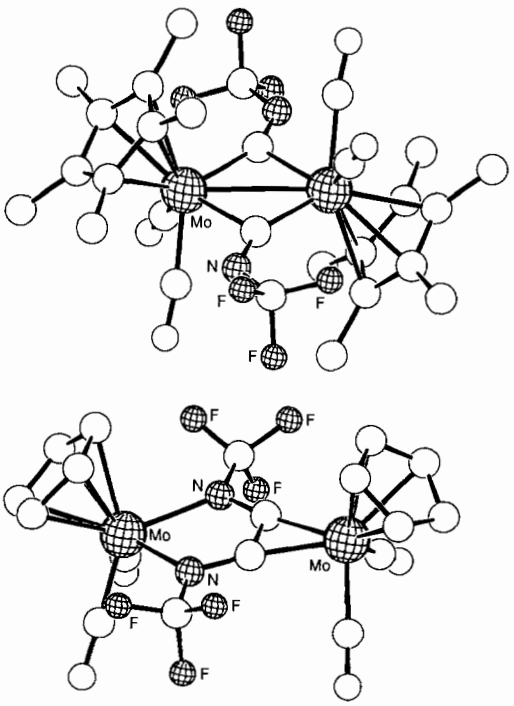
$[Fe_2(CNCF_3)_6(\mu_2\text{-}CNCF_3)_3]$ (**64**) is formed at room temperature by the decomposition of $[Fe(CNCF_3)_5]$ (**61**). According to spectroscopic data,[95] **64** has a structure that is analogous to $[Fe_2(CO)_9]$[104] and $[Fe_2(CNEt)_9]$.[105] On the NMR time scale there is no exchange of terminal and bridging ligands at room temperature. $[Ru_2(CO)_6(\mu_2\text{-}CNCF_3)_3]$ (**71**) is formed as a by-product during the reaction of $[Ru_3(CO)_{11}(CH_3CN)]$ or $[Ru_3(CO)_{10}(CH_3CN)_2]$ with **1**.[102] In contrast to the extremely unstable $[Ru_2(CO)_9]$[106] **71** is a very stable compound. According to its spectroscopic data, **71** has a structure that is analogous to $[Fe_2(CO)_9]$[104] and $[Ru_2(CN\text{-}iPr)_9]$.[107]

The tendency of the trifluoromethyl isocyanide ligand to occupy the bridging position is particularly apparent in the compounds $[CpM(CO)_2(\mu_2\text{-}CNCF_3)]_2$ (M = Mo, W; Cp = C_5H_5, C_5Me_5) (**66**).[101, 103] In the analogous carbonyl species[108] as well as in the substitution products with regular isocyanides,[109] only terminal ligands are found. The synthesis of these compounds proceeds by the addition of **1** to the metal–metal triple bond in $[Cp(CO)_2M{\equiv}M(CO)_2Cp]$.[101, 103]

Initially one molecule of **1** is added, forming the species **65**, which possesses a μ_2-η^2-bridging trifluoromethyl isocyanide ligand. According to the spectroscopic data, these complexes have a structure analogous to the corresponding phenyl isocyanide complex.[110] The reaction with an excess of **1** yields different products depending on the reaction conditions. At 0 °C, red $[CpM(CO)_2(\mu_2\text{-}CNCF_3)]_2$ (**66**) is formed, which transforms at

room temperature into the deep violet $[CpM(CO)_2(\mu\text{-}F_3C{-}N{=}C{=}C{=}N{-}CF_3)M(CO)_2Cp]$ (**67**). Both structures have been proven by a crystal structure analysis (Fig. 4).



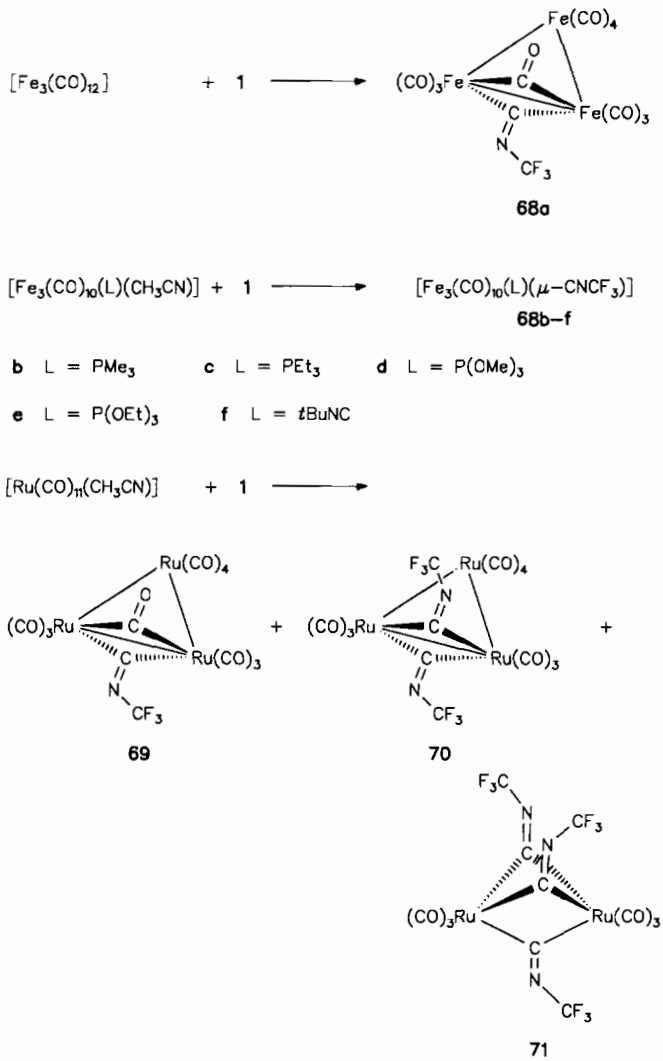


Fig. 4. Molecular structure of **66b** (top) and **67a** (bottom) in the crystal.

Even though **67** has (formally) an odd number of electrons at the metal centers, it is diamagnetic. It is still unclear how the dimerization can proceed so readily, forming a diazabutatriene ligand. In any case, the reaction is more straightforward than those of niobium(III) and tantalum(III) compounds with *tert*-butyl isocyanide, where dimeric isocyanide ligands occur as well.[111] The reductive coupling of coordinated isocyanide and carbonyl ligands has been the subject of extensive experimental as well as theoretical studies by the groups of Lippard,[112] Filippou,[113] and R. Hoffmann.[114]

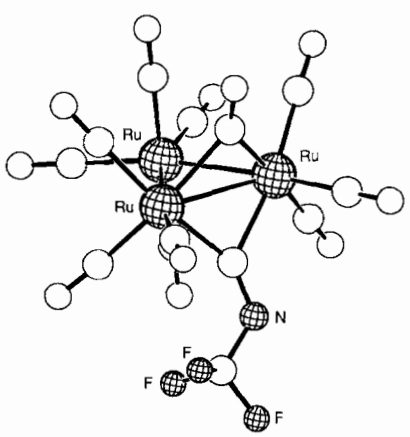
5.2.2. Trinuclear Clusters Containing the Trifluoromethyl Isocyanide Ligand

The trinuclear carbonyl clusters of the iron triad $[M_3(CO)_{12}]$ (M = Fe, Ru, Os) have very interesting structural and dynamic properties. In the solid state $[Fe_3(CO)_{12}]$ contains two different types of iron atoms. Two of them have three terminal and two bridging ligands each, while one of them has only terminal ligands. Its symmetry is close to C_{2v}.[115] In contrast, the corresponding ruthenium[116] and osmium[117] compounds and their derivatives contain exclusively terminal ligands and hence display D_{3h} symmetry.

The synthesis of the trifluoromethyl isocyanide-substituted derivatives was performed by the replacement of a carbonyl or preferably a labile acetonitrile ligand. The crystal structure analyses of the isostructural compounds of iron (**68a**)[118] and ruthenium (**69**)[102] indicate that the trifluoromethyl isocyanide ligand

again occupies a bridging position. Thus the ruthenium species is forced into the $[Fe_3(CO)_{12}]$ structure. In contrast, regular isocyanides occupy terminal axial positions.[119]

Attempts to prepare the corresponding osmium compounds by substitution of the labile acetonitrile ligand in $[Os_3(CO)_{11}(CH_3CN)]$ lead to the isolation of $[Os_3(CO)_{11}(\mu_2\text{-}CNCF_3)_2]$ (**72**)



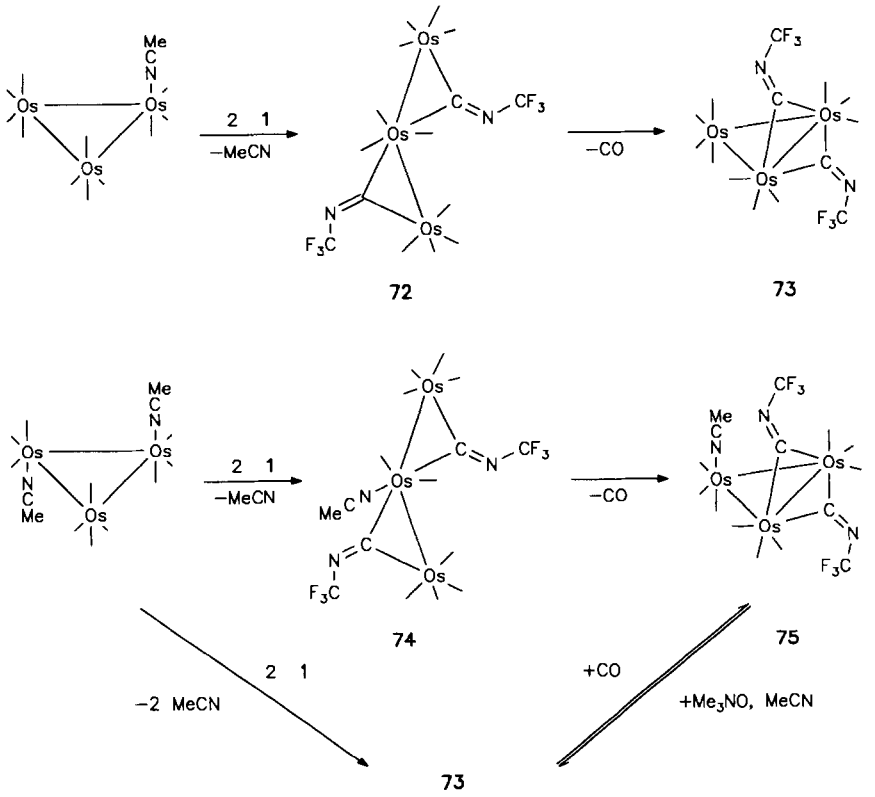


Fig. 5. Molecular structure of **69** in the crystal.

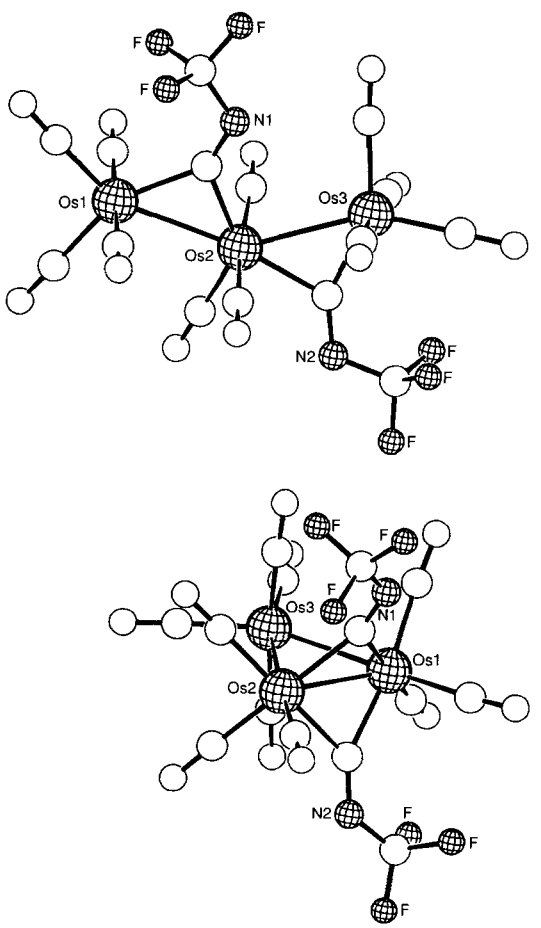
and its degradation product $[Os_3(CO)_{10}(\mu_2\text{-}CNCF_3)_2]$ (**73**).[120] Compound **72** is a derivative of the hypothetical compound $[Os_3(CO)_{13}]$ and hence a potential structural model for the products of ligand addition to $[M_3(CO)_{12}]$ clusters. Studies of these clusters with respect to ligand substitution and cluster fragmentation yielded a rate law that was interpreted as a combination of a dissociative and associative mechanism.[121] The isolation, structural analysis, and further reactivity of **72** as a metastable intermediate of such a reaction contributes to the understanding of the mechanism of these reactions, which are of fundamental interest in cluster chemistry.[122]

Cluster **72** is an "open" triosmium cluster, in which both $CNCF_3$ ligands bridge one metal–metal bond each. The two trifluoromethyl isocyanide ligands are structurally inequivalent (Fig. 6). One of them is located in the interior, the other one on the exterior of the open metal triangle. At low temperatures, this is also the case in solution. At −34 °C the ^{19}F NMR spectrum shows two singlets with an intensity ratio of 1:1. When the temperature is raised, however, the signals coalesce by a yet unknown mechanism; at room temperature only a broad signal at $\delta = -60.2$ is observed.

It is even more astonishing that the reaction of $[Os_3(CO)_{10}(CH_3CN)_2]$ and **1** also leads to the successful isolation and structural characterization of the "open" cluster **74**. This compound can react further, by loss of either the acetonitrile or a carbonyl ligand, to yield **73** or **75**.[123] The addition of a trifluoromethyl isocyanide ligand with breaking of the metal–metal bond therefore appears to compete successfully with the substitution of the second acetonitrile ligand. The structures of **74** and **75** are, with the exception of the presence of the acetonitrile ligand, very similar to those of the non-substituted compounds **72** and **73**. The two $CNCF_3$ ligands in **75** remain inequivalent in solution, while an increase in temperature leads to signal broadening for **74**.

Dodecacarbonyltriiron is nonrigid in solution; even at −150 °C all carbonyl ligands are equivalent on the NMR time scale.[124] Cotton and Troup explained this very low energy process ($\Delta G^{\ddagger} < 6\ kcal\,mol^{-1}$) with a "merry-go-round" mechanism requiring the simultaneous opening and reforming of carbonyl bridges. An alternative mechanism, proposed by B. F. G. Johnson, contains a rotation of the iron triangle around the C_2 axis, leading to a nonbridged D_3 structure.[125] A further rotation yields a structure with μ_3-carbonyl ligands. Recent EXAFS studies indicate that in frozen hexane solutions $[Fe_3(CO)_{12}]$ has most probably D_3 symmetry, while frozen solutions in the polar solvent dichloromethane contain unbridged as well as bridged structures.[126]

A number of different phosphane and phosphite derivatives have been synthesized in order to increase the activation barrier for the ligand exchange process; in no case, however, has it been possible to stop the



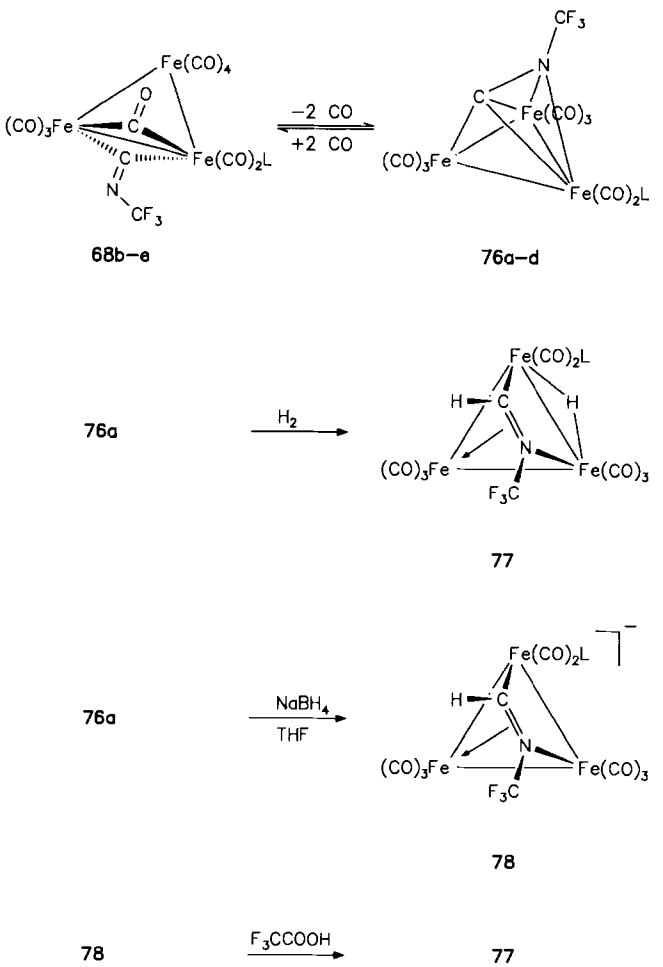


Fig. 6. Molecular structure of **72** (top) and **73** (bottom) in the crystal.

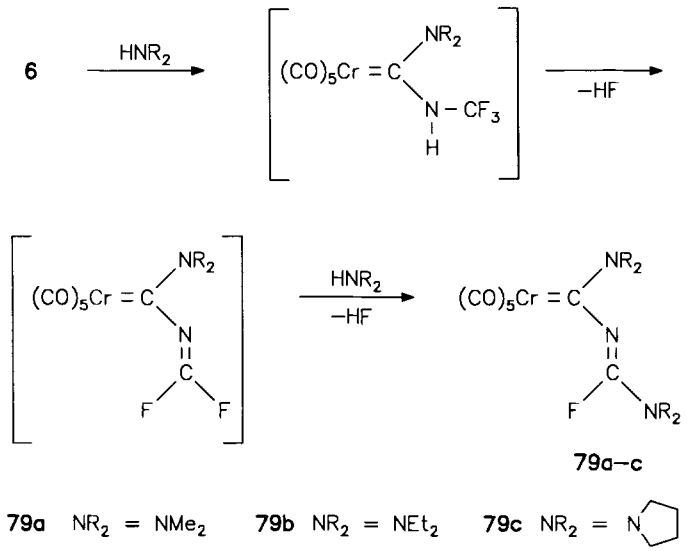
exchange process by decreasing the temperature.[127] Johnson et al. explained the spectra using the ligand polyhedron model,[127] while Mann et al. demonstrated that the ^{13}C NMR spectra of $[Fe_3(CO)_{11}(L)]$, $[Fe_3(CO)_{10}(L)_2]$, and $[Fe_3(CO)_9(L)_3]$ (L = a phosphane or phosphite ligand) can be explained by using the "merry-go-round" mechanism as well.[128] The bridged compound **68a**[129] was the first dodecacarbonyltriiron derivative for which it was possible to obtain a ^{13}C NMR spectrum, at $-110\,^{\circ}C$, that corresponds to the rigid solid-state structure. However, an unambiguous signal assignment was impossible. Only the introduction of additional phosphane or phosphite ligands in the compounds **68b–e** enabled the unambiguous signal assignment for the parent compound as well. When the temperature is increased, these compounds also undergo exchange of certain carbonyl ligands. Lentz and Marshall proposed a mechanism that is in accord with the experimental findings and leaves the trifluoromethyl isocyanide ligand in its preferred bridging position.[130] Mann later showed that our spectra can also be explained by a mechanism involving a concerted opening and reforming of bridges.[131] After a total of six intermediates with terminal $CNCF_3$ ligands, another isomer with a bridging trifluoromethyl isocyanide ligand is obtained. Recently Johnson et al. applied their ligand polyhedron model to these compounds and showed that an explanation of the experimental data is also possible using this model.[132]

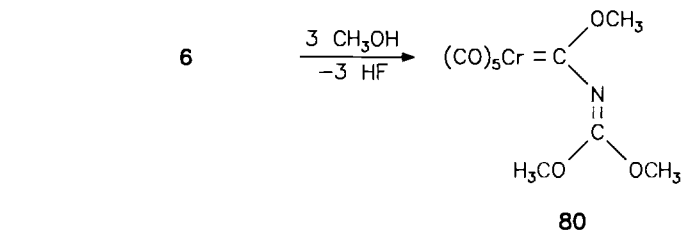
In the course of the study of the compounds **68b–e** (L = PMe_3, PEt_3, $P(OMe)_3$, $P(OEt)_3$) it was noted that carbon monoxide is reversibly eliminated when the temperature is slightly raised, which leads to the clusters **76a–d**.[133] These compounds **76a–d** are the first examples for a η^2-(μ_3-C-μ_2-N)-bridging trifluoromethyl isocyanide ligand, which acts as a six-electron donor. The C=N bond is oriented perpendicular to an iron–iron bond. This coordination mode is also found in $[Fe_3(CO)_9(\mu_3\text{-}\eta^2\text{-CN-}t\text{Bu})]$.[119a] A η^2-(μ_3-C-μ_2-O)-bridging carbonyl ligand was first demonstrated in 1979 by W. A. Herrmann et al. in $Cp_3Nb_3(CO)_7$.[134] A similar coordination mode of CO with two or three metal centers is also assumed for the absorption of carbon monoxide on metal surfaces.[135] Metal clusters have been repeatedly proposed as highly simplified models for intermediates in reactions on the metal surface of heterogeneous catalysts.[136] As a result of these considerations, **76c** (L = $P(OMe)_3$) was allowed to react with molecular hydrogen. Even under mild conditions the hydrido-μ_3-η^2-N-(trifluoromethyl)formimidoyliron cluster **77** was formed nearly quantitatively[133] (see Section 5.3).

5.3. Reactions of Coordinated Trifluoromethyl Isocyanide



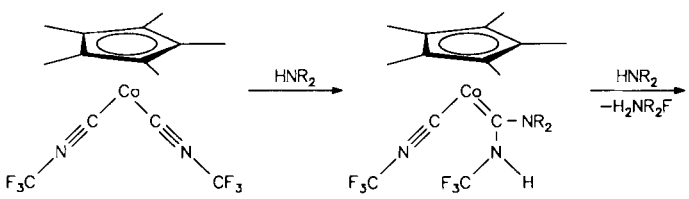
The coupling of two trifluoromethyl isocyanide ligands with the formation of a diazabutatriene ligand was discussed in Section 5.2.1.

Only five years after the designed synthesis of the first carbene complex by E. O. Fischer et al.,[137] Chatt et al. were able to demonstrate in 1969 that coordinated isocyanides are readily attacked by nucleophiles to afford carbene complexes.[138] Further reactions of isocyanide complexes have been discussed in several review articles.[11, 139] Fehlhammer et al. thoroughly examined the reaction of pentacarbonyl(trichloromethyl isocyanide)chromium with nucleophiles.[140]

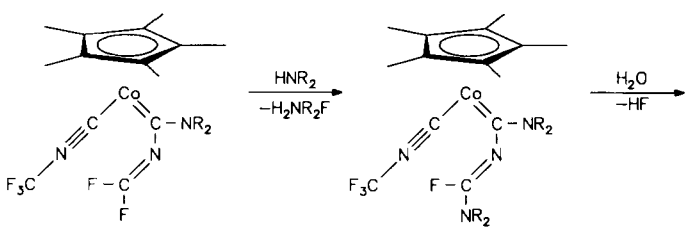


It is therefore not surprising that coordinated trifluoromethyl isocyanide also reacts readily with nucleophiles.[141] We have extensively studied these reactions on the pentacarbonylchromium complex **6**, and obtained the carbene complexes **79a–c** and **80**. It is noteworthy, however, that even such weak nucleophiles like methanol react without the addition of base and that in the course of the reaction the usually rather inert trifluoromethyl group is completely degraded. The hope of obtaining fluorinated heterocycles by the use of hydrazine derivatives was vain, because nucleophilic substitution replaced even the last fluorine substituent.[141]

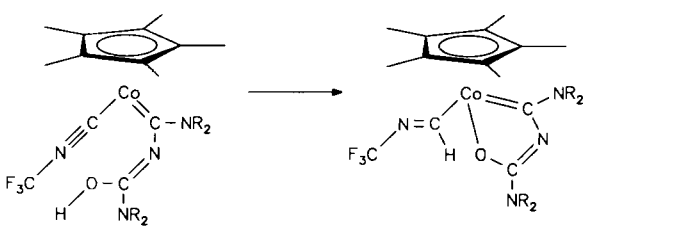
An unexpected result was obtained from the reaction between nucleophiles and (pentamethylcyclopentadienyl)bis(trifluoromethyl isocyanide)cobalt **54**.[142] Only in the presence of water was it possible to obtain any crystalline products. According to the crystal structure analysis, the isolated cobaltacycle **81** contains a pentamethylcyclopentadienyl and an *N*-trifluoromethylformimidoyl ligand. The reaction scheme shows a plausible mechanism for the formation of this species. One of the two trifluoromethyl isocyanide ligands has become completely degraded by successive nucleophilic attacks by the amine and can be found integrated into the metallacycle. The second one has been transformed into the η^1-bound *N*-trifluoromethylformimidoyl ligand.



Another *N*-trifluoromethylformimidoyl ligand, in this case μ_3-η^2-bound, is obtained by the reaction of the trinuclear iron

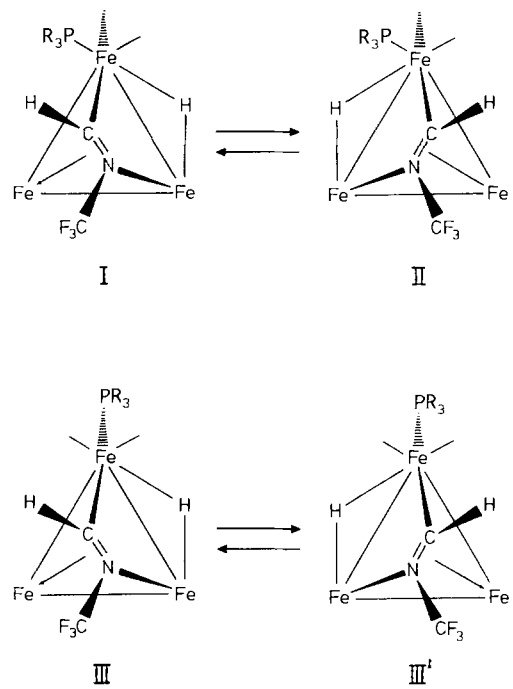


79a $NR_2 = NMe_2$ **79b** $NR_2 = NEt_2$ **79c** NR_2 = N



80

54



81a–c

81a $NR_2 = NMe_2$ **81b** $NR_2 = NEt_2$ **81c** NR_2 = N

cluster **76a** with hydrogen.[133] The iron cluster **77** that is formed contains, according to spectroscopic studies, an *N*-trifluoromethylformimidoyl as well as an μ_2-hydrido ligand. The μ_3-bridged **77** is present as a mixture of the isomers I–III, of which I and II, as well as III and III′ interconvert rapidly at room temperature (Scheme 2). The stepwise hydrogenation with sodium borohydride, followed by the protonation of the anionic cluster **76** by trifluoroacetic acid also leads to **77**, but in a different isomer ratio of I, II, and III.

Scheme 2. Structural isomers of compound **77** (only the framework of the cluster is shown).

5.4. Complexes of the Other Fluorinated Isocyanides

The coordination chemistry of fluorinated isocyanides other than CF_3NC is just beginning. The chromium complexes **7**, **8**, **13**,[26] **15**, **16**,[29] **17**, and **18**[28] are known for isocyanides with perfluoropropyl, perfluorobutyl, dichlorofluoromethyl, dichlorotrifluoroethyl, tetrachlorofluoroethyl, fluoromethyl, or difluoromethyl substituents. A crystal structure analysis is available for the difluoromethyl isocyanide complex **18** [Cr–CN 195.6(2), $Cr-CO_{trans}$ 190.0(2), $Cr-CO_{cis}$ 190.9-191.5(2) pm].[143] A slightly longer $metal-C_{isocyanide}$ bond and a slightly shorter bond to the *trans*-carbonyl ligand than to the *cis*-carbonyls are indications for the lower ratio of the π-acceptor and σ-donor strengths of the difluoromethyl isocyanide ligand. This had also been inferred from spectroscopic data. For 2-fluoroethyl and 2,2,2-trifluoroethyl isocyanide the complexes $[Ru(tpp)(CNCH_2CH_2F)_2]$, $[Ru(tpp)(CNCH_2CF_3)_2]$, and $[Fe(tpp)(CNCH_2CH_2F)_2]SO_3CF_3$ (tpp = *meso*-tetraphenylporphyrin) have been described.[20] The chromium complexes **19**, **20**,[29] and **23**[37] are known for the only recently prepared alkenyl isocyanides. The crystal structure analysis of **19** (Fig. 7) shows a somewhat longer $metal-C_{isocyanide}$ bond than $metal-C_{CO}$ bonds.[29]

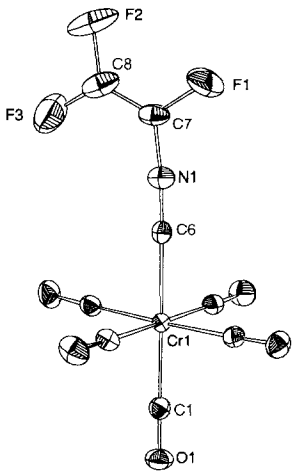


Fig. 7. Molecular structure of **19** in the crystal. Important distances [pm] and angles [°]: Cr1–C6 194.2(2), Cr1-C1 190.9(2), Cr1–CO_{cis} 190.2(2)-191.4(2), C6–N1 116.2(2), C7–N1 135.7(2), C7–C8 131.3(3), Cr1-C6-N1 177.8(1), C6-N1-C7 173.6(2), N1-C7-C8 123.8(2).

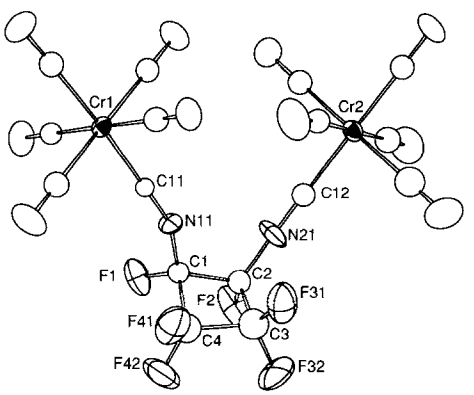
The reaction of **19** with pyrrolidine leads to a complete degradation of the complex, yielding $(C_4H_{10}N)_3[CrF_6]$.[144] Dimerization of **19** affords the first examples of complexes with 1,2,3,3,4,4-hexafluoro-1,2-diisocyanocyclobutane (**22a,b**).[34] The crystal structure of the *cis* isomer (Fig. 8) demonstrates that



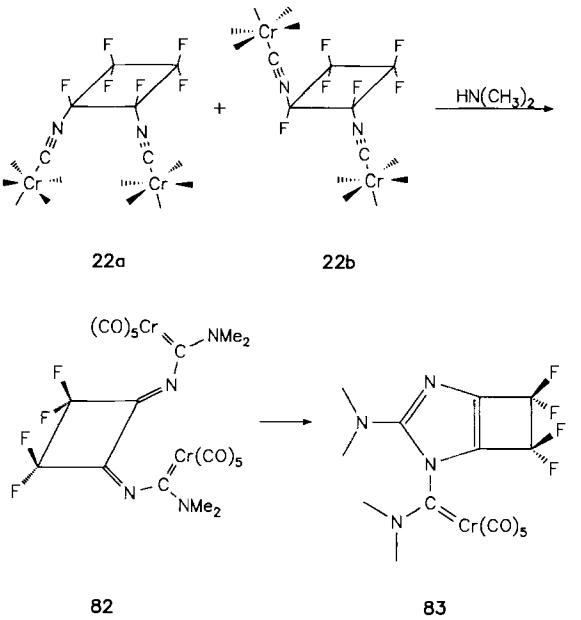


Fig. 8. Molecular structure of **22a** in the crystal.

it is clearly possible to accommodate two bulky substituents on the same side of the cyclobutane ring. Both chromium atoms have a nearly octahedral coordination environment; the various metal–$C_{carbonyl}$ bond lengths [188.1(7)–191.4(6) pm] are very similar and are not significantly different from the bond lengths to the isocyanide carbon atoms [Cr1–C11 190.3(6), Cr2–C21 190.0(6) pm]. In addition, the position of the intense carbonyl bands in the IR spectra indicate that these fluorinated diisocyanides are also excellent π-acceptors.

Correspondingly, **22a,b** react readily with nucleophiles like dimethylamine. Upon nucleophilic attack on both isocyanide carbon atoms and HF elimination, the primary product is the dicarbene complex **82**, which can be isolated in the form of deep blue crystals that are unstable at room temperature. The crystal structure analysis indicates that the lone pair on N1 is directed towards the p orbital of C26 (Fig. 9), which enables the facile cyclization to an imidazole ring with loss of a pentacarbonylchromium fragment, yielding the stable carbene complex **83**. If

this reaction could be generalized and the organometallic protecting group cleaved, it would represent a convenient synthesis for imidazole derivatives with an annelated fluorine-substituted four-membered ring.

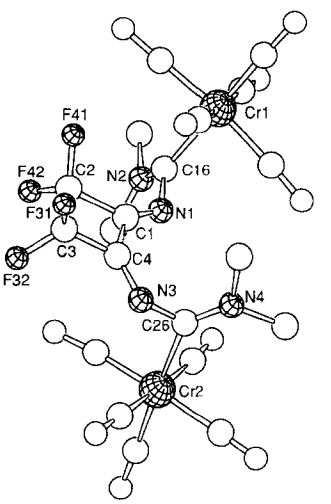

Fig. 9. Molecular structure of **82** in the crystal.

The fluorinated aryl isocyanide **2**, which is available in larger quantities, can be utilized for the direct synthesis of complexes. Previously, the manganese halfsandwich complex **84**,[22] as well as pentacarbonyl(pentafluorophenyl isocyanide)chromium **85**,

$$[Cp^*Mn(CO)_2(thf)] + 2 \longrightarrow [Cp^*Mn(CO)_2(CN{-}C_6F_5)]$$
84

$$[(CO)_5Cr(C_6H_{14})] + 2 \longrightarrow [(CO)_5Cr(CN{-}C_6F_5)]$$
85

$$[Ni(CO)_4] + 4\ 2 \longrightarrow [Ni(CN{-}C_6F_5)_4]$$
86

and the homoleptic nickel complex **86** had been prepared.[145] While there are only a few studies on pentafluorophenyl isocyanide complexes, they clearly indicate that **2** is by no means as good a π-acceptor ligand as **1**.

6. Outlook

Fluorinated isocyanides have proven to be a multifaceted class of compounds with a significant potential in synthesis. These compounds are excellent building blocks for two reasons: their unusual ligand properties, especially those of trifluoromethyl isocyanide, and their increased reactivity relative to regular isocyanides. The latter property, however, also increases the difficulty of handling. Unfortunately, some of these compounds, like the bifunctional trifluorovinyl isocyanide **11**, cannot be prepared by regular methods of organic synthesis and the pyrolysis of metal complexes only yields very small quantities. Early results indicate that **11**, in its "tamed" version (that is, stabilized on a pentacarbonylchromium moiety), is an excellent synthetic building block that enables the synthesis of further fluorinated isocyanides in the coordination sphere. For this and other reasons, further studies are necessary to explore the potential of fluorinated isocyanides in synthesis fully.

The research described in this article was made possible by my enthusiastic coworkers, to whom I wish to express my sincere gratitude. I wish to thank Prof. Dr. Konrad Seppelt for the constant support of my work. Numerous studies would not have been possible without the successful collaboration with the research groups of Prof. Dr. R. D. Adams, Dr. G. Bertrand, Prof. Dr. H. Bock, Prof. Dr. H. Bürger, Prof. Dr. P. Botschwina, Prof. Dr. H. Dreizler, Prof. Dr. J. Fuchs, Prof. Dr. H. Hartl, Prof. Dr. E. Illenberger, Prof. Dr. P. Luger, Prof. Dr. H. Oberhammer, Prof. Dr. K. Seppelt, Prof. Dr. J. S. Thrasher, Prof. Dr. L. Weber, Prof. Dr. M. Weidenbruch, and Prof. Dr. G. Wilke. My special gratitude belongs to Prof. Dr. D. D. DesMarteau (Clemson University, South Carolina), at whose institute I was allowed to work in 1991. This work was supported by the Deutsche Forschungsgemeinschaft, the Graduiertenkolleg "Synthese und Strukturuntersuchung niedermolekularer Verbindungen" der Freien und der Technischen Universität Berlin, and by the Fonds der Chemischen Industrie.

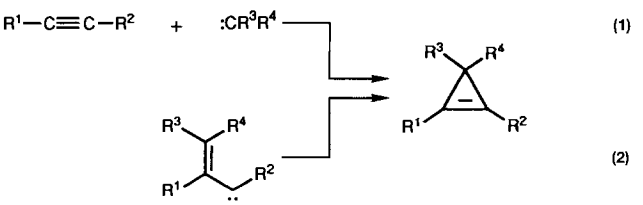
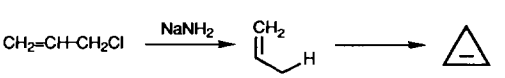
Gas-Phase Synthesis of Reactive Molecules Using Adsorbed Reagents

W. E. Billups* and Dianne J. McCord



Base-induced elimination reactions have found wide application in the synthesis of strained alkenes. The method is often complicated by a competing process in which the incipient alkene is trapped by nucleophilic addition of the base. Recent studies have shown that the bimolecular side reactions can be avoided when bases such as potassium *tert*-butoxide are supported on an inert surface like silica gel and the reaction is carried out in vacuo. This vacuum gas-solid reaction (VGSR) procedure has the additional advantage that very unstable species may be isolated under conditions that allow detailed studies of their physical and chemical properties. The scope of this procedure has been extended to include the use of fluoride salts supported on glass helices to effect the elimination of β-halosilanes. The fluoride route to strained alkenes is particularly attractive since the reaction may be carried out at very moderate temperatures and the starting materials are readily available. This review describes the development of this vacuum gas-phase procedure and its application in the synthesis and characterization of small-ring alkenes and bicycloalkenes, including methylenecyclopropene, spiropentadiene, bicyclopropenyls, 1,2- and 1,3-bridged cyclopropenes, and other simple cyclopropenes.

1. Introduction

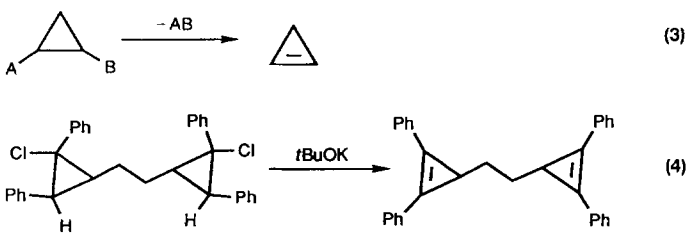


This review describes the development of a vacuum gas-phase procedure[1, 2] and its application in the synthesis and characterization of a wide variety of theoretically significant reactive intermediates which have, for the most part, not been accessible by known methodology. A common feature of these compounds is the incorporation of the cyclopropene ring. As the most highly strained cycloalkenes, the cyclopropenes have played a major role in the development of important concepts such as chemical reactivity and aromaticity.[3, 4] Their high strain energy often results in unexpected reactions such as facile [2+2] cycloaddition reactions and isomerization to species normally considered to be of high energy. The cyclopropenes thus represent one of the cornerstones of modern structural chemistry by virtue of their high energy content and the unusual properties that arise from their unique bonding. They continue to spark the imagination of organic chemists.

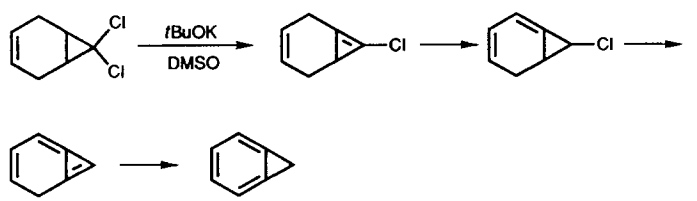
Historically, the syntheses of cyclopropenes fall into three general catagories:

1. The addition of carbenes[5, 6] to alkynes leads to the construction of the ring directly by either a concerted or stepwise process depending on the spin multiplicity of the carbene [Eq. (1)]. The ease with which halocarbenes can be generated has led to a plethora of halocyclopropenes.[7–17] This route is not limited to free carbenes, as carbenoids also add readily to alkynes yielding cyclopropenes.[18–30]

2. The formation of vinylcarbenes can be effected with relative ease from either 3*H*-pyrazoles or allylic diazo compounds. Subsequent ring closure of the vinylcarbene leads directly to the cyclopropene [Eq. (2)].[31–53] In a number of other cases, the vinyl carbene can be generated by the base-induced elimination of an appropriate allylic halide (Scheme 1).[54]



Scheme 1. Synthesis of cyclopropene.



3. A final method is the 1,2-elimination of suitable precursors to yield a cyclopropene [Eq. (3)].[4] Indeed, the first authenticated synthesis of cyclopropene itself was reported in 1922 by Dem'yanov and Doyarenko, who found that trimethylcyclo-

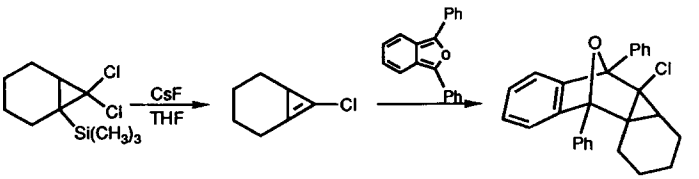
propylammonium hydroxide undergoes a Hofmann elimination at 300 C on platinized clay.[55] Perhaps the most commonly employed procedure involves the dehydrohalogenation of a halocyclopropane with potassium *tert*-butoxide in either dimethyl sulfoxide (DMSO) or tetrahydrofuran (THF). A typical example is outlined in Equation 4.[56] In a number of in-

stances the cyclopropene has been observed to undergo a base-catalyzed prototropic rearrangement in which the endocyclic double bond isomerizes to an exocyclic position. This results usually in a thermodynamically more stable product, as illustrated by the formation of benzocyclopropene from 7,7-dichlorobicyclo[4.1.0]hept-3-ene and strong base (Scheme 2).[57, 58]

Scheme 2. Synthesis of benzocyclopropene.

The use of *tert*-butyllithium and other lithium reagents to effect the elimination of halogen from mono- and dihalocyclopropanes has also been reported.[59–63] The highly strained compounds **1**[62] and **2**[63] were synthesized by this procedure.



1

2

An important discovery by Chan and Massuda[64] demonstrated that halocyclopropenes can be prepared readily by the fluoride-induced elimination of β-dihalocyclopropylsilanes and trapped as illustrated in Scheme 3. The halocyclopropenes that result from these elimination reactions have become important building blocks in organic chemistry.[65, 66]

Scheme 3. Synthesis of a cyclopropene by fluoride ion mediated elimination of a β-halocyclopropylsilane and a subsequent trapping reaction.

Although these elimination reactions have found wide application in the synthesis of cyclopropenes, the method is often complicated by a competing process in which the incipient alkene is trapped by nucleophilic addition of the base that was used to induce the elimination.[67, 68] Several recent studies have shown that these bimolecular reactions can be avoided when the base is supported on an inert surface and the reaction is carried out in vacuo.[1, 2] This procedure, now commonly known as the vacuum gas–solid reaction (VGSR) technique, has the additional advantage that very unstable species may be isolated under conditions that permit detailed studies of their physical and chemical properties. Billups and Lin extended the scope of this procedure to include the use of fluoride salts supported on glass helices to effect the elimination of β-halosilanes.[2] This route to strained alkenes is particularly attractive, since the reaction can be carried out under very mild conditions and the starting materials are readily available.[69]

2. Experimental Techniques

2.1. The Gas-Phase Reactions

The apparatus used for these gas-phase reactions is illustrated in Figure 1. Dehydrohalogenation reactions can be carried out by using potassium *tert*-butoxide adsorbed onto inert surfaces such as Chromosorb W or silica gel. Dehydrochlorinations of

W. E. Billups is Professor of Chemistry at Rice University, Houston, Texas (USA), where he served as Chairman of the Department from 1985 until 1991. He received his bachelor's degree from Marshall University in 1961 and his Ph.D. from the Pennsylvania State University in 1970. He was employed as a research chemist by Union Carbide Corporation from 1961 until 1968. His research interests include the chemistry of small-ring systems, reactive intermediates, metal atom chemistry, and more recently fullerene chemistry.

chlorocyclopropanes have been carried out from 160 °C to 320 °C. The pressure is typically 10 mTorr (1.33 Pa). Dehydrobromination reactions have been carried out at ambient temperature. Ideally, products are collected in traps cooled by liquid nitrogen (labeled H in Fig. 1) for further studies on their chemical and physical properties. NMR spectra can be obtained by collecting the product in an NMR tube attached to the bottom of trap H with deuterated solvent that is introduced from the solvent trap G. This procedure allows compounds that are stable above −108 °C to be characterized readily using standard low-temperature techniques. In those cases where the intermediate is allowed to react with a trapping reagent, the material is introduced slowly from the solvent trap onto the walls of trap H as the product is collected.

2.2. Matrix Isolation Spectroscopy

Although the gas-phase route described above allows very unstable molecules to be isolated and characterized by low-temperature NMR spectroscopy, in a number of instances we have used matrix isolation spectroscopy to identify reactive molecules. This usually involves low-temperature isolation of the reactive species followed by cocondensation with argon onto a matrix surface for characerization by FT-IR spectroscopy. Alternatively, the gas-phase reaction apparatus (actually a microversion) can be connected directly to the matrix apparatus so that the product is cocondensed with argon at 12 K directly onto the matrix surface. The infrared spectrum is recorded by reflection. A brief description of the state-of-the-art apparatus used in these studies follows.

The apparatus[70] shown in Figure 2A is interfaced to an FT-IR vacuum spectrometer. The multisurface copper block used in matrix isolation (labeled a in Fig. 2A) is shown in more detail in Figure 2B. This design permits independent matrix isolation studies with sixty rhodium-plated copper surfaces. In this way the contents of a cold trap can be fractionally distilled onto the various surfaces until the concentration of the desired species is optimized, and, when necessary, concentrations can be determined by direct measurement of the ratio of matrix gas to guest with an integral cooled quartz crystal microbalance.

The infrared spectrum of methylenecyclopropene, which is presented in Figure 3, was recorded using this technique (see Section 3.2). After the surface which contained the optimum concentration of methylenecyclopropene was identified, the ma-

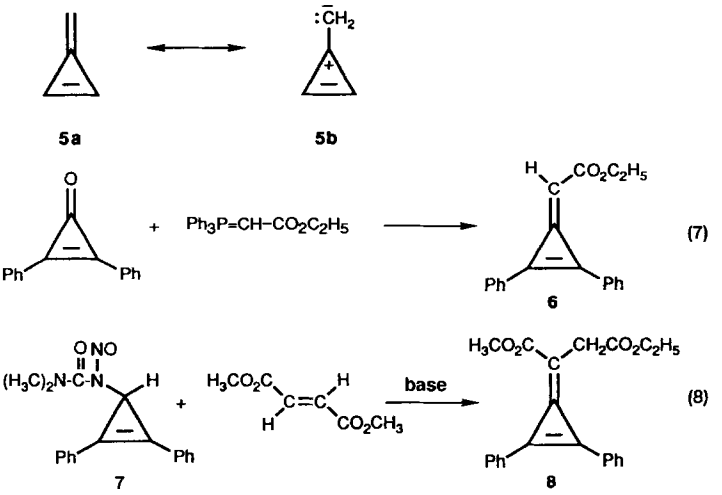
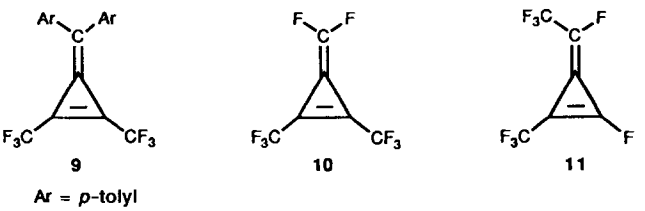
trix was photolyzed. The absorption bands of the photolysis product, mainly vinylacetylene, point downward, whereas those of methylenecyclopropene point upwards.

3. Gas-Phase Dehydrohalogenation of Halocyclopropanes Using Potassium *tert*-Butoxide Supported on Chromosorb W

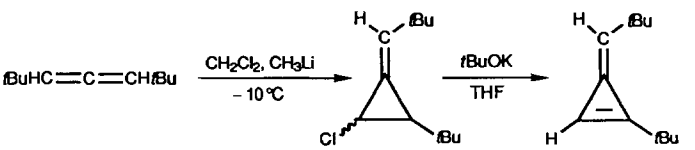


3.1. Simple Cyclopropenes

The use of adsorbed reagents to effect gas-phase elimination reactions was reported first by Denis et al. in 1980.[1a] They found that bromocyclopropane could be converted to cyclopropene in good yield by passing the bromide over solid potassium *tert*-butoxide supported on silica gel [Eq. (5)]. Spirocyclopropene **3** was synthesized from **4** under the same conditions [Eq. (6)].

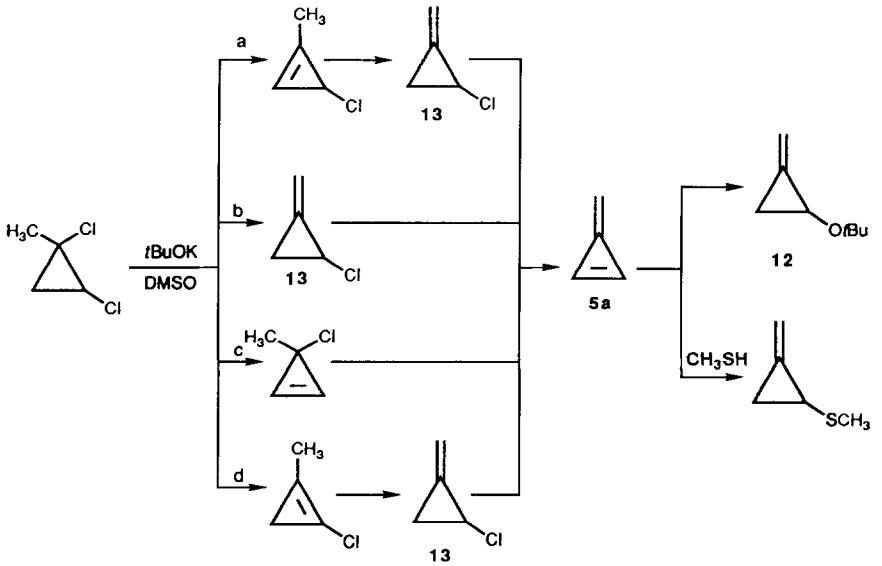


3.2. Methylenecyclopropene



Our involvement in this field began with the synthesis of methylenecyclopropene (**5a**).[71-73] As a member of the C_4H_4 family of hydrocarbons, this, the simplest cross-conjugated cyclic hydrocarbon, has been of interest not only to theoreticians[74] but also to synthetic chemists.[75] Moderately stable derivatives of methylenecyclopropene were first reported in 1964 [Eqs. (7) and (8)]. Battiste[76] formed **6** by a Wittig reaction of diphenylcyclopropenone, and Jones and Denham[77] found that a base-induced reaction of the *N*-nitrosourea **7** with

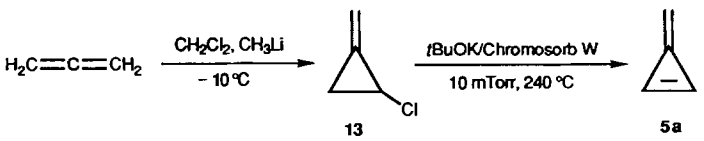
dimethyl fumurate yielded **8**. These and other derivatives[78] owe their stability to the aromatic character obvious in the dipolar formula **5b**. Inductive effects caused by strong electron-withdrawing groups also lead to stable derivatives. For example, **9** is a perfectly stable compound with a dipole moment of 7.42 D.[79] Methylenecyclopropenes **10** and **11** most likely derive their stability from the same effect.[80,81]



Moderately stable derivatives have also been synthesized in which the stability is derived from steric protection provided by bulky *tert*-butyl groups (Scheme 4).[82,83] The tetramethyl derivative, however, has only transient existence.[84]

Scheme 4. Synthesis of a sterically hindered methylenecyclopropene.

Despite the impressive array of derivatives, evidence for the parent hydrocarbon remained inconclusive prior to 1984.[71-73] Indirect evidence[75d] for methylenecyclopropene was provided by the isolation of **12** when 1,2-dichloro-1-methylcyclopropane was treated with potassium *tert*-butoxide in dimethylsulfoxide (Scheme 5). This observation can be rationalized by assuming the intermediacy of methylenecyclopropene (**5a**). Additional support for this assumption is found when an external nucleophile (MeS^-) is added to the reaction medium. Although the sulfide is not sufficiently basic to induce the elimination of HCl

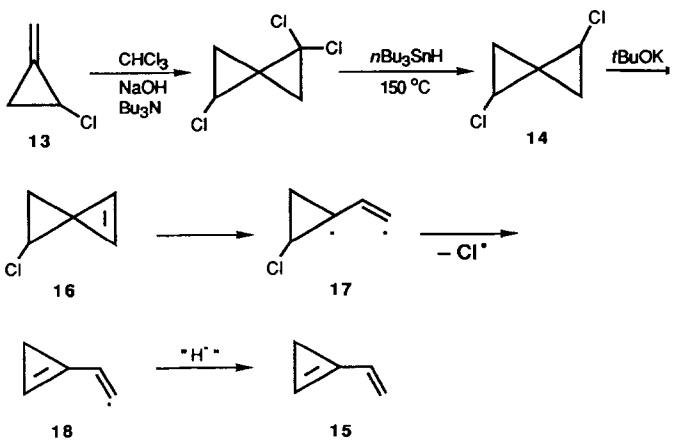


Scheme 5. Generation of methylenecyclopropene **5a** and subsequent reactions.

from the starting material, it is more nucleophilic than *tert*-butoxide and will add more readily to the cyclopropenyl double bond.

Factors that contribute to the instability of methylenecyclopropene include perhaps as much as 78 kcal mol^{-1} of strain energy, a high index of free valency at the exocyclic position resulting from the large contribution of the zwitterionic resonance structure, and the absence of steric protecting groups to inhibit bimolecular reactions. The gas-phase technique using a supported base to effect the dehydrohalogenation of a simple starting material would thus appear to provide the most direct approach to this elusive compound.

The precursor chosen for the gas-phase study, 1-chloro-2-methylenecyclopropane (**13**) appears in paths a, b, and d of Scheme 5 and would seem to be the starting material of choice for the synthesis of methylenecyclopropene. **13** can be synthesized from allene in a straightforward fashion. As expected, the elimination of HCl from **13** was accomplished readily by using the supported base.[71] The corresponding bromide[85] can be converted to **5a** at more modest temperatures.[72]

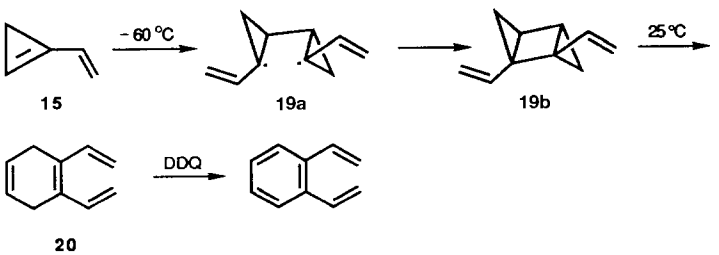


Photolysis of methylenecyclopropene in argon at 15 K through a quartz window using the matrix technique (see Section 2.2) gave mainly vinylacetylene. The two bands at 1770.3 and 1518.9 cm^{-1} arise from coupling between the stretching vibration of the *exo* double bond and that of ring deformation.[86] The NMR spectrum of methylenecyclopropene at $-98\,^{\circ}C$ in [D$_8$]THF displays two triplets ($J = 2.2$ Hz) at $\delta = 3.47$ (exocyclic protons) and 8.61 (ring protons). These chemical shifts emphasize the exceptional polarity of the π electron system.

With an abundant supply of methylenecyclopropene, other detailed spectroscopic measurements could be undertaken to answer some of the long-standing questions regarding the contribution of polar resonance structures to the ground state. Methylenecyclopropene has been thought of as pseudoaromatic,[74c, 87] nonaromatic,[88] and antiaromatic.[89] This issue has been largely resolved through the determination of the electric dipole moment and molecular structure by microwave spectroscopy.[90] Analysis of the experimental and calculated dipole moments, the calculated electron distribution, and the experimental and calculated molecular structures for methylenecyclopropene led to the conclusion that dipolar resonance structure **5b** constitutes about one-fifth of the ground state character of methylenecyclopropene, but it only contributes a π-delocalization energy comparable to that of 1,3-butadiene. These results infer that methylenecyclopropene is nonaromatic.

3.3. 1-Vinylcyclopropene

Elimination of HCl from dichlorospiropentane **14** provided an intriguing test for the gas-phase dehydrohalogenation, since the elimination of both equivalents of HCl would yield spiropentadiene (see Section 4.1.). When **14** was synthesized (Scheme 6) and introduced slowly into a column packed with

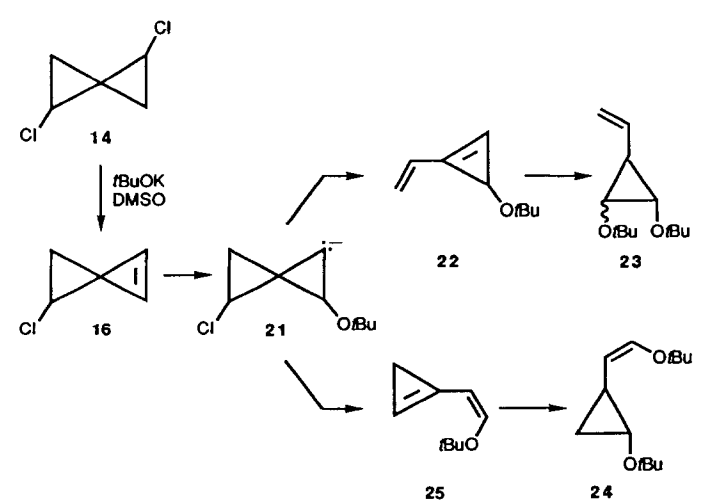


Scheme 6. Synthesis of dichlorospiropentane **14** and its transformation to vinylcyclopropene **15**.

potassium *tert*-butoxide supported on Chromosorb W at 320 °C and 5–10 mTorr (0.66–1.33 Pa), a major product, provisionally identified as 1-vinylcyclopropene **15** was isolated. Confirmation of this assignment was provided by comparison with an "authentic" sample prepared by subjecting 1-chloro-2-vinylcyclopropane to the same reaction conditions.[2]

A possible mechanism to explain the formation of 1-vinylcyclopropene is illustrated in Scheme 6. Elimination of HCl from

14 would yield spiropentene **16**. Cleavage of a C–C bond in **16** would give biradical **17**; this process would be facilitated by the high temperature required for the elimination. Subsequent scission of the C–Cl bond would afford radical **18**, which could then abstract a hydrogen atom from *tert*-butanol to give 1-vinylcyclopropene. The isolation of acetone along with **15** provides compelling evidence that *tert*-butanol serves as the hydrogen atom donor.

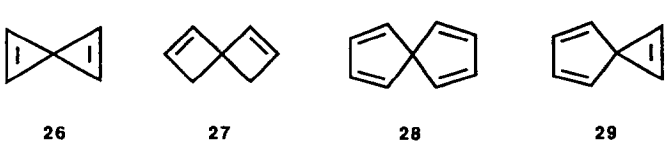


1-Vinylcyclopropene dimerizes readily at −60 °C via **19a** to give tricyclohexane **19b**, which rearranges slowly to **20**. *ortho*-Divinylbenzene was isolated when **20** was reacted with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).

Scheme 7. Dimerization of vinylcyclopropene **15**.

Although the formation of a biradical would normally be an endothermic process, the facile dimerization of **15** can be understood from a thermodynamic standpoint. Benson's and O'Neal's additivity rules can be used to estimate the heats of formation of strain-free models of **15** and **20** as 26.2 and 65.6 kcal mol^{-1}, respectively.[91a] These values, along with the known strain energies[91b] of cyclopropene (55.2 kcal mol^{-1}) and cyclopropane (27.5 kcal mol^{-1}), can then be used to show that the dimerization to the biradical is exothermic by some 39 kcal mol^{-1}. The driving force for this dimerization is, of course, primarily the decrease in strain. The failure to observe products from ring opening of the cyclopropene to yield vinylcarbene intermediates is consistent with calculations which predict a high barrier for this process.[92]

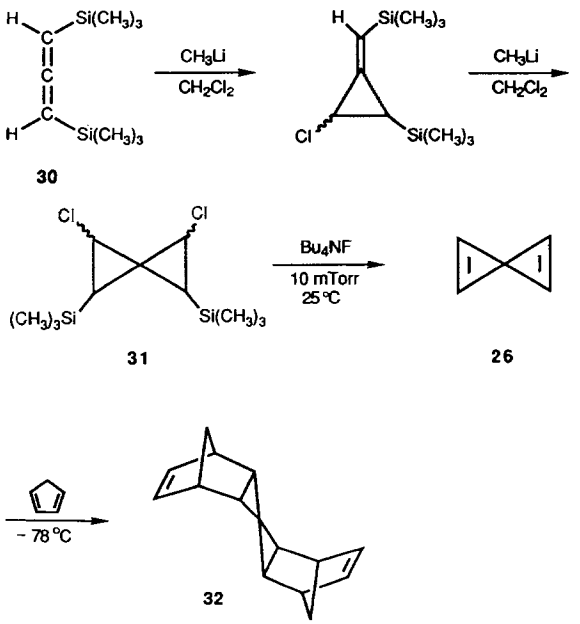
Results from a study of the dehydrohalogenation of **14** in solution[67] stand in contrast to those from the gas-phase elimination and thus emphasize the advantages provided by the gas-phase method. Only products **23** and **24** resulting from nucleophilic addition reactions could be isolated from the solution-phase reaction. Experiments to elucidate the mechanism of formation of these products have not been carried out; however, the pathways illustrated in Scheme 8 are not unreasonable. Spiropentene **16** would be expected to undergo nucleophilic addition to yield anion **21**, which could collapse to **22**, followed by addition of *tert*-butoxide and protonation to yield **23**.[67] Alternatively, ring opening of the cyclopropyl anion with loss of chloride would yield **24** (via **25**). Formation of a single isomer of **24** (*cis* double bond) may result from a concerted ring opening of the anion.



Scheme 8. Dehydrochlorination of **14** in solution.

4. Gas-Phase Elimination of β-Halocyclopropylsilanes Using Solid Fluoride Salts

Synthesis and characterization of methylenecyclopropene and vinylcyclopropene prompted investigation into the use of other supported reagents as a route to reactive intermediates. The fluoride route discovered by Chan and Massuda[64] (Scheme 3) seemed particularly attractive, since β-halocyclopropylsilanes are readily available and the reaction can be carried out at very mild temperatures. In the following section we describe some of our results in which solid fluoride salts were used to effect the gas-phase elimination of β-halocyclopropylsilanes.



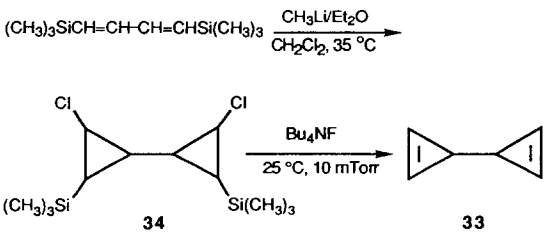
4.1. Spiropentadiene

Perhaps the greatest advertisement for the gas-phase fluoride route to highly energetic molecules is the synthesis of spiropentadiene **26** ("bowtiediene").[93] The spiro-connected cycloalkenes are of interest, since they can, in principle, exhibit interesting properties resulting from the two π systems being held in perpendicular planes by a common carbon atom. Such through-space interactions of nonconjugated π systems are commonly referred to as homoconjugation[94] or, in this case, spiroconjugation.[95, 96] Spectroscopic evidence would seem to support the presence of spiroconjugation in derivatives of **27**,[97] **28**,[98, 99] and **29**,[100] and calculations indicate that this may also apply for **26**.[94, 95] A range of values for the strain energy of spiropentadiene **26** from 110 to 145 kcal mol^{-1} has been calculated.[101–104]

The synthesis of **26** required the sterically hindered allene **30** as a point of departure. Although **30** had been synthesized previously by reaction of the anion of 1,3-bis(trimethylsilyl)propyne with sodium sulfate decahydrate,[105] a somewhat higher yield was obtained by treating the tosylhydrazone of

bis(trimethylsilyl)propynone with sodium cyanoborohydride in a two-phase system at pH 1.[106] Under these conditions none of the isomeric propyne could be detected by ^{1}H NMR spectroscopy. The allene could be converted in low yield to the desired precursor **31** by the sequential addition of chlorocarbene. Introduction of **31** into a column containing nBu$_4$NF on glass helices afforded **26** along with a complex mixture of products (Scheme 9).

Scheme 9. Synthesis of spiropentadiene **26**.



Although **26** exists only fleetingly, it was possible to detect a signal for the cyclopropenyl protons at $\delta = 7.62$ in the NMR spectrum ([D$_8$]THF, $-105\,^\circ$C). Upon warming, a sparingly soluble polymer is produced. Spiropentadiene **26** can be intercepted with cyclopentadiene to yield the Diels–Alder adduct **32**.

Experimental verification of the anticipated properties of **26** has not been reported; however, calculations[107] predict a standard heat of formation of 157.4 kcal mol^{-1}, which is more than twice the experimental heat of formation of 66.2 kcal mol^{-1} for cyclopropene,[108] and consistent with the high energy content expected for spiropentadiene.

4.2. Bicyclopropenyls

4.2.1. 2,2′-Bicyclopropenyl

(CH)$_6$ valence isomers of benzene have attracted the attention of chemists for well over a century.[109] Although Dewar benzene, benzvalene, and prismane have been known for a number of years, a fourth isomer, 2,2′-bicyclopropenyl **33**, was first prepared in 1989 (Scheme 10).[110] Starting material **34** was prepared by treating 1,4-bis(trimethylsilyl)buta-1,3-diene with an excess of chlorocarbene. Elimination of trimethylsilyl chloride from **34** by reaction with supported fluoride salts yielded **33**, which decomposes above approximately $-10\,^\circ$C.

Scheme 10. Synthesis of 2,2′-bicyclopropenyl (**33**).

Apart from historical interest, the possibility that the two double bonds might couple through the σ framework is intriguing from a theoretical perspective.[111–113] In order to confirm some of the properties of **33** anticipated earlier by theoreticians, high-quality crystals were prepared by Boese et al.[114] using a zone-melting procedure with focused infrared light, and the X-ray structure was determined at 103 K.[115, 116] As expected, the conformation of **33** in the solid state was found to be *anti* with C_i symmetry (Fig. 4). The most salient feature of **33** is the extremely short central bond (1.503(1) Å), which indicates significant sp^2 hybridization. This is also apparent from the C1′-C1-H1 angle of 113.7(6)° and the C1-C1′-(center C2, C3) angle of 124.7°.

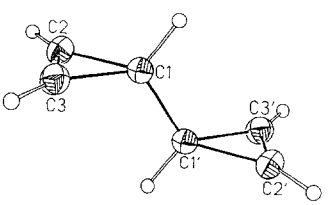


Fig. 4. Crystal structure of 2,2′-bicyclopropenyl.

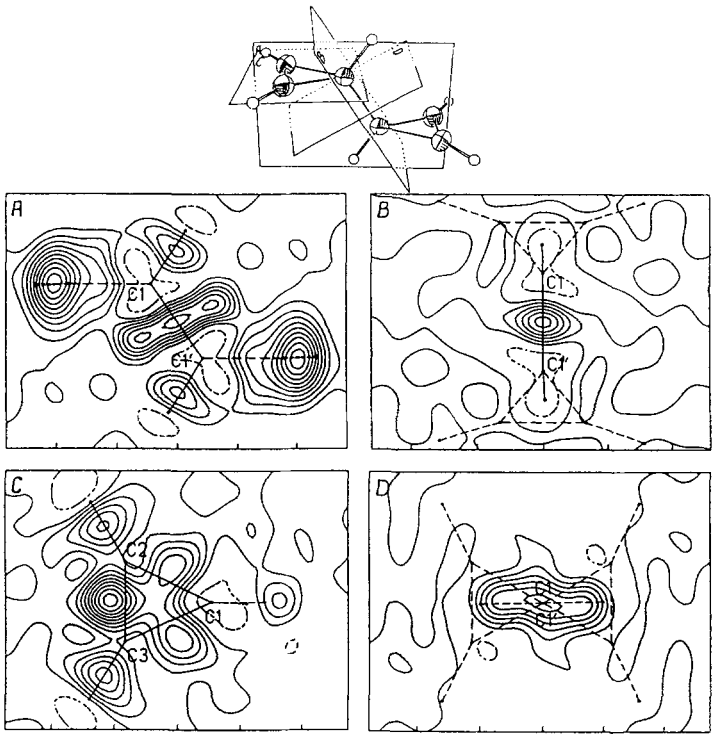
The length of the double bond of **33** is comparable to that in cyclopropene, which was determined by microwave spectroscopy[117] to be 1.2939(4) Å; however, the single bonds in the ring (1.512(1) Å) are slightly longer than in cyclopropene (1.509(1) Å). This may be explained by the observation that, in general, bond lengths in the gas phase are found to be longer than in the solid state. Since a bond of similar length was found between the two rings of bicyclopropyl (X-ray structure, *anti* conformer[118] 1.4924(4) Å, gas electron diffraction[119] 1.508 Å), which was also shorter than the endocyclic bonds[119] (1.5052(3), vicinal; 1.5046(4), distal), we ascribe this effect to the higher σ character of this bond relative to a normal C–C bond.[120] In 3-vinylcyclopropene[121] (Section 4.5) the endocyclic double bond is even shorter (1.279(1) Å) than that in **33** and the conjugation in the exocyclic C–C bond shortens this distance to 1.476(1) Å.

In contrast to **33**, the hexa-*tert*-butyl derivative[122] was found to exist exclusively in the *gauche* conformation as a result of the severe steric interactions between the *tert*-butyl groups. This results in a lengthening of the central bond to 1.570(3) Å. The C–C bonds in the rings (1.550(2), 1.536(2) Å) are also longer, but the length of the double bond (1.294(2) Å) agrees well with that in **33**.

Electron density maps (Fig. 5) of **33** are particularly revealing with regard to the through-bond effect. In map A the expected circular pattern of the electron density in the plane of the σ bond is distorted to an elliptical shape owing to π-bonding contributions. Maps B and D show that the distortion is restricted to the plane of the bonds and not in all directions.

The photoelectron spectrum of **33** recorded by Gleiter et al.[114] exhibits three peaks of different heights well separated



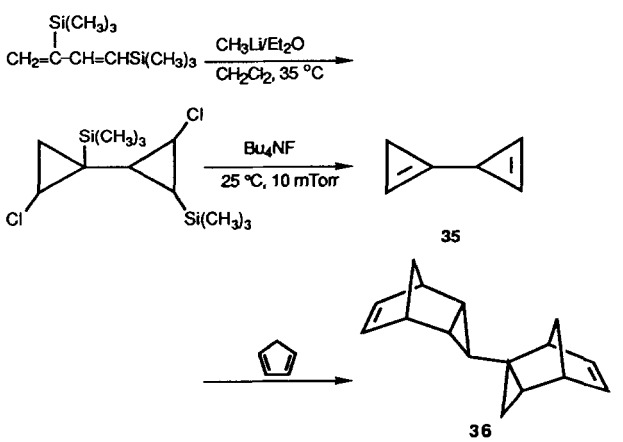


Fig. 5. X X electron density maps of 2,2'-bicyclopropenyl with a distance of 0.05 eÅ^{-1} (negative, dashed lines).

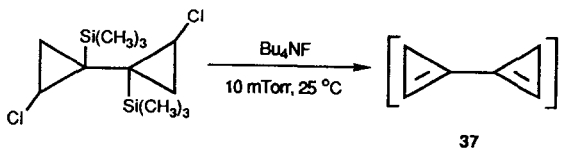
from a smaller fourth one. This result is rationalized in terms of a roughly 2:1 mixture of *anti* and *gauche* conformers in the gas phase.

4.2.2. 1,2'-Bicyclopropenyl

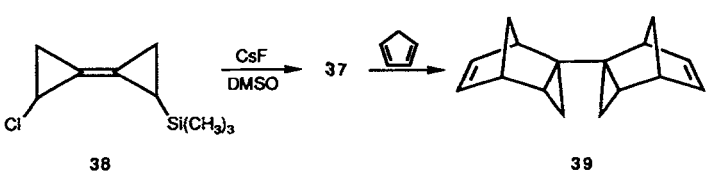
The synthesis of 1,2'-bicyclopropenyl **35** is illustrated in Scheme 11.[110] In view of the facile polymerization described earlier for **33**, it is perhaps not surprising that **35** was observed



Scheme 11. Synthesis of 1,2'-bicyclopropenyl (**35**).

to polymerize above −30 °C. It was, however, possible to secure NMR spectral data at −50 °C and to trap the cyclopropene with cyclopentadiene to yield the Diels–Alder adduct **36**. Unfortunately, it was not possible to secure a single crystal, and X-ray structural data could not be obtained.

4.2.3. 1,1'-Bicyclopropenyl

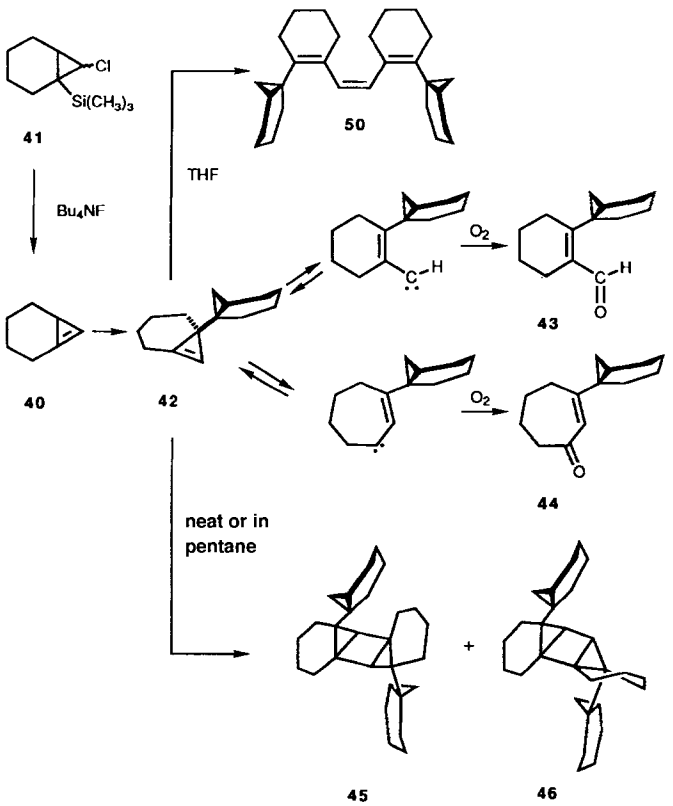


1,1'-Bicycloprop-1-enyl (**37**) is perhaps the most highly strained conjugated diene. Two sterically protected derivatives have been reported,[123] but no reports describing the synthesis of the parent compound have been published.[124] The elimination reaction presented in Equation 9 yielded a white polymeric

(9)

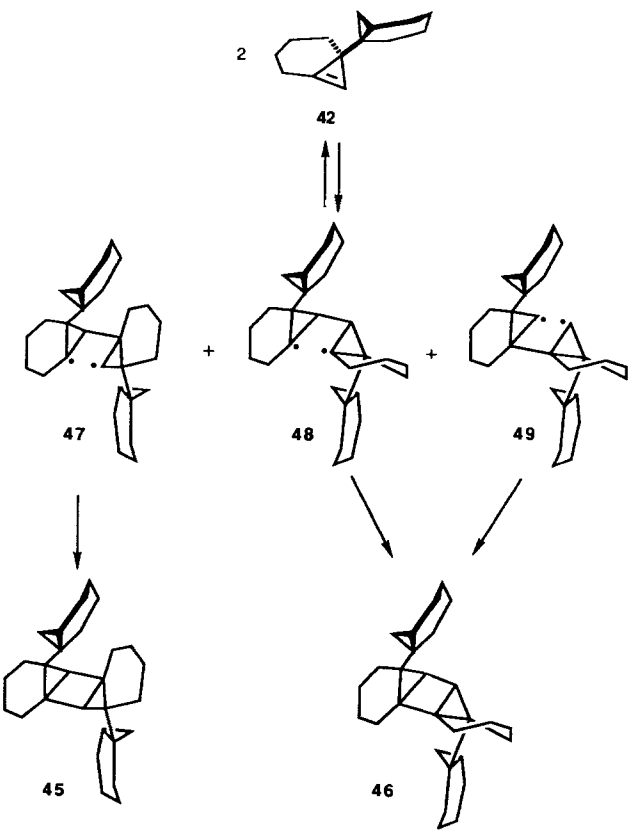
solid; however, in one instance a small amount of volatile material could be isolated which exhibited NMR signals at $\delta = 0.71$ and 7.36, consistent with what might be expected for the diene. Above −90 °C these signals began to diminish, and at room temperature rapid polymerization was observed. It was not possible to isolate a Diels–Alder adduct with cyclopentadiene.

An alternative precursor, compound **38**, was found to give the same polymeric material upon elimination in the gas phase;[125] however, when this precursor was allowed to react with cesium fluoride in dimethyl sulfoxide containing a large excess of cyclopentadiene, the cycloadduct **39** was formed as a mixture of diastereomers in 61 % yield. Since **38** can only yield **37** by means of a 1,4-elimination, the existence of **37** as a discrete species is indeed confirmed (Scheme 12). The use of **37** as a building block in synthesis remains to be exploited.



Scheme 12. Synthesis and trapping of 1,1'-bicyclopropenyl (**37**).

4.3. 1,3-Bridged Cyclopropenes



Although 1,3-bridged cyclopropenes can be isolated when the fused ring has more than seven carbon atoms, evidence for more highly strained systems has relied, for the most part, on trapping experiments.[126] The 1,3-bridged cyclopropene **40** was chosen for our work, since its properties had been the object of considerable speculation,[127] but no syntheses had been reported.

We found that **40** could be generated readily at room temperature by passing the precursor **41** over nBu$_4$NF deposited on glass helices.[128] The yield was nearly quantitative as shown by a trapping experiment with cyclopentadiene. The synthesis and chemistry of **40** is summarized in Scheme 13.

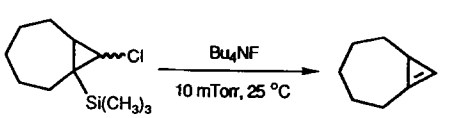
Dimerization of **40** by an ene reaction to yield **42** occurred readily below −90 °C. Cyclopropenes with a hydrogen atom at C3 often undergo ene reactions in which a hydrogen atom is transferred to the double bond of a second molecule with the simultaneous formation of a carbon–carbon bond.[129] The additional strain in **40** would probably account for this facile

Scheme 13. Synthesis and dimerization of **40** and other reactions.

Scheme 14. Dimerization of **42**.

dimerization. Steric interactions are presumably too severe to allow transfer of a hydrogen atom from a third molecule of **40** to yield a trimer.

Cyclopropene **42** is unexpectedly stable possibly due to steric protection provided by the bicycloheptyl pendant. The stabilization of reactive intermediates from bimolecular reactions by sterically hindered substituents is, of course, a strategy frequently used in the preparation of reactive molecules.[130, 131]

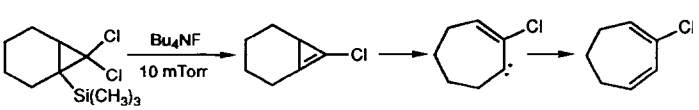


Exposure of **42** to dioxygen yields the oxidation products **43** and **44**. Although these unexpected products can be rationalized in terms of the carbenes[132] shown in the scheme, the direct reaction of the cyclopropene with molecular oxygen to yield the carbonyl derivatives is a viable alternative. Experiments to delineate these pathways have not been carried out.

When the ene dimer **42** was allowed to warm slowly to room temperature with rigorous exclusion of dioxygen, a white crystalline compound shown by mass spectroscopy to be a tetramer of **40** could be isolated. X-ray crystallographic studies established the structure of this compound as the tricyclohexane **45** with *trans,anti* configuration. A second tetramer identified by X-ray analysis as **46** was isolated when the dimer was diluted with pentane and allowed to stand at room temperature for several days. Isomers **45** and **46** are dimers of **42** that differ only in the configuration about the tricyclohexane framework.

A plausible rationalization for the formation of the tricyclohexanes is illustrated in Scheme 14.[133] Initial bond formation could occur to yield biradicals **47**, **48**, and **49**. Collapse of **47** with carbon–carbon bond formation would yield **45**. Formation of **46** would require either biradical **48** or **49** with subsequent formation of the four-membered ring. The factors controlling the regiochemistry of these dimerizations are obviously delicately balanced, since the biradicals have comparable stabilities.

A third tetramer **50** could be isolated to the complete exclusion of the tricyclohexanes when **42** was allowed to dimerize in tetrahydrofuran. The origin of this product has not been established.

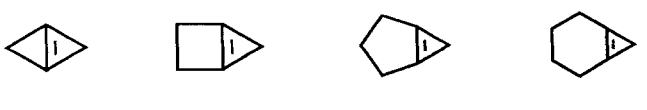


Other 1,3-bridged cyclopropenes, including the surprisingly stable hydrocarbon **51**, can also be synthesized readily [Eq. (16)].[129]

(10)

51

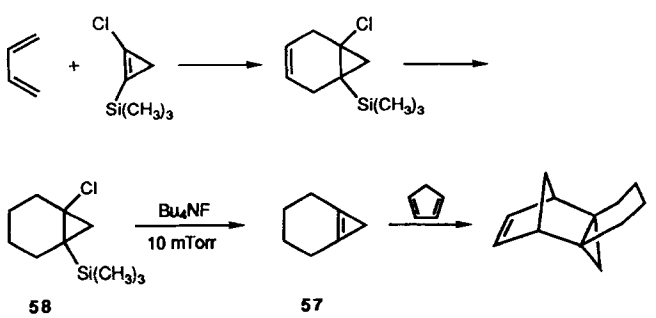
In contrast to **40**, the chloro derivative **52** trapped by Chan and Massuda[64] was observed to rearrange quantitatively in the gas phase to **53**, a product of thermal ring opening (Scheme 15).[128] The cyclopropene–vinylcarbene rearrangement depicted is an unusually facile process, as only **53** could be detected even at −90 °C.



52 **53**

Scheme 15. Synthesis and rearrangement of **52** in the gas phase.

4.4. 1,2-Bridged Cyclopropenes



There has been much interest in the 1,2-bridged cyclopropenes, since calculations predict that pyramidalization will be important for those compounds in which the size of the bridging ring is small, as in **54**–**57**.[134] The predicted strain energies,

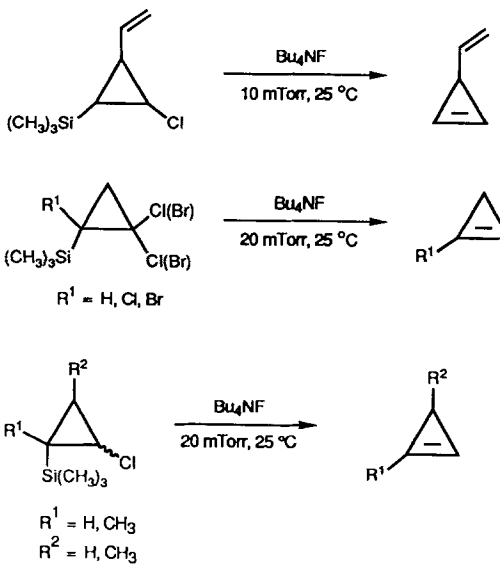
54 **55** **56** **57**

inversion barriers, bond properties, and atom properties indicate that bicyclopentene may be a transition state for the carbon scrambling of methylenecyclobutylidene and also indicate that bicyclobutene should have an unusual structure and charge density distribution.[135] Cyclopropenes **56** and **57** are expected to be fairly "normal" compounds exept for their high strain energies.

Compounds **56** and **57** have been synthesized in solution by dehalogenation of 1,5-dihalobicyclo[3.1.0]hexanes and 1,6-dihalobicyclo[4.1.0]heptanes, respectively.[61, 136] However, when the cyclopropenes were generated in the gas phase using either potassium atoms or solid methyllithium on glass helices, the products of thermal ring opening, methylenecyclopentene and methylenecyclohexene, were formed.[136] The less exothermic gas-phase route to **57** using solid fluoride salts was particularly attractive, since compound **58**, a viable precursor to **57**, can be synthesized readily by catalytic hydrogenation of the Diels–Alder adduct of 1-chloro-2-trimethylsilylcyclopropene[65] and 1,3-butadiene (Scheme 16).

58 **57**

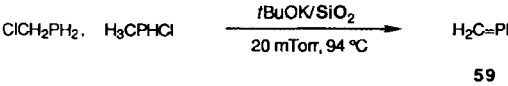
Scheme 16. Synthesis and trapping of **57**.



The discrete existence of **57** as a gas-phase entity could be demonstrated by subjecting **58** to the same reaction conditions used to synthesize **40** and trapping the short-lived intermediate with cyclopentadiene (Scheme 16).[2] It is interesting that this cyclopropene, in the absence of a trapping reagent, gives the ene dimer **42** described earlier for **40** as well as a new ene dimer identified as **42a**, a diastereomer of **42**. Attempts to record the spectral properties of **57** using both matrix isolation spectroscopy and low-temperature NMR spectroscopy have been unsuccessful.

42a

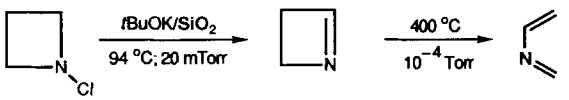
4.5. Other Simple Cyclopropenes



We have found the VGSR technique to be widely applicable to the synthesis of simple cyclopropenes which might be too unstable to isolate under ambient conditions.[127] 3-Vinylcyclopropene can be cited as an example [Eq. (11)]. It was possible to prepare this unstable compound and then secure a single crystal (m.p. 181 K) using the technique of Boese et al.[115, 116] so that high-quality structural data could be obtained.

Other simple cyclopropenes including cyclopropene itself could be synthesized [Eqs. (12) and (13)]. Although the halocyclopropenes [Eq. (12)] can be generated with equal ease in solution,[59, 60, 66, 137, 138] we find that it is sometimes advantageous to generate them in the absence of solvent.

4.6. Formation of Reactive Intermediates Containing Heteroatoms



Phosphaethene (**59**), the unstable parent compound in the phosphaalkene series, can be generated very cleanly by vacuum dehydrochlorination of either chloromethylphosphane or 1-chloroethylphosphane over potassium *tert*-butoxide on silica gel [Eq. (14)].[139]

59

By connecting the vacuum apparatus directly to a photoelectron spectrometer, the photoelectron spectrum of **59** generated in situ could be recorded. The PE spectrum suggests a significant energetic separation between the $^2A''$ and $^2A'$ ionic states, implying that the double bond should exhibit an enhanced reactivity toward transition metals in competition with the lone pair on phosphorus.

Application of the VGSR technique to effect the elimination of HCl from *N*-chloroazetidine has also been reported.[140] The resulting 1-azetidine could be converted to the labile azadiene **60** by flash vacuum pyrolysis at 400 °C and 10^{-4} Torr (Scheme 17).

60

Scheme 17. Dehydrochlorination of *N*-chloroazetidine and pyrolysis of the resulting 1-azetidine.

No reports describing the chemistry of this potentially useful compound have appeared.

4.7. Summary and Outlook

Although applications of the VGSR technique have been limited to the few reagents described in this review, there is good reason to believe that numerous other reagents can be adsorbed onto inert surfaces and used in synthesis. For example, other more reactive forms of "naked fluoride" might prove to be useful.[141] Some preliminary results suggest that Peterson olefination might be carried out using the VGSR technique.

Finally, the technique described in this review benefits from the many other favorable attributes normally associated with heterogeneous reaction conditions. Most important perhaps is the accelerated rate under mild reaction conditions and the ability to isolate reactive species under conditions where their chemistry can be explored in detail.

We wish to thank our talented and motivated collaborators without whose contribution this article could not have been written. Thanks are also due to Professors Roland Boese (Essen) for X-ray structural data and Rolf Gleiter (Heidelberg) for the photoelectron spectrum of 2,2'-bicyclopropenyl. In acknowledging financial support for the work presented in this review, we extend our gratitude to the National Science Foundation (USA), the Robert A. Welch Foundation, the Petroleum Research Fund administered by the American Chemical Society, and the Humboldt Foundation who provided a Senior Scientist Award to W.E.B.

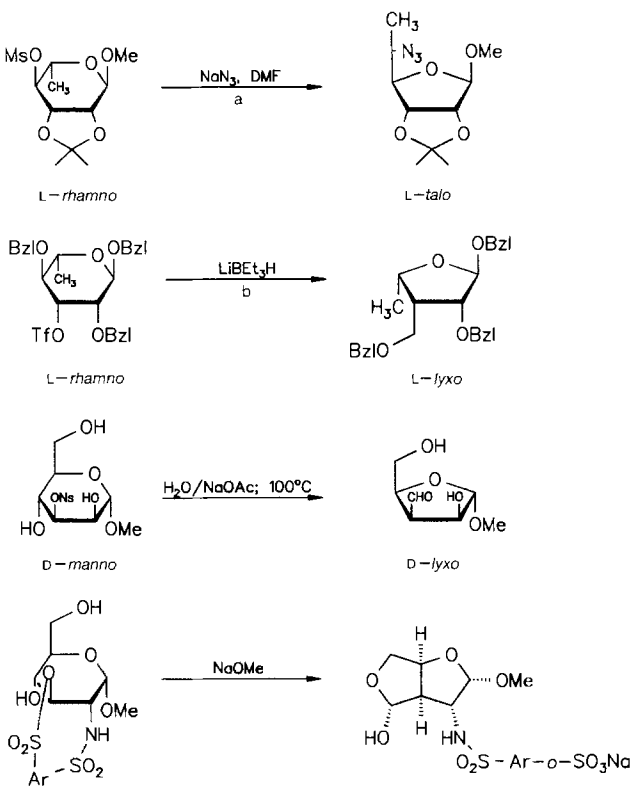
Ring Contractions in Carbohydrates

Hartmut Redlich*

The polyfunctional character of carbohydrates has always been a cause of the apparently unusual reactions that even an alert observer would not immediately consider as plausible. Thus, in the eyes of many chemists, "sugar chemistry" obtained a certain reputation that was not necessarily to its advantage. Certainly, those products, obtained occasionally from this group of compounds or their derivatives, that could be regarded as the result of a ring contraction have also contributed to this view.

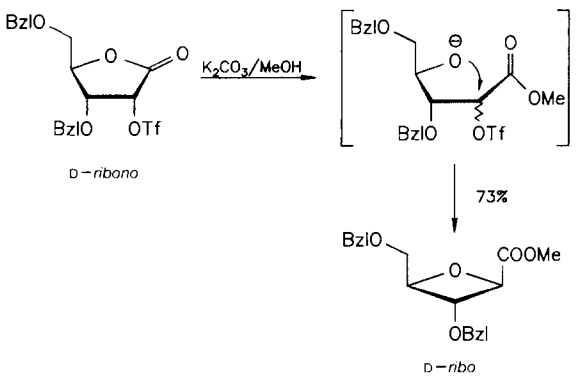


As early as 1838 (!) E. Peligot reported in his well-known publication[1] in which the name glucose was suggested for a certain hexose that sugars are converted into strong acids (acide tres énergique) with dilute calcium or barium hydroxide solution. Only a little later (according to the then prevalent understanding of time), in 1879, the same author reported on the base-induced conversion of glucose, fructose, or invert sugar into the crystalline product named by him as "α"-glucosaccharin.[2] Formation of this branched, ring-contracted lactone from the corresponding unbranched (cyclic?) starting compound can only be explained by exchange of position of O and C atoms (Scheme 1). More recently, this chiral, branched compound has attained importance as an extremely inexpensive starting material for the synthesis of chiral natural products from carbohydrates.[3]

D-glucose "α"-glucosaccharine

Scheme 1. Reaction conditions. a: 0.7 M $Ca(OH)_2$, room temperature, 1–2 months, about 10% yield. The systematic name for "α"-glucosaccharine is 2-C-methyl-D-*ribono*-1,4-lactone.

Initially the transformation of sugars in basic media into saccharinic, isosaccharinic, and metasaccharinic acids was traced to the activity of the carbonyl group in the unprotected sugar. Nevertheless it subsequently became clear that even complete protection of all the functional groups in a sugar was no guarantee against surprises—mostly of the unwanted variety. From the wealth of material compiled over the years only a selection of such reactions, which were initially planned as simple nucleophilic substitutions, is summarized below. It will be left to the reader to trace the devious path of the actual course of the reaction (Scheme 2; hint: the reaction always begins with an "internal" nucleophile).[4]



Scheme 2. a: Reflux. b: Dioxane. Ms = CH_3SO_2; Bzl = $C_6H_5CH_2$; Tf = CF_3SO_3; Ns = *p*-NO_2-C_6H_4-SO_2; Ar = arenediyl.

G. W. J. Fleet et al. used intramolecular substitution of carbohydrate lactones in the sense considered here as a deliberate element in the synthetic plan of a series of experiments. These compounds undergo facile ring contraction when a leaving group is situated in α-position to the lactone group, which thereby possesses electrophilic character. In the case of the four isomeric pentose-γ-lactones oxetanecarboxylic acid esters with various configurations were formed; the latter are suitable for the

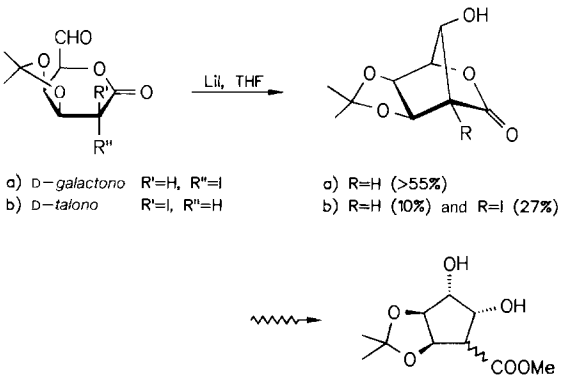
synthesis of nucleoside analogues.[5] Such oxetane nucleosides show biological activity against viruses. The stereochemical course of these substitutions (Scheme 3) suggests that an open-chain 4-hydroxy-2-*O*-trifluoromethanesulfonyl ester is formed initially. As a result of the low configurational stability of the leaving group in the position α to the ester group, the intramolecular substitution takes place with preferential formation of the oxetane with a *trans* configuration of the substituents at C2 and C3.

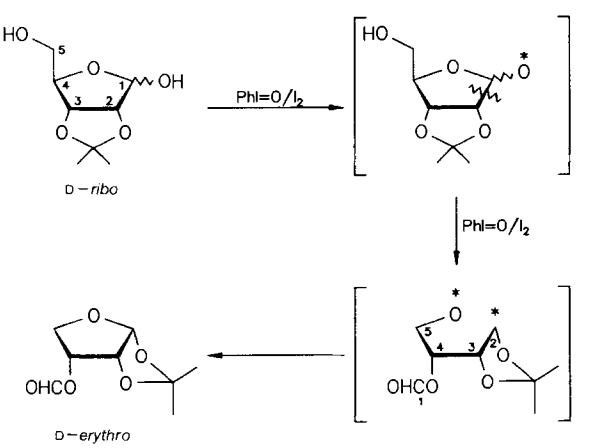


Scheme 3.

With the δ-lactones 2,5-disubstituted tetrahydrofurans are formed in the same fashion.[5] Fleet et al. were able to devise a very short synthesis of (3*R*)-hydroxy-(+)-muscarine and (+)-muscarine starting from L-rhamnose, without using protecting groups (Scheme 4).[5]

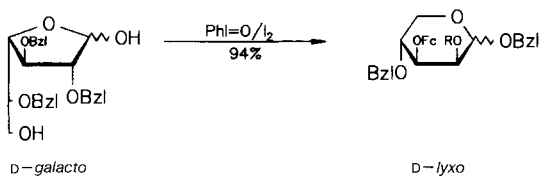
Scheme 4.

Without doubt the particular relationships at the α-position of the carbohydrate lactones play a central part in these reactions, which are facile for a very wide range of examples. The example given in Scheme 5, which formally shows the same exposition as that in the examples previously discussed (leaving group in the α-position to the lactone), demonstrates that quite unusual reactions are thereby also possible. If the α-position is offered an acceptor in the form of an aldehyde group at C6, this



Scheme 5.

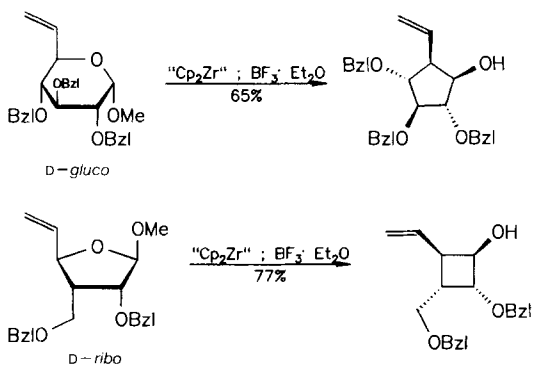
compound reacts in the sense of an intramolecular aldol addition on treatment with lithium iodide in THF at room temperature, to give a five-membered carbocyclic ring.[5] C2 acts here as a nucleophile; a reductive addition takes place for the *galactono*-configuration, whereas direct addition is found to a large extent for the *talono*-configuration. In the meantime this principle has been extended to the synthesis of six-membered rings.[5] The carbocycles obtained in this manner possess a high level of functionality and are thus suitable for numerous further syntheses.



The advantage of carefully directed ring contraction with carbohydrates is obvious: from inexpensive starting materials one can obtain carbo- or heterocyclic compounds containing several functional groups in optically pure form, synthesis of which would otherwise be difficult.

This option has become particularly clear with two recent reports. Using the reagent iodosylbenzene/iodine E. Sua'rez et al.[6] have converted cyclic carbohydrate derivatives that are unblocked at the anomeric position and at a "suitable" distance therefrom (Scheme 6) into other cyclic derivatives that contain

Scheme 6.

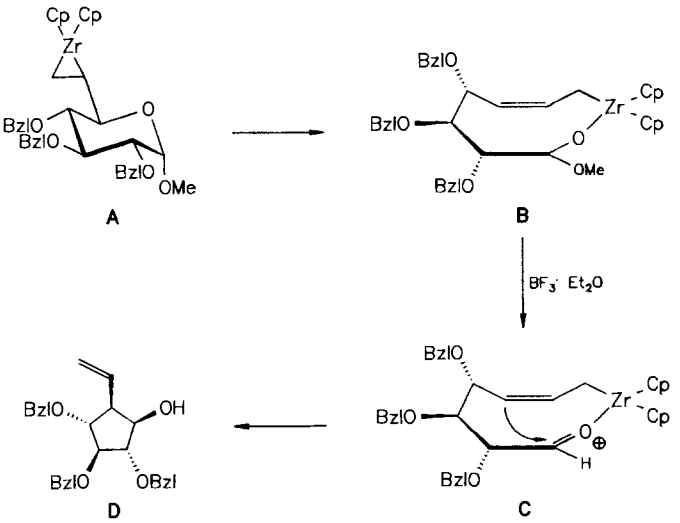


one less carbon atom and now blocked at the anomeric position. In this process, which takes place by a radical mechanism, the anomeric carbon atom is eliminated from the cyclic compound together with the oxygen atom. Recombination of the intermediate diradical leads to the formation of a new heterocycle. Depending on the starting compound, various ring sizes result

Scheme 7. Fc = CHO; R = $C_6H_5CH_2$.

from this process; as shown in Scheme 7, even ring expansions with excellent yields are possible.

Preparative advances in carbohydrate chemistry can frequently be regarded as a reflection of general developments in organic chemistry. While carbanionic and then radical processes were at the center of the development of new methods during the last two decades, the work of T. Taguchi et al.[7] heralds a new direction: reactions of carbohydrates catalyzed by transition metals. Thus, the action of $[Cp_2Zr(n\mathrm{Bu})_2]$ followed by $BF_3 \cdot OEt_2$ on carbohydrate derivatives containing a terminal double bond induces, according to the authors, quite unusual ring contractions (Scheme 8), which lead in a single synthetic step to highly functional carbocycles in very good yield and mostly with very high diastereoselectivity. Two examples from this work are the cyclopentane and cyclobutane shown in Scheme 8. Hitherto, products of this type could only be obtained by way of multistep reaction sequences.[8]



Scheme 8. $[Cp_2Zr(n\mathrm{Bu})_2]$ was used to generate the reactive Cp_2Zr unit.

The foundation for the initially surprising course of this process is the reaction, observed by the authors, of the zirconocene equivalent ("Cp_2Zr") with allyl ethers (Scheme 9), which apparently takes place smoothly even under such complicated circumstances as at protected carbohydrate derivatives (**A**, Scheme 10) and leads in that case to the nine-membered zirconacycle **B**. $BF_3 \cdot OEt_2$ promotes the decomposition of the hemiacetal-

Scheme 9.

Scheme 10.

zirconate to the oxonium ion **C**, which reacts intramolecularly to give the carbocycle **D**. The stereochemical course that is always observed (substituents on the new C–C bond *cis*, but *trans* to the other substituents adjacent to the side chain) is in very good agreement with this propposal.

One can only hope that such attractive synthetic successes will persuade other chemists (again) that carbohydrates are worthy objects for "their" chemistry.

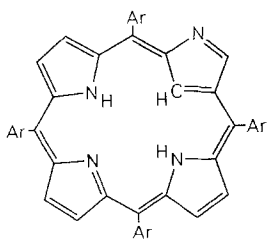
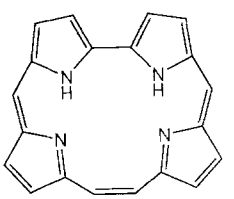
New Porphyrin Isomers

Jonathan L. Sessler*



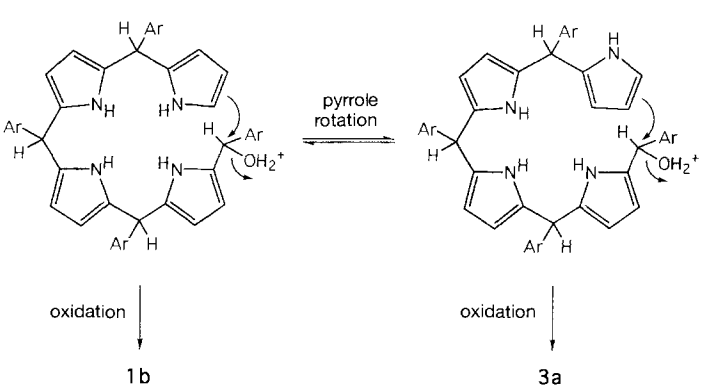
The porphyrins, derived from the parent $C_{20}H_{14}N_4$ system porphine (**1a**), are among the most widespread and important of all naturally occurring macrocycles. Not surprisingly, therefore, they have been both the subject of attention for synthetic chemists and a source of conceptual inspiration. Thus, in recent years reports have appeared not only of porphyrins, inspired by biological examples, that are capped, dimerized, or otherwise functionalized,[1] but also of abiotic, porphyrin-like systems whose frameworks are expanded,[2,3] fused,[4] or heteroatom substituted.[5–7] Interestingly, however, in spite of the increasing attention that is being given to chemistry of these latter analogues, relatively little work has been devoted to the generation of $C_{20}H_{14}N_4$ macrocyclic tetrapyrroles that are isomers of porphyrin per se. Indeed, with the obvious and important exception of Vogel's porphycene (**2**),[8] the seminal report of which was made in 1986, no nonnatural porphyrin isomers had been reported through the end of 1993. Now, two teams working on opposite sides of the globe have succeeded quite independently in preparing the α-to-β′-linked porphyrin isomers **3**.[9,10] Also, a conference abstract describing the synthesis of an alkyl-substituted derivative of the dimethine-containing isomer **4** has just



1a R = H
1b R = $C_6H_4CH_3$
1c R = C_6H_5

2

3a Ar = $C_6H_4CH_3$
3b Ar = C_6H_5



4

appeared.[11] Thus, in recent months the number of porphyrin isomers has suddenly doubled from two to four, while the lexicon of porphyrin-related trivial terms has expanded to include "mutant porphyrin", "N-confused prophyrin", and "corrphycene" used by the original authors to describe structures **3a**, **3b**, and **4**, respectively.[9–11]

The α-to-β′-linked porphyrin isomer **3**, which has appeared in two separate peer-reviewed publications, is the subject of this highlight. Here, the independent Polish and Japanese syntheses of the two α-to-β′-linked porphyrin derivatives **3a** and **3b** are worthy of special note. Taken together, the strategies serve not only to introduce a new type of porphyrin isomer but also to challenge the hitherto commonly held assumption that tetraarylporphyrins are the only useful porphyrinic products to result from classic[12,13] pyrrole + aryl aldehyde oxidative condensations. The Polish team led by Latos-Grażyńzki[9] found that the $BF_3 \cdot Et_2O$-catalyzed reaction of *p*-tolylaldehyde with excess pyrrole (1.75 molar equiv) at room temperature under nitrogen for one hour followed by oxidation with *p*-chloranil produces a 4:1 mixture of tetra-*p*-tolylporphyrin (**1b**) and **3a**; the overall yield of the latter compound is roughly 5%.[14] Interestingly, these workers report that when a 1:1 mixture of starting materials is first condensed and then oxidized under the same conditions, little or no α-to-β′-linked isomeric porphyrin (that is **3a**) is produced. By contrast, the Japanese team of Furuta et al. found that compound **3b** could be prepared, even from a 1:1 ratio of starting materials, provided that stoichiometric quantities of HBr are used to effect the acid-induced condensation.[10] However, as was true for their Polish competitors, these workers found that the product was only obtained in approximately 5–7% yields, being "contaminated" by about a 4 molar equivalent excess of the corresponding porphyrin **1c**.

Based on their findings Latos-Grażyńzki et al. have suggested that their mutant porphyrin **3a** is produced as the result of a final "twisted" porphyrinogen-forming macrocyclization (Scheme 1), while a more normal ring closure gives rise to the usual tetraarylporphyin **1b**.[9] Certainly, such a proposal is consistent with earlier suggestions[14,15] and also with the work of Furuta et al.[10] In this latter instance, however, the twisting needed to produce the β-linked "N-confused porphyrin" **3b**, or at least its porphyrinogen-like precursor, is possibly induced by a specific bromide anion template effect. If this proves true, the findings of Furuta et al.,[10] along with other earlier suggestions

Scheme 1. Ar = $C_6H_4CH_3$.

Austin, TX 78712 (USA)
Telefax: Int. code + (512)471-7550

in the literature,[16] might be of generalized significance: They would augur well for potential syntheses of other "unusual" porphyrin-like entities by anion-facilitated cyclization procedures.

Like porphine and porphycene, the new porphyrin isomers **3a** and **3b** can be considered as heteroatom-containing 18-π-electron annulenes. Not surprisingly, therefore, in solution both compounds display properties characteristic of [4*n* + 2] aromaticity. For instance, both **3a** and **3b** show porphyrin-like Soret and O-type absorption bands in their UV/Vis spectra.[9-10] Further, ^{1}H NMR spectra of these derivatives display signals for internal protons that are shifted to higher field as the result, presumably, of the porphyrin-like aromatic ring current. For instance, the unique internal β-protons of **3a** and **3b** resonate at approximately $\delta = -5.1$ vs. TMS, while the various external β-protons all resonate between $\delta = 8.5$ and 9.0.[9, 10] Thus, for this kind of porphyrin isomer, upfield shifts on the order of $\Delta\delta = 13.5-14$ are achieved as the result of the—figuratively speaking—isomer-inducing pyrrole ring flip.

The available structural information, although still limited, is also consistent with the formulation of **3a** and **3b** as aromatic compounds. For instance, the X-ray structure of the free-base form of **3b** reveals that this system, albeit not quite flat, deviates but slightly from planarity,[10] while that of the Ni^{II} complex of **3a**[9] reveals a structure that is essentially flat and thus, supports the notion that, at least in some instances, the new α-to-β′-linked porphyrin isomers **3** can assume the near-planar, porphyrin-like conformations expected of highly conjugated, aromatic systems. More importantly, it also serves to reveal that the nickel center is ligated at similar distances (about 1.96 Å) by four in-plane donor atoms, namely three porphyrin-like nitrogens and one anionic carbon. This, in turn, suggests an unusual labilization of the inner C–H bond in **3a** and lends credence to the suggestions[9, 10] that "mutant" or "N-confused" (depending on whether the Polish or Japanese nomenclature is preferred) α-to-β′-linked porphyrins could emerge as interesting ligands. They might, for instance, find application as alternatives to the more classic dianionic, tetraazaporphyrins in a range of metal-binding or bioinorganic modeling studies or serve as good systems with which to stabilize often labile metal-to-carbon coordination modes. Thus, it is possible that these new porphyrin analogues, like the porphycenes that preceded them,[8] will provide a portal into a new and rich subarea of porphyrin-related research.

Whether the above promise is realized remains, of course, to be seen. Nonetheless, the syntheses of **3** highlighted herein should provide a stimulus to all those that seek to prepare other new porphyrin isomers and analogues: They, in their own way, confirm that the already rich chemistry of porphyrins can bear still more fruit. Indeed, a wide range of porphine-type isomers of generalized formula $C_{20}H_{14}N_4$ can be conceived. These could include systems such as **5** and **6** that extend the porphycene concept,[17] those such as **7** that involve pyridine-for-pyrrole substitution, as well as ones such as **9** and **10** that represent intellectual extensions of the Latos-Grażyńzki and Furuta approach. While not all will prove to be useful, or even stable under normal laboratory conditions, these and other $C_{20}H_{14}N_4$ species stand, at the very least, as fascinating targets, tantalizing all those who might be challenged by exciting problems involving the organic synthesis of nonnatural products. In this context, the synthesis of **7** seems particularly challenging (and unlikely) given Breitmaier's recent unsuccessful efforts to obtain **8**,[6] while that of **10** and its long-dreamed-about all-carbon analogue **11**, both of

which require the presence of four carbon-bound hydrogens within the central macrocyclic space, seem particularly intriguing. It remains an open question when these or other enticing porphyrin congeners will actually be prepared.

[2,6-*i*Pr$_2$C$_6$H$_3$(Me$_3$Si)NTl]$_4$—A Covalent Thallium(I)–Nitrogen Compound with Weak Arene–Thallium Interactions**

Said D. Waezsada, Thomas Belgardt, Mathias Noltemeyer, and Herbert W. Roesky*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

Within the scope of our work on compounds of Group 13, which contain elements with low coordination numbers,[1–3] we achieved the first synthesis of a thallium(I) compound with the coordination number 2 a few years ago.[1] Obtaining a coordination number of 1 was the aim of subsequent investigations, to which end we have now tried coordination with the space-filling, nitrogen-containing 2,6-diisopropylphenyl-*N*-trimethylsilyl amine ligand.[4, 5] The lithium salt **1** reacts with TlCl in *n*-hexane to give the desired compound **2**.

1 2

The thallium compound **2** is a pale yellow solid, which is very sensitive to hydrolysis. A single-crystal X-ray structural analysis of **2** showed as the most important finding a tetrameric skeleton (**3**) in the solid state (Fig. 1). The aggregate contains, surprisingly, four arene–Tl interactions as well as four weak Tl–Tl contacts. The Tl atoms in **3** are each fixed approximately above the phenyl ring center of the neighboring molecule (mean distance 311 pm). The different substituents on the arene in **3** clearly hardly influence the η^6-coordination at the thallium center. Structural investigations on arene complexes of Group 13 have until now only been known for tetrahalometalates.[6] In [Mes$_6$Tl$_4$][GaBr$_4$]$_4$[7] (Mes = 1,3,5-Me$_3$H$_3$C$_6$) the corresponding arene–Tl distance is 294 pm and is thus noticeably shorter. These differences can easily be explained by the stronger donor–acceptor ability of the MesTl$^+$ unit relative to the tetrameric aggregate **3**. This leads to a strengthening of the arene–Tl bond. The Tl–Tl contacts (on average 406 pm) in **3** are clearly longer than those in the element (on average 340 pm[8]). The inter-

[2,6-*i*Pr$_2$C$_6$H$_3$(Me$_3$Si)NTl]$_4$ **3**

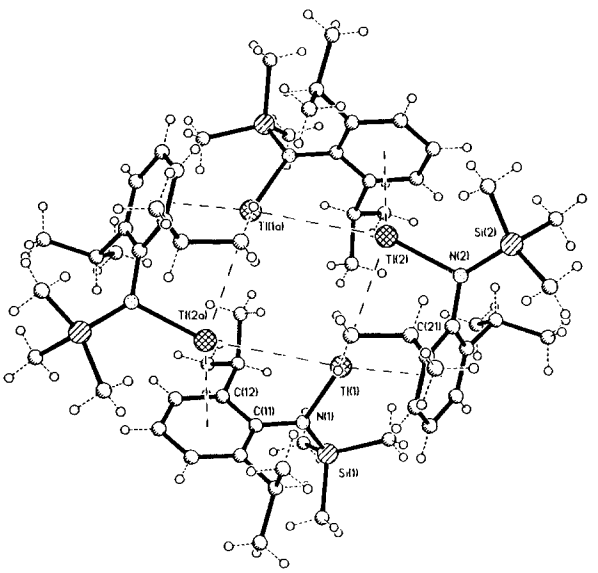

Fig. 1. Crystal structure of the tetramer **3**. Selected bond lengths [pm] and bond angles [°]: Tl(1)-N(1) 230.7(6), N(1)-Si(1) 170.1(7), N(1)-C(11) 140.5(11), Tl(2)-N(2) 230.5(6), N(2)-Si(2) 169.8(7); C(11)-N(1)-Si(1) 124.5(5), C(11)-N(1)-Tl(1) 109.4(5), Si(1)-N(1)-Tl(1) 126.1(3).

thallium bond in [AsPh$_4$]$_2$[Tl$_2$(Se$_2$C=C(CN)$_2$)$_2$] is, for comparison, 354.7(4) pm.[9]

The Tl–N bond lengths in **3** (on average 230 pm) lie between those of [Tl{N(SiMe$_3$)$_2$}$_3$] (on average 208.9 pm)[10] and those in (C$_9$H$_{21}$N$_2$SiTl)$_2$ (252.0(8)–273.7(8) pm).[11] To our knowledge no covalent arene complexes of Group 13 have yet been structurally described; the known compounds[6] are assembled ionogenically. Contrary to expectations H. Schumann et al. could not determine any thallium–arene interactions in [(Me$_4$C$_5$)Me$_2$Si(C$_6$H$_5$)Tl] in the solid state.[12] The arene–metal bond in lower homologues of Group 13 is plausibly interpreted as a HOMO–LUMO interaction.[6] This is not directly transferable to thallium complexes since the metal radius contracts strongly in this case, and the electrons are thus more strongly shielded (relativistic effects).[13] For the self-organization of **2** into the tetramer **3**, we assume weak donor–acceptor interactions; the metal–metal contacts can be considered as very weak.[14] Tetramer **3** is not stable in the gas phase and only the monomer **2** is found in the EI mass spectrum.

Experimental Procedure

A suspension of **1** (1.3 g, 5.1 mmol) in *n*-hexane (30 mL) was added dropwise to a slurry of TlCl (1.2 g, 5.1 mmol) in *n*-hexane (20 mL) at 0 °C. To allow the reaction to proceed to completion, the mixture was stirred for 12 h at room temperature. LiCl was subsequently separated by filtration, and the yellow solution was concentrated to 5 mL under vacuum. Compound **3** (1.8 g, 78%) precipitated as yellow crystals within 12 h. MS(EI): *m/z* 453 (M^+,7), 249 (M^+–Tl, 50), 73 (SiMe$_3$, 100%); ^{1}H NMR (C$_6$D$_6$, TMS): δ = 0.25 (s, 9H, SiMe$_3$), 1.20 (d, 6H, *i*Pr, J = 6.9 Hz), 1.33 (d, 6H, *i*Pr, J = 6.9 Hz), 3.77 (sept., 2H, *i*Pr, J = 7.0 Hz), 6.92 7.30 (m, 3H, arene).

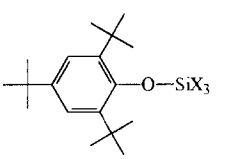
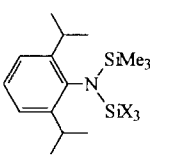
Stable Silanetriols as Building Blocks for the Synthesis of Titanasilasesquioxanes—Model Compounds for Titanium-Doped Zeolites**

Norbert Winkhofer, Andreas Voigt, Hendrik Dorn, Herbert W. Roesky,* Alexander Steiner, Dietmar Stalke, and Armin Reller



Dedicated to Professor F. Albert Cotton on the occasion of his 65th birthday

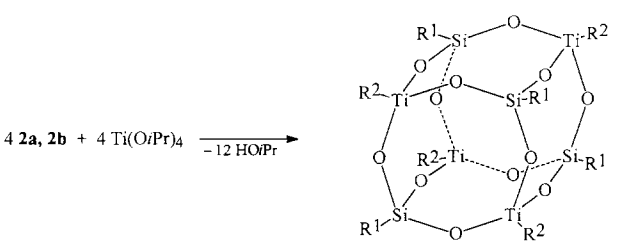
Titanium-doped zeolites catalyze the reaction of H_2O_2 with a variety of substrates such as arenes and alkenes.[1] The oxidative cleavage of hydrazones by TS1/H_2O_2 was also described recently,[2] and the oxidation of nonactivated hydrocarbons with this system is particularly impressive.[3, 4] The zeolites TS1 and TS2 are morphologically related to ZSM-5 (MEL) and ZSM-11 (MFI). In recent reports large-pore titanium zeolites have been described, which permit the oxidation of larger substrates.[5–7] The active centers were investigated by spectroscopic methods. In this way the structure of ETS-10 was recently determined by a combination of powder diffraction and solid-state NMR data.[8] All of the titanium zeolites studied display a characteristic IR band at 960 cm^{-1}.[9, 10]



We have been interested for quite some time in the synthesis of defined metallasiloxanes as model compounds for catalytic metal systems on SiO_2 supports.[11, 12] In this context we are also directing efforts towards the preparation of three-dimensional structures starting from isolated silanetriols.

Syntheses of silasesquioxanes, in other words compounds with the composition $(RSiO_{3/2})_8$, have been reported.[13] For example, trisilanol *c*-Hex$_7$Si$_7$O$_9$(OH)$_3$ derived from cyclohexylsilasesquioxane can be prepared. The OH groups are bound to three silicon atoms and point in the direction of the unoccupied corner of this cubane-type structure. Feher et al. took advantage of this and prepared a series of monometalated polyhedral oligometallasilasesquioxanes (POMSS) by "corner-capping reactions" in which the polyhedral structure is completed or its unoccupied corners are capped.[14, 15]

Our goal was the simple synthesis of metallasilasesquioxanes with higher metal content. We started with monomeric silanetriols, which could be obtained by the controlled hydrolysis of trichlorosilanes **1a,b**. Several representatives of this class of compounds have been described; however, their chemistry is for the most part unexplored.[16, 17] The reaction of the kinetically stabilized silanetriols **2a,b** with titanium isopropoxides gives the target compounds in high yields.



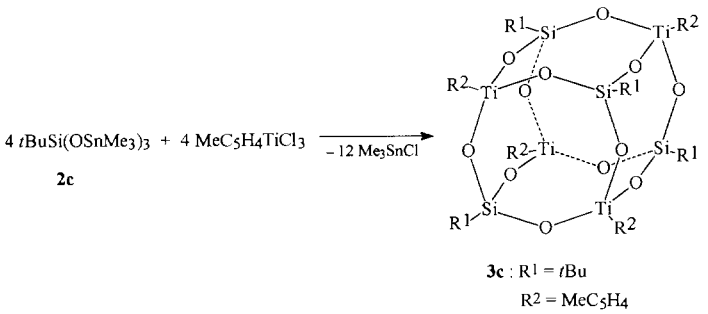
1a : X = Cl
2a : X = OH

1b : X = Cl
2b : X = OH

The main problem in syntheses with silanetriols is their tendency to undergo condensation reactions, particularly in the presence of acids. We have reported elsewhere on the condensation reaction of *t*BuSi(OH)$_3$ with Re_2O_7 to yield [(*t*BuSiO(OReO$_3$)]$_4$.[18]

Despite its bulky organic substituents, compound **2a** proved to be quite labile; it can be isolated in pure form, but in solution and in the presence of traces of acid **2a** undergoes condensation with cleavage of 2,4,6-tri(*tert*-butyl)phenol. Thus, deliberate reaction is possible only with halogen-free Ti(O*i*Pr)$_4$. Relative to **2a**, silanetriol **2b** is remarkably stable. It reacts smoothly with Ti(O*i*Pr)$_4$ and TiCl(O*i*Pr)$_3$ to give **3b**; condensation is not apparent in solutions of **2b** even after several hours. We attribute this behavior to the reduced electrophilicity of the OH-bound Si atom, owing to the neighboring donor atom. Products **3a** and

3a : R^1 = 2,4,6-*t*Bu$_3$C$_6$H$_2$O
3b : R^1 = 2,6-*i*Pr$_2$C$_6$H$_3$N(SiMe$_3$)
R^2 = O*i*Pr



4 **2b** + 4 TiCl(O*i*Pr)$_3$ $\xrightarrow[-\ 4\ NEt_3\cdot HCl\ -\ 8\ HOiPr]{+\ 4\ NEt_3}$ **3b**

3b are metallasilasesquioxanes with completely hydrolyzable leaving groups.

In the reaction of silanetriol tBuSi(OH)$_3$ it proved advantageous to use SnMe$_3$ protecting groups (→ **2c**). In this way alkyl-

substituted silanetriols could be treated with titanium trihalides. The resulting product **3c** provided single crystals. An X-ray structure analysis[19] demonstrated that alternating silicon and titanium atoms form the corners of a cube with an average Si···Ti edge length of 332.1 pm (Fig. 1). The twelve Si···Ti edges are each bridged by an oxygen atom in an μ^2 fashion (average Si–O distance: 161.6 pm; average Ti–O distance: 179.4 pm). The average Si-O-Ti angle formed is 153.9°. The body diagonal of the Ti_4Si_4 cube is approximately 570 pm. The bond lengths and angles are within the range of the corresponding values for eight-membered siloxane rings.[23]

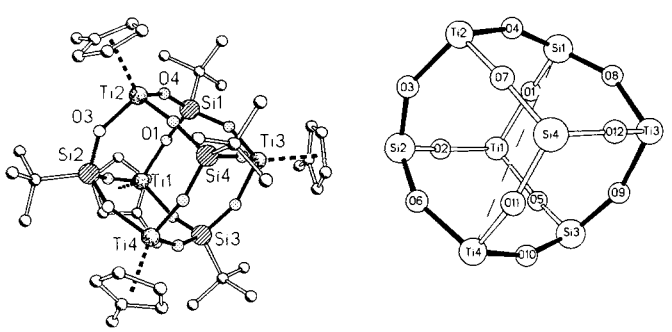

Fig. 1. Crystal structure of **3c**; left: with organic substituents, right: only the $Si_4O_{12}Ti_4$ framework is shown. Average distances [pm] and angles [°]: Ti-O 179.4, Si-O 161.6, Si···Si 458.1, Ti···Ti 480.6, Si···Ti 332.1; Si-O-Ti 153.9.

The IR spectra of **3a–c** show strong absorptions around $\tilde{\nu} \approx 960\ cm^{-1}$. A band in this region, whose assignment is not certain, is characteristic for the catalytically active forms of TS1, TS2, and TiZSM48. Huybrechts et al.[3] assign this band to the stretching vibration of the Ti=O group, whereas Corma et al.[6] attribute it to that of the SiO^- groups. Other authors interpret this band, the intensity of which depends on the titanium content of the zeolite, as the Si–O stretching vibration of the polarized $Si-O^{\delta-}-Ti^{\delta+}$ unit.[24] We believe that the data for the model compounds **3a–c** indicate that this band corresponds to the Si-O-Ti stretch, since Ti=O and $Si-O^-$ units do not exist in these compounds.

Our preparation of titanasilasesquioxanes is a facile synthetic route leading to a new class of compounds, the polytitanasilasesquioxanes, which are suitable model compounds for titanium-containing redox zeolites. We are currently studying the catalytic activity of these compounds. In addition the reactive substituents on the silicon and titanium atoms indicate that crosslinking to form zeolitic materials may be possible.

Experimental Procedure

1a: A suspension of 2,4,6-tBu$_3$C$_6$H$_2$OLi·Et$_2$O [25] (48.5 g, 0.14 mol) in toluene (ca. 130 mL) was added dropwise over 1 h to a solution of $SiCl_4$ (31.1 g, 0.18 mol) in toluene (ca. 450 mL). The reaction mixture was heated at reflux for 18 h, the precipitated LiCl removed by filtration over Celite, and the solvent removed under vacuum. The light brown solid was purified by fractional sublimation under vacuum (10^{-2} Torr, 90–95 °C). A small amount of 2,4,6-tri(*tert*-butyl)phenol sublimed first and was discarded. **1a** (40.8 g, 73%) was finally obtained as a white solid. M.p. 108 °C; ^{1}H NMR (250 MHz, C_6D_6, TMS): $\delta = 1.25$ (s, 9H, *p*-C(CH$_3$)$_3$), 1.49 (s, 18H, *o*-C(CH$_3$)$_3$), 7.46 (s, 2H, H$_{arene}$); ^{13}C NMR (63 MHz, $CDCl_3$, TMS): $\delta = 31.4$ (C(*C*H$_3$)$_3$), 31.5 (C(CH$_3$)$_3$), 34.7 (*C*(CH$_3$)$_3$), 35.3 (*C*(CH$_3$)$_3$), 123.4 (C$_{arene}$), 139.7 (C$_{arene}$), 145.4 (C$_{arene}$), 148.0 (C$_{arene}$); ^{29}Si NMR (80 MHz, C_6D_6, TMS): $\delta = -49.5$; IR (Nujol): $\tilde{\nu} = 1600$, 1422, 1224, 1122, 999, 881, 589, 460 cm^{-1}; MS (70 eV): *m/z* (%): 396 (11) [M^+], 247 (100) [$C_{17}H_{27}O^+$].

1b: A solution of (iPr$_2$C$_6$H$_3$)N(SiMe$_3$)Li [26] (60.1 g, 0.24 mol) in diethyl ether (200 mL) was added dropwise to a stirred solution of $SiCl_4$ (59.9 g, 0.35 mol) and diethyl ether (100 mL) at 0 °C. After 12 h of stirring at room temperature the precipitated LiCl was filtered off and washed with *n*-hexane (2 × 30 mL). The filtrate was concentrated to dryness under vacuum. Recrystallization from pentane furnished **1b** as a white solid. Yield: 84.6 (94%). M.p. 138 °C; ^{1}H NMR (400 MHz, $CDCl_3$, TMS): $\delta = 0.25$ (s, 9H, Si(CH$_3$)$_3$), 1.23 (d, $^3J_{HH} = 6.8$ Hz, 6H, CH(CH$_3$)(CH$_3$)), 1.26 (d, $^3J_{HH} = 6.8$ Hz, 6H, CH(CH$_3$)(CH$_3$)), 3.39 (sept, $^3J_{HH} = 6.8$ Hz, 2H, CH(CH$_3$)$_2$), 7.12 (m, 3H, H$_{arene}$); ^{29}Si NMR (49 MHz, $CDCl_3$, TMS): $\delta = -27.5$ ($SiCl_3$), 12.3 (Si(CH$_3$)$_3$); IR (Nujol): $\tilde{\nu} = 1255$, 1102, 980, 889, 871, 841, 609, 598 cm^{-1}; MS (70 eV): *m/z* (%): 383 (40) [M^+], 368(100) [M^+ – Me].

2a: A solution of **1a** (18.5 g, 46.7 mmol) in anhydrous diethyl ether (ca. 70 mL) was added dropwise within 1 h to a vigorously stirred emulsion of water (2.5 g, 0.14 mol) and aniline (13.1 g, 0.14 mol) in anhydrous diethyl ether (ca. 500 mL) in an ice bath. After 2 h the ice bath was removed, and the reaction mixture was stirred for 2 h at room temperature. The precipitated aniline hydrochloride was filtered off and the clear solution concentrated under vacuum. When the solution reached a volume of 50 mL, **2a** precipitated as a white solid, which was removed by filtration and washed with a small amount of pentane (15 mL) (12.3 g, 77%). M.p. 168 °C; ^{1}H NMR (250 MHz, [D$_6$]DMSO, TMS): $\delta = 1.23$ (s, 9H, *p*-C(CH$_3$)$_3$), 1.39 (s, 18H, *o*-C(CH$_3$)$_3$), 6.50 (s, 3H, OH), 7.14 (s, 2H, H$_{arene}$); ^{13}C NMR (63 MHz, [D$_6$]DMSO, TMS): $\delta = 31.2$ (C(*C*H$_3$)$_3$), 31.5 (C(*C*H$_3$)$_3$), 34.0 (*C*(CH$_3$)$_3$), 35.0 (*C*(CH$_3$)$_3$), 121.7 (C$_{arene}$), 139.5 (C$_{arene}$), 140.9 (C$_{arene}$), 150.0 (C$_{arene}$); ^{29}Si NMR (50 MHz, [D$_6$]DMSO, TMS): $\delta = -83.7$; IR (Nujol): $\tilde{\nu} = 3500$, 1602, 1246, 1125, 978, 907, 814 cm^{-1}; MS (70 eV): *m/z* (%): 340 (37) [M^+], 325 (100) [M^+ – Me].

2b: **1b** (61.9 g, 0.16 mol) was added dropwise over 3 h to a vigorously stirred emulsion of water (8.7 g, 0.49 mol) and aniline (45.1 g, 0.49 mol) in diethyl ether (1.3 L) at 0 °C. The solution was allowed to warm slowly to room temperature and then stirred a further 12 h. The solution was concentrated under vacuum to 1/3 of its volume. The precipitated aniline hydrochloride was filtered off and the remaining solvent removed under vacuum. The pale yellow crude product was washed with pentane (2 × 15 mL). The pure product (45.8 g, 88%) was a white solid. M.p. 131 °C; ^{1}H NMR (250 MHz, [D$_6$]DMSO, TMS): $\delta = 0.05$ (s, 9H, Si(CH$_3$)$_3$), 1.10 (d, $^3J_{HH} = 6.8$ Hz, 6H, CH(CH$_3$)(CH$_3$)), 1.15 (d, $^3J_{HH} = 6.8$ Hz, 6H, CH(CH$_3$)(CH$_3$)), 3.65 (sept, $^3J_{HH} = 6.8$ Hz, 2H, CH(CH$_3$)$_2$), 5.74 (s, 3H, OH), 6.92 (m, 3H, H$_{arene}$); ^{29}Si NMR (49 MHz, [D$_6$]DMSO, TMS): $\delta = -67.3$ (Si(OH)$_3$), 3.8 (Si(CH$_3$)$_3$); IR (Nujol): $\tilde{\nu} = 3344$, 1584, 1315, 1250, 1178, 987, 920, 836, 814 cm^{-1}; MS (70 eV): *m/z* (%): 327(54) [M^+], 312 (100) [M^+ – Me].

2c: A suspension of tBuSi(OH)$_3$ (3.3 g, 24.0 mmol) in *n*-hexane (40 mL) was treated with a solution of N(SnMe$_3$)$_3$ (12.2 g, 24.0 mmol) in *n*-hexane (20 mL), upon which the temperature of the reaction mixture increased. After 12 h of stirring at room temperature, the reaction mixture was heated at reflux for 1 h to ensure complete reaction. After the solvent was removed by distillation, the product was distilled (10^{-2} Torr, 95–100 °C). **2c** (13.6 g, 91%) was obtained as a colorless material which solidified in the receiving flask. ^{1}H NMR (250 MHz, C_6D_6, TMS): $\delta = 0.29$ (s, 27H, Sn(CH$_3$)$_3$), 1.18 (s, 9H, C(CH$_3$)$_3$); ^{29}Si NMR (49 MHz, C_6D_6, TMS): $\delta = -46.7$ (s); MS (70 eV): *m/z* (%): 567 (100) [M^+ – tBu].

3a: A solution of Ti(iOPr)$_4$ (1.36 g, 4.8 mol) in *n*-hexane (15 mL) was added dropwise over 30 min to a solution of **2a** (1.36 g, 4.0 mmol) in *n*-hexane/THF (30 mL/10 mL) at room temperature. The reaction mixture was stirred 12 h and then concentrated under vacuum, upon which a white solid precipitated. The crude product was filtered off, washed with *n*-hexane (5 mL), and then dried under vacuum to give **3a** (1.51 g, 85%) as a yellowish solid. M.p. 238 °C; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 1.04$ (d, 6H, CH(CH$_3$)$_2$), 1.29 (s, 9H, *p*-C(CH$_3$)$_3$), 1.47 (s, 18H, *o*-C(CH$_3$)$_3$), 4.45 (sept, 1H, CH(CH$_3$)$_2$), 7.26 (s, 2H, H$_{arene}$); ^{13}C NMR (63 MHz, $CDCl_3$, TMS): $\delta = 25.5$ (CH(*C*H$_3$)$_2$), 31.4 (C(*C*H$_3$)$_3$), 31.7 (C(*C*H$_3$)$_3$), 34.5 (*C*(CH$_3$)$_3$), 35.2 (*C*(CH$_3$)$_3$), 82.1 (*C*H(CH$_3$)$_2$), 122.4 (C$_{arene}$), 139.7 (C$_{arene}$), 142.8 (C$_{arene}$), 148.8 (C$_{arene}$); ^{29}Si NMR (80 MHz, $CDCl_3$, TMS): $\delta = -116.4$; IR (Nujol): $\tilde{\nu} = 1430$, 1244, 1120, 1059, 973, 906, 645, 478 cm^{-1}; MS (70 eV): *m/z* (%): 1777(7) [M^+], 247(100) [$C_{17}H_{27}O^+$].

3b: A solution of 1 N $TiCl(OiPr)_3$ in *n*-hexane (5.1 mL, 5.1 mmol) was added within 5 min to a suspension of **2b** (1.67 g, 5.1 mmol) and triethylamine (0.52 g, 5.1 mmol) in *n*-hexane/THF (30 mL/20 mL) at room temperature. The reaction mixture was stirred for 12 h and then heated to 60 °C for 3 h. The suspension was concentrated to dryness under vacuum and the residue taken up in pentane and filtered. The solution was stored at + 5 °C. After two weeks colorless, tetrahedral crystals (1.89 g, 86%) formed.

3b: A solution of $Ti(OiPr)_4$ (1.99 g, 7.0 mmol) in THF (15 mL) was added within 5 min to a stirred suspension of **2b** (2.29 g, 7.0 mmol) in THF (40 mL). The reaction mixture was stirred for 12 h and then heated to 60 °C for 3 h. Workup as in the other preparation of **3b** gave colorless, tetrahedral crystals (2.60 g, 86%). ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 0.02$ (s, 9H, $Si(CH_3)_3$), 0.95 (d, $^3J_{HH} = 6.1$ Hz, $CH(CH_3)_2$), 1.15 (d, $^3J_{HH} = 6.8$ Hz, 6H, $CH(CH_3)(CH_3)$), 1.24 (d, $^3J_{HH} = 6.8$ Hz, 6H, $CH(CH_3)(CH_3)$), 3.50 (sept, $^3J_{HH} = 6.8$ Hz, 2H, $CH(CH_3)_2$), 4.25 (sept, $^3J_{HH} = 6.1$ Hz, 1H, $CH(CH_3)_2$), 6.98 (s, 3H, H_{Aren}); ^{29}Si NMR (49 MHz, $CDCl_3$, TMS): $\delta = -96.5$ (Si-O), 6.3 ($Si(CH_3)_3$); IR (Nujol): $\tilde{\nu} = 1250$, 993, 968, 861, 842, 458 cm^{-1}; MS (70 eV): *m/z* (%): 1725 (100) [M^+].

3c: A solution of **2c** (1.90 g, 3.0 mmol) in 1,2-dimethoxyethane (DME) (8 mL) was added dropwise to a solution of $MeC_5H_4TiCl_3$ (0.70 g, 3.0 mmol) in DME (8 mL) at −60 °C. The reaction solution was allowed to warm slowly to room temperature and was then stirred for 2 d. A fine white precipitate was filtered from the turbid solution and washed with DME (2 mL). Yield 0.34 g (44%). ^{1}H NMR (250 MHz, C_6D_6, TMS): $\delta = 1.20$ (s, 9H, $C(CH_3)_3$), 2.23 (s, 3H, CH_3), 6.11 (m, 2H, C_5H_4), 6.25 (m, 2H, C_5H_4); ^{29}Si NMR (79 MHz, C_6D_6, TMS): $\delta = -68.6$ (s); IR (Nujol): $\tilde{\nu} = 1023$, 974, 799 cm^{-1}; MS (70 eV): *m/z* (%): 983 (100) [$M^+ - t$Bu].

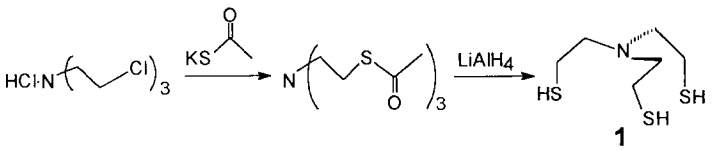
Trigonal-Bipyramidal Technetium and Rhenium Complexes with Tetradentate NS_3 Tripod Ligands**



Hartmut Spies,* Matthias Glaser, Hans-Jürgen Pietzsch, F. Ekkehardt Hahn,* Oliver Kintzel, and Thomas Lügger

Our interest in coordination compounds of rhenium and technetium is based on the relevance of radionuclides of these metals for diagnosis and therapy in nuclear medicine. The gamma emitter ^{99m}Tc ($t_{1/2} = 6.02$ h, $E\gamma = 140.6$ keV) has already served for several years as the "work horse" in nuclear medicine for radiodiagnostic examinations. Coordination compounds of the β-emitter ^{186}Re are of current interest as cytotoxic radiotherapeuticals. In the concept of bifunctional pharmaceuticals, those technetium and rhenium complexes that are suitable for coupling to biologically relevant anchor groups lend themselves in particular to the design of new radiotracers. The previously known species suitable for coupling are almost without exception square-pyramidal oxo complexes of tetradentate ligands,[1-3] in which the properties, and thus the in vivo behavior, of a biomolecule is strongly influenced by the coupling to the polar M=O unit. In promising tracers, however, this influence should be kept as small as possible. It is to be expected that ligands which, in spite of extensive shielding of the metal,[4] still allow the coupling to a biomolecule, are particularly suitable. In this sense, complexes of tetradentate NS_3 tripod ligands present an interesting alternative to the oxo complexes. In the presence of a coligand, such ligands could lead to weakly polar, trigonal-bipyramidal complexes in which the metal atom is more strongly shielded than in the square-pyramidal oxo complexes. We report here on the syntheses, structures, and properties of trigonal-bipyramidal Re^{III} and Tc^{III} complexes which contain the tetradentate NS_3 tripod ligand 2,2′,2″-nitrilotris(ethanethiol) **1** and a triphenylphosphane or isocyanide ligand.

The ligand **1** was obtained by reaction of tris(2-chloroethyl)-amine with potassium thioacetate[6a] followed by reduction with $LiAlH_4$[6b] in accordance with Scheme 1.[5] A problem in the workup of the reaction mixture is posed by the presence of acidic and basic functions in the same molecule. The formation of ionic

Scheme 1. Synthesis of the ligand **1**.

reaction products (hydrochloride or thiolate) can be suppressed in a satisfactory manner by the introduction of CO_2 into the reaction mixture, which has previously been hydrolyzed with neutral, degassed water.

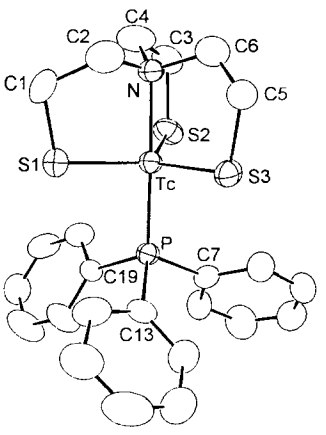
Technetium and rhenium complexes of the ligand **1** are possible in principle both by the in situ reduction of the metalates MO_4^-, as well as by ligand exchange on reactive M^{III} compounds (Schemes 2 and 3). In general, the ligand exchange reactions

Scheme 2. Synthesis of the technetium complexes **2** and **3**.

prove to be more advantageous as regards both the yield and the avoidance of side products.

The violet Tc^{III} complex **2** is formed in 62% yield by the action of a mixture of **1** and the pertechnate reducing agent triphenylphosphane[7] in an ethanol/water solution of pertechnate made acidic by acetic adic. The ligand exchange reaction of $[TcCl_3(PPh_3)_2(MeCN)]$[8] with **1** also leads to the complex **2** in good yield. In this reaction, a small amount of a blue complex **3** can be isolated as a side product, which is presumed to have the composition $[Tc(\mathbf{1})(PPh_3)_2]$[5] (Scheme 2).

The X-ray structure analysis on crystals of **2**[9] (Fig. 1) shows that a pentacoordinate trigonal-bipyramidal complex has indeed been formed. The tetradentate ligand **1** occupies three equatorial



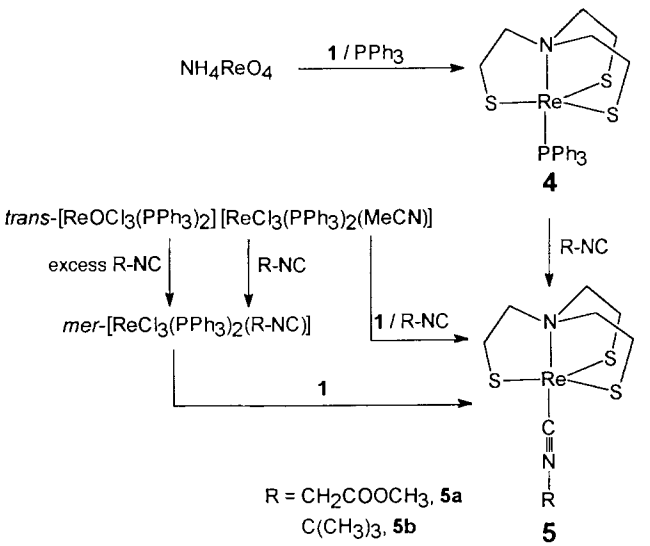


Fig. 1. Structure of the complex **2** in the crystal (ORTEP). Selected distances [Å] and angles [°]: Tc-S1 2.228(2), Tc-S2 2.224(2), Tc-S3 2.227(2), Tc-P 2.325(2), Tc-N 2.192(5); S1-Tc-S2 119.29(7), S1-Tc-S3 119.92(7), S1-Tc-P 93.83(6), S1-Tc-N 85.01(2), S2-Tc-S3 118.73(7), S2-Tc-P 95.61(7), S2-Tc-N 85.5(2), S3-Tc-P 94.92(6), S3-Tc-N 85.19(14), P-Tc-N 178.7(2) [9].

and one axial position, whereas the second axial position is occupied by a triphenylphosphane ligand. The tripodal topology of **1** obviously stabilizes the Tc^{III} ion and forces the formation of this coordination polyhedron. Only a very small number of trigonal-bipyramidal Tc^{III} complexes are known.[10] An example with the PS_3 tripod ligand 2,2′,2″-phosphanetriyltris(benzenethiol) was reported by de Vries et al.[10b] Bond lengths and angles in **2** lie within the expected range for Tc^{III} thiolates.[10b, 11] The small deviations of the angles on the technetium atom from the values for a trigonal bipyramid are remarkable.

The concept for the preparation of **2** can be applied to the synthesis of the analogous mixed-ligand rhenium(III) complex **4** (Scheme 3).[5] This can also be obtained by the reduction of per-

Scheme 3. Synthesis of the rhenium complexes **4** and **5**.

rhenate by triphenylphosphane in the presence of **1** in an ethanol/water solution made acidic by hydrochloric acid. Preliminary investigations show, moreover, that the rate of reaction is highly dependent on the type of the phosphane and is particularly high with alkylphenyl substituted phosphanes.[12] We found no indication for the formation of octahedral diphosphane complexes of the type $[Re(\mathbf{1})(PPh_3)_2]$.

Aside from perrhenate, Re^{III} compounds are also suitable starting reagents for the synthesis of trigonal-bipyramidal mixed-ligand Re^{III} complexes. In addition, these also provide a simple route to complexes in which the axial phosphane is replaced by an isocyanide ligand. Re^{III} complexes of the type *mer*-$[ReCl_3(PPh_3)_2(R{-}NC)]$ may be obtained by the exchange of acetonitrile in $[ReCl_3(PPh_3)_2(MeCN)]$ or by an excess of isocyanide in the combined reduction/substitution of $[Re^{V}OCl_3(PPh_3)_2]$.[12, 13] They react with **1** to give the complexes **5** (Scheme 3). Alternatively, **5** can also be obtained starting from $[ReCl_3(PPh_3)_2(MeCN)]$ in a "one pot" synthesis with an equimolar mixture of **1**/R−NC. In both cases an octahedral Re^{III} complex changes into a trigonal-bipyramidal complex on coordination of the ligand **1**, which confirms once again the preference for this coordination geometry in complexes of **1**. The most simple preparative method of obtaining **5** is, however, the direct exchange of the phosphane ligand in **4** for one equivalent of isocyanide in CH_2Cl_2.[5]

Compounds **4** and **5a** were characterized by X-ray structure analysis (Fig. 2).[9] Both complexes have trigonal-bipyramidal geometry. The molecular parameters of **4** are very similar to those of **2**. In the molecular structure of **5a**, the large deviation

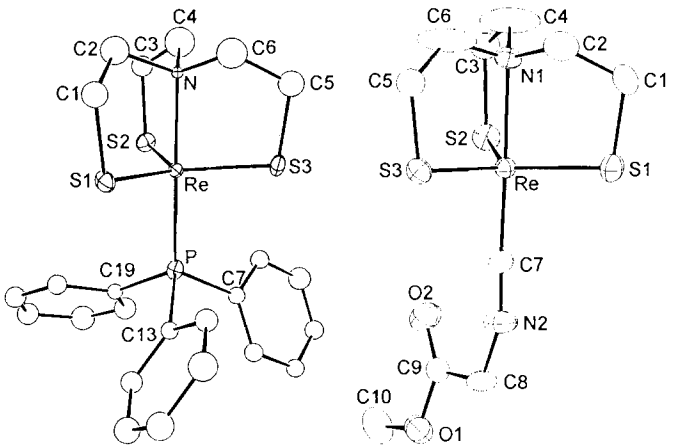

Fig. 2. Structure of the complexes **4** (left) and **5a** (right) in the crystal (ORTEP). Selected distances [Å] and angles [°] in **4**: Re-S1 2.243(6), Re-S2 2.222(6), Re-S3 2.240(6), Re-P 2.306(7), Re-N 2.18(2); S1-Re-S2 120.4(2), S1-Re-S3 119.3(2), S1-Re-P 93.6(2), S1-Re-N 85.2(5), S2-Re-S3 118.3(2), S2-Re-P 95.3(2), S2-Re-N 86.4(5), S3-Re-P 95.1(2), S3-Re-N 84.3(4), P-Re-N 178.2(5); in **5a**: Re-S1 2.231(2), Re-S2 2.235(2), Re-S3 2.238(2), Re-N1 2.231(7), Re-C7 1.905(9), C7-N2 1.200(12); S1-Re-S2 118.87(8), S1-Re-S3 119.31(8), S1-Re-N1 85.2(2), S1-Re-C7 96.1(2), S2-Re-S3 119.74(8), S2-Re-N1 85.3(2), S2-Re-C7 94.6(3), S3-Re-N1 85.2(2), S3-Re-C7 93.8(3), N1-Re-C7 178.7(3), Re-C7-N2 173.9(8), C7-N2-C8 150.8(9) [9].

of the C7–N2–C8 angle from the expected linearity [150.8(9)°] and the length of the C7–N2 bond [1.200(12) Å] (expected value approximately 1.150 Å) are particularly noticeable. These indicate, together with the very low wavenumber for the IR absorption of the NC stretching vibration (1940 cm^{-1}), a strengthened back bond to the isocyanide carbon atom from the rhenium atom, which, due to the coordination by sulfur, is very electron-rich. The great extent of the bending of an isocyanide due to coordination to an electron-rich transition metal has previously only rarely been observed in such clarity.[14]

With the complexes **2**, **4**, and **5**, we present a new type of neutral, trigonal-bipyramidal, mixed-ligand complex of Tc^{III} and Re^{III}. A similar coordination geometry is only to be found in the complex [Tc(PS_3)(*i*PrNC)] with the aromatic trithiol tripod PS_3.[10b] The complex **5a** is of special interest for further investigations. In principle, complexes of this type could be coupled to molecules with a specific biodistribution by the formation of an amide via the ester function, as has already been demonstrated for the $^{99m}Tc^{V}O$ complex of the tetradentate ligand 6-*p*-aminobenzyl-3,3,9,9-tetramethyl-4,8-diazaundecane-2,10-dionedioxime (PnAO).[3] The chelate unit in **5a** is less polar than in the square-pyramidal [TcO(PnAO)], however. For radiopharmaceutical preparations of complexes of the type **5a**—starting from MO_4^- reagents—the reaction conditions would have to be modified. We are currently investigating the possibility of coupling technetium and rhenium to biological anchor groups on the basis of the concept described above.

[9] Structure analyses: red-violet crystals of **2** were obtained by evaporation of the solvent from a benzene/methanol solution. Crystals of **4** (crystallized from toluene) were very thin, air-sensitive platelets. The diffraction data for this compound were therefore measured at −100(5) °C. After measuring all symmetry-independent intensities in the 2θ range of 5.4–40°, crystal decomposition was observed and the data collection had to be interrupted. Only a relatively small data set was thus available. For this reason, only the Re, P, and S atoms were refined with anisotropicic thermal parameters in the least-squares procedure. While the quality of the diffraction data does not allow a detailed discussion of the bond lengths and angles in **4**, it is sufficient to allow an unequivocal determination of the geometry of the molecule. Compound **5a** can be crystallized from CH_2Cl_2/Et_2O. Structure parameters: **2** [**4**] {**5a**}: $C_{24}H_{27}NPS_3Tc$ [$C_{24}H_{27}NPReS_3$] {$C_{10}H_{17}N_2O_2ReS_3$}, monoclinic [monoclinic] {monoclinic}, space group $P2_1/c$ [$P2_1/n$] {$P2_1/c$}, a = 8.906(2) [10.855(3)] {7.827(4)}, b = 25.804(6) [16.707(4)] {13.866(3)}, c = 11.061(4) [15.441(5)] {13.627(6)} Å, β = 108.42(2) [92.62(2)] {93.19(7)}°, V = 2414(2) [2797(2)] {1476(2)} $Å^3$, Z = 4 [4] {4}, $\rho_{exp.}$ = 1.53 [1.53] {2.17}, $\rho_{ber.}$ = 1.527 [1.526] {2.157} $g\,cm^{-3}$, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), $\mu(Mo_{K\alpha})$ = 9.1 [46.8] {87.4} cm^{-1}, 4233 [2592] {2589} symmetry-independent data measured at 20(5) [−100(5)] {20(5)} °C in the 2θ range 2–50 [5.4–40] {2–50}. Equilibrium between Isocyanide and Carbene Complexes in Coordination Compounds of 2,6-Dihydroxyphenyl Isocyanide**

F. Ekkehardt Hahn,* Matthias Tamm, and Thomas Lügger

We reported recently on the reactions of $Fe(CO)_4$ and $M(CO)_5$ complexes (M = Cr, W) of 2-trimethylsiloxyphenyl isocyanide (**1**).[1] After hydrolysis of the Si–O bond, these react by intramolecular attack of the hydroxy group on the isocyanide carbon

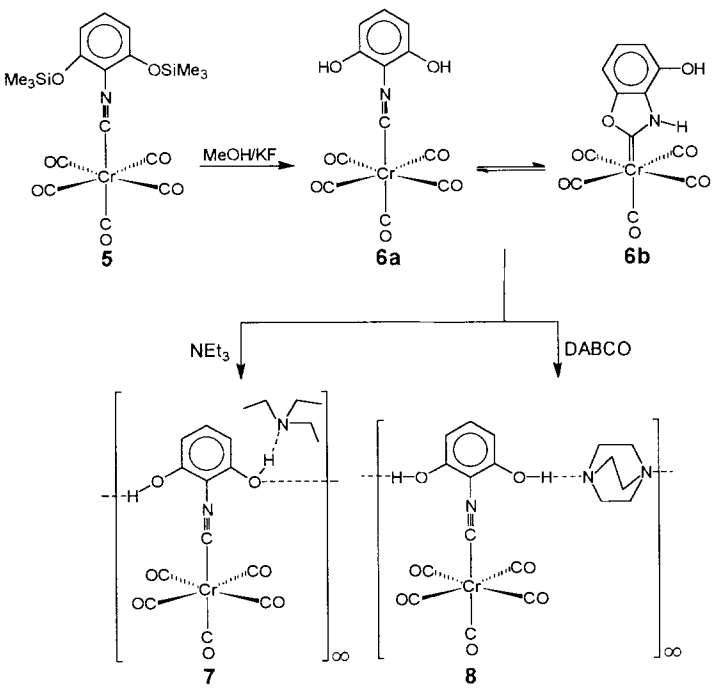
to form carbene complexes **3** (Scheme 1).[2, 3] The intermediately formed complex **2** could not be isolated. The driving force for the intramolecular reaction is the stability of the cyclic carbene ligand in **3**, which has a five-membered aromatic heterocycle.

Scheme 1. Reaction of coordinated 2-trimethylsiloxyphenyl isocyanide upon cleavage of the Si–O bond.

Normally, the intramolecular carbene formation from 2-hydroxyphenyl isocyanide is hindered when the latter is coordinated to a particularly electron-rich transition metal fragment. The nucleophilic attack of the oxygen atom on the isocyanide carbon atom is then made difficult, as this is deactivated by (d–p) π back bonding. In such cases, a mixture of isocyanide (**2**) and carbene (**3**) complexes is obtained.[4] The strength of the (d–p) π back bond, and consequently the position of the equilibrium between the complexes of types **2** and **3**, may be predicted from the force constant for the N≡C triple bond as calculated according to Cotton.[5]



We have now investigated the behavior of the doubly trimethylsiloxy-substituted ligand 2,6-bis(trimethylsiloxy)phenyl isocyanide (**4**) coordinated to Cr(0), after hydrolysis of the Si–O bonds. In this case, a mixture is obtained in which the isocyanide (**6a**) and the carbene (**6b**) complexes are in equilibrium with one another (cf. Scheme 3). We report here on a new way of shifting the equilibrium completely to the side of either the isocyanide or the carbene, without altering the electronic properties of the metal center.

Scheme 2. Synthesis of the ligand **4**.

For the synthesis of the ligand **4** (Scheme 2),[6] the nitro group of commercially available nitroresorcinol is first reduced with Pd/H_2 and the resulting primary amine converted into 4-hydroxybenzoxazol according to Erlenmeyer et al.[7] After double deprotonation with two equivalents of *n*BuLi, this reacts regiospecifically with trimethylchlorosilane under *O*-silylation, as is known for benzoxazol.[1]

The reaction of **4** with $[Cr(CO)_5(thf)]$ leads to the isocyanide complex **5**.[8] This reacts after cleavage of the Si–O bonds to give a mixture containing the isocyanide complex **6a** and the carbene complex **6b**[9] (Scheme 3). The force constant for the N≡C stretching vibration in **6a** (1724 Nm^{-1}, calculated from the IR absorption measured in the mixture) indicates strong back bonding to the isocyanide carbon in **6a**, and explains the incomplete carbene formation. For comparison: Because of the weaker (d–p) π back bonding in **1c**, a force constant of 1791 Nm^{-1} was calculated,[2] and complete conversion into the carbene complex **3c** is observed on cleavage of the Si–O bond.[2] The mixture **6a/6b** can also be characterized quantitatively by ^1H NMR spectroscopy.[9] In the spectrum, resonances are found for the N*H* proton in **6b** at $\delta = 13.68$ and for the O*H* protons in **6a** and **6b** at $\delta = 9.57$. The amounts of the components in the mixture were determined from the integrals (59% **6a** and 41% **6b**).

Scheme 3. Reaction of a mixture of **6a/6b** with weak bases.

The reaction of isocyanide complexes with alcohols resulting in the formation of carbene complexes is normally catalyzed by bases.[10] In contrast to this, we found that by selection of specific bases, a stabilization of the coordinated 2,6-dihydroxyphenyl isocyanide is possible, even against the preferred intramolecular nucleophilic attack.

If two equivalents of triethylamine are added to a solution of the **6a/6b** mixture in dichloromethane, the expected shift in equilibrium to the carbene side is not observed. After removal of solvent, a colorless powder is obtained whose infrared spectrum shows exclusively absorptions for a pentacarbonyl(isocyanide)chromium complex (cf. **7**; $\nu(NC) = 2154\ cm^{-1}$).[11] The ^1H NMR spectrum of this complex contains signals which indicate the formation of a 1:2 adduct **6a**·$2NEt_3$. The reaction of the **6a/6b** mixture with one equivalent of the dibasic amine 1,4-diazabicyclo[2.2.2]octane (DABCO) proceeds similarly (exclusive formation of an isocyanide complex **6a**·DABCO; cf. **8**; $\nu(NC) = 2149\ cm^{-1}$).[11] The isocyanide complex **6a** is obviously stabilized by the addition of these amine bases to such an extent that the equilibrium **6a/6b** is shifted completely to the side of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1357 $ 10.00+.25/0

the pentacarbonyl(2,6-dihydroxyphenylisocyanide)chromium–amine adduct.

In order to understand the mechanism of the unusual stabilization of 2,6-dihydroxyphenyl isocyanide complexes by amine bases, X-ray structure analyses of the triethylamine and the DABCO adducts of **6a** were carried out.[1,2] These show that in both cases the isocyanide complex is stabilized by the formation of N···H hydrogen bridges to the hydroxy protons. In contrast to the structure in solution, crystals of the triethylamine adduct contain only one molecule of triethylamine per molecule **6a**, and consequently this complex can be formulated as **6a**·NEt_3 (**7**; Fig. 1, left).[1,3] Complex **7** crystallizes, polymerized through hydrogen bridges, as shown in Scheme 3. Crystals of the product of the reaction of **6a**/**6b** with DABCO consist of hydrogen-bridged polymers **6a**·DABCO (**8**, Scheme 3; Fig. 1, right).[1,3]

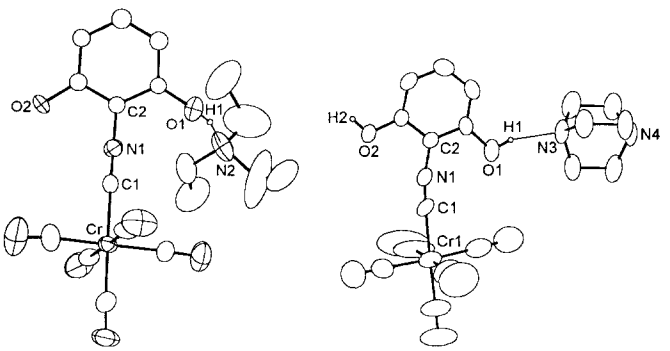


Fig. 1. Structures of the complexes **7** (left) and **8** (right) in the crystal (ORTEP). The asymmetric unit of **8** contains two almost identical molecules and one acetone molecule (not shown). Selected distances [Å] and angles [°] for **7**: Cr-C1 1.977(12), C1-N1 1.164(13), N1-C2 1.396(14), O1-H1 1.28(13), H1···N2 1.38(12), O1···N2 2.634(14), O1···O2* 2.525(11); Cr-C1-N1 177.7(10), C1-N1-C2 172.8(12), O1-H1···N2 164(8). The position of the H atom bonded to O2 could not be determined, symmetry code (*)x, 1/2−y, 1/2 + z; for **8**·0.5$(CH_3)_2CO$ (molecule 1, see [13] for further data): Cr1-C1 1.989(8), C1-N1 1.145(8), N1-C2 1.391(8), O1-H1 0.79(6), H1···N3 1.93(6), O1···N3 2.668(7), O2-H2 0.80(6), H2···N4* 1.87(6), O2···N4* 2.667(6); Cr1-C1-N1 176.3(6), C1-N1-C2 168.7(6), O1-H1···N3 154(7), O2-H2···N4* 170(6), symmetric code (*) x, 1/2 − y, 1/2 + z.

The use of weak bases (the pK_s values of phenol and the tertiary amines employed are of the same order of magnitude) obviously does not lead to deprotonation of the hydroxy groups and an increase in their nucleophilicity, but rather to the formation of hydrogen bridges and thus to the stabilization of the isocyanide complexes. A shift of the **6a**/**6b** equilibrium completely to the side of the isocyanide complexes stabilized by O–H···N hydrogen bonds is thereby achieved.

Attempts to shift the equilibrium to the carbene side must therefore be carried out with stronger bases which are capable of completely deprotonating the hydroxy groups. If a mixture of **6a**/**6b** is treated with two equivalents KO*t*Bu, and the dianion thus formed is then alkylated with two equivalents of methyl iodide, the *N*,*O*-dimethylated carbene complex **10** can be obtained in good yield (Fig. 2). The *N*-methylated complex **9** formed as intermediate can be obtained by the addition of only one equivalent of KO*t*Bu and MeI. After deprotonation, the phenolic oxygen atom of **6a** is sufficiently nucleophilic to allow the intramolecular cycloaddition to proceed to completion. The subsequent alkylation of the anion prevents the reverse reaction leading to the isocyanide complex, and a complete shift of the **6a**/**6b** equilibrium to the side of the mono- or dimethylated carbene complex is achieved.[2,3]

With the synthesis of the complexes **7**, **8**, and **10**, we present a procedure for the selective displacement of the **6a**/**6b** equilibrium between the isocyanide and carbene complexes by means of suitable bases. The complexes **7** and **8** are the first examples for which the normally preferred intramolecular carbene formation in coordinated 2-hydroxyphenyl isocyanides could be prevented.[2,3] This is the first time that such isocyanide complexes have been successfully stabilized without alteration of the electronic properties or the steric situation at the metal atom. Conversely, the carbene complexes **9** and **10** can be isolated when the $N-C_{carbene}$ atom in a mixture of **6a**/**6b** is alkylated by reaction with strong bases and MeI.

[6] **4**: Correct elemental analysis. For the synthesis, 4-hydroxybenzoxazol [7] (10 g, 74 mmol) was dissolved in anhydrous THF (200 mL) at −78 °C. *n*BuLi (60 mL of a 2.5 M solution in hexane, 150 mmol) was added slowly by syringe. The monolithiated salt started to precipitate during the addition of the first half of the *n*BuLi. Further addition of *n*BuLi caused the precipitate to redissolve, however. After complete addition, stirring was continued for a further 3 h at −78 °C. Me_3SiCl (20 mL, 158 mmol) was subsequently added to the reaction mixture, and the clear brown solution was stirred for about 12 h at room temperature. All volatile components were then removed under vacuum. *n*-hexane (100 mL) was added, and the insoluble LiCl filtered off. The brown solution in *n*-hexane was concentrated by removing the solvent under reduced pressure; **4** was obtained as a colorless oil by distillation at 85 °C/0.06 mbar. Yield 18.73 g (91%). IR (KBr film): ν[cm^{-1}] = 2125 (NC); ^{1}H NMR (270 MHz, $CDCl_3$): δ = 7.09 (t, 1H; Ar-H), 6.52 (d, 2H; Ar-H), 0.32 (s, 18H, CH_3); $^{13}C\{^1H\}$ NMR (67.93 MHz, $CDCl_3$): δ = 170.3 (NC), 152.4 (Ar-C-O), 129.1 (*p*-Ar-C), 113.1 (*o*-Ar-C), 0.1 (Si-C), the signal Ar-*C*-NC was not observed.

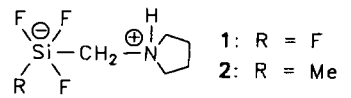
[8] **5**: correct elemental analysis. Selected analytical data: green oil, yield 8.1 g (96%); IR (KBr-film): ν[cm^{-1}] = 2149 (s, NC), 2060 (s, CO), 1992 (sh, CO), 1945 (vs, br, CO); ^{1}H NMR (270 MHz, $CDCl_3$): δ = 7.06 (t, 1H; Ar-H), 6.50 (d, 2H; Ar-H), 0.32 (s, 18H; CH_3); $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 217.1 (*trans*-CO), 214.8 (*cis*-CO), 174.0 (NC), 152.7 (Ar-C-O), 129.1 (*p*-Ar-C), 113.0 (*o*-Ar-C), 0.1 (Si-C), the signal Ar-*C*-NC signal was not observed; MS (70 eV): m/z 471 (M^+, 8.0%), 331 (M^+ − 5 CO, 100).
[9] Mixture **6a**/**6b**: For the preparation, **5** (8.1 g, 17 mmol) was dissolved in anhydrous methanol (50 mL). A small sample of KF (0.2 g) was added, and the mixture was stirred at room temperature for 2 d. All volatile components were removed under vacuum, and a colorless powder was obtained. After chromatographic purification (Al_2O_3, 4% H_2O, methanol:diethyl ether 1:1), a mixture of **6a**/**6b** (5.3 g, 95%) was obtained. Selected analytical data: IR (KBr): ν[cm^{-1}] = 3526 (m, NH **6b**), 3379 (m, OH **6a**,**b**), 2128 (s, NC **6a**), the bands for the CO absorptions could neither be resolved nor assigned; ^{1}H NMR

(250 MHz, [D$_6$]acetone): δ = 13.68 (s, br, 1H; NH **6a**), 9.57 (s, 3H; OH **6a**, **6b**), 7.25 (d, 2H; Ar-H **6b**), 7.10 (t, 1H; Ar-H **6a**), 6.89 (t, 1H; Ar-H **6b**), 6.56 (d, 2H; Ar-H **6a**); ^{13}C{^{1}H} NMR (62.90 MHz, [D$_3$COD]: δ = 230.0 (carbene-C), 222.7 (*trans*-CO **6b**), 218.8 (*trans*-CO **6a**), 218.2 (*cis*-CO **6b**), 216.0 (*cis*-CO **6a**), 175.6 (NC **6a**), 155.9, 130.7, 107.4, 106.9 (Ar-C **6a**), 156.0, 126.1, 114.4, 121.1, 111.6, 102.3 (Ar-C **6b**); MS (70 eV): *m/z* 327 (M^+ **6a**, **6b**, 17.0%), 187 (M^+ − 5CO, 100).

[10] a) K. H. Dötz, H. Fischer, P. Hofmann, F. R. Kreissl, U. Schubert, K. Weiss, *Transition Metal Carbene Complexes*, VCH, Weinheim, **1983**; b) B. Crociani in *Reactions of Coordinated Ligands, Vol. 1* (Ed.: P. S. Braterman), Plenum Press, New York, **1985**.

[11] Correct elemental analysis for **7**–**10**. **7**: ^{1}H NMR (250 MHz, [D$_6$]acetone, 1:2-triethylamine adduct): δ = 7.02 (m, 3H; Ar-H), 2.88 (quart, 12H; NCH_2), 1.15 (t, 18H; CH_2-CH_3), O-H-Resonance signal was not observed; IR (KBr, of the crystalline solid **7**): ν[cm^{-1}] = 3418 (m, O-H···N), 2154 (m, NC), 2062 (s, CO), 1988 (sh, CO), 1914 (vs br, CO). – **8**: ^{1}H NMR (250 MHz, [D$_6$]acetone): δ = 7.08 (m, 3H; Ar-H), 2.89 (s, 12H; NCH_2); IR (KBr): ν[cm^{-1}] = 3421 (m, O-H···N), 2149 (m, NC), 2061 (s, CO), 1990 (sh, CO), 1922 (vs br, CO). – **10**: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.18 (t, 1H; Ar-H), 6.80 (d, 2H; Ar-H), 4.26 (s, 3H: NCH_3), 3.97 (s, 3H; OCH_3); ^{13}C{^{1}H} NMR (62.90 MHz, CD_2Cl_2): δ = 231.1 (carbene-C), 222.3 (*trans*-CO), 217.7 (*cis*-CO), 155.3, 147.2, 126.7, 122.6, 107.6, 104.2 (Ar-C), 57.0 (OCH_3), 37.4 (NCH_3); MS (70 eV): *m/z* 355 (M^+, 13.0%).



[12] The size and the scattering power of crystals of **7** were very small. For this reason, only a limited data set with $F_o^2 \geq 3\sigma(F_o^2)$ was available for the calculations. In order to keep the number of refinement parameters small, the six atoms of the aromatic ring were refined with isotropic thermal parameters. Crystals of **8** contained two almost identical molecules of **8** and one acetone molecule (the methyl groups of which were disordered) in the asymmetric unit. Structure parameters: **7** [**8**·0.5$(CH_3)_2CO$] {**10**}: $C_{18}H_{20}CrN_2O_7$ [$C_{19.5}H_{20}CrN_3O_{7.5}$] {$C_{14}H_9CrNO_7$}, monoclinic [orthorhombic] {monoclinic}, space group $P2_1/c$ [*Pbca*] {$P2_1/n$}, a = 12.713(8) [18.200(5)] {6.885(3)}, b = 15.328(8) [21.691(6)] {13.969(4)}, c = 11.950(6) [23.700(4)] {15.772(3)} Å, β = 117.92(4) [90.0] {97.83(2)}°, V = 2058(4) [9356(7)] {1502.8(14)} Å^3, Z = 4 [16] {4}, $\rho_{exp.}$ = 1.37 [1.32] {1.58}, $\rho_{calcd.}$ = 1.383 [1.330] {1.570} g cm^{-3}, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), $\mu(Mo_{K\alpha})$ = 5.8 [5.2] {7.8} cm^{-1}, 2688 [5821] {2641} symmetry-independent data measured at −100(5) [20(5)] {20(5)} °C in the 2θ range 2–45 [2–45] {2–50}°. Structure solution with Patterson methods, refinement of the position parameters of all non-hydrogen atoms with anisotropicic thermal parameters (ring atoms in **7** isotropic). C–H atomic positions calculated [d(C–H) = 0.95 Å] with $B_{eq(H)} = 1.3\,B_{eq(C)}$; no hydrogen atoms were calculated for acetone in **8**·0.5$(CH_3)_2CO$; H 1 in **7** and all O–H in **8**·0.5$(CH_3)_2CO$ were found and refined with constant B_{eq} = 4.0 Å^2. R = 4.90 [6.95] {3.76}, R_w = 6.14 [9.06] {4.85} for 901 [3551] {1764} structure factors $F_o^2 \geq 3\sigma(F_o^2)$ [absorption correction for **7** and **8**·0.5$(CH_3)_2CO$] and 226 [559] {208} variables.

Hexacoordinate Silicon in a Compound with an F_5SiC Unit**

Reinhold Tacke* and Mathias Mühleisen

Anions with penta- and hexacoordinate silicon such as $[RSiF_4]^-$, $[RSiF_5]^{2-}$, and $[R_2SiF_4]^{2-}$ (R = organic substituent) have been known for about thirty years.[1] More recently salts containing the anions $[R_2SiF_3]^-$ [2] and $[R_3SiF_2]^-$ [2c, 3] have also been reported. Whereas the aforementioned λ^6Si-organofluorosilicates have not been structurally characterized, the structural chemistry of λ^5Si-organofluorosilicates has been investigated in great detail in the past few years.[4] We have recently extended these studies with investigations on zwitterionic (molecular) λ^5Si-organofluorosilicates[5] (examples: zwitterions **1**[5a] and **2**[5d]). We report here on the synthesis and structural characterization of **5**·H_2O, the first zwitterionic λ^6Si-organofluorosilicate. The zwitterion **5** is the first molecular compound of hexacoordinate silicon with an F_5SiC unit and contains a hexacoordinate (formally twofold negatively charged) Si atom and two tetracoordinate (formally single positively charged) N atoms. The crystal structure analysis of **5**·H_2O is the first solid-state structural characterization of an λ^6Si species with an F_5SiC unit.

The λ^6Si-silicate **5** was prepared by the reaction of (chloromethyl)triethoxysilane (**3**)[6] with 1-methylpiperazine to yield silane **4**, which was treated with hydrofluoric acid; the product was isolated as monohydrate **5**·H_2O.

Compound **5**·H_2O crystallizes in the space group $P\bar{1}$ with one pair each of crystallographically independent zwitterions and water molecules in the asymmetric unit.[7] The crystal structure is dominated by intermolecular N–H···F and O–H···F hydrogen bonds. All of the donor functions are involved in the three-dimensional hydrogen-bonding network, which has a marked surplus of acceptor functions (donor/acceptor ratio 8:34). The structures of the two independent zwitterions (Fig. 1) are very similar. The Si–C distances [194.6(1) and 194.3(2) pm] are distinctly greater than those in the zwitterionic λ^5Si-organofluoro-

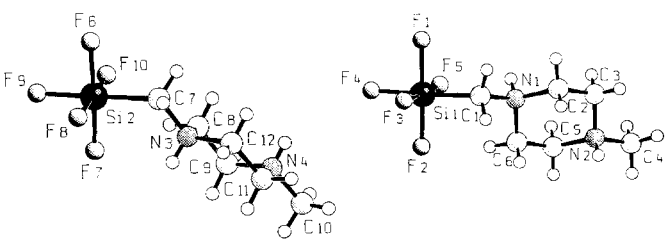

Fig. 1. Structures of the crystallographically independent zwitterions in the crystal of **5**·H_2O. Selected distances [pm] and angles [°] (standard deviations in parentheses): Si1-F1 174.0(1), Si1-F2 168.5(1), Si1-F3 171.6(1), Si1-F4 169.0(1), Si1-F5 170.8(1), Si1-C1 194.6(1); F1-Si1-F2 177.59(5), F1-Si1-F3 89.27(5), F1-Si1-F4 87.73(5), F1-Si1-F5 87.47(5), F1-Si1-C1 89.54(5), F2-Si1-F3 91.40(5), F2-Si1-F4 89.97(5), F2-Si1-F5 91.81(5), F2-Si1-C1 92.79(5), F3-Si1-F4 88.31(5), F3-Si1-F5 176.56(5), F3-Si1-C1 89.02(5), F4-Si1-F5 90.45(5), F4-Si1-C1 176.21(5), F5-Si1-C1 92.06(5). – Si2-F6 171.7(1), Si2-F7 168.8(1), Si2-F8 172.9(1), Si2-F9 169.2(1), Si2-F10 170.5(1), Si2-C7 194.3(2); F6-Si2-F7 177.87(5), F6-Si2-F8 89.24(5), F6-Si2-F9 88.13(5), F6-Si2-F10 89.69(5), F6-Si2-C7 89.33(5), F7-Si2-F8 89.59(5), F7-Si2-F9 90.04(5), F7-Si2-F10 91.38(5), F7-Si2-C7 92.47(5), F8-Si2-F9 87.82(5), F8-Si2-F10 176.57(5), F8-Si2-C7 91.03(5), F9-Si2-F10 88.89(5), F9-Si2-C7 177.23(6), F10-Si2-C7 92.21(5).

silicates investigated previously.[5] In contrast, the Si–F distances [168.5(1)–174.0(1) pm] are comparable in length to the axial Si–F bonds in the latter compounds.[5] Similar distances were also determined for the $[SiF_6]^{2-}$ ion (typically in the region of 168–170 pm).[4a] The bond angles in $\mathbf{5}\cdot H_2O$ deviate only slightly from the ideal values of 180° [maximum deviation 3.8 and 3.4°] and 90° [maximum deviation 2.8 and 2.5°], and thus the coordination polyhedra around the two Si atoms may be described as only slightly distorted octahedra. The relevant structural parameters are listed in the legend to Figure 1.

NMR spectroscopic investigations[8] have shown that **5** is also present as a zwitterion in solution (D_2O, [D_6]DMSO). The presence of the quaternary ammonium centers can be inferred indirectly from the chemical shifts of the ring protons in D_2O and [D_6]DMSO and from the detection of the NH protons in [D_6]DMSO. The hexacoordination at silicon is demonstrated indirectly by the ^{19}F NMR spectrum of **5** in D_2O (two signals with an intensity ratio of 4:1); in contrast, the spectrum of **5** in [D_6]DMSO shows only a relatively broad ^{19}F resonance signal, which could indicate dynamic molecular processes. ^{29}Si NMR spectra of **5** in D_2O and [D_6]DMSO could not be obtained (^{29}Si CP/MAS NMR: $\delta = -177.2$).

Experimental Procedure

4: A solution of **3** [6] (16.9 g, 79.4 mmol), 1-methylpiperazine (7.95 g, 79.4 mmol), and triethylamine (12.1 g, 120 mmol) in toluene (200 mL) was stirred under reflux for 24 h and then at room temperature for 48 h. Solvent and unreacted triethylamine were removed under reduced pressure, and the residue was treated with *n*-pentane (300 mL). The precipitate was filtered off, and the filtrate was concentrated under reduced pressure and then fractionally distilled using a Vigreux column to provide a colorless, clear liquid; yield 17.9 g (82%), b.p. 90 °C/0.2 Torr; correct C,H,N analysis; ^1H NMR ([D_6]DMSO): $\delta = 1.13$ (t, $^3J(H,H) = 7.0$ Hz, 9H; CCH_3), 1.87 (s, 2H; $SiCH_2$), 2.10 (s, 3H; NCH_3), 2.10–2.40 (m, 8H; ring H), 3.76 (q, $^3J(H,H) = 7.0$ Hz, 6H; CH_2O); ^{13}C NMR ([D_6]DMSO): $\delta = 18.5$ (CCH_3), 44.0 ($SiCH_2$), 46.1 (NCH_3), 55.4, 56.2, 58.2 (CH_2O, ring C); EI-MS: *m/z* (%): 276 (21) [M^+], 261 (5) [$M^+ - CH_3$], 247 (14) [$M^+ - C_2H_5O$], 206 (100).

$\mathbf{5}\cdot H_2O$: Hydrofluoric acid (1.5 M, 12.1 mL, 18.2 mmol HF) was added dropwise at 0 °C over 1 h to a stirred solution of **4** (1.00 g, 3.62 mmol) in water (20 mL). The resulting clear solution was stirred for 2 h at 0 °C and then treated with ethanol (100 mL), which caused a solid to precipitate. After the solid was removed by filtration, the filtrate was concentrated to ca. 10 mL under reduced pressure. Ethanol (100 mL) was added and the precipitated solid filtered off. The combined precipitates were washed with ethanol (3 × 10 mL) and then recrystallized from water at room temperature (crystallization by slow evaporation of the solvent). The crystals obtained were dried in a stream of nitrogen (room temperature): yield 685 mg (74%) colorless crystals, M.p. 202–204 °C (decomp); correct C,H,N,F analysis; ^{29}Si CP/MAS NMR (59.6 MHz, $\nu_{rot} = 3740$ Hz, contact time 4 ms, time between pulses 3 s, 1958 accumulated spectra): $\delta = -177.2$ ($\nu_{1/2} = 675$ Hz); ^1H NMR (D_2O): $\delta = 2.25$ (s, 2H; $SiCH_2$), 3.00 (s, 3H; CH_3), 3.25–4.05 (m, 8H; ring H); ^1H NMR ([D_6]DMSO): $\delta = 2.15$–2.30 (m, 5H; CH_3, $SiCH_2$), 2.75–3.00 (m, 4H; ring H), 3.25–3.35 (m, 6H; ring H, H_2O), 8.4 (br. s, 2H; NH); ^{13}C NMR (D_2O): $\delta = 46.0$ (CH_3), 53.9, 54.9 (ring C), 60.5 (m, unresolved C,F couplings; $SiCH_2$); ^{13}C NMR ([D_6]DMSO): $\delta = 45.2$ (CH_3), 51.7, 54.4 (ring C), $SiCH_2$ not detected; ^{19}F NMR (D_2O): $\delta = -113.7$ (s, 4F), -123.5 (s, 1F); ^{19}F NMR ([D_6]DMSO): $\delta = -112.1$ (br. s, $\nu_{1/2} = 63$ Hz); FD-MS (DMSO, 11 kV): *m/z* (%): 236 (9) [$(M - 2H)^+$], 198 (100) [$(M - 2HF)^+$].

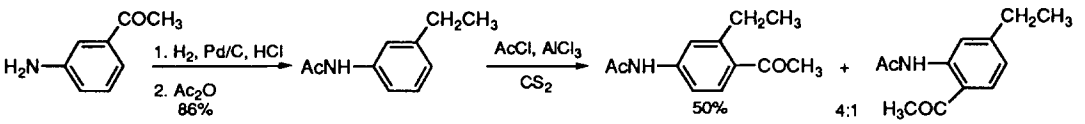
Iterative Divergent/Convergent Approach to Linear Conjugated Oligomers by Successive Doubling of the Molecular Length: A Rapid Route to a 128Å-Long Potential Molecular Wire**

Jeffry S. Schumm, Darren L. Pearson, and James M. Tour*



The ultimate computational system would consist of logic devices that are ultra dense, ultra fast, and molecular-sized.[1] Even though state-of-the-art nanopatterning techniques allow lithographic probe assemblies to be engineered down to the 100 Å gap regime,[2] the possibility of electronic conduction based upon single or small packets of molecules has not been addressed, and the feasibility of molecular electronics remains theoretically controversial.[1, 3] In an attempt to assess the possibility of molecular wire[4] conduction by spanning the 100 Å probe gaps with small packets of molecules, we describe here the synthesis of phenylalkyne oligomers that remain in a near-linear conformation owing to the 1,4-substitution of the phenylene units and the linearity of the alkyne moiety. This arrangement should minimize undesired conformational changes during adhesion and testing in the nanofabricated probes. Our approach to such a molecular framework involves a rapid iterative method that doubles molecular length with each iteration.[5] We obtained an air- and light-stable, linear conjugated oligomer that is 128 Å long which could also serve as a useful model for understanding

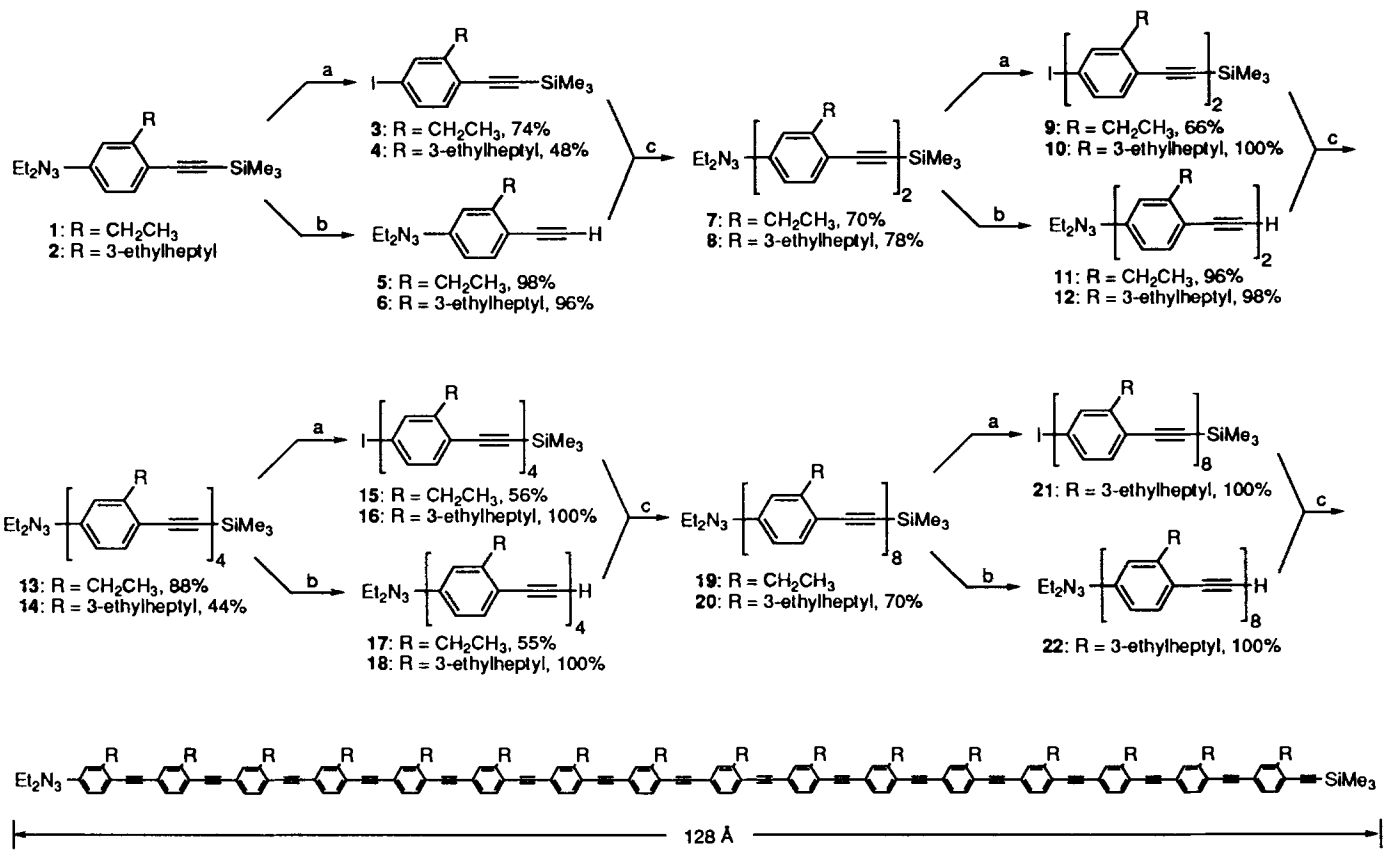
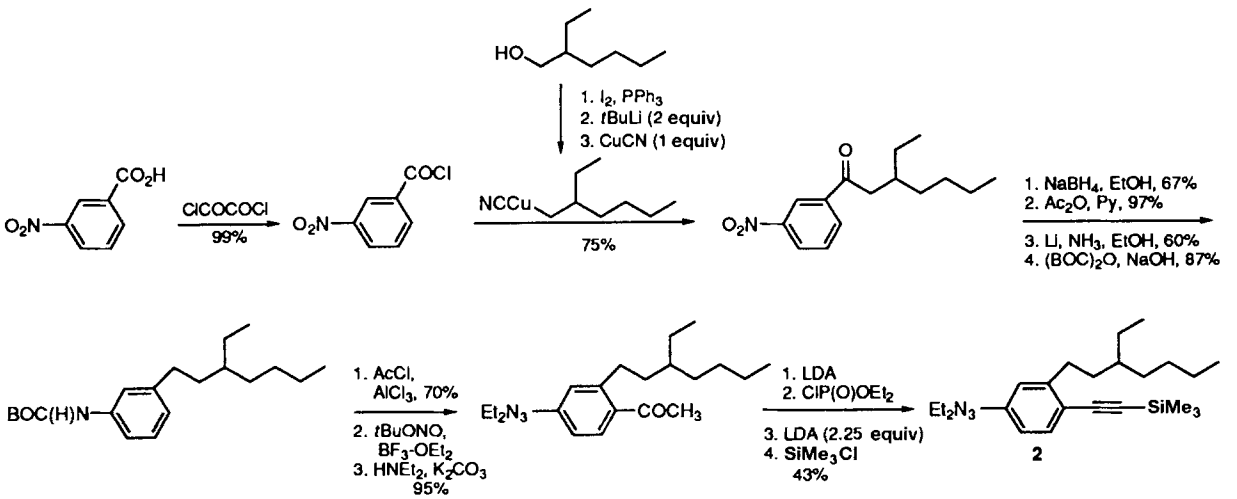
bulk properties of the polymeric material.[4i, j, 6] Moreover, since the the ends of this product should be easily functionalized, the ends may serve as "molecular alligator clips" for making surface contacts to metal probes for molecular electronics studies.[7]



The synthesis of the ethyl-substituted monomer **1** is shown in Equations (1) and (2) (LDA = lithium diisopropylamide).[8]



The iterative divergent/convergent approach to doubling the length of the molecule is shown in Scheme 1. Just three different reactions are needed at each stage to double the molecular length.[5c, d, 9] We initially conducted the synthesis starting from the monomer **1**, assuming that ethyl groups would provide sufficient solubility to permit formation of a 16-mer long enough to bridge the lithographically derived probe gaps. Unfortunately, the octamer **19** was nearly insoluble. Therefore, we were only able to obtain a UV/VIS spectrum and a mass spectrum (direct ionization) (Table 1).

In an effort to insure the solubility of the linear rigid-rod oligomer through to the 16-mer, we prepared the monomer **2** as shown in Scheme 2. We tried numerous methods to concomitantly reduce both the ketone and the nitro moieties; however, all methods failed, including the Pd-C/H_2/HCl reduction used in the synthesis of **1** [Eqs. (1) and (2)]. Therefore the multistep reaction sequence shown in Scheme 2 had to be utilized which also required a *tert*-butylnitrite-promoted[10] formation of the intermediate diazonium species. In addition to possessing a longer alkyl chain than **1**, **2** also has a stereogenic center. Successive dimerization thus affords numerous diastereomers that will retard crystallization and thereby increase solubility. Indeed, we were delighted to discover that both the octamer **20** and the

16-mer **23** (Scheme 1) were quite soluble and could be adequately characterized by spectroscopy. While **1**, **2**, **7**, **8**, **13**, **14**, and **19** were characterized by electron impact (EI) MS, in order to obtain MS data on **20** and **23**, it was necessary to use matrix-assisted laser desorption/ionization (MALDI) MS (Table 1). **23** is 128 Å long according to force field calculations (MMX) with extended Hückel and multiconformational parameters.

Table 1. Selected data for compounds **13**, **14**, **19**, **20**, and **23**.

13: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2965, 2872, 2151, 1590, 1503, 1401, 1246, 841; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.46 (d, J = 7.9 Hz, 1H), 7.45 (d, J = 8.0 Hz, 1H), 7.45 (d, J = 8.2 Hz, 1H), 7.40 (d, J = 7.8 Hz, 1H), 7.39 (br. m, 2H), 7.35 (d, J = 1.3 Hz, 1H), 7.32 (dd, J = 7.9, 1.7 Hz, 1H), 7.32 (dd, J = 7.9, 1.7 Hz, 1H), 7.29 (d, J = 1.9, 1H), 7.27 (dd, J = 8.2, 1.6 Hz, 1H), 7.23 (dd, J = 8.2, 2.1 Hz, 1H), 3.76 (q, J = 7.2 Hz, 4H), 2.885 (q, J = 7.5 Hz, 2H), 2.884 (q, J = 8.2 Hz, 2H), 2.87 (q, J = 7.5 Hz, 2H), 2.79 (q, J = 7.6 Hz, 2H), 1.32 (t, J = 7.6 Hz, 6H), 1.31 (t, J = 7.6 Hz, 3H), 1.26 (t, J = 7.6 Hz, 3H), 0.25 (s, 9H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 151.75, 147.50, 147.22, 146.69, 146.62, 133.29, 132.75, 132.54, 132.50, 131.33, 131.26, 131.21, 129.18, 129.06, 129.03, 124.45, 123.85, 123.79, 122.78, 122.68, 122.16, 120.72, 118.88, 117.96, 103.82, 100.29, 94.99, 94.80, 93.08, 90.93, 89.98, 89.73, 28.33, 28.05, 28.03, 27.99, 15.21, 15.05, 15.01, 14.80, 0.33; Low-Resolution (LRMS) calcd for $C_{47}H_{51}N_3Si$: 685; found: 685.

14: IR (neat): $\tilde{\nu}$[cm^{-1}] = 2956, 2151, 1595, 1464, 1402, 1236, 1103; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.48–7.27 (m, 12H), 3.76 (q, J = 7.1 Hz, 4H), 2.98–2.70 (m, 8H), 1.82–1.63 (m, 4H), 1.59–1.05 (m, 46H), 1.05–0.78 (m, 24H), 0.27 (s, 9H); LRMS calcd for $C_{75}H_{107}N_3Si$: 1077.8; found: 1077.9; UV/VIS (CH_2Cl_2): λ_{max} = 372 nm, UV 10% edge value = 421 nm; M_n = 1335, M_w = 1388, M_w/M_n = 1.06.

19: MS statistical isotopic range calculated for $C_{87}H_{83}N_3Si$: 1198 (95%), 1199 (100%), 1200 (55%); found: 1098.6 [M^+ – Et_2N_3, 100 amu]; UV/VIS (CH_2Cl_2): λ_{max} = 364 nm, UV 10% edge value = 500 nm.

20: IR (neat): $\tilde{\nu}$[cm^{-1}] = 2952, 2198, 2147, 1464, 827; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.48–7.27 (m, 24H), 3.77 (q, J = 7.1 Hz, 4H), 2.98–2.63 (m, 16H), 1.84–1.58 (m, 8H), 1.58–1.10 (m, 86H), 1.10–0.78 (m, 48H), 0.27 (s, 9H); UV/VIS (CH_2Cl_2): λ_{max} = 376 nm; UV 10% edge value = 422 nm; M_n = 2800, M_w = 2960, M_w/M_n = 1.05; MALDI-MS (sinapinic acid matrix, positive ion mode) average molecular weight calculated for $C_{143}H_{195}N_3Si$: 1984; found for M + 1 m/z = 1791 ± 9(peak maximum, large error due to broad signal), [M^+ – $SiMe_3$ (73 amu), – N_3Et_2 (100 amu), – C≡C (24 amu), typical products of phenylalkyne cleavage [11]].

23: IR (neat): $\tilde{\nu}$[cm^{-1}] = 2956, 2927, 2360, 2340, 1506, 1458; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.47–7.24 (m, 48H), 3.77 (q, J = 7.1 Hz, 4H), 2.95–2.65 (m, 32H), 1.82–1.58 (m, 16H), 1.58–1.10 (m, 166H), 1.10–0.70 (m, 96H), 0.26 (s, 9H); UV/VIS (CH_2Cl_2): λ_{max} = 376 nm, UV 10% edge value = 422 nm; M_n = 6649, M_w = 7114, M_w/M_n = 1.07; MALDI-MS (sinapinic acid matrix, positive ion mode) average molecular weight calculated for $C_{279}H_{371}N_3Si$: 3795; found for M + 1 m/z = 3486 ± 14 (peak maximum, large error due to broad signal), [M^+ – $SiMe_3$ (73 amu), N_3Et_2 (100 amu), – C≡C (24 amu), typical products of phenylalkyne cleavage, – C_8H_{17} fragment at 113 amu typical fragment from cleavage of a benzyl group [11]].

The optical spectra are interesting in that a saturation of the systems appears to have occurred by the octamer stage, such that doubling the length of the conjugated π-electron system causes no change in the position of the absorbance maximum (Figs. 1, 2). We also noticed that the extention of the π-electron system with the triazene substituent shifts the absorbance maxima bathochromically.

The results of the size exclusion chromatography (SEC) are shown in Figure 3 and compared with the actual molecular weights (MW) of the oligomers. SEC is not a direct measure of

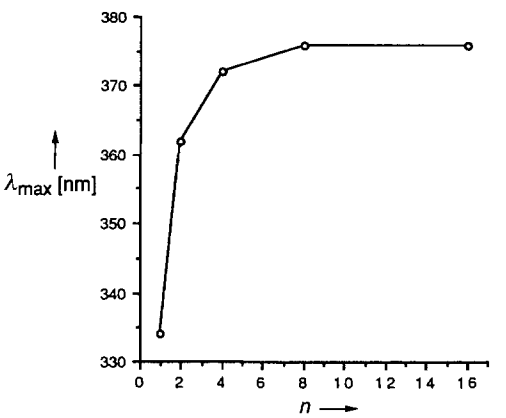

Fig. 1. UV absorbance maxima (CH_2Cl_2) of **2**, **8**, **14**, **20**, and **23** (monomer through 16-mer, respectively).

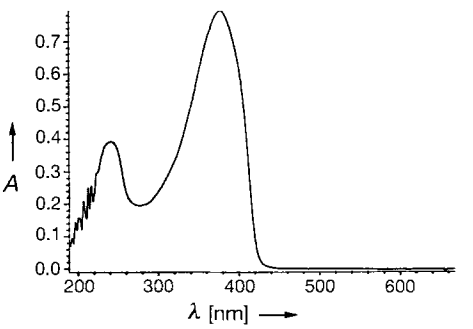

Fig. 2. UV/VIS spectrum of the 16-mer **23**. A = absorption (arbitrary units).

MW but a measure of the hydrodynamic volume. Thus, by SEC using randomly coiled polystyrene standards, the number average molecular weights (M_n) of rigid-rod polymers are usually greatly overestimated relative the actual molecular weights. Accordingly, the SEC-determined M_n values of the octamer **20** (M_n = 2800, actual MW = 1981) and the 16-mer **23** (M_n = 6650, actual MW = 3789) are much greater than the actual MWs. These results further confirm the formation of the 16-mer **23**. Also, as predicted, the monomer **2**, dimer **8**, and tetramer **14** have M_n values that are reasonably close to the actual MWs (slope $\approx$1.0 in Fig. 3) because they are in the low MW region, in which the polystyrene standards are not coiled. In all cases, the SEC-determined values of M_w/M_n are 1.04–1.07. Thus Figure 3 can serve as a useful calibration chart for very rigid linear oligomers as they compare to polystyrene standards by SEC.

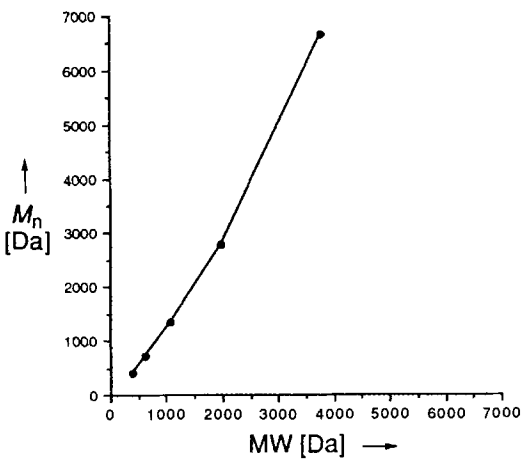

Fig. 3. M_n values determined by SEC (THF, polystyrene) versus the actual molecular weights MW of **2**, **8**, **14**, **20**, and **23**, (monomer through 16-mer, respectively).

Thus we have prepared rigid linear conjugated oligomers by an iterative divergent/convergent approach in which the monomeric unit is doubled. These oligomers may be well-suited as molecular wires in nanopatterned assemblies.

Change of Orientation of Axial Imidazole Ligands in a Cytochrome b Model Complex in Response to a Change in the Oxidation State of the Metal Center**

Frank Wiesemann, Ralf Wonnemann, Bernt Krebs,* Heike Keutel, and Ernst-G. Jäger*

Iron complexes with anionic, tetraazamacrocyclic, Schiff base ligands exhibit a close relationship to iron porphyrins if the higher σ and π basicity of these ligands[1, 2] is attenuated by the electron-withdrawing effects of free carbonyl substituents in the *meso* position (COOEt in **1**, COMe in the more hydrophilic acetyl derivatives[3a]). For instance, in analogy to heme proteins of the metmyoglobin type, the iron(III) complex **1b** forms stable adducts in solution with a multitude of axial ligands, which can be exchanged through dynamic equilibria: amines, amino acids and N-heterocycles, phosphanes and phosphites, nitriles and isonitriles, hydroxide, halides, pseudohalides, as well as other

anions, such as nitrite, sulfite, thiosulfate, complex cyanides, and ethynyl derivatives.[3b] In this respect, **1b** resembles the heme-containing iron proteins more closely than do free heme or most synthetic iron porphyrins.[4]

Cytochromes of the b group occupy a key position in the vectorial charge transfer during photosynthesis and in the respiratory chain.[5, 6] They contain hemes with low-spin iron centers and two axial imidazole (HIm) ligands. It is assumed that different orientations of the axial ligands with respect to the equatorial Fe–N bonds of the porphyrin are of importance for the function of the cytochromes.[6–13] These orientations depend on the valence state of the central atom. In low-spin iron(III) porphyrins one often finds a coplanar orientation in which both ligand planes lie above an equatorial N-Fe-N axis (Fig. 1, type a)).[7, 8] This orientation should be thermodynamically favored due to π interactions between the half-filled metal t_{2g} orbital and π orbitals of the imidazole ring.[8, 9] When the axial ligands are sterically encumbered or when they are not π donors, the mutually perpendicular (Fig. 1, type b) or coplanar (Fig. 1, type c) orientations dominate in which the ligand planes lie between the equatorial donor atoms.[10] These are also observed in the iron(II) complexes.[11] According to NMR data, the rotational barrier is low as long as there are no additional interactions.[12] The mutually perpendicular orientation in which each ligand plane lies above one N-Fe-N axis (Fig. 1, type d) has been postulated for certain cytochromes of the b group based on ESR data.[7] This orientation could be enforced by hydrogen bonds between the imidazole and carbonyl groups of the protein. Until now, this orientation may have been experimentally achieved but only in disordered crystals of a model porphyrin with different imidazole ligands.[13]

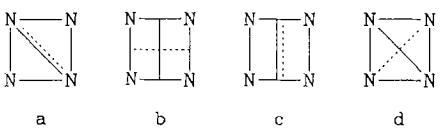

Fig. 1. Idealized orientations of the axial imidazole ligands in cytochrome b model complexes relative to the equatorial Fe–N bonds in the iron porphyrin complex [7-13].

We were able to obtain, crystallize, and structurally characterize the iron complexes **1a** and **1b** as low-spin bis(imidazole) adducts with iron in the oxidation states II and III, respectively. In iron(III) derivative **1b** the orientation of the imidazole rings is close to type d in Figure 1; this is the first occurrence of this orientation in a pure compound. The comparison of the two structures demonstrates impressively to what extent a change in oxidation state of the central atom, with no change in the first coordination sphere, can influence the orientation of the planes of axial ligands (coplanar in **1a**, nearly perpendicular in **1b**), the position of peripheral substituents (the carbonyl groups in **1a** are oriented in opposite directions, in **1b** in the same direction), the intermolecular interactions (four H bonds to four neighboring molecules in **1a**, and to two in **1b**), and the thus induced long-range order (three-dimensional network for **1a**, parallel, one-dimensional molecular strands for **1b**). Figures 2 and 3 show the crystal structures for both compounds; Figure 4 shows stereoprojections of the packing in the respective crystals.

The iron(II) complex **1a** crystallizes in the space group $P2_1/n$ with the iron atom at the inversion center. The ethoxy chains of the ester groups (O(2), C(7), C(8)) and the methyl group on the ring (C(4)) are disordered (1:1). The ^{1}H NMR spectra of the free ligands demonstrate that the methyl groups (C(4a), C(4b)) are *cis*.[14] The iron(III) derivative **1b** crystallizes in the space group $C2/c$; the atoms Fe(1), P(1), F(2), and F(4) are located on the two-fold axis. The anions in **1b** show no anomalies.

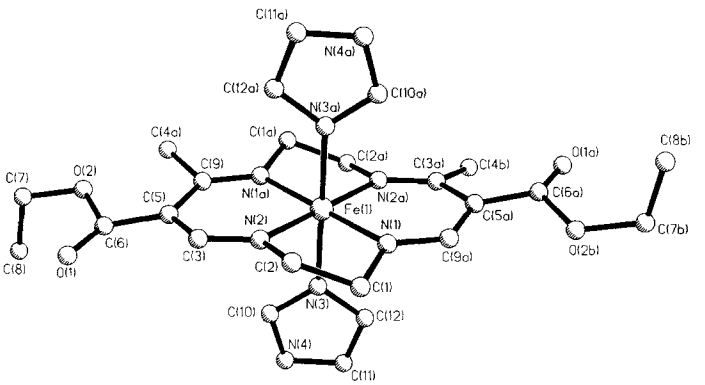

Fig. 2. Crystal structure of **1a**. Selected bond lengths [Å] and angles [°]: Fe(1)-N(1) 1.916(3), Fe(1)-N(2) 1.914(3), Fe(1)-N(3) 2.006(4), N(1)-C(1) 1.453(5), N(2)-C(2) 1.474(5), C(1)-C(2) 1.514(6), N(2)-C(3) 1.291(6), C(3)-C(5) 1.422(6), C(5)-C(9) 1.440(6), C(9)-N(1a) 1.300(5), C(5)-C(6) 1.421(6), C(6)-O(1) 1.202(7), C(6)-O(2) 1.465(10), C(10)-N(4) 1.345(6), N(4)-C(11) 1.353(6), C(11)-C(12) 1.362(6); N(1)-Fe(1)-N(2) 87.6(2), N(1)-Fe(1)-N(2a) 92.4(2), N(2)-Fe(1)-N(3) 91.14(15), N(1)-Fe(1)-N(3) 89.54(15), N(3)-Fe(1)-N(3a) 180.0; torsion angles [°]: C(1a)-C(2a)-N(2a)-Fe(1) 31.2, Fe(1)-N(1)-C(2) −30.9, N(1)-Fe(1)-N(3a)-C(10a) 43.2, N(2)-Fe(1)-N(3)-C(10) 49.2, C(5)-Fe(1)-N(3)-C(12) −179.5, C(10)-N(3)-N(3a)-C(10a) −180.0, C(3)-C(5)-C(6)-O(1) −1.7.

In both cases, the central atom has octahedral coordination. The equatorial Fe–N distances (1.88–1.92 Å) are somewhat shorter than those in porphyrins (1.97–2.00 Å) and are also nearly independent of the oxidation state. In both complexes, the axial Fe–N distances (2.00 Å) are in the range characteristic for low-spin iron(II) porphyrins and somewhat longer than those found in most low-spin iron(III) porphyrins (1.97 Å).[8, 11] The bond angles around the iron atom reflect the lower symmetry of the equatorial ligand (alternating five- and six-membered rings) compared to that in porphyrins. In both cases the central atom lies exactly in the $[N_4]$ plane. The six-membered chelate rings are bent by only about 5–6° along the N–N axes.

The five-membered chelate rings in **1a** exhibit the normal half-chair conformation; the ethylene bridges are both rotated in the same direction 40° out of the central [N_4] plane. The bond angle and the C–C distance (1.51 Å) are typical for sp^3-hybridized carbon atoms. In contrast, in **1b** only the ethylene bridge on the side of the methyl substituents shows the normal torsion angle (− 40°). The opposite five-membered chelate ring is nearly planar; the nearly ideal eclipsed conformation of the methyl groups and the C–C distance of 1.43 Å indicate partial double bonds in the ethylene bridge. This could stem from interactions with the π system of the six-membered chelate rings and possibly from interactions with the partially occupied t_{2g}^5 orbital of the central atom.

Apart from this altered ring conformation, the following differences between the iron(II) and the iron(III) complex are especially noteworthy:

1. The planes of both imidazole rings in **1a** are exactly coplanar and point directly to the *meso* position of the six-membered rings (cf. Fig. 1, type c). In **1b**, they are rotated by 64° with respect to each other and are nearly aligned along the equatorial N-Fe-N axes (Fig. 1, type d).

2. The ester groups in **1a** are each rotated by 13° out of the central [N_4] plane, and the two carbonyl functionalities point in opposite directions. In **1b**, the orientation of the ester groups is characteristic for such chelate complexes, namely the carbonyl moiety points in the direction of the neighboring methyl group on the chelate ring.[12, 15] The rotation out of the central [N_4] plane (32° in both cases) is larger than that found in **1a**.

3. The crystal structures of both compounds are characterized by intermolecular hydrogen bonds between the NH groups of the axial imidazoles and the peripheral carbonyl groups on the macrocycle (Fig. 4). In **1a**, each molecule is linked by four single H bonds (N···O distance of 2.72 Å) to a total of four neighboring molecules, which results in a three-dimensional network. In **1b**, each complex cation forms two H bonds to each of two neighbors (N···O distance of 2.88 Å). This one-dimensional linkage leads to an arrangement of paired chains which are surrounded—without any covalent interactions—by the hexafluorophosphate counterions.

Without prior knowledge of the energies involved, it is impossible to say whether rearrangements on the molecular level lead to the different intermolecular networks, or whether differences in the crystal packing forces, which could be caused by the incorporation of the anions in **1b**, force the structural adjustment of the H bonds and the molecular units. Some arguments support the proposition that the change in orbital occupancy at the central atom from t_{2g}^6 to t_{2g}^5 affects primarily the immediate environment, that is, the conformation of the chelate rings and the orientation of the imidazole units.[16] On the other hand, there are examples among similar macrocyclic chelate complexes in which crystal packing forces and details of the molecular structure are determined by the water molecules that link peripheral ester groups of neighboring chelate molecules in a one-dimensional fashion through hydrogen bonds.[17]

In any case, the simple model system presented here is an instructive example for the far-reaching structural consequences of a valence change of the central atom. The conformation of chelate rings, the orientation of the π-electron systems of axial ligands or peripheral substituents, the formation of hydrogen bonds and the resulting order of larger molecular aggregates are all affected solely by this valence change. It is possible that the rearrangements that are linked to the charge change also influence the direction of the charge transfer—as long as all these events happen within the same time frame.

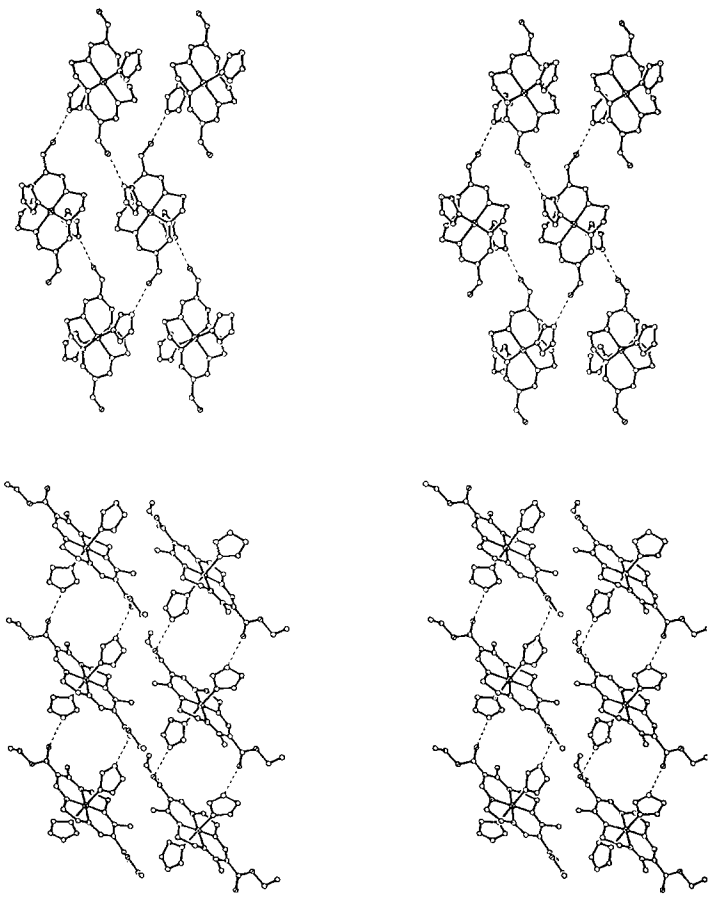

Fig. 4. Stereoprojections of the arrangements of **1a** (top) and **1b** (bottom) in their respective crystal lattices. For clarity the disordered methyl and ethyl groups in **1a** and the PF_6^- anions in **1b** have been omitted.

For iron(III) porphyrins, a conformation of axial imidazole ligands corresponding to Figure 1 type d has been predicted to lead to an ESR spectrum with a "strong g_{max}" > 3.[13] For samples of **1b** both in the form of a crystalline powder and in a methanol glass we have found normal rhombic ESR spectra with $g = 1.98, 2.09, 2.15$. It follows that the splitting in energy of the d_{xz} and d_{yz} orbitals is not determined by the relative position of the molecular planes of axial ligands, but more likely by the low symmetry of the equatorial ligand.

Experimental Procedure

Compound **1a** was prepared according to the general procedure outlined in ref. [18]. In order to avoid the formation of oligomeric products, a larger excess of imidazole was added: Under exclusion of air, iron(II) acetate [19] (3.48 g, 0.02 mol), 6,13-bis(ethoxycarbonyl)-5, 14-dimethyl-1, 4, 8, 11-tetraazatetradeca-4, 6, 12, 14-tetraene (7.31 g, 0.02 mol), and imidazole (10 g, 0.15 mol) in 120 mL of methanol were heated to reflux for 15 min. Upon cooling, dark red crystals of the diadduct **1a** formed, which were washed with a small amount of cold methanol. Insufficient exclusion of air leads to a color change to deep green. Yield: 9.2 g (83%), diamagnetic. $FeC_{24}H_{34}N_8O_4$, 554.4 g mol^{-1}, satisfactory elemental analyses for Fe, C, H, N.

1b: Iodide **1c** [3b] (0.3 g, 0.55 mmol) and imidazole (2 g, 30 mmol) were dissolved in 20 mL of methanol. A filtered solution (G4 sintered glass frit) of NH_4PF_6 (5 g, 30 mmol) in 20 mL of methanol was added. The resulting mixture was heated to reflux for 15 min. Slow cooling led to the separation of dark green crystals, which were washed with a small amount of very cold methanol and dried in air. Yield: 0.22 g (57%), $\mu_{eff} = 1.78\ \mu_B$. $FeC_{24}H_{34}N_8O_4PF_6$, 699.4 g mol^{-1}, satisfactory elemental analyses for Fe, C, H, N. ESR spectra: ERS-300 spectrometer (former Zentralwerkstatt für wissenschaftlichen Gerätebau, Berlin Adlershof); X band; $p = 0.2$ mW; 1,1-diphenyl-2-picrylhydrazyl (DPPH) as external standard. Compound **1b** was measured as a solid at 150 K, compound **1c** in a methanol glass (10^{-3} mol L^{-1}) at 77 K in the presence of 1 mol L^{-1} of imidazole.

Crystal structure analyses: Crystal data for **1a** ($C_{24}H_{34}N_8O_4Fe$): monoclinic, $P2_1/n$, $a = 11.973(3)$, $b = 7.473(1)$, $c = 14.604(4)$ Å, $\beta = 95.27(2)°$, $Z = 2$, $V = 1301.2$ Å^3, measurement temperature 150 K, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), 2848 independent reflections, 2046 with $I > 1.96\sigma(I)$, $R = 0.065$, $wR^2 = 0.1689$, structure solution by direct methods, refinement by full matrix least squares method on F^2 (SHELXL 93). Crystal data for **1b** ($C_{24}H_{34}N_8O_4PF_6Fe$): monoclinic, $C2/c$, $a = 17.430(13)$, $b = 17.746(9)$, $c = 10.164(7)$ Å, $\beta = 110.95(5)°$, $Z = 4$, $V = 2936.02$ Å^3, measurement temperature 290 K, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), 2316 independent reflections, 1419 with $I > 1.96\sigma(I)$, $R = 0.0479$, $wR^2 = 0.1406$, structure solution by direct methods, refinement by full matrix least squares method on F^2 (SHELXL 93). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository numbers CSD-400554 (**1a**) and CSD-400556 (**1b**).

[16] The imidazole ligands could stabilize their orientations in **1b** by π-donor bonds, provided that the $d_{xz, yz}$ orbitals are higher in energy than the d_{xy} orbital and only slightly split in energy. This, however, should be evident in the ESR spectrum [7]. The bond lengths within the imidazole rings in **1b** are 1% shorter than those in **1a** (1.340(6) vs. 1.353(6) Å). While this change is not significant for the individual bonds, it is noteworthy and in agreement with π interactions in **1b** that this shift occurs in the same direction for all bonds. In the iron(II) complex **1a** no stabilization by π-donor bonds is possible, and the sterically most favorable orientation, in the direction of the six-membered chelate rings, is adopted.

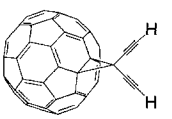
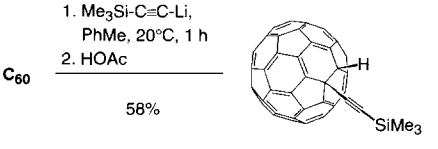
Fullerene–Acetylene Hybrids: On the Way to Synthetic Molecular Carbon Allotropes**



Harry L. Anderson, Rüdiger Faust, Yves Rubin, and François Diederich*

Our interest in carbon-rich materials[1] has prompted us to explore routes to molecular carbon allotropes based on both fullerenes and acetylenes. Among the attractive targets are the cyclic polyynes **1** and **2** in which peripheral C_{60} spheres stabilize a central acetylenic core through steric shielding and interact with this core through the cyclopropane rings. Related macrocyclic polyynes have been reported,[1, 2] but "end-capping" with methanofullerenes would avoid the incorporation of heteroatoms and yield new types of carbon allotropes.



1 **2**

A common precursor for compounds **1** and **2** is diethynylmethanofullerene **3**[3] from which the desired acetylenic carbocycles could be assembled by oxidative coupling. In light of the radical-trapping properties of C_{60},[4] the viability of such a reaction for coupling fullerene derivatives was questionable.

3

Here we describe the first steps towards the construction of **1** and **2**, namely two synthetic entries to symmetrically and unsymmetrically substituted diethynylmethanofullerenes, as well as the previously unknown hydroethynylation of C_{60} leading to **4** (Scheme 1).[5] The formation of bis(butadiynyl)methanofullerene **5** (Scheme 3) and the dumbbell-shaped

derivative **6** (Scheme 4) under Hay coupling conditions demonstrates the feasibility of the proposed route to the new allotropes **1** and **2**.

Nucleophilic addition to C_{60} is among the most common reaction types in fullerene chemistry.[5, 6] Surprisingly, the use of acetylide nucleophiles has not previously been reported. Initial attempts to react C_{60} with chloromagnesium acetylide failed, and no reaction was observed in toluene at room temperature, even with a large excess of the nucleophile. Lithium trimethylsilylacetylide, on the other hand, reacted with the fullerene under these conditions to produce **4** upon quenching with acetic acid (Scheme 1). This reaction proceeded much slower than the addition of aromatic or aliphatic organolithium and Grignard reagents.[5] The structure of **4** is evident from its spectral data (Table 1); the characteristic ^{1}H NMR resonance at $\delta = 6.92$ corresponds to the fullerene proton. The addition proceeds in a 1,2 fashion across the junction of two six-membered rings, as judged by the 32 distinct fullerene resonances in the ^{13}C NMR spectrum of **4**. The signals of the newly formed sp^3 carbon centers appear at $\delta = 61.8$ (C_{sp^3}–H) and $\delta = 55.1$ (C_{sp^3}–C_{sp}). Evidently, the successful synthesis of **4** suggests a new entry into mixed fullerene–acetylene molecular scaffolding.[1b, 7]

Rubin et al.[3] recently prepared symmetrically protected bis(trimethylsilylethynyl)methanofullerene[60] by reacting C_{60} with carbenes derived from the tosylhydrazone of 1,5-bis(trimethylsilyl)-1,4-pentadiyn-3-one.[8] We applied this methodology to obtain the unsymmetrically protected species **7** in 28% yield (Scheme 2). We also explored an ionic route to diethynylmethanofullerenes inspired by Bingel's recent report[9] that fullerenes can be cyclopropanated by α-halocarbonyl compounds in the presence of base. We found that bromopentadiyne **8**[10] reacts with C_{60} to form bis(trimethylsilylethynyl)methanofullerene **9** in 55% yield (Scheme 2) in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). Since the pK_a of **8** is probably less than 21 (in EtOH),[11] it should be acidic enough to be deprotonated by DBU (pK_a = 24.3 in MeCN).[12] Alternatively DBU could react as a nucleophile and displace bromide from **8** to give a more acidic salt,[13] which would be deprotonated to form an ylid, which could attack C_{60}.

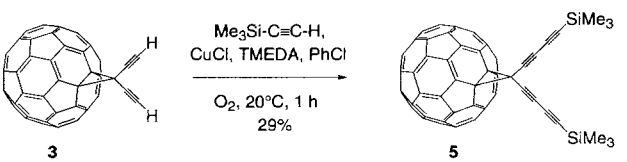
UV/VIS: λ_{max} [nm] = 258 (ε 107000), 329 (35500), 436 (2200), 488 (1500), 687 (100). FAB-MS: *m/z* 1011.0 (M^+), 720.0 (C_{60}).

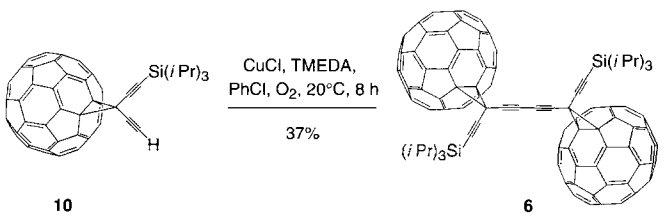


10: FT-IR: $\tilde{\nu}$ = 3289 (m), 2922 (s), 2856 (s), 2167 (w), 2119 (w), 1456 (m), 1422 (m), 672 (m), 522 (s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.88 (s, 1 H), 1.20 (s, 21 H). ^{13}C NMR (CS_2/C_6D_6): δ = 146.21, 146.12, 145.78, 145.65 (several overlapping peaks), 145.30, 145.19, 145.15, 144.97, 144.89, 144.28, 144.26, 143.28 (several overlapping peaks), 143.18, 142.61, 142.41, 142.36, 142.34, 141.38, 141.36, 139.42, 98.21, 87.61, 76.47, 74.94, 73.35, 29.51, 18.95, 11.66. UV/VIS: λ_{max} [nm] = 258 (ε 148000), 328 (45700), 406 (4700), 434 (3200), 493 (2200), 688 (890). FAB-MS: *m/z* 939.0 (M^+), 719.8 (C_{60}).

[a] ^{1}H and ^{13}C NMR spectra were measured at 500 MHz and 125.8 MHz, respectively; IR and UV/VIS spectra were recorded in KBr and CH_2Cl_2, respectively.

The silyl groups in **7** and **9** greatly enhance the solubility of these fullerene derivatives in common organic solvents (THF, hexane, aromatic hydrocarbons), which facilitates their spectroscopic characterization (Table 1). Both cyclopropanations occur at the 6,6 ring junction leading to structures with closed transannular bonds.[14] In the ^{13}C NMR spectra all 16 C_{sp^3} fullerene resonances expected for **9** (C_{2v} symmetry) are well resolved between δ = 147 and δ = 139, while only 28 out of the 31 C_{sp^3} resonances are clearly discernible for **7** with C_s symmetry. Diagnostic for both compounds are the resonances of the methano bridge C atoms at δ = 32.24 (**7**) and δ = 27.91 (**9**), along with their respective bridgehead carbon signals at δ = 75.98 (**7**) and δ = 76.04 (**9**).

Protodesilylation of **7** and **9** is rapidly effected by K_2CO_3 in MeOH/THF to generate regioselectively deprotected **10** and the parent hydrocarbon **3**.[3] The NMR signals of the acetylenic protons appear at δ = 2.87 (**3**) and δ = 2.88 (**10**, Table 1).



In order to probe the potential of diethynylmethanofullerenes as building blocks for molecular carbon allotropes, **10** and **3** were subjected to Hay coupling conditions (Schemes 3 and 4). Initial attempts at homocoupling of **3** did not yield tractable products, which prompted us to try heterocoupling to trimethylsilylacetylene under conditions previously developed for the preparation

Scheme 3. Synthesis of dibutadiynylmethanofullerene **5**. TMEDA = *N,N,N',N'*-tetramethylethylenediamine.

of butadiynyl porphyrins.[15] In situ preparation of the Hay catalyst [CuCl·TMEDA, O_2] in chlorobenzene in the presence of **3** and a large excess of trimethylsilylacetylene indeed furnished bis(butadiynyl)methanofullerene **5**, which was readily isolated by column chromatography (SiO_2, cyclohexane). The butadiynyl substructure of **5** is easily identified in its ^{13}C NMR spectrum by the four resonances observed in the typical range for acetylenic carbon atoms (δ = 89.32, 87.57, 70.88, and 68.62; Table 1). A total of 17 distinct fullerene carbon signals (16 between δ = 146 and 138, one at δ = 74.41) indicates no change of symmetry on passing from **3** to **5**, which demonstrates that the methanofullerene moiety remains intact in the course of the coupling reaction.

Similarly, monoprotected diethynylmethanofullerene **10** could be homocoupled to the butadiynyl-linked "dimeric" methanofullerene **6** in 37% yield (Scheme 4). In contrast to previously

10 **6**

Scheme 4. Synthesis of the dumbbell-shaped fullerene derivative **6**.

reported dumbbell-shaped molecules containing two fullerene moieties,[16] the black shiny crystals of **6** are reasonably soluble in cyclohexane, toluene, and CS_2, and complete spectroscopic characterization was possible (Table 1, Fig. 1). Matrix-assisted

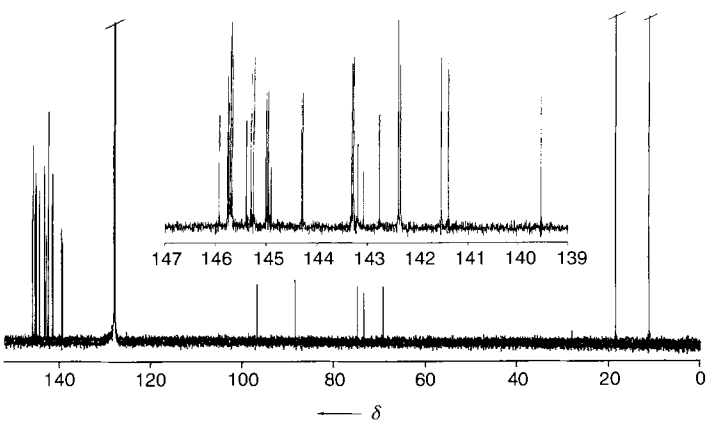


Fig. 1. ^{13}C NMR spectrum of **6** in CS_2/C_6D_6. The inset shows an expansion of the aromatic region of the fullerene signals.

laser-desorption time-of-flight (MALDI-TOF) mass spectrometry in the negative-ion mode with 2,5-dihydroxybenzoic acid as the matrix confirmed the "dimeric" nature of **6** with a signal at m/z 1877.6 ($C_{148}H_{42}Si_2$; calculated 1876.1 g mol^{-1}). In the ^{13}C NMR spectrum (Fig. 1) 31 fullerene resonances are distinguishable (30 in the aromatic region, one at δ = 73.95). The signals of the four acetylenic carbon atoms appear at δ = 97.20, 88.90, 75.31, and 69.72, while the methano bridge C atoms resonate at δ = 28.61. The electronic absorption spectrum is remarkably similar in shape and intensity to those of other methanofullerenes,[14] which indicates little electronic interaction between the two fullerene units. The electrochemistry of this material is currently under investigation, and we are working on transforming **5** and **6** into new molecular carbon allotropes.

Experimental Procedure

4: A solution of C_{60} (500 mg, 0.695 mmol) in toluene (600 mL) was treated with lithium trimethylsilylacetylide (10 mL of 0.2 M solution in THF, 2.0 mmol) under N_2. The purple solution slowly discolored, and a black precipitate formed. After 1 h thin-layer chromatography (TLC) showed that most of the C_{60} had been consumed, so the reaction was quenched with acetic acid (0.5 mL). The product was isolated by column chromatography (SiO_2/cyclohexane), and recrystallization from CS_2/Et_2O yielded 324 mg (58%) of black crystals.

9: DBU (300 μL, 2.01 mmol) was added under N_2 to a solution of C_{60} (500 mg, 0.694 mmol) and **8** (400 mg, 1.39 mmol) in toluene (550 mL). After 4 h the product was isolated by column chromatography (SiO_2/cyclohexane). The product was recrystallized from cyclohexane to yield 305 mg (47% or 55% based on recovered starting material) of large black cubic crystals.

10: To a solution of **7** (126 mg, 0.125 mmol) in THF (50 mL) was added MeOH (25 mL) and K_2CO_3 (50 mg, 0.362 mmol). After 20 min at room temperature the reaction was complete by TLC. The suspension was partitioned between toluene (100 mL) and H_2O (100 mL), and the organic phase was washed with H_2O (3 × 20 mL) and dried over $MgSO_4$. Filtration and removal of solvent left a red solid that was loaded on a short column of silica and eluted with hexane. Evaporation of solvent furnished a black material that was recrystallized from CS_2/Et_2O to yield 75 mg (64%) of bronze flakes.

6: A suspension of **10** (70 mg, 0.075 mmol) and CuCl (600 mg, 6.0 mmol) in chlorobenzene (100 mL) was stirred vigorously with TMEDA (0.85 mL, 5.5 mmol) under dry air for 8 h. The product was isolated by column chromatography (SiO_2/cyclohexane), and recrystallization from CS_2/Et_2O furnished 26 mg (37%) of black, shiny plates.

1,1-Di-, 1,2,3-Tri-, and 1,1,4,4-Tetra-*tert*-butyl-1,3-butadiene**

Henning Hopf,* Ralf Hänel, Peter G. Jones, and Peter Bubenitschek

Dedicated to Professor Virgil Boekelheide on the occasion of his 75th birthday

Highly substituted dienes exist predominantly in nonplanar, and in the extreme case orthogonal, conformations, which in turn result in chemical behavior distinctly different from that of planar 1,3-dienes.[1] Prerequisites for a systematic study of the relationship between orthogonality and reactivity of di- and polyenes are methods of synthesis that are not only efficient, but also offer sufficient scope for application. Now, after we presented a procedure for the convenient preparation of highly alkylated 1,3-dienes that have *tert*-butyl groups at C2 and C3 in 1991, we describe new routes to terminal *tert*-butylated butadienes.

5,5-Dimethyl-4-*tert*-butyl-1,3-hexadiene (**3**) is accessible by the reaction of di-*tert*-butylketone (**1**) with allylmagnesium bromide and dehydration of the resulting alcohol **2**. Depending on the reaction conditions, varying amounts of the Wagner–Meerwein product **4** are formed in this elimination: whereas this 1,5-hexadiene derivative arises exclusively with *para*-toluenesulfonic acid/benzene, the proportion when using thionyl chloride/pyridine is only about 70%, and a virtual reversal of the product ratio (89% **3**, 11% **4**, GC analysis) is achieved if **2** is initially converted into its *p*-nitrobenzoate, and this ester is finally decomposed thermally (100 → 160 °C); **3** is obtainable in gram quantities in this manner.

For the synthesis of (*Z*)-4-*tert*-butyl-2,2,6,6-tetramethyl-5-methylene-3-heptene (**6**) the previously employed "*tert*-butylcuprate" method with diacetate **5** as starting material proved advantageous (yield 63%). 3,6-Di-*tert*-butyl-2,2,7,7-tetramethyl-3,5-octadiene (**8**) was finally obtained by reduction of the diol **7** with $LiAlH_4$. All experiments afforded **8** as a mixture with the [3]cumulene **9** and the allyl alcohol **10** (typical composition of the reaction mixture after a reduction period of 33 days: 3% **7**, 16% **10**, 67% **8** + **9**, 13% unidentified product; GC analysis).

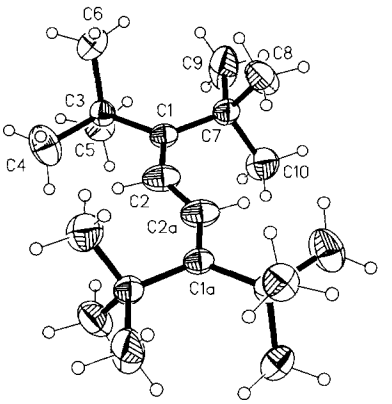

Fig. 1. The molecular structure of **8** in the crystal (ellipsoids represent 50% probability).

Although the complete chromatographic separation/purification of these compounds has not yet been successful, crystals that were suitable for an X-ray crystal analysis[3] could be picked out manually. As Figure 1 shows, **8** has crystallographic inversion symmetry. The bond lengths C1–C2 (134.6(3) pm) and C2–C2a (135.3(4) pm) differ only marginally. The torsion angle C3-C1-C2-C2a (−179.3(4)°) and C1-C2-C2a-C1a (180°) confirm the planarity of the molecular skeleton. The angle C1-C2-C2a is widened to 142.2(3)°,[4] which apparently in this sterically strained system is easier to tolerate than loss of planarity.

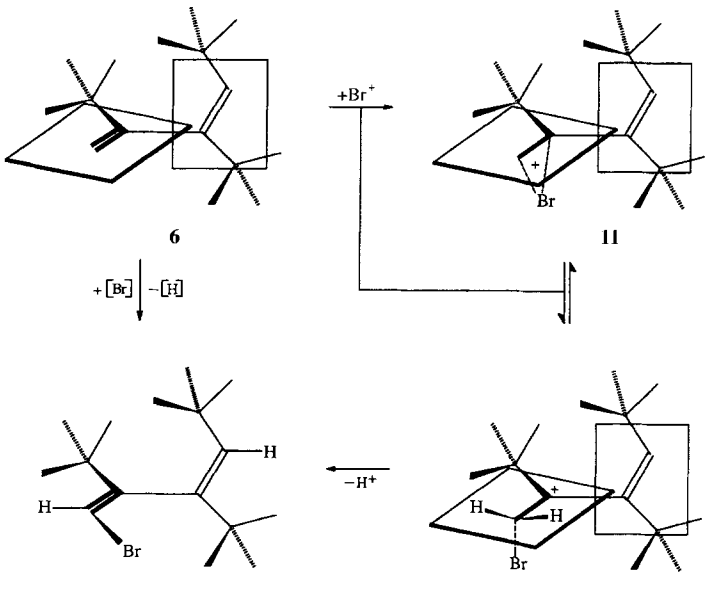
To gain a first impression of the reactivity of the new dienes, whose structures can deduced without ambiguity from the spectroscopic data (Table 1), we treated **6** with bromine in trichloro-

Table 1. Spectroscopic data of **3**, **6**, and **8** [a].

3: ^{1}H NMR ($CDCl_3$): δ = 1.23, 1.36 (2 × s, each 9H, *t*Bu), 5.03–5.09 (m, 2H, 1-H), 6.02 (d, J = 11.2 Hz, 1H, 3-H), 6.93–7.03 (m, J = 11.2 Hz, 1H, 2-H); ^{13}C NMR ($CDCl_3$): δ = 156.8 (s, C-4), 136.4, 124.4 (2 × d, C-2, C-3), 115.9 (t, C-1), 38.7, 37.7 (2 × s, C-5, C-7), 33.7, 31.8 (2 × q, CH_3); UV (CH_3CN): λ_{max} (ε) = 242 nm (8620); IR (film): $\tilde{\nu}$ = 3087 cm^{-1} (= CH_2), 1620 (C = C), 901(> C = CH_2); MS (70 eV): *m/z* (%) = 166 (12, M^+), 109 (100), 57 (92); elemental analysis for $C_{12}H_{22}$ (166.31): calc. C 86.67, H 13.33; found C 86.58, H 13.31

6: ^{1}H NMR ($CDCl_3$): δ = 1.04, 1.08, 1.18 (3 × s, each 9H, *t*Bu), 4.76 (d, J = 1.8 Hz, 1H, 8-H), 5.15 (d, J = 1.9 Hz, 1H, 8-H), 5.32 (s, 1H, 3-H); ^{13}C NMR ($CDCl_3$): δ = 156.3, 146.2 (2 × s, C-4, C-5), 135.2 (d, C-3), 114.3 (t, C-8), 36.2, 35.0, 33.4 (3 × s, C-2, C-6, C-9), 32.5, 31.6 (q, CH_3); UV (CH_3CN): λ_{max} (ε) = 195 nm (13600); IR (film): $\tilde{\nu}$ = 3078 cm^{-1} (= CH_2), 901 (> C = CH_2); elemental analysis for $C_{16}H_{30}$ (222.41): calc. C 86.40, H 13.60; found C 86.38, H 13.66

8: (mixture with **9**): ^{1}H NMR ($CDCl_3$): δ = 1.23, 1.33 (2 × s, each 18 H, *t*Bu), 6.42 (s, 2H, 4-H, 5-H); ^{13}C NMR ($CDCl_3$): δ = 151.2 (s, C-3, C-6), 123.0 (d, C-4, C-5), 39.1, 37.2 (2 × s, C-2, C-7, C-9, C-11), 32.74, 32.0 (q, CH_3); GC/MS (40 eV): *m/z* (%) = 278 (2, M^+), 165 (34), 109 (24), 57 (100)



12: ^{1}H NMR ($CDCl_3$): δ = 1.05, 1.18, 1.22 (3 × s, each 9H, *t*Bu), 5.39 (s, 1H, 4-H), 6.28 (s, 1H, 1-H); ^{13}C NMR ($CDCl_3$): δ = 154.1, 140.0 (s, C-4, C-5), 137.9 (d, C-8), 106.8 (d, C-3), 37.5, 36.1, 33.9 (3 × s, C-2, C-6, C-9), 32.2, 31.2, 29.9 (3 × q, CH_3); UV (CH_3CN): λ_{max} (ε) = 194 nm (14400); IR (Film): $\tilde{\nu}$ = 3078 cm^{-1} (= CH_2), 647 (C–Br); GC/MS (40 eV): *m/z* (%) = 302/300 (2, M^+), 246/244(2), 165(7), 109(7), 57(100); elemental analysis for $C_{16}H_{29}Br$ (301.31): calc. C 63.78, H 9.70; found C 63.69, H 9.55.

[a] The NMR spectra were recorded at 400 MHz(^{1}H) and 100.6 MHz (^{13}C).

[**] Sterically Hindered Double-Bond Systems, Part 6. We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for the support of our research. Part 5: H. Hopf, M. Traetteberg, R. Hänel, *Chem. Ber.* in press.

methane at 0–5 °C. Instead of the expected 1,2- and/or 1,4-adducts, the monobromide **12** in which the butadiene part has been *retained* was isolated exclusively (yield 60%).

To explain this observation we postulate an initial Br attack at the sterically less hindered side of the less substituted double bond of **6**. Whether this forms a bromonium ion (**11**) or an "open carbenium ion" (**13**, orthogonal allyl cation) is unknown. At any rate this intermediate cannot be captured by the usual back-side attack because of extreme steric shielding. It can, however, be stabilized by deprotonation to form **12**. The *trans* arrangement of bromine and *tert*-butyl substituents in **12** is concluded from NOE difference measurements (Table 1). Thus **6** favors substitution (by addition/elimination) over addition, and thus behaves *regeneratively, like a classical arene*.

[3] Crystal data for **8**: $C_{20}H_{38}$. $P\bar{1}$, $a = 609.8(2)$, $b = 820.3(3)$, $c = 1028.0(3)$ Å, $\alpha = 75.73(2)$, $\beta = 85.71(2)$, $\gamma = 71.47(2)°$, $V = 0.4725(3)$ Å^3, $Z = 1$, $T = -100$ °C. A colorless prism 0.7 × 0.45 × 0.12 mm was mounted in inert oil (type RS3000, Fa. Riedel de Haën). On a Siemens R3 diffractometer, 2736 intensities ($Mo_{K\alpha}$ radiation, $\lambda = 71.073$ pm, $2\theta_{max} = 55°$) were measured, of which 2151 were independent ($R_{int} = 0.017$). The structure was solved with direct methods and refined anisotropically on F^2 (program SHELXL-93, G. M. Sheldrick, University of Göttingen). The final $wR(F^2)$ value was 0.186, with a conventional $R(F)$ of 0.061, for 97 parameters. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-400686 and the journal citation.
[4] A reviewer pointed out that the wide angle C1-C2-C2a could be a result of disorder in view of the "large displacement parameters" of the atom C2. Such effects are always possible in principle and cannot be completely ruled out here. With a U_{eq} value of only 0.046 Å^2 for C2, however, we see no reason to expect a particularly large error and also no chance to resolve any disorder.

Synthesis and Ligative Behavior of a Gallacyclopentadiene**

Alan H. Cowley,* François P. Gabbaï, and Andreas Decken

Boracyclopentadienes (boroles) have been known for several years[1] and continue to attract attention, for example, as ligands.[2] However, surprisingly little information is available regarding the heavier group 13 metallacyclopentadienes. In fact, structurally authenticated examples of such compounds are confined to one aluminacyclopentadiene, which was isolated as an Et_2O adduct and as a Ni(cod) complex (cod = 1,5-cyclopentadiene).[3] We report here the synthesis and X-ray crystal structure of the first neutral gallacyclopentadiene[4] and the corresponding $(\eta\text{-}C_5H_5)Co$ complex.

Since 1-phenyl-2,3,4,5-tetramethylboracyclopentadiene dimerizes,[5] it was clear that the isolation of the desired gallium analogue demanded the use of a bulkier aryl group. Accordingly, the zirconacyclopentadiene **1**[6] was treated with $Ar'GaCl_2$ (Ar' = 2,4,6-tBu$_3$C$_6$H$_2$)[7] in C_6H_6 solution. The reaction, which takes place over a 48 h period at 25 °C, affords a 73% yield of gallacyclopentadiene **2**.

1

2, M = Ga
3, M = In

Ar' = 2,4,6-tBu$_3$C$_6$H$_2$; X = Cl, Br

The proposed formula for **2** is consistent with elemental analysis data and with the observations that a) the base peak in the CI mass spectrum corresponds to M^+, b) no peaks are detectable at higher m/z values (Table 1), and c) ^{1}H and ^{13}C NMR spectra exhibit the anticipated resonances in the appropriate intensity ratios (Table 1).

An X-ray structure analysis of **2**[8] showed that the asymmetric unit contained two independent molecules. However, the metrical parameters for molecules I (Fig. 1) and II are very similar and neither molecule exhibits unusually short intermolecular interactions. The five-membered gallacyclopentadiene ring is planar, the maximum deviation from the least-squares plane being 0.013 Å for C(21). The Ar'Ga group is bonded to the tetramethylbutadiene moiety in a symmetrical fashion such that the endocyclic bond angle is about 45° smaller than the exocyclic angles. The Ga–C(aryl) bond is slightly shorter than the other two Ga–C bonds; however, all three distances fall in the range for single bonds. The double bonds within the gallacyclopentadiene ring are localized as indicated by the fact that the C(20)–C(21) distance is considerably larger than the other two C–C distances. A further interesting feature of the structure of **2** relates to the near orthogonality of the Ar' and gallacyclopentadiene rings (dihedral angles = 83.6 and 84.4° in molecules I and

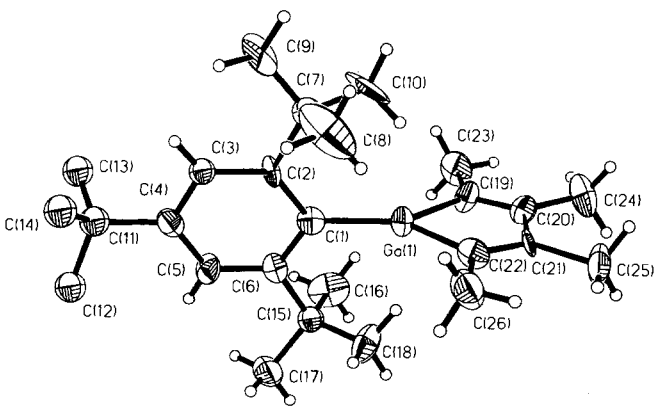
II, respectively). Such an arrangement, which minimizes the steric interactions between the *o*-*t*Bu and 2,5-methyl groups, undoubtedly contributes to the stability of the base-free gallacyclopentadiene **2**.



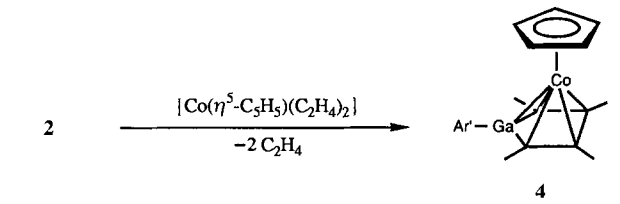


Fig. 1. View of **2** showing the atom labeling scheme. There are two independent molecules in the asymmetric unit; molecule I is shown here. The *p*-*t*Bu groups are disordered. Important bond lengths [Å] and angles [°]: Ga(1)-C(1) 1.888(21), Ga(1)-C(19) 1.953(22), Ga(1)-C(22) 1.937(26), C(19)-C(20) 1.313(37), C(20)-C(21) 1.542(37), C(21)-C(22) 1.312(37), C(1)-Ga(1)-C(19) 134.5(10), C(1)-Ga(1)-C(22) 135.4(10), C(19)-Ga(1)-C(22) 90.1(11), Ga(1)-C(19)-C(20) 108.0(18), C(19)-C(20)-C(21) 116.1(22), C(20)-C(21)-C(22) 118.9(22), Ga(1)-C(22)-C(21) 106.9(19).

The reaction of **1** with $Ar'InBr_2$[7a] proceeds analogously to that with $Ar'GaCl_2$ and affords the first neutral indacyclopentadiene **3**. It has not yet been possible to grow single crystals of **3** suitable for X-ray analysis. However, the mass spectral and NMR data for **3** (Table 1) are remarkably similar to those for **2**, hence an analogous structure can be proposed.

The ligative behavior of **2** is of potential interest in regard to the development of single-source precursors for the deposition of intermetallic phases such as β-CoGa.[9] Thus **2** reacts with $[Co(\eta^5\text{-}C_5H_5)(C_2H_4)_2]$ to afford the cyclopentadienylcobalt(I) complex **4**.

The proposed formula for **4** is in accord with elemental analysis data and the observation of the molecular ion together with satellites of the correct isotopic abundances in the CI mass spectrum (Table 1). Support was provided by the ^{1}H and $^{13}C\{^1H\}$ spectra which exhibit all the expected resonances in the appropriate relative intensities. An X-ray structure analysis of **4** (Fig. 2)[8] revealed that attachment of the $(\eta^5\text{-}C_5H_5)$Co moiety

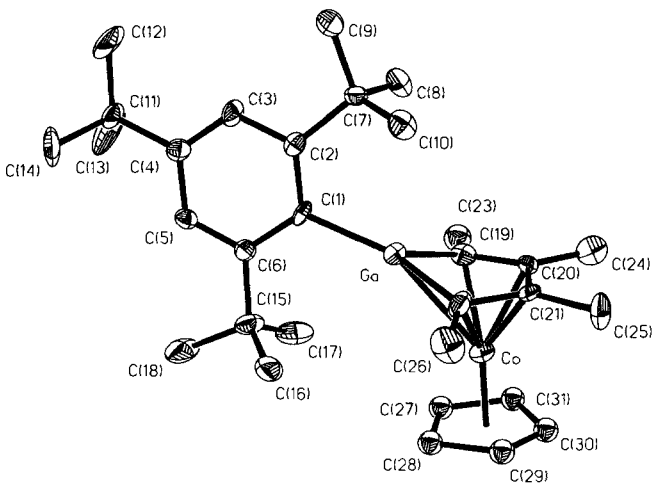

Fig. 2. View of **4** showing the atom labeling scheme. Important bond lengths [Å] and angles [°]: Ga-C(1) 1.988(12), Ga-C(19) 1.921(12), Ga-C(22) 1.918(15), C(19)-C(20) 1.414(22), C(20)-C(21) 1.459(19), C(21)-C(22) 1.434(19), Co-Ga 2.706(2), Co-C(19) 2.089(13), Co-C(20) 1.986(24), Co-C(21) 1.981(13), Co-C(22) 2.109(13), C(1)-Ga-C(19) 133.7(6), C(1)-Ga-C(22) 140.2(5), C(19)-Ga-C(22) 85.9(6), Ga-C(19)-C(20) 110.6(10), C(19)-C(20)-C(21) 113.6(11), C(20)-C(21)-C(22) 114.4(12), Ga-C(22)-C(21) 109.6(10). The dihedral angle between the C(19)-Ga-C(22) and Ga-C(1)-C(2)-C(3)-C(4)-C(5)-C(6) planes = 85.6 .

to the gallacyclopentadiene ring resulted in the following: a) the gallacyclopentadiene ring changes from a planar to an envelope conformation with an angle of 21.8° between the C(19)-Ga-C(22) and C(19)-C(20)-C(21)-C(22) planes such that the Ga atom resides 0.52 Å above the latter plane; b) within experimental error, all three C–C bond lengths in the gallacyclopentadiene ring became essentially equal; c) the Ga–C(aryl) bond length increases by about 0.1 Å. Although observation a) implies η^4 attachment of the $(\eta^5\text{-}C_5H_5)$Co moiety to the gallacyclopentadiene ring, it is interesting to note that the Co–Ga distance in **4** (2.706(2) Å) is considerably shorter than the sum of van der Waals radii and only slightly longer than the range of 2.38 to 2.58 Å that has been reported for the few compounds that feature this linkage.[10] From the standpoint of the number of skeletal bonding electrons, **4** can be viewed as a *nido* cluster provided the Ar'Ga moiety is included in the framework.

Experimental Procedure

2: Solid $Ar'GaCl_2$ (1.40 g, 3.63 mmol) and $[(C_5H_5)_2Zr(C_4Me_4)]$ (1.20 g, 3.63 mmol) were mixed in a 100 mL Schlenk flask, then dissolved in benzene (30 mL). The reaction mixture was stirred for 48 h at 25 °C following which the benzene was

removed under reduced pressure. Extraction of the resulting residue with pentane (15 mL), followed by solvent removal, afforded a 73% yield of white microcrystalline **2** (m.p. 103 °C). X-ray quality crystals were grown from a concentrated pentane solution.

4: A mixture of $[(C_5H_5)Co(C_2H_4)_2]$ (0.12 g, 0.69 mmol) and **2** (0.29 g, 0.69 mmol) in benzene (5 mL) was stirred for 15 h following which the benzene was removed under reduced pressure. Extraction of the residue with pentane, followed by cooling of the resulting solution to −20 °C resulted in two successive crops of crystals of **4** (m.p. 201 °C) in a combined yield of 40%.

$[Be(dad)_2]$: Synthesis and Structure of a Diazabutadieneberyllium Complex**

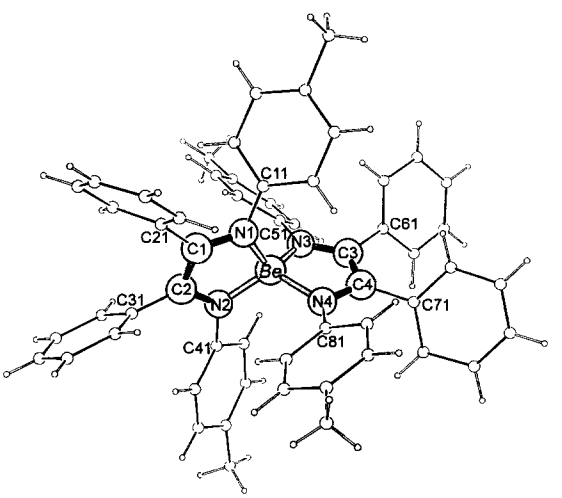
Karl-Heinz Thiele,* Volker Lorenz, Gerhard Thiele, Peter Zönnchen, and Joachim Scholz

Diazadiene complexes of electron-poor transition elements[1, 2] are most often prepared from metal halides and diazabutadienes in the presence of alkali metals or magnesium and are a well-investigated class of compounds. In contrast, little information is available about diazadiene complexes of elements of the second main group.[3–5] We report here on the synthesis of a diazadieneberyllium complex and its structure in the solid state and in solution.

On treatment of beryllium chloride with the diazadiene **1** and sodium according to Equation (a), crystals with a metallic luster of composition $[Be(dad)_2]$ (**2**) can be isolated.

$$\underset{\mathbf{1}}{BeCl_2 + 2\ dad} + 2\ Na \xrightarrow{\text{toluene}} \underset{\mathbf{2}}{[Be(dad)_2]} + 2\ NaCl \qquad (a)$$

In crystalline form **2** is astoundingly stable to oxygen and moisture. In finely powdered form or in solution an immediate reaction takes place, recognizable by the color change from black-green to yellow. In hydrocarbons **2** is only slightly soluble; these solutions are, however, strongly colored. The EI mass spectrum contains an intense molecular ion peak [*m*/*z* (%) 786 (75)] and the characteristic fragmentation pattern of a diazadiene. The volatility under conditions of the mass spectrometric experiment indicates that **2** is monomeric. The structure determined by X-ray diffraction is shown in Figure 1.[6]



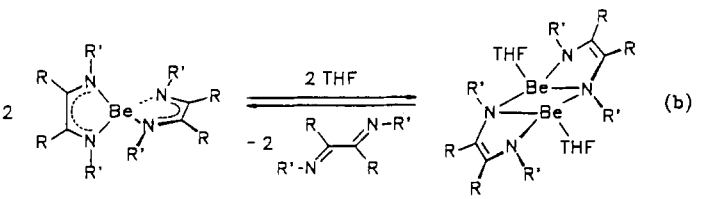


Fig. 1. Crystal structure of **2**. Selected bond lengths [pm] and angles [°]: Be-N1 170(2), Be-N2 169(2), Be-N3 168(2), Be-N4 173(2), N1-C1 132(1), N2-C2 137(1), N3-C3 134(1), N4-C4 135(1), C1-C2 141(1), C3-C4 140(1), N1-C11 141(1), C1-C21 151(1), C2-C31 148(1), N2-C41 143(1), N3-C51 143(1), C3-C61 148(1), C4-C71 150(1), N4-C81 141(1); N1-Be-N2 94.3(8), N3-Be-N4 94.4(8), N1-Be-N3 115.6(10), N1-Be-N4 113.4(10), N2-Be-N3 123.1(11), N2-Be-N4 117.6(10), Be-N1-C1 108.5(8), Be-N2-C2 109.4(9), Be-N3-C3 109.9(9), Be-N4-C4 106.7(8), N1-C1-C2 116.0(10), C1-C2-N2 111.4(10), N3-C3-C4 113.3(10), C3-C4-N4 115.2(10).

According to the crystal structure two *cis*-configured dad ligands surround the Be atom; the ligating N atoms occupy the vertices of a distorted tetrahedron. The Be–N distances lie between 167 and 174 pm and are thereby longer than those in beryllium amides, which are, for example, 157.3 pm in $[\{Be(NMe_2)_2\}_3]$ and 156.2 pm in $[Be\{N(SiMe_3)_2\}_2]$.[7, 8] The heterodiene frameworks N1–C1–C2–N2 and N3–C3–C4–N4 together with the Be atom form two planes that are almost orthogonal to each other. Thus, a spiranoid system is present. The C=N and C–C bond lengths in the free ligand are 127.0 and 152.7 pm, respectively.[9] Relative to these lengths, the N–C bonds in **2** are distinctly

lengthened and the C–C bonds shortened, from which a charge delocalization in the ligand may be concluded. The EPR spectrum of the crystalline compound displays an intense signal without fine structure ($g = 2.004$), which suggests that **2** is paramagnetic. The spectrum does not change on dissolving the compound in nonpolar solvents ($g = 2.006$). Since in the EPR spectrum of **2** no half field signal is observed, the dad ligands are independent radical anions each with spin $S = 1/2$, and the Be atom is in the oxidation state II. Analogous ions also exist in diazadiene complexes of aluminum and gallium. In these compounds only one diazadiene ligand is present as radical ion; the other can be formulated as an enediamide ion.[10, 11] Comparable with **2** are diazadienelanthanide complexes of the type $[Ln(NR{=}CH{-}CH{=}NR)_3]$ containing exclusively radical anions on the metal atom. Because the solubility of **2** is too small and its nature is paramagnetic, no interpretable ^{1}H NMR spectrum could be obtained in [D$_8$]toluene. Surprisingly, however, sharp signals are observed in the spectrum recorded in [D$_8$]THF. Under the influence of the donor, **2** is converted into the diamagnetic compound **3** accord-

R = C$_6$H$_5$, R' = C$_6$H$_4$-4-CH$_3$

ing to Equation (b): an intramolecular disproportionation takes place in which one of the radical anions transfers its electron to the other ligand at the Be atom to form a free dad ligand and an enediamide ion. Possibly a beryllium enediamide intermediate is formed first and stabilizes by dimerizing with the formation of enediamide bridging ligands to yield **3**. In the ^{1}H NMR spectrum this reaction can be monitored by the appearance of a singlet for the methyl protons of the free ligand **1** at $\delta = 2.16$ and two singlets for the methyl groups of the nonequivalent *p*-tolyl groups of the enediamide ions at $\delta = 2.24$ and 2.26. Analogously the ^{13}C NMR spectrum of **1**, recorded in [D$_8$]THF, displays the CH$_3$ signal of **1** at $\delta = 20.93$ and two singlets at $\delta = 23.19$ and 14.34 for the CH$_3$ groups of the enediamide ligands of **3**. Similar structures with enediamide bridging ligands were discussed for Mg complexes on the basis of NMR data, and were proven for the Mn complex $[\{Mn(NPh{-}CPh{=}CPh{-}NPh)\cdot THF\}_2]$ by X-ray structure analysis.[4] Dimeric structures and indications of equilibria in solution are also prevalent in the conversions of dialkylberyllium compounds with other chelating ligands like *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, 2,2′-bipyridyl, and dimethoxyethane.[13]

Experimental Procedure

2: Anhydrous $BeCl_2$ (0.77 g, 9.66 mmol) were added to a solution of **1** (7.5 g, 19.3 mmol) in toluene (200 mL) at 20 °C. The mixture was stirred for 24 h, after which sodium (0.44 g, 19.3 mmol) was added, and the mixture again stirred for 3 days, during which time the color changes from the initial orange-yellow to deep red and finally dark brown. After the solvent was removed under vacuum, the residue was extracted in a continuous extractor with hot toluene. Compound **2** separates as a black-green, microcrystalline substance. Yield 3.5 g (46%). Repeated recrystallization from hot toluene produces crystals suitable for X-ray structure analysis. Correct elemental analysis (C, H, N); EI-MS (70 eV): *m*/*z* (%): 786 (75) [M^+], 388 (45) [dad$^+$], 194 (100) [Me-4-C$_6$H$_4$N=CPh$^+$].

3: ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): $\delta = 7.85$–6.40 (m, C$_6$H$_5$, C$_6$*H*$_4$-4-Me), 2.26, 2.24 (s, C$_6$H$_4$-4-*Me*); ^{13}C NMR (75 MHz [D$_8$]THF, 25 °C): $\delta = 150$–120 (C$_6$H$_5$, C$_6$H$_4$-4-Me), 23.2, 14.3 (C$_6$H$_4$-4-*Me*).

1: ^{1}H NMR (200 MHz, [D$_8$]THF, 25 °C): $\delta = 2.16$ (s, 6H, C$_6$H$_4$-4-*Me*), 6.82 (d, 4H, $^3J_{(H,H)} = 8$ Hz, C$_6$*H*$_4$-4-Me), 6.44 (d, 4H, $^3J_{(H,H)} = 8$ Hz, C$_6$*H*$_4$-4-Me), 7.82 (m, 4H, C$_6$H$_5$), 7.32 (m, 4H, C$_6$H$_5$).

Bis(tetramethylbutynediol)nickel(0), the First Pure Monoalkyne Complex of Nickel and Its Chemistry**

Dirk Walther,* Andreas Schmidt, Thomas Klettke, Wolfgang Imhof, and Helmar Görls

"Pure" alkyne complexes of nickel, which exclusively contain monoalkynes as ligands can be considered an attractive goal in organometallic synthesis as numerous catalytic transformations of alkynes on nickel(0) centers are known. The simplest stable compound should be of the type $[Ni^0(alkyne)_2]$; however, such complexes have not previously been isolated[1] even though stable platinum(0) complexes of this type exist.[2]

We report here on the synthesis of bis(tetramethylbutynediol)nickel(0) (**1**) the first stable alkyne–nickel complex, which contains solely monoalkynes as ligands and which is formed surprisingly easily by treating $[Ni(cod)_2]$ (cod: cycloocta-1,5-diene) with alkyne [Eq. (a)] in boiling THF (reaction time 6 h). Compound **1** can be obtained from THF/hexane as lemon yellow crystals.

$$[Ni(cod)_2] + 2\ HO{-}C(CH_3)_2{-}C{\equiv}C{-}C(CH_3)_2{-}OH \longrightarrow [Ni\{(HO{-}C(CH_3)_2{-}C{\equiv}C)_2\}] \quad (a)$$

1

According to the results of the crystal structure analysis[3] (Fig. 1) the nickel(0) center is surrounded by four C atoms of the alkyne groups in a distorted tetrahedral fashion. Ni–C and C≡C bond lengths as well as the C≡C–C bond angles lie within the expected range. No agostic interactions are observed for the H atoms of the CH_3 groups and the nickel center; hence, compound **1** truly is an alkyne–nickel(0) complex.

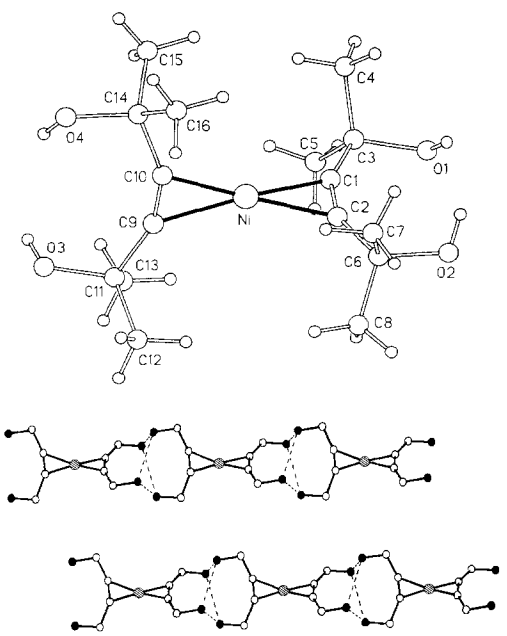

Fig. 1. Structure of molecules **1** and their packing in the crystal (the methyl groups were omitted for clarity). ●: O, ⊗: Ni, ○: C, ---: H bonds. Selected bond lengths [Å] and angles [°]: Ni-C1 1.90(1), Ni-C2 1.851(9), Ni-C9 1.905(7), Ni-C10 1.82(1), C1-C2 1.278(7), C9-C10 1.21(1), O1-O3A 2.74, O1-O4A 2.76, O2-O3A 2.72, O2-O4A 2.81; C1-Ni-C2 39.8(2), C9-Ni-C10 37.7(3), C2-C1-Ni 68.1(8), Ni-C2-C1 72.1(7), C10-C9-Ni 67.3(7), Ni-C10-C9 75.0(8), C2-C1-C3 156(1), C1-C2-C6 154(1), C10-C9-C11 158(1), C9-C10-C14 152(1).

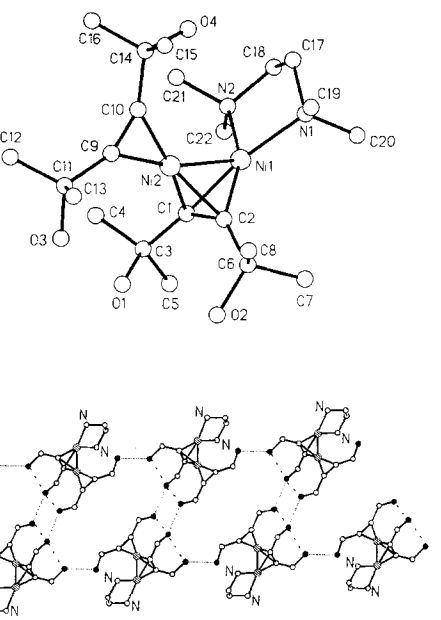
In the solid state the molecules are connected by four intermolecular hydrogen bonds between neighboring, coordinated butynediols. The resulting polymer-like chain structure consists of C_4 tetrahedra that surround the coordinated nickel(0) and O_4 tetrahedra; the two types of tetrahedra are separated by CMe_2 "spacer" groups. (Fig. 1, bottom).

As expected, two signals (for CH_3 and OH) are observed in the ^1H NMR spectrum ($[D_8]$THF) of **1**. In addition to the signals for the $C(CH_3)_2$ groups, the ^{13}C NMR spectrum exhibits one signal for the coordinated alkyne carbon atoms at $\delta = 206$. This strong deshielding of the alkyne carbon atoms in **1** indicates– in conjunction with the short average Ni–C distance of 1.86 Å—that the alkyne ligand acts as a four-electron donor.[9] In contrast, the alkyne has to be considered a two-electron ligand in compounds of type $[NiL_2(butynediol)]$, where the solid-state structure is also influenced by hydrogen bonding.[4]



Compound **1** shows a rich chemistry, which will be illustrated by three examples: Addition of *N,N,N',N'*-tetramethylethylenediamine (tmeda) to **1** results in displacement of one alkyne ligand and formation of an intermediate, which, however, is not isolated but instead reacts further with **1** [Eq. (b)] to yield the

$$\mathbf{1} + \text{tmeda} \longrightarrow [Ni(\text{tmeda})\{\mu\text{-}(HOC(CH_3)_2C{\equiv}C)_2\}] \xrightarrow{\mathbf{1}} [(\text{tmeda})Ni\{\mu\text{-}(HOC(CH_3)_2C{\equiv}C)_2\}Ni\{(HOC(CH_3)_2C{\equiv}C)_2\}] \quad (b)$$

2

deep red, binuclear complex **2**. Binuclear nickel(0) complexes stabilized by phosphane-containing bridging and terminal alkyne ligands are already known for ethyne.[5]

The crystal structure analysis of **2** showed that the molecules are connected by four intermolecular hydrogen bonds to give a double-stranded structure (Fig. 2).[3] Furthermore, there are two intramolecular hydrogen bonds between bridging alkynes and between bridging and terminal alkynes. In contrast to **1**, the two OH groups of the terminal alkyne are far appart.

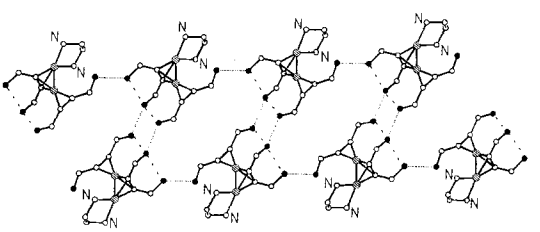


Fig. 2. Structure of molecules **2** and their packing in the crystal (cf. Fig. 1). Selected bond lengths [Å] and angles [°]: Ni1-Ni2 2.449(1), Ni1-C1 1.879(2), Ni1-C2 1.907(2), Ni2-C1 1.968(3), Ni2-C2 1.938(3), C1-C2 1.344(3), Ni1-N1 2.024(2), Ni1-N2 2.035(2), Ni2-C9 1.847(2), Ni2-C10 1.876(3), C9-C10 1.268(3), O1-O2 2.727, O1-O3 2.900, O1-O3A 2.735, O3-O1A 2.735, O2-O4B 2.726, O4-O2C 2.726; Ni1-C1-Ni2 79.04(9), Ni1-C2-Ni2 79.1(1), Ni1-Ni2-C1 48.86(7), Ni1-Ni2-C2 49.86(7), Ni1-C2-C1 68.1(1), Ni2-C1-C2 68.7(1), Ni2-Ni1-C1 52.10(7), Ni2-Ni1-C2 51.01(8), C1-Ni1-C2 41.59(9), Ni2-C2-C1 71.1(1), C1-Ni2-C2 40.24(9), Ni1-C1-C2 70.3(1), N1-Ni1-N2 87.25(9), C3-C1-C2 136.9(2), C6-C2-C1 138.4(2), C11-C9-C10 152.1(2), C14-C10-C9 149.6(2).

As the catalytic cyclotetramerization of alkynes probably proceeds via binuclear nickel species,[6] **2** can be regarded as a model compound for the initial steps of this reaction. Its structure makes it plausible that OH groups—fixed in distinct positions by hydrogen bonds—can influence the selectivity of C–C bond formations (cf. Ref. [7]).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1374 $ 10.00+.25/0

Substitution of an alkyne in **1** by a ligand without functional groups yields compound **3** [Eq. (c)] in which the OH groups

$$\mathbf{1} + \text{cod} \rightarrow [\text{Ni(cod)}\{(\text{HOC(CH}_3)_2\text{C}\equiv)_2\}] \quad \text{(c)}$$

3

form both intra- and intermolecular hydrogen bonds to neighboring complex molecules. This leads to a third "connecting" principle in the crystal, which results in a polymeric chain with helical structure for the coordinated alkynols (Fig. 3).[3]

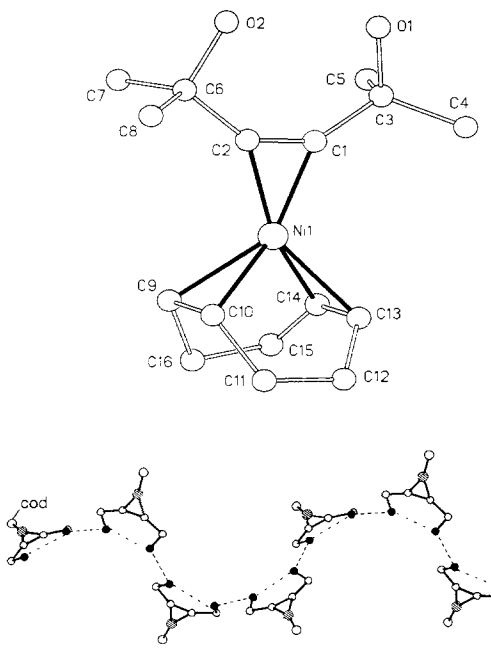

Fig. 3. Structure of molecules **3** and their packing in the crystal (cf. Fig. 1, in the bottom figure the cod ligand is represented by its center of gravity. O3 and O4 represent the hydroxyl groups of the second symmetry-independent molecule of **3**). Selected bond lengths [Å] and angles [°]: Ni1-C1 1.868(6), Ni1-C2 1.854(6), Ni1-C9 2.079(9), Ni1-C10 2.064(8), Ni1-C13 2.080(8), Ni1-C14 2.055(8), C1-C2 1.251(9), O1-O2 2.75, O1-O4A 2.74, O2-O3B 2.79; C1-Ni1-C2 39.3(3), C9-Ni1-C10 37.4(3), C10-Ni1-C13 84.6(4), C13-Ni1-C14 38.3(4), C14-Ni1-C9 86.8(5), C3-C1-C2 144.5(6), C6-C2-C1 142.8(6).

Rupture of the polymeric structure can be achieved by compounds that can interact with the OH groups of the alkynes but do not possess element–H bonds suitable for hydrogen bonding. For example, compound **4**, formed by treating **1** with Ph_3P in acetonitrile [Eq. (d)], has a dimeric structure in the crystal.

$$\mathbf{1} + \text{PPh}_3 \rightarrow [\text{Ni(PPh}_3)_2\{(\text{HOC(CH}_3)_2\text{C}\equiv)_2\}] \quad \text{(d)}$$

4

Acetonitrile is disordered in the crystal and binds to one OH group of the alkynediol. An intermolecular hydrogen bond between neighboring monomers and two intramolecular hydrogen bonds complete the binuclear structure (Fig. 4).[3]

The special significance of the OH groups becomes apparent when comparing the formation reactions of **1**–**3** with the reaction of the dimethoxy derivative of tetramethylbutynediol with $[Ni(cod)_2]$. When using this alkyne under the reaction conditions which otherwise cleanly yield **1**, thermal decomposition to elemental nickel is observed. Therefore, attempts to synthesize a binuclear complex analogous to **2** yielded only decomposition products.

This strengthens the notion that peripheral influences (here hydrogen bonds) do not only play a role in the formation and

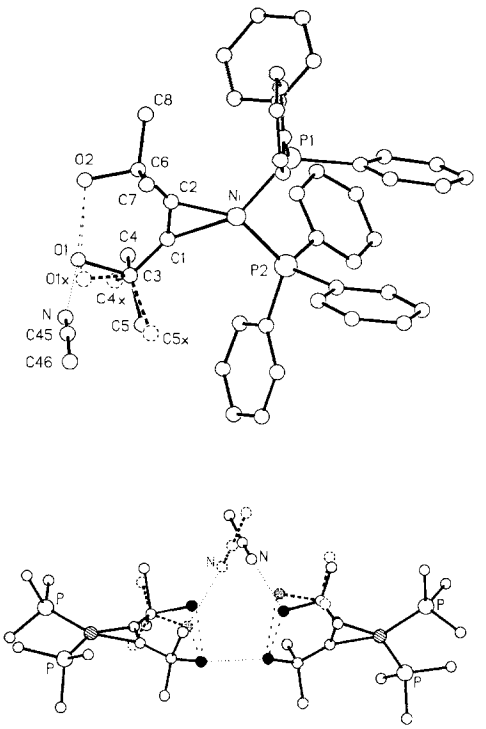

Fig. 4. Structure of molecules **4** and their packing in the crystal (for clarity the phenyl groups are represented in the figure by the ipso carbon atoms). Selected bond lengths [Å] and angles [°]: Ni-P1 2.1892(8), Ni-P2 2.1895(8), Ni-C1 1.88, Ni-C2 1.914(2), C1-C2 1.260(4), O1-O2 2.640, O1-N 2.911, O1X-O2 2.805, O2-O2A 2.828; P1-Ni-P2 101.86(3), C1-Ni-C2 38.7(1), C3-C1-C2 142.2(3), C6-C2-C1 139.9(2).

thermal stability of the solid-state structures but are also of significance in solution.

Experimental Procedure

All reactions were carried out under an inert argon atmosphere.

1: 10 mmol $[Ni(cod)_2]$ and 20 mmol tetramethylbutynediol were refluxed in 30 mL THF for 6 h. After removal of THF and cod by vacuum destillation followed by addition of ether, the reaction product was collected on a filter and washed with hexane. Yield: approximately 60%, lemon yellow powder; single crystals were obtained from THF/hexane. IR (Nujol) $\tilde{\nu} = 1889\ cm^{-1}$ (C≡C), 3271 cm^{-1} (OH). ^1H NMR ([D$_8$]THF): $\delta = 1.36$ (s, CH_3), 2.08 (s, OH). ^{13}C NMR ([D$_8$]THF): $\delta = 32.1$ (CH_3), 69.9 (CMe_2OH), 206.3 (C≡C) [8].

2: To a solution of **1**, prepared in situ by treating 2.8 mmol $[Ni(cod)_2]$ with 5.6 mmol alkyne, was added 10 mmol tmeda, and the mixture was stirred for 2 h. The solution was reduced in volume, and after layering with hexane, red crystals of **2** were obtained. IR (Nujol) $\tilde{\nu} = 1573\ cm^{-1}$ (C≡C), 1842 cm^{-1} (C≡C), 3266 cm^{-1} (OH). ^1H NMR ([D$_8$]THF): $\delta = 1.30$–1.60 (m, CH_3), 2.13–2.29 (m, CH_2), 2.50 (s, N–CH_3), 2.78 (s, N–CH_3), 3.44 (s, OH), 3.83 (s, OH), 4.20 (s, OH). ^{13}C NMR ([D$_8$]THF): $\delta = 32.7$ (CH_3), 33.5 (CH_3), 46.1 (CH_2), 49.3 (N–CH_3), 50.6 (N–CH_3), 58.9 (CMe_2OH), 59.5 (CMe_2OH), 117.9 (C≡) [8].

3: Compound **3** is prepared as described above for **1** from equimolar amounts of $[Ni(cod)_2]$ and alkyne. Orange powder; single crystals were obtained from THF/hexane. IR (Nujol) $\tilde{\nu} = 1807\ cm^{-1}$ (C≡C), 3247 cm^{-1} (OH). ^1H NMR ([D$_8$]THF): $\delta = 1.28$ (s, CH_3), 2.0–2.4 (m, CH_2), 4.24 (s, OH), 5.39 (s, CH=). ^{13}C NMR ([D$_8$]THF): $\delta = 30.8$ (CH_3), 32.0 (CH_2), 70.0 (CMe_2OH), 94.7 (CH=), 137.1 (C≡C) [8].

4: Compound **4** was prepared from $[Ni(Ph_3P)_2(tetramethylbutynediol)]$ [4c] in hot acetonitrile. IR (Nujol) $\tilde{\nu} = 1770\ cm^{-1}$ (C≡C), 2215 cm^{-1} (C≡N), 3286 cm^{-1} (OH) [8].

Magnetic Properties of Aromatic Transition States: The Diels–Alder Reactions**

Rainer Herges,* Haijun Jiao, and Paul von Ragué Schleyer

Dedicated to Professor Werner Kutzelnigg on the occasion of his 60th birthday

Evans et al. first recognized the analogy between the π electrons of benzene and the six electrons in the cyclic transition state of the Diels–Alder reaction of butadiene and ethylene.[1] Generalized through the Woodward–Hoffmann rules[2] and the Hückel–Möbius method[3, 4] to many pericyclic reactions, it has often been suggested that thermal pericyclic reactions take place preferentially through aromatic transition states.[5] Although the parent Diels–Alder reaction between butadiene and ethylene is taken as the prototype of pericyclic processes,[6] the energy of concert is relatively small.[7]

We now apply magnetic properties as criteria[8–10, 11b] to investigate the nature of concerted transition states for the first time specifically for the Diels–Alder reactions of ethylene both with butadiene and cyclopentadiene. While the magnetic properties of transition states cannot be measured, both chemical shifts and magnetic susceptibilities can be computed conveniently. The accuracy of the IGLO[11a] results for ground states suggest that they may be applied to analyze the nature of transition structures as well. Moreover, we examine the changes of chemical shifts and magnetic susceptibilities along the reaction path for the reaction of ethylene with butadiene. These results are presented in Figures 1 and 2.

The geometries of the individual points on the reaction coordinate were optimized at the ab initio RHF/3-21G level[12] within the C_s point group, and were employed for IGLO calculations with a Huzinaga DZ basis set.[13] During the reaction (read Figures from right to left), eight of the ten olefinic protons of

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The authors thank Prof. W. Kutzelnigg for suggesting that magnetic susceptibility might be used to characterize aromatic transition states. Dr. U. Fleischer also provided helpful comments. H. J. is grateful for a fellowship of the Shanxi Normal University.

butadiene and ethylene gradually become aliphatic protons in cyclohexene. Similar to the ^{13}C chemical shifts,[14] the proton chemical shifts should decrease continuously (i.e. from $\delta \approx 5-7$ to $\delta \approx 1-2$). However, this is not the case. Electronic effects due to delocalization are not negligible. The delocalization of the six electrons in the transition state results in ring current shielding and deshielding effects similar to those in aromatic compounds. Most pronounced is the shielding of the "inner" protons of the butadiene moiety. The maximum upfield deviation from a hypothetical monotonous[15] function on the reaction path ($\Delta\delta \approx -3.5$) coincides with the transition state structure ($r = 2.1$ Å; see Fig. 1). Deshielding effects also are apparent. The chemical shifts of the "outer" protons of butadiene deviate from a monotonous sigmoidal relationship by $\Delta\delta \approx +2.8$ in the transition structure.

Besides ^1H chemical shifts, exaltation A of the magnetic susceptibility χ is a magnetic property uniquely associated with systems with cyclic delocalization of electrons.[16, 18] χ is more negative for aromatic compounds than for nonaromatic analogues, thus, for instance, the values for χ of benzene and fulvene are -54.8×10^{-6} and -43.0×10^{-6} cm^3 mol^{-1}, respectively.[16c] Similarly, we now find χ to be more negative in the aromatic transition states of pericyclic reactions, for example TS1 and TS2 (see Fig. 3), than in the starting materials or products (see also Fig. 4). In Figure 2 the magnetic susceptibility χ and the energy of the system ethylene + butadiene are plotted as a function of the reaction coordinate.[17] The maximum of the χ curve, which indicates an aromatic transition state, almost coincides with the energy maximum.

While Figures 1 and 2 illustrate the trends, calculations of the stationary points at higher levels of theory give a quantitative estimate of the effects (geometry optimizations and frequency calculations: MP2(fu)/6-31G*, single-point energies: MP4SDTQ/6-31G*//MP2(fu)/6-31G*; ^1H chemical shift calculations: IGLO/II//MP2(fu)/6-31G*). The stationary point geometries on the reaction path of the Diels–Alder reaction of ethylene and butadiene are shown in Figure 3a and those of the Diels–Alder reaction of ethylene and cyclopentadiene in Figure 3b. The energies of the seven structures are listed in Table 1. Note that the calculated and experimental activation entropies and energies agree remarkably well.

The optimized geometries (Fig. 3) were used to perform IGLO calculations (basis set II) of the ^1H chemical shifts and magnetic suceptibilities (Fig. 4).

For starting materials and products the calculated and experimental ^1H chemical shifts are in good agreement. Because transition states of symmetry allowed pericyclic reactions are described

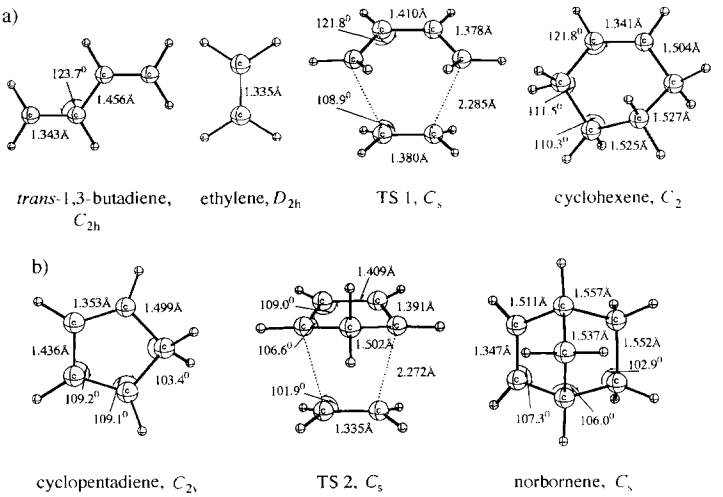

Fig. 3. Calculated geometries of the stationary points on the reaction path of the Diels–Alder reaction of a) butadiene with ethylene (MP2(fu)/6-31G*) and b) cyclopentadiene with ethylene (MP2(fu)/6-31G*).

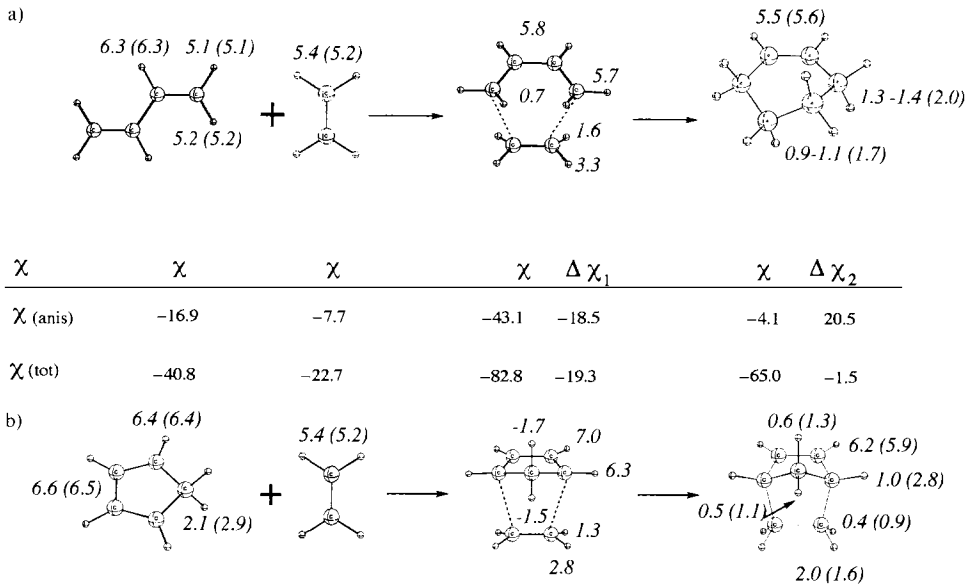

reasonably by single determinant wavefunctions,[6] an adequate treatment of the magnetic properties on the Hartree–Fock level can be expected for the transition structures as well. The general trends along the reaction path (Figs. 1 and 2) are confirmed by the stationary point computations at a considerably higher level of theory (Fig. 4). In general, upfield shifts in the shielding range of the ring current in the transition state are more pronounced than downfield shifts of the signals of the protons in the periphery. Note the large upfield shift of the two methylene protons located above the cyclic delocalized transition state system of the Diels–Alder reaction of cyclopentadiene and ethylene (Fig. 4b, $\delta = -1.5, -1.7$), indicating a strong shielding effect of the ring current.

The calculated magnetic susceptibilities χ(tot) for both transition states are 17.7×10^{-6} and 19.3×10^{-6} cm^3 mol^{-1}, respectively, more negative than those for the starting materials. (The differences from the values for the products are -14.5×10^{-6} and -17.8×10^{-6} cm^3 mol^{-1}, respectively). These values may be compared with the magnetic susceptibility exaltation[18] -13.4×10^{-6} computed for benzene at the same level. The magnetic susceptibility anisotropies, χ(anis), as is characteristic of aromatic compounds,[19] are more negative in the transition states by 18.5×10^{-6} and 20.9×10^{-6} cm^3 mol^{-1} than in the starting materials. Both, χ(tot) and χ(anis) indicate the

Fig. 4. IGLO calculated magnetic susceptibilities χ [10^{-6} cm^3 mol^{-1}] (diamagnetic, paramagnetic, and nonlocal contributions), relative magnetic susceptibilities (relative to the sum of the χ values of the starting materials) $\Delta\chi_1$ and $\Delta\chi_2$ as well as the ^{1}H chemical shifts for the stationary points of the Diels–Alder reaction of a) 1,3-butadiene and ethylene (IGLO//MP2(fu)/6-31G*) and b) cyclopentadiene and ethylene (IGLO//MP2(fu)/6-31G*). The measured values of the chemical shifts are given in parentheses.

pronounced aromatic character of the transition structures TS1 and TS2.

Application of the term "aromatic" to pericyclic transition states is justified. This concept is useful in predicting the stereochemistry and mechanism of these reactions.[2–4] Criteria for aromaticity, such as bond length equalization, cyclic delocalization of electrons, and stabilization relative to open chain analogues also hold for pericyclic transition states.[5, 6] The magnetic properties are also criteria in this concept. The abnormal chemical shifts as well as the magnetic susceptibility and the anisotropy enhancement now provide an additional basis for the aromaticity concept of pericyclic transition states.[20]

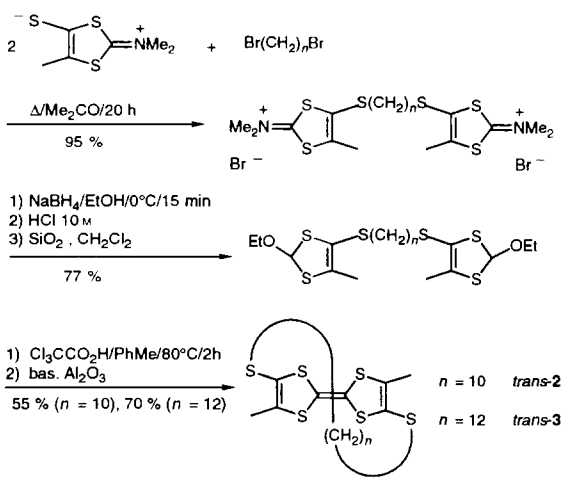
[14] The ^{13}C chemical shifts do not exhibit ring current effects in the transition state. The ^{13}C chemical shift functions of the carbon atoms in butadiene and ethylene changing hybridization from sp^2 to sp^3 exhibit a sigmoidal shape like the central Δ-Δ-curve in Figure 1.
[15] A sigmoidal function similar to the carbon chemical shift curve [14] was assumed.
[16] a) For a review see: H. J. Dauben, Jr., J. D. Wilson, J. L. Laity, *Nonbenzoid Aromaticity, Vol II*, (Ed.: J. P. Snyder), Academic Press, New York 1971, and references therein; b) *J. Am. Chem. Soc.* **1968**, *90*, 811; c) *ibid.* **1969**, *91*, 1991.
[17] The length of the forming π bonds between ethylene and butadiene was decreased in steps of 0.05 Å from 3.0 to 1.6 Å and the remaining geometry parameters were optimized on each point within the C_s point group.
[18] The magnetic susceptibility exaltation Λ, is defined as the difference between the measured bulk susceptibility and the susceptibility predicted on the basis of an increment system ($\Lambda = \chi_M - \chi_M$) [16].
[19] The magnetic susceptibility anisotropy is defined as the difference between the magnetic susceptibility value along the axis perpendicular to the ring and the average value along the in-plane axes. R. C. Benson, W. H. Flygare, *J. Am. Chem. Soc.* **1970**, *92*, 7523. Since the delocalized system in the transition state of the Diels–Alder reaction is not planar, the plane of the sp^2 carbon atoms of butadiene and cyclopentadiene were used as the reference plane. The susceptibility anisotropy was determined as the difference between the magnetic susceptibility value along the axis perpendicular to the reference plane and the average value along the in-plane axes.
[20] In nonpericyclic transition states, ring current effects are not to be expected. According to our calculations on the automeric reaction of CH_3F with F^- (3-21G opt, IGLO, DZ), χ even increases slightly along the reaction coordinate ($\Delta\chi = +25 \times 10^{-6}$ cm^3 mol^{-1}).



trans-cis Isomerization upon One-Electron Oxidation of [12]- and [14]Tetrathiafulvalenophanes

Kamal Boubekeur, Christine Lenoir, Patrick Batail,* Roger Carlier, André Tallec,* Marie-Pierre Le Paillard, Dominique Lorcy, and Albert Robert*

The effect of electron-transfer processes on the conformation of molecules[1] is a continuing central theme in many fields of molecular chemistry with implications on the structure of molecular assemblies, their electronic and chemical sensing properties, and the associated switching processes.[2] Here, we report on a remarkable conformational interconversion upon oxidation within a series of constrained cagelike molecules which function as reversible redox systems.[3] In addition, we present a correlation between the switching rate in solution, as determined by cyclic voltammetry, and the molecular cage constraints observed in the solid state. The general strategy for synthesizing such tetrathiafulvalenophanes was described recently.[4] It was found[5] that the $-S(CH_2)_6S-$ bridge is much too short to preserve the planarity of the central tetrathiafulvalene (TTF) core; thus **1**[4, 5] is *cis*-substituted. Because of the severe bending at the "dithiolene S···S hinges" (by 47° and 34°) compounds of this type only oxidize irreversibly.[6] The synthesis of **2**[7] and **3**[8] was designed (Scheme 1) in order to remove the inner redox unit constraints. In addition, the substitution of methyl for *para*-tolyl was favored in order to achieve a molecular shape better suited for compact intermolecular binding.

1 Ar: *para*-tolyl

Scheme 1. Syntheses of **2** and **3**.

Although the central TTF unit in the neutral cage with the $-S(CH_2)_{10}S-$ bridge, *trans*-**2**, is not planar, it is significantly less folded (23°) than **1**, and the bridge is now long enough to enable the *trans* configuration[9] (Fig. 1a). The analysis of the molecular structure of the oxidized donor cage in its cation radical salt $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-}$,[10] reveals that the neutral cage constraints have been removed since the central TTF core in *cis*-$\mathbf{2}^{\bullet+}$ is planar (Fig. 1b). Another salient effect is the evidence (Fig. 1) for a *cis* configuration of the oxidized cage molecule. In the neutral *trans* cage, *trans*-**3**,[11] the $-S(CH_2)_{12}S-$ bridge is now found to be long enough to bridge the planar, nonoxidized TTF unit (Fig. 1c). Likewise, one observes that the cage molecule switches from *trans* to *cis* upon oxidation, as revealed by the crystal structure of its cation radical salt, $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$[12] (Fig. 1d). The *cis* configuration of $\mathbf{2}^{\bullet+}$ and $\mathbf{3}^{\bullet+}$, with the alkyl chains pointing away from the central TTF cores (Figs. 1b and 1d, respectively), allow for these TTF cores to be strongly dimerized in the crystal structures of $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-}$ and $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$ (Fig. 2). Thus, uniform chains of non-interacting dimers develop across close-packed associations of the outer $-S(CH_2)_nS-$ bridges within the inorganic cluster anion framework (Fig. 2).

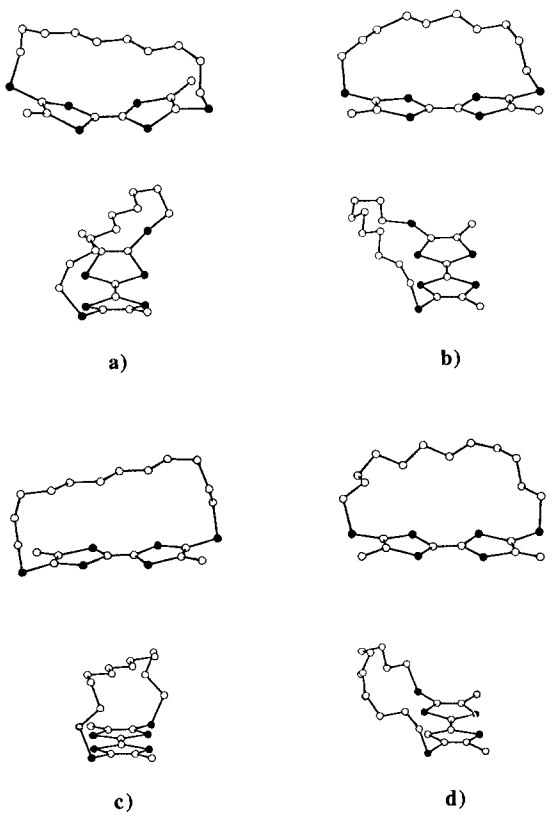


Fig. 1. Crystal structures of the tetrathiafulvalenophanes; views of the molecules parallel (bottom) and perpendicular (top) to the central C–C double bond. a) *trans*-**2**; b) *cis*-**2** in $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-}\cdot 2CH_3CN$; c) *trans*-**3**; d) *cis*-**3** in $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$.

The cyclic voltammetry data shows that the coupled, heterogeneous electron transfer and isomerization reactions proceed according to an EC mechanism (EC = electron transfer with subsequent chemical reaction).[13] Thus, as exemplified in the case of **2** in Figure 3a, the first anodic scan reveals two one-elec-

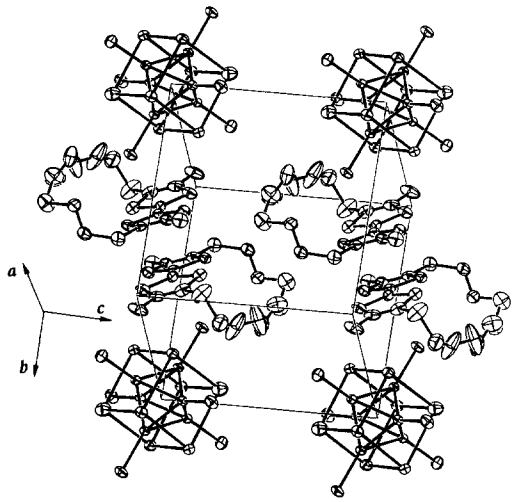

Fig. 2. ORTEP view of the unit cell packing in $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-} \cdot 2CH_3CN$. The solvent molecules as well as four cluster anion molecules have been omitted for clarity. The ellipsoïds are at the 40% probability level. A similar solid-state structure is observed in $(cis\text{-}\mathbf{3})_2^{+}[Re_6S_5Cl_9]^{-}$.

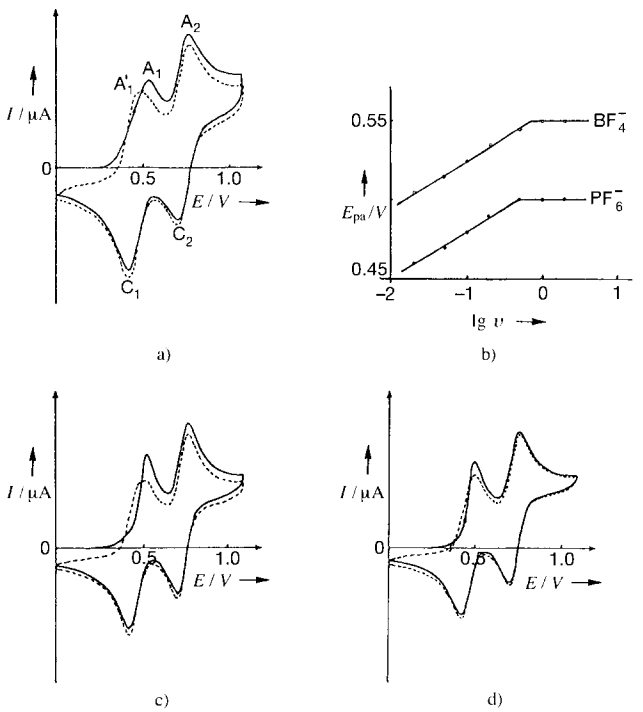

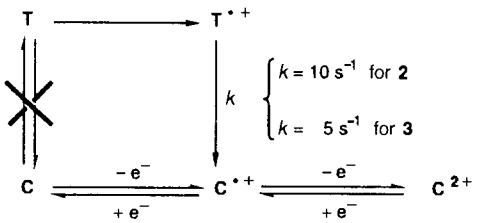

Fig. 3. Cyclic voltammograms of *trans*-**2** (10^{-3} M) in a solution of Bu_4NX (1 M; $X = BF_4^-$ or PF_6^-) in CH_2Cl_2. The cyclic voltammograms are recorded with a 1 mm^2 PT30 Tacussel electrode; potentials vs. standard calomel electrode (SCE). a) Scan speed 1 Vs^{-1}; b) variation with the scan speed v of the peak potential A_1 for *trans*-**2**; c) scan speed 100 mVs^{-1}; d) scan speed 20 mVs^{-1}.

tron waves A_1 and A_2, associated on the reverse scan with the cathodic waves C_1 and C_2, respectively. The peak potentials A_2, C_1 and C_2 are independent of the scan speed and the coupled peaks A_2/C_2 correspond to a reversible system ($\Delta E_p = 0.06$ V). Note that for slow scan speeds v ($v < 0.5$ Vs^{-1}), the peak potential for A_1 is shifted towards positive potentials as v increases, with shifts of 0.03 V per decade of v that is, $E_p(A_1) = 0.510(0.555) + 0.03 \lg v$ for PF_6^- (BF_4^-), respectively. For $v > 1$ Vs^{-1}, $Ep(A_1)$ is independent of the scan speed (Fig. 3b).

The shape of A_1 appears different when the second scan occurs at low speed (Fig. 3c, d), while a novel peak (A_1') involved in a reversible system with C_1 is observed for higher scan speeds (Fig. 3a). The same variation in the voltammogram shape is observed when the potential is reversed at 0.6 V. These are characteristic features of an EC mechanism.[13] Thus, the electrochemical oxidation of the *trans* molecule is followed (Scheme 2) by the chemical isomerization reaction (rate constant k). For the threshold scan speed v_i, the first oxidation peak potential becomes independent of v (Fig. 3b). Thus, for **2**, $k/v_i = 20.8$ at 25 °C,[13] which yields $v_i = 0.50$ Vs^{-1} and $k = 10.4$ s^{-1} with PF_6^- and $v_i = 0.6$ Vs^{-1} and $k = 12.5$ s^{-1} with BF_4^-. Therefore, the rate of isomerization appears to be essentially independent of the nature of the anion.

Scheme 2.

The features of the cyclic voltammograms shown in Figure 3 are consistent with the previously mentioned kinetic data. Thus, for high scan speeds (Fig. 3a), on the first scan, the neutral *trans* cage (T) is oxidized first and it is the neutral *cis* cage (C) which gets oxidized on the second scan (see Scheme 2). Note that the broadening of the second scan oxidation wave results from the concomitant oxidation of a small amount of the neutral *trans* cage T which by then had diffused to the electrode. Since larger amounts of T diffuse at lower scan speeds, the second scan oxidation peak in this case is much broader (Fig. 3c). At low scan speed ($v = 0.02$ Vs^{-1}, Fig. 3d), no broadening of the first oxidation peak occurs at the second scan. Indeed, at such low scan speed, there is essentially coalescence of the first oxidation peaks for T and C.

Finally, the standard oxidation potentials E^0 (Table 1) for the series of processes summarized in Scheme 2 have been determined from the cyclic voltammograms obtained for scan speeds higher than 1 Vs^{-1}. Interestingly the difference in E^0 between the $T^{\bullet+}/T$ and $C^{\bullet+}/C$ processes amounts to about 0.065 V (6 $kJ\,mol^{-1}$), regardless of the anion. Note that $E^0_{C^{2+}/C^{\bullet+}}$ is also independent of the anion (for **2**). Conversely, one observes (Table 1) that the first electron transfer from either T or C is always easier (by 1 $kJ\,mol^{-1}$) in the presence of PF_6^-, a more nucleophilic anion.

A similar study for *trans*-**3** has so far only been carried out in the presence of PF_6^-. The qualitative features of the cyclic voltammograms are identical to those of *trans*-**2**. The oxidation potentials of *trans*-**3** and *cis*-**3** being now closer (0.025 V), the quantitative analysis is more difficult than in the case of **2**. It is conclud-

Table 1. Standard oxidation potentials E^0 [V] for **2**/**3** (vs. SCE) in 1 M solutions of Bu_4NX in dichloromethane ($X = PF_6^-$, BF_4^-).

Potential	Anion	
	PF_6^-	BF_4^-
E^0 ($T^{\bullet+}/T$)	0.47/0.48	0.52/0.48
E^0 ($C^{\bullet+}/C$)	0.40/0.45	0.46/0.46
E^0 (C^{2+}/C)	0.75/0.83	0.74/0.73

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1380 $ 10.00+.25/0

ed, however, that the isomerization rate for *trans*-**3** is half that for *trans*-**2** (Scheme 2). This observation nicely supplements the former structural analysis (Fig. 1) which also suggests that *trans*-**2**, (Fig. 1a) being significantly more strained than *trans*-**3** (Fig. 1c), would, given the opportunity, undergo a faster conformational change. Therefore, the present combination of structural and kinetic studies demonstrates that one driving force for the isomerization of such redox cage molecules is to achieve the less constrained planar configuration for their $TTF^{\bullet+}$ cores, that is, the *cis* configuration, even for the longer bridge. The first event of the EC mechanism now involves the creation of the oxidized *trans* cages $T^{\bullet+}$; one expects therefore that the subsequent lengthening of the inner TTF central double bond will result in an increase of the steric constraints within the cages in their *trans* configuration. Thus, the electron transfer also increases the tension within the *trans* cages, while at the same time weakening the central double bond. These combined events appear quite effective at driving the *trans* to *cis* isomerization even in the case of the somewhat less constrained *trans* cage **3**. Indeed, while the aliphatic fragment of the $-S(CH_2)_{12}S-$ bridge is properly locked in within the crystal structure of *trans*-**3** (Fig. 1c), it is found highly disordered within the structure of $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$,[12] which indicates that the cage in the *cis* configuration is unconstrained and fairly flexible (Fig. 1d).

Future reports on this unique system will focus on the design and properties of molecular solid-state assemblies based on such redox-active nonplanar molecules whose molecular shape switches upon electron transfer.

The structure was solved by direct methods. The full-matrix least-squares refinements of 109 parameters from 1519 reflections with $I > 3\,\sigma(I)$ converged at $R = 0.035$ and $R_w = 0.056$ [12].

[10] Shiny, black paralellepiped single crystals of $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-} \cdot 2CH_3CN$ were harvested after five days of anodic oxidation under constant low current (1.5 μAmp) at a platinum wire electrode of *trans*-**2** (0.025 mmol) in a 7/1 acetonitrile/dichloromethane solution of $(Bu_4N)_2(Re_6S_6Cl_8)$ (0.022 mmol). The latter was prepared according to published procedures [14]. Crystal structure for $(cis\text{-}\mathbf{2}^{\bullet+})_2[Re_6S_6Cl_8]^{2-} \cdot 2CH_3CN$: $C_{40}H_{58}Cl_8N_2Re_6S_{20}$, $M = 2.072.44$, triclinic, space group $P\bar{1}$, $a = 12.010(6)$, $b = 13.795(7)$, $c = 10.692(1)$ Å, $\alpha = 95.99(2)$, $\beta = 102.58(2)$, $\gamma = 75.61(5)°$, $V = 1672.7$ Å^3, $Z = 1$, $\varrho_{calcd} = 2.06$ g cm^{-3}; $Mo_{K\alpha}$ radiation; absorption corrections by Ψ-scan; 7598 independent reflections with ω-2 θ scans were measured up to $\theta = 28°$ at 293 K on an Enraf-Nonius CAD4 diffractometer. The structure was solved by the Patterson method. The full-matrix least-squares refinements of 334 parameters from 4244 reflections with $I > 3\,\sigma(I)$ converged at $R = 0.034$ and $R_w = 0.043$. The cation radical cores of the *cis* cage molecules form strong, discrete fully oxidized diamagnetic dimers in the crystal in agreement with the absence of an ESR signal.

[11] Crystal structure for *trans*-**3**: $C_{20}H_{30}S_6$, $M = 462.85$, yellow flat crystals, triclinic, space group $P\bar{1}$, $a = 9.633(2)$, $b = 10.308(2)$, $c = 13.350(2)$ Å, $\alpha = 110.16(1)$, $\beta = 98.04(1)$, $\gamma = 105.74(2)°$, $V = 1157.1$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.33$ g cm^{-3}, $Mo_{K\alpha}$ radiation; absorption corrections by Ψ-scan; 4503 independent reflections with ω-2θ scans were measured up to $\theta = 26°$ at 293 K on an Enraf-Nonius CAD4 diffractometer. The structure was solved by direct methods. The full-matrix least squares refinements of 235 parameters from 2956 reflections with $I > 3\,\sigma(I)$ converged at $R = 0.029$ and $R_w = 0.034$.

[12] Brittle, black paralellepiped single crystals of $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$ were harvested after five days of anodic oxidation under constant low current (1.5 μAmp) at a platinum wire electrode of *trans*-**3** (0.021 mmol) in a 7/1 acetonitrile/dichloromethane solution of $(Bu_4N)_2[Re_6S_5Cl_9]$ (0.026 mmol). The latter was prepared according to published procedures [14]. Crystal structure for $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$: $C_{40}H_{60}Cl_9Re_6S_{17}$, $M = 2.522.25$, triclinic, space group $P\bar{1}$, $a = 12.086(6)$, $b = 13.939(8)$, $c = 11.306(2)$ Å, $\alpha = 90.69(3)$, $\beta = 103.67(3)$, $\gamma = 75.53(5)°$, $V = 1790$ Å^3, $Z = 1$, $\varrho_{calcd} = 2.34$ g cm^{-3}, $Mo_{K\alpha}$ radiation; absorption corrections by Ψ-scan; 8278 independent reflections with ω-2θ scans were measured up to $\theta = 28°$ at 293 K on an Enraf-Nonius CAD4 diffractometer. The structure was solved by the Patterson method. Note that, not only was the thermal motion for all atoms of the *cis*-**3** cation found to be significantly larger than for the other three structures but also the located carbon atoms of the $-S(CH_2)_{12}S-$ fragment, which are consistently found all on one side of the molecule only, exhibited considerable instability when treated as independent atoms in the refinement procedure, leading to unrealistic geometries. Therefore the final refinement stages were conducted imposing restraints on bond lengths and angles for this fragment using the program XTAL3.2 [15]. Thus, the full-matrix least-squares refinements of 253 parameters from 3950 reflections with $I > 3\,\sigma(I)$ converged at $R = 0.115$ and $R_w = 0.161$. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-58143. A single, quasi-isotropic ESR line (temperature independent linewidth of 4.3 Gauss with g values extremes of 2.0065 and 2.010) is observed on a single crystal of $(cis\text{-}\mathbf{3})_2^{\bullet+}[Re_6S_5Cl_9]^-$. The spin susceptibility shows a Curie-type behavior in agreement with the presence of discrete, noninteracting mixed-valence dimers in the structure.

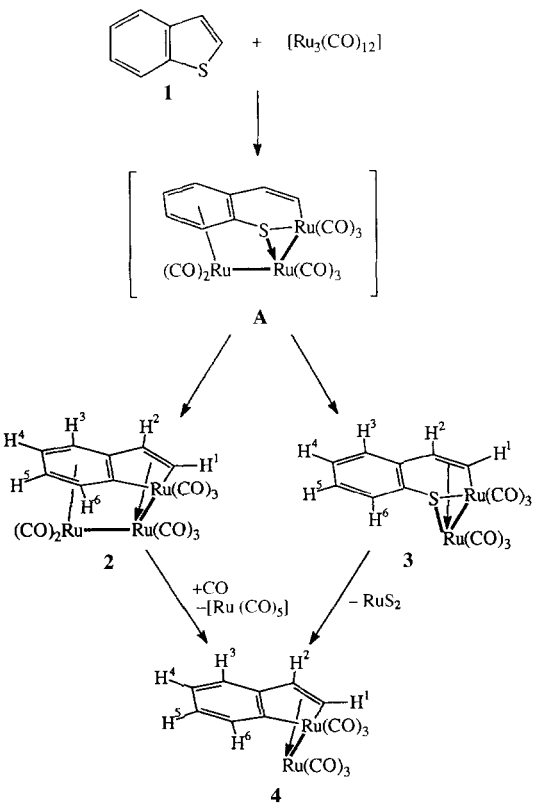
sulfur from the heterocycle, and the homogeneous desulfurization of thiophenes with transition-metal compounds has provided models for the catalytic heterogeneous dehydrosulfurization of thiophenic components of crude oil.

The cluster $[Fe_3(CO)_{12}]$ reacts with thiophene with loss of the sulfur atom to give the ferrole compound $[Fe_2(\mu\text{-}C_4H_4)(CO)_6]$,[4] while $[Fe_2(\mu\text{-}C_4H_3MeS)(CO)_6]$ as well as the sulfur-free species $[Fe_2(\mu\text{-}C_4H_3Me)(CO)_6]$ are formed from 2-methylthiophene.[5, 6] Similarly the reaction of $[Ru_3(CO)_{12}]$ with thiophene[7] gives the sulfur-free species $[Ru_2(\mu\text{-}C_4H_4)(CO)_6]$ derived by C–S bond cleavage as in the iron case, but in addition the tetranuclear cluster $[Ru_4(\mu_3\text{-}S)(\mu\text{-}C_4H_4)(CO)_{11}]$, which contains separate S and C_4H_4 ligands within the same molecule. Better yields were obtained from 2-methylthiophene, and in this case, products of both C–S and C–H bond cleavage were obtained: $[Ru_3(\mu\text{-}H)(\mu\text{-}C_4H_2MeS)(CO)_{10}]$ (*exo* and *endo* isomers) and $[Ru_4(\mu_3\text{-}S)(\mu\text{-}C_4H_3Me)(CO)_{11}]$. With osmium, C–H rather than C–S bonds are cleaved exclusively, and $[Os_3(CO)_{12}]$ or $[Os_3(CO)_{10}(MeCN)_2]$ react with thiophene to give the thienyl isomers $[Os_3(\mu\text{-}H)(\mu\text{-}C_4H_3S)(CO)_{10}]$ (*exo* and *endo* isomers in rapid equilibrium), which decarbonylate to the "thiophyne" cluster $[Os_3(\mu\text{-}H)_2(\mu_3\text{-}C_4H_2S)(CO)_9]$.[8–11]



Benzo[*b*]thiophene **1** and dibenzothiophene more closely correspond to the major sulfur components in fossil fuels than thiophene, and these compounds are difficult to activate.[12] The first example of metal-assisted opening and hydrogenation of **1** was described by Rauchfuss et al.,[6] who treated **1** with $[Fe_3(CO)_{12}]$ to obtain the benzothiaferrole $[Fe_2(C_8H_6S)(CO)_6]$, which was hydrogenated to give ethylbenzene together with some 2-ethylbenzenethiol, bis(2-ethylphenyl) sulfide, and bis(2-ethylphenyl) disulfide. Also oxidative addition of the C–S bond of **1** with $[(C_5Me_5)Rh(PMe_3)(Ph)H]$ was reported.[13] Recently oxidative addition of **1** to iridium(I) gave an iridium(III) complex that could be selectively hydrogenated to give the 2-ethylbenzenethiolate ligand at iridium(III).[14] We now report the synthesis of the clusters $[Ru_3(C_8H_6)(CO)_8]$ (**2**), $[Ru_2(C_8H_6S)(CO)_6]$ (**3**), and $[Ru_2(C_8H_6)(CO)_6]$ (**4**), obtained from the reaction of $[Ru_3(CO)_{12}]$ with **1** under relatively mild conditions.

The reaction of $[Ru_3(CO)_{12}]$ with **1** under reflux in THF gave, compounds **2**, **3**, and **4** in 28, 17, and 10% yield, respectively, after TLC work-up (Scheme 1). The clusters were characterized by ^1H NMR and IR spectroscopy, and the X-ray structure of **2** was determined.[15]

Compounds **2** and **4** are formed by C–S bond cleavage and extrusion of the sulfur atom. Compound **3** is closely related to that obtained by Rauchfuss from the reaction of benzo[*b*]thiophene and $[Fe_3(CO)_{12}]$;[6] their ^1H NMR spectra correspond. The dinuclear compound **3** was isolated and heated in cyclohexane for 20 min to afford an insoluble black by-product, which suggests the formation of RuS_2, and the sulfur-free compound **4**, since the spectroscopic data of **4** resemble those of the product obtained from the debromination of 1,4-dibromocyclooctatetraene with $[Ru_3(CO)_{12}]$ in hydrocarbon solvent (the metallaindene complex $[Ru_2(C_8H_6)(CO)_6]$), the most likely structure is that shown in Scheme 1. The X-ray structure of the osmium analogue was reported.[16]

Although **4** was obtained in low yield (10%), this can be increased considerably if the reaction is carried out under carbon monoxide. ^1H NMR ($CDCl_3$ solution) and IR monitoring (showing the presence of $Ru(CO)_5$) confirmed that **2** can be converted quantitatively into **4** at room temperature under 1 atm of CO over a period of 24 h (Fig. 1).

Under our reaction conditions, no decacarbonyl or nonacarbonyl clusters such as the *exo* and *endo* isomers $[Ru_3(\mu\text{-}H)(\mu\text{-}C_8H_5S)(CO)_{10}]$ or their expected decarbonylation products

Scheme 1. Synthesis of **2**, **3**, and **4**.

$[Ru_3(\mu\text{-}H)_2(\mu\text{-}C_8H_4S)(CO)_9]$ were obtained on treating **1** with $[Ru_3(CO)_{12}]$. Probably compound **A** containing a ring-opened benzo[*b*]thiophene ligand bonded to an opened Ru_3 triangle is formed in the early stages of the reaction (Scheme 1) and con-

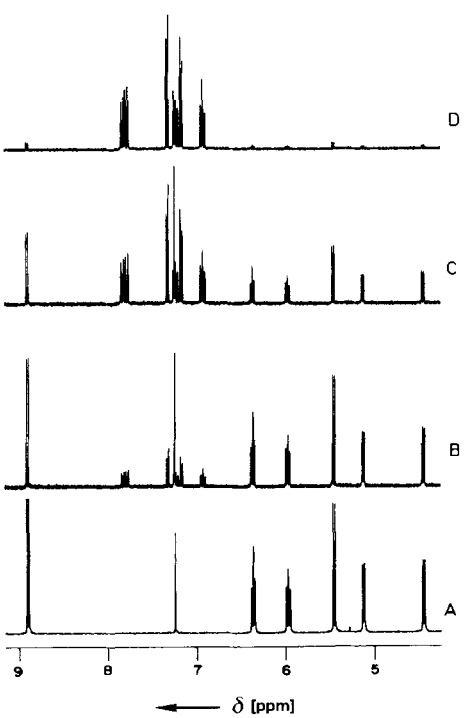


Fig. 1. Monitoring of the conversion **2** → **4** ($CDCl_3$, CO 1 atm) by ^1H NMR spectroscopy. A: Initial spectrum; B: after 70 min; C: after 5 h; and D: after 24 h, showing the clean, almost quantitative, conversion to compound **4**.

verts readily to the dinuclear ring-opened compound **3**, or is desulfurized to afford cluster **4**. A single-crystal X-ray structure for **2** (see Fig. 2) was needed to establish the mode of bonding. The desulfurized ligand is bonded to three metal atoms as an 10-electron donor to give a 50-electron cluster with only two Ru–Ru bonds.

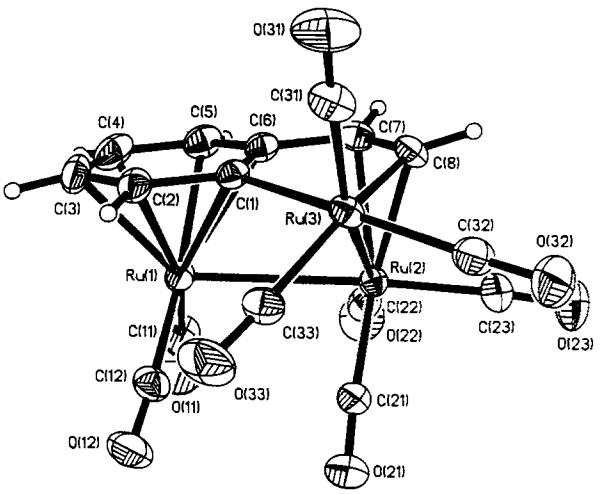

Fig. 2. Molecular structure of **2**: selected bond lengths [Å] and angles [°]: Ru(1)–Ru(2), 2.946(2); Ru(2)–Ru(3), 2.781(2); Ru(2)–C(7), 2.257(5); Ru(2)–C(8), 2.237; Ru(1)–C(1), 2.322(5); Ru(1) C(4), 2.294(6); Ru(3)–C(1), 2.088(6); Ru(3)–C(8), 2.058(6); C(1)–C(2), 1.413(8); C(2) C(3), 1.430(9); C(3)–C(4), 1.40(1); C(4)–C(5), 1.41(1); C(5)–C(6), 1.424(8); C(6)–C(7), 1.458(8); C(7)–C(8), 1.400(9); C(1)–C(6), 1.454(8); Ru(1)···Ru(3), 3.815(2); Ru(2)···C(1), 2.934(6); Ru(2)···C(6), 2.657(6); Ru(1)-Ru(2)-Ru(3), 83.5(1); Ru(1)-C(1)-Ru(3), 119.6(2); Ru(3)-C(1)-C(6), 113.9(4); Ru(1)-C(1)-C(6), 72.9(3); Ru(3)-C(8)-C(7), 116.8(4); Ru(3)-C(8)-C(7), 72.7(3); C(2)-Ru(1)-C(5), 76.0(2); C(3)-Ru(1)-C(6), 75.6(2); Ru(1)-C(6)-C(7), 128.3(3); Ru(2)-C(7)-C(6), 88.6(3).

$[Ru_3(C_8H_6)(CO)_8]$ (**2**) is the first example of a fully characterized trinuclear Ru complex containing a 1-ruthenaindene system. The nine atoms of the bicyclic metallaindene system are substantially coplanar; the $C_8H_6Ru(CO)_3$ unit can thus be regarded as an 8-electron-donor ligand π-complexed to the $Ru_2(CO)_5$ group.

Experimental Procedure

$[Ru_3(CO)_{12}]$ (0.200 g) and **1** (0.200 g) were heated at reflux in tetrahydrofuran (50 cm^3) for 24 h under N_2. The orange-brown solution was evaporated to dryness under reduced pressure, and the residue separated by TLC on silica with n-hexane as eluent into three bands, which yielded **2** (yellow, 28%), **3** (yellow-orange, 17%), and **4** (yellow, 10%). A solution of **2** (0.020 g) in $CDCl_3$ (0.5 cm^3) under CO (1 atm) showed complete conversion to compound **4** in 24 h at room temperature (monitored by ^1H NMR spectroscopy). Crystals of compound **2** for structure determination were obtained from cyclohexane. **2**: IR (cyclohexane): $\tilde{\nu}$(CO) [cm^{-1}] = 2077 s, 2045 vs, 2017 vs, 2003 s, 1980 m, 1963 m; ^1H NMR ($CDCl_3$, 300 MHz, 296 K, J in Hz): δ = 8.89 (d, H^1), 5.45 (d, H^2), 4.44 (dd, H^3), 5.96 (ddd, H^4), 6.36 (ddd, H^5), 5.11 (dd, H^6) [$J(H^1H^2)$ = 6.3, $J(H^3H^4)$ = 6.7, $J(H^3H^5)$ = 1.1, $J(H^4H^5)$ = 6.0, $J(H^4H^6)$ = 1.3, $J(H^5H^6)$ 5.8]. **3**: IR (cyclohexane): $\tilde{\nu}$(CO) [cm^{-1}] = 2088 m, 2061 s, 2021 s, 2014 vs, 2000 m. ^1H NMR (CD_3COCD_3, 300 MHz, 296 K, J in Hz): δ = 9.04 (d, H^1), 6.08 (dd, H^2), 7.18 (dddd, H^3), 6.91 (ddd, H^4), 7.05 (ddd, H^5), 7.22 (dd, br, H^6) [$J(H^1H^2)$ = 10.0, $J(H^2H^3)$ = 0.6, $J(H^3H^4)$ = 7.6, $J(H^3H^5)$ = 1.2, $J(H^3H^5)$ = 0.5, $J(H^4H^5)$ = 7.5, $J(H^4H^6)$ = 1.4, $J(H^5H^6)$ = 7.5]. $[Fe_2(C_8H_6S)(CO)_6]$ [6]: IR (cyclohexane): $\tilde{\nu}$(CO) [cm^{-1}] = 2077 m, 2044 vs, 2005 s, 1993 w. ^1H NMR (CD_3COCD_3, 300 MHz, 296 K, J in Hz): δ = 9.04 (d, H^1), 5.67 (d, H^2), 7.06 (dd, H^3), 6.81 (ddd, H^4), 6.99 (ddd, H^5), 7.12 (dd, H^6) [$J(H^1H^2)$: 9.1, $J(H^3H^4)$ = 7.6, $J(H^3H^5)$ = 1.2, $J(H^4H^5)$ = 7.5, $J(H^4H^6)$ = 1.2, $J(H^5H^6)$ = 7.5]. **4**: IR (cyclohexane): $\tilde{\nu}$(CO) [cm^{-1}] = 2082 m, 2051 vs, 2010 vs, 1992 m, 1984 s. ^1H NMR (CD_3COCD_3, 300 MHz, 296 K, J in Hz): δ = 7.53 (d, H^1), 7.45 (d, H^2), 8.04 (ddd, H^3), 7.35 (ddd, H^4), 7.05 (ddd, H^5), 7.89 (d, br, H^6) [$J(H^1H^2)$ = 6.5, $J(H^3H^4)$ = 8.5, $J(H^3H^5)$ = 1.1, $J(H^3H^6)$ = 1.0, $J(H^4H^5)$ = 6.7, $J(H^4H^6)$ = 1.2, $J(H^5H^6)$ = 8.3].

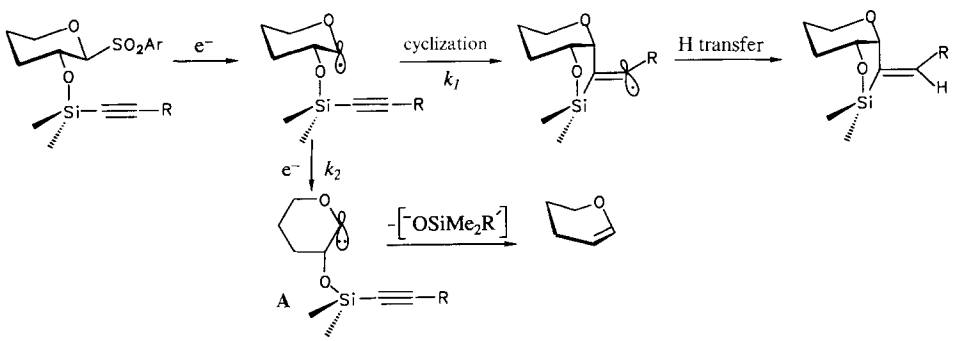
Samarium Iodide Induced Intramolecular C-Glycoside Formation: Efficient Radical Formation in the Absence of an Additive

Daniel Mazéas, Troels Skrydstrup,* Olivier Doumeix, and Jean-Marie Beau*



Of the numerous existing methods for C-glycoside construction,[1] the intramolecular free radical cyclization employing the temporary silicon connection reported by Stork et al. lends itself as the most attractive.[2] The reaction conditions are mild and complete stereochemical control at the anomeric center may be achieved by the judicious choice of the linking hydroxy group (i.e. the oxygen of the substrate which carries the silicon tether). Only a few examples of this reaction are known, however, and in each case the tin hydride based procedure coupled with phenylselenoglycosides has been applied for radical generation at the anomeric center.[2–4]

In the last few years samarium(II) iodide has not only emerged as a unique alternative for carrying out reductive radical cyclization reactions of unsaturated haloalkanes, but has shown greater versatility as well.[5, 6] However, for efficient single-electron transfer with concomitant radical formation, the reducing potential of SmI_2 has to be augmented by the addition of a cosolvent such as hexamethylphoshoramide (HMPA).[7] Reductive desulfonyl-

[*] Dr. T. Skrydstrup, Prof. Dr. J.-M. Beau, D. Mazéas, O. Doumeix

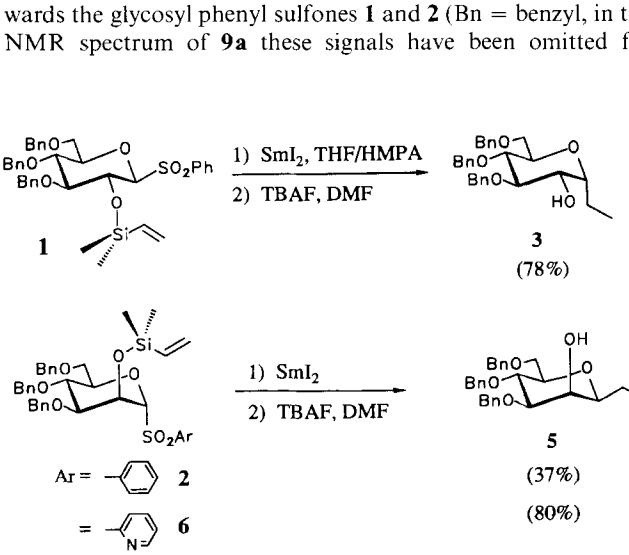
Telefax: Int. code + 38417281

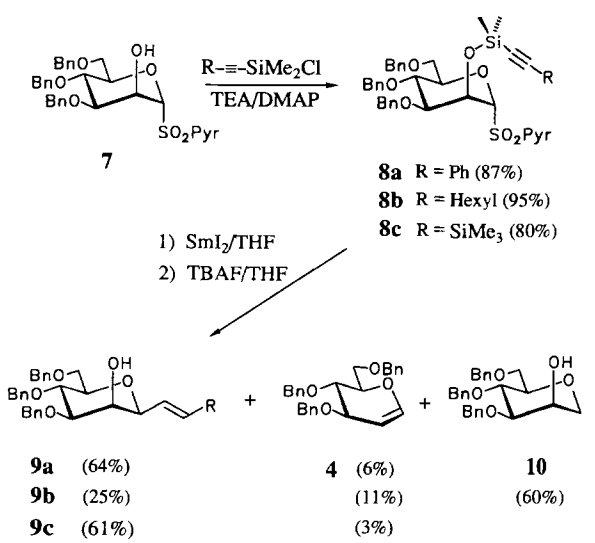
ation of phenylsulfones, which involves a transient radical species, has likewise been observed with the SmI_2/HMPA system.[8, 9] Again, in the absence of HMPA, the phenylsulfones are devoid of any reactivity, though a notable exception has been provided by Trost et al.[10] for geminal bis-sulfones. We now report an application of the SmI_2-promoted radical cyclizations that uses glycosyl aryl sulfones in connection with the above-mentioned silicon-tethered appraoch as an alternative to C-glycoside construction. The particular highlight of this procedure lies in the fact that by fine tuning the aryl sulfone moiety, SmI_2 alone is sufficient for effective radical formation at the anomeric center, thus avoiding the use of the additive HMPA. In addition, we report the first stereoselective synthesis of a C-disaccharide by employing the 5-*exo* cyclization mode.

The essential features of this strategy are illustrated in Scheme 1. One-electron transfer to the π^* (SO_2Ar) orbital of the

Scheme 1. The actual conformation of the α-orientated anionic species **A** of this kind is presently unknown which explains the Haworth representation of this intermediate. If an alkenylsilyl group is used instead of an alkynyl silyl group, a one-electron reduction and protonation occurs in the final step of the reaction.



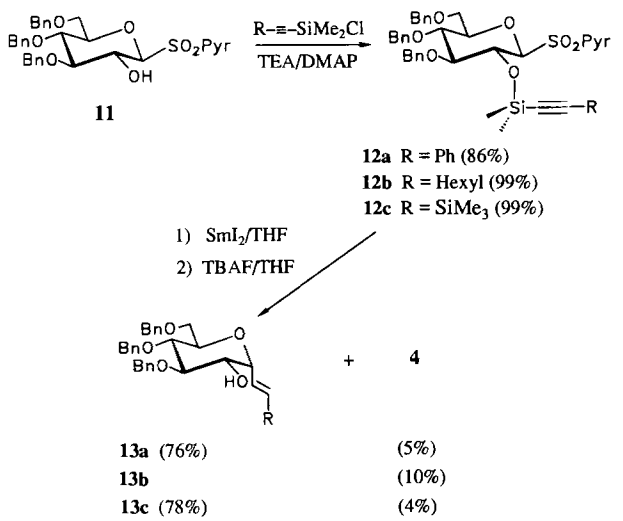
sulfonylglycoside from SmI_2 leads to fragmentation and generation of the radical at the anomeric position. At this stage, for efficient C-glycoside formation, 5-*exo* ring closure onto the silicon-tethered alkyne or alkene group (k_1) must precede the second electron transfer step (k_2). The newly formed radical center could then either abstract hydrogen from THF (C=C) or undergo one-electron reduction (C–C). Inefficient cyclization, on the other hand, would be measured by formation of the α-anion **A**, which would probably lead to the corresponding glucal by β elimination.



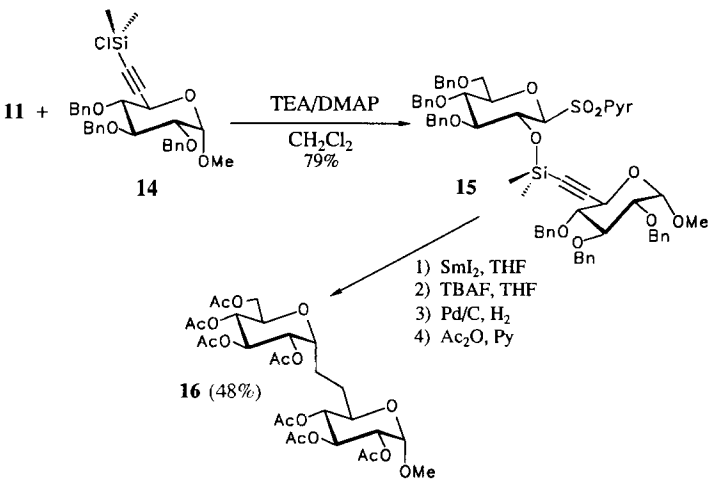
To examine this approach, our efforts were first directed towards the glycosyl phenyl sulfones **1** and **2** (Bn = benzyl, in the NMR spectrum of **9a** these signals have been omitted for clarity), each prepared from their corresponding C2-alcohols[9] and commercially available dimethylvinylsilyl chloride. Treatment of a 0.01 M THF solution of phenyl sulfone **1** and SmI_2 (5 equiv) with HMPA (11 equiv) at 20 °C led to rapid consumption of the starting material. Desilylation with four equivalents of tetrabutylammonium fluoride (TBAF) in dimethylformamide (DMF) (4 h, 60 °C)[11] gave the α-C-ethylglucoside **3** in good overall yield (78%) with no sign of 3,4,6-tri-*O*-benzyl glucal (**4**). In contrast, under identical conditions mannoside **2** led to a low yield of the β-C-mannoside **5** (37%) with essentially glucal **4** as the only other compound detected. Hence a slow cyclization rate (k_1) in the case of **2** appears as the major concern and may be attributed to the preference for an α configuration by the radical.[12]

One way of increasing the cyclization efficiency would be to extend the lifetime of the radical by simply slowing down the rate of the second electron transfer or, in other words, reducing the redox potential of SmI_2. Omission of HMPA would allow this, although at the expense of the first electron transfer into the $\pi^*(SO_2Ar)$ orbital. Therefore decreasing the LUMO energy level of the aryl sulfone group would be desirable and could be accomplished, for example, by including nitrogen in the arene ring.[13, 14]

Screening a variety of nitrogen-containing arenes revealed that mannosyl 2-pyridyl sulfones[15] proved to be the most convenient to prepare and, more importantly, were instantaneously reduced in the presence of SmI_2 without an additive.[16] Hence slow addition of two equivalents of SmI_2 (ca. 30 min) to a well-degassed 0.01 M THF solution of **6** at 20 °C provided the β-C-glycoside **5** in 80% overall yield after desilylation. No glucal was detected. An added advantage of this procedure is that completion of the reaction is easily monitored from the persistent blue color of excess SmI_2.



A series of acetylenic silyl-tethered derivatives **8a–c** were tested to expand the scope of this reaction. Each was prepared in good yields by adding dichlorodimethylsilane (3.0 equiv) to the pre-



formed lithiated alkynes in THF at −78 °C (warming to 20 °C, 2 h) followed by evaporation of the excess Me_2SiCl_2, and silylation of alcohol **7** (0.2 equiv) in the presence of triethylamine (TEA) and dimethylaminopyridine (DMAP) in CH_2Cl_2.[17] Two-step reductive radical cyclization and desilylation (2 equiv. TBAF, THF, 0 °C) afforded the vinylic-β-C-glycosides **9a–c** under similar conditions as for the reactions of **6**. With the activated alkynes **8a** and **8c**, reasonable yields were obtained (*E*:*Z* ratio, ≈10:1) comparable to the one previously reported for **9a** using the tin hydride procedure.[2] On the other hand, **8b** gave a poor yield, clearly reflecting the lowered rate for the 5-*exo*-dig cyclization with respect to the 5-*exo*-trig mode of **6**. In all three cases, glucal **4** was also recovered albeit in low yields. Interestingly, the reduction product **10** was likewise isolated which, in the case of **8b**, corresponded to a remarkable 60% yield. This 1-deoxy sugar could have originated from protonation of a possible stable samarium mannoside species. The implications of this result are under further investigation.

Our attention was then directed towards the silylated glucose derivatives **12a–c**, each prepared in excellent yields from alcohol **11**. In contrast to **8**, rapid addition of SmI_2 (5–8 equiv) to a 0.007 M solution of glucosyl sulfones **12** in THF and subsequent desilylation afforded the best yields of the α-C-glycosides **13a–c**. As expected, the yields were generally higher than those of **9** and excellent *trans*-selectivities (*E*:*Z* ratio, >50:1) were also exhibited. A complex mixture of products was obtained with **12b**, nevertheless, exhaustive hydrogenation (H_2, Pd/C) and acetylation (Ac_2O, pyr) gave the tetra-*O*-acetyl-α-C-octylglucoside (Ac instead of Bn and CH_2CH_2 instead of CH=CH in **13b**) in a 53% overall yield with the major by-product again representing a 1-deoxy sugar.

Finally, a fast and efficient stereoselective synthesis of methyl-α-C-isomaltoside was performed by using the above strategem. Coupling of the two subunits **11** and **14** proceeded well providing intermediate **15** in 79% yield based on sulfone **11**. Cyclization in the presence of SmI_2 and further transformation furnished the methyl C-isomaltoside as its crystalline peracetate **16**[18] in a good 48% overall yield (four steps).[19]

In summary, samarium iodide promoted radical cyclizations provide a good alternative to the corresponding tin hydride method for intramolecular C-glycoside formation, with the added advantage of avoiding the sometimes tedious process of removing tin-containing by-products. Extension of this procedure to the preparation of C-glycoside analogues of biologically important O-glycosides is currently underway in our laboratory.

Experimental Procedure

C-Mannoside formation (**9a**): A 0.1 M solution of SmI_2 in THF (3.4 mL, 0.34 mmol) was added over a period of 30 min by syringe to a well-degassed solution of **8a** (59.5 mg, 0.081 mmol) in THF (8 mL) at 20 °C. Saturated aqueous NH_4Cl was added and the mixture was extracted twice with CH_2Cl_2. The combined organic phases were washed twice with water, dried (Na_2SO_4), and evaporated to dryness. The residue was redissolved in THF (3 mL), cooled to 0 °C, and 1.0 M TBAF in THF (165 μL, 0.165 mmol) was added. After stirring for 30 min, water and CH_2Cl_2 were added, and the organic phase was washed twice with water, dried (Na_2SO_4), and evaporated to dryness. Flash chromatography (heptane:EtOAc, 9:1) gave **9a** as a colorless syrup (28 mg, 64% yield, *E*/*Z* = 10:1). The *E*/*Z* mixture could be separated by column chromatography. *E* isomer: ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 2.40 (br. s, 1H, OH), 3.54 (ddd, 1H, *J* = 9.6, 4.5, 2.3 Hz, H-5), 3.70 (dd, 1H, *J* = 9.1, 3.2 Hz, H-3), 3.77 (dd, 1H, *J* = 10.8, 4.5 Hz, H-6a), 3.81 (dd, 1H, *J* = 10.8, 2.3 Hz, H-6b), 3.89 (dd, 1H, *J* = 9.6, 9.1 Hz, H-4), 4.09 (d, 1H, *J* = 3.2 Hz, H-2), 4.10 (br. d, 1H, *J* = 6.2 Hz, H-1), 6.40 (dd, 1H, *J* = 16.1, 6.2 Hz, *H*C=CPh), 6.74 (br. d, 1H, *J* = 16.1 Hz, C=C*H*Ph), 7.21–7.46 (m, 20H, 4 Ph); *Z* isomer: δ = 6.13 (dd, 1H, *J* = 11.6, 8.8 Hz, *H*C=CPh), 6.77 (d, 1H, *J* = 11.6 Hz, C=C*H*Ph).

C-Glucoside formation (**13c**): A 0.1 M solution of SmI_2 in THF (13 mL, 1.3 mmol) was added quickly to a stirred solution of **12c** (122 mg, 0.167 mmol) in THF (24 mL). After stirring for 10 min, the reaction mixture was worked up and desilylated as for **9a**. Flash chromatography (heptane:EtOAc, 8:1) gave 69.5 mg of **13c** as a colorless syrup (78% yield, *E*/*Z* > 50:1): *E* isomer: ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.13 (s, 9H, $SiMe_3$), 2.68 (d, 1H, *J* = 5.8 Hz, OH), 3.65–3.72 (m, 2H, H-3,4), 3.74 (dd, 1H, *J* = 10.4, 4.0 Hz, H-6a), 3.82 (ddd, 1H, *J* = 7.5, 5.8, 4.6 Hz, H-2), 3.83 (dd, 1H, *J* = 10.4, 5.2 Hz, H-6b), 4.04 (ddd, 1H, *J* = 9.2, 5.2, 4.0 Hz, H-5), 4.47 (ddd, 1H, *J* = 4.6, 4.1, 1.7 Hz, H-1), 4.55 (d, 1H, *J* = 12.1 Hz, C*H*Ph), 4.59 (d, 1H, *J* = 11.2 Hz, C*H*Ph), 4.64 (d, 1H, *J* = 12.1 Hz, C*H*Ph), 4.68 (d, 1H, *J* = 11.6 Hz, C*H*Ph), 4.71 (d, 1H, *J* = 11.2 Hz, C*H*Ph), 4.79 (d, 1H, *J* = 11.6 Hz, C*H*Ph), 6.11 (dd, 1H, *J* = 19.2, 1.8 Hz, C=C*H*$SiMe_3$), 6.24 (1H, dd, *J* = 19.2, 4.1 Hz, C*H*=C$SiMe_3$), 7.22–7.40 (m, 15H, 2 Ph). The *Z* isomer was not detected.

[14] The essentials of this approach have been applied by A. Kende, J. S. Mendoga, *Tetrahedron Lett.* **1990**, *31*, 7105–7108, for the reductive elimination of β-hydroxy imidazolyl sulfones with only SmI_2. The corresponding phenyl sulfones were unreactive under identical conditions.
[15] For other applications of 2-pyridyl sulfones see: J. B. Baudin, G. Hareau, S. A. Julia, O. Ruel, *Bull. Soc. Chim. Fr.* **1993**, *130*, 336–357, and references therein.
[16] The 2-pyridylsulfonyl glycosides were easily prepared as previously described for the phenyl sulfones (see ref. [9]). Attempts to prepare the corresponding imidazolyl sulfones were problematic and interestingly, the free C2 hydroxyl group failed to be silylated.
[17] The procedure reported by Stork and Keitz led to low or no yields of silylated products (G. Stork, P. Keitz, *Tetrahedron Lett.* **1989**, *30*, 6981–6984). In the case of a nonvolatile alkyne, the excess could easily be recovered by desilylation of the major by-product, the dialkynyldimethylsilane. Attempts to prepare an alternative and more efficient silylation method is underway in our laboratory.

New Materials for Liquid Crystal Displays: Structure–Property Relationship of 2-Fluoropyridines**

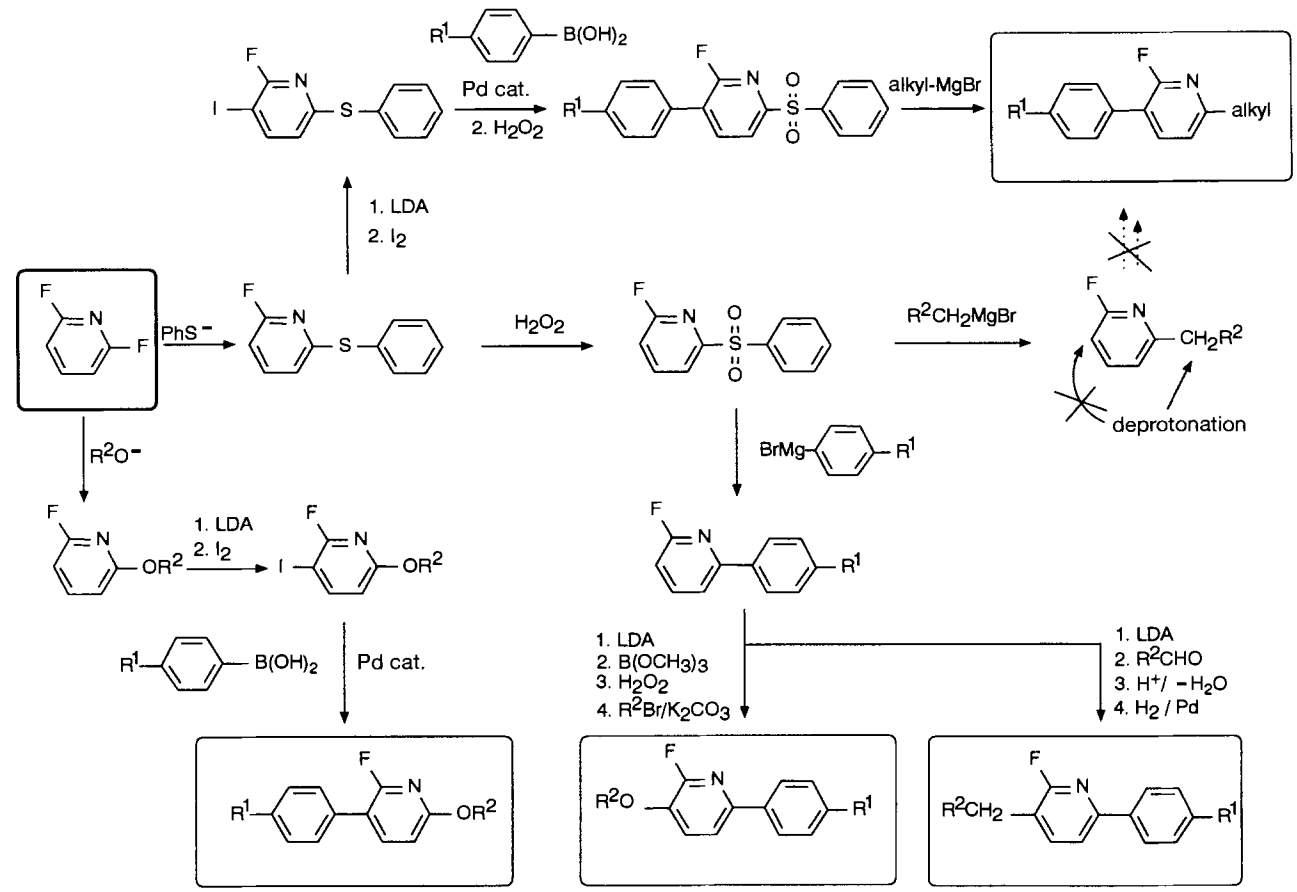
Volker Reiffenrath* and Matthias Bremer

The development of improved liquid crystal displays (LCDs) for devices[1] for the automotive industry, lap-top computers, or television sets, for example, is a challenging interdisciplinary goal for the 1990s. Liquid crystals used in devices are anisotropic materials that exhibit two different dielectric constants parallel ($\varepsilon_\parallel$) and perpendicular ($\varepsilon_\perp$) to the long molecular axis. This is a prerequisite for the observation of electro-optical effects. Most LCDs produced today are based on the twisted nematic cell (TNC).[2] This requires liquid crystals with positive values of the dielectric anisotropies ($\Delta\varepsilon = \varepsilon_\parallel - \varepsilon_\perp$), which can be realized by the introduction of polar terminal substituents into the rodlike mesogenic molecules.

In contrast, for applications based on electrically controlled birefringence (ECB)[3] or positive-contrast guest–host (GH,[4] a technique in which a small amount of a dye is added) there is continuing interest in liquid crystalline materials with strongly negative $\Delta\varepsilon$, implying large values of $\varepsilon_\perp$. A negative value of $\Delta\varepsilon$ can be achieved by the introduction of lateral polar substituents. This often also leads to the formation of tilted smectic-C (S_C)[5] phases, which are essential for ferroelectric liquid crystal (FLC)[6] applications. The ideal substituent should be strongly polar, form an angle of 90° with the long molecular axis, and, for optimum switching speeds, should not increase viscosity. Our solution to this problem is based on 2-fluoropyridine as a new building block for liquid crystals.[7]

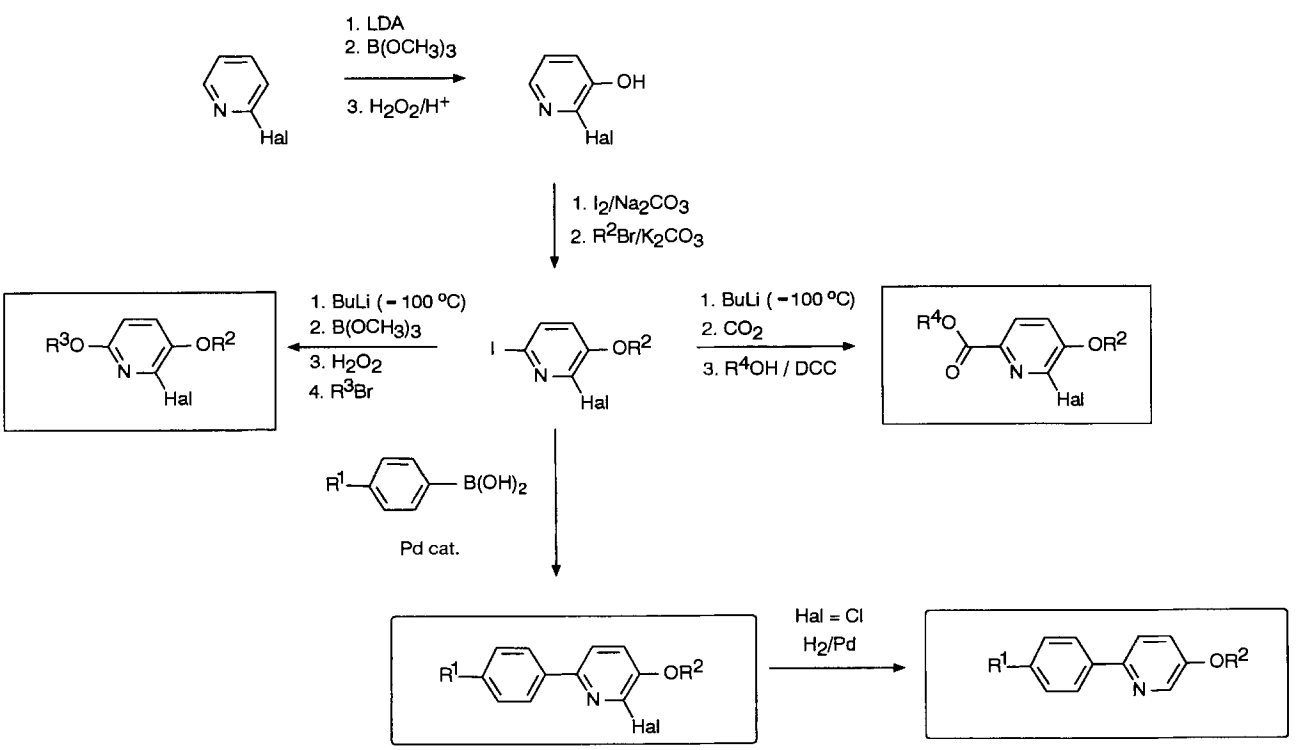
The fluoropyridines offer two possible 3,6-substitution patterns (**A** and **B**), which lead to different physical properties of the liquid crystals. Starting from two commercially available materials, we synthesized a host of new compounds based on the 2-fluoropyridine moiety (Schemes 1 and 2). Key steps are *ortho*-metallation,[8] carbon–carbon bond formation by palladium-catalyzed boronic acid coupling,[9] and displacement of aromatic sulfonyl groups by Grignard reagents.[10]

The iodopyridine, which appears as an intermediate in Scheme 2, is easily accessible by electrophilic iodination.[11] Interestingly, the use of 2-chloropyridine enables halogen-free 3-alkoxypyridines to be synthesized: The chlorine atom only serves as a directing group for metalation and is removed by hydrogenation in the final step.



Because of the polar substituents, the molecular dipole moment of **1** exhibits strong components along the molecular axis and perpendicular to it. Therefore, large values for both $\varepsilon_\perp$ and $\varepsilon_\parallel$ and a small positive $\Delta\varepsilon$ are found.[12] Replacement of the terminal fluorine by an ethoxy group in **2** reduces both dielectric constants, and not only, as expected, $\varepsilon_\parallel$. "Flipping" the pyridine ring (**2** → **3**, Table 1) results in a dramatic increase of $\varepsilon_\perp$ and thus in a strongly negative $\Delta\varepsilon$.

As this intriguing effect was not observed for the corresponding alkyl-substitued pyridines **4** and **5**, the oxygen atoms in **2** and **3** must play a significant role. To understand this surprising behavior better we carried out semiempirical model calculations (AM1).[13] 2-Fluoro-6-methoxy- and 2-fluoro-3-methoxypyridine were used to model the polar head groups of compounds **2** and **3**. The C-O-C-N dihedral angle θ was varied stepwise from 0° to 180°, but kept fixed while all other geometric parameters were fully optimized in the energy minimization. The calculations show that rotation from the *syn* into the *anti* structure enhances the molecular dipole moment of both pyridines especially in the y direction (Fig. 1).



Figures 2 and 3 give the overall dipole moments and the rotational barriers as a function of the dihedral angle θ. Although the calculated dipole moments for the *syn* and *anti* conformers

of the two pyridines are qualitatively similar, the relative energies are reversed. Thus, 2-fluoro-6-methoxypyridine probably exists mainly in the *syn* conformation with a small dipole moment (Fig. 2), whereas 2-fluoro-3-methoxypyridine is dominated by the more stable *anti* structure (Fig. 3) and therefore should exhibit a much larger dipole moment, especially perpendicular to the long molecular axis (Fig. 1). Since the dielectric anisotropy of

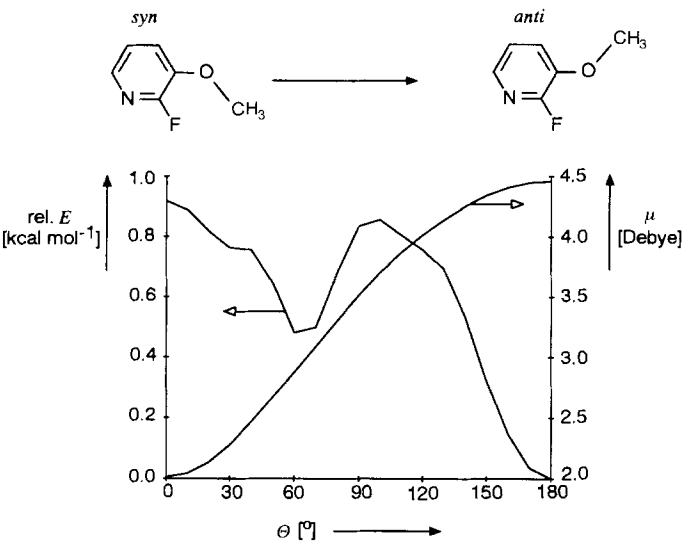

Fig. 3. The energy profile of the rotation about the pyridine-oxygen bond and total dipole moments in 2-fluoro-3-methoxypyridine.

a liquid crystal is directly related to the molecular dipole moment,[14] a simple explanation for this initially surprising result can be given.

While the introduction of a second alkoxy group (**10** → **11**, Table 1) into the difluorobenzenes[15] leads to an increase of $\Delta\varepsilon$ due to rotational preferences, the opposite behavior is found for the pyridines **7** and **8**. Now, flipping the pyridine ring (**8** → **9**) has, as expected, almost no effect on the dielectric anisotropy. The somewhat larger negative values of $\Delta\varepsilon$ found for **8** and **9** relative to **2** can also be rationalized by model calculations: The two-dimensional torsional energy surface of 2-fluoro-3,6-dimethoxypyridine was calculated, and the Boltzmann-weighted dipole moments[16] were computed for the gas phase at 298 K. The calculations yield an overall dipole moment of 2.1 Debye with a parallel contribution μ_x of only 0.1 Debye and a perpendicular dipole of 2.1 Debye (compare the values given in Fig. 1).

The examples **12**–**16** (Table 1) show the influence of incorporation of a carbonyl group. Depending on the substitution pattern of the pyridine ring, either a decrease or an increase of the dielectric anisotropy is observed.

Not only the dielectric properties can easily be tuned by the substitution pattern of the pyridine moiety, but also the mesophase behavior of long-chain liquid crystals. As indicated above, the introduction of lateral polar substituents in many cases favors the formation of S_C phases.[5, 15] In accord with earlier results for 2,3-difluorophenylene derivatives **20** and **24** (Table 1),[15] replacement of the phenyl rings by the fluoropyridine moiety in **17** and **21**[17] induces a S_C phase in **19** and **23**, respectively. Interestingly, this is not the case for the less polar compounds **18** and **22**. It appears that the substitution pattern leading to the more polar molecule favors the formation of the S_C phase.

We have shown that energetically preferred rotamers of alkoxy-substituted fluoropyridines strongly influence the dielectric properties of liquid crystals. We have synthesized new materials that offer broad S_C phases as well as distinctly negative dielectric anisotropy to improve the performance of modern liquid crystal displays with high information content.

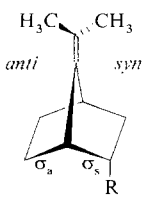
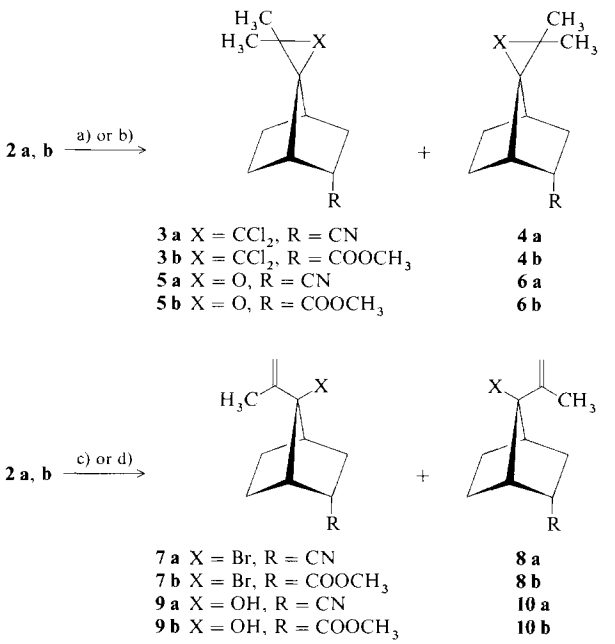
Electrostatic vs. Orbital Control of Facial Selectivities in π Systems: Experimental and Theoretical Study of Electrophilic Additions to 7-Isopropylidenenorbornanes**

Goverdhan Mehta,* Faiz Ahmed Khan, Shridhar R. Gadre*, Rajendra N. Shirsat, Bishwajit Ganguly, and Jayaraman Chandrasekhar*



Dedicated to Professor C. N. R. Rao on the occasion of his 60th birthday

Evaluation of the relative importance of electrostatic and orbital effects in determining facial selectivities of π systems (π-facial selectivity) in nucleophilic and electrophilic additions to trigonal carbon centers is currently a topic of intense debate.[1–3] We have recently reported[2] the addition of electrophiles such as BH_3, peracid, and $Hg(OAc)_2$ to some *endo*-substituted 7-methylenenorbornanes, for example **1a**, with sterically indistinguishable π faces and reconciled the observed *syn*-face selectivity in terms of the Cieplak model,[4] according to which the electrophiles should approach **1a** from the face opposite to the more electron-rich σ_a bond. However, on the basis of PM3 calculations on 7-methylenenorbornyl derivatives **1a**, **1c**, and related systems, it has been proposed[3] that the initial approach of a charged reagent would be along the *anti* side, governed by electrostatics, and the subsequent nucleophilic attack (for example, by water) would lead to the observed product stereochemistry.



1a R = R¹ = $COOCH_3$
1b R = F, R¹ = H
1c R = R¹ = F
1d R = CN, R¹ = H
1e R = R¹ = CN

Studies on CCl_2 and halonium ion additions to these systems were suggested for providing further insights. We now report experimental facial selectivities for the addition of such electrophiles to 7-isopropylidenenorbornane derivatives (**2**) and provide interpretations on the basis of ab initio molecular electrostatic potentials (MEP) and electron densities, as well as semiempirical transition state energetics. The use of the isopropylidene unit offers significant advantages. From an experimental point of view, the double bond becomes more reactive, which enables the study of carbene additions.[5] Further, unlike in **1**, the site of electrophilic attack is likely to be at C7 and not at C8, a factor which is crucial for interpretation of the experimental results. Finally, the mechanistic details of electrophilic attack in **2** are unambiguous and the steric neutrality on the two π faces is maintained.

2a R = CN
2b R = $COOCH_3$

7-Isopropylidenenorbornanes **2** smoothly undergo dichlorocarbene and singlet oxygen addition, epoxidation, and reaction with the bromine(I) cation. The reaction conditions, yields, and products obtained are shown in Scheme 1, and the π-face selectivities are summarized in Table 1. Structures of diastereomers were determined on the basis of ^1H and ^{13}C NMR data, but more specifically through the greater deshielding of the C_2 *exo*-proton in the *syn*-addition products (**3**, **5**, **7**, **9**) relative to that of the *anti*-products (**4**, **6**, **8**, **10**).[2, 6, 7]

3a X = CCl_2, R = CN — **4a**
3b X = CCl_2, R = $COOCH_3$ — **4b**
5a X = O, R = CN — **6a**
5b X = O, R = $COOCH_3$ — **6b**

7a X = Br, R = CN — **8a**
7b X = Br, R = $COOCH_3$ — **8b**
9a X = OH, R = CN — **10a**
9b X = OH, R = $COOCH_3$ — **10b**

Scheme 1. Electrophilic additions to **2**. a) $Cl_3CCOO^-Na^+$, dimethoxyethane (DME)/tetrachloroethylene, Δ, 80–93%; b) *m*-chloroperbenzoic acid (*m*-CPBA), Na_2CO_3, CH_2Cl_2, 0–5 °C, 90–95%; c) *N*-bromosuccinimide, 10% aqueous DME, 95%; d) $^1O_2$, *hv*, methylene blue, CH_2Cl_2, then $NaBH_4$, MeOH, 75–81%.

Table 1. Experimental ratios of *syn*- and *anti*-addition products of **2** with $:CCl_2$, *m*-CPBA, Br^+, and $^1O_2$ [a].

Compound	$:CCl_2$		*m*-CPBA		Br^+		$^1O_2$	
	syn	*anti*	*syn*	*anti*	*syn*	*anti*	*syn*	*anti*
2a	78	22	77	23	72	28	78	22
	3a	**4a**	**5a**	**6a**	**7a** [b]	**8a** [b]	**9a**	**10a**
2b	60	40	62	38	59	41	61	39
	3b	**4b**	**5b**	**6b**	**7b** [b]	**8b** [b, c]	**9b**	**10b**

[a] Product ratios (±5%) are based on ^1H NMR spectra. [b] Exhibits marked propensity for allylic rearrangement. [c] Could not be obtained pure but its presence was inferred from high-field NMR data.

The results confirm that even a single electron-withdrawing substituent in the *endo* position is capable of inducing *syn*-facial electrophilic addition, thus reinforcing our earlier observations.[2] There is also no ambiguity about the initial direction of attack of Br^+. Since the nucleophilic attack on the bromonium ion is followed by an elimination to give the olefins **7** and **8**, the loca-

tion of the bromine atom in these products directly reveals the direction of the initial electrophilic attack. Based on the observed product ratios, the charged electrophile Br^+ as well as neutral CCl_2 prefer to approach the *syn* face of **2a** and **2b**.

To delineate the nature of the electronic control of the observed selectivities, we carried out a topographical analysis of the molecular electrostatic potentials of **1a**, **b** and **2a**, **b** at the ab initio level with the 6-31G basis set, using the parallel SCF program INDMOL.[8] In particular, we focused on the MEP minima whose depth generally correlates with electron density. For both series of compounds, the MEPs about the two π faces are unsymmetrical; the (3, +3) critical point on the *anti* face consistently has a more negative value (Table 2). A similar asymmetry computed for **1c** at the PM3 level has been identified as the principal factor determining facial selectivity for the approach of charged electrophiles.[3] However, as the MEP values at the critical points are significantly less negative than those obtained for typical C=C bonds,[9] electrostatic influences are probably not of primary importance in determining the facial selectivities in these compounds.

Table 2. MEP at (3, +3) minimum and electron density at bond critical point (all values in Hartree) [a].

Cmpd. [b]	MEP at critical point		Density at bond critical point	
	syn	*anti*	σ_s	σ_a
1a	−0.0208	−0.0269	0.2096	0.2174
1b	−0.0270	−0.0307	0.2121	0.2165
1c	−0.0129	−0.0202	0.2130	0.2166
1d	−0.0193	−0.0234	0.2112	0.2169
1e	−0.0012	−0.0083	0.2116	0.2172
2a	−0.0174	−0.0222	0.2114	0.2172
2b	−0.0278	−0.0305	0.2109	0.2171

[a] At a critical point of a scalar field f, $\nabla f = 0$. The critical points are classified in terms of the eigenvalues of the Hessian operator. The MEP and bond critical points are (3, +3) and (3, −1) types in the scalar fields. For details of MEP and density topography see Ref. [10]. [b] MNDO optimized geometries. The olefinic units are essentially planar in all the derivatives.

To confirm the potential role of orbital interactions in determining the facial selectivities in these substrates, the unsymmetrical donor abilities of the σ_s and σ_a bonds (see structures **1** and **2**) were characterized in terms of the electron densities at the corresponding bond critical points (Table 2). In all systems with electron-withdrawing groups, the σ_a bond consistently has a greater density. Operation of Cieplak-type orbital interactions[4] would then lead to the observed *syn*-facial selectivity.

Semiempirical MO calculations on the bromonium ion intermediates resulting from **2**, as well as carbene addition transition states, lead to several additional insights (Table 3). Optimization of the bromonium ion intermediates at the PM3 level[11] leads to classical structures, and cyclic forms are not minima.

Table 3. Calculated heats of formation in kcal mol^{-1} of classical intermediates formed by Br^+ additions and transition states for $:CCl_2$ additions to **2**.

Cmpd.	Site of electrophilic attack	Br^+ [a]		$:CCl_2$ [b]	
		syn	*anti*	*syn*	*anti*
2a	C-7	228.64	229.41	91.53	92.37
	C-8	236.29	236.55	93.17	93.21
2b	C-7	109.05	109.26	−23.11	−22.52
	C-8	115.64	115.76	−21.66	−21.65

[a] PM3 method. [b] AM1 method.

The calculations confirm that Br^+ prefers to attack the C7 center, rather than C8 (by 6–7 kcal mol^{-1}), as a less strained tertiary carbocation is formed in the former. The computed *syn*–*anti* energy differences are small. Nevertheless, for both **2a** and **2b**, the ion formed by addition to the *syn* face is consistently more stable, in agreement with the observed facial selectivities. Interestingly, the preference is larger for the ions formed by attack at C7 and not C8, particularly for **2a** [ΔE (*anti*–*syn*) = 0.8 and 0.3 kcal mol^{-1}, respectively)]. Greater unfavorable electrostatic interactions are anticipated between the Br^+ ion at C7 and *syn* face of **2a**. These are evidently overcome by effective orbital stabilization involving the Br-C-7σ* MO and the relatively electron-rich antiperiplanar σ_a bond.

Transition state energies determined with the AM1 procedure[11] for CCl_2 addition to **2** are also consistent with the observed stereoselectivities.[12] Since the least motion pathway for the addition of a carbene to an olefin is a forbidden pathway,[13] the transition structure is highly unsymmetrical. In effect, the carbene forms a bond to one of the olefinic carbon atoms with a C-C-C angle of about 90°. The chlorine atoms are tilted towards the other carbon, which has a planar coordination characteristic of a carbocation. These features have significant consequences for the facial selectivities of **2**. In view of the unsymmetrical nature of the olefins, two sets of first order saddle points, characterized by a closer approach of the carbene to C7 or C8, are obtained for the *syn*- as well as *anti*-facial additions. Interestingly, the energetically favored transition states correspond to CCl_2 attack at C7. As a result, the newly formed C–C bond is more responsive to the unsymmetrical orbital effects from σ_a and σ_s orbitals. Further, as the chlorine atoms are tilted upwards in the corresponding transition states, any contribution from electrostatic interactions from the norbornyl unit are precluded. Overall, a clear preference for *syn*-facial attack results. For the transition states for attack at C8, there is negligible facial selectivity. Orbital effects and electrostatic interactions seem to cancel.[14]

In summary, we have demonstrated a consistent, remote substituent control of the facial selectivities in electrophilic additions to *endo*-substituted 7-isopropylidenenorbornanes. With ab initio and semiempirical MO calculations, it has been clearly shown that the observed preferences are primarily due to orbital effects.

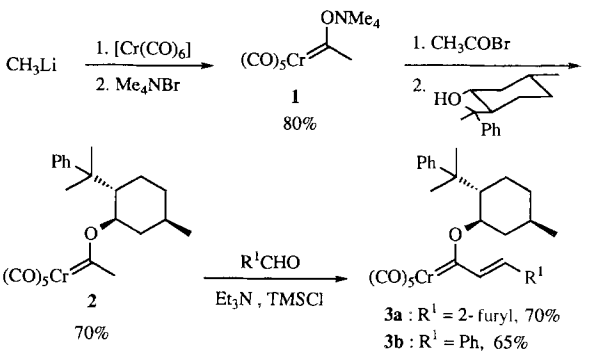
[14] Ab initio calculations (3-21G) on the AM1 transition structures for CCl_2 addition to **2a** support the general conclusions. Total energies [Hartree] for *syn*- and *anti*-facial addition structures: −1429.12927 and −1429.12620 for C7 approach; −1429.12650 and −1429.12433 for C-8 approach, respectively. Thus, the former structures are energetically favored. Further, *syn*-face attack is preferred to a greater extent in the transition structures corresponding to C7 approach (1.9 vs 1.4 kcal mol^{-1} for C8 approach).

Asymmetric Michael Additions to Chiral α,β-Unsaturated Alkoxycarbene Chromium Complexes**

José Barluenga,* Javier M. Montserrat, Josefa Flórez, Santiago García-Granda, and Eduardo Martín



The Michael reaction is one of the fundamental processes for carbon–carbon bond formation; and significant advances in asymmetric 1,4-conjugate addition reactions, involving chirally modified substrates or a chiral reaction medium, have been achieved.[1] α,β-Unsaturated Fischer carbene complexes, which are increasingly playing an important role in organic synthesis,[2] behave as reactive Michael acceptors. Since the pioneering work by Casey et al. on additions[3] of carbon nucleophiles, several other nucleophiles have been 1,4-added to heteroatom-stabilized alkenyl-[4] and alkynylcarbene[5] complexes with good regioselectivities and diastereoselectivities;[6] but thus far no examples of enantioselective Michael additions to α,β-unsaturated Fischer carbene complexes are known. The asymmetric Michael reactions of chiral prolinol-derived aminocarbene complex anions to cyclic enones have been recently described.[7] We report herein on highly diastereoselective conjugate additions of β-oxygen-functionalized organolithium compounds, alkyllithium reagents, and lithium enolates to chirally modified α,β-unsaturated alkoxycarbenechromium complexes that are readily available in optically pure form.

In a previous report[8] we described the diastereoselective one-pot synthesis of strained tricyclic ethers by reaction of properly substituted β-oxygen-functionalized organolithium compounds with Fischer vinylcarbene complexes. In order to prepare these unusual tricyclic structures as enantiomerically pure compounds

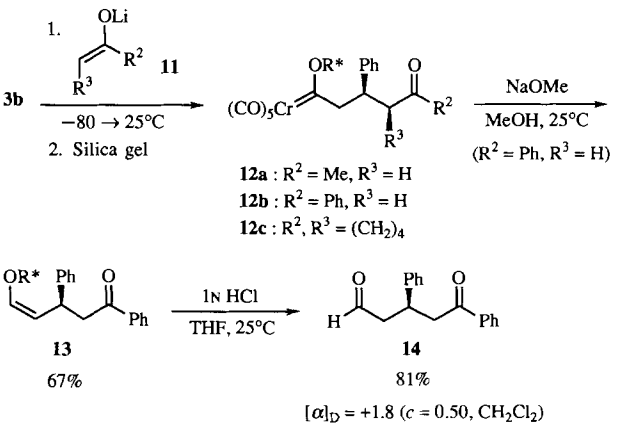
[d] Optical rotations were recorded in CH_2Cl_2 at 20–25 °C, c = 0.25–0.35 g 100 mL^{-1}. [e] Absolute configuration of the new stereogenic center formed in the addition step. Determined by X-ray analyses of compounds **8a** and **12a** (entries 3, 6) and proposed by analogy in all the other adducts assuming the same stereochemical model. [f] Based on enol ether **6**. [g] Determined by HPLC (Chiralcell OD-H, hexane:2-propanol, 3:1) of compound **7** in comparison with the corresponding racemic mixture. [h] Based on the corresponding enol ether **9b**, **9c**. [i] Determined by HPLC (Chiralcell OD-H, hexane:THF, 6–12:1) of 2,4-dinitrophenylhydrazone derivatives of the corresponding aldehydes **10** in comparison with the corresponding racemic products.

alkoxide exchange and cyclopropanation reactions were not observed, probably due to the bulkiness of the 8-phenylmenthyl group. While this approach has so far not led to tricyclic ring systems,[14] the high asymmetric induction observed in the reaction prompted us to study the addition of other organolithium compounds and these results represent the first examples of asymmetric conjugate additions to Fischer vinylcarbene complexes.



Scheme 2 shows the Michael reaction of another β-oxygen-functionalized organolithium **4** (R^2 = Ph) with carbene complex **3b** (R^1 = Ph) which gave, after purification by silica gel chromatography, adduct **5b**. Removal of the pentacarbonylchromium fragment by basic treatment with sodium methoxide[15] in methanol, afforded the less stable (*Z*)-enol ether[3c] **6** (*J* = 6 Hz, vinyl protons). The (−)-8-phenylmenthyl chiral auxiliary was removed and recovered (80%, after column chromatography) by acid hydrolysis (1 N, HCl) of **6** which led to the cyclic hemiacetal **7** as a single product (Table 1, entry 2), indicating high asymmetric induction in the conjugate addition and also in the intramolecular cyclization reaction. The relative configuration of the newly formed stereogenic carbon centers of **7** was established by analysis of the coupling constants for the methine protons and by a difference NOE experiment. Under the same reaction conditions, the addition of alkyllithium reagents to α,β-unsaturated carbene complex **3b** led diastereoselectively to the Michael adducts **8**. Removal of the transition metal moiety and the chiral auxiliary as previously described gave rise to the optically active β-substituted aldehydes **10** with high enantiomeric excesses (Scheme 3, Table 1, entries 3–5). Both vinyl ethers **9** were

Scheme 3. Asymmetric Michael additions of alkyllithium compounds. Yields of **9b** and **9c** are based on **3b**; both vinyl ethers are a mixture *Z*:*E*, 6:1.

isolated as a 6:1 mixture of diastereoisomers (*Z*:*E* ratio determined from the ^{1}H NMR spectrum; J_{cis} = 6.9 Hz, J_{trans} = 12.1 Hz, vinyl protons). The lithium enolates **11**, generated from the corresponding ketones by treatment with lithium diisopropylamide (LDA) at −78 °C in tetrahydrofuran,[16] may also be added as donors to the optically active acceptor **3b**, yielding the 1,4-adducts **12** in uniformly high diastereomeric excesses (Table 1, entries 6–8). The Michael addition of the lithium enolate of cyclohexanone to Fischer vinylcarbene complexes takes place with *syn* diastereoselectivity;[6] thus, this stereochemistry was assumed for compound **12c**. Metal and chiral auxiliary-free products are easily accessible in high enantiomeric purity as indicated in Scheme 4 with the transformation of **12b** into the 1,5-dicarbonyl compound **14**.[17]

The absolute configuration of the newly formed stereogenic center at the β position of the carbene complex was determined by the single-crystal X-ray structure analysis of compounds **8a**[18] (Fig. 1) and **12a**.[19] In all other products it was assigned by analogy.

Scheme 4. Asymmetric Michael additions of lithium enolates of ketones.

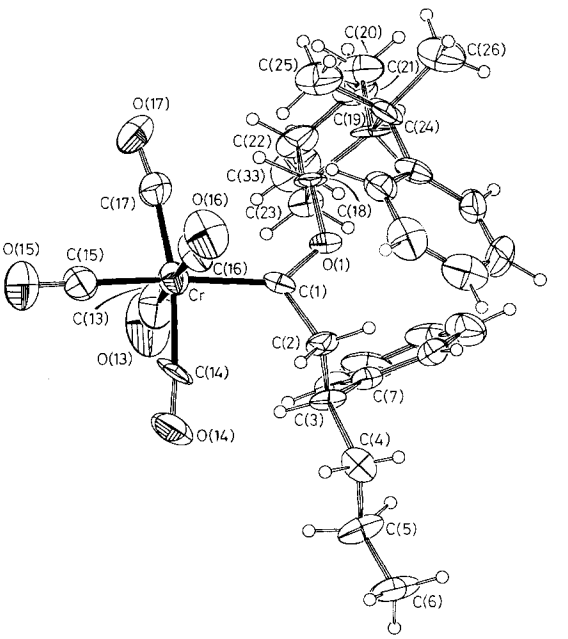


Fig. 1. Crystal structure of **8a**. Selected bond lengths [Å] and bond angles [°]: Cr(1)-C(1) 2.056(7), O(1)-C(1) 1.288(6), C(1)-C(2) 1.528(8), C(2)-C(3) 1.528(8), C(3)-C(7) 1.476(9), C(3)-C(4) 1.563(11); C(15)-Cr(1)-C(1) 172.8(4), C(1)-O(1)-C(18) 125.2(5), O(1)-C(1)-C(2) 103.4(5).

The asymmetric induction that has been observed in all these reactions can be explained in terms of the model shown in Figure 2. In this drawing of the most stable conformation the appropriately positioned phenyl group shields selectively the front face of the double bond by π,π-orbital overlap[20] forcing the nucleophile to attack preferentially on the opposite side.[21] This model is similar to the "π-stacking" one previously proposed by W. Oppolzer et al.[22] for cuprate additions to enoates and the one depicted by E. Nakamura et al.[6] to explain the diastereoselective *syn* Michael addition of enolates to Fischer vinylcarbene complexes.

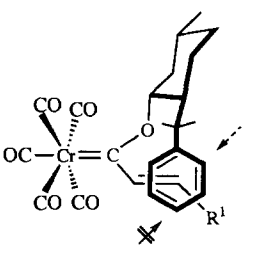

Fig. 2. Model proposed to explain the asymmetric induction of the Michael additions discussed here.

The net transformations described here are the synthetic equivalent of Michael additions of alkyllithium compounds and ke-

tone enolates to α,β-unsaturated aldehydes. The present carbene route offers an attractive alternative to this otherwise generally difficult reaction.[1a, d, 23]

Experimental Procedure

10b: To a cooled (−80 °C) solution of **3b** (1.44 g, 2.68 mmol) in THF (30 mL) was added a 2.5 M solution of BuLi in hexane (1.15 mL, 2.8 mmol) under nitrogen and the mixture was stirred at −80 °C for 1 h and between −80 °C and room temperature for 0.5 h. After removal of the solvents in vacuo a solution of NaOMe (ca. 0.5 M) in MeOH (20 mL) was added and the mixture was stirred at room temperature for 3 h. MeOH was removed and the residue was purified by column chromatography (silica gel, hexane: Et_2O, 4:1) to give 0.83 g (76%) of **9b**. To a solution of **9b** (0.75 g, 1.86 mmol) in THF (30 mL) was added 1 M HCl (3 mL) and the mixture stirred at room temperature for 10 h. The solvent was removed in vacuo and the residue was purified by column chromatography (silica gel, hexane: Et_2O, 10:1) to give 0.29 g (82%) of **10b**.

[17] All new compounds were characterized spectroscopically (^1H, ^{13}C NMR, IR) and by mass spectrometry.

[18] Crystal data for **8a**: $C_{33}H_{38}CrO_6$, $M_r = 582.63$, orthorhombic, space group $P2_12_12_1$, $a = 10.875(3)$, $b = 14.134(4)$, $c = 20.91(1)$ Å, $V = 3214.(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.20$ g cm^{-3}, $F(000) = 1232$, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 3.8$ cm^{-1}, $T = 293$ K. Yellow crystal (0.20 × 0.10 × 0.10 mm) obtained from a hexane solution at −30 °C. Enraf-Nonius CAD4 diffractometer. ω-2θ scan technique. Of 6609 reflections measured ($0 < \theta < 25°$), 5637 used in refinement. The structure was solved by Patterson methods with the program SHELXS86 [24] and expanded by DIRDIF [25]. An absorption correction was applied by using DIFABS [26]. Full-matrix least-squares refinement on $|F|^2$ was made with SHELXL93 [27]. All non-hydrogen atoms were anisotropically refined. Most hydrogen atoms were located by difference Fourier synthesis. Final conventional $R = 0.048$ (for 1550 $F_o > 4\sigma(F_o)$) and $wR2 = 0.131$ (for all reflections (5637)) $w = 1.0/[\sigma^2(F_o^2) + (0.0625P)^2]$ where $P = (\mathrm{Max}(F_o^2, 0) + 2F_c^2)/3$. The absolute configuration was checked with the BIJVOET Program [28] and gave $B = 0.46(7)$ for the 100 strongest Friedel pairs. (Flack χ parameter [29] 0.0076(402)). Total number of parameters 394. Residual electron density less than 0.18 eÅ^{-3}. The plot in Figure 1 was made by EUCLID package [30]. Further details of the crystal structure determination are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[19] A complete description of the X-ray structure analysis and absolute configuration determination for **12a** has been deposited at the Cambridge Crystallographic Data Centre.

New Cyclic Derivatives of 3′-Amino-3′-deoxyadenosine-5′-diphosphate, -triphosphate, and -methylenebis(phosphonate)**

Michael Morr* and Victor Wray

Dedicated to Professor Fritz Wagner on the occasion of his 65th birthday

Whereas a number of chemical syntheses of 3′-amino-3′-deoxyadenosine (3′-AdA) (**1**) have been described,[1] we have been engaged for a long time in its preparation by fermentation of *Helminthosporium* sp. 215.[2] Compound **1**, the basic component of the antibiotic nucleoside puromycin,[3] has also been modified by us in many ways. Thus **1** was phosphorylated to 3′-AdA-5′-monophosphate (**9**), which in turn was cyclized with dicyclohexylcarbodiimide (DCC) or water-soluble carbodiimide (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride, EDC) to yield the cAMP-analogue 3′-AdA-3′,5′-cyclophosphate (**12**) (3′-NH-cAMP).[4, 5] This was used for inhibition studies with cAMP-dependent protein kinase.[6] A further derivative of **1**, 3′-AdA-5′-triphosphate (**7**) (3′-NH_2-ATP), proved to be of bio-

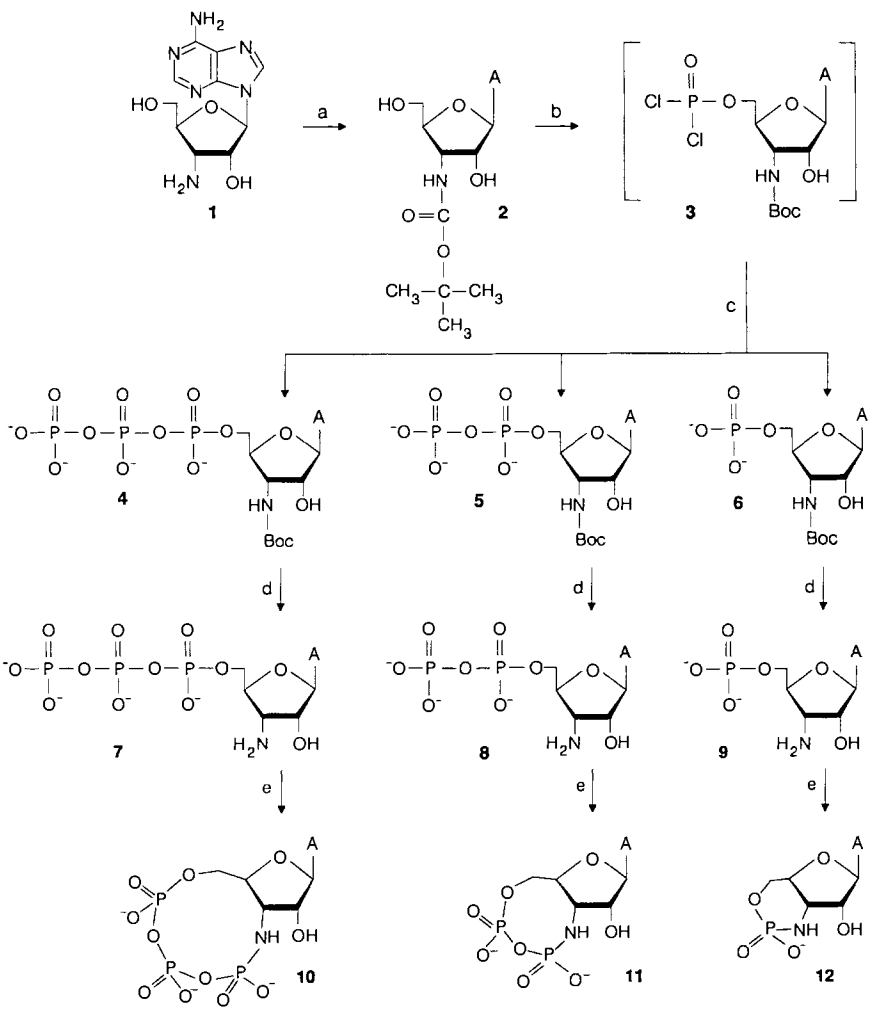
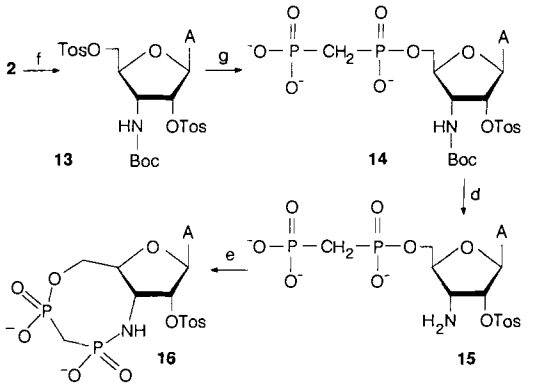
[**] We are grateful to Mrs. D. Döring, Technical University of Braunschweig, for recording the FAB mass spectra.



chemical interest. It was first prepared enzymatically by Marutzky[7] from **9** with myokinase and pyruvate kinase and served as an ATP-analogue in substrate binding studies with leucyl-tRNA-synthetase.[8] Van Boom et al. prepared **7** by phosphorylation of the 5′-OH group according to the triester method and by activation of protected **9** with morpholine and subsequent reaction with diphosphoric acid.[9] Apart from its use in the study of protein biosynthesis, **7** was shown to be an effective inhibitor of the DNA-dependent RNA polymerase from Ehrlich ascites tumor cells[10] and *E. coli*.[11–13]

Phosphorylation of **1** according to Yoshikawa[14] with $POCl_3$ in triethylphosphate furnishes different products depending on the reaction conditions. Thus, phosphorylation in suspension gives almost exclusively 3′-amino-5′-chloro-3′,5′-dideoxyadenosine[15] accompanied by a small amount of **9**. When **1** is dissolved in hot triethylphosphate and then phosphorylated with $POCl_3$, one obtains 3′-AdA-5′-phosphorodichloridate (not isolated) which is converted exclusively to **12** by alkaline hydrolysis.



A repetition of the synthesis of **12** from impure **9** (containing some 3′-AdA-5′-diphosphate (**8**) and the triphospate (**7**) by the cyclization method with water-soluble carbodiimide led to the surprising observation that **7** and **8** also underwent complete cyclization to yield **10** and **11**, respectively. For subsequent studies on a larger scale, **7** and **8** were prepared according to Yoshikawa[14] and Ludwig.[16] The *tert*-butoxycarbonyl (Boc) protecting group is introduced into **1** with di-*tert*-butyldicarbonate[17] in *N*,*N*-dimethylformamide (DMF) to give 3′-*N*-Boc-3′-deoxyadenosine (**2**).[18] Phosphorylation with $POCl_3$ in triethylphosphate yields the intermediate **3** (not isolated), which is converted with bis(tri-*n*-butylammonium) diphosphate[16] in good yield to 3′-*N*-Boc-ATP (**4**), and small amounts of 3′-*N*-Boc-ADP (**5**) and 3′-*N*-Boc-AMP (**6**). By ion-exchange chromatography on DEAE-sephadex [HCO_3^- form, H_2O/triethylammonium hydrogencarbonate buffer (pH 7.5) gradient], removal of the *N*-Boc protective group with trifluoroacetic acid (TFA) and repeated chromatography, **7**, **8**, and **9** are obtained (Scheme 1).

Cyclization of **7** and **8** proceeds in very good yields with EDC (5- to 10-fold excess, nucleotide concentration 1–2 mg mL^{-1}) at pH 7.0–7.5 to 3′-AdA-3′,5′-cyclodiphosphate (**11**) and 3′-AdA-3′,5′-cyclotriphosphate (**10**), respectively. Purification is achieved by ion-exchange chromatography on DEAE-sephadex (see above). Compound **11** is the first derivative of the naturally occurring adenosine-3′,5′-cyclodiphosphate (cADP)[19] which has been isolated from the red alga *Porphyra perforata* and synthesized by cyclization of adenosine-3′,5′-diphosphate with DCC.[20, 21] cADP inhibits the cAMP-dependent protein kinase and bovine phosphodiesterase;[21] in the presence of N^6,2′-*O*-dibutyryl-3′,5′-cAMP it inhibits the spontaneous germinal vesicle breakdown (GVBD) of cultured mouse oocytes.[22] No naturally occurring cyclic ATP derivatives have been found so far; **10** is the first derivative of cATP. Straight chain γ derivatives of ATP with different amines were prepared by Knorre et al. by reaction with DCC.[23] Orgel et al. investigated the reactions of AMP, ADP, ATP, and ATeP (adenosine-5′-tetraphosphate) with water-soluble carbodiimide without observing any intramolecular cyclization.[24]

After tosylation of the 3′- and 5′-positions of **2** with tosyl chloride in pyridine/4-dimethylaminopyridine (DMAP) to **13**, a further interesting derivative, **14**, of **1** was obtained by selective nucleophilic substitution of the 5′-*O*-tosyl group with tris-(tetra-*n*-butylammonium) methylenebis(diphosphonate).[25] Removal of the 3′-*N*-Boc protective group with TFA and cyclization of **15** with EDC at pH 7.0–7.5 followed by the usual purification on DEAE-sephadex furnishes good yields of 3′-amido-3′-deoxy-2′-*O*-tosyladenosine-3′,5′-cyclomethylenebis(phosphonate) (**16**) (Scheme 2). The new cyclic derivatives are very stable with respect to hydrolysis of the P–N bond. Whereas **12** is already cleaved to **9** at pH 5 because of the large ring strain, compounds **10**, **11**, and **16** are completely stable at pH 3 since ring strain is less important here. At pH 2, the half-life times of P–N bond cleavage are about 30 h, 18 h, and 4 h for **10**, **11**, and **16**, respectively.

Scheme 1. a) $(Boc)_2O$, DMF, 92%; b) $POCl_3$, $OP(OEt)_3$, 90%; c) $(Bu_3NH)_2H_2P_2O_7$/Bu_3N/DMF, 0 °C, 5 min, 1 M $(Et_3NH)HCO_3$ buffer (pH 7.5), column chromatography: DEAE-sephadex (HCO_3^-), H_2O/$(Et_3NH)HCO_3$ buffer gradient, **4** 65%, **5** 20%, **6** 12%; d) TFA, 5 min, room temperature, column chromatography as under b), **7** 85%, **8** 70%, **9** 92%; e) EDC, pH 7–7.5, column chromatography as under b), **10** 88%, **11** 90%.

Scheme 2. cADP analogues with NH and CH_2 in the ring system: f) TsCl, DMAP, pyridine, 75%; g) $(Bu_4N^+)_3HOP(O)(O^-)CH_2P(O)(O^-)_2$, CH_3CN, 68%, d) see Scheme 1, **15** 85%; e) see Scheme 1, **16** 88%.

The structures of **7**, **8**, **10**, **11**, **15**, and **16** were confirmed from their FAB mass spectra[26] and from their ^1H, ^{13}C, and ^{31}P NMR data (Tables 1 and 2). The assignments of these NMR data followed from a straightforward comparison with detailed literature data for **9** and its 3′,5′-cyclophosphate **12**.[5] Two ^{31}P NMR signals were observed for **8**, **11**, **15**, and **16**, and three for **7** and **10**. Ring formation in **10**, **11**, and **16** was confirmed by the observation of ^{31}P spin coupling to H3′ and to C2′, C3′, C4′, and C5′. Two-dimensional $^1H,^1H$-COSY and a ^1H-detected heteronuclear multiple-quantum coherence $^{13}C,^1H$ correlation allowed unambiguous assignments of the signals in **16**. The presence of the methylene group bound directly to both phosphorus atoms in **15** and **16** was indicated by the two large $J(^{31}P,^{13}C)$ values observed for this carbon nucleus.

Table 1. ^1H NMR data of **7**, **8**, **10**, **11**, **15**, and **16** in D_2O.

The Spin Density Distribution in the Tetracyanoethylene Radical Anion, $[TCNE]^{\bullet -}$, by Single-Crystal Polarized Neutron Diffraction**

Andrey Zheludev, André Grand, Eric Ressouche, Jacques Schweizer,* Brian G. Morin, Arthur J. Epstein,* David A. Dixon,* and Joel S. Miller*

Several classes of molecule/organic-based magnetic solids based upon the tetracyanoethylene radical anion, $[TCNE]^{\bullet -}$, have been reported.[1] These include $[Fe(C_5Me_5)_2]^{\bullet +}[TCNE]^{\bullet -}$, with a critical temperature T_c of 4.8 K,[1] $[V(TCNE)_x]\cdot y(CH_2Cl_2)$ ($T_c \approx 400$ K),[1, 2] and $[MnTPP]^{\bullet +}[TCNE]^{\bullet -}$ (TPP = *meso*-tetraphenylporphyrinato) ($T_c = 18$ K).[1, 3] In the former class of magnetic materials the $[TCNE]^{\bullet -}$ is an isolated ion approximately parallel to the plane of the C_5Me_5 rings of adjacent $[M(C_5Me_5)_2]^{\bullet +}$ radical cations. In contrast, the $[TCNE]^{\bullet -}$ radical anions coordinate directly to metal ions in a bridging *trans*-μ_2 arrangement for the latter classes of materials. In all cases the odd number of electrons in $[TCNE]^{\bullet -}$ is crucial to the magnetic properties of the material. To understand the spin coupling mechanism that leads to the cooperative magnetic behavior of these classes of materials it is important to understand the spin distribution in the $[TCNE]^{\bullet -}$ radical anion. Herein, we report the spin distribution within $[TCNE]^{\bullet -}$ as determined from the single-crystal polarized neutron diffraction of $Bu_4N^+[TCNE]^{\bullet -}$.

The spin density in a radical of a known structure can be determined from neutron scattering by aligning the spins by means of an external magnetic field at low temperature and measuring the magnetic neutron scattering amplitudes (magnetic structure factors) at the Bragg scattering positions. The use of polarized neutrons increases the sensitivity of the method, since the nuclear scattering enhances the magnetic signal.[4] The crystal structure of $Bu_4N^+[TCNE]^{\bullet -}$ was determined by both X-ray[5a] and unpolarized neutron diffraction.[5b] The planar $[TCNE]^{\bullet -}$ radical anions are isolated both from the cations and from each other in the crystal.

The magnetic structure factors F_M are the Fourier components of the magnetization (spin) density. Reconstruction of the spatial spin density from the experimental magnetic structure factors is an Inverse Fourier (IF) problem, which is solved within the limitations of the accuracy and completeness of the polarized neutron diffraction data.[6] Because the data are noisy, the sampling of data points in reciprocal space is somewhat arbitrary, and the spatial resolution of the diffraction experiment is limited, several approaches for solving the IF problem were utilized.

Model-independent IF methods not involving any a priori knowledge of the spin density distribution were used to determine the spin density. The most straightforward method requires calculation of the IF sum over the Bragg reflections for which the F_M values were determined. This widely used approach is not suitable for incomplete and noisy data. Furthermore, since not all of the Fourier components are known, there are many three-dimensional spin density distributions (maps) which fit the data.

The recently developed maximum of entropy (MaxEnt) technique[7-10] selects the most probable spin density distribution—the one which maximizes the Boltzmann entropy—and gives much better results than conventional Fourier inversion. Figure 1 represents the MaxEnt reconstructed spin density projected onto the $[TCNE]^{\bullet -}$ molecular plane. The MaxEnt reconstruction reveals three key features: 1) The unpaired electron resides only on the $[TCNE]^{\bullet -}$ radical anion. 2) Most of the spin is localized on the central sp^2-carbon atoms, with smaller, but significant, spin densities at the nitrogen atoms, and even smaller and *negative* spin densities on the sp-carbon atoms. 3) The spin density on the sp^2-carbon atoms is not centered on these atoms, but it is bent away from the midpoint of the central C–C bond.

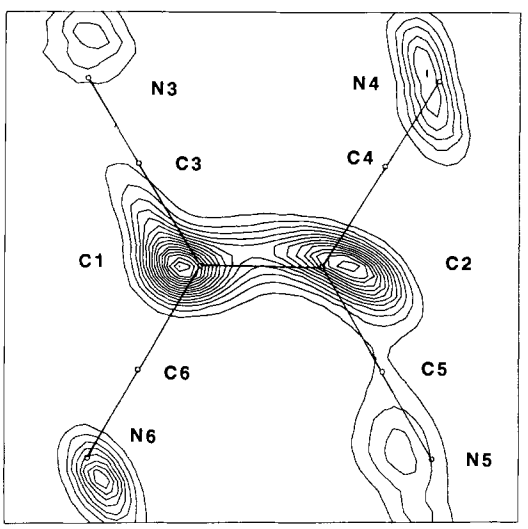

Fig. 1. Projection of the MaxEnt reconstructed spin density of $[TCNE]^{\bullet -}$ onto the molecular plane (xy).

Alternatively, the IF problem can be solved by using a parametrized model of the spatial spin density distribution and refining the parameters to fit the experimental structure factors. A good model should be flexible enough to describe the actual density with as few parameters as possible. A simple, frequently used model is based on individual atomic magnetic wavefunctions.[4] In this framework a LCAO-type wavefunction is constructed at each atomic site from standard Slater-type atomic orbitals.[11]

The simplest model for $[TCNE]^{\bullet -}$ uses the $|p_z\rangle$ orbitals (where z is the axis perpendicular to plane of the ion) for the C and N atoms. The atomic spin populations and radial exponents were refined by using a modification of the least-squares program MOLLY.[12] The results, however, are not very satisfactory as the residual estimated standard deviation (χ^2) is large (i.e. 1.8). The refined spin populations on each chemically equivalent sp^2-C are different [i.e. 0.185(7) and 0.256(7) μ_B].

The spin density on the sp^2-carbon atoms cannot be properly described by only using axially symmetrical $|p_z\rangle$ orbitals, since the unpaired electron resides in an antibonding π^* orbital which

[**] Contribution No. 6619. The authors gratefully acknowledge the support of the Department of Energy, Division of Materials Sciences (Grant Nos. DE-FG03-93ER45504 and DE-FG02-86BR45271) has given to enable these studies and the single-crystal X-ray analysis provided by Carlos Vazquez, William J. Marshall, and Joseph C. Calabrese (DuPont).

is bent away from the center of the central C–C bond. Hence, a model permitting more freedom of the spin density shape is required. More flexibility can be obtained by directly modeling the spin density rather than the magnetic wavefunction. This can be accomplished by expanding the spin density around the nuclei in a multipolar series.[13] In this model the spin density is treated as a sum of real spherical harmonic functions centered at each atomic site.

After several trial refinements the hybrid model with only a minimal basis set of orbitals perpendicular to the molecular plane (i.e., the $|2p_z\rangle$ orbitals for the nitrogen and sp-carbon atoms) and a multipolar expansion of the spin density, was chosen. This multipolar expansion was truncated at orbital index = 3 (i.e., only mono-, di-, quadru-, and octapoles were included). To minimize the number of adjustable parameters, maximum advantage was taken of molecular symmetry. Only those functions which are even with respect to z and y were utilized (with the x axis parallel to the C–C double bond). Furthermore, the spin densities on the sp^2-carbon atoms were constrained to be symmetric with respect to the plane perpendicular to the central C–C bond and passing through its midpoint. The final refinement was improved ($\chi^2 = 1.4$) with refined spins on each sp^2-carbon atom of 0.255(3) μ_B (Table 1). The projection of the spin density along the z axis onto the approximate molecular plane is presented in Figure 2.

Table 1. Characteristic parameters of the spin densities calculated and refined atomic spin populations of $[TCNE]^{\bullet -}$ in μ_B and comparison with the results from NLDFT calculations [a].

	Wavefunction refinement	Multipolar expansion of the spin density	NLDFT TZVP [b]

N6	0.120(8)	0.118(6)	0.15
total spin	0.789(22)	0.761(17)	1.00

[a] Negative values correspond to an excess of electrons with β spin. [b] A triple-zeta valence potential based on the structure determined from neutron diffraction was used for the NLDFT calculations. [c] N = number of parameters/number of observed flipping ratios. [d] Experimental estimated standard deviation.

To ascertain if the spin density on the other atoms of $[TCNE]^{\bullet -}$ has the $|2p_z\rangle$ shape, preliminary refinements in which the contributions from these atoms were reduced to spherical ones were made ($\chi^2 = 1.8$). Hence, the $|2p_z\rangle$ orbital model better fits the observed densities.

The model with only the sp^2 carbon atoms symmetrized provides the best fit[14] to the experimental data. The greatest spin contribution (66%) is from the sp^2-carbon atoms. The contribution from the nitrogen atoms is also significant (52%), while the total spin contribution from the sp-carbon atoms is small (−20%) and *negative*. The multipole expansion shows that the spin density is not centered over the nuclei at the sp^2-carbon atoms, but is bent away from the midpoint of the central C–C bond consistent with the results of the MaxEnt analysis shown in Figure 1.

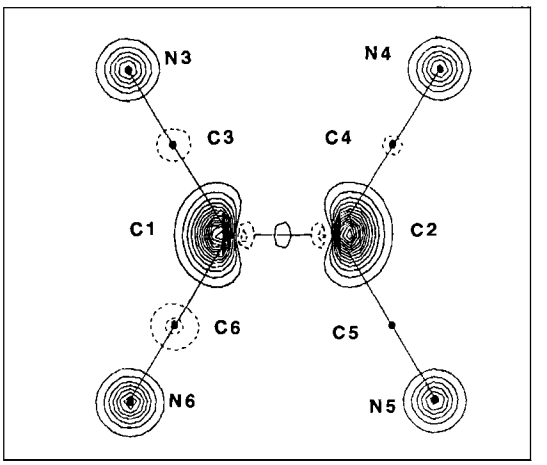

Fig. 2. Projection of the spin density reconstructed by model refinement of $[TCNE]^{\bullet -}$ onto the molecular plane.

The averaged experimental spin populations of the sp^2-carbon, sp-carbon, and nitrogen atoms are 33, −5, and 13%, respectively, of the total spin. The relative magnitudes of the spins per atom are in good agreement with previous estimates based on ESR spectroscopic data and molecular orbital models.[15] The signs and magnitudes of the spin populations are also consistent with the results of ab initio calculations.[16] Molecular orbital-based methods exaggerate the negative spin on the sp-carbon atoms and the spin populations on the nitrogen atoms, while calculations based on density functional theory (DFT) correctly predict the magnitudes of the spin populations. The calculated geometry at the self-consistent nonlocal DFT (NLDFT) level agrees well with the structure determined by neutron diffraction (Table 1). The central C–C distance is calculated to be 0.019 Å longer than the experimental value, but it is within two estimated standard deviations (esds). The C–CN distance is only 0.005 Å too long and the CN distance is 0.009 Å too long. The NC-C-CN angle is calculated to be smaller than the experimental value by 1.6°, and the calculated value for the C-C-N bond angle is slightly more linear than the average experimental value. The spin density on the sp^2-carbon atoms are bent away from the midpoint of this C–C bond. This is in agreement with the antibonding character of the SOMO and confirmed that the magnetic molecular orbital of the $[TCNE]^{\bullet -}$ radical is the π^* orbital.

Polarized neutron diffraction is presently the most powerful tool for determining the absolute spin density of a radical. In contrast to resonance techniques, it can be used to determine the shape of the spin density as well as the total spin populations. The results show that the excess α-spin on the $[TCNE]^{\bullet -}$ is not completely localized on the sp^2-carbon atoms, but is distributed across the radical since it has significant contributions from the nitrogen atoms. This is important since it demonstrates that both ionic $[TCNE]^{\bullet -}$ (as observed for $[Fe(C_5Me_5)_2][TCNE]$) and covalently bonded (as observed for [MnTPP][TCNE] and $[V(TCNE)_x]\cdot y(CH_2Cl_2)$) have the possibility for strong magnetic interactions with neighboring spin sites consistent with the bulk magnetic behavior observed for these materials. The combination of sophisticated experimental and theoretical techniques provide the basis for a better understanding of molecule-based magnetism.

[5] a) X-ray analysis: A $0.40 \times 0.38 \times 0.45$ mm crystal of $[Bu_4N][TCNE]$ (M_r = 370.96) was grown from Et_2O/MeCN and belongs to the monoclinic space group $P2_1/n$ (no. 14); $a = 14.651(3)$, $b = 8.446(1)$, $c = 19.669(5)$ Å, $\beta = 106.21(1)^\circ$, $V = 2337.1$ Å^3, $Z = 4$, $\rho_{calcd} = 1.053$ g cm^{-3}, $\mu_{Mo} = 0.60$ cm^{-1} at $-70\,^\circ$C. Using an Enraf-Nonius CAD4 diffractometer, 4040 reflections were measured with graphite-monochromated $Mo_{K\alpha}$ radiation. With 244 variables, the structure was refined by using 1560 data for which $I > 3\sigma(I)$ to convergence of $R = 0.049$ and $R_w = 0.046$. b) Neutron diffraction (10 K): $a = 14.550(36)$, $b = 8.263(13)$, $c = 19.686(48)$ Å, $\beta = 106.14(15)^\circ$.

[6] Two series of polarized neutron measurements were performed on the DN2 diffractometer at the Siloe reactor (CEA, Grenoble). A $7.4 \times 3.6 \times 1.7$ mm crystal grown by slow diffusion of diethyl ether into an acetonitrile solution of the salt was mounted in a cryomagnet and cooled down to 1.8 K in an applied field of 4.65 T. In the first experiment, the crystal was mounted with the b axis parallel to the magnetic field. In the second experiment, the crystal was rotated to align the $[10\bar{1}]$ axis collinear to the magnetic field. With both orientations, 211 independent data were collected up to $\sin(\theta/\lambda) = 0.36$, with the incident wavelength $\lambda = 1.205$ Å for the neutrons. There is one significant restriction in the measurements. The construction of the lifting-counter and the split-coil cryomagnet permits access only to a "slice" in reciprocal space for each mounting of the sample. For example, in the first series of experiments only the $(h0l)$, $(h1l)$, and $(h2l)$ Bragg reflections could be measured. Thus, the resolution in the vertical direction is poor. Nevertheless, the data are sufficient for the reconstruction of a projection onto the ac plane which is essentially the $[TCNE]^{\cdot -}$ molecular plane. The problem is only partly solved by mounting the crystal in the second orientation since on projection along the $[10\bar{1}]$ axis two symmetrically equivalent $[TCNE]^{\cdot -}$ units overlap. Thus, the second series of experiments does not reveal much information of the spin density distribution perpendicular to the molecular plane.

[10] The MaxEnt technique strictly applies to positive densities, but the method can be modified to treat sign alternating densities by considering the α- and β-spin densities as being independent.

[11] Note that in this model the wavefunction is squared at each site and then their squares summed. This is formally incorrect as a linear combination of the atomic wavefunctions should be formed prior to squaring of the resulting wavefunction. As we allow for negative spin populations, this introduces a cross-term and significantly more complex equations. Considering the available data, the additional computational effort is not justified.

[14] Other calculations (i.e., enforced D_{2h} symmetry on the spin density distribution, but not on the structure and a multipolar expansion for $[TCNE]^{\cdot -}$ in D_{2h} symmetry) to determine if the fit could be improved were undertaken. The results are not substantially changed from those of the model given with only the sp^2-carbon atoms being symmetrized.

To Help You Help Yourself

McGraw-Hill Encyclopedia of Chemistry. 2nd edition. Edited by *S. P. Parker*. McGraw-Hill, New York, 1993. 1236 pp., hardcover $ 95.50.—ISBN 0-07-045455-8

This alternate selection of the Library of Science is one of five new editions of McGraw-Hill technical encyclopedias, the others dealing with astronomy, engineering, environmental science and engineering, and physics. Much of the material has been taken from the 20-volume 7th edition of the *McGraw-Hill Encyclopedia of Science and Technology* (1992) (see G. B. Kauffman, *Angew. Chem.* **1993**, *105*, 1154; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1217), with additional articles prepared especially for the volume. Written to be accessible to nonspecialists, the hundreds of signed articles, replete with bibliographies for further reading, are the contributions of 407 distinguished authorities from around the world, including several Nobel laureates. In addition to comprehensive coverage of analytical, inorganic, organic, and physical chemistry, the book also deals with the related disciplines of biochemistry, physics, molecular biology, and materials science.

Each article begins with a definition and presents a concise but complete explanation of the topic. The material has been extensively revised, cross-referenced, and updated to reflect the latest developments such as fullerenes, light-scattering photometry, reactive intermediates, and ultrafast molecular processes (although cold fusion and superconductivity are neglected). The book is well-designed with an outstanding visual layout (wide margins, easy-to-read type, and bold headings), and the text is amplified and supplemented with hundreds of structural formulas, equations, graphs, tables, drawings, and photographs to clarify the presentation. A 36-page index (4 columns per page) facilitates the retrieval of information. Although most articles are authoritative and accurate, the entry on cobalt incorrectly states that the ammines of cobalt were discovered in 1894 by Werner, and the entry on coordination complexes does not employ the 1990 IUPAC inorganic nomenclature for formulas and names.

This attractive, moderately priced, user-friendly encyclopedia will be invaluable to chemists, chemical educators, students, librarians, science writers, and anyone seeking basic, clear, up-to-date information about the central science.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Two Books on Capillary Electrophoresis

Capillary Electrophoresis of Small Molecules and Ions. By *P. Jandik* and *G. Bonn*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 298 pp., hardcover DM 108.00/$ 65.00.—ISBN 3-527-89533-7/1-56081-533-7

As the title indicates, this book concentrates on one particular area of application of capillary electrophoresis (CE), namely the analysis of small molecules and ions. The more familiar fields of application of CE, such as the analysis of biomolecules (DNA, proteins, polysaccharides, etc.), are treated only marginally. Of the nearly 300 pages, 210 are devoted to the principles of CE and the instrumental aspects and 70 to applications.

The book begins with a short introduction outlining the history of the development of the method. The second chapter, "Fundamentals of Capillary Electrophoresis" (about 60 pp.), explains the most important variables in the CE method and gives a simple and easily understandable account of the theory illustrated by many clear diagrams. The separation techniques are only outlined briefly here, so that one gets no more than an indication of the complexity. Micellar electrokinetic chromatography is only described very briefly, even though it is the most commonly used method for the separation of small molecules and ions. There is a very lucid account of band broadening effects caused by Joule heating and electrodispersion. In Chapter 3, "Instrumentation for Capillary Electrophoresis", the authors give a comprehensive description of the various components of a CE system. They also devote about a hundred pages to commonly encountered problem areas in CE, such as detection methods, the improvement of sensitivity, sample injection techniques, and reproducibility. The section on the handling of capillary columns is very useful, especially for beginners in CE. Coupling techniques are also described, and altogether this is a very useful review of modern CE technology. The last two chapters of this excellent book describe many practical examples under the titles "Selected Applications of Counterelectroosmotic Capillary Electrophoresis" and "Application Examples of Coelectroosmotic Capillary Electrophoresis". The concepts "coelectroosmotic" and "counterelectroosmotic" introduced here are a useful aid to understanding the migration processes occurring in the capillary column. These chapters explain a large variety of separation procedures, and describe not only direct detection methods but also the indirect UV detection method and methods based on the derivatization of samples.

One of the authors previously worked for a manufacturer of CE instruments, and has consequently been able to include many specialized illustrations in this book, which are a particular feature of the detailed description of indirect UV detection.

Despite some minor weaknesses this book can be strongly recommended for newcomers to CE. Readers experienced in

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1401 $ 10.00+.25/0

the field should also find something of interest here, since this excellent survey of CE techniques reflects the current state of the art.

Practical Capillary Electrophoresis. By *R. Weinberger*. Academic Press, New York, 1993. 312 pp., hardcover $ 53.00.—ISBN 0-12-742355-9

This book of about 300 pages provides a more broadly based survey of the commonly used separation mechanisms in capillary electrophoresis than does the one reviewed above. It covers the instrumental and theoretical aspects, and also applications, which are in this case integrated into the descriptions of the various separation techniques. Rather than going into great detail, the author has set out to give the reader a general overview of the range of potential applications of CE. The basic chemistry underlying the separation procedures is described, and possible sources of error are discussed.

The twelve chapters cover the various separation techniques, such as capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), capillary isoelectric focussing (CIEF), micellar electrokinetic chromatography (MEKC), and capillary electrochromatography (CEC), as well as sample injection, detection, and basic principles. One chapter summarizes all the separation techniques discussed, so as to help readers who wish to develop their own particular methods. Further help is available from the many clearly set out tables, which enable one to quickly review the possibilities. References to the original publications are provided so that one can go into specific points in greater depth if necessary. Another chapter includes a discussion of likely future developments in CE. Because of its textbook style this volume can be thoroughly recommended for beginners in the field. Those already experienced in the use of CE are unlikely to find much in the book that is new to them.

Analysis with Supercritical Fluids: Extraction and Chromatography. Edited by *B. Wenclawiak*. Springer, Berlin, 1992. XIV, 213 pp., hardcover DM 148.00—ISBN 3-540-554203/0-387-55420-3

There is currently a great interest in the use of supercritical fluids in chromatography, either as a mobile phase (supercritical fluid chromatography, SFC) or as a solvent (supercritical fluid extraction, SFE). Ten years ago, with the introduction of "capillary" (more precisely, open-tubular) column SFC, it was commonly predicted that it would replace many of the applications of gas chromatography (GC) and high-performance liquid chromatography (HPLC). Although this did not occur, SFC has now established itself as a viable variant of chromatography. On the other hand, SFE, the younger brother of SFC in analytical chemistry (though long familiar as an industrial process) rapidly established itself as a very important sample preparation technique.

In the case of a rapidly growing field, it is very important to have at intervals good, up-to-date compilations from which one can learn about the newest developments and their relationship to the fundamentals of the technique. Obviously, this was the purpose of this multi-authored book.

The book consists of eleven chapters. After a brief (8 pp.) "Introduction for Novices" on SFC and SFE by the editor, G. M. Schneider discusses in detail the physicochemical principles of supercritical fluid separation processes (23 pp.). This is followed by a chapter on the basic principles of analytical SFE by J. W. King and J. E. France (29 pp.). In the following chapters S. B. Hawthorne deals with the combination of SFE and GC (13 pp.), E. Klesper and F. P. Schmitz with gradients in SFC (26 pp.), and T. Greibrokk with sample introduction techniques in SFC (16 pp.). (I do not like the restriction to "injection techniques" implied by the title of the latter chapter). The next chapter by C. F. Poole and his associates discusses in detail the stationary phases used in packed-column SFC (18 pp.). This is followed by a chapter by M. Schleimer and V. Schurig on enantiomer separation by capillary SFC (17 pp.). The next two chapters deal with the combinations of SFC with mass spectrometry (J. D. Pinkston, 27 pp.) and FT-IR (L. T. Taylor and E. M. Calvey, 12 pp.). In the last chapter M. L. Lee and his associates discuss supersonic jet spectroscopy (SJS) with supercritical fluids (13 pp.). At the end of the book some basic references on SFE/SFC are given, followed by a three-page appendix listing "recommended literature" from 1992.

In my opinion the book has two major shortcomings. The first is that three chapters which should have been included are missing. (a) A chapter should have described the system of a supercritical fluid chromatograph, including pumps and detectors (FID and UV), the selection of analytical conditions including the mobile phase, and the instrumentation of SFE. (b) The book has a chapter devoted to the packed columns used in SFC. However, it is almost inconceivable that it does not also have a chapter on the *open-tubular* columns used in SFC. After all, as correctly pointed out by the editor in the preface, modern SFC could not exist without them. This can actually be seen from the illustrations in the book: practically every chromatogram (except those included in the packed-column chapter) was obtained on open-tubular columns (which are not discussed). How could the most important component of a modern SFC system be neglected? (c) The book deals with SFC and SFE, and includes discussions on the combination of a number of techniques ("hyphenated systems") such as SFE-GC, SFC-MS, SFC-FT/IR or SFC-SJS. However, the most obvious combination is missing, namely the coupling of SFE with SFC.

The second shortcoming concerns the up-to-dateness of the discussions. The editor's preface is dated August 1992 and in it he mentions that the articles were "collected over a period of one year", which would mean that the individual contributions should cover the field up to the first part of 1991. However, this is not the case. The chapter by Schleimer and Schurig is an exception, but in the ten other chapters one can find no references from 1991–1992 and only a very few from 1990; out of a total of 453 references only 14 (3.1%!) are from 1990. By contrast, in the chapter by Schleimer and Schurig 51.1% of the references (24 out of 47) are from 1990–1992. This is not a coincidence: it clearly indicates that all the other chapters were written in the period 1989–1990. Evidently the editor was aware of this discrepancy and added a supplement containing "recommended literature" from 1992, consisting of 53 citations. This is laudable, but it still omits results reported in 1990 and 1991.

I have a few minor criticisms. For example, I disagree with the use of the term "capillary columns" instead of "open-tubular columns"; after all, the small-diameter packed columns may also be described as "capillaries". In the figure

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1402 $ 10.00+.25/0

captions, columns should be identified more precisely, and one should avoid trade names: stationary phases *must* be specified by their chemical composition and not by the particular manufacturer's fantasy name. Also the format of the references given in the book does not conform to the *Chemical Abstracts* usage.

These shortcomings, especially the missing chapters, restrict the book's general usefulness, particularly because its general title implies that it provides a unified discussion of analytical SFC and SFE. However, within this limitation the book presents a wealth of useful information. The chapters are well written and represent good summaries of the topics treated. Thus, everyone who is interested in SFC and SFE will find something valuable in it.

Chemical Vapor Deposition. Principles and Applications. Edited by *M. L. Hitchman* and *K. F. Jensen*. Academic Press, London, 1993. 677 pp., hardcover £ 75.00.—ISBN 0-12-349670-5

Chemical vapor deposition (CVD), as a method for preparing thin solid films, has undergone intensive development during the last twenty years, and is now of major importance in a wide variety of technological applications, for example in microelectronics, optoelectronics, energy technology, and the reduction of friction and wear. There has long been a need for a book treating the many different aspects of this method, which is of fundamental importance in surface coating technology. The book reviewed here fills this gap admirably, and has been written to meet the needs of readers from a variety of disciplines. The editors have brought together thirteen recognized experts in their individual fields to prepare ten chapters that deal with different aspects of this complex subject, and can be read independently of each other.

Chapter 1 outlines the historical development of the method and its main characteristics. The accompanying bibliography provides an introduction to the extensive literature on CVD, and is remarkably comprehensive. Chapter 2, "Fundamentals of Chemical Vapor Deposition", explains the interdependence between chemical kinetics, reaction mechanism, and the fluid dynamics of the reaction system in relation to the growth of the deposited film. Current ideas regarding the mathematical modeling of CVD processes are discussed, together with likely future developments. Chapter 3 contains a highly informative review of modern diagnostic methods for CVD processes, including techniques such as flow imaging, spatially resolved temperature measurements, and analysis of the composition of the gas phase. This is followed in Chapter 4 by a very useful and comprehensive discussion of low-pressure CVD, illustrated by the outstanding example of polycrystalline silicon. Potential applications to other systems such as dielectrics and to metals such as tungsten, aluminum, and copper for VLSI (very large scale integration) metal deposition are also discussed. Chapter 5 is concerned with silicon epitaxy, describing not only conventional methods but also new trends, for example the development of new semiconductor components such as Si:Ge heterobipolar transistors with a band-gap chosen to suit the application. Chapter 6 is the longest in the book, and addresses the problems of the gas phase epitaxy of III/V materials prepared from organometallic molecules. The treatment is a concise but updated sequel to recent monographs on this topic (M. Razeghi, *The MOCVD Challenge*, Hilger, London, **1989**; G. B. Stringfellow, *Organometallic Vapor-Phase Epitaxy*, Academic Press, London, **1989**). The next two chapters are concerned with variants of the CVD method that are not (purely) thermal in nature, plasma-CVD and photo-CVD. The aspects covered, each in an appropriate degree of detail, are the physico-chemical fundamentals, experimental techniques, reactor design, and modeling, with up-to-date examples of particular applications (dielectrics, metals, semiconductors, diamond) which provide good illustrations of the advantages of the methods (e.g., low process temperatures, selective deposition). Whereas most of the book is concerned with the physico-chemical processes involved in film deposition, Chapter 9 gives an interesting insight into electronic and optical characterization methods that are directly related to the electrical properties of electronic devices produced by CVD (e.g., optical reflection and transmission measurements, vibrational spectroscopy, electron spin resonance spectroscopy, determination of current–voltage characteristics, photoconductivity measurements, and capacitance spectroscopy). These methods are especially applicable to amorphous α-Si:H and α-Si_xN_{1-x} films prepared by plasma-CVD. The main emphasis here is on the problems of characterizing defect structures. To conclude the book, Chapter 10 deals with applications of CVD to the reduction of friction and wear, and with the special structural problems posed by thick CVD films, such as roughness and adhesion.

Starting from well-established CVD processes and applications, the book gives a very good account of the current state of knowledge, and also discusses the most recent development trends. The many literature references, extending up to about 1991, are arranged according to the individual chapters, thus affording a very good basis for further reading on special topics. The subject index too is excellent. The structure of the book results in a certain amount of overlapping on several of the topics. For example, ideas concerning the modeling of CVD processes are perhaps repeated more often than necessary. Altogether, however, the book is carefully written and nicely produced. It can be recommended not only for everyone working in the field of chemical vapor deposition, but also unreservedly for interested readers from other related disciplines and newcomers to the subject.

Solid State Chemistry. Synthesis, Structure, and Properties of Selected Oxides and Sulfides. By *A. Wold* and *K. Dwight*. Chapman and Hall, New York, 1993. 245 pp., hardcover $ 19.95.—ISBN 0-412-03621-5

How is it possible to compress the subject matter of a textbook designed for a one-semester course on solid state chemistry into less than 250 pages, even though these are closely printed? That is the feat that has been attempted by the authors of this book. It consists of a very superficial general part covering the structure, characterization, and properties of solids, followed by a highly subjective selection of topics which is strongly biased towards the special research interests of the two authors. In the course of this, some important aspects of the mental toolkit needed for solid state chemistry are abbreviated almost beyond recognition (e.g., spectroscopic methods are given one page, X-ray diffraction three pages), or are omitted completely (e.g., the sphere packing principle, lattice energy, defect chemistry). As is already indicated by the book's subtitle, the second part is concerned with a special class of solid compounds, namely some selected transition metal oxides and sul-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1313-1403 $ 10.00+.25/0

fides. The authors justify this very personal choice of subject matter close to their own research interests by claiming that only in this way is it possible to include experimental results that are highly reproducible. The examples discussed in the book cannot represent more than a very tiny segment of the large and fascinating subject of solid state chemistry. In principle the inclusion of a chapter on preparative methods before the specialized part of the book is a good feature, but even here some important aspects are cut down to an unacceptable extent (flux methods are given seven lines, chemical transport one page, and high-pressure syntheses half a page). Without any introduction to the structural aspects or their geometrical basis, the following chapter goes straight into a description of the monoxides of transition metals. The first structural diagram in the book shows the crystal structure of CuO. Following the trend set by the general part of the book, where a lengthy chapter is devoted to the electronic properties of semiconductors, the book places particular emphasis throughout on transition metal oxide semiconductors. Even here, however, much space is wasted by reproducing numerous conductivity curves for the compounds concerned, sometimes filling the whole page and conveying little information. There is, of course, a mention at the end of the oxides chapter of the modern ceramic cuprate superconductors. The final chapter is devoted to transition metal sulfides. As in the oxides chapter, there are many large, and not particularly well drawn, crystal structure diagrams showing the basic structural types. The electronic properties of the compounds under discussion are explained by means of energy band schemes, usually greatly simplified. As in other textbooks on solid state chemistry, there are exercise problems at the end of each chapter (with answers at the end of the book), and also lists of original publications, some of which are quite extensive. Here, instead of listing, for example, over 150 references to original papers on ternary and higher transition metal oxides, it would have been much more useful to give a limited selection of relevant review articles and textbooks.

To summarize, one cannot really recommend this book to a large readership as an accompaniment to lecture courses. The main criticisms are that the choice of topics is very subjective and unrepresentative, that important concepts and facts are sometimes treated very superficially, and that the diagrams and the text layout are rather unattractive. The book will not succeed in awakening an enthusiasm for the fascinating subject of solid state chemistry in readers approaching it for the first time (including students).

Sulphones in Organic Synthesis. (Tetrahedron Organic Chemistry Series, Vol. 10.) By *N. S. Simpkins*. Pergamon, Oxford, 1993. 381 pp., paperback £ 30.00, hardcover £ 55.00.—ISBN 0-08-040284-4 (paperback), 0-08-040283-6 (hardcover)

The use of sulfones in organic synthesis has become much more important during the last twenty years. Their synthetic potential now rivals that of the carbonyl group in versatility. This monograph by N. S. Simpkins focuses attention on the synthetic aspects of SO_2 compounds, which have the important advantage of being easily obtainable. The book consists of nine chapters, and the literature coverage extends in general up to the end of 1990, including also some important original publications up to the end of 1991. A brief introduction to the chemistry of sulfones (4 pp.) is followed by a chapter of 94 pages on the preparation of sulfones (e.g., alkylaryl, dialkyl, vinyl and other unsaturated and functionalized sulfones), each class being treated in accordance with its relative importance. The next chapter (82 pp.) deals comprehensively with sulfonyl carbanions, describing their formation, structures, stereochemistry, and wide variety of reactions. This is followed by chapters on addition reactions of unsaturated sulfones (25 pp.), rearrangements of sulfones (19 pp.), the cycloaddition chemistry of unsaturated sulfones (26 pp.), and the formation of CC double bonds by sulfone elimination (35 pp.). The book ends with chapters on the chemistry of cyclic sulfones (43 pp.) and desulfonation reactions (38 pp.).

The author's method of classifying the now very broad subject of sulfones and their chemistry according to compound type and reaction type has turned out successfully. He has included not only well-established routine syntheses using sulfones but also others that are less well known and have only recently been developed; all of these are described in detail. In the discussion of the palladium-catalyzed synthesis of allylsulfones (Ch. 2) the author has omitted to mention the work of Y. Tamaru et al. (*J. Chem. Soc. Chem. Commun.* **1978**, 367) and of U. M. Dzemilev et al. (*Zh. Org. Khim.* **1978**, *14*, 2223; see also *J. Organomet. Chem.* **1993**, *455*, 1–27). In his introduction the author explains that the book's main purpose is to emphasize and illustrate the growing importance of sulfones in organic synthesis; this aim has certainly been achieved. In particular the many clearly set out reaction schemes make it easy for the reader to understand the reactions described and the related factual information.

The monograph gives a good account of the current state of knowledge regarding sulfones in organic synthesis, and forms an important addition to the relevant review articles in "Houben–Weyl" and "Patai". It is essential to all departmental libraries involved in any way with organic synthesis.

Peptidyl-Prolyl *cis/trans* Isomerases and Their Effectors

Gunter Fischer*

Dedicated to Professor Alfred Schellenberger on the occasion of his 65th birthday

Changes in the conformation of the units within the peptide chain are the elementary processes in the folding of a protein into its native three-dimensional structure. Even a few years ago protein folding in vivo was considered to be an autonomous process not requiring the help of enzymes or auxiliary substances. Recently an increasing number of proteins that assist in the folding process have been found; these include enzymes that catalyze conformational interconversions. The *cis/trans* isomerization of the peptide bond N-terminal to a proline residue is catalyzed by peptidyl-prolyl *cis/trans* isomerases (PPIases). Two families of these ubiquitous and phylogenetically highly conserved enzymes are known, the cyclophilins and FK506-binding proteins. Their catalytic activity is extremely high —the rate constants for the bimolecular reactions they catalyze approach the diffusion-controlled limit for enzyme–substrate reactions. These enzymes increase the rate of isomerization in oligopeptides as well as in intermediates in protein folding. It is not yet known which structural units in the cell serve as substrates and exactly which reactions are catalyzed. However, these isomerases have been shown to interact with the heat shock proteins of the nonactivated steroid receptors and with the gag polyprotein of the AIDS HIV-1 virus. The immunosuppressive agents cyclosporin A and FK506 are highly effective inhibitors for PPIases. Surprisingly these compounds affect the signal cascade of T cells but not through enzyme inhibition; the inhibitor–enzyme complexes themselves are the active agents. These complexes exhibit properties not displayed by the individual components and thus are able to affect other cellular components. The current model of the suppression of the antigen- and mitogen-stimulated clonal expansion of T cells is presented here.

1. Introduction

There are a number of reactions in the cell for which increasing the rate or controlling the selectivity seems unnecessary or even wasteful, since they are rapid and seemingly specific without enzymatic catalysis. The production of an enzyme would be wasteful. Such autonomous processes within the cell generally include those in which biological substances undergo conformational interconversions. Biochemists are especially interested in conformational interconversions in proteins, since proteins are the central regulatory elements in living systems.

This view was confirmed by the results of many denaturing/renaturing experiments on proteins. It was shown that starting from denatured protein, in which residual elements of the original secondary structure of the polypeptide chain are not detectable, small single-domain globular proteins often refold rapidly to yield the conformation of the native protein under renaturing conditions. No external agents have to be added to enhance or speed up the process. These results indicate that there is not much evolutionary pressure for organisms to develop enzymes capable of recognizing proteins as substrates and speeding up the rate of conformational interconversions within proteins.

One specific intracellularly relevant conformational interconversion, namely the *cis/trans* isomerization of the N-terminal amide bond of the amino acid proline, requires a relatively long time. This apparent paradox was explained in 1984 when we discovered and isolated a peptidyl-prolyl *cis/trans* isomerase (PPIase) which was the first enzyme found to catalyze a conformational interconversion at a formally single bond.[1] New enzymes naturally become targets in screening studies of the culture filtrates of microorganisms for effectors and are particulary interesting in drug development.[2] However, in the case of the PPIases things developed a little differently. Long after the clinical use of the immunosuppressive cyclosporin A (CsA), a cyclic undecapeptide, and following the identification of a cytosolic receptor protein for CsA by Handschumacher et al.,[3] N. Takahashi et al.[4] and we[5] were able to demonstrate the PPIase activity of this receptor and the inhibitory effect of CsA on enzyme catalysis. Based on these results, studies on the immunosuppressive peptidomacrolide FK506 were carried out; isolation of the receptor and enzymological experiments were conducted simultaneously, and a PPIase, which proved to be insensitive to CsA, was detected and shown to be inhibited by FK506.[6]

Telefax: Int. code + (345)647126

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1414-1415 $ 10.00+.25/0

Totally unexpected was the finding from American research groups that the suppressive effect of these drugs on the clonal expansion of T cells is not simply due to the direct inhibition of PPIase activity. According to current knowledge, the protein presents ligands with changed conformation in the drug–protein complex to another cellular component, the Ca^{2+}/calmodulin-dependent protein phosphatase, calcineurin, whose dephosphorylating activity is in turn inhibited (see Section 9).[7–9]

Therefore in this review we discuss not only the properties and mechanism of reactions catalyzed by PPIases, but also the biological effects of the complexes of these enzymes with immunosuppressives.

2. Proline—A Molecular Switch

In the restructuring of polypeptide chains, slow partial reactions taking up to hours are often found when proline forms part of the chain.[10, 59] Such folding processes are not only observed in the test tube in artificial denaturation/renaturation reactions, but are seen in vivo in ribosomal protein synthesis and maturation, in the transport of polypeptides through membranes, in the disposal of malfunctioning proteins, in ligand binding, and in the oligomerization of proteins.[11] In many processes the observed ratio of the *cis* and *trans* isomers transiently does not correspond to the thermodynamic equilibrium but reflects the immediate surroundings of the polypeptide.

To illustrate the folding problem a section of a polypeptide chain is shown in Figure 1. Rotation about the formally single bonds in the peptide backbone and in the side chains is responsible for the flexibility of the chain. These rotations determine most of the dynamic processes in proteins, including folding. As uncoupled elementary processes they are generally fast (relaxation times $\ll 1$ s), with the exception of changes in ω; however, owing to interactions and neighboring group effects the observed time scales in polypeptides range from 10^{-11} to 10^{3} s. Especially slow conformational changes arise from the well-known delocalization of electrons in the amide bond and are even more pronounced if additional steric constraints are imposed by the proline ring (Fig. 2.). In contrast to C(O)NH bonds, the two lowest energy arrangements of the prolyl peptide bond, *cis* ($\omega \approx 0^{\circ}$) and *trans* ($\omega \approx 180^{\circ}$), are of comparable thermodynamic stability. In principle polypeptides with n proline residues can form 2^n isomers as partners for recognition processes and as reaction partners at the molecular level in the cell. Proteins have the strong tendency to form three-dimensional structures. Since the *cis* and *trans* isomers in these structures are no longer equal in energy, the less preferred isomer is not likely to exist in the folded chain.

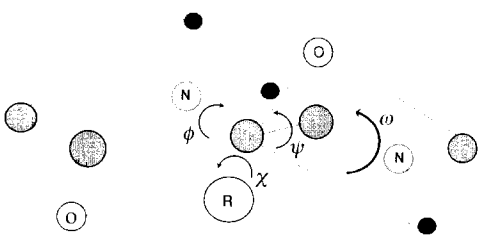

Fig. 1. Labeling of the torsion angles in a polypeptide chain.

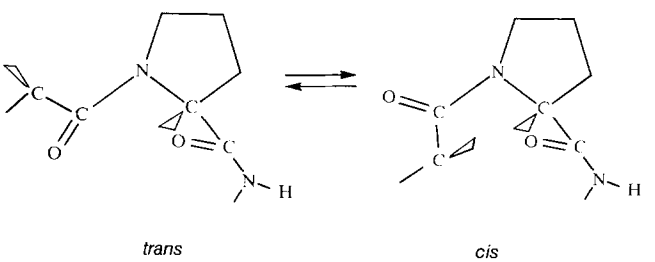

Fig. 2. The *cis/trans* isomerization of a peptide bond N-terminal to proline.

Obviously *cis/trans* isomerization leads to periodic changes in the positions of neighboring chain segments, because the propagation direction of the polypeptide backbone is different in each isomer. In this respect *cis/trans* isomerization at the peptide bond N-terminal to proline resembles a molecular switch with the following characteristics:

1. There are two switch positions; other positions are unstable.
2. The energy needed to operate the switch is high on the energy scale for biological recognition processes.
3. Operation of the switch leads to an amplification of an effect at the place where the signal arrives. In the case of the proline switch this amplification manifests itself chiefly in the form of a mechanical movement, which may be the movement of a segment of the protein backbone.

Gunter Fischer, born in 1943 in Altenburg, Thuringia (FRG), was trained as a chemical technician (1959–1962) before he completed his chemistry studies at the University of Halle in 1967. In 1971 he completed his first dissertation on research with A. Schellenberger on the reactivity of α-keto acids; in 1978 he finished his second dissertation on the reactivity of amide groups. After some time at the Forschungszentrum Biotechnologie/Berlin, he accepted positions in 1988 as "Dozent" of biochemistry at the University of Halle and in 1990 as a guest professor at the University of Würzburg. Since 1992 he has been the director of the research group "Enzymology of the Peptide Bond" of the Max Planck Society in Halle, and in 1993 he accepted a chair for molecular biochemistry at the University of Halle. His research focuses on the structure and activity of protein folding enzymes and the effect of imino acids on peptide conformation.

4. Isomerization catalysts such as the PPIases act as variable components for reducing the switch resistance, and in the presence of many switches they assure extra selectivity. The switching resistance (the rotation barriers) is controlled by varying the enzyme concentration, and the selection of switching elements by means of enzyme specificity.

An example of a photoactivated switching process is the biologically very important *cis/trans* isomerization of the C=C bonds in retinal and retinal proteins.[12]

3. Peptidyl-Prolyl *cis/trans* Isomerases and Other Immunophilic Proteins

When present even in catalytic amounts PPIases are able to increase the rate of isomerization of the prolyl-peptide bond (see Fig. 2.) in a suitable peptide substrate. In examinations of any mammalian cell material the activities of a number of PPIases, which differ in their molecular weight distribution and isoelectric behavior, are apparent (Figs. 3 and 4.). This supports the idea that a whole range of such enzymes could exist.

In enzyme nomenclature PPIases are classified under the *cis/trans* isomerases (EC number 5.2.1.8). In the literature they are often referred to as "rotamases"[13] or "rotomases"[14] based on the term "rotamerization" for the process of conformational change. At the present time two families of proteins with PPIase activity are known: the cyclophilins (Cyp) and the FK506-binding proteins (FKBP) (synonyms FK506-binding PPIases, macrophilins). Which specific enzymatic function characterizes the two groups of enzymes?

The enzyme-catalyzed isomerization at proline is reversible, and thus the *cis* and *trans* conformers must coexist. If irreversible reactions are coupled to the *cis/trans* equilibrium, then the catalyzed partial reactions *cis* → *trans* and *trans* → *cis* can be analyzed separately. For all three cases solid experimental data supporting in vitro PPIase catalysis are available. But which of these is primarily catalyzed by these enzymes in vivo can only be

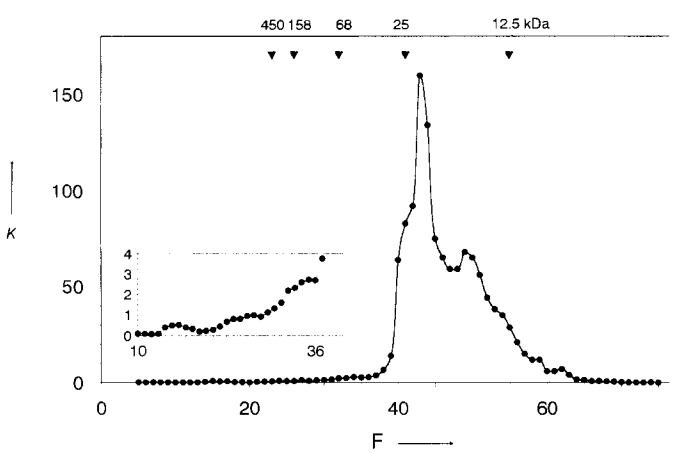

Fig. 3. Separation of the PPIase activity from pig kidney cytosol according to molecular weight [kDa]. The activity was determined with Suc-Ala-Phe-Pro-Phe-4-nitroanilide by measuring the catalytic factor K in each fraction F: $K = (k_c - k_u)/k_u$, where k_u is the first-order rate constant of the uncatalyzed isomerization and k_c is the first-order rate constant of the catalyzed isomerization. (FPLC separation on a Bio-GPC-Diol column (330 × 10 mm)). The insert shows the plot for fractions 10 to 36 on a larger scale.

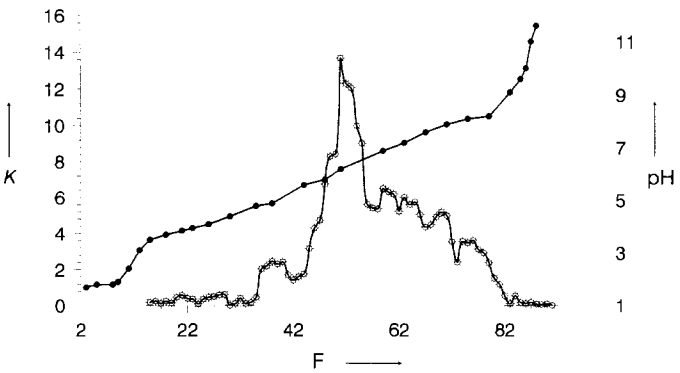

Fig. 4. Separation of PPIase activity (☼) from pig kidney cytosol according to the isoelectric behavior of the enzymes in a pH gradient (●); the activity determination as described for Fig. 3. Separation on a continuous free-flow electrophoresis system (Octopus, Dr. Weber Co., Ismaning (FRG)) at 5 °C in 0.2% Servalyt (pH 3–10), 0.1% dextran (M = 1 kDa).

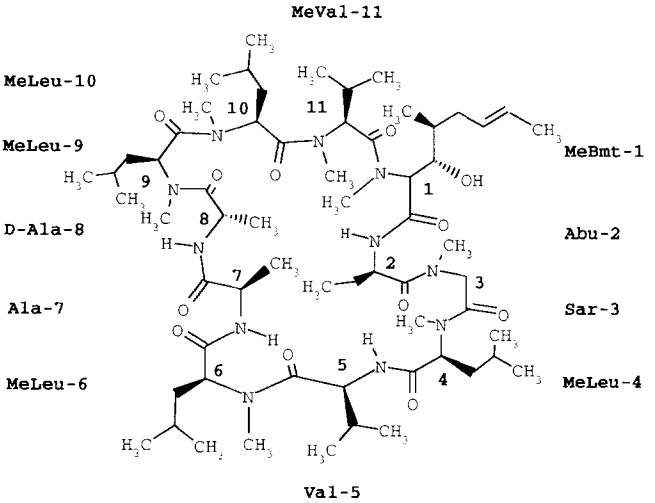
the subject of speculation at present. If human Cyp18cy (for details on the nomenclature of the PPIase families see ref. [15]), is offered Suc-Ala-Ala-Pro-Phe-4-nitroanilide as substrate and the PPIase concentration is kept very low during the *cis* → *trans* isomerization, then normal Michaelis–Menten kinetics are observed for the conformational isomerism, without curves with sigmoid character at low substrate concentrations $[S]_0$ or other effects in plots of v versus $[S]_0$ (v corresponds to the reaction rate). The increase in reaction rate for the *cis* → *trans* isomerization in oligopeptide substrates (when $[S]_0 \ll K_m$) is linearly dependent on the enzyme concentration.[11, 16, 17]

Of course under the standard reaction conditions for activity tests (enzyme concentration $[E]_0 \ll [S]_0$) PPIases do not change the *cis/trans* ratio of the substrate. However, the isomer distribution after the substrates[18, 19] (and inhibitors)[20, 21] are bound to PPIase does not correspond to that of the free ligands in the solid state or in solution. Sometimes either the *trans* isomer or the *cis* isomer binds better to the enzyme. When the substrate and PPIase are present in stoichiometric amounts or when there is an excess of PPIase, the isomer equilibrium of proline-containing polypeptides can be completely changed. This is important in studies of cellular processes involving PPIases since high intracellular enzyme levels have been found. For example, in the cytosol of human erythrocytes the concentration of cyclophilins is at least 4 μM[22] and thus can easily exceed the concentration of a potential intracellular substrate.

For catalytic activity PPIases must also be able to recognize a specific proline residue forming part of a linear polypeptide chain and bind to it. The ability to bind substrate can be increased through a combination of secondary interactions at specific subsites. Under these circumstances PPIases could act as binding proteins with a specific proline recognition function. Indeed, the eight-stranded, antiparallel β-barrel structure of human Cyp18cy resembles that of typical binding and transport proteins for small hydrophobic molecules such as bilin-binding protein, retinol-binding protein, and streptavidin, although the binding sites of these proteins for their ligands have different structures.[23, 24]

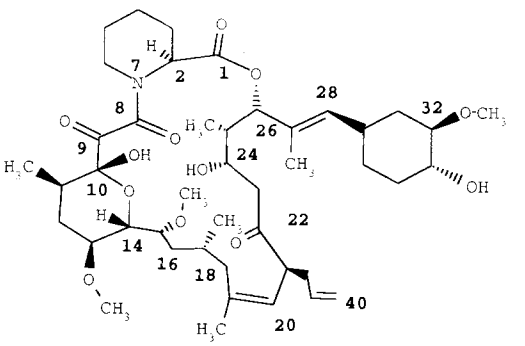
According to our current knowledge, PPIases are not able to substantially increase the rate of isomerization for open-chain *N*-alkylpeptide bonds in oligopeptides. This implies that in the

catalysis of protein folding it is the proline moiety that is important and not a special property of the peptide bond itself.[25]



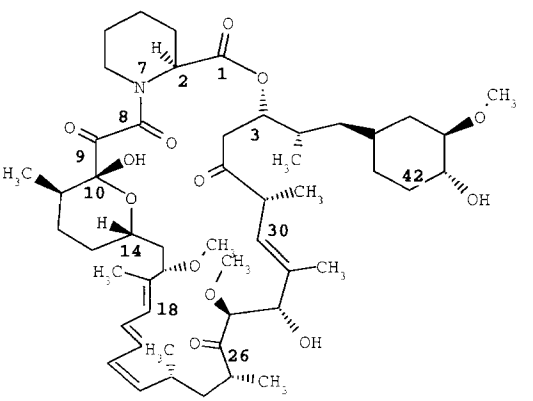
The amino acid sequences of cyclophilins and FKBPs have little in common,[26] not even in that part of the peptide chain probably important for enzyme activity; the structural homology of the putative active sites is also not very great.[27] The two groups of enzymes can be easily distinguished by their differing inhibition by cyclosporin A and peptide macrolides. Thus only CsA and its derivatives inhibit cyclophilins, while FKBPs are inactivated by specific peptide macrolides. Cross-inhibition has not been observed.

Within the two families the amino acid sequences are highly conserved throughout living systems. Within the isoforms of cyclophilins and FKBPs of a particular cell type a central region apparently important for enzyme activity is complemented by C-terminal and N-terminal extensions of differing lengths. Such sequence conservation in the course of evolution is indicative of a central role for the corresponding protein function within the cell.



For a number of PPIase genes the position on the human genome is already known: human Cyp23sec is on chromosome 15,[28] Cyp150mem on chromosome 3,[29] FKBP12cy on chromosome 20, and FKBP13cy on chromosome 11.[30] In a human gene bank derived from leukocyte DNA, a single functional Cyp18cy gene and fifteen pseudogenes were found to be present.[31]

S. L. Schreiber et al. introduced the term "immunophilins"[32] for the families of PPIases in order to point out the role of PPIases as receptor proteins in the mammalian immune system. This term refers to the formation of drug–protein complexes with the immunosuppressive drugs cyclosporin A, rapamycin, and FK506 (Fig. 5.). Cyclosporin A, rapamycin, and FK506 (synonym: tacrolimus) are natural products derived from microorganisms, which have a specific effect on the immune system[33, 34] and also affect other systems and tissues.[35] In antigen-stimulated T lympocytes the immunosuppressive drugs block signal transduction in the Ca^{2+}-dependent pathways leading to clonal expansion of the cells. One of the main factors in the repression of the T-cell response after triggering of the receptor–CD3 complex by an antigen or mitogen is assumed to be the inhibition of gene expression of a number of important lymphokine genes. This could include the genes for a variety of interleukins (IL-2, IL-3, IL-4), factors such as GM-CSF (granulocyte macrophage colony stimulating factor), tumour necrosis factor α (TNFα), and γ interferon, as well as the oncogene c-myc.[36] Regulation seems to take place at the level of translocation of components of the hitherto not very well biochemically characterized transcription factors (AP-3, NF-AT, NF-κB) from the cytosol to the nucleus.[37]



There are many more immunophilic proteins than just those with proven PPIase activity.[38, 39] Amongst others, the immunosuppressive CsA derivatives [D-Lys(ε-dansyl)^8]-CsA and [D-Dab(Boc)^8]-CsA with dissociation constants $K_d = 60 \pm 33$ nM and 570 ± 380 nM, respectively, bind as strongly to G-actin from Jurkat cells as to the PPIases from the same cell homogenate.[40] In addition, SSA1, a cytosolic yeast protein and analogue of the heat shock protein hsp70 which is structurally related to actin, can bind [D-Lys(ε-dansyl)^8]-CsA with a dissociation constant of

Cyclosporin A

FK506

Rapamycin

Fig. 5. Immunosuppressive inhibitors of the peptidyl-prolyl *cis*/*trans* isomerases. In cyclosporin A MeBMt is (4*R*)-4[(*E*)-2-butenyl]-4-*N*-dimethyl-L-threonine and Abu is L-α-butyric acid. Substitution of FK506 at C21 (ethyl group instead of allyl) yields the immunosuppressive ascomycin.

53 nM.[40] In situ affinity photolabeling of fibroblasts, hepatocytes, and lymphoid cell lines with [^{3}H]*N*-(diazotrifluoroethyl)benzyl-D-Lys^8-cyclosporin leads to a variety of specifically labeled proteins which can be detected and separated using SDS (sodium dodecylsulfate) polyacrylamide gel electrophoresis. The molecular weight of these proteins is in the range of about 20–200 kDa, and they can be assigned only in part to the known PPIases.[39, 41] Among the identifiable material is a membrane

protein of the Na^+/D-glucose cotransporter of the kidney with a molecular weight of 75 kDa.[42]

In fact the specific binding of interleukin-8 (IL-8) to CsA (K_d = 850 nM) is in some sense immunochemically similar to that with PPIases, since there is cross reactivity with an antiserum against human recombinant IL-8 with a cytosolic PPIase. However, interleukin-8 shows no PPIase activity in a standard test.[43] Interestingly, a cytosolic, 50 kDa immunophilic protein from Jurkat and spleen cells which has not been well characterized has a high affinity for both CsA (K_d = 39 nM) and FK506 (K_d = 2 mM) without showing any PPIase activity. Both rapamycin and CsA can be displaced from the binding site by [^{3}H]-dihydro-FK506.[44]

Investigation at the molecular level is still needed to understand the binding of cyclosporin derivatives to the membrane-bound P glycoprotein (170 kDa),[45] which is responsible for a special type of multidrug resistance in malignant cells. Like these cyclosporins, FK506 and the PPIase inhibitor rapamycin also prevent the P glycoprotein from pumping cytotoxic substances out of the cell by binding to it with high affinity.[46]

Thus immunophilic proteins are a much larger group than just the PPIases. On the other hand, amongst the PPIases are proteins with relatively little affinity for cyclosporin A (Table 1) and FK506 (Table 2) and which therefore cannot be classified as immunophilic.

4. Measuring Enzyme Activity

Table 3 lists the methods of measuring PPIase activity known up to the present. They are often based on the production of pure *cis* or *trans* isomers or at least an isomeric distribution different from that expected based on the reaction conditions alone. This allows investigation of the kinetics of the reestablishment of equilibrium and thus the rate of the *cis/trans* isomerization. When dynamic NMR spectrometry is employed, the activity for the compounds in the unperturbed *cis/trans* equilibrium is measured. The *cis* and *trans* forms of linear proline-containing oligopeptides can sometimes be separated by low-temperature HPLC,[47] but the lifetime of the isolated pure conformers is

Table 3. Methods for measuring the catalytic activity of peptidyl-prolyl *cis/trans* isomerases.

Method	Detection	Reaction direction	Substrate type	Application in homogenates	Ref.
Isomer specific proteolysis	UV/VIS; fluorescence	*cis* → *trans*	oligopeptides	yes	[1, 4, 51, 60]
NMR spectroscopy	saturation transfer line broadening	*trans* ⇄ *cis*	oligopeptides, short proteins	no	[55–57, 61]
Solvent jump	fluorescence; UV/VIS	*trans* → *cis* *cis* → *trans*	oligopeptides	yes	[52, 53]
Folding/refolding	fluorescence	*trans* → *cis*; *cis* → *trans*	proteins	no	[16, 62, 63]
	UV/VIS	*trans* → *cis*; *cis* → *trans*	proteins	no	[62, 64]
	circular dichroism	*trans* → *cis*; *cis* → *trans*	proteins	no	[65]
	proteolysis	*trans* → *cis*; *cis* → *trans*	proteins	no	[65, 136]
	enzymatic activity	*trans* → *cis*; *cis* → *trans*	proteins	yes	[66–68]

typically too short for kinetics experiments. Therefore it is better to hydrolyze the peptide bond with a isomer-specific protease and use the coupled irreversible bond cleavage to temporarily disturb the conformational equilibrium. This reaction allows the kinetics (and thermodynamics) of the conformational equilibrium to be analyzed, because many proteases are $>10^4$ times more specific for the all-*trans* conformer of a substrate (this number refers to the value of k_{cat}/K_m; k_{cat} is the turnover rate and K_m is the Michaelis constant). Isomer-specific proteolysis is also observed when the isomerizable bond is far away from the bond cleaved in the protease reaction (Fig. 6.).[48–50]

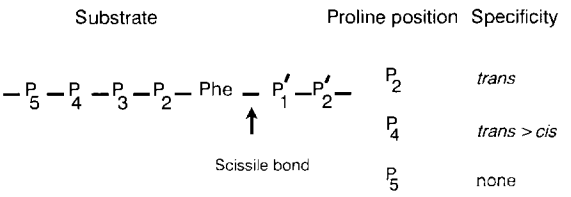

Fig. 6. Schematic representation of the *cis/trans* conformation specificity of α-chymotrypsin for proline-containing substrates with this amino acid in different positions within the peptide chain; based on the specificity constant k_{cat}/K_m. The positions of the other bonds of the protease substrate relative to the reactive bond between P_1 and P_1' are labeled according to the nomenclature of Berger and Schechter [264].

Figure 7 shows that when $[E]_0 k_{cat}^{S*} \gg k_{-1} K_m^S$, the rate of enzyme-catalyzed product formation v for a common reaction product starting from conformers in equilibrium can approach a limit when the equilibrium is affected by a very active isomer-specific protease. At higher enzyme concentrations $[E]_0$ and when an unreactive isomer S is present, the rate of product formation v is independent of the protease concentration. In this case it depends only on the rate of conversion of the unreactive conformer (k_1; for peptide bond isomers *cis* → *trans*), which can be easily followed by using a chromogenic protease substrate.

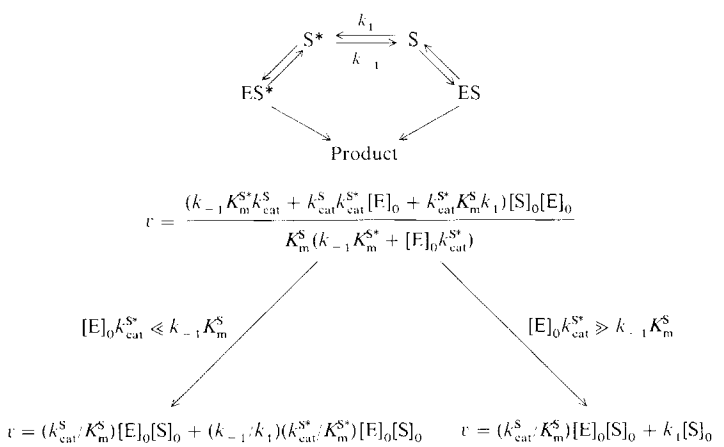

Fig. 7. The rate of formation v of a common product formed in an enzyme-catalyzed reaction from a substrate present in different conformations under steady-state conditions ($[S^* + S]_0 \ll K_m^{S*}, K_m^S$).

The resulting reaction is first order, and the increase of the reaction rate of the isomerization *cis* → *trans* upon addition of PPIase can be seen in the plot in Figure 8. If the substrate concentration is adjusted so that $[S]_0 \ll K_m$ is valid for the PPIase reaction, then the first-order rate constant k_b [s^{-1}] of the catalyzed reaction (k_u [s^{-1}] is the constant for the uncatalyzed reaction) directly gives the rate constant for the bimolecular PPIase-catalyzed reaction (k_{cat}/K_m [$M^{-1}s^{-1}$] = $(k_b - k_u)/[E]_0$). The isomer-specific proteolysis method can be varied in line with the molecular structure of the substrate and the protease sensitivity of the PPIase. It can be used to assay PPIase activity even in crudely prepared biological materials. The limit of detection for human recombinant Cyp18cy is an enzyme concentration of about 0.02 nM in the measuring solution.

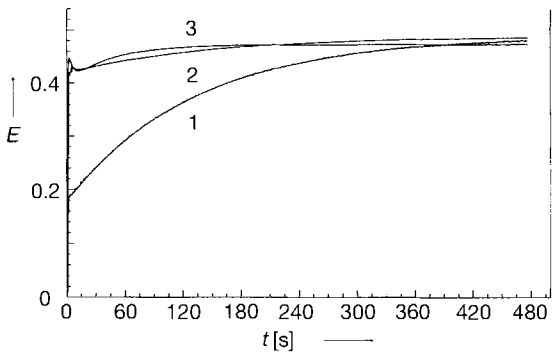

Fig. 8. Reaction course for the cleavage of Suc-Ala-Phe-Pro-Phe-4-nitroanilide by the isomer-specific protease subtilisin type VIII (0.15 mg mL^{-1} in 0.035 M hepes buffer, pH 7.8 at 13 °C); activity detected at 390 nm. 1) Uncatalyzed *cis* → *trans* isomerization started with the peptide dissolved in 0.2 M LiCl/trifluoroethanol; 2) uncatalyzed *cis* → *trans* isomerization started with the peptide dissolved in dimethyl sulfoxide; 3) as in curve 2, but with 5 nM Cyp18cy. The spikes at the beginning are mixing artifacts.

Since the amplitude of the isomerization reaction is limited owing to the low *cis* isomer level, (about 5–30% of the total concentration, depending on the peptide structure), obtaining an adequate signal/noise ratio is problematic; at high substrate concentrations solubility problems may arise. D. Rich et al.[51] were able to show that in a solution of the standard substrate Suc-Ala-Ala-Pro-Phe-4-nitroanilide in LiCl/trifluoroethanol (0.235–0.47 M) more than 50% *cis* isomer can be obtained, which makes the activity determination much easier (Fig. 8.).

If such a solvent jump is used for peptides whose fluorescence is quenched intramolecularly, for example the fluorogenic substrate 2-aminobenzoyl-Gly-Ala-Pro-Phe(4-NO_2)-Xaa-NH_2, then it is possible to measure the rate of isomerization without adding a protease enzyme.[52] After such a jump, conversion from the *cis* to the *trans* conformation leads to an increase in fluorescence. With the substrate Ala-Ala-Pro-Tyr(3-NO_2)-AlaNH_2 basically the same procedure can be used to measure the catalytic activity of PPIase in reversible equilibrium, although in this case a drop in absorbance at 428 nm in the UV/VIS spectrum is monitored.[53] The signal measured results from the differing pK_a values of the 3-nitrotyrosyl residue in the two conformational states of the peptide.[54]

One-dimensional NMR spectrometry can be used to determine the relaxation rates of the conformers in the presence of catalytic amounts of enyzme based on saturation transfer[17, 55, 56] or line broadening.[57, 58] The interconversion rate of the conformers of most *cis* and *trans* prolyl-peptide bonds is slow on the NMR timescale. Therefore separate signals are observed for nuclei near the isomerization center for both molecular forms. In the

presence of PPIase concentrations of >1 μM, the standard substrate Suc-Ala-Ala-Pro-Phe-4-nitroanilide displays coalesced NMR signals owing to a large increase in the interconversion rate. The catalyzed chemical exchange was also demonstrated in a NOESY experiment on human calcitonin$^{1-32}$ by the appearence of extra cross peaks in the presence of Cyp18cy (Fig. 9.).[58]

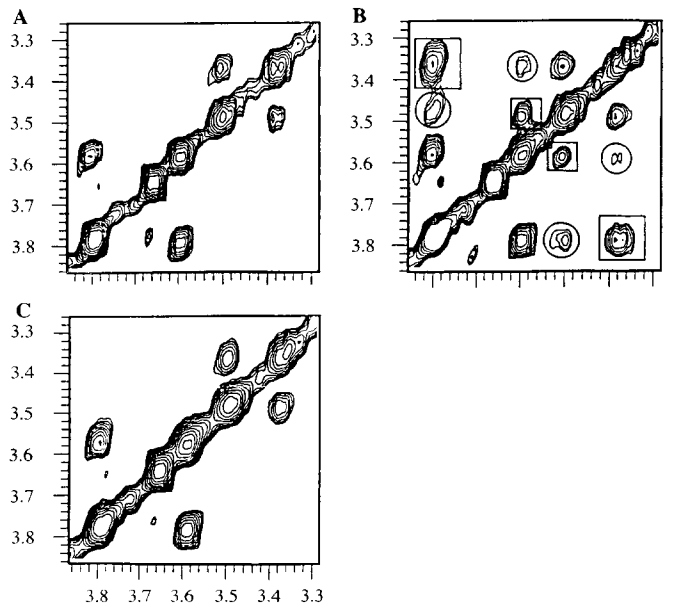

Fig. 9. The proline region (δ-ring signals) of the ^{1}H NMR NOESY spectrum of human calcitonin$^{1-32}$. **A**: in phosphate buffer, pH 6.8; **B**: as in **A** but in the presence of 25 μM Cyp18cy; **C**: as in **B** but with inhibition of the Cyp18cy activity by an excess of CsA. The extra cross peaks (in boxes) in **B** are due to rapid *cis/trans* exchange at the Phe-^{23}Pro in the presence of PPIase. The NOESY cross peaks between the δ ring protons in *cis* and *trans* ^{23}Pro resulting from the catalytic action of PPIase are circled [58]. The axes are labeled with the chemical shifts (δ).

When the kinetics of protein refolding and unfolding is examined,[10, 59] it is possible to find slower folding phases which often have their origins in the *trans* → *cis* isomerization of one or more prolyl-peptide bonds. Tyrosine and tryptophan residues in the neighborhood of the proline can act as probes for following the course of the isomerization, since changes in polarity during the folding process lead to changes in their fluoresence or absorbance. RNase T1 has proved to be a particularly suitable substrate for both families of PPIases having two *cis* bonds (namely Tyr$-^{39}$Pro and Ser$-^{55}$Pro) in the native state. Under conditions where both kinetic processes can be observed separately both were catalyzed by PPIases.[25] The low concentrations (<1 M) of urea and guanidinium hydrochloride in the refolding solution were tolerated by the cytosolic PPIase without substantial loss of activity.

5. Cyclophilins

For many of the 35 known protein sequences showing homology to the cyclophilin familiy of the PPIases (Scheme 1) isolation as proteins, characterization, and confirmation of their enzyme activity has been possible. A list of cyclophilins and their characteristic properties is given in Scheme 1.

Besides their tightly conserved central region comprising 130 amino acids, eukaryotic cyclophilins all have a high affinity for cyclosporin A ($K_i \ll 1$ μM) and many of its derivatives. Prokaryotic enzymes generally have a lower affinity,[104, 105, 115] though this may not always be the case.[103, 116]

The amino acids that are completely conserved in the sequence are distributed over the central region and most are coded for in the fourth exon.[166] The polypeptide chain of Cyp18 is relatively short, which implies that these amino acids are involved at the active site and have something to do with the activation of the catalytic process. For human Cyp18cy the three-dimensional structure has been determined down to a resolution of 1.63 Å by NMR spectrometry and X-ray crystallography.[18, 23, 24] The resulting structure shows that the conserved amino acids are located along a cleft along a β-sheet region (Fig. 10.). The conserved region is shown to be quite extended and is in fact larger than the hypothetical substrate binding site for short-chain oligopeptides. Amongst the presently known six isoforms of the human cyclophilins, Cyp18cy has a particularly broad distribution and is considered to be the receptor protein responsible for the immunosuppressive effect of CsA.

Amongst the sequence regions responsible for the localization of proteins in the cell, Cyp19cy has the terminal CXXL known as a signal for post-translational digeranylation. This sequence motif is mostly found in small G proteins and allows the regulated anchoring of the protein in the membrane.[117] Experimental results clearly demonstrating post-translational modification of cyclophilins are lacking at the present time. The cell adhesion signal motif RGD is present in a number of secretory cyclophilins in the core region of the sequence. However, the location of this sequence in the three-dimensional structure of the molecule is unknown, and no specific biological function has been assigned to it in the relevant cyclophilins.

Highly purified mammalian Cyp18cy enzymes are thermally and chemically stable (the enzymes retain full activity for months at 4 °C in buffer solution), but due to their highly hydrophobic nature, exposure to a plastic surface is enough to cause denaturation.[118] Cytosolic enzymes of the Cyp18cy type are widely distibuted in tissues and cell types of mammals and are found in high concentrations; however, the quantitative results seem to depend to a large extent on the method used for the determination. In mammals Cyp18cy is not restricted to lymphocytes—a fact which may help explain the side effects associated with CsA therapy.[119]

Kidney tubules and endothelial cells contain about 10 μg of Cyp18cy per mg of total protein, while T cells contain slightly less (3.1–7.0 μg mg^{-1}).[120, 121] In body tissues the concentration is about 1–3 μg mg^{-1}; skin and the deepest and most neuron-rich regions of the brain[122] have the highest levels.[121] There are large variations in localization and concentration within individuals,[123] and in other investigations lymph nodes and spleen were found to have the highest Cyp18cy levels.[118] A finding that tumor cells may have elevated levels[124] has not been confirmed by subsequent work.[121] Cyp18cy was detected by electron microscopy and confocal fluoresence microscopy not only in the cytosol but also in the nuclear membrane and in the outer regions of the Golgi apparatus. A cell-specific increase in Cyp18cy concentration, which was dramatic for liver and kidney, was found after treatment with CsA.[118, 125]

Scheme 1. For an explanation see p. 1423.

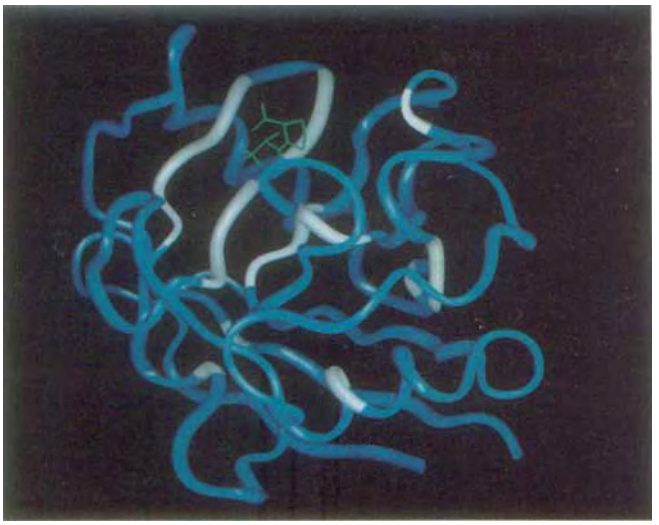

Fig. 10. A three-dimensional model of human recombinant Cyp18cy in the presence of the dipeptide Ala-Pro (shown in green) based on the results of X-ray diffraction studies [19]. Areas of highly conserved amino acids in the cyclophilin family are shown in white.

An unexpected high level of relatedness between human Cyp41cy and Cyp18cy in maize (67.3% identity) and the ubiquitous presence in tissues (brain > (liver, kidney, thymus, spleen) > lungs) is indicative of a special cellular function for this PPIase in mammals.[90, 108] This hypothesis is confirmed by the fact that this enzyme forms part of the oligomeric nonactivated estrogen receptor.[91] The long C-terminal extention on the PPIase homologous core region of Cyp41cy shows homology with the C-terminal of FKBP59, the PPIase component of the nonactivated progesterone receptor. Other components of the steroid receptors, the heat shock proteins hsp90 and hsp70, are also molecules specialized in mediating correct protein folding; their effect at the molecular level on the receptor function remains unknown.

This restriction also applies to Cyp158mem located on the outer membrane of $CD3^-$,$CD16^+$ granulocytes (natural killer cells), which plays a role in the recognition of tumor cells and in the cytotoxicity of killer cells. The amino acid sequence and the results of experiments with antibodies raised against sequence-derived peptides support the view that the N-terminal PPIase part of the molecule is extracelluarly anchored on the transmembrane segments and thus can take part directly in intercellular contact.[98]

It seems likely that *Drosophila* Cyp26mem, the tissue-specific ninaA protein from the compound eyes of fruit flies, plays a role in the catalysis of the synthesis, folding, and transport of the photosensitive Rh1-Rh6 rhodopsin and/or maintaining its stability. Cyp26mem is an integral membrane protein with a Cyp18cy-homologous sequence in the core region, which is located in the lumen of the endoplasmic reticulum (ER).[78, 88] If the Cyp26mem gene is deactivated, then abnormal opsin, the precursor of rhodopsin, accumulates in the ER to such an extent that it causes uncontrolled proliferation of the ER.[126] Random mutagenesis of fruit flies leads to point mutations in Cyp26mem, which lead to fruit fly phenotypes with defective rhodopsin production. Subsequent analysis showed that the amino acids affected are located in the postulated active site of the homologous Cy18cy, whose three-dimensional structure has been determined.[127]

There is also a group of cyclophilins that are secretory proteins and have the corresponding signal sequences added to the amino acid sequence (Scheme 1 and Table 2). Although it lacks an N-terminal signal sequence, Cyp18cy like IL-1 can be secreted through the cell membrane when certain stimuli are applied to the cell.[128] Secretory cyclophilins may contain the ER retention signal VEKPFAIKE at the C-terminus in addition to a signal sequence.[96] The transport of these cyclophilins out of the cell and their de novo synthesis is stimulated by growth factors.[129] This sequence motif data is consistent with the experimental finding that high PPIase activity levels are found in the lumen of the endoplasmic reticulum.[130] Of possibly biological significance is the observed colocalization of these proteins with typical ER proteins, such as the Ca^{2+}-binding protein calreticulin.[96] The hypothesis of C. M. Deber et al.[131] that the *cis/trans* isomerization of prolyl bonds plays a role in dynamic processes in membrane channels finds support in the fact that transport proteins that can be blocked by cyclosporin A have been observed, for example, in the inner mitochondrial membrane.[132] In studies of inhibitors analogous to CsA the inhibition constant K_i for the inactivation of the rat homologue of Cyp22mito was found to be proportional to the IC_{50} values for the blocking of the Ca^{2+} transport through these membrane pores.[133] In studies with CsA-resistant mutants of *Neurospora crassa* with a genetic defect for a functional Cyp24mito, M. Tropschug et al. were able to demonstrate for the first time that the inhibition of the PPIase activity itself is not responsible for the biological effect of CsA but rather that the CsA–Cyp complex must be cytotoxic.[87]

Deletion of the genes for Cyp20mito, Cyp17cy, and Cyp23sec even in the form of a triple mutant in the yeast *Saccharomyces cerevisiae* does not affect the viability of the cells.[99] However, when cells are exposed to stress conditions, the effect of the Cyp deletion becomes clear. Cyp20mito is essential for the growth of the yeast on L-lactate at 37 °C, and the Cyp20mito mutant is temperature sensitive.[100] In plant cells a Northern blotting

Human Cyp18cy (human cyclophilin A, human cyclophilin 1) [69]; bovine (pig) Cyp18cy (bovine (pig) cyclophilin A) [4,5,70]; rat Cyp18cy (rat cyclophilin A) [71], (the sequence of hamster Cyp18cy to identical to 97.6%) [72]; mouse Cyp18cy (mouse cyclophilin A) [73]; chicken Cyp (partial sequence) [74]; *L. esculentum* Cyp18cy (tomato) [75]; *B. napus* Cyp18 (rape) [75]; *Z. mays* Cyp18 (maize) [75]; *P. vulgaris* Cyp18cy (bean) [76]; *A. thaliana* Cyp18 [77]; *D. melanogaster* Cyp18cy (fruit fly) [78]; *D. discoideum* Cyp18 (slime mold) [79]; *C. albicans* Cyp18cy (yeast) [80]; *S. pombe* Cyp18 (yeast) [81]; *S. cerevisae* Cyp17cy (yeast cyclophilin A) (yeast) [82,83]; *E. granulosus* Cyp17 (tapeworm) [84]; *S. japonicum* Cyp20 [85]; *N. crassa* Cyp24mito [86,87]; *D. melanogaster* Cyp26mem (ninaA) (fruit fly) [88,89]; chicken Cyp22sec (S cyclophilin) [74]; human Cyp41cy (Cyp-40, ERB cyclophilin) [90,91]; human Cyp24sec (secreted cyclophilin-like protein SCLP) [92]; human Cyp23sec (human cyclophilin B, cyclophilin-2)[93]; rat Cyp26sec (CyLP; rat cyclophilin B) [94] (the sequence in ref. [94] probably contains a mistake in the reading frame which was corrected in ref. [95]; the corrected sequence is shown here. It is possible that a further base insertion leads to a stop codon at amino acid ^{208}Glu) [96]; human Cyp22mito (human cyclophilin-3) [97]; human Cyp158mem (NK-TR protein) [98]; mouse Cyp22sec (mouse cyclophilin-2) [95]; mouse Cyp23sec (mouse cyclophilin C) [8]; *S. cerevisiae* Cyp20mito (yeast cyclophilin-3) (yeast) [99,100]; *S. cervisiae* Cyp23sec (yeast cyclophilin B) [101]; *S. cerevisiae* Cyp36 (Scc3) [102]; *S. chrysomallus* Cyp18 [103]; *Synechococcus sp.* Cyp15, [A. Kaplan, PIR CSYC42]; *E. coli* Cyp18cy (*E. coli* b) [104]; *E. coli* Cyp21peri (*E. coli* a) [104,105]; an open reading frame in *Salmonella typhimurium* (gene bank M32355) is almost indentical to *E. coli* Cyp21peri.

analysis demonstrated an increase in Cyp18cy mRNA in response to stress conditions.[76] The more than twofold increase in transcription of the Cyp18cy gene of *Saccharomyces cervisiae*, which was observed in response to heat shock, shows certain parallels to a typical stress 70 gene SSA1. The corresponding Cyp promoter proved to be heat inducible. Disabling the genes for Cyp17cy and Cyp23sec drastically reduces the ability of the yeast cells to survive heat shock.[134]

5.1. Catalytic Properties

Up until the present time, enzyme kinetic parameters have been determined almost exclusively for reactions of Cyp18cy (see Table 1). With regard to the enzyme–substrate interaction, the rate constants k_{cat}/K_m (*cis* → *trans*) for the bimolecular reaction approach the diffusion limit of 2×10^8 M^{-1}s^{-1} in the best cases.[135] A reliable method for determining the number of active sites by titration is not yet available; however, it is possible to use the increased intensity of the tryptophan fluorescence to follow the titration with the competitive inhibitor CsA. For human Cyp18cy the following kinetic constants were determined with the standard substrate Suc-Ala-Ala-Pro-Phe-4-nitroanilide: $K_m = 0.87$ mM (*cis*), $k_{cat} = 12\,700$ s^{-1} (*cis*) (0 °C).[51] These data show that the cytosolic cyclophilins at least are highly evolved enzymes with respect to their catalytic function. Because of the high k_{cat} values, these enzymes increase the rate of the reaction substantially, $k_{cat}/k_u \approx 10^6$, over that of the already fast uncatalyzed isomerization.

Information on the specificity of Cyp18cy for secondary binding sites (the nomenclature of the secondary binding sites is analogous to that of proteases;[264] isomerizable bond between positions P_1 and P'_1) is at present only available in some detail for the amino acids Xaa and Yaa in Suc-Ala-Xaa-Pro-Yaa-4-nitroanilide. In comparisons of the best and worst peptide substrates having uncharged and charged side chains Xaa, the values for the ratio k_{cat}/K_m differ by less than 20-fold.[97, 115, 162, 163] The differences for Yaa tend to be somewhat less, and for variations at at position P_1 the values of k_{cat} show a greater range of variation than those of k_{cat}/K_m.[266] The succinyl residue in the standard substrate can be replaced with a glutaryl residue without changing k_{cat}/K_m or even removed completely with minimal effect on the rate constants. The P_2 position also has an effect on specificity.[97]

At present three-dimensional structures have been determined only for substrate–Cyp18cy complexes.[18, 19, 23] For both the dipeptide Ala-Pro and a tetrapeptide substrate, whose *cis*/*trans* isomerization is readily catalyzed, only the *cis* isomer (angle at the peptide $\omega = -3°$) was observed as preferred bound conformation. The conformation of Cyp18cy on binding of the dipeptide does not change significantly compared to that of free Cyp18cy. However, since Ala-Pro is not a substrate but only a weak inhibitor, complex formation with longer peptide chains could lead to more significant changes in the enzyme structure. Our kinetic studies indicate that Cyp18cy binds the substrate calcitonin$^{1-32}$ with regiospecificity. The isomerization of the central Phe-^{23}Pro bond is strongly catalyzed; in contrast, the isomerization of the terminal Ala-^{32}ProNH_2 bond is not catalyzed at all.[58]

A number of slow processes in protein folding reactions can be catalyzed by cyclophilins,[62, 64–66] and thus have been identified without doubt as *cis*/*trans* isomerizations. During the refolding of a protein, the PPIases definitely act as true catalysts, and unlike molecular chaperones they do not depend on the presence of stoichiometric amounts of the helper protein or low molecular weight additives.[137] In the special case of recombinant carbonic anhydrase under certain refolding conditions the effect of porcine Cyp18cy was to increase the rate of refolding as well as the refolding yield.[138] The effect on yield seems to be independent of the enzymatic catalysis, and thus an additional chaperone function might be assigned to the enzyme. However, significant increases in refolding yield were also observed when stoichiometric amounts of foreign protein were added to the refolding solution (a nonspecific protective effect of added protein).[265] The catalytic effects of PPIases on refolding rates can always be blocked by inhibiting the PPIase with CsA. In contrast, cyclosporin H which is of similiar hydrophobicity but is noninhibitory did not affect the catalysis of the refolding processes.

Like the catalysis of *cis*/*trans* isomerizations by PPIases, which are linked in the assay to an isomer-specific proteolysis (see Section 4), the *cis* → *trans* or *trans* → *cis* isomerization in the PPIase-catalyzed refolding of proteins is linked to an irreversible reaction, namely the quasi-irreversible formation of a stable three-dimensional protein structure under renaturing conditions. It has already been demonstrated experimentally that during protein folding catalysis in both isomerization directions takes place.[62, 139] The catalytic efficiency of cyclophilins with macromolecular substrates under conditions where $[S] \ll K_m$ is at least ten times less than with short-chain substrates. This is certainly caused in part by the extended diffusion times with large molecules.

Kinetic analysis of PPIase-catalyzed protein refolding beyond the qualitative finding that the rate of reaction increases is very complicated because of the existence of many poorly defined substrate states. In the most thoroughly investigated refolding process, that of unfolded RNase T1,[25] the *trans* Ser-^{55}Pro unit is accessible to the catalyst while the *trans* Tyr-^{39}Pro bond is not because of steric shielding. The resulting formation of intermediate structures that already possess the *cis* Ser-^{55}Pro unit of the native structure is not a property of the fully unfolded chain, but rather it is reached in the early stages of refolding. The early formation of native structure elements may be the reason why Cyp18cy cannot catalyze certain partial reactions in protein refolding involving *cis*/*trans* isomerizations.[67] When cytosolic cyclophilins from a variety of organisms are used in the refolding of this model protein, parallels can be drawn between catalytic activity of all these enyzmes with a tetrapeptide substrate and the two slow, catalyzable processes in the formation of the native structure of RNase T1.[16] With the exception of *E. coli* Cyp18cy, which catalyzes the very slow *cis* Tyr-^{39}Pro isomerization relatively well, there are five other, not very phylogenetically related cyclophilins, which recognize the secondary binding sites of the RNase T1 polypeptide chain equally well and have similar substrate steric requirements. This finding can be taken as evidence of evolutionary conservation of protein-folding catalysis.

When attempting to develop models of de novo protein formation in the the cell it must be borne in mind that the oxidative refolding of reduced RNase T1 (the molecule contains two disulfide

bridges in the native state) is synergetically accelerated by the presence of protein disulfide isomerase and *E. coli* Cyp18cy.[140] Although protein unfolding catalyzed by PPIases is supported by the concept of microscopic reversibility, it is not so easy to demonstrate experimentally. This was achieved by Mücke and Schmid with reduced and *S*-carboxymethylated RNase T1 which can be unfolded simply by employing a concentration jump from 0.2 to 3 M NaCl. The surprisingly simple kinetics of the unfolding process showed a nonlinear catalytic increase in rate of reaction which was dependent on the concentration of *E. coli* Cyp18cy.[63]

The catalysis of isomer interconversion in native proteins, which is very interesting from a physiological point of view, did has not received much attention. However, 50 μM Cyp18cy (porcine) was found to have no effect on the rate of *cis/trans* isomerization of the Gly-^{43}Pro bond in native calbindin D_{9k}.[61]

At present quantitative data for protein folding catalyzed in vivo are lacking. Among the positive qualitative findings are the CsA-linked slowing down of the formation of the three-dimensional structure of transferrin in the endoplasmic reticulum,[141] the increased protein yield in coexpression experiments,[142] and the effect of gene deletions.[143] In addition a single kinetic value is known, namely the 1.4-fold reduction caused by CsA for the rate of triple helix formation in procollagen from fibroblasts.[144] Here, too, the inhibition of PPIase activity through CsA was used as an investigative tool. However, the relatively small kinetic effect led to considerable changes in the reaction product, because the increased time scale of protein folding due to the inhibition meant that a higher degree of posttranslational modification was possible in the triple helix.

5.2. Inhibition

All cyclophilins bind CsA with binding constants ranging from nM to several μM (Table 1). Their enyzme activity seems to be competitively inhibited by CsA; however, this result has been verified only for human Cyp18cy, which binds very tightly to the inhibitor. The CsA–Cyp18cy binding constants reported in the literature show a wide range (by a factor of greater than 100). This can be explained by the dependence of the association constants on the protein concentration, which has its origins in the oligomerization of free Cyp18cy or in the formation of a decamer complex[145] which has already been observed in the solid state.

The specificity of the binding and inhibition is demonstrated by the mininal affinity of cyclophilins for D-^{11}MeVal-cyclosporin (CsH). Further structures that act as reversible cyclophilin inhibitors at a comparable level of effectiveness are not known at present. A variety of proline-containing oligopeptides that appeared to be potential competitive inhibitors proved not very effective at inhibiting the test reaction with Suc-Ala-Ala-Pro-Phe-4-nitroanilide when both components were kept at less than 1 mM.[146]

Interesting from a pharmacological point of view is the finding of D. Rich et al. that the binding of CsA to Cyp18cy is a relatively slow, pseudo-first-order reaction under the reaction conditions and can be divided up into at least two or three kinetically relevant processes. In addition, the binding parameters depend on the type of solvent cyclosporin A was dissolved in prior to the start of the inhibition reaction.[51, 147, 148] The time dependence of the inhibition constants (with an apparent half-life of 29 s for the middle phase) is reflected by the different values: $K_i = 61$ nM shortly after addition of CsA to Cyp18cy, $K_i = 2.5$ nM after 30 min (Fig. 11.). The reaction with the mature form of

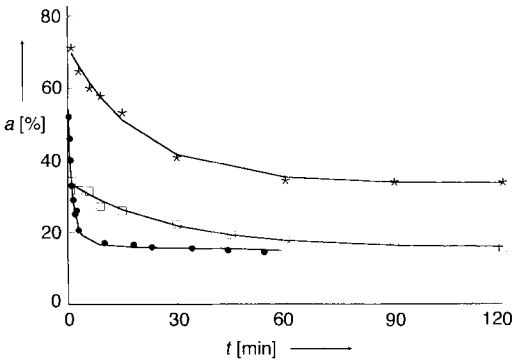

Fig. 11. Time dependence of the residual activity a [%] of the reaction of CsA (●) with Cyp18cy as well as FK506 (*) and rapamycin (□) with FKBP12cy at 10 °C and 15 °C (rapamycin). CsA (10 nM in reaction mixture) and Cyp18cy (1.5 nM); FK506 (25 nM in reaction mixture); rapamycin (34 nM in reaction mixture), FKBP12 40 nM each. All stock solutions of the effectors are in $EtOH/H_2O$ (50/50 vol%) [263].

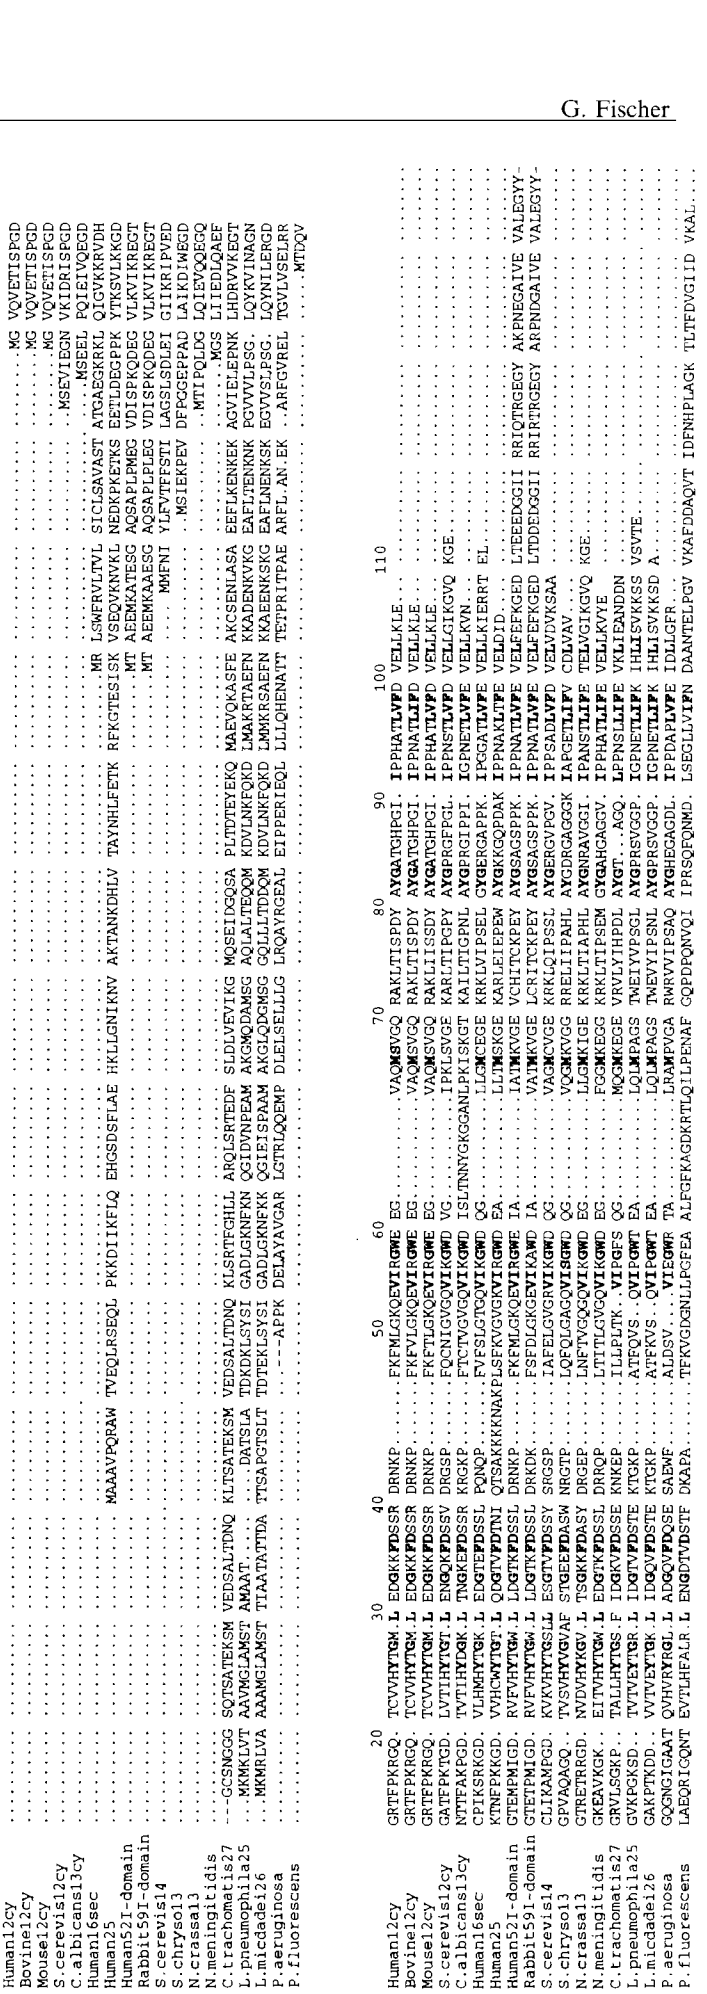
Cyp22mito (rat) also exhibits phases with different reaction rates. In this case the half-life is significantly longer and indicative of an enzyme-dependent conformational change during the formation of stronger CsA–CsA complexes. The origin of the "memory" of CsA for nature of the solvent stems mainly from the conformational heterogeneity of CsA in solution.[149] The form of CsA active in inhibition with a *trans* conformation at ^{9}MeLeu-^{10}MeLeu[21, 150] is present in low concentrations in many solvents (e.g. tetrahydrofuran); in others CsA is almost exclusively present in the active form (tetrahydrofuran/LiCl[151]). Thus this concentration determines the K_i value at the start of the reaction which is usually calculated from the total amount of CsA. However, CsA does not seem to be a suicide inhibitor since according to current knowledge Cyp18cy cannot catalyze the *cis* → *trans* conversion in CsA. Many CsA derivatives only reach a final equilibrium after several hours when the ligands are optimally adapted to their host protein. When dimethyl sulfoxide is used as a solvent the approach to equilibrium is slowed even further. Even under these unfavorable conditions for structure–activity relationships a very nearly linear dependence for the binding of 96 CsA derivatives to bovine Cyp18cy versus the ability to suppress T-cell proliferation was found.[152] However, two derivatives ("off-diagonal analogues")[153] showed great deviations from this correlation which leads to doubt that the inhibition of the Cyp18cy activity alone leads directly to immunosuppression. ^{6}MeAla-CsA strongly inhibits the catalysis ($K_i = 9$ nM),[154] and although its structure is very similar to that of CsA, this derivative showed only 1% of the immunosuppressive effect of CsA.[155] In contrast, ^{1}MeBm$_2$t-cyclosporin binds weakly ($K_i = 2240$ nM; bovine Cyp18cy)[153] but still shows 12% of the immunosuppressive effect of CsA on the activiation of the IL-2 transcription factor NF-AT.[154, 156]

Macromolecular CsA derivatives prepared from aminodextran (molecular weight ca. 70 kDa) or serum albumin by covalent



linkage of CsA with the side chain of the (4*R*)-4-[*trans*-butenyl]4,*N*-dimethyl-L-threonine residue inhibit Cyp18cy only ten times less effectively than CsA itself. The IL-2 release from EL-4 lymphocytes can be inhibited by this CsA derivative with an IC_{50} value of 60 nM (about 4% of the CsA activity under the same conditions). Even the coupling of aminodextran-CsA to agarose beads does not prevent the immunosuppressive effect, as long as contact to the cell surface is ensured.[157] This implies the existence of a(n) (additional?) receptor for CsA on the surface of T cells. However, one property of ^{6}MeAla-CsA does not fit the present model for the action of CsA (see Section 9)—this derivative does not act as a CsA antagonist in the (phorbol ester/ionomycin)-activated T-cell proliferation test.[153]

The three-dimensional structure of human CsA–Cyp18cy was determined by X-ray crystallography[145] and NMR spectrometry.[158] The structure of Cyp18cy was shown to be hardly affected by complex formation, whereas the three-dimensional structure of CsA in the complex is dramatically different from that in unpolar, nonaqueous solution[160] or in the solid state;[161] for example, intramolecular hydrogen bonds of CsA are not found in the complex. The CsA residues 1–3 and 9–11 (see Fig. 5) are involved in the contact to the cyclophilin surface, which binds the ligands in a hydrophobic pocket formed from the side chains of the amino acids ^{121}Trp, ^{60}Phe, ^{57}Ile, ^{122}Leu, ^{113}Phe, ^{126}His, ^{101}Ala, ^{103}Ala, and ^{73}Thr. As was already known from the increase in the fluorescence intensity on complex formation and from mutagenesis experiments,[163, 164] ^{121}Trp is a determinant for the especially strong binding of CsA to the cyclophilin.

The binding region consists of four antiparallel β-pleated sheets and is identical with the pocket for the substrate acetyl-Ala-Ala-Pro-Phe-amidomethylcoumarin.[23] However, compared to this peptide CsA binds to cyclophilins in the opposite propagation direction of the peptide chain.[150]

6. FK506-Binding Proteins

Cytosolic FKBPs (synonym: macrophilins), which are made up of less than 110 amino acids and have molecular weights of about 12 kDa, are amongst the smallest known enzymes. A common feature of these enzymes apart from sequence homology is their inhibition by FK506 and rapamycin (Table 2). There is no evidence of oligomerization of the enzyme at catalytic concentrations. FKBP12cy from mammalian tissues function as receptors for the immunosuppressive effect of peptidomacrolides, and it was receptor studies with these compounds that revealed the enzyme nature of the FK506-binding proteins.[6] At present 18 sequences with homology are known (Scheme 2) which were for

Scheme 2. Amino acid sequences for FK506-binding peptidyl-prolyl *cis/trans* isomerases known at the genetic level. The numbers above the sequences refer to the FKBP12cy (human) sequence. Human FKBP12cy [32,166,167]; bovine FKBP12cy [168]; mouse FKBP12cy [169]; *S. cerevisiae* FKBP12cy (RPB or RBP1 protein) [26,170,171]; *C. albicans* FKBP13 [172]; human FKBP16 (FKBP-13) [173]; human FKBP25 [174–176] (bovine FKBP25 is 97% homologous [177]); human FKBP52cy (p56, hsp56) [178]; rabbit FKBP52 (hsp binding immunophilin, HBI; p59 [179]; *S. cerevisiae* FKBP14 [180]; *S. chrysomallus* FKBP [181]; *N. crassa* FKBP13 [182]; *N. meningitidis* FKBP [183]; *C. trachomatis* FKBP27 (Mip-like protein) [184]; *L. pneumophila* FKBP25mem (Mip protein) [185,186]; *L. micdadei* FKBP26 (Mip protein) [187]; *P. aeruginosa* FKBP25 [188]; *P. fluorescens* FKBP [189].

the most part identified using the standard test for PPIases. In addition, there are FKBPs which have not been sequenced yet but whose inclusion in this family has been demonstrated by cross-reactivity with anti-FKBP12cy antibodies and FK506 sensitivity.[110, 165]

A high-resolution three-dimensional structure was determined for human FKBP12;[20, 219, 221] however, no structure is yet available for the enzyme–substrate complex. The structure of FKBP12cy with a bound FK506 molecule is shown in Figure 12. The highly conserved amino acids in the FKBP sequences (Scheme 2) are distributed all over the protein molecule.

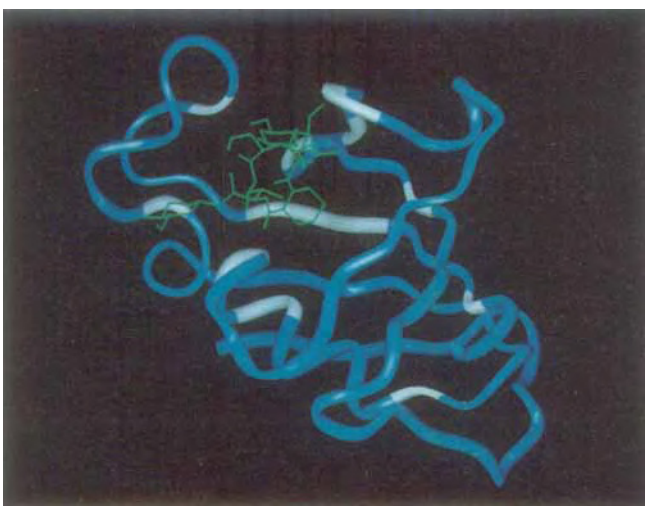


Fig. 12. Three-dimensional model of the FK506–FKBP12 complex [20]. FK506 is shown in green; amino acids that are highly conserved in FKBP sequences are shown in white.

The kinetic constants of recombinant FKBPs do not differ significantly from those of PPIases from natural sources,[180, 196] although a post-translational phosphorylation in vitro has been reported (the FKBP12 chain contains a consensus sequence for protein kinase C: ^{35}KKFDS*SRD).[197] The clustering of conserved residues is less pronounced than in the cyclophilins; however, these residues are also found in the cleft forming the binding site of FK506 (Fig. 12).

The stability of human FKBP12 is impressive ($T_m \approx 68$ °C) and increases further when complexed with peptidomacrolides.[198] In contrast to cyclophilins, after denaturation and unfolding with urea ($c_m \approx 4.3$ M) FKBP12 refolds to the native form and regains full enzyme activity.[199]

Like cyclophilins, FKBP12cy are widely distributed in human tissues, and especially high levels are found in certain regions of the brain.[200] The concentration of FKBP12cy in the cytosol of lymphocyte cells is extraordinarily high for an enzyme ($c \approx 20$ μM).[197, 201] The subcellular distribution pattern is not constant but depends on the functional state of the cell; FKBP12cy tends to be localized in regions near the cell nucleus, as is the case with Cyp18cy.[202] A further unexpected similarity between Cyp18cy and FKBP12cy is their chemotactic effect on neutrophils, an effect that is detectable down to nanomolar concentrations with FKBP12cy.[203] CsA and FK506 block the chemotactic activity of the corresponding binding partners, while the PPIase inhibitors ^{6}MeAla-CsA and rapamycin do not. This shows that the site of attack is actually the Ca^{2+}-dependent signal transduction. The observation that FKBP12cy possesses a hepatocyte growth stimulating activity at a dose of 1 μg per kg of tissue during liver perfusion fits in well with this extracellular activity.[204] The inhibition of the chemotactic effect of PPIases has been put forward as an alternative to the IL-2 model to explain the immunosuppressive effect of CsA and FK506.[205]

The yeast analogue of FKBP12cy is coded for by a nonessential gene, whose elimination, or simply the exchange of Tyr^{89}Asp in the enzyme,[206] blocks the fungicidal effect of rapamycin.[168, 170, 207] In the wild-type yeast rapamycin blocks growth by fixing the cells irreversibly in the G1 phase of the cell cycle. FK506 is an anatogonist of rapamycin. The rapamycin–FKBP12cy complex probably inhibits a phosphatidylinositol-3-kinase.[171, 208]

As is also the case for the second FKBP protein found in *Saccharomyces cerevisiae* (FKBP14mem), the activity of the yeast PPIases is greater than the FKBPs from other sources by almost 100-fold (Table 2). The signal sequence of FKBP14mem leads to the localization of this enzyme mainly in the microsomal fractions.[180] The deletion of the gene in this case as well does not lead to the generation of a phenotype under normal conditions. However, the level of nonglycosylated, unfolded precursor proteins in the endoplasmic reticulum is increased by a tunicamycin treatment, and the expression of FKBP14mem is also increased.[209]

The related human FKBP16sec is the major FKBP in mast cells,[210] and in the form of a FKBP16 homologue it is the major FKBP of leaf cells of plants.[110] However, in Jurkat cells it makes up only about 2% of the amount of FKBP12cy.[173] FKBP25 is especially interesting because it contains a localization signal for the cell nucleus and shows DNA binding properties through a helix-turn-helix motif.[174, 177, 211]

A further similarity with the biochemistry of the cyclophilins is the fact that both protein families have been demonstrated to form part of the steroid receptors. An integral component of the heterooligomeric, nonactiviated glucocorticoid receptor (ca. 300 kDa) is a heat shock protein (52 kDa) with two regions homologous to FKBPs.[194] The N-terminal domain has 49% homology with human FKBP12cy. There is an additional FKBP-related domain with a somewhat vague functional significance, and further similarity to a calmodulin-binding consensus sequence can be recognized.[212] FKBP52, which is probably dimeric in the native state, is directly connected to the cytoskeleton and binds to affinity columns for FK506.[193] It is PPIase active and inhibited by peptidomacrolides.[213] After initial unsuccessful attempts, an effect of FK506 on the functioning of the receptor was found—an increase in the rate of transcription of specific genes. Conditions of reduced steroid induction have to be used so that the effect can be monitored.[214]

The C-terminal region of FKBP52 is 34% identical with the same 140 amino acid region in Cyp41cy, the PPIase component of the nonactivated estrogen receptor.[90, 91]

Pathogenic bacteria seem to be predestined to express membrane-bound FKBPs on their surfaces (see Scheme 2).[215] For example *Legionella pneumophila*, the pathogen causing Legionnaires' disease, is an intracellular phagocytic parasite of lung macrophages and monocytes.[216] The mip protein

(FKBP25mem) is thought to be the pathogenicity factor on the surface of *Legionella* (about a 100-fold reduction in virulence is observed in FKBP25mem-negative mutants).[217] The N-terminal extension to the FKBP homologous core of the mature protein is predicted to have a high helix content, which could contribute to the anchoring of the protein to the membrane. The PPIase activity can be inhibited with FK506,[185] and the enzyme is probably present as a dimer.[218] However, the exact sites of interaction for FKBPs on the molecular level during pathogenesis remain unclear.[215]

6.1. Catalytic Properties

The catalytically active concentrations of FKBPs have been determined up until now by titration with FK506 or rapamycin by following the decrease in the intensity of the protein fluorescence[219] or approximated by blocking the enzyme activity with stoichiometric amounts of inhibitors. In contrast to cyclophilins FKBPs exhibit a high level of subsite specificity for the amino acid at position P_1 on the substrate chain.[162, 180, 185, 190] Especially high values of k_{cat}/K_m are observed with amino acids in this position having hydrophobic side chains, whereas glycine and charged amino acids lead to peptides that are hardly utilized by the enyzmes at all. Indeed, there is a linear relationship between k_{cat}/K_m (human FKBP12cy) and the hydrophobic capacity factor R' of the amino acid side chain.[146] Such a specificity distribution makes sense biologically only if the cell has different enzymes available with differing specificity for secondary binding sites, as is the case of proteases. However, this does not seem to be the case with FKBPs, since all enzymes examined so far show a similar catalytic pattern (Fig. 13). With the optimum substrate

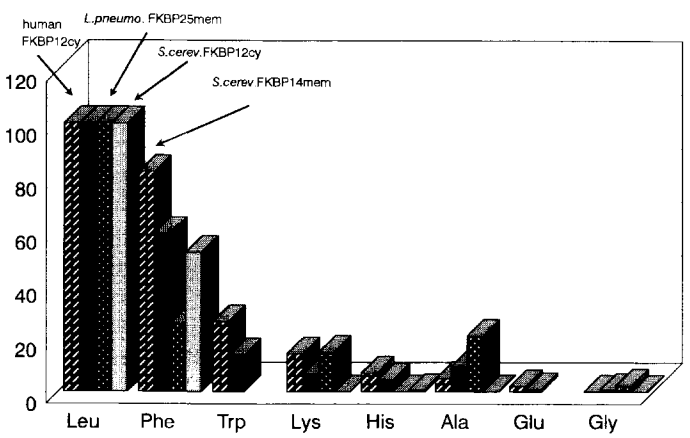

Fig. 13. Relative substrate specificity k_{cat}/K_m [%] is plotted on the y axis for a variety of FKBPs for substrates of the type Suc-Ala-Xaa-Pro-Phe-4-nitroanilide with Xaa = Leu (100%) [162,180,185].

Suc-Ala-Leu-Pro-Phe-4-nitroanilide for FKBP12cy, the k_{cat}/K_m value is about ten times less than with Cyp18cy. This is mostly due to the k_{cat} term [597 s^{-1}] and not the K_m constant.[220]

Although FKBPs are less effective than cyclophilins, they can also catalyze protein folding;[182] at present not much data is available.

6.2. Inhibition

Rapamycin and FK506 bind strictly stoichiometrically (1:1 with human FKBP12cy) and sometimes very strongly to FKBPs; in doing so they reversibly inhibit PPIase activity (Table 2). The rate of inhibition is time-dependent for both of the inhibitors, and thus the course of the reaction is comparable with the formation of the CsA–Cyp complex formation (see Fig. 11). The origin of this slow first-order process is probably the supply of *trans* isomer of the inhibitor by the uncatalyzed isomerization after the consumption of the equilibrium level of the *trans* isomer. Although the immunosuppressive effect of rapamycin differs from that of FK506 so much that a separate receptor seems likely, no specific rapamycin-binding protein has yet been found in Jurkat cells.[222] With rapamycin, too, inhibition of PPIase activity and rapamycin-specific immunosuppression can be separated from each other.[223]

In an FK506 dimer (FK1012), in which two units of FK506 are linked by a bis(carbamoyl)-4-xylylenediamine bridge at the C40 atom of FK506, both halves possess a high affinity for FKBP (K_i^1 = 0.06 nM; (K_i^2 = 0.76 nM). Thus chimeric proteins consisting of an FKBP part and an effector part can form dimers in situ and start a oligomerization-dependent signal cascade. Addition of FK506 monomers can be used to turn the signal cascade off.[224]

The enthalpy of formation for these complexes and other thermodynamic data suggest that hydrophobic interactions play a dominant role in complex formation.[225] This finds additional support in the structure of the FK506–FKBP complex, since all of the amino acid residues near the binding center possess hydrophobic side chains (Fig. 14).

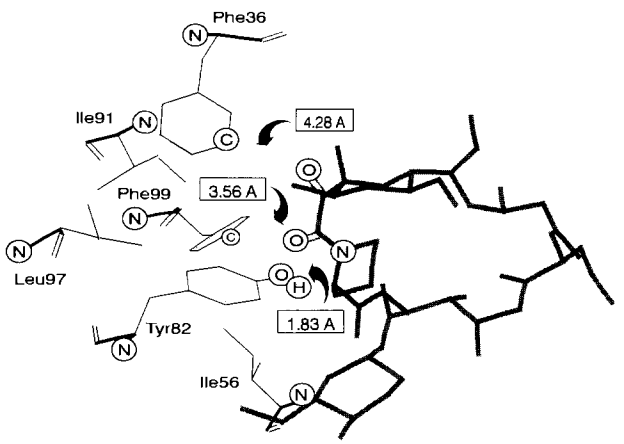

Fig. 14. All amino acids that have an atom located within 5.5 Å of the peptide carbonyl group of FK506 (section of the molecule represented with a thick gray line) in the FK506–FKBP12 complex [20]. The nitrogen atoms are marked in the backbone of the polypeptide chain (thick black lines). Distances are given for a number of atoms that are especially close together. The distances refer to the atoms connected by thin lines.

Similar to the situation with the cyclophilins, a linear relationship exists for FK506 derivatives between the parameter for the binding to FKBP12 ($\lg IC_{50}$) and the blocking of IL-2 release from stimulated Jurkat cells. Off-diagonal compounds include rapamycin and 506BD in particular (Fig. 15), a synthetic compound which first showed the discrepancy between inhibition of

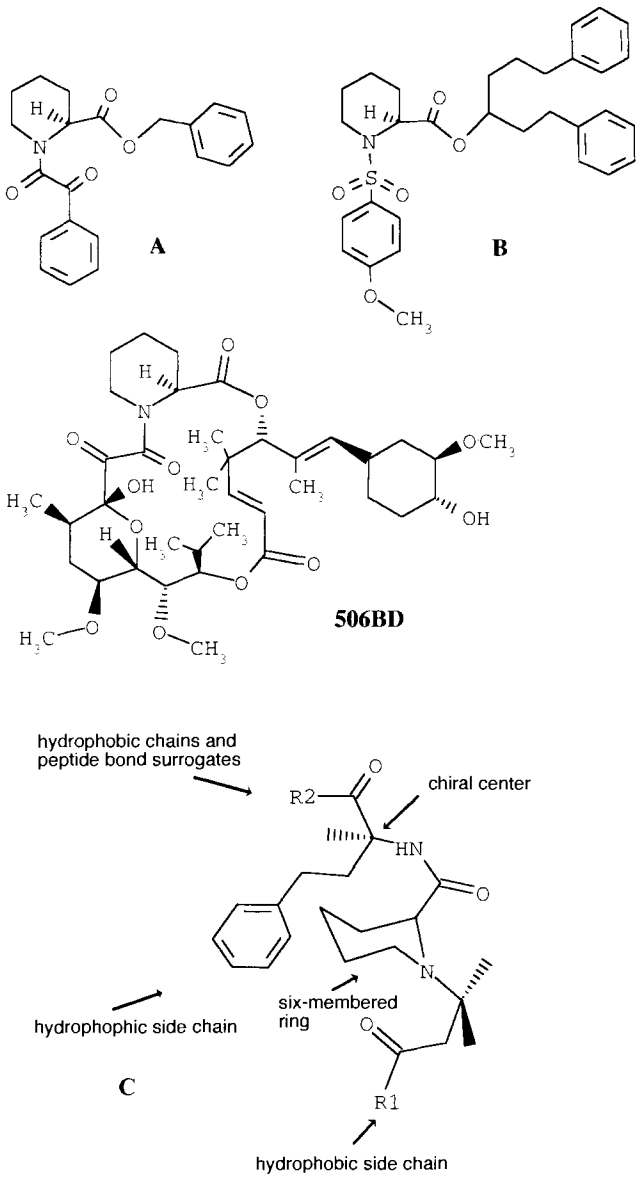

Fig. 15. Structures of a number of synthetic inhibitors of FKBP12cy.

PPIase activity and the effect on T cells.[226] Both compounds have a high affinity to PPIases and inhibit their activity while not affecting IL-2 production.[227] These off-diagonal derivatives act as sensitive probes for investigations into the calcineurin model of immunosuppression.

The α-dicarbonyl unit in FK506 and rapamycin deviates considerably from s-*trans* planarity. The α-carbonyl group is also situated perpendicular to the plane of the amide group in the enzyme–FK506 complex (see Fig. 12.).[20, 228] However, this is not a consequence of the macrocyclic structure, since local strain forces the α-carbonyl group out of the dicarbonyl plane even in simple pyruvdialkylamides.[229]

Complex formation leads to a change in conformation of the amide bond of FK506; the *cis* conformation is found in the solid state, a mixture of isomers is present in aqueous solution, and after binding to FKB12cy it acquires the *trans* conformation. The conformation of free rapamycin is the same as that found in the complex, which could explain the greater complex formation constant compared to that of the rapamycin–FKBP complex. In contrast to rapamycin, FK506 is not chemically stable, as was demonstrated in a solution of ethanol/water; it tautomerizes slowly at the hemiketal C10 atom with racemization and formation of a keto structure at C10.[230] Both macrolides are considered to be transition state analogues for the PPIase-catalyzed conversions, since the spatial arrangement of the α-carbonyl group relative to the peptide bond in the ground state corresponds to that in the transition state of the isomerization.[13] FK506 becomes less inhibitory after replacement of the OH group at position C10 with a peptide bond.[231] This implies that FK506 is probably not a transition state analogue for a natural substrate containing a Leu-Pro dipeptide unit.

The conformational homology of FK506 to α-ketoacid amides explains why new inhibitors were first based on this structural unit. Compound **4** in Figure 15, a phenylglyoxylic acid derivative, has a much simpler structure than FK506 but a K_i value of 1.5 μM and is thus is a fairly good inhibitor.[232] Compound **B** which has a sulfonamide group has improved inhibitory activity (K_i = 5 μM),[233] while structure **C** proposed by Hauske et al.[234] has the extrapolated structural elements for an optimum FKBP inhibitor based on the information extracted from the data of 56 structures.

7. Intracellular Binding Proteins for PPIases

Proteins that are specifically associated with PPIases in intact cells or in cell homogenates can give clues about the biological function of the enzymes and natural substrates. Owing to the high K_m values of human Cyp18cy and FKBP12 for oligopeptides and the projected low affinities of PPIases for protein substrates, it is not likely that complexes of PPIases with cellular substrates will accumulate. Therefore it is questionable whether the lifetimes of PPIase complexes with good polypeptide substrates are long enough to be detected by analytical methods. However, PPIase binding partners can be detected in stable heterooligomeric complexes.

The binding of immobilized proteins of the heat shock family hsp90 to human Cyp18cy depends on the Mg^{2+}/ATP concentration; however, binding does not require the hydrolysis of ATP and cannot be blocked by addition of CsA. Consequently, an affinity column with Cyp18cy as ligand binds the heat shock proteins hsp70 and hsp90.[235] A 77 kDa glycoprotein from AC-6 bone marrow cells was retained by a column with the immobilized PPIase-active fusion protein consisting of glutathione-S-transferase and Cyp23sec (mouse). The fusion protein was bound to glutathione agarose as carrier. Interestingly, the targeted glycoprotein was found to have a cysteine-rich sequence region typical for cell surface molecules.[8, 236]

An unexpected finding is that the proline-free peptide CGY-DVSTAQKIIAKL can integrate specifically with yeast Cyp17cy. This was demonstrated in cross-linking studies with bis(sulfosuccinimidyl)suberate. The cross-linking can be blocked by CsA and is not observed with the reverse sequence.[237]

An elegant molecular biological method[238] can detect protein–protein interactions in a yeast system by means of the transcription of a reporter gene in vivo. In the search for potential binding partners of the gag polyprotein of the HIV-1 virus

in a protein bank coded by human cDNA, the only specific binding partners for $Pr55^{gag}$ were Cyp18cy and Cyp23sec.[239] Gag proteins from related viruses do not bind or in the case of the simian virus SIV-1 only bind Cyp23sec. The formation of the $Pr55^{gag}$–Cyp complex occurs also in vitro with isolated proteins and was also observed with the p24 fragment of $Pr55^{gag}$. The associations can be disrupted by the addition of CsA. However, it is still unclear what relevance these results have to the pathogenesis after infection with HIV-1. The addition of CsA has been shown to block HIV-1 replication and especially the formation of syncytes with multiple nuclei from T cells.[240]

Fewer binding proteins for the FKBPs have been found thus far. FKBP12cy binds strongly and very specifically to the ryanodin receptor and can be copurified with it. The rynodin receptor is the 565kDa Ca^{2+} channel of skeletal muscle. It seems likely that FKBP12cy is located on the cytoplasmic side of the sarcoplasmic reticulum.[241]

8. Mechanisms of PPIase-Catalyzed Reactions

The rate of the uncatalyzed *cis/trans* isomerization of the prolyl-peptide bond depends relatively little on the nature of the adjacent amino acids but on the state of folding of the polypeptide chain.[25] Both a rate increase and a decrease are found for the isomerization of polypeptide chains compared to that found in oligopeptides. A specific intramolecular catalysis of the isomerization of the proline bond resulting from the arginine side chains in dihydrofolate reductase has been proposed;[242] however, it is very difficult to separate such a group-specific effect from structure-dependent effects.

Acid catalysis has not been detected except at extreme pH values, and the action of OH^- ions as nucleophiles in the isomerization reaction has been inferred only indirectly.[243] *cis/trans* Conformational interconversions are more rapid in nonaqueous solvents (the rate constant is increased by up to 100-fold) because the ground state of the isomers is destabilized and thus the electronic delocalization in the amide bond is reduced.[244]

We described the plausible reaction mechanisms for the enzyme-catalyzed *cis/trans* isomerization early on[245] and present a modified version in Figure 16. A number of these reaction paths imply that an intermediate with a covalently bound substrate is formed in the course of the catalysis. In any case the crucial elementary step is a reduction in the double bond character of the C–N bond. So far investigations on PPIases do not provide evidence to support the two postulated mechanisms involving cleavage of a C–H bond. The enzyme-bound nucleophile $E-X^-$ and the electrophile $E-X^+$ could also represent enzyme-bound water molecules, and in fact a role for water in the mechanism of the catalyzed isomerization is currently under consideration.

The interpretation of the kinetic data for PPIase-catalyzed reactions is made more difficult by the presence of multiple enzyme forms[146] with differing catalytic properties. The pH dependence of the reaction of Cyp18cy with tetrapeptide substrates, whose catalytic effect (k_{cat}/K_m) decreases at low pH, can

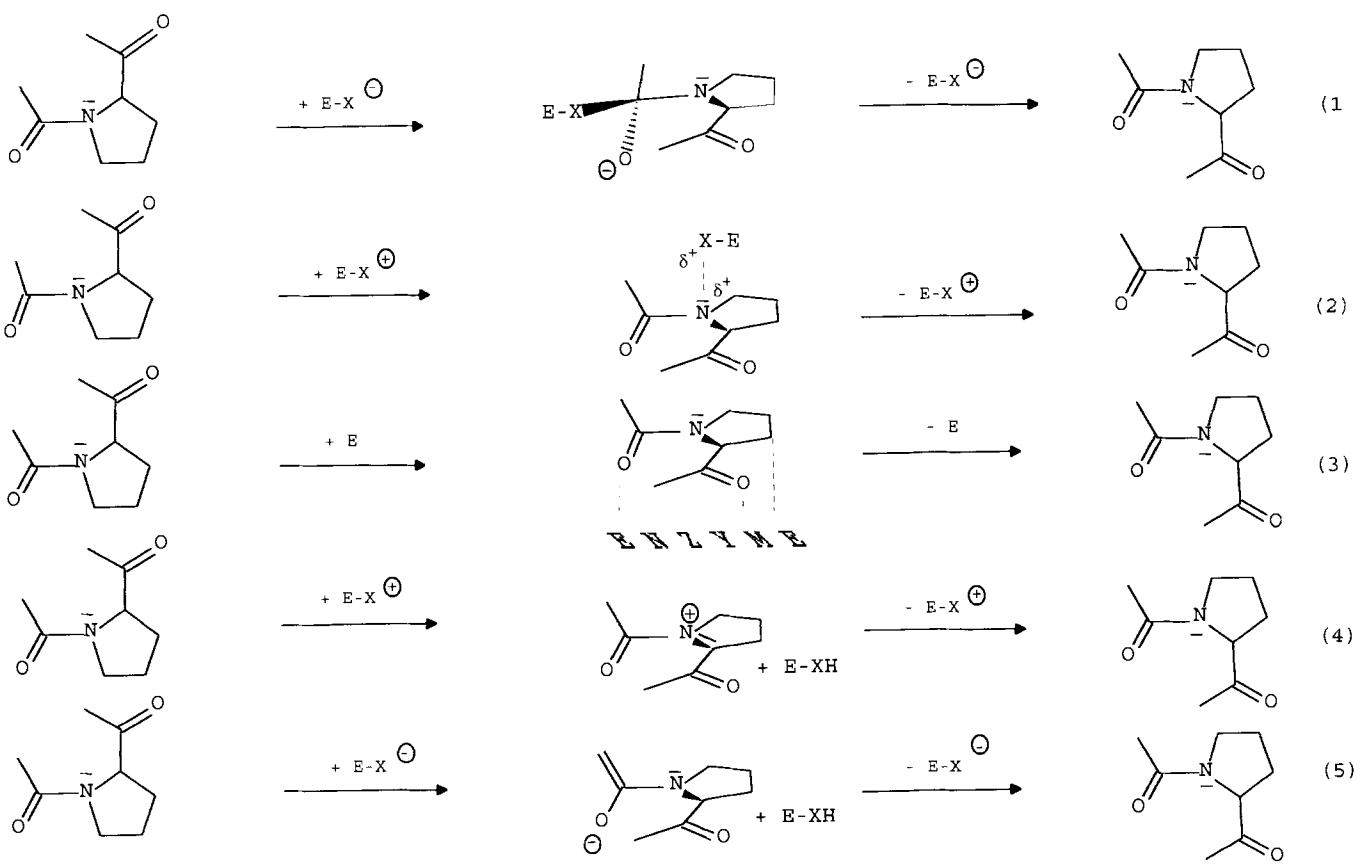

Fig. 16. Hypothetical reaction mechanisms for the PPIase-catalyzed *cis/trans* isomerization of the prolyl-peptide bond. E–X corresponds to an enzyme-bound reactive group. In every mechanism the lone pair is pushed towards the nitrogen atom; in other words, the electrons are not delocalized in the amide bond

be described by the transfer of a proton with a pK_a of 5.9[266] (literature value 4.92[246]). Together with the low enthalpy of activation, $\Delta H^{\neq} = 0.3-3$ kcal mol^{-1},[146, 246, 247] this parameter implies an unusual mechanism of catalysis.

At first glance secondary kinetic isotope effects greater than 1.0 for Xaa-Pro substrates with a $C_\alpha(D)H$ unit in the Xaa residue (found in both enzyme families), solvent deuterium isotope effects $(k_{cat}/K_m)_{H_2O}/(k_{cat}/K_m)_{D_2O} \approx 1$, and the fact that k_{cat}/K_m is largely independent of pH (for pH values above 7) seem to imply a very simple mechanism, possibly with a noncovalent transition state (Eq. (3) in Fig. 16). In this mechanism the strong binding of the transition state to the enzyme, reflected by an angle $\omega \approx 90°$ at the prolyl-peptide bond, must then be responsible for lowering the free enthalpy of activation $\Delta G^{\neq}$ (conformational twist mechanism).[146] The transfer of the substrates from the aqueous medium into the hydrophobic enzyme area could simultaneously lead to the reduced electron delocalization in the ground state and the contribution to the catalytic effect discussed previously.

As ^{126}His is near the isomerization center in the complex (Ala-Pro)–Cyp18cy, it is a good candidate for a catalytically active side chain (Fig. 17). A backbone segment (^{102}Asn to

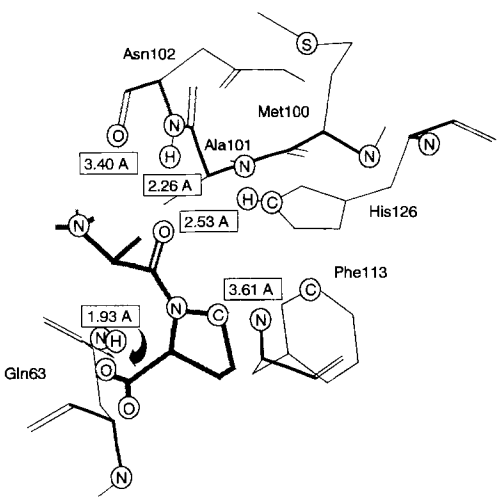

Fig. 17. All amino acid residues of the cytosolic cyclophilin [19] that have an atom located within 5.5 Å of the oxygen atom of the peptide carbonyl group of the bound dipeptide Ala-Pro (thick gray line). For the hidden amide group of the side chain of ^{63}Gln the H···O distance given is indicative of a strong hydrogen bond. For further information see Fig. 14.

^{100}Met) of the protein is almost parallel to the peptidyl residue Xaa in the Xaa-Pro unit but oriented opposite to the chain polarity. The carbonyl group adjacent to the Ala-Pro unit forms a hydrogen bond to the backbone NH group of ^{102}Asn; in the FK506–FKBP complex this function is performed by the ^{82}Tyr–OH group (see Fig. 14). In this complex no other functional amino acid side chains are in near the isomerization center. The effect of the hydrogen bond between the side chain of ^{63}Gln and the carboxyl group of Ala-Pro, which does not occur in polypeptide substrate, could differentiate structurally between this inhibitory dipeptide complex and the substrate–Cyp18 complex. In the tetrapeptide complex ^{55}Arg is also at a suitable position for hydrogen bonding.[118]

Site-specific mutagenesis was used to rule out the nucleophilic role of SH groups in the mechanism of catalysis in Cyp18cy.[248] This was inferred from inhibitor data and the identification of a cysteine residue protected from SH modification in the CsA–Cyp complex.[5] ^{115}Cys is near the active center but too far away from the peptidyl carbonyl unit of the substrate for nucleophilic attack. Furthermore, the binding of CsA and enzymatic activity can be separated from another by mutation experiments; for example, a more than 100-fold decrease in the ability of the W121A mutant enzyme to bind CsA is accompanied by only a 11.4-fold reduction in catalytic activity. Even the practically inactive enzymes H126Q, F60A, and R55A can still bind CsA; quantitative data is not available.[164]

Based on the qualitative results of the in vivo performance of Cyp26mem from *Drosophila melanogaster*,[127] mutations at Gly130Asp, Gly108Asp, Gly64Asp, Gly65Asp, and Asn35Lys (the numbering is based on that of human Cyp18cy) lead to enzymes with diminished activity.

Compared to cyclophilins, much more quantitative data is available for FKBP enzymes with point mutations. The exchange of the single cysteine residue (Cys22Ala), the successive exchange of all five serine residues, and exchange of two of the total of seven threonine residues (Thr75Ala, Thr96Ala) eliminated potential nucleophiles and hydrogen bond donors. None of the resulting enzymes showed significant reductions in activity or in affinity for FK506 or rapamycin.[220]

However, as observed for the cyclophilins, mutant enzymes in this protein family must exist whose enzyme activity can be separated from FK506 binding. For example, the Phe36Tyr mutation in FKBP12cy[213] does not affect the affinity for the inhibitor, but the enzyme activity is drastically reduced. In the case of Asp37Val exchange in the same enzyme, both processes are almost totally uncoupled, and this time a relatively great loss of affinity for FK506 is also observed.[249] This tendency is also seen to almost the same extent in *Legionella pneumophila* FKBP25mem upon the substitution of Asp37Leu (numbering based on human FKBP12cy), an amino acid that is highly conserved within the FKBP family.[218] Amongst those amino acids near the active center (see Fig. 17) that were tested in *Legionella pneumophila* FKBPmem, are ^{36}Phe and ^{99}Phe in addition to ^{82}Tyr. ^{87}His seems to play no role in catalysis.[249]

9. Immunosuppressor–PPIase Complexes and the Calcineurin Model

The loss of PPIase activity when the receptors Cyp18cy and FKBP12cy bind CsA and FK506, respectively, is not enough on its own to explain the blocking of T-cell activation by these compounds. The second highly effective immunosuppressive peptidomacrolide, rapamycin, is an even better inhibitor of FKBP12cy than of FK506, but its biological activity has a completely different molecular basis. Instead of blocking the transcription of key genes early in the signal transduction cascade, as was found for inhibition with CsA and FK506, rapamycin affects constitutive cell division by blocking the $G_1 \rightarrow S$ phase.[191, 250, 251] It appears that a rapamycin–FKBP complex blocks the rise in activity of p70S6 kinase which normally occurs when the IL-2

receptor or CD28 is stimulated.[252-253] This effect is not restricted to T cells.[254]

In addition, a series of CsA and FK506 derivatives (the off-diagonal analogues referred to previously) specifically inhibit PPIase activity with their excellent affinity but show a different effect or no effect at all in the in vitro IL-2 transcription models and T-cell activation tests.[153, 226] That these compounds, FK506, and CsA all have a common receptor binding site can be demonstrated by the antagonistic effect of the biologically inactive derivatives in transcription tests. These results along with those of deletion experiments carried out on the genes for Cyp12cy and FKBP12cy in yeast and *Neurospora crassa* make it clear that the specific binding of the immunosuppressive compounds to these receptors is a necessary step in blocking the T-cell response, but it is not in itself enough to cause the effect. Thus it seems that the components responsible for the immunosuppressive effect are in fact the ligand–PPIase complexes themselves. They possess properties not found in the free ligand or protein alone.

By using affinity chromatography with carrier-bound FK506–FKBP or CsA–Cyp, S. L. Schreiber et al. and Weissman et al. were able to demonstrate that calcineurin/calmodulin is the common binding protein for these complexes.[7, 8] However, rapamycin–FKBP12cy did not bind these proteins. This heteromeric protein phosphatase (consisting of calcineurin A, calcineurin B, calmodulin, Ca^{2+}) is inhibited in its hydrolysis activity towards protein phosphates (but not towards 4-nitrophenylphosphate) by CsA–Cyp18cy and FK506–FKBP with a K_i value of 35 nM. In a quantitative test of transcription activity of the IL-2 specific transcription factor NF-AT_p, a number of off-diagonal analogues of FK506 and CsA showed the expected correlation between K_i value for calcineurin and the IC_{50} value in the transcription model.[154] The cellular target molecule for the phosphatase activity of calcineurin was found to be the roughly 120 kDa, cytosolic, phosphorylated component of the multimeric transcription factor NF-AT.[255] NF-AT_p is present in the cell nucleus in the unphosphorylated form. A lack of calcineurin activity is thought to prevent translocation of NF-AT_p, such that the active transcription complex at the IL-2 promoter (which consists proteins of the Jun and Fos families and the DNA-binding NF-AT) cannot be turned on owing to the lack of the cytosolic component (Fig. 18).[256] This strong calcineurin inhibition is a special property of the cytosolic FKBP12 and Cyp18cy complexes. In comparison, the binding of FK506 to mature FKBP16mem leads to 200-fold reduction in inhibition for the phosphatase.[192]

It still remains to be explained at the molecular level why the PPIase–effector complexes inhibit calcineurin and not the free constituents of the complex. Structure–activity analyses for a large number of FK506 derivatives that all bind FKBP12cy but have different effects on IL-2 release indicate that very subtle effects are responsible. Based on these data and the three-dimensional structures of the complexes, an approximate effector region for the active substances has been postulated, which is responsible for the contact to calcineurin. In the case of CsA this is amino acids 5–8, and for FK506 the carbon chain C17–C32.

Thus in contrast to ascomycin (for structure see legend for Fig. 5), C18-hydroxyascomycin is inactive in the IL-2 test but a strong antagonist of FK506 and rapamycin effects.[257] As expected it does not affect calcineurin activity. The structures of

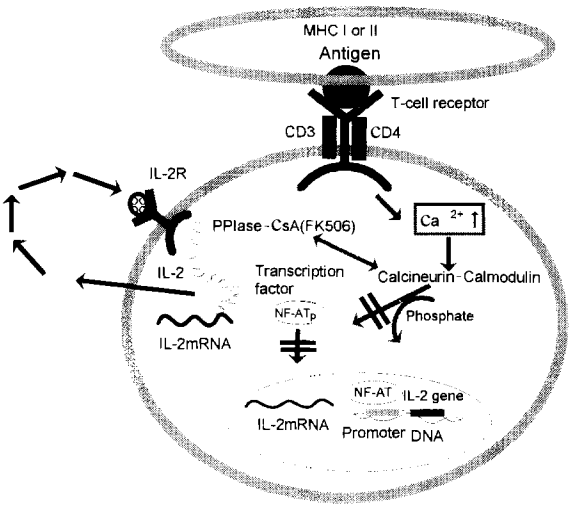

Fig. 18. Hypothetical mechanism for the suppression of antigen- or mitogen-stimulated clonal T-cell expansion by CsA or FK506. Inhibition of calcineurin activity by the CsA(FK506)–PPIase complex leads to the interruption of the signal transduction after T-cell stimulation. The IL-2 receptor triggers an independent signal pathway. MHC = major histocompatibility complex.

the two complexes with FKBP12 were determined.[258] A comparison reveals that the structural differences between biologically active and inactive complexes (F506–(human FKBPcy12) and ascomycin–(human FKBP12cy), respectively) are so minimal that the addition of the single OH group of hydroxyascomycin must affect the oligomeric calcineurin complex (which has a net molecular weight of 100 kDa).[213] If the C18-hydroxyascomycin–(yeast FKBP12cy) complex is used in an inhibition test for calcineurin, the phosphatase activity is blocked almost as effectively as with FK506–(human FKBP12cy). Surprisingly, the three-dimensional crystal structure of this complex shows the same peptidomacrolide conformation as in the inactive human complex. Thus whether a substance–protein complex is inactive or active is decided by the nonconserved amino acids in the sequences of each FKBP. Such subtle relationships are also seen in complexes of CsA derivatives with Cyp18cy and Cyp23sec.[156, 260]

The effects of CsA–PPIase complexes (and the FKBP–PPIase complexes) probably extend further than to just T cell and relatively slow transcription regulation. Stimulation of the IgE receptor results in the fast release of histamine ($t_{1/2} \approx 10$ min!) and can be blocked by FK506 and CsA. This fast release of histamine from mast cells was also found to be linked to inhibitor–PPIase complexes.[261] In the guard cells of higher plants the influx of K^+ ions is regulated by the intracellular level of Ca^{2+} which serves as a secondary messenger. The K^+ channel is blocked by high levels of Ca^{2+}, and this blocking effect can be eliminated by the addition of CsA–Cyp18cy or FK506–FKBP12cy. Deblocking can be achieved by addition of CsA alone but not with FK506 alone. The reason for this is that the major component of cells' own FKBPs (a FKBP16 homologue) gives an inhibitor complex that is inactive towards calcineurin.[110]

It should also be mentioned that a second proline-specific enzyme, dipeptidyl peptidase IV as CD26, specifically influences the antigen-induced signal transduction in T cells. The blocking of proteolytic activity by inhibition,[262] as demonstrated by CsA and FK506, leads to reduction of IL-2 secretion.

10. Outlook

Since the discovery of the first peptidyl-prolyl *cis/trans* isomerase the number of sequenced enzymes has increased dramatically. Many of these PPIases play a role in an as yet unexplained way in cellular regulation systems and may play a role in cell–cell interactions. In order to understand the course of events on a molecular level, the in vivo effectors or substrates must be identified and the effect of *cis/trans* isomerization on the properties of a polypeptide chain must be investigated. Naturally we expect that the number of known PPIase sequences will increase further, and perhaps new activity tests will identify new PPIase families. In addition, these proteins offer enzymologists the chance to study the mechanistic background of the simplest chemical "reaction", the rotation of a single bond. The PPIases are the first enzymes known that are specialized for the catalysis of conformational changes. They are probably specific for proline-containing polypeptides. It is interesting to speculate whether further conformases with completely different target molecules exist in cells.

I would like to thank my previous and current co-workers, those who conducted the first investigations after the discovery of these enzymes, Dr. Holger Bang and Dr. Carla Mech,† and those who joined our group later, Dr. habil. Gerhard Küllertz, Dr. Jens Rahfeld, and Dr. Mike Schutkowski. They have all worked enthusiastically on our contribution to the research discussed here. Without the flood of ideas and the work of the Ph. D. and M. Sc. students it would not have been possible to carry out the experiments presented here. The collaboration with the groups of Franz X. Schmid (Bayreuth), Jörg Hacker (Würzburg), Klaus Kühn (Martinsried), Kurt Lang (Penzberg), and Sture Forsen (Lund) enabled us to acquire the techniques and methods necessary for investigating the enzymes. I would like to thank Prof. Hengming Ke for the coordinates of the cyclophilin and cyclophilin–(Ala-Pro) structures which were used in creating Figures 10 and 17. The financial support of the Max-Planck-Gesellschaft, the Deutsche Forschungsgemeinschaft, the Volkswagenstiftung, the Boehringer-Ingelheim-Stiftung, and the Fonds der Chemischen Industrie is gratefully acknowledged.

[15] Because increasing numbers of isoenzymes in the PPIase family have been discovered, some of the abbreviations for the enzymes have become inexact and confusing. For the unequivocal naming of cyclophilins and FKBPs we assume the following abbreviations: Cyp and FKBP stand for the two respective families of PPIases. The abbreviations Cyp and FKBP are followed by the molecular weight (kDa) of the amino acid sequence of the complete preprotein obtained from the nucleotide sequence. When the location is known, then the abbreviations cy (cytosolic), mit (mitochondrial), sec (secretory), mem (membrane bound) follow the molecular weight. The organism from which the protein comes is noted in front of or after the enzyme abbreivation, if needed. The cross references to several of the other abbreviations in the literature are given in the footnotes to Scheme 1 (Cyp) and Scheme 2 (FKBP).

Conformational Requirements for Sweet-Tasting Peptides and Peptidomimetics

Toshimasa Yamazaki, Ettore Benedetti, Darin Kent, and Murray Goodman*

The molecular basis of taste has been extensively studied over many years. The research carried out in our laboratories is focused on the elucidation of detailed structure–taste relationships of peptides and peptidomimetics using an "integrated" approach employing synthesis, analysis of NMR spectra, computer simulations, and X-ray crystallography. Various peptidomimetic residues have been incorporated to introduce predictable structural constraints into taste ligands. These constraints eliminate some of the molecular flexibility and allow us to develop structure–activity relationships. We describe here the topochemical requirements of the sweet and bitter taste receptor(s) and develop detailed structure–taste relationships with considerable predictive power for peptides and related molecules.

1. Introduction

The transduction of taste is believed to be initiated by receptor proteins located on the surface of the taste cell. In terms of structural biochemistry, the taste ligand and the receptor protein form a host–guest complex which produces a sense of taste. The structures of taste receptors have not been identified, but it is clear that the taste ligand must assume specific three-dimensional structures, so-called bioactive conformations, when interacting with the taste receptor. The bioactive conformation must be one of the accessible conformations of the isolated ligand. We contend that interactions of receptors with ligands cannot convert inaccessible structures to allowed conformations.

A wide variety of unrelated compounds are known to elicit a sweet taste. An early attempt to generalize common structural features (glucophores) among sweet molecules was made by Shallenberger and Acree,[1] who proposed the existence of a hydrogen bond donor (AH) and a hydrogen bond acceptor (B) in sweet molecules (AH/B model). Based on results obtained from a systematic study of unrelated sweet molecules such as sugars, saccharin, chloroform, unsaturated alcohols, and 2-amino-1-propoxy-4-nitrobenzene, the distances between these two groups have been determined to be within a range of 2.5 to 4.0 Å.[1] The AH and B groups form a bioactive complex through two intermolecular hydrogen bonds between the taste ligand and the sweet receptor. Studies on a series of potently sweet 2-amino-4-nitrobenzene derivatives led Deutsch and Hansch[2] to suggest that a hydrophobic binding area is also necessary for a compound to taste sweet. Kier et al.[3] extended the theory of Deutsch and Hansch and estimated the distances between the hydrophobic site (X) and the AH and B groups to be approximately 3.5 Å for AH–X and 5.5 Å for B–X (AH/B/X model). In Figure 1, several types of sweet molecules are shown with labeled AH/B/X groups and calculated intergroup distances. Based on preferred conformations of various amino acids calculated by using the extended Hückel theory, it was

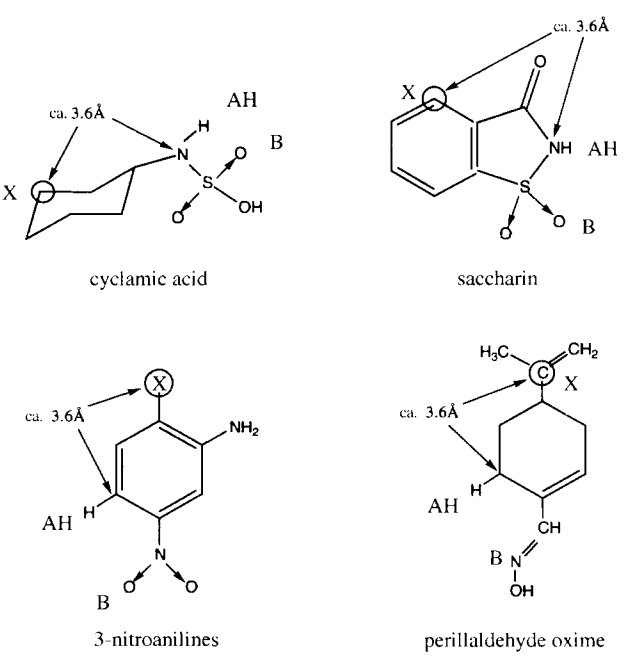

Fig. 1. Representatives of four classes of sweet molecules; the AH, B, and X groups are labeled and the AH–X distances are given.

concluded that the aromatic groups of D-phenylalanine, D-tyrosine, and D-tryptophan were ideal candidates for the hydrophobic X group and that side chains smaller than the isobutyl group of leucine did not fulfill the spatial requirements of the X glucophore. The AH/B system in amino acids is adequately represented by the charged amino and carboxylate groups. Similarly, third binding sites have been identified in sugars by Shallenberger and Lindly[4] and in dipeptide esters by van der Heijden et al.,[5] but the concepts of third binding sites are not identical to those proposed by Kier.

Since the initial discovery of the potent sweet taste of L-aspartyl-L-phenylalanine methyl ester (aspartame, L-Asp-L-Phe-OMe, **1**: approximately 200 times sweeter than sucrose) by Mazur et al.,[6] extensive structure–activity studies of peptide-based taste molecules have been carried out. Dipeptides containing two chiral amino acids can have four possible stereoisomers, which generally taste different. In the case of the aspartyl-phenylalanine methyl ester stereoisomers, only the L-L isomer is sweet, while all the other isomers are bitter.[6] The L-aspartic acid residue of **1** is necessary for a sweet taste and can be replaced by aminomalonic acid (Ama), which is a shorter homologue of aspartic acid.[7, 8] A higher homologue L-Glu-L-Phe-OMe is bitter.[6] As in the case of Asp-Phe-OMe, the absolute configuration of the Ama residue of Ama-L-Phe-OMe is also critical for sweet taste. It was originally proposed that (*S*)-Ama-L-Phe-OMe (**6**) would be sweet as its configuration is analogous to that of **1**;[7] however, we recently established that (*R*)-Ama-L-Phe-OMe (**5**) is 800 times sweeter than sucrose, while (*S*)-Ama-L-Phe-OMe (**6**) is tasteless.[8] We have determined these configurational assignments by X-ray analysis of the two isomers. The taste properties observed for the four diastereomers of Asp-Phe-OMe and for the two diastereomers of Ama-L-Phe-OMe demonstrate that distinct spatial requirements at the α-carbon atom of the N-terminal residues, namely, an L configuration for the Asp residue and an (*R*) configuration for the Ama residue, must be fulfilled for the molecule to elicit a sweet taste. In these analogues, the protonated amino and carboxylate groups of the N-terminal residue represent the AH and B groups of the Shallenberger and Acree glucophore hypothesis. The benzyl side chain of phenylalanine functions as the hydrophobic moiety X.

Although the N-terminal residue of L-Asp-L-Phe-OMe (**1**) and (*R*)-Ama-L-Phe-OMe (**5**) must be conserved, the C-terminal L-phenylalanine methyl ester can be replaced by a variety of other amino acid derivatives and related structures without a decrease in sweetness. The amino acid derivative must have a hydrophobic X group comparable in size to the benzyl side chain in the correct orientation. As suggested by Mazur[9] and Ariyoshi,[10] the C-terminal residue of sweet dipeptide derivatives has two hydrophobic groups of differing size. These groups are composed of the amino acid side chain and the ester or amide group. In the L configuration, the C-terminal amino acid side chain is required to be larger than the ester or amide group; the relationship is reversed in the D configuration.

Ariyoshi[10] explained the sweet taste of aspartyl dipeptides on the basis of Fischer projections. The Ariyoshi model is quite convenient for the prediction of taste properties of peptidelike molecules. The "sweet formula" (Fig. 2a) is consistent with those of the sweet L-aspartyl dipeptide derivatives reported in the literature, while the "non-sweet formula" (Fig. 2b) is consistent with the L-aspartyl dipeptides devoid of sweet taste.

The application of Fischer projections to the study of three-dimensional peptide taste ligands is limited because of the two-

Murray Goodman was born in New York, NY in 1928 and received his Ph.D. in chemistry from the University of California, Berkeley in 1953. He then carried out postdoctoral research at the Massachusetts Institute of Technology and at Cambridge University, England. In 1956 he joined the faculty of the Polytechnic Institute of Brooklyn as an Assistant Professor and was appointed Full Professor in 1964. Three years later he became Director of the Polymer Research Institute at the Polytechnic. In 1970 he accepted a position as Professor of Chemistry at the University of California, San Diego, where he served as Chairman of the Chemistry Department from 1976 to 1981. He has received many honors and awards, including the Scoffone Medal of the University of Padua, a Humboldt Professorship, and the Max Bergmann Medal. He is Editor of the journal Biopolymers and has published more than 350 original research papers in the area of biopolymers and their model structures. His research focuses on the use of computer-aided design of bioactive molecules, synthesis of peptides and peptidomimetics, and spectroscopic characterization of novel biomolecular systems.

Ettore Benedetti was born in Naples, Italy in 1940 and completed his Ph.D. research in chemical crystallography in 1965 under the direction of Professor Alfonso M. Liquori. During three years of postdoctoral research with Professor Murray Goodman at the Polytechnic Institute of Brooklyn he began his studies on the structure and conformation of peptides and polypeptides. He joined the Science Faculty of the University of Naples, where he was appointed Full Professor of General Chemistry and Director of the Institute of Chemistry in 1975. He is a member of the Advisory Board of Biopolymers and on the Editorial Board of the International Journal of Peptide and Protein Research. His research interests lie in peptide chemistry: the structure–activity relationships of numerous peptide systems have been the object of his investigations, which have been carried out with a variety of experimental and theoretical techniques, for the understanding of the mechanism of action of biologically relevant systems.

dimensional nature of the model. The Ariyoshi model does not explain the sweet taste of L-Asp-(*S*)-gAla-TMCP (**12**) (see Table 1) which appears to fit the "non-sweet formula". This result indicates that the molecular basis of taste must be defined by the three-dimensional structure of the molecule, that is, the relative spatial arrangements of the three glucophores AH, B, and X. From the conformational analysis of a series of aspartyl-based dipeptides incorporating stereoisomeric peptides and peptidomimetics as the second residue, we have developed a three-dimensional model, the "L model", describing the conformational requirements for sweet and bitter tastes.[11]

In this paper, we describe how the L model for sweet taste has been developed through conformational studies of peptide-based taste ligands using X-ray crystallography, NMR spectroscopy, and computer simulations. The compounds examined are peptide-based taste ligands such as aspartame (**1**) and peptide-based analogues incorporating stereoisomeric changes in residues and peptidomimetics (Table 1). The X-ray crystal structures of all these analogues have been elucidated.[8, 11, 12] Compounds **5** and **6** contain an aminomalonyl residue at the first position, all others have the L-aspartyl residue of the parent dipeptide **1**. In all aspartame analogues studied the AH and B groups are represented by the protonated amino and the side-chain carboxylate groups of the N-terminal residue [L-Asp,(*R*)-Ama, or (*S*)-Ama] of the molecule. The first eight analogues **1**–**8** (Type A) contain the hydrophobic element X in the side chain of the second residue. In the remaining five analogues **9**–**13** (Type B), the X group is the C-terminal amide or ester group. The L-aspartyl derivatives shown in Table 1 are dipeptide derivatives in the cases of **1**, its hydrochloride salt **2**, and analogues **9** and **10**. The remaining compounds in Table 1 incorporate various peptidomimetics as the second residue such as α-methylphenylalanine in **3** and **4**, cyclohexylglycine in **7** and **8**, a retro-inverso peptide of alanine in **11** and **12**, and α-aminocyclopropanecarboxylic acid in **13**. The structures of the peptide-based taste ligands in Table 1 are illustrated in Figure 3. Our model requires that the N-terminal residue be conformationally fixed when the molecule binds to the taste receptor. The relative orientation of the X group to the fixed AH/B groups is determined by the conformation of the second residue. Each peptidomimetic residue used in this study displays unique conformational preferences. Therefore, it is possible to identify specific topochemical arrays that produce a sweet or bitter taste.

2. X-Ray Structure Analysis

The following sections describe the X-ray crystallography studies on the peptide-based taste ligands listed in Table 1. In Table 2, results of the crystallographic analyses relevant to the scope of this paper are presented. All crystal structures deter-

[a] Molecular formulas are shown in Fig. 3; for definitions of Types A and B see text. [b] The taste was determined by a three-member panel by a qualitative "sip and spit" taste assessment of a dilute solution of the molecule in water without any pH adjustment.

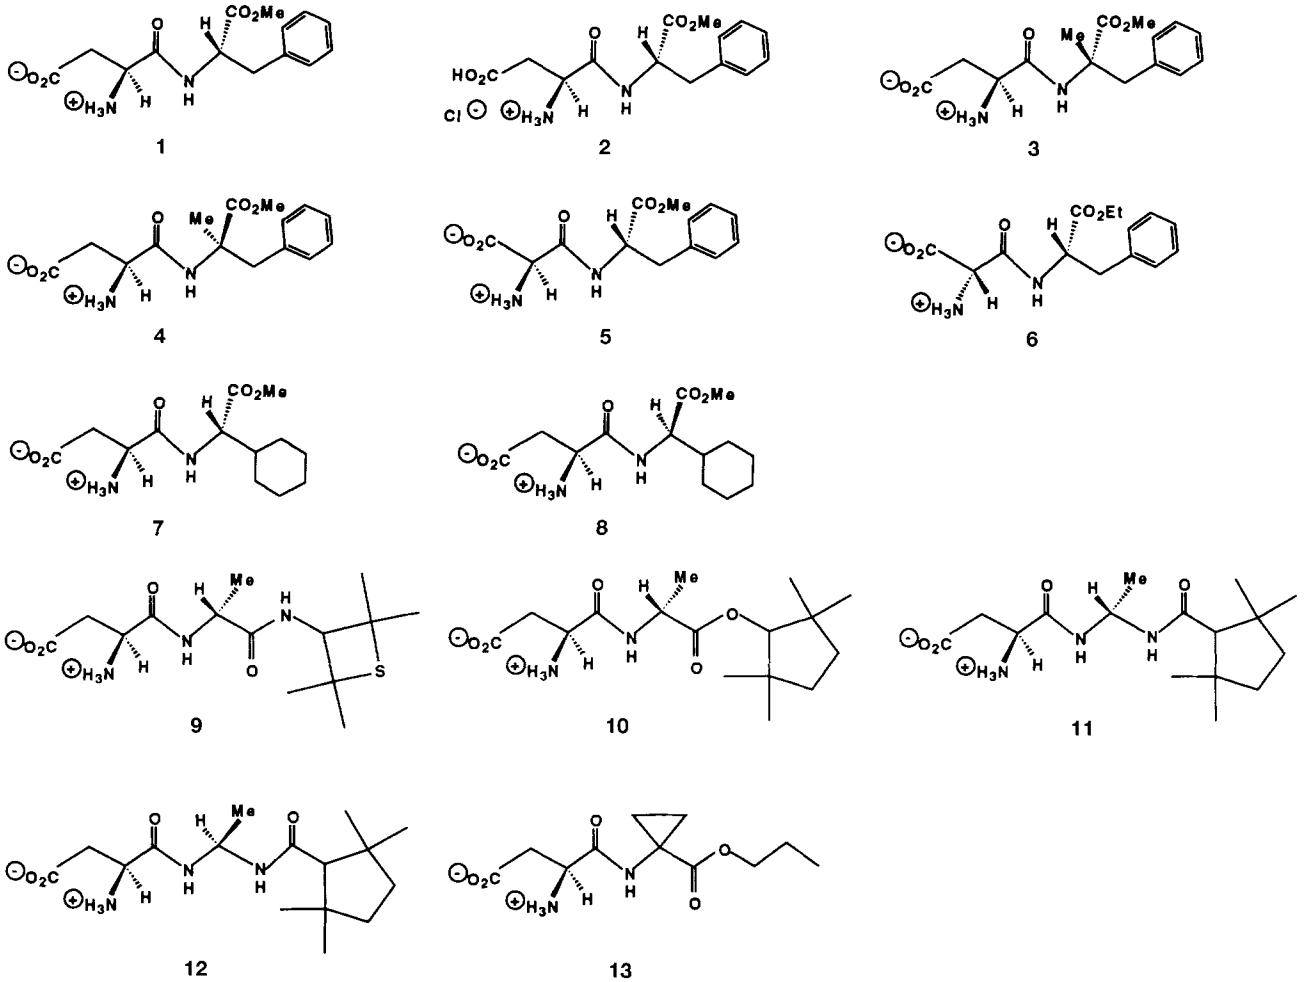

Fig. 3. Structures of peptide-based taste ligands presented in Table 1.

mined by diffraction techniques have been refined to a degree of accuracy ranging from very good to reasonable, with R-factor values between 0.033 and 0.103. The estimated standard deviations of bond lengths and bond angles are in the ranges of 0.002–0.02 Å and 0.1–1.4°, respectively; that of torsion angles is not greater than 5°. The crystals of all the compounds except **6** contain one or more molecules of water in the unit cell. In the crystals of **5** and **9**, four independent molecules with slightly different conformations constitute the asymmetric unit. The X-ray diffraction studies of the retro-inverso taste ligands **11** and **12** were carried out on a crystal composed of these two diastereomeric molecules. The torsion angles describing the backbone and side-chain conformations of all the peptide-based taste ligands studied are listed in Table 3.

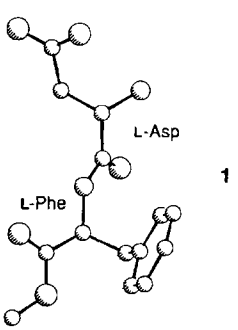
[a] Torsion angles were measured according to IUPAC convention. [b] For **5** and **9** the independent molecules in the unit cell are denoted by **a**–**d**.

2.1. Conformations and Packing of Peptide-Based Taste Ligands in the Solid State

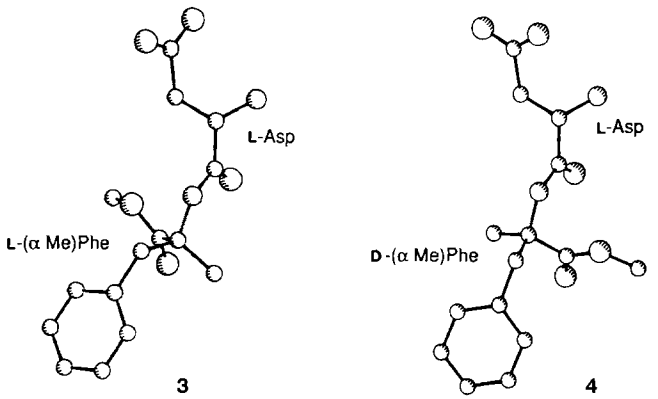


Dipeptide esters with an unprotected N-terminal residue can be considered rather flexible molecules. However, in their crystal structures only two areas of the (ϕ, ψ) map seem to be more densely populated with conformations characterized by (ϕ, ψ) values of (−160°, 180°) and (−70°, 170°).[13] The conformation of a molecule in the crystalline state is greatly affected by packing forces. Among the most important are electrostatic interactions between charged groups, hydrogen bonds, and van der

Waals and hydrophobic interactions, such as the stacking of aromatic groups, and alkyl–phenyl and alkyl–alkyl interactions. Molecules in the crystalline state assume conformations that maximize molecular packing. In general, the most efficient packing is achieved when molecules adopt extended or semi-extended conformations.

The crystal structures of aspartame and the related analogues are no exception to this trend, even though they show a more pronounced variety of conformations owing to the presence of more or less hindered peptidomimetics. In the crystalline state, all of the peptide-based taste ligands, except for aspartame hydrochloride (**2**), exist as zwitterions; the N-terminal amino group is positively charged, and the side-chain carboxylate of the N-terminal residue is negatively charged. Evidence of the zwitterionic structures is seen in the C–O bond lengths, which are intermediate between those of a single and a double bond, and in the fact that the NH_3^+ cation acts as a hydrogen bond donor to three acceptor groups. In these structures the charged groups of the zwitterion are close together allowing for better electrostatic interactions and intra- and intermolecular hydrogen bond formation. For this reason the AH/B unit is referred to as the zwitterionic ring. The conformation of the aspartyl residue is highly conserved. On the average, the torsion angles ψ^1, ω^1, χ_1^1, and $\chi_{2,1}^1$ assume values of +156, +175, −69, and −173° (or +7° for $\chi_{2,2}^1$), respectively. The conformation about the Asp C^α–C^β bond (χ_1^1) is *gauche*$^-$ (g^-). The carboxylate group of the aspartyl side chain is nearly coplanar with the C^α–C^β bond; the $\chi_{2,1}^1$ and $\chi_{2,2}^1$ dihedral angles are close to 180 and 0°, respectively. The conformations of the Ama residue in compounds **5** and **6** are very similar to those of the aspartyl-containing molecules.

The conformation of the second residue varies greatly, depending upon the configuration and the conformational constraints of the molecules. Aspartame (**1**) itself is the only compound that adopts a structure in which the second residue has an almost fully extended backbone conformation ($\phi^2 = -156.8°$ and $\psi^2 = -173.6°$) (Fig. 4).[20] The value of +61.7° (*gauche*$^-$: g^+) observed for the Phe side chain torsion angle χ_1^2 is allowed when the peptide backbone is in the extended conformation.

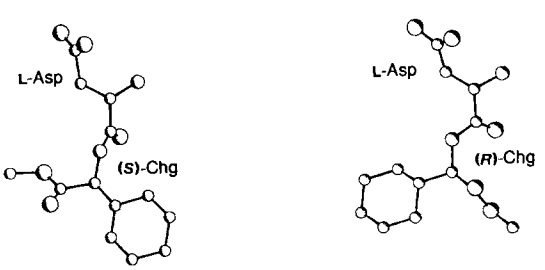


The torsion angles observed for aspartame hydrochloride (**2**)[12b] in the crystalline state are similar to those observed for aspartame itself with the exception of the χ_1^1 angle of the aspartyl residue. In aspartame hydrochloride χ_1^1 assumes a value of −155.9° (*trans* conformation, t); in other words, the side-chain carboxyl group is rotated away from the positively charged N-terminal NH_3^+ group. Electrostatic interactions between the N-terminal charged group and the chloride ions are mediated by the cocrystallized water molecules.

1

Fig. 4. Molecular structure of **1** in the crystalline state. The structure is drawn in a projection perpendicular to the plane defined by the atoms C^β, N, and C(O) of the Asp residue.

The X-ray structures of the diastereomeric aspartame analogues **3** (sweet)[12c] and **4** (bitter)[12d] are shown in Figure 5. In contrast to **1** in which the second residue has an extended backbone conformation, the α-methylphenylalanine residue assumes a right-handed helical conformation in **3** with $\phi^2 = -42.3°$ and $\psi^2 = -48.3°$, and a left-handed helical conformation in **4** with $\phi^2 = 49.0°$ and $\psi^2 = 47.9°$. Folded helical structures, in other words, 3_{10}- and α-helices, are highly preferred in peptides containing α,α-dialkylamino acid residues.[14] In both diastereomers, the (α-Me)Phe side chain assumes the *trans* conformation about the C^α-C^β bond defined by an angle $\chi_1^2 = 171.8°$ for the sweet L-L isomer and 173.2° for the bitter L-D isomer. The crystal structure of both diastereomers is essentially the same and determined primarily by molecular packing forces. In fact, the relative orientation of the zwitterionic ring of the aspartyl moiety and the benzyl side chain, which are major groups for hydrophilic and hydrophobic interactions, respectively, is exactly the same in both structures.

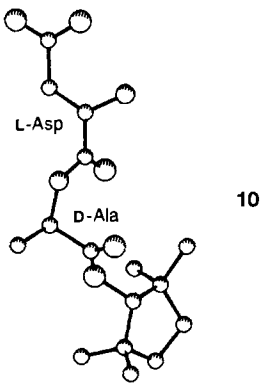


3 **4**

Fig. 5. Molecular structures of the diastereomeric taste ligands **3** and **4**.

In the crystalline state, both the sweet (*R*)-aminomalonyl compound **5** and its tasteless (*S*) analogue **6** adopt similar molecular structures in which the L-Phe residues assume semi-extended backbone conformations and the $\chi_1^2 = t$ side-chain conformation.[8] In these structures, the zwitterionic ring of the N-terminal residue and the benzyl side chain of the second residue are 180° apart from one another in a planar linear array as in sweet **3** and bitter **4**.

The X-ray crystal structures[11g] of the two diastereomeric molecules **7** (sweet) and **8** (bitter) are shown in Figure 6. Both compounds are highly hydrophilic at the N-terminus and have nearly identical conformations at that residue. Conversely, the C-terminal portions of the two molecules, which are hydrophobic, assume conformations in which the cyclohexyl moieties



7 **8**

Fig. 6. X-ray crystal structures of the diastereomers **7** and **8**; projection perpendicular to the plane defined by the atoms C^β, N, and C(O) of the Asp residue.

point in opposite directions relative to the zwitterionic ring of the aspartyl residue.

The molecular structure of the sweet-tasting L-aspartyl-D-alanine derivative **10**[12e] is shown in Figure 7. The D-alanyl residue adopts a semiextended backbone conformation characterized by the torsion angles $\phi^2 = 64.3°$ and $\psi^2 = -140.9°$, which are appropriate for a residue with a D configuration. The zwitterionic ring of the aspartyl moiety and the C-terminal 2,2,5,5-tetramethylcyclopentyl ester group are arranged in an almost planar parallel array.

10

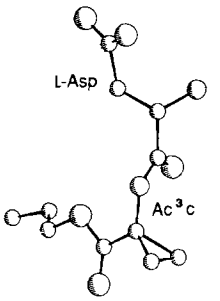


Fig. 7. An X-ray crystal structure of dipeptide ester **10**; projection perpendicular to the plane defined by the atoms C^{β}, N, and C(O) of the Asp residue.

The sweet-tasting L-aspartyl-D-alanine derivative **9** crystallizes with four molecules in the asymmetric unit.[11d] The conformation of the L-aspartyl residues in the four independent molecules is highly conserved with no torsional variance of more than 25°. The N-terminal aspartyl residues are zwitterionic in all four molecules. The backbone torsion angle of the D-Ala residue (ϕ^2) shows the greatest variability; that in one molecule (126.0°) differs from that in the other three (70.3° on the average) by approximately 60°. The C(O)-N-C^1-H torsion angle of the C-terminal TAN group in the former molecule (−36.0°) is approximately 60° away from the values observed in the latter three molecules (+24.0° on the average). However, the overall structure of the four independent molecules is essentially the same as that of the sweet-tasting **10**.

In the crystalline state the two retro-inverso diastereomers **11** and **12**, both intensely sweet, show ϕ^2 and ψ^2 values centered at −100 and +100° for the (*S*)-gAla residue and values equal and opposite for the (*R*)-gAla residue.[11b] Their conformations are influenced by the presence of two geminal NH groups, which are involved in the formation of intermolecular hydrogen bonds. The relative orientations of the zwitterionic ring of the aspartyl moiety and the largest hydrophobic group of the molecule (i.e. the C-terminal TMCP group) in the L-(*R*) and L-(*S*) isomers are similar to those of the sweet **7** and the bitter **8**, respectively (Fig. 6). This observation demonstrates clearly that X-ray crystal structures cannot provide clear, concise information on the structure–taste relationships of these flexible peptide-based taste ligands; both isomers are intensely sweet although they adopt equal but opposite conformations at the C-terminus.

In compound **13**[12f] (Fig. 8) the aspartyl moiety has the same conformation as that observed in all previously described compounds except aspartame hydrochloride. The Ac^3c residue contains an acute twist of the peptide backbone characterized by the ϕ^2 and ψ^2 angles of −78.4 and −0.6°, respectively. These values are in the "bridge" region of the Ramachandran map.

The molecular packing schemes for all of the peptide-based taste ligands investigated are quite similar, while the molecular structures in the crystalline state are substantially different. As examples, the packings of compound **9** and those of the diastereomeric aminomalonyl-containing compounds **5** and **6** are shown in Figures 9 and 10, respectively. Because of the presence of the positively charged NH_3^+ group and the negatively charged COO^- group of the side chain of the N-terminal residue, electrostatic interactions are the most important factors holding the molecules together in the solid state. The electrostatic interactions maximize the number of hydrogen bonds and donor groups involved in hydrogen bonding. The oppositely charged groups cluster with one another and with solvent molecules (mostly water), giving rise to complicated patterns of intermolecular hydrogen bonds. In all structures, the resulting hydrophilic core is surrounded by a hydrophobic surface which is formed by the stacking and packing of the hydrophobic side chains of the second residue or the C-terminal protecting groups. The peptide-based taste ligands assume conformations in the crystalline state that maximize this type of molecular packing. In all structures, with the exception of the aspartame hydrochloride salt (**2**), the N-terminal aspartyl or aminomalonyl residues assume the same zwitterionic form. In addition,

13

Fig. 8. An X-ray crystal structure of **13**; projection perpendicular to the plane defined by the atoms C^{β}, N, and C(O) of the Asp residue.

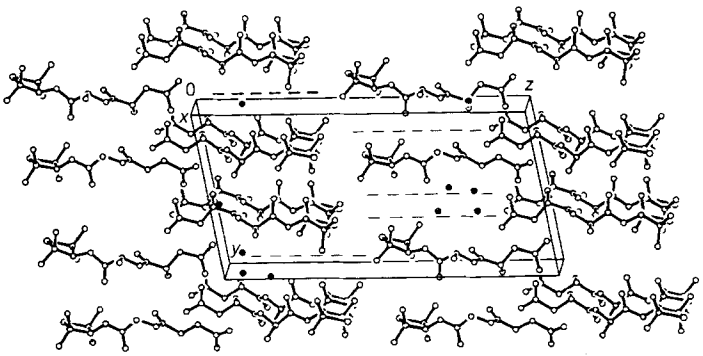

Fig. 9. Molecular packing of **9** in the crystal including water molecules in the unit cell. To clearly show the positions of the water molecules, several molecules of **9** are represented only by dashed lines.

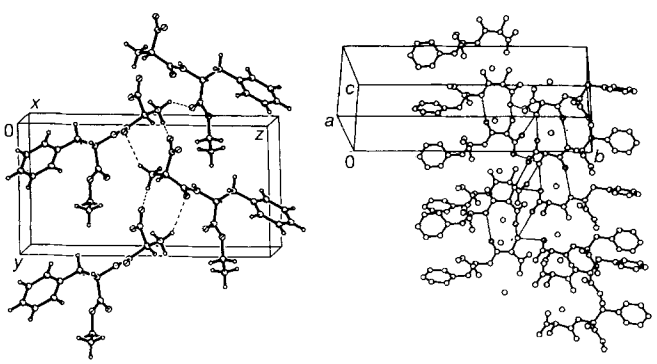

Fig. 10. Molecular packings for **6** (left) and **5** (right) in the crystal. Hydrogen bonds between the hydrophilic moieties are represented by dashed lines. The circles on the right-hand side that are not involved in any bonds correspond to the O atoms of water molecules.

the average ϕ^2 angle in the C-terminal residues assumes values of approximately $+85$ or $-85°$ depending upon the configuration. The other two torsion angles, ψ^2 and χ_1^2, describe the conformation of the second residue and exhibit great variation. In conclusion, the conformations assumed by each molecule in the crystalline state are mainly determined by packing forces.

2.2. Relationship between the Taste and the Crystal Structure of Peptide-Based Taste Ligands

All of the sweet, bitter, and tasteless ligands described here are zwitterionic at the N-terminus, except for aspartame hydrochloride (**2**). The topology of the zwitterionic portion is such that the protonated α-amino and the side-chain carboxylate groups of the N-terminal residue can act as the AH/B functionalities necessary to elicit the sweet taste.

The orientation of the hydrophobic X group with respect to the AH/B groups is substantially different from one analogue to the next. The sweet analogues **7** (Fig. 6) and **11** adopt L-shaped conformations, in which the zwitterionic ring of the L-aspartyl moiety containing the AH/B groups forms the stem of the L in the direction of the y axis, and the X group projects out along the base of the L in the direction of the $+x$ axis. The sweet analogues **12** and **13** (Fig. 8) adopt reversed L-shaped conformations, in which the X group projects along the $-x$ axis. The bitter analogue **8** also adopts a reversed L shape (Fig. 6). In the X-ray structures of the sweet analogues **3** (Fig. 5), **5**, **9**, and **10** (Fig. 7), the X group projects out along the $-y$ axis, resulting in extended structures in which the AH/B groups and the X group are planar and form an angle of roughly 180°. These extended structures are very similar to those observed for the bitter molecule **4** (Fig. 5) and the tasteless molecule **6**. In the X-ray structure of aspartame (**1**), the hydrophobic benzyl side chain (X) projects into the $+z$ dimension (Fig. 4).

The analyses of these crystal structures clearly indicate that the solid-state conformations alone give no information on the relationship between the taste properties and the structures of these peptide-based taste ligands.

3. NMR Spectroscopy and Computer Simulations

Since the X-ray crystal structures of the taste ligands of the aspartame family fail to provide a consistent relationship between taste and molecular structure, we must search for further accessible conformations of the molecules. For this purpose, preferred conformations in solution were estimated by NMR spectroscopy and computer simulations.[8, 11, 12] Packing forces are nonexistent in solution; the molecules are solvated and exist as equilibrium mixtures of various preferred conformers.

The preferred conformations of taste ligands **1**–**13** in solution were estimated from nuclear Overhauser effects (NOE) and ^1H–^1H vicinal coupling constants.[15] The results are summarized in Table 4. In all of the L-aspartyl-based analogues, the L-aspartyl residue shows the same conformational preferences independent of the structure and configuration of the second residue. The conformations of the L-aspartyl residue are defined by the ψ^1 angle (60–180°) and the preference of the side chain for the g^- conformation ($\chi_1^1 = -60°$). These conformations are preserved not only in the sweet molecules but also in the bitter molecules **4** and **8**. The ψ^1 angle of the (*R*)-Ama residue of the sweet-tasting molecule **5** is also restricted to the same range (60–180°) as the L-Asp residue, while that of the (*S*)-Ama residue of the tasteless molecule **6** is restricted to opposite values (-180 to $-60°$).

The preferred conformations of the second residues are divided into several categories depending upon molecular type. Among the molecules **1**–**8** belonging to Type A, which contain the hydrophobic glucophore X in the side chain of the second residue, the sweet-tasting molecules **1**, **3**, **5**, and **7** prefer negative values of -180 to $-60°$ for the ϕ^2 angle of the second residue. Conversely, the bitter molecules **4** and **8** prefer positive values for ϕ^2; for the D-(α-Me)Phe residue in **4**, ϕ^2 is 60–180°, and for the (*R*)-Chg residue in **8**, ϕ^2 is 98 and 142°. Although the N-terminal residues are different in **1**, **5**, and **6**, their L-Phe side chains display the same conformational preferences. The preferred conformer of the L-Phe side chain χ_1^2 was found to be g^- (43–48%); the t and g^+ conformers comprise 14–19% and 37–39%, respectively. The preferred conformations in solution are

Table 4. Conformations of taste ligands **1**–**13** determined by ^1H NMR spectroscopy.

Residue	Bond								
		Type A:	**1**	**3**	**4**	**5**	**6**	**7**	**8**
Asp/Ama	ψ^1: C^α-C(O)		60 to 180°	60 to 180°	60 to 180°	60 to 180°	−180 to −60°	60 to 180°	60 to 180°
	χ_1^1: C^α-C^β	g^- (ca. −60°)	55%	56%	55%	–	–	50%	49%
		t (ca. 180°)	21%	22%	23%	–	–	27%	26%
		g^+ (ca. 60°)	24%	22%	22%	–	–	23%	25%
Residue 2	ϕ^2: N-C^α		−180 to −60°	−180 to −60°	60 to 180°	−180 to −60°	−180 to −60°	−142, −98°	98, 142°
	χ_1^2: C^α-C^β	g^- (ca. −60°)	48%			44%	43%	[a]	[a]
		t (ca. 180°)	14%			19%	18%	17% [a]	[a]
		g^+ (ca. 60°)	38%			37%	39%	[a]	16% [a]
		Type B:	**9**	**10**	**11**	**12**	**13**		
Asp	ψ^1: C^α-C(O)		60 to 180°	60 to 180°	60 to 180°	60 to 180°	60 to 180°		
	χ_1^1: C^α-C^β	g^- (ca. −60°)	59%	60%	60%	58%	62%		
		t (ca. 180°)	19%	18%	18%	20%	16%		
		g^+ (ca. 60°)	22%	22%	22%	22%	22%

	ψ^2: C^α-C(O)								
C-Terminus	τ^3		0° ± 60° [b]	0° ± 60° [c]	0° ± 60° [d]	0° ± 60° [d]			

[a] Since cyclohexylglycine has one β-proton, the rotational isomeric state analysis of the ^1H-^1H vicinal coupling constant $J(\alpha,\beta)$ provides only a fraction of the conformer in which the α- and β-protons orient *trans* to each other. [b] τ^3 is the C(O)-N-C^1-H angle of the C-terminal 2,2,4,4-tetramethylthietanylamide group. [c] τ^3 is the C(O)-O-C^1-H angle of the C-terminal 2,2,2,5-tetramethylcyclopentyl ester group. [d] τ^3 is the N-C(O)-C^1-H angle of the C-terminal 2,2,5,5-tetramethylcyclopentanecarbonyl group.

clearly different from the conformations of the L-Phe side chain of aspartame (**1**) ($\chi_1^2 = +61.7°$), **5** ($\chi_1^2 = -175.3 \pm 5.0°$), and **6** ($\chi_1^2 = 179.2°$) in the crystalline state.

Among the dipeptide taste molecules belonging to Type B, which contain the hydrophobic element X in the C-terminal amide or ester group, the D-Ala residue of compound **9** prefers positive values (60–180°) for ϕ^2 and a broad range of values for ψ^2. Similarly, the D-Ala residue of compound **10** prefers positive values of 60–180° for ϕ^2. The Ac^3c residue of compound **13** assumes a ϕ^2 angle of $0 \pm 90°$. In compounds **11** and **12**, which have retro-inverso gAla residues with (*R*) and (*S*) configurations, respectively, no clear conformational preferences were identified for the second residues from the ^{1}H NMR studies alone.

The accessible (or preferred) conformations of any given molecule are strongly influenced by van der Waals interactions. These steric interactions can be estimated by using any one of the many existing force fields such as CHARMm[16] and DISCOVER.[17] The conformational analyses carried out on the peptide-based taste ligands allow the identification of virtually all minimum-energy conformations. These conformations represent preferred structures within the accessible conformational space of the molecule.

An extensive search for minimum-energy conformations was carried out in a stepwise fashion, starting with small model compounds such as *N*-methylamide derivatives of the N-terminal residues [L-Asp-NHMe, (*R*)-Ama-NHMe, and (*S*)-Ama-NHMe] and *N*-acetyl derivatives of the C-terminal residues [Ac-L-Phe-OMe, Ac-L-Phe-OEt, L- and D-Ac-(α-Me)Phe-OMe, (*R*)- and (*S*)-Ac-Chg-OMe, Ac-D-Ala-TAN, Ac-D-Ala-OTMCP, (*R*) and (*S*)-Ac-gAla-TMCP, and Ac^3c-O*n*Pr] and working toward the structures of the peptide-based taste ligands. This treatment is based on the assumption that interresidue interactions are trivial for the determination of preferred conformations of the taste ligands. This assumption is supported by the ^{1}H NMR data which indicate that the N-terminal L-aspartyl residue shows the same conformational preferences independent of the structure and configuration of the second residue and that the conformation of the second residue is independent of the structure and configuration of the N-terminal residue.

The NMR studies revealed that the L-Asp side chain assumes three conformational states with a preference for the g^- state over the t and g^+ states (see Table 4). However, the AH/B-containing aspartyl moiety could be conformationally fixed when the molecules bind to the taste receptors. We, as well as other groups, have assumed that the g^- structure for the L-aspartyl residue is the bioactive conformation based on the following:

1) The distances between the AH (protonated α-amino) and B (β-carboxylate) groups required for sweet taste sensation (2.5–4.0 Å) are achieved only when the aspartyl side chain assumes either the g^- or g^+ state.

2) All of the peptide analogues studied prefer the g^- state about the aspartyl side chain in solution as revealed by the NMR studies, in other words, 50–60% for g^- and 20–25% for g^+.

3) All of the peptide analogues examined, with the exception of the aspartame hydrochloride salt (**2**), adopt the g^- state in the crystalline state.

Thus, in the following sections only the conformers with a g^- state for the aspartyl side chain are included. As a result, topological differences in molecular structures for each analogue are derived from differences in the conformations of the second residue.

3.1. Preferred Conformations of Type A Taste Ligands

Sixteen minimum-energy conformations consistent with the ^{1}H NMR parameters obtained in solution were calculated for L-Asp-L-Phe-OMe (**1**). The results indicate that the L-Phe residue has great flexibility, since the L-Asp residue adopts the same structure with (ψ^1, ω^1, χ_1^1, $\chi_{2,1}^1$) ≈ (175°, 180°, −56°, −170°) on the average in these conformations. The lowest energy conformation is very similar to the X-ray crystal structure.[12a]

The relative spatial arrangements of the three glucophores of **1**, the protonated N-terminal amino group (AH), the carboxylate group (B) of the Asp residue, and the aromatic group (X) of the Phe residue, are defined by a set of six angles: ψ^1, ω^1, χ_1^1, and $\chi_{2,1}^1$ of L-Asp, and ϕ_2 and χ_1^2 of L-Phe. Since the first four angles of the Asp residue are essentially the same for all minimum-energy conformations, the remaining two angles, ϕ^2 and χ_1^2, define the spatial arrays of the glucophores. According to the observed combinations of these two angles, six preferred topochemical arrays of the AH, B, and X glucophores are obtained for the sweet-tasting L-Asp-L-Phe-OMe (**1**) (Fig. 11). The

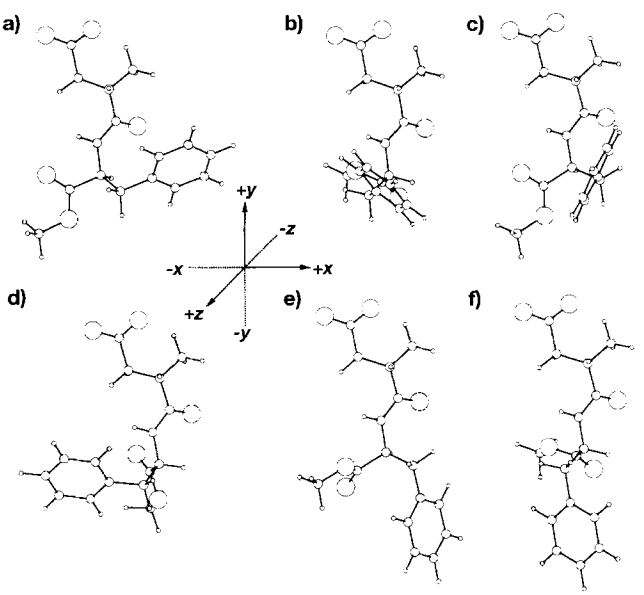

Fig. 11. Preferred conformations of aspartame (**1**). In all the conformations, the L-aspartyl moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure which projects along the $+y$ axis. The hydrophobic phenylalanine side chain projects along the $+x$ axis in a), along the $+z$ axis in b) and c), along the $-x$ axis in d), and along the $-y$ axis in e) and f).

calculated ϕ^2 angle is restricted to two regions: between −165 and −140°, and between −90 and −60°. For the χ_1^2 angle, three values were calculated: ca. 180° (t), ca. −60° (g^-), and ca. +60° (g^+). The conformation shown in Figure 11a, in which the ϕ^2

and χ_1^2 angles assume values of -148 and $-61°$ (g^-), respectively, assumes an L-shaped structure; the AH- and B-containing zwitterionic ring of the aspartyl moiety forms the stem of the L along the $+y$ axis, and the hydrophobic X group projects along the base of the L along the $+x$ axis. The structure with the X group projecting into the $+z$ dimension shown in Figure 11b exhibits ϕ^2 and χ_1^2 angles of -67 and $-60°$ (g^-), respectively. A similar topochemical array is observed in Figure 11c, in which the Phe residue adopts the angles $\phi^2 = -163°$ and $\chi_1^2 = +58°$ (g^+). The structure shown in Figure 11d with $\phi^2 = -73°$ and $\chi_1^2 = +59°$ (g^+) is defined by a reversed L-shaped structure, in which the X group projects along the $-x$ axis. In Figures 11e and 11f, the X group projects along the $-y$ axis, which results in extended structures with the AH/B groups and the X group in a planar array. These extended structures require the side chain χ_1^2 angle to be roughly 180° (t) but are less dependent upon the ϕ^2 angle.

The minimum-energy conformations calculated for the sweet-tasting L-Asp-L-(α-Me)Phe-OMe (**3**) are very similar to those of **1**. Therefore, the preferred topochemical arrays of the AH, B, and X glucophores of both compounds are equivalent. These results indicate that substitution of an α-methyl group for the α-proton of the L-Phe residue does not affect the preferred conformations of the L-aspartyl dipeptide molecules.

The bitter L-Asp-D-(α-Me)Phe-OMe (**4**) adopts essentially the same structures for the L-Asp moiety as its diastereomer **3** and aspartame (**1**), both of which are sweet. The ϕ^2 angle calculated for the D-(α-Me)Phe residue of **4** has values between 157 and 187°, and between 58 and 78°. These ranges of angles are opposite to those calculated for the L-(α-Me)Phe residue of the sweet-tasting **3**. Consequently, the preferred topochemical arrays of the AH, B, and X glucophores of the bitter dipeptide **4** are different from those of the sweet analogues **1** and **3**. No L-shaped structures are accessible to **4**; instead, this bitter analogue assumes structures with a large $-z$ component, in which the hydrophobic benzyl side chain (X) projects into the $-z$ dimension and the D-(α-Me)Phe residue adopts the angles $\phi^2 = 160°$ and $\chi_1^2 = 71°$ (g^+). This kind of structure was not observed for the sweet analogues **1** and **3**.

The three-dimensional structures of the glucophores of sweet-tasting **5** are topochemically equivalent to those of **1**. In contrast, the preferred topochemical arrays of the AH, B, and X glucophores of the tasteless analogue **6** are different from those of the sweet analogues **1**, **3**, and **5**, and the bitter analogue **4**. Neither L-shaped structures nor structures with a large $-z$ component are accessible to **5**. When the zwitterion formed by the protonated amino group (AH) and carboxylate group (B) of the (*S*)-Ama residue is placed along the $+y$ axis, the hydrophobic Phe side chain mostly projects into the space defined by the $-x$, $-y$, and $+z$ axes.

In contrast to analogues **1**–**6**, which show large flexibilities in the second residue, the Chg residue in analogues **7** and **8** displays unique and restricted conformational preferences. Conformations are found in which the cyclohexyl side chain has substituents either in *axial* or in *equatorial* positions; the axial form is calculated to be at least 7 kcal mol^{-1} higher in energy than the equatorial.[11g] Therefore, only the conformers in which the substituent is *equatorial* will be considered. In both diastereomers **7** and **8**, the conformation about the N–C^α bond (ϕ^2) of the Chg residue is the primary determinant of the relative spatial arrangements of the AH, B, and X glucophores. Since the cyclohexane ring is directly attached to the α-carbon of the second residue, a rotation of the cyclohexyl side chain about the C^α–C^β bond (χ_1^2) causes minimal change in the relative position of the X group. In each diastereomer, the calculated ϕ^2 angles are restricted to two regions: from -145 to $-131°$ and from -97 to $-77°$ for the sweet-tasting **7** and from 77 to 102° and roughly 140° for the bitter-tasting **8**. These values agree with the experimental values estimated from the ^{1}H NMR studies (Table 4). In **7** the hydrophobic cyclohexyl side chain (X) orients along the $+x$ axis (forming an L-shaped structure) when the (*S*)-Chg residue adopts the ϕ^2 angle in the range of -145 to $-131°$ (Fig. 12a). With ϕ^2 in the range of -97 to $-77°$, the

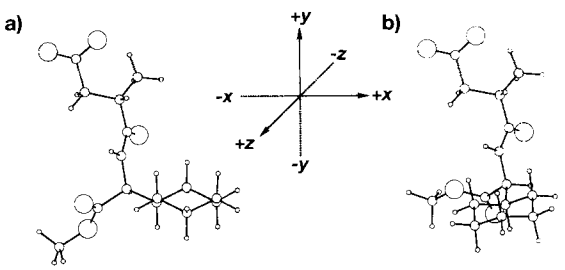

Fig. 12. Preferred conformations of **7**. In both, the L-aspartyl moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure which projects along the $+y$ axis. The hydrophobic cyclohexyl side chain projects along the $+x$ axis in a) and along the $+z$ axis in b).

cyclohexyl side chain projects into the $+z$ dimension (in front of the stem of the L structure, Fig. 12b). In contrast, the cyclohexyl side chain of **8** orients along the $-x$ axis (reversed L shape, Fig. 13a) with $\phi^2 = 77$–$102°$ for the (*R*)-Chg residue, and in the $-z$ axis (behind the stem of the L, Fig. 13b) when the angle ϕ^2 is about 140°. In the latter structures the molecule possesses a large $-z$ component.

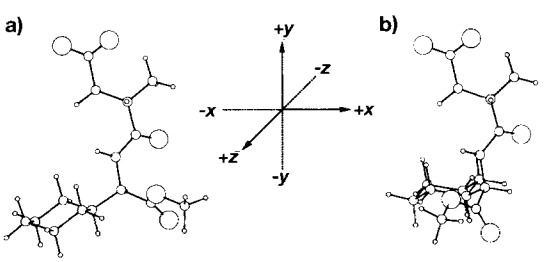

Fig. 13. Preferred conformations of **8**. In both, the L-aspartyl moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure which projects along the $+y$ axis. The hydrophobic cyclohexyl side chain projects along the $-x$ axis in a) and along the $-z$ axis in b).

3.2. Preferred Conformations of Type B Taste Ligands

Fourteen minimum-energy conformations were calculated for the diastereomeric pair **11** and **12**, in which the L-Asp side chain is in the g^- state. These fourteen structures are subdivided into seven families according to the (ϕ^2, ψ^2) conformation of the gAla residue. Each family contains two minimum-energy con-

formations with different values of the torsion angle τ^3 of the C-terminal TMCP group which is defined as N-C(O)-C^1-H; one structure has $\tau^3 \approx +20°$ and the other has $\tau^3 \approx -20°$. The results of computer simulations lead to two interesting and important conclusions regarding the conformational features of these retro-inverso molecules:

1) None of the minimum-energy conformations has (ϕ^2, ψ^2) $\approx$ ($+100°$, $-100°$) or (ϕ^2, ψ^2) $\approx$ ($-100°$, $+100°$) in the gAla residue, although these values are observed in the X-ray crystal structures[11b] of **11** and **12**, respectively. There is no similarity observed between the calculated and X-ray structures. These results indicate that the X-ray crystal structures of the retro-inverso analogues **11** and **12** represent accessible conformations in solution but are not minimum-energy structures. The two geminal NH groups of the gAla residue are involved in intermolecular hydrogen bonds in the X-ray structure.

2) The gAla residue adopts both negative and positive ϕ^2 angles without preference, which is in agreement with the results of the ^{1}H NMR studies. These ϕ^2 values indicate that there are no clear conformational preferences for this residue. In this respect, the retro-inverso analogues are distinguished from the other dipeptides which show clear conformational preferences for the second residue.

Since the L-aspartyl residue assumes the same conformation in both analogues, the (ϕ^2, ψ^2) conformation of the second residue (gAla) determines the relative spatial orientation of the C-terminal hydrophobic TMCP group (X) and the AH/B glucophores in the aspartyl moiety. A rotation about the C(O)–C^1 bond (τ^3) causes little relative change in the position of the X group. Minimum-energy structures of the sweet-tasting **11** are shown in Figure 14. The molecule assumes extended structures when the (*R*)-gAla residue adopts conformations with (ϕ^2, ψ^2) = (163°, −165°), (ϕ^2, ψ^2) = (63°, −165°), and (ϕ^2, ψ^2) = (−52°, 161°), as shown in Figures 14a, 14b, and 14c, respectively. In the structure shown in Figure 14d, the (*R*)-gAla residue adopts a conformation with (ϕ^2, ψ^2) = (165°, −66°) which causes the hydrophobic TMCP group (X) to project into the $+z$ dimension. In the structure shown in Figure 14e, in which the (*R*)-gAla residue adopts a conformation with (ϕ^2, ψ^2) = (161°, 51°), the X group points into the space between the $+z$ axis and the $-x$ axis. The molecule forms a reversed L shape with the X group projecting along the $-x$ axis when the (*R*)-gAla residue adopts a conformation with (ϕ^2, ψ^2) = (−57°, −66°), as shown in Figure 14f. In the conformation with (ϕ^2, ψ^2) = (64°, 57°) the retro-inverso molecule is arranged in an L shape with the X group projecting along the $+x$ axis (Fig. 14g).

As shown in Figure 15, the sweet-tasting **12** assumes topochemical structures similar to those of its diastereomer **11**. Extended structures are observed when the (*S*)-gAla residue is in conformations with (ϕ^2,ψ^2) = (−164°, 163°), (ϕ^2, ψ^2) = (−67°, 164°), and (ϕ^2, ψ^2) = (52°, −160°), as shown in Figures 15a, 15b, and 15c, respectively. In the structure shown in Figure 15d, the (*S*)-gAla residue adopts a conformation with

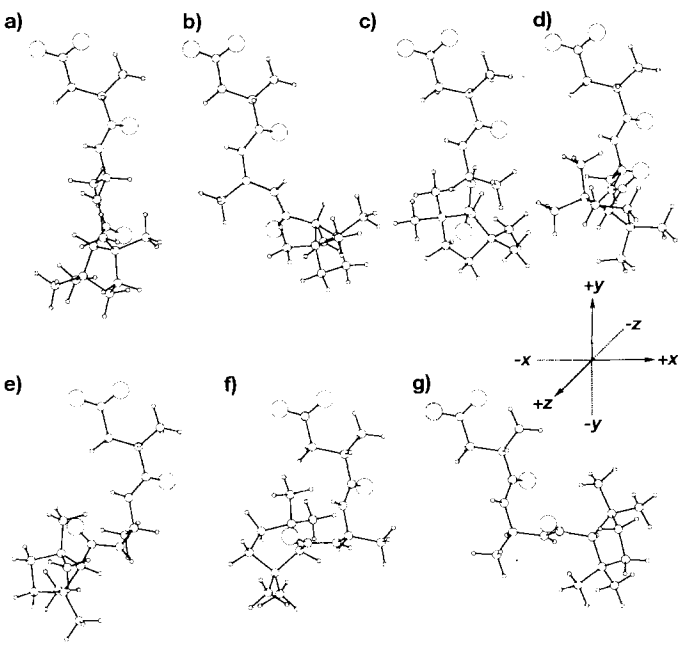

Fig. 14. Preferred conformations of **11**. In all the conformations, the L-Asp moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure, which projects along the $+y$ axis. The C-terminal TMCP group, which serves as the hydrophobic X glucophore, projects into the $-y$ dimension in structures a), b), and c), into the $+z$ dimension in structure d), and into the space between the $+z$ axis and the $-x$ axis in structure e). Structure f) has a reversed L shape with the TMCP group projecting along the $-x$ axis; structure g) has an L shape with the same group projecting along the $+x$ axis.

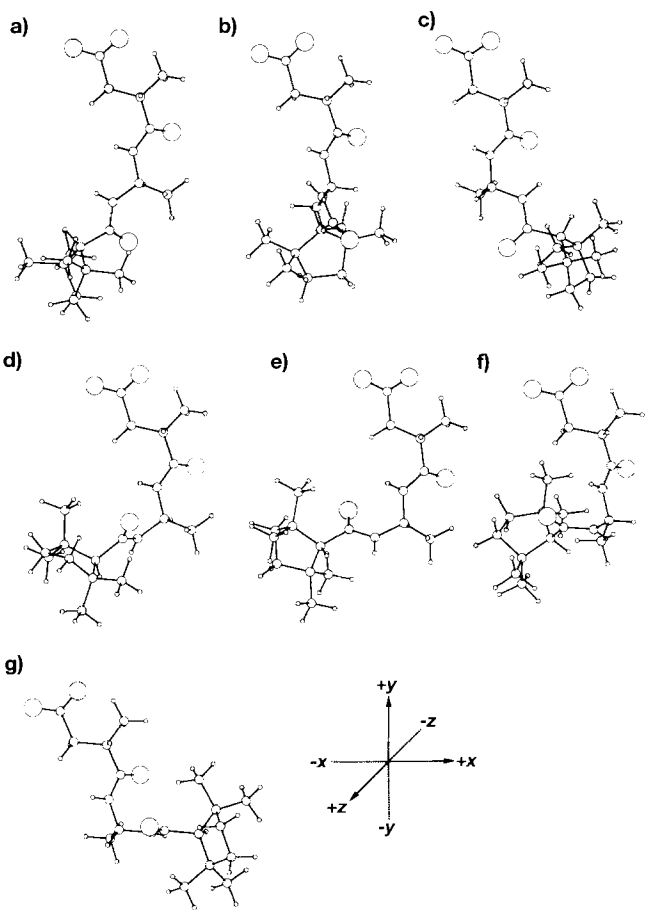

Fig. 15. Preferred conformations of **12**. In all the conformations, the L-Asp moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure, which projects along the $+y$ axis. The C-terminal TMCP group, which serves as the hydrophobic X glucophore, projects into the $-y$ dimension in structures a), b), and c), and into the space between the $+z$ axis and the $-x$ axis in structure d). Structures e) and f) have reversed L shapes with the TMCP group projecting along the $-x$ axis; structure g) has an L shape with the same group projecting along the $+x$ axis.

$(\phi^2, \psi^2) = (-159°, -54°)$, which causes the X group to point into the space between the $+z$ axis and the $-x$ axis. In the reversed L-shaped structures shown in Figures 15e and 15f, the (*S*)-gAla residue is in conformations with $(\phi^2, \psi^2) = (-164°, 62°)$ and $(\phi^2, \psi^2) = (-66°, -57°)$, respectively. The L-shaped structure shown Figure 15g requires $(\phi^2, \psi^2) = (55°, 65°)$.

Similar topochemical arrays of the AH, B, and X glucophores were observed for the sweet D-Ala-containing analogues **9** and **10**, although the D-Ala residue of these molecules adopts only positive ϕ^2 values (60–180°).

The α-aminocyclopropanecarboxylic acid (Ac^3c) residue displays quite unique (ϕ, ψ) conformational preferences. For ϕ, only two narrow regions are equally accessible for Ac^3c: one with $\phi = 70 \pm 30°$ and the other with $\phi = -70 \pm 30°$. On the other hand, accessible regions for ψ of Ac^3c are relatively broad. Two energy minima are observed for each allowed ϕ value: $\psi \approx 55$ and 180° for $\phi \approx +70°$, and $\psi \approx -55$ and 180° for $\phi \approx -70°$. Because of the structural constraints of the Ac^3c residue, four families of minimum-energy conformations were calculated for the sweet L-Asp-Ac^3c-O*n*Pr (**13**). In all of the families, the aspartyl moiety assumes essentially the same structure $((\psi^1, \omega^1, \chi^1_1, \chi^1_{2,1}) \approx (175°, 180°, -56°, -170°))$. Four similar families have been reported by Taylor et al.,[18] but their ψ^2 values are different from ours because they have assumed a two-fold potential about the C^α–C(O) bond of the Ac^3c residue with minima at 0 and 180°. Each family consists of minimum-energy conformations that are different from one another in terms of the conformation of the C-terminal *n*-propyl ester group. The conformation of the *n*-propyl ester group is less critical to the relative spatial arrangements of the AH, B, and X glucophores than the (ϕ^2, ψ^2) conformation of the Ac^3c residue.

Figure 16 shows accessible conformations for the sweet-tasting **13**. In the Ac^3c conformation with $(\phi^2, \psi^2) = (70°, 57°)$ the dipeptide molecule is arranged in an L shape (Fig. 16a) with the hydrophobic *n*-propyl ester (X) projecting along the $+x$ axis. Conversely, in the conformation with $(\phi^2, \psi^2) = (-70°, -57°)$ a reversed L-shaped structure (Fig. 16c) is observed with the X group projecting along the $-x$ axis. In Figures 16b and 16d, the L-Asp-Ac^3c-O*n*Pr molecule assumes extended structures with $(\phi^2, \psi^2) = (73°, -177°)$ and $(\phi^2, \psi^2) = (-74°, 177°)$, respectively.

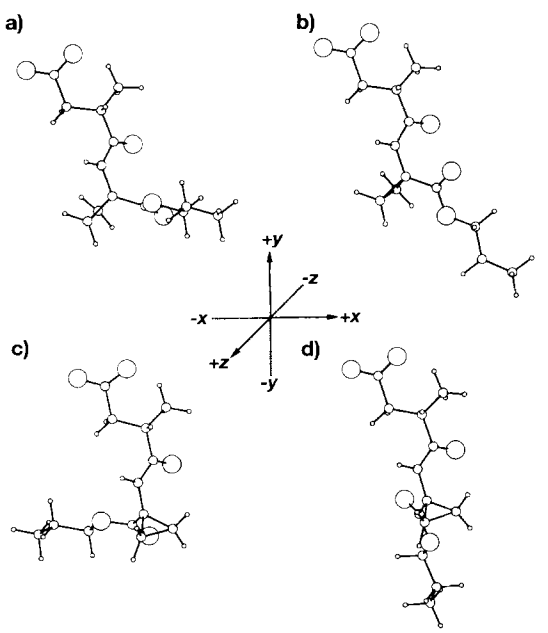

Fig. 16. Preferred conformations of **13**. In all the conformations, the L-Asp moiety containing the AH and B glucophores assumes essentially the same zwitterionic structure which projects along the $+y$ axis. The molecule assumes a) an L shape with the hydrophobic *n*-propyl ester group projecting along the $+x$ axis and c) a reversed L shape with the same group projecting along the $-x$ axis. The *n*-propyl ester group projects into the $-y$ dimension in structures b) and d).

4. A Three-Dimensional Model for Taste

The topochemical arrays of the AH (hydrogen bond donor), B (hydrogen bond acceptor), and X (hydrophobic element) glucophores accessible in the peptide-based taste ligands investigated are divided into five classes:

I: an L-shaped structure with the AH- and B-containing zwitterionic ring of the N-terminus (L-Asp, (*R*)-Ama, or (*S*)-Ama) forming the stem of the L in the y axis and the hydrophobic X group projecting along the base of the L in the $+x$ axis;

II: a reversed L-shaped structure with the X group projecting along the $-x$ axis;

III: an extended structure in which the AH/B moiety of the zwitterionic ring and the X group form an angle of nearly 180° in a planar linear array, and the X group projects into the $-y$ dimension;

IV: a structure with the X group projecting into the $+z$ dimension;

V: a structure with significant extension of the X group into the $-z$ dimension.

All of the sweet-tasting analogues with the exception of **7** and **13** adopt common topochemical arrays of the AH, B, and X glucophores (classes I–IV) as shown in Table 5. The topochemical array in which the X group projects into the $-z$ dimension (class V) is accessible to none of the sweet-tasting analogues including **7** and **13**. Therefore, this topochemical array is excluded as a candidate for the bioactive conformation necessary for sweet taste.

Table 5. Topochemical arrays of AH, B, and X glucophores in **1**–**13**.

Compound		Taste	Topochemical arrays [a]				
			I	II	III	IV	V
Type A							
1	L-Asp-L-Phe-OMe	sweet	yes	yes	yes	yes	no
3	L-Asp-L-(α-Me)Phe-OMe	sweet	yes	yes	yes	yes	no
4	L-Asp-D-(α-Me)Phe-OMe	bitter	no	yes	yes	yes	yes
5	(*R*)-Ama-L-Phe-OMe	sweet	yes	yes	yes	yes	no
6	(*S*)-Ama-L-Phe-OEt	tasteless	no	yes	yes	yes	no
7	L-Asp-(*S*)-Chg-OMe	sweet	yes	no	no	yes	no
8	L-Asp-(*R*)-Chg-OMe	bitter	no	yes	no	no	yes
Type B							
9	L-Asp-D-Ala-TAN	sweet	yes	yes	yes	yes	no
10	L-Asp-D-Ala-OTMCP	sweet	yes	yes	yes	yes	no
11	L-Asp-(*R*)-gAla-TMCP	sweet	yes	yes	yes	yes	no
12	L-Asp-(*S*)-gAla-TMCP	sweet	yes	yes	yes	yes	no
13	L-Asp-Ac^3c-O*n*Pr	sweet	yes	yes	yes	no	no

[a] For a definition of the topochemical arrays see text.

Among the sweet-tasting analogues, **7** is particularly informative with regard to the orientation of the X group relative to the

AH and B groups. Since the conformationally constrained cyclohexyl group is bonded directly to the α-carbon of the second residue in this analogue, the hydrophobic X group sweeps out an arc nearly coplanar with the xz plane. Thus, no extended structures (class III) in which the X group projects out along the $-y$ axis are accessible to this analogue. Dipeptide **7** can only assume two types of topochemical arrays, class I and class IV. The sweet-tasting **13** is also informative. This analogue adopts the L-shaped (class I), the reversed L-shaped (class II), and the extended (class III) structures. However, no structures in which the hydrophobic *n*-propyl ester (X) projects into either the $+z$ dimension (class IV) or the $-z$ dimension (class V) are accessible to this analogue because of the constrained Ac^3c residue. Only the L-shaped structure (class I) is common to both of the sweet analogues **7** and **13**. As is evident in Table 5, the L-shaped structure is the only topochemical array of the AH, B, and X glucophores that is accessible to all sweet-tasting analogues. From these results, we conclude that the L-shaped structure is necessary for sweet taste. Our conclusion is further strengthened by the fact that no L-shaped structures (class I) are accessible to either the tasteless analogue **6** or the bitter analogues **4** and **8** (Table 5). The L-shaped structures of aspartame (**1**) (Type A with the Phe side chain as the hydrophobic X group) and **9** (Type B with the C-terminal TAN group as the X group) are shown in Figure 17.

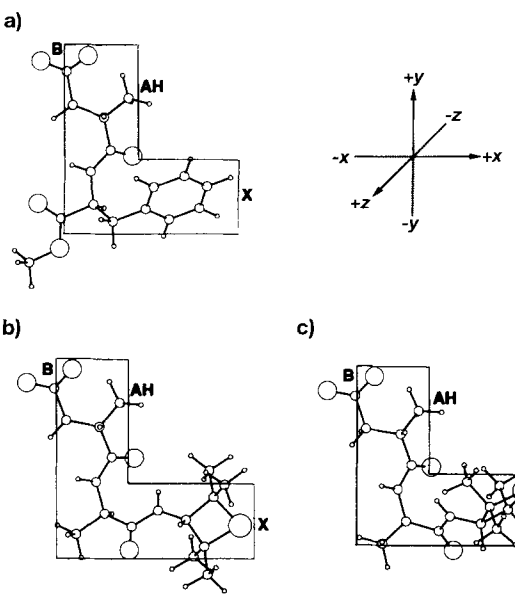

Fig. 17. The L-shaped structures of a) **1** and b), c) **9**, which produce a sweet taste. In all the structures, the AH- and B-containing zwitterionic ring of the L-Asp moiety forms the stem of the L in the $+y$ axis, and the hydrophobic X group projects out along the base of the L in the $+x$ axis. The zwitterionic ring is coplanar with the plane of the L.

Structural requirements for the bitter taste produced by peptide-based molecules can be deduced by comparing accessible topochemical arrays of the bitter molecules **4** and **8** with those of the sweet and tasteless analogues. Dipeptide **4** can assume four topochemical arrays: structures of classes II, III, IV, and V. In contrast, only two topochemical arrays, structures of classes II and V, are accessible to **8** because of the constrained cyclohexylglycine residue. Thus, the class II and class V structures are common to the bitter analogues **4** and **8**. In the class V structures, the molecules possess large $-z$ components. Although the reversed L-shaped array (class II) is also accessible to most of the sweet and tasteless analogues, the class V topochemical array is unique to the bitter analogues **4** and **8** (Table 5). We postulate that this topochemical array with a large $-z$ component, which results from the projection of the X group behind the stem of the L into the $-z$ dimension, produces a bitter taste. The class V topochemical structures of **4** and **8** are shown in Figure 18.

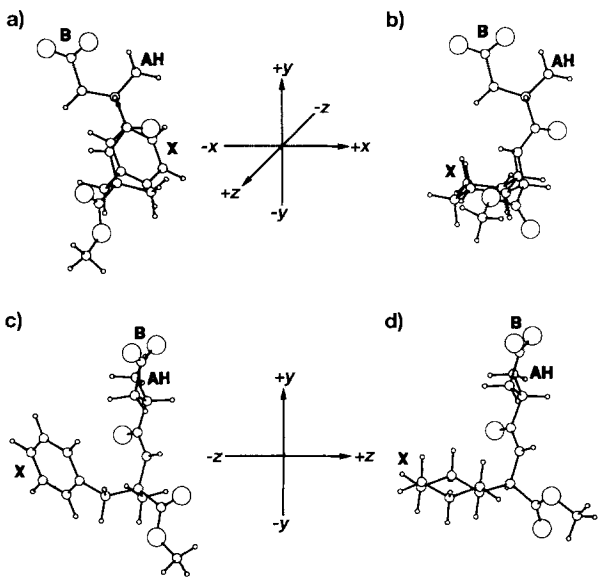

Fig. 18. The topochemical structures which produce the bitter taste of a) **4** and b) **8**. In these structures, the hydrophobic X glucophore projects into the $-z$ dimension, in other words, behind the stem of the L (see Fig. 14). Thus, these structures possess large $-z$ components which are clearly seen in the projections along the yz axes of the structures of **4** (c) and **8** (d).

The Type A dipeptide molecule **6** assumes topochemical arrays of classes II, III, and IV, but neither the class I L-shaped structures necessary for sweet taste nor the class V structures required for bitter taste are accessible. Thus, this molecule is tasteless. Although we have not discussed tasteless molecules belonging to Type B in this review, several such compounds such as D-aspartyl-D-alanine(2,2,4,4-tetramethylthietanyl)-amide,[11d] a stereoisomer of **9**, have been reported. Conformational studies by NMR spectroscopy and computer simulations reveal that this compound can assume structures of classes II, III, and IV but not of classes I or V.

The relationship between the topochemical arrays of the AH, B, and X glucophores and tastes developed here for peptide-based taste ligands is illustrated in Figure 19.

In all five classes of topochemical arrays of the AH, B, and X glucophores presented in Table 5, the N-terminal residue adopts essentially the same structure: $(\psi^1, \omega^1, \chi_1^1, \chi_{2,1}^2) \approx (175^\circ, 180^\circ, -56^\circ, -170^\circ)$ for L-Asp and $(\psi^1\ \omega^1, \chi_{1,1}^1) \approx (175^\circ, 180^\circ, -170^\circ)$ for (*R*)-Ama. In all compounds, the protonated amino (AH) and the side-chain carboxylate (B) groups are arranged in the correct geometry for them to act as the AH/B functionalities. The differences in overall structure and in taste arise from the

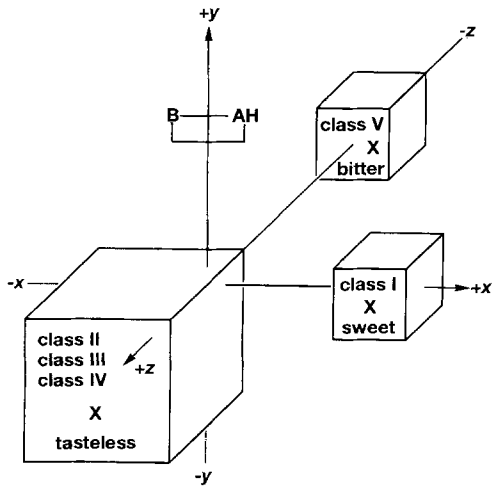

Fig. 19. A schematic illustration of the relationship between topochemical arrays of the AH, B, and X glucophores and tastes. The α-carbon atom of the second residue of the taste ligands is located at the origin of the *xyz* coordinate system, i.e. at (0, 0, 0).

conformation of the second residue. The ϕ^2 and χ_1^2 angles are critical for the overall structures and taste properties of Type A analogues. For Type B analogues, the ϕ^2 and ψ^2 angles are critical for their tastes. These angles determine the relative orientation of the hydrophobic X function with respect to the AH/B functions. In Type A analogues, the L-shaped structure necessary for sweet taste requires the torsion angles $\phi^2 = -150^\circ \pm 30^\circ$ and $\chi_1^2 \approx -60^\circ$ (g^-) in the second residue; in Type B analogues $\phi^2 = 70^\circ \pm 30^\circ$ and $\psi^2 = 0^\circ \pm 60^\circ$ are required.

The class V structures, which possess a large $-z$ component and produce a bitter taste, also require specific torsion angles for the second residue: $\phi^2 = +150^\circ \pm 30^\circ$ and $\chi_1^2 \approx +60^\circ$ (g^+) for Type A and $\phi^2 = -70^\circ \pm 30^\circ$ and $\psi^2 = +60^\circ \pm 30^\circ$ for Type B. The ϕ^2 and ψ^2 angle requirements for Type B analogues were estimated from conformational studies of the bitter Type B compounds L-asparty-L-alanine-2,2,4,4-(tetramethylthietanyl)amide[11d] and L-aspartyl-L-alanine-(2,2,5,5-tetramethylcyclopentyl)amide[19] by NMR spectroscopy and computer simulations. The former compound is a stereoisomer of the sweet-tasting L-Asp-(*S*)-gAla-TAN (**9**), and the latter is the parent compound of the sweet-tasting L-Asp-(*S*)-gAla-TMCP (**12**).

As mentioned in Section 1, the absolute configuration of the second residue is a critical factor in determining the taste properties of dipeptide taste ligands. For Type A taste ligands, an L-amino acid residue at position 2 is necessary for sweet taste, while incorporation of a D-amino acid at the same position produces bitter taste. For Type B analogues, a D-amino acid at position 2 is necessary for sweet taste, while incorporation of an L-amino acid at the same position results in a bitter or tasteless molecule. The configurational requirements of the second residue that must be fulfilled for a molecule to elicit a sweet taste can be explained with the ϕ^2 requirements of the L-shaped structures. The conformation with $\phi^2 = 70 \pm 30^\circ$ is required for the L-shaped structures of dipeptide taste ligands belonging to Type B. For L-amino acids, this structure is energetically less stable than the conformation with negative values of ϕ^2. The L-shaped structures of dipeptide analogues belonging to Type A require the angle ϕ^2 to assume a value of $-150 \pm 30^\circ$. Such a structure is not accessible to D-amino acids.

In order to generalize the angle requirements of dipeptides with sweet and bitter tastes, we introduce the dihedral angle θ_ϕ^2 defined by C(O)-N-C^α-R_2 [C(O)-N-C^α-X (hydrophobic glucophore) in Fig. 2a]. The θ_ϕ^2 angle can be related to the torsion angle ϕ^2 as $\theta_\phi^2 = \phi^2 - 120^\circ$ for taste ligands of Type A which have an L- or (*S*) configuration at position 2, $\theta_\phi^2 = \phi^2 + 120^\circ$ for analogues of Type A which have a D- or (*R*) configuration at position 2, and $\theta_\phi^2 = \phi^2$ for Type B dipeptide analogues. Therefore, the L shape needed for sweet taste requires $\theta_\phi^2 = 90 \pm 30^\circ$ for Type A and $\theta_\phi^2 = 70 \pm 30^\circ$ for Type B. These two θ_ϕ^2 angle ranges are very close to each other. In contrast, the class V structure which produces a bitter taste requires $\theta_\phi^2 = -90 \pm 30$ for Type A and $\theta_\phi^2 = -70 \pm 30^\circ$ for Type B. These results indicate that the positive θ_ϕ^2 value of $80 \pm 40^\circ$ is required for sweet taste, while the negative θ_ϕ^2 value of $-80 \pm 40^\circ$ is required for bitter taste.

5. Comparison of the L Model with Other Molecular Models for Sweet Taste

In addition to our L model, several other molecular models for sweet taste have been reported in the literature. In the following sections, comparison of the L model with other molecular models is addressed.

5.1. Comparison with the Temussi Model

Temussi et al.[22] analyzed the preferred conformations of aspartame (**1**) by using ^{1}H NMR spectroscopy and potential energy calculations. As a bioactive conformation of aspartame, they proposed an extended structure in which the AH/B-containing zwitterionic ring of the L-Asp moiety and the hydrophobic benzyl side chain (X) of the L-Phe residue form a planar parallel array with an angle of nearly 180° (Class III in this review). This structure resulting from the $\chi_1 = g^-$ (ca. -60°) and t (ca. 180°) states for the L-Asp and L-Phe side chains, respectively, was originally reported to be the most stable in solution. After Siemion and Picur[21] argued against the $\chi_1 = t$ preference of the L-Phe side chain, Temussi et al.[20] reported that the most stable form of aspartame in solution is a structure with both the L-Asp and L-Phe side chains in the $\chi_1 = g^-$ state. This revision was based on the assignments of the two β-protons of the L-Phe residue by the ^{1}H NMR studies of aspartame containing a stereospecifically β-monodeuterated phenylalanine, (2*S*, 3*S*)-[3-^{2}H]-Phe. However, they insisted that the bioactive conformation of aspartame remained the extended structure as originally reported.

Temussi's structural model differs from our L model in the side-chain χ_1 angle of the second residue (L-Phe of aspartame). This residue assumes the t (ca. 180°) state in Temussi's model and the g^- (ca. -60°) state in our model. Since the L-Phe residue of aspartame adopts both χ_1 states in solution with a preference of g^- over t, it is clear that the aspartame molecule adopts both extended and L-shaped structures (Fig. 11 and Table 5). Thus it

is impossible to discriminate between the two models on the basis of aspartame alone. However, our studies reveal that the L-shaped structure is the only topochemical structure accessible to all of the sweet analogues and that no L-shaped structures are accessible to the bitter and tasteless analogues (Table 5). In addition, extended structures which fit the Temussi model are not accessible to the sweet molecule **7**, and the bitter molecule **4** and the tasteless molecule **6** can also assume extended structures. These results provide evidence in favor of the L model over the extended structure model.

5.2. Comparison with the van der Heijden Model

It has been demonstrated that the sweetness potencies of a wide variety of L-aspartyl-based dipeptide derivatives are dependent on the length and size of the C-terminal amide or ester groups and the side-chain substituent of the second residue.[23] Based on these findings, van der Heijden et al.[24] criticized Temussi's model[22] and postulated an alternative structure as a bioactive conformation of aspartame, in which both the L-Asp and L-Phe side chains assume the $\chi_1 = g^-$ (ca. $-60°$) state. Molecular models and the STERIMOL approach were used to calculate the distances AH – B, AH – X, and B – X as 3.0, 4.5, and 7.3 Å, respectively. Van der Heijden et al. argued that their model correlates better with taste properties of a series of dipeptide taste ligands than Temussi's model. In terms of the side-chain conformations of the L-Asp and L-Phe residues, the van der Heijden model is in agreement with our L model. In addition, the AH–B, AH–X, and B–X distances calculated for our L-shaped structures of aspartame are 2.9, 5.2 and 7.5 Å, respectively, values which are close to those of the van der Heijden model. This suggests that the backbone conformations of the two proposed models are similar, although the torsion angles describing the backbone conformation have not been reported for the van der Heijden model.

5.3. Comparison with the Görbitz Model

As a bioactive conformation of aspartame, Görbitz[12b] has proposed a rather compact structure, with distances of 2.9 Å for AH–B, 3.7 Å for AH–X, and 5.2 Å for B–X. This structure correlates well with the Kier triangular model[3] developed for sweet-tasting amino acids. However, it should be mentioned that the AH–X and B–X distances required for sweet taste must be reevaluated, because dipeptide taste ligands are much sweeter than the amino acids used for development of the Kier triangular model. The Görbitz bioactive structure is described by the angles $\psi^1 = 82.0°$, $\omega^1 = -172.0°$, $\chi_1^1 = +60.0°$ (g^+), and $\chi_{2,1}^1 = -65.0°$ for the L-Asp residue, and $\phi^2 = -128.0°$, $\psi^2 = 166.8°$, $\chi_1^2 = -60.0°$ (g^-), and $\chi_{2,1}^2 = -85.0°$ for the L-Phe residue. As for the conformation of the L-Phe residue, the ϕ^2 and χ_1^2 angle values of Görbitz's structure agree with the angles of $\phi^2 = -150° \pm 30°$ and $\chi_1^2 \approx -60°$ (g^-) required in our L model. On the other hand, the conformations of the L-Asp residue are different in the two models. The major difference arises from the side chain χ_1^1 conformation. Görbitz's compact structure assumes the g^+ (ca. $+60°$) state about the L-Asp side chain, while our L model assumes the g^- (ca. $-60°$) state. Both states provide similar distances between the AH and B glucophores in the aspartyl moiety, in accordance with the AH–B distances found in many nonpeptide sweet-tasting molecules (2.5–4.0 Å). Because all of the aspartyl-based dipeptide analogues prefer the g^- state (50–60%) over the g^+ state (20–25%) about the aspartyl side chain in solution, as revealed by the NMR studies, we have assumed the $\chi_1^1 = g^-$ state for the L-Asp residue as a bioactive conformation. All aspartyl-based analogues studied, with the exception of the aspartame hydrochloride salt (**2**), adopt the g^- state in the solid state. It is not possible on the basis of the present data to choose between the $\chi_1^1 = g^+$ and g^- states for the active form of the L-aspartyl side chain. One method of answering this question is by examining a stereoisomer of the N-terminal L-aspartyl residue of taste ligands in the aspartame family.

5.4. Comparison with the Tinti–Nofre Model

Tinti, Nofre, et al.[25] demonstrated that the COO^- and NO_2 (or CN) groups, previously considered as B sites in the Shallenberger–Acree hypothesis,[1] participate by specific and distinct interactions with the taste receptors to elicit a sweet taste. They postulated that the NO_2 or CN group comprises a D site, in other words, a fourth binding site in addition to the AH, B, and X glucophores.[26] The significance of this fourth binding site was demonstrated with a highly potent, sweet *N*-(4-cyanophenylcarbamoyl)-L-aspartyl-L-phenylalanine methyl ester (14000 times sweeter than sucrose), which is a hybrid compound of the two sweeteners 4-cyanophenylcarbamoyl-β-alanine (450 times sweeter than sucrose)[27] and aspartame (**1**) (200 times sweeter than sucrose).[6] This hybrid contains the AH, B, X, and D glucophores within a single structure. On the basis of these findings, Tinti and Nofre[28] have proposed an eight recognition site model, with four high-affinity sites designated as AH (hydrogen bond donor), B (anionic group such as COO^-), G (hydrophobic group, equal to X in the AH/B/X model), and D (hydrogen bond acceptor), and with four secondary sites designated as Y, E_1, E_2 (hydrogen bond acceptors), and XH (hydrogen bond donor). The relative distances between these sites and their Cartesian coordinates have been outlined. However, the authors do not describe how they estimated these distances and coordinates. According to Tinti and Nofre, the simultaneous interaction of a taste ligand with all of these receptor recognition sites is not required to generate a sweet response. A lower number of interaction sites is often sufficient to initiate a sweet taste. The sweetness potency of a compound depends both on the number of active sites involved in the ligand–receptor interaction and on the effectiveness of each individual interaction.

The taste ligands discussed here (Table 1) contain six of the eight sites postulated by Tinti and Nofre,[28] namely, AH (NH_3^+), B (COO^-), G (hydrophobic group either in the side chain of the second residue or in the C-terminal amide or ester group), Y (C=O of the amide bond between residues 1 and 2), XH (NH of the amide bond between residues 1 and 2), and either E_1 (C=O of the second residue in Type A analogues) or E_2 (C=O of the second residue in Type B analogues). Of the

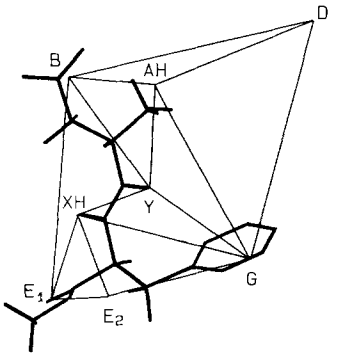

Fig. 20. Superposition of the Tinti–Nofre model (thin lines) with our L model (thick lines) for the bioactive structure of aspartame **1**. For a definition of the recognition sites in the Tinte–Nofre model see the text.

four high-affinity sites, the peptide derivatives lack the D site. Figure 20 shows a comparison of the Tinti–Nofre model with our proposed bioactive L-shaped structure of aspartame. The agreement between the two models is quite good as far as the relative positions of the AH, B, G, Y, XH, and E_1 sites are concerned.

6. Conclusion

We have presented the results of comprehensive structure–activity studies on a series of peptide derivatives of the aspartame family. The compounds fall into two classes. The first (Type A) are dipeptide derivatives containing the hydrophobic group X in the side chain of the C-terminal residue; the second (Type B) contain the hydrophobic group X as either an amide or ester functionality at the C-terminus. In both families, it is not possible to relate the crystal structure directly to the taste properties of the molecules. The solid-state conformation is determined primarily by packing forces. Therefore, it is not possible to assign bioactive conformations on this basis alone.

Examination of the molecules in solution using NMR spectroscopy and computer modeling has led us to propose a general structural model for the sweet and bitter tastes of these molecules. For sweet molecules an L shape is required, in which the zwitterionic ring of the N-terminal residue forms the stem of the L and the hydrophobic group X forms the base of the L. The two groups are coplanar. For bitter molecules, the orientation of the zwitterionic ring is identical, but the hydrophobic group X exhibits a large -*z* coordinate. All other topochemical arrays lead to tasteless molecules. The work presented in this review clearly demonstrated that all of the sweet molecules have accessible coplanar L-shaped structures; those molecules that are not sweet cannot assume these L-shaped structures.

Our model also incorporates many features of other molecular models for sweet taste described in the literature. However, as a result of the correlation and comparison of molecular structures, our model overcomes the limitations of other published structural studies. We are currently examining other peptidomimetic and non-peptide molecules to further refine and to test the the general predictive ability of our model.

The authors gratefully acknowledge the financial support of the National Institutes of Health (DE05476).

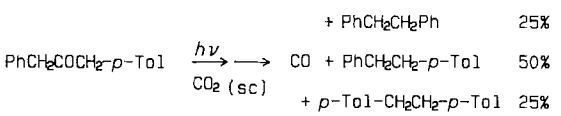
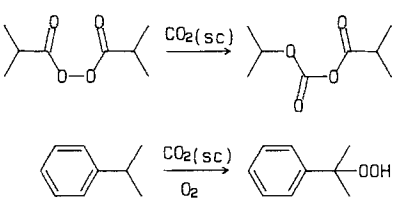
Reactions in Supercritical Carbon Dioxide



Gerd Kaupp*

The increasing global stress on the environment due to atmospheric pollutants from anthropogenic sources, in addition to those stemming from natural emissions, necessitates certain restrictions, for example on the use of organic solvents. For instance, lacquering is more and more frequently performed in a solvent-free fashion, and a great deal of effort is being made to avoid organic solvents in chemical syntheses, through the use of crystal photolyses,[1] gas/solid reactions,[2] and solid/solid reactions.[3] An additional environmentally friendly approach is the use of supercritical carbon dioxide $CO_{2(sc)}$ as solvent for chemical syntheses. It is nontoxic, cheap, and nonflammable. It has already proven useful in some large-scale extraction processes in the food industry (e.g., decaffeination of coffee or extraction of hops).[4] In these processes, pressure or density changes lead to solubility variations which can also be exploited for chemical reactions in $CO_{2(sc)}$.

The favorable ecological properties of CO_2, especially when it is used in a closed loop system, are counterbalanced by the effort and expense associated with the use of high-pressure installations. High-pressure operations are more readily realized in large-scale production processes than in university or research laboratories. These suffer not only from an increasing lack of funding, but also from the continually changing safety directions and lack of clearly assigned responsibilities. This has deterred academic researchers from undertaking and teaching high-pressure experiments. This misdirected development must be halted because of the detrimental effects on the environment. Many syntheses that cannot be performed as solid-state reactions rely on the use of inert solvents of medium polarity, which are frequently delicate. Therefore $CO_{2(sc)}$, with the critical temperature, pressure, and density values of $T_c = 31.06\,^{\circ}C$, $p_c = 73.83$ bar, $D_c = 0.467\,g\,mL^{-1}$, ought to be utilized.[5] In terms of polarity, $CO_{2(sc)}$ [Dimroth-Reichardt $E_T(30)$ value of 32[6]] is roughly comparable to carbon tetrachloride. However, differences remain when the Kamlet–Taft π^* solvatochromicity parameter ($\pi^* = -0.2$) [7] is taken into account. Thus, $CO_{2(sc)}$ could be used as a replacement for commonly used organic solvents. Until now, however, it appears that most experiments have been primarily governed by academic curiosity.

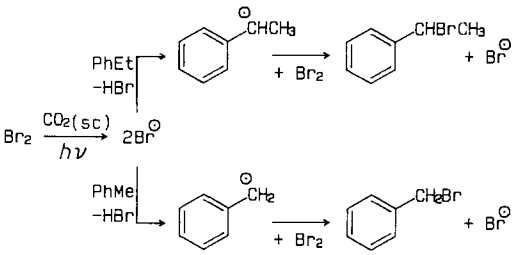


Diels–Alder reactions have shown no discontinuities in reaction rates when liquid CO_2 is replaced by $CO_{2(sc)}$, as long as the density is kept constant.[8] The reaction rates were roughly equal to those in solvents at normal pressures.[9, 10]

Laser flash photolysis studies of benzophenone with H donors in $CO_{2(sc)}$ have shown that the local substrate clusters, which are considered crucial for the reactivity, exchange rapidly (in picoseconds) with the supercritical medium.[11] The photochemical α-cleavage of asymmetric benzyl ketones also indicated that there is no cage effect for radical recombinations in $CO_{2(sc)}$.[12] The products are formed in a statistical ratio (see Scheme 1).

Scheme 1. Tol = tolyl.

The carboxy inversion of diacyl peroxides has been interpreted as being an ionic reaction. In $CO_{2(sc)}$ it proceeds with a 17% yield (40 °C, $d = 0.93\,g\,mL^{-1}$), but slower than in CCl_4 or $CHCl_3$ (Scheme 2).[7] Radical chain reactions like the well-known oxidation of cumene to cumene hydroperoxide also led to lower yields in $CO_{2(sc)}$ (110 °C, 200–414 bar), probably because it was not possible to prevent chain termination reactions due to the metal container (Scheme 2).[13]



Scheme 2.

Recently, however, a number of studies were published which demonstrated that radical brominations[14] and polymerizations,[15] hydroxyformylations,[16] CO_2 hydrogenations,[17] catalytic additions/cycloadditions on CO_2,[18, 19] and enzymatic reactions[20, 21] in $CO_{2(sc)}$ can proceed providing better (or roughly equal[19]) results than the corresponding reactions in conventional solvents.

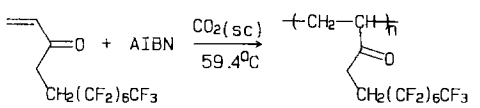
The bromination of toluene with bromine in $CO_{2(sc)}$, photochemically initiated through a sapphire window, led to benzyl bromide (74%) and 4-bromotoluene (11%). Ethylbenzene afforded 1-bromo-1-phenylethane in 95% yield (Scheme 3).[14] In

Scheme 3.

order to demonstrate that uncomplexed bromine atoms act as chain propagators, toluene and ethylbenzene were photobrominated in a competition study at pressures of 75 to 423 bar and at 40 °C. Over the entire pressure range, the reactivity of the benzylic secondary C–H bond in ethylbenzene was found to be about 30 times greater than that of the corresponding primary C–H bond in toluene. The analogous value for the reactivity in CCl_4 at 40 °C is 36. The bromine atoms in $CO_{2(sc)}$ are therefore particularly free. It would be important to determine quantum yields (chain lengths) at various pressures to learn more about mechanistic aspects and other details of the reaction.

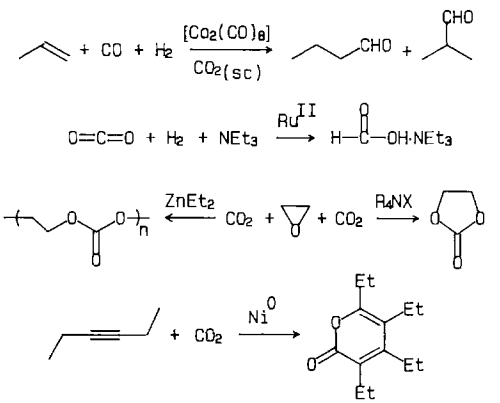


The same study[14] also dealt with the heterogeneous *N*-bromosuccinimide (NBS) bromination (Ziegler bromination; Scheme 4) of toluene in $CO_{2(sc)}$. The reaction (40 °C, 170 bar,

Scheme 4.

4 h) was initiated photochemically with azobis(isobutyronitrile) (AIBN). In CCl_4, this reaction proceeds without succinimidyl radicals, with the same selectivity as the direct bromination. The yield is quantitative on the 4 mmol scale; no 4-bromotoluene is observed.

Homogeneous fluoroalkene polymerizations (and copolymerizations) also proceed in $CO_{2(sc)}$ after AIBN initiation.[15] In this case it is advantageous that highly fluorinated polymers ($> 250000\ g\,mol^{-1}$) and copolymers are very soluble (up to 25%) in $CO_{2(sc)}$ at high pressures. This means that no chlorofluorocarbons must be employed as solvents. The homopolymer ($270000\ g\,mol^{-1}$) shown in Scheme 5 can be obtained from

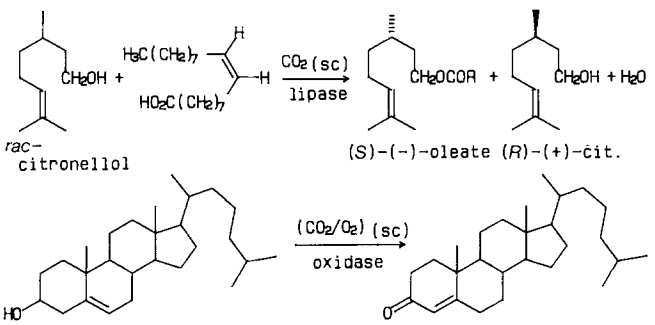


FOA

Scheme 5.

FOA in $CO_{2(sc)}$ (59.4 °C, 207 bar, 48 h, no Trommsdorff effect[15]) in 65% yield. The product can be precipitated from the homogeneous solution by pressure release. It would be useful, however, to develop a workup procedure that does not offset the use of $CO_{2(sc)}$ by the necessity to dissolve the raw product in 1,1,2-trifluorotrichloroethane. Statistical copolymers of FOA are also surprisingly soluble in $CO_{2(sc)}$. The kinetic parameters of the thermal AIBN decomposition in $CO_{2(sc)}$ have been determined accurately, and 1,1-difluoroethylene was telomerized correspondingly.[13] The basis for applications has been established.

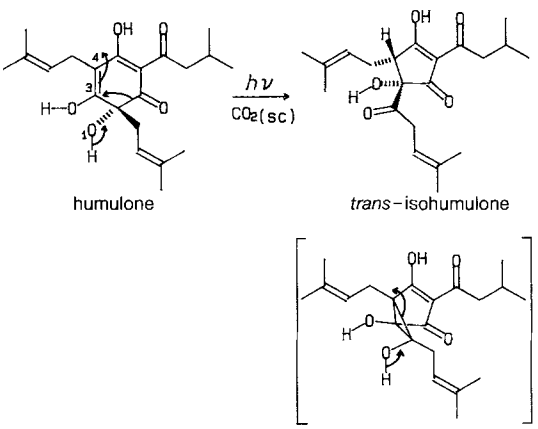
$CO_{2(sc)}$ is an inert solvent for radical reactions. This is also true for cobalt-catalyzed hydroformylations of propene and other alkenes to the corresponding aldehydes.[16] These reactions profit from the good miscibility in $CO_{2(sc)}$ (Scheme 6). The



Scheme 6.

reaction mixture is less viscous, which leads to sharp ^{59}Co NMR signals (quadrupole nucleus), which in turn allows the identification of the catalytically active species by high-pressure NMR spectroscopy. The hydrogenation of double bonds is not a competing reaction in this instance. There are Ru^{II} catalysts, however, which hydrogenate the C_1 building block CO_2 homogeneously to formic acid as long as this reaction is coupled to salt formation. The reaction in $CO_{2(sc)}$ (50 °C, 86 bar H_2, 207 bar CO_2, dissolved NEt_3) proceeds with the highest rate of the numerous variants of this reaction, namely 1400 mole of formic acid per mole of catalyst per hour. This turnover frequency (TOF) is reduced to $1.3\ h^{-1}$ for the same composition when liquid CO_2 (at 15 °C) is employed. All other high-pressure variants of this reaction in liquid solvents yield much lower TOF values.[17] This behavior indicates the favorable effect of the high solubility of H_2 in $CO_{2(sc)}$ as well as the high mass transport rate. The well-known and well-studied copolymerizations of CO_2 and oxiranes and their cycloadditions to cyclic carbonates such as ethylene carbonate (Scheme 6) have also been successfully performed in supercritical mixtures.[18] It turned out, however, that the industrial production of ethylene carbonate (similar to propylene carbonate) in a liquid (product) phase (190–200 °C, total pressure 80 bar) is more economical for capacities of 4000 t per year and installation when it is run nearly stoichiometrically.[22] In the cases of substituted or polycyclic oxiranes, solvents are usually added and 1 to 40 bar of CO_2 are

introduced, depending on the catalyst employed.[18] Homologous cyclic ethers (oxetanes, tetrahydrofurans, etc.) are also expected to undergo cycloaddition to CO_2 and should be tried in $CO_{2(sc)}$. A [2 + 2 + 2]cycloaddition of two moles of 3-hexyne to one mole of CO_2 in the presence of the catalyst $[\{Ni(cod)_2\}Ph_2P(CH_2)_4PPh_2]$ and of benzene (25 °C, 50 bar, 20 h at 120 °C), led to tetraethylpyranone (57%) (Scheme 6).[23] A preliminary attempt to improve this yield by using the same catalyst in $CO_{2(sc)}$ failed (102 °C, 93 g of CO_2 in 200 mL, 69 h, 35%).[19] It appears, however, that attempts to improve this yield are still in progress in spite of a number of experiments that have reproduced it.[19]



Enzyme-catalyzed esterifications (immobilized lipase MY) of *rac*-citronellol with oleic acid in $CO_{2(sc)}$ close to the critical point led stereoselectively to 1.2–5.8% of citronellol oleate (Scheme 7).[20] Only at the critical temperature (31 °C, 84 bar)

Scheme 7.

does the (*S*)-(−)-citronellol oleate form with 99% optical purity. Even small temperature increases (4–9 °C) led to a drastic reduction of the optical purity; pressure increases (up to 190 bar) had the same effect. This result was explained by the formation of clusters near the critical point, where pressure and temperature changes have particularly strong effects. No esterification took place in water-saturated cyclohexane. Good yields (75% at a residence time of only 13 s) were reported for the enzymatic oxidation (immobilized cholesterol oxidase from *G. chrysocreas*) of cholesterol in supercritical CO_2/O_2 (9:1) (Scheme 7).[21] Co-solvents, like *tert*-butyl alcohol, that increase the solubility and, to an even larger extent, those that assist aggregate formation, increase the rate of the reaction (fourfold in this case). Further examples for biocatalyses in $CO_{2(sc)}$ are summarized in reference [24].

Apparently, unnoticed by the recent studies, the photolysis of hops extracts in $CO_{2(sc)}$ has been developed into an established industrial process.[25] The $CO_{2(sc)}$ extract contains the so-called α-acids (vinylogous carboxylic acids), for instance humulone, which are primary bittering agents with limited stability. These are isomerized into α-isoacids, such as *trans*-isohumulone (Scheme 8), stable and more soluble bittering agents, which give beer its characteristic taste. The conventional brewing method achieved this transformation in low yields by boiling the hops in the wort. It is more efficient to add the ingredients stemming from hops to the cold finished beer. This, however, requires the isomerization of the air-sensitive α-acids to be performed photochemically in the $CO_{2(sc)}$ extract before the addition to the beer.

Scheme 8.

The quantum yield ϕ is 0.03. The mechanism of this [1,2,3,4] rearrangement[26] is unknown. Formally, the reaction can be considered an H migration from the OH group to the end of a four-membered chain with a concomitant acyl group migration from position 2 to 3 within that chain. According to the current canon of photochemistry, an oxa-di-π-methane rearrangement with subsequent [1,3]-H-migration and ring opening was formulated.[25] It is said that this procedure affords special protection to the flavors of the hops ingredients.

The current state of knowledge indicates the versatility of $CO_{2(sc)}$ as a reaction medium and gives reason to be optimistic that in the future more reactions will be carried out in the ecologically sound $CO_{2(sc)}$ (closed loop systems) rather than in organic solvents. The theoretical and mechanistic basics have essentially been established and a great deal of practical knowledge has been acquired from the widespread extraction processes utilizing $CO_{2(sc)}$. Therefore nothing should stand in the way of further industrial applications. For teaching purposes, it can only be hoped that textbooks on experimental techniques will soon include material about "unusual reaction media".

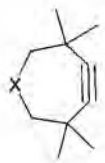
Triple Bonds in Small Rings: Testing the Limits of Chemical Bonds

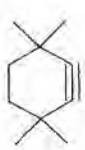
Wolfram Sander*



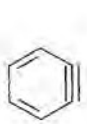
Since the pioneering work of Wittig et al.[1] on strained cycloalkynes, molecules with triple bonds deviating significantly from linearity have fascinated chemists. Cyclooctyne (**1**) is the last carbocyclic parent compound that is stable under "normal" conditions. The deviation from linearity in this compound, 21.5°,[2] is reflected in its increased reactivity. Cycloheptyne (**2**), bent by 30–35°, has a half-life of only one hour at −76 °C. To stabilize smaller cycloalkynes either substituents that suppress dimerization must be introduced α to the triple bond, or heteroatoms X (Si, S) with long C–X or X–X bonds must be incorporated in the ring to reduce ring strain. In the 1970s Krebs et al. used this approach to synthesize a series of derivatives of cycloheptyne (**2**) and characterize them chemically and by spectroscopy.[2] Tetramethylcycloheptyne **2a** can be isolated at room temperature, and thiacycloheptyne **2b** and silacycloheptyne **2c** are even more stable.

1 $n = 6$
2 $n = 5$
3 $n = 4$
4 $n = 3$
5 $n = 2$
6 $n = 1$

2a

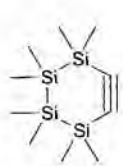


2b X = S
2c X = Si



Carbocyclic derivatives of cyclohexyne (**3**) are considerably more reactive than **2** and are thus isolable only at low temperatures by matrix techniques. Wentrup et al.[3] reported on the matrix isolation of the parent compound, cyclohexyne (**3**), which could be characterized only by a pair of IR bands at 2105 and 2090 cm^{-1}. The tremendous reactivity of **3** was evident in studies of tetramethylcyclohexyne **3a**,[4] which dimerizes already at temperatures below 77 K. The first step in the dimerization is the abstraction of a hydrogen atom from one of the methyl groups, which is indicative of the strong diradical character of **3a**. Thus α-methyl groups do not suffice to effectively stabilize cyclohexyne. **3a** undergoes photochemical carbonylation to yield the corresponding cyclopropenone;[4] in contrast, cycloalkynes with larger rings can be prepared by irradiation of cyclopropenones.[5]

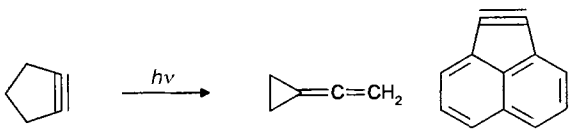
The derivative of cyclohexyne that has been investigated most thoroughly is *o*-didehydrobenzene (**3b**). Chapman et al.[6] reported on the matrix isolation of **3b** in the 1970s. The question of the position of the C≡C stretching vibration, which should give information on the strength of the triple bond, was disputed for some time and first determined in 1992 by Radziszewski et al.[7]



Recently Ando et al.[8] isolated the first six-membered cyclic alkyne at room temperature. Tetrasilacyclohexyne **3c** has an impressive half-life of 8 h in decane at 174 °C! This cycloalkyne is stabilized both by steric shielding and the long C–Si and Si–Si bonds.

3a

3b



3c

To date the single derivative of cyclopentyne characterized unequivocally by spectroscopy is acenaphthyne **4a**, which was

obtained by Chapman et al.[9] in several steps by irradiation of a matrix-isolated diazoketone. Cyclopentyne (**4**) could not be prepared by this route, since this cycloalkyne is photolabile and rearranges to ethenylidenecyclopropane by a photochemical [1,3] shift.

4 **4a**

ameter of 1 mm was used; and the products were trapped directly on a cold spectroscopic window. The reaction of disilane **7** under these conditions allowed easy access to the C_2H_2Si potential energy surface. In agreement with the calculations of Schaefer et al.[13] the thermolysis yielded 1-silacyclopropenylidene (**8**)

7 **8** **6a**

Only calculations are available for cyclobutyne (**5**) and cyclopropyne (**6**), as spectroscopic proof is lacking. Extensive ab initio calculations by Schaefer III et al.[10] predict an activation barrier of 25 kcal mol^{-1} for the rearrangement of **5** into butatriene. This indicates that cyclobutyne (**5**) should be isolable in a matrix; however, suitable precursors have not yet been available for testing these predictions. Based on the typical scaling of calculated harmonic frequencies, a medium-intensity IR absorption of the triple bond is expected at 1800–1850 cm^{-1}. In contrast to **5**, the structure of cyclopropyne (**6**) does not correspond to a minimum on the potential energy surface but to the transition state for the degenerate rearrangement of propadienylidene.[10]

Considering all this, the successful synthesis and characterization of a three-membered ring compound with a C≡C bond by G. Maier, H. P. Reisenauer, and H. Pacl[11] is even more remarkable. The key here was the application of a new technique in gas-phase pyrolysis, which has considerable advantages over standard flash vacuum pyrolysis (FVP). This new method, first described by Chen et al.,[12] serves to decrease the typical contact times in flash pyrolysis from 1–100 ms to roughly 10 μs. Conditions in a conventional pyrolysis reactor include pressures of $\approx 10^{-3}$ mbar, temperatures from 400 to 1000 °C, and heating zones several cm in length; with the new experimental set-up pressures of roughly one bar, temperatures of up to 1700 °C, and very short heating zones only a few mm in length with pyrolysis tube nozzles having small cross-sections are employed. The precursor is mixed with a large excess of helium, and the gas mixture is cooled to 40 K by adiabatic expansion (jet-cooled) immediately after leaving the pyrolysis zone. The molecular beam is pulsed through a magnetic valve to maintain the high vacuum on the side of the expanding gas flow. In this experiment the sample is subjected to a temperature gradient of over 1600 K within 50 μs. In conventional flash pyrolysis the mean free path exceeds the dimensions of the reactor, and energy is thus transferred by collisions with the walls. Undesired reactions frequently occur with the result that very reactive molecules such as diradicals and carbenes do not "survive" these conditions and "stick" to the walls of the reactor. In the method described by Chen et al. energy is transferred by collisions with the inert gas and is thus much gentler.

Maier et al.[11] combined this method with the matrix isolation technique. Helium was replaced with argon; instead of a pyrolysis oven a heated corundum capillary with an inner di-

as the most stable C_2H_2Si isomer. Photolysis with monochromatic light led selectively to a series of C_2H_2Si isomers such as ethynylsilylene and vinylidenesilylene, which previously had been studied only theoretically and each of which are the first examples of their respective classes of compounds. A further C_2H_2Si isomer formed reversibly from **8** was assigned the structure of 3-silacyclopropyne (**6a**). The calculations by Schaefer et al.[13] predict that this structure, like cyclopropyne, does not correspond to a minimum on the potential energy surface but rather to a transition state. However, in comparison to cyclopropyne and relative to the open-chain reference compounds, silacyclopropyne was judged to be stabilized by the silicon atom by roughly 30 kcal mol^{-1}. Only when correlation interactions are considered (MP2/6-31G(d,p)) is a minimum found, and the calculated IR absorptions now agree quite well with the experimental.[11]

The research group of G. Maier has succeeded in characterizing the first cyclopropyne, a molecule previously not considered to exist. Is this compound a cycloalkyne or a diradical? How large is the singlet–triplet gap, and how does the tremendous ring strain affect the reactivity? Answers to these questions are eagerly awaited.

Enantioselective Reactions in a Static Magnetic Field—A False Alarm!

On August 20, 1993, we received a communication from E. Breitmaier, Bonn, in which he, together with his coauthors, G. Zadel, C. Eisenbraun, and G.-J. Wolff, reported on "Absolute Asymmetric Syntheses in a Static Magnetic Field". In view of the potential importance of the disclosed results, the communication was immediately sent to three referees. Referee A recommended acceptance with minor alterations ("The results must be regarded as being of great importance to this field. They should be published in Angewandte Chemie with minor alterations."). Referee B requested major changes, and referee C recommended rejection. On September 22, the correspondence author was then informed that the manuscript would have to be revised before a decision could be made (the referees' reports were enclosed with the letter).

On September 29, we received a revised manuscript with the modified title "Enantioselective Reactions in a Static Magnetic Field". In the accompanying letter, the author commented on the two critical reports; in particular, the points not taken into consideration in the revised version were addressed. The new manuscript and the accompanying letter were presented to referees B and C, whereupon referee B then agreed to publication. He wrote, "The importance of these disclosures is such that they must now be made available to our professional colleagues in order to allow an international debate to take place." Referee C remained unconvinced. "This work is inherently flawed and is not suitable for publication." Both responses—each just under a page long—were sent to the correspondence author on October 11, together with a request that he examine the points raised. On October 13, he replied that the editorial office should not rush their decision on whether to publish, since "the results and potential applications have already been documented in a patent application." The correspondence author was then informed by telephone that the manuscript would be printed in the "most concise form possible."

Not long afterwards, in a letter dated October 24, the correspondence author asked for a delay in publication: "Next week our laboratory will be receiving a cryomagnet (4–5 tesla) on loan. We would like to repeat some of the experiments described in the communication before we send you the final version of the manuscript. Also, in view of the heavy criticism raised by one of the referees, we would once again like to carefully check the reproducibility of our results. The experiments will be completed by the beginning of December." The final version of the manuscript was received on December 8. The accompanying letter stated: "As explained previously, we have, once again, reproduced the most important experiments in response to the heavy criticism; in these experiments, a cryomagnet, which is at present charged to 2.1 tesla, was used. We have included 1-phenylpropanol as an additional example; *N*-methylamphetamine has been omitted as a precaution, since this compound is a highly active designer drug and a very desirable target. I hope that this version meets with your approval." The manuscript was then edited and published.[1]

The publication met with an enthusiastic response,[2] but even at an early stage misgivings were voiced. One such occasion was the discussion organized at short notice during this year's Bürgenstock "Stereochemistry Conference" in Switzerland,[3] where the coauthor G. Zadel presented the results.

The whole affair culminated at the beginning of June with two contributions to the Correspondence section describing many failed attempts at reproducing the results.[4, 5] These were sent to E. Breitmaier with a request that he respond to them by June 17. On June 21, E. Breitmaier broke the news to us that the coauthor G. Zadel had, after reinvestigation of his working procedure by other co-workers of the group,[6] confessed to having manipulated the reaction solutions prior to the experiments and that all results reported in the publication[1] must therefore be regarded as invalid.[6]

The most critical of the three referees was right, and I regret not having taken his advice. This publication certainly generated much excitement, and many groups worldwide invested time and money as a result, a situation which could have been avoided.[7] But, all too often, the established "peer review" system is accused of stifling unconventional publications which might introduce a paradigm change.[8] Had they been correct, the results described in the publication would have been of such great importance, regardless of how they might have been explained, that preventing publication would have been untenable.

Attempts to Carry Out Enantioselective Reactions in a Static Magnetic Field

Ben L. Feringa,* Richard M. Kellogg,* Ron Hulst, Charon Zondervan, Wim H. Kruizinga

In a recent article in this journal Zadel, Eisenbraun, Wolff, and Breitmaier reported enantioselective reactions in a static magnetic field.[1] The results were dramatic: prochiral aldehydes were treated with aliphatic Grignard reagents to produce (chiral) alcohols with enantiomeric excesses (*ee*) of 57–98%, and reductions of some aryl alkyl ketones with lithium aluminum hydride (LAH) proceeded with 11–68% *ee*.

These results have produced excitement in the chemical community. At an informal meeting during the recent Bürgenstock Stereochemical Conference in Switzerland Dr. Zadel reported on these remarkable experiments to a large group of highly interested stereochemists. The interest stems first from the fact that these results seem to contradict straightforward theory from which one concludes that static magnetic fields are not chiral.[2] Previous claims of enantioselective syntheses in magnetic fields have been shown to be spurious; a recent example not cited in reference [1] involves the electrochemical reduction of α-keto acids in magnetic fields.[3, 4] Circumventing these theoretical barriers might be possible; we mention, for example, the concept of "true" and "false" chirality as introduced by Barron.[5] Another possibility is that a small stereochemical bias might be amplified by a large nonlinear effect[6] or asymmetric autocatalysis.[7]

From the practical side these claims of enantioselective reactions could have profound implications for the manner in which asymmetric synthesis is carried out in academic and industrial laboratories. In an extreme scenario the painstakingly developed methods relying on chiral auxiliaries and optically active catalysts could be supplanted by simply conducting reactions in large magnets.

Independent confirmation of these important experiments is clearly of great importance to the chemical community.

We have repeated the Breitmaier experiments in our own laboratories with magnets having flux densities of 0.3 and 1.2 Tesla. In addition our colleague Prof. Bert Meijer in Eindhoven has also carried out these experiments in magnets available to him and has obtained results fully analogous to ours as described below. We have also contacted Prof. Breitmaier and have carried out experiments in his laboratories in Bonn with the same magnets used in his original work. Glassware and chemicals were brought from our laboratories, and the enantiomeric excesses were determined in Groningen.

We take this opportunity to express our sincere appreciation to Prof. Breitmaier and his co-workers for their hospitality, as well as openness and cooperativity in helping us to reproduce these experiments. The results of our experiments are summarized in Tables 1 and 2.

Table 1. Reduction of acetophenone [a] by addition to LAH.

Run	B_o [T]	LAH [mg]	Solvent	Aceto-phenone [a]	t [d] [min]	Con-version [%]	Isolated yield [%]
1 [b]	0.3	90	2 mL THF/ 2 mL C_6H_6	200 mg in 200 μL C_6H_6	30	100	86
2 [b]	0.3	80	2 mL THF/ 2 mL C_6H_6	204 mg in 1 mL C_6H_6	60	100	91
3 [b]	0.3	122	2 mL THF/ 2 mL C_6H_6	300 mg in 3 mL C_6H_6	60	100	86
4 [b]	0.3	80	2 mL THF/ 4 mL C_6H_6	206 mg in 200 μL C_6H_6	75	100	82
5–8 [b]	0.3	Runs 1–4 repeated in C_6H_6; comparable conversions					
9–12 [b]	0.3	Runs 1–4 repeated with twice the concentrations; yields ca. 70–75%					
13–15 [b]	0.3	Runs 1, 3, and 4 repeated in 1.5 mL THF and 0.5 mL C_6H_6; comparable conversions					
16–18 [b]	0.3	Runs 1, 3, and 4 repeated in 0.5 mL THF and 1.5 mL C_6H_6; comparable conversions					
19 [b]	0.3	Run 1 repeated in THF; comparable conversion					
20 [b]	0.3	130	1 mL THF	359 mg in 2.5 mL C_6H_6 [a]	40	100	> 75
21 [b]	0.3	25	0.6 mL THF/ 1.3 mL C_6H_6	90 mg in 2 mL C_6H_6 [a]	45	100	95
22 [c]	0.3	80	2 mL THF/ 4 mL C_6H_6	289 mg [a] in 6 mL C_6H_6	60	90	69
23–26 [b]	1.2	Runs 1–4 repeated; comparable conversions					
27–43 [b]	1.2	Runs 5–21 repeated; comparable conversions					
44 [c]	2.3	80	2 mL THF/ 4 mL C_6H_6	228 mg [a] in 6 mL C_6H_6	60	90	69

[a] Acetonaphthone was used in runs 20–22, propionaphthone in run 44. [b] Experiments conducted in Groningen. [c] Experiments conducted in Bonn in the Breitmaier laboratory. [d] Addition time.

All experiments were performed using Schlenck techniques except for the experiments conducted in Bonn, which were carried out without special precautions. Solvents were dried over Na/K. The solutions were added through a Teflon tube attached to a stainless steel needle that was kept 2–3 mm above the surface of the solution. Alternatively, the Teflon tube without an attached stainless steel needle was kept 2–3 mm above the surface of the solution. The experiments were performed at room temperature.

Table 2. Reaction of benzaldehyde with CH_3MgI in a magnetic field flux of 0.3 T.

Run	CH_3MgI	Benzaldehyde	Addition time [min]	Conversion [%]	Isolated yield [%]
1 [a]	1.4 mmol in 1 mL Et_2O	100 µL in 0.2 mL C_6H_6/ 1 mL Et_2O	60	100	80
2	Run 1 repeated; addition over 90 min; comparable conversion				
3 [b]	2.7 mmol in 3 mL Et_2O	300 µL in 0.2 mL C_6H_6/ 1 mL Et_2O	90	100	80

[a] The solution of benzaldehyde was added to the Grignard reagent. [b] The Grignard reagent was added to the solution of benzaldehyde.

Two magnets were used in Groningen: a 0.3 T permanent horseshoe magnet with a homogeneous magnetic field between the poles, dimensions: 4 cm (diameter) × 3 cm (separation); and an electromagnet (Bruker B-E 20 C 8) adjusted to 1.2 T with a homogeneous field between the poles, dimensions: diameter 7.8 cm (diameter) × 3 cm (separation). The field strengths were checked with a Gaussian meter. The magnets used in Bonn were like those described in reference [1]; the Bruker magnet was adjusted to 2.3 T. The field strengths were not checked.

The reaction mixtures were quenched with an excess of water and extracted with ether. Conversions were determined by ^1H NMR spectroscopy (300 MHz, recorded in $CDCl_3$) or gas chromatography (GC). Optical rotations were measured in methanol or toluene, and the enantiomeric excesses were determined by GC using a chiral column (WCOT fused silica, CP-cyclodextrine-β-2,3,6-M-19, 0.25 mm × 50 m, 7501 Chrompack). Baseline separations were obtained in all cases. The experimental error in the *ee* determination is estimated to be 1%. In no case did we observe a distribution of enantiomers that deviated within experimental error from a 50:50 ratio.

At this time on the basis of the experiments that have been carried out, we must conclude that we have been unsuccessful in reproducing the Breitmaier results. At the request of the editor of *Angewandte Chemie* we make these initial results available.

Absolute Asymmetric Synthesis Solely under the Influence of a Static Homogeneous Magnetic Field?

Gerd Kaupp* and Thorsten Marquardt

Absolute asymmetric synthesis is of utmost importance for the origin of chirality on earth. The physical and chemical foundations for the generation of chirality in the absence of chiral auxiliaries are well known.[1] Therefore it was surprising to read of the claim in a publication by Breitmaier et al.[2] that solely the application of a static homogeneous magnetic field (with a strength of 0.2–2.1 T) induces efficient (*Re*)/(*Si*) differentiation in homogeneous solutions of aromatic aldehydes and ketones when they are reduced or added to Grignard reagents (Scheme 1). It was mentioned that the alcoholates formed precipitate in gelatinous form. The *ee* values of the isolated alcohols were claimed to be very high (up to 98%) and easily reproducible.[2] (*R*) and (*S*) products were reported to form at random but always with the same *ee* value.[2]

$$ArCRO + LiAlH_4 \longrightarrow ArCHR(OH) \longleftarrow RMgX + ArCHO$$

However, contrary to scientific practice, no explanation or comment was given regarding the basic question that inevitably arises: how can a homogeneous magnetic field alone create face differentiation in violation of basic principles? These circumstances should have halted publication of the paper but of course not its rapid dissemination through secondary bibliographical literature[3] after publication. Scrutiny of the case is, however, also required owing to possible implications in research funding policies. Supporting agencies and their referees should not judge the important field of absolute asymmetric synthesis as being unnecessarily complicated.

A *theoretical analysis* reveals severe self-contradictions in the work of Breitmaier et al.[2] A static magnetic field in its homogeneous range is clearly directional but not chiral. Therefore it cannot create chirality in the form of *ee* values in reactions of achiral molecules in the absence of further directional fields. It does not help to invoke the Faraday effect, which is well known from magnetooptic rotational dispersion, or magnetic circular dichroism. Only the superposition of additional directional fields could give rise to chiral field action.[4]

Breitmaier et al. reported[2] that the same reaction in the same magnetic field gives (*R*) and (*S*) products randomly though with the same *ee* values. For symmetry reasons one would have to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1414-1459 $ 10.00+.25/0

conclude that the direction of the unknown chirality-donating additional fields in relation to the magnetic field is reset at random prior to every new run. Such a proposal cannot be considered seriously. Therefore, any analysis of the results of Breitmaier et al.[2] would have to be based on a chemical explanation.

The formation of gelatinous precipitates after the dropwise addition of the reagents into homogeneous solutions is mentioned very briefly in the publication. If we try to devise a model for the action of the magnetic field on the chemical reaction based on this observation, we will again fail due to symmetry reasons. Contrary to self-seeding in the crystallization of achiral molecules that organize in chiral space groups, an event that may yield only one kind of enantiomorphous crystals if the process is highly effective,[1, 5] there is no similar mechanism for the selective precipitation of chiral alcoholates from a homogeneous solution even under the influence of a homogeneous magnetic field. Thus, the products that might eventually precipitate in microcrystalline form must first be generated chemically. That means, any face differentiation would have to occur prior to the precipitation.

At constant field direction (note the relation to possible additional fields) the authors report that either (*Re*) or (*Si*) reactions predominate at random[2] (that is to say from the beginning until the end of the run) and that the reagents are added dropwise to the homogeneous solution. Therefore the gravitational field cannot be invoked. Since the magnetic field is achiral, there cannot be (*Re*)/(*Si*) differentiation at this stage, and the (local) transgression of the solubility product for the (*R*) alcoholate occurs at the same time as that for the (*S*) alcoholate. Enantiomeric (*R*) and (*S*) crystallites will precipitate side by side if the system does not favor amorphous phases or racemic mixed crystals instead. In the former case it would be conceivable that the directional magnetic field might select between the enantiomorphous species of crystals if it is assumed that these crystals may in some way enantioselectively catalyze the primary reaction while the reagent is added to the solution. However, even this model of magnetic activation of chiral catalysts is not applicable here, because it is reported that either the (*R*) or the (*S*) products predominate at random.

Furthermore according to Breitmeier et al. seeding (only in the magnetic field) with the (*R*) product results in the formation of the (*R*) product with a high *ee*-value, and seeding with the (*S*) product has the opposite effect.[2] For symmetry reasons similar inconsistencies would also emerge with other explanations. Therefore, it must be concluded that the experiments of Breitmaier et al.[2] can be reproduced only if further unspecified requirements are fulfilled.

Accordingly, our *attempts at verification* failed. We requested more detailed reaction conditions from the correspondence author, who provided some "tips"[6] which were more detailed than the experimental description in reference [2]. We followed these guidelines as closely as possible, even though we could not always understand their purpose (the end of the needle used in the addition should be centered within the field about 0.5 cm above the solution of substrate or reagent; addition should be very slow; one should not stir but pass a very slow stream of nitrogen through the solution or move the flask occasionally; diethyl ether or tetrahydrofuran (THF) may be used instead of diisoamyl ether; the aldehyde may be added to the solution of RMgX in ether/benzene, which is centered in the magnetic field; the choice of magnet was not critical in Bonn: a permanent magnet 0.35 T, 7 cm, an electromagnet 0.2–1.4 T, 7 cm, and a cryomagnet 2.1 T, 15 cm, were all successful in Bonn). We still obtained products with *ee* values of zero.

In our experiments we used the homogeneous magnetic field of a 90 MHz Perkin-Elmer R 32 NMR spectrometer without the probe inserts. As we had set out to prove or disprove expressly the claim that contrary to elementary principles[4] an achiral magnetic field solely might create the *ee* values,[2] we applied our magnetic field as efficiently as possible and used a vessel for the reported scale of the reaction that filled the homogeneous field space as completely as possible. This deviation from the conditions at Bonn (50 mL three-necked flask centered in the homogeneous range) should enforce any magnetic field action whatsoever, but not decrease it.

We never detected any optical rotation for the reaction products [pure enantiomer: $[\alpha]_D = \pm 46.3^\circ$ ($c = 1$, toluene)] in the reactions of acetophenone with $LiAlH_4$ and of benzaldehyde with CH_3MgI when the carefully worked-up raw material was analyzed polarimetrically (detection limit of the Polarotronic Universal of Schmidt and Hensch: $\alpha = \pm 0.01^\circ$; $d = 20$ cm). We conducted eight different runs with numerous variations according to reference [2] and later on taking into account the "tips" we received.[6]

Our *reaction flask* consisted of a glass cylinder which was flattened at its closed end (width 5.0 cm, o.d. 1.00 ± 0.01 cm, i.d. 0.60 ± 0.01 cm, filling height initially 2.0 cm, after addition of the reactants 4.0 cm; addition time ≥ 2 h; pole distance 1.4 cm; pole diameter 7.5 cm; distance between addition needle and surface of the reaction mixture 6–8 cm and 0.5–1.5 cm). The flask was fixed as close to the center of the magnetic field as possible with an external clamp and flushed with argon prior to the experiment. A strong or weak or no stream of argon was passed through the solution (in the latter case the vessel was shaken every 15 min).

The size of the runs was as described in reference [2]. CH_3MgI was prepared in THF or in diethyl ether, and in the latter case the solution was diluted with benzene (1:1 by volume). The chemical yields were quantitative in the reductions with $LiAlH_4$ and 85–95% in the Grignard reactions. Every reaction was terminated while still in the magnetic field by addition of water, and NH_4Cl was used for neutralization. The diethyl ether extracts were concentrated to dryness under vacuum, diluted with toluene up to a volume of 10 mL, and analyzed polarimetrically.

In view of the complete failure to reproduce either type of claimed absolute asymmetric syntheses in a homogeneous magnetic field, we did not repeat the other examples reported by Breitmaier et al.[2] outside Bonn for reasons of cost. There is no reason to expect to obtain *ee* values different from zero in those cases either.

In *conclusion* we maintain that in the experiments that provided the spectra in Figure 1 in reference [2] particular conditions must have prevailed which were neither mentioned in the publication[2] nor in the private communication.[6] Absolute asymmetric syntheses under the influence of physical fields continue to require that the field be chiral.[4] A homogeneous field alone is not chiral, and it cannot effect (*Re*)/(*Si*) differentiation. This

fact must be stated here plainly in view of the apparent sensation created[3] by the paper of Breitmaier et al.[2]

No Enantioselective Reactions in a Static Magnetic Field

Based on part of the PhD thesis by G. Zadel (completed 1993) and parallel investigations by Catja Eisenbraun the communication "Enantioselective Reactions in a Static Magnetic Field" appeared under my auspices together with G. Zadel, C. Eisenbraun, and G. J. Wolff in this journal (*Angew. Chem.* **1994**, *106*, 460; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 454). Several independent research groups have informed me since that the experiments reported (1,2-addition of Grignard compounds to aldehydes; reduction of prochiral ketones with lithium aluminum hydride), contrary to the results published by us gave no enantiomeric excesses. In light of this I instructed three experienced co-workers from my research group (F. Keller, K. Berlin, and T. Marx) to repeat the most important experiments [reduction of 2-acetylnaphthalene with lithium aluminum hydride to (*R*)- or (*S*)-1-(2-naphthyl)ethanol; 1,2-addition of methylmagnesium iodide to benzaldehyde to give (*R*)- or (*S*)-1-phenylethanol] completely independently from the chief experimentalist (G. Zadel). These co-workers carried out several experiments in Bonn and Karlsruhe, some in my presence but all in the absence of G. Zadel, and could detect no measureable enantiomeric excesses (NMR with $[Eu(hfc)_3]$, GC with β-cyclodextrin, polarimetry). In one case, we were able to prove quite clearly (GC-MS, polarimetry) that the starting solution prepared by G. Zadel for the reduction of propiophenone with lithium aluminum hydride also contained considerable amounts of (+)-1-phenylpropanol in addition to propiophenone. G. Zadel admitted this deception and two other manipulations in front of witnesses. Therefore we must assume that the data in the publication as well as "successful" attempts at reproducing the results by other co-workers in my research group and guest scientists in the presence of G. Zadel came about because of consistent and particularly cleverly disguised manipulations. I therefore wish to disassociate myself and the coauthors C. Eisenbraun and G. J. Wolff from all the experimental results in this publication.

Bond-Stretch Isomers and Spin-State Isomers: A Comment on the Article "Bond-Stretch Isomers: Fact not Fiction"[1]

Gerard Parkin* and Roald Hoffmann

Molecules which differ only in the length of one or several bonds have been termed bond-stretch isomers. The first reports of this phenomenon, both theoretical[2] and experimental,[3] date back to the early 1970s, while the first comprehensive article was published in 1988 by Jean, Lledos, Burdett, and Hoffmann.[4] The 1988 article summarized the phenomenon and provided a theoretical rationalization, and thereby stimulated considerable interest in the subject.

However, in 1991 it was discovered that the original example of bond-stretch isomerism in transition metal complexes was an artifact due to crystallographic disorder[5, 6] Thus, it was demonstrated that the green "isomer" of *cis-mer*-$[MoOCl_2(PMe_2Ph)_3]$ was in fact a solid solution of blue *cis-mer*-$[MoOCl_2(PMe_2Ph)_3]$ and yellow *mer*-$[MoCl_3(PMe_2Ph)_3]$, and that the crystallographic disorder between an oxygen atom and a chlorine atom was manifested by an *apparent* increase in the Mo=O bond length. Indeed, it is presently recognized that impurities may commonly serve to modify apparent bond lengths.[7] There is therefore no longer a well-characterized example of bond-stretch isomerism for which it can be stated with certainty that the observed bond-length changes are not an artifact. Nevertheless, it is still possible that one day the phenomenon of bond-stretch isomerism will be experimentally verified.

It was, therefore, of great interest to read an article in this journal titled "Bond-Stretch Isomers: Fact not Fiction".[1] By its title, the article implies that examples of bond-stretch isomers have been discovered. However, the content of the article is not related to the concept of bond-stretch isomerism in the spirit in which it was originally discussed,[4] but rather is concerned with the well-established, valuable, and interesting phenomenon of *spin-state* isomerism, in which changes in bond length are associated with changes in spin-state.

Three review articles on bond-stretch isomerism[7–9] have indeed discussed the phenomenon of spin-state isomerism, and also related effects such as "deformational isomerism".[10, 11] However, bond-stretch isomerism was a concept that was introduced for isomers of the same spin-state, on the same potential energy curve, for which there was no obvious explanation. It may have been a failing of the original papers not to have excluded spin-state isomerism from the definition, but a reading of those papers and a general sense of the community make it clear that the interest of the bond-stretch isomerism phenomenon resides in those cases where the isomers belong to the same spin state. As interesting as they are, there is no special intrigue associated with the observed changes in bond lengths for spin-state isomers.

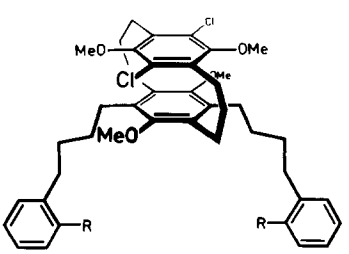
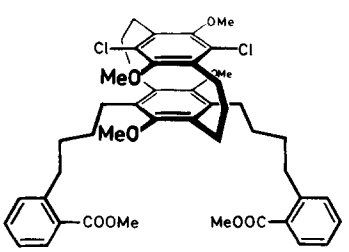
Synthesis and Properties of a Vertically Stacked Porphyrin-Quinone(1)-Quinone(2) Cyclophane**

Heinz A. Staab,* Moana Tercel, Rüdiger Fischer, and Claus Krieger

In multiple electron transfers, such as those assumed to occur in the primary process of biological photosynthesis, the question arises as to which structural factors favor a consecutive, stepwise electron transfer and which an integrated process relying on electronic coupling. Until now, the hypotheses (e.g. "superexchange") offering a theoretical explanation for the second of these mechanisms have frequently been developed in a rather ad hoc fashion. Further experimental investigations into the effect of structure, distance, and spatial orientation of the electron systems involved in these processes are required. In this context, a series of model compounds based on porphyrin-quinone(1)-quinone(2) cyclophane **1** have proved to be interesting because their steric and electronic structures can be defined unambiguously and varied systematically. In the vertically stacked P-Q(1)-Q(2) sequence, the weak acceptor Q(1), whose electron affinity is comparable to that of duroquinone, is adjacent to the porphyrin. The structure of the cyclophane dictates that the substantially stronger electron acceptor dichlorobenzoquinone Q(2) is fixed at such a distance from P that direct P···Q(2) interactions are negligible. In the classical case of a discrete, stepwise process, the slowest and thus rate-determining step in **1** is expected to be the photoinduced electron transfer from P* to Q(1). However, time-resolved fluorescence measurements[1] show that electron transfer in **1** does not occur at a rate comparable to that in the sterically and electronically analogous P–Q(1) system in the series of single-bridged quinone–porphyrin cyclophanes;[2] electron transfer is in fact approximately a thousand times faster (solvents *n*-hexane, toluene): for **1** the fluorescence lifetime of 2–3 ps, independent of solvent polarity, is of the same order of magnitude as the value recorded for the single-bridged porphyrin–dichloroquinone cyclophane P–Q(2).[2] The dramatic effect on the rate of photoinduced electron transfer produced by the higher electron affinity of Q(2) in P-Q(1)-Q(2), despite the remoteness of Q(2) from P, can be rationalized if we assume that the central Q(1) π-electron system mediates a sufficiently effective electronic coupling between P and Q(2). As an alternative explanation it might also be considered that the strong transannular interactions in the benzoquinone cyclophane moiety of **1**, Q(1)–Q(2), result in the formation of a coherent acceptor unit with an electron affinity greater than that of the isolated Q(1) acceptor.[1] Evidence for one or other of these mechanisms can be obtained from analogues of **1** in which the factors mentioned above can be influenced separately. On the one hand, spacers in porphyrin–quinone cyclophane analogues of **1** can be used to vary the P···Q distance systematically while leaving the vertical arrangement unchanged;[3] on the other hand, Q(1)···Q(2) interactions can be altered selectively by moving from the [3.3]paracyclophane system present in **1** to higher [n.n]paracyclophanes



1



2

or by synthesizing the corresponding pseudogeminal isomers (see below). This approach has been used for investigating charge-transfer interactions in analogous paracyclophane quinhydrones.[4]

The synthesis of **1** described below establishes a general strategy for the preparation of a series of analogues of **1**, in which there is a graduated variation in the P···Q(1) and Q(1)···Q(2) interactions. In tackling this synthesis, we were able to draw on our experience from the syntheses of [n.n]paracyclophanes[4] and porphyrin–quinone cyclophanes.[5] The porphyrin–[3.3]-paracyclophane triad **2**, which already contains the complete carbon skeleton of **1** as well as the oxygen functionalities in the [3.3]paracyclophane moiety, was chosen as a suitable precursor to **1**. It was hoped that transformation of **2** into **1** could be achieved by cleavage of the methoxy groups followed by oxidation. By analogy with the synthesis of single-bridged porphyrin cyclophanes,[5] dicarboxylic ester **3** was expected to be a key intermediate in the preparation of **2**. Dialdehyde **5**, which is required for the porphyrin synthesis, should be accessible from **3** via **4** by standard procedures of reduction and partial oxidation. The only feasible route to the fully substituted carbocyclic [3.3]paracyclophane system in **3** involved the vapor-phase pyrolysis[6] of disulfones obtained from appropriately substituted dithia[4.4]paracyclophanes. A crucial question here concerned

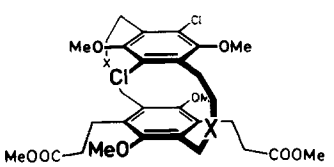
[**] Photoinduced Electron Transfers in Porphyrin–Quinone Cyclophanes, Part 11. – Part 10: H. A. Staab, C. Krieger, C. Anders, A. Rückemann, *Chem. Ber.* **1994**, *127*, 231–236.

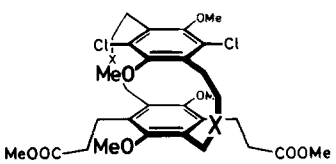
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1414-1463 $ 10.00+.25/0

the order in which the [3.3]paracyclophane unit and the long side chains attached to the "lower" ring in **3** should be assembled.

An attempt was first made to start the synthesis from dithia[4.4]paracyclophanes in which the required ring substituents, including the complete side chains of **3**, were already present. Unfortunately, the corresponding disulfones had such low volatilities that thermal decomposition predominated in the vapor-phase pyrolysis. The pseudogeminal [3.3]paracyclophane **6** was the only product that could be isolated in yields (ca. 3%) too poor to allow further transformations.[7] An attempt was then made to introduce the side chain after the [3.3]paracyclophane unit in **3** had been assembled. Coupling of 1,4-dibromo-2,5-bis(bromomethyl)-3,6-dimethoxybenzene[8] and 1,4-dichloro-2,5-bis(mercaptoethyl)-3,6-dimethoxybenzene[7] yielded the appropriately substituted dithia[4.4]paracyclophanes (methanol/THF, cesium carbonate, dilution technique; 52% yield). Oxidation to the disulfones followed by vapor-phase pyrolysis (535 °C, 10^{-5} Torr) gave, after chromatographic separation, the two isomeric 5,8-dibromo-14,17-dichloro-6,9,15,18-tetramethoxy[3.3]paracyclophanes **7** (26% yield) and **8** (29% yield).[9] It



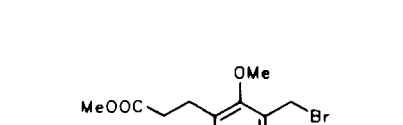
7



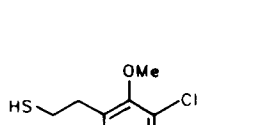
8

was hoped that a palladium-catalyzed Heck vinylation[10] at the bromo-substituted position would then allow introduction of the side chains (in this type of reaction, bromo substituents are known to react selectively in the presence of chloro substituents). It turned out, however, that **7** and **8** were totally inert, even though the conditions employed were identical to those used in the Heck reaction of 1,4-dibromo-2,5-dimethoxy-3,6-dimethylbenzene with methyl acrylate, in which yields of 80–90% were achieved.[5] Clearly, steric interactions with the [3.3]paracyclophane unit hindered the reaction. Attempts at increasing reactivity in the Heck reaction by using the iodo derivatives of **7**/**8** failed because of the poor, nonreproducible yields obtained in the cyclization and pyrolysis reactions.

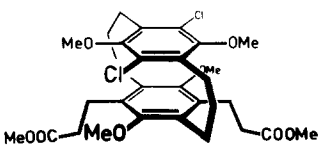
As a compromise between these two unsuccessful synthetic strategies, a new concept for the synthesis of **3** via a central [3.3]paracyclophane unit with shorter side chains was developed. The side chain would have to be short enough to allow successful pyrolysis of the disulfones, but at the same time long enough to circumvent steric interactions with the fully substituted paracyclophane system. With a judicious choice of terminal functionality, the subsequent chain extension to give **3** could then be achieved in a short and promising reaction sequence. Dithia[4.4]paracyclophanes **9** and **10**, each bearing two C_3 side chains in the form of methoxycarbonylethyl groups, were chosen as starting materials for the synthesis of disulfones **11** and **12**, respectively.



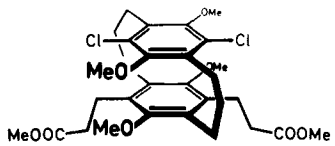
9: X = S
11: X = SO_2



10: X = S
12: X = SO_2



Cyclization of 1,4-bis(bromomethyl)-2,5-bis(2-methoxycarbonylethyl)-3,6-dimethoxybenzene (**13**) and 1,4-dichloro-2,5-(2-mercaptoethyl)-3,6-dimethoxybenzene (**14**)[11] (KOH, methanol/THF, dilution technique; 46% yield) gave the isomers **9** and **10** (1.2:1, according to ^{1}H NMR). The disulfone isomers **11** and **12** were obtained by oxidation with *m*-chloroperbenzoic acid (dichloromethane, 90 h at 20 °C; 85% yield).[12] Vapor-phase pyrolysis of the mixture of disulfone isomers **11**/**12** (535 °C, 10^{-5}–10^{-6} Torr) gave a mixture of carbocyclic [3.3]paracyclophanes in 45% yield. The isomers were separated by chromatography (silica gel, hexane/diethyl ether, 4:1) and recrystallized from methanol. The elemental analyses and spectroscopic data (^{1}H NMR, MS) for isomer A (22% yield, m.p. 191–192 °C) and isomer B (22% yield, m.p. 196–197 °C) were consistent with the expected structures. Assignment of the isomers to the pseudoortho and pseudogeminal series was only possible by X-ray structure analysis; it was thus established that A has the pseudoortho structure **15** and B the pseudogeminal structure **16**.[13]



13

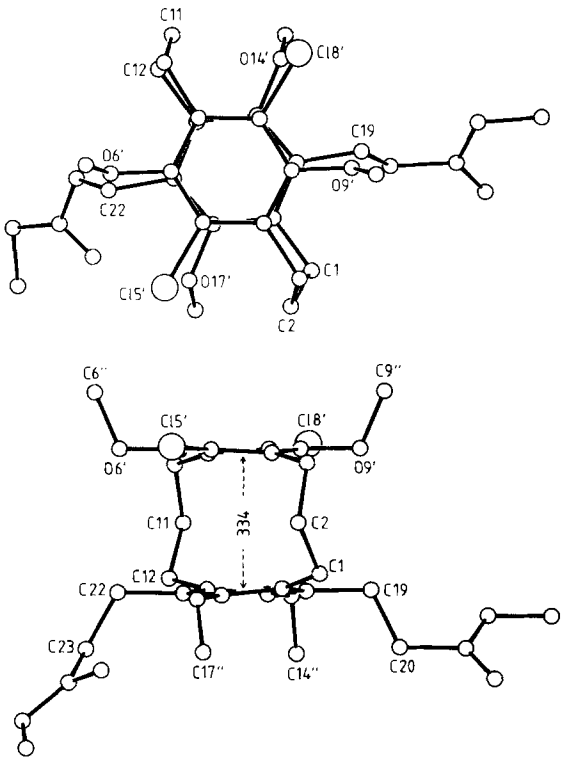
14

15

16

The molecular structures of both isomers show practically eclipsed orientations of the nearly planar six-membered rings, with an interplanar distance of 334 pm. The C_3 side chains on the "lower" six-membered ring lie in a plane perpendicular to that of the ring and point, as expected, away from the "upper" ring of the [3.3]paracyclophane. Figure 1 shows the molecular structure of **15** in a top view onto the plane of the ring (top) and in a side view (bottom). It may be assumed that the spatial arrangement in the [3.3]paracyclophane moiety of **1** largely corresponds to that shown for **15**. Starting the synthesis from **15** guarantees, above all, that the benzoquinone units in **1** will be in a pseudoortho relationship. An analogous synthetic sequence starting from **16** would then yield the pseudogeminal isomer. This compound is of interest because of the expected differences in Q(1)···Q(2) interactions as compared to **1**.

In the first step towards the synthesis of **3**, **15** was either converted directly into the corresponding aldehyde[9] (m.p. 216–220 °C, from cyclohexane) by reaction with diisobutylaluminum hydride (toluene, −78 °C; 62% yield), or else it was first reduced to the bis(3-hydroxypropyl) derivative[9] (lithium aluminum hydride, THF, 20 °C; 96% yield; m.p. 249–252 °C, from methanol) and then oxidized to the aldehyde with pyridinium



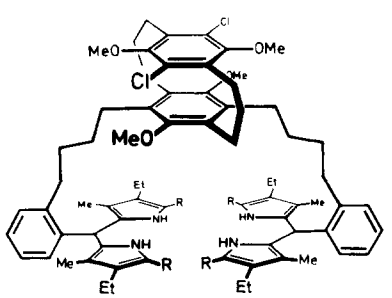


Fig. 1. Crystal structure of **15**. Top: top view onto the plane of the six-membered ring; bottom: side view.

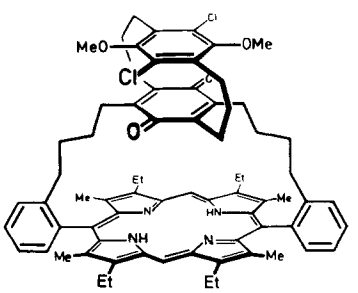
chlorochromate (dichloromethane, celite/magnesium sulfate; 70% yield). The Wittig reaction of the dialdehyde with (2-methoxycarbonylbenzyl)triphenylphosphonium bromide[14] (sodium methanolate, THF; 85% yield, mixture of *cis* and *trans* isomers) followed by hydrogenation (Pd/C, ethyl acetate/methanol, 1 h, 20 °C) led to formation of **3**[9] (ca. 95% yield, m.p. 139–140 °C, from methanol/chloroform, 4:1).

The dicarboxylic ester **3** was reduced to the corresponding bis(2-hydroxymethylphenyl) compound **4**[9] (m.p. 109–110.5 °C) with lithium aluminum hydride (THF, 20 °C; nearly quantitative yield). Partial oxidation with pyridinium chlorochromate (dichloromethane, celite/magnesium sulfate; 92% yield) gave dialdehyde **5**[9] (m.p. 135–137 °C). In an analogous procedure to that described for the synthesis of single-bridged tetraethyltetramethylporphyrins,[5] **5** was condensed with 2-benzyloxycarbonyl-3-ethyl-4-methylpyrrole[15] to give the corresponding bis(dipyrrylmethyl) compound **17**[9] (conc. hydrochloric acid, ethanol, 4 h at reflux; 98% yield). Cleavage of the benzyl groups by hydrogenolysis (Pd/C, THF) yielded the tetracarboxylic acid **18**. Finally, the [3.3]paracyclophane-bridged porphyrin **2**[9] (crimson microcrystals; m.p. > 330 °C) was obtained from **18** by cyclization with triethyl orthoformate in dichloromethane/trichloroacetic acid followed by dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).



17: R = COOBz
18: R = COOH

The unusually poor yield of 2% obtained in the porphyrin synthesis may be ascribed to the steric hindrance presented by the two methoxy groups in the "lower" paracyclophane ring. The methoxy groups in both six-membered rings of the paracyclophane system are twisted out of the plane of the ring, so as to avoid steric interactions with other ring substituents; they are forced into a conformation—also observed in the molecular structures of **15** and **16** (Fig. 1)—in which the methoxy groups in the "upper" ring point upwards and those in the "lower" ring downwards. The latter hinder the formation of the porphyrin ring in **2**.

The ^{1}H NMR spectrum of **2** also provides evidence for the existence of such steric interactions: whereas in all the precursors of **2** both sets of [3.3]paracyclophane methoxy protons have very similar δ values (e.g. **3**: 3.46, 3.51; **5**: 3.45, 3.51; **17**: 3.42, 3.49), in the ^{1}H NMR spectrum of **2**, only one of the singlets, corresponding to two of the four methoxy groups, appears in this region [δ = 3.28 (s, 6H)]. The protons belonging to the other two methoxy groups absorb at δ = 1.12 (s, 6H) (all values given for $CDCl_3$, 500 MHz). This large upfield shift indicates that the methoxy protons in the central ring of **2** are positioned in very close proximity to the porphyrin system and thus experience an anisotropic shielding effect.[16]

Attempts to obtain **1** by demethylation of **2** with boron tribromide (dichloromethane, 70 min, 20 °C) and subsequent dehydrogenation with DDQ did not lead to formation of the expected product. Instead, a compound was obtained in which only one of the six-membered rings of the paracyclophane unit had been converted into a quinone. Surprisingly, it was found that the more sterically shielded methoxy groups of the middle ring had been demethylated, thus forming compound **19**[9] [^{1}H NMR: δ(MeO) = 3.38 (s, 6H), no methoxy signals at $\delta \approx 1.1$; $CDCl_3$, 500 MHz]. In order to find suitable reaction conditions for ether cleavage in **2**, preliminary experiments were performed with several demethylating agents on a model compound synthesized for this purpose.[17] Demethylation of **2** was finally achieved with boron triiodide (dichloromethane, 49 h under argon at 20 °C with exclusion of light). Subsequent oxidation with DDQ gave the target compound **1** (48% yield; purple-colored needles from hexane/benzene, 5:1; m.p. > 330 °C). Elemental analysis and spectroscopic data confirmed the proposed structure for **1**. Investigations into photoinduced electron transfers in **1** and **19** were recently described in a joint publication with Michel-Beyerle, Heitele, et al.;[1] some of the results obtained are summarized in the introduction to this communication.

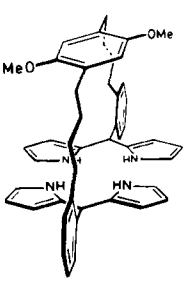
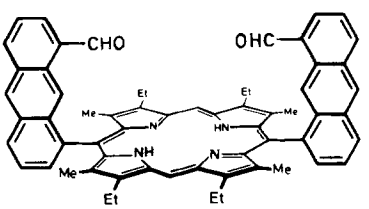
Synthesis and Properties of a Vertically Stacked Porphyrin(1)-Porphyrin(2)-Quinone Cyclophane**

Heinz A. Staab* and Thomas Carell

Photoinduced electron transfers over several successive porphyrin and quinone units have found increasing interest in the context of the primary process in biological photosynthesis. The mechanisms of these "multistep" electron-transfer reactions are not yet well understood. Further examination of model compounds is necessary in which the structure, distance, and orientation of the π systems involved are defined and can be varied systematically. Complementary to numerous studies conducted by other research groups concentrating primarily on porphyrin–quinone systems with lateral arrangements, we synthesized cyclophane-type structures, in which the double bridging of the vertically stacked porphyrin and quinone units leads to a relatively rigid structure.[1] In these systems the effect of single parameters—the electron affinity of the quinones, the donor strength of the porphyrins, and the distance and orientation of the porphyrin and quinone components—can be examined while the other parameters are held constant.[2] This "cyclophane concept" has been extended to multistep electron-transfer systems, as the porphyrin-quinone(1)-quinone(2) cyclophane described in the preceding communication[3] demonstrates. We report here on the vertically stacked porphyrin(1)-porphyrin(2)-quinone cyclophane **1**. The two different porphyrin units in **1** are aligned parallel to each other and separated by roughly 500 pm; the porphyrin that is the weaker donor is flanked by the quinone, which functions as an electron acceptor. The geometric relationships and electronic interactions in the "upper" portion of the triad correspond to those in 5,10,15,20-tetraarylporphyrins with one quinone bridge.[4]



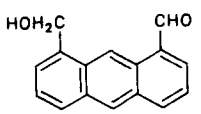
1



2

In analogy to previous syntheses of porphyrin–quinone cyclophanes[1, 3, 4] non-quinoid **2** was the targeted precursor of **1**, since it contains the complete carbon framework of **1** and should provide **1** upon cleavage of the methoxy groups and subsequent oxidation. For the construction of **2** we considered the condensation of 1,4-bis{4-[2-(bis-2-pyrrolylmethyl)phenyl]butyl}-2,5-dimethoxybenzene (**3**) with *syn*-5,15-bis(1-formyl-8-anthryl)-2,8,12,18-tetraethyl-3,7,13,17-tetramethylporphyrin (**4**). Since we had already prepared **3** in related work,[4] the main problems to be worked out in the synthesis of **2** were the synthesis of **4** and its cyclization with **3**.

3



4

Anthracene 1,8-dicarboxylic acid[5] was converted via its dimethyl ester into 1,8-bis(hydroxymethyl)anthracene,[6] which was treated with triphenylmethyl chloride (1 equiv, pyridine, 15 h, 50 °C) to give 1-hydroxymethyl-8-triphenylmethoxymethylanthracene (32% yield)[7] in addition to 1,8-bis(triphenylmethoxymethyl)anthracene (20% yield).[7] Oxidation of the

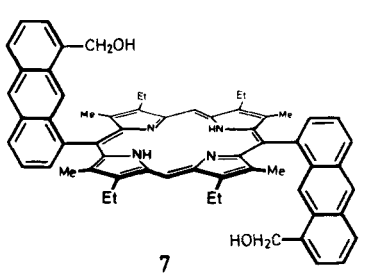
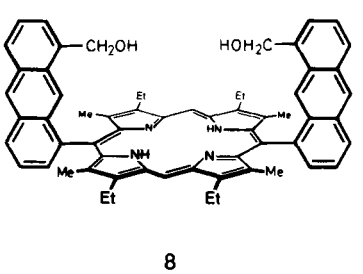
[**] Photoinduced Electron Transfer in Porphyrin–Quinone Cyclophanes, Part 12. – Part 11: ref. [3].

free hydroxymethyl group of the former (dimethylsulfoxide (DMSO), dichloromethane, oxalyl dichloride, −70 °C; yield 90%) led to 1-formyl-8-triphenylmethoxymethylanthracene (m.p. 215 °C),[7] and subsequent hydrolysis (acetic acid, 100 °C; yield 65%) furnished 1-formyl-8-hydroxymethylanthracene (**5**, m.p. 132 °C).[7] In a procedure better suited for large-scale preparation, **5** was obtained from 1,8-bis(hydroxymethyl)-anthracene by means of its partial acetylation to 1-acetoxymethyl-8-hydroxymethylanthracene (1 equiv acetyl chloride, sodium hydride, dioxane; m.p. 118–120 °C)[7] in 33% yield (18% yield of 1,8-bis(acetoxymethyl)anthracene as well). Oxidation of the free hydroxymethyl group (conditions as above; 90% yield) to give 1-acetoxymethyl-8-formylanthracene (m.p. 110 °C)[7] and cleavage of the acetyl group (ammonia/methanol, 12 h, 20 °C; yield 75%) led to **5**. The second component for the construction of the "lower" porphyrin unit of **2**, bis(3-ethyl-4-methyl-2-pyrrolyl)methane (**6**), was obtained from the corresponding α-ethoxycarbonyl compound by basic hydrolysis and decarboxylation.[8]

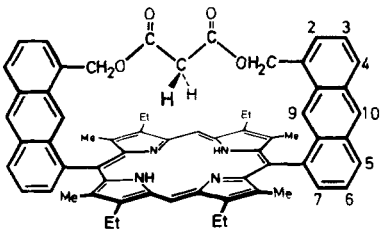


5



6

The cyclization of **5** and **6** was conducted in methanol under argon with *p*-toluenesulfonic acid as catalyst.[9] The porphyrin-containing precipitate was oxidized with chloranil (THF, 20 min, exclusion of light). Standard workup yielded a violet product, which was separated by chromatography (silica gel, toluene/ethyl acetate, 10:1) into product fractions A and B. Further purification of both fractions by medium-pressure chromatography and recrystallization from dichloromethane/methanol furnished two products in analytically pure form (A: 29%, B: 26% yield). The ^{1}H NMR spectra (500 MHz, [D$_6$]DMSO) and ^{13}C NMR spectra (90.6 MHz, CD_2Cl_2, ^{1}H broad band decoupled; assignment by ^{13}C–^{1}H COSY), as well as the mass spectra and other spectroscopic data for the two products, were very similar and corresponded to those of the anticipated *syn* and *anti* atropisomers **7**[7] and **8**.[7] In similar



7

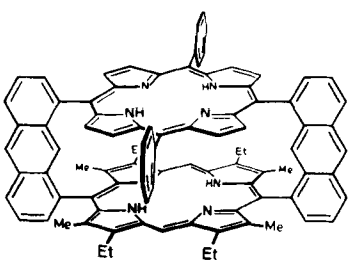
8

cases different R_f values have been used to differentiate between the isomers;[10] this was the case here as well (A: 0.37, B: 0.08; silica gel, toluene/ethyl acetate, 4:1). Unequivocal assignment of the isomers was possible by making use of the different spatial arrangement of the hydroxymethyl groups: only with B did reaction with malonyl dichloride (*N*-methylmorpholine, dichloromethane, 30 min, −78 °C) lead to an intramolecular malonate bridge, indicating that B must be the *syn* compound **8**. The compound obtained was unambiguously assigned structure **9** based on its analytical data (^{1}H and ^{13}C NMR, Liquid Secondary Ionization (LSI) MS, high-resolution MS). A noteworthy feature of **9** is the extremely high-field signal for the central methylene protons of the malonate unit at $\delta = -2.54$ (360 MHz, $CDCl_3$), which is explained by the position of these protons above and within the ring current of the porphyrin system. In an attempt to increase the overall yield of **8**, compound **7** was heated at reflux in ethylene glycol (200 °C). Some thermal *anti–syn* isomerization of **7** was indeed observed, but thermal decomposition dominated under these conditions.

9

Oxidation of the two hydroxymethyl groups in **8** to the formyl groups in **4** in the presence of the porphyrin unit was not possible under typical conditions for mild oxidation (e.g. pyridinium chlorochromate, dichloromethane; DMSO, oxalyl dichloride, dichloromethane; silver carbonate/silica gel, toluene). The transformation succeeded, however, with the molybdenum-picolinato-*N*-oxido-peroxo complex[10] (1,2-dichloroethane, 24 h at 50 °C under argon; 60% yield) and with the "hypervalent iodine" reagent ("periodinane"[11]) prepared from iodobenzoic acid, potassium bromate, and acetic anhydride in dichloromethane (5 °C, monitored by thin-layer chromatography; 82% yield). Following chromatography (silica gel, toluene/ethyl acetate, 4:1) and recrystallization from dichloromethane/methanol, compound **4** was obtained as violet crystals (m.p. > 300 °C). The spectroscopic data (^{1}H NMR, MS including high resolution of the molecular ion peak at *m/z* 886) confirmed the proposed structure.

The second porphyrin system in **2** was constructed by condensation of **3** and **4** in propionic acid (30 min at 20 °C, 30 min at 90 °C, 1 h at 140 °C).[12] Oligomers and polymers were removed by successive column chromatography (silica gel, toluene/ethyl acetate, 15:1), medium-pressure chromatography (silica gel 60, toluene/ethyl acetate, 100:1), and high-pressure chromatography (silica gel, toluene); each time only the first fraction was subjected to further purification. Due to this procedure after precipitation from dichloromethane/methanol/water (10:10:1) **2** was obtained in a yield of only 2%.



In the ^{1}H NMR spectrum (500 MHz, CD_2Cl_2) of **2** two NH signals (each s, 2H) are observed at $\delta = -4.58$ and -4.18, which correspond to the two differently substituted porphyrin systems. The extreme upfield shift compared to analogous signals of related porphyrins demonstrates that both pairs of NH protons are also affected by the ring current effect of the neighboring porphyrin ring. The other ^{1}H NMR signals could be assigned in almost complete accord with the structure of **2** with the help of COSY experiments and comparisons with other spectra. In the mass spectrum (LSI-MS positive ion mode) the expected cluster near the molecular ion peak at *m/z* 1534 is evident; high resolution of the M^+ and the MH^+ peaks confirms the molecular formula of **2** ($C_{108}H_{94}N_8O_2$).

The last steps in the synthesis of **1** were the demethylation of the dimethoxybenzene unit (boron trifluoride, dichloromethane) and the oxidation of the resulting hydroquinone with DDQ in analogy to the syntheses of simple quinone-bridged porphyrins.[1, 2] After medium-pressure chromatography (silica gel, toluene/ethyl acetate, 100:1) and precipitation from dichloro-

methane/methanol/water (10:10:1), **1** was obtained in 70% yield based on **2**. The purity and structure of **1** were confirmed by analytical high-pressure chromatography (Nucleosil, toluene/*n*-hexane, flow rate = 1 mL min^{-1}, t_R = 3.68 min) and by the ^{1}H NMR and mass spectra. The ^{1}H NMR spectrum (500 MHz, CD_2Cl_2, assignment with COSY and NOE experiments) corresponds to the ^{1}H NMR spectrum of the precursor **2** with the exception of signals reflecting the changes in the "upper" ring. In the mass spectrum (LSI-MS positive ion mode) the expected peak cluster occurs at the base peak *m/z* 1507, which arises from the $[M + 3H]^+$ ion. High resolution of the M^+ and $[M + 2H]^+$ signals confirms the molecular formula $C_{106}H_{88}N_8O_2$.

The absorption spectra of **1** and **2** are almost superimposable in the long-wavelength region dominated by the porphyrin chromophores. This implies that it makes no difference whether the porphyrin is bridged by a quinoid or a non-quinoid unit, which is in agreement with the results from related single-bridged systems.[2] In contrast to the porphyrin–quinone cyclophanes previously studied,[1–4] in **1** and **2** two different porphyrin chromophores are linked in a cyclophane-like fashion; the unit in the middle is a tetraarylporphyrin, that underneath is an octaalkyldiarylporphyrin. The absorptions of **1** and **2** in the regions of the Soret band and the Q bands show that the spectra are not simply superpositions of the absorptions of the two porphyrin chromophores. In particular the Soret bands of **1** and **2** are shifted to shorter wavelengths in comparison to those of the isolated porphyrins with the same substitution patterns; they also do not occur as separate absorptions that can be assigned to the individual porphyrin chromophores. This is apparently the result of electronic interactions between the two porphyrin units in **1** and **2**.

In studies of the fluorescence of **1** solvent-dependent quenching was observed. The "relative quantum yield" of the fluorescence of **1** based on that of the non-quinoid triad **2** is almost independent of the wavelength of the excitation and was determined to be 42% in *n*-hexane, 7% in toluene, and 2.5% in dichloromethane; these findings are in qualitative agreement with preliminary measurements of the fluorescence lifetimes.[13] Here, too, the participation of the porphyrin(1)–porphyrin(2) unit is unclear (e.g. with regard to the electron transfer versus energy transfer). Further insight should be provided by investigations on the porphyrin(1)–porphyrin(2) cyclophane **10**, which was prepared in this context and will be described elsewhere.[14] In compound **10**, which lacks only the quinone bridge of triad **1**, the interaction of the two porphyrin units should correspond to that in **1**.

A Highly Convergent Synthesis of the Lewis^y Blood Group Determinant in Conjugatable Form**

Victor Behar* and Samuel J. Danishefsky*

Dedicated to Professor R. U. Lemieux

The role of carbohydrates as signaling molecules in the context of biological processes has only recently been appreciated.[1, 2] Carbohydrate molecules, carrying detailed structural information, tend to exist as glycoconjugates (cf. glycoproteins and glycolipids) rather than as free entities. Given the complexities often associated with isolating the conjugates in homogeneous form, the opportunities for synthesis are apparent.[3, 4]

The carbohydrate domains of the blood group substances, contained in both glycoproteins and glycolipids, are widely distributed. The early focus on these systems centered on their role in determining blood group specificities.[5] Intriguingly, ensembles related to the blood group substances in conjugated form are encountered as markers for the onset of various tumors.[6] Carbohydrate-based tumor antigenic factors may find applications at the diagnostic level, as resources in drug delivery, or, ideally, in immunotherapy.[7]

Major advances in glycoconjugate synthesis will require the attainment of high degrees of convergence, good stereocontrol,

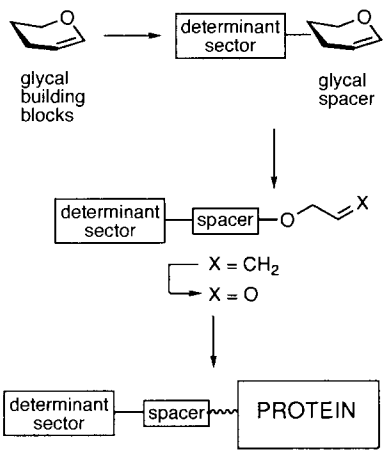
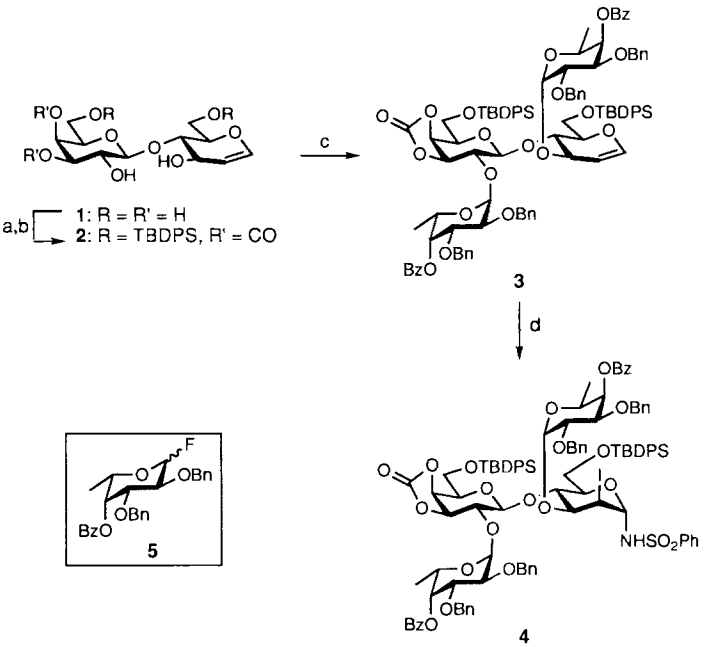
and relief from the burdens associated with the manipulation of blocking groups. Another requirement is that of delivering the carbohydrate determinant with appropriate provision for conjugation to carrier proteins or lipids.[8] In this communication we show how the use of glycals both as glycosyl donors and as glycosyl acceptors can be exploited to accomplish such ends. We do so in the context of a straightforward synthesis of the Le^y (type 2) system.[9]

The Le^y hapten was first isolated from a blood group glycoprotein in 1966 by Kabat, Lloyd et al.[10a] Subsequently, Potapov[10b] discovered an antibody to this carbohydrate antigen. Interest in the Le^y antigen stems from the existence of a number of glycoproteins and glycolipids which contain this substructure and are associated with human colonic adenocarcinoma[11] as well as human liver adenocarcinoma.[12] Both Le^y and Le^x antigenic structures are of general interest due to the preponderance of highly fucosylated polylactosamine glycolipids that are found to accumulate in other human carcinomas.[7f, 13] Our synthesis provides for the determinant to be insulated from the conjugation device by a carbohydrate spacer module which can, in principle, be broadly varied (Fig. 1). Through appropriate insulation, the likelihood that the protein or lipid carrier might distort the recognition property of the determinant is thus minimized.





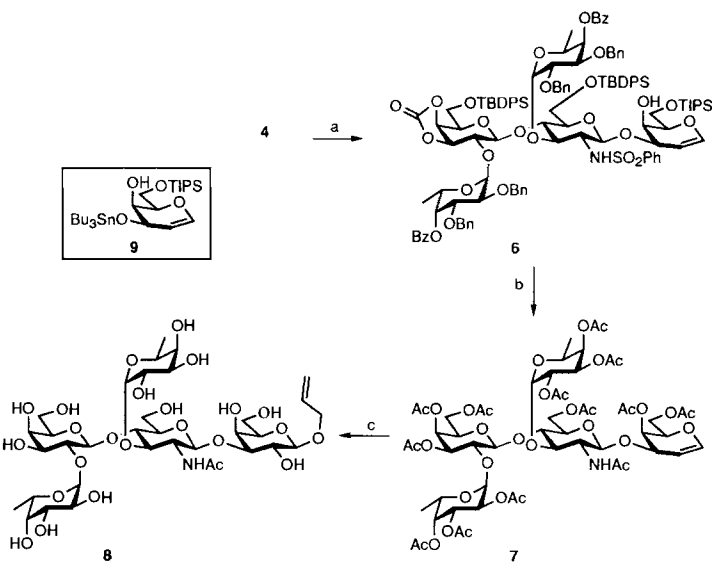


Fig. 1. Glycal assembly leading to neoglycoproteins.

Construction of the Le^y determinant commenced with lactal (**1**)[14] (Scheme 1). Capping both primary hydroxyl groups as their *tert*-butyldiphenylsilyl (TBDPS) ethers under standard conditions was followed by simple engagement of the 3′ and 4′ hydroxyl functions as a cyclic carbonate **2**. The stereospecific introduction of two α-linked fucose residues gave the tetrasaccharide glycal **3** in 51% yield in a single step. The donor used was the known fluorosugar **5**[15] following a modification of the original Mukaiyama conditions (see Experimental Procedure).[16] Glycal **3** corresponds to the Le^y hapten, lacking the N-acetyl function in the glucose residue. We next sought to introduce this group as well as a galactose spacer module.

Methodology which we developed previously[17] proved to be appropriate toward these goals. Glycal **3** was treated with iodonium dicollidine perchlorate ($I(coll)_2ClO_4$) and benzenesulfonamide to afford the iodosulfonamide **4**. Azaglycosylation with the 3-stannyl ether of galactal (**9**)[18] in the presence of silver tetrafluoroborate gave the pentasaccharide glycal **6** in 75% yield (Scheme 2; see also Experimental Procedure). Having **6** in hand, one can iterate the azaglycosylation sequence or activate the glycal as its epoxide and continue with further glycosylations. In terms of convergence, conciseness, and simplicity, we believe that this method offers advantages over earlier worthy efforts directed toward Le^y.

Scheme 1. a) TBDPSCl, imidazole/DMF, 84%; b) carbonyldiimidazole, cat. imidazole, THF, 65%; c) **5**, di-*tert*-butylpyridine, $AgClO_4$, $SnCl_2$, ether, 51%; d) $PhSO_2NH_2$, $I(coll)_2ClO_4$, 94%.

Scheme 2. a) **9**, $AgBF_4$, 4 Å molecular sieves, THF, 75%; b) i: tetrabutylammonium fluoride (TBAF), THF; ii: Na/NH_3; iii: Ac_2O, pyridine, 52%; c) i: 3,3-dimethyldioxirane; allyl alcohol, $ZnCl_2$, 72%; ii: NaOMe, MeOH, quant.

Anxious to demonstrate the ability to fashion a conjugatable form of Le^y hapten, we chose to concentrate on the formation of the allyl glycoside. The feasibility of converting the sulfonamido group into the target acetamide was demonstrated. Glycal **6** was deprotected in two steps as shown. Peracetylation afforded acetamido glycal **7**. Activation of the glycal as its epoxide with dimethyldioxirane,[19] followed by epoxide opening with allyl alcohol in the presence of zinc chloride, gave the

desired peracetylated β-allyl pentasaccharide which was deacetylated by the action of methoxide to provide the target Le^y hapten as its β-allyl glycoside **8**.[20] The aldehyde, derived by ozonolysis of **8**, was conjugated to BSA by the method of Bernstein and Hall.[8a] Approximately 15 carbohydrate pentamers were introduced, presumably at lysine residues.

In summary, the work demonstrates the versatility of glycals both as donors and as acceptors, takes advantage of 1,2 glycal epoxides and their presumed N-sulfonylaziridine counterparts, and opens the way for analogous syntheses of this kind. The biological properties of such systems linked to carrier proteins will be investigated and described in due course.

Experimental Procedure

3: To lactal carbonate **2** (2.00 g, 2.47 mmol) was added fucosyl fluoride **5** (4.44 g, 9.86 mmol). The mixture was azeotroped five times with benzene and placed under high vacuum for two hours. Under an argon atmosphere di-*tert*-butyl pyridine (2.77 mL, 12.33 mmol) and dry ether (16 mL) were added. 2.0 g of freshly activated 4 Å molecular sieves were added and the mixture stirred for one hour at room temperature. In an argon glove bag, $SnCl_2$ (2.34 g, 12.33 mmol) and $AgClO_4$ (2.56 g, 12.33 mmol) were added. The flask was equipped with a reflux condenser and the reaction heated to reflux for 72 h. The reaction was quenched with saturated bicarbonate (5 mL) and filtered through a pad of celite. The filtrate was diluted with ethyl acetate (50 mL) and washed twice with saturated bicarbonate, twice with saturated copper sulfate, and twice with saturated brine. The organic phase was dried over $MgSO_4$ and concentrated. Flash chromatography in 20% ethyl acetate/hexanes afforded 2.10 g (51%) of a white foam **3**: $[\alpha]_D = -78.9$ ($c = 0.555$, $CHCl_3$); IR (thin film): $\tilde{\nu}$ = 3040, 3000, 2905, 2860, 2830, 1820, 1800, 1710, 1635, 1585, 1570, 1480, 1460, 1440, 1415, 1370, 1350, 1300, 1260, 1205, 1145, 1100, 950, 735, 695 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 8.09 (d, J = 8.12 Hz, 2H), 8.00 (d, J = 8.26 Hz, 2H) 7.66 (m, 4H), 7.59 (d, J = 6.74 Hz, 4H), 7.56 (t, J = 7.27 Hz, 1H), 7.30–7.50 (m, 22H) 7.16–7.26 (m, 10H) 7.09 (m, 2H), 6.99 (t, J = 7.59 Hz, 2H) 6.89 (t, J = 7.97 Hz, 1H), 6.43 (d, J = 6.08 Hz, 1H), 5.46 (bs, 1H), 5.38 (bs, 1H), 5.35 (d, J = 3.42 Hz, 1H), 4.89 (d, J = 11.35 Hz, 1H), 4.75–4.80 (m, 4H), 4.72 (d, J = 5.88 Hz, 2H), 4.69 (d, J = 4.27 Hz, 2H), 4.36–4.55 (m, 5H), 4.28 (q, J = 6.51 Hz, 1H), 4.17 (bd, J = 5.46 Hz, 1H), 3.90–4.00 (m, 6H), 3.85 (d, J = 2.99 Hz, 1H), 3.82 (d, J = 2.89 Hz, 1H), 3.56–3.78 (m, 4H), 1.07 (m, 24H); HR-MS (FAB): calcd for $C_{99}H_{106}O_{20}Si_2Na$ 1694.6740; found 1694.6787.

6: Iodosulfonamide **4** (230 mg, 0.12 mmol) was azeotroped five times with dry benzene and placed under high vacuum for two hours. A solution of tin ether **9** (15 equiv) (generated by azeotropic removal of water overnight with a Dean–Stark trap equipped with freshly activated 4 Å molecular sieves from 6-TIPS-galactal (561 mg, 1.80 mmol) and bis(tributyltin) oxide (673 µL, 1.32 mmol) in benzene (80 mL)) in THF (2.4 mL). To this solution stirring under an argon atmosphere was added 200 mg of freshly activated 4 Å powdered molecular sieves. After the mixture had been stirred for one hour at room temperature it was cooled to −78 °C and a solution of silver tetrafluoroborate (187 mg, 0.96 mmol) in THF (2.4 mL) was added by cannula. The mixture was allowed to warm to room temperature over 15 hours, during which time it had turned bright yellow, and the reaction was quenched by the addition of saturated bicarbonate (2 mL). The reaction mixture was filtered through a pad of celite into a separating funnel. The celite pad was washed thoroughly with ethyl acetate. The organic phase was washed twice with saturated bicarbonate and twice with saturated brine. The organic phase was dried over $MgSO_4$. Concentration and chromatography in 25% ethyl acetate/hexanes gave 193 mg (75%) as a white foam **6**: $[\alpha]_D$ −126.4 (c = 0.505, $CHCl_3$); IR (thin film): $\tilde{\nu}$ = 3500, 3040, 3000, 2905, 2840, 1820, 1800, 1705, 1635, 1590, 1440, 1410, 1255, 1195, 1100, 1080, 1035, 815, 730, 695 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 8.09 (app t, 4H), 7.08–7.65 (m, 46H), 6.90 (t, J = 7.65 Hz, 3H), 6.76 (d, J = 6.91 Hz, 2H), 6.12 (d, J = 6.59 Hz, 1H), 5.50 (bs, 1H), 5.45 (bs, 1H), 5.28 (app t, 2H), 3.03–4.91 (m, 36H), 1.09 (m, 45H); LR-MS (FAB): calcd for $C_{120}H_{141}NO_{26}SSi_3Na$ 2153; found 2153.

An Interactive Strategy for the Assembly of Complex, Branched Oligosaccharide Domains on a Solid Support: A Concise Synthesis of the Lewis^b Domain in Bioconjugatable Form**

John T. Randolph* and Samuel J. Danishefsky*

In the previous communication, we described an application of the glycal assembly method to the construction of the Lewis^y

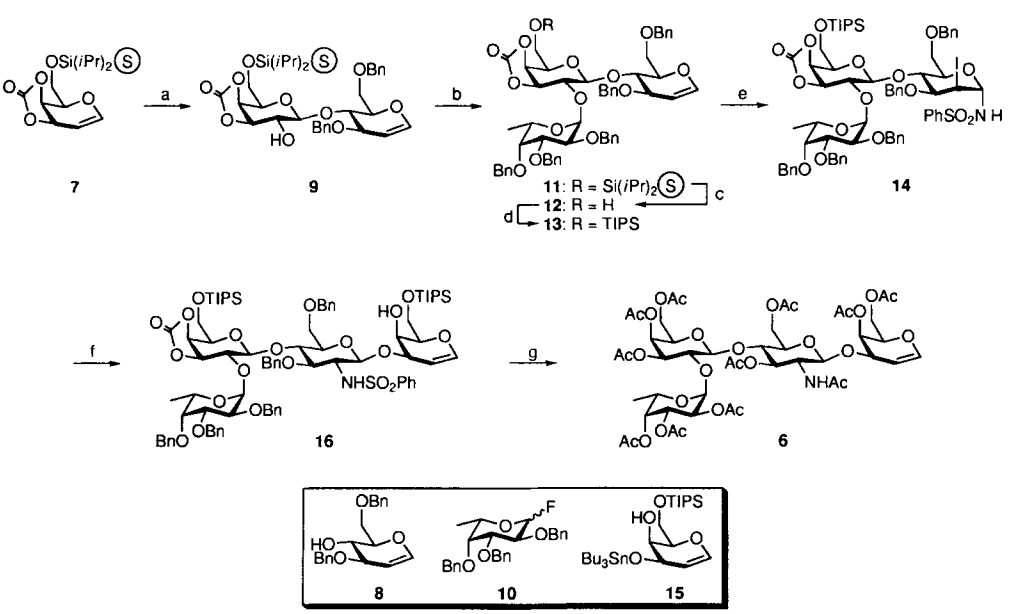
determinant.[1] In this report, we describe the construction of the Lewis^b determinant.[2] As before, our synthesis results in equipping the reducing end of the antigen with a suitable device for subsequent attachment to carrier protein. An intervening spacer element (lactose) is incorporated to insulate the recognition domain from the bioconjugation module.

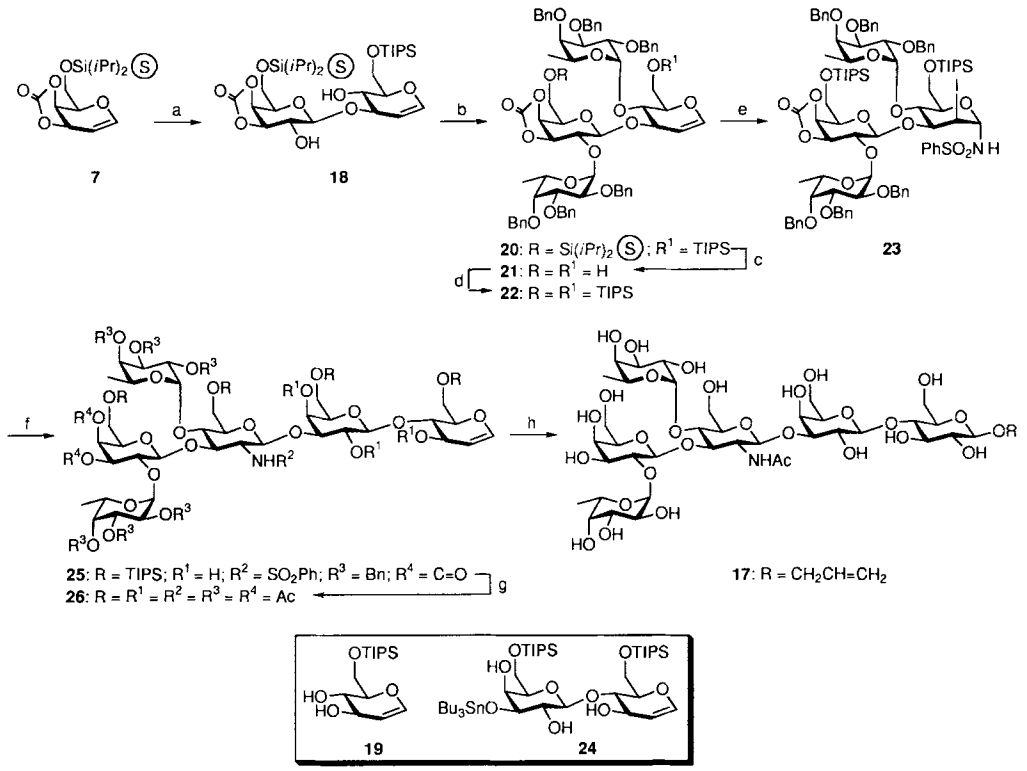
The Le^b blood group determinant is of particular current interest. Thus, Borén et al. have recently identified the Le^b blood group antigen as a mediator for the binding of *Helicobacter pylori* to human gastric epithelium.[3] In addition, it was found that a Le^b hexasaccharide as well as a soluble neoglycopeptide conjugate of the Le^b antigenic determinant were highly effective agents for inhibiting bacterial binding. This finding is, in principle, of considerable interest. Thus, clinical studies have identified *H. pylori* as a causative agent in gastric and duodenal ulcers.[4] Considerable evidence exists to suggest that antimicrobial treatments are an effective means of dealing with *H. pylori* infection.[5] Since bacterial attachment is a prerequisite to infection,[6] soluble Le^b receptor analogues may emerge as therapeutic candidates which could well serve as alternatives to broad-spectrum antibiotics.

The assembly of the Le^b (type 1) domain was, from our perspective, a more difficult undertaking than was the Le^y (type 2) target, wherein lactal was used as a very convenient starting material. In the case of a type 1 determinant, lactal is obviously not a useful starting material. It seemed appropriate to use the synthesis of the Le^b system as an opportunity to explore significant extensions to our recently disclosed polymer-based oligosaccharide construction method.[7] The essence of that strategy is summarized in Scheme 1. Polymer-bound glycal **1** is activated for glycosyl donation by direct formation of a 1,2-anhydro derivative **2**. Reaction of **2** with acceptor glycal **3** furnishes **4**. Reiteration is achieved by direct epoxidation and reaction with the next acceptor **3**. The self-policing nature of the method, and the major simplification arising from "one time" purification at the end of the synthesis, have been described.[7, 8]

Scheme 1. A strategy for the solid-phase synthesis of oligosaccharides using the glycal assembly method. Ⓢ = solid support, P = protecting group.



Scheme 2. Application of the solid-support method to the assembly of branching patterns of complex carbohydrates. Ⓢ = solid support, P = protecting group.



In the work reported herein, we explore an important additional dimension of the polymer-bound method. Here we take cognizance that each glycosylation event generates a unique C_2 hydroxyl (marked with an asterisk in Scheme 2). In principle, (and in fact, vida infra) this hydroxyl group can function as a glycosyl acceptor upon reaction with a solution-based donor. The glycal linkage of **5**, still housed on the support, can be further elongated. In this way, branching at C_2 is accomplished while minimizing the requirement for protecting group machinations.[9]

In principle, this branching can be implemented at any pyranose site in a growing chain. For such an application, it would be necessary to cap all previously generated hydroxyl groups generated on the "polymer side" (nonreducing end) of the growing domain. In short, the nexus of the proposal is that the polymer-bound oligosaccharide can serve as donor or as acceptor wherever appropriate.

The tetrasaccharide glycal **6**, bearing H-type 2 blood group specificity, was our initial goal (Scheme 3). Polymer-supported galactal **7**[10] was allowed to react with a solution of 3,3-dimethyldioxirane[11] to provide the corresponding 1,2-anhydrosugar glycosyl donor, which was treated with a solution of glucal derivative **8** in the presence of $ZnCl_2$ to provide **9**.[12] This polymer-bound disaccharide acted as a glycosyl acceptor upon treatment with a solution of fucosyl fluoride **10**[13] in the presence of $Sn(OTf)_2$. Polymer-bound **11** was thus generated. Retrieval of the trisaccharide glycal from the support was accom-

S = solid support.

plished by using tetrabutylammonium fluoride (TBAF) to afford **12** in 50% overall yield from **7**.[14]

We next demostrated how the trisaccharide, retrieved from the polymer, could be further elaborated. Toward this end, compound **12** was converted to silyl ether **13** by reaction with triisopropylsilyl chloride (TIPSCl). The latter was converted to the iodosulfonamide derivative **14** by the action of $I(coll)_2ClO_4$ in the presence of $PhSO_2NH_2$.[15] Reaction of **14** with the galactal stannyl ether derivative **15** in the presence of $AgBF_4$ gave **16** in 77% yield.[16] Tetrasaccharide glycal **16** was deprotected and then peracetylated to afford **6** (62% overall yield for three steps).

Having accomplished the synthesis of the full H-type determinant by sequential polymer- and solution-based maneuvers, we could direct our attention to the synthesis of the more complex Le^b hexasaccharide **17** (Scheme 4). Polymer-bound galactal **7** was converted to **18** upon epoxidation with 3,3-dimethyldioxirane followed by reaction with glucal derivative **19**. This disaccharide diol was then bisfucosylated by using fucosyl donor **10** in the presence to $Sn(OTf)_2$ to afford **20**. Retrieval from the support with TBAF provided **21**, which was obtained in 40% overall yield from **7**. Compound **21** reacted with TIPSCl to give **22**.

Iodosulfonamide **23**, obtained from **22** using $I(coll)_2ClO_4$ and $PhSO_2NH_2$, reacted with lactal derivative **24** in the presence of $AgBF_4$ to provide the hexasaccharide glycal **25** in 55% yield.[16] Deprotection of **25** was accomplished in two stages (TBAF to remove the silyl ethers, followed by Na/NH_3 reduction to remove the aromatic protecting groups). The crude product was peracetylated to give **26** in a 51% overall yield. Compound **26** was converted, via the 1,2-anhydrosugar derivative, to allyl glycoside **17**, which was readily activated by ozonolysis to the aldehyde ($R = CH_2CHO$). Coupling to the protein human serum albumin (HSA) by the method of Bernstein and Hall was accomplished.[17] Approximately 33 carbohydrate hexamer units were incorporated, presumably at lysine residue sites.

In summary, we have extended our solid-support glycal assembly method for complex carbohydrate domain synthesis to include the branching patterns needed for critical systems in biorecognition processes. Specifically, the determinant for the binding of *H. pylori* to human gastirc epithelium has been stereospecifically fashioned, with simplicity, in a way which provides significant relief from some of the complexities of protecting group manipulations. The biological properties of our new glycoprotein construct will be reported in due course.

There is every reason to believe that the solid-phase methodology to date is only a first generation version of what is possible.[18, 19] Important new variations of the technique and new applications will be described shortly.

Experimental Procedure

6: ^1H NMR (400 MHz, $CDCl_3$): $\delta = 6.39$ (d, 1H, $J = 6.2$ Hz, H_1 galactal), 5.65 (d, 1H, $J = 8.9$ Hz, NHAc), 5.35 (d, 1H, $J = 3.8$ Hz), 5.33 (m, 1H), 5.29 (d, 1H, $J = 2.6$ Hz), 5.27 (d, 1H, $J = 3.1$ Hz), 5.17-5.09 (m, 2H), 4.97-4.90 (m, 2H), 4.81 (dd, 1H, $J = 3$ Hz, $J = 6.1$ Hz, H_2 galactal), 4.75 (d, 1H, $J = 8.0$ Hz), 4.52 (m, 1H), 4.48 (dd, 1H, $J = 12.0$ Hz, $J = 1.6$ Hz, 1H), 4.44-4.06 (m, 8H), 3.88-3.77 (m, 4H), 3.61 (m, 1H), 2.18-1.97 (m, 33H, $COCH_3$), 1.18 (d, 3H, $J = 6.5$ Hz, CH_3 fucose); ^{13}C NMR ($CDCl_3$): $\delta = 170.80$, 170.77, 170.72, 170.67, 170.62, 170.34, 170.21, 170.09, 170.01, 169.99, 169.65, 144.92 (C_1 galactal), 100.22, 98.83, 98.58, 95.55, 74.48, 73.38, 73.13, 73.06, 71.48, 71.01, 70.68, 67.97, 67.42, 67.18, 67.05, 65.94, 64.83, 62.35, 62.22, 60.88, 60.37, 54.21, 23.23, 22.15, 20.85, 20.82, 20.79, 20.76, 20.65, 20.61, 20.57, 15.51 (C_6 fucose); IR (thin film): $\tilde{\nu} = 3368.7$ (NH), 2965.6, 2934.6, 1746.5 (C=O), 1537.5, 1435.9, 1371.3, 1228.5, 1065.0, 1046.0 cm^{-1}; $[\alpha]_D^{23} = -51.1$ ($c = 1.8$, CH_2Cl_2); HRMS (FAB) ($C_{46}H_{63}NNaO_{28}$): calcd: 1100.3434, found 1100.3436.

21: Polymer-bound galactal **7** (loading = 0.75 mmol glycal g^{-1}), which had been placed in a round-bottom flask equipped with a fritted outlet, was suspended in CH_2Cl_2 under N_2, cooled to 0 °C, and then treated with a solution of 3,3-dimethyldioxirane. The mixture was stirred (teflon-coated magnetic stir bar) for 40 min at 0 °C, after which time the soluble material was removed by filtration through the fritted outlet (N_2 pressure). The polymer-bound 1,2-anhydrosugar was evacuated (ca. 0.1 Torr) for several hours in order to dry the material for the next step. This material was once again placed under N_2 before being treated with **19** (ca. 10 molar equivalents as a 0.5 M solution in THF). The suspension was cooled to 0 °C, and treated with $ZnCl_2$ (ca. 2 molar equivalents as a 1.0 M solution in THF). The reaction mixture was allowed to warm slowly to room temperature (over ca. 2 h), and then stirred for an additional 3-4 h. Soluble material was removed by filtration, and polymer **18** was washed several times with THF and then dried in vacuo. Solid $Sn(OTf)_2$ (ca. 4 molar equivalents) was added to compound **18** in a glove bag, and the mixture was placed under N_2 and cooled to 0 °C before being treated with **10** (ca. 5 molar equivalents as a 0.2 M solution in THF) and di-*tert*-butylpyridine (ca. 8 molar equivalents). The suspension was allowed to warm to room temperature and

stirred 8–10 h. The mixture was rinsed with anhydrous THF (2 times), 1,4-dioxane (2 times), again with THF, and then dried in vacuo. Compound **20** (100 mg) was suspended in THF, treated with a 1:3 mixture of AcOH and TBAF (ca. 0.2 M in TBAF, ca. 10 molar equivalents), and the mixture was stirred for 18 h at 40 °C. The polymer was rinsed with THF (3 times), and the combined rinsings were concentrated and purified by column chromatography on silica gel (1:1 EtOAc:hexanes). Compound **21** (18 mg) was obtained as a colorless solid (40% overall yield from 7): ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.40–7.25 (m, 30H, Ar*H*), 6.18 (d, 1H, J = 6.0 Hz, H_1 glucal), 5.26 (d, 1H, J = 3.5 Hz, H_1 fucose), 5.09 (d, 1H, J = 3.7 Hz, H_1 fucose), 4.96 (dd, J = 10.8 Hz, 2H, PhCH_2), (4.90–4.56 (m, 13H), 4.43 (m, 1H), 4.15–4.06 (m, 4H), 3.97 (dt, 1H, J = 8.3 Hz, J = 2.4 Hz), 3.87–3.65 (m, 10H), 3.64 (d, J = 1.7 Hz, 1H), 3.57 (d, J = 1.7 Hz, 1H), 2.69 (br, 1H, OH), 2.52 (br, 1H, OH), 1.11 (d, 3H, J = 7.0 Hz, CH_3 fucose), 1.09 (d, 3H, J = 7.0 Hz, CH_3 fucose); ^{13}C NMR ($CDCl_3$): δ = 153.37 (C=O), 145.75 (C_1 glucal), 138.60, 138.52, 138.19, 137.61, 128.55, 128.52, 128.44, 128.24, 128.16, 128.07, 127.62, 127.56, 127.45, 98.71, 98.38, 97.65, 97.34, 79.26, 78.87, 78.67, 78.01, 77.79, 77.65, 76.37, 76.10, 74.92, 74.40, 74.16, 73.95, 72.86, 72.64, 72.53, 67.43, 67.29, 61.31, 60.90, 16.65 (C_6 fucose), 16.53 (C_6 fucose); IR (thin film): $\tilde{\nu}$ = 3467.0 (OH), 3029.6, 2923.6, 1807.2 (C=O), 1647.3, 1496.0, 1453.5, 1358.1, 1240.2, 1095.6, 1049.2, 738.5, 697.2; $[\alpha]_D^{23}$ = −82.5 (c = 0.4, CH_2Cl_2); HRMS (FAB): ($C_{67}H_{74}NaO_{18}$): calcd. 1189.4772, found 1189.4757.

25: To a mixture of **23** (60 mg, 34 μmol) and powdered 4 Å molecular sieves (200 mg) under N_2 was added, by canula, a solution of **24** (0.21 mmol) in anhydrous THF (1.5 mL). The stirred suspension was cooled to −78 °C before being treated with a solution of $AgBF_4$ (0.21 mmol) in anhydrous THF (0.25 mL). The mixture was stirred and allowed to slowly warm to room temperature overnight. The suspension, which had developed a bright yellow color, was heated, with stirring, at 45 °C for an additional 36 h, until the TLC (2:5 EtOAc:hexanes) showed no trace of **23**. The mixture was treated with saturated aqueous NH_4Cl (5 mL) and then extracted with EtOAc (3 × 10 mL), and the organic phase was dried over $MgSO_4$. The crude product was purified by silica gel chromatography (1:3 EtOAc:hexanes) to give **25** as a colorless oil (42 mg, 55%): ^{1}H NMR (400 MHz, [D_6]acetone): δ = 8.17 (d, 2H, J = 7.3 Hz, $PhSO_2$), 7.50–7.20 (m, 33H, Ar*H*), 6.52 (d, 1H, J = 10.5 Hz, N*H*), 6.30 (dd, J = 6.0 Hz, J = 1.5 Hz, 1H, H_1 glucal), 5.35–5.32 (m, 2H), 5.25 (d, 1H, J = 7.9 Hz), 5.15 (m, 2H), 4.99–4.92 (m, 3H), 4.86–4.52 (m, 14H), 4.45 (dd, 1H, J = 7.91 Hz, J = 2.4 Hz), 4.32–4.23 (m, 3H), 4.22 (m, 1H), 4.17 (d, 1H, J = 10.1 Hz), 4.08–3.84 (m, 18H), 3.79–3.73 (m, 2H), 3.66 (m, 1H), 3.55 (t, 1H, J = 6 Hz), 3.50 (dd, J = 9.7 Hz, J = 2.8 Hz, 1H), 1.33 (d, 3H, J = 6.5 Hz, CH_3 fucose), 1.31 (d, 3H, J = 6.4 Hz, CH_3 fucose), 1.20–0.98 (m, 84H, 3 × Si(*i*Pr)$_3$); ^{13}C NMR ([D_6]acetone): δ = 145.66 (C=O), 132.72, 131.48, 131.45, 131.28, 131.16, 130.77, 130.48, 121.31, 120.11, 119.86, 119.78, 119.25, 95.63, 94.70, 91.37, 89.64, 89.31, 86.52, 73.38, 72.24, 71.00, 70.71, 70.37, 69.80, 69.59, 69.06, 68.23, 67.92, 67.38, 67.10, 66.49, 65.67, 65.33, 64.60, 64.34, 64.03, 63.45, 63.30, 59.46, 58.83, 58.37, 54.45, 53.32, 49.86, 19.67 (C_6 fucose), 18.42 (C_6 fucose), 9.55, 9.48, 9.45, 9.31, 9.23, 3.82, 3.70, 3.64; IR (thin film): $\tilde{\nu}$ = 3491.9 (OH), 3030.1, 2941.2, 2865.5, 1835.8, 1819.5, 1649.8, 1496.2, 1462.3, 1349.9, 1245.5, 1155.2, 1095.1, 1049.4, 882.2, 734.8, 692.0 cm^{-1}; $[\alpha]_D^{23}$ = −33.8 (c = 2.0, CH_2Cl_2); HRMS (FAB): ($^{12}C_{120}{}^{13}CH_{179}NNaO_{29}SSi_4$): calcd 2278.1292, found 2278.1296.

[8] Recently, van Boom et al. (C. M. Timmers, G. A. van der Marel, J. H. van Boom, *Recl. Trav. Chim. Pays-Bas*, **1993**, *112*, 609) found that glycosylation of a particular acceptor with the α epoxide derived from 3,4,6-tri-*O*-benzyl-D-glucal gave only a 4:1 ratio of β:α linked disaccharides. The minor product was previously missed [12] because of its close chromatographic correspondence to the unreacted glycosyl acceptor. With a more complicated acceptor, van Boom confirmed strict β-glycoside preference. Subsequent to our earliest publication, it has been found that the epoxide derived from 3,4,6-tri-*O*-benzyl-D-glucal is the most problematic of the glycosyl donors, which we have occasionally employed, leading to modest amounts of α-glycoside. The implication that the finding of minor amounts of α-glycoside in a particular solution-based experiment invalidates the solid-phase method, which uses completely different resident protecting groups, is, as will be shown, premature.

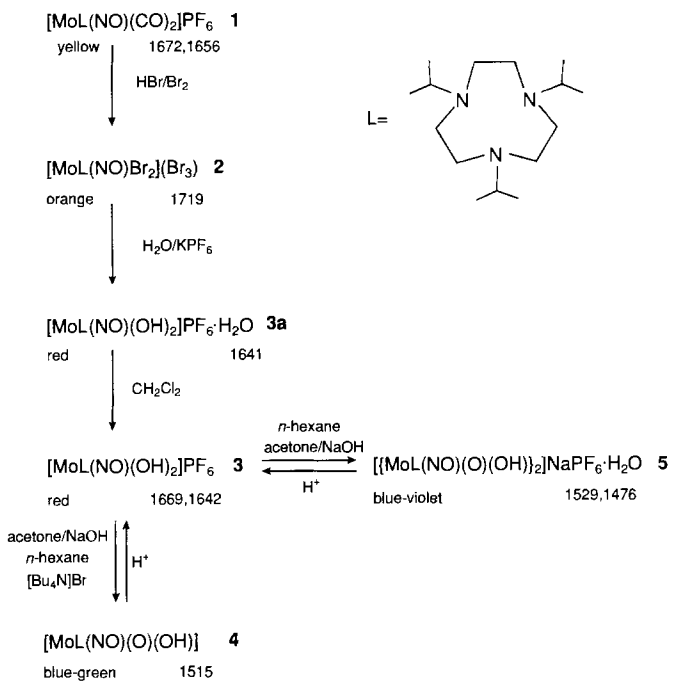
The First Mononuclear Nitrosyl(oxo)molybdenum Complex: Side-On Bonded and μ_3-Bridging NO Ligands in $[\{MoL(NO)(O)(OH)\}_2]NaPF_6 \cdot H_2O$**

Jochen Böhmer, Gabriele Haselhorst, Karl Wieghardt,* and Bernhard Nuber



The combination of a strong π donor and a π acceptor ligand in a transition metal complex leads to an interesting situation in terms of electron density, because a strong ($p_\pi \rightarrow d_\pi$)-donor bond requires an electron-deficient metal center, whereas stable ($d_\pi \rightarrow p_\pi$)-backbonding requires an electron-rich metal center. An example of a strong π acceptor is the nitrosyl ligand, and the terminal oxo group is a good π donor. Mononuclear nitrosyloxo complexes are as yet unknown,[1] but two μ-oxo-bridged nitrosylmolybdenum complexes[2, 3] of the $\{Mo-NO\}^4$ type[4] have been structurally characterized. In both cases, the $Mo-O_{oxo}$ dis-

tances are short (about 1.89 Å) and indicate multiple bond character. McCleverty et al.[5] have also shown that the Mo-O_{oxo} bonds of octahedral alkoxonitrosylmolybdenum(II) complexes have ($p_\pi \rightarrow d_\pi$) double-bond character. They explained this finding by the 18-electron configuration yielded by the formation of an oxygen–metal ($p_\pi \rightarrow d_\pi$) double bond.

We have now tried to synthesize nitrosylmolybdenum complexes of the $\{Mo-NO\}^4$ type containing a terminal oxo ligand based on the following considerations: although the $\{Mo-NO\}^4$ unit is sufficiently electron-rich to stabilize a linear Mo–NO group, it leads in octahedral complexes containing five purely σ ligands only to relatively electron-deficient 16-electron species. The formation of a ($p_\pi \rightarrow d_\pi$) oxygen–metal bond should therefore give a complex having a stable 18-electron configuration. Our intention was to suppress potential μ-oxo-bridging, by using the sterically demanding cyclic triamine 1,4,7-triisopropyl-1,4,7-triazacyclononane (L).[6] Scheme 1 shows the synthetic

Scheme 1. Preparation of **1**–**5**. The numbers indicate the ν(NO) stretching frequencies in cm^{-1} (KBr pellets).

route to the first mononuclear nitrosyloxomolybdenum complex. Nitrosylation of $[MoL(CO)_3]$[6] with $NaNO_2$ and HCl in methanol, followed by addition of KPF_6, gave yellow, air-stable crystals of salt **1**, which contains an 18-electron complex cation of the $\{Mo-NO\}^6$ type. Oxidation of **1** with bromine in 48% HBr yielded salt **2** (the 16-electron complex cation is of type $\{Mo-NO\}^4$). The bromide ions in the cation of **2** are relatively substitution-labile and can be exchanged for two OH^- groups in a boiling H_2O/tetrahydrofuran mixture (3:1). This exchange produced salt **3**, which could also be isolated in crystalline form as the monohydrate **3a**. Interestingly, a solution of **3** in acetone, which is initially red, changes its color to blue-green upon addition of NaOH. When such a solution was salted out with [nBu$_4$N]Br and overlaid with n-hexane, slow diffusion of the two layers gave blue-green crystals of the neutral complex **4**. When no $[Bu_4N]Br$ was added, blue-violet single crystals of **5** crystallized. Aqueous solutions of **4** and **5** slowly revert to red **3**; this conversion takes place rapidly when protons are added. The pK_a

of the acid/base equilibrium (a) was determined by spectrophotometry (Fig. 1) and, separately, by titration to be 9.0(1) at 20 °C in H_2O.

$$3 \rightleftharpoons 4 + H^+ \qquad \text{(a)}$$

The X-ray structure analyses[7] of **3** and **4** (Figs. 2 and 3 and Table 1) confirm the mononuclear structures. The MoL(NO)

X-Mo-Y	103.0(2)	103.6(3)	103.5(2)	103.2(2)

[a] Mo–N distance *trans* to the Mo–NO unit. [b] Mo–N distances *cis* to the Mo–NO unit. [c] Mo=O distance. [d] Mo–$O_{hydroxy}$ distance; [e] Mo–N distance *trans* to Mo=O unit; [f] the data in the first column refer to the neutral complex [MoL(NO)(O)(OH)] with side-on coordination of the NO ligands to one Na^+ ion, and those in the second column to the complex with O coordination of the NO ligand to two Na^+ ions (Fig. 4).

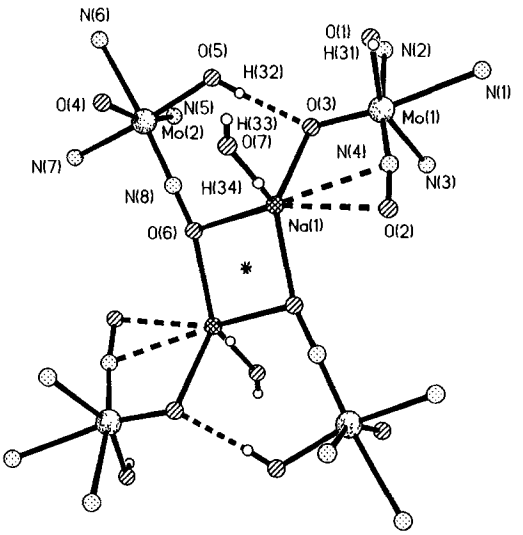
fragment is present in both complexes; the Mo–NO unit is nearly linear and the M–NO distance of 1.75 Å is short and invariant; it corresponds to that of an Mo–N multiple bond displaying efficient ($d\pi \rightarrow p\pi$) backbonding. The differences in the N–O bond lengths are not significant within the relatively large experimental error. This is an astounding result in the light of the large variation in stretching frequency from 1719 cm^{-1} in **2** to 1476 cm^{-1} in **5**. The Mo–O bonds of the two *cis* hydroxo ligands in **3** are approximately 1.90 Å long and thus somewhat shorter than a Mo–O single bond, whose length is typically 1.98–2.10 Å. If the double bond is resonance-stabilized, the cation in **3** attains an 18-electron configuration (Scheme 2). The large O-Mo-O bond angle of 103.0(2)° also lends support to this interpretation.

Scheme 2.

Deprotonation of the cation in **3** yields the mononuclear nitrosyloxomolybdenum complex **4**, the structure of which is shown in Figure 3. The very short Mo–O_{oxo} distance of 1.775(7) Å is an indication of the ($p_\pi \rightarrow d_\pi$) double-bond character of the Mo=O group, whereas the Mo–$O_{hydroxo}$ bond of 1.983(7) Å must be interpreted as a single bond, since it is significantly longer than in **3**. In the IR spectrum of **4**, the ν(Mo=O) stretching band is at 813 cm^{-1}. The ν(OH) stretching band can also be detected unambiguously as a sharp band at 3648 cm^{-1}. Neither the oxo nor the hydroxo group is involved in the intermolecular O–H···O interactions in the crystal packing of **4**.

The crystal structure of **5** (Fig. 4) is notable. The unit cell contains two crystallographically independent neutral [MoL(NO)(O)(OH)] complexes that are coordinated to the Na^+ ions to give a tetranuclear structural unit and form the centrosymmetric dication $[\{MoL(NO)(O)(OH)\}_4Na_2(H_2O)_2]^{2+}$ in the crystal assembly. These units are linked to one another through an intermolecular O(4)···H–O(1a)–H hydrogen bond (not shown in Fig. 4); the charge is balanced by isolated PF_6 anions.

Interestingly the nitrosyl groups of the two crystallographically independent neutral complexes of the cluster are coordinated to the Na^+ ions in different ways. The NO groups of Mo(1) forms a side-on bond, since the N(4)–Na(1) and Na(1)–O(2) distances of 2.775(4) and 2.782(4) Å are almost identical. The shortest calculated distance of the Na^+ ion from the π electron density of this NO^+ ligand is 2.71 Å. In contrast, the NO group of Mo(2) is attached to two Na^+ ions through the bridging O(6)



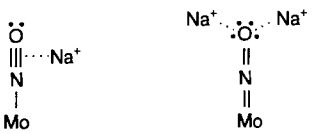


Fig. 4. Schematic structure of a $[\{MoL(NO)(O)(OH)\}_4Na_2(H_2O)_2]^{2+}$ cluster in crystals of **5**. The neutral [MoL(NO)(O)(OH)] unit corresponds largely to that in **4**. For clarity, the carbon atoms and the hydrogen atoms attached to this unit are not shown; * is a crystallographic center of symmetry. Selected distances [Å] (see also Table 1): Na(1)-N(4) 2.775(4), Na(1)-O(2) 2.782(4), Na(1)-O(3) 2.435(4), Na(1)-O(6a) 2.543(4), Na(1)-O(7) 2.366(4); Na(1)-O(6) 2.386(4); Na(1)···Na(1a) 3.791(3); O(3)···O(5) 2.748(6), O(4)···O(1a) 2.715(6).

(μ_3-(NO)-1-κN:2,3-$\kappa^2 O$). In an idealized form, the bonding of the two new structural motifs can be represented by the resonance structures shown in Scheme 3. The Na···O and Na···N interactions are likely to be predominantly of an ionic nature.

Scheme 3.

The Na^+ ion completes its coordination sphere by binding to the oxo group O(3) at Mo(1) and by binding to a water molecule; the overall structure is a strongly distorted NO_5Na octahedron. Within the cluster, the OH group at Mo(2) forms an intramolecular hydrogen bond to the oxo group O(3) at Mo(1). It is instructive to compare the IR spectroscopic properties of the neutral [MoL(NO)(O)(OH)] complexes in **4** and **5** with their structural properties, because the ν(NO) stretching frequency is a sensitive guage of different electron density distributions. In

the crystals of **4**, in which the neutral complexes are not linked to one another by hydrogen bonds or even Na^+ ions, the observed ν(NO) frequency is observed at 1515 cm^{-1}. It thus appears at a much lower energy than in **2** (1719 cm^{-1}) or in **3** (1669, 1642 cm^{-1}). This effect must be attributed to the different strengths of the ($p_\pi \rightarrow d_\pi$) donor bonds in the complexes: the two Br^- ligands in **2** are weaker π-donor ligands than the two HO^- ligands in **3**, whereas the terminal oxo group in **4** is a very strong π donor. The occupation of the π*(NO) orbitals increases in the order $Br^- < HO^- < O^{2-}$, which is related to a weakening of the N–O bond.

As described above, in the crystals of **5** the NO ligands are coordinated to the Na^+ ions in two ways. The IR spectrum therefore shows two ν(NO) vibrations of relatively low intensity, one at 1529 cm^{-1} and the other at the very low frequency of 1476 cm^{-1}(!). The corresponding oxo ligands are also coordinated in different ways: because of the coordination of O(3) to Na(1) and its participation in an intramolecular O-H···O bond, the Mo(1)–O(3) distance is 1.781(3) Å and thus significantly longer than the Mo(2)–O(4) distance of 1.754(3) Å where O(4) only participates in a weak intermolecular O-H···O bond. The oxo group Mo(1)=O(3) in **5** is therefore a comparatively weaker π donor, which is why the higher energy NO stretching frequency of 1529 cm^{-1} should be assigned to this neutral complex. The N–O bond in the complex containing the Mo(2)=O(4) group (stronger π donor) is weakened to a greater extent. This effect may even be intensified by coordination of the NO ligands to *two* Na^+ ions through the oxygen atom O(6). The low-energy ν(NO) stretching frequency of 1476 cm^{-1} is therefore assigned to the neutral complex containing the (μ_3-(NO)-1-κN:2,3-$\kappa^2 O$) bridge. Although this interpretation is supported by the two different N–O bond lengths of 1.241(5) and 1.265(6) Å, the difference is just within experimental error (3 σ).

Complexes **2**, **3**, **4**, and **5** are isoelectronic $\{Mo-NO\}^4$ compounds. The electron density on the molybdenum center is formally increased by the strong π donor O^{2-} in **4** and **5** but can again be lowered by occupation of the π*(NO) orbitals to give a nitrosyl ligand of typical NO^- character. This synergistic bonding model is shown in Figure 5: the d_{xz} orbital localized on the central atom is occupied by two electrons in the $\{Mo-NO\}^4$ complexes as is the p orbital on the O^{2-} ligand, whereas the π* orbital on the NO ligand is initially unoccupied, which implies that π electron density is transferred from the O^{2-} ligand to the Mo center and from there to the π*(NO) orbital.

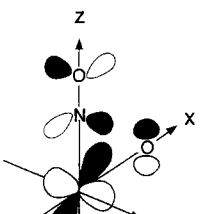

Fig. 5. Model of the π-bonding in the Mo(NO)(O) unit in **4** and **5**.

Experimental Procedure

1: 36% HCl (10 mL) was slowly added to a stirred mixture of [MoL(CO)$_3$] (1.0 g, 2.3 mmol) and $NaNO_2$ (0.30 g, 4.3 mmol) in methanol (100 mL) to give a clear yellow solution accompanied by foaming. After removal of the solvent, the yellow residue was dissolved in H_2O (200 mL), the resulting solution filtered, and a solution of KPF_6 (0.30 g) in H_2O (100 mL) added to the filtrate. A yellow precipitate formed. Yield: 1.20 g (90%).

2: Bromine (1.0 mL) was added to a solution of **1** (1.0 g, 1.7 mmol) in 48% HBr (30 mL), which was then stirred for 10 min. The orange, microcrystalline product obtained was filtered off and washed with ether. Yield: 1.0 g (75%). The analogous PF_6^- salt was obtained from **2** after addition of $NaPF_6$.

3, **3a**: A solution of **2** (1.0 g, 1.3 mmol) in H_2O (30 mL) and tetrahydrofuran (10 mL) was heated at reflux for 5 h. KPF_6 (1.0 g) was added to the filtered solution. Slow evaporation of the solvent gave red crystals of the monohydrate **3a**. Yield: 0.60 g (85%). The anhydrous compound **3** was obtained by recrystallization of **3a** from CH_2Cl_2.

4: Solid NaOH (0.05 g) was added to a solution of **3** (0.10 g, 0.17 mmol) in acetone (1.0 mL), followed by stirring. After the color had changed from red to blue-green, $[Bu_4N]Br$ (0.05 g) was added, and the solution was overlaid with *n*-hexane (1 mL). Slow diffusion of the two layers produced crystals of **4**. Yield: about 0.03 g.

5: When synthesis of **4** was carried out without the addition of $[Bu_4N]Br$, violet crystals of **5** precipitated. Yield: about 0.03 g.

All compounds gave correct elemental analyses (C,H,N).

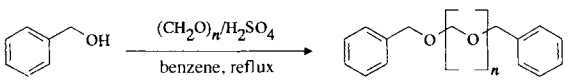
On the Helicity of Oligomeric Formaldehyde

Christian R. Noe,* Christian Miculka, and Jan W. Bats



Since the formulation of the term "stereoelectronic factor" by E. J. Corey a multitude of work has been carried out illustrating the existence and the significance of this effect.[1] Nevertheless,

this concept still meets with skepticism.[2] The main reason for this is that most of the investigations are carried out on polar, multifunctional carbohydrates, in which the relatively weak stereoelectronic effects can often be hidden by other factors. In addition, certain cases of the stereoelectronic effect, such as the anomeric or *gauche* effect, are frequently interpreted as isolated phenomena of individual bonds, and the stereoelectronic properties of the molecule as a whole are neglected. The purpose of investigations into stereoelectronic effects should be to indicate the possibilities and limitations of the interpretation based on considerations of the relevant frontier orbital interactions such as $n-\sigma^*$, $\pi-\sigma^*$, $n-\pi^*$, $\sigma-\sigma^*$, and $\sigma-\pi^*$, which are offered by the very visual valence bond model.

Poly(oxymethylene) can be considered an almost ideal example of a compound with a stereoelectronically determined conformation, because in this simple molecule each bond can be fixed stereoelectronically. The helical conformation of polymeric formaldehyde has been known for a long time[3] and clearly differentiates this compound from polyethylene, which lacks special stabilization and prefers the expected achiral *anti* conformation on steric grounds. Previously, we interpreted the *gauche* configuration of oligomeric formaldehyde determined by X-ray data[4] as an indication of the stereoelectronic effect: we noticed a diastereoselective 1,10 induction between inducing and prochiral centers, which were separated by a tetra(oxymethylene) chain. The direction and extent of the observed induction in the reaction was attributed to the helical stabilization of the chain by stereochemical effects. An X-ray structure analysis of oligo- or poly(oxymethylene)s providing structural details such as bond lengths, bond angles, and torsion angles has not yet been reported.

The melting point of the dimethyl-substituted pentamer of formaldehyde is 18.3 °C.[5] We attempted, therefore, to obtain higher melting formaldehyde oligomers by simply heating paraformaldehyde and benzyl alcohol under acid catalysis. We chose benzyl alcohol since the phenyl group, as well as the oxygen atom, is a "stereoelectronically active", planar (pl) ligand[6] on account of its σ^* orbital. This reaction provided a mixture of chromatographically separable products **1**–**5**.[7]

$n = 1 - 5$

1 - 5

Crystals of the pentamer **5** suitable for X-ray analysis could be obtained by low-temperature crystallization from chloroform/hexane.[8] The unit cell contains two independent molecules, which have a C_2 axis passing through the central carbon atom (Fig. 1). All the torsion angles in the chain are between $-62°$ and $-68°$ and indicate the expected *gauche* configuration, which results in helicity. Since both helices have the same handedness and thus the same absolute configuration, it can be assumed that **5** crystallizes in two enantiomorphic crystal forms.

Consideration of the molecules in the unit cell indicates that they are not identical but rather conformational isomers differentiated by the orientation of the benzyl groups. In molecule **A** the continuous (−)-*gauche* conformation of the chain is continued up to C_{Ar} of the phenyl group; the aryl ligand thus assumes the expected position of a pl ligand following the critera of the b(ulky), pl(anar), H rule (Fig. 2).[6] In molecule **B** C_{Ar} of the phenyl group lies almost antiperiplanar to the first carbon atom

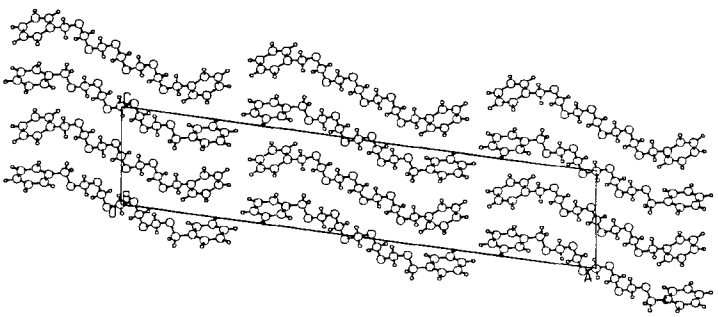

Fig. 1. Crystal structure of **5**; helical conformers with the same absolute configuration within the unit cell are shown.

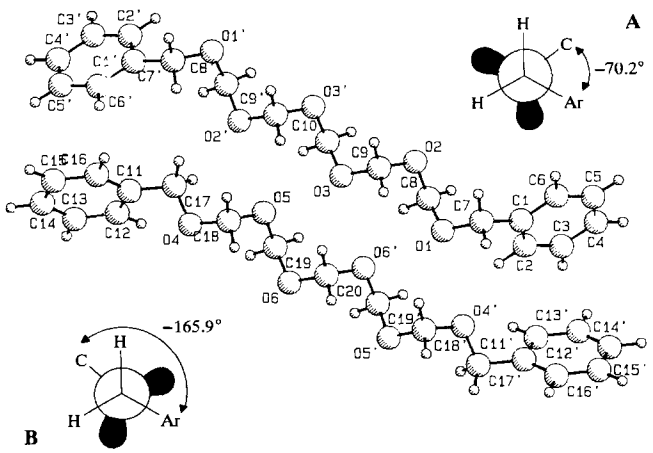

Fig. 2. The two conformational isomers of **5**. In molecule **A** a nonbonding electron pair of the first oxygen atom lies synperiplanar to the antibonding orbital of the aromatic unit (pl ligand).

in the chain, thus assuming the preferred position of a b ligand according to the b, pl, H classification.

The definition of "stereoelectronically determined" bond lengths and angles is provided best by an oligomeric oxymethylene structure. Uniform $n-\sigma^*$ interactions between all atoms along the chain occur without disturbance from other structural elements. The concomitant regular shortening of bonds should in turn be apparent in an X-ray structural analysis. In this respect the results are remarkable: there is not a continuous, symmetrical reduction in bond lengths such that the bonds are close to the same length. Rather a systematic pattern of bonding is seen along the chain (Table 1). In the middle of the chain two shortened bonds (bond lengths ca. 139 pm) alternate with two normal bonds (bond lengths ca. 142 pm). Each oxygen atom has one shortened bond and one of normal length. Partic-

ularly amazing is that the molecules **A** and **B** in the unit cell are, to our knowledge, isomers of a type not previously known. For each bond in the chain the difference in the bond lengths in the two isomers is at least 1.7 pm (in the middle of the chain on average 2.8 pm).

In the benzyl groups of conformer **B** the $C_{Ar}-CH_2$ bond is shortened. This effect is made plausible by the almost orthogonal position of the aromatic unit to the C—O bond and the concomitant $\pi-\sigma^*$ interactions. As is indicated by the bond angle at the benzylic carbon atom (Fig. 3), this should be substantially weaker than the $n-\sigma^*$ interactions in molecule **A**. It is probable that the pattern of bond lengths in the oxymethylene chain in **A** is influenced by the ends of the molecule.

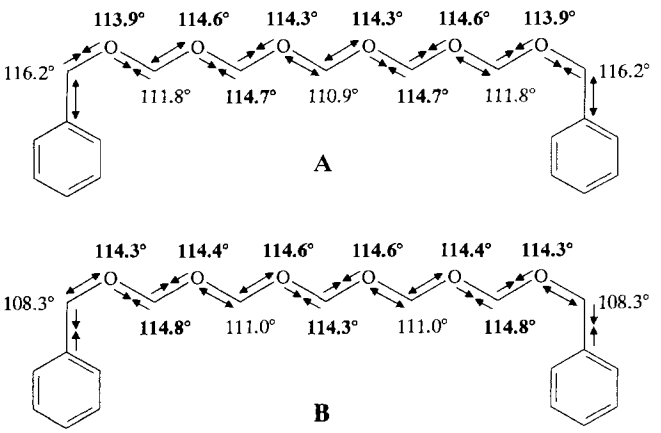

Fig. 3. Patterns of bond lengths and angles in the pentameric formaldehyde derivative **5**.

In connection with stereoelectronic effects the discussion often circles round the question of whether the geometry at the oxygen atom is better described by canonical orbitals or, on practical grounds, by the preferred, graphic model of sp^3 hybridization.[1a] Actually the observed angles lie consistently in a range between 120° (trigonal planar) and 109.5° (sp^3 tetrahedral angle). The oxymethylene structure offers the opportunity to define a standard value for a "stereoelectronically determined" bond angle at oxygen of 114.4° (Fig. 3).

While the bond angles at oxygen in both molecules **A** and **B** indicate almost no variation, the carbon atoms in the chain have an alternating pattern of bond angles, which should be eliminated by the stereoelectronic contribution to their bonding which imparts an increased double bond character (which would be characterized in turn by an increase in the bonding angle towards sp^2). Thus, the O-C-O angle at each carbon atom between two shortened bonds corresponds very closely to the angles at the oxygen atoms (average value 114.7°); the other bond angles are closer to the value at an sp^3 atom (average value 111.3°).

Table 2. Observed torsion angles in the chain of **5** in degrees (in each case the second half of the molecule is ignored).

Molecule **A**		Molecule **B**	
C6-C1-C7-O1	152.9(0.3)	O4-C17-C11-C16	100.4(0.4)
C1-C7-O1-C8	−70.2(0.3)	C18-O4-C17-C11	−165.9(0.3)
C7-O1-C8-O2	−68.4(0.3)	O5-C18-O4-C17	−67.1(0.4)
O1-C8-O2-C9	−66.5(0.3)	C19-O5-C18-O4	−68.5(0.3)
C8-O2-C9-O3	−65.7(0.3)	O6-C19-O5-C18	−64.9(0.3)
O2-C9-O3-C10	−65.2(0.3)	C20-O6-C19-O5	−62.1(0.4)
C9-O3-C10-O3'	−68.1(0.3)	O6'-C20-O6-C19	−66.4(0.3)

The torsion angles in the middle of the chain (Table 2) indicate the deviation from the ideal staggered *gauche* configuration because of the stereoelectronic effect, which leads to a slight twisting of the poly(oxymethylene) helix (Fig. 4).

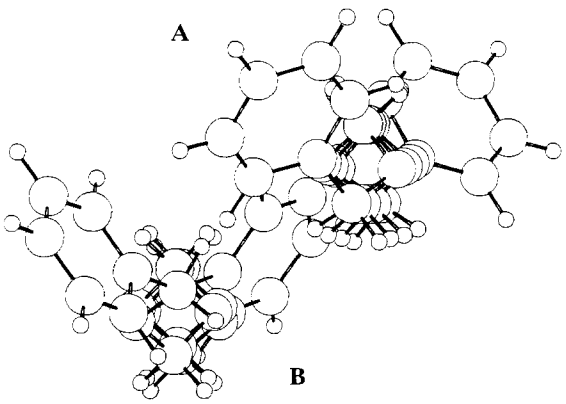

Fig. 4. Comparison of the secondary helices of molecules **A** and **B**. The smaller variation in torsion angles in molecule **A** lead to a more regular secondary helix.

In connection with the *exo* anomeric effect, the Φ torsion angle allows us to define a standard value of 66.3° (cf. that derived from the X-ray analysis of a glycolnitrile acetal[6] of 72.6°).

We are currently studying the structure of oligo- and poly(oxymethylene) helices and the asymmetric induction in their formation.

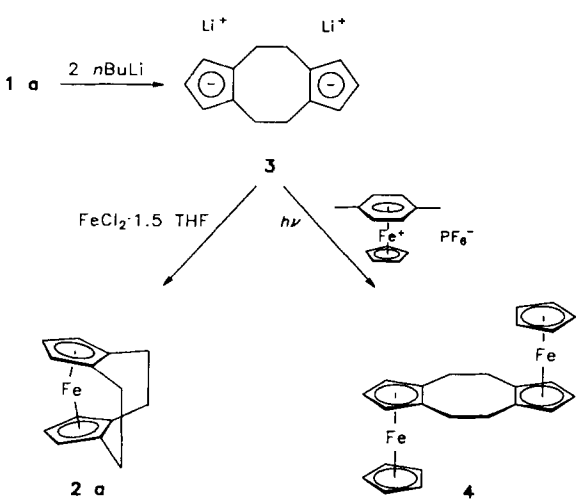
Synthesis and Structure of the First [2₂]Metallocenophanes**

Klaus Hafner,* Carsten Mink, and Hans Jörg Lindner

Dedicated to Professor Virgil Boekelheide on the occasion of his 75th birthday



Bent metallocenes with a nonplanar arrangement of the ring ligands proved to be components of efficient catalysts for the stereoselective polymerization of alkenes.[1] Rigid metallocene derivatives of the fourth subgroup having a short bridge and consequently exposed metal center were found to be particularly well suited.[2] Numerous metallocenophanes have been prepared with one or more bridges of various lengths, but surprisingly [2](1,1')[2](2,2')-metallocenophanes **2** are not known,[3] even though the considerable conformational rigidity of the ligand system and the large dihedral angle between the planes of the rings indicates that they could serve as components of homogeneous catalysts.

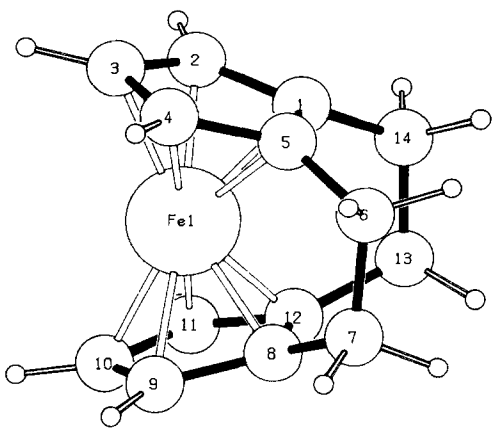
In the course of investigations on dicyclopenta[*a*,*e*]cyclooctene, a 14π electron system with cyclic delocalization,[4] we discovered a simple route to tricyclo[9.3.0.0^{4,8}]tetradeca-4,7,11,14-tetraene (**1**),[5] which proved to be a suitable starting material for metallocenophanes of type **2**. We report here on the

synthesis and structure of ferrocenophane **2a** and zirconocenophane dichloride **2b**, the first [2₂]metallocenophanes.

The dilithium compound **3** was prepared by double deprotonation of **1a** with *n*BuLi in THF at 25 °C. The ^{1}H, ^{13}C, and ^{6}Li

NMR spectra of **3** indicate that it exists as a contact ion pair at −60 °C.[5] The reaction of **3** with (η^6-*p*-xylene)(η^5-cyclopentadienyl)iron hexafluorophosphate[6] at 25 °C by irradiation with a halogen lamp (300 W, Osram Concentra) provided the *trans*-[2₂](1,2)-ferrocenophane (**4**)[7] (18% yield, yellow crystals, decomp > 230 °C), which was previously synthesized by Schlögl et al.[8] from substituted ferrocenes in multistep procedures. Compound **3** reacted with $FeCl_2 \cdot 1.5\,THF$ in THF at 25 °C to afford [2](1,1')[2](2,2')-ferrocenophane **2a** as deep red plates (decomp > 210 °C)[9] in 41% yield.[10] The complex is stable at −50 °C under inert gas but rapidly decomposes at room temperature, particularly in solution.

The X-ray structure analysis of **2a**[11] (Fig. 1) indicates considerable torsion of the two decks. The dihedral angle between



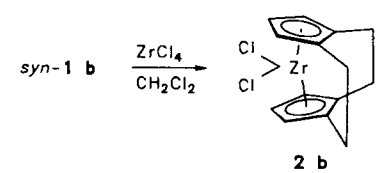


Fig. 1. Crystal structure of **2a** [11]. Selected distances [Å] and angles [°]: C1-C2 143.1(12), C5-C6 149.5(9), C6-C7 150.1(10); C5-C6-C7 113.7(5), C4-C5-C6 128.3(7).

the planes of the two rings is 28.8°, considerably larger than in the known ferrocenophanes.[3] The two small dihedral angles in the bridges (8.2(10) and 6.9(10)°) indicate that the five-membered rings are almost perfectly eclipsed. The average C–C bond length in the cyclopentadienyl ligands (141 pm) corresponds to that of other ferrocenophanes, whereas the average Fe–C distance in **2a** (201 pm) is much shorter.

In contrast to [2]ferrocenophane, which is more Lewis basic than ferrocene,[12] treatment of **2a** with trifluoroacetic acid in dichloromethane at −60 °C did not provide a well-defined protonation product but rather brown-black products insoluble in standard solvents.

In analogy to the synthesis of zirconocene dichloride[13] the reaction of *syn*-6,13-bis(trimethylsilyl)tricyclo[9.3.0.0^{4,8}]-tetradeca-4,7,11,14-tetraene (**1b**) with zirconium tetrachloride in dichloromethane at 25 °C furnished [2](1,1')[2](2,2')-zirconocenophane dichloride (**2b**) in 61% yield as colorless needles (decomp > 270 °C). Compound **2b** can be obtained in analytically pure form by sublimation at 230 °C/10^{-2} mbar.[14]

An X-ray structure analysis of **2b**[11] (Fig. 2) shows that the average Zr–C distance (249 pm) is considerably longer than that in the known [2]zirconocenophane dichlorides.[15] The dihedral angle between the planes of the rings (62.9°) in **2b** is the

[**] This work was supported by the Fonds der Chemischen Industrie and by Degussa AG, Frankfurt/Main.

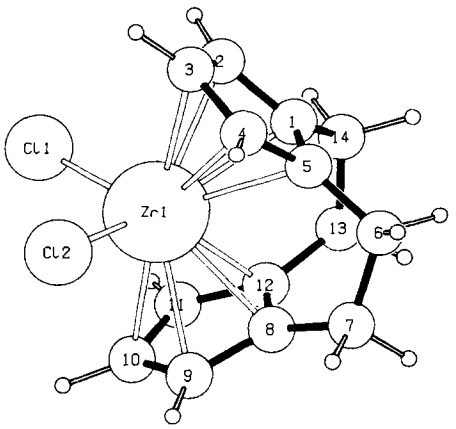

Fig. 2. Crystal structure of **2b** [11]. Selected distances [Å] and angles [°]: C1-C2 140.0(7), C5-C6 150.6(7), C6-C7 149.0(8), Zr-Cl 244.2(1); C5-C6-C7 114.1(4), C4-C5-C6 127.7(5), Cl-Zr-Cl 97.95(5).

largest observed in these compounds. As in **2a** the dihedral angles in the bridges of **2b** (18.6(7) and 20.7(8)°) indicate an approximately eclipsed configuration of the five-membered rings.

Owing to the molecular structure of the new rigid zirconocenophane **2b**, catalytic activity for the stereoselective polymerization of alkenes can be anticipated for this compound or substituted chiral derivatives. Moreover, application of complexes of type **2b** appears promising for C–C bond-forming reactions with metallocene derivatives from the fourth subgroup, which are currently of interest,[16] as well as for the synthesis of novel metallacycles.[16, 17]

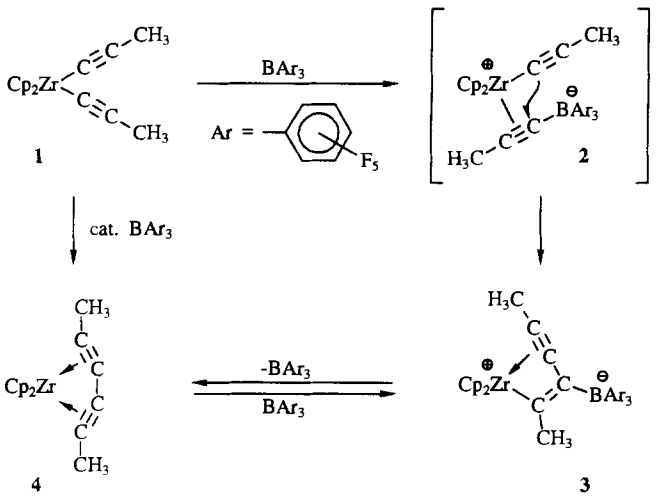
Heterodimetal–Betaine Chemistry: Catalytic and Stoichiometric Coupling of Alkynyl Ligands under the Joint Influence of Zirconium and Boron Centers**



Bodo Temme, Gerhard Erker,* Roland Fröhlich, and Matthias Grehl

We have recently shown that the joint influence of zirconium and boron centers can be used for C–H activation in (μ-hydrocarbon)Zr–B complexes.[1] Beyond this there is evidence that $[Cp_2ZrR]^+/BR_4^-$ ion pairs and betaines are of significance in homogeneous Ziegler–Natta polymerization.[2, 3] We therefore wanted to investigate the previously poorly developed chemistry of Zr–B-containing heterodimetallic betaine complexes.[2] It was found that such $[\{Cp_2ZrR\}^+\{(\mu\text{-}R)BR_3^-\}]$ betaine complexes (to date hardly known) form very easily and that they readily rearrange under carbon–carbon coupling in a way that is typical for this class of compounds, to form an interesting heterodimetal-substituted organic skeleton. In this communication we describe a typical example.

Bis(propynyl)zirconocene (**1**) was obtained by the reaction of $[Cp_2ZrCl_2]$ with two molar equivalents of propynyllithium.[4] The reaction of **1** with tris(pentafluorophenyl)borane in a 1:1 molar ratio in toluene at room temperature rapidly gave the (μ-R)Zr–B betaine complex **3** in 83% yield. The ^{1}H and ^{13}C NMR spectra of complex **3** show resonance signals at δ = 5.32 and 116.3, respectively, for the Cp rings, as well as two singlets at δ = 2.26, 1.04 and 29.7, 10.7, respectively, for the methyl groups. The ^{13}C NMR resonances of the μ-2,4-hexadiyne ligand, which is unsymmetrically coordinated to the participating metal centers, appear at δ = 255.0, 108.5, and 105.0 (the B–*C* signal was not observed).

[**] This work was supported by the Fonds der Chemischen Industrie and the Alfried-Krupp-von-Bohlen-und-Halbach-Stiftung.

The formation of the organometallic betaine **3** can be rationalized by a simple reaction sequence. We assume that the first step involves a transfer of a σ ligand from the zirconium center to the boron atom.[5] Subsequently the insertion of the newly formed boron-substituted alkyne into the remaining metal–carbon σ bond at the zirconium atom presumably leads to the direct formation of **3**.[6]

The reaction takes a different course if **1** is treated with less than one equivalent of $B(C_6F_5)_3$. Thus the reaction of **1** with less than 1 mol% of this borane (room temperature, toluene) leads to C–C coupling of the alkynyl ligands and formation of the isomeric product (η^4-2,4-hexadiyne)zirconocene **4**. Presumably this triarylborane-catalyzed reaction proceeds via **3** as an intermediate, from which the rearranged zirconium complex **4** is liberated by transfer of $B(C_6F_5)_3$ to **1**. As expected, complex **3** also catalyzes the conversion of **1** to **4**.

We treated the (μ-2,4-hexadiyne)zirconium–boron betaine complex **3** with *tert*-butyl isonitrile and discovered a surprising reaction pathway. A simple CNR insertion into the reactive zirconium–carbon σ bond of **3** does not take place. Rather, we obtained the product **7** in good yield through a rearrangement

of the framework and a subsequent reaction with two isonitrile units. An isonitrile building block has been incorporated under C–C coupling and the formation of a cationic ZrNC three-membered ring;[7] for stabilization a second isonitrile then attached itself to the very electrophilic Zr^+ center.[8]

Compound **7** was characterized by an X-ray crystal structure analysis (Fig. 1). The metal complex **7** contains a Cp_2Zr^+ structural unit to which an iminomethyl ligand is η^2-coordinated. Furthermore a $C{\equiv}N{-}CMe_3$ ligand is bonded in a lateral position to the $(\eta^2\text{-}C{=}NR)ZrCp_2^+$ subunit. The nitrogen atom of the iminomethyl ligand occupies the central position in the plane of the σ ligands at the bent metallocene unit. The most remarkable structural feature in **7** is the substituted methylenecyclopropene unit, which is bound to the C5 atom of the ZrNC three-membered ring. The atoms C4 and C2 bear methyl substituents, and the $B(C_6F_5)_3$ unit is bound to C1. This boron-substituted methylenecyclopropene framework was formed by rearrangement of the BAr_3-substituted μ-2,4-hexadiyne ligand of the starting material **3**. Compound **7**, like **3**, is an organometallic betaine complex; the boron atom formally carries the negative charge, and consequently the zirconium center is positively charged. The C1–C2 bond of the central methylenecyclopropene unit of **7** is short [1.326(10) Å]. Its neighboring carbon–carbon bonds in the strained three-membered ring are clearly longer [1.417(10)Å C1–C3; 1.392(10)Å C2–C3], and also the adjacent C3–C4 double bond is only a little shorter [1.389(19)Å]. We assume that the regioselective incorporation into the betaine system stabilizes the very strained hydrocarbon framework in this case.[9] The whole $B^-(\mu\text{-organo})Zr^+$ betaine unit is planar [*0*(C3-C4-C5-N6) 178.5(9)°] and lies in the the σ-ligand plane of the bent metallocene.

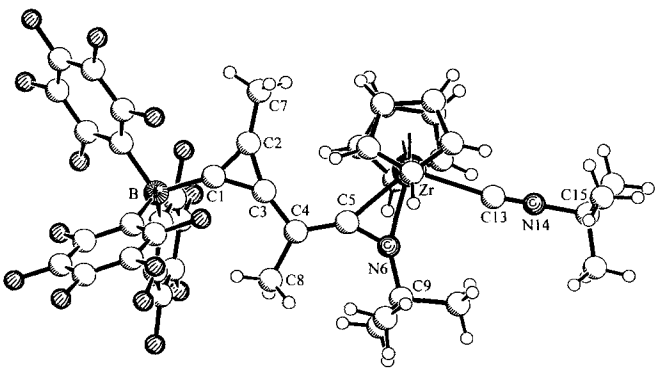

Fig. 1. Molecular geometry of **7**. Selected bond lengths [Å] and bond angles [°]: B-C1 1.627(11), B-C(Ar) (average value) 1.646(11), C1-C2 1.326(10), C1-C3 1.417(10), C2-C3 1.392(10), C2-C7 1.465(10), C3-C4 1.389(10), C4-C8 1.510(10), C4-C5 1.426(10), C5-N6 1.292(9), C5-Zr 2.217(8), N6-Zr 2.177(6), Zr-C13 2.377(9), C13-N14 1.133(9); B-C1-C3 147.5(7), B-C1-C2 151.1(7), C2-C1-C3 60.9(5), C1-C2-C3 62.7(6), C1-C2-C7 146.4(8), C3-C2-C7 150.7(7), C1-C3-C2 56.4(5), C1-C3-C4 143.7(7), C2-C3-C4 160.0(8), C3-C4-C8 115.6(7), C3-C4-C5 117.0(7), C8-C4-C5 127.4(7), C4-C5-N6 139.4(7), C4-C5-Zr 149.4(6), Zr-C5-N6 71.2(4), C5-N6-Zr 74.6(4), C5-N6-C9 133.1(6), C9-N6-Zr 152.3(5), C5-Zr-N6 34.2(2), C5-Zr-C13 121.0(3), Zr-C13-N14 172.0(7), C13-N14-C15 175.6(8).

It was noticed from the formation of **3** from **1** and $B(C_6F_5)_3$ that the alkyne insertion into the Zr–C(sp) σ bond proceeds rapidly in a Zr–B-containing betaine.[10] We therefore assume that, analogously to the above, a betaine-assisted insertion of an alkyne into a Zr–C(sp^2) σ bond is possible. Under these conditions it is apparent that the formation of the Zr–B-substituted methylenecyclopropene framework in the above-mentioned reaction can be taken as an intramolecular alkyne insertion. Compound **3** is possibly in equilibrium with the three-membered ring isomer **5**, though the equilibrium lies almost completely on the side of **3**. Only on addition of the isonitrile does the coordina-

tively unsaturated equilibrium partner **5** react preferentially and thus open the way for the formation of **7** from **3** and *tert*-butyl isonitrile.

These examples show that organometallic betaine compounds with a combination of transition metal and main group metal are easily accessible and that they make characteristic carbon–carbon coupling reactions possible. These variants in the chemistry of heterodimetallic complexes could open interesting routes to new stoichiometric reactions and catalytic processes.

Experimental Procedure

3: Precooled toluene was added at −78 °C to a mixture of **1** (1.50 g, 5.0 mmol) and tris(pentafluorophenyl)borane (2.56 g, 5.0 mmol). The mixture was then slowly warmed to room temperature with stirring and stirred for a further 4 h. The yellow precipitate which formed was filtered off, washed with toluene (30 mL), and dried under vacuum. Yield of **3**: 3.75 g, 81%; m.p. = 74 °C (decomp.). ^{1}H NMR ([D$_6$]benzene): δ = 5.32 (s, 10H, Cp), 2.26 (s, 3H, CH$_3$), 1.04 (s, 3H, CH$_3$); ^{13}C NMR (CD_2Cl_2): δ = 255.0, 151.2 (^1J(CF) = 232 Hz), 142.0 (^1J(CF) = 242 Hz), 140.1 (^1J(CF) = 240 Hz), B(C_6F_5)$_3$, 116.3 (Cp), 108.5, 105.0, 29.7 (CH$_3$), 10.7 (CH$_3$), B–*C* not observed; IR (KBr): $\tilde{\nu}$ = 3120, 2970, 2929, 1644, 1516, 1461, 1376, 1276, 1092, 1018, 977, 815, 761, 694 cm^{-1}. The corresponding hafnium–boron compound **8** was prepared analogously and isolated in 82% yield. M.p. = 78 °C (decomp.). ^{1}H NMR ([D$_6$]benzene): δ = 5.27 (s, 10H, Cp), 2.34 (s, 3H, CH$_3$), 1.00 (s, 3H, CH$_3$); IR (KBr): $\tilde{\nu}$ = 3118, 2967, 2927, 1646, 1517, 1463, 1381, 1279, 1094, 1017, 980, 806, 772, 697 cm^{-1}. Correct elemental analysis for $C_{34}H_{16}BF_{15}Hf\cdot C_7H_8$. The ($\mu$-hexadiyne)Hf–B betaine structure was confirmed for **8** by an X-ray structure analysis, which was, however, not discussed here in detail due to its high *R* value of 0.096.

4: Compound **1** (570 mg, 1.9 mmol) in toluene (30 mL) was stirred with tris(pentafluorophenyl)borane (6 mg, 12 μmol, 0.6 mol%) for 3 d at room temperature. Subsequently the solvent was removed under vacuum, and the resulting complex **4** was washed with pentane (20 mL). M.p. = 105 °C (decomp.). ^{1}H NMR ([D$_6$]benzene): δ = 5.09 (s, 10H, Cp), 2.83 (s, 6H, CH$_3$); ^{13}C NMR ([D$_6$]benzene): δ = 171.7, 132.5, 104.2 (Cp), 18.5 (CH$_3$); IR (KBr): $\tilde{\nu}$ = 3092, 2967, 2900, 1439, 1362, 1263, 1098, 1012, 797, 540, 456 cm^{-1}. We had already prepared the analogous (η^2-2,4-hexadiyne)hafnocene compound **9** earlier by photolysis (HPK 125, pyrex filter, toluene) of bis(propynyl)hafnocene [11]: isolated yield 2.5 g (66%), m.p. = 103 °C (decomp.). ^{1}H NMR ([D$_6$]benzene): δ = 5.04 (s, 10H, Cp), 2.86 (s, 6H, CH$_3$); ^{13}C NMR ([D$_6$]benzene): δ = 173.1, 105.8, 103.4 (Cp), 19.3 (CH$_3$); IR (KBr): $\tilde{\nu}$ = 3100, 2900, 1440, 1360, 1260, 1010, 800 cm^{-1}. Correct analysis for $C_{16}H_{16}Hf$.

7: Compound **3** (200 mg, 0.22 mmol) was suspended in toluene (5 mL), *t*-BuN≡C (0.16 mg, 1.9 mmol) was added, and the mixture stirred for 30 min at room temperature. After cooling to −20 °C complex **7** precipitated in the form of fine needles (210 mg, 91% yield). Crystals suitable for X-ray analysis were obtained by recrystallization from hot toluene (m.p. = 59 °C). ^{1}H NMR ([D$_8$]THF): δ = 5.73 (s, 10H, Cp), 2.52 (s, 6H, CH$_3$), 2.03 (s, 3H, CH$_3$), 1.69 (s, 9H, *t*Bu), 1.28 (s, 9H, *t*Bu); ^{13}C NMR ([D$_8$]THF): δ = 204.0, 169.0 (^1J(BC) = 63.7 Hz), 158.1, 152.3, 146.9, 84.5; B(C_6F_5)$_3$: 149.1 (^1J(CF) = 233 Hz), 139.7 (^1J(CF) = 246 Hz), 137.7 (^1J(CF) = 251 Hz), 106.2 (Cp), 60.0 ($C(CH_3)_3$), 57.5 ($C(CH_3)_3$), 31.6 ($C(CH_3)_3$), 29.3 ($C(CH_3)_3$), 23.4 (CH$_3$), 12.0 (CH$_3$); *ipso*-B(C_6F_5)$_3$ carbon not observed; IR (KBr): $\tilde{\nu}$ = 2986, 2932, 2873, 2195, 1809, 1642, 1580, 1513, 1495, 1465, 1374, 1277, 1188, 1092, 1045, 1013, 978, 893, 801, 731, 686 cm^{-1}. Correct analysis for $C_{44}H_{34}BF_{15}N_2Zr\cdot C_7H_8$.

Data for the X-ray structure analysis of **7**: Formula $C_{44}H_{34}BF_{15}N_2Zr\cdot 3C_7H_8$, M = 1254.2, crystal size 0.15 × 0.1 × 0.1 mm, a = 13.354(4), b = 14.778(5), c = 17.269(5) Å, α = 65.31(1), β = 73.08(2), γ = 89.95(2)°, V = 2934(2) Å^3, $\rho_{calcd.}$ = 1.420 gcm^{-3}, μ = 2.78 cm^{-1}, Z = 2, triclinic, space group $P\bar{1}$ (no. 2), Enraf–Nonius CAD 4 diffractometer, λ = 0.71073 Å, (ω − 2θ) scan, 8229 measured reflections ($\pm h$, $\pm k$, $-l$), [sinθ/λ]$_{max}$, 0.55 Å^{-1}, 7915 independent and 3693 observed reflections [$F \geq 4\sigma(F)$], 725 refined parameters, R = 0.063, wR^2 = 0.135, max. residual electron density 0.63(−0.50) e Å^{-3}, direct methods, H-atom positions calculated. Programs used: SHELX 93, SCHAKAL. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-400795, the names of the authors, and the journal citation.

Chlorine Trioxide: Spectroscopic Properties, Molecular Structure, and Photochemical Behavior**

Hinrich Grothe and Helge Willner*

Several years ago the symmetric ClO_3 radical was postulated as intermediate in the formation of chloryl perchlorate $O_2ClOClO_3$ from ClO_2 and O_3[1, 2] and in the gas-phase photolysis of ClO_2.[3] Despite its key role for the understanding of the chemistry of binary chlorine oxides and its potential significance for the chemistry of the stratosphere,[4] its existence could not yet be established. The determination of the molecular weight of gaseous Cl_2O_6[6] and the molecular magnetic properties of liquid Cl_2O_6[6] led to the formulation of the equilibrium $Cl_2O_6 \rightleftharpoons 2ClO_3$, which found its way into many textbooks. A few years ago, however, we showed that such an equilibrium does not exist.[2] Since experimental evidence was lacking, comprehensive ab initio calculations have been undertaken for different isomers to predict the physical molecular properties of the

ClO_3 radical,[7, 8] and in this way the structure and infrared spectrum of the ClO_3 radical were calculated.[8] Now we describe the first experimental evidence for ClO_3 through vacuum flash pyrolysis of chlorine perchlorate Cl_2O_4 and matrix isolation of the products.

Vacuum flash pyrolysis of thermolabile compounds generates transient species, which can easily be trapped in a matrix and characterized by spectroscopy. By this method the $CH_3C(O)OO$ radical, for example, was synthesized by pyrolysis of peroxyacetyl nitrate and detected by IR spectroscopy.[9] We have now studied the pyrolysis products of chlorine perchlorate[10] (diluted in neon, argon, or oxygen in the ratio 1:400). At a pyrolysis temperature of 400 °C, a Cl_2O_4 partial pressure of 10^{-3} mbar, and a residence time of the Cl_2O_4 molecules in the pyrolysis zone of a few ms, 50% of the Cl_2O_4 decomposes into ClO and a new chlorine oxide. The proportion of the decomposed Cl_2O_4 can be determined by comparison of the IR spectra of the matrix-isolated starting compounds (that is, without pyrolysis). ClO was identified through the UV spectrum of the matrix-isolated products (Fig. 1). As in the gas phase, ClO in the matrix also

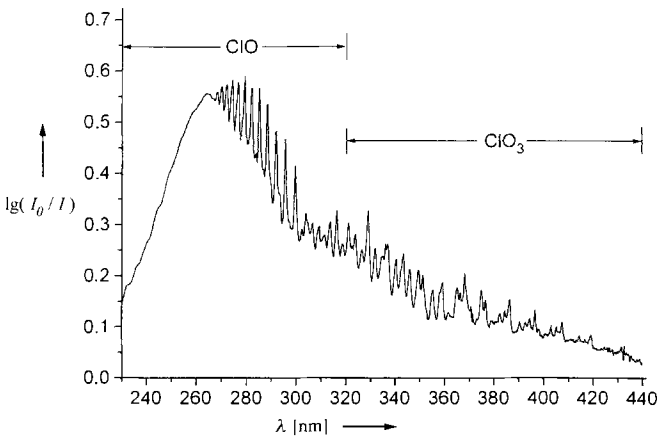

Fig. 1. UV spectrum of the products of the vacuum flash pyrolysis of $ClOClO_3$ in a neon matrix. Below 250 nm unchanged $ClOClO_3$ distorts the band profile of ClO in this region.

absorbs between 230 and 330 nm; the absorption band displays vibrational fine structure.[11] Furthermore, the values of the weak IR absorptions at 843.76 (^{35}ClO) and 836.57 cm^{-1} (^{37}ClO) in the neon matrix agree well with those recorded in the gas phase ($v_0, {}^2\Pi_{3/2}$) of 844.199 and 837.106 cm^{-1}.[12] Figure 2 shows the complete IR spectrum of the new chlorine oxide, and the vibrational wavenumbers are listed in Table 1. The ratio of the intensities of these bands was unchanged in several experiments. The intensity decreases monotonically during the photolysis of the matrix, which suggests that the bands stem from one species. The threshold for the photodissociation lies at 530 nm, and the photolysis product shows bands at $\tilde{\nu}(OO) = 1549.1$ and $\tilde{\nu}(^{35}ClO) = 839.4\ cm^{-1}$ (neon matrix). In contrast, the photolysis of the new chlorine oxide in an O_2 matrix yields ClO_2 and O_3.

The IR bands of the new chlorine oxide display an isotope pattern consistent with a molecule containing one chlorine atom. In experiments with ^{18}O-enriched Cl_2O_4, four isotopomers were detected (Fig. 3), from which it is deduced that the molecule incorporates three oxygen atoms. These findings and the number of IR-active fundamental modes (four) prove unambiguously the presence of a ClO_3 species with C_{3v} symmetry, for which the irreducible representation (a) is valid.

$$\Gamma_{vib} = 2\ a_1\ (IR, Raman\ p) + 2e\ (IR, Raman\ dp) \qquad (a)$$

Finally the good agreement of the measured and calculated values (see Table 1) leaves no doubt about the detection of the ClO_3 radical and confirms the assignment of the vibrational bands.

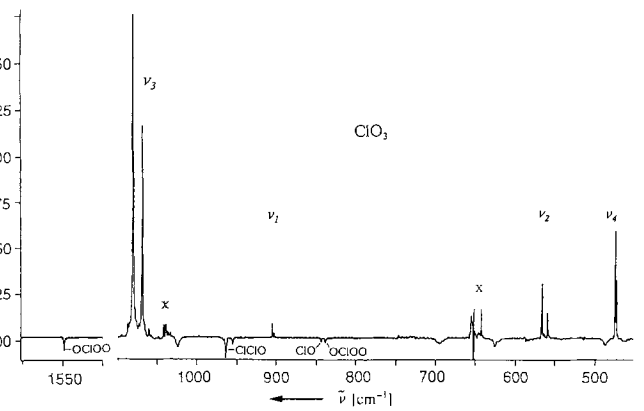

Fig. 2. Difference spectrum of the IR spectra of the pyrolysis products of Cl_2O_4 isolated in a neon matrix before and after the photolysis with light of wavelength greater than 420 nm. The bands of the ClO_3 point upwards and those of the OClOO isomer downwards. The bands of the photostable chlorine perchlorate that are not completely compensated are labeled X. ClClO is the photolysis product of ClOCl, which arises from the hydrolysis of chlorine perchlorate.

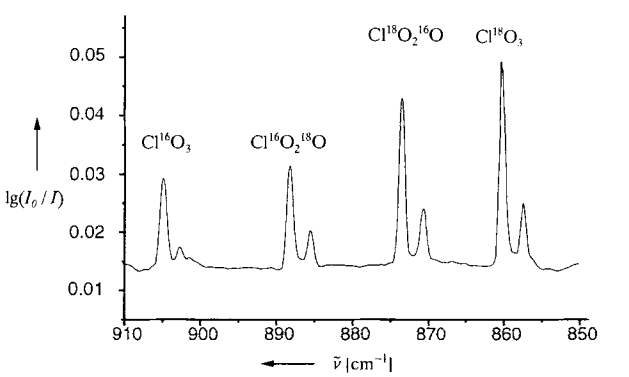

Fig. 3. IR bands of the symmetric Cl–O stretching band ν_1 of ^{18}O-enriched ClO_3, isolated in a Ne matrix.

The bond angle and harmonic force field were calculated from the analysis of the complete vibrational spectra of the four isotopomers of the ClO_3 radical. The required anharmonicity correction of the fundamental vibrations were performed according to Ref. [13]. Thus, the comparison of the isotope pairs $^{35}Cl^{16}O_3/^{37}Cl^{16}O_3$ and $^{35}Cl^{16}O_3/^{35}Cl^{18}O_3$ affords a O-Cl-O bond angle of $113.5 \pm 2^\circ$ (computed by ab initio methods: 114°[8]). The Cl–O force constant is $6.21 \times 10^2\ N\,m^{-1}$, and from a comparison of the corresponding force constants and bond lengths of ClO_2[13] (7.055 $N\,m^{-1}$, 146.98 pm) and ClO[12] (4.713 $N\,m^{-1}$, 156.96 pm), a ClO bond length of 150.0 ± 1 pm (calculated by ab initio methods: 144.5 pm[8]) is estimated. As anticipated, the O-Cl-O bond angle and the Cl–O force constant in the ClO_3 radical are both larger than in the ClO_3^- ion (106.6°, $5.87 \times 10^2\ N\,m^{-1}$).[14]

The UV spectrum of ClO_3 (Fig. 1) overlaps with that of ClO below 300 nm. Like the UV spectra of ClO and ClO_2,[11] it displays a pronounced vibrational fine structure, which, however, has a smaller absorption cross-section than ClO. The excitation of ClO_3 in a matrix with light of wavelength greater than 420 nm leads to OClO and O. In an O_2 matrix the O atom is trapped as O_3; in a neon matrix it reacts with OClO to OClOO, an unsymmetrical ClO_3 isomer. From the position of the O–O vibration and from the slight red shift of the Cl–O vibration relative to that of ClO in a neon matrix (see above), the bond between ClO and O_2 is deduced to be very weak. This isomer absorbs UV light below 295 nm. After photolysis the bands of OClOO disappear from the IR spectrum, and a van der Waals complex $[ClO/O_2]$ remains in the matrix cage with $\tilde{\nu}(^{35}ClO) = 844.4\ cm^{-1}$.

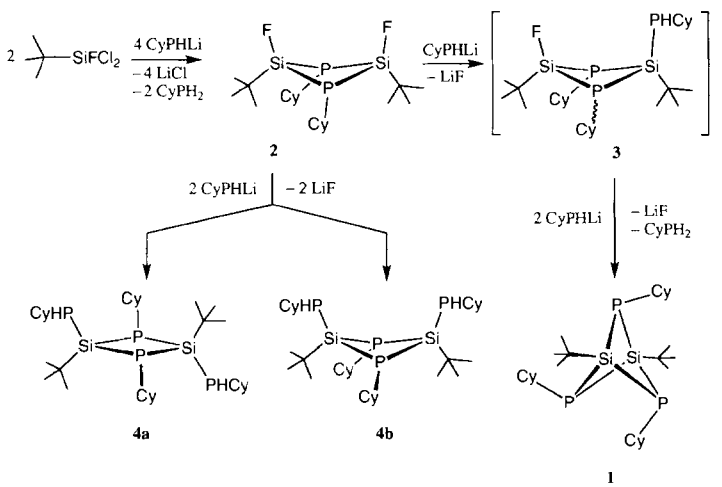
$(t\mathrm{BuSi})_2(PC_6H_{11})_3$: A Propellane-Like Cyclosilaphosphane with Remarkable Structure**

Matthias Driess,* Rolf Gleiter, Rudolf Janoschek,* Hans Pritzkow, and Michael Reisgys

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

Since the synthesis of [1.1.1]propellane[1a] and because of its remarkable stability, the question of the existence of hetero-[1.1.1]propellanes **A** containing heavy elements of group 14 as framework atoms and of the related heterobicyclo[1.1.1]-pentanes **B** has become very topical. **A** and **B** possess remarkable electronic structures, which differ significantly from those



of the carbon compounds. For example, the bridged centers X1 and X3 are at almost the same distance from one another in each of the corresponding framework topologies **A** and **B**, and exhibit only a weak bonding interaction. This is substantiated by theoretical studies[1b] as well as by some structural data from corresponding pentasila[2a] and pentastanna compounds.[2b]

Interesting questions with regard to the chemical bonding also arise for structurally analogous compounds of the types **C** and **D**, in which the two centers X (X = Si, Ge, Sn) are bridged by three methylene groups or heteroatoms Y (Y = CH_2, O, S). Quantum chemical calculations for **C** and **D** gave unusually short X–X distances and an antibonding interaction between the two centers X; the difference in electronegativity between X and Y appears to play a key role.[3] Whereas a propellane analogue of type **C** has so far not been prepared, 2,4,5-triselena-1,3-disilabicyclo[1.1.1]pentane $[(Me_3Si)_3C-Si]_2Se_3$,[4] a compound of type **D**, was synthesized recently. We report here on the first 2,4,5-triphospha-1,3-disilabicyclo[1.1.1]pentane **1**, the electronic structure of which we have determined by photoelectron spectroscopy and quantum chemical calculations (MP2/6-31G*, RHF/DZ + POL). Its molecular structure can be explained simply with a consistent bonding model. Compound **1**[5] is formed by the reaction of tBuSiFCl$_2$ with CyPHLi (Cy = cyclohexyl) in the molar ratio 1:3 in THF in 33% yield. In this reaction the lithium phosphanide acts as a nucleophile and as an auxiliary base. Surprisingly, not only the kind of the *tert*-butyltrihalogensilane employed, but also the solvent used plays a

decisive role in the success of the synthesis: the desired bicyclic system was not obtained (^{31}P NMR) either with tBuSiCl$_3$ instead of tBuSiFCl$_2$ or with Et$_2$O instead of THF as solvent. The reaction mechanism for the formation of **1** is not yet known. We assume that the cyclocondensation of tBuSiFCl$_2$ and CyPHLi initially leads to the P$_2$Si$_2$ heterocyclobutane **2** as an intermediate. With additional phosphanide, **2** is converted into the *Si*-phosphanyl-substituted 1,3-diphospha-2,4-disilacyclobutane **3** and the diastereomeric *Si,Si'*-diphosphanyl-substituted derivatives **4** (Scheme 1).

Scheme 1. Postulated mechanism of the formation of **1**, **2**, **4a,b**. Cy = cyclohexyl.

Metalation of the exocyclic phosphorus atom in **3** with CyPHLi and subsequent cyclization with elimination of LiF leads to the formation of **1** (Scheme 1). In agreement with this mechanism is the fact that in addition to **1** only the compounds **4a,b** are formed. Compounds **4a,b** were characterized by NMR spectroscopy, mass spectrometry, and X-ray crystallography (Fig. 1a,b).[6, 7] Furthermore, **2** was isolated[6] and characterized by an X-ray crystal structure analysis.[7] Whereas a folded cycle is present in **2** and **4b**, the Si$_2$P$_2$ framework in **4a** possesses an inversion center.

The structure of **1** can be derived from the simple NMR spectra and its composition is confirmed by mass spectrometry and elemental analysis.[5] The ^{31}P NMR spectrum shows a singlet at $\delta = -69.7$ and the ^{29}Si NMR spectrum reveals a quartet at $\delta = -14.1$ with ^1J(Si, P) = 61.6 Hz. The value of the coupling constant ^1J(Si, P) is unexpectedly high for a four-membered cyclosilaphosphane and lies in the range normally associated with three-membered Si,P ring systems.[8] An X-ray crystal structure analysis of **1**[7] confirms that the bicyclic system has an unusual ring geometry (Fig. 2).

The endocyclic bond angles at the pyramidally coordinated P atoms lie between 66.7(1) and 67.4(1)°, that is they correspond to those in three-membered rings, whereas values between 82 and 85 are found in 1,3-diphospha-2,4-disilacyclobutanes (Fig. 1a,b).[9] Due to the acute inner angle at the phosphorus in **1**, the two Si atoms are remarkably close to each other (2.518(3) Å). This distance could imply a bonding interaction between the Si atoms, since it lies in the range for Si–Si single bond lengths (2.3–2.7 Å). Similar geometric relations were also observed for the Si$_2$Se$_3$ bicyclic system [(Me$_3$Si)$_3$CSi]$_2$Se$_3$.[4] A Si–Si bond strengthened by three-center bonds ("σ-bridging π orbitals") was proposed as an explanation for this extraordinary

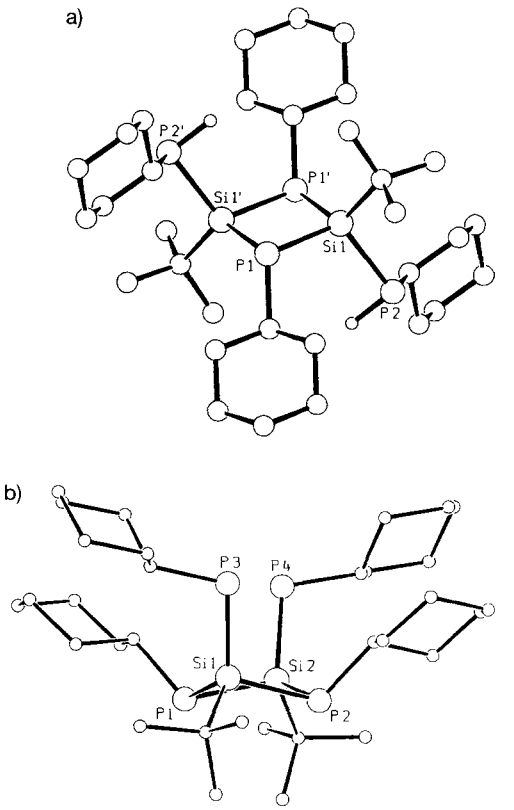

Fig. 1. a) Crystal structure of **4a**. Selected distances [Å] and angles [°]: Si1–P1 2.261(3), Si1–P2 2.278(4), Si1'–P1 2.274(4); Si1'-P1-Si1 83.86(12), P1'-Si1-P1 96.14(12), P2-Si1-P1 112.23(10), P2-Si1-P1' 107.56(12). b) Crystal structure of **4b**. Selected distances [Å] and angles [°]: Si1–P1 2.271(2), Si2–P1 2.272(1), Si1–P2 2.269(1), Si2–P2 2.269(2), Si1–P3 2.258(1), Si2–P4 2.269(1); Si2-P1-Si1 82.16(5), Si2-P2-Si1 82.28(5), P1-Si1-P2 92.71(5), P1-Si2-P2 92.67(5).

structure and thus an analogy to the bonding in chalcogen disiliranes was made. However, in this bonding model derived from calculations not all occupied orbitals were completely included.[4] Taking all the occupied orbitals into consideration, our calculations result in a net positive charge at the silicon atoms (0.665) and a total Si–Si bond order of −0.260, that is, in contrast to the proposed bonding model, an antibonding Si–Si interaction occurs. In comparison: the Si–Se bond order in the Si$_2$Se$_3$ bicyclic system is 0.323.[10]

Thus, what are the reasons for the unusual structure of **1**? We assume that geometric factors, in particular, are responsible for the short Si–Si distance and the small endocyclic angles at the phosphorus atoms. There is a tug-of-war between the three Si-P-Si and the six P-Si-P angles. Every increase of

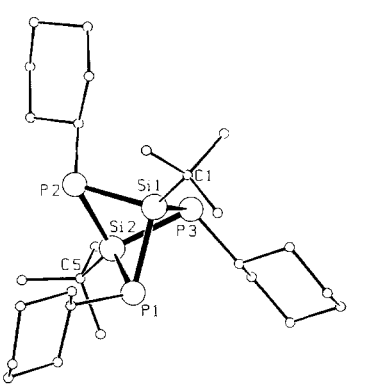

Fig. 2. Crystal structure of **1** (for the part with the higher occupation density). Selected distances [Å] and angles [°]: Si1–C1 1.906(6), Si1–P1 2.294(3), Si1–P2 2.274(3), Si1–P3 2.275(3), Si2–C5 1.900(5), Si2–P1 2.286(4), Si2–P2 2.267(3), Si2–P3 2.261(3); Si1-P1-Si2 66.7(1), Si1-P2-Si2 67.3(1), Si1-P3-Si2 67.4(1), P1-Si1-P2 91.0(1), P2-Si1-P3 93.6(1), P1-Si1-P3 91.7(1), P1-Si2-P2 91.4(1), P2-Si2-P3 94.2(1), P1-Si2-P3 92.3(1).

the Si–Si distance and thus the widening of the three Si-P-Si angles would lead to a reduction of the six already very small P-Si-P angles. A Si-P-Si inner angle of 82°, usual for Si_2P_2 cyclobutanes, would lead to a P-Si-P angle of 83° in **1**.[11] A reduction of the Si-P-Si angle to 67° lowers the angle strain at the silicon atoms (increase of the endocyclic P-Si-P angles to 93°). As a result of this the P-Si-P angles are approximately the same size as the endocyclic ones in **4b**, and somewhat smaller than those in **4a**. However, the Si–Si distance in **4a** is 3.02 Å and that in **4b** is 2.98 Å, and the mean exocyclic P-Si-P angles are 109.9 (**4a**, Fig. 1a) and 114° (**4b**, Fig. 1b), respectively.

MO calculations[12] on $(MeSi)_2(PMe)_3$ (Fig. 3, Table 1), as for the Si_2Se_3 bicyclic system, resulted in a Si–Si bond order of

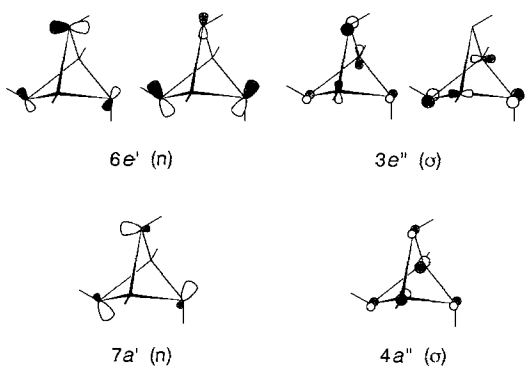

Fig. 3. Calculated frontier orbitals for the Si_2P_3 framework.

−0.300 and a Si–P bond order of 0.348. In the equilibrium structure the P atoms—like in the structure of **1**—are pyramidally coordinated (molecular symmetry C_{3h}). The calculated

Table 1. Comparison of several distances [Å] and angles [°] of **1** with the corresponding calculated values of $(MeSi)_2(PMe)_3$ (RHF/DZ + POL) [12].

	1	$(MeSi)_2(PMe)_3$
Si-Si	2.518(3)	2.548
P-Si	2.261(3)–2.294(3)	2.262
Si-C	1.900(5), 1.907(7)	1.870

orbital energies were correlated (Koopmans theorem,[13] Table 2) with the measured ionization energies (vertical transitions) from the photoelectron spectrum of **1**.

Table 2. Experimental ionization energies I_{vi} (vertical transitions) of **1** [eV] and calculated orbital energies $-\varepsilon_i$ [12] of $(MeSi)_2(PMe)_3$ [C_{3h}].

Assignment	I_{vi} (**1**)	$-\varepsilon_i$ ($(MeSi)_2(PMe)_3$)
6e' (n)	7.3	8.3
7a' (n)	8.2	9.6
3e" (σ)	8.4	9.7

The comparison of the results of the MO calculation and photoelectron spectroscopy shows that the highest occupied orbitals (Fig. 3, Table 2) are of the n_P type (lone pair of electrons at phosphorus). The first n_P ionization energy is about 0.5 and the σ_{SiP} energy is about 1 eV lower than that in other silylphosphanes.[14] Interestingly, the calculated inversion barriers at the phosphorus atoms[15] in $(HSi)_2(PH)_3$ are 41.2 (MP2/6-31G*) and in $(MeSi)_2(PMe)_3$ 43.3 kcal mol^{-1} (RHF/DZ + POL) per P atom, compared with 35.4 kcal mol^{-1} in PH_3 (MP2/6-31G*) and 13.4 kcal mol^{-1} in $MeP(SiMe_3)_2$ (RHF/DZ + POL). A lower P inversion barrier (15–20 kcal mol^{-1}) was calculated for P_2Si_2 heterocyclobutanes, like for $MeP(SiMe_3)_2$, due to the σ donor effect ($Si^{\delta+}-P^{\delta-}$).[9] The inversion barriers for $(HSi)_2(PH)_3$ and $(MeSi)_2(PMe)_3$, which are spectacularly high for silylphosphanes, can be explained by the strongly antibonding interactions between the pure p-like lone pairs of electrons at the trigonal-planar configurated phosphorus atoms (molecular symmetry D_{3h}). According to MP2/6-31G* calculations the D_{3h} structure of $(HSi)_2(PH)_3$ is that of the triplet state, which lies even lower—by 1.9 kcal mol^{-1}—than that in the D_{3h} optimized singlet state.[12] We are currently investigating whether it is possible to synthesize a compound containing a trigonal-planar coordinated phosphorus by using suitable bulky electropositive substituents.

Experimental Procedure

$C_6H_{11}PH_2$ (5.3 g, 45.7 mmol) dissolved in THF (150 mL) was monolithiated at −70 °C with *n*BuLi (18.3 mL, 2.5 M solution in hexane). *t*BuSiFCl$_2$ (2.65 g, 15.2 mmol) dissolved in THF (50 mL) was added dropwise to this solution over an hour. After the pale red solution had been allowed to warm slowly to room temperature, the solvent was removed under vacuum (10^{-2} Torr) and the pale yellow, solid residue was taken up in toluene (50 mL). LiCl was removed by filtration and the solvent was removed again under vacuum. Compound **1** was isolated by crystallization from hexane. Yield: 1.3 g (2.54 mmol; 33%), colorless crystals, m.p. 211–213 °C.

2 and **4a, b** were obtained from the mother liquor after several fractionating crystallizations [6].

[15] Although the structure with a planar configurated phosphorus atom is irrelevant for the singlet state, the relative energy with respect to that of the minimum, divided by three, can be defined as the "average inversion barrier" at the phosphorus atoms.

A Highly Distorted and an Undistorted Borirane, C-B-H Hyperconjugation Induced by C-Si-H Hyperconjugation**

Christian Balzereit, Claudia Kybart, Heinz-Jürgen Winkler, Werner Massa, and Armin Berndt*

The methyleneborane **1**[1] adds trimethylsilylacetylene (**2**) at −30 °C to give the 1,4-diboraspiro[2.3]hex-5-ene **3**, whose four-membered ring is extended already at this temperature by the addition of another molecule of **2** to form the six-membered ring of the 1,4-diboraspiro[2.5]octa-5,7-diene **4** (Dur = 2,3,5,6-tetramethylphenyl). Some physical data of **3** and **4** are given in Table 1; Figure 1 shows the crystal structures of **3** and **4**.[2] The four-membered ring in **3** is folded by 30° along the short[3] (186.9 pm) B–C diagonal. This was to be expected because of the shielding of the boron atom ($\delta(^{11}B) = 32$) and the deshielding of the neighboring tricoordinate C atom ($\delta(^{13}C) = 176.1$), which indicate a strong 1,3 interaction.[4]

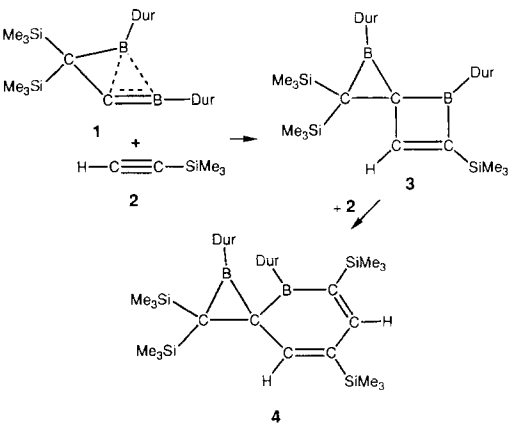

Table 1. Some physical data of **3**, **4**, and **8**.

3: Colorless crystals, m.p. 100 °C (decomp), yield (NMR spectroscopic): quantitative. ^{1}H NMR (400 MHz, $CDCl_3$, −30 °C): $\delta = 0.02, 0.39$, (each s, each 9H, $SiMe_3$ on the three-membered ring, 0.23 (s, 9H, $SiMe_3$ on the four-membered ring), 2.28, 2.35, 2.38, 2.39, 2.49, 2.77 (each s, in total 24H, *o*- and *m*-CH_3), 7.05, 7.44 (each s, each 1H, *p*-H), 8.11 (s, 1H, CH in the four-membered ring); ^{13}C NMR (100 MHz, $CDCl_3$, −30 °C): $\delta = -1.3$ (q, 3C, $SiMe_3$ on the four-membered ring), 2.1, 3.0 (each q, each 3C, $SiMe_3$ on the three-membered ring), 19.3, 19.5, 19.95, 20.0, 20.5, 20.8 (each q, in total 8C, *o*- and *m*-CH_3), 24.7 (s, 1C, CSi_2), 53.1 (s, 1C, CB_2), 129.9 (d, 1C, *p*-C), 131.7 (s, 1C, *i*-C), 132.3, 132.5, 133.7, 134.5 (each s, each 1C, *o*- and *m*-C), 137.5 (d, 1C, *p*-C), 138.4 (s, 1C, *i*-C), 146.0 (br. s, 2C, *o*-C in the three-membered ring), 154.3 (d, $^1J(C,H) = 168$ Hz, 1C, CH in the four-membered ring), 176.1 (s, 1C, =CB in the four-membered ring); ^{11}B NMR (96 Hz, pentane, −10 °C): $\delta = 32, 69$.

4: Colorless crystals, m.p. 143 °C (conversion into **8**), yield 60%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = -0.23, -0.03, 0.21, 0.29$ (each s, each 9H, $SiMe_3$), 1.40, 1.44, 1.79, 2.03, 2.13, 2.18, 2.26, 2.49 (each s, each 3H, *o*- and *m*-CH_3), 6.79, 7.16 (each s, each 1H, *p*-H), 7.12, 7.91 (each d, $^4J(H,H) = 0.7$ Hz, each 1H, CH in the six-membered ring); ^{13}C NMR (100 MHz, $CDCl_3$, −30 °C): $\delta = -0.8, 0.5, 3.8, 4.0$ (each q, each 3C, $SiMe_3$), 17.7, 19.8, 20.0, 20.2, 20.3, 20.8, 21.5, 23.1 (each q, each 1C, *o*- and *m*-CH_3), 42.3 (s, 1C, CSi_2), 71.7 (s, 1C, CB_2), 129.4, 136.4 (each d, each 1C, *p*-C), 130.9 (s, 1C, BCSi), 131.8, 132.5, 132.8, 133.0, 133.3, 134.1, 136.1, 142.2, 143.6 (each s, each 1C, *o*- and *m*-C and CSi in the six-membered ring), 143.9, 147.2 (each s, each 1C, *i*-C), 152.5 (d, $^1J(C,H) = 148$ Hz, 1C, CH in the six-membered ring), 161.4 (d, $^1J(C,H) = 152$ Hz, 1C, CH in the six-membered ring); ^{11}B NMR (96 Hz, $CDCl_3$, 25 °C): $\delta = 57, 69$.

8: Colorless crystals, m.p. 134 °C, yield: quantitative. ^{1}H NMR (500 MHz, $CDCl_3$, −30 °C): $\delta = -0.34, 0.04, 0.16, 0.31$ (each s, each 9H, $SiMe_3$), 1.68, 2.02, 2.16, 2.26, 2.28, 2.29, 2.46, 2.51 (each s, each 3H, *o*- and *m*-CH_3), 4.01 (d, $^3J(H,H) = 4.6$ Hz, 1H, HCSi), 6.95, 7.02 (each s, each 1H, *p*-H), 7.23 (d, $^3J(H,H) = 4.6$ Hz, 1H, =CH in the six-membered ring; ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): $\delta = -0.9, 0.6, 1.1, 3.6$ (each q, each 3C, $SiMe_3$), 19.8, 20.1, 20.4, 21.0, 21.1, 22.2, 25.5 (each q, in total 8C, *o*- and *m*-CH_3), 48.6 (s, 1C, CSi_2), 62.6 (d, $^1J(C,H) = 117$ Hz, 1C, CHSi), 130.5, 130.9 (each d, each 1C, *p*-C), 132.2, 132.51, 132.54, 132.8, 133.6, 133.9, 134.2, 134.9, 135.5, 136.0 (each s, each 1C, *o*- and *m*-C and =CSi), 138.5 (s, 1C, $BCCSi_2$), 146.0, 146.7 (each s, 1C, BCCSi); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 43, 72$.

HF/STO-3G or 6-31G* and MP2/6-31G* calculations on the unsubstituted 1,4-diboraspiro[2.3]hex-5-ene and on boracyclobutene, respectively, had given fold angles of 13, and 28°[5] and 33°[6], respectively. The B–C distances in the borirane ring of **3** (151.9 and 154.4 pm) correspond to those calculated for

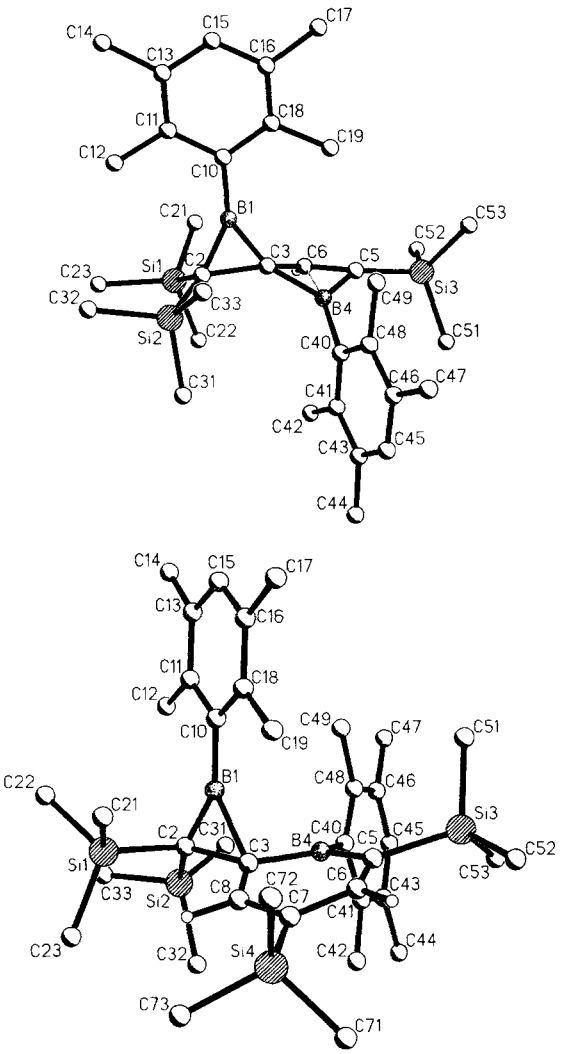

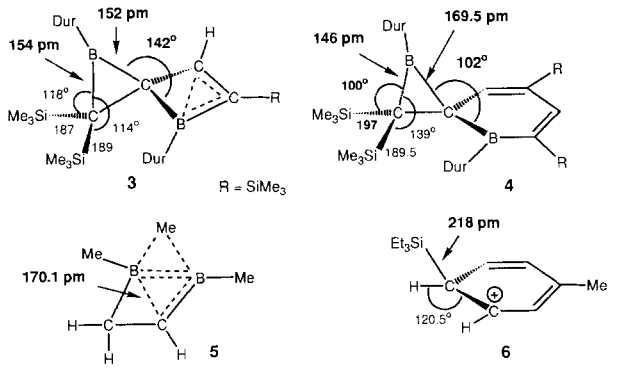

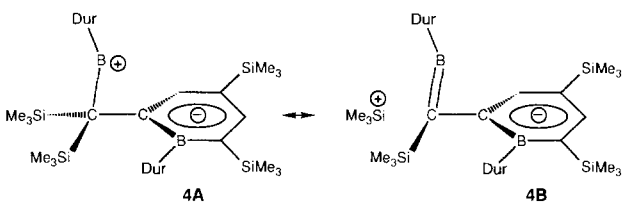

Fig. 1. Crystal structures of **3** (top) and **4** (bottom). Important distances [pm] and angles [°]: **3**: B1-C2 154.4(7), C2-C3 160.7(6), B1-C3 151.9(7), C3-B4 162.0(7), B4-C5 153.4(7), C5-C6 137.7(6), C6-C3 151.1(7), C6-B4 186.9(7), B1-C10 153.9(7), C2-Si1 188.8(4), C2-Si2 187.1(5), B4-C40 157.6(7), C5-Si3 184.3(5); B1-C3-C2 59.1(3), B4-C3-C6 73.2(3), B1-C3-B4 141.7(4), C2-C3-B4 139.5(4), B1-C3-C6 126.4(4), C2-C3-C6 128.2(4), B1-C2-Si1 118.3(3), B1-C2-Si2 114.4(3). **4**: B1-C2 146.0(10), C2-C3 163.4(10), B1-C3 169.5(11), C3-B4 157.0(12), B4-C5 155.9(11), C5-C6 132.6(10), C6-C7 145.5(11), C7-C8 138.2(10), C8-C3 144.5(10), B1-C10 152.1(11), C2-Si1 197.1(8), C2-Si2 189.5(7), B4-C40 158.4(11), C5-Si3 188.9(8), C7-Si4 184.5(8); B1-C3-C2 52.0(4), B4-C3-C8 115.4(6), B1-C3-B4 102.3(6), C2-C3-B4 126.4(6), B1-C3-C8 121.9(6), C2-C3-C8 118.0(6), B1-C2-Si1 100.1(5), B1-C2-Si2 139.5(6).

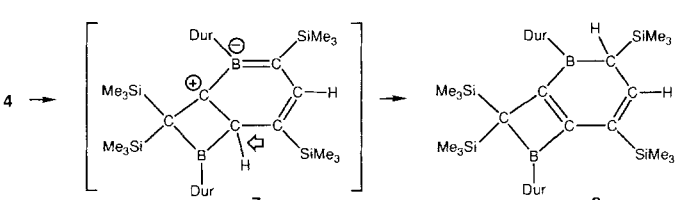
1-methylborirane (153.0 pm[7]). The C2–C3 and the B1–C3 bonds of the three-membered ring bend similarly with respect to the B4-C3-C6 plane of the four-membered ring (by 29.9 and 29.2°, respectively); the B1-C3-B4 angle (141.7°) is similar in size to the C2-C3-B4 angle (139.5).

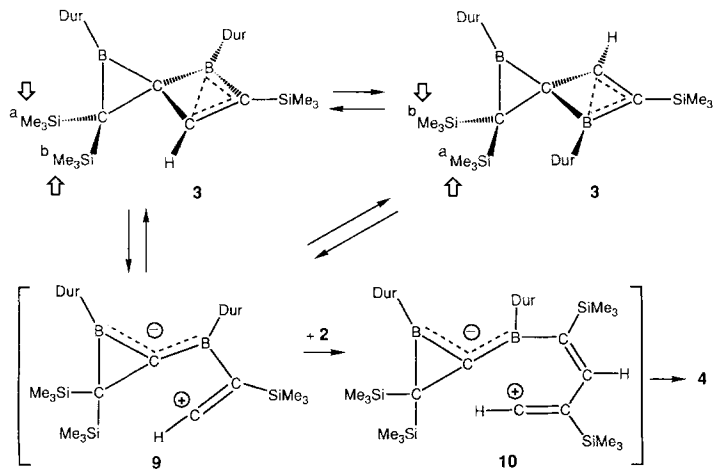
In contrast, in **4** the C2–C3 bond lies almost in the B4-C3-C8 plane of the six-membered ring (deviation 4.7°), that is, C3 resides in an almost trigonal-planar environment formed by C2, B4, and C8. The B1-C3-B4 angle (102.3°) differs significantly from the C2-C3-B4 angle (126.4°). The plane of the borirane ring forms an angle of 72.5° with the B4-C3-C8 plane of the six-membered ring, that is, it is tilted by 17.5° toward the boron atom B4. The angle between the corresponding planes in **3** is 87.6°. The B1–C3 bond in **4** (169.5 pm) is 17 pm longer than that in **3**. A B–C bond (170.1 pm) of similar length was calculated for the nonclassical borylborirane **5**;[8] B–C distances of up to ≤158.0 pm have been determined experimentally for boriranes.[8]

The distortions in **4** are indicative of strong C–B hyperconjugation of the B1–C3 bond of the three-membered ring with the boracyclohexa-2,4-diene ring corresponding to the resonance structure **4A**. The formation of the 6π electron arene probably



makes a major contribution to the strength of this effect. In **3** the electron deficiency of the boron atom of the four-membered ring is overcome by the formation of the 2π electron homoarene.

Distortions similar to those in **4** were recently described for the cyclohexadienyl cation **6**, isoelectronic with respect to the six-membered ring, with a C–Si instead of the strained C–B bond as σ donor.[9]



The increased electron deficiency at the boron atom of the three-membered ring (cf. **4A**) caused by the strong C–B hyperconjugation in **4** leads to strong C–Si hyperconjugation with the C2–Si1 bond (cf. **4B**), as indicated by a remarkably long C2–Si1 bond (197.1 vs. 189.5 pm for C2–Si2), a small B1-C2-Si1 angle (100.0° vs. 139.5° for B1-C2-Si2), and a very short C2–B1 distance (146.0 pm). In **3**, C–Si hyperconjugation with B1 as the electron-deficient center plays no significant role, as is apparent from the undistorted structure. The prerequisite for significant C–Si hyperconjugation in boriranes is evidently pronounced electron deficiency at the boron atom, which in **4** is caused by C–B hyperconjugation (resonance structure **4A**).

The weak B1–C3 bond in **4** is broken in solution even at room temperature: **4** rearranges within several days into the isomeric 2,7-diborabicyclo[4.2.0]octa-4,6-diene **8** (Table 1). Compound **8** forms as the only product when **4** melts. The constitution of **8** was confirmed by an X-ray structure analysis.[10]

The zwitterion **7** is probably the intermediate in this rearrangement; **7** can be considered as a σ complex of an intramolecular electrophilic substitution of **4A**. Migration of the proton to the carbanionic C atom bound to the boron atom in the six-membered ring gives **8**.

The ^1H and the ^{13}C NMR spectra show two sharp signals for the geminal trimethylsilyl groups in **3** only below $-30\,^\circ C$. These signals broaden at higher temperatures and coalesce at 30 and 20 °C, respectively. The barrier for the exchange was estimated to be 14 kcal mol^{-1}. We propose the zwitterion **9** as an intermediate. In **9** the negative charge is stabilized by π–π delocalization in a 1,3-diboraallyl anion and the positive charge of the vinyl cation[11] is stabilized by C–Si and C–B hyperconjugation. The formation of **4** can be readily explained by the addition of **2** to **9** and the cyclization of the resulting compound **10**.

Experimental Procedure

3: **2** (0.46 mL, 3.3 mmol) was added dropwise to **1** (1.53 g, 3.3 mmol) in pentane (20 mL) at −78 °C. The reaction mixture was slowly warmed to −30 °C and concentrated under vacuum at this temperature until crystallization began. Compound **3** crystallized at −30 °C overnight. The crystals were separated by filtration (D3 frit) and washed with pentane.

4: **2** (1.0 mL, 7.24 mmol) was added dropwise to a solution of **1** (1.66 g, 3.62 mmol) in pentane (20 mL) at −78 °C. After the mixture had been allowed to warm to −10 °C, it was concentrated and crystals of **4** were separated by filtration (D3 frit).

8: **4** was converted quantitatively into **8** by heating for 5 min at 143 °C.

[2] Crystal structure analyses: colorless crystals of **3** and **4** were investigated on a four-circle diffractometer (CAD4, Enraf-Nonius) at −80 °C with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). **3**: $C_{33}H_{54}B_2Si_3$, crystal dimensions $0.3 \times 0.3 \times 0.5$ mm, monoclinic, space group $P2_1/c$, $Z = 4$, $a = 895.5(2)$, $b = 2088.4(4)$, $c = 1901.2(4)$ pm, $\beta = 95.01(3)^\circ$, $V = 3542.0 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.044$ g cm^{-3}; 4954 measured reflections in the range up to $2\theta_{max} = 110^\circ$ (ω scans), 4446 of which were independent, 3341 reflections with $F_0 > 3\sigma(F_0)$ were used for the further calculations after Lorentz and polarization correction; no absorption correction ($\mu = 13.6$ cm^{-1}). The structure was solved by direct methods and refined against the F_0 data with full matrix. All hydrogen atoms were located by difference Fourier syntheses and were included in the calculation riding on their bonding partners and refined groupwise with isotropic temperature factors. Anisotropic temperature factors were used for all the remaining atoms except boron. $R = 0.056$, $wR = 0.049$ ($w = 1/\sigma^2(F_0)$), maximal residual electron density 0.33 eÅ^{-3}. **4**: $C_{38}H_{64}B_2Si_4$, crystal dimensions $0.6 \times 0.6 \times 0.3$ mm, monoclinic, space group $P2_1/c$, $Z = 4$, $a = 1226.0(2)$, $b = 1361.3(3)$, $c = 2545.3(5)$ pm, $\beta = 102.09(3)^\circ$, $V = 4153.8 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.047$ g cm^{-3}; 5860 measured reflections in the range up to $2\theta_{max} = 110^\circ$ (ω scans), 5219 of which were independent, 3760 reflections with $F_0 > 3\sigma(F_0)$ were used for further calculations after Lorentz and polarization correction; the structure solution and refinement as for **3** led to $R = 0.080$, $wR = 0.063$, and a maximal residual electron density of 0.54 eÅ^{-3}. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-58199.

Stable Tetrakis(trialkylsilyl)disilenes; Synthesis, X-Ray Structures, and UV/VIS Spectra**

Mitsuo Kira,* Toyotaro Maruyama, Chizuko Kabuto, Keisuke Ebata, and Hideki Sakurai*

The chemistry of stable disilaethenes (disilenes) has been the subject of extensive studies since the first isolation of tetramesityldisilene in 1981 by West et al.[1] However, the variety in substituents of the disilenes whose structures have been determined by X-ray crystallography is rather limited; the substituents include alkyl, aryl, $(Me_3Si)_2N$, and very recently Me_3Si groups, but in addition these disilenes bear at least two aromatic groups.[2] Recent theoretical studies have shown that the geometry, stability, and electronic structure of disilenes should be affected significantly by substituents.[3] One of the most fascinating theoretical findings is that silyl substituents should increase the bond dissociation energy of disilenes; tetrasilyldisilenes have been suggested as interesting goals for synthesis.[3a] We report herein the isolation and characterization of tetrakis(trialkylsilyl)disilenes **1a**–**1c**,[4] which show unexpected features in their X-ray structures and NMR and UV/VIS spectra in comparison with previously isolated disilenes.

1a, $R_3Si = iPr_2MeSi$
1b, $R_3Si = tBuMe_2Si$
1c, $R_3Si = iPr_3Si$

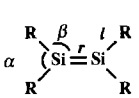
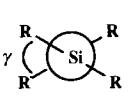
Disilene **1a** was prepared by refluxing a mixture of bis(diisopropylmethylsilyl)dibromosilane and sodium (2.6 equiv) in toluene for 6 h. After filtration of sodium bromide, the filtrate was condensed in vacuo and cooled to −20 °C to give yellow crystals of **1a**, which were isolated in 27% yield after filtration under argon. Disilene **1c** was obtained in 11% yield by reductive coupling of bis(triisopropylsilyl)dibromosilane with lithium naphthalene (2.3 equiv) in THF at −78 °C. Disilene **1b** was prepared by photolysis[5b, 6] of the corresponding cyclic trisilane, which was obtained in 47% yield by reductive coupling of bis(*tert*-butyldimethylsilyl)dibromosilane with lithium naphthalene in THF at −78 °C.[7] Disilenes **1a**–**1c** are highly air- and moisture-sensitive in solution but survived for a day in the solid state exposed to air. Physical data of these compounds are summarized in Table 1.

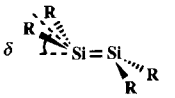
Table 1. Physical data of **1a**–**c**.



1a: yellow crystals; m.p. 142 °C; ^{1}H NMR (300 MHz, C_7D_8, TMS): δ = 0.38 (s, 12H, CH_3Si), 1.20 (d, ^3J(H,H) = 7.1 Hz, 24H, CH_3C), 1.27 (d, ^3J(H,H) = 7.2 Hz, 24H, CH_3C), 1.35–1.47 (m, 8H, CH); ^{13}C NMR (75.5 MHz, C_7D_8, TMS): δ = −6.8 (CH_3Si), 16.4 (CH), 19.3 (CH_3C), 21.3 (CH_3C); ^{29}Si NMR (59.6 MHz, C_7D_8, TMS): δ = 11.7 (Si2), 144.5 (^1J(Si,Si) = 50.3 Hz, Si1); UV/VIS (hexane): λ_{max} (ε) = 293 (2100), 357 (1400), 412 nm (7600); MS: *m/z* (%): 572 (2) [M^+], 129 (14), 73 (59), 59 (100); HRMS calcd for $C_{28}H_{68}Si_6$ 572.3969, found 572.3947.



1b: light orange crystals; ^{1}H NMR (300 MHz, C_6D_6, TMS): δ = 0.44 (s, 24H, CH_3Si), 1.07 (s, 36H, CH_3C); ^{13}C NMR (75.5 MHz, C_6D_6, TMS): δ = 0.97 (CH_3Si), 19.6 ($(CH_3)_3C$), 28.4 (CH_3C); ^{29}Si NMR (59.6 MHz, C_6D_6, TMS): δ = 6.04 (Si2), 142.1 (^1J(Si,Si) = 51.5 Hz, Si1); MS: *m/z* (%): 516 (0.5) [M^+], 287 (7), 73 (100); UV/VIS (hexane): λ_{max} (ε) = 290 (2500), 361 (1700), 424 nm (2600); HRMS calcd for $C_{24}H_{60}Si_6$ 516.3311, found 516.3309.



1c: yellow crystals; ^{1}H NMR (300 MHz, C_6D_6, TMS): δ = 1.35 (d, ^3J(H,H) = 7.3 Hz, 72H, CH_3), 1.61 (sept, ^3J(H,H) = 7.3 Hz, 12H, CH); ^{13}C NMR (75.5 MHz, C_6D_6, TMS): δ = 17.4 (CH_3), 21.4 (CH); ^{29}Si NMR (59.6 MHz, C_6D_6, TMS): δ = 16.4 (Si2), 154.5 (^1J(Si,Si) = 48.3 Hz, Si1); MS: *m/z* (%): 684 (0.4) [M^+], 303 (36), 129 (22), 101 (19), 87 (35), 73 (68), 59 (100); UV/VIS (hexane): λ_{max} (ε) = 296 (5400), 370 (2400), 425 (1300), 484 nm (1900); HRMS calcd for $C_{36}H_{84}Si_6$ 684.5189, found 684.5194.

The structures of **1a**–**1c** were determined by single-crystal X-ray diffraction studies.[8] Important structural parameters for **1a**–**1c** are summarized in Table 2. The ORTEP drawing for **1c** is shown in Figure 1. The spatial arrangement at the Si=Si bond depends significantly on the alkyl substituents at the saturated silicon atoms. Thus, in both **1a** and **1c** the substituents at central silicon atoms are *trans* to each other and bent out of the plane of the double bond (bend angle δ) by 5.4 and 10.2°, respectively; in **1b** the double bond is twisted by 8.9° (γ), but the substituents are not bent. The Si=Si bonds in **1a**–**1c** are roughly 0.1 Å longer than those in other known disilenes (2.14–2.16 Å).[2, 10] Theoretical calculations had predicted that the introduction of a silyl group into disilene would force a planar arrangement around the Si=Si bond, and that the Si=Si bond length would not be significantly different from that in the parent disilene.[3] Our experimental results are apparently not in accord with this prediction. The trialkylsilyl groups do not exert only electronic effects; severe steric repulsion among the trialkylsilyl groups could be responsible for the deformation from planarity and elongation of the Si=Si bond in the solid state. It is suggested that the potential energy surfaces are rather flat not only for twisting and bending but also stretching of the double bond; the disilene double bond could be referred to a *soft* double bond compared with the *hard* double bond of a simple olefin. The difference in the deformation mode among **1a**–**1c** may originate in the symmetry operation in the crystal structure.[8]

Table 2. Comparison of structural parameters of disilenes [a].

Disilene	r/Å	l/Å	α/°	β/°	γ/° [b]	δ/° [c]
1a (R = *i*Pr$_2$MeSi)	2.228(2)	2.374(2) 2.366(4)	115.3(1)	120.3(1) 124.1(1)	0	5.4(0)
1b (R = *t*BuMe$_2$Si)	2.202(1)	2.377(2) 2.383(2)	112.5(0)	122.9(0) 124.5(0)	8.9(1)	0.1(0)
1c (R = *i*Pr$_3$Si)	2.251(1)	2.400(2) 2.411(2)	114.9(0)	126.3(0) 117.5(0)	0	10.2(0)
Mes$_2$Si=SiMes$_2$ [13b]	2.143	1.879	116.8	120.7	3	13

[a] Standard deviations in parentheses. [b] γ = dihedral angle. [c] δ = bend angle.

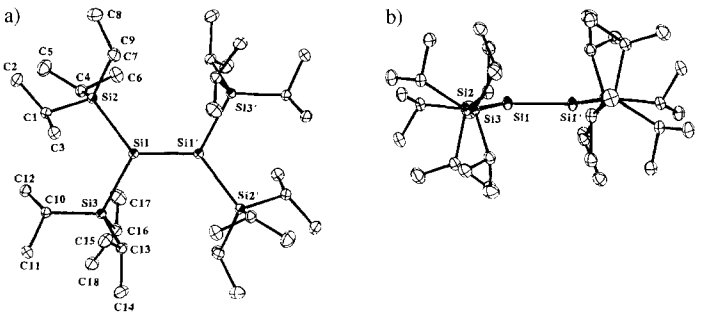


Fig. 1. Crystal structure of **1c** (ORTEP plot). a) Top view; b) side view.

The structures determined in the solid state may not be retained in solution, as shown in the unusual substituent effects in the UV/VIS spectra of **1a**–**1c** (vide infra).

The ^{29}Si NMR resonances for the tricoordinate silicon atoms in **1a**–**1c** (δ = 144.5, 142.1, and 154.5, respectively) appear at remarkably lower fields than those in the known disilenes, which lie between + 49 and + 98.[2a, 5c] These unusually low-field resonances may be compared with the corresponding ^{13}C NMR signals for tetrakis(trimethylsilyl)ethylene (δ = 195.3) and related silylethylenes[11a] which all appear at much lower fields than the corresponding signals of the parent ethylene (δ = 122.8). The origin of the effects of the trialkylsilyl substituents remains open.[11b]

While **1a**–**1c** are yellow to light orange in the solid state,[12] their solutions are quite different in color: the solutions in hexane at room temperature are yellow, orange, and dark red, respectively. The electronic spectra for the three disilenes were also very different, as shown in Figure 2. Since the bands for the π–π^* transition appear near 400 nm for the known disilenes,[2c] the absorption maxima observed at 412, 424, and 425 nm for **1a**, **1b**, and **1c**, respectively, are assigned to the π–π^* transition. Interestingly, the absorption coefficients of these maxima decrease significantly in this order; in the spectrum of **1c** there is a unique broad band at around 480 nm besides the low-intensity band for the π–π^* transition at 425 nm. The disilenes **1a** and **1b** show reversible thermochromism in hexane from light yellow (< 0 °C) to dark red (> 50 °C), as was also found for tetramesityldisilene.[13] The origin of the thermochromism may be attributed to a thermal equilibrium between the bent and twisted conformations, in analogy to the classical thermochromic olefins like bianthrones.[14] In contrast, the color of **1c** in solu-

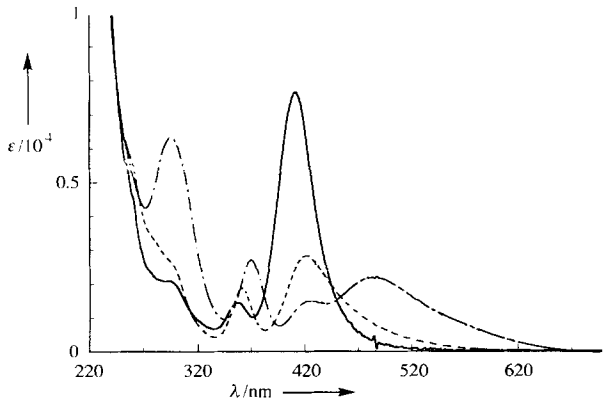

Fig. 2. UV/VIS spectra of **1a**–**1c** in hexane at room temperature: **1a** (—); **1b**, (- - -); **1c**, (· –·).

tion is apparently temperature independent. The extraordinary color change for this most crowded disilene from yellow in the solid state to dark red in solution suggests that in solution **1c** assumes a twisted form as the most stable conformation to relieve steric strain.

[4] Although tetrakis[bis(trimethylsilyl)methyl]disilene was isolated as the first stable tetraalkyldisilene, no X-ray analysis was reported [5a]. Tetrakis(triethylsilyl)disilene was first detected by UV spectroscopy during photolysis of hexakis(triethylsilyl)cyclotrisilane but was not isolated [5b]. In 1992 West et al. isolated (*E*)- and (*Z*)-1,2-bis(2,4,6-triisopropylphenyl)disilenes; in these compounds the trimethylsilyl groups exert no remarkable effects on the structure [5c].

[7] Disilene **1a** was obtained also by the photolysis of the corresponding cyclotrisilane, which was prepared by the reductive coupling of the corresponding dibromosilane with lithium naphthalene in THF at −78 °C in 35% yield.
[8] The following holds for all the structure determinations. The reflection intensities were collected on a Rigaku AFC-5PR diffractometer with a rotating anode (45 kV, 200 mA) using graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71069 Å). Since the peak profiles for **1b** were broad at low temperatures, **1b** was measured at room temperature; **1a** and **1c** were measured at low temperature. Crystal data for **1a** (150 K): triclinic, space group $P\bar{1}$, a = 11.225(10), b = 11.651(7), c = 8.571(8) Å, α = 103.20(7), β = 111.03(8), γ = 105.22(6)°, V = 942.6(17) Å^3, Z = 1, ρ_{calcd} = 1.01 g cm^{-3}. A total of 5157 reflections were measured, of which 2655 [$F_0 > 3\sigma(F_0)$] were used in refinement. R = 0.105, R_w = 0.105. – Crystal data for **1b** (286 K): monoclinic, space group $C2/c$, a = 22.585(4), b = 7.988(1), c = 20.778(4) Å, β = 108.84(1)°, V = 3548.0(11) Å^3, Z = 4, ρ_{calcd} = 0.968 g cm^{-3}. A total of 5243 reflections were measured, of which 2866 [$F_0 > 3\sigma(F_0)$] were used in refinement. R = 0.060, R_w = 0.057. Crystal data for **1c** (170 K): monoclinic, space group $C2/c$, a = 19.220(3), b = 14.384(1), c = 17.089(2) Å, β = 110.88(1)°, V = 4414.5(11) Å^3, Z = 4, ρ_{calcd} = 1.03 g cm^{-3}. A total of 4973 reflections were measured, of which 3593 [$F_0 > 3\sigma(F_0)$] were used in refinement. R = 0.055, R_w = 0.076. The molecules of **1a** and **1c** have a crystallographic center of symmetry, while **1b** has a twofold symmetry axis. All calculations were performed with an ACOS-2000 computer at Tohoku University with the UNICS III system and the RANTAN81 program. Whereas the R values for **1b** and **1c** were rather reasonable, **1a** gave a relatively high R value. The final electron density map for **1a** showed a few of meaningful residual peaks near the Si=Si bond. These peaks are explainable by assuming a similar phenomenon to that observed in (*E*)-1,2-di(1-adamantyl)dimesityldisilene [9]. By including only three Si atoms of the minor component with the occupancy of 15%, the R value dropped by 0.04. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

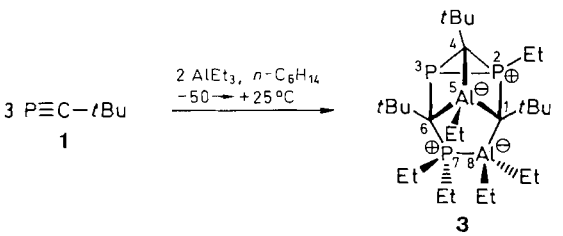
The First Carbon–Phosphorus–Aluminum Cage Compounds: Cyclooligomerization of Phosphaalkynes with Trialkylaluminum Compounds**

Bernhard Breit, Andreas Hoffmann, Uwe Bergsträsser, Louis Ricard, François Mathey, and Manfred Regitz*

Dedicated to Professor Reinhard Schmutzler on the occasion of his 60th birthday

Recently we found that the phosphaalkyne **1** can be spirocyclotrimerized with aluminum trichloride in the molar ratio 3:1 with the incorporation of the Lewis acid to give the stable complex **2**. Removal of the metal halide by addition of dimethyl

sulfoxide in the presence of a further equivalent of **1** leads to the desired formation of a cagelike phosphaalkyne cyclotetramer.[11]



In the present communication we report on completely different cyclooligomerization reactions of **1** with triethylaluminum: surprisingly, polycycles are obtained highly selectively with the

[**] Phosphorus Compounds, Part 77. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. Part 76: W. Eisfeld, U. Bergsträsser, M. Slany, M. Regitz, *Tetrahedron Lett.* **1994**, *35*, 1527-1530.

incorporation of the Lewis acid, the composition of which depends on the solvent chosen.

If the reaction mixture containing the phosphaalkyne **1** and triethylaluminum (molar ratio 3:2) in *n*-hexane is allowed to warm up from −50 °C to room temperature, the carbon–phosphorus–aluminum compound **3** can be isolated in 91% yield;

polycycles comprising this combination of elements were hitherto unknown.[2]

The composition of **3** is apparent from the ^{1}H NMR spectrum: it is made up from three *tert*-butyl groups and six ethyl groups, which are magnetically inequivalent (Table 1). Also in agreement with the structure of **3** is the ^{31}P NMR spectrum which exhibits three high field absorptions,[3] which show $\lambda^3\sigma^3$ and $\lambda^4\sigma^4$ phosphorus with the mutual couplings (Table 1). In the ^{13}C NMR spectrum of the same compound, absorptions are found for the framework carbon atoms between $\delta = 32.8$ and 68.3, and the high-field signal with its two ^1J(P,C) couplings (51.8 and 23.4 Hz) is assigned unequivocally to C4. The migration of three *Al*-ethyl groups to phosphorus atoms is indicated by significant low field shifts and the occurrence of ^1J(P,C) couplings for the corresponding methylene carbon atoms.

Confirmation of the structure of the cage compound **3** was achieved by an X-ray crystal structure analysis (Fig. 1).[4, 5] Almost all the structural data including the P15–Al28 distance (2.4538 Å) lie in the expected range.[6] The only exceptions are the bond lengths P7–C8 (1.757 Å) and P7–C2 (1.770 Å), which are comparatively short.[7]

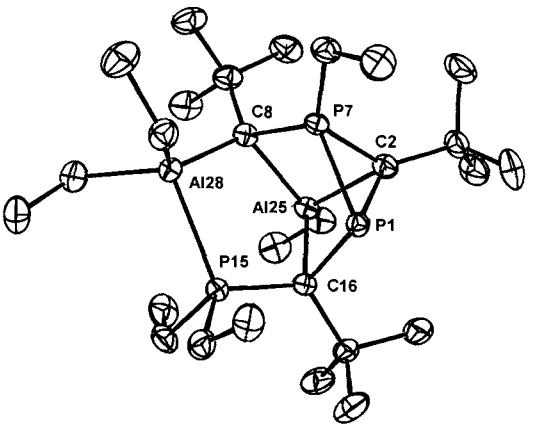

Fig. 1. Crystal structure of **3** (ORTEP). Selected bond lengths [Å] and angles [°]: P1–P7 2.1672(6), P1–C2 1.905(2), P1–C16 1.903(2), P7–C2 1.770(2), P7–C8 1.757(2), P15–Al28 2.4538(7), P15–C16 1.816(2), Al25–C2 2.115(2), Al25–C8 2.105(2), Al25–C16 2.075(2), Al28–C8 2.035(2); P7-P1-C2 51.04(6), P7-P1-C16 102.26(6), C2-P1-C16 97.71(8), P1-P7-C2 56.79(6), P1-P7-C8 111.05(6), C2-P7-C8 108.95(8), Al28-P15-C16 107.60(6), C2-Al25-C8 85.76(7), C2-Al25-C16 86.37(7), P1-C2-P7 72.17(7), P1-C2-Al25 84.83(7), P7-C2-Al25 80.65(7), P7-C8-Al25 81.22(7), P7-C8-Al28 103.18(8), Al25-C8-Al28 114.29(8), P1-C16-P15 107.66(9), C8-Al25-C16 100.91(7), P15-Al28-C8 94.67(5), P1-C16-Al25 85.98(7), P15-C16-Al25 108.59(8).

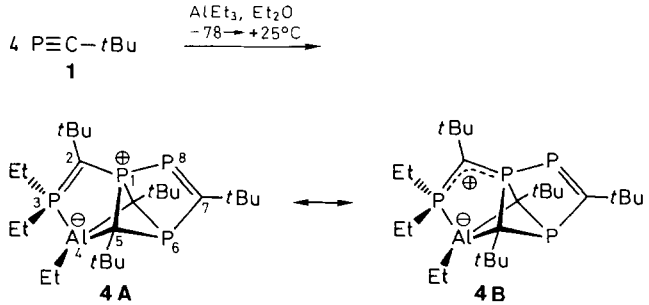
Table 1. Selected spectroscopic data of the cage compounds **3** and **4** [a].



3: ^{1}H NMR (400.1 MHz): $\delta = 0.47$–0.66 (m, 6H, AlCH_2CH$_3$), 1.02–2.30 (m, 24H, AlCH$_2$CH_3/PCH_2CH_3), 1.41, 1.54 (each s, each 9H, C(CH$_3$)$_3$), 1.66 (d, ^4J(P,H) = 0.6 Hz, 9H, C(CH$_3$)$_3$); ^{13}C NMR: $\delta = 4.2$ (m, broad, 2 × AlCH$_2$CH$_3$), 8.2 (s, broad, AlCH$_2$CH$_3$), 8.8 (dd, ^2J(P,C) = 13.2, ^3J(P,C) = 7.6 Hz, PCH$_2$CH$_3$), 10.0, 10.2 (each s, AlCH$_2$CH$_3$), 10.9 (d, ^2J(P,C) = 5.1 Hz, PCH$_2$CH$_3$), 11.1 (d, ^2J(P,C) = 4.9 Hz, PCH$_2$CH$_3$), 11.3 (s, AlCH$_2$CH$_3$), 20.3 (d, ^1J(P,C) = 17.6 Hz, PCH$_2$CH$_3$), 20.8 (d, ^1J(P,C) = 8.3 Hz, PCH$_2$CH$_3$), 24.2 (pseudo-t, ^1J(P,C) = 12.3 Hz, PCH$_2$CH$_3$), 32.8 (dd, ^1J(P,C) = 51.8 and 23.4 Hz, C4), 34.6 (dd, ^3J(P,C) = 8.3, ^4J(P,C) = 3.8 Hz, C(CH$_3$)$_3$), 34.8 (dd, ^3J(P,C) = 8.4 and 5.0 Hz, C(CH$_3$)$_3$), 35.2 (d, ^2J(P,C) = 6.1 Hz, C(CH$_3$)$_3$), 36.6 (d, ^3J(P,C) = 13.7 Hz, C(CH$_3$)$_3$), 37.0 (dd, ^2J(P,C) = 9.7 and 3.3 Hz, C(CH$_3$)$_3$), 40.3 (d, ^2J(P,C) = 7.9 Hz, C(CH$_3$)$_3$), 45.8 (m, C1), 68.3 (m, C6); ^{31}P NMR: $\delta = -147.3$ (dd, ^1J(P,P) = 162.9, ^2J(P,P) = 21.7 Hz, P3), −61.6 (d, ^1J(P,P) = 162.9 Hz, P2), −1.2 (d, ^2J(P,P) = 21.7 Hz, P7).

4: ^{1}H NMR (400.1 MHz): $\delta = 0.55$ (q, ^3J(H,H) = 8.1 Hz, 2H, AlCH_2CH$_3$), 0.97–1.06 (m, 6H, 2 × PCH$_2$CH_3), 1.22 (s, 18H, 2 × C(CH$_3$)$_3$), 1.40 (s, 9H, C(CH$_3$)$_3$), 1.43 (t, ^3J(H,H) = 8.1 Hz, 3H, AlCH$_2$CH_3), 1.47 (d, ^4J(P,H) = 0.9 Hz, 9H, C(CH$_3$)$_3$), 1.69–1.78 (m, 4H, 2 × PCH_2CH$_3$); ^{13}C NMR: $\delta = 0.8$ (m, broad, AlCH$_2$CH$_3$), 10.3 (d, ^3J(P,C) = 2.6 Hz, AlCH$_2$CH$_3$), 12.8 (d, ^2J(P,C) = 4.1 Hz, 2 × PCH$_2$CH$_3$), 26.6 (dd, ^1J(P,C) = 22.0, ^3J(P,C) = 2.2 Hz, 2 × PCH$_2$CH$_3$), 32.4 (dd, ^3J(P,C) = 11.4 and 7.2 Hz, C(CH$_3$)$_3$), 33.4 (d, ^2J(P,C) = 4.8 Hz, C(CH$_3$)$_3$), 35.2–35.4 (m, 3 × C(CH$_3$)$_3$), 35.6 (d, ^2J(P,C) = 12.1 Hz, C(CH$_3$)$_3$), 36.4 (dd, ^2J(P,C) = 8.8 and 3.8 Hz, 2 × C(CH$_3$)$_3$), 44.0–44.6 (m, broad, C5/C9), 59.3 (d, broad, ^1J(P,C) = 39.8 Hz, C2), 108.0 (d, broad, ^1J(P,C) = 40.9 Hz, C7); ^{31}P NMR: $\delta = -32.8$ (m, P6), −1.0 (d, broad, ^2J(P,P) = 122.0 Hz, P3), + 87.1 (ddd, ^1J(P,P) = 320.6, ^2J(P,P) = 122.0 and 14.4 Hz, P1), + 208.0 (dd, ^1J(P,P) = 320.6, ^2J(P,P) = 10.8 Hz, P8).

[a] ^{1}H (TMS), ^{13}C (100.6 MHz, TMS) and ^{31}P NMR spectra (80.8 MHz, 85% of H_3PO_4) in C_6D_6. Numbering of the atoms as in the formula.

most all the structural data including the P15–Al28 distance (2.4538 Å) lie in the expected range.[6] The only exceptions are the bond lengths P7–C8 (1.757 Å) and P7–C2 (1.770 Å), which are comparatively short.[7]

If **1** is allowed to react with AlEt$_3$ in the molar ratio 4:1 in diethyl ether instead of in *n*-hexane, the carbon–phosphorus–aluminum polycycle **4** is obtained in 74% yield; there is no evidence in the ^{31}P NMR spectrum for the formation of **3** as a by-product.

The same ratio of the reaction partners is also apparent from in the ^{1}H NMR spectrum of **4** (Table 1). In contrast to **3** at least one phosphorus atom has a $\lambda^3\sigma^2$ configuration ($\delta = 208.0$);[8] it is split into a double doublet by both ^1J(P,P) and ^2J(P,P) coupling (320.6 and 10.8 Hz, respectively). This is in correspondence with the resonance of C7 at $\delta = 108.0$ with a typical P coupling of 40.9 Hz. The second P–C double bond of **4** has methylenephosphorane character; the fact that the resonance for the ylidic carbon appears at $\delta = 59.3$ is acceptable.[9] The relatively high field position of P3 ($\delta = -1.0$) results from the shielding effect of the neighboring aluminate group. The onium phosphorus P1 ($\delta = 87.1$) shows the expected couplings to P8 and P3[10] (Table 1). The $\lambda^3\sigma^3$ phosphorus P6 absorbs at high field ($\delta = -32.8$) as expected. For the tetracycle **4**, as in the case of **3**, a low-field shift and ^1J(P,C) couplings for the methylene carbon atoms originally bound to Al indicate ethyl migration to

the phosphorus. The latter and also the constitution of the reaction product were confirmed by an X-ray crystal structure analysis (Fig. 2).[5, 11] This analysis shows that the aluminum and all

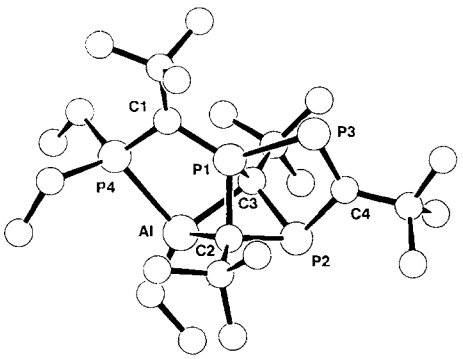


Fig. 2. Crystal structure of **4** (SCHAKAL-Plot). Selected bond lengths [Å] and angles [°]: P4–Al 2.441(3), C3–Al 2.038(6), P1–C1 1.713(6), P2–C2 1.853(6), P1–C3 1.813(6), P3–C4 1.651(6), P3–P1 2.235(2), C2–Al 2.039(6), P4–C1 1.743(6), P1–C2 1.834(6), P2–C3 1.868(6), P2–C4 1.917(6); C1-P1-P3 122.2(2), C3-P2-C2 78.2(3), C4-P2-C3 98.8(3), C1-P4-Al 95.5(2), C3-Al-P4 95.5(2), P2-C2-P1 86.1(3), Al-C2-P2 89.5(3), Al-C3-P2 89.1(3), P3-C4-P2 116.9(3), C2-P1-P3 103.5(2), C2-P1-C1 120.1(3), C3-P1-P3 103.1(2), C3-P1-C1 119.3(3), C4-P2-C2 100.2(3), C4-P3-P1 88.6(2), C2-Al-P4 96.7(2), C3-Al-C2 70.2(2), P4-C1-P1 105.0(3), Al-C2-P1 81.8(2), Al-C3-P1 82.3(2).

the phosphorus atoms as well as the carbon atoms C1 and C4 lie in one plane.[12] The P3–C4 distance (1.651 Å) lies in the range expected for P–C double bonds.[13] However, the very similar bond lengths P4–C1 and P1–C1 (1.743 and 1.713 Å, respectively) are indicative of an extensive delocalization of the positive charge over the PCP unit according to **4A**↔**4B**; they lie in the range between those of P–C single[6] and P–C double bonds.[14]

The question of the formation mechanism of the two completely different products **3** and **4** cannot be answered conclusively. However, it is assumed that the Lewis acid initially attacks at the phosphaalkyne carbon of **1**.[1] Then Et–P=C(*t*Bu)($AlEt_2$) is formed by a [1,2]-ethyl shift. Not later than after the analogous 1,2 addition of Et–P=C(*t*Bu)($AlEt_2$) to a further equivalent of **1**, the reaction must branch out. That compound **4** contains one equivalent, whereas **3** contains two equivalents of Lewis acid, must be due to the blocking effect of the Lewis base diethyl ether.

Experimental Procedure

3: A solution of the phosphaalkyne **1** [15] (0.35 g, 3.5 mmol) in *n*-hexane (3 mL) was added dropwise to a solution of triethylaluminum (0.23 g, 2.0 mmol) in *n*-hexane (3 mL) and stirred at −50 °C (exclusion of oxygen and moisture). After the reaction mixture had been allowed to warm to 25 °C over the course of 12 h, the solvent was removed at 25 °C/10^{-3} mbar and the residue was left to crystallize at −78 °C in a little *n*-hexane. Yield: 0.48 g (91%) colorless crystals; m.p. 175 °C.

4: A solution of the phosphaalkyne **1** [15] (0.40 g, 4.0 mmol) in diethyl ether (3 mL) was added dropwise to a solution of triethylaluminum (0.11 g, 1.0 mmol) in diethyl ether (3 mL) and stirred −78 °C (exclusion of air and moisture). After the reaction mixture had been allowed to warm to 25 °C over the course of 12 h, the solvent was removed at 25 °C/10^{-3} mbar to yield a red-brown oil after a further 36 h. Yield: 0.38 g (74%); red-brown crystals obtained from little *n*-hexane or diethyl ether; m.p. 168 °C.

Synthesis and Molecular Structure of Calcium Bis(trimethylstannanide)·4THF**

Matthias Westerhausen*

In the cocondensation of calcium with trimethylsilyltrimethylstannane and the subsequent reaction with bromobenzene and water, Mochida and Yamanishi[1] isolated hydrolysis products of $Me_3Si–Ca–SnMe_3$, in particular hexamethyldisiloxane, trimethylstannane, hexamethyldistannane, and hydroxy(trimethyl)stannane. However, the authors also ob-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. J. Weidlein for helpful discussions and Dr. W. Schwarz for the collection of the data set.

tained hexamethyldisiloxane, hexamethyldistannane, and hydroxy(trimethyl)stannane in a control experiment performed in the absence of calcium. Calcium stannanides have already proved themselves as polymerization initiators in the synthesis of polyacrylonitrile;[2] spectroscopic proof has as yet, however, only been obtained for calcium bis{tris[bis(trimethylsilyl)-methyl]stannanide}·2DME (DME = dimethoxyethane) with ions separated by solvent.[3]

After stirring for three days at room temperature, the insertion product calcium bis(trimethylstannanide)·4THF (**1**) can be isolated from the heterogeneous reaction of calcium with hexamethyldistannane in THF according to Equation (a). Compound **1** is recrystallized from a solvent mixture of THF and *n*-pentane.

$$Ca + Me_3Sn{-}SnMe_3 \xrightarrow{THF} \underset{\mathbf{1}}{[(Me_3Sn)_2Ca]\cdot 4\,THF} \quad (a)$$

A small amount of calcium bis[tris(trimethylstannyl)stannanide]·4THF (**2**) is also formed in this reaction in accordance with Equation (b), because both the calcium and the compound **1** already formed compete for the hexamethyldistannane still remaining. (The analogous reaction of lithium trimethylstannanide with $Me_3Sn{-}SnMe_3$ has already been resolved mechanistically.[4]) The NMR data of the $(Me_3Sn)_3Sn$ fragment bonded to calcium in **2** listed in Table 1 are remarkable, especially because of the large ^1J(Sn–Sn) and ^2J(Sn–Sn) coupling constants of 5806 and 873 Hz, respectively. By the use of an approximately seven-fold excess of hexamethyldistannane over calcium, compound **2** can be isolated nearly quantitatively.

$$[(Me_3Sn)_2Ca]\cdot 4\,THF + 6\,Me_3Sn{-}SnMe_3 \longrightarrow \underset{\mathbf{2}}{[\{(Me_3Sn)_3Sn\}_2Ca]\cdot 4\,THF} + 6\,SnMe_4 \quad (b)$$

The calcium bis(stannanide) **1** also shows characteristic spectroscopic parameters. The ^1J(Sn–C) coupling constant in the $^{13}C\{^1H\}$ NMR spectrum is extraordinarily small (106 Hz). The singlet at $\delta(^{119}Sn\{^1H\}) = -203$ is shifted upfield relative to that of lithium trimethylstannanide.[5]

Table 1. NMR spectroscopic data of the compounds **1** and **2**.

1: ([D$_8$]THF, 30 °C): ^{1}H: $\delta = -0.36$. ^{13}C: $\delta(SnMe_3) = -5.00$ (^1J(Sn-C) = 106.3 Hz, ^1J(C-H) = 122.4 Hz, ^3J(C-H) = 2.9 Hz). ^{119}Sn{^{1}H}: $\delta = -203.32$
2: ([D$_8$]THF, 30 °C): ^{1}H: $\delta = -0.25$. ^{13}C{^{1}H}: $\delta = -3.05$ (^1J(Sn-C) = 116.1 Hz, ^2J(Sn-C) = 11.0 Hz. ^3J(Sn-C) = 19.9 Hz). ^{119}Sn{^{1}H}: $\delta(SnMe_3) = -100.75$, $\delta(SnSn_3) = -1071.52$ (^1J(Sn-Sn) = 5806.2 Hz, ^2J(Sn-Sn) = 873.0 Hz)

Calcium bis(stannanide) **1** crystallizes from THF/*n*-pentane in the form of colorless cuboids in the centrosymmetric space group $P\bar{1}$.[6] The calcium atom lies on the crystallographic center of inversion. In Figure 1, the second half of the molecule indicated by primed numbers is generated from the point symmetry. The calcium atom is coordinated in a distorted octahedral fashion by two tin atoms and four oxygen atoms of the THF ligands in the *trans* configuration. The stereoscopic representation in Figure 2 of a projection along the Sn–Ca–Sn′ axis shows that the plane described by the oxygen atoms is tipped slightly from an orientation perpendicular to this axis (Sn–Ca–O1 87.5°, Sn–Ca–O2 90.8°) due to the steric repulsion between the methyl group with C1 and the THF ligand

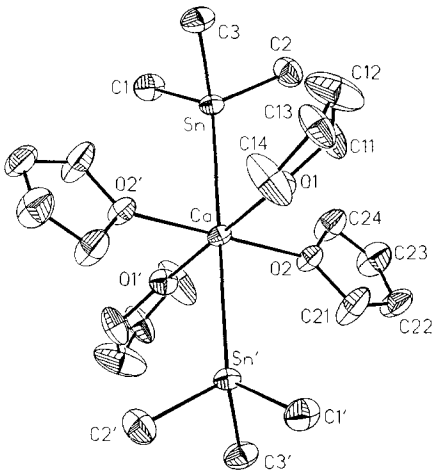

Fig. 1. Structural model of calcium bis(trimethylstannanide)·4THF (**1**); the numbering can be completed accordingly. The ellipsoids represent 30% probability. Selected distances [pm] and angles [°]: Ca-O1 236.3(3), Ca-O2 239.4(3), Ca-Sn 327.21(3), Sn-C1 219.6(5), Sn-C2 219.7(6), Sn-C3 220.1(5); C1-Sn-C2 96.4(3), C1-Sn-C3 97.9(2), C2-Sn-C3 95.2(3), Ca-Sn-C1 124.6(2), Ca-Sn-C2 120.5(2), Ca-Sn-C3 116.1(2), Sn-Ca-O1 87.52(8), Sn-Ca-O2 90.78(8).

with O1′ (torsional angle C1–Sn–Ca–O1′ 19.0(2)°). At the same time, the Ca–Sn–C1 angle is widened to 124.6°. The Ca–Sn bond length of 327 pm lies within the broad range of lengths observed in binary Ca–Sn phases, which increase with increasing tin content (Ca_2Sn 318 pm,[7] $Ca_{31}Sn_{20}$ 307–366 pm,[8] CaSn 327 pm,[9] and $CaSn_3$ 334 pm [10]).

The average C–Sn–C bond angle of 96.5° found in the trimethylstannanide substituent can be explained by the almost exclusive participation of p orbitals on the tin atom; the lone pair of electrons thus shows predominantly s character. This finding is confirmed by the unusually small ^1J(Sn–C) coupling constant. In comparison to Me_3Sn substituents bonded to transition metal elements, such as in, for example, $Me_3Sn{-}Mo(H)Cp_2$ (Sn–C 217 pm, C–Sn–C 102°[11]) $Me_3Sn{-}Mn(CO)_5$ (Sn–C 213 pm, C–Sn–C 107°[12]), and $[Me_3Sn{-}Ru(CO)_4]_2$ (Sn–C 215 pm, C–Sn–C 107°[13]), as well as in tetramethylstannane,[14] remarkably long Sn–C bonds in conjunction with small C–Sn–C angles appear in the calcium derivative **1**. Similar structural parameters may be observed in the triphenylstannanides of lithium[15] and potassium,[16] although the latter is built up of separate ions in the solid due to the complexation of the cation with 18-crown-6.

The THF ligands coordinated to the calcium atom are in the *envelope* (n = 1) or in the *twist* (n = 2) conformation, although the atoms C11/C11a, C13/C13a, and C14/C14a of one of the

THF molecules are disordered and have occupancies of 6/4 for two sites. The atoms O1 and C12 are common to both partial structures. The surface normals of the planes C(n1), O(n), C(n4) form angles of 41.8° (n = 1) and 78.6°(n = 2) to the surface normals of the plane calculated from the oxygen atoms. Both the large displacement of the THF ligand labeled n = 1 from the orthogonal arrangement of the CaO_4 plane and the realization of the *envelope* conformation are based on the interaction with the trimethylstannanide substituents already mentioned above. The Ca–O bond lengths of 236 and 239 pm lie within the characteristic range.

The vibrational spectra can be interpreted with the knowledge of the D_{3d} symmetry of the $(Me_3Sn)_2Ca$ fragment. The asymmetric stretching vibration $\nu_{as}(CaSn_2)$ is found at 231 cm^{-1} and is only observed in the IR spectrum. The exclusively Raman active symmetric vibration $\nu_s(CaSn_2)$ occurs at 69 cm^{-1}, which results in an estimated force constant of 53 Nm^{-1}. The $\nu(SnC_3)$ vibrations (463 cm^{-1}) are in agreement with the findings commented on above, and have clearly lower wavenumbers than those of organo(trimethyl)stannanes.

Calcium bis(stannanide) **1** is obtained in good yield, is soluble in the usual organic solvents, and forecasts a rapid development of the organometallic chemistry of the heavy alkali earth metal calcium, which until now was only accessible with difficulty; the successful investigation of lithium trimethylstannanide is referred to at this point.[17]

Experimental Procedure

All manipulations were carried out in purified anhydrous argon (BTS catalyst, P_4O_{10}). Distilled calcium (0.4 g, 10 mmol, 24% excess) and hexamethyldistannane (2.5 g, 7.6 mmol) were stirred for three days at room temperature in THF (30 mL). After removing all solids (excess calcium), all volatile components were removed under vacuum at room temperature. The residue was dissolved in a THF/*n*-pentane mixture. Compound **1** crystallized at −60 °C in the form of colorless cuboids. Yield: 3.0 g (4.6 mmol) 61%. M.p. 92–93 °C (decomposition, in argon). IR (nujol mull between CsBr plates): ν = 1309 (w), 1295 (w), 1245 (vw), 1172 (w), 1149 (w), 1074 (w), 1032 (vs), 918 (s), 878 (vs), 722 (vs), 678 (m), 463 (vs), 231 (s), 210 (m), 175 cm^{-1} (m).—Raman (on a single crystal): ν = 1034 (w), 920 (w), 889 (w), 723 (m), 678(vw), 472 (s), 463 (vs), 175 (s), 69 cm^{-1} (m).—Correct C,H analysis.

Keronopsins A and B, Chemical Defence Substances of the Marine Ciliate *Pseudokeronopsis rubra* (Protozoa): Identification by Ex Vivo HPLC

Gerhard Höfle,* Silke Pohlan, Gotram Uhlig, Karin Kabbe, and Dorothee Schumacher

The ciliate *Pseudokeronopsis rubra* lives in the shallow regions of the world's oceans, and is notable for its deep red color and its deterrent effect on predators and competitors for food supplies.[1, 2a] The orange, aqueous extracts of this organism are not merely antibiotic, but also display a variety of other biological activities.[2b, c] Thus, other ciliates and flagellates are paralyzed or even killed by these extracts,[2d] the cleavage divisions of sea urchin eggs are inhibited, and larval morphogenesis is greatly disturbed.[2e] In *Euplotes* (Ciliate), an inhibition of the inward calcium transport through the cell membrane has been reported.[3] It is also remarkable that an albino mutant of *P. rubra* takes up the yellow pigment from the extracts and then displays the negative phototactic behavior which is typical of this species.[2a] Till now, attempts to purify the toxins that are responsible for these effects, and that presumably also act as photoreceptors, have been unsuccessful.

Using HPLC analysis, we found that the composition and stability of aqueous and aqueous-methanolic extracts vary considerably depending on their history. Four main components were usually present in approximately equal amounts; we named them keronopsin A_1, A_2 (λ_{max} = 440 nm), B_1, and B_2 (λ_{max} = 420 nm) (Fig. 1). Although methanolic extracts of lyophilized cells were stable, the content of A_1 and A_2 decreased rapidly in aqueous extracts of fresh cells, with a concomitant

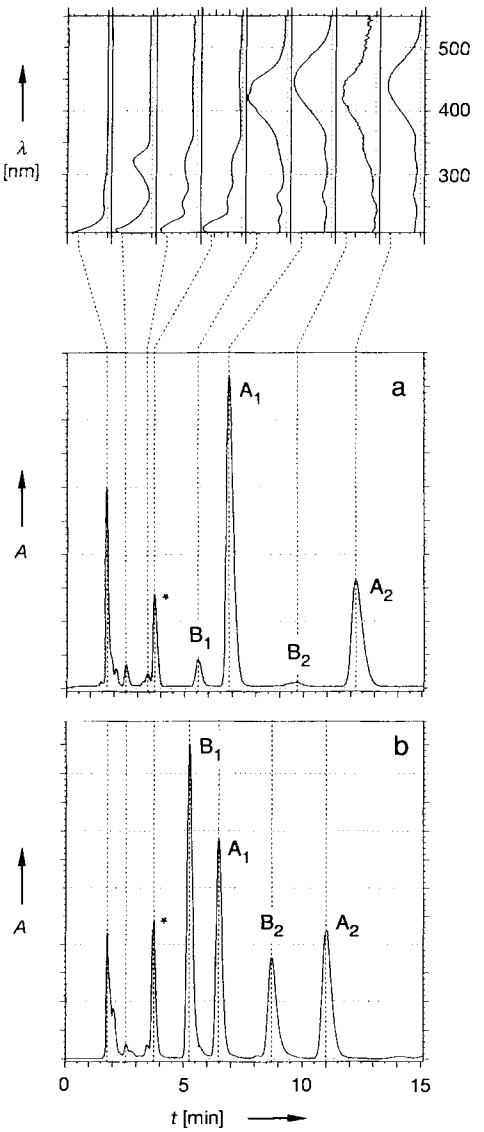

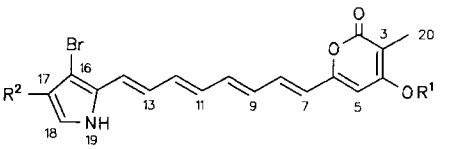

Fig. 1. Analytical HPLC of *Pseudokeronopsis rubra* constituents with the keronopsins A_1, A_2, B_1, and B_2, and pseudokeronopsin A(*): a) 300 living organisms in 20 μL water, b) methanol extract of lyophilized cells (Nucleosil RP-18, 7 μm, 4 × 25 cm, methanol/0.05 M ammonium acetate buffer = 68:32, pH = 8.2, 1.2 mL min^{-1}, diode array detection at 210–550 nm.

increase in B_1 and B_2 (τ about 10–20 min). However, a minor component called pseudokeronopsin A, which absorbs at considerably shorter wavelength, was stable.[4]

In order to determine the keronopsin composition in living organisms with as little change as possible, we applied a known number of organisms directly from a culture onto the HPLC column (ex vivo HPLC). The extremely fragile cells were lyzed on contact with the eluent, releasing their contents for immediate separation. A usable chromatogram could be obtained with as few as ten organisms (corresponding to about 1 μg fresh weight); with 100–300 organisms even trace components could be determined, without significantly affecting the peak widths and retention times. Besides pseudokeronopsin, the living cells contained almost exclusively keronopsins A_1 and A_2 (Fig. 1). Keronopsins B_1 and B_2 were present in low (and variable) amounts, and apparently arose from mechanically damaged cells.

To isolate these compounds, methanolic cell extracts were first subjected to a crude fractionation over Sephadex in methanol and then chromatographed on RP-18 silica gel with the eluent used for analytical HPLC. After freeze-drying of the aqueous methanolic fractions, keronopsins A_1 (**1a**) and B_1 (**1c**) were obtained as brick red, amorphous powders, whereas A_2 (**1b**) and B_2 (**1d**) were brown-red (Table 1). Components A_1 and

Keronopsin A_1 (**1a**), $R^1 = SO_3Na$, $R^2 = H$
Keronopsin A_2 (**1b**), $R^1 = SO_3Na$, $R^2 = Br$
Keronopsin B_1 (**1c**), $R^1 = H$, $R^2 = H$
Keronopsin B_2 (**1d**), $R^1 = H$, $R^2 = Br$

A_2 were unstable, as in the crude extract. Traces of acid led to their conversion into B_1 and B_2, respectively; in the dry state A_1 may also polymerize spontaneously to yield a black solid. Both reactions could be effectively prevented by addition of a small amount of sodium hydrogen carbonate before workup.

1d: $R_f = 0.62$ (silica gel, dichloromethane/acetone/methanol = 15/4/1); IR (KBr): $\tilde{\nu}$ = 1650 (sst), 1575 (sh), 1544 (sst) cm^{-1}; UV/VIS (CH_3OH): λ_{max} (log ε) = 229 (4.20), 397 sh (4.70), 419 (4.84), 439 sh (4.79) nm; FD-MS: *m/z* (%): 456 (54), 454 (100), 452 [$M + H^+$].

According to the ^{1}H and ^{13}C NMR spectra, the keronopsins are closely related, highly unsaturated compounds containing a 1,8-disubstituted octatetraene moiety. From the isotope pattern of the M^+ signal (*m/z*: 375/373) in the EI-mass spectrum, keronopsin B_1 (**1c**) contains a bromine atom; together with the elemental analysis this affords the molecular formula $C_{18}H_{16}BrNO_3$. By analysis of the 1D and 2D NMR spectra it was possible to assign a singlet at δ = 1.84 to a methyl group and two signals at δ = 11.20 and 11.37 to exchangeable protons. In addition, 6 quaternary and 11 methine C atoms in the sp^2 region

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1414-1496 $ 10.00+.25/0

were assigned. From the chemical shifts and the coupling constants of 2.5 Hz, 17-H, 18-H, and 19-H were assigned to the protons of a pyrrole ring. This pyrrole ring carries the octatetraenyl and bromo substituents in the 2- and 3-positions, respectively, as confirmed by the chemical shifts in the ^{13}C spectrum and by the COLOC spectrum (COLOC = correlation by long-range couplings). This substitution pattern is also apparent from the strong NOEs (NOE = nuclear Overhauser enhancement effect) between 19-H and 13-H/18-H, and between 17-H and 18-H. The remaining $C_6H_4O_3$ fragment is a 4-hydroxy-2-pyrone, which is connected to the octatetraenyl residue at C-6, and carries a methyl group in the 3-position. This assignment was confirmed by the COLOC spectrum and by a strong NOE between 5-H and 7-H. Keronopsin B_1 therefore has structure **1c**, and is present predominantly in the conformation depicted.

From the isotope pattern of the M^+ signal in the FD mass spectrum (m/z:456/454/452), keronopsin B_2 (**1d**) contains a second bromine atom. This is found at C-17, since the ^1H and ^{13}C NMR spectra of the two compounds were identical, apart from the absence of the 17-H signal. The same is true for keronopsins A_1 (**1a**) and A_2 (**1b**), which also have one and two bromo substituents, respectively, at C-16 and C-17 of the pyrrole ring. Keronopsins A_1 and A_2 differ from B_1 and B_2 only in the pyrone ring. The signal for the 4-hydroxy group is missing, the signal for 5-H is shifted by $\Delta\delta = 0.6$ downfield, and the signal for C-3 is moved by $\Delta\delta = 5$ downfield—the signals for C-2 and C-4 are shifted by $\Delta\delta = 4-6$ upfield, which suggests the presence of a 4-acyloxy substituent. From elemental analysis and negative-ion FAB-MS, keronopsins A_1 and A_2 are the sodium salts of sulfates **1a** and **1b**, which explains both their ready solubility in water and their hydrolysis by acid to **1c** and **1d**, respectively. In addition this latter reaction is accelerated by the sodium hydrogen sulfate which it releases. In organic solvents and during lyophilization, small amounts of sodium hydrogen sulfate can also induce polymerization; **1a** and **1c** are particularly susceptible to this, due to their free α- and β-positions in the pyrrole residue.

The hydrolysis of **1a** and **1b** in crude extracts, in contrast to that of the pure substances, cannot be stopped by addition of sodium hydrogen carbonate, but can be inhibited by high methanol concentrations or by brief boiling. Clearly the organism possesses a thermolabile sulfatase, which only comes into contact with keronopsins A when the cells are disrupted, and converts them into the more toxic[5] B compounds. This reaction may possibly also take place after uptake into the cellular food vacuole or in the stomach of predators, crippling or killing them, thus reducing the number of victims in the total population.

Single-Crystal EPR Spectroscopy on $[^{57}Fe(NO)(S_2CNEt_2)_2]$: The "Triplet Signal" in the EPR Spectrum of $[Fe(S_2CNEt_2)_3]$**

Reinhard Kirmse,* Simone Saluschke, Einar Möller, Eduard J. Reijerse, Edward Gelerinter, and Norman V. Duffy

Tris(diethyldithiocarbamato)iron(III) $[Fe(S_2CNEt_2)_3]$ is a classical spin-crossover system and a typical textbook example.[1a,b] The results of the first EPR investigation on the spin equilibrium $S = 1/2 \rightleftharpoons S = 5/2$ of $[Fe(S_2CNEt_2)_3]$ in solution (both spin states are EPR active) were reported by Cotton and Gibson in 1971.[2] In the EPR spectra besides the $S = 5/2$ and $S = 1/2$ signals for Fe^{III}, an additional triplet of lines near $g = 2.0$ was observed, originating from the interaction of an unpaired electron with the ^{14}N nucleus (nuclear spin $I = 1$). The question whether this signal could be assigned to the complex $[Fe^{I}(NO)(S_2CNEt_2)_2]$ (**1**)[3a,b] was, at that time, only shortly discussed.

1

In our investigation of $[Fe/In(S_2CNEt_2)_3]$ single crystals we also observed this triplet of lines together with the signals for $S = 5/2$ and $S = 1/2$. The assignment of the triplet to a Fe^{II}

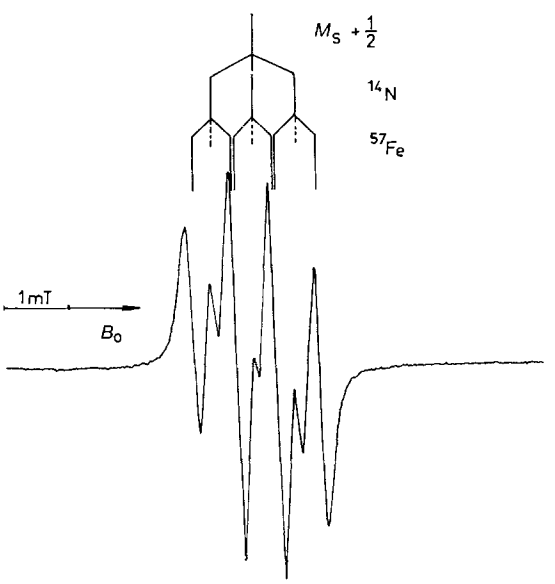

Fig. 1. The single-crystal EPR spectrum of **1** in $[In(S_2CNEt_2)_3]$. For this B_0 field direction $A^{Fe} = A^N$.

radical complex of the type $[(S_2CNEt_2)_2Fe^{II}(S_2CNEt_2)^{\cdot}]$ seemed obvious,[4] but could be excluded based on the results reported here.

To assure reliable interpretation we prepared $[^{57}Fe(NO)(S_2CNEt_2)_2]$ (^{57}Fe enrichment $\approx 80\%$) and performed a single-crystal EPR investigation on the magnetically diluted system $[^{57}Fe(NO)(S_2CNEt_2)_2/In(S_2CNEt_2)_3]$ to determine the structure and bonding. The diamagnetic host complex $[In(S_2CNEt_2)_3]$ crystallizes in the space group $A2/a$ with two nonequivalent molecule positions; the molecules themselves have approximately D_3 symmetry.[5] For the incorporation of the "pyramidal" $[Fe(NO)(S_2CNEt_2)_2]$[6] a maximum of six magnetically nonequivalent sites are feasible.[7a] However, first ENDOR spectra (ENDOR = electron nuclear double resonance) reveal that only two of the six sites are occupied by the guest complex $[Fe(NO)(S_2CNEt_2)_2]$.[7b]

Figure 1 shows a single-crystal EPR spectrum for a particular magnetic field orientation, and Figure 2 an anglular dependence

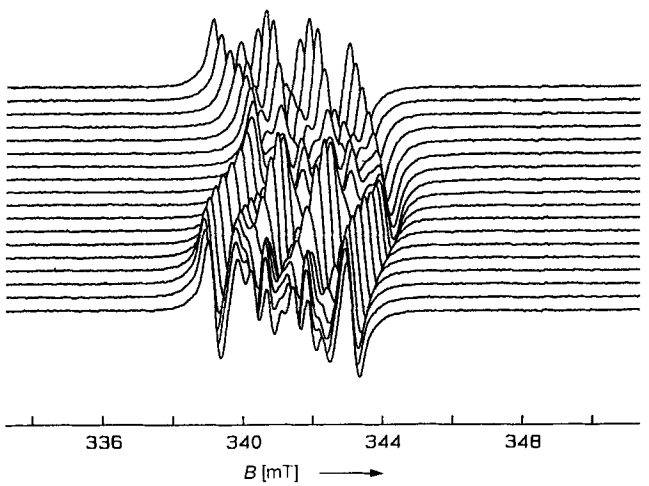

Fig. 2. Stack plot of the deppendence of the EPR spectrum of **1** on the angle in the x,y plane of the laboratory coordinate system.

as well as the complexity of the EPR spectra. The spectra reveal a very well resolved $^{14}N(NO)$ and ^{57}Fe hyperfine structure; parameters for the tensors g, A^{Fe} and $A^{N}(NO)$ obtained from the spectral analysis[8] are summarized in Table 1. Figure 3 illustrates the orientation of the principal tensor axes in the molecule studied. For reasons of symmetry a principal ^{14}N tensor axis is expected to fall along the bond vector of the N–O multiple bond.[9] The angle of 8° between the z axis of the molecule and the tensor component A_1^N corresponds surprisingly well with

Table 1. Principal values [a] of the tensors g, A^{Fe}, and A^{N} and the angles between the principal tensor axes.

Principal tensor values			Angle [°]			
g	$g_1 = 2.049$			g_1	g_2	g_3
	$g_2 = 2.044$		A_1^{Fe}	90	0	90
	$g_3 = 2.036$		A_2^{Fe}	0	90	90
			A_3^{Fe}	90	90	0
A^{Fe}	$A_1^{Fe} = 17.9$					
	$A_2^{Fe} = 12.6$			A_1^{N}	A_2^{N}	A_3^{N}
	$A_3^{Fe} = 1.9$		A_1^{Fe}	83	66	25
			A_2^{Fe}	87	25	115
A^{N}	$A_1^{N} = 13.8$		A_3^{Fe}	8	84	85
	$A_2^{N} = 12.0$					
	$A_3^{N} = 11.5$					

[a] Coupling constants in 10^{-4} cm^{-1}; exp. error: $g_i \pm 0.001$, A_i^{Fe}, $A_i^{N} \pm 0.2$.

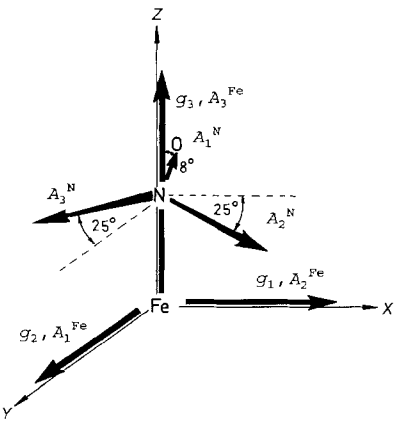

Fig. 3. The orientation of the principal axes of the tensors g, A^{Fe}, and $A^{N}(NO)$ in the molecular coordinate system.

with the Fe-N-O angle determined by X-ray crystal structure analysis.[6] Furthermore, the orientation of the other two principal ^{14}N tensor axes shows that the projection of the NO bond axis on the x,y plane of the molecular coordinate system (according to the crystallographic results) does not fall along the axis bisecting the S_2CNEt_2 ligand (= x axis). Rather, an angle of $\approx 20°$ with respect to the x axis was found. Accordingly, upon incorporation into $[In(S_2CNEt_2)_3]$, **1** maintains its geometry to the greatest possible extent.

For the molecular orbital with the unpaired electron [Eq. (a)],[3a,10] the following values for the spin density distribution in

$$\Psi(A_1) = \alpha\phi(\mathrm{Fe}) \pm \alpha'\phi(\mathrm{N^{NO}}) - (\alpha''/2)(\sum\phi_i(S_i)) \qquad \text{(a)}$$

the first coordination sphere are obtained from the observed hyperfine structure interaction (^{57}Fe, ^{14}N) by using standard formalism:[11] $\alpha^2(Fe) \approx 52\%$, $(\alpha')^2 \approx 6\%$. Thus about 58% of the spin density is located in the Fe–NO unit. Interactions with other nuclei were not observed in the EPR experiment.

The EPR parameters obtained indicate clearly that the triplet of the earlier investigation originates from the ^{14}N nucleus of the NO ligand and not from a radical complex of the type $[(S_2CNEt_2)_2Fe^{II}(S_2CNEt_2)^{\cdot}]$, for which the ^{14}N coupling would be attributed to the ^{14}N nucleus of the $S_2CNEt_2^-$ ligand. Furthermore, for the latter compound a different "pattern" for the principal axis system of the ^{14}N tensor would be expected,[12] and the ^{57}Fe hyperfine structure splitting should be hardly detectable. In contrast to earlier investigations on $[^{57}Fe(NO)(S_2CNEt_2)_2]$[3c] a pronounced rhombic symmetry of the A tensor of ^{57}Fe was expected and verified.

Possible nitrogen sources for the complex **1**, which forms spontaneously in the preparation of $[Fe^{III}(S_2NCEt_2)_3]$, include the nitrogen atom of the $S_2CNEt_2^-$ ligand, the protective gas (N_2) employed during the preparation, or a small amount of NO_3^- ion present in starting materials. The nitrogen in the $S_2CNEt_2^-$ ligand could be excluded through ^{15}N labeling, since a ^{15}N hyperfine structure doublet was not observed.[13] The subsitution of Ar for N_2 as the protective gas did not lead to any change in the intensity of the triplet signal. On the other hand, a very clear reduction in the EPR signal intensity (signal still however detectable) was found when analytical pure $FeCl_3$ (NO_3^- content $< 0.01\%$) was used. Obviously traces of NO_3^- in the starting material are responsible for the spontaneous formation of **1**. The high detection sensitivity of EPR spectroscopy (concentrations of ≈ 0.001 mol% are detectable when line widths are narrow) confirms this conclusion.

Experimental Procedure

$[In(S_2CNEt_2)_3]$ was synthesized by treating $Na(S_2CNEt_2)$ with $InCl_3$ [14]; ^{57}Fe labeled $[Fe(NO)(S_2CNEt_2)_2]$ was prepared in a one pot reaction employing $^{57}FeSO_4 \cdot 7H_2O$ (prepared from ^{57}Fe), NO, and $Na(S_2CNEt_2)$ [15]. Yield: 50%.

Magnetically diluted $[Fe(NO)(S_2CNEt_2)_2/In(S_2CNEt_2)_3]$ single crystals were obtained after about 6 weeks by slowly crystallizing a benzene solution containing both components in the ratio of 0.5% (Fe complex) to 99.5% (In complex) under a controlled N_2 stream. The edges of the crystals were up to 5 mm long.

EPR spectra: The spectra were recorded in X Band ($\nu \approx 9.7$ GHz) at $T = 295$ K with a spectrometer of the type ESP 300 E (Bruker). For the measurement of the angular dependence, the spectra were collected in three planes normal to each other in 10° divisions at 5° intervals. The data was evaluated with the program "MAGRES" [8].

To establish the N_2 source for the formation of **1** during the preparation of $[Fe/In(S_2CNEt_2)_3]$ crystals and powders, $[Fe(S_2CNEt_2)_3]$ prepared from analytically pure $FeCl_3$ (Fluka, NO_3 content < 0.01%) was used. Either N_2 or Ar was applied as the protective gas for the synthesis.

[6] Crystal structure data have been reported for a) $[Fe^I(NO)(S_2CNMe_2)_2]$ by G. R. Davies, J. A. J. Jarvis, B. T. Kilbourn, R. H. B. Mais, P. G. Owston, *J. Chem. Soc. A* **1970**, 1275–1283; and b) $[Fe^I(NO)(S_2CNEt_2)_2]$ by M. Colapeitro, A. Domenicano, L. Scaramuzza, A. Vaciago, L. Zambonelli, *Chem. Commun.* **1967**, 583–584. The two structures are very similar: Fe-N-O angle (T = 295 K) ≈ 174°; the projection of the N–O vector onto the x,y plane of the molecule gives an angle of ≈ 20° to the x axis.

[7] a) Statistically the NO ligand could replace every ligand of the $[In(S_2CNEt_2)_3]$ molecule, which would then lead to three structurally different and simultaneously to three magnetically different sites per In complex. Thus for the unit cell with two nonequivalent molecule positions, there are six sites in total. The same number of nonequivalent magnetic sites also exists for O_h symmetry (for monodentate ligands). Since 180° symmetry can not be distinquished in an EPR experiment, of the six different sites in this case only three magnetic nonequivalent sites per molecule, as for D_3 symmetry, are possible. b) ENDOR investigation: S. Saluschke, R. Böttcher, R. Kirmse, unpublished results. Why only two insertion positions are occupied cannot be solved by this investigation.

[8] The EPR spectra were described with the spin Hamiltonian operator $H_{sp} = \beta_e B_0 \cdot g \cdot S + S \cdot A^{Fe} \cdot I^{Fe} + S \cdot A^{N} \cdot I^{N}$. The analysis was performed with the program "MAGRES": C. P. Keijzers, E. J. Reijerse, P. Stam, M. F. Dumont, M. C. M. Gribnau, *J. Chem. Soc. Faraday Trans. 1* **1987**, *83*, 3493–3503.

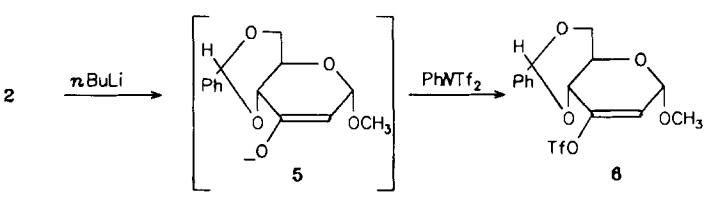
Enol Triflate Pyranoses, Versatile Reagents for the Formation of Conjugated Systems on Pyranoses**

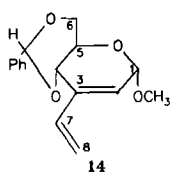


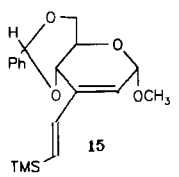
Yousef Al-Abed, Taleb H. Al-Tel, Christoph Schröder, and Wolfgang Voelter*

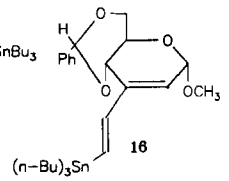
Over the last few years a whole series of synthetic routes have been described in which conjugated enals and dienes derived from carbohydrates are used in Diels–Alder reactions to obtain chiral carbocyclic systems as starting materials for the synthesis of natural products.[1] Thus, methyl-4,6,-*O*-benzylidene-2,3-dideoxy-3-C-vinyl-α-D-*erythro*-hex-2-enopyranoside (**14**) has finally been synthesized, after a less successful attempt,[1a] from methyl-α-D-glucopyranoside in seven[1i] or six[1j] steps in an overall yield of about 15%, based on the starting material. These multistep syntheses of diene **14** should be shortened drastically by the use of the enol triflate **6**. The synthesis of **6** from **3**, which is produced in two steps from commercially available **1** via **2**,[2] was unsuccessful: after a 10 to 15 h reaction at −78 to −30 °C with *n*BuLi and *N*-phenyltrifluoromethanesulfonimide ($PhNTf_2$),[3] only anomerization to **4** was observed.

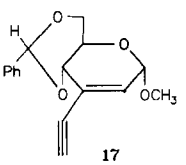
With trifluoromethanesulfonic anhydride as reagent instead of trifluoromethanesulfonimide the reaction solution turned black when the temperature was increased from −78 to −30 °C; numerous decomposition products could be detected by thin-layer chromatography.

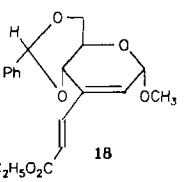
However, treatment of **2** with *n*BuLi in THF, at −40 °C for 30 min (formation of the enolate **5** is indicated by red coloration

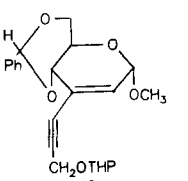


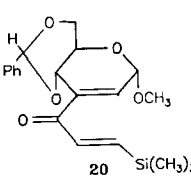












and disappearance of the starting material as shown by thin-layer chromatography), reaction of the resulting enolate solution with four equivalents of $PhNTf_2$ at −78 °C over 30 min, and then at −20 °C for 6 h gave the desired enol triflate **6** in 85%

Table 1. Products and yields from the reaction of vinyl triflate **6** with unsaturated tributylstannyl derivatives or Michael acceptors.

Reagent	Product	Yield [%]	Selected ^{1}H NMR data (250 MHz, $CDCl_3$)
Bu_3Sn (**7**)	 **14**	100	δ = 6.21 (dd, J = 17.7, 11.4 Hz, H-7), 5.60 (d, J = 17.8 Hz, H-8), 5.57 (br. s, H-2), 5.15 (dd, J = 11.2, 1.4 Hz, H-8), 4.89 (d, J = 2.1 Hz, H-1)
Bu_3Sn, $SiMe_3$ (**8**)	 **15**	100	δ = 6.32 (d, J = 19.3 Hz, H-7), 6.40 (d, J = 19.3 Hz, H-8), 5.60 (br. s, H-2), 4.88 (br. s, H-1)
Bu_3Sn, $SnBu_3$ (**9**)	 **16**	75	δ = 6.41 (d, J = 19.7 Hz, H-7), 6.70 (d, J = 19.7 Hz, H-8), 5.61 (br. s, H-2), 4.91 (br. d, J = 2.1 Hz, H-1)
$HC\equiv CSnBu_3$ (**10**)	 **17**	80	δ = 5.90 (s, H-2), 4.86 (br. s, H-1)
Bu_3Sn, CO_2Et (**11**)	 **18**	80	δ = 7.12 (d, J = 16.1 Hz, H-7), 6.29 (d, J = 16.1 Hz), 5.59 (br. s, H-2), 4.91 (br. d, J = 2.1 Hz, H-1)
$HC\equiv CCH_2OTHP$ (**12**)	 **19**	87	δ = 5.93 (br. s, H-2), 4.87 (br. s, H-1), 4.32 (s, 2H, H-9)
$H_2C=CCO_2Et$ (**13**)	**18**	83	see above
Bu_3Sn, $SiMe_3$ (**8**) + CO	 **20**	60	δ = 6.68 (d, J = 18.8 Hz, H-8), 7.12 (d, J = 18.9 Hz, H-9), 6.24 (t, J = 2.5 Hz, H-2), 4.89 (dd, J = 2.6, 1.1 Hz, H-1)

isolated yield after workup (the temperature should not be allowed to rise above 5 °C).

Compound **6** has shown itself to be a versatile reagent for the synthesis of pyranosides containing conjugated units, as already described for carbocyclic systems.[4] Reaction of **6** with tributylvinylstannane (**7**), tetrakis(triphenylphosphane)palladium(0) and lithium chloride according to Scott and Stille,[5] gave compound **14**, described by López et al.,[1a] in almost quantitative yield. With the same method, the conjugated compounds **15**–**18** are obtained from **6** in 80 to 100% yield by reaction with *trans*-1-tri-*n*-butylstannyl-2-trimethylsilylethylene (**8**),[6] *trans*-1,2-bis(tri-*n*-butylstannyl)ethylene (**9**),[6] ethynyltributylstannane (**10**), or *trans*-2-tributylstannylethyl acrylate[7] (**11**) (Table 1). The dienes **14**–**16** are chiral starting materials for the formation of carbocyclic systems that contain other reactive centers for further reactions by the Diels–Alder reaction. For example, the enyne **17** can be used as starting material for a regiospecific 1,2-functionalization of the olefinic double bond.[8] The conjugated systems can be synthesized easily by treating olefins with Michael acceptor properties or acetylenes with the enol triflate **6**.[9] Thus, the diene **18** and the enyne **19** are prepared in 80–85% yield from **6** by reaction with ethyl acrylate (**13**) or 2-propargyloxytetrahydropyran (**12**), respectively, in the presence of bis(triphenylphosphane)dichloropalladium(II) and triethylamine at 70 °C in dimethylformamide in 10 h.

Divinyl ketones can be prepared from the vinyl triflate **6** by a palladium-catalyzed reaction with **8** and carbon monoxide, as shown by the example of **20**. The successful insertion of CO is, however, strongly dependent on the temperature. If compound **6** is, according the literature,[10] treated with **8** at 55–60 °C, diene **15** is the predominant product. After a 10 h reaction at 20 °C only the starting material could be isolated. Even increasing the CO pressure from 1 to 3 atm did not lead to an improvement in the yield of **20**. On the other hand, when the reaction was carried out for 12 h at 50 °C, **20** could be obtained in 60% yield, together with 25% of **15**. Chiral divinylketones such as **20** could be used as Michael acceptors for numerous nucleophiles[11] or for the synthesis of optically active cyclopentenones by the Nazarov reaction.[12]

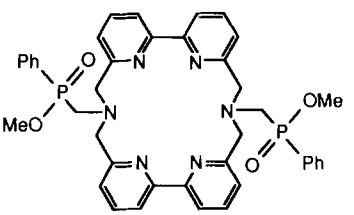
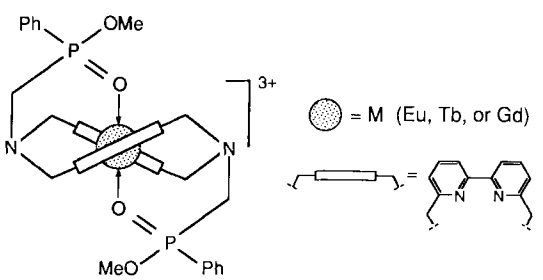
Luminescent Eu^{3+} and Tb^{3+} Complexes of a Branched Macrocyclic Ligand Incorporating 2,2′-Bipyridine in the Macrocycle and Phosphinate Esters in the Side Arms**



Nanda Sabbatini,* Massimo Guardigli, Fabrizio Bolletta, Ilse Manet, and Raymond Ziessel*

Lanthanide ions, in particular Eu^{3+} and Tb^{3+}, are interesting luminescent species for fluoroimmunoassay (FIA) because of the long lifetimes of their emitting states, which allow enhancement of the sensitivity by time-resolved measurements.[1] However, the Eu^{3+} and Tb^{3+} ions are characterized by low absorption coefficients;[2] consequently, direct excitation of the ion results only in low luminescence intensity. To overcome this problem, complexes of these ions with efficient chromophores have been prepared in order to obtain intense emission after an energy transfer from the excited ligand to the metal ion.

The first type of lanthanide complexes studied for application in FIA are the Eu^{3+} chelates.[3] These complexes are widely used in commercial kits, but the procedure is complicated because of a) the use of two chelates, b) the insolubility of the luminescent chelate in water, which is the solvent of interest in FIA, and c) the need to protect the chelated ion from interaction with the solvent.[3]



More recently, a different approach to the use of lanthanide ions in FIA, based on their complexation with cage-type ligands incorporating chromophoric groups, aims at simplified procedures by using compounds that simultaneously show solubility and kinetic inertness in water, shielding of the enclosed ion, and intense metal luminescence. Among the species studied, complexes of branched macrocyclic ligands incorporating the 2,2′-bipyridine (bpy) and the 1,10-phenanthroline chromophoric groups have drawn special attention because of their high molar extinction coefficients and efficient shielding of the enclosed metal ion.[4] For this class of compounds, only the Eu^{3+} complex of the ligand incorporating two bpy units in the macrocycle and two bpy units in the branches shows a luminescence intense enough to be interesting for application in FIA,[4a, 5] but the complex undergoes decomposition when used in immunological analyses, most likely because of weak coordination of the ion by the bpy units in the side arms. Research is therefore directed at introducing groups into the branches that are known to have better ligating properties towards lanthanide ions.

In this paper we present the novel, branched macrocyclic ligand **1**, which contains two bpy moieties in the macrocycle and phosphinate ester groups in the branches. The syntheses of the ligand **1** and the $[M \subset \mathbf{1}]^{3+}$ complexes (M = Eu, Tb, or Gd) are reported as well as their photophysical properties.

1

Ligand **1** has been synthesized as a mixture of diastereoisomers in a straightforward manner by treating the bpy · bpy macrocycle[6] (that is, H at the positions of the phosphinate ester groups) with paraformaldehyde and dimethylphenylphosphonite under anhydrous conditions, in a procedure adapted from the method described in the literature[7] (yield 45%, FAB-MS 731 $[M^+ + H]$). The $[M \subset \mathbf{1}]^{3+}$ complexes (M = Eu, Tb, or Gd) have been prepared as previously described:[8] $[Eu \subset \mathbf{1}]Cl_3 \cdot 3H_2O$ (yield 78%, FAB-MS 953 $[M^+ - Cl]$); $[Tb \subset \mathbf{1}]Cl_3 \cdot 2H_2O$ (yield 76%, FAB-MS 959 $[M^+ - Cl]$); $[Gd \subset \mathbf{1}]Cl_3 \cdot 3H_2O$ (yield 79%, FAB-MS 958 $[M^+ - Cl]$). Interestingly, the FT-IR spectra of these complexes display a significant shift (17 cm^{-1}) to lower frequency of the P–O stretching frequency indicating, as expected, strong coordination of this group to the metal.[9]

$[M \subset \mathbf{1}]^{3+}$

All the photophysical properties of solutions of the Eu^{3+}, Tb^{3+}, and Gd^{3+} complexes in water were unchanged for several days; these complexes are thus kinetically inert in this solvent. The absorption spectra of the complexes (Fig. 1) are characterized by intense bands in the UV region. By analogy with other lanthanide complexes of bpy-based ligands,[4a] these bands are attributed to bpy $\pi-\pi^*$ transitions which undergo some red shift upon complexation (Table 1). The shoulders in the 250–280 nm region correspond to the weak absorption of the phenyl moiety. Comparison of the absorption spectrum with the luminescence excitation spectrum of the metal obtained upon excitation of the ligand (Fig. 1) indicates that energy transfer from the excited ligand to the emitting metal ion takes place; the emitting state

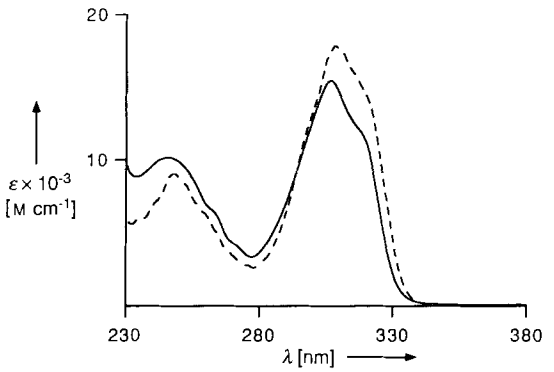

Fig. 1. Absorption (—) and luminescence excitation (- - -) spectra of the $[Eu \subset \mathbf{1}]^{3+}$ complex in water (similar absorption spectra were obtained for $[Tb \subset \mathbf{1}]^{3+}$ and $[Gd \subset \mathbf{1}]^{3+}$, and a similar luminescence excitation spectrum for $[Tb \subset \mathbf{1}]^{3+}$).

of the metal is clearly populated through absorption by the bpy unit, while the involvement of the phenyl moiety cannot be unequivocally assessed.

To study the behavior of the ligand-centered excited states in the energy transfer, the properties of the lowest singlet and triplet excited states belonging to the bpy moiety have been investigated. The lifetimes of the singlet excited state of the ligand and the fluorescence quantum yields of the ligand in the Gd^{3+}, Tb^{3+}, and Eu^{3+} complexes have been measured (Table 1). Comparison of the results obtained shows that $[Tb \subset \mathbf{1}]^{3+}$ and $[Eu \subset \mathbf{1}]^{3+}$ exhibit fluorescence quantum yields respectively about two times and fifty times lower than that of $[Gd \subset \mathbf{1}]^{3+}$. This might imply an energy transfer from the lowest singlet excited state of the ligand to the Eu^{3+} and Tb^{3+} emitting states. Such a process should take place with a rate constant greater than $10^9\ s^{-1}$ and $10^{10}\ s^{-1}$ for $[Tb \subset \mathbf{1}]^{3+}$ and $[Eu \subset \mathbf{1}]^{3+}$, respectively (calculated from the fluorescence quantum yield values in Table 1). It is not possible to decide whether the rate constant values are reasonable, because the only value available for an analogous process refers to an energy transfer from the ligand-centered triplet excited state.[10] Finally, it is worthwhile noting that the lower quantum yield of $[Eu \subset \mathbf{1}]^{3+}$ relative to that of $[Tb \subset \mathbf{1}]^{3+}$ may be due to nonradiative deactivation of the singlet excited state of the ligand to low-lying metal states (ligand-to-metal charge transfer, LMCT).[4, 11]

The lowest triplet excited state of the ligand has been investigated by studying the bpy phosphorescence and triplet–triplet absorption in the $[Eu \subset \mathbf{1}]^{3+}$, $[Tb \subset \mathbf{1}]^{3+}$, and $[Gd \subset \mathbf{1}]^{3+}$ complexes. Both these quantities could be measured for $[Gd \subset \mathbf{1}]^{3+}$ but not for $[Eu \subset \mathbf{1}]^{3+}$ or $[Tb \subset \mathbf{1}]^{3+}$ (Table 1). Since the energy of the lowest triplet excited state of 21 500 cm^{-1}, obtained from the highest energy feature of the phosphorescence of the $[Gd \subset \mathbf{1}]^{3+}$ complex (Table 1), lies above the Eu^{3+} $^5D_0$ and Tb^{3+} $^5D_4$ emitting states and below the first excited state of the Gd^{3+} ion, the behavior observed is ascribed to deactivation of the ligand triplet excited state by energy transfer to the Eu^{3+} or Tb^{3+} ions. An analogous conclusion was drawn for other Eu^{3+} and Tb^{3+} complexes of ligands containing bpy units.[4a]

Metal luminescence lifetime and quantum yields, obtained upon ligand excitation under various experimental conditions, are collated in Table 2. For both the $[Tb \subset \mathbf{1}]^{3+}$ and $[Eu \subset \mathbf{1}]^{3+}$ complexes comparison of the lifetimes and quantum yields in H_2O and D_2O solutions indicates that nonradiative deactivation through the O–H vibrations[12] occurs. By using the Horrocks and Sudnick equation[13] 1.3 and 1.4 water molecules are estimated to coordinate the metal ion in the $[Tb \subset \mathbf{1}]^{3+}$ and $[Eu \subset \mathbf{1}]^{3+}$ complexes, respectively. In the $[Tb \subset \mathbf{1}]^{3+}$ complex, the strong temperature dependence of the lifetimes indicates that an important role in the decay of the Tb^{3+} emitting state is played by a thermally activated process. As previously suggested for Tb^{3+} complexes of other ligands incorporating bpy units,[4a] such a process most likely involves the bpy lowest triplet excited state. In fact, as mentioned above, this level lies at 21 500 cm^{-1}, that is, 1100 cm^{-1} above the Tb^{3+} emitting level, and therefore it may be thermally populated at room temperature. Moreover, the quenching of the Tb^{3+} luminescence by oxygen ($k_q = 1.1 \times 10^6\ M^{-1}\ s^{-1}$, obtained from the values in Table 2) suggests that the Tb^{3+} $^5D_4$ level is in equilibrium with the bpy lowest triplet excited state. In fact, the luminescent states of the lanthanide ions are not quenched by oxygen;[10] thus quenching of the Tb^{3+} luminescence reasonably involves the bpy lowest triplet excited state. This hypothesis is supported by the observation that the bpy lowest triplet excited state in $[Gd \subset \mathbf{1}]^{3+}$ is quenched by oxygen ($k_q = 5.0 \times 10^8\ M^{-1}\ s^{-1}$, obtained from the lifetime values in Table 1). The same behavior has previously been found for analogous lanthanide complexes.[4a]

In conclusion, the $[Eu \subset \mathbf{1}]^{3+}$ and $[Tb \subset \mathbf{1}]^{3+}$ complexes show interesting properties for applications in FIA. They are kinetically stable in water, and the metal ions are well protected against deactivation of the luminescent excited states by water. Moreover, the luminescence intensity is rather high, in spite of the relatively low molar extinction coefficients resulting from the presence in the ligand **1** of only two efficient chromophores. Substitution of the weakly absorbing phenyl units in the phosphinate groups by efficient chromophores should result in an even more intense luminescence, if absorption is followed by efficient energy transfer to the metal ion. As mentioned in the discussion of the luminescence excitation spectra of the metal, the involvement of the phenyl moiety in the energy transfer to the metal ion cannot be proved. However, for lanthanide complexes containing phosphinic or phosphonic groups incorporating benzyl or phenyl units a quite efficient energy transfer has recently been reported.[14]

Experimental Procedure

1: A suspension of the bpy · bpy macrocycle (200 mg, 0.51 mmol) and anhydrous paraformaldehyde (350 mg) in THF (100 mL) was heated at 60 °C for 2 h. Then, dimethylphenylphosphonite (0.24 mL, 1.52 mmol) was added under argon, and the mixture was heated at reflux for 24 h in a Soxhlet apparatus containing 3 Å molecular sieves (10 g). After cooling to room temperature the solvent was evaporated, and the residue was dissolved in the minimal amount of CH_2Cl_2 (about 20 mL). After filtration over celite, hexane (about 35 mL) was added as a counter solvent. Slow evaporation of the solvent caused the precipitation of the pure, white polymethylenephosphinate ester **1** as a diastereoisomeric mixture (yield 45%). UV/VIS (MeOH): λ_{max} [nm] (ε) = 299 (21 200), 245 (16 100). ^{1}H NMR (200.1 MHz, $CDCl_3$, 25 °C): δ = 8.33 (d, 4H, ^3J(H, H) = 8.1 Hz), 7.83 – 7.41 (m, 14H), 7.23 (d, 4H, ^3J(H, H) = 7.5 Hz), 3.71 (d, 6H, ^3J(P, H) = 11.6 Hz, OCH_3), 3.93 (s, 8H, CH_2-bpy), 3.03 (d, 4H, ^2J(P, H) = 6.5 Hz, CH_2P). $^{13}C\{^1H\}$ NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 156.33 (quart. C), 151.93 (quart. C), 148.76 (CH), 133.30 (CH), 132.35 (d, ^3J(P, C) = 10 Hz, *m*-Ar), 131.56 (CH), 130.30 (d, ^1J(P, C) = 120 Hz, C(Ar)(P)), 129.63 (CH), 128.05 (d, ^2J(P, C) = 13 Hz, *o*-Ar), 61.73 (CH_2-bpy), 59.40 (d, ^1J(P, C) = 123 Hz, CH_2P), 53.04 (d, ^2J(P, C) = 7 Hz, OCH_3). $^{31}P\{^1H\}$ NMR (81.0 MHz, $CDCl_3$, 25 °C): δ = 41.76 (s). MS (FAB$^+$ in *m*-nitrobenzylalcohol (*m*-NBA) as matrix): *m/z* 731 (M^+ + H). FT-IR (KBr pellet): $\tilde{\nu}$[cm^{-1}] = 2927, 2857, 1730, 1595, 1577, 1439, 1176 (P=O), 1122, 1035, 796. Anal. Calcd. for $C_{40}H_{40}N_6O_4P_2$ (Mr = 730.75).

Lanthanide complexes: To a solution of **1** (30 mg, 0.04 mmol) in CH_2Cl_2 (2 mL) an equimolar quantity of the lanthanide salt ($MCl_3 \cdot 6H_2O$, M = Eu, Tb or Gd), dissolved in methanol (3 mL) was added. After 2 h heating at 60 °C, the solvent was removed under reduced pressure, and the residue was recrystallized twice by slow diffusion of diethyl ether into an ethanol solution. $[Eu \subset \mathbf{1}]Cl_3 \cdot 3H_2O$ (yield 78%). UV/VIS (H_2O): λ_{max}[nm] (ε) = 307 (15 100), 246 (9900). MS (FAB$^+$ in *m*-NBA): *m/z* 953 (M^+ – Cl), 918 (M^+ – 2Cl) FT-IR (KBr pellet): $\tilde{\nu}$ = 1159 cm^{-1} (P=O). Anal. Calcd. for $C_{40}H_{40}N_6O_4P_2EuCl_3 \cdot 3H_2O$ (Mr = 989.07 + 54.05): $[Tb \subset \mathbf{1}]Cl_3 \cdot 2H_2O$ (yield 76%). UV/VIS (H_2O): λ_{max}[nm] (ε) = 306 (15 300), 246 (10 100). MS (FAB$^+$ in *m*-NBA): *m/z* 959 (M^+ – Cl), 924 (M^+ – 2Cl). FT-IR (KBr pellet): $\tilde{\nu}$ = 1159 cm^{-1} (P → O). Anal. Calcd. for $C_{40}H_{40}N_6O_4P_2TbCl_3 \cdot 2H_2O$ (Mr = 996.03 + 36.06): $[Gd \subset \mathbf{1}]Cl_3 \cdot 3H_2O$ (yield 79%). UV/VIS (H_2O): λ_{max}[nm] (ε) = 306 (14 200), 245 (9800). MS (FAB$^+$ in *m*-NBA): *m/z* 958 (M^+ – Cl), 923 (M^+ – 2Cl). FT-IR (KBr pellet): $\tilde{\nu}$ = 1159 cm^{-1} (P → O). Anal. Calcd. for $C_{40}H_{40}N_6O_4P_2GdCl_3 \cdot 3H_2O$ (Mr = 994.36 + 54.05).

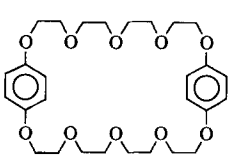
A New Class of Novel Macrocyclic Mesogens**



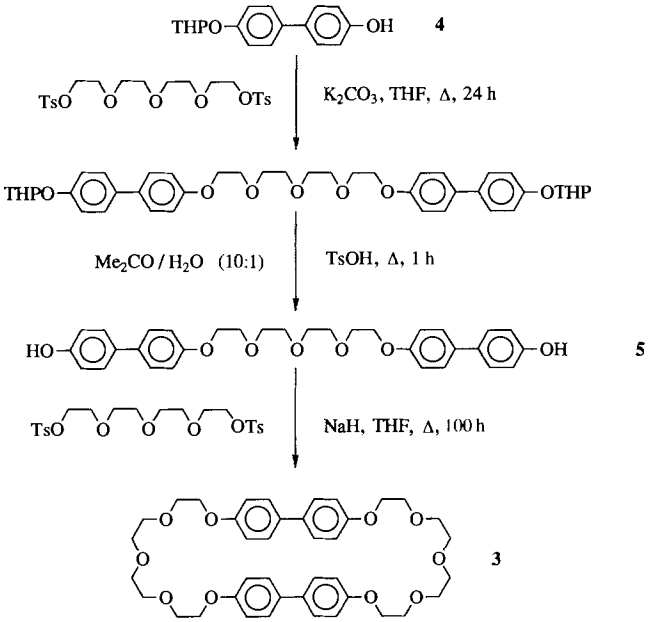
Peter R. Ashton, Detlev Joachimi, Neil Spencer, J. Fraser Stoddart,* Carsten Tschierske, Andrew J. P. White, David J. Williams, and Kerstin Zab

Since Pedersen[1] announced his discovery of the crown ethers in 1967, the amazing ability of these compounds to form complexes with a wide range of species, including alkali metal and alkaline earth metal cations and ammonium and alkylammonium ions, has had a widespread influence on the subsequent development of supramolecular chemistry.[2] In retrospect, therefore, it is hardly surprising that crown ethers, and the structurally related aza-crown ethers, have also been used[3] as building blocks in liquid crystal chemistry.

More recently we have shown[4a] that π-electron-deficient aromatic dications such as paraquat $\mathbf{1}^{2+}$ can be complexed, as its bis(hexafluorophosphate) salt, by crown ethers containing π-electron-rich arenes. Indeed, the macrocyclic polyether **2** proved

$\mathbf{1}^{2+}$

2



to be one of the most efficient molecular receptors for bipyridinium dications. These adducts—sustained by π–π aromatic stacking and electrostatic interactions, including hydrogen

bonding—became[4b] subsequently the basis for the template-directed synthesis[5] of numerous catenanes and rotaxanes.

As part of our early investigations on the complexation behavior of **1** · $2PF_6$ with crown ethers like **2**, we had anticipated that replacement of the paraphenylene units in **2** by 4,4′-biphenyl units might enhance complexation between host and guest species. 1,4,7,10,13,26,29,32,35,38-Decaoxa[13.0.13.0]paracyclophane **3**[6] was synthesized in three steps (Scheme 1) starting from 4′-(2-tetrahydropyranyloxy)-4-dihydroxybiphenyl (**4**).[7] The X-ray crystal structure[8] of **3** shows (Fig. 1) that the macrocycle, in contrast with **2**, is self-filling; the two biphenyl units (twist angle, 11°) are aligned parallel and staggered with respect to each other about a crystallographic center of symmetry. The benzene rings are close enough for partial overlap (interplanar separation of 3.41 Å between rings A and A′, and a centroid–centroid separation of 4.78 Å). This geometry is commensurate with conventional parallel π–π stacking.[9] The molecules pack to form chevron-like sheets (Fig. 2) that have adjacent layers oriented to optimize T-type edge-to-face interactions[10] between the aromatic components with centroid–centroid separations between interacting rings of 4.96 Å: the centroid–centroid vectors are inclined by about 73° to the ring planes.

Scheme 1. Synthesis of **3**. THP = tetrahydropyranyl.

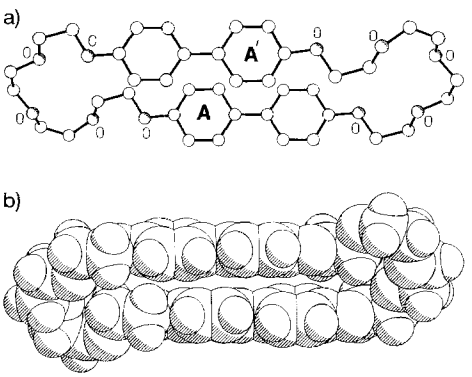

Fig. 1. a) Structure of **3** (crystallized from Et_2O) in the crystal showing the staggered parallel arrangement of the biphenyldiyl units, and b) a space-filling representation of the side view of the framework representation. Crystal data: orthorhombic, $a = 16.492(7)$, $b = 8.405(4)$, $c = 25.880(9)$ Å, $V = 3587$ Å^3, space group *Pbca*, $Z = 4$, $\rho_{calcd} = 1.275$ g cm^{-3}, 2746 independent measured reflections, 1309 with $|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 125°$, Siemens P4/PC diffractometer, ω scans, $Cu_{K\alpha}$ radiation, graphite monochromator, solved by direct methods and refined anisotropically to $R = 0.064$, $R_w = 0.064$.

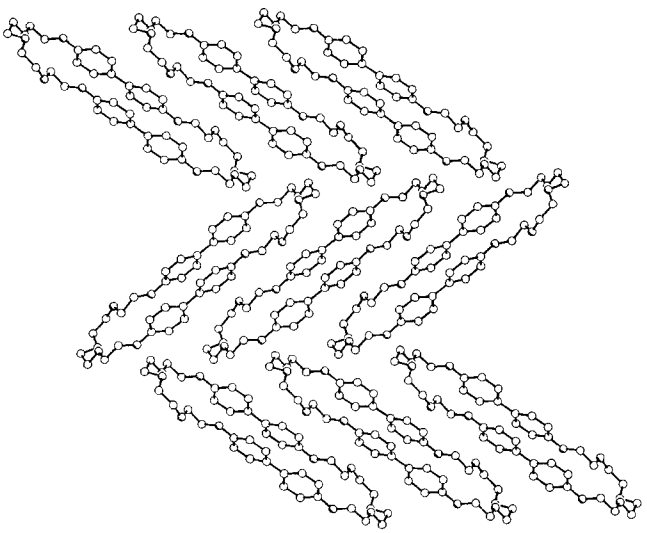

Fig. 2. The packing of molecules of **3** in two dimensions in the solid state.

Unfortunately, **3** is almost insoluble in solvents such as Me_2CO and MeCN, which we employ[4] routinely in complexation studies with bipyridinium salts. However, **3** includes two rigid biphenyl systems which are typical mesogenic structural elements of liquid crystals. Since the molecules of **3** have a rodlike shape (Fig. 1) in the solid state, arranging themselves (Fig. 2) in a smectic-like manner, we decided to investigate the compound for possible mesomorphic properties. Polarizing microscopy and differential scanning calorimetry established that **3** is indeed a thermotropic mesogen, showing enantiotropic smectic phases[11] with an unexpectedly high mesophase stability, as indicated by the high clearing temperature (Table 1). On cooling the isotropic liquid to 209 °C, a rapid formation of batonnets can be observed, which coalesce to a focal-conic fanlike texture with pseudotropic areas typical of a smectic A-type mesophase.[11] At 196 °C, the focal-conic fan texture changes to an arced focal-conic texture,

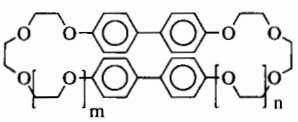
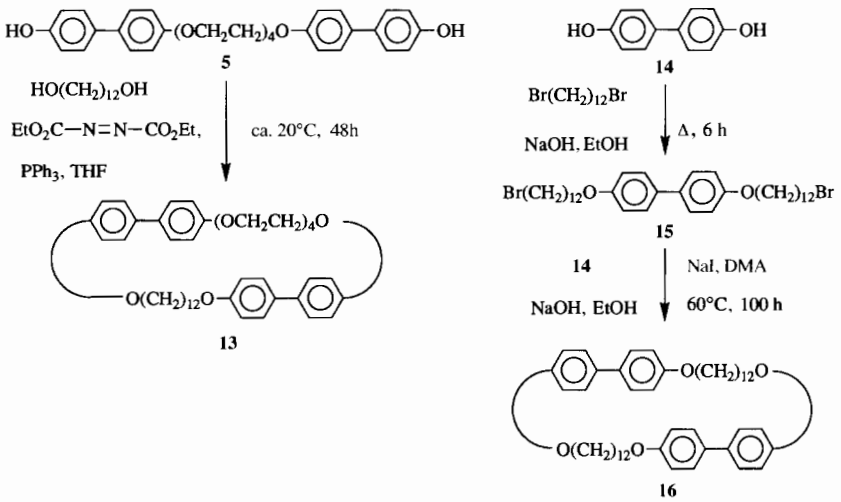
[a] Determined by means of a hot-stage polarizing microscope. [b] Abbreviations: cr = crystalline; S_E = smectic E phase; S_A = smectic A phase; S_B = smectic B phase; is = isotropic liquid; S, S_1, S_2, S_3 = unidentified smectic phases.



while the homeotropic areas, which appeared dark originally, start to show birefringent platelet areas with overlapping transparent platelets. This feature is unique to the smectic E phase.[11] Further cooling leads to crystallization at 190 °C. Reheating gives a melting point of 193 °C.

Unlike the polyether cyclophane **3**, its acyclic counterpart, 4,4′-bis[2-(2-methoxyethoxy)ethoxy]biphenyl (**6**), which has a molecular structure very similar to that of a typical conventional liquid crystal, does not form an enantiotropic mesophase at all. On supercooling to room temperature, not even a monotropic mesophase could be detected. However, biphenyl derivatives, for example, **7** and **8** with aliphatic side chains of comparable length to the oligoethylene glycol chains in **6** are known[12] to exhibit



liquid crystalline behavior. Nevertheless, their clearing temperatures are below 100 °C, just as one would expect[13] for a mesogen with only one biphenyl unit in its rigid core.

Thus, in the case of **3**, not only are liquid crystalline properties present, but the clearing temperature is a lot higher than one anticipates[13] from a mesogen with only one biphenyl unit in its rigid core. The coupling of two appropriate rigid units[14] by flexible terminal chains seems to constitute a new and powerful approach towards mesophase induction and stabilization. This realization immediately poses several questions. For example, how does the length of the polyether chains linking the two aromatic units influence the mesomorphic behavior? Is this new principle of mesophase stabilization unique for compounds with polyether chains as linking units or does it also occur in compounds which contain aliphatic side chains? To answer these questions, we have synthesized compounds with structures related to **3**, but having polyether and aliphatic chains of differing lengths (**9**–**12** and **13** and **16**).

3, m = n = 2
9, m = 1, n = 2 **11**, m = 2, n = 3
10, m = 1, n = 3 **12**, m = n = 3

The comparison of **3** and **9**–**12** in Table 1 shows how the mesophase behavior is influenced by varying the length of the polyether chains. The type of mesophase exhibited is not affected: all the compounds show S_E and S_A mesophases. The shortening of one bridging chain by one ethyleneglycol unit (for instance, **9** compared to **3**) increases the melting as well as the clearing temperature. However, **9** exhibits slightly anomalous behavior in having only a monotropic smectic E phase, that is, the melting point increases beyond the smectic E/smectic A temperature and so the smectic E phase for this compound can only be observed on supercooling. The smectic E mesophase of all these other compounds shows enantiotropic behavior. Compound **10** is a constitutional isomer of **3**, containing one longer and one shorter polyether chain. "Desymmetrization" leads, as expected, to a lower melting and clearing temperature and a smaller range of enantiotropic mesomorphic properties. Lengthening of the polyether chains (**11** and **12** compared to **3**) also lowers the clearing and melting temperatures. This effect is well-known for conventional, acyclic, rodlike liquid crystals.[13]

Scheme 2. Synthesis of paracyclophanes **13** and **16**. The reaction giving **13** was performed at higher dilution. DMA = dimethylacetamide.

To gauge how important polyether bridging chains are for the mesophase stabilization effect, we substituted one or both polyether chains of **3** with aliphatic chains in the syntheses of the biphenylophanes **13** and **15**, respectively (Scheme 2). The phase transitions for **3**, **13** and **16**, listed in Table 1, reveal that the influence of the type of linking chain on the mesophase stability, that is, on the clearing temperatures, is not very strong. In fact, the replacement of *both* polyether chains by aliphatic chains (**16**) leads to a decrease in the clearing temperature of 13 K. The replacement of only one polyether link by an aliphatic chain (**13**) leads to a slightly larger decrease in mesophase stability. Interestingly, however, as the nature of the bridging links becomes more aliphatic, the type of smectic mesophase changes. Smectic A is still evident, but the smectic E phase is no longer observed.

We may conclude that linking rigid mesogenic groups in macrocycles with flexible units has a mesophase stabilizing effect. The type of mesophase formed by macrocycles is also likely to depend on the structure of the incorporated rigid aromatic units. We are now constructing cyclophane derivatives with different mesogenic units to investigate this dependence.

Experimental Procedures

3: A solution of **5** (0.53 g, 1.0 mmol) and tetraethyleneglycol bistosylate (0.60 g, 1.2 mmol) in dry THF (250 mL) was added to a stirred suspension of NaH (0.05 g, 1.2 mmol) in dry THF (100 mL) under reflux over 4 h. The mixture was stirred for a further 96 h under reflux. The solvent was evaporated off, and the residue partitioned between $CHCl_3$ and dilute HCl. The organic layer was separated and, after washing with H_2O and saturated aqueous NaCl solution, dried over Na_2SO_4. Removal of the solvent in vacuo gave a solid, which was purified by chromatography on SiO_2 (CH_2Cl_2:Et_2O, 4:1). Further purification by several recrystallizations from EtOAc gave pure **3** (0.03 g, 4.1%). M.p. 193 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.28 (m, 8H), 6.82 (m, 8H), 4.05 (m, 8H), 3.91 (m, 8H), 3.75 (m, 16H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 157.9, 133.2, 127.5, 114.8, 71.0, 70.8, 69.8, 67.6; positive ion FAB-MS: m/z = 727 ($[M + K]^+$, 13%), 711 ($[M + Na]^+$, 31%), 688 ($[M]^+$, 100%), 613 (26), 593 (9), 576 (7). Single crystals suitable for X-ray crystallography were grown from Et_2O.

9–**12**: These compounds were prepared analogously to **3** (Scheme 1) by using the appropriate ethyleneglycol bistosylates. **9**: (0.01 g, 1.5%), m.p. 212 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.39–7.21 (m, 8H), 6.82 (m, 8H) 4.10–4.02 (m, 8H),

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/1414-1505 $ 10.00+.25/0*

3.94–3.84 (m, 8H), 3.80–3.71 (m, 12H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 158.0, 157.9, 133.2, 127.5, 115.1, 114.8, 71.2, 71.0, 70.8, 69.9, 69.8, 67.7; FAB-MS: *m/z* = 644 ($[M]^+$, 100%), 613 (7), 460 (51), 424 (11), 391 (15); **10**: 0.09 g (21.1%), m.p. 182 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.37–7.23 (m, 8H), 6.90–6.79 (m, 8H) 4.11–4.02 (m, 8H), 3.94–3.83 (m, 8H), 3.80–3.69(m, 16H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 158.0, 157.9, 133.3, 133.2, 127.5, 115.1, 114.8, 71.1, 71.0, 70.9, 69.9, 69.8, 67.6; FAB-MS: *m/z* = 711 ($[M + Na]^+$, 6.1%), 688 ($[M]^+$, 100), 460 (11); **11**: 0.01 g (2.1%), m.p. 172 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.35–7.26 (m, 8H), 6.89–6.80 (m, 8H) 4.10–4.03 (m, 8H), 3.93–3.85 (m, 8H), 3.78–3.68 (m, 20H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 157.9, 133.3, 127.5, 114.9, 71.0, 70.9, 70.8, 69.8, 67.6; FAB-MS: *m/z* = 732 ($[M]^+$, 48%), 257 (24), 239 (51), 185 (81), 169 (66), 152 (100), 136(95), 107 (61); **12**: m.p. 156 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.34 (m, 8H), 6.86 (m, 8H), 4.08 (t, *J* = 4.7 Hz, 8H), 3.87 (t, *J* = 4.7 Hz, 8H), 3.76–3.66 (m, 24H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 157.9, 133.4, 127.6, 114.9, 71.0, 70.8, 69.8, 67.6; FAB-MS: *m/z* = 777 ($[M + H]^+$).

13: At 0 °C, a solution of **5** (0.45 g, 0.9 mmol) and 1,12-dodecanediol (0.20 g, 1.0 mmol) in dry THF (250 mL) was added dropwise to a solution of diethyl azodicarboxylate (0.63 g, 3.6 mmol) and triphenylphosphane (0.94 g, 3.6 mmol) in dry THF (75 mL) over 5 h. The solution was allowed to warm up to room temperature, and stirring was continued for 48 h. Removal of the solvent in vacuo gave an oily residue to which $MeOH/H_2O$ (10:1) was added. The mixture was heated at reflux for 1 min before being allowed to cool to room temperature. The precipitated material was separated from the supernatant (containing mainly triphenylphosphane oxide) and purified by chromatography on SiO_2 (CH_2Cl_2:Et_2O, 4:1). Further purification by several recrystallizations from EtOAc finally gave pure **13** as a white crystalline solid (0.03 g, 5.1%). M.p. 166 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.42–7.38(m, 8H), 6.93–6.83 (m, 8H), 4.07 (t, *J* = 4.8 Hz, 4H), 3.97 (t, *J* = 7.5 Hz, 4H), 3.88 (t, *J* = 4.8 Hz, 4H), 3.77–3.66 (m, 8H), 1.86–1.72 (quint. *J* = 7.5 Hz, 4H), 1.54–1.25 (m, 16H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 158.2, 157.9, 133.5, 133.1, 127.6, 114.9, 114.8, 70.9, 69.8, 67.9, 67.6, 28.9, 28.7, 28.4, 28.3, 25.5; positive ion-FAB-MS: *m/z* = 696 ($[M]^+$, 100%), 613 (6), 460 (50), 440 (14).

16: Solutions of **15** (0.68 g, 1.0 mmol) and the disodium salt of **14** (0.25 g, 1.1 mmol) in dimethylacetamide (200 mL each) were added simultaneously to a solution of NaI (2.0 g, 13.3 mmol) in dimethylacetamide (80 mL) over 90 min at 60 °C. Stirring was continued for a further 100 h. The light green reaction mixture was allowed to cool to room temperature before being poured into ice/H_2O (1500 mL). The white precipitate was filtered off and partitioned between $CHCl_3$ and dilute HCl (100 mL). Insoluble material was removed by filtration. The organic layer was washed with H_2O, saturated aqueous $NaHCO_3$, H_2O, and saturated aqueous NaCl solution. After drying over Na_2SO_4, the solvent was removed by evaporation, and the residue was purified by chromatography on SiO_2 ($CHCl_3$). This product was recrystallized from EtOAc to give pure **16** as white shining needles. (0.02 g, 2.6%). M.p. 168 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.43 (m, 8H), 6.91 (m, 8H), 3.98 (t, *J* = 6.5 Hz, 8H), 1.78 (quint, *J* = 6.7 Hz, 8H), 1.52–1.22 (m, 32H); ^{13}C NMR (75.5 MHz,$CDCl_3$): δ = 158.2, 133.3, 127.6, 114.9, 67.9, 29.1, 28.9, 28.8, 28.7, 25.7; FAB-MS: *m/z* = 704 ($[M]^+$, 9%), 460 (100), 440 (30), 391 (22), 351 (12).

[14] A similar observation has been reported recently by Percec and Kawasumi for macrocycles incorporating conformationally flexible rodlike mesogens. They demonstrated that low molecular weight macrocycles based on 1-(4'-hydroxybiphenyl-4-yl)-2-(4-hydroxyphenyl)butane and flexible spacers "exhibit a higher ability to generate liquid crystalline phases than do their low-molar mass linear and both their linear and cyclic high-relative-molecular-mass homologues". However, the observed mesophase stabilization by cyclization is much less pronounced than in the examples reported here—probably as a result of the steric bulk of the branched mesogenic systems employed in these investigations. See V. Percec, M. Kawasumi, *Adv. Mater.* **1992**, *4*, 572; *J. Mater. Chem.* **1993**, *3*, 725; *J. Chem. Soc. Perkin Trans. 1* **1993**, 1319.

1,3-Dialkoxycalix[4]arenecrowns-6 in 1,3-Alternate Conformation: Cesium-Selective Ligands that Exploit Cation–Arene Interactions**

Rocco Ungaro,* Alessandro Casnati, Franco Ugozzoli, Andrea Pochini, Jean-François Dozol, Clement Hill, and Hélène Rouquette

Calixarene and particularly calix[4]arene derivatives have recently attracted considerable attention, since they can bind alkali and alkaline earth metal cations selectively with an efficiency comparable to that of cryptands.[1] Their complexation properties seem to be highly dependent not only on the nature of the donor groups but also on their stereochemical arrangement, which is determined by the conformation of the calix: cone, partial cone, 1,3-alternate, or 1,2-alternate (Fig. 1).[2] The 1,3-

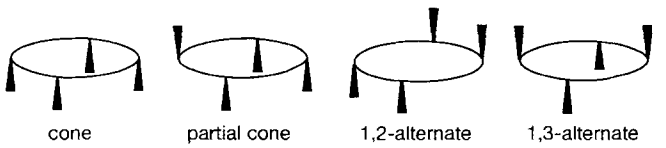

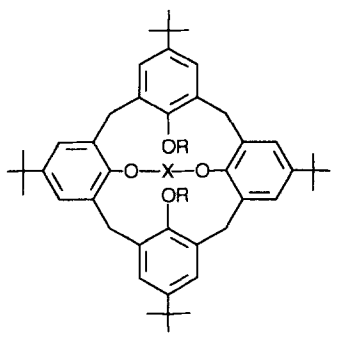

Fig. 1. Schematic representations of the four possible conformations of calix[4]-arenes. Filled triangles represent the arene rings; the ellipses represent the best plane containing the methylene bridges.

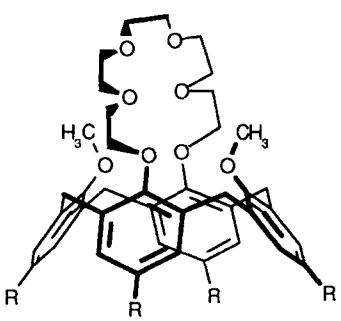
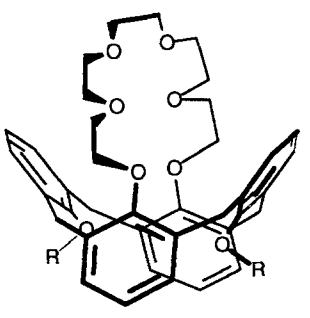
dialkoxy-*p*-*tert*-butylcalix[4]arenecrowns-5 **I**, for example, especially when fixed in the partial cone conformation, exhibit an exceptionally high selectivity for potassium ions over other alkali metal ions.[3, 4] This has led to their use in ion-sensitive field effect



I: X = $(CH_2CH_2O)_3CH_2CH_2$
R = alkyl



transistors (ISFETs)[5] and in supported liquid membranes[6] for the detection and separation, respectively, of alkali metal ions. The results are comparable to those obtained with the best potassium ionophore known so far, valinomycin.

Recently we have addressed the important problem of the removal of cesium and actinides from medium-level radioactive waste.[7, 8] The long-lived ^{137}Cs must be extracted from an aqueous solution which is 1 M in HNO_3 and 4 M in $NaNO_3$.[7] Here we report on calix[4]arenecrowns-6 which, when fixed in the 1,3-alternate conformation, are extremely selective in the extraction of cesium over sodium ions from an acidic aqueous phase containing metal nitrates. Studies of both solutions and solids point to the decisive role of cesium–arene interactions in determining the properties of such ligands.

We first synthesized the 1,3-dimethoxycalix[4]arenecrown-6 **1** (see Table 1), because we previously observed that 1,3-dimethoxy-*p*-*tert*-butylcalix[4]arenecrown-6 **2** had a slight binding preference for cesium ions in chloroform solution.[3]

A titration experiment of **1** with cesium picrate in CD_3CN revealed some interesting features. Free **1** exists in solution mainly (>50%) in the cone conformation, which can be recognized in ^1H NMR spectra (Fig. 2a) by the doublets at $\delta \approx 3.2$ and 4.4 for the protons in the methylene bridge ($ArCH_2Ar$). In the corresponding cesium complex (Fig. 2b) the AX system coalesces to a singlet at $\delta \approx 3.7$, which indicates the rearrangement of **1** into the 1,3-alternate conformation. This conformation, which can be indicated as C_1 + +, − −, + +, − − according to a recently proposed notation,[10] is clearly shown in the X-ray crystal structure of the cesium picrate complex (Fig. 3). It crystallizes in the triclinic system ($P\bar{1}$) and shows two independent complexes in the asymmetric unit.[11] In both, the cesium ion appears to be coordinated by eight oxygen atoms (six from the calixcrown, two from the picrate ion, which acts as bidentate ligand), and by two opposite arene rings. To maximize the cesium–arene interaction the ligand changes its conformation into 1,3-alternate. The Cs^+ ion interacts in η^3 fashion with C(3B), C(4B), and C(5B), and in η^2 fashion with C(3D) and C(4D) of the arene ring. The Cs–C contacts range from 3.431(10) to 3.684(8) Å in one independent unit of the complex and from 3.354(7) to 3.588(8) Å in the second. These values compare with

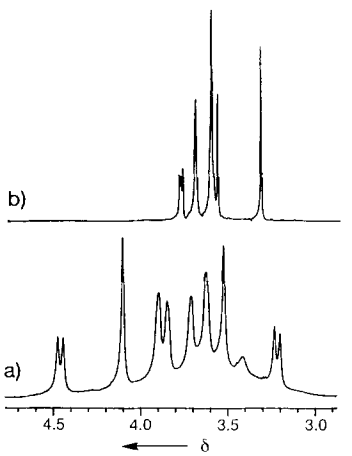

Fig. 2. ^1H NMR spectra (CD_3CN, 400 MHz) of a) free **1** and b) its cesium picrate complex.

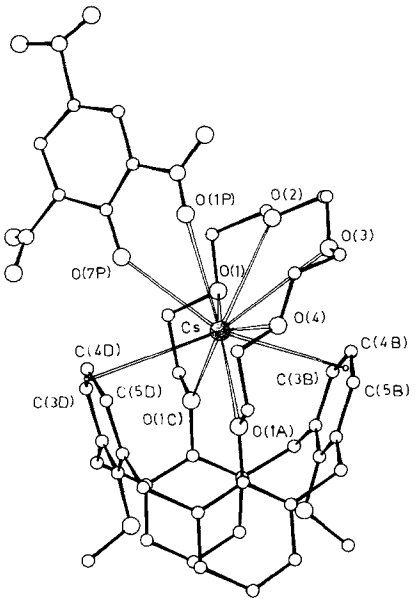

Fig. 3. X-ray crystal structure of the complex of **1** and cesium picrate. PLUTO plot of one of the two independent complexes. Selected distances [Å] in the two molecules: Cs-O (1A) 3.319(5) [3.468(5)], Cs-O(1C) 3.300(5) [3.269(9)], Cs-O(1) 3.212(5) [3.294(5)], Cs-O(2) 3.333(6) [3.398(6)], Cs-O(3) 3.670(10) [3.401(7)], Cs-O(4) 3.265(9) [3.196(7)], Cs-O(1P) 3.413(9) [3.360(10)], Cs-O(7P) 3.094(6) [3.147(6)], Cs-C(3B) 3.649(9) [3.588(8)], Cs-C(4B) 3.431(10) [3.354(7)], Cs-C(5B) 3.548(9) [3.566(7)], Cs-C(3D) 3.684(8) [3.549(7)], Cs-C(4D) 3.568(7) [3.422(7)], Cs-C(5D) 3.864(7) [3.807(8)].

those reported[12, 13] for systems for which cesium–arene interactions have been documented. The low-field shifts (0.1–0.7 ppm) in the ^{1}H NMR spectrum experienced by the arene protons of **1** upon complexation of cesium can be due to the presence of such interactions also in solution. However, the profound changes in the NMR spectra owing to the conformational rearrangement of the ligand complicate the analysis.

These observations, which clearly suggest that in this class of ionophores the preferred conformation to bind cesium is the 1,3-alternate, led us to synthesize preorganized ligands having this structure. It is known that substituents bulkier than ethyl block the interconversion between conformational isomers in tetraalkoxycalix[4]arenes.[14] Therefore, the reaction of the diametrically substituted 1,3-dialkoxycalix[4]arenes[4, 14b] with pentaethylene glycol di-*p*-toluenesulfonate in the presence of Cs_2CO_3 in CH_3CN[15] provided compounds **3**–**5** in good yields (>80%) in the fixed 1,3-alternate conformation (see Table 1). Probably in this case the cesium ion acts as template in determining the stereochemical outcome of the cyclization reaction. The binding abilities of compounds **1** and **3**–**5** have been tested by extraction of the ions from an aqueous solution 1 M in nitric acid and 5×10^{-4} M in ^{137}Cs or ^{22}Na nitrate into a 10^{-2} M solution of the ligand in hexyl 2-nitrophenyl ether. The amount of ^{137}Cs or ^{22}Na extracted into the organic phase was measured by γ spectrometry. These values were used to calculate the distribution coefficients $D_{(M^+)}$ as the ratio of the metal ion concentration in the organic phase versus the metal ion concentration in the aqueous phase.[16] Table 2 gives the technically important Cs^+/Na^+ selectivities as $\alpha = D_{(Cs^+)}/D_{(Na^+)}$.

As expected ligands **3**–**5** fixed in the 1,3-alternate conformation show much higher efficiency and selectivity than the conformationally flexible compound **1**. This is explained by the preorganization of the ligand[3] and by the fact that the less polar 1,3-alternate conformation[17] prefers cesium over sodium and

Table 2. Selectivities and extraction percentages of cesium and sodium nitrates. For details see text.

Compound	% Cs extracted	% Na extracted	α
1	3.78	0.27	14.4
3	96.6	<0.1	>28500
4	97.0	<0.1	>33000
5	95.0	0.18	10650

allows the interaction of the cesium ion with the π-electron cloud of the arene rings. The complexation properties of these ligands are the result of the simultaneous operation of several effects: the size of the crown ether ring, the polarity of the calix conformation, and the strength of the cation/π-electron interactions.[18] The easy removal of cesium cation from the complexes by stripping[16] and the consequent possibility of recycling the ligands, as well as their high lipophilicity, which allows their use in supported liquid membranes,[6] make these new cesium-selective ionophores highly attractive for treatment of radioactive waste.

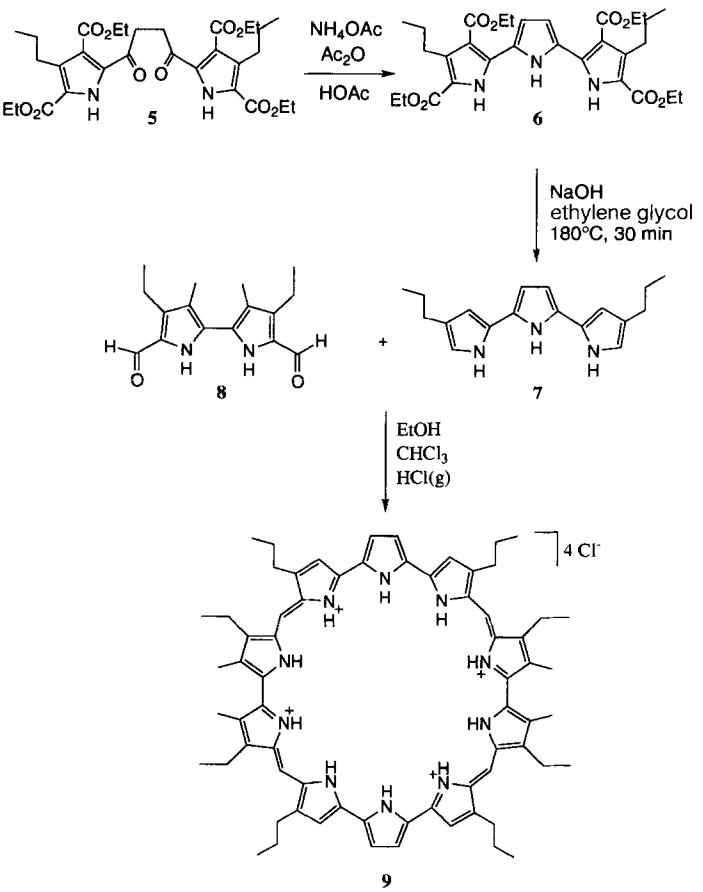
Turcasarin, the Largest Expanded Porphyrin to Date**



Jonathan L. Sessler,* Steven J. Weghorn, Vincent Lynch, and Martin R. Johnson

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

In recent years, the chemistry of large pyrrole-containing macrocycles has been receiving increasing attention.[1–6] Much of this interest reflects the fact that these compounds, known generically as "expanded porphyrins", bear analogies to the well-studied porphyrins, yet display chemical properties such as anion binding, which have no parallel in the chemistry of porphyrins or other naturally occurring tetrapyrrolic macrocycles. Further interest in expanded porphyrins is derived from the study of extended conjugated π-electron systems. Indeed, much recent attention has been devoted to making ever larger conjugated π-electron systems that absorb in the far-red region of the visible spectrum. For instance, the octavinylogous porphyrin **1** prepared by Franck et al. is a conjugated 34 π-electron system.[2] Also in the all-pyrrole category, expanded porphyrins with as many as six pyrrole subunits have been prepared.[3, 6b] One example is rubyrin **2**, which has a conjugated system with 26 π-electrons.[3] Other even larger expanded porphyrins that rely on additional non-pyrrole subunits to define the macrocycle core have also been prepared. For instance, torrand **3**[4] with eight nitrogen atoms and the Schiff base derived macrocycle **4**[5] each have extended π-conjugation pathways with visible absorptions considerably red-shifted relative to those of the porphyrins.

In spite of these successes, however, the need to prepare other new systems for the study of aromaticity and π-conjugation remains.[6] We therefore wish to report here the synthesis of a new class of expanded porphyrins, namely the ten pyrrole containing macrocycle **9**[7] ([40]decaphyrin-[0.0.1.0.1.0.0.1.0.1]-[8]). This system, which to the best of our knowledge is the highest order expanded porphyrin characterized to date, is prepared by the acid-catalyzed condensation of 4,4′-diethyl-5,5′-diformyl-3,3′-dimethyl-2,2′-bipyrrole (**8**)[9] with 2,5-bis(4-propyl-2-pyrrolyl)pyrrole (**7**) (Scheme 1). After purification, one obtains a 20% yield of a compound that formulates as **9** and, depending on its degree of protonation, displays an intense purple to blue to green color in organic solvents. Thus, in view of its color, we have assigned the trivial name turcasarin to this macrocycle (from Middle English "turcas").

Scheme 1. Synthesis of **9**.

Turcasarin **9** may be considered a 40 π-electron annulene. Thus, turcasarin should not be aromatic according to the (4*n* +

2) rule for aromatic systems. However, like its smaller aromatic congeners pentaphyrin[6a] and rubyrin, it displays a rather intense absorption in the visible portion of the electronic spectrum that is considerably red-shifted compared to that of the porphyrins. On the other hand, no evidence of ring current effects are seen for the pyrrolic proton resonances in the ^{1}H NMR spectrum. Thus, **9** can be considered a nonaromatic compound with a delocalized π system.

In addition to providing a test of aromaticity, NMR studies were also used to obtain solution-state structural information. The ^{13}C NMR spectrum indicates, for instance, that the frame of the macrocycle has apparent C_2 symmetry, as judged by the number of observable peaks. The ^{1}H NMR spectrum (Table 1)

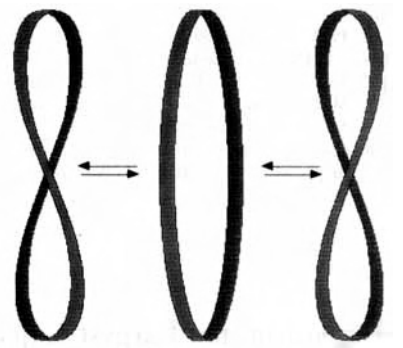

Fig. 1. Schematic representation showing the interconversion between the two limiting enantiomeric conformations of macrocycle **9**. These conformations may be considered as left- or right-handed twists along the long axis of a presumed open, pseudo-circular intermediate.

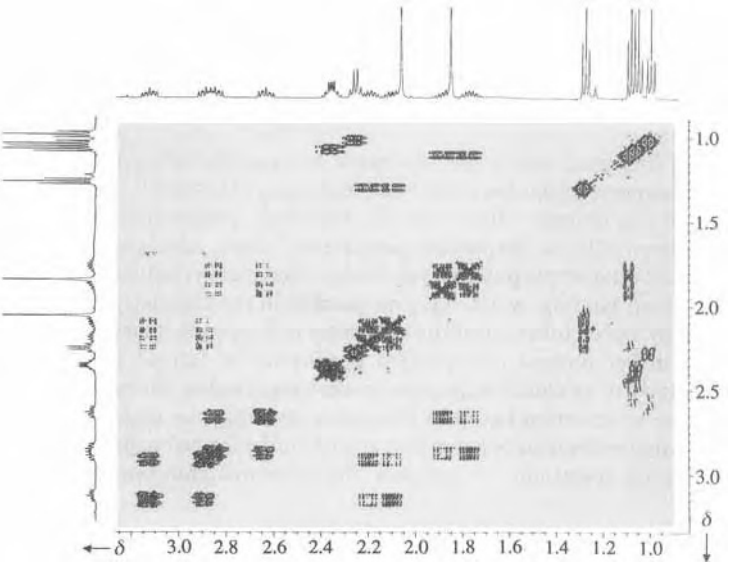

Fig. 2. Two-dimensional H,H-correlated spectrum (H,H COSY) of the alkyl region of macrocycle **9** that allowed definitive peak assignments to be made. Paired sets of crosspeaks indicate near C_2 symmetry in the molecule and provide evidence for diastereotopic protons in the propyl side chains.

is also consistent with C_2 symmetry as judged by the number of signals in the interior NH and exterior β-pyrrolic and *meso*-proton region. The signals in the alkyl region, on the other hand, prove more complex; no clear assignment of symmetry or structure is possible from immediate inspection. In fact, complex splitting patterns for the methylene protons of the alkyl side chains are observed.[10]

These complex splitting patterns led us to suggest that the macrocycle may exist in two limiting conformations. These two conformations result from a twist along a long axis of the molecule as shown in Figure 1. Molecule **9** could therefore exist as a pair of enantiomers. It would thus be disymmetric even though it possesses no formal stereogenic centers. Such a postulate of conformational chirality, even though unexpected for a fully conjugated macrocycle, would, of course, account for the observed complex splitting patterns, which arise as the result of an imposed diastereotopicity on the alkyl side chains.

Definitive assignments of the ^{1}H NMR signals were made based on COSY (Fig. 2) and NOESY experiments. The NOESY spectrum also shows significant exchange crosspeaks in all regions, indicating that the two enantiomers can readily interconvert, at least on the timescale of such experiments. However, variable-temperature ^{1}H NMR spectra ($CDCl_3$, -50 °C to $+50$ °C), by virtue of displaying very little change in the chemical shifts, indicate that this interconversion is slow on the NMR timescale at room temperature. This slow interconversion could reflect conformational stabilization imposed by the presumably strong hydrogen bonding interactions between the macrocycle and the chloride anions which are observed in the solid state (vide infra).

Solid-state structural information was obtained from a single-crystal X-ray structure of the tetrahydrochloride salt of **9** (Fig. 3).[11] In accord with what was found in the solution-phase NMR experiments, the tetraprotonated form of macrocycle **9** is found to adopt a nearly C_2-symmetric, twisted "figure-eight" conformation in the solid state, and not an open "circular" conformation. This twisted conformation serves to define two enantiomers (both of which are seen in the X-ray structure) such that the structure of **9** in the solid state more closely resembles the "twisted ribbons" in Figure 1, rather than the open, circle-like "loop".

As can be seen in Figure 3, the twist observed in the solid state also serves to define two pentaphyrin-like "hemi-macrocycles" as well as four smaller "pockets". Occupying each of these pockets is a chloride anion which is close enough to form a hydrogen

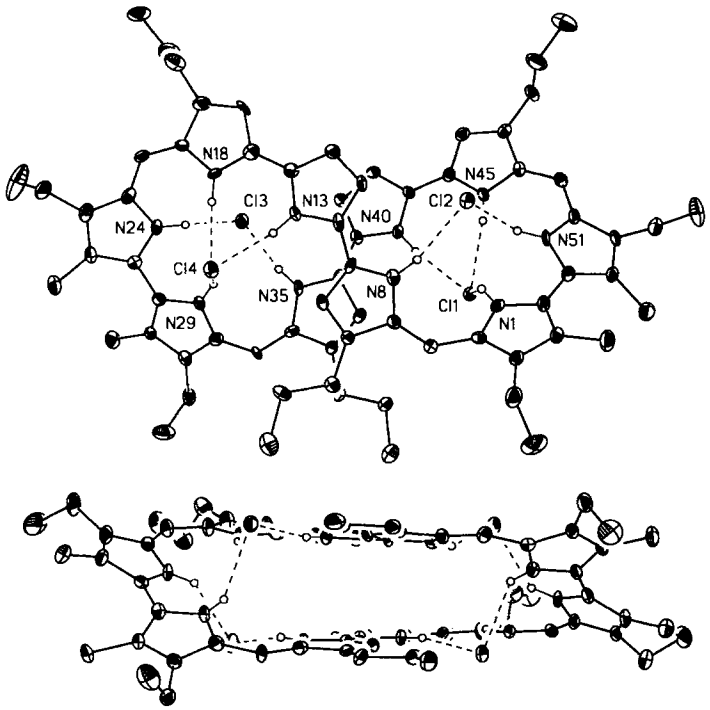

Fig. 3. Top and side views of the tetraprotonated form of **9** ($(C_{68}H_{74}N_{10})^{4+}$ $(Cl^-)_4$) with partial labeling showing the conformation of the macrocycle and the binding of the Cl^- ions. At the point of "ribbon crossing" the interplane separation is 3.268 Å. Further important distances [Å] and angles [°] N1-H1a···Cl1, N···Cl 3.133(11), H···Cl 2.442(11), N-H···Cl 133.9(10); N40-H40a···Cl1, N···Cl 3.054(10), H···Cl 2.178(10), N-H···Cl 164.3(11); N45-H45a···Cl1, N···Cl 3.194(10), H···Cl 2.370(10), N-H···Cl 152.4(11); N8-H8a···Cl2, N···Cl 3.190(10), H···Cl 2.353(10), N-H···Cl 154.8(11); N51-H51a···Cl2, N···Cl 3.116(11), H···Cl 2.334(11), N-H···Cl 145.2(11); N24-H24a···Cl3, N···Cl 3.133(11), H···Cl 2.349(11), N-H···Cl 145.5(11); N35-H35a···Cl3, N···Cl 3.161(11), H···Cl 2.280(11), N-H···Cl 166.0(11); N13-H13a···Cl4, N···Cl 3.069(10), H···Cl 2.183(10), N-H···Cl 167.8(11); N18-H18a···Cl4, N···Cl 3.194(11), H···Cl 2.375(11), N-H···Cl 151.4(11); N29-H29a···Cl4, N···Cl 3.132(10), H···Cl 2.459(10), N-H···Cl 131.9(10). Because the hydrogen atoms are at idealized positions, the resulting estimated standard deviations for quantities involving them are underestimated. Thermal ellipsoids were scaled to the 30% probability level. For clarity, only N–H hydrogen atoms are shown.

bond with the N–H group. These hydrogen bonding interactions are currently considered to account for the slow conformational interconversion observed at room temperature in solution on the NMR timescale. However, it is of interest to note that at the point of "ribbon crossing" the two pyrrole-containing π systems are separated from one another by a van der Waals distance of 3.268 Å.

The presence of four pockets binding chloride anions in the tetraprotonated form of **9** leads us to predict that this macrocycle, in analogy to several other expanded porphyrins,[1] could serve as an anion binding and transport agent in solution. Further, the observation that the twisting present in this decapyrrolic system serves to define two "hemipentaphyrins" leads us to suggest that system **9**, like pentaphyrin itself,[13] could chelate uranyl ions.[14] Of greatest interest, however, is perhaps the simple finding that conjugated, polypyrrolic macrocycles need not be flat or nearly flat but can adopt conformations that make them potentially chiral. To the best of our knowledge, such a conceptualization is new within the context of the expanded porphyrins.

Experimental Procedure

6: Dipyrrylbutanedione **5** (23.54 g, 40 mmol) [15], ammonium acetate (vacuum dried at 50 °C, 91.1 g, 1 mol), acetic anhydride (32 mL, 0.33 mol), and glacial acetic acid (150 mL) were held at reflux under argon for 18 h, poured into stirred ice water (400 mL), and stirred for 1 h. The solid was collected by filtration, washed with water, and dissolved in CH_2Cl_2. The CH_2Cl_2 solution was washed with water, diluted with methanol, and concentrated on the rotary evaporator until the volume was roughly 50 mL. The flask contents were cooled in ice for 1 h, and the solid was collected by filtration, washed (MeOH, Et_2O), and dried to give the pure product as light yellow needles or powder (17.85 g, 31.3 mmol, 78%).

7: Terpyrrole tetraester **6** (5.7 g, 10 mmol), NaOH (10 g, 400 mmol), and ethylene glycol (100 mL) were stirred under argon and heated at reflux. When the solution reached a temperature of 180 °C, it was heated for another 30 min and cooled. When the solution reached 100–120 °C, the flask contents were diluted with water (70 mL, degassed by the freeze-pump-thaw method) and allowed to cool to room temperature. The mixture was diluted to 400 mL with ice water. The solid obtained was separated by filtration under argon (an aluminum foil cover and a pipette as the gas inlet is fine), washed with water, and dried in vacuo to give the pure product as a tan to light green powder (2.62 g, 9.3 mmol, 93%).

9: Bipyrrole **8** (72.5 mg, 2.67×10^{-4} mol) was dissolved in 20 mL absolute ethanol with the aid of a heat gun. $CHCl_3$ was added (500 mL), followed by terpyrrole **7** (74.9 mg, 2.67×10^{-4} mol). HCl gas was bubbled into the stirred reaction mixture for 5 min. The reaction was then stirred under argon for 4 h. The $CHCl_3$ was removed with a rotary evaporator. The ethanolic residue was treated with concentrated aqueous $NaHCO_3$ until effervescence ceased and then extracted into $CHCl_3$. The organic layer was separated, dried over Na_2SO_4, and concentrated to dryness in vacuo. The residue was taken up in a minimum amount of CH_2Cl_2, and NH_3 gas was bubbled into the solution for 1 min. The resulting solution was purified by chromatography on a pretreated column (2 cm × 20 cm) of silica gel (before the column was packed, NH_3 was bubbled through a slurry of CH_2Cl_2 and silica gel). The first major purple band (CH_2Cl_2 eluent) was collected, and washed with water (2 × 25 mL) and 1 N HCl (3 × 25 mL). The organic layer was then separated, dried over Na_2SO_4, and concentrated to dryness in vacuo. Recrystallization from CH_2Cl_2 layered with hexanes gave pure **9** as shiny green metallic crystals (62.9 mg, 5.34×10^{-5} mol, 20%).

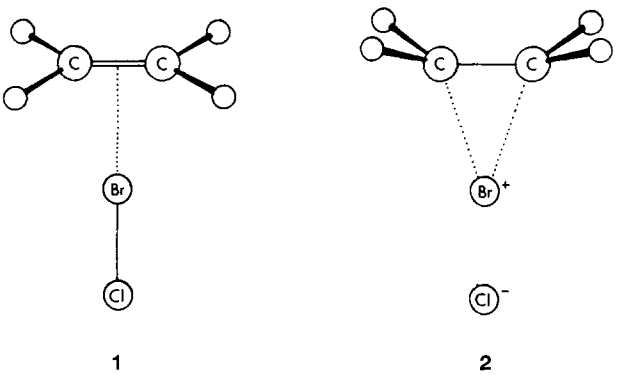
Nonreactive Interactions between Ethene and Halogens: Detection of a π-Donor Complex $C_2H_4 \cdots BrCl$ by Rotational Spectroscopy**

Hannelore I. Bloemink, Kelvin Hinds, Anthony C. Legon,* and Joanna C. Thorn



We report the first characterization of a molecular π-donor complex formed by ethene with a halogen or interhalogen in the gas phase. The microwave spectrum of $C_2H_4 \cdots BrCl$ was observed by employing a fast-mixing nozzle to keep the chemically reactive components separate until the point at which they expanded simultaneously into the evacuated Fabry–Pérot cavity of a Fourier transform (FT) microwave spectrometer. Complexes formed where the gases met had very low internal energies and underwent collisionless expansion before further progress along the reaction coordinate could occur. Properties of frozen species were then determined from an analysis of the rotational spectrum.

The addition reaction of, for example, molecular bromine to an alkene under "dark" conditions, that is, in the absence of radical initiation, and in a polar environment has been thoroughly investigated.[1] It is assumed to proceed through an intermediate formed when electrophilic Br_2 first encounters the nucleophilic alkene.[2] If the electrophile is BrCl, the addition reaction is about 400 times faster,[1, 2] in accordance with the idea that the polar interhalogen $^{\delta+}BrCl^{\delta-}$ is a better electrophilic halogenating agent than Br_2.

Two types of reactive intermediate can be envisaged for a halogen and a π donor such as ethene. Following the proposal of Mulliken,[3] we refer to an "outer" (weak) complex of the type **1**, and an "inner" complex **2** in which there is significant charge transfer. Under dark, polar conditions, one mechanism proposed[4, 5] for the addition of a halogen to an alkene proceeds from the initial pre-equilibrium complex of type **1** to the halogenium ion of type **2**, which subsequently suffers nucleophilic attack by, for example, Cl^-. Other, similar mechanisms are discussed in reference [1]. Although reactive intermediates of types **1** and **2** have been much invoked, they are difficult to characterize experimentally, particularly for the prototype alkene C_2H_4 because of rapid subsequent reaction. It is therefore of interest to isolate any molecular complex formed by ethene with, for example, BrCl and to determine its properties. What is the geometry of the complex? What is the extent of electric charge redistribution when it is formed? Is **1** or **2** the more appropriate description in the gas phase?

1 **2**

While rotational (microwave) spectroscopy has proved a powerful method for observing molecular complexes isolated in the gas phase,[6] it is usually conducted with premixed components in contact with surfaces, particularly those of metals. Since even so-called gaseous additions of chlorine and bromine to ethene are reactions on polar surfaces,[1] premature reaction of the premixed gases occurs. The problem of reaction has been overcome here by carrying out rotational spectroscopy on a jet of the gas mixture supersonically expanded from a fast-mixing nozzle[7] into the spacious Fabry–Pérot cavity of a FT microwave spectrometer. The essential feature of the fast-mixing nozzle is that the reactive components mix only as they expand simultaneously from a pair of coaxial and coterminal tubes into the evacuated cavity. Complexes of C_2H_4 and BrCl are formed only at the interface of the concentric gas flows, in the absence of surfaces. Moreover, they are in collisionless expansion within a few nozzle diameters (after about 10 μs in our experiment) and are then frozen at a very low effective temperature until they encounter a wall of the vacuum chamber.

The ground-state rotational spectrum of (C_2H_4, BrCl) observed in this way was that of a nearly prolate asymmetric-top

molecule with a nonzero a component of the electric dipole moment.[8] Each transition carried a nuclear quadrupole hyperfine structure characteristic of the presence of two nuclei of spin $I = {}^3/_2$. A detailed analysis of the $J = 5 \leftarrow 4$ and $4 \leftarrow 3$ transitions with the Watson A reduction[9] led to the ground-state rotational constants A_0, B_0, and C_0, the centrifugal distortion constants Δ_J and Δ_{JK}, the halogen nuclear quadrupole coupling constants $\chi_{aa}(X)$ and $\chi_{bb}(X) - \chi_{cc}(X)$, and the bromine spin-rotation constant $M_{bb}(Br)$, listed in Table 1 for the isotopomers (C_2H_4, $^{79}Br^{35}Cl$) and (C_2H_4, $^{81}Br^{35}Cl$). By using BrCl as the halogen we ensured that any species of type **1** had a significant electric dipole moment and hence a spectrum of reasonable intensity. The spectroscopic constants of Table 1 allow several conclusions about the nature of the observed complex to be drawn.

Table 1. Ground-state spectroscopic constants of two isotopomers of (C_2H_4, BrCl) [a].

Spectroscopic constant	(C_2H_4, $^{79}Br^{35}Cl$)	(C_2H_4, $^{81}Br^{35}Cl$)
A_0 [MHz]	25114(95)	25016(99)
B_0 [MHz]	1228.2834(2)	1228.3003(2)
C_0 [MHz]	1188.2822(2)	1188.2984(2)
Δ_J [kHz]	0.682(5)	0.679(5)
Δ_{JK} [kHz]	21.4(3)	21.5(3)
χ_{aa}(Br) [MHz]	882.54(3)	737.34(3)
χ_{aa}(Cl) [MHz]	− 94.71(2)	− 94.72(2)
$\{\chi_{bb}(Br) - \chi_{cc}(Br)\}$ [MHz]	12.88(5)	10.75(5)
$\{\chi_{bb}(Cl) - \chi_{cc}(Cl)\}$ [MHz]	− 0.21(4)	− 0.25(4)
M_{bb}(Br) [kHz]	− 3.4(3)	− 4.0(3)
P_b [uÅ^2] [b]	16.98(4)	17.03(4)
P_c [uÅ^2]	3.13(4)	3.17(4)
σ_f [kHz] [c]	2.3	2.3

[a] Numbers in parentheses are standard errors in units of the least significant digit. [b] $P_\alpha = \frac{1}{2}(I_\beta + I_\gamma - I_\alpha)$; α, β, γ to be permuted over a, b, c. [c] Standard deviation of the fit.

First, the value of A_0 for both isotopomers is only slightly larger than the rotational constant $C_0 = 24824.17(5)$ MHz of free ethene.[10] This provides strong evidence that the BrCl subunit lies along the c axis of ethene, that is, along the C_2 axis perpendicular to the ethene plane, as in **1**. The small increase almost certainly arises from zero-point effects.[11] The difference $B_0 - C_0$ is also consistent with the arrangement in **1** and the $^{79}Br/^{81}Br$ isotopic invariance of the rotational constants establishes that the Br atom lies close to the complex's center of mass. The planar moments P_b and P_c (see Table 1) are almost unchanged from $P_a = 16.8665(1)$ uÅ^2 and $P_b = 3.49188(2)$ uÅ^2, respectively, of free ethene.[10] Not only does this confirm that the angular geometry is that of type **1**; it also shows that the dimensions of ethene are at most weakly perturbed by complex formation.

Second, the assumption of weak interaction is reinforced when the nuclear quadrupole coupling constants are considered. For both isotopomers, χ_{aa}(Br) and χ_{aa}(Cl) are little changed from the corresponding values $\chi_0(X)$ for free BrCl.[12] This suggests only small changes in the electric field gradient along the BrCl axis when the diatomic molecule takes up its equilibrium position along the ethene c axis. Moreover, the difference $\chi_{bb}(X) - \chi_{cc}(X)$ is a small fraction of $\chi_0(X)$[12] for both X = Br and Cl, so demonstrating that the axial symmetry of the BrCl electric charge distribution is only slightly perturbed. Likewise, the value $k_\sigma = 10.5(1)$ Nm^{-1} for the intermolecular stretching force constant, as determined[13] from Δ_J, also suggests a weak interaction. It is similar in magnitude to those of many hydrogen-bonded complexes[14] and in particular that of the isostructural analogue (C_2H_4, HCl).[15] Significant charge transfer to give a complex of the inner type **2** would be expected to lead to a stronger interaction through the incipient chemical bonds. The parallelism of the properties of (C_2H_4, HCl) and (C_2H_4, BrCl) makes it likely that electrostatic interpretations[16, 17] of the properties of the former (especially the angular geometry) also apply to the latter.

Finally, the rotational constants B_0 and C_0 of (C_2H_4, BrCl) lead, under the assumption of unchanged component geometries,[18, 19] to 2.979(1) Å for the distance of the midpoint of the C=C bond to the Br atom in **1**.

Experimental Procedure

Rotational spectra of (C_2H_4, BrCl) were observed with a pulsed-nozzle FT microwave spectrometer [20] fitted with a fast-mixing nozzle [7]. A mixture of approximately 2% ethene (Argo International) in argon was pulsed through the outer of the two concentric tubes of the nozzle at a rate of 2 Hz from a pressure of 3 atm and mixed with a continuous flow of an equimolar mixture of chlorine and bromine (Aldrich) issuing from the exit of the inner tube. The halogen mixture flow rate was adjusted to give a steady pressure of 1×10^{-4} Torr in the vacuum chamber of the spectrometer. Spectra were observed in the range of frequencies 8–13 GHz. For each isotopomer approximately 75 hyperfine components associated with six rotational transitions were measured with an estimated accuracy of 2 kHz.

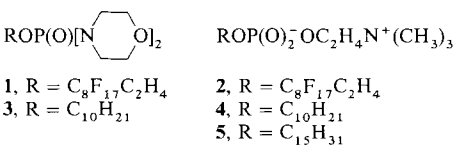
Stable Flexible Fibers and Rigid Tubules Made from Single-Chain Perfluoroalkylated Amphiphiles**

Françoise Giulieri, Marie-Pierre Krafft, and Jean G. Riess*



Supramolecular assemblies of amphiphiles have raised considerable interest at the crossroads of chemistry, physics, and biology. Vesicles, for example, are being intensively investigated as models of membranes and as drug carriers.[1] More recently, much attention has been given to a variety of microstructures with cylindrical geometry such as rods, tubules, and ribbons.[2, 3] Some of these structures have potential as building blocks in biomolecular engineering (delivery vehicles, microsurgery materials, etc.) or as novel elements of molecular devices for information processing and signal generation in material sciences (composites, liquid crystal media for electrooptics and microelectronics).[4] As the latter structures are more organized than vesicles, their study can also provide further insight into the molecular basis of the evolution of life with the use of self-organizational principles.[3]

One of the key driving forces for the formation of elongated structures appears to be the hydrophobic interactions between the amphiphiles' hydrophobic chains. Previously, these interactions were, however, not considered to be sufficient. They had to be supplemented by other intermolecular interactions such as hydrogen bonding, polymerization or metal coating, the introduction of rigid rodlike segments in the structure, and usually by the use of chiral molecules in order to achieve such cylindrical microstructures.[2, 3, 5] A stabilizing agent such as sodium dodecylsulfate is often required to avoid crystallization. Helical fibers have been obtained from dispersions of chiral amphiphiles derived from alkylaldonamides,[6, 7] amino acids,[8] and conjugated phospholipid nucleosides.[9] Cochleate lipid cylinders (formed by fusion of unilamellar vesicles into bilayer sheets which then fold spirally) have been reported to form with the addition of Ca^{2+} ions to phospholipids.[10] Ultrathin hollow capillaries made from polymerizable diacetylenic phosphatidycholines and stabilized by polymerization, which can be metalated, were also reported.[3, 11]

We have recently reported the formation of highly stable, heat-sterilizable vesicles from single-chain fluorinated amphiphiles without any additives.[12] Extended aggregates were then observed to form upon sonication of dispersions of these vesicles. The use of highly fluorinated compounds in medicine and biology has been reviewed lately.[13]

We report here that stable cylindrical aggregates including both flexible long fibers and rigid hollow tubules can be formed spontaneously at room temperature from unsonicated dilute dispersions of nonchiral fluorinated single-chain amphiphiles without requiring hydrogen bonding, polymerization, or any stabilizing additives. This shows that the strong hydrophobic forces developed by the fluorinated chains alone can suffice for the formation of microstructures more organized than vesicles. These supramolecular assemblies can have different morphologies and different rates of growth depending on the surfactant's polar head. We also found that the use of mixtures of two fluorinated surfactants can accelerate the growth of the flexible fibers.

Two perfluoroalkylated single-chain surfactants were used: a neutral one, dimorpholinophosphoramidate **1**,[14] and a zwitterionic one, phosphocholine **2**.[15] The hydrogenated analogues decyldimorpholinophosphoramidate **3**, decylphosphocholine **4**, and pentadecylphosphocholine **5** were prepared for comparative studies.

These fluorinated surfactants have no chiral center to stabilize their assemblies; there is no rigid segment to promote molecular alignment, nor is there any possibility of specific intermolecular binding. The behavior of **1** and **2** compared to that of their hydrogenated analogues **3** and **4**, and to that of the hydrogenated the surfactant **5**, whose hydrophobicity is equivalent to that of **2**,[16] clearly shows the impact of the fluorinated chain on the aggregation and organization of these amphiphiles.

Fibers were observed to form readily from unsonicated dispersions of both **1** and **2**, in other words with little or no energy input. The required 6% w/v dispersions are prepared simply by formation of thin films of the amphiphiles and hydration at 50 °C with gentle swirling by hand.

Rigid tubule-like aggregates (Fig. 1a, b) were observed by phase contrast optical microscopy within hours after preparation of dispersions of **1**. The aggregates then have a length of typically 10 to 50 μm and a diameter of 0.1 to 0.5 μm. A tubule structure consisting of wrapped bilayer sheets[2] is supported by the reversible transformation of these structures into large vesicles, which can be observed by optical microscopy at 40 °C.[11b]

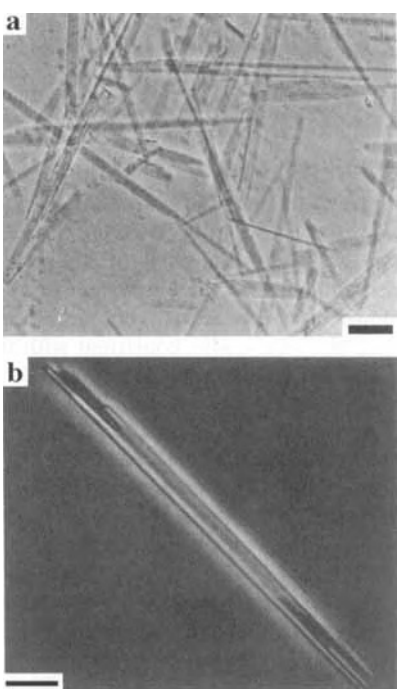


Fig. 1. Phase contrast optical micrographs of a) tubules obtained from **1**, b) an isolated tubule of 1. The length of the bars corresponds to 8 μm (a) and 4 μm (b).

Above 40 °C, optical polarization microscopy shows the presence of characteristic defects of a lamellar phase (maltese crosses) which are not present in the more organized tubular structures. These tubules are hollow, as can be seen in Figure 1 b, and break easily when manipulated. The fluorinated tubules are stable at room temperature with no significant modification of their size nor growth of three-dimensional crystals for at least six months at 20 °C.[17]

Fibers formed from **2** were found to be macroscopically completely different from those formed from **1**. Whereas **1** formed rigid linear hollow tubules, curved flexible filaments slowly appeared in unsonicated dispersions of **2**. After one month these fibers (ca. 10 μm in length and 0.1 μm in diameter) could be observed by transmission electron microscopy (Fig. 2a). After four months at a storage temperature not exceeding 20 °C, they had grown enough that they were visible by phase contrast and Nomarsky optical microscopy. These fibers are then very long (50–500 μm) and thin (1–5 μm in diameter) and can be branched. With time they start forming networks. When manipulated, these fibers are flexible and do not break. Their curved and branched structure, their flexibility, and the fact that they tend to form networks indicate that their microstructure is probably different from that of the tubules formed from **1**. They are not crystalline, as evidenced by polarization optical microscopy and the absence of electronic diffraction when observed by negative staining electron microscopy.

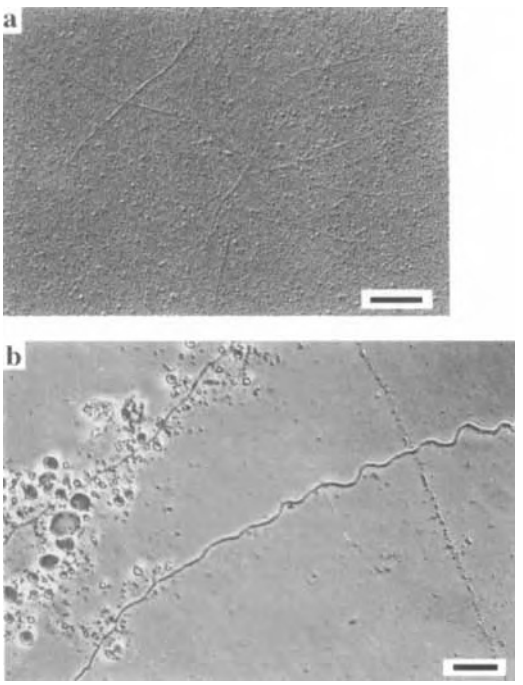

Fig. 2. a) Au/C shadowed transmission electron micrograph of the flexible fibers of **2**; b) phase contrast electron micrograph showing the reversible transformation at 50 °C of the flexible fibers of **2** into large vesicles. The length of the bars is 0.5 μm (a) and 8 μm (b).

The fluorinated fibers formed from **2** are reversibly transformed into larger vesicles at temperatures above 50 °C (Fig. 2b). These fibers are likely to be an intermediate state in the evolution of the supramolecular assemblies towards a tubular organization. A few similar flexible and branched fibers were transiently observed in dispersions of **1**; they are, however, transformed into tubules within hours, an observation that is in line with the above hypothesis. No crystallization was observed under these conditions, by contrast with the typical behavior of hydrocarbon amphiphiles.[5]

The rate of formation of the long flexible and branched fibers can be increased significantly by using equimolar mixtures of the fluorinated amphiphiles **1** and **2**. The resulting fibers have the same appearance as those prepared from dispersions of **2**, but they grow much more rapidly. Thus, fibers 50-μm long visible by optical microscopy were obtained after only two weeks. No tubules were observed in the optical micrographs.

In contrast, the hydrogenated analogues **3** and **4** (up to 20% w/v dispersions) did not form supramolecular assemblies of any sort, either spherical or elongated, according to electron or optical microscopy. Fibers were also not found in dispersions of **5**, the amphiphile whose CMC is comparable to that of **2**. This indicates the decisive strong effect of the fluorinated chain on the structuring of the amphiphiles into supramolecular assemblies.

The driving force of the formation of fibers and tubules from fluorinated amphiphiles reported here contrasts with that of bolaamphiphiles (the arborols), which also form fibers and in which the interactions between a multitude of amide groups bind the polar heads together so tightly that the hydrophobic effect is negligible.[18] The arborol-based fibers are formed by favored head-group interactions, while contact between the hydrophobic oligomethylene chains becomes almost impossible. The opposite situation is found with the amphiphiles investigated here, their interactions occur primarily between the fluorinated chains.

In addition to their strong hydrophobic character, the all-*trans* conformation of the fluorinated chains[19] may also play a role in favoring the formation of fibers, as is supposed to be the case for polymerizable phospholipids.[3]

Metal Complexes of Marine Peptide Metabolites: A Novel Ag_4 Cluster**

Peter Wipf,* Srikanth Venkatraman, Chris P. Miller, and Steven J. Geib

The structural variety of oxazole- and thiazole-containing alkaloids that have recently been isolated from marine as well as terrestrial microorganisms is astounding.[1] The spectrum of pharmacological properties of these natural products includes exceedingly high cytotoxic and antiviral activities. In many cases, metal ion chelation has been postulated to be at least partly responsible for the biological activity.[2] However, there is a dearth of experimental evidence for metal binding that would support these hypotheses.[2]

We have recently completed the total synthesis of the highly modified cyclopeptide westiellamide (**1**).[3] Watters et al. isolated this marine cytotoxin from the ascidian *Lissoclinum bistratum*,[4] which has been the source of a wide variety of biologically active compounds.[5] We now report the structure of a novel $[Ag_4(\mathbf{1})_2]$ complex that is formed by addition of silver salts to a solution of the natural product.

The X-ray structure of **1** (Fig. 1) reveals that all N–H bonds and the lone pairs of the other nitrogen atoms are directed

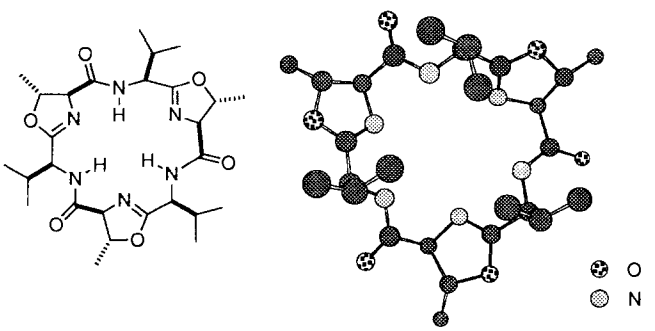

Fig. 1. Structural formula and the crystal structure of westiellamide (**1**).

towards the interior of the 18-membered macrocycle.[4a] This topology is quite common for a range of *Lissoclinum* peptides and appears suitable for metal ion chelation.[2, 6] However, there is only one report on the solid-state structure of a carbonate-bridged binuclear copper(II) complex of the related 24-membered ascidiacyclamide.[7] The conspicuous lack of data on metal chelation properties of cyclopeptides from ascidians can be explained, at least in part, by the problem of isolating sufficient quantities of material from natural sources. Our approach to the synthesis of dihydrooxazole-containing peptides by means of cyclooligomerization provides a convenient source of synthetic **1** and related macrocyclic ring systems.[3, 8] Whereas only weak interactions between **1** and gold(III), cadmium(II), cerium(III), copper(I), copper(II), iron(II), iron(III), mercury(II), potassium(I), lithium(I), magnesium(II), sodium(I), nickel(II), and zinc(II) salts were detected in screening studies, we observed a remarkable affinity of **1** toward silver(I) ions. NMR titration experiments in [D_4]methanol indicated the formation of a C_3-symmetric silver–**1** complex with a 2:1 stoichiometry and an association constant of $>10^5$. An X-ray analysis of a crystal obtained from an aqueous solution of **1** and $AgClO_4$, $[Ag_4(\mathbf{1})_2](ClO_4)_4$ (**2**), revealed the presence of a unique Ag_4 cluster sandwiched between two neutral macrocyclic ligands (Fig. 2a).[9]

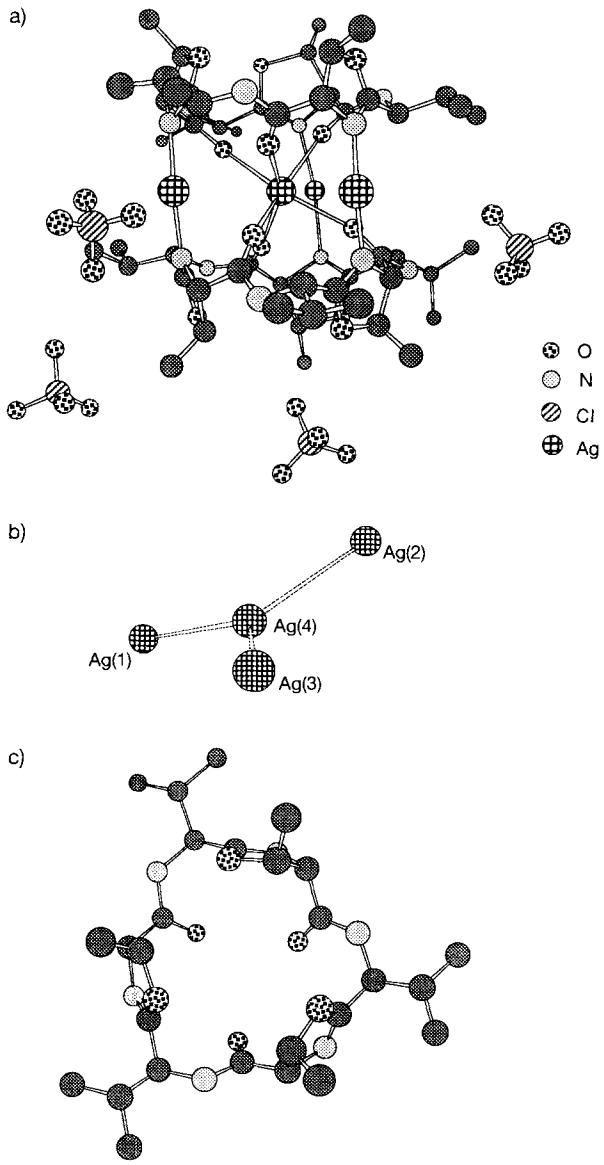

Fig. 2. Crystal structure of **2**. a) Complete salt (without hydrogen atoms). b) Ag_4 cluster. Selected distances [Å] and angles [°]: Ag(1)-Ag(4) 3.44, Ag(2)-Ag(4) 4.00, Ag(3)-Ag(4) 3.25, Ag(1)-Ag(2) 6.47, Ag(1)-Ag(3) 5.78; Ag(1)-Ag(4)-Ag(3) 118.9, Ag(1)-Ag(4)-Ag(2) 120.7, Ag(1)-Ag(2)-Ag(3)-Ag(4) 0.0. c) Cyclopeptide ligand.

Several features of this complex are noteworthy. The silver atoms of the tetranuclear cluster assume a novel distorted trigonal-planar arrangement (Fig. 2b). In contrast, numerous Ag_4 clusters[10] with tetrahedral[10] or distorted square-planar geometries have been found in silver thiolate and halide complexes.[11] The Ag(4)–Ag distances in **2** range from 3.25 to 4.00 Å. This is long compared to the distance in elemental silver (2.89 Å) and, with the exception of the Ag(4)–Ag(2) distance, similar to those in other Ag_3 and Ag_4 clusters, for example in cobalt–and

rhodium–silver complexes (2.83, 3.00 Å),[12, 13] silver–phosphane complexes (3.22, 3.36 Å),[14, 15] organotelluride–silver ions (3.13 Å),[10d] and piperazine–silver iodide (3.29 Å).[16] Since any bonding interactions between silver atoms in these metallic clusters are considered weak at best,[17] we conclude that the $[Ag_4]^{4+}$ unit in **2** is probably exclusively stabilized by coordination to the neutral macrocyclic ligands. The four perchlorate anions are noncoordinating; the shortest silver–oxygen contact is 2.95 Å.

Interestingly, the central silver ion, Ag(4), is coordinated to six carbonyl oxygen atoms that form a slightly distorted trigonal prism with an average twist angle of 22°.[18] The Ag(4)–O distances range from 2.41 to 2.55 Å, with an average length of 2.47 Å. In comparison, the Ag–O distance in a peptide–silver complex was found to be 2.57 Å.[19] In **2**, Ag(1), Ag(2), and Ag(3) are linearly coordinated to the nitrogen atoms of two dihydrooxazoles with bond lengths of 2.10 to 2.15 Å and N-Ag-N angles of 163.6 to 168.2°. The Ag–N distances are indicative of strong binding and are among the closest Ag–N contacts yet observed.[20] This unique inclusion is able to overcome the substantial electrostatic repulsion of the four Ag^+ ions.

The structure of the 18-membered macrocycle undergoes drastic changes upon binding silver ions. Both in solution and in the solid state,[21] uncomplexed **1** assumes the rather flat conformation shown in Figure 1 with planar dihydrooxazoles and axially oriented side chains and with all nitrogen atoms pointing inwards. As a consequence of metal chelation, the 18-membered macrocycles basically turn inside out and the side chains assume equatorial positions (Fig. 2c). The carbonyl groups point inwards and the dihydrooxazole rings are close to orthogonal to the macrocyclic ring. N_{oxaz}-C-C-N_{amide} and ϕ_{Val} dihedral angles, for example, change from a mean of 20.4° and −144.0°, respectively, in **1**, to a mean of 133.8° and −64.0°, respectively, in **2**.

The association constant of **2** in [D_4]methanol was too high to be determined by NMR spectroscopy. In [D_4]methanol/D_2O (9:1), an average K_a of $2.8 \times 10^{13}\ M^{-5}$ was determined by titration of **1** with silver perchlorate or silver triflate and integration of the ^1H NMR signals for **2**. Interestingly, the complexation seems to be highly cooperative; only uncomplexed ligand and the 4:2 complex are evident in the spectrum.[22] The rate of decomplexation appears to be slow in the (300 MHz) NMR timescale; no line broadening due to dynamic effects is observed.

Determination of the temperature dependence of the association constant in [D_4]methanol/D_2O (8:2) between 304 and 325 K allowed the calculation of the free enthalpy (ΔH^0) and entropy (ΔS^0) of formation of the complex as $-123\ kJ\,mol^{-1}$ and $-191\ J\,K^{-1}\,mol^{-1}$, respectively. The large negative entropy value leads to a considerable decrease of the association constant when the temperature of the solution is increased. All solution NMR data are in agreement with the solid-state structure of **2**.

We propose the following mechanistic scheme to explain both the observed high cooperativity and Ag^I selectivity. An initial weak association of a silver ion to the carbonyl groups of two molecules of **1** induces a ring inversion of the macrocycles and establishes an octahedral coordination sphere around Ag^+. The major energy barrier in the complexation is the formation of this labile complex, and subsequent rapid stabilization is achieved by the energetically very favorable linear complexation of silver ions to the nitrogen atoms of the dihydrooxazole rings. In order for a metal ion to be complexed in this way, it has to be stable in both octahedral and linear coordination geometries and its charge may not exceed +1, since otherwise the electrostatic repulsion within the complex becomes too large. Only silver(I) fulfills all these requirements.

Our studies have established first direct evidence for the interaction of marine *Lissoclinum* peptides with metal ions. The molecular structure of the westiellamide–silver complex **2** is unique; no analogous complexes are known in silver cluster or natural products chemistry. We will now investigate the biological role of metal chelation in the cytotoxic activity of **1** and its analogues.

[9] X-ray crystallographic data for **2**: orthorhombic, $P2_12_12_1$, $a = 13.739(3)$, $b = 20.864(5)$, $c = 28.778(6)$ Å, $V = 8249(3)$ Å^3, $Z = 4$, $\varrho_{calcd} = 1.581\ g\,cm^{-3}$, 23 °C. A Siemens P3 diffractometer was used to collect 11426 reflections ($4° \le 2\theta \le 45°$), 7691 of which with $F_o > 6\sigma(F_o)$ were used in the solution and refinement. A semiempirical absorption correction (XEMP) was applied to all data ($\mu(Mo_{K\alpha}) = 1.139\ mm^{-1}$). Structure was solved by direct methods which located the four Ag ions; remaining non-hydrogen atoms were located from subsequent difference Fourier syntheses and refined anisotropically. Hydrogen atom positions were calculated (d(C H) = 0.96 Å). Structure refined to $R_F = 0.0642$ and $R_{wF} = 0.0790$; GOF = 1.71; greatest residual electron density $1.13\ e\,Å^{-3}$ (near Ag(2)). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation. Complex **2** is slightly photosensitive.

[21] The ^{1}H NMR coupling constants ($^3J_{HH}$) of a solution of **1** in $CDCl_3$ are in agreement with the conformation found in the solid state. Additionally, the C_3 symmetry is conserved, and no conformers are frozen out at $-25\,^\circ C$.

[22] **2**: ^{1}H NMR (300 MHz, CD_3OD/D_2O, 9/1): $\delta = 4.72$ (br. s, 2H), 4.28 (d, 1H, $J = 9.0$ Hz), 2.20–2.09 (m, 1H), 1.52 (d, 3H, $J = 5.0$ Hz), 1.09 (d, 3H, $J = 6.5$ Hz), 1.02 (d, 3H, $J = 6.7$ Hz).

Synthesis and Structure of the First Titanium(IV) α-Amino Acid Complexes**

Thomas M. Klapötke, Hartmut Köpf, Inis C. Tornieporth-Oetting,* and Peter S. White*

Metallocene dichlorides $[Cp_2MCl_2]$ (M = Ti, V, Nb, Mo) and *cis*-diamminedichloroplatinum(II) complexes have been of great interest owing to their antitumor properties.[1] Although numerous experiments indicate that metallocene dichlorides inhibit DNA synthesis, it has not been possible to synthesize titanium model complexes containing biologically important ligands under physiological conditions.[2] Only in nonaqueous solvents like THF or toluene has the synthesis of a few titanium(IV) model complexes and some titanium(III) complexes starting from $[Cp_2TiCl_2]$ succeeded, but the latter complexes are less important, because the reduction of titanium(IV) to titanium(III) in biological systems is not very likely.[1–5] Nevertheless, quite recently DNA–metal binding by Cp_2Ti complexes has been established by inductively coupled plasma (ICP) spectroscopy analysis.[6] In contrast, numerous stable Pt^{II} model complexes have been synthesized in aqueous solution.[7] Some authors claimed that the active antitumor species is not the titanocene complex but rather the cyclopentadiene released during the decomposition of Cp_2Ti compounds.[8] Later it was shown by in vivo experiments that neither cyclopentadiene (C_5H_6) nor its dimer ($C_{11}H_{12}$) are the active antiproliferative moieties in antitumor non-platinum complexes.[9] Because the pronounced antitumor properties of $[Cp_2TiCl_2]$ have been confirmed (e.g. against Ehrlich ascites tumor, sarcoma 180, melanoma B16, colon carcinoma 38, as well as several human tumors grafted onto athymic mice),[1, 9] the well-planned synthesis of a titanocene model complex containing a naturally occurring ligand is of great importance. The coordination behavior of $[Cp_2TiCl_2]$ towards α-amino acids has not been thoroughly investigated, and until now no titanium α-amino acid complex has been synthesized and structurally characterized.[10] In contrast, the coordination chemistry of Pt^{II} and Pd^{II} compounds towards amino acids is well understood and has been investigated by multinuclear NMR spectroscopy.[11, 12] It has been established that the coordination of amino acids to Pt^{II} and Pd^{II} compounds through a nitrogen or an oxygen atom or as a chelating ligand through nitrogen and oxygen atoms simultaneously depends on the pH of the aqueous reaction medium.[11, 12] The structures of many Pd^{II} amino acid chelate complexes have been determined by X-ray diffraction methods.[13]

Here we report for the first time on titanocene α-amino acid complexes $[Cp_2Ti(aa)_2]^{2+}[Cl]_2^-$ (aa = α-amino acid) which were prepared from biologically active $[Cp_2TiCl_2]$. Whereas $[Cp_2TiCl_2]$ hydrolyzes slowly in aqueous systems and does not react with amino acids like glycine to give the desired titanocene amino acid complex,[14, 15] the reaction of $[Cp_2TiCl_2]$ with stoichiometric amounts of an amino acid in the waterlike solvent MeOH (not necessarily anhydrous) afforded the shiny orange complexes **1**–**3** in good yields [Eq. (a)].

$$[Cp_2TiCl_2] + 2\,aa \xrightarrow{MeOH} [Cp_2Ti(aa)_2]^{2+}[Cl]_2^- \qquad (a)$$

1: aa = $^-O_2CCH_2NH_3^+$ = glycine
2: aa = $^-O_2CCH(CH_3)NH_3^+$ = L-alanine
3: aa = $^-O_2CC(CH_3)_2NH_3^+$ = 2-methylalanine

Complexes **1**–**3** are stable solids at room temperature and not sensitive towards air and moisture. The ^{1}H NMR spectra were recorded in D_2O. In **1** the protons bound to the α-C atom of the coordinated amino acid are shifted to significantly lower field in comparison with those of the free amino acid (**1**: $\delta(CH_2) = 3.68$, glycine: $\delta(CH_2) = 3.38$). Whereas the proton at the α-C atom of **2** also shows a significant shift to lower field, the methyl protons in **2** and **3** are only slightly shifted to lower field (**2**: $\delta(CH) = 3.87$, $\delta(CH_3) = 1.40$, L-alanine: $\delta(CH) = 3.63$, $\delta(CH_3) = 1.35$, **3**: $\delta(CH_3) = 1.52$, 2-methylalanine: $\delta(CH_3) = 1.47$). The signals of the NH_3^+ groups are observed neither in the ^{1}H NMR spectra of **1**–**3** nor in the spectra of the free amino acids but can be observed as expected in the ^{14}N NMR spectra. A noteworthy feature in the IR spectra of **1**–**3** is a very strong absorption due to the asymmetric ν(COO) stretching vibration and a strong band that can be assigned to the symmetric ν(COO) stretching vibration. In line with the observations of Nakamoto et al. concerning the vibrational data of metal amino acid complexes, the ν_{as}(COO) bands in the spectra of **1**–**3** are shifted to higher wavenumbers and ν_s(COO) modes are shifted to lower wavenumbers compared with the corresponding bands of the free amino acids.[16] A detailed discussion of the vibrational data (IR, Raman) and further experimental data (MS, UV) will be published shortly.

Slow evaporation of the solvent from an aqueous solution of **3** yielded orange-red crystals suitable for X-ray structure determination.[17] The structure of the cation in **3** is presented in Figure 1. The cation in **3** has approximately C_2 symmetry and a titanium center with distorted tetrahedral coordination sphere. The Cp rings are eclipsed. The Ti–O distance of 1.961 Å agrees with the expected value for a Ti–O single bond ($\sum r_{cov}$(TiO) = 1.98 Å)[18] and compares well with that of other O-coordinated titanocene complexes.[19] Moreover, the C2–O3 bond length (1.21 Å) compares nicely with the length of the double bond in R_2CO (R = H, CH_3),[20] but the O1–C2 bond length of 1.286 Å is significantly shorter than the length of C–O single bonds in alcohols (d(C–O) = 1.42 Å).[21] Along with a recently reported gold(I) complex[22] containing an O-coordinated hippurato amino acid ligand, compound **3** is one of the few ex-

Passmore for providing ^{14}N/^{15}N NMR facilities and Dipl.-Chem. M. Kempf for recording the DCI mass spectrum. We also thank both referees for valuable suggestions.

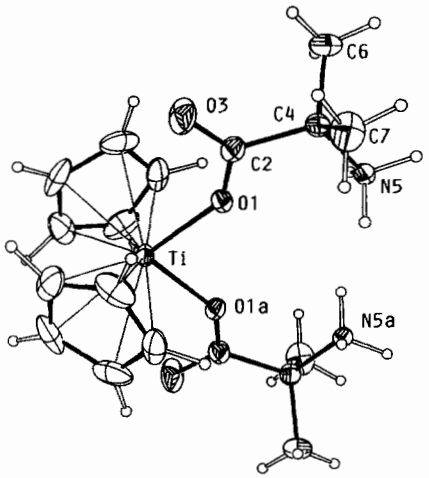

Fig. 1. Structure of the cation in **3** [17]. Important bond lengths [Å] and angles [°]: Ti-O1 1.9610(19), O1-C2 1.286(4), C2-O3 1.210(4); O1-Ti-O1a 90.75(8), Ti-O1-C2 141.21(19), O1-C2-O3 125.1(3). Hydrogen atom positions calculated [17].

amples of a complex in which the amino acid coordinates solely through the carboxylato group.[23]

Complexes **1**–**3** are the first titanocene α-amino acid complexes to be prepared and characterized. Polymeric titanocene and Pt^{II} complexes with amino acids have been reported;[24] however, their structures have not yet been determined by diffraction methods. Because of the very good solubility of these complexes in water and the likely low toxicity, we will investigate their antitumor properties.

Experimental Procedure

$[Cp_2TiCl_2]$ (8 mmol, 2.0 g) was stirred with the relevant amino acid (16 mmol; glycine: 1.20 g, L-alanine: 1.43 g, 2-methylalanine: 1.65 g) in 10 mL MeOH at room temperature. The precipitated orange red solid **1**, **2**, and **3**, respectively, was filtered off and dried in vacuo (**1**: 2.65 g, 83%, $T_{decomp} > 160$ °C; **2**: 1.43 g, 38%, $T_{decomp.} > 100$ °C; **3**: 3.30 g, 93%, $T_{decomp} > 240$ °C).

1: ^{1}H NMR (60 MHz, D_2O, 25 °C, D_2O int.): $\delta = 6.57$ (s, 10H, Cp), 3.68 (s, 4H, CH_2); ^{14}N NMR (28.90 MHz, D_2O, 25 °C, $MeNO_2$): $\delta = -352.1$ (s, NH_3^+); IR (KBr pellet): $\tilde{\nu}$[cm^{-1}] = 1655 vs ($\nu_{as}(COO^-)$), 1368/1362 s ($\nu_s(COO^-)$), 523 ms (ν(TiO)); Raman (60 mW, 25 °C): $\tilde{\nu}$[cm^{-1}] = 1443 (1) (ω(CC), Cp, δ(CH_2)), 1131 (6) (δ(CH), Cp, γ(NH_3^+)), 425 (3) (ν(TiCp)), 360 (6) (ν(TiCp)), 307 (2), 265 (10), 154 (1).

2: ^{1}H NMR (60 MHz, D_2O, 25 °C, D_2O int.): $\delta = 6.62$ (s, 10H, Cp), 3.87 (q, ^3J(H,H) = 7.6 Hz, 2H, CH), 1.40 (d, ^3J(H,H) = 7.6 Hz, 6H, CH_3); ^{14}N NMR (28.90 MHz, D_2O, 25 °C, $MeNO_2$): $\delta = -339.8$ (s, NH_3^+); IR (KBr pellet): $\tilde{\nu}$[cm^{-1}] = 1660 vs ($\nu_{as}(COO^-)$), 1375 ($\nu_s(COO^-)$); Raman (60 mW, 25 °C): $\tilde{\nu}$[cm^{-1}] = 1133 (5) (δ(CH), Cp, ν(CCN)), 828 (1) (γ(CH), Cp), 425 (3) (ν(TiCp)), 366 (5) (ν(TiCp)), 261 (10), 143 (3).

3: ^{1}H NMR (60 MHz, D_2O, 25 °C, D_2O int.): $\delta = 6.62$ (s, 10H, Cp), 1.52 (s, 12H, CH_3); ^{14}N NMR (28.90 MHz, D_2O, 25 °C, $MeNO_2$): $\delta = -327.9$ (s, NH_3^+); ^{15}N NMR (40.54 MHz, D_2O, 25 °C, $MeNO_2$): $\delta = -329.5$ (q, ^1J(N,H) = 18 Hz, NH_3^+); IR (KBr pellet): $\tilde{\nu}$[cm^{-1}] = 1655 vs ($\nu_{as}(COO^-)$), 1383 ($\nu_s(COO^-)$); Raman (60 mW, 25 °C): $\tilde{\nu}$[cm^{-1}] = 1132 (2) (δ(CH), Cp), 425 (2) (ν(TiCp)), 385 (2), 363 (5) (ν(TiCp)), 266 (10); DCI-MS *m/z*: 384, $[Cp_2Ti(2\text{-methylalanine})_2]^+$. – All compounds gave correct elemental analyses (C,H,N,Cl: **1**, **3**; C,H,N: **2**).

Probability, Fractals and the Physical World

Chaos and Complexity. By *B. Kaye*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XXII, 593 pp., paperback DM 78.00.—ISBN 3-527-29007-9/1-56081-798-4

This book is intended as a popular introduction to some modern interdisciplinary ideas of chaos, fractals, and scaling. It is addressed mainly to a readership of high-school students and university beginners. The main content of the book is well described by its subtitle: "Discovering the Surprising Patterns of Science and Technology". The main goal of the book is stated in the last paragraph of the author's introduction: its readers should "gain a new appreciation of the physical significance of the theorems of probability theory and also grasp the significance of fractal structures manifest in the physical world around us". This is the main idea of the book, and therefore its title "Chaos & Complexity" is misleading.

Starting from some preliminary explanations of the concepts of dynamical chaos, the author switches to a very necessary introductory discussion of classical probability problems, including Buffon's needle and the Poisson distribution (although there are mistakes in both equations representing the Poisson distribution, on pp. 209 and 210) and others of a less classical nature, such as hyperbolic (scaling) probability distributions. This introduction is very interesting and motivating, and also provides young readers with ideas for simple experiments they can do by themselves in order to become familiar with the concepts and methods of probability theory and applied statistics, and to appreciate their relevance in science and everyday life. According to the classification adopted on page 7, all the cases described here are random rather then chaotic.

The greater part of the book is devoted to consideration of different fractal sets and objects. The concepts of fractal geometry leading to the notion of fractal dimension(s) form an important part of modern material and geological sciences and engineering, and also find applications in other fields, such as biology and social science. This notion gives us an important and experimentally measurable characteristic of rough lines and surfaces, such as coastlines and landscapes, catalyst surfaces, dusts, etc. The author is an expert in this field of characterization of fractal objects, and therefore the chapters devoted to the properties and characterization of real systems, such as aerosols, powders, aggregates, and mixtures are not only brilliantly written but also very interesting, even for a specialist.

Here I would like to stress once more that these topics are mostly classified by the scientific community as belonging to the fields of random (or stochastic) processes, fractals, scaling, growth or roughening phenomena, etc., which normally implies an "external" source of randomness, such as thermal Brownian motion, quenched disorder, and so on. This can be easily seen by comparing the titles of numerous conferences on these topics. Therefore, the greater part of the book is devoted to something other than the subject of its title. Only a small part of the book treats what scientists normally refer to as dynamical chaos. The only problems that can be considered as such are the logistic map (May's equation) discussed in Chapter 12 and parts of Chapters 2 and 14 on iteration of maps and the form of basins of attractors. The main questions of stability, sensitivity to initial conditions, and predictability are only briefly mentioned in the introductory Chapter 1 (see the discussion of the butterfly effect).

Although the author has a good habit of using a dictionary to explain the etymology and meanings of terms he uses and provides us with much interesting information in many other cases, the word "complex" is an unfortunate exception, being used more or less as a synonym for the word "complicated". The notion of complexity is not even analyzed (for a deeper discussion see, e.g., *Applied Chaos Theory. A Paradigm for Complexity*, by A. B. Çambel, Academic Press, 1993), and consequently many interesting points, such as hierarchical and algorithmic definitions of complexity, or problems of evolution of complex systems, which can be useful for an introductory text, remain unexplained.

Unfortunately some statements are unclear or vague, and some citations are inaccurate: e.g., the attribution of the uncertainty principle to Karl Heisenberg instead of Werner Heisenberg (p. 4), a reference to "Peratoe" (instead of V. Pareto) on page 442, and the three times erroneously transcribed name of N. Ya. Vilenkin.

Overall, the book is a very interesting introductory text which is more suitable for inspiration than for learning. It can serve as a source of additional material and fresh jokes and anecdotes concerning the whole field of probability and fractal geometry, and as a brilliant advertisement for this new field of science and new way of thinking. If this advertisement works, the reader will then turn to other texts that are more accurate and precise (see the discussion of these two concepts on p. 134).

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Too chaotic, too complex! In the book review section in issue 12 the cover of the book "Chaos and Complexity" was incorrectly depicted with the review of the book "Chemistry Imagined. Reflections on Science." The correct picture is shown here.

Molecular Catalysts for Multielectron Redox Reactions of Small Molecules: The "Cofacial Metallodiporphyrin" Approach**

James P. Collman,* Paul S. Wagenknecht, and James E. Hutchison

The role of metalloenzymes in important biological transformations has attracted increasing attention over the past several decades. Of the many chemical transformations mediated by enzymes, few are as challenging as multielectron redox reactions. Recent studies have revealed a partial structural and mechanistic description of these redox-active metalloenzymes, but there is much still to be learned regarding the mechanisms of substrate transformation. Due to the complexity of the metalloenzyme systems, simplified model systems are employed to mimic structural or functional features of the enzyme. In multielectron redox enzymes, several metals are probably involved in both substrate binding and the subsequent redox reactions. Thus, functional mimics of multielectron redox enzymes might also need two or more metal centers to be efficacious. The roles of multiple metal centers are to 1) increase the substrate's affinity for the catalyst, 2) increase the rate of electron transfer to the bound substrate, 3) increase the reactivity of the bound substrate, and 4) inhibit deleterious side reactions. Determining the importance of each factor may help in the development of these catalysts. Cofacial metallodiporphyrins, because of the control they provide over the geometric and electronic properties of the synthetic reaction center, are ideal bimetallic model complexes. The knowledge gained from model studies will help in understanding the mechanisms of metalloenzymes and can be used to design new homogeneous catalysts to effect multielectron transformations.

1. Introduction

In the regime of redox chemistry there is an important, general problem which has been resolved in nature and certain heterogeneous catalysts: the catalysis of multielectron redox reactions involving small gaseous molecules (O_2, H_2, and N_2) (Scheme 1). Catalysis of such redox reactions is extraordinarily challenging from a kinetic point of view despite the fact that the thermodynamic potentials for the overall multielectron change may be favorable. In nature metalloenzymes facilitate these transformations. In certain cases, heterogeneous catalysts have been developed to effect the same reactions, although not necessarily by the same mechanisms.

Scheme 1. Selected redox transformations catalyzed by metalloenzymes.

Many examples of multielectron redox reactions are found in enzymatic systems[1] such as sulfite reductase,[2] nitrate reductase,[3] cytochrome *c* oxidase,[4, 5] blue copper oxidases,[6, 7] pseudocatalase,[8] photosystem II,[9] nitrogenase,[10, 11] and hydrogenase.[12] In each case, the enzyme is thought to have one or more metals at the active site and in many cases the enzyme may also include active peripheral metal sites. Mechanisms for these multielectron transformations are largely obscure and form a major research theme in bioinorganic chemistry.[13] The present review discusses recent progress toward development of functional, synthetic models for redox processes involving $O_2 \rightleftharpoons H_2O$, $H_2 \rightleftharpoons H^+$, and $N_2 \rightleftharpoons NH_3$.

These transformations are extremely important in biology and technology. For example, the key step in life-sustaining, aerobic respiration is the four-electron reduction of O_2 to H_2O. This reduction is catalyzed by the membrane-associated, multimetalloenzyme, cytochrome *c* oxidase. The energy derived from O_2 reduction is used by a proton pump to establish a membrane potential.[14] This membrane potential drives the synthesis of the energy-rich molecule, ATP. In heterogeneous catalysis, the electrochemical reduction of dioxygen to water assumes a major role in the cathode of fuel cells. In fact, the efficiency of power production by fuel cells is limited by the efficiency of the best catalyst (Pt) for this transformation.

[**] Nearly 30 years ago Professor Henry Taube introduced this subject to Professor James Collman and encouraged his study of catalytic dioxygen reduction. Thus this article is dedicated to him.

Even the simplest multielectron redox reaction, oxidation of H_2 to $2H^+$ or its reverse, reduction of H^+, is kinetically challenging. In nature hydrogenase enzymes contained in a variety of bacterial and algal species catalyze this transformation in both directions and utilize the electronic energy in hydrogen for redox transformations within the cells of the organism.[12] In fact, hydrogenase enzyme-catalyzed CO_2 fixation supplies the sole carbon source for growth for several organisms.[15] Many heterogeneous catalysts promote this $H^+ \rightleftharpoons H_2$ transformation; the best studied is Pt, which is used to set the standard potential for the normal hydrogen electrode (NHE).

The reduction of molecular N_2 to NH_3 plays a major role in the biosphere because the inert atmospheric gas, N_2, must be fixed (i.e. converted into nutrients such as NH_3 usable by plants) before plants can perform the biosynthesis of proteins required by animals. The enzymes that carry out this transformation, the nitrogenase enzymes, are indeed famous. All nitrogenase enzymes have several metals, most commonly Fe and Mo, at their active sites. Until recently, the conventional (Fe/Mo) nitrogenase system was presumed to bind N_2 at the Mo site. Crystallographic work on *Azotobacter vinelandii*[16] by Rees et al. indicates that as many as three Fe atoms may be engaged in binding N_2; Mo appears to be coordinatively saturated. Despite this new information, the mechanism of biological reduction of nitrogen remains unknown. The commercial reduction of N_2 by the famous Haber–Bosch hydrogenation catalyst is well-developed and has played a major role in world history by providing economical sources of fixed nitrogen for use especially in agriculture (fertilizer) and military applications (munitions).

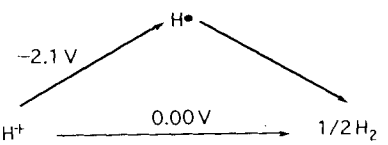
In each of the enzymatic examples cited in this section, multiple metal centers a) bind and alter the reactivity of the substrate and/or b) direct the timing and redox potential of the redox equivalents. This review focuses on the design and implementation of molecular, multielectron catalysts based primarily on cofacial metallodiporphyrins. In Section 2, the energetic constraints of these transformations and the analytical techniques used in these studies are examined. Sections 3 and 4 describe the structural properties of a select number of cofacial diporphyrins and the application of the cofacial metallodiporphyrin approach to preparing multielectron redox catalysts, respectively. Detailed accounts of the application of this strategy to redox transformations of O_2/H_2O, H_2/H^+, and N_2/NH_3 complete this review.

J. P. Collmann

P. S. Wagenknecht

J. E. Hutchison

James P. Collman was born in Beatrice, Nebraska, USA, in 1932 and received B. S. and M. S. degrees from the University of Nebraska in 1954 and 1956 and then a Ph.D. from the University of Illinois in 1958 under the supervision of R. C. Fuson. From 1958–1967 he was on the faculty of the University of North Carolina at Chapel Hill; in 1967 he moved to Stanford University where he is Daubert Professor of Chemistry. His research interests are very broad extending across inorganic and organic chemistry but also including superconductivity. His principal research is directed toward the invention and study of functional synthetic mimics of heme protein active sites. His work has been recognized by many awards, the most recent being the American Society Award for Distinguished Service to Inorganic Chemistry. He is a member of the National Academy of Sciences USA.



Paul S. Wagenknecht, born in 1964, studied chemistry until 1986 at Furman University where he performed undergraduate research with Noel Kane-Maguire. He then attended Stanford University as a National Science Foundation Predoctoral Fellow where he worked with James P. Collman and Nathan Lewis. His thesis research was concerned with utilizing dihydrogen complexes as functional models of hydrogenase enzymes. After receiving his Ph.D. in September 1991, he worked with Jack Norton at Colorado State University on the mechanism of proton transfer to and from tungsten hydrazido complexes relevant to nitrogen fixation. His current research interests include preparing and studying new crown and cryptand compounds as functional models of metalloenzymes.

James E. Hutchison was born in 1962 and raised in Oregon, USA. He studied chemistry until 1986 at the University of Oregon with Richard G. Finke and received his Ph.D. in 1991 under the supervision of James P. Collman for work on the binding of dihydrogen, dioxygen, and dinitrogen by cofacial metallodiporphyrins in the context of preparing multielectron redox catalysts. He is a National Science Foundation Postdoctoral Fellow and worked with Royce W. Murray at the University of North Carolina at Chapel Hill on the synthesis and electrochemistry of new redox-active self-assembled monolayers and highly concentrated redox liquids. He is now a member of the chemistry faculty at the University of Oregon where his research interests involve synthetic and mechanistic studies and electron transport.

2. General Principles

2.1. Thermodynamic and Kinetic Limitations

At the heart of this general problem is the fact that when one considers the multielectron redox reactions as a series of single-electron/single-proton transfer steps, one or more of the redox potentials are highly unfavorable, even though the overall multielectron redox process is thermodynamically favorable. For example, the reduction of two protons to dihydrogen occurs at 0.00 V vs. NHE, whereas the reduction of a single proton to a highly unstable hydrogen atom requires an extra two volts driving force[17] (Scheme 2). There are analogous thermodynamic impediments along other multielectron redox pathways involving a series of single-electron steps. For this reason, it is not feasible to carry out these reactions by outer-sphere electron transfer processes at an otherwise inert electrode. Catalysts are required to facilitate these transformations.

Scheme 2. Proton reduction to dihydrogen.

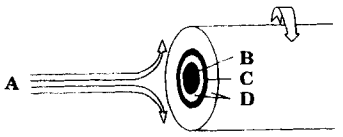
Possible catalysts will bind gaseous substrate molecules thereby providing lower energy pathways by stabilizing the intermediates relative to the substrate. This catalysis may be brought about either by raising the energy of the substrate or by lowering the energy of the transition states and/or intermediates. Another important feature of the binding is substrate specificity. A catalyst should bind the substrate but exclude inhibiting ligands. Because N_2, O_2, and H_2 are small molecules, catalysts with small pockets for substrate binding can exclude larger competitive inhibitors.

Another important issue concerns the role of protons in each of the catalytic cycles. Coordination of a ligand such as O_2 or N_2 may render the substrate a stronger Brønsted base. Protonation of the coordinated ligand makes the substrate more susceptible to reduction. Conversely, the binding of H_2 by a metal atom can make that ligand much more acidic. Deprotonation of the bound H_2 facilitates oxidation. For these reasons, the properties of coordination compounds formed between pairs of metals and these gaseous molecules in various oxidation states and over particular pH ranges are of great interest.

Microscopic reversibility is a useful principle in the analysis of certain redox processes. In a model for N_2 fixation it has been possible to observe the *reverse* of certain stages in the overall six-electron transformation (see Section 7.3). According to microscopic reversibility, these paths are theoretically available in the reductive direction; the same E^0 and pH values must be applicable, although the sequence of electron addition/removal, proton addition/removal will be the exact reverse when traversed in the opposite direction (see Section 7.4).

In examining an electrocatalyst two criteria are used to define its efficiency: overpotential and catalyst turnover rate. Recall that most multielectron processes require additional energy input if they are to proceed through several uncatalyzed single-electron transfer steps. The overpotential is the extra voltage that must be applied to overcome this "impediment". This means that for reductions, voltages more negative than the overall thermodynamic potential (for the multielectron change) must be applied; for oxidations, voltages more positive than the overall thermodynamic potential must be applied. We are interested here in preparing efficient catalysts with little to no overpotential, that is, the substrate transformation should occur at or near the thermodynamic potential. The second characteristic of catalyst efficiency is the turnover rate. If the substrate transformation within the catalyst is efficient, electrons can be transferred at a high rate, resulting in high current densities. Possible kinetic bottlenecks in the catalytic cycle, include substrate binding, proton transfer, electron transfer, and product release; these are discussed below.

2.2. Catalyst Screening and Electrochemical Methods



Electrochemical methods are essential in assaying the electrocatalytic properties of cofacial metallodiporphyrins. Cyclic voltammetry, rotating disk and rotating ring-disk electrochemical techniques are the most frequently used techniques in these studies. In the case of a slower reaction, current densities may be too low to be measured by these electrochemical methods. Slower reactions may be easier to monitor in solution by following product formation using NMR spectroscopy, gas or liquid chromatography, or ion- or molecule-selective electrodes. When feasible, spectroelectrochemical methods can be used to detect intermediates. The electrochemical methods are discussed briefly below. More detailed discussions appear in Section 5.

Normally when screening porphyrinic electrocatalysts they are first adsorbed onto an edge-plane graphite (EPG) electrode. Adsorption onto EPG offers advantages over solution catalysis because less catalyst is needed ($< 10^{-9}$ mol cm^{-2}) and electron transfer to the electrode-confined species is very fast. EPG is inexpensive, has a high surface area and, most importantly, adsorbs porphyrins strongly. Adsorption is performed by briefly dipping an EPG electrode into a nonaqueous, dilute solution of the catalyst. The porphyrins have been shown to adsorb in the form of islands up to 30 monolayers thick.[18] Assays of catalytic activity are performed with these porphyrin-modified electrodes.

Cyclic voltammetry is a rapid and easy method to screen these catalyst electrodes. Cyclic voltammograms of a solution containing the substrate are performed with the modified EPG electrode and an unmodified "control" EPG electrode. A catalytic effect can be seen as a decrease in the substrate transformation overpotential or an increase in the current density for the catalyst-coated electrode relative to the bare electrode.

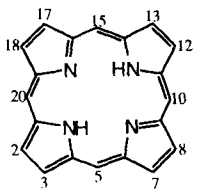
To obtain more information about the kinetics of substrate transformation rotating disk electrode (RDE) experiments are performed.[19] In the typical experiment the EPG electrode is rotated at 100 rpm, while the potential is scanned through the region of interest. The plateau or limiting current is readily determined from the resulting sigmoidal voltammogram. Rotating the electrode replenishes the substrate at the electrode surface, resulting in higher limiting currents as the rotation rate is increased. An analysis of the limiting current versus the rotation rate allows a determination of the number of electrons transferred as well as the limiting rate constant.

A modification of the rotating disk electrode is the rotating ring-disk electrode (RRDE).[20] In this variation of the RDE experiment the disk is encircled by a platinum ring which is separated from the disk by an insulating layer. The potentials of the two electrode surfaces can be controlled independently. As the RRDE is rotated, solution flows first past the disk, and then past the ring (Scheme 3). The electrode products from the disk are uniformly swept past the ring where electroactive products can be detected. Thus, the ring monitors the formation of products at the disk.

Scheme 3. Schematic of rotating ring-disk experiment. A) Electrolyte and substrate flow. B) Edge-plane graphite disk. C) Platinum ring. D) Teflon shrouding.

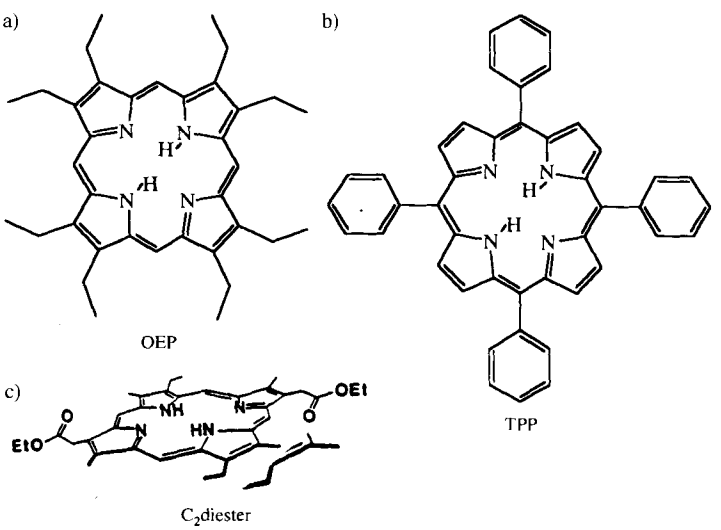
Now that the energetic concerns governing the multielectron reductions and the tools available to examine the efficacy of possible catalysts have been presented, we next discuss the application of cofacial metallodiporphyrins to the multielectron redox reactions.

3. Cofacial Metallodiporphyrins



3.1. History

Cofacial diporphyrins (defined here as molecular assemblies in which two porphyrins are held in a stacked orientation) have a rich history that began two decades ago with simple covalently linked diporphyrins. Research into the area of covalently linked diporphyrins was initiated by Schwarz et al.[21] in order to study energy transfer between adjacent chromophores. Their first diporphyrin was covalently linked at the β-pyrrollic position by a single amide linkage. In this predecessor of the cofacial diporphyrin, however, the two porphyrins were not constrained to a stacked geometry.

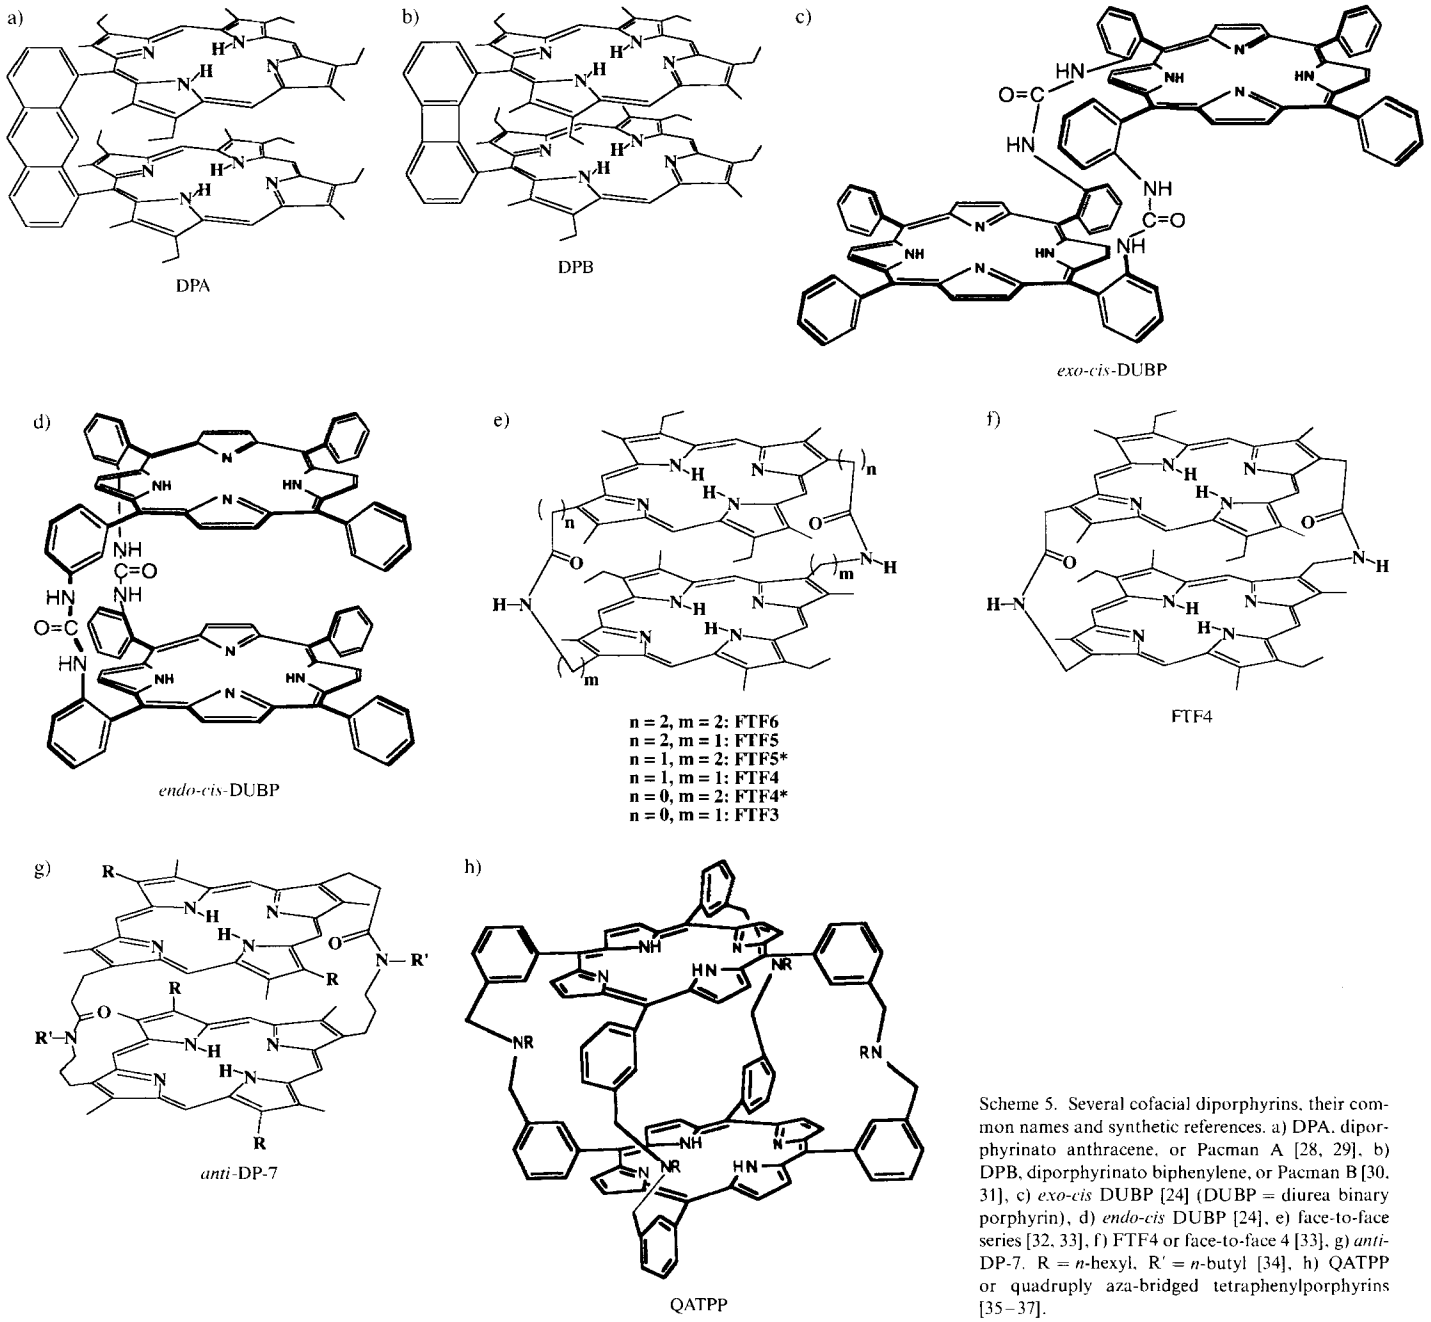


The first reports of cofacial diporphyrins were presented by Kagan[22] and Ogoshi et al.[23] at symposia in the mid 1970s. In 1977 the first published articles on cofacial diporphyrins appeared nearly contemporaneously by Collman et al.,[24] Ogoshi et al.,[25] Chang et al.,[26] and Kagan et al.[27] Most of this work still focused on the chemical relevance of these assemblies to the energy transfer process in chlorophylls. In our first article,[24] however, we proposed the use of these porphyrin dimers as catalysts for the four- and six-electron reductions of O_2 and N_2, respectively. Therein we stated "We have approached this problem by constructing a new class of so-called 'face-to-face porphyrins' in which two porphyrin rings are held in parallel conformation. Thus, two metal atoms might act in concert to bind and reduce dioxygen (or dinitrogen) in the gap between the porphyrin rings. Eventually these binuclear, cyclophane porphyrin complexes are to be attached to graphite to be tested as electrode catalysts." Though considerable effort has been expended on the syntheses of these ligands for different purposes by Sanders et al.[38] and others,[37] we will focus our discussion on the cofacial diporphyrins which have been central to the development of electrocatalysts.

3.2. Nomenclature

Since that initial burst of activity, a great number of cofacial diporphyrins have been synthesized. These assemblies have an extensive trivial nomenclature but as a class have been referred to as "cofacial", "*strati*", "face-to-face", and "stacked". The diporphyrins have been linked by one to four linkers at the *meso*-positions (5, 10, 15, or 20 positions, Scheme 4) or by two linkers at the 2 and 12 (β-pyrrollic) positions. Scheme 5 shows several of the most utilized diporphyrin ligands with their trivial names.[37] Several monoporphyrins which will be discussed in Section 5 are shown in Scheme 6. Within this review, ovals or linked ovals will be used to depict porphyrins or cofacial diporphyrins, respectively. The figure captions will indicate the specific porphyrin employed.

Scheme 4. Porphine with numbering of the centers.



Scheme 6. Monomeric porphyrins discussed in this review. a) OEP or octaethylporphyrin, b) TPP or tetraphenylporphyrin, c) mesoporphyrin diethyl ester.

3.3. Structure

The initial goal of preparing the face-to-face porphyrins was to hold two porphyrins rigidly together in a coplanar arrangement. Several spectral features initially confirmed this arrangement and eventually crystallographic data was obtained as proof of structure. The spectroscopic means of determining the arrangement of the porphyrins is still quite important in characterizations and is explained below.

3.3.1. UV/VIS Spectroscopy

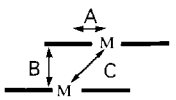
An important feature of porphyrin spectra is the Soret band, an intense band usually appearing between 389 and 440 nm of the UV/VIS spectrum.[39] Three of the early papers on cofacial diporphyrins report a blue shift and/or broadening of the Soret band of the diporphyrin relative to the Soret of the correspond-

Scheme 5. Several cofacial diporphyrins, their common names and synthetic references. a) DPA, diporphyrinato anthracene, or Pacman A [28, 29], b) DPB, diporphyrinato biphenylene, or Pacman B [30, 31], c) *exo-cis* DUBP [24] (DUBP = diurea binary porphyrin), d) *endo-cis* DUBP [24], e) face-to-face series [32, 33], f) FTF4 or face-to-face 4 [33], g) *anti*-DP-7. R = *n*-hexyl, R' = *n*-butyl [34], h) QATPP or quadruply aza-bridged tetraphenylporphyrins [35–37].

ing monomeric porphyrin halves.[24, 26, 27] Especially noteworthy is the comparison of *exo-cis* DUBP with *endo-cis* DUBP,[24] two diporphyrins which differ only in that the *endo* isomer is arranged with the porphyrins stacked on top of each other, whereas the *exo* isomer has the porphyrins arranged in an "anti" conformation (Scheme 5c and d). The Soret band of the *endo-cis* DUBP shows a 15–17 nm shift to shorter wavelength, whereas the Soret band of the *exo-cis* DUBP remains unshifted. This blue shift and the broadening of the Soret band appear to be peculiar to the cofacial diporphyrins and not to diporphyrins in general. Chang correlated this behavior of the Soret band with an exciton coupling between the two coplanar porphyrin rings.[40] These characteristic Soret bands are routinely used for initial structural determinations of cofacial diporphyrins. Such shifts in the Soret band are also seen in porphyrins linked by coordinate bonds; these compounds are not discussed here because they do not exhibit electrocatalytic activity. This is because the required coordination sites are blocked by the bridging ligand.

3.3.2. ^1H NMR Spectroscopy

The ^{1}H NMR spectra of porphyrins reflect the strong ring current of the aromatic porphyrin macrocycle. This ring current imparts an upfield shift to signals of the NH protons of free base porphyrins. In a true "face-to-face" porphyrin, the chemical shifts of protons on one porphyrin ring should be affected by the ring current of the second porphyrin as well. Thus, the NH proton signals should be shifted even further upfield for the cofacial diporphyrins relative to the corresponding monomer halves. In-



deed, two early papers reported an upfield shift of approximately 2 ppm for the NH protons of the diporphyrin relative to those of the monomer.[24, 26] The magnitude of this shift was also correlated with the length of the linker. Chang[40] found that diporphyrins linked by two five-atom bridges displayed a larger upfield shift of NH protons (4.7 ppm) relative to the corresponding monomer than a diporphyrin linked by two seven-atom bridges (2.4 ppm). We[33] and Bruice[35] have synthesized series of porphyrins which show the same trends, though we found instances where the nature of the linker upsets this correlation between linker length and NH resonance.[32]

3.3.3. EPR Spectroscopy

Distances between the metal centers in dimetalated diporphyrins have been determined by studying the dipolar interaction of two Cu^{II} or two Co^{II} paramagnetic centers.[24, 40, 41] The most noteworthy study is that of Eaton et al.[41] who used EPR spectroscopy to determine metal–metal distances and interplanar separations for several compounds with known crystal structures. Good agreement (± 0.4 Å) between EPR spectroscopic data and crystallographic data was demonstrated.

3.3.4. Crystallographic Data

The desired face-to-face geometry, supported by the above spectroscopic data, is confirmed by crystallographic data. The structures of these diporphyrins have several unique characteristics as outlined in Scheme 7. The two porphyrin rings are generally displaced relative to an eclipsed geometry by a distance known as the lateral shift.[45] The inter-ring separation is defined as the perpendicular distance between the pair of best planes of the macrocycles. Ct represents the center of the porphyrin with respect to the four nitrogen atoms and many studies report Ct–Ct distances for free base porphyrins. Table 1 displays the crystallographic M–M distances, the distance between two metals bound by the porphyrin cores, and the interplanar separations for all crystallographically characterized cofacial metallodiporphyrins.

Scheme 7. Structural parameters for cofacial diporphyrins. A) Lateral slip, B) inter-ring separation, and C) Ct Ct or M M distance.

The crystallographic data indicate a similarity amongst the inter-ring separations, that is, most of the values are approximately 3.5 Å. This distance is due in part to the $\pi-\pi$ interactions between the aromatic macrocycles as suggested by Scheidt's systematic evaluation of solid-state interactions between porphyrin rings.[45] The magnitude of this attraction between rings is evident in the case of $[Cu_2(DPB)]$. This diporphyrin with the biphenylene linker was synthesized to hold the two porphyrins perpendicular to the backbone in an eclipsed geometry approximately 3.8 Å apart. Regardless, the two porphyrins undergo a lateral shift of 1.52 Å to achieve optimum $\pi-\pi$ overlap with an inter-ring separation of 3.45 Å (Fig. 1).[43]

Table 1. X-ray crystallographic data for cofacial metallodiporphyrins.

Compound	M–M [Å]	Interring separation [Å]	Ref.
$[Cu_2(FTF6)]$	6.33	3.87	[42]
$[Ni_2(DPA)]$	4.57	3.9	[43]
$[Cu_2(DPB)]$	3.81	3.45	[43]
[CoAl(OEt)(DPB)]	4.37	3.54	[29]
$[Co_2(DPB)]$	3.73		[31]
$[Co_2(FTF4)]$	3.42	3.54	[44]
$[Cu_2(DP\text{-}7)]$	5.22	3.52	[34]

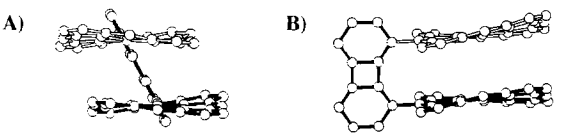


Fig. 1. Structural distortion of $[Cu_2(DPB)]$. A) Front view, and B) side view.

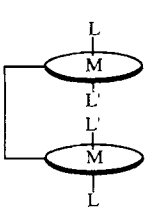
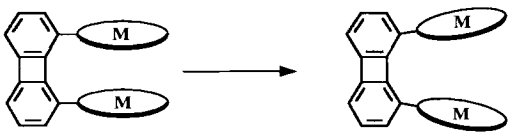


Initially, we suggested that such flexibility of the diporphyrin unit would be of importance in the accommodation of and chemical transformation of small molecules within the "face-to-face" porphyrin cavity.[24] However, the synthesis and structural analysis of $[Cu_2(FTF6)]$, a cofacial metallodiporphyrin linked at the *meso*-positions, demonstrated otherwise.[42] Because of the strong $\pi-\pi$ interactions, this complex distorts to achieve optimum $\pi-\pi$ overlap, resulting in a lateral shift of 5 Å. Apparently the linkers in this system are too flexible to constrain the porphyrins to a true "face-to face" geometry, thus the two metals are not arranged to act in concert on a small molecule. To ensure the close and truly "face-to-face" approach of two metalloporphyrins, only the shortest and most rigid linkers are appropriate. Consequently, most catalysis has been performed with the FTF4, DPB, and DPA derivatives.

3.3.5. Molecular Modeling

Recently, Bruice et al.[35–37, 46] have utilized molecular modeling to determine Ct–Ct distances for the quadruply (Scheme 5h) and triply aza-bridged cofacial tetraphenylporphyrins. These investigations suggested that these diporphyrins are very flexible and the Ct–Ct distance for a single diporphyrin can fluctuate by over 2 Å.

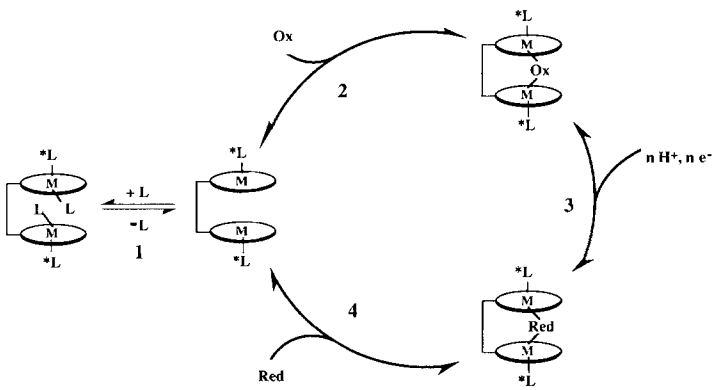
3.4. General Properties of Diporphyrins



In order to understand substrate binding within the metallodiporphyrin cavity, its coordination sphere needs to be considered. Each porphyrin ring is a tetradentate ligand capable of binding a metal center, leaving two axial coordination sites on each metal (Scheme 8). The substrates that can bind to the inner coordination sites are limited by the size of the cavity between the porphyrins, whereas the outer coordination sites should coordinate any ligand capable of binding to metalloporphyrins.

Scheme 8. Generic ligated cofacial metallodiporphyrin. The ligands L are ligated to the outer coordination sites. The ligands L' occupy the inner coordination sites or "pocket".

Typically, catalysts are prepared by blocking the outside coordination sites with axial ligands leaving the coordination sites in the pocket open for substrate binding.



To control the size of the inner coordination pocket, several linkers have been utilized to attach the two porphyrins of the diporphyrin. The most robust and chemically inert of these are the anthracene and biphenylene bridges of the DPA and DPB ligands, respectively. Additionally, because of the rigidity of these linkers, the DPB and DPA ligands display small lateral shift parameters[4,5] and therefore most closely approximate a true face-to-face geometry. However, some flexibility is desired because during the transformation of a substrate bound in the pocket, the geometric binding constraints of the modified substrate will unavoidably change. The DPB and DPA ligands are capable of such flexibility because only one linker connects the diporphyrin unit. Thus, the diporphyrin can open its "bite" as shown in Scheme 9.[4,7] These geometric factors will be important in the binding and transformation of the substrate in each of the examples shown in Sections 5–7.

Scheme 9. Distortion of the DPB ligand to create a larger binding pocket.

4. The Invention of Cofacial Metallodiporphyrin Electrode Catalysts for Multielectron Redox Processes

Careful analysis of a generic multielectron redox cycle based on cofacial metallodiporphyrins can be useful in designing a possible catalyst. In Scheme 10, clockwise rotation through the

Scheme 10. Cofacial metallodiporphyrin approach to multielectron redox catalysis. Ox = oxidized form of the substrate/product pair and Red = the reduced form. 1 = "Formation of the active site", 2, 4 = substrate binding or product release depending upon whether the transformation is oxidizing or reducing, 3 = the multielectron transfer steps.

cycle corresponds to substrate reduction, whereas counterclockwise rotation involves substrate oxidation. There are principally four steps in the cycle: 1) creation of the active site, 2) substrate binding and activation, 3) addition or removal of electrons and protons, and 4) liberation of the product.

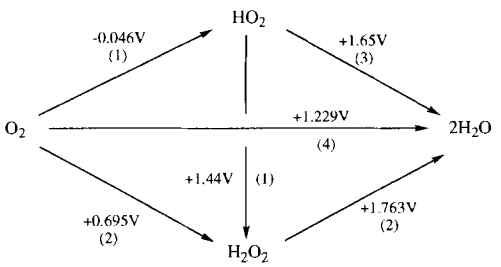
In order to bind one (or two) substrate molecules in the pocket of the catalyst, there must be open, interior coordination sites. Practically, this means that if interior inhibiting ligands are present, the substrate must be able to displace them. In some cases it is necessary to block the outer coordination sites with strong axial ligands so that substrate binding is required to occur within the cavity. If the catalyst precursor contains a metal–metal bond bridging the two inner coordination sites, a *trans* ligand is required to weaken or break this bond thus creating the active site. In the cases where outer axial ligands are employed, care must be taken to ensure that they are bulky enough to be excluded from the active site cavity.

All of the multielectron redox transformations involve bond formation or rupture in the substrate; therefore, the cofacial metallodiporphyrin must bring reactants together to facilitate bond formation or weaken the substrate bond to be broken. Both of these processes begin with substrate binding. Although *strong* binding of the substrate to the active site is not a prerequisite for catalysis, some affinity of the catalyst for the substrate is required. The affinity of the catalyst for the substrate relative to its affinity for other competing substrates determines the specificity or selectivity of the catalyst.

In the third phase of catalysis, electron and proton transfers occur. The cofacial metallodiporphyrin can facilitate these transformations because a) the catalyst acts as an electron reservoir mediating the timing and potential of electron transfers between the electrode and the substrate and/or b) the catalyst/substrate complex is more easily oxidized/reduced than the free substrate. During these steps, protons must be added to or removed from the substrate/catalyst complex. Because the catalyst affects the pK_a of the bound substrate, it may affect the order of electron/proton transfers.

The final step in the cycle is release of product from the catalyst. This stage can be problematic if the product binds too tightly to the catalyst. Frequently this step can be assisted by protonation of the bound product or replacement of bound product by incoming substrate.

This analysis reveals that there are structural and electronic parameters that are important in designing a functional catalyst. The principal controllable parameters are the spacial position of the two metal centers and the nature of each metal center. The position of the metals can be controlled in a cofacial diporphyrin by varying the number and type of bridges between the two porphyrin rings. The reactivity of the metal centers is varied by changing the metal, the electron richness of the porphyrin ring, or the nature of the axial ligands *trans* to the active site. Cofacial metallodiporphyrins allow for a great deal of control over many of the geometric and electronic features of the synthetic reaction center. Systematic manipulation of the geometric parameters was illustrated in the discussion of the variety of cofacial diporphyrins in Section 3.



5. The Four-Electron Reduction of Dioxygen

5.1. Background

Electrode materials that catalyze the four-electron reduction of dioxygen at or near its thermodynamic reduction potential

(+1.23 V vs. NHE) would be ideal fuel-cell cathodes and would allow maximal energy conversion in these cells. All known electrodes catalyze the reduction of dioxygen at more negative potentials, that is with some overpotential. For example, metallic platinum, the most efficient fuel-cell cathode known, operates at an overpotential of nearly 600 mV.[48-50] The limiting potential for a given electrode will be governed primarily by the reduction pathway.

Scheme 11 shows the reversible standard electrode potentials connecting O_2 and its reduction products: hydroperoxyl, hydrogen peroxide, and water.[51] The one-electron change connecting O_2 with HO_2 (hydroperoxyl) is quite unfavorable. In fact, this one-electron change is more than one volt more negative than the $E_{1/2}$ connecting O_2 directly with $2H_2O$—the desired four-electron change. This means that an otherwise catalytically inert electrode acting as a simple source of electrons for outer-sphere electron transfer would produce an infinitesimally small quantity of HO_2 at the thermodynamic potential for the overall four-electron transformation. It is therefore not possible to reduce O_2 to $2H_2O$ at this four-electron thermodynamic potential by an initial one-electron change. The thermodynamic potential for the two-electron change occurs at about + 0.7 V. Thus hydrogen peroxide cannot be a free intermediate if an oxygen-reducing electrode is to operate at or near the thermodynamic potential for four-electron dioxygen reduction (+1.23 V).[33] In designing a four-electron dioxygen reduction catalyst, the one- and two-electron paths must be avoided.

Scheme 11. Dioxygen reduction to water. The number of electrons transferred is given in parentheses.

Our approach to this problem was based on the knowledge that various monomeric transition metal macrocyclic complexes (phthalocyanines and porphyrins) catalyze the reduction of dioxygen to H_2O_2.[52] Cobalt is the metal with the most positive M^{II}/M^{III} redox potential[53] that still binds O_2 with measureable affinity.[54] Thus, we first considered that the two Co^{II} sites of cofacial diporphyrins could collectively bind and reduce O_2 to the peroxide stage. Intuition suggested that further reduction of the peroxide group might take place, especially in the presence of sufficient proton flux. In addition, it had been suggested that two metals might favor a four-electron reduction by minimizing the energy costs arising from spin, ligand, and solvent reorganization associated with a four-electron change.[24]

5.2. Four-Electron Reduction of Dioxygen by Cofacial Bis(Cobalt) Diporphyrins

After a great deal of experimentation,[48] a particular cofacial bis(cobalt) diporphyrin, $[Co_2(FTF4)]$,[55] adsorbed on an EPG electrode was found to catalyze the reduction of O_2 by an overall four-electron change—without the intermediacy of free H_2O_2. By exploring a range of cofacial diporphyrins possessing different linking groups, containing different metal centers, and having diverse metal–metal separations, we found that only special situations would promote this four-electron change—most other cofacial metallodiporphyrins catalyze the two-electron reduction to H_2O_2.

Nearly contemporaneously, others reported similar four-electron reductions of O_2. One notable class of four-electron O_2 reduction catalysts is the bis(cobalt) complexes of biphenylene- and anthracene-bridged diporphyrins, $[Co_2(DPB)]$ and $[Co_2(DPA)]$, respectively.[56] Other metal complexes of these arene-bridged ligands proved useful in our studies of redox reactions involving H_2 (Section 6) and N_2 (Section 7). To date a wide variety of cofacial diporphyrins have been prepared. Their electrochemical and catalytic dioxygen reduction properties are summarized in Table 2. The remainder of Section 5 describes what is known about the dioxygen reduction mechanism, the factors that determine two- versus four-electron reduction pathways, and the future development of this class of catalysts.

5.2.1. *Rotating Disk Electrochemical Studies*

The ring-disk experiment[19, 20, 57] shown in Figure 2 illustrates the successful four-electron reduction of O_2 for $[Co_2(FTF4)]$ (analogous experiments with $[Co_2(DPB)]$ and $[Co_2(DPA)]$ yield similar results). The rotating ring-disk electrode (RRDE, see Scheme 3) is placed in contact with an oxygenated aqueous electrolyte solution, and variable potential is applied to the disk, starting from a high, positive potential. The rotation of the electrode assembly causes the electrode products (water and hydrogen peroxide) to be ejected radially across the ring while bringing fresh solution vertically to the disk. As the disk potential is made

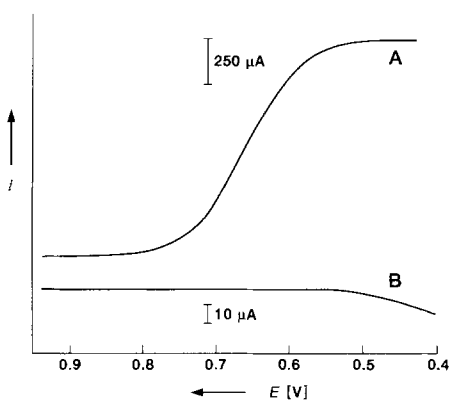


Fig. 2. Rotating ring-disk voltammogram for the reduction of dioxygen by $[Co_2(FTF4)]$. A) Disk current and B) ring current.

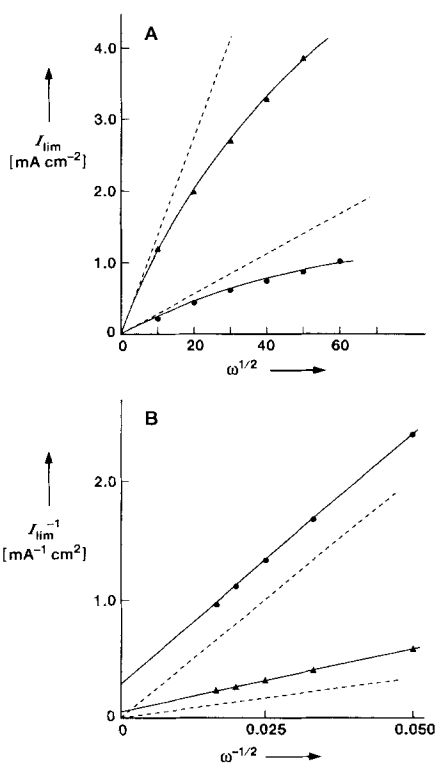
more reducing, the ring potential is held at +1.4 V where any catalytically produced hydrogen peroxide is oxidized back to dioxygen thus allowing sensitive detection of the two-electron product. Note that with the most effective four-electron catalyst, $[Co_2(FTF4)]$, the ring shows no oxidation of H_2O_2 at the platinum ring; thus the 2e product, H_2O_2, is not released to the solution.[33, 55, 58, 59] When the disk potential is scanned more negative than + 0.55 V vs. NHE, the electrode ring begins to sense the production of H_2O_2. Thus $[Co_2(FTF4)]$ catalyzes the four-electron process only over a limited potential range.

The RRDE was used to determine the product distribution and kinetic parameters of these electroreductions.[19, 33, 57] It is possible to quantify the production of hydrogen peroxide using the collection efficiency, N_0,[19, 65] and the ratio of the currents at the ring and disk. However, the magnitudes of the ring currents are often low and irreproducible.[58, 63, 66] The dependence of the disk currents upon the rotation rate ω often yields more quantitative information. As the ring-disk assembly is rotated more rapidly, the rate of delivery of the substrate from solution to the disk is increased. Correspondingly, the overall rate of the catalytic reduction of O_2 is increased as manifested by increased disk currents. The limiting current is proportional to $\omega^{1/2}$ and to the number of electrons (n) in the reduction as described by the Levich equation.[67]

Figure 3 shows the experimental and calculated Levich[67] and Koutecky–Levich plots[68] for RDE voltammograms of dioxygen reduction by $[Co_2(FTF4)]$ on EPG at increasing rotation rates. At higher rotation rates the experimental Levich curve increasingly deviates from the calculated line because the reaction rate is no longer limited simply by the rate of dioxygen delivery to the electrode. This curvature is consistent with a rate-limiting chemical step preceeding the electron transfer step(s) and likely reflects the rate of either dioxygen binding to the catalyst and/or protonation of the bound substrate.[33, 58] The experimental Koutecky–Levich (K–L) plots are linear and have the same slopes as the calculated four-electron line. From the intercept of the K–L plot and the surface coverage, the rate of dioxygen reduction can be determined (ca. 400 s^{-1} for $[Co_2(FTF4)]$).[58] Through the use of the RRDE, a number of cofacial metallodiporphyrins have been screened for four-electron reduction activity and these results are summarized in Table 2.



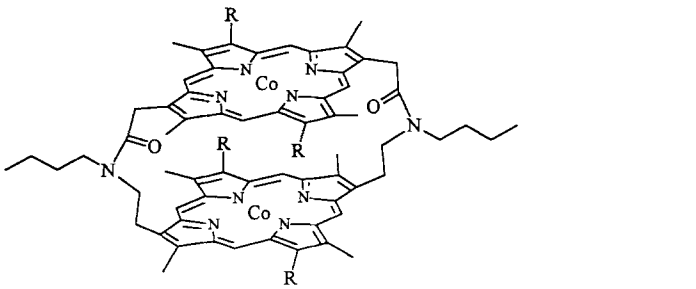


Fig. 3. Levich (A) and Koutecky–Levich (B) plots of rotating disk limiting currents in air (●) and dioxygen saturated (▲) 1 M CF_3COOH (TFA). The dashed lines represent the calculated responses for the mass transfer limited, four-electron reductions of dioxygen in air- and dioxygen-saturated solutions. ω in rpm.

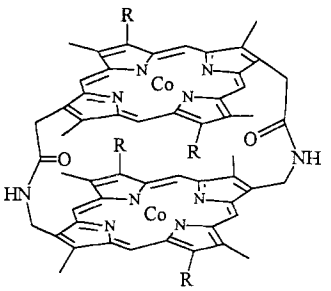
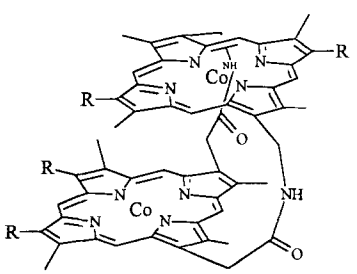
5.2.2. *Fundamental Characteristics of the Dioxygen Electroreduction*



A series of cofacial bis(cobalt)-substituted diporphyrin catalysts were systematically examined for their activity in the four-electron reduction of O_2. As shown in Table 2, only three catalysts show excellent four-electron activity (FTF4, DPB, and DPA); the others vary from pure two-electron activity to intermediate values. The extent of four-electron activity depends both on the nature of the two metal centers and the distance between them. The distance dependence is more pronounced in the FT*Fn* series[58] than in the related DPB, DPA family.[61] Apparently, a preferred orientation of the two metal sites is necessary to stabilize intermediates and guide the reaction along the four-electron path. The fact that complexes $[Co_2(DPB)]$ and $[Co_2(DPA)]$ with arene bridges have Co–Co separations that vary by nearly an Ångstrom,[43] yet have identical catalytic activities,[56] implies that the geometric requirement is less strict in this series. These singly bridged molecules may be flexible enough to adopt the optimum metal–metal distance (see Section 3.4).

The $[Co_2(FTF4)]$ complex mentioned above does not form hydrogen peroxide as a free intermediate in the four-electron reduction of dioxygen.[33, 55, 58] One line of evidence that hydrogen peroxide is not an intermediate is that the ratio of the disk-to-ring current in the RRDE experiment is independent of the rotation rate. If free hydrogen peroxide were produced, at higher rotation rates it would be swept from the electrode surface before it could be further reduced to water and would result in increased ring currents.[69] These complexes do catalyze the reduction of free hydrogen peroxide in the absence of dioxygen,[18, 62] however, the rate is 30-fold slower (the rate constants of the heterogeneous reaction being 0.003 vs. 0.98 cm s^{-1} for the $[Co_2(FTF4)]$[18] catalyst) than the rate of dioxygen reduction.



A more detailed understanding of the mechanism of the four-electron reduction can be obtained by reexamining the thermodynamic potentials of overall redox transformations of O_2 to H_2O (see Scheme 11). Note that the thermodynamic potential for the two-electron change occurs at about 0.7 V (at pH = 0). It is significant that all of the overall four-electron catalysts thus far discovered begin the electrocatalytic reduction of O_2 at values near 0.7 V. A logical interpretation of this result is that all of these reactions proceed through an intermediate which has the character of H_2O_2. This peroxide probably remains bound due to kinetic factors such as decreased lability due to chelation by two metals and more rapid subsequent reduction to H_2O compared with hydrolysis, which would release free H_2O_2.

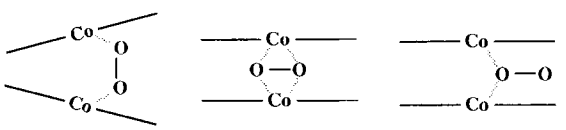
[a] For compound abbreviations see Schemes 5 and 6. $E_{surface}$ is the $E_{1/2}$ value determined for the surface adsorbed porphyrin from cyclic voltammetry. $E_{1/2}(O_2)$ is the half-wave potential for dioxygen reduction found from the RDE experiments. I_{lim} is the limiting current from the RDE experiement at the designated rotation rate ω. All electrolyte solutions are saturated with dioxygen unless otherwise noted. The number of electrons, n, transferred in the dioxygen reduction is determined by Koutecký–Levich analysis or estimated from the data given in the indicated references. All potentials given are vs. NHE. Those originally reported vs. SCE were converted using NHE = SCE + 0.242 V. [b] When two values are given, they are for the two distinct surface waves or dioxygen reduction waves. [c] Air-saturated electrolyte. [d] *p*TPyrP = *meso*-tetrakis(4-pyridyl)porphyrin.

The distribution of two- and four-electron products is strongly dependent on the pH of the oxygenated electrolyte solution.[33, 58, 62] For [Co_2(FTF4)], below pH = 3.5 little or no H_2O_2 is detected by the Pt ring, indicative of a four-electron process. Reductions carried out at pH values above 4.5 yield predominantly hydrogen peroxide, the product of the two-electron reduction. These results suggest that a relatively strong acid ($pK_a < 4.5$) is needed to promote subsequent reduction of intermediates by an apparent heterolytic O–O bond cleavage reaction. Above pH = 6, surface voltammetry of the catalyst under N_2 suggests that oxo or hydroxo ligands bind to the cobalt centers, possibly blocking the active site of the catalyst so that two-electron reduction occurs at the exterior cobalt site in the same manner as for monomeric cobalt porphyrins.[70]

5.2.3. *The Mechanism of Dioxygen Reduction in Catalysis by Cofacial Bis(Cobalt) Diporphyrins*



Next, consider the probable "activated complex" that is the structure of the electrocatalytic system that initiates the kinetically slow step in four-electron reduction. First it has been demonstrated that the rate of O_2 reduction is linearly related to the cofacial diporphyrin catalyst concentration.[18] Second the limiting current and therefore the reaction rate is proportional to the partial pressure of O_2. This suggests that the catalyst becomes oxygenated before or during the rate-limiting step. Finally, the pH dependence indicates that bound O_2 is probably protonated giving a conjugate acid with a pK_a value of about 4.0. Thus, it seems probable that binding/protonation of O_2 to the catalyst site is rate-limiting; this leaves in question the oxidation state of the bis(cobalt) complex that binds O_2.

Initially, we assigned the most active form of the catalyst by examining the cyclic voltammetry of the catalytic electrode in the absence of O_2; a surface wave was found close to the potential at which the four-electron reduction of O_2 begins.[33] The active form of the catalyst was first assigned to the $Co^{II}Co^{II}$ state. Subsequently, solution studies[71, 72] showed that the mixed-valence form of the catalyst, $Co^{II}Co^{III}$, exhibits a very high affinity for O_2, much more so than the $Co^{II}Co^{II}$ state. The intermediate complex can be thought of as a μ-superoxo complex, in which an O_2 ion is simultaneously bound to two equivalent Co^{III} sites. This hypothesis is well supported by equilibrium binding studies,[72] as well as isolation and full characterization[31] of the intermediate. Differential pulse polarographic investigations of [Co_2(FTF4)] surface waves over a wide pH range and in the presence of axial ligands suggest that the surface wave associated most closely with dioxygen reduction is a $Co^{III}Co^{III}$ to $Co^{II}Co^{III}$ process.[18, 73] We conclude that the mixed-valence complex is the active form of the catalyst. This idea is reinforced by the observation that when the electrocatalytic reaction is performed at more reducing (lower) potentials, the rotating ring-disk experiment shows some production of H_2O_2.[33] At these more reducing potentials the $Co^{II}Co^{II}$ form of the catalyst would be present on the electrode. Apparently, it is less effective in promoting the four-electron pathway.

Additional evidence for the mixed-valence hypothesis comes from the fact that only one redox-active metal, Co, need be present to catalyze the four-electron reduction. When one Co atom is substituted by a redox-inactive metal having the same

charge, Al^{III}, a four-electron reduction of O_2 is observed in parallel to the two-electron reduction.[60] In fact, it was found that only a single cobalt atom need be present in the cofacial porphyrin system with the other ring in its protonated "free base" form.[60, 62] This protonated form can serve as a Lewis acid effecting four-electron reduction of O_2. Thus, in the mixed-valence complex, $Co^{II}Co^{III}$, the Co^{III} is probably serving as a Lewis acid site. If, however, the other porphyrin ring is substituted with a metal such as Cu (which has no affinity for any axial ligand), only two-electron reduction of O_2 is observed.[60] A Lewis acid is probably required to hold the partially reduced substrate in the diporphyrin cavity so that it does not dissociate before complete reduction.

The efficiency of catalysis is controlled not only by the choice of metals, but also by the M–M distance of the cofacial metallodiporphyrin (see Section 3 and Table 2). Structural and spectroscopic studies to elucidate the geometry and reactivity of the μ-superoxo complex (a putative intermediate along the catalytic pathway) have been attempted. Based upon X-ray crystal structures of the bis(cobalt) derivatives[31, 44] and EPR[31, 33, 71, 74] and Raman studies[75] of μ-superoxo complexes of the bis(cobalt) compound, plausible geometries of the transition state incorporating the proton have been proposed (Scheme 12).[31, 44, 75] The precise geometry remains a matter of speculation. The proton is not shown in Scheme 12

Scheme 12. Proposed dioxygen binding modes for $[Co_2(FTF4)]$.

5.3. Recent Developements and Future Challenges

Recently other catalysts have been shown to promote the four-electron reduction of O_2. A remarkable example, which is still not well understood mechanistically, is the catalysis by the monoporphyrin [Ir(OEP)H].[50] This system is as good a four-electron catalyst as the previous, best bis(cobalt) complexes (Table 2). Catalysis is also observed when [Ir(OEP)I] or [Ir(OEP)OOH] is initially deposited on the electrode, but only after an activation process at a reducing potential. The dimer, $[Ir(OEP)]_2$, exhibits good catalytic activity without any activation. Whether or not the Ir–Ir bond of the dimer reacts directly with O_2 is a major question. This Ir catalyst shows similarities to the bis(cobalt) complexes. Its activity is also pH dependent, but not as dramatically as that of the bis(cobalt) systems; both have the same initial limiting potential, 0.7 V. In contrast, the [Ir(OEP)] system does not reduce free H_2O_2 and sustains four-electron reduction over a greater potential range than the bis(cobalt) systems (Fig. 4). Despite its greater potential range for pure four-electron reduction, the [Ir(OEP)] catalyst becomes almost inactive at potentials more reducing than 0.2 V vs. NHE.

Another important but poorly understood aspect of the electrocatalytic reduction of O_2 is the apparent requirement for

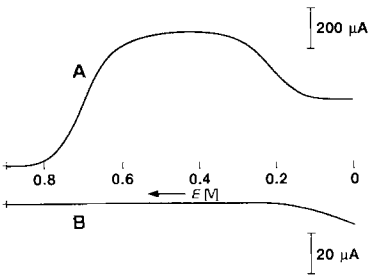


Fig. 4. Rotating ring-disk voltammogram of [Ir(OEP)H] in O_2-saturated solution. A) Disk current and B) ring current. The potential is given relative to the standard hydrogen electrode (SHE).

catalyst adsorption on EPG electrodes. Attempts to bind these catalysts to other electrodes while preserving their four-electron activity have been unsuccessful. For example, experiments in which these catalysts were either in solution or bound to acidic polymers (Nafion) near non-graphitic electrode surfaces failed. Although the underlying reasons for this requirement are not clear, one can speculate about probable causes. It seems likely that the intermediate stages in the four-electron reduction of O_2 are unstable towards hydrolysis. Thus, if electrons are not delivered rapidly enough to these systems, the intermediate H_2O_2 will leach into solution. There may be surface groups on the EPG electrodes[76] that facilitate electron transfer to the cobalt centers or the cobalt–oxygen complex. Another possibility is that there may be some kind of special additional association (axial coordination) with the EPG electrode surface perhaps through a quinone or phenol function associated with the metal sites. There is a very strong association between EPG and these catalysts which seem to bind in tight clusters.[18] More weakly bound catalyst layers are not effective in promoting the four-electron reduction of O_2.[18]

This electrode association phenomenon has one possible exception. Anson et al. found that a special monomeric cobalt (tetrakis(4-pyridyl)porphyrin), with four $[Ru(NH_3)_5]^{2+}$ groups around the porphyrin periphery, can effect the four-electron reduction of O_2 when this complex is incorporated in a Nafion layer next to an EPG electrode surface.[77] Given the strong adsorption of porphyrins to graphite, some or all of the observed catalysis in Nafion may be due to surface-adsorbed porphyrins. Subsequent studies of analogous cobalt porphyrins possessing one to four peripheral ruthenium centers adsorbed directly on to the EPG electrode show that three or more ruthenium centers are required to obtain the four-electron reduction.[64, 78]

The potential at which four-electron reduction occurs for the above ruthenated cobalt porphyrins is much lower than that for the best bis(cobalt) catalyst; furthermore, a two-electron path is always observed (15%). Additionally, the activity of this catalyst is particularly dependent on the method of electrode surface preparation. Although the mechanism of this catalysis is unknown, these results suggest that the Ru centers become fully reduced (to Ru^{II}) and then, in concert with the EPG electrode, deliver all four electrons to the Co-O_2 center. There is a similarity between these results and that of cytochrome *c* oxidase, in which all four electrons must be loaded before the four-electron reduction of O_2 is achieved. The rates of these intramolecular electron transfers are apparently sufficiently rapid to effect four-electron reduction.

Another recent, related application of cofacial metallodiporphyrins is a functional analogue of manganese catalase (pseudo-

catalase).[8] Because the active site of pseudocatalase is thought to consist of two closely spaced manganese centers Naruta et al.[79] employed a cofacial bis(manganese) diporphyrin, [Mn_2(DPB)], to effect the disproportionation of hydrogen peroxide to oxygen and water. In this case the cofacial diporphyrin system appears to create an active reaction center that is bimetallic yet avoids a deleterious side reaction (μ-oxo complex formation).

Dioxygen reduction by mono- and cofacial diporphyrins continues to attract interest. In addition to attempts to develop new, more efficient catalysts, there is considerable interest in elucidating the role of the EPG electrode in these electroreductions. Work is in progress to attach cofacial diporphyrins to different electrode surfaces that are more amenable to spectroscopic studies of the catalytic species in situ. Covalent attachment of catalysts to such electrodes should reduce leaching of the catalyst from the electrode surface. The most significant challenge is to try to break the 0.7 V barrier by employing new heterobimetallic systems or through the use of peripherally substituted cofacial diporphyrins. Such peripheral substitution with electronegative groups might also protect the porphyrin ligand from decomposition due to the reduction by-product, H_2O_2.

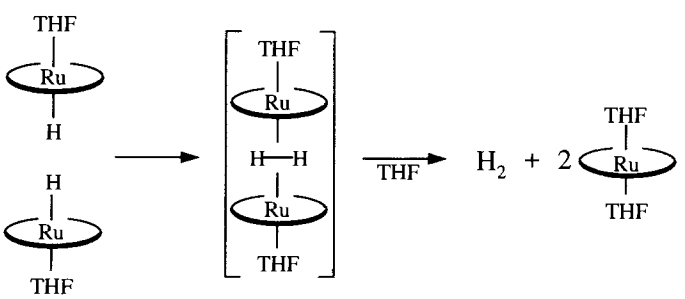
6. The Reduction of Protons and Oxidation of Hydrogen

6.1. Background

The discovery and understanding of molecular electrode catalysts for the hydrogen electrode reaction have captured the attention of chemists for the last century. Efficient catalysts for this reversible two-electron conversion occur naturally in the hydrogenase enzymes; the mechanism is not yet understood.

At several metal surfaces the hydrogen electrode reaction is fully reversible. It thus occurs at the thermodynamic potential, determined by the solution pH according to the Nernst equation specific to this reaction:

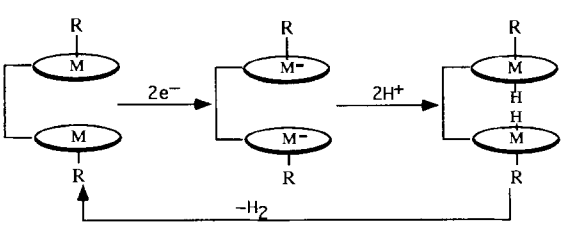
$$2\,H^+ + 2\,e^- \rightleftharpoons H_2$$
$$E_{1/2} = 0.00\ V - 0.059\ V \times pH$$



At many other metal surfaces, however, an overpotential is required to reduce protons or to oxidize hydrogen. As stated in Section 2, this overpotential arises because the reduction of a single proton by one electron, which results in the formation of an unstable hydrogen atom [Eq. (a)], occurs at -2.10 V vs. NHE.[17]

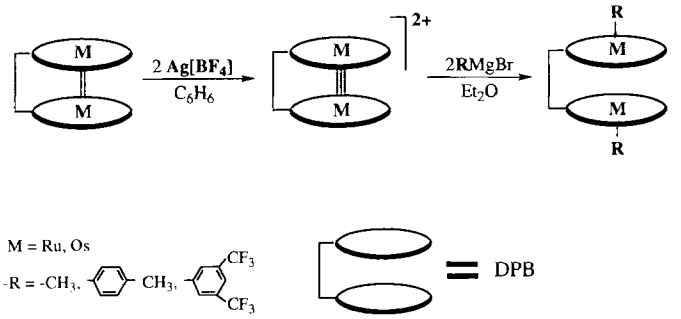
$$H^+ + e^- \longrightarrow H^\bullet \qquad \text{(a)}$$

The oxidation of dihydrogen must also proceed along extremely unfavorable pathways: either the initial oxidation of H_2 to H_2^+ if oxidation occurs first, or the deprotonation of H_2 to H^- if deprotonation occurs first. Lowering the barrier of these high-energy pathways allows certain metal surfaces to catalyze the hydrogen electrode reaction. Presumably, hydrogenase enzymes utilize the iron or nickel present in the active site to stabilize high-energy intermediates or destabilize the substrate. One of the long-term goals of research into the hydrogen electrode reaction has been to synthesize bimetallic complexes which will show the same catalytic activity as metal surfaces and hydrogenase enzymes.



6.2. Proton Reduction Catalysts

Spiro et al.[80] and Espenson et al.[81] independently developed Co^I complexes which catalytically evolve dihydrogen at relatively low overpotentials. In both systems H_2 production was shown to proceed in part by a mechanism involving both metal centers in which two cobalt hydrides eliminate one molecule of dihydrogen. In order to facilitate hydrogen elimination from two metal hydrides, both Bitterwolf et al.[82] and Mueller-Westerhoff et al.[83] have prepared bridged bis(metallocenes) in which the two metal hydrides are held in close proximity. These systems catalytically reduce protons to hydrogen as well, presumably through a dinuclear elimination of hydrogen from the two linked metal hydrides. Research in our own laboratories has demonstrated that ruthenium(III) and osmium(III) octaethylporphyrin hydrides also eliminate hydrogen by an analogous mechanism[84] (Scheme 13). These results suggested that cofacial metallodiporphyrins might act as efficient electrocatalysts for proton reduction.



Scheme 13. Schematic illustration for the reductive elimination of dihydrogen from [Ru(OEP)(thf)H].

The challenge of this research was to synthesize a cofacial metallodiporphyrin with the outer faces blocked by axial ligands so that two protons could react with the metals only on the inside of the pocket. The resulting metal hydrides would then be in the ideal geometry to eliminate dihydrogen. The desired catalytic cycle is shown in Scheme 14. The catalysts shown in Scheme 15 were prepared by alkylation of [Ru_2(DPB)] and [Os_2(DPB)]. These complexes proved to be moderate catalysts (two to three turnovers in 20 minutes) for the reduction of protons at mercury pool electrodes in THF.[85]

Scheme 14. Catalytic cycle for proton reduction using cofacial metallodiporphyrins.

Scheme 15. Synthesis of proton reduction catalysts.

Varying the central metal and axial ligands (Scheme 15) changed the reduction potentials by approximately 600 mV (Table 3). Complexes with more positive reduction potentials may also have lower overpotentials for proton reduction. Unfortunately, the reduced forms of these catalysts become less basic as their reduction potentials become more positive. Thus, stronger acids are needed to carry out the catalysis shown in Scheme 14 for the compounds having more positive reduction potentials. The variation of basicity with reduction potential is that expected from the Nernst equation. Consequently, though cofacial metallodiporphyrin catalysts for proton reduction were prepared, the overpotential was not significantly affected by varying the reduction potential of closely related catalysts. These catalysts are furthermore handicapped by slow reaction kinetics; apparently solvent molecules competitively inhibit the reaction site by coordination with the metal centers.[85]

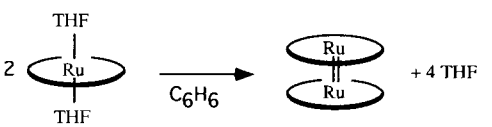
The data were recorded at a scan rate of 100 mVs^{-1}. [b] Conversions used: $FeCp_2^+/FeCp_2 = +0.31$ V vs. SCE; SCE = +0.24 V vs. NHE.

6.3. Hydrogen Oxidation



Oxidation of dihydrogen occurs at its thermodynamic potential at metal surfaces such as platinum. To our knowledge, however, no molecular catalysts for the oxidation of dihydrogen were previously known. Monomeric $[Ru(OEP)(thf)_2]$ is capable of binding dihydrogen which in turn is readily deprotonated. The resulting hydride is capable of reducing NAD^+ analogues and has been invoked in a scheme for H_2O/D_2O exchange.[86] This reactivity is quite reminiscent of hydrogenase enzyme reactivity and suggests that cofacial metallodiporphyrins might be useable as hydrogen oxidation catalysts.

Our approach to this problem[87] was to bind bulky axial ligands to the outer faces of a $[Ru_2(DPB)]$ complex in the presence of 1 atm of dihydrogen. The H_2 could then bind only inside the pocket of the bis(ruthenium) complex. Two equivalents of the bulky imidazole ligand 1-*tert*-butyl-5-phenylimidazole, *Im, were added to $[Ru_2(DPB)]$ in the presence of 1 atm of dihydrogen. The reaction forming $[Ru_2(DPB)(*Im)_2(H_2)]$ (Scheme 16) is quantitative. The dihydrogen molecule is bound as molecular hydrogen with the H–H axis parallel to the porphyrin planes as determined by the dipole–dipole coupling constant in a 620 MHz ^1H NMR experiment.[88] Our hope was that we could readily deprotonate the dihydrogen complex and that the resulting anion would undergo subsequent oxidation. Unfortunately, the complex does not deprotonate even with very strong bases such as NaH. This compound also proved to be incapable of hydrogen oxidation or proton reduction catalysis when adsorbed onto an EPG electrode.

Scheme 16. Preparation of the bridged dihydrogen complex $[Ru_2(DPB)(*Im)_2(H_2)]$.

Earlier success with the $[Ru(OEP)(thf)_2]$ monomer[86] suggested that it may be a good hydrogen electrode catalyst. When $[Ru(OEP)(thf)_2]$ is adsorbed onto an EPG electrode moderate hydrogen oxidation activity is found with an overpotential of 0.15 V. Further experiments demonstrated that the active form of the catalyst was actually the "cofacial dimer" $[Ru(OEP)]_2$ resulting from dimerization of two $[Ru(OEP)(thf)_2]$ molecules to form a Ru–Ru double bond. Such a dimerization has also been observed in solution (Scheme 17).[89] Rotating disk experiments with $[Ru(OEP)]_2$ adsorbed onto an EPG electrode in a basic aqueous solution saturated with both argon and hydrogen are shown in Figure 5. Note the significant oxidation wave in the hydrogen-saturated solution (Fig. 5b) which is not present under argon (Fig. 5a). The catalytic wave was also absent if no catalyst was adsorbed onto the electrode.[88]

Scheme 17. Dimerization reaction of $[Ru(OEP)(thf)_2]$.

Curiously, there is an absence of a steady-state current (i.e. the i-V curve has a peak rather than a steady-state plateau) in the slow scan rotating disk experiment under hydrogen. (Note the similarity between this behavior and that discussed earlier for dioxygen reduction, Sections 5.2 and 5.3.) The decrease in the oxidation current after the plateau indicates that the dihydrogen oxidation process is being inactivated at more positive

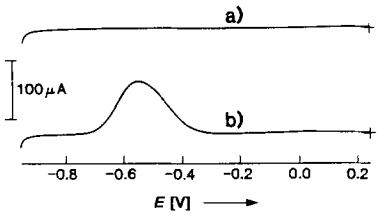


Fig. 5. Rotating disk voltammograms of a $[Ru(OEP)]_2$-modified EPG electrode in a basic aqueous solution (pH = 13). Scan rate = $5\,mVs^{-1}$, $\omega = 100$ rpm. a) Argon-saturated solution, b) hydrogen-saturated solution.

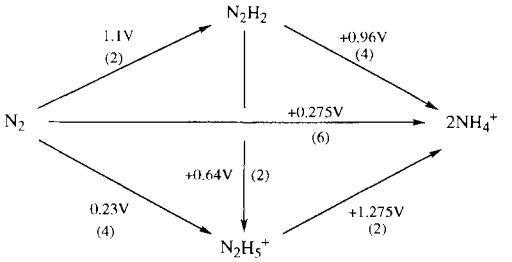
potentials. This is strictly an inactivation of the catalyst and *not* a destruction of the catalyst; subsequent scans through the wave show identical behavior. This decrease in oxidation current as the electrode is biased more positive suggests that the binding of dihydrogen occurs only within a certain potential window. At more positive potentials, the catalyst may be in an oxidized form which does not bind dihydrogen.[88]



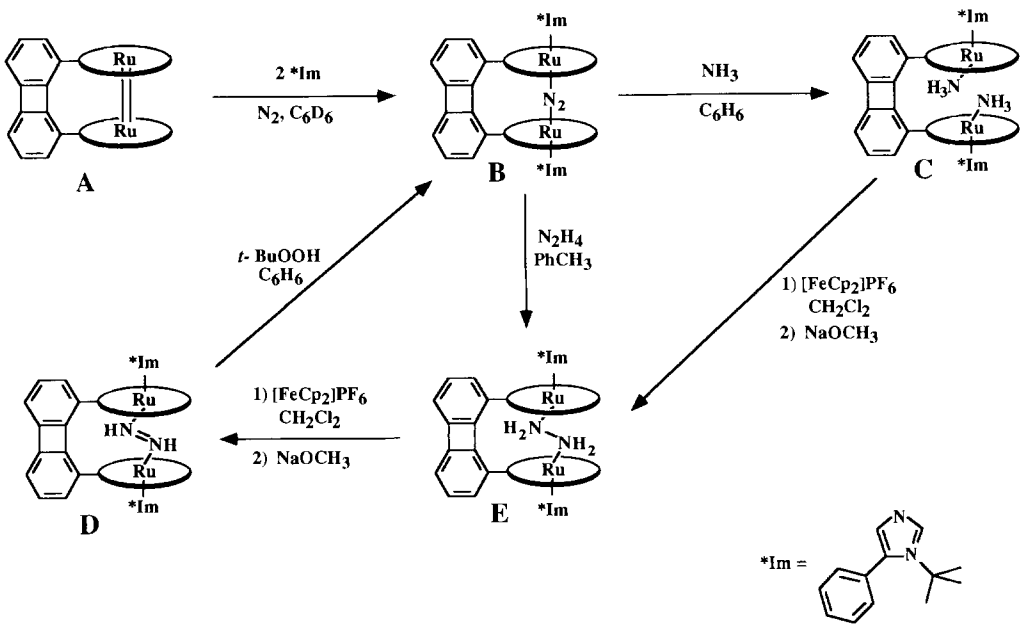
The oxidation current for dihydrogen is also pH dependent. (Again, this behavior parallels the case for the diporphyrin catalyzed oxygen reduction discussed in Section 5.) When identical experiments were performed in solutions in the pH range 10–13, the oxidation wave was found to move to a more positive potential and the current to decrease in intensity with decreasing pH, until the oxidation is nearly unobservable at pH = 10. Presumably, bound dihydrogen cannot be deprotonated when the pH of the solution is less than 10. Additionally, there is a decrease in the oxidation current when the solution pH is changed from 13 to 14. Addition of 1 M KBr to solutions at pH 13 also suppressed the oxidation current. Addition of 1 drop of pyridine (< 0.1% v/v) to the pH 13 solution completely suppressed the oxidation current. These experiments suggest that other ligands (OH^-, Br^- and pyridine) compete for the binding site of dihydrogen.[88]

Though the mechanism for this hydrogen oxidation remains largely unknown, the above experiments suggest that the binding of dihydrogen to a metal and the deprotonation are important steps. Unfortunately, these two requirements oppose each other. Binding of dihydrogen requires electron density on the metal to be donated into the antibonding orbitals of dihydrogen. Unfortunately, this renders the bound dihydrogen less acidic. Too little electron donation from the metal to dihydrogen renders the dihydrogen complex too short-lived to be deprotonated. On the other hand too much electron donation renders the bound dihydrogen too hydridic to be deprotonated. This latter phenomenon is responsible for the catalytic impotence of the $[Ru_2(DPB)(*Im)_2(H_2)]$ complex. Such a dilemma demonstrates the tightrope that must be traversed in designing these electrocatalysts.

7. The Interconversion of Dinitrogen and Its Nitrogen Hydrides

7.1. Background

Dinitrogen is perhaps the most challenging substrate to reduce electrocatalytically. Rupture of the first π bond of the N–N triple bond requires 130 kcal mol^{-1}, and the first ionization potential (15.6 eV) of the N_2 molecule rivals that of argon.[90] Various multielectron pathways linking dinitrogen with ammonia are shown in Scheme 18. Although the initial electron transfers are difficult, the overall thermodynamics of four- and



Scheme 18. Reduction of dinitrogen to ammonia.

six-electron reductions are exergonic. As was the case for dioxygen reduction (Section 5.1), the key to successful catalyst design is to avoid the initial one- or two-electron paths.

Although we proposed in 1977 that the cofacial metallodiporphyrin approach might also be applied to the electroreduction of dinitrogen,[24] progress toward this goal has been much slower than the development of the four-electron dioxygen catalysts. Although we were drawn initially toward early transition metal and certain heterobimetallic complexes of cofacial diporphyrins,[91] our primary target was a bis(ruthenium) compound because of the known dinitrogen coordination chemistry of ruthenium porphyrins.[92] The limited reactivity of known, bridged dinitrogen complexes[93] suggested that a bis(ruthenium) diporphyrin would not be a good dinitrogen electrode catalyst. However, through the study of the bis(ruthenium) dinitrogen complex and its nitrogen hydride analogues we hoped to learn which factors were important in designing better catalysts. Although the goal of electroreduction of dinitrogen to hydrazine (four electrons) or ammonia (six electrons) has still not been achieved, the information from these solution studies is being applied toward developing a functional electroreduction catalyst.

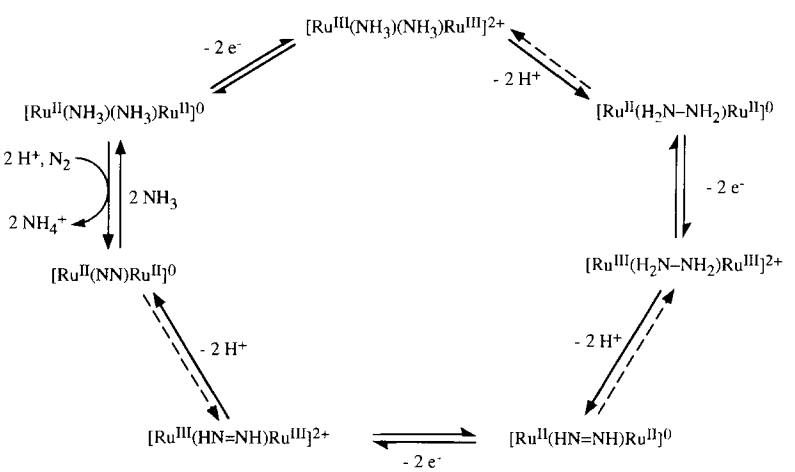
7.2. Stable Nitrogen and Nitrogen Hydride Complexes

The first step toward developing a dinitrogen electroreduction catalyst was to find a cofacial bis(ruthenium) diporphyrin that has a reasonable dinitrogen affinity and binds dinitrogen *between* the two metals. Initially, bis(ruthenium) complexes of FTF4, DPB, and DPA with exterior axial triphenylphosphane ligands and open internal coordination sites inside were prepared.[91] Although these complexes bind hydrazine within the cavity, they have no affinity for dinitrogen. After some experimentation, it was found that use of a nitrogenous axial ligand, 1-*tert*-butyl-5-phenylimidazole, provides a bis-five-coordinate complex that has a substantial dinitrogen affinity[94] (see Scheme 19). In fact, this N_2 complex, $[(\mu\text{-}N_2)Ru_2(DPB)(Im^*)_2]$, is substantially more stable than corresponding ruthenium monoporphyrin N_2 complexes (perhaps because of the "chelate" effect of the two metal centers).[47] The dinitrogen complex has been well-characterized[47] and seems to have the properties of a linear, bridged dinitrogen complex such as $[\{Ru(NH_3)_5\}_2N_2]$.[93] That the DPB framework can accomodate this geometry is unexpected given its dimensions (Section 3.3.4). There must be considerable flexibility in the porphyrin rings and/or displacement of the metal centers from the planes of the porphyrin rings. Given the bridging nature of this dinitrogen complex, one would

Scheme 19. Synthetic interconversions of dinitrogen and nitrogen hydride complexes of $[Ru_2(DPB)]$. **A**) The metal–metal bonded dimer, $[Ru_2(DPB)]$, **B**) the bridged dinitrogen complex, $[(\mu\text{-}N_2)Ru_2(DPB)(*Im)_2]$, **C**) the bis(ammine) complex, $[(NH_3)_2Ru_2(DPB)(*Im)_2]$, **D**) the bridged diazene complex, $[(\mu\text{-}N_2H_2)Ru_2(DPB)(*Im)_2]$, and **E**) the bridged hydrazine complex, $[(\mu\text{-}N_2H_4)Ru_2(DPB)(*Im)_2]$.

predict that it is not easily protonated.[47] Indeed, a very strong acid is required to protonate this complex (Section 7.4).

In hope of learning the requirements for a successful dinitrogen reduction catalyst, the plausible two-electron/two-proton intermediates (diazene, hydrazine, and bis(ammine) complexes) along the multielectron reduction pathway were prepared and characterized.[94] The synthetic methodology is shown in Scheme 19. The process of developing synthetic, oxidative conversions between these species led to a more detailed examination of these oxidations to determine whether the nature of these transformations could yield information about catalytic conversions between dinitrogen and ammonia.



7.3. Oxidative Interconversions and Ammonia Oxidation

Oxidation of the bis(ammine) complex **C** with *tert*-butylhydroperoxide led not only to formation of the bridged hydrazine-complex **E**, but also to formation of the bridged diazene and dinitrogen complexes (**D** and **B**, respectively). Subsequent electrochemical oxidations as well as chemical oxidations employing either atom-transfer reagents such as *tert*-butylhydroperoxide or a combination of an outer-sphere oxidant (ferricinium) and a base were investigated to understand the redox and acid-base chemistry of each of the two-electron/two-proton steps. All of these intermediates have now been connected by oxidation, deprotonation, and ligand replacement reactions which describe a cycle (Scheme 20) for ammonia oxidation and provide insight into the reverse process, dinitrogen reduction.

The redox potential and a limiting pK_a of the base required for deprotonation in each of the oxidation steps has been determined.[95] Because the bis(ammine) complex **C** and the bridged hydrazine complex **E** could not be deprotonated (over the pH range studied) prior to oxidation,[95] the order of removal of electrons and protons from the complexes is known. In the pH range of the experiments ($pH \leq 16$), it appears that oxidation must occur prior to deprotonation in all steps. The most difficult oxidation and deprotonation of these conversions set pH and potential limits on this ammonia oxidation cycle ($+0.71$ V vs. NHE for the second oxidation of the diazene complex and a pK_a of about 16 for the deprotonation of the dicationic diruthenium bis(ammine) complex). Thus, for the cycle to proceed, the potential must be $\geq +0.71$ V and the pH of the solution ≥ 16.

A key transformation that cannot be controlled by pH or electrode potential is the N–N bond forming step ($[Ru^{III}(NH_3)(NH_3)Ru^{III}]^{2+} \rightleftharpoons [Ru^{II}(NH_2\text{–}NH_2)Ru^{II}]$). This thermally controlled step proceeds rapidly during oxidation, however, its reverse, an endothermic bond cleavage reaction, is likely to impede possible reduction cycles.

A possible kinetic limitation for the ammonia oxidation cycle involves replacement of the product (dinitrogen) by reactant (ammonia). The dinitrogen ligand is replaced slowly by ammo-

Scheme. 20. Catalytic oxidation (and reduction) cycle linking NH_3 and N_2. The bold arrows represent steps which have been accomplished.

nia in the neutral $Ru^{II}Ru^{II}$ complex; however, under the conditions required for ammonia oxidation catalysis, the complex should exist in the $Ru^{II}Ru^{III}$ state where the dinitrogen ligand would be much more easily replaced.[95]

Attempts to observe ammonia oxidation catalysis utilizing the dinitrogen complex adsorbed on EPG electrodes were unsuccessful, since uncoated EPG itself is a reasonable oxidation catalyst. Future research will be directed at attaching these catalysts to less active electrode materials.

7.4. Prospects for a Dinitrogen Reduction Catalyst

Our initial goal was to try to develop a dinitrogen reduction catalyst. Based on the oxidation chemistry described in Section 7.3, we can comment on the requirements for such a catalyst. Considering the reverse reaction of each oxidation step in the context of microscopic reversibility, it is predicted that the reductions will occur by first proton, then electron, addition. The limiting conditions for dinitrogen reduction can also be estimated (-0.22 V vs. NHE to reduce the diazene complex monocation and an acid stronger than trifluoroacetic acid to protonate the dinitrogen ligand). It is unlikely that any catalyst based on this system could reduce dinitrogen beyond the hydrazine intermediate due to the apparent required thermal N–N bond cleavage (see Section 7.3).[95]

In order to design a catalyst that can carry out the reduction of nitrogen to ammonia, a different reaction pathway may be required. In particular, metals having a lower d-electron count that favor formation of metal nitrides may be necessary. Possible catalysts employing cofacial diporphyrins containing transition metals found in the nitrogenase enzymes such as molybdenum, vanadium and iron are presently being studied.

8. Summary and Outlook

Some general principles of catalyst design can be gleaned from the results obtained with cofacial diporphyrin catalysts for multielectron redox reactions. The engineered cofacial diporphyrins provide a powerful framework for developing constrained bimetallic reaction centers. The multielectron catalytic pathways can be broken down into individual steps, which often can be studied independently. Additionally, using the principle of microscopic reversibility, the reverse catalytic cycle can be used to gain insight into the forward process.

A strong connection exists between the coordination and reactivity of the bound substrate. The chemical properties of the catalyst/substrate complex are perhaps more important than the catalyst's affinity for the substrate. For example, coordination of O_2 leads immediately to a partially reduced substrate (O_2^-). Conversely, coordination of H_2 renders this ligand acidic and facilitates deprotonation and subsequent oxidation. Coordination of N_2 by certain metal complexes, on the other hand, renders this ligand basic, facilitating protonation and further reduction.

Electrochemical limitations of a pathway derive from the most reducing or most oxidizing potential required for a catalytic reduction or oxidation, respectively. For example, the potential necessary for the catalytic reduction of dioxygen must be more negative than the most reducing potential for any single step. However, if the electrode potential is made too negative, the oxidation state of the catalyst will change and the activity of the catalyst may decrease. Similar potential dependencies are apparent for dihydrogen oxidation and dinitrogen reduction. *Thus, these molecular catalysts are active only within a well-defined potential range.*

Limiting pH ranges can be predicted from the Brønsted acidities of intermediates. Dihydrogen oxidation is a good example. This oxidation requires a deprotonation of bound dihydrogen, and thus the pH of the solution must be near or greater than the pK_a of bound dihydrogen. Again, similar behavior in proton reduction, oxygen reduction, and nitrogen reduction is observed.

Taken together, these considerations lead to an understanding of the limiting potential for the overall electrocatalytic reaction and the pH range under which this will function. From the overall limiting potential, one sees that most catalysts operate at an overpotential. One important caveat stems from this fact: *if there is an overpotential for the catalytic system in one direction, it is thermodynamically impossible for that catalyst to work using the microscopic reverse of the forward pathway.* Performing such a process would mean operating at an "underpotential". All of the catalysts surveyed here operate with an overpotential. Thus, it appears that most successful electrocatalysts will be useful in only one direction; a different or modified catalyst must be discovered for the reverse reaction.

Cofacial metallodiporphyrin catalysts appear to be most efficient when they are intimately associated with the electrode. This suggests rapid electron transfer is necessary, so that the desired electrocatalytic transformation occurs more rapidly than deleterious side reactions not involving electron transfer (such as hydrolysis or dissociation). In one case, a catalyst previously loaded with all four electrons required for O_2 reduction gives some four-electron reaction.[79] This system is reminiscent of enzymes such as cytochrome *c* oxidase, which are only effective when all four reducing equivalents are loaded.

Finally, the product of an electrocatalytic transformation must be labile; otherwise this product will inhibit further electrocatalytic cycling. For example, the two NH_3 molecules in nitrogenase enzymes must be replaced by N_2. It is interesting to note that this is possible in the bis(ruthenium) system that we have studied.

The role of a second metal (when required) varies. Both metals may be redox-active (as in the case of the bis(cobalt) catalyst for the reduction of O_2). Alternatively, the second metal may serve as a Lewis acid which both activates substrate and intermediates towards further reduction and kinetically stabilizes these intermediates, preventing undesirable side reactions along the multielectron path.

Examination of these electrocatalysts reveals similarities between the metallodiporphyrin catalysts and the respective enzyme systems, even though they are structurally different. One example of this is found in the overpotential for cytochrome *c* oxidase compared with the overpotential for the four-electron O_2 reducing catalysts (when these are adjusted for differences in pH). Apparently, both systems go through the same thermodynamic barrier, involving the intermediacy of bound peroxide. Parallels also exist between the H_2 oxidizing system and hydro-

genases. Experiments have shown that the [Ru(OEP)] catalyst is capable of activating dihydrogen to deprotonation, affording a hydride which is capable of reactivity similar to that manifested by the hydrogenase systems.[86] It is also curious that nitrogenase enzymes produce H_2 during nitrogen fixation. The bis(ruthenium) cofacial diporphyrin system described in Section 7, which binds dinitrogen tenaciously, forms a stable H_2 complex, which can be displaced by N_2. It is tempting to suggest nitrogenase enzymes carry out a prior reduction of H^+ and that the resulting H_2 complex "reserves" a coordination site for the incoming N_2 ligand.[111]

Systematic investigation has allowed us to break down the multielectron redox transformations into a series of steps. Many of the problems in these simple steps have not been solved but rather defined. Solutions to the overpotential and reversibility problems are still actively being sought. Searches are not confined to the substrates mentioned above, but include methane activation, water oxidation, CO_2 and CO reduction, and others. The search for new and better catalysts continues to be guided by the desire for a deeper understanding of how the natural enzymes solve such seemingly complex problems with relative ease.

The work described in this review was the result several important collaborations. The collaborative efforts of Prof. Fred Anson, Carl Koval, Richard Durand, and Prof. Nate Lewis at Cal Tech; Howard Tennent at Hercules Powder Co; Prof. Maurice L'Her and Yves LeMest at Université de Bretagne Occidentale, Brest, France; and Prof. Roger Guilard and Michel Angel Lopez at Université de Bourgogne, Dijon, France were most crucial. For the results obtained at Stanford, the creativity and hard work of a number of past students and research associates are most appreciated. The contributions of these associates are included in the reference section of this review. Among the key contributors to these projects are: Carmen Susanna Bencosme, Craig Barnes, Leng Leng Chng, Peter J. Denisevich, Eric Evitt, Michael Elliot, Matthew Ennis, Robert Gagne, Yunkyoung Ha, Thomas R. Halbert, Neil Hendricks, Kimoon Kim, Yutaka Konai, Charles Leidner, Matthew Marrocco, Brian Miller, Lisa McElwee White, Kurt Meier, Bryan D. Miller, Eric Schmittou, and Ben Tovrog. We thank Prof. Royce Murray (University of North Carolina), and Prof. Robert Hembre (University of Nebraska), for critical discussions and suggestions, and Hilary Arnold, Leng Leng Chng, H. T. Fish, and David Tyvoll for proofreading. Financial support from the NSF and NIH is gratefully acknowledged.

[54] The binding of O_2 is, itself, a redox reaction in which simultaneously the metal center undergoes a one-electron oxidation and O_2 undergoes a one-electron reduction in the formation of the metal-dioxygen complex. There is a strong correlation between the $E_{1/2}$ value for M^{II}/M^{III} reduction and the affinity for O_2: lower $E_{1/2}$ values result in greater O_2 equilibrium affinities.

Synthesis and Reactions of Optically Active Cyanohydrins

Franz Effenberger*

Cyanohydrins have always held a place of importance both as technical products and as reagents in organic chemistry. It is surprising, therefore, that optically active cyanohydrins have been extensively investigated and employed for syntheses relatively recently. This can be explained by the fact that only in the past few years have enzymatic methods made chiral cyanohydrins readily available in high optical purity. Chiral cyanohydrins are widespread in nature in the form of the respective glycosides and serve roughly 3000 plants and many insects as antifeedants. For the preparative organic chemist, this class of compounds offers an enormous synthetic potential for making other chiral compounds accessible. In a few instances, the pharmacological principle of a drug also incorporates a chiral cyanohydrin as constitutive structural element. In the development of novel, physiologically active compounds all possible stereoisomers must be synthesized and investigated with respect to their activity range and the pathway of their metabolic transformations and/or degradation. The development of simple synthetic procedures for such compounds, which also entail a high degree of stereoselectivity, therefore has prime importance. To this end chiral cyanohydrins may serve as stereochemically pure starting materials.

In the present review, the following topics will be addressed: enantioselective addition of hydrogen cyanide (HCN), catalyzed by the enzymes (*R*)- and (*S*)-oxynitrilase, to aldehydes and ketones yielding (*R*) and (*S*) cyanohydrins, respectively; enantioselective addition of HCN to aldehydes catalyzed by cyclic dipeptides; enantioselective esterification of racemic cyanohydrins and enantioselective hydrolysis of cyanohydrin esters catalyzed by lipases and esterases, respectively; transformation of the nitrile group of chiral cyanohydrins to provide optically active α-hydroxycarboxylic acids, aldehydes, and ketones, as well as 2-amino alcohols; sulfonylation of the OH group of chiral cyanohydrins to furnish optically active α-sulfonyloxynitriles which undergo S_N2 displacement of the activated OH group yielding α-azido-, α-amino, and α-fluoronitriles with inverted configuration.

1. Introduction

A whole series of procedures has been developed in the last few years for preparing optically active cyanohydrins as precursors for α-hydroxycarboxylic acids, α-hydroxy aldehydes, and vicinal amino alcohols, which have thus become accessible in stereochemically pure form.[1–3]

The stereoselective syntheses of cyanohydrins can be classified into chemical and enzymatic (enzyme-catalyzed) procedures. The most important chemical methods are the diastereoselective addition of trimethylsilyl cyanide[4] and related cyanide-transfer agents[5] to chiral aldehydes, and the enantioselective addition of trimethylsilyl cyanide to aldehydes in the presence of chiral catalysts.[6, 7] Enzymatic procedures leading to optically active cyanohydrins include the oxynitrilase-catalyzed enantioselective addition of HCN to aldehydes, the enantioselective hydrolysis of cyanohydrin ester racemates with esterases, and the enantioselective esterification of cyanohydrin racemates with lipases.

In special cases cyclic dipeptides also catalyze the enantioselective addition of HCN to aldehydes;[8] this procedure does not fit into the chemical/enzymatic classification. Formally, cyclic dipeptides can be considered chiral catalysts; however, structural similarities to the active center of oxynitrilases, the structure of which is not yet known, cannot be ruled out completely.

If one weighs the advantages and disadvantages of the chemical and enzymatic methods for preparing optically active cyanohydrins, the scales tip in favor of enzyme-catalyzed processes as general techniques, both with respect to the *ee* values attainable and possible adaptation for the preparation of cyanohydrins on a technical scale. This does not exclude the possibility, though, that other processes might be more advantageous in special cases.

This review focuses on the enzyme-mediated procedures and the use of cyclic dipeptide catalysts for the synthesis of optically active cyanohydrins, in particular aldehyde cyanohydrins, because of their practical importance. In addition, the tremendous potential of optically active cyanohydrins for the synthesis of other important chiral compounds will be discussed.

2. (*R*)-Oxynitrilase-Mediated Addition of HCN to Aldehydes

One of the first asymmetric synthesis effected by enzymes ("durch Enzyme bewirkte asymmetrische Synthese"[9]), published by L. Rosenthaler in 1908, concerns the preparation of mandelonitrile from benzaldehyde and HCN, with emulsin as source of the enzymatic catalyst. Rosenthaler gave detailed information on the course of the reaction and the effect of the reaction conditions on the optical yield, but this interesting example of an enzyme-catalyzed asymmetric synthesis was not followed up for many years.[10]

More than fifty years later E. Pfeil et al. took up the idea and developed it into a more general procedure. The enzyme (*R*)-oxynitrilase [EC 4.1.2.10], which actually catalyzes the addition of HCN to benzaldehyde, was isolated from bitter almonds (*Prunus amygdalus*), purified, and characterized.[11] It was shown that (*R*)-oxynitrilase accepts other aromatic aldehydes besides its natural substrate benzaldehyde, as well as saturated and unsaturated aliphatic and heterocyclic aldehydes; in each case, the enzyme catalyzes the formation of the corresponding (*R*) cyanohydrin.[12] (*R*)-Mandelonitrile was prepared with 86% *ee* (determined from the specific rotation), which was very high for that time. For less reactive aldehydes, however, the optical yield decreased dramatically; thus, this simple procedure for the preparation of (*R*) cyanohydrins found virtually no practical application for the next two decades.

All efforts failed to improve the optical yields under the conditions used by Pfeil et al. (solvent: water or water/ethanol; pH 5–6 corresponding to the activity optimum of the enzyme).[12b, 13a] Under these conditions the chemical addition of HCN to aldehydes leading to racemic products cannot be suppressed and prevails especially when the enzyme-catalyzed reaction is slow.

The decisive breakthrough for this process came when it was discovered that the undesirable chemical addition is more or less suppressed in organic solvents that are not miscible with water, for example ethyl acetate or diisopropyl ether (Fig. 1).[13] As Figure 1 shows, the uncatalyzed addition of HCN to benzaldehyde is very slow indeed in ethyl acetate. Thus even for aldehydes that are poor substrates for the enzyme, the enzymatic process predominates over the chemical addition in these media, and products with high *ee* values result (see Scheme 1, Table 1).[13] In contrast to most other enzyme-catalyzed reactions, (*R*)-oxynitrilase combines low substrate specificity with high enantioselectivity; for example, it accepts aromatic and aliphatic aldehydes and converts them to the respective cyanohydrins with high enantioselectivity (Table 1). Even with sterically demanding substrates such as isopentyl aldehyde, high

Franz Effenberger was born in 1930 in Goldenstein (North Moravia), studied chemistry from 1951 to 1956 at the Technische Hochschule in Stuttgart, and received his PhD in 1959 with H. Bredereck. He completed his "Habilitation" in Stuttgart in 1964 and spent a year at the University of Michigan, Ann Arbor, with P. A. S. Smith. He was a Winnacker Fellow from 1964 to 1969. In 1972 he succeeded H. Bredereck at the University of Stuttgart. He was a guest professor in 1977 at Cornell University in Ithaca and in 1989 at the Ecole Supérieure de Physique et Chimie Industrielles in Paris. He received the Alexander-von-Humboldt-Forschungspreis in 1991. He is interested in preparative and mechanistic aspects of electron-rich π systems (enol ethers, aminobenzenes, donor–acceptor substituted polyenes, and oligothiophenes), synthesis and reactions of α-amino acids, and applications of enzyme reactions in organic synthesis with emphasis on stereoselective C–C bond formation.

ee values (83%) are obtained. The reaction of 3-phenoxybenzaldehyde strikingly illustrates the advantage of the organic compared to the aqueous reaction medium: the uncatalyzed reaction is suppressed to the extent that even after 192 h the corresponding (*R*) cyanohydrin is obtained with 98% *ee* (Table 1). Only the reaction of pyridine-3-carbaldehyde gives an unsatisfactory optical yield (14% *ee*) in ethyl acetate. A change of the organic medium to diisopropyl ether suffices to raise the *ee* value once more to a satisfactory 82% (Table 1).

The use of organic solvents in enzyme-catalyzed reactions has been widely reported,[14] especially for such processes where water is the actual reagent. Among these are ester-, amide-, and peptide-forming or -cleaving reactions catalyzed by lipases, amidases, and proteases.[14] Water does not actually take part in the (*R*)-oxynitrilase-catalyzed cyanohydrin formation, but it probably promotes the chemical addition of HCN to the carbonyl double bond.

Of the many organic solvents that have been tested for oxynitrilase-mediated reactions,[15] diisopropyl ether has proven especially advantageous with respect to the *ee* values obtained. This is illustrated strikingly by a number of reactions listed in Table 1 which were carried out in both ethyl acetate and diisopropyl ether. Moreover, enzyme activity in diisopropyl ether can be maintained even over a period of several weeks (Fig. 2). In ethyl acetate, in contrast, (*R*)-oxynitrilase activity is diminished by more than 50% within a few hours (Fig. 2). The lower water content in diisopropyl ether compared to that in ethyl acetate[16] apparently affects both (*R*)-oxynitrilase activity and stability very favorably.

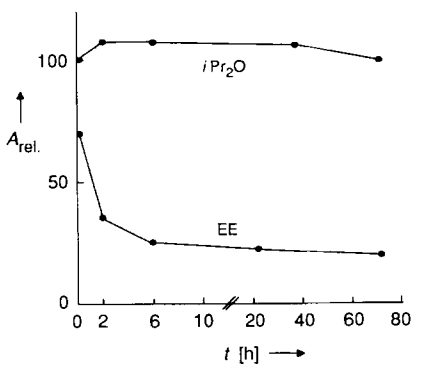

Fig. 2. Plot of the relative activity A of (*R*)-oxynitrilase on a crystalline cellulose support (Avicel) in ethyl acetate (EE) and diisopropyl ether (iPr_2O) [15].

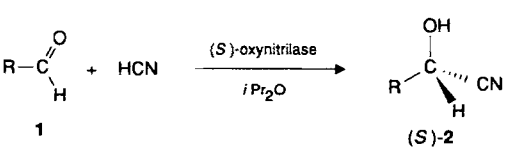
For the reactions carried out in organic solvents it is particularly advantageous to employ enzymes bound to a suitable support, for example a crystalline cellulose material such as Avicel. Thus, the "support-bound" enzyme may be filtered off after the reaction is complete and reused as catalyst. (*R*)-Oxynitrilase in organic solvents also accepts rather high substrate concentrations (up to 2 mol L^{-1}) without decreasing the *ee* values; thus, product formation is characterized by a highly favorable space–time yield.[16] The reaction may even be run in a continuous mode: the starting materials are dissolved in the organic solvent and then passed over a column loaded with the support-bound enzyme,[15a] or alternatively, kept in a membrane reactor whence the products are separated from unreacted starting materials and the catalyst by evaporation.[15b]

In aqueous medium the oxynitrilase-catalyzed addition of HCN to aldehydes may be carried out with high selectivity also by simply lowering the pH of the reaction medium below 4.0, where the chemical addition is largely suppressed.[17] Enzyme activity, however, is also reduced at such low pH values. This may be compensated for by employing higher enzyme concentrations; still, reactions with the less reactive aldehyde substrates have poor selectivity. Also, this process is not conductive to the reaction of aldehydes that are poorly or not at all soluble in water.

Many attempts have been reported to avoid the use of the highly toxic, free hydrogen cyanide in the synthesis of cyanohydrins. For instance, aldehydes in water/ethanol have been treated with potassium cyanide and acetic acid in the presence of (*R*)-oxynitrilase; the respective (*R*) cyanohydrins were obtained, though with lower optical yields.[18] Transcyanation with acetone cyanohydrin as HCN donor in the presence of (*R*)-oxynitrilase has been reported to give (*R*) aldehyde cyanohydrins and acetone;[19] however, the selectivities claimed by the authors could not be reproduced.[20]



3. (*S*)-Oxynitrilase-Mediated Addition of HCN to Aldehydes

An enzyme that preferentially cleaves (*S*) cyanohydrins into aldehydes and HCN, and thus may also be expected to catalyze the reverse reaction, was first isolated from *Sorghum bicolor* and characterized by Conn and Bové in 1961.[21a] This (*S*)-oxynitrilase [EC 4.1.2.11] and the (*R*)-oxynitrilase [EC 4.1.2.10] from bitter almonds differ in both structure[11b, 21b, 22] and catalytic properties. The most striking structural difference is that (*R*)-oxynitrilase has a prosthetic group (flavine adenine dinucleotide, FAD) which is missing in (*S*)-oxynitrilase. Removal of the FAD moiety from the (*R*)-oxynitrilase results in complete loss of the catalytic activity.

It is substantially more time-consuming to isolate amounts of (*S*)-oxynitrilase sufficient for preparative purposes from *Sorghum bicolor* than it is to isolate (*R*)-oxynitrilase from bitter almonds. Consequently, this enzyme has been applied in organic syntheses only very recently.[23, 24]

(*S*)-Oxynitrilase from *Sorghum* catalyzes exclusively addition of HCN to aromatic and heteroaromatic aldehydes to yield the respective (*S*) cyanohydrins (Scheme 2), but it does not accept aliphatic aldehydes as substrates.[23, 24] The selectivities in organic solvents are comparable for the two enzymes (Tables 1, 2).

For the synthesis of (*S*) cyanohydrins, reactions in organic solvents rather than in aqueous medium are particularly advantageous since much smaller amounts of the poorly accessible

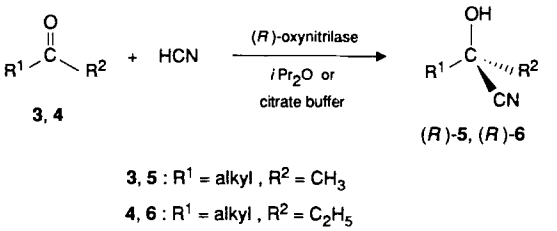
enzyme are required. In addition some technically interesting (*S*) cyanohydrins, such as those from 3-phenoxybenzaldehyde and various heteroaromatic aldehydes, are difficult to prepare in an aqueous system owing to the low solubility of the respective aldehydes.[24]



Recently, the catalytic activity of another (*S*)-oxynitrilase, isolated from the leaves of the rubber plant (*Hevea brasiliensis*), was investigated.[25] In contrast to (*S*)-oxynitrilase from *Sorghum*, this enzyme was found to accept both aliphatic and aromatic aldehydes; however, the enantioselectivity of the reaction proved to be unsatisfactory for a number of substrates tested.[25]

Despite all improvements in the isolation of (*S*)-oxynitrilase from *Sorghum bicolar* L.,[26] industrial application of this enzyme requires the respective gene to be cloned in pro- or eucaryotic organisms and overexpressed. So far, 90% of the native hydroxynitrile lyase (HNL) has in fact been cloned.[26b]

4. (*R*)-Oxynitrilase-Mediated Addition of HCN to Ketones

The few optically active ketone cyanohydrins described in the literature have as a rule been obtained by stereoselective addition of HCN or of cyanides to ketones that already have a stereogenic center. Thus, addition of HCN to 17-oxosteroids proceeds with very high diastereoselectivity.[27] Comparable optical induction is observed for the addition of $Me_2Si(CN)_2$ to chiral β-hydroxyketones,[28] of Et_2AlCN to chiral β-ketosulfoxides,[29] and of trimethyl-(2-propenyl)silane to chiral acyl cyanides.[30] The enantioselective hydrolysis of racemic esters of cyanohydrins with yeast cells from *Pichia miso* gives only poor chemical yield.[31]

The defense mechanism in which HCN is released from *O*-glycosyl cyanohydrins (cyanogenesis) by enzymes, is effective with both aldehyde and ketone cyanohydrins;[32] thus, ketones are likewise expected to be substrates for oxynitrilases. For the (*R*)-oxynitrilase from bitter almonds [EC 4.1.2.10] the natural substrate is benzaldehyde; surprisingly, this enzyme also catalyzes the addition of HCN to ketones (Scheme 3),[33] and (*R*) cyanohydrins are formed from 2-alkanones in good chemical yield and with excellent *ee* values.[33a] 3-Alkanones are much less suitable substrates; the respective cyanohydrins are obtained only with unsatisfactory chemical yield and also much lower optical purity (Table 3).[33] The best results for the synthesis of (*R*) ketone cyanohydrins are again obtained in organic

solvents; the *ee* values for reactions in citrate buffer (pH ≤ 4) are comparable if at least double the amount of enzyme is employed (Table 3).[33b] (*S*)-Oxynitrilase from *Sorghum bicolor* does not accept ketones as substrates.[24]

5. Cyclodipeptides as Catalysts for the Enantioselective Addition of HCN to Aldehydes

Inoue et al. showed that cyclic dipeptides (1,4-dioxopiperazines) containing a histidine moiety also catalyze the asymmetric addition of HCN to benzaldehyde to provide optically active mandelonitrile.[8, 34] The highest selectivity (87% *ee* of (*R*)-mandelonitrile) was obtained with the cyclic dipeptide from (*S*)-histidine and (*S*)-phenylalanine (Table 4).[34c] The reaction is not restricted to benzaldehyde. It has been extended to other aromatic aldehydes and numerous heterocyclic and aliphatic aldehydes; in most cases, though, the selectivity was unsatisfactory (Table 5).[34c, 35, 36] With ketones, the corresponding cyanohydrins are obtained with very low enantioselectivi-

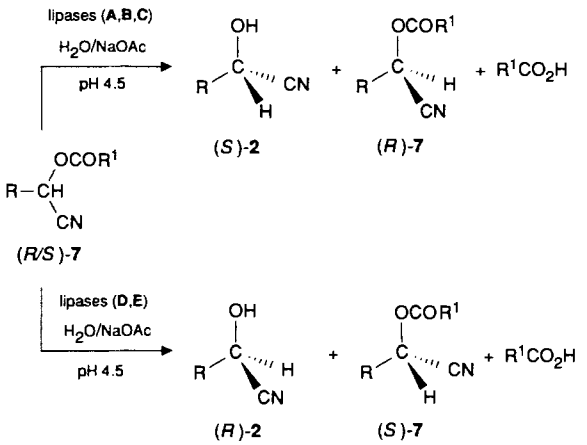
ties.[36b] In virtually all cases examined so far, cyclic dipeptide catalysts with (*S*,*S*) configuration favor the formation of (*R*) cyanohydrins. Only with *cyclo*[(*S*)-His-(*S*)-Leu] are (*S*) cyanohydrins formed preferentially.[34b] The dipeptide catalyst *cyclo*[(*R*)-His-(*R*)-Phe] gives an excess of the (*S*) product, the respective *cyclo*[(*S*)-His-(*S*)-Phe] an excess of the (*R*) cyanohydrin (Table 4).[36a] This possibility of inverting the product configuration by simply changing the catalyst was employed in the synthesis of (*S*)-3-phenoxybenzaldehyde cyanohydrin,[36, 37] the alcohol component of a commercially important pyrethroid.[38]

The mechanism of the enantioselective addition of HCN to aldehydes under cyclic dipeptide catalysis still remains to be unraveled. Nothing definite is known yet, for instance, of the structure of the transition state or of intermediates, despite many efforts.[36a, 39]



Acyclic dipeptides also show limited catalytic activity for enantioselective HCN addition to aldehydes; however, acceptable selectivities were obtained only in the presence of certain titanium complexes.[40]

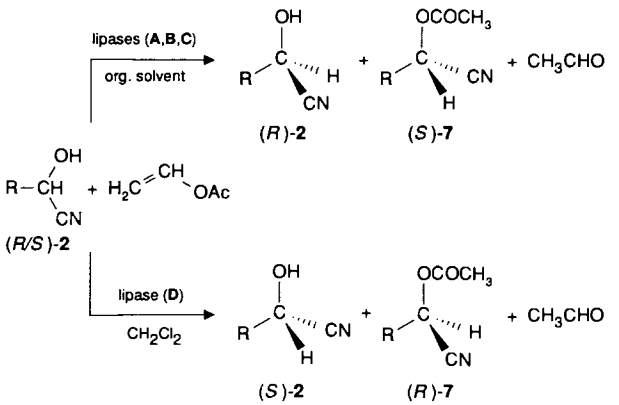
6. Preparation of (*R*) and (*S*) Cyanohydrins by Kinetic Resolution with Esterases and Lipases

Aldehyde cyanohydrins are secondary alcohols and thus may form esters with carboxylic acids. Esterase-catalyzed hydrolysis or lipase-catalyzed esterification thus might be utilized to separate the enantiomers of either racemic cyanohydrins or cyanohydrin esters.[41]

6.1. Enantioselective Hydrolysis of Racemic Cyanohydrin Esters

If saponification of cyanohydrin acetate racemates catalyzed by ester hydrolases from *Pseudomonas sp.* is carried out in a phosphate buffer at pH 7, only the unreacted cyanohydrin acetates are isolated in stereochemically pure form. Under the reaction conditions the chiral cyanohydrins apparently are racemized.[42] Only in a few cases are the free cyanohydrins isolated as more or less pure enantiomers.[43] Hydrolysis with lipases in a sodium acetate buffer at pH 4.5 without exception affords both cyanohydrin esters and cyanohydrins in optically active form.[41] Lipases from *Pseudomonas fluorescens* (**A**), lipase PS (**B**) and lipase P (**C**), preferentially cleave the (*S*) cyanohydrin acetates; with lipases from *Candida cylindracea* (**D**) and with lipase AY (**E**), on the other hand, the (*R*) cyanohydrins are formed (Scheme 4).[41] For the lipases **A**, **B**, and **C**, aromatic

Scheme 4. Enantioselective hydrolysis of racemic cyanohydrin esters (R = C_3H_7, C_6H_5; R^1 = CH_3, C_3H_7, C_5H_{11}, $C_6H_5CH_2$) with various lipases to give (*R*) cyanohydrins and (*S*) cyanohydrin esters, and (*S*) cyanohydrins and (*R*) cyanohydrin esters; lipase from *Pseudomonas fluorescens* (**A**), lipase PS (**B**), lipase P (**C**), lipase from *Candida cylindracea* (**D**), and lipase AY (**E**).



cyanohydrin esters are good substrates (R = C_6H_5), but aliphatic derivatives (R = C_3H_7) are not. Butyrates (R^1 = C_3H_7) yield (*S*) cyanohydrins with the highest selectivities (97% *ee*). The situation is reversed for lipases **D** and **E**; for these enzymes, the aliphatic cyanohydrin esters (R = C_3H_7) are good substrates, and the butyrates (R^1 = C_3H_7) once again give (*R*) cyanohydrins with the highest selectivities (up to 86% *ee*).

6.2. Enantioselective Esterification of Cyanohydrin Racemates

Chiral cyanohydrins do not racemize to any significant extent in organic solvents. Lipase-catalyzed enantioselective esterification of a cyanohydrin racemate in organic solvents thus appears especially suitable for racemate resolution when the unprotected optically active cyanohydrin is desired.[41, 43] With vinyl acetate, for which acylation is not reversible,[44] and in dichloromethane as solvent,[41] the lipases **A**–**D** exhibit the same configurational specificity as that observed in the enantioselective hydrolysis of the ester racemates described in Section 6.1 (Scheme 5).

The highest optical yields for the (*S*) acetates (*S*)-**7**, up to 98% *ee*, for aromatic cyanohydrins have been obtained with *Pseudomonas fluorescens* lipase (**A**),[41] which also catalyzes the acetylation of aliphatic cyanohydrins yielding the acetates (*S*)-**7**.

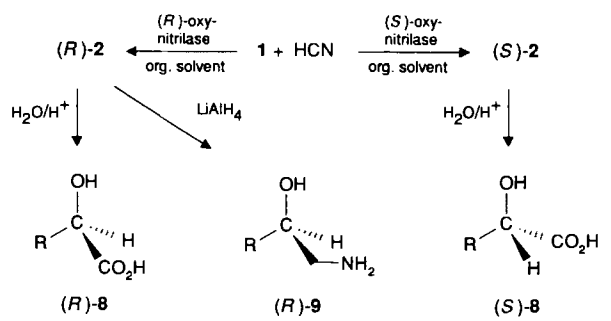
One principal disadvantage of kinetic resolution is that at most 50% of the racemic material can be obtained as the desired enantiomer. It is generally necessary, therefore, to subsequently racemize the remaining undesired enantiomer and to return the resulting racemate to the process. The enantioselective acetylation of a cyanohydrin racemate may also be carried out with

Scheme 5. Enantioselective esterification of cyanohydrin racemates (R = C_3H_7, C_6H_5, $C_6H_5CH_2CH_2$, 4-HOC_6H_4, 3-$CH_3OC_6H_4$, etc.) with vinyl acetate in organic solvents with various lipases (cf. Scheme 4).

isopropenyl acetate in an organic solvent and in the presence of a basic ion exchange resin that is sufficiently basic to cause racemization of the cyanohydrin, but not of the optically active cyanohydrin acetate formed.[45] Thus, a subsequent, separate racemization is no longer required, and the racemic substrate can be completely converted into one enantiomer. The subsequent hydrolysis of the enantiomerically pure cyanohydrin acetates can be conducted under nonracemizing conditions.

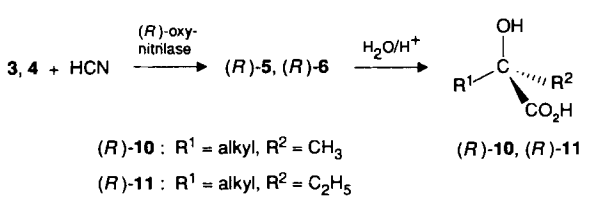
Apart from the enantioselective hydrolysis of cyanohydrin ester racemates (Section 6.1) and the enantioselective esterification of such racemic cyanohydrins (Section 6.2), racemic mixtures of cyanohydrin esters can be resolved by lipase-catalyzed transesterification with high-boiling alcohols in organic solvents.[41, 46]

7. Stereoselective Reactions of Optically Active Cyanohydrins



Since chiral cyanohydrins as α-substituted carboxylic acid derivatives have considerable synthetic potential, subsequent stereoselective reactions should lead to other important classes of compounds with stereogenic centers. Two types of reactions of cyanohydrins can be differentiated: reactions of the CN function which do not involve the α-hydroxyl moiety, and those in which reaction occurs at the OH group. Application of either reaction type in general synthesis requires racemization-free processes.

7.1. Reactions of the Nitrile Group



In contrast to α-amino acids, only a few optically active α-hydroxycarboxylic acids are found in nature. General processes for the preparation of chiral α-hydroxycarboxylic acids therefore had to be developed. Today, they are accessible by straightforward chemical synthesis,[47] by fermentation,[48] and by enzymatic processes.[49, 50] Specific (*S*) α-hydroxycarboxylic acids may be obtained by diazotization of natural L α-amino acids in aqueous medium. The diazonium salts formed initially undergo intramolecular substitution to the respective α-lactones with inversion of configuration; these are hydrolyzed, again with inversion, to give α-hydroxycarboxylic acids with a configuration identical to that of the starting α-amino acid. The (*S*) enantiomers thus obtained may be converted into the corresponding (*R*)-2-hydroxycarboxylic acids by activation of the OH group followed by S_N2 displacement with an oxygen nucleophile.[51]

The racemization-free hydrolysis of chiral cyanohydrins offers an interesting general route to (*R*) and (*S*) 2-hydroxycarboxylic acids. Hydrolysis of an optically active cyanohydrin with concentrated hydrochloric acid was first described for mandelonitrile where it was used to probe for the optical purity of the nitrile.[10a] Other authors later on assumed that in some cases acid-catalyzed hydrolysis of unprotected cyanohydrins resulted in partial racemization.[31, 35a] O-protected cyanohydrins, on the other hand, are hydrolyzed with a high degree of retention of configuration to the respective α-hydroxycarboxylic acids in both acidic[52] and basic media.[44a] Since both the formation of a cyanohydrin and its cleavage to the aldehyde and HCN are base catalyzed, one might expect that the acid-catalyzed hydrolysis of unprotected cyanohydrins would proceed without racemization.

(*R*) and (*S*) cyanohydrins derived from aldehydes[13c, 23] and (*R*) ketone cyanohydrins[33] are indeed hydrolyzed by concentrated hydrochloric acid to give the corresponding (*R*) and (*S*) hydroxycarboxylic acids, respectively, in excellent chemical yield and with complete retention of configuration (Schemes 6, 7; Tables 6, 7). Actually, such hydrolyses can be carried out quite simply. In the first step, the optically active cyanohydrins are prepared from the parent carbonyl compound and HCN in an organic solvent under enzyme catalysis. The Avicel-bound enzyme is filtered off, the solvent removed, and the cyanohydrin residue hydrolyzed with concentrated hydrochloric acid directly and without any additional purification step. The HCl is removed, and the α-hydroxycarboxylic acids are extracted with

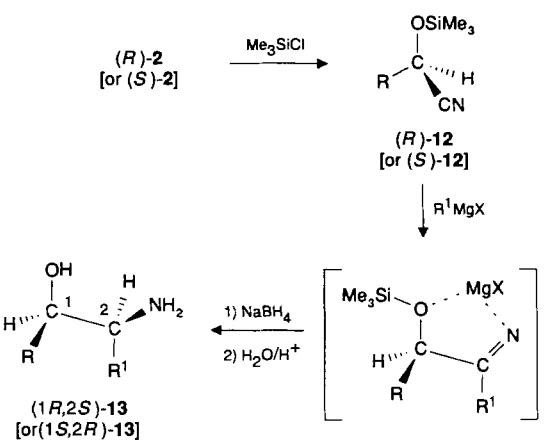
diethyl ether, isolated, and characterized. Comparison of the optical purity of the crude cyanohydrins with that of the isolated and purified α-hydroxycarboxylic acids shows hydrolysis to proceed virtually without racemization in all cases investigated (Tables 6, 7).

A wide spectrum of cyanohydrins is easily accessible by the enzymatic procedure outlined above. The acid-catalyzed hydrolysis of the optically active cyanohydrins, which can be conducted without racemization, thus represents a general route for the preparation of chiral α-hydroxycarboxylic acids.

Optically active α-hydroxy aldehydes are also important structural elements in natural products and thus might also be employed as chiral starting materials in asymmetric syntheses.[52] Direct conversion of optically active cyanohydrins into the corresponding α-hydroxy aldehydes would make this class of compounds easily accessible. Cyanohydrin racemates in fact have been hydrogenated with Raney nickel in acidic medium to α-hydroxy aldehydes.[53a] When this procedure was extended to optically active cyanohydrins, the configuration of the isolated products indicated that hydrogenation occurs with a high degree of retention of configuration.[53b] Because of the moderate yields and the difficult product isolation, however, selective hydrogenation of α-hydroxycarboxylic acids (see above) appears a much more favorable route to chiral α-hydroxy aldehydes.[52d, 54]



Hydrogenation of chiral cyanohydrins to 2-amino alcohols is also of considerable preparative interest, since these compounds have a wide spectrum of biological activity.[55] They may be categorized as adrenalin-type derivatives (amino function at a primary carbon atom) or ephedrin-type derivatives (amino function at a secondary carbon atom). Adrenalin-type 2-amino alcohols can be prepared from O-protected chiral cyanohydrins by various hydrogenating procedures without any trace of racemization.[4a, 43a, 56] Interestingly, free chiral cyanohydrins may also be hydrogenated directly and without racemization to the corresponding amino alcohols.[13c] Here, as in the synthesis of α-hydroxycarboxylic acids, the chiral cyanohydrins obtained from enzyme-catalyzed HCN addition in organic solvents can be applied directly, without any specific purification, for the hydrogenation process (Scheme 6, Table 8).[13c]

Preparation of 2-amino alcohols of the ephedrin type starting from cyanohydrins was first described by Krepski et al.; O-protected racemic cyanohydrins were reacted with Grignard reagents, and the resulting imino intermediates were subsequently hydrogenated with $NaBH_4$.[57] This method was also applied successfully to (*R*) and (*S*) cyanohydrins.[58, 59] Investigation of the stereochemistry of this reaction for both (*R*) and (*S*) cyanohydrins established that the Grignard addition pro-

ceeds without any racemization at C-1. The hydrogenation at C-2 is highly diastereoselective owing to chelate control; *erythro* products are formed almost exclusively (Scheme 8, Table 9).[59] On the other hand, the *threo* compounds are formed predominantly when *N*-diisobutylaluminum hydride is added to the O-protected cyanohydrin before the organolithium reagent is added.[60] This procedure, however, is decidedly less diastereoselective.[60]

Table 9. Synthesis of 2-amino alcohols (1*R*,2*S*)- and (1*S*,2*R*)-**13** from the respective cyanohydrins (*R*)- and (*S*)-**2** (crude products) by formation of the trimethylsilyl ethers (*R*)- and (*S*)-**12**, Grignard reaction, and subsequent hydrogenation of sodium borohydride [59].

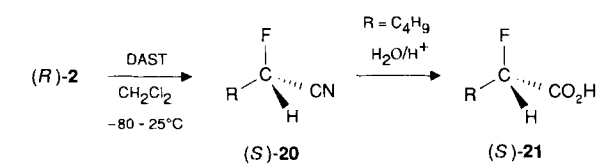
In both hydrogenation[61a] and Grignard reaction[61b] with O-protected cyanohydrins, imines are formed initially; these may be subjected to transimination with primary amines to furnish biologically interesting N-substituted amino alcohols. Addition of HCN to the imino compounds affords β-hydroxy α-amino acids stereoselectively, if one starts out with a chiral cyanohydrin.[62] Hydrolysis of the imino compounds formed by addition of Grignard reagents to O-protected chiral cyanohydrins yields optically active acyloins.[18a, 63]

7.2. Reactions of the Hydroxyl Group



The synthetic potential of optically active cyanohydrins can be extended tremendously if the OH group is converted into a good leaving group which may be exchanged stereoselectively with a wide range of nucleophiles.[64] Nucleophilic substitution reactions with activated α-hydroxycarboxylic acids and esters are well established,[51a, 65] but little is known about the analogous reactions of α-hydroxynitriles.[66] So far only α-halonitriles have been prepared in optically pure form.[66] The halide ion released upon reaction of these compounds is a good nucleophile and leads to partial racemization of the chiral α-halonitriles during nucleophilic substitution.[66] α-Sulfonyloxynitriles (*R*)-**14**, which are easily accessible from chiral cyanohydrins (*R*)-**2** by sulfonylation, have a much higher configurational stability than the α-halonitriles (Scheme 9).[64] α-Sulfonyloxynitriles derived from aliphatic cyanohydrins are considerably more stable than those from aromatic cyanohydrins.[64] Under mild conditions aliphatic α-sulfonyloxynitriles (*R*)-**14** react with nucleophiles with complete inversion of configuration; the aromatic analogues react with weak nucleophiles with at least partial racemization.[64]

Nucleophilic substitution of optically active α-sulfonyloxynitriles (*R*)-**14** allows access to a great variety of interesting compounds, such as α-azidonitriles (*S*)-**15**, α-aminonitriles (*S*)-**16**, α-amino acids (*S*)-**17**, and aziridines (*S*)-**18** in optically pure form (Scheme 9).[64] Aliphatic cyanohydrins (*S*)-**2**, which are not accessible by the (*S*)-oxynitrilase-catalyzed addition of HCN to aldehydes,[23, 24] may be prepared by S_N2 reactions of the stable (*R*) 2-sulfonyloxynitriles (*R*)-**14** with acetates.[64b] The resulting cyanohydrin esters (*S*)-**19** then are hydrolyzed to the cyanohydrins (*S*)-**2**.

Scheme 9. Stereoselective reactions of sulfonyl-activated (*R*) cyanohydrins with nucleophiles with inversion of configuration. $R^1 = CH_3$, CF_3, 4-$CH_3C_6H_4$.

Sulfonyl-activated cyanohydrins are often employed in synthesis, since both the cyanohydrin and the nucleophile can be varied. In addition, direct stereoselective reactions of the cyanohydrin OH group are also feasible with special reagents. (*S*) Fluoronitriles (*S*)-**20**, for instance, may be prepared directly and in good optical yield from the (*R*) cyanohydrins (*R*)-**2** by reaction with diethylaminosulfur trifluoride (DAST).[67] These α-fluoronitriles (*S*)-**20** then are hydrolyzed to the α-fluorocarboxylic acids (*S*)-**21** without notable racemization (Scheme 10).[67]

$R = C_3H_7$, C_4H_9, $(H_3C)_2CHCH_2$, *c*-C_6H_{11}, C_6H_5

Scheme 10. Preparation of (*S*) 2-fluoronitriles and (*S*)-2-fluorocarboxylic acids from (*R*) cyanohydrins.

Another example of a stereoselective reaction in this context is the Mitsunobu reaction of optically active cyanohydrins in the presence of carboxylic acids, which takes place with inversion of configuration, thus permitting preparation of (*S*) cyanohydrins directly from their (*R*) isomers.[68]

8. Summary and Outlook

The enzyme-catalyzed asymmetric synthesis of cyanohydrins known for close to ninety years has only in the last decade turned into an important instrument for organic synthesis. The markedly improved enantioselectivities are possible primarily by suppression of the chemical cyanohydrin formation. This can be achieved either by employing an organic solvent or by working at low pH values.

(*R*) Cyanohydrins in particular have become easily accessible by this procedure, and their considerable synthetic potential as α-substituted carboxylic acid derivatives has been firmly established within a few years. Reactions of optically active cyanohydrins can be conducted with retention of chirality, and further stereogenic centers can be introduced diastereoselectively. Thus chiral cyanohydrins open up routes to other important classes of compounds with stereogenic centers. The synthetic potential of chiral cyanohydrins appears particularly important for the diastereoselective synthesis of drugs with stereogenic centers. Even if drugs like 2-amino alcohols are still applied in racemic form today, all stereoisomers are required for registration, since the activity spectrum and metabolism of each isolated stereoisomer must be established. Chiral cyanohydrins frequently open simple and direct routes to the individual stereoisomers.

The (*R*)-oxynitrilase from bitter almonds has a broad substrate spectrum and can be obtained readily in industrial quantities. In contrast, the substrate spectrum of (*S*)-oxynitrilase from *Sorghum* is restricted mainly to aromatic aldehydes, and the poor availability of this enzyme is more or less prohibitive for industrial applications. Future developments in the synthesis of optically active cyanohydrins are thus expected primarily in extending the substrate spectrum of (*S*)-oxynitrilases and in improving their availability. (*S*)-oxynitrilases from other organisms (plants, insects) may extend and improve the substrate spectrum. The poor accessibility of (*S*)-oxynitrilases, however, will be overcome only by cloning and overexpression in a sufficiently efficient production organism.

Modification of the active center(s) of the oxynitrilases, which is prerequisite for further optimization of the substrate selectivity, requires knowledge of the complete enzyme structure. Currently, little or rather almost nothing is known about the three-dimensional structure of oxynitrilases. If this deficit can be overcome, oxynitrilases will gain even more importance in the synthesis of chiral compounds.

The enthusiastic commitment of my co-workers, who are cited in the references, has helped to bridge the gap between organic synthesis and enzymology which has been decisive for our successful exploitation of chiral cyanohydrins in synthesis. My special gratitude is due to Drs. Thomas Ziegler and Siegfried Förster who played a major role from the beginning in the development of the work described in this review. Dr. Angelika Baro was strongly engaged in the drafting of this article, for which I am very grateful. Generous financial support of this work by the Bundesministerium für Forschung und Technologie (BMFT) under the auspices of the "Zentrales Schwerpunktprogramm Bioverfahrenstechnik Stuttgart" is gratefully acknowledged, as is the constant support by the Fonds der Chemischen Industrie.

Ligands as "Compass Needles": How Orientations of Alkene, Alkyne, and Alkylidene Ligands Reveal π-Bonding Features in Tetrahedral Transition Metal Complexes

Vernon C. Gibson*

This article outlines the strikingly simple structural pattern to which transition metal complexes containing π-bonding ligands conform, and suggests simple rules (and ligand classifications) by which the pattern can be understood, and by which individual structures can be rationalized or predicted. Alkenes, alkynes, and alkylidene ligands adopt distinct orientations with respect to other ligands attached to a transition metal because of competition between the various ligand types for metal–ligand π bonds, whatever the coordination geometry. However, a particularly interesting feature of the tetrahedral geometry is that "single-faced" π ligands can function as "sensors" of relative ligand π-donor capacities for all other groups attached to the metal. Here, using simple "triad representations" of tetrahedral complexes, a simple qualitative analysis is presented that builds on calculations by Hoffmann et al. and which allows preferred ligand orientations and relative ligand π-bond strengths to be deduced for a wide variety of these transition metal complexes.

1. Introduction

Ligands that are capable of forming only a single π interaction with a metal center often adopt distinct orientations with respect to other ligands attached to a metal center. Provided there is no steric conflict, such orientation effects are a consequence of the competition that arises between the different ligands for π bonding to the metal and are relatively well understood for octahedral complexes where the alignment of the ligands along the coordinate axes allows a clear distinction between the d orbitals responsible for forming π bonds (the t_{2g} set) and σ bonds (the e_g set). The situation is much less clear for structures where the orbitals are no longer directed along, or perpendicular to, the metal-ligand axes. A good example is the tetrahedral geometry whose traditional representation within a cube (with the x, y, and z axes emerging from the centers of the faces) is shown in Figure 1.

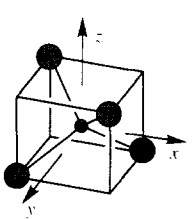

Fig. 1. Relationship of ligand positions with respect to x, y, z axes in a tetrahedral complex.

Competitive effects are, therefore, not so readily assessed for tetrahedral species and it is often necessary to resort to quantum chemical calculations. However, complexes with tetrahedral geometry are particularly attractive for the study of competitive ligand π bonding due to the ability of metal centers with this coordination geometry to accommodate up to four multiply bonded ligands all of which necessarily engage in competition for the available p and d metal orbitals capable of π bonding.[1]

Here, we shall examine a series of tetrahedral and pseudo-tetrahedral complexes containing either alkene, alkyne, or alkylidene ligands and exploit their orientation preferences to evaluate the relative π-donor capacities of the other attendant ligands. This task is facilitated by many recent additions to the family of pseudo-tetrahedral four-coordinate transition metal complexes, particularly examples containing relatively hard, strong π donors such as oxo and imido ligands, and these will be highlighted during the subsequent discussion. We shall also include within the definition of tetrahedral complexes those containing polyene or polyenyl ligands which are considered to occupy a single coordination site. Such systems were the basis of extended Hückel calculations by Hoffmann et al.[2, 3] which first laid the foundations for an understanding of the factors influencing the preferred orientations of carbene, alkene, alkyne, and allyl ligands L with respect to the ancillary Cp ligands in these pseudo-tetrahedral environments. We shall not dwell on the details of MO calculations here but rather call on their qualitative findings to draw together these seemingly quite different yet structurally related systems, to assess the influence of different π-bonded ligands on the structural patterns observed, and to develop a simple unified approach to predicting ligand orientations and relative π-bond strengths in these tetrahedral and pseudo-tetrahedral environments.

2. A Triad Representation of Tetrahedral and Pseudo-Tetrahedral Complexes

To assist the analysis, a simple triad representation of a tetrahedral complex will be used (related to Newman projections for organic systems). If we consider a tetrahedral complex containing the four ligands A, B, C, D, and the metal atom M, and view the molecule along the A–M axis, then the three ligands B, C, and D present a triad which is conveniently represented by the triangle notation shown in Figure 2a. Here, the metal atom lies

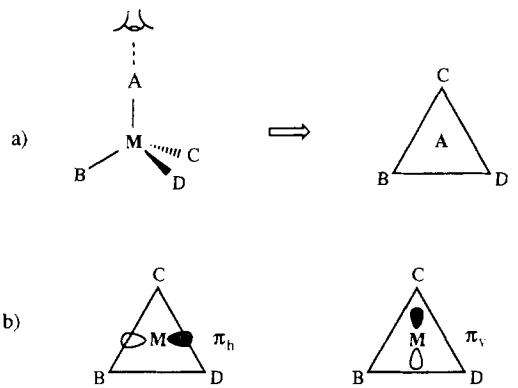

Fig. 2. A triad representation of a tetrahedral complex. a) View along the A–M axis. b) The metal orbitals with π symmetry (π_v and π_h) which are available for interaction with the ligand A.

above the plane defined by B, C, and D and directly beneath the ligand A which lies at the center of the triangle along the normal to the BCD plane. If the ligand A is capable of π bonding to the metal center, it could interact with either (or both) of the metal orbitals with π symmetry (π_h or π_v) shown in Figure 2b which illustrate the MBCD pyramid as viewed from A. Note that the metal orbitals π_h and π_v are represented as p-type orbitals lying parallel to the BCD plane, but they could equally be forward-projecting lobes of dπ orbitals or, as is more likely the case hybrids of both p and d orbitals. This representation captures the essence of MO calculations[2, 3] in which the authors aligned the z axis along the A–M vector and where ligand C is Cp and B and D are carbonyl or nitrosyl ligands.

Note that the metal orbitals have been shown aligned (for convenience) with respect to the M–C axis, but it is evident that the orbitals could also be orientated with respect to either the M–B or M–D axes. Since the π bonding ligands compete for the available metal orbitals with dπ symmetry in a tetrahedral environment, the orientation of the available π symmetry orbitals for ligand A will in effect depend on which of ligands B, C, or D can form the strongest π bonds.

3. Ligand Types

Before proceeding further, we first need to consider the electronic and orbital characteristics of the types of ligands. Table 1 shows the frontier orbitals of a variety of ligands, classified as σ, π, or δ according to their potential for bonding to the metal; the π symmetry orbitals are assigned h or v subscripts depending on whether they align with the "horizontal" or "vertical" metal π orbitals in the diagrams shown in Figure 2b.

The ligands are grouped according to the number of orbitals with π symmetry available for bonding to the metal atom:

1. Π_1-type ligands; these have only one π symmetry orbital and therefore can form at most a double bond to the metal atom consisting of a sigma and pi interaction (1σ, 1π). Such ligands have, on occasion, been referred to as "single-faced" π ligands.
2. Π_2- and $\Pi_{2'}$-type ligands; these possess two π symmetry orbitals and thereby can form two equivalent π bonds potentially giving rise to a triple bond to the metal (1σ, 2π). It is helpful to make a distinction between ligands with degenerate π levels and those with π orbitals differing in energy, since for the latter, one of the π orbitals becomes energetically more accessible to the metal. These latter ligands with non-degenerate π orbitals we shall denote as $\Pi_{2'}$ ligands.

Figure 3 shows the principal s and p (or σ and π) ligand orbitals for each ligand type with accompanying energy level diagrams to emphasize the similarities and differences within, and between, categories. Thus, for the Π_1 ligands, the singlet carbene has a vacant p orbital and so is able to accept π-electron density from the metal, while the amido ligand has three electrons distributed between its two available orbitals and so will

Vernon C. Gibson born in 1958 in Grantham, England, studied chemistry at the University of Sheffield before moving to the University of Oxford where he was awarded a D. Phil. in 1983 for work on the coordination and organometallic chemistry of the early transition metals carried out in the group of M. L. H. Green. He then spent two years as a NATO post-doctoral researcher at the California Institute of Technology with J. E. Bercaw before returning to England to take up a lectureship in chemistry at Durham University in 1986, where he is now a full Professor of Chemistry. His interests lie in synthetic, structural, and mechanistic inorganic and organometallic chemistry, with a particular emphasis on transition-metal compounds containing metal–ligand multiple bonds and their applications in polymer synthesis.

Table 1. Classification of ligands by the number and type of their frontier orbitals.

Ligand A	Electrons available	Frontier orbitals
1) Π_1-ligands		
R, C, H	2	σ, p_h
R, N, H	3	σ, p_h
>C=C<	2	σ, π^*_h
–C≡C–	2	σ, π^*_h
2) Π_2-ligands		
CO	2	σ, π^*_h, π^*_v
NO	3	σ, π^*_h, π^*_v
R, C	3	σ, p_h, p_v
R, N	4	σ, p_h, p_v
O	4	σ, p_h, p_v
R, O	5	σ, p_h, p_v
Cl	5	σ, p_h, p_v
	3	σ, π_h, π_v
	4	σ, π_h, π_v, δ^*
	5	σ, π_h, π_v, δ^*_1, δ^*_2
3) $\Pi_{2'}$-ligands		
	3	σ, π_h, π^*_v
–C≡C–	4	σ, π^*_h, π_v, δ^*
	4	σ, π_h, π^*_v, δ^*

act as a net π donor to the metal. Simple energy level diagrams can be derived for the cyclic Π_2 ligands, C_nH_n, by standing the ring on an apex. It can be seen that the π levels are

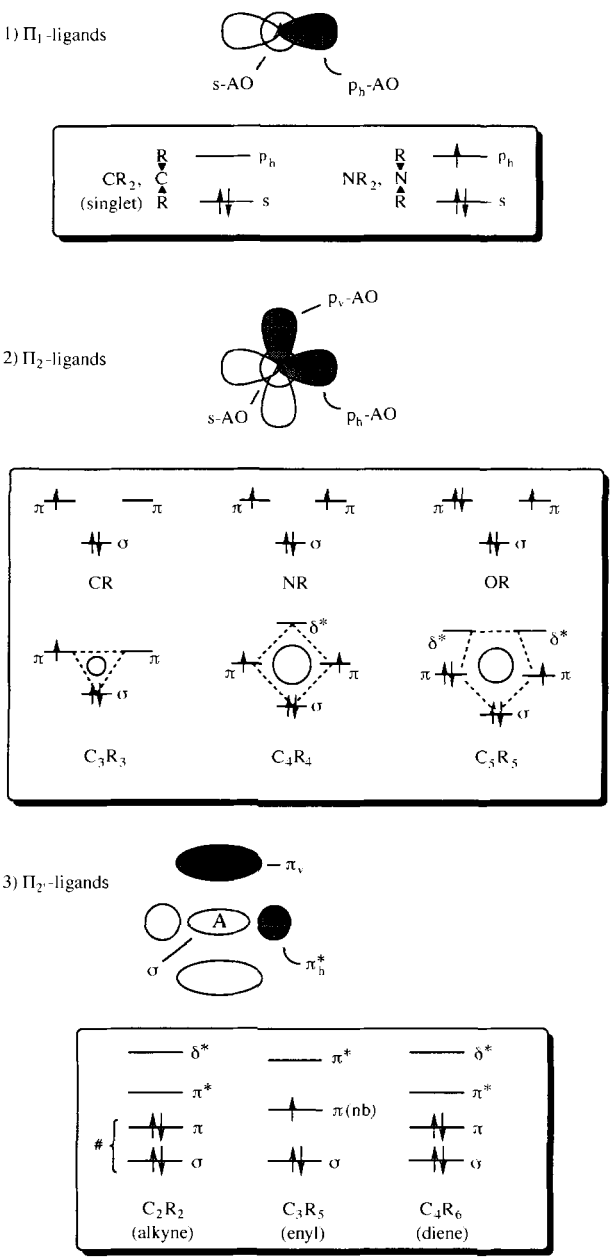

Fig. 3. Frontier orbitals of some representative ligands. The two orbitals indicated by # are the degenerate pair of filled alkyne C–C π-bonding MOs, but are shown as non-degenerate because of their different orientations with respect to the metal ligand axis. The MOs of $\Pi_{2'}$ ligands are represented by a four-electron alkyne ligand.

degenerate[*] in each case and therefore directly comparable with CR, NR, and OR. By contrast, it can be seen that the π levels for $\Pi_{2'}$ ligands are non-degenerate.

Of particular interest to this study are the Π_1 ligands such as alkylidene (CHR), amido (NHR), alkene (C_2R_4), and the "two-electron" alkyne ligand (C_2R_2), which have available only one π orbital for interaction with a metal center and so an orientation preference should be observed depending upon which of the

[*] It should be noted that a Jahn–Teller distortion would remove the degeneracy for an isolated fragment. The view shown in Figure 3 is adopted to assist comparisons between the different ligand types and for the purpose of electron "book-keeping".

metal π_h or π_v orbitals is the most accessible. In the following sections, we shall examine the effect of either one or two of the three ligands in the triad dominating the π-donor bonding.

4. Complexes Possessing Two Dominant Π_2-Donor Ligands

Let us first consider triad representations for complexes containing cyclopentadienyl (Cp) or imido (NR) groups in combination with ancillary alkene ligands (Fig. 4). Figure 4a shows a typical triad representation for a zirconocene alkene complex of the type $[Cp_2Zr(H_2C{=}CHR)(PMe_3)]$.[4] Here, the C=C bond of the alkene ligand orientates in the plane that contains the Zr–P bond, the so-called equatorial binding plane or binding wedge of the metallocene fragment. This is, of course, the well-established bent metallocene geometry for which the electronic constraints are well-documented both through their extensive derivative chemistry[5] and through detailed quantum chemical calculations.[6] The frontier orbitals of the bent $[Cp_2M]$ unit are shown in Figure 5, which illustrates their shapes and projections in the *yz* plane. Thus, if we consider a triad representation for a $[Cp_2ML]$ fragment (Fig. 6), we find that it is only the π_v orbital (with respect to L) that is accessible to a fourth π-bonding ligand. It is also worth noting that, since this ligand approaches in the *yz* plane but *between* the *y* and *z* axes, the π interaction will largely consist of a "side-on" interaction with the "d_{yz}" $1a_1$ orbital of the metal atom (Fig. 7).

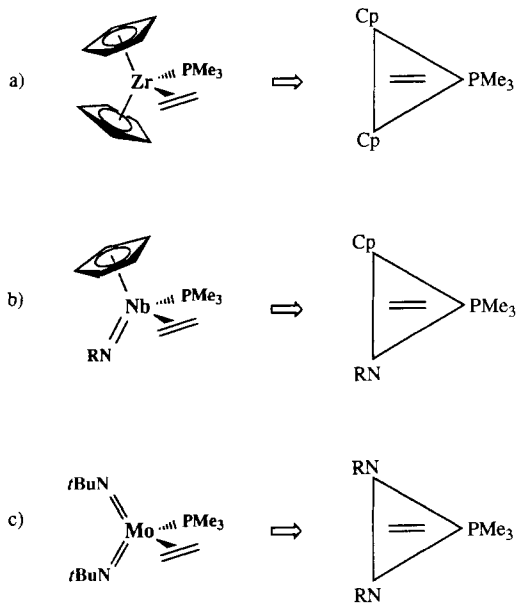

Fig. 4. Triad representations of complexes containing cyclopentadienyl and imido ligands in combination with alkene ligands: a) bent metallocene derivatives; b) half-sandwich imido complexes; c) bis(imido) complexes.

According to this description the π_h orbital is virtually inaccessible to a fourth π-bonding ligand since it is heavily involved in π bonding to the Cp rings, and therefore any interaction with the π_h orbital would necessarily weaken the π bonds between the Cp ligands and the metal center. The orientation preference would be expected to be lost only if the π_v orbital is filled (i.e. a d^2 metal center) and the Π_1 ligand is a π donor such as an amide.

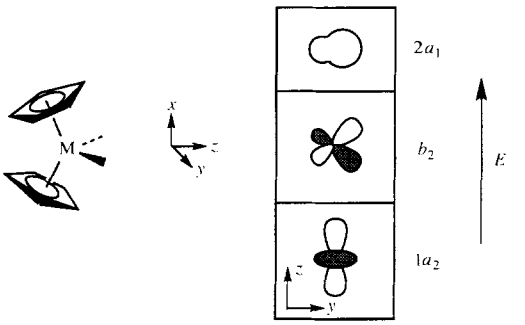

Fig. 5. The frontier orbitals of the bent $[Cp_2M]$ metallocene fragment illustrating their shapes and orientations with respect to the *y* and *z* axes.

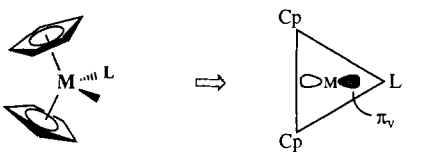

Fig. 6. A triad representation illustrating the orientation of the π-symmetry orbital available for bonding to a fourth ligand in a $[Cp_2ML]$ fragment. The π_v orbital is vertical with respect to the ligand L.

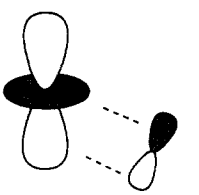

Fig. 7. The side-on π interaction between a d_{z^2}-type metal orbital and a π-symmetry ligand orbital.

More recently, a related series of half-sandwich niobium imido complexes has been synthesized;[7] these show a similar alignment of the alkene C=C bond, orientated towards the phosphane ligand when viewed as a triad representation (see Fig. 4b). Precisely the same "metallocene-like" orientation is found for the alkene ligand in $[Mo(NtBu)_2(H_2C{=}CHMe)(PMe_3)]$[8] (see Fig. 4c). At first sight the close relationship apparent between bent metallocenes, half-sandwich imido, and bis(imido) systems may not seem at all obvious. However, when the symmetry properties of the frontier orbitals for the Cp and NR units are taken into consideration, the situation becomes much clearer, since both of these fragments are seen to bind to a metal using a combination of 1σ and 2π interactions (see Table 1); the Cp group of course also has two δ-symmetry acceptor orbitals available for back-donation but provided these δ-bonding interactions are weak, they will have minimal impact on the metal–ligand bonding. The alkene ligand, then, effectively orientates towards the σ-bonded phosphane group so as to avoid direct competition with the dominant Π_2-donor groups for metal–ligand π bonds.

An analogous situation is found for the alkylidene derivatives $[Cp_2Ta(CHPh)(CH_2Ph)]$[9] and $[Cp^*Nb\{N(2,6\text{-}iPr_2C_6H_3)\}(CHPh)(PMe_3)]$[10] ($Cp^* = C_5Me_5$) (Fig. 8). Here, the p orbital of the benzylidene ligands is orientated with one lobe pointing in the direction of the σ-bonded group and with the other lobe bisecting the Π_2-donor groups (the orientations of the alkylidene substituents are indicated by wedge lines); this again avoids competition with the Cp and NR ligands for π bonds.

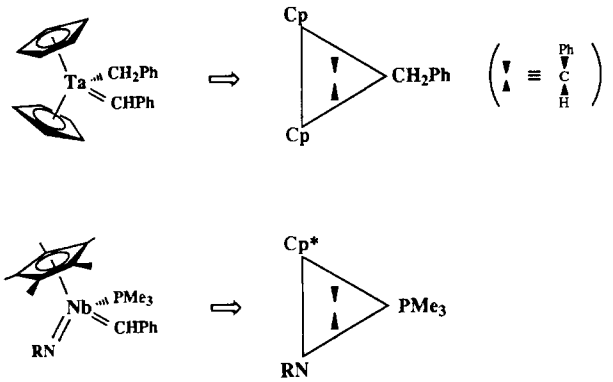

Fig. 8. Triad representations showing alkylidene ligand orientations in $[Cp_2Ta(CHPh)(CH_2Ph)]$ and $[Cp^*Nb(NR)(CHPh)(PMe_3)]$.

Thus the alignments of the alkene double bond and the alkylidene substituents differ by 90°.

The OR ligand can also act as a Π_2 donor (see Table 1) and therefore, as far as the symmetries of its frontier orbitals are concerned, it can be regarded as being pseudo-isolobal with the Cp ligand. It should come as little surprise, then, that the two substituted phenolato complexes, $[Ta\{O(2,6\text{-}tBu_2C_6H_3)\}_2(CHSiMe_3)(CH_2SiMe_3)_2]$[11] and $[Ti\{O(2,6\text{-}Ph_2C_6H_3)\}_2(C_2H_4)(PMe_3)]$[12] shown in Figure 9 also display related orientation preferences to those seen in the cyclopentadienyl and imido systems.

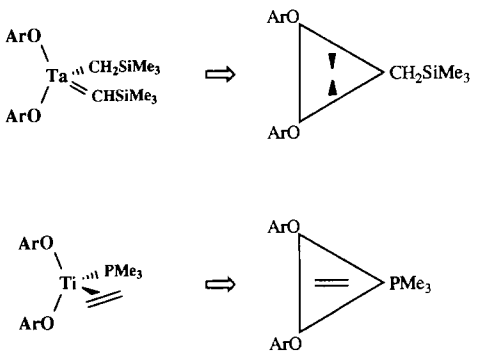

Fig. 9. Triad representations showing alkene and alkylidene ligand orientations in substituted bis(phenolato) complexes.

5. Complexes Possessing One Dominant Π_2-Donor Ligand

Now, if we bear in mind the orientation preferences we have just witnessed for bis(phenolato) complexes in Section 4, we can then examine the effect of placing a very strong NR donor group in competition with the two alkoxo ligands through the four-coordinate alkylidene(imido) complexes $[M\{N(2,6\text{-}iPr_2C_6H_3)\}(CHCMe_3)(OtBu)_2]$ (M = Mo, W)[13] and $[Mo(NtBu)(CHCMe_3)\{OCH(CF_3)_2\}_2]$.[14] The triad representation of a structurally characterized derivative shown in Figure 10a reveals that the alkylidene ligand now bisects the R'O–OR' edge of the triangle and aligns in the direction of the NR group.

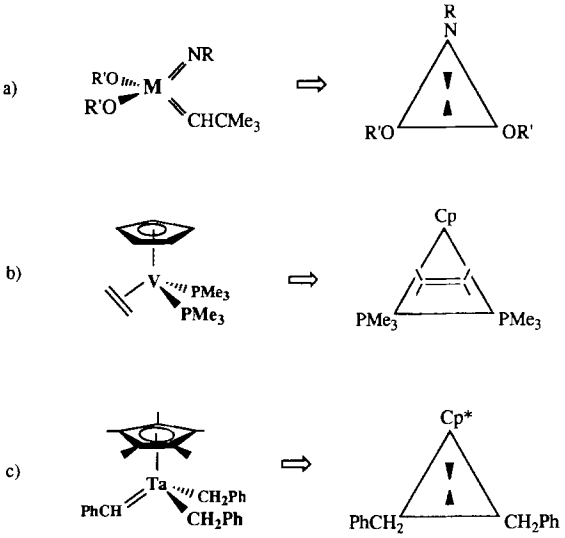

Fig. 10. Examples of complexes possessing a single dominant Π_2-donor ligand: a) $[M\{N(2,6\text{-}iPr_2C_6H_3)\}(CHCMe_3)(OtBu)_2]$ (M = Mo, W); b) $[CpV(PMe_3)_2(C_2H_4)]$; c) $[Cp^*Ta(CHPh)(CH_2Ph)_2]$.

This orientation is consistent with the imido ligand now dominating the π-donor bonding, a point the alkylidene ligand neatly emphasizes by pointing towards it in each of the complexes. A related alkene complex of the type $[Mo(NR)(H_2C{=}CH_2)(OR')_2]$, not to our knowledge synthesized to date, would be anticipated to align its alkene π-acceptor orbital with the π_h orbital of the metal atom, resulting in the alkene orientation illustrated in Figure 11.

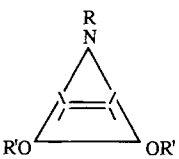

Fig. 11. The anticipated orientation of an ethene ligand in a hypothetical complex of the type $[Mo(NR)(H_2C{=}CH_2)(OR')_2]$.

An analogous orientation effect is found in the cyclopentadienyl vanadium complex $[CpV(PMe_3)_2(C_2H_4)]$[15] (see Fig. 10b). Here, since the PMe_3 ligands cannot function as π donors, the cyclopentadienyl ligand dominates the bonding, a point the alkene ligand helpfully "underlines" by its orientation. The dominance of the cyclopentadienyl ligand is also apparent in the complex $[Cp^*Ta(CHPh)(CH_2Ph)_2]$[16] (see Fig. 10c) in which the plane of the alkylidene substituents aligns with the metal-ring centroid vector, so pointing to the Cp ligand as the dominant π-bonding ligand. If the π system in the ligand is extended, for example, in $[CpTiCl_2\{{=}N{=}C(tBu)_2\}]$,[17] the preferred orientation of the substituents changes by a 90° twist, as expected in this complex for alignment of the nitrogen p orbital with the π_h orbital. Similar "twists" are found in complexes containing cumulene-type ligands such as vinylidene and allenylidene.

The origin of the orientation effect in "tetrahedral" complexes possessing a single dominant Π_2-donor ligand can be seen by considering the d orbital splitting diagram in Figure 12: for convenience and clarity this is derived unconventionally with the z axis aligned along the Π_2-ligand–metal axis. Here, instead of the usual "3 over 2" pattern, the degeneracy of the upper triplet is split into an e and a_1 set. There are now two sets of

doubly degenerate orbitals, the upper set (d_{xz}, d_{yz}) allowing π-interactions with the π donor to be maximized, while the lower *e* set ($d_{x^2-y^2}$, d_{xy}) aligns orthogonal to the M–Π_2 ligand bond thereby minimizing interactions with the Π_2 ligand. Since we are now viewing the molecule side-on to the M ; (Fig. 12), it is apparent that d_{xy} effectively correspon ıe π_h orbital viewed from A, while both d_{xz} and d_{z^2} can interactions with A in the vertical plane (π_v). Note that d_{xz} is already engaged in π bonding with the "axial" Π_2-ligand and that the d_{z^2} orbital is σ bonding with respect to the Π_2 ligand whilst also being capable of forming a π interaction with the ligand A of the type illustrated in Figure 7. This provides a simple pictorial illustration of the competition for ligand–metal π bonds in "tetrahedral" complexes.

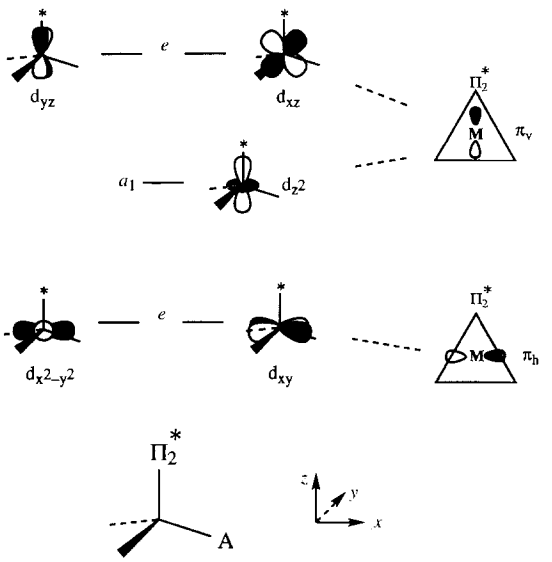

Fig. 12. Splitting diagram for the d orbitals of the metal atom in a tetrahedral complex possessing a single dominant Π_2-donor ligand (derived with the *z* axis aligned in the direction of the Π_2-ligand).

An interesting situation arises when the strongly π-donating NR unit is in competition with a strong polyenyl π donor such as the cyclopentadienyl ligand. A series of half-sandwich niobium,[18] molybdenum,[19] and rhenium[20] compounds of general formula [CpM(NR)Cl_2] shows a significant ring-slippage along with an orientation preference for the C_5R_5 ring such that one of the ring carbon atoms eclipses the M–NR bond (the ring is orientated so as to "point" to the NR group). This is illustrated in Figure 13a for [CpNb(NR)Cl_2] by using the triad notation viewed down the ring centroid-metal axis.

The ring-slippage has been attributed in general terms to the strong *trans* influence of the imido ligand leading to a weakening of the two metal–carbon bonds *trans* to the NR group and a consequent adjustment towards an allyl-ene Cp bonding situation.[18–20] However, the ring distortion also follows from our previous observations for complexes with a "single dominant" NR π-donor ligand. For the two π-type interactions of the cyclopentadienyl group, it is expected that the interaction perpendicular to the M–N bond (**I** in Fig. 13b), that is the one with the π_h orbital, will be stronger than that with the metal π-symmetry orbital (π_v) nearly parallel to the M–N bond (**II** in

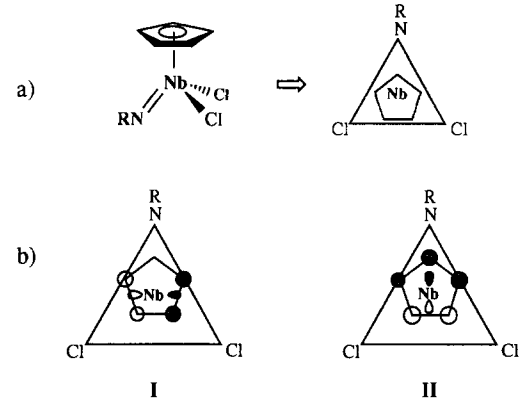

Fig. 13. A triad representation of half-sandwich imido complexes of the type [CpNb(NR)Cl_2]: a) orientation of the Cp ligand; b) π interactions between the orbitals of the Cp ligands and the π_v and π_h orbitals of the metal atom.

Fig 13b). Consequently, the filled π-level of the Cp ligand in **II** will remain largely ligand centered and give rise to the allyl-ene distortion.

6. Complexes Containing Π_2' Ligands

Orientation effects are also often seen for Π_2' ligands in competition with strong Π_2 donors. The strongest π interaction might again be expected to be with the π_h orbital, but the orientation of the Π_2' ligand is less easily predicted since their frontier π-symmetry orbitals are non-degenerate (see Fig. 3) and either of the π interactions could dominate. Just which will dominate will depend on a number of factors including i) the relative energies of the π and π* levels of the ligand orbitals relative to π_h and π_v orbitals of the metal fragment, and ii) the directional properties of the ligand π orbitals (with respect to the metal). We shall not elaborate on these factors here, but the structures of the acetylene complex [Cp*Ta(PhC≡CPh)Cl_2][21] and the benzyne complex [Cp*Ta(C_6H_4)Me_2][22] should be noted (Fig. 14). In both complexes the alkyne ligand functions as a four-electron donor. The orientation of the diphenylacetylene is the same as that expected for a Π_1 ligand, indicating that the π bonding may be dominated by alignment of the π*-acceptor orbital with the π_h orbital. However, steric factors have also been suggested to play a role since the less bulky benzyne ligand is found to align in a perpendicular orientation. The alignment of the butadiene ligand in [CpTa(butadiene)Cl_2][23a] (Fig. 14c) is consistent with the butadiene π-donor orbital interacting with the π_h orbital, the π*-acceptor orbital then aligning with the π_v orbital.

A useful illustration of how the π-bonding capacities of Π_2 and Π_2' ligands can be compared in a complex is provided by the example, [CpNb(η^4-butadiene)(η^2-PhC≡CMe)(PMe_3)][23b] which, in addition to possesing a Π_2 Cp ligand, has two different Π_2' ligand systems (the butadiene and alkyne groups) attached to the metal center (Fig. 14d). Without knowing anything about the detailed MO description of the complex, the orientation of the alkyne indicates that the π-donor bonding is dominated by the Cp and butadiene ligands, a point reinforced by low-frequency ^{13}C NMR shifts for the acetylenic carbon atoms which reflect little or no donation of electron density from the alkyne's orthogonal π system.

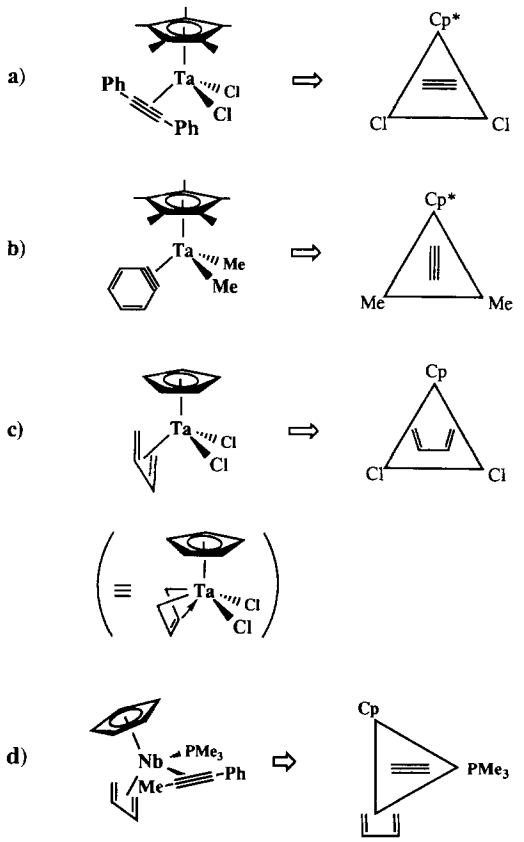

Fig. 14. Triad representations for complexes possessing Π_2 ligands in competition with Π_2 donors: a) [Cp*Ta(PhC≡CPh)Cl_2]; b) [Cp*Ta(C_6H_4)Me_2]; c) [CpTa(C_4H_6)Cl_2]; d) [CpNb(C_4H_6)(PhC≡CMe)(PMe_3)].

7. Low-Valent Systems

Although the analysis presented so far has largely focused on high-valent complexes (i.e. those with metal centers in high oxidation states) where π-donor interactions are of overriding significance, the first detailed MO studies of the factors influencing the orientations of Π_1 ligands were carried out by Hoffmann et al.[2, 3] on low-valent complexes of the type [CpM($CO)_2$L] and [CpM(CO)(NO)(L)] (where L is a Π_1 ligand such as carbene, alkene, or alkyne). For the non-symmetrical nitrosyl case, the orientation preference of the carbene ligand in, for example, [CpCr(CO)(NO)(CPh_2)][24] has been interpreted in terms of the relative π-acidities of the CO and NO^+ groups.

How does this description compare with the treatment we have adopted for the complexes with π-donor ligands and metal atoms in high oxidation states described in the previous sections? Qualitatively, we would expect very little difference: the MO descriptions of the fragments [CpM($CO)_2$] and [CpM(CO)(NO)] also apply to high-valent transition metal systems, since irrespective of whether the ligands are π donors or π acceptors (e.g. NR, Cl, vs. CO etc.) they bind to the metal using similar combinations of σ and π symmetry orbitals (see Table 1). It is only the relative energies of the orbitals and the localization of the electrons ultimately in ligand- or metal-centered MOs that distinguish the situations in high- and low-valent systems.

Thus, in accord with a π-donor approach, CO and NO could be considered to lie at the weak end of a π-donor scale. It then

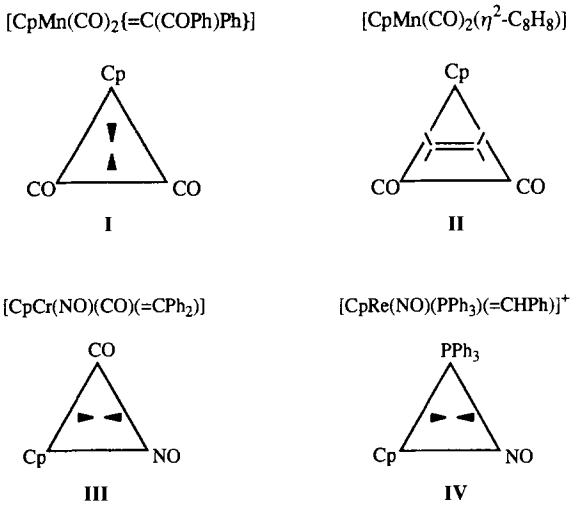

Fig. 15. Triad representations of some low-valent complexes containing Π_1 ligands.

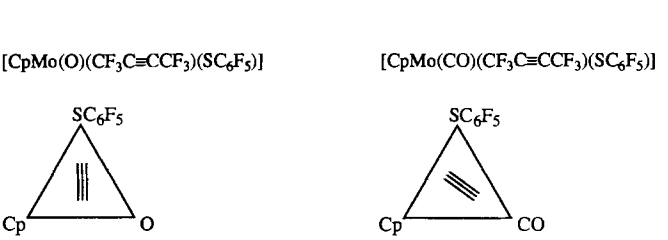
follows that the symmetrical dicarbonyl complexes [CpMn($CO)_2$(L)] (L = Π_1 ligand, e.g. carbene, alkene, alkyne etc.) would be expected to show an alignment of their Π_1 ligands with respect to the single dominant π-donor, the cyclopentadienyl group. This is indeed the case as exemplified by complexes **I**[25] and **II**[26] in Figure 15.

For the mixed carbonyl(nitrosyl) complex [CpCr(CO)(NO)(CPh_2)],[24] (**III**) and the related rhenium phosphane complex [CpRe(NO)(PPh_3)(=CHPh)][PF_6][27] (**IV**) the relative donor capacities of CO in comparison to those of NO are seen to be important. If NO is considered as a neutral ligand (rather than as the nitrosonium ion), it may be regarded as a better π-donor than CO and the alignment of the p orbital of the carbene ligand with the weaker π donor ligands CO and PPh_3 can be ascribed to the Cp and NO ligands dominating the π-donor bonding resulting in an orientation preference reminiscent of the type seen in bent metallocene derivatives.

Finally, perhaps one of the best illustrations of a Π_1 ligand acting as a molecular sensor of π-donor capacity can be found in the complexes [CpMo(O)($CF_3C{\equiv}CCF_3$)(SC_6F_5)] and [CpMo(CO)($CF_3C{\equiv}CCF_3$)(SC_6F_5)][28] (Fig. 16). In the oxo derivative, an 18 electron count is achieved with the acetylene acting as a two-electron (Π_1) ligand and the acetylene is directed towards the SC_6F_5 group showing that the cyclopentadienyl and oxo ligands dominate the π-donor bonding. However, when the oxo ligand is replaced by a carbonyl group, the Cp and SC_6F_5 ligands now dominate the π-donor bonding, and the acetylene responds like a compass needle, reorientating towards the CO ligand. Thus, here the Π_1-acetylene is clearly acting as an indica-



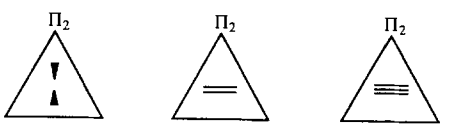


Fig. 16. Triad representations of [CpMo(O)($CF_3C{\equiv}CCF_3$)(SC_6F_5)] and [CpMo(CO)($CF_3C{\equiv}CCF_3$)(SC_6F_5)] illustrating how the alkyne ligand acts as a sensor of π-donor capacity.

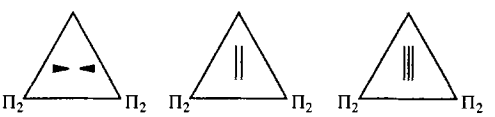
tor of relative ligand π-donor strength. Analogous orientation effects are also seen in the tungsten complexes [CpW(O)(PhC≡CPh)(Ph)][29] and [CpW(O)(PhC≡CH)(CH_2CO_2Et)],[30] where the acetylene aligns with the Ph and CH_2CO_2Et groups, respectively, and even in heterobimetallic systems such as [Cp(O)(PhC≡CPh)MoRu(CO)$_2$Cp][31] where the molybdenum-bound acetylene aligns with the Mo–Ru bond.

8. Summary



Ligands capable of forming two strong π bonds to a metal atom dominate the bonding in tetrahedral and pseudo-tetrahedral complexes allowing ligands capable of forming only one π interaction to be exploited as sensors to identify the dominant π-bonding groups. These observations lead to some general rules that (in the absence of overriding steric influences) govern the preferred orientations of Π_1 ligands in the presence of strong Π_2 donor groups:

1. For "tetrahedral" species containing a single dominant Π_2-donor, if a triad notation is employed, the substituents of an ancillary carbene or alkylidene ligand will point to the strongest π donor **A**, while an alkene or alkyne ligand will doubly or triply "underline" it (**B** and **C**, respectively).

A **B** **C**

2. For complexes containing two strong Π_2-donor ligands, the alkene and alkyne groups point to the weakest π donor (**E** and **F**, respectively), the alkylidene substituents "underline" it (or provide it with a bow tie!) (**D**).

D **E** **F**

By comparing a series of complexes, it is thereby possible to derive a qualitative ordering of ligand π-bond strengths. For example, from the limited range of examples outlined here the imido group is seen to π bond more effectively than OR, Cp, and Cl ligands, whereas the Cp ligand π bonds more strongly than Cl and SR ligands. All of these ligands of course dominate the solely σ-bonding groups such as PMe_3 and alkyl and π-acceptors such as CO, CHR, and alkenes.

We have found it useful to highlight relationships between complexes containing ligands of a similar class (Π_1, Π_2, Π_2, etc.). Such relationships should not be regarded as rigid, but rather as an aid for understanding stoichiometry and structural patterns in new and seemingly unrelated systems, while at the same time providing a useful basis for evaluating their likely reactions.[32]

Professor Ken Wade is thanked for many helpful and stimulating discussions.

Binary Encoding of Compound Libraries

Peter Eckes*

During the last decade supramolecular chemistry has developed into a new area of chemical research. Thinking in terms of supramolecular functional units has also influenced current views of biological processes. Modern methods in molecular biology, genetic engineering, and structure analysis have provided the information necessary to understand supramolecular interactions in biological systems. Despite these findings, the rational de novo design of drugs and pesticides that interfere in biological processes by means of supramolecular interactions is still in its infancy.

Random screening remains an important component in the search for biologically active compounds which has also profited from recent developments in the life sciences. Efficient testing systems make it possible to study the activity of thousands of compounds with a molecular target annually. In addition to individual synthesized compounds, mixtures of substances like those in plant extracts, marine organisms, and fermentation broths can also be tested.

Inspired by the tremendous diversity of molecules active in biological systems, chemists have recently developed methods for the synthesis of libraries of compounds for the rapid identification of molecules with biological activity. This research appears to have altered prototypical synthetic chemistry by the introduction of concepts from biology. The result is combinatorial chemistry aimed at the preparation of many structurally diverse compounds.

Research in combinatorial chemistry has been summarized in a series of review articles.[1] Most of the published work describes the synthesis and application of libraries of biooligomers. The preference of peptide and oligonucleotide libraries can be explained by two points: 1) Since the pioneering work of Merrifield and Letsinger, the synthesis of these compounds has been constantly improved. 2) Established methods exist for the determination of the molecular structure even of miniscule samples. The particular challenge in the application of the concepts of peptide and oligonucleotide libraries to libraries of smaller organic molecules is identifying the components in the mixtures prepared by combinatorial methods that participate in supramolecular interactions.

Brenner and Lerner suggested the first solution to this problem.[2] They proposed generating an encoded compound library by combining the split method[3] (see Scheme 2) with two sequential combinatorial steps. In this approach the information for the starting material for the second combinatorial step in the synthesis is stored in the first combinatorial step, the coding step. If a product is deemed "active" in a later test, the encoded sequence information indicates the structure of the active compound independent of the chemistry used in the synthesis.

The viability of the approach was proved with a peptide library. Whereas Nielsen et al.[4] relied on an oligonucleotide code analogous to that in nature, Kerr et al.[5] employed an amino acid code. Despite the independence of synthesis and analysis, both approaches appear to have intrinsic problems: 1) The synthetic sequence of two combinatorial reaction steps requires the development of an orthogonal protecting group strategy for the compound library and the code. 2) In the generation of the diversity of molecules in the two combinatorial steps a tag molecule may also take part in supramolecular interactions. 3) With oligonucleotides in particular the number of possible reactions is limited owing to their chemical lability.

Still et al.[6] have developed an interesting new concept based on the approach of Lerner et al.[2] which appears to solve the aforementioned problems and thus opens up new perspectives for combinatorial chemistry. In two recent papers they describe encoding peptide libraries with a binary code.[6,7] In this approach the tag molecules are not linked to each other sequentially. Thus decoding does not result from the determination of the sequence information but from the formal assignment of the binary code for individual tag molecules and their mixtures. The principle of the encoding is represented in Table 1.

Table 1. Coding compound libraries with a binary code. The letters A–E represent the starting compounds employed, T_1–T_4 the tag molecules.

Starting cmpd.	Step	Binary code	Tag molecule
A	1	10	T_1
B	1	01	T_2
C	1	11	$T_1 + T_2$
D	2	10	T_3
E	2	01	T_4
F	2	11	$T_3 + T_4$

The efficiency of this encoding strategy can be demonstrated with a hypothetical example. X tag molecules can be used to encode $2^X - 1$ starting compounds per reaction step. Thus in an N-step reaction sequence the application of combinatorial principles makes it possible to encode a compound library with

[*] Dr. P. Eckes

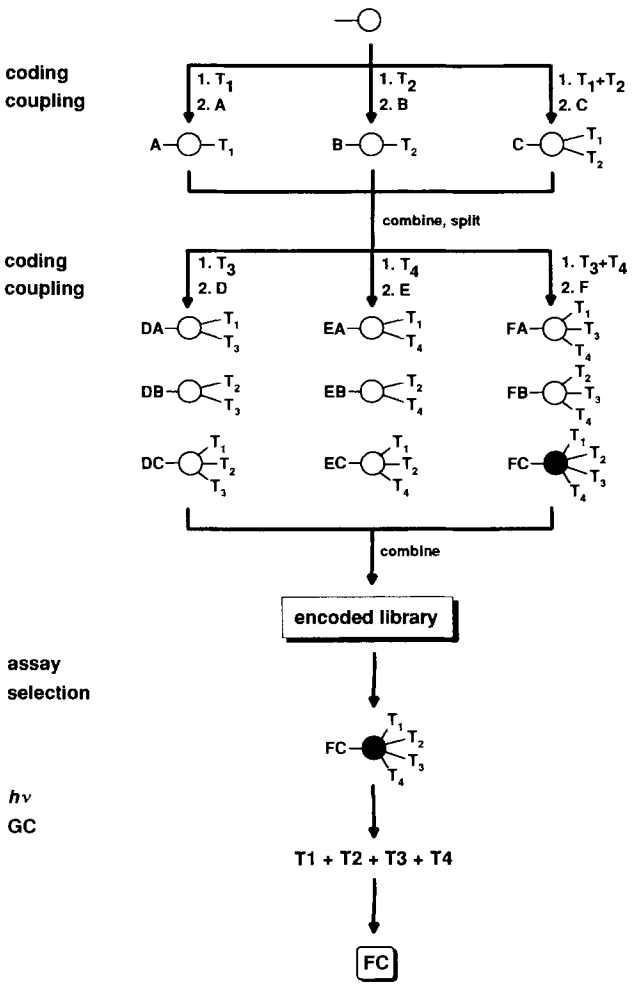
$(2^X - 1)^N$ components with only $X \cdot N$ types of tag molecules. For example, 20 code molecules can be used to code 923 521 compounds prepared in a four-step process.

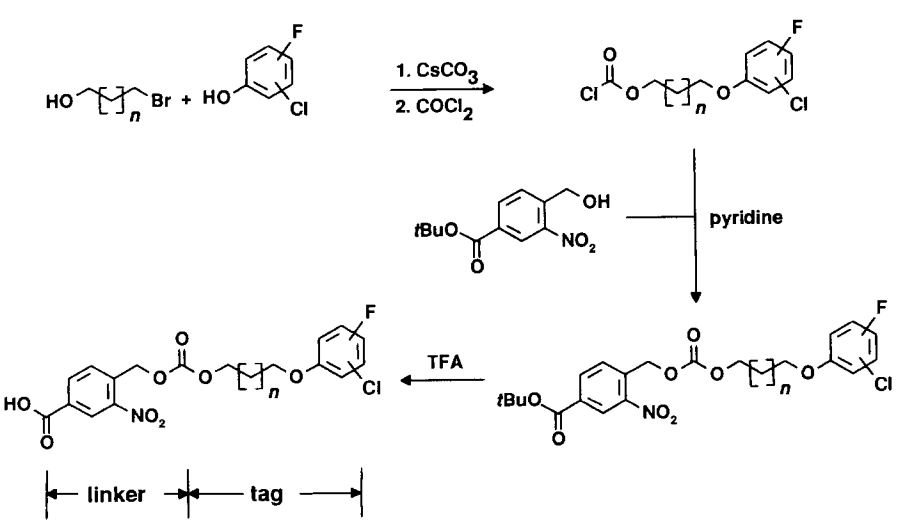
A series of homologous chlorofluoroarenes serve as tag molecules, which can be separated by capillary gas chromatography. The code molecules can be detected even in attomolar concentrations with electron capture detectors.



The tag molecules are synthesized according to a simple building block principle shown in Scheme 1. The code molecules are bound to the polymeric support through amide bonds; only a small proportion (< 1 %) of the free amino groups are used in each coding step. The tags are released later by photochemical cleavage of the *o*-nitrobenzyl linker.

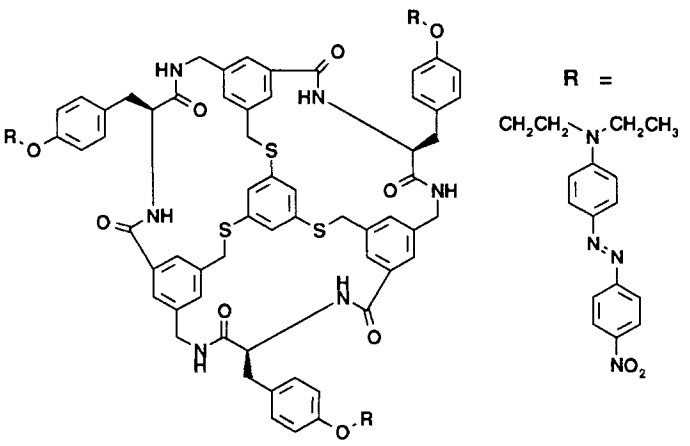
In Scheme 2 the construction of a peptide library with a binary code is illustrated. The polymeric support is labeled with the molecular "bar code" in separate reaction flasks. Then the actual coupling reaction with the different amino acids is conducted, still in the separate flasks. Thus the tag molecule and the starting compound have a one-to-one correspondence. By combining and splitting the support particles, defined mixtures are obtained, which can be encoded and coupled in the same way.

The resulting compound library is screened in functional assays, and the support particles linked to "active" molecules are identified. After selection of a particle, photochemical cleavage of the support-bound tag molecules, and silylation of the tag molecules, the code can be read by gas chromatography, and thus the compound that participates in supramolecular interactions can be identified.



One drawback of the new coding strategy is that in the published procedure[6,7] the assay is still conducted with support-bound compounds. Thus undesired interactions with the support that may lead to changes in conformation affecting binding cannot be ruled out.

As a first test[6] Still et al. screened a encoded peptide library theoretically composed of 117649 14-mers against a monoclonal murine anti-c-MYC antibody. In this peptide library the six N-terminal amino acids were varied (H_2N-XXXXXXEEDLGGGG-support; X can be amino acids D, E, I, K, L, Q, or S). To distinguish the particles to which the anti-c-MYC antibodies bind, the authors employed the color reaction of a second antibody coupled to alkaline phosphatase. All peptide sequences that were determined by decoding the stained particles had a high degree of homology to the MYC epitope. Deviations in the sequence occurred in at most two positions. As a control the affinity of five peptides in solution was determined. All of the IC_{50} values measured were in the lower micromolar range.



Scheme 2. Schematic description of the construction of a compound library encoded by a binary code, and of the selection of structures from this library that interact in a supramolecular ensemble. —○ denotes the support.

In the second example[7] a peptide ligand was identified which binds selectively to the synthetic receptor **1** (Scheme 3), which is labeled with a red azo dye. The encoded tripeptide library used by Still et al. in their screening included L- and D-amino acids and had various acylated N termini. It was possible here, too, to identify a series of sequences whose marked affinity to the synthetic receptor **1** was confirmed by synthesis and tests in solution.

Scheme 1. Synthesis of the tag molecules. TFA = trifluoroacetic acid.

1

Scheme 3. The synthetic receptor 1 labeled with an azo dye R.

Still et al. have proved the viability of their concept with these two examples,[6,7] and have shown that combinatorial chemistry is a useful tool for the study of supramolecular interactions. Certainly the advantages of binary coding will first be realized fully in the synthesis of compound libraries of small organic molecules.[8] The future of combinatorial chemistry promises to be interesting.

New Ionic, Isoelectronic Analogues of CO_2 and CS_2

Thomas M. Klapötke*

Several isoelectronic analogues of CO_2 have been known for a long time and are well characterized. These include neutral N_2O ($C_{\infty v}$) and the ionic species N_3^- ($D_{\infty h}$), CN_2^{2-} ($D_{\infty h}$), and NO_2^+ ($D_{\infty h}$).[1] In the last few years, in particular, great progress has been made in the area of these simple 22-electron (16-valence-electron) X=Y=Z species. Thus, all of the possible $X{=}Y{=}Z^n$ systems that contain X, Y, and Z elements of the second period and net charges ($-4 \leq n \leq +4$) have been computed by ab initio methods and many ions were predicted to be locally stable.[2] In meantime several of these unknown species have been prepared and characterized, for example CBN^{4-} and C_3^{4-}, and these species together with their heavier CS_2 analogues are highlighted here.

The structurally well-characterized ionic, isoelectronic analogues of CO_2 known to date are summarized in Table 1 together with three isoelectronic ions of CS_2, the heavier homologue of CO_2. Furthermore, the BAs_2^{3-} anion, which is isoelectronic to CSe_2, has been reported ($d_{BAs} = 186.8$ pm).[3]

In all cases the bond lengths in the ions isoelectronic to CO_2 and CS_2 are appropriate for bond orders greater than unity, and therefore significant $(p\text{-}p)_\pi$ bonding has to be considered. Even in the recently published PCS^- ion the C–S bond length (162 pm) is significantly shorter than the value expected for a typical single bond (cf. d_{CS} (thioether) $\approx$ 182 pm).[7] However, the NBO (NBO = natural bond orbitals) analysis for the PCS^- ion based on an ab initio calculation (HF 6-31 + G*), $d_{PC} = 157$ pm, $d_{CS} = 164$ pm) clearly indicates that $P{\equiv}C - S^-$ is the most favored Lewis structure (NBO charges [e]: P −0.03, C −0.63, S −0.34).[15]

Table 1. Bond lengths of CO_2 and CS_2 and their ionic, isoelectronic analogues [a].

X=Y=Z	d_{XY} [pm]	d_{YZ} [pm]	Ref.	X=Y=Z	d_{XY} [pm]	d_{YZ} [pm]	Ref.
OCO(g)	116.3		[4]	SCS(g)	155		[4]
ONO^+	115		[4]	SNS^+	146		[5, 6]
NNN^-	118		[4]				
NCO^-	121	113	[4] [b]	PCS^-	155.5	162.0	[7]
NCN^{2-}	123.0		[8]				
NBN^{3-}	135.8		[9, 10]	PBP^{3-}	176.7		[3]
CBN^{4-}	144	138	[11, 12]				
CCC^{4-}	134.6		[13]				

[a] Ions that are isoelectronic or isovalence-electronic to OCS, for example $SeCN^-$ [1] are also known; however, they are not discussed here. Polymeric structures have been proposed for the compounds Li_3AlN_2, Li_3GaN_2, Li_3AlP_2, and Li_3AlAs_2 [3]. Formally isosteric transition metal species (e.g. $[FeN_2]^{4-}$ isosteric to SiS_2) have been described see ref. [14]. [b] The fulminate ion CNO^- isomeric to the cyanate ion is also known [1].

With the exception of the C_3^{4-} ion all species quoted in Table 1 can be regarded as linear within the reported standard deviations. Interestingly, the C_3^{4-} ion exhibits C_{2v} symmetry with a C-C-C bond angle of 169.0(6)°; the C–C distances of 134.6(4) pm are consistent with the expected value for C–C double bonds of 135 pm.[13] A comparison of the experimentally determined structural parameters of the C_3^{4-} ion with those computed by ab initio methods showed that the unusual deviation from linearity can be explained by matrix effects caused by the trigonal prismatic coordination of the C_3^{4-} ion by Ca^{2+} ions.

In all ions isoelectronic to CO_2 the most electropositive atom always occupies the central Y position in the X=Y=Z species. This is consistent with theoretical calculations which predict that this isomer will always be the most stable.[16]

Most of the anionic 16-valence-electron species that are isoelectronic to CO_2 and CS_2 were synthesized by high-temperature solid-state reactions in sealed niobium or tantalum ampoules. For example, the compounds $Sr_3(BN_2)_2$[10] and K_3BP_2[3] were prepared at 1000 °C from strontium nitride and BN or from K and BP, respectively. Ca_3Br_2CBN and Sr_3Cl_2CBN were synthesized at 950 °C from the corresponding metal, its dihalide, boron nitride, and graphite.[11] In analogy, $Ca_3Cl_2C_3$ was formed from calcium, $CaCl_2$, and graphite at 900 °C.[13] The synthesis of the first compound containing an isolated PCS^- ion was achieved in solution by treatment of lithium bis(trimethylsilyl)phosphanide with equimolar amounts of *O,O'*-diethyl thiocarbonate [Eq. (a)].[7]

$$S{=}C(OC_2H_5)_2 + [(CH_3)_3Si]_2P\text{-}Li \xrightarrow{\text{DME, } -50\,^\circ C} [Li(dme)_3][PCS] + 2\,H_5C_2OSi(CH_3)_3 \quad (a)$$

(dme = 1,2-dimethoxyethane)

The SNS^+ ion is classically obtained by oxidation of a mixture of tetrasulfurtetranitride and sulfur with AsF_5 [Eq. (b)];[6] however, two new laboratory syntheses are more convenient and do not involve the use of explosive S_4N_4 [Eqs. (c) and (d)].[17]

$$S_4N_4 + \tfrac{1}{2}S_8 + 6\,AsF_5 \longrightarrow 4[SNS][AsF_6] + 2\,AsF_3 \quad (b)$$

$$S_8[AsF_6]_2 + NaN_3 \longrightarrow [SNS][AsF_6] + NaAsF_6 + N_2 + \tfrac{3}{4}S_8 \quad (c)$$

$$[N(SCl)_2][AlCl_4] + SnCl_2 \longrightarrow [SNS][AlCl_4] + SnCl_4 \quad (d)$$

Of all the ions considered here so far, the SNS^+ cation has attracted the most interest as a starting material in preparative inorganic chemistry. The preparation of new pseudoaromatic S–N heterocycles [Eq. (e)], unusual, thermally stable radicals [Eq. (f)], and polymeric sulfur nitride, $(SN)_x$, [Eq. (g)] demonstrate the synthetic potential of the SNS^+ cation in main group chemistry.[6]

$$S_2N^+ + SN^+ \longrightarrow \overline{[N\text{-}S\text{-}N\text{-}S\text{-}S]}^{2+} \quad (6\pi \text{ aromatic}) \quad (e)$$

$$S_2N^+ + F_3C\text{-}C{\equiv}C\text{-}CF_3 \longrightarrow [(F_3C)\overline{C\text{-}S\text{-}N\text{-}S\text{-}C}(CF_3)]^+ \xrightarrow{\text{red.}} [(F_3C)\overline{C\text{-}S\text{-}N\text{-}S\text{-}C}(CF_3)]^{\bullet} \quad (7\pi \text{ radical}) \quad (f)$$

$$S_2N^+ + N_3^- \longrightarrow 2/x(SN)_x + N_2 \quad (g)$$

Earlier this year the synthesis, isolation and characterization of the CBN^{4-} ion, an additional molecule isoelectronic to CO_2, was achieved. It had been predicted for many years on the basis of quantum mechanical calculations that this anion should be stable. This result should encourage the synthesis of new analogues of CO_2 and CS_2. The most likely possible new anions include: NCB^{4-} isomeric to the experimentally characterized CBN^{4-},[11] NCC^{3-} and OBC^{3-} isoelectronic with NBN^{3-},[10] and OBN^{2-} analogous to the known NCN^{2-}.[8] One particularly exciting challenge in this field that remains is the synthesis of the highly charged cations analogous to CO_2, namely O_3^{2+} and FNF^{3+}; these are predicted to be locally stable.[2]

Template Effects in New Self-Replicating Molecules**

M. Morgan Conn, Edward A. Wintner, and Julius Rebek, Jr.*

Template effects, the enhancement of reactions by complementary surfaces, lie at the heart of many chemical and biological processes.[1] A special form of templating occurs when two complementary molecules are covalently bound.[2] If the product enhances its own formation, replication is possible. This has been shown to be the case for short nucleic acids[3] and other self-complementary structures.[4, 5] We describe here a new replicating system which, by its geometry, minimizes the effects of the inevitable background reactions associated with such systems. We give evidence that the autocatalysis that is observed arises from template effects, and suggest an advantage of replication by these means.

The carbazole derivative **1** is a nearly ideal complement to the purine unit of adenine.[6, 7] The imides can chelate the purine unit through simultaneous Watson–Crick and Hoogsteen base-pairing, and stacking interactions are possible between the extended surface of the carbazole and the purine moieties. The result is high binding affinity in $CDCl_3$ ($K_a \approx 10^5$), MeOH ($K_a = 130$), and even H_2O ($K_a = 150$).[8] The tight binding also provides unambiguous positioning of the two complementary components.[7] The new replicator utilizes these features and contains a biphenyl spacer between the carbazole nitrogen atom and an electrophilic component (structure 7). The complementary structure for the replication experiments is the 5′-amino-5′-deoxy-2′,3′-*O*-isopropylideneadenosine **2**.

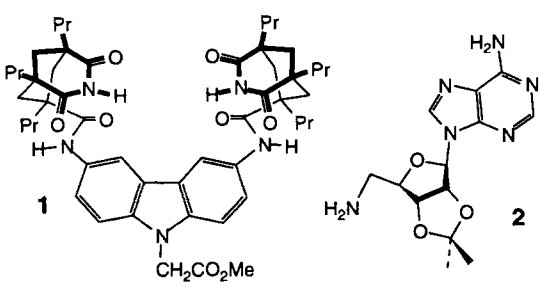

Figure 1 shows the geometry predicted in a modeling study[9] for a bimolecular complex between **2** and the biphenylcarbazole as the methyl ester **6**. The amine and ester groups are separated by a significant distance, at least 5.8 Å. This distance is well enforced; the diimide-bound adenine has only limited motion within the complex. Since the two reactive centers cannot approach each other within the complex, covalent bond formation between the amine and ester groups must occur in an intermolecular sense.

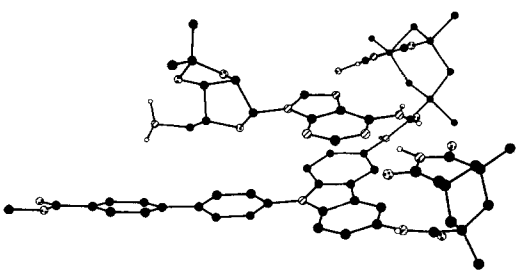

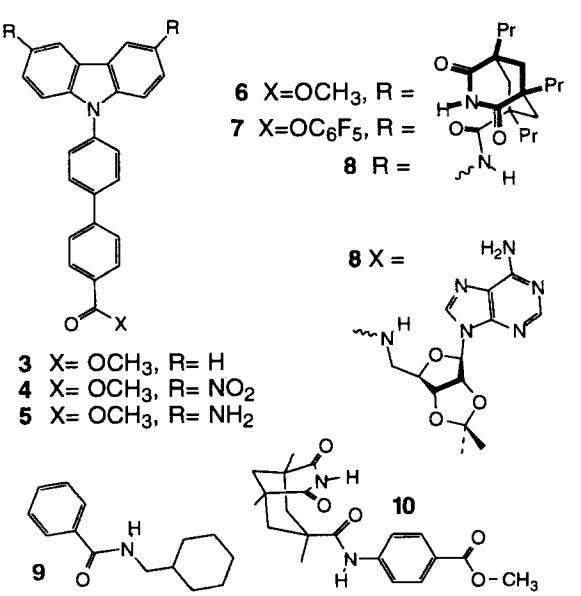

Fig. 1. Structure of a complex of **2** and **6** as predicted by molecular modeling [9].

Synthesis of the biphenylcarbazole derivative **6** proceeded through Ullmann coupling[10] of methyl 4′-iodobiphenyl-4-carboxylate and carbazole to give **3**, followed by nitration (HNO_3/HOAc) to **4**, and reduction (H_2/Pd-C, THF) to the diamine **5**.[11] Condensation of **5** with the tripropyl derivative of Kemp's triacid as the imide acid chloride gave the methyl ester **6**.[12] Demethylation of **6** was achieved by S_N2 dealkylation with thiolate anion,[13] and condensation of the corresponding acid chloride (prepared by reaction with oxalyl chloride) with adenosine **2** produced the self-complementary amide **8**. Demethylated **6** was also used to give **7** through coupling with pentafluorophenol (1-ethyl-3-(3-dimethylamino)carbodiimide (EDC), 4-dimethylaminopyridine (DMAP), THF).

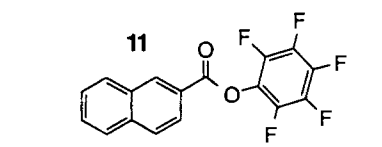
[**] This work was supported by the National Science Foundation (NSF) (Grant No. 9119995-CHE). M. M. C. thanks the National Science and Engineering Research Council (NSERC) and E. A. W. the NSF for predoctoral fellowships.

As anticipated, compound **6** has very high affinity for adenine. The slow exchange processes of the molecule lead to highly broadened ^{1}H NMR spectra during titration in $CDCl_3$, and the binding constant can only be estimated as $10^5\ M^{-1}$. In the more competitive [D_8]THF, the association constant between **6** and 2′,3′-isopropylidene adenosine was found by ^{1}H NMR titration to be $570\ M^{-1}$ at 298 K. This value is based on the downfield shift of the imide proton from $\delta = 9.65$ to $\delta = 12.87$ during titration.



Kinetic studies of the coupling reactions[14] were performed in $CHCl_3$/THF mixtures using the pentafluorophenyl active ester **7** and amine **2**. Appearance of the amide product **8** was followed by high-performance liquid chromatography (HPLC) with various additives as controls. For example, the benzoyl derivative **9** presents a secondary amide function in a steric environment similar to that of **8**, but the structure lacks recognition elements. The results are summarized in Table 1 and reveal the following:

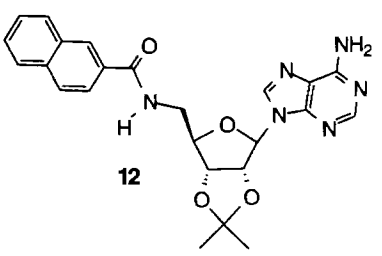


Table 1. Average initial rates v for the reaction of **2** with **7** and **11** [14].

Reactants	Additive (0.5 equiv.)	v [$\mu M\,min^{-1}$], ±5%	Reactants	Additive (0.5 equiv.)	v [$\mu M\,min^{-1}$]
2 + **7**	–	1.71 ± 0.06	**2** + **7**	**6**	1.18 ± 0.10
2 + **7**	**8**	2.63 ± 0.11	**2** + **11**	–	3.78 ± 0.06
2 + **7**	**10**	1.72 ± 0.02	**2** + **11**	**12**	4.08 ± 0.03
2 + **7**	**9**	1.56 ± 0.08			

1) *Autocatalysis occurs in the complementary system.* Addition of the product **8** increases the rate of the coupling reaction of ester **7** with **2**. Experiments with **7** and **2** at concentrations of 6.2 mM show a 54% increase in initial rate with 0.5 equivalents of added **8** (Table 1). This enhancement is comparable to that observed with our original replicators.[5]

2) *The benzoyl amide does not catalyze the reaction.* The coupling rate of **7** with **2** is not increased by the addition of the secondary amide **9**. Furthermore, the coupling of **2** with **11** under identical conditions is not significantly enhanced by addition of amide **12**; under these conditions, the general formation of secondary amides is not appreciably autocatalytic. These results are consistent with those of other self-replicating systems involving adenine recognition.[5]

3) *The adenosine moiety is not an effective catalyst for the formation of secondary amides.* This is shown by the failure of product **12** to catalyze the coupling of **2** with **11** significantly.

4) *The imide function alone is not responsible for the autocatalysis.* This was established by control experiments with the methyl ester **6**. This molecule does not catalyze the reaction of **7** with **2**; rather, some inhibition results as a consequence of its sequestering the adenosine amine in an unproductive complex. Additional experiments with **10**, which competes only poorly for adenosines, further support the conclusion that the imide group is an ineffective catalyst.

5) *Self-replication is the result.* Separated, the individual features and functionalities of **8** are unable to account for the autocatalysis observed. Instead, the effect of the whole molecule is greater than the sum of the effects of its parts. The most elegant explanation for the autocatalytic nature of **8** is that the molecule serves as a template for its own formation: the reaction between **2** and **7** or between two complexes of **2**·**7** is slow, but once formed, template **8** can bring together **2** and **7** in a productive termolecular complex. Within the complex, functional groups are presented is such a way that a tetrahedral intermediate is easily reached. The intermediate is modeled[9] in Fig. 2.

What are the consequences of complexation for replicators? The rate of formation of **8** compared with that of **12** under these conditions reveals that recognition *slows* the rate of coupling by a factor of two; in the presence of **2**, pentafluorophenyl esters such as **11** which are unable to complex **2** are twice as reactive toward amines than is ester **7**. For the same reasons, however, noncomplexed esters are also more exposed to side reactions. Structures that recognize each other and form complexes become stabilized; the surfaces in contact are protected from external, often harmful reagents, and the protected structures react primarily with molecules that are specifically complexed with them.[15] Accordingly, molecular recognition offers advantages for evolution at the molecular level; survival as well as replication is enhanced.

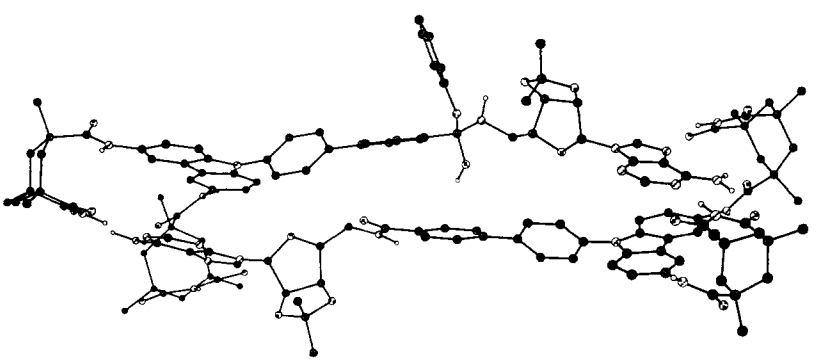

Fig. 2. Structure of the tetrahedral intermediate in a termolecular complex of **2**, **7**, and **8** as predicted by molecular modeling [9].

Our current targets are molecules in which functional groups are incorporated into the template for *chemical catalysis* of the replication step.[16] These include functions that can enhance proton transfers in the tetrahedral intermediates which are formed and destroyed along the coupling pathway. In addition, these high-affinity molecules augur well for the synthesis of structures capable of replication in aqueous media.

Reciprocal Template Effects in a Replication Cycle**

Roland J. Pieters, Ivan Huc, and Julius Rebek, Jr.*

The enhancement of chemical reactions by complementary surfaces—template effects—is widespread in biological and chemical processes.[1] Nucleic acid replication is the typical example: one strand acts as a template for the other's formation. We have earlier described self-complementary structures[2] and their ability to act as templates in self-replicating systems and as subunits for molecular assemblies. Here we show that template effects operating in a reciprocal sense, in a replication cycle, can be even more efficient than the self-replicating systems.

The molecular recognition involved is the chelation of the purine nucleus of adenine by two imides attached to a carbazole surface. The imides provide simultaneous Watson–Crick and Hoogsteen base pairing, while the carbazole and the purine interact by π stacking. High binding affinities between these two components ($K_a = 10^4$–10^5 M^{-1}) are observed in organic solvents.[3] We have now outfitted the two components with complementary chemically reactive functions, nucleophilic amines and electrophilic activated esters, for covalent coupling reactions. Specifically, amines **1** and **3** and *p*-nitrophenyl esters **2** and **4** were prepared (Scheme 1). The slow reaction of amine **1** with

Scheme 1. Amines (**1** and **3**), esters (**2** and **4**), and their coupling products (templates) **5** and **6**. PNP = *p*-nitrophenyl.

were prepared (Scheme 1). The slow reaction of amine **1** with ester **2** (each 0.05 mM) in chloroform in the presence of triethylamine produced **5**.[4] The initial rate was 1.5×10^{-8} M min^{-1} (Table 1). Likewise, amine **3** and ester **4** gave **6** at an initial rate of 4.3×10^{-9} M min^{-1} under the same conditions.

The accelerating effects of templates in these bisubstrate reactions were observed as follows: in the presence of the receptor **6**, **1** and **2** reacted to give **5** at a rate up to 12 times that of the background reaction.[5] As shown in Table 1, the acceleration was reduced by the competitive binding partner 9-ethyladenine and by the actual product **5**. Maximum rate acceleration was observed when two equivalents of the template **6** were used (Fig. 1).[6] Addition of further amounts of template led to lower coupling rates; the two reactive components form complexes on different template molecules and become increasingly separated. In control experiments with one equivalent of **7** (Scheme 2), a molecule that bears many of the structural and functional

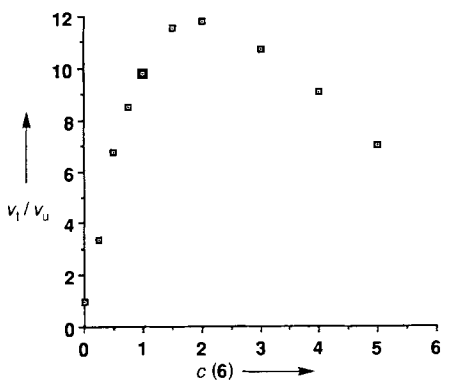
1 + 4						2200

[a] $c(1) = c(2) = c(3) = c(4) = 0.05$ mM, $c(Et_3N) = 4$ mM, Solvent: $CHCl_3$, $T = 25$ °C. [b] Averaged values from multiple independent runs; standard deviations ±15%.



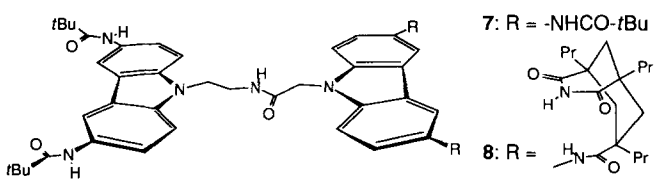


Fig. 1. The acceleration of the initial rate of the reaction between **1** and **2** (template catalyzed rate: v_t; uncatalyzed rate: v_u) as a function of the concentration of **6** (in equivalents). $c(1) = c(2) = 5 \times 10^{-5}$ M, $c(NEt_3) = 4 \times 10^{-3}$ M, solvent: $CHCl_3$, $T = 25$ °C.

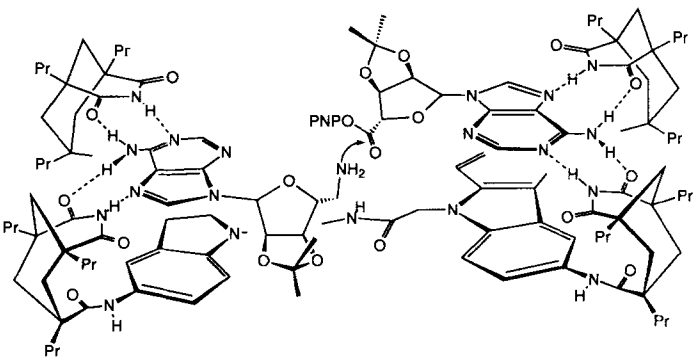

Scheme 2. Structures of molecules used as controls.

features of the template but lacks the recognition elements, no rate enhancement in the reaction of **1** with **2** was observed. Similarly, addition of one equivalent of **8**, containing one binding site, did not increase the coupling rate. These observations can be explained by the formation of a termolecular complex (Scheme 3).[7]

The reciprocal template, product **5**, proved capable of catalyzing the coupling of **3** and **4**. The observed rate enhancement over the uncatalyzed reaction was fivefold, and again, product inhibition with **6** and competitive inhibition with 9-ethyladenine was observed.

The rate enhancements here are comparable to those observed by Kelly[1d, e] for templates for bimolecular S_N2 reactions and are considerably larger (by an order of magnitude) than those observed for template effects involving *self*-complementary structures.[2a, b] The reciprocal templating effects of **5** and **6** formally represent a replication cycle. Whether these cycles are generally more efficient than the minimalist self-complementary replicators is the subject of ongoing research.

Scheme 3. The proposed termolecular complex responsible for the enhanced rates for the reaction of **1** with **2**.

In the meantime, we note that large rate accelerations can be achieved in complexes of a bimolecular sort.[8] Thus, reaction of amine **3** with active ester **2** at concentrations of 0.05 mM was 3500 times faster than the reaction of **1** with **2**. The reaction of amine **1** with ester **4** was 500 times faster than the reaction of **3** with **4**. In both cases, the products are self-complementary, but due to the flexibility of the spacers between the reactive functions, they remain folded shut in intramolecular complexes.[9]

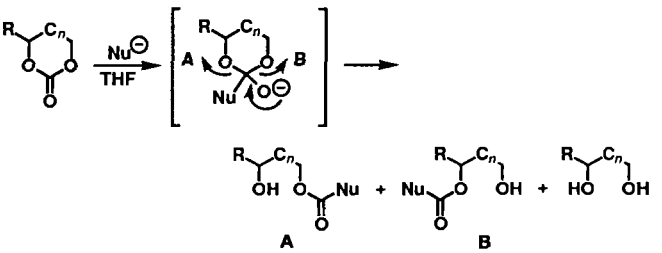
[4] The rate was determined by monitoring the release of *p*-nitrophenolate spectrophotometrically at 330 nm. Typically reactions were monitored to at least 30% conversion, and initial rates were obtained for up to 10% conversion.



[5] The products were analyzed as follows: two solutions were prepared both 0.1 mM **1** and **2** and 8 mM NEt_3 (in 20 mL $CHCl_3$). One of these also contained 0.1 mM **6**, which led to an initial rate eight times faster than that without **6** (determined spectrophotometrically). After 72 h the solvent and NEt_3 were removed, and the residues were redissolved in [D_6]DMSO and analyzed by ^{1}H NMR spectroscopy. In both cases **5** was the only observed product.

[6] Due to the low concentrations of the reagents used and binding constants of $K_a = 10^4 - 10^5$ M^{-1}, the receptors are not fully saturated with guests. Therefore the maximum is not at one equivalent of template **6**.

[7] A referee suggested that these control experiments show that catalysis by simple amides as proposed by Menger et al. (F. M. Menger, A. V. Eliseev, N. A. Khanjin, *J. Am. Chem. Soc.* **1994**, *116*, 3613) can be excluded. Menger's experiments showed that high concentrations (generally 30 mM) are required for simple amides to exert their (small) catalytic effects, whereas accelerations due to a template in the same system are operative at concentrations as low as 0.33 mM [2a]. Template effects are highly dependent on the magnitude of the association constants of the species involved and, as the present work shows, can be observed at concentrations orders of magnitude lower than required for simple amide catalysis.

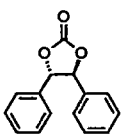
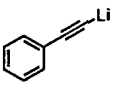
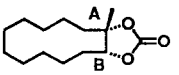
Synthesis of C-2 Taxol Analogues**

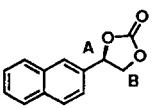
Kyriacos Costa Nicolaou,* Elias A. Couladouros, Phillipe G. Nantermet, Joanne Renaud, Rodney Kiplin Guy, and Wolfgang Wrasidlo

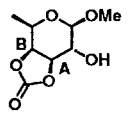
Taxol (**1**)[1, 2] is currently of substantial interest due to its exceptional chemistry,[3] biology,[3a, 4] and medical applications.[3, 4] Researchers in both academic and industrial laboratories have been devoting considerable time and effort to the











1 Taxol

design, synthesis, and biological evaluation of taxol analogues[3, 5] with the aim of attaining pharmacological properties superior to those exhibited by the parent compound. In this communication we report a general method for the regioselective functionalization of cyclic carbonates by nucleophilic ring opening and its application in the synthesis of a series of new taxoids functionalized at C-2; a family of compounds hitherto difficult to obtain.[6]

A key observation made during the total synthesis of taxol (**1**)[2a] involved the opening of a five-membered cyclic carbonate with PhLi. This reaction proceeded with exquisite regio- and chemoselection and gave a high yield of the desired product. The addition of nucleophiles to carbonates to provide esters has seen only rare use[7] and reports of such regioselective manipulation of a cyclic carbonate are rather scarce.[8] Expanding the scope of this reaction and demonstrating its wide applicability in the taxol field were the objectives of this program.

Scheme 1 shows the general strategy for the regioselective functionalization of cyclic carbonates by ring opening with nucleophilic reagents. The examples listed in Table 1 demonstrate

Table 1. Regioselective synthesis of esters through nucleophilic addition to cyclic carbonates.

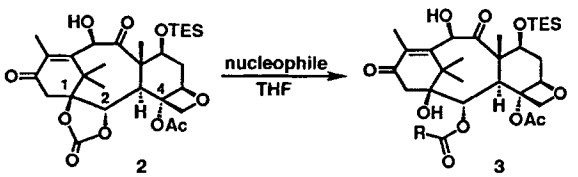
4			3.5	−78	30	93 [a]:0:0



[a] Yield based on 70–90% conversion.

the wide range of both substrates and nucleophiles that undergo this reaction and the considerable selectivities attained. The predominant product in each reaction was the ester; the only side product detected in several cases was the diol. In all cases except the primary/secondary, the exclusive product was the less substituted ester **A**. In the primary/secondary cases, the regioselectivity was about 4:1 in favor of **A**.

When applied to taxoid **2**, available from both total synthesis[2a] and semisynthesis,[9] this ring-opening process produced a number of novel taxoids **3** (Table 2). The remarkable selectivity of this reaction was quite striking, particularly in view of the three additional carbonyl groups present in the substrate **2**. Steric shielding must be largely responsible for the protection of the latter sites against the reactive nucleophiles employed. Products obtained by this method are particularly interesting in that they provide access to taxols with additional functionalities at C-2.

[a] Reaction also produced variable amounts of the C-4 hydroxy and C1-C2 dihydroxy compounds. [b] Yield based on 50–80% conversion. [c] Yield based on desilylated acetylenic compound obtained after workup. [d] 10–20% conversion only.

This position has been recognized as important for biological activity.[3] To explore such structure–activity relationships we have undertaken the conversion of compounds **3a–d** to taxoids (**7a–d**).

Several compounds of type **3** have previously been converted to taxoids.[2a] Thus acetylation of **3a–d** (Scheme 2) provided

Scheme 2. Synthesis of novel taxoids **7** [11]. a) Ac_2O/CH_2Cl_2 (1/4), Et_3N (5 equiv), 4-dimethylaminopyridine (cat.), 75–85%; b) $NaBH_4$ (10 equiv), MeOH, 0 → 25 °C, 80–90%; c) 1. $NaN(SiMe_3)_2$ (2.5 equiv), **6** (2 equiv), THF, 0 °C; 2. HF · py, THF, 25 °C, 65–85%. TES = triethylsilyl.

the corresponding 10-acetyl compounds **4** in high yield. Stereocontrolled sodium borohydride reduction of the enone carbonyl of compounds **4** led to the desired 13-α-hydroxyl compounds **5a–d** in excellent yields. Finally, coupling of these baccatin III analogues with the side-chain β-lactam **6** using Ojima's protocol,[10] followed by deprotection resulted in the formation of the new taxoids **7a–d** in high overall yields (Scheme 2).

Preliminary biological evaluation of selected compounds from this series (Table 3) revealed cytotoxicities comparable to that of taxol for the thiophene analogue **7b** and the furanyl analogue **7a**, a cytoxicity considerably less than that of taxol for the *p*-dimethylaminophenyl taxoid **7c**, and essentially no activity for the naphthalene compound **7d**. These results suggest rather well-defined demands by the taxol receptor for the C-2 ester group.[6]

The chemistry described above opens a practical approach to previously inaccessible C-2 taxol analogues and provides new opportunities for drug design and development in the taxol field. Studies directed at further refinement of the characteristics of the binding domain for taxol are currently underway in this laboratory.

[11] Selected physical data of the compounds **3b**, **4b**, **5b**, and **7b**.—**3b**: Amorphous solid: $R_f = 0.56$ (silica, ethyl acetate/hexanes 1/1); IR (film): $\tilde{\nu} = 3403, 2945, 2881, 1717, 1669, 1520, 1413, 1360, 1248, 1078\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 7.84$ (dd, $J = 1.0, 3.5$ Hz, 1H, thiophene), 7.64 (dd, $J = 1.0, 5.0$ Hz, 1H, thiophene), 7.14 (dd, $J = 3.5, 5.0$ Hz, 1H, thiophene), 5.53 (d, $J = 6.5$ Hz, 1H, 2-H), 5.29 (d, $J = 2.5$ Hz, 1H, 10-H), 4.90 (br d, $J = 7.5$ Hz, 1H, 5-H), 4.44 (A of AB, d, $J = 8.5$ Hz, 1H, 20-H), 4.35 (dd, $J = 6.5, 10.5$ Hz, 1H, 7-H), 4.29 (d, $J = 2.5$ Hz, 10-OH), 4.19 (B of AB, d, $J = 8.5$ Hz, 1H, 20-H), 3.90 (d, $J = 6.5$ Hz, 1H, 3-H), 2.89 (A′ of A′B′, d, $J = 19.5$ Hz, 1H, 14-H), 2.62 (B′ of A′B′, d, $J = 19.5$ Hz, 1H, 14-H), 2.43–2.49 (m, 1H, 6-H), 2.15 (s, 3H, OAc), 2.07 (s, 3H, 18-CH_3), 1.85–1.91 (m, 1H, 6-H), 1.73 (s, 1H, 1-OH), 1.54 (s, 3H, 19-CH_3), 1.21 (s, 3H, 16-CH_3), 1.13 (s, 3H, 17-CH_3), 0.91 (t, $J = 8.0$ Hz, 9H, $Si(CH_2CH_3)_3$), 0.49–0.56 (m, 6H, $Si(CH_2CH_3)_3$); FAB-HRMS ($C_{33}H_{46}O_{10}SSi$ [$M + H^+$]): calcd: 663.2659; found: 663.2655.—**4b**: Amorphous solid; $R_f = 0.56$ (silica, ethyl acetate/hexanes 1/1); IR (film): $\tilde{\nu} = 3456, 2956, 1711, 1669, 1525, 1413, 1376, 1264, 1227, 1073\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 7.84$ (dd, $J = 1.5, 4.0$ Hz, 1H, thiophene), 7.63 (dd, $J = 1.5, 5.0$ Hz, 1H, thiophene), 7.13 (dd, $J = 4.0, 5.0$ Hz, 1H, thiophene), 6.56 (s, 1H, 10-H), 5.58 (d, $J = 6.5$ Hz, 1H, 2-H), 4.90 (br d, $J = 8.0$ Hz, 1H, 5-H), 4.44 (dd, $J = 7.0, 10.5$ Hz, 1H, 7-H), 4.42 (A of AB, d, $J = 8.5$ Hz, 1H, 20-H), 4.18 (B of AB, d, $J = 8.5$ Hz, 1H, 20-H), 3.85 (d, $J = 6.5$ Hz, 1H, 3-H), 2.91 (A′ of A′B′, d, $J = 19.5$ Hz, 1H, 14-H), 2.64 (B′ of A′B′, dd, $J = 1.0, 19.5$ Hz, 1H, 14-H), 2.48–2.55 (m, 1H, 6-H), 2.20 (s, 3H, OAc), 2.15 (s, 3H, OAc), 2.14 (s, 3H, 18-CH_3), 1.83–1.88 (m, 1H, 6-H), 1.65 (s, 3H, 19-CH_3), 1.23 (s, 3H, 16-CH_3), 1.16 (s, 3H, 17-CH_3), 0.88 (t, $J = 8.0$ Hz, 9H, $Si(CH_2CH_3)_3$), 0.53–0.59 (m, 6H, $Si(CH_2CH_3)_3$); FAB-HRMS ($C_{35}H_{48}O_{11}SSi$ [$M + Cs^+$]): calcd: 837.1741; found: 837.1736.—**5b**: Amorphous solid; $R_f = 0.34$ (silica, ethyl acetate/hexanes 1/1); IR (film): $\tilde{\nu} = 3478, 2945, 2892, 1717, 1519, 1365, 1238, 1083\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 7.85$ (dd, $J = 1.5, 3.5$ Hz, 1H, thiophene), 7.61 (dd, $J = 1.5, 5.0$ Hz, 1H, thiophene), 7.12 (dd, $J = 3.5, 5.0$ Hz, 1H, thiophene), 6.43 (s, 1H, 10-H), 5.51 (d, $J = 7.0$ Hz, 1H, 2-H), 4.94 (br d, $J = 7.5$ Hz, 1H, 5-H), 4.78–4.83 (m, 1H, 13-H), 4.45 (dd, $J = 7.5, 10.5$ Hz, 1H, 7-H), 4.41 (A of AB, d, $J = 8.0$ Hz, 1H, 20-H), 4.19 (B of AB, d, $J = 8.0$ Hz, 1H, 20-H), 3.82 (d, $J = 7.0$ Hz, 1H, 3-H), 2.48–2.54 (m, 1H, 6-H), 2.24 (s, 3H, OAc), 2.21–2.26 (m, 2H, 14-CH_2), 2.16 (d, $J = 1.0$ Hz, 3H, 18-CH_3), 2.15 (s, 3H, CH_3), 2.00 (d, $J = 5.0$ Hz, 1H, OH), 1.85–1.89 (m, 1H, 6-H), 1.66 (s, 1H, 19-CH_3), 1.58 (s, 1H, 1-OH), 1.15 (s, 3H, 16-CH_3), 1.02 (s, 3H, 17-CH_3), 0.90 (t, $J = 8.0$ Hz, 9H, $Si(CH_2CH_3)_3$), 0.55–0.59 (m, 6H, $Si(CH_2CH_3)_3$); FAB-HRMS ($C_{35}H_{50}O_{11}SSi$ [$M + Cs^+$]): calcd: 839.1897; found: 839.1893.—**7b**: Amorphous solid: $R_f = 0.44$ (silica, ethyl acetate/hexanes 3/1); IR (film): $\tilde{\nu} = 3417, 2929, 1715, 1649, 1521, 1460, 1417, 1368, 1247, 1076\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 7.90$ (dd, $J = 1.0, 4.0$ Hz, 1H, thiophene), 7.73 (d, $J = 7.0$ Hz, 2H, NBz), 7.63 (dd, $J = 1.0, 5.0$ Hz, 1H, thiophene), 7.32–7.51 (m, 8H, Ar), 7.14 (dd, $J = 4.0, 5.0$ Hz, 1H, thiophene), 6.96 (d, $J = 9.0$ Hz, 1H, NH), 6.24 (s, 1H, 10-H), 6.19 (br t, 1H, $J = 9.0$ Hz, 13-H), 5.75 (dd, $J = 2.5$ Hz, 9.0 Hz, 1H, 3′-H), 5.55 (d, $J = 7.0$ Hz, 1H, 2-H), 4.94 (br d, $J = 8.0$ Hz, 1H, 5-H), 4.76 (dd, $J = 2.5, 5.0$ Hz, 1H, 2′-H), 4.41 (A of AB, d, $J = 8.5$ Hz, 1H, 20-H), 4.32–4.40 (m, 1H, 7-H), 4.24 (B of AB, d, $J = 8.5$ Hz, 1H, 20-H), 3.73 (d, $J = 7.0$ Hz, 1H, 3-H), 3.52 (d, $J = 5.0$ Hz, 1H, 2′-OH), 2.50–2.56 (m, 1H, 6-H), 2.44 (d, $J = 4.0$ Hz, 1H, 7-OH), 2.35 (s, 3H, OAc), 2.29 (d, $J = 9.0$ Hz, 2H, 14-CH_2), 2.22 (s, 3H, OAc), 1.84–1.90 (m, 1H, 6-H), 1.76 (s, 3H, 18-CH_3), 1.66 (s, 3H, 19-CH_3), 1.23 (s, 3H, 16-CH_3), 1.10 (s, 3H, 17-CH_3); FAB-HRMS ($C_{45}H_{49}NO_{14}S$ [$M + Cs^+$]): calcd: 992.1928; found: 992.1952 (the experimental error (0.0024) lies within the accepted limits.).

A Water-Soluble Prodrug of Taxol with Self-Assembling Properties**

Kyriacos Costa Nicolaou,* Rodney Kiplin Guy, Emmanuel Nicolauo Pitsinos, and Wolfgang Wrasidlo

Taxol (**1**, Fig. 1) is a novel anticancer agent, originally isolated from the American Pacific yew tree (*Taxus brevifolia*)[1] which, due to its important in vivo biological activity,[2] has elicited much research effort from chemists,[3–7] biologists,[2, 6] and clinicians.[2] Despite its current usage in the clinic for treatment of ovarian cancer and its much celebrated status as a major advance in cancer chemotherapy, taxol suffers from extremely low solubility in water ($< 5 \times 10^{-6}$ M). Thus taxol is applied clinically in a mixture of Cremaphor (a polyoxyethylated castor oil) and ethanol. Unfortunately this formulation often induces significant side effects, including strong hypersensitivity reactions.[8] Although premedication and slow administration of the drug can circumvent some of these problems clinically,[9] the entire protocol is rather cumbersome and requires extensive monitoring of procedures and patients.[10] While taxol's impressive efficacy has driven clinical usage of the drug forward despite these shortcomings, a water-soluble form of taxol could completely obviate these problems and both expand its usage and dramatically improve its pharmacological profile.

Numerous attempts have been made to improve the solubility and pharmacological properties of taxol.[11–17] Among the most notable taxol derivatives synthesized so far are those in which the C-2′ and C-7 hydroxyl groups of the molecule are engaged in a functional group that collapses, upon in vivo activation, releasing taxol. Conjugates of this type are termed prodrugs. Owing to persisting problems with solubility and bioavailability, none of these prodrugs have been applied successfully in the clinic. Successful application of these compounds requires that their properties be finely balanced. On the one hand, they must be hydrophilic for formulation purposes, while on the other, they must be lypophilic for therapeutic purposes. Furthermore, to avoid execretion through the kidneys they must rapidly convert from the hydrophilic to lypophilic form.

[**] This work was supported by the National Institutes of Health, the Office of Naval Research (a predoctoral fellowship to R.K.G.), and The Scripps Research Institute. We thank Drs. R. Milligan and X. Chan for the TEM studies, S. Mauch for the in vivo animal studies, and R. Merlock for development and execution of HPLC and tubulin experiments, Gary Siuzdak for assistance with mass spectrometry, and D.-H. Huang for his help with the NMR studies.

In pursuing a program directed at the design and chemical synthesis of novel derivatives of taxol in which the C-2′ and C-7 hydroxyl groups are functionalized, we prepared taxol-2′-methylpyridinium acetate (taxol-2′-MPA **2**; Fig. 1a), a compound that was expected to be quite reactive towards nucleophilic displacement.[18] Compound **2** was prepared by the method of Mukaiyama et al.[19] from taxol (**1**) and 2-fluoro-1-methylpyridinium tosylate (1.2 equiv) in the presence of triethylamine (1.5 equiv) in dichloromethane (25 °C, 0.5 h). Purification by reversed-phase high-pressure liquid chromatography (RP-HPLC) followed by ion exchange (tosylate for acetate) and lyophilization gave pure taxol-2′-MPA (**2**) in 90% yield as an amorphous white solid (Fig. 1b). Spectroscopic and analytical data were in accord with structure **2**. Preliminary investigations (vide infra) revealed that this compound has a number of important properties, including hydrolytic stability, high solubility in water, the ability to release taxol rapidly in human plasma, cytotoxicity and antitumor properties similar to those of taxol, and aggregation behavior.

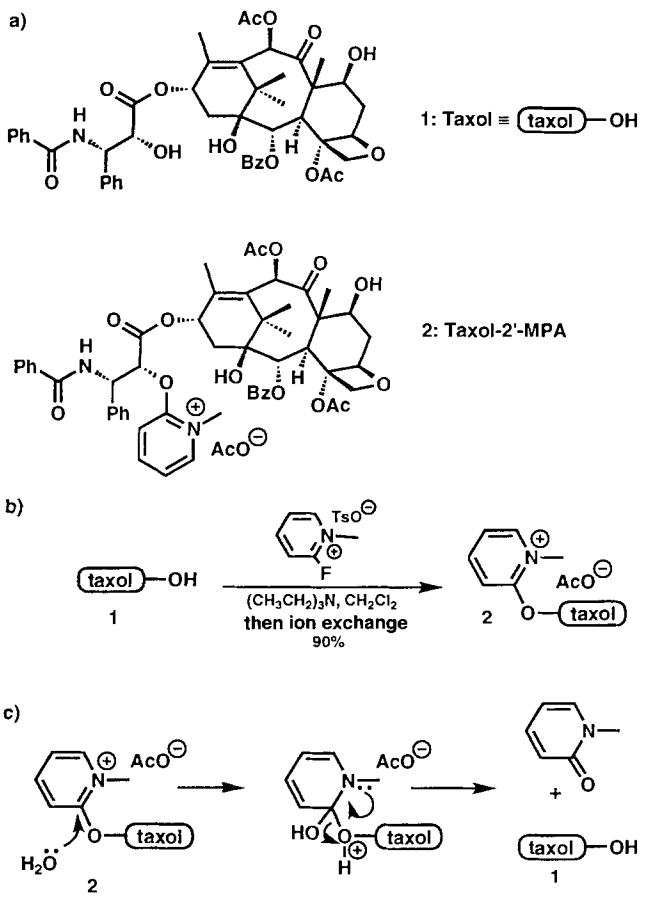

Fig. 1. a) Molecular formulas of taxol (**1**) and taxol-2′-MPA (**2**); b) synthesis of **2**; c) possible mechanism for release of **1** from **2**.

Taxol-2′-MPA (**2**) exhibits high stability both in the solid state and in aqueous solutions. In all studies carried out, the only degradation products detected were taxol (**1**) and the pyridinone that results from hydrolysis of the pyridinium salt (Fig. 1c). Owing to differences in retention times under the HPLC conditions used and differing ultraviolet (UV) absorption maxima ($\lambda_{280}/\lambda_{254} = 1.6$ for **2** and 0.3 for **1**), the stability of **2** was easily assayed by HPLC using UV detection. Taxol-2′-MPA (**2**) appears to be completely stable in the solid state at ambient temperatures for at least 30 days. In water, 5% dextrose, or 0.9% saline solution, **2** is stable for several days at ambient temperatures (Fig. 2) but begins to exhibit slow degradation after four days. In phosphate-buffered saline (PBS) or ammonium acetate buffers of

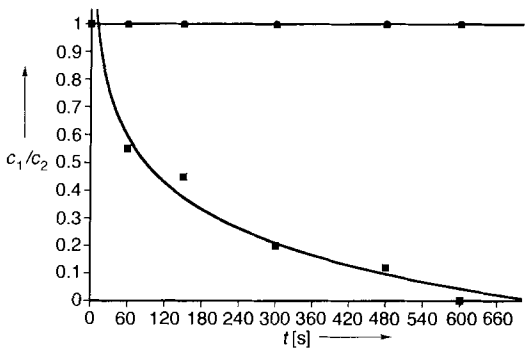

Fig. 2. Rates of taxol release from taxol-2′-MPA (**2**) in aqueous solutions at 25 °C. Although **2** is stable in water and aqueous buffer solutions (horizontal line), extraction with CH_2Cl_2 of plasma treated with **2** showed complete conversion of **2** into taxol (**1**) within 10 min (curve, 20% of total recovered). c_1 is the concentration of free **2**; c_2 is the concentration of free taxol.

pH 6.0 to 7.3, **2** is stable at ambient temperatures for at least 21 days. However, taxol-2′-MPA (**2**) shows limited and varying stability in 5% aqueous HCl (pH 1.1), brine (ca. 6 M aqueous NaCl), and aqueous ethanolic solutions. Most significantly, **2** rapidly converts to taxol (**1**) when incubated at 37 °C with human plasma (< 10 min, Fig. 2). In experiments with pure albumin taxol (**1**) was also rapidly released. Furthermore, in studies with tritiated **2** in mice, only 5% of the compound was excreted through the kidneys as taxol, a result that is in complete accord with the behavior of taxol.[20] These results strongly suggest that **2** functions in vivo as a prodrug to taxol. It should be noted that the excellent bioavailability of **2** stands in contrast to a number of previously synthesized protaxols,[16] which are rapidly excreted through the kidneys.[21] The release of taxol from **2** is presumed to be the result of a nucleophilic attack by water or another nucleophile at the 2-position of the pyridinium moiety as indicated in Figure 1c. Whether this rapid reaction in human plasma is enzyme-assisted remains to be clarified.

The solubility and partition coefficient data for taxol-2′-MPA (**2**) and taxol (**1**) were determined using HPLC. In 100 mM PBS **2** exhibited asolubility of 1.5 mM and a partition coefficient (octanol/water) of 50; the corresponding values for taxol were < 0.0015 mM and 10000. It should be noted that the solubility of taxol is at the detection limit of the HPLC instrument used and thus represents an upper limit. The solubility of **2** was determined at a concentration at which the solution was clear and noncolloidal and thus represents a lower limit. Compound **2** demonstrated similar solubilities in various buffer systems in the pH range 6.2 to 7.4. In pure water the solubility appears limited only by the formation of clear colorless gels at high concentrations (> 20 mM). These data clearly show that **2** is orders of magnitude more soluble in water than the parent taxol (**1**). The solubility exhibited by **2** in a range of aqueous systems is significantly higher than taxol's clinically relevant dosages (3–30 μM).

Microtubule polymerization–depolymerization experiments[22] with taxol-2′-MPA (**2**) revealed very similar effects to those observed with guanosine-5′-triphosphate (GTP)/saline controls and drastically different from those elicited by taxol. Thus, **2** demonstrated no stabilization of microtubules upon

$CaCl_2$ addition, which reflects the compound's lack of intrinsic activity and its chemical stability in the medium used for this assay. This result is in accord with the behavior of other 2'-substituted derivatives.[23-25] Taxol (**1**), recovered from human plasma to which compound **2** was added, exhibited the expected stabilization of microtubules, which again indicates that **2** acts as a prodrug for taxol.

Taxol-2'-MPA (**2**) was tested for its cytotoxicity against a series of cell lines that included leukemia, ovarian, lung, breast carcinoma, and melanoma cells (Fig. 3). The cytotoxicity profiles for **2** were compared to those of taxol and found to be quite similar, although some differences were noted. Both compounds exhibited IC_{50} values ranging from 10^{-5} to 10^{-12} M with means close to 1 nM. Extremely high cytotoxicity levels were recorded for human leukemia, metastatic melanoma, and cervical carcinoma cells. Overall, and as expected for a taxol prodrug, **2** shows the same remarkable tumor cell selectivity and cell line specificity as taxol.

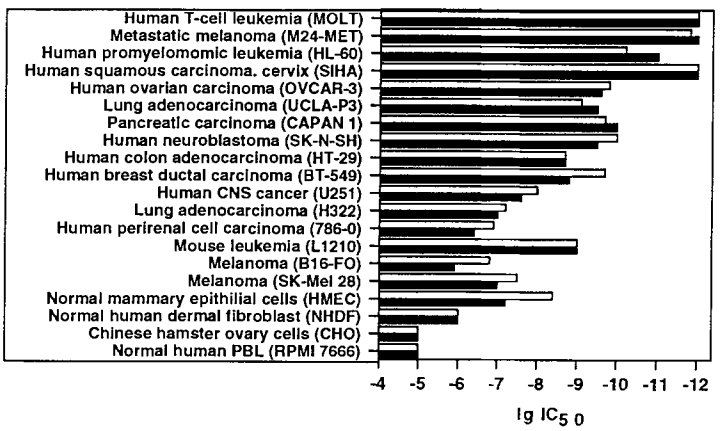

Fig. 3. Cytotoxicities of taxol-2'-MPA (**2**, white bar) and taxol (**1**, black bar) against a series of cell lines.

The promising in vitro results and solubility profile of taxol-2'-MPA (**2**) prompted us to study its in vivo action and compare it with that of taxol by using nude mice inflicted with human prostate carcinoma xenografts (Fig. 4). In contrast to taxol (**1**), compound (**2**) was formulated in sterile 5% aqueous dextrose solution without Cremaphor, which demonstrates the suitability of **2** for simple bolus administration and its first advantage over the parent compound. Several experiments with mice revealed that taxol-2'-MPA exhibits tumor growth inhibition equal to that of taxol at the same molar concentration; both compounds demonstrated impressive antitumor properties as compared to controls (Fig. 4). Most impressively, in studies in which **1** and **2** were both applied at the maximum tolerated dose (MTD) of taxol, taxol showed significant toxicity (four of eight animals died before the study's end), while taxol-2'-MTA showed no visible toxicity (four of eight animals were also tumor free at the end of this study).

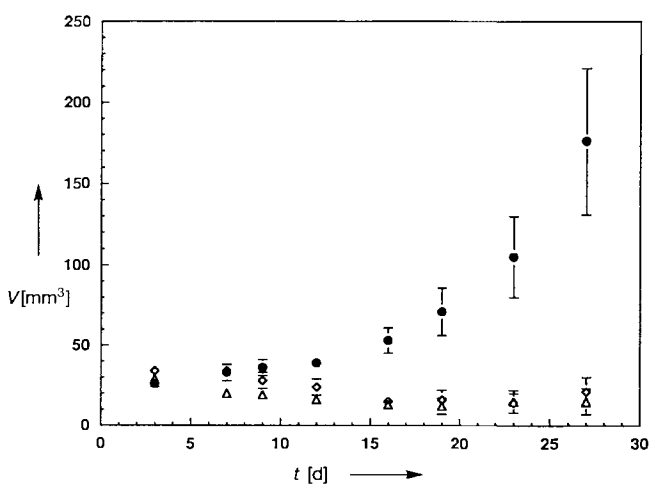

Fig. 4. In vivo efficacy of taxol-2'-MPA (**2**) in prostate tumor xenograft nude mouse model: 5% dextrose (●), taxol (△), and taxol-2'-MPA (◇).

The novel molecular structure of taxol-2'-MPA and its high solubility in aqueous media prompted us to investigate its self-assembly properties. Molecular self-assembly is a phenomenon of considerable current interest. Much of the excitement is derived from the potential of this process to form nanostructures with possible applications in materials science and medicine.[26-28] Central to these investigations are the contributions from chemistry, which include the design and synthesis of self-assembling molecules such as lipid-based[29] and H-bonded structures.[30] Living systems also use extensively self-assembling processes to construct nanostructures; microtubules, taxol's cellular target,[31] are a prominent example.

Taxol-2'-MPA (**2**) was found to form several types of assemblies, including regular helices and micelles, depending on the nature of the media. This rather serendipitous finding is not that surprising, since the molecular structure of **2** is ideal for self-assembly processes.[32-34] It combines a highly hydrophobic segment (taxol skeleton) with a polar head (pyridinium moiety), a characteristic feature of many self-aggregating molecules. While self-assembly is known for planar amphiphiles such as the antiasthmatic cromolyn, it is, to our knowledge, unknown in such globular molecules. Furthermore, the chirality of the structure apparently induces helicity in long nanostructures formed by this building block.[35-38] Although aqueous solutions of **2** were optically clear at all concentrations examined ($< 1 \times 10^{-3}$ M), buffered solutions with concentrations exceeding 1×10^{-3} M exhibited a blue haze to the naked eye and diffuse scattering of monochromatic light, both characteristic properties of colloids. At higher concentrations colloidal gels form. UV absorption measurements at 340 nm, a wavelength at which **2** exhibits no absorption, showed an exponential increase in optical density (OD) above 4×10^{-4} M, a result also characteristic of colloid formation.

Transmission electron microscopy (TEM) confirmed the presence of supramolecular structures in these solutions. Thus, 1 mM solutions of **2** in PBS displayed uniform aggregates of fibrillar structure (Fig. 5A) with helical conformations. These nanostructures exhibited varying lengths up to 800 Å but a consistent diameter of roughly 80 Å with a helical twist of about seven units per turn (Fig. 5c). Additionally, in freshly sonicated aqueous solutions of **2** (1 mM) spherical structures (Fig. 5B) with a consistent diameter of about 50 Å were observed. Highly concentrated solutions (colloidal, ca. 2×10^{-3} M) revealed more complicated molecular architectures; meta tubules assembled from the original filaments (Fig. 6).

We described here the novel physical, chemical, and biological properties of taxol-2'-MPA (**2**), a compound obtained in one step and in high yield from taxol (**1**). Compound **2** appears to be superior to taxol (**1**) as an antitumor agent based on its aqueous solubility and in vivo action against tumor xenografts. The data presented in this paper suggest that taxol-2'-MPA (**2**) is a prime candidate for development as an anticancer agent. Other taxoids such as taxotere[39] may be similarly modified to afford more

effective agents. Furthermore, other functional groups similar to the pyridinium moiety could be introduced at the 2′-, 7-, or other appropriate positions of taxoids to endow the new derivatives with such properties. The impressive properties of **2** may be attributable to its ability to self-assemble into nanostructures in aqueous media. Studies aimed at elucidating the relationship between such nanostructures and activity are currently under way.

Experimental Procedure

Synthesis of 2: Taxol (10.2 mg, 0.012 mmol) was dissolved in dichloromethane (0.4 mL) and treated sequentially at ambient temperature and under an atmosphere of dry argon with triethylamine (2 μL,1.3 equiv) and 2-fluoro-1-methylpyridinium tosylate (4.0 mg, 1.2 equiv). The clear colorless solution rapidly turned to a clear pale yellow. After stirring for 30 min at ambient temperature the reaction was judged complete, as no taxol remained and only one compound was apparent by HPLC (Vydak 22.5 mm × 250 mm C18 column, 10 mM NH_4OAc in 20% aq. methanol → methanol over 30 min, 9 mL min^{-1}. UV, *R*: **2**, 26.2 min; **1**, 28.8 min). The crude product was purified by HPLC, and solvent was removed in vacuo to give **2** (11 mg, 90%). ^1H NMR ($CDCl_3$, 500 MHz) δ = 1.07 (s, 3H, C16-H), 1.11 (s, 3H, C17-H), 1.62 (s, 3H, C19-H), 1.76 (s, 3H, C18-H), 1.85 (m, 1H, C6-βH), 2.00 (s, 3H, C10-OAc), 2.1–2.2 (br. m, 2H, C14-H), 2.2 (s, 3H, C4-OAc), 2.53 (overlapping s and m, 4H, C6-H, counterion OAc), 3.67 (d, 1H, *J* = 7.0 Hz, C3-H), 4.05 (s, 3H, N-CH3), 4.10 (d, 1H, *J* = 8.5 Hz, C20-H, A of AB), 4.22 (d, 1H, *J* = 8.5, C20-H, B of AB), 4.31 (dd, 1H, *J* = 8.7, 10.7 Hz, C7-H), 4.87 (dd, 1H, J = 1.0, 7.7 Hz, C5-H), 5.50 (d, 1H, J = 7.0 Hz, C2-H), 5.70 (br. t, 1H, *J* = 8.0 Hz, C2′-H), 5.95 (dd, 1H, *J* = 1.0, 8.0 Hz, C13-H), 6.20 (s, 1H, C10-H), 6.46 (br. d, 1H, *J* = 10.0 Hz, C3′-H), 7.08 (t, 1H, J = 7.5 Hz, NH), 7.33–7.45 (m, 7H, Ar-H), 7.57 (t, 2H, *J* = 8 Hz, Ar-H), 7.69 (d, 2H, *J* = 9.0 Hz, Ar-H), 7.79 (d, 1H, *J* = 9.0 Hz, Ar-H), 8.01 (dd, 2H, *J* = 1.0, 8.0 Hz,Ar-H), 8.14 (d, 1H, *J* = 8.0 Hz, Ar-H), 8.29 (d, 2H, *J* = 7.0 Hz, Ar-H), 8.41 (t, 1H, *J* = 7.0 Hz, Pyr-H), 10.48 (d, 1H, *J* = 7.0 Hz, Pyr-H). IR (neat, KCl) $\tilde{\nu}$[cm^{-1}]: 3640–3120 (bm), 3030–2870 (bm), 2320 (m), 1720 (s), 1630 (m), 1560 (m), 1500 (m), 1360 (s), 1160 (m), 1070 (m), 700 (m). UV/VIS ($CHCl_3$): λ_{max} [nm] = 254, 280. FAB-HRMS: calc for M^+ $C_{53}H_{57}O_{14}N_2$: 945.3810; found: 945.3810

Stability Studies: **2** was dissolved in the aqueous system with the aid of sonication for 5 min. Aliquots were removed at the times shown in Figure 2, partitioned into dichloromethane to quench the reaction, and analyzed by using a Waters Maxima HPLC instrument equipped with an autoinjector (3.9 × 300 mm C18 column equipped with a precolumn; flow rate 1.5 mL min^{-1}; eluent gradient A–B over 30 min where A is 80% 80 mM NH_4OAc (pH 6.0) and B is 100% methanol; UV diode-array detector). The ratio of **2** (c_1, R_f = 16.2 min) to taxol (c_2, R_f = 16.8 min) remaining was determined from the relative areas of the peaks after normalization with previously determined calibration curves. The stability studies in aqueous solutions were continued for more than two weeks; little degradation was exhibited by the buffered solutions of **2**.

Solubility Studies: Solubility was determined dissolving the compound in solvent with the aid of sonication (5 min), centrifuging the sample, and injecting the supernatant into an HPLC instrument (for conditions, see Stability Studies). The values reported were normalized using calibration curves constructed for both compounds by preparing solutions with known concentrations in the range 1×10^{-6} to 1×10^{-3} M in dichloromethane and subjecting to them HPLC analysis under the same conditions. Partition coefficients were determined by dissolving the compound in the organic phase, shaking the resulting solution with water for 10 min, and analyzing each phase by HPLC as described above. No degradation of **2** was noted during these studies.

Cytotoxicity Measurements: Cells were plated on 96 well plates with the following controls: no cells and toxic control (1×10^{-3} M sodium dodecyl sulfate (SDS)). The drug was added to the first set of wells and diluted according to standard dilution methods from these wells. Plates were incubated at 37 °C under 5% carbon dioxide in sterile air in an humidified incubator for 72 h. A solution (50 μL) of 2,3-bis-(methoxy-4-nitro-5-sulfophenyl)-5-[(phenylamino)carbonyl]-2*H*-tetrazolium hydroxide, XTT, 1 mg mL^{-1}) in PBS (100 mM) was added to each well. In the presence of viable cells, this colorless clear solution is enzymatically transformed to give a pink coloration. The plates were read at 450 nm using a microplate reader (Molecular Devices Thermomax).

In Vivo Efficacy: The tumor model was generated from an ATTC PC-3 prostate carcinoma cell line that was maintained under standard cell proliferation conditions (37 °C, 5% carbon dioxide in sterile air). Each cohort was comprised of eight randomly chosen, female athymic nude mice, for a total population size of 24. Hemocytometer-counted cells suspended in Hanks medium (Gibco, Grand Island, NY) were implanted subcutaneously (10^6 cells in 0.4 mL per mouse). Solid tumor growth was measured on each third day and tumor volume determined using the equation (length) × (width)^2(0.5). Equimolar amounts of the test compounds (1.0 μM) were injected intraperitoneally on days 1, 3, 5, 7, 9, and 11 using the following media: control, 5% dextrose in water (D5W); taxol, suspended in Cremaphor/D5W (5/95, 18.0 mg kg^{-1} of animal weight); taxol-2′-MPA, dissolved in D5W (23.9 mg kg^{-1} of animal weight). The procedures used for the maintenance of tumors and the experimental details were according to protocols set forth by the Developmental Therapeutics Program, National Cancer Institute (NCI). Inferences about efficacy were drawn by ANOVA followed by protected t-test. For example: day 9 (worst case); after ANOVA shows significant variance at the 0.06 level, t-test shows taxol and taxol-2′-MPA are significantly different from the control at the 0.04 level. After day 9, each data set is significantly different from the others at better than 0.05 confidence limit. Data shown as mean value with standard error.

Trigonal Symmetry as a Host Design Element: Novel Conformation of Dodecakis(3,5-dimethylphenylthio)coronene in its 1,4-Dioxane Clathrate**

Gary A. Downing, Christopher S. Frampton, David D. MacNicol,* and Paul R. Mallinson

It is becoming increasingly apparent that the rotational symmetry of the individual host molecule is a key strategic design factor for the discovery and development of new series of host compounds capable of forming crystalline inclusion compounds.[1] The significance of a C_2 axis is highlighted by design of hosts related to *exo*-2, *exo*-6-dihydroxy-2,6-dimethylbicyclo[3.3.1]nonane,[2] tetraphenylene-derived hosts,[3] roof- and scissor-type hosts,[4] and naphthalene-based spider hosts;[5] whilst the crucial importance of a C_3 axis is well represented by hosts of the cyclotriphosphazene type,[6] cyclododecatriene-based hosts,[7] racemic and optically resolved *trans,anti,trans, anti,trans*-perhydrotriphenylene,[8] cyclotriveratrylene and related hosts,[9] and hexa-hosts (i.e. hexasubstituted benzenes designed to produce cavities)[10] along with their Piedford counterparts.[11]

The hexa-host series,[10] members of which typically display an *ababab* conformation with regular alternation of side-chain units above and below the central benzene core, suggested to us an analogous series of hosts possessing *six pairs* of side-chain units corresponding to a dodecasubstituted coronene nucleus. To explore the possibility of synthesizing such novel hosts, the suitable precursor perchlorocoronene **1** was prepared in high yield by perchlorination of coronene under $SO_2Cl_2/S_2Cl_2/AlCl_3$ conditions.[12] The molecular structure of **1**, determined by single-crystal X-ray analysis[12] and electron microscopy[13] at 1 Å resolution, was found to be markedly nonplanar, reflecting pronounced *peri* interactions, and to have symmetry close to D_{3d}. The molecule displays two concave faces and its conformation was found to be, in an extension of our earlier nomenclature,[14] of the highly promising *aabbaabbaabb* type with pairs of chlorine atoms alternating regularly above and below the mean plane of the coronene nucleus. The presence of this conformation in related molecules should enhance host characteristics, not only because of the C_3 axis normal to the central coronene core, but also because of the favorable overall molecular shape reminiscent of a higher order hexa-host (vide infra). Preliminary studies[12] indicated that persubstitution of **1** with arenethiolate nucleophiles was readily achieved at ambient temperature, employing 1,3-dimethylimidazolidin-2-one (DMEU) as solvent. The resulting dodecasubstituted coronenes were, however, found to display rather limited host properties indicating that design of the side-chain unit would be of critical importance.

We now report the synthesis of the versatile coronene-based host dodecakis(3,5-dimethylphenylthio)coronene **2** with an optimized side chain. Host **2** was found to form stable crystalline inclusion compounds with many guests, for example, *N*-methylmorpholine, 1,4-dioxane, 1,4-thioxane, THF, tetrahydrothiophene, cyclohexanone, cycloheptanone, and DMEU, all with a common host–guest ratio of 1:2. In addition, we describe results of a detailed single-crystal X-ray analysis of the 1,4-dioxane adduct of **2**, undertaken to elucidate the structure and conformation of host **2** as well as the host–guest packing in this highly crystalline inclusion compound. Also, briefly reported is the synthesis of the dodecaether host dodecakis(3,5-dimethylphenoxy)coronene **3**, the first member of a new class of molecule, featuring the same favored 3,5-dimethyl substitution pattern in the side-chain moiety.

2, X = S

3, X = O

The 1,4-dioxane inclusion compound of **2** is triclinic,[15] space group $P\bar{1}$, with two host and four 1,4-dioxane guest molecules per unit cell. Interestingly, the well-formed crystals of this adduct are weakly diffracting at room temperature, so X-ray data had to be collected at low temperature (120 K). The stereoview shown in Figure 1 illustrates the molecular structure of **2**. As can be seen the molecule's coronene core is markedly nonplanar. A key feature of the molecule is an approximate C_3 axis normal to the central coronene core. Since the molecule occupies a general position in the unit cell, this is not required by the crystallographic symmetry. Corresponding to this noncrystallographic C_3 axis, there are two types of pairs of side chain moieties, splayed or parallel, respectively above and below the coronene nucleus. Satisfyingly, the host molecule possesses the *aabbaabbaabb* conformation, alternating pairs of sulfur atoms being displaced above and below the mean plane of the twelve most central carbon atoms (see Fig. 2 and legend). The six carbon atoms of the central benzene ring and the carbon atoms directly attached to it, whilst close to planarity,

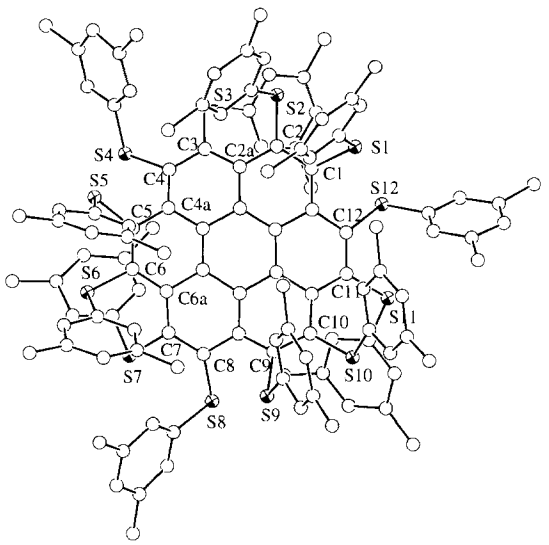

Fig. 2. A view of **2** in its 1,4-dioxane adduct, illustrating the host's atomic numbering scheme. Displacements of approximately C_3-related pairs of sulfur atoms from the mean plane of the central twelve carbon atoms are: S1,S2: −1.12, −0.85; S5,S6: −1.20, −0.78; S9,S10: −1.26, −0.90. − S3,S4: +1.28, +1.14; S7,S8: +1.50, +1.25; S11,S12: +1.20, +1.25. From the same mean plane, related displacements of the C atoms are: C1,C2: −0.38, −0.34; C5,C6: −0.42, −0.34; C9,C10: −0.44, −0.39. − C3,C4: 0.49, +0.40; C7,C8: +0.57, +0.47; C11,C12: +0.50, +0.45. Carbon atoms C6a,C2a, and C4a show respective displacements of +0.06, +0.04, and −0.03 Å from this plane. The remaining nine central carbon atoms are coplanar to within ± ca. 0.02 Å. Estimated standard deviations for S and C, 0.002 and 0.007 Å, respectively.

are not so accurately planar as in the perchlorocoronene precursor.[12]

Figure 3 illustrates the host–guest packing in 1,4-dioxane · **2** viewed along the *a* axis. There are two crystallographically independent 1,4-dioxane guest molecules, both occupying general positions. A pair of well-ordered molecules of the first type may be seen close to $\frac{1}{2}, \frac{1}{2}, \frac{1}{3}$ and $\frac{1}{2}, \frac{1}{2}, \frac{2}{3}$, straddling the center of the cell; whilst the second type of guest, close to 0,0,1, is incompletely located. The corresponding (isostructural)[15] 1,4-thioxane adduct of **2** also exhibits two similar guest sites, with apparent interchange of order and disorder for the two sites.

The above-noted approximate C_3 symmetry does not arise purely from chance, but reflects approximate trigonal packing of the molecules of **2**. This is, perhaps, best appreciated from Figure 4 which corresponds to the view along the rhomb diagonal of a cell approximating to $R\bar{3}$; however, the guests' orientation pattern (only well-ordered guest shown) does not conform to the approximate trigonal packing. The outline of the true triclinic cell (viewed approximately normal to its *ab* plane) is also shown in Figure 4 for comparison.

The dodecaether host compound **3** analogous to **2** forms light yellow crystals of a 1,4-dioxane adduct on recrystallization from the same solvent. However, in this case the crystals are monoclinic, not triclinic, and a host–guest ratio of about 1:6 has been established by ^{1}H NMR. A single-crystal X-ray analysis of this 1,4-dioxane adduct of **3** is currently underway.

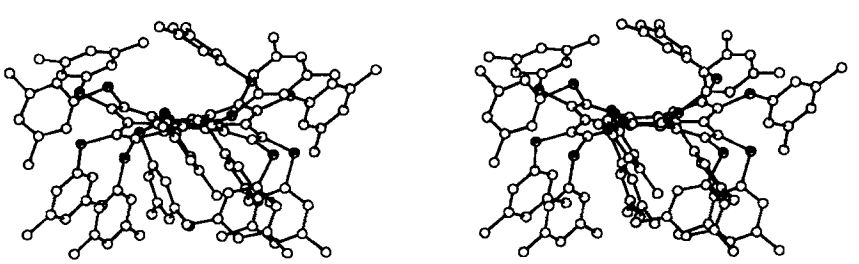

Fig. 1. A stereoview of the molecular structure and conformation of **2** in its 1,4-dioxane adduct.

Experimental Procedure

Synthesis of **2**: **1** [12] (0.25 g, 0.3 mmol) and sodium 3,5-dimethylbenzenethiolate (1.15 g, 7.2 mmol), prepared from 3,5-dimethylbenzenethiol and sodium in absolute ethanol, were stirred in 20 mL of dry, degassed DMEU for two days at ambient temperature, under N_2. The mix-

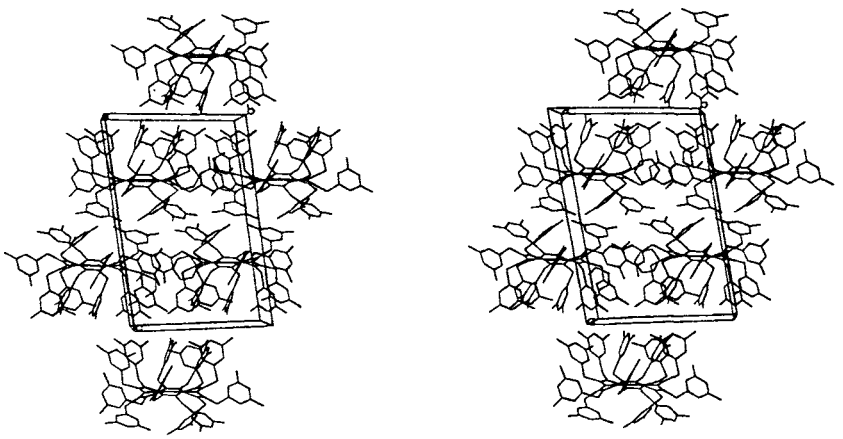

Fig. 3. A stereoview of the host–guest packing in the 1,4-dioxane clathrate of **2**. Two well-ordered 1,4-dioxane guest molecules may be seen around $\frac{1}{2}, \frac{1}{2}, \frac{1}{3}$ and $\frac{1}{2}, \frac{1}{2}, \frac{2}{3}$, whilst the second guest type, represented by only five atoms, is shown close to two cell corners.

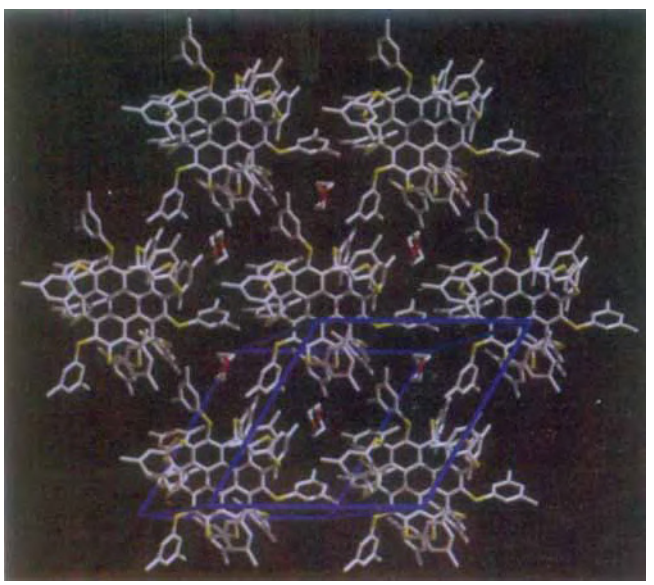

Fig. 4. A view of the approximate trigonal packing of the host molecules of **2** in its 1,4-dioxane adduct (only well-ordered type of 1,4-dioxane guest shown).

ture was then added to toluene (250 mL), washed with water (250 × 10 mL), and evaporation of the solvent gave a red oil, from which compound **2** was obtained (as its 1,4-dioxane adduct) on recrystallization from 1,4-dioxane/methanol; yield 0.52 g (90%), purple crystals, m.p. 275–278 °C (1,4-dioxane adduct). ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 1.89$ (s, 72H), 6.25 (s, 24H), 6.55 (s, 12H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 21.1$, 123.6, 124.4, 127.1, 134.4, 137.5, 138.8, 139.7; FAB MS: *m/z*: 1933.52 (±0.17) [M^+ + H]; $C_{120}H_{109}S_{12}$ requires 1933.52.

Synthesis of **3**: **1** [12] (0.2 g, 0.28 mmol) and sodium 3,5-dimethylphenolate (1.20 g, 9.8 mmol), prepared from 3,5-dimethylphenol and sodium in absolute ethanol, were stirred in 20 mL of dry hexamethylphosphoric acid triamide for seven weeks at 90 °C, under N_2. The mixture was then added to toluene (350 mL), washed with water (350 × 10 mL), and evaporation of the solvent gave a brown oil which was chromatographed (dry column) on silica gel (97/3, 40–60 °C petrol/diethyl ether) to afford 88 mg (18%) of **3** as a yellow powder, m.p. 291–292 °C. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 2.00$ (s, 72H), 6.04 (s, 24H), 6.40 (s, 12H); FAB MS: *m/z*: 1741 [M^+ + H].

A General Synthetic Strategy for Neutral Phosphorus-Containing Dendrimers

Nathalie Launay, Anne-Marie Caminade, Roger Lahana, and Jean-Pierre Majoral*

Dendrimers, highly branched functionalized molecules formed by iterative reaction sequences, are attracting considerable attention in organic, supramolecular, and polymer chemistry.[1] Until now few of these macromolecules have contained main group

elements such as silicon[2] or phosphorus.[3] Only phosphorus dendrimers having charges within the cascade structure and elaborated to three generations have been reported,[3] and no example of neutral phosphorus dendrimers has yet been described.

We report here on the easy, high-yielding preparation of up to fourth-generation neutral cascade molecules in which the core and subsequent branch points are pentavalent phosphorus atoms. These dendrimers possess at the periphery up to 48 of two of the most reactive functional groups in organic and main group element chemistry—aldehyde groups and phosphorus–chlorine bonds.

The first step consists of the reaction of trichlorothiophosphorous(V) (1 equiv) with the sodium salt of 4-hydroxybenzaldehyde **1** (3 equiv) to give **2**. Subsequent addition of the hydrazine derivative **3** leads quantitatively to **4a**, a first-generation dendrimer possessing six P–Cl bonds (Scheme 1). Further elaboration to second-, third-, and fourth-generation cascade molecules is accomplished by repetition of these two steps (Scheme 1). In each reaction cycle terminal aldehyde groups and then terminal dichlorothiophosphoryl groups are introduced quantitatively and remain available for continued reactions. No protection/deprotection procedure is necessary, and the only by-products are sodium chloride and water! All the compounds, including those of the fourth generation, **7a** ($M = 11269$) and **7b** ($M = 15381$), are stable and remain perfectly soluble in a variety of organic solvents (chloroform, THF, etc.). All the dendrimers were characterized by NMR and IR spectroscopy, and elemental analysis (Table 1). Mass spectrometry (FAB or electron spray) is useful for dendrimers up to the second generation (**5b**: m/z: 3418 $[M+1]^+$).

Remarkably the construction of each generation can be easily followed by ^{31}P NMR spectroscopy: all phosphorus sites are distinguishable at each generation by their ^{31}P NMR chemical shifts and by the intensities of the different signals (Fig. 1 and Table 2).

Table 1. Selected physical and spectroscopic data of compounds **4**–**7** [a,b].

4a: white powder; m.p. 70–71 °C (decomp). ^1H NMR ($CDCl_3$): $\delta = 3.5$ (d, $^3J_{HP_1} = 14$ Hz, 9H, P_1-N-Me), 7.1 (dd, $^3J_{HH} = 8.6$, $^4J_{HP_0} = 1.6$ Hz, 6H, H-C_2), 7.7 (d, $^4J_{HP_1} = 2.5$ Hz, 3H, CH=N), 8.0 (d, $^3J_{HH} = 8.6$ Hz, 6H, H-C_3); $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 31.2$ (d, $^2J_{CP_1} = 13.2$ Hz, P_1-N-CH_3), 120.9 (d, $^3J_{CP_0} = 5.1$ Hz, C_2), 128.3 (s, C_3), 131.4 (s, C_4), 139.8 (d, $^3J_{CP_1} = 18.7$ Hz, CH=N), 151.0 (d, $^2J_{CP_0} = 7$ Hz, C_1)

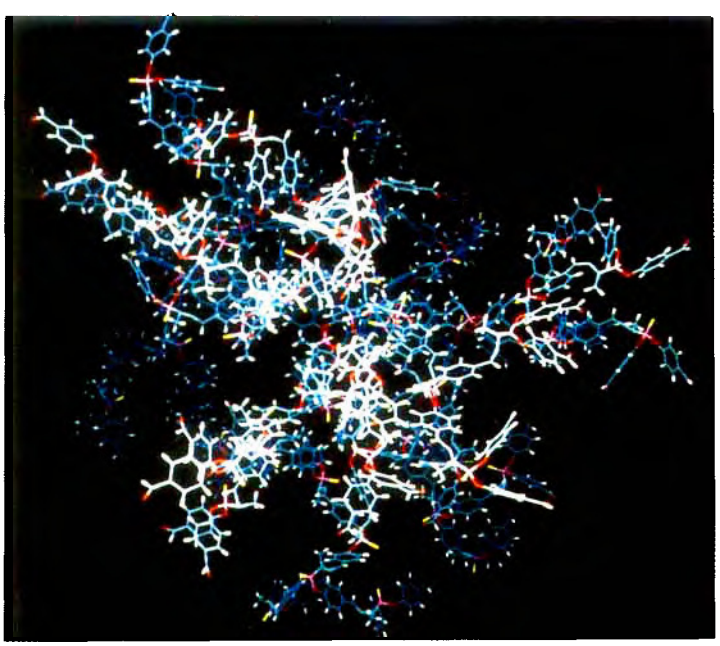

Fig. 2. Structure of dendrimer **7b** from molecular modeling.

The structure of compound **7b** was calculated using the molecular modeling package MAD[4a] on an SGI Indigo XS24 R4000. The basic template $N-N(CH_3)-P(S)[O-p-(C_6H_4)-CH=O]_2$ was constructed and minimized; in the conformational analysis a tree searching algorithm[4b] with an extended MM2 force field and a Newton-Raphson minimizer was used. The force field was tuned using results from X-ray structure analyses. Four iterative three-step procedures were then used to build the full molecule from the external ends to the core phosphorus. Finally, the template obtained was grafted three times on the phosphorus core $(S)P[O-p(C_6H_4)CHO]_3$ resulting in the whole dendrimer, which was given a final check to avoid steric contacts. The resulting structure is shown in Figure 2.

Our synthetic approach appears to be also effective for the formation of dendrimers having alternating thiophosphoryl and phosphoryl groups, or phosphoryl groups exclusively, since analogous reactions can be conducted with either $H_2NN(CH_3)P(O)Cl_2$ (**8**), then **3** (or vice versa), or with **8** only.[5] Introduction of other functional groups (amino, phosphino, vinylic, allylic, acidic groups, (etc.) is in progress,[6] and applications of these cascade molecules in catalysis and coordination chemistry are being investigated.

Experimental Procedure

7a: A solution of polyaldehyde **6b** (0.0166 mmol, 0.123 g) in 4 mL of $CHCl_3$ was added at 25 °C to a solution of the freshly prepared hydrazine derivative **3** (0.4 mmol, 0.072 g) in 4 mL of $CHCl_3$ containing 4 Å molecular sieves. The resulting mixture was stirred 12 h then filtered. The solvent was removed to give a yellow powder which was washed with 10 mL of ether.

7b: A solution of **7a** (0.01 mmol, 0.113 g) in 5 mL of THF was added dropwise at 25 °C to a suspension of the sodium salt **1** (0.48 mmol, 0.069 g) in 5 mL of THF. After 12 h of stirring at 25 °C, the resulting mixture was filtered. The solvent was removed to give a white powder which was washed with 10 mL of ether.

Ferromagneto-Structural Correlations in $[Mn(OC_6X_3H_2)_2(bipy)]_2$ Compounds, X = Cl, Br**

Marcel Wesolek, Daniel Meyer, John A. Osborn,* André De Cian, Jean Fischer,* Alain Derory, Patrick Legoll, and Marc Drillon*

The search for ferromagnetic molecular materials continues apace.[1] Ideally in such structures the spin carriers (e.g. organic radicals,[2] transition metal ions,[3] or their hybrids[4]) need to be incorporated into molecules which are functionalized so that when these molecules assemble into a two- (or preferably three-) dimensional network, the resulting supramolecular structure should also provide ferromagnetic interactions between the constituent molecules. However, the factors that determine such desired intermolecular magnetic effects in the solid state are not well understood although an orbital approach would seem the most attractive.[1d] An initial objective for the synthetic chemist is the discovery of molecules which display the appropriate magnetic properties and to attempt to correlate these effects with detailed structural features. We present here the syntheses, X-ray crystal structures, and magnetic studies on two new dinuclear manganese(II) complexes which, although possessing rather simply functionalized ligands, are found to exibit both intramolecular and intermolecular ferromagnetic interactions.

The complexes **1** and **2** are formed in two steps by treatment of $MnBr_2(CH_3CN)_2$ with two equivalents of the sodium salt of

$Mn_2(OC_6X_3H_2)_4(bipy)_2$ **1**, X = Cl; **2**, X = Br; bipy = bipyridine

the corresponding 2,4,6-trisubstituted phenol in THF and, after filtration of NaBr, the addition of one equivalent of bipyridine. Crystals suitable for X-ray structure analysis and magnetic measurements were obtained after recrystallization from hot CH_3CN.

The X-ray crystal structures[5] of both **1** and **2** (Fig. 1) show an essentially identical dimeric core, in which two identical Mn^{II} ions are symmetrically bridged by two phenoxy ligands. The

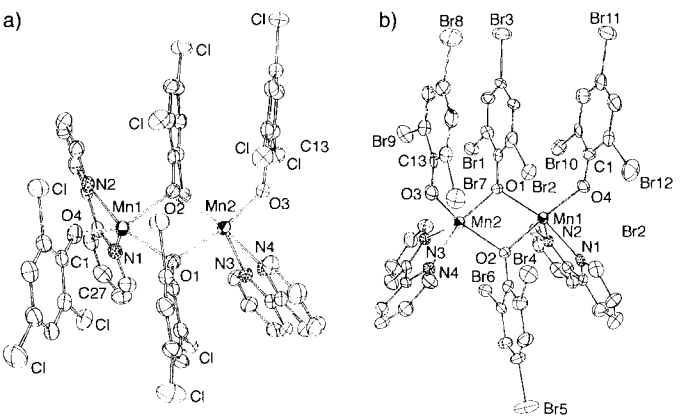

Fig. 1. Crystal structures of **1**(a) and **2**(b). Selected bond lengths [Å] and angles [°]: **1** (**2**): Mn1-N1 2.232(4) (2.241(7)), Mn1-N2 2.250(4) (2.218(6)), Mn2-N3 2.209(4) (2.235(6)), Mn2-N4 2.248(4) (2.248(6)), Mn1-O1 2.123(3) (2.160(5)), Mn1-O2 2.139(3) (2.198(5)), Mn1-O4 1.996(3) (2.039(5)), Mn2-O1 2.173(3) (2.178(5)), Mn2-O2 2.125(3) (2.120(5)), Mn2-O3 2.045(3) (2.024(5)), C-X between 1.727(5) and 1.748(5) (1.875(7) and 1.921(8)), average values 1.737(5) (1.896(7)). Mn···Mn 3.369(1) (3.424(2)), Mn1-O2-Mn2 104.8(1) (104.9(2)), Mn1-O1-Mn2 103.7(1) (104.2(2)), O1-Mn1-O2 75.3(1) (74.6(2)), O1-Mn2-O2 74.5(1) (75.8(2)), Mn1-O4-C1 137.0(1) (138.4(5)), Mn2-O3-C13 132.4(3) (137.9(5)), N1-Mn1-N2 73.5(1) (73.7(2)), N3-Mn2-N4 74.1(1) (73.1(2)), N1-Mn1-O4 114.9(1) (85.7(2)), N2-Mn1-O4 87.4(1) (103.7(2)), N3-Mn2-O3 90.1(1) (110.0(2)), N4-Mn2-O3 102.4(1) (86.0(2)).

Mn–Mn distances and internal core angles Mn-O-Mn in the two complexes are very similar. Each Mn ion is further bound to a terminal phenoxy ligand and a bipyridine ligand, leading to a highly distorted trigonal bipyramidal geometry about each Mn ion. However, the arrangement of the ligands in **1** and **2** differ markedly. In **1** each terminal phenoxy ligand is involved in a stacking interaction with one of the bridging phenoxy groups: the dihedral angles φ formed between the the aromatic planes are 7.3(8)° and 12.7(5)°, and the neighboring C–C separations vary from 3.26 to 3.79 Å. In **2**, however, the two terminal phenoxy ligands and one of the bridging phenoxy ligands form an intramolecular triple stack of phenyl units on one side of the dimer, creating dihedral angles of 0.6 and 6.9° and proximate C–C separations varying from 3.27 to 3.51 Å.

In the crystal both **1** and **2** form chains in which the bipyridine ligands of each dimer are involved in intermolecular π-π interactions with the bipyridine ligands of the neighboring dimers in the chain (Fig. 2). In both **1** and **2** two different bpy–bpy separations are found in which the intermolecular C–C distances vary from 3.29 to 3.43 Å and 3.58 to 3.89 Å, respectively for **1** and from 3.11 to 3.52 Å and 3.25 to 3.61 Å for **2**. The major difference between the two structures is that in **1** no interchain contacts are observed: the 2,4,6-trichlorophenoxy ligands show no intermolecular π-π interactions or Cl–Cl contacts. However in **2**, although no intermolecular π-π interactions are observed between the 2,4,6-tribromophenoxy ligands, a direct interchain Br^3–Br^6 contact is observed at 3.615 Å (0.3 Å shorter than a van der Waals contact).

Magnetic measurements were carried out in the temperature range 1.7–300 K with a SQUID magnetometer at an applied

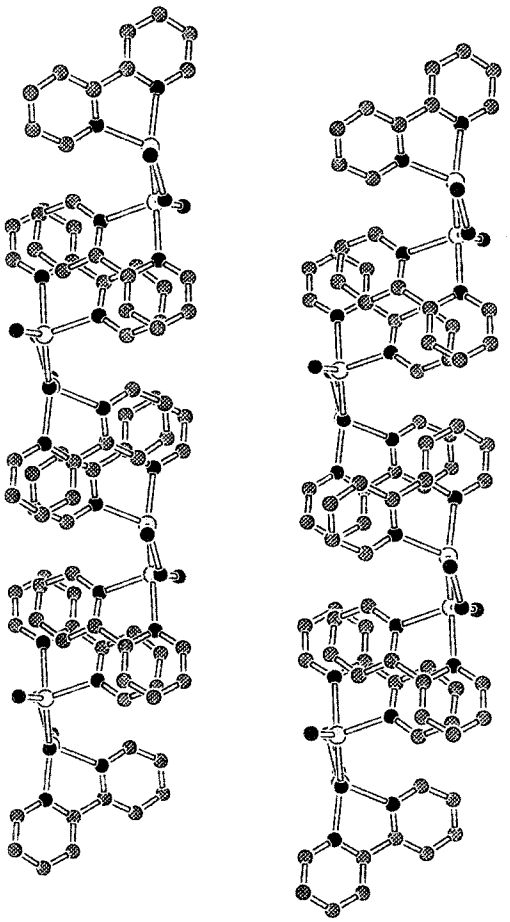

Fig. 2. Packing of **2** in the crystal. The substituted rings of the phenoxy ligands are omitted for clarity. Yellow: Mn; red: O; blue: N.

field $H = 300$ Oe. Figure 3 shows the temperature dependence of the $\chi_M T$ product for both **1** and **2**. Above 100 K, the magnetic behavior obeys a Curie–Weiss law in agreement with two isolated manganese(II) ions per molecule; the effective magnetic moment at 300 K is 5.93 μ_B per manganese atom for **1** and 5.67 μ_B per manganese atom for **2**. Upon cooling, $\chi_M T$ increases, which

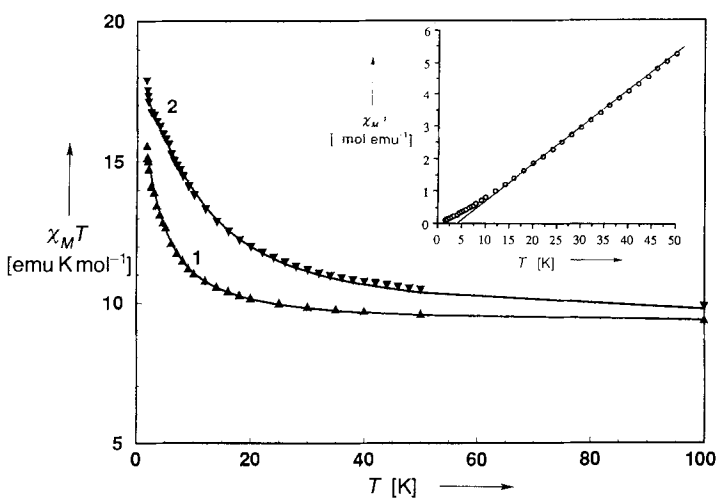

Fig. 3. Temperature-dependence of the product of the molar susceptibility and temperature for **1** and **2**. The inset represents the thermal variation of χ_M^{-1} for **2** and gives a Curie–Weiss temperature of 3.6 K.

is the signature of intramolecular ferromagnetic interactions within the dimeric manganese(II) units. At very low temperatures $\chi_M T$ exceeds the value predicted ($\chi_M T = 15$) for an $S = 5$ ferromagnetic ground state, reflecting the influence of intermolecular ferromagnetic correlations between neighboring Mn^{II} dimers which are more significant in **2** than in **1**. Specific heat capacities were determined in the temperature range 1.1–20 K, in zero magnetic field (Fig. 4). A minimum of C_p is observed around 2 K, whose width and height differ for both compounds, followed by a noticeable increase at higher temperature which is mainly related to the lattice contribution. At very low temperature (ca. 1 K), the divergence of C_p is probably due to the onset of a long-range magnetic ordering.

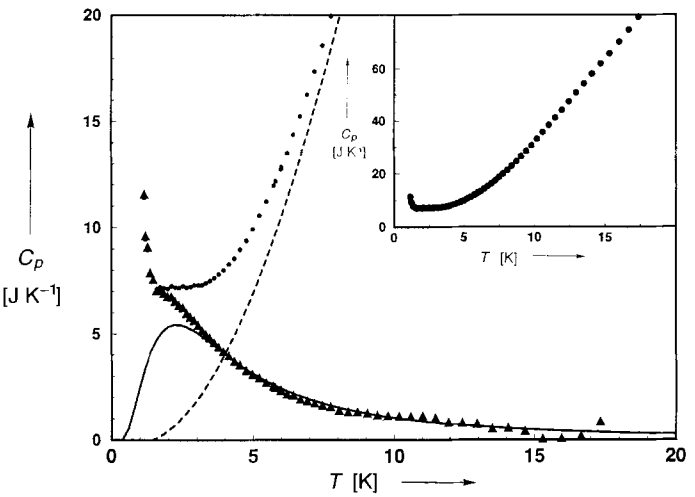

Fig. 4. Temperature-dependence of the specific heat C_p (exp., •), the lattice contribution (calcd. – – –), and the magnetic contribution (calcd. —); ▲ is the difference between the experimental values and the lattice contribution. The inset shows the variation of C_p in the 1.1–17.4 K range.

The magnetic properties of both compounds can be analyzed by considering the isotropic model of $S = 5/2$ dimeric units, described by the Hamiltonian (a). The influence of the interac-

$$\hat{H} = -J\,\hat{S}_1\,\hat{S}_2 - g\mu_B\hat{H}\,(S_1^z + S_2^z) \qquad \text{(a)}$$

tions between the dimers is taken into account through a molecular field contribution θ within the expression[6] of χ_M. In addition, the diamagnetic contribution is estimated from Pascal's values (-680×10^{-6} for **1** and -800×10^{-6} for **2**). Such a model leads to very good fits of the experimental values of $\chi_M T$ (Fig. 3). The calculated values for the intra-(J) and intermolecular(θ) ferromagnetic interactions (expressed in K) are +0.74, $+8.7\times10^{-3}$ for **1** and +2.25, +0.19 for **2**, respectively. In both cases g has a value of 2.04. Using the above results, the magnetic contribution to the specific heat, namely the Schottky-type anomaly[6] can be readily deduced. A maximum of C_p is predicted at 2.2 K for **1** and at 6.8 K for **2**. As displayed in Figure 4 for compound **1**, the theoretical curve agrees well with the experimental one deduced from raw data by substraction of the lattice contribution, approximated to be 0.024 T^3.

An intramolecular ferromagnetic interaction between the Mn^{II} ions in these complexes was somewhat unexpected since dimeric Mn^{II} compounds bridged by phenoxy ligands are generally either paramagnetic or antiferromagnetic,[7] although one complex[8] shows weak ferromagnetism ($J = +0.2$ cm^{-1} or 0.29 K for comparison with our values). However, there ap-

pears to be no simple relation between the magnetism and observed Mn-O-Mn angles[4] which varied from 82.2 to 115.8°. This ferromagnetic effect in **1** and **2** may result from the distorted trigonal bipyramidal field about the Mn^{II} ions, an explanation offered to interpret similar behavior in phenoxy-bridged complexes[9] of Fe^{III} and Fe^{II}. However, although the Mn_2O_2 core geometries are very similar in **1** and **2**, the intramolecular ferromagnetic interaction is three times larger for the latter. Although small differences in stereochemical or electronic effects may be responsible, we suggest that the triple stack structure of the phenoxy ligands in **2** could offer further spin exchange through π-π interactions across the dimer. For **1**, in which only pairwise stacking of phenoxy ligands occurs, this effect may be smaller or indeed cause diminution of the overall ferromagnetism. Calculations will be necessary to clarify this point.

The intermolecular ferromagnetic effect can also be related to structural features. The π-π interaction between bipyridine ligands in the chains would appear to offer an important junction for the transmission of magnetic effects, possibly by a McConnell spin polarization mechanism. However, this interaction in **1** alone does not give rise to appreciable ferromagnetism. Hence the 20-fold increase in θ in **2** would appear to indicate that the interchain Br–Br contacts are crucial in greatly increasing the correlation length. The onset of a long-range ordering below 1 K indicated by the specific heat measurements may also result from this mechanism.

In conclusion the dimeric Mn^{II} compounds **1** and **2** form ferromagnetic chain structures in the crystalline state; however, additional interchain interactions appear to be needed to achieve significant ferromagnetic effects. The π-π stacking interactions responsible for the chain structure thus may only play a significant role in the magnetism by a further increase in the dimensionality of the overall structure.[3d] Although the effects in these systems are as yet modest, research is currently underway in which such magneto-structural features will be incorporated in the design of magnetic molecular materials.

Preparation and Preliminary Characterization of a Covalently Pillared Zirconium Phosphate–Diphosphonate with Interlayer Microporosity**

Giulio Alberti,* Fabio Marmottini, Sonia Murcia-Mascarós, and Riccardo Vivani

The recent progress in the chemistry of the γ-M^{IV} phosphates (compounds which were for many years formulated as $M^{IV}(HPO_4)_2 \cdot 2H_2O$ and now as $M^{IV}PO_4(H_2PO_4) \cdot 2H_2O$[1] and our improved knowledge of the structures of γ-layers of these compounds[2] has renewed the interest in these materials. Many organic derivatives, prepared in topotactic reactions similar to those initially proposed by Yamanaka,[3] have recently been obtained and characterized.[4] Furthermore, our recent successful synthesis of a microporous pillared zirconium diphosphonate with layers of α-type[5] has stimulated our interest in the preparation of microporous γ-compounds.

We found that, whereas pillared compounds of the α-type can only be prepared by direct synthesis, the covalent pillaring for the γ-type can be achieved more readily by a topotactic reaction between γ-zirconium phosphate (γ-ZrP, **1**) and a suitable diphosphonic acid.[6] No appreciable porosity was found in the first pillared γ-compounds; however, it was immediately recognized that the lack of interlayer microporosity very probably had to be ascribed either to the short length of the diphosphonate groups employed, or to their excessive crowding in the interlayer region. Therefore, a longer rigid diphosphonate group, such as biphenyldiphosphonate, was chosen as the pillar and a systematic study of the gradual replacement of the origi-

nal $H_2PO_4^-$ ions was performed. The hope was to find some stable phases with a concentration of pillars sufficiently low for the creation of interlayer microporosity. Therefore, many samples with an increasing percentage of pillars were prepared from **1**, and characterized by chemical analysis[7] and X-ray powder diffraction.[8] The results obtained for a selected number of samples, **2a**–**2e**, are summarized in Table 1. The following gen-

Table 1. Experimental data for selected samples with the general formula $ZrPO_4(H_2PO_4)_{1-x}[C_{12}H_8(PO_2OH)_2]_{x/2}$ **2**.

Product	Volume [a] [mL]	Moles taken up [b] [%]	x	n [c]	d [d] [Å]	d [e] [Å]
2a	94	94	0.28	3.1	16.4	16.3

2c	126	90	0.34	3.1	16.7	16.4
2d	156	81	0.39	2.5	16.7	16.4
2e	188	77	0.44	2.7	17.0	16.7

[a] Volume of the 0.005 M solution of the diphosphonic acid used in the topotactic reaction for 1 g of γ-ZrP **1**. [b] Percent of moles of diphosphonate groups in the initial solution taken up by 1 g of **1**. [c] Moles of water per mol of Zr in samples conditioned at 90% r.h. [d] Interlayer distance of samples conditioned at 90% r.h. [e] Interlayer distance of anhydrous samples at 200 °C.

eral trends were observed: 1) If the topotactic replacement is less than 50%, a large proportion of the diphosphonate ions initially present in the solution is taken up by the solid, while an equivalent number of $H_2PO_4^-$ groups is released into the solution; in this respect this topotactic reaction is similar to an anion-exchange process in which monovalent anions are exchanged, with very high selectivity, by bivalent anions [Eq. (a)]. In accordance

$$ZrPO_4(H_2PO_4)\cdot 2H_2O + x/2\ R(PO_2OH)_2^{2-} \rightleftarrows ZrPO_4(H_2PO_4)_{1-x}[R(PO_2OH)_2]_{x/2}\cdot nH_2O + x\ H_2PO_4^- \quad (a)$$

with this exchange reaction the expression "percentage of pillaring" is equivalent to "percentage of topotactic replacement of $H_2PO_4^-$ with diphosphonate groups"; the x values reported in Table 1 are related, by the factor 100, to these percentages.

2) The characteristic peak at 12.25 Å, corresponding to the interlayer distance of γ-$ZrPO_4(H_2PO_4)\cdot 2H_2O$[9], disappears completely for very low percentages of pillaring ($\leq$10%) with the introduction of the diphosphonate groups; correspondingly, a hydrated phase of composition $ZrPO_4(H_2PO_4)_{1-x}[R(PO_2OH)_2]_{x/2}\cdot nH_2O$, in which x ranges from less than 0.1 to 0.58, was formed (the interlayer distances of wet samples range between 17.0 and 18.0 Å).

The samples were conditioned at room temperature over a saturated $BaCl_2$ solution at about 90% relative humidity (r.h.) and the water content (nH_2O) was determined by dehydration at 200 °C. The stability of the pillared compounds to dehydration was then studied by determining the variation of their X-ray patterns at 200 °C. In the pillaring range 28–44% the interlayer distance was found not to change appreciably with dehydration. On the other hand, an increase in the intensity of a peak at 9.4 Å, characteristic of anhydrous **1**, together with a decrease in the intensity of the peak corresponding to the anhydrous pillared phase (16.0–16.3 Å), was found at pillaring percentages < 25%. In other words, when less than a quarter of the original $H_2PO_4^-$ ions are replaced, the pillared phase seems to be stable only in the presence of intercalated solvent; when the water is removed, a segregation into two immiscible solid phases (the anhydrous **1** and the anhydrous pillared phase) is observed. In contrast at pillaring percentages $\geq$ 25%, stable phases can be obtained even in the absence of interlayer water.

Thus, taking into account that the microporosity should increase with the dilution of the pillars, the maximum interlayer microporosity must be expected at the minimum concentration of pillars that assures the stability of the anhydrous phase, that is 25–28% pillaring. The determination of the volume of the micropores and the specific surface area of anhydrous samples at different pillaring percentages showed that their maximum (ca. 0.12 $cm^3 g^{-1}$ and ca. 320 $m^2 g^{-1}$, respectively) is obtained at the value expected (Fig. 1). Furthermore, the Horvath–Kawazoe[10] differential pore volume plot of sample **2a** (Fig. 2) showed a narrow micropore size distribution with an average diameter of 5.8 Å.[11]

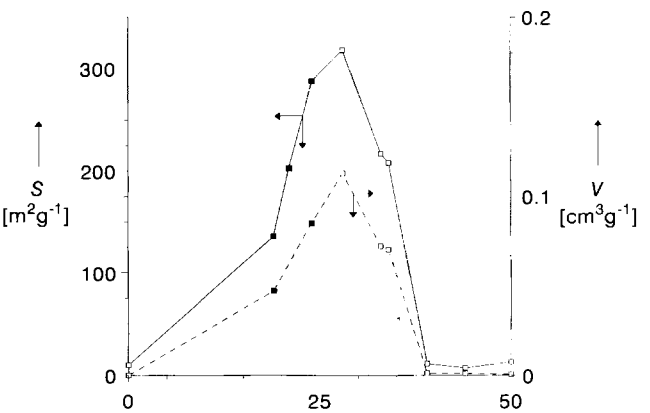

Fig. 1. Specific surface area S, and volume of the micropores V of anhydrous samples as a function of the pillaring percentages. □ and ■ refer to monophasic and biphasic systems, respectively.

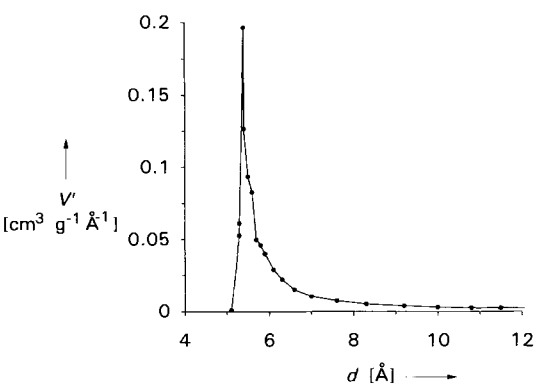

Fig. 2. Differential pore volume V' as a function of the pore diameter d of sample **2a**.

The thermal stability was determined by thermogravimetry and evolved gas analysis (EGA) as well as by X-ray powder diffraction with a high-temperature camera. The weight loss at temperatures lower than 200 °C was attributed to hydration water only. At temperatures higher than 220 °C, as confirmed by EGA, the organic pillars decompose even in inert atmosphere. In each case, the final product in air is cubic ZrP_2O_7 so that the total weight loss of the samples can be calculated from their initial composition. In general, the agreement between calculated and experimental values was good. As an example, the thermogravimetric curve of sample **2a** is shown in Figure 3. Unfortunately, the degree of crystallinity of sample **2a** was not sufficient for the unambiguous determination of the cell parameters. We therefore attempted to recrystallize this sample in a hydrothermal bomb at 215 °C for six days, but unambigu-

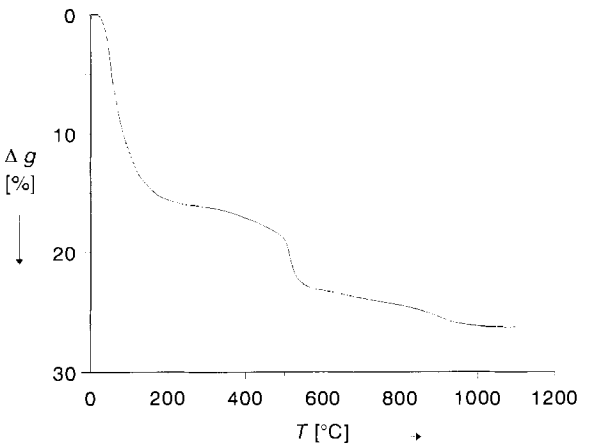

Fig. 3. Thermogravimetric curves (heating rate: 5 K min^{-1}; air flow) of sample **2a** (previously conditioned over a saturated $BaCl_2$ solution to 90% r.h.). The total weight loss Δg (25.9%) is in good agreement with the value expected from its composition (25.4%).

ous cell parameters were still not obtained. Thus, we tried to recrystallize a more thermally stable pillared derivative of **1** such as the previously described $ZrPO_4(H_2PO_4)_{0.06}[C_4H_8(PO_2OH)_2]_{0.47}\ 1.3H_2O$.[16] In this case, since it was possible to operate at 250 °C for six days, a considerable increase of the degree of crystallinity was achieved and the following cell parameters were obtained: orthorhombic, $a = 5.382$, $b = 6.625$, $c = 13.017$ Å. Since the a and b parameters were very similar to those of the original γ-ZrP ($a = 5.386$, $b = 6.636$ Å), it can be deduced that the inorganic backbone of the γ-layer remains practically unaltered; this is true not only after the replacement of the original $H_2PO_4^-$ with monophosphonate[4] but even after pillaring with diphosphonate groups.

Based on this result, some computer structural models were generated (Fig. 4). These models used: a) the original a and b parameters of the γ-layer, b) the regular distribution of pillars that have replaced up to 25% of the $H_2PO_4^-$ groups, c) the calculated length of the diphosphonate groups, and d) the interlayer distance of sample **2a** determined experimentally. The distance between adjacent pillars is in good agreement with the value derived from the surface analysis of the pores. Furthermore, all the X-ray reflections of sample **2a** can be indexed for a monoclinic unit cell which is similar to that derived from the model: $a = 10.750$, $b = 13.220$, $c = 16.723$ Å, $\beta = 98.451°$. Together with the microporous pillared compounds of α-type obtained recently,[5] the covalent pillaring of layered structures with organic groups presented here opens an alternative route for the preparation of new molecular sieves and/or "shape-selective" catalysts.

Experimental Procedure

2a–**2e**: In each experiment γ-$ZrPO_4(H_2PO_4)\cdot 2H_2O$ (1 g) (particle size: 0.5–10 μm) was treated, under shaking at 75 °C for four days, with different volumes (see Table 1) of a 0.005 M solution of 4,4'-biphenyldiphosphonic acid (**3**) in water acetone (1/1). The solids were separated by centrifugation and washed twice with water/acetone (75 mL).

1 and **3** were prepared as described in refs. [9] and [12], respectively. ^{31}P NMR (200 MHz, 50 mg of compound dissolved in 1 mL of 2 M HF in [D_6] DMSO, 25 °C): δ (**3**) = 19.5 (m, br. PCH(Ar)), δ (**1**) = 4.3 (s); the shifts are relative to D_3PO_4 in D_2O, external.

The surface analysis was carried out with the Micromeritics ASAP 2010 Micropore System, the EGA with a Stanton thermobalance coupled with a quadrupole mass Spectrometer (Thermolab-Fisons).

Molecular Recognition of C_{60} with γ-Cyclodextrin**

Zen-ichi Yoshida,* Hideko Takekuma, Shin-ichi Takekuma, and Yoshiharu Matsubara

Based on the superaromaticity concept we predicted that C_{60} was a soccerball-type molecule.[1a] Since C_{60} has been available on a preparative scale,[1b] one of our big concerns associated with biomimetic studies on enzymes[2, 3] has been the molecular recognition of C_{60} at active sites in the hydrophobic pocket of enzymes and the resulting biological functions.[4]

Very recently such an exciting example was reported for the inhibition of HIV-1 protease by C_{60} derivatives;[5] we were interested in the fundamental problem of how C_{60} interacts with the cylindrical hydrophobic cavity of γ-cyclodextrin (γ-CyD) in the complex formed on recognition of C_{60} by γ-CyD in water. Such a host–guest interaction is generally investigated in the equilibrium system in solution, in which, however, other complexes of different compositions can exist. To avoid this problem, the stable inclusion complex of defined composition should be studied. For this reason we have tried to prepare a stable C_{60}/γ-CyD complex; an unstable complex of nondefined composition has already been reported.[7] The preliminary examination of the complex formation in the two phase solution system (fullerenes in toluene, γ-CyD in water) demonstrated that, firstly, among α-, β- and γ-cyclodextrins only γ-CyD formed the complex and, secondly, γ-CyD recognized only C_{60} in the solution of C_{60} and C_{70}. The latter observation is particularly interesting because, judging from the cavity size of γ-CyD (9 Å circular opening) and the size of soccerball C_{60} (7 Å diameter) and rugbyball C_{70} (7 Å diameter at the equator, 8 Å between poles), γ-CyD can accommodate both C_{60} and C_{70}.

Here we report the first preparation of the stable, water-soluble C_{60}/γ-CyD (1:2) complex ("bicapped buckminsterfullerene") and the spectral investigation for elucidation of the molecular recognition of C_{60} by γ-CyD.

The synthesis of the stable complex (samples **A**, **B**, and **C**) (see Experimental[6, 7]) has the following features: 1) efficient formation of the complex by expelling C_{60} from toluene solution into the aqueous γ-CyD solution, utilizing the anomalously large solubility decrease of C_{60} in toluene at 118 °C,[8, 9] and 2) strengthening of the interaction between C_{60} and γ-CyD by dehydration of the hydrated complex by heating under vacuum. The obtained samples **A**, **B**, and **C** can be stored in crystalline form without decomposition. However, they differ in their stability in aqueous solution. At room temperature, sample **A** commences to eliminate C_{60} from the complex in solution after 10 h. On the other hand samples **B** and **C** are stable in aqueous solution at least for one and three days, respectively. These samples, and sample **C** in particular, can therefore be employed to investigate the molecular recognition of C_{60} with γ-CyD.

Although X-ray diffraction of the C_{60}/γ-CyD (1:2) complex ($[\alpha]_D^{20}$: +126° for sample **C**) has not yet been accomplished because of difficulty in growing single crystals for this purpose, a bicapped structure (Fig. 1) is deduced on the basis of the ^1H and ^{13}C NMR and elemental analyses.

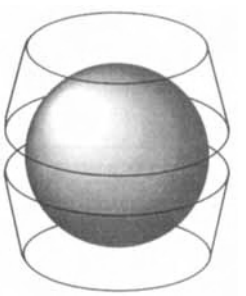

Fig. 1. Model of the C_{60}/γ-CyD (1:2) complex (bicapped buckminsterfullerene).

Evidence for molecular recognition is obtained from the CD spectra (Fig. 2) for the C_{60}/γ-CyD complex (samples **A**, **B**, and **C**) in aqueous solution (pH 6.8, 25 °C). Since C_{60} is chromophoric but achiral and γ-CyD is chiral but nonchromophoric, this indicates induction of chirality by the host (γ-CyD) in the guest (C_{60}). It is worth noting that increasing dehydration gives rise to more intense negative (in particular at 230 nm) and positive (in particular at 258 nm) CD bands which suggests increas-

ing interaction due to orbital steering between C_{60} and the functional groups (active sites -O- and OH) of γ-CyD as these become increasingly exposed.

This interaction (recognition) is elucidated by NMR spectroscopy. The chemical shifts of the ^1H NMR spectrum (500 MHz) and ^{13}C NMR spectrum (125 MHz) for γ-CyD and the C_{60}/γ-CyD complex (sample **C**) are shown in Tables 1 and 2,

respectively. From the substantially low-field shifts of $\delta = 0.24$ for C3-*H*,[10, 11] $\delta = 1.95$ for C1 and $\delta = 1.95$ for C4, we conclude that the specific interaction leading to chirality induction and the stability of the complex is the charge transfer from the n-donor (the hydroxy oxygen atom bound to C_3 and the ether oxygen between adjacent glucose units) to C_{60}, as shown in Figure 3. The reasons are following: 1) C_{60} does not behave as

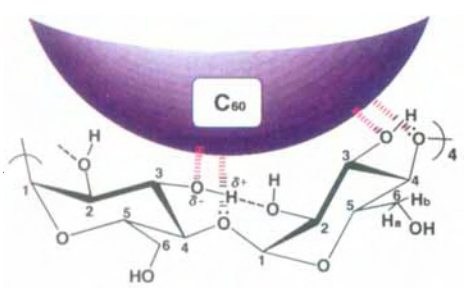

Fig. 3. Mode of interaction in the C_{60}/γ-CyD complex based on the HGS stereochemical molecular model (HGS = Hinomoto Gouseijushi Seisakujo) and X-ray crystal structure of γ-CyD and C_{60}.

a π base like benzene but as an extremely strong electron acceptor (electron affinity: 2.7 eV),[12, 13] and ether oxygen and alcoholic oxygen functions are known to serve as the n-donor in charge-transfer complex formation with iodine (electron affinity: 2.5 eV);[14] 2) intermolecular hydrogen bonding between OH groups and π-electron systems is not observed even for electronegative, substituted benzenes (like benzonitrile) and alkenes (like acrylonitrile);[15] 3) molecular models and X-ray structures of γ-CyD and C_{60} indicate that the ether oxygen atom and the strongly hydrogen-bonded oxygen atom at C3 (C3-OH···OH-C2) between adjacent glucose units are favorably situated for charge transfer to C_{60}.[16, 17] Since the characteristic NIR and ESR spectra[18, 19] of the anions of C_{60} were not observed, the amount of the charge transfer is considered to be smaller than one elementary charge.

The specific interaction due to such a charge transfer in addition to size and shape recognition between C_{60} and biological systems (for example, enzymes like HIV-1 protease where the active site is a carboxylate n-donor[5, 20]) should presumably be reflected in the specific biological functions of C_{60}.

Experimental Procedure

The mixture of two liquid phases consisting of a solution of γ-CyD (67 mg, 52 μmol) in water (10 mL) and a solution of C_{60} (or C_{60}/C_{70} mixture, 92/8) (20 mg) in toluene (10 mL) was refluxed at 118 °C for 30 h under vigorous magnetic stirring. After cooling to room temperature, the aqueous layer containing precipitated C_{60}/γ-CyD complex was centrifuged. The purple crystals were washed with cold water (10 mL) and dried in vacuo (sample **A**). The obtained crystals were dissolved in warm (50–60 °C) water (200 mL), and filtered to remove the insoluble materials (C_{60} eliminated from unstable complexes). The filtrate was freeze-dried to give 40 mg of stable C_{60}/γ-CyD complex (sample **B**, HPLC purity > 99.8%). These crystals were then recrystallized from water and dried at 55 °C for 24 h to provide the purple plates (sample **C**, the most stable complex). A similar result was obtained by using an efficient freeze-dry system (e.g. Labconco LL-6). Sample **C**: M.p. > 290 °C; $[\alpha]_D^{20}$: +126° (c = 0.1 in water) [compare $[\alpha]_D^{20}$ (γ-CyD): +177°, (c = 0.1 in water)]; UV/VIS (water): λ_{max} [nm] (log ε) = 214 (5.10), 231 sh (4.83), 260 (5.08), 332 (4.63), 408 (3.24), 493 sh (2.73), 536 (2.81), 574 sh (2.70), 601 (2.73), 629 sh (2.46); IR (KBr): $\tilde{\nu}$ [cm^{-1}] (bands that are not assigned to γ-CyD or C_{60}) = 1641, 1430 sh, 1410, 1369, 1335, 1101 sh, 1078, 1026, 937, 731, 581, 527; C, H analysis for $C_{156}H_{190}O_{95}$ ($C_{60} \cdot 2$ γ-CyD $\cdot 15$ H_2O): calcd. C, 52.26; H, 5.30; found: C, 52.23 H, 4.88. The 1:2 composition of C_{60} and γ-CyD was confirmed from the ratio of the areas of the corresponding ^{13}C NMR spectral peaks to C_{60} and γ-CyD (analytical mode: single pulse with heterogated decoupling without NOE). The ^1H and ^{13}C NMR spectral data of this complex suggest a symmetric structure for C_{60}/γ-CyD (1:2) complex (see Figure 1), because the signals for the two γ-CyD units were not split.

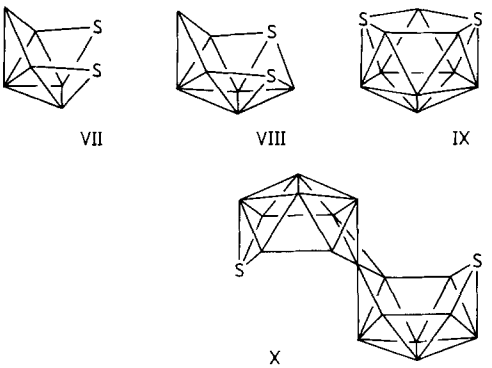
Macropolyhedral Boron-Containing Cluster Chemistry: Isolation and Characterization of the First Macropolyhedral Thiaborane, the *arachno*-Type $[9,9'\text{-}S_2B_{17}H_{18}]^-$ Ion**



Tomáš Jelínek, John D. Kennedy,* Bohumil Štíbr, and Mark Thornton-Pett

The structural variety of polyhedral boron hydride chemistry is in principle also available to any combinations of main-group elements that have the same numbers of valence electrons. However, heteroborane chemistry, other than that of the carbaboranes,[1] is surprisingly limited. Apart from the carboboranes, the best-exemplified and most diverse main-group polyhedral heteroboranes are the thiaboranes. However, only seven basic contiguous monothiaborane building blocks are available (cluster geometries I–VI, Scheme 1).[2–19]

Scheme 1.

These comprise the nine-vertex *nido*[2] and *arachno*[3–6] $\{SB_8\}$ systems (I and II, respectively), the ten-vertex *closo* $\{SB_9\}$ system (IV),[3, 7–11] the ten-vertex *nido*[4, 11–14] and *arachno*[11, 14–17] $\{SB_9\}$ systems (both of gross geometry III), the eleven-vertex *nido* $\{SB_{10}\}$ system (V),[3, 12, 18] and the twelve-vertex *closo* $\{SB_{11}\}$ system (VI).[3, 10, 12, 19] In contrast to the very extensive known dicarbaborane chemistry,[1] only three dithiaborane building blocks (geometries VII–IX, Scheme 2) are known.[20–22] These comprise the eight-vertex *hypho* $\{S_2B_6\}$ system (VII),[20] the nine-vertex *arachno* $\{S_2B_7\}$ system (VIII),[20, 21] and the eleven-vertex *nido* $\{S_2B_9\}$ system (IX).[22]

Scheme 2.

There is current interest in large macromolecular units based on assemblies of heteroborane clusters with twelve vertices and fewer.[23] The individual clusters of reported assemblies are however generally linked together by a single two-electron two-center σ bond, or by a single common atom, generally of a metallic element. An alternative approach to large boron-based molecules is to use larger contiguous heteroborane building blocks that are based upon the fusion of smaller polyhedral clusters rather than upon clusters that are joined by single linkages. Here there is value in the discovery and delineation of new intercluster bonding modes that will facilitate the development of this new area of "macropolyhedral" heteroborane chemistry.

We now report our preliminary results on the isolation and characterization of the presently unique large nineteen-vertex macropolyhedral dithiaborane anion, $[S_2B_{17}H_{18}]^-$ (cluster connectivity as in X, Scheme 2). This is the first structurally characterized macropolyhedral heteroborane, and it also demonstrates for the first time a structure in which two *arachno*-type subclusters are fused to form a boron macropolyhedron. Previous macropolyhedral structures have been limited to fusions among *nido*- and *closo*-type clusters.

The $[S_2B_{17}H_{18}]^-$ ion, isolated in 48% yield as its $[PPh_4]^+$ salt, is obtained by the action of elemental sulfur on a solution of the *anti*-$[B_{18}H_{20}]^{2-}$ ion (formed from *anti*-$B_{18}H_{22}$ and NaH in THF),[24, 25] followed by chromatographic separation of the products. It was identified and characterized by X-ray diffraction analysis (Fig. 1) and NMR spectroscopy (Fig. 2). The principal other product is the known[3, 12, 18] *nido*-$[7\text{-}SB_{10}H_{11}]^-$ ion (45%), identified by NMR spectroscopy. The formation of the $[S_2B_{17}H_{18}]^-$ ion from the *anti*-$\{B_{18}\}$ skeleton involves a marked change in structure: incorporation of the two sulfur atoms is accompanied by loss of one boron center and there is an interesting reduction in the intimacy of the intercluster fusion. From two boron atoms held in common in $[B_{18}H_{20}]^{2-}$ there is a conversion to a somewhat more open structure that has one boron atom in common and has the interboron linkage B(8)–B(8′) (Scheme 3; open circles represent BH units).

The structure of this $[B_2B_{17}H_{18}]^-$ ion (Fig. 1) derives formally from the fusion, with two common vertices, between a ten-vertex *arachno* $\{SB_9\}$ cluster and an eleven-vertex *arachno* $\{SB_{10}\}$ cluster, although a useful alternative model consistent with the inherent twofold symmetry consists of two ten-vertex *arachno* $\{SB_9\}$ clusters fused with one common boron atom (B(9)) and with one additional intercluster link (B(8)–B(8′)). The *arachno* nature of the two $\{SB_9\}$ subclusters is readily apparent: a) the similarity of the NMR properties with those of the *arachno*

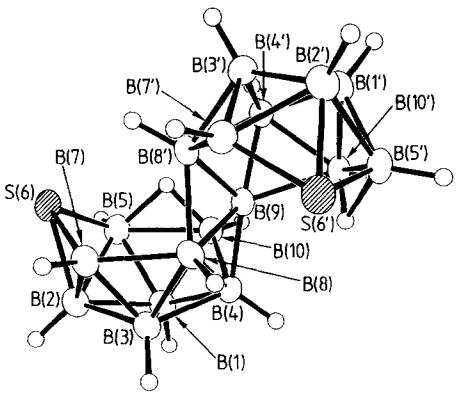

Fig. 1. Molecular structure (ORTEP) of the $[S_2B_{17}H_{18}]^-$ ion in $[PPh_4][S_2B_{17}H_{18}]$. In the solid state the anion approximates closely to the twofold rotational symmetry implicit in its liquid-state NMR properties. Selected interatomic distances: B(5)-S(6) 1.905(3), B(7)-S(6) 1.886(3), B(5')-S(6') 1.901(3), B(7')-S(6') 1.878(2), B(7)-B(8) 1.896(4), B(8)-B(9) 1.788(3), B(5)-B(10) 1.858(3), B(9)-B(10) 1.873(3), B(7')-B(8') 1.904(3), B(5')-B(10') 1.858(3) and B(9)-B(10') 1.873(3) Å. The dihedral angles B(9)B(4)B(2)S(6)/B(9)B(4')B(2')S(6') and B(5)B(7)B(8)B(10)/B(5')B(7')B(8')B(10') are 112.1(1) and 16.92(1)°, respectively, and the intercluster linkage B(8)-B(8') is 1.874(3) Å.

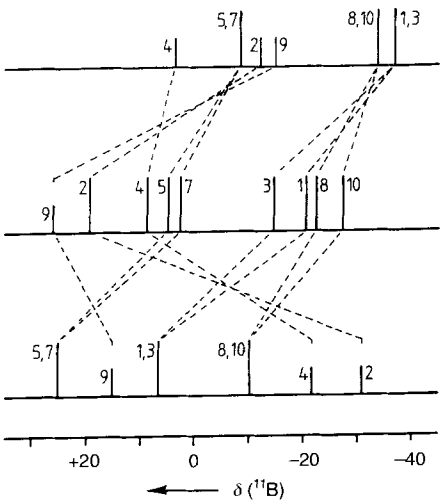

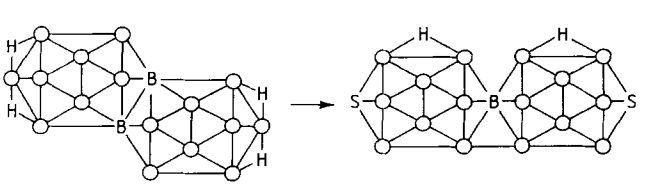

Fig. 2. Stick diagram of the chemical shifts and relative intensities in the ^{11}B NMR spectra of (top) the *arachno* $[6\text{-}SB_9H_{12}]^-$ ion [14], (center) the $[S_2B_{17}H_{18}]^-$ ion, and (bottom) *nido* $[6\text{-}SB_9H_{11}]$ [14]. Hatched lines join equivalent cluster positions in the three compounds. The B(9) position is that involved in the common vertex, and the B(2) position is antipodal to B(9). The typical *arachno* ten-vertex chemical-shift ordering [26, 27] is retained in $[S_2B_{17}H_{18}]^-$, although there is a general decrease in cluster shielding compared to the single-cluster *arachno* monoanion $[SB_9H_{12}]^-$. The typical *arachno* → *nido* inversion of shielding order [14, 26, 27], in particular the shift of $\delta(^{11}B(2))$ and $\delta(^{11}B(4))$ from low to extreme high field, is readily seen in the comparison with *nido*-SB_9H_{11}.

$\{SB_9\}$ cluster model of *arachno*-$[6\text{-}SB_9H_{12}]^-$ itself (Fig. 2) is confirmatory; in particular, the general NMR diagnostic ten-vertex *arachno* versus ten-vertex *nido* shielding characteristics,[26, 27] and also those specifically established for the $\{SB_9\}$ system,[14] are clearly *arachno*; b) the *arachno*-type bridging hydrogen atom at the (5,10) position is also diagnostic of ten-vertex *arachno* character; in particular, this position is occupied in preference to the (9,10) position that is specific to *nido*-type cluster behavior, both in single-cluster species[27] and in fused-cluster macropolyhedral species.[25] The similarities of the NMR spectra also suggest that the origin of the cluster bonding orbital associated with the (7,8) bridging hydrogen in *arachno*-$[6\text{-}SB_9H_{12}]^-$ is closely related to that involved in the (8,8') linkage in the $\{S_2B_{17}\}$ species, and that the overall ten-vertex $\{$*arachno*-$SB_9\}$ cluster electronic structure is thereby not drastically perturbed by the fusion. This is of interest because there was previously no precedent for how two *arachno*-type ten-vertex clusters might fuse, if at all.

The convenient preparation of the $[S_2B_{17}H_{18}]^-$ ion in reasonable yield provides an entry into the chemistry of macropolyhedral thiaboranes. Further work on these and related systems, as well as on the extension to macropolyhedral boron species containing heteroatoms other than sulfur, is in progress.[28]

Scheme 3.

Experimental Procedure

$[PPh_4][S_2B_{17}H_{18}]$: *anti*-$B_{18}H_{22}$ (300 mg; 1.36 mmol) and NaH (120 mg; 5.0 mmol) were stirred in THF (30 mL) for 2 h, filtered, and elemental sulfur (500 mg, 15.6 mg-atoms of S) added to the filtrate. The mixture was stirred at about 20 °C (4 h), then heated at reflux (8 h), cooled, and filtered. The yellow filtrate was evaporated to dryness, and extracted with CH_2Cl_2/aqueous HCl (1:3). The CH_2Cl_2 layer was separated and evaporated, and the resulting yellow viscous residue was dissolved in aqueous K_2CO_3 (95% solution, 30 mL). This solution was filtered, aqueous $[PPh_4]Cl$ (1 M; 10 mL) was added, and the resulting precipitate filtered off, washed with H_2O, and dried in vacuo. The precipitate was separated chromatographically [silica gel: CH_2Cl_2/C_6H_{14} (3:1)], yielding two main fractions. The first [R_f(anal.) 0.35 in CH_2Cl_2] was crystallized from CH_2Cl_2/hexane as yellow crystals and identified as $[PPh_4][S_2B_{17}H_{18}]$ (400 mg; 0.66 mmol; 48%), and the second [R_f(anal.) 0.23 in CH_2Cl_2] was identified as $[PPh_4]$[*nido*-7-$SB_{10}H_{11}$] (300 mg; 0.61 mmol; 45% by NMR spectroscopy) [25].

X-ray diffraction analysis: $[PPh_4][S_2B_{17}H_{18}]$, $M = 605.4$, triclinic, $a = 11.042(2)$, $b = 11.242(2)$, $c = 14.425(4)$ Å, $\alpha = 67.102(12)$, $\beta = 86.137(12)$, $\gamma = 81.521(12)°$, $V = 1631.4(5)$ Å^3, space group $P\bar{1}$ (no. 2), $Z = 2$, $\rho_{calcd} = 1.232$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.231$ mm^{-1}, $F(000) = 628$. 8402 reflections (5744 were unique) were measured on a Stoe STAD14 diffractometer ($2\theta_{max} = 50°$) using ω-θ scans and on-line profile fitting. The structure was solved by direct methods [SHELXS-86] and refined on F^2 using all 5744 independent reflections [SHELXL-93] with anisotropic displacement parameters for non-hydrogen atoms, freely refined borane H atoms and constrained phenyl H atoms. $wR_2 = [\Sigma w(F_o^2 - F_c^2)/\Sigma F_o^2]^{1/2} = 0.1161$, $R_1 = \Sigma \| F_o| - |F_c\| / \Sigma F_o = 0.0404$ [on 5141 F values with $F_o^2 > 2.0\sigma(F_o^2)$], goodness of fit on $F^2 = 1.047$ on 477 parameters. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ (UK), on quoting the full journal citation.

NMR spectra: ^1H and ^{11}B NMR data for $[PPh_4][S_2B_{17}H_{18}]$ in $(CD_3)_2CO$, 294 303 K; $\delta(^{11}B)$ [approximate coupling constant $^1J(^{11}B\text{-}^1H)$ [Hz] in square brackets] $\delta(^1H)$: BH(1) −20.5 [145] +1.83, BH(2) +19.3 [157] +4.34, BH(3) −14.7 [170] +1.86, BH(4) +8.6 [145] +3.56, BH(5) +4.9 [154 (coupling to μ-H not resolved, <ca. 10 Hz] +3.20, BH(7) +2.6 [145] +2.84, BH(8) −22.4 [137] −0.52, B(9) +26.2, BH(10) −27.2 [147/44] +1.34; assignments by $[^{11}B\text{-}^{11}B]$-COSY and $^1H\{^{11}B\}$ NMR experiments; there is a minor uncertainty among the 2, 3, and 7 positions due to weak COSY cross-peaks; $\delta(\mu\text{-}H)(5,10) - 0.64$; $\delta(^1H)[PPh_4]^+$ between +7.4 and +8.2 (400 MHz). ^1H and ^{11}B NMR data for $[PPh_4][SB_{10}H_{11}]$, measured and ordered as above: BH(1) −36.3 [143] +1.02, BH(2,3) −17.9 [J obscured] +1.60, BH(4,6) −5.8 [148] +2.18, BH(5) −17.1 [J obscured] +1.38, BH(8,11) −11.9 [140] +1.76, BH(9,10) −17.3 [J obscured] +1.28; $\delta(\mu\text{-}H)$ (9,10) − 3.95; $\delta(^1H)[PPh_4]^+$ between +7.4 and +8.2 (400 MHz).

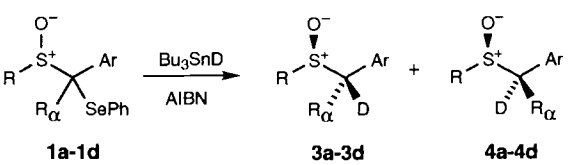
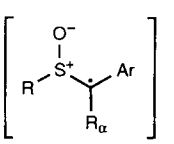
Stereoselective Reactions of Sulfinylated Benzyl Radicals: Effects of Solvents and Lewis Acids**

Philippe Renaud,* Thierry Bourquard, Michèle Gerster, and Nadira Moufid



Dedicated to Professor M. Schlosser on the occasion of his 60th birthday

The control of the stereoselectivity in the reactions of acyclic radicals is presently a field of intensive research.[1] The 1,2-transfer of chirality has attracted a great deal of attention, and different models have been proposed to account for the observed diastereoselectivities. Substituted benzyl radicals of type **I** have been reported to react with good diastereoselectivity, and a model based on allylic 1,3-strain was proposed to explain the stereochemical outcome.[2] We are presently interested in using easily accessible and highly versatile sulfoxides for the control of 1,2-induction in reactions of acyclic radicals.[3, 4] We report here a study of sulfinylated radicals of type **II**, for which an unusual influence of the solvent on the diastereoselectivity was observed. Moreover, an exceptional degree of inversion of the stereoselectivity was obtained in the presence of bulky Lewis acids such as Yamamoto's methylaluminum diphenoxide derivatives. A comparison with the deuteration of deprotonated sulfoxides of type **III** is also presented.



I **II** **III**

The radical precursors **1a–1d** have been prepared from the corresponding benzyl sulfoxides by selenenylation using LiHMDS/PhSeCl (HMDS = hexamethyldisilazane). Radical deuteration of these compounds with Bu_3SnD/azobisisobutyronitrile (AIBN)[5] gave the corresponding α-deuterosulfoxides **3** and **4** (for the definition of the substituents see Table 1).

1a-1d **3a-3d** **4a-4d**

2a-2d

The influence of the solvent is summarized in Table 1. With the exception of **1d** (entry 12) low to medium stereoselectivities were observed in CH_2Cl_2 (entries 1,7, and 9). A pronounced increase of the diastereoselectivity in favor of compound **3** was observed by running the deuteration in benzene (entries 2, 8, 10,

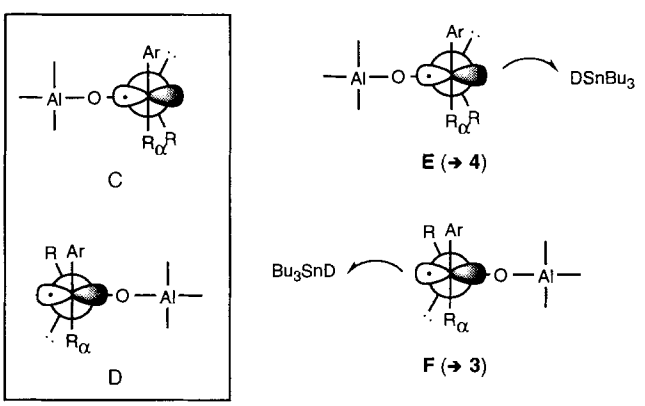
and 13) or THF (entries 3 and 11). For compound **1a**, the highest selectivity (entry 4, **3a**:**4a** 85:15) was obtained in mesitylene, which demonstrates that the steric bulk of the aromatic solvent is an important factor. Interestingly, we observed a partial inversion of stereoselectivity for **1a** in 2,2,2-trifluoroethanol (entry 6, **3a**:**4a** 35:65). Compound **1d** which possesses a methyl substituent in α-position gave **3d** with diastereoselectivities of 93% *ds* in CH_2Cl_2 and 96% *ds* in benzene (entries 12 and 13, respectively).

All these results may be rationalized by considering the two calculated minimum energy conformations A and B of the radical type **2** (Scheme 1).[6, 7] In noncoordinating solvents such as

Scheme 1. Conformations A and B of the radical type **2**, and models **A**–**D** for possible approaches of Bu_3SnD.

CH_2Cl_2, both conformers of **2a** and **2b** have similar energies; thus, attack from either face leading to **3** and **4** is possible (models **A**–**D**). Radical **2c** exists almost exclusively in conformation A due to strong allylic 1,3-interactions caused by the presence of the *ortho*-chlorine atoms. The low selectivity in dichloromethane may be interpreted by attack of A from either face (models **A** and **B**). For the deuteration of **1d** (R_x = Me), the role of the methyl substituent may be explained by a destabilization of conformer B due to *gauche* interactions with the group R bound on the sulfur atom (1,2-allylic interactions); thus, the preferred pathway leads almost exclusively to **3** through the transition state depicted in model **A**.[8] The solvent effect may also be explained by looking at the different models. Aromatic solvents are known to complex efficiently sulfoxides at the sulfur atom *anti* to the S–O bond.[9] For both conformers A and B, this type of complexation results in a shielding of the face, leading to the minor diastereoisomer **4** (models **B** and **D**, respectively), and thus reactions leading to **3** according to model **A** and **C**, respectively, are favored. The effect of THF is certainly similar to that of benzene, as already demonstrated in cyclic systems. 2,2,2-Trifluoroethanol has an opposite effect because of hydrogen bonding with the oxygen atom.[10]



Next, we investigated the effect of Lewis acids[11] on the stereoselectivity of the deuteration of **1a**, **1b**, and **1d**. The results are summarized in Table 2. Lithium perchlorate and [Eu(dpm)$_3$] (dpm = 2,2,6,6-tetramethylheptane-3,5-dionato), which are very efficient for the control of the stereoselectivity in cyclic systems,[4d, 4e] reduced strongly the diastereoselectivity of the deuteration. However, the main isomer formed was still **3** (entries 1 and 2). With the very bulky and oxophilic methylaluminum di(2,6-di-*tert*-butyl-4-methylphenoxide) (MAD) and methylaluminum di(4-bromo-2,6-di-*tert*-butylphenoxide) (MABR),[12] an excellent selectivity (>97% *ds*, entries 3 and 5)

Table 2. Effect of Lewis acids on the deuteration of **1a**, **1b**, and **1d** (Ar = Ph) [5].

Entry	Cmpd.	R	R_x	Solvent	Lewis acid (equiv.)	Yield [%]	**3**:**4**
1	**1a**	Ph	H	CH_3CH_2CN	$LiClO_4$ (1.2)	51	58:42
2	**1a**	Ph	H	CH_2Cl_2	[Eu(dpm)$_3$] (1.1)	95	54:46
3	**1a**	Ph	H	CH_2Cl_2	MAD (1.1)	85	2.5:97.5
4	**1a**	Ph	H	CH_2Cl_2	MAD (0.1)	89	62:38
5	**1a**	Ph	H	CH_2Cl_2	MABR (1.1)	84	<3:97
6	**1a**	Ph	H	CH_2Cl_2	MABR (0.1)	91	52:48
7	**1b**	Me	H	CH_2Cl_2	MAD (1.1)	77	4.3:95.7
8	**1d**	Ph	Me	C_6H_6	MAD (1.1)	86	42:58
9	**1d**	Ph	Me	CH_2Cl_2	MAD (1.1)	73	14:86

was obtained for **1a** with preferential formation of **4a**. Deuteration of **1b**, which was unselective in CH_2Cl_2 gave also preferentially **4b** with 95% *ds* (entry 7). The inversion was also observed with **1d** but to a lesser degree (entry 9, 86% *ds*). Unlike what we observed in cyclic systems,[4e] the effect of the Lewis acid is not catalytic. In the presence of 10 mol% of MAD or MABR, a nearly 1:1 mixture of isomers was formed (entries 4 and 6, respectively).

The effect of methylaluminum diphenoxides can be understood by considering two conformations C and D of the radical type **2** (Scheme 2). Conformation C corresponds to a minimum

Scheme 2. Conformations **C** and D of the radical type **2** complexed with MAD and MABR, and models **E** and **F** for possible approaches of Bu_3SnD.

1,3-allylic strain situation, where the $OAlR_3$ group plays the role of the largest substituent. Preferential attack of the radical *anti* to the bulky $OAlR_3$ group of the most stable conformer C gives **4** (model **E**). The lower selectivity observed for **1d** may be explained by destabilizing *gauche* interactions (1,2-allylic strain) caused by the presence of an α-methyl group in C; thus, the contribution of conformer D (model **F**) to the stereoselectivity becomes more important.

Finally, for comparison purposes, we carried out the ionic deuteration ($LiNiPr_2$/BuLi/D_2O, −78 °C) of benzyl phenyl sulfoxide and 2,6-dichlorobenzyl phenyl sulfoxide. These reactions yielded **3a**:**4a** (54:46) and **3c**:**4c** (> 98:2), respectively. The ionic deuteration of benzyl methyl sulfoxide has been reported previously and affords **3b**:**4b** as a 94:6 mixture of isomers.[13] Thus, the same diastereoisomer is preferentially formed for both ionic deuterations and radical deuterations without added Lewis acids. However, no inversion of the diastereoselection has ever been reported for the ionic deuteration.

In conclusion, we have demonstrated that sulfinylated benzyl radicals may be used for highly stereoselective reactions. The sense and the degree of stereoselectivity can be controlled by proper choice of the solvent and by the adjunction of Lewis acids. In the presence of the latter, the radical method is complementary to the ionic reaction. Our simple model for the stereoselectivity, which is based on conformational analysis of the radical intermediate, has good predicting power and will be further investigated by examining directly the possible transition states with computational techniques.

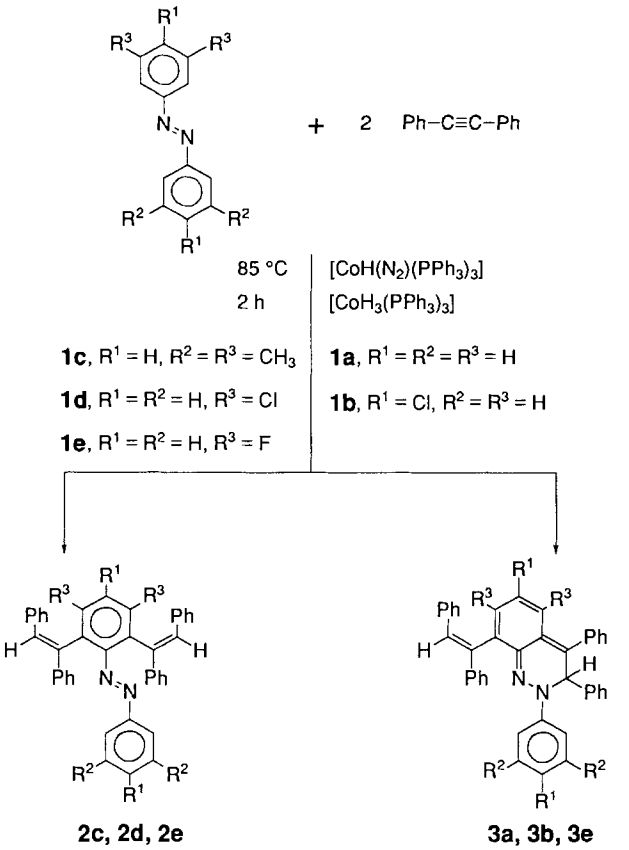
Functionalization of Aromatic Azo Compounds by the Cobalt-Catalyzed, Regioselective Double Addition of Tolane: 2,6-Distilbenylazobenzenes and 2,3-Dihydrocinnolines**

Günther Halbritter, Falk Knoch, Alexander Wolski, and Horst Kisch*

Dedicated to Professor Borislav Bogdanović on the occasion of his 60th birthday



Easily accessible aromatic azo compounds can, as a rule, only be utilized in the synthesis of heterocycles if they are activated by transition metal carbonyls (M = Co, Ru). Thus, C–N coupling can be achieved with carbon monoxide,[1] alkynes,[2] amines, and alcohols.[3] A generally unwanted side reaction is the *ortho*-semidine rearrangement, which usually is accompanied by N=N cleavage, and which is also observed in the presence of iron carbonyls.[4] On the other hand, in the presence of $[CoClL_3]$ (L = PPh_3)[5] or $[Pd(pap)(CH_3CN)_2]^+$ (pap = *ortho*-(phenylazo)phenyl)[6] and tolane, *N*-arylaminoindole or 2-arylcinnolinium salts are formed in a stoichiometric reaction with retention of the N–N bond, as a result of a 1:1 addition. We have now found that, when $[CoH_3L_3]$ or $[CoH(N_2)L_3]$ is used, a catalytic, regioselective 2:1 addition of tolane takes place to give the previously unknown 2,6-di-(*trans*-stilbenyl)azobenzene derivatives and 2,3-dihydrocinnolines.

When $[CoH(N_2)(PPh_3)_3]$ or $[CoH_3(PPh_3)_3]$ is added to a molten mixture of diphenylacetylene (tolane) and azobenzene **1a** or its derivative **1b** at 85 °C, a vigorous evolution of gas and a red coloration occurs instantly. The products **3a** or **3b**, respectively, are obtained as red powders, which can be purified by column chromatography (Scheme 1).

The X-ray crystal structure analysis[7, 8] of **3b** indicated that an alkyne molecule had been inserted into each of the *ortho*-C–H bonds of one of the benzene rings, and that one of the so formed *trans*-stilbene groups was bonded to the N atom of the N=N bond attached to the other benzene ring, to form a previously unknown 2,3-dihydrocinnoline ring (Fig. 1).[9] The *ortho*-quinoid system is characterized by the alternating C–C bond lengths in the ring of approximately 135 and 143 pm and the short C10–N1 and C15–C1 distances of about 132 and 137 pm, respectively. The nitrogen atom N2 lies only 1.6 pm above the plane defined by the N1, C2, and C20 atoms. That this allows a conjugation of the quinoid system with the 4-chlorophenyl substituent is indicated by the shortened bonds between N1 and N2 (135 pm) and N2 and C20 (141 pm). In general, the aromatic character of the benzenoid ring of the dihydrocinnoline system remains intact. Accordingly, only the 1,2- and the more stable 1,4-dihydro derivatives have been previously described in the literature.[10] The few known examples, in which an *ortho*-quinoid system forms part of the cinnoline framework, 4-phenyl-4*H*-cyclopentacinnoline,[11] 3(2*H*)-cinnoline,[12] and a pyrrolo[1,2*b*]cinnoline derivative,[13] always have an sp^2 hybridized C atom in the 3-position, allowing the formation of planar systems which are stabilized by conjugation. However, in **3b** this atom is sp^3 hybridized.

Scheme 1. Synthesis of 2,6-distilbenylazobenzenes **2** and 2,3-dihydrocinnolines **3**.

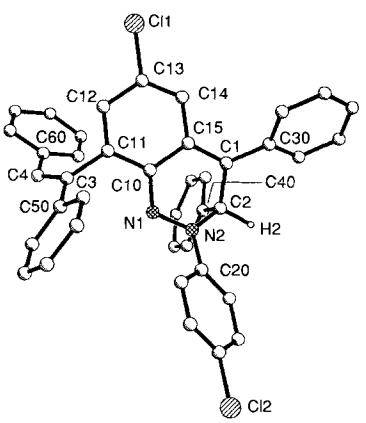

Fig. 1. Crystal structure of **3b**. With the exception of H2 the hydrogen atoms have been omitted for clarity. Selected distances [pm] and angles [°]: N1-N2 135.1(7), N2-C2 147.0(8), C2-C1 152.8(9), C1-C15 137.5(8), C15-C14 143.3(9), C14-C13 134.9(9), C13-C12 142.2(9), C12-C11 136.2(9), C11-C10 143.8(9), C10-N1 132.4(8), C20-N2 141.2(8); N2-C2-C1 104.3(5), C2-C1-C15 113.9(5), C1-C15-C14 125.1(5), C15-C14-C13 119.2(5), C14-C13-C12 124.7(6), C13-C12-C11 118.7(5), C12-C11-C10 119.9(5), C11-C10-N1 117.0(5), N2-N1-C10 115.7(5), N1-N2-C20 115.7(5), N1-N2-C2 120.0(4), C2-N2-C20 124.3(5), C1-C2-C40 114.5(5), N2-C2-C40 112.4(5).

When 3,5,3′,5′-tetramethylazobenzene (**1c**) is used as the azo component, the reaction mixture turns orange, and **2c** is obtained as an orange powder, which can be purified by extraction with ether. As can be seen from its crystal structure analysis,[14, 8] a regioselective insertion of an alkyne in each of the *ortho*-C–H bonds of one of the benzene rings has also taken place; however, without the simultaneous formation of a C–N bond (Fig. 2).[15] These products, the 2,6-di-(*trans*-stilbenyl)-azobenzene derivatives, are also not described in the literature. 3,5-Dichloroazobenzene (**1d**) similarly yields only the distilbenyl product **2d**, while **2e** and **3e** are both formed with 3,5-difluoroazobenzene (**1e**). Single-crystal X-ray structure analyses have been carried out for both compounds.[16, 8] In each case the yields are between 70 and 80%, the turnover number varies from 3–15 mmol product/mmol catalyst.

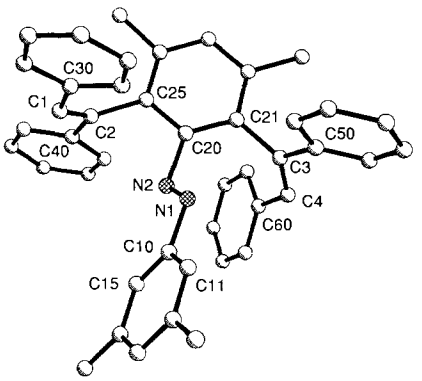

Fig. 2. Crystal structure of **2c**. The hydrogen atoms have been omitted for clarity. We have assumed the following mechanism for the formation of distilbenylbenzenes **2**: Firstly the initial complex [CoH(ArN=NAr)L_3] is formed by the substitution of N_2 or H_2, respectively, in the catalyst precursor; the subsequent orthometalation to give the dihydrido complex presumably proceeds by a nucleophilic attack of the cobalt center, since both 3,5-dihalogenoazobenzenes **1d** and **1e** are attacked regioselectively at the substituted benzene nucleus,[17] as can be concluded from the structures of **2d** and **2e**. Insertion of the alkyne in a Co–H bond[18] yields a *trans*-stilbenyl ligand whose subsequent migration to the metalated C atom leads to the 2-(*trans*-stilbenyl)azobenzene complex. Renewed attack of the Co center on the stilbenylphenyl nucleus[19] and repetition of the above reaction steps yields a 2,6-di(*trans*-stilbenyl)azobenzene complex, which is transformed to the product **2** and the initial complex by the entrance of a new azo compound.

The 2,3-dihydrocinnolines **3** are formed in an uncatalyzed reaction starting from **2**, as the experiments with 3,5-difluoroazobenzene **1e** indicate [Eq. (a)]. When the mixture **2e**/**3e**, prepared by chromatographic work-up,[20] is irradiated in dichloromethane at −30 °C, an orange powder precipitates. The X-ray diffraction pattern of this material indicates the presence of only **2e**.[21] On warming to room temperature the solution turns red and, according to the UV/Vis spectrum, the mixture is again present. UV/Vis spectroscopy for **3a**, **3b**, and **3e** shows that a uniform reaction sequence occurs in this photochromic system because at 355, 375, and 346 nm, respectively, there is an isosbestic point. The *ortho*-quinoid system of **3e** has

$$\mathbf{2e} \underset{h\nu,\ -30\ ^\circ C}{\overset{\text{ca. } 20\ ^\circ C}{\rightleftharpoons}} \mathbf{3e} \qquad \text{(a)}$$

an intense band at 515 nm ($\varepsilon \approx 10000\ M^{-1}cm^{-1}$), while **2e** absorbs only weakly in this region (490 nm, $\varepsilon \approx 1000\ M^{-1}cm^{-1}$). The absence of ring closure in the case of the 3,5-disubstituted azobenzene derivatives **1c** and **1d** could be due to the greater spatial requirements of the substituents (R^3 = Me, Cl) in comparison to those of **1a** and **1b** (R^3 = H), which should make the formation of a planar transition state more difficult. Accordingly, only the 2,3-dihydrocinnoline derivative is formed from 3,3'-dimethylazobenzene.

Experimental Procedure

All operations were carried out under an atmosphere of nitrogen, and with anhydrous, N_2-saturated solvents.

General procedure: To a melt of two parts tolane and one part of the azo compound **1** at 85 °C was added, in portions, the appropriate amount of catalyst (in the case of **1a**, **1b**, and **1d** 0.25 equivalents, for **1c** 0.066 equivalents and for **1e** 0.33 equivalents). The mixture was then stirred for two hours at 85 °C. For **1a**, **1b**, and **1e**, the resultant material was dissolved in CH_2Cl_2, alumina added, and the mixture evaporated to dryness. The resulting powder was chromatographed on alumina (neutral, activity I, ICN) with petroleum ether/THF 10/1 (v/v). For **1c**, the reaction mixture was stirred with petroleum ether and the remaining solid extracted with ether in a Soxhlet extractor. For **1d**, dissolution in CH_2Cl_2, filtration through alumina, and evaporation to dryness gave a solid which was dissolved in a minimum amount of CH_2Cl_2 and overlayered with twice the volume of methanol to precipitate the product.

All compounds gave correct C,H,N analyses and the corresponding molecular ion peaks in their mass spectra (EI, 70eV).

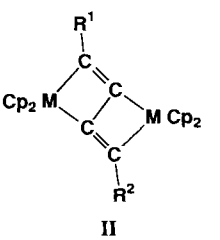
[17] This is also observed in the orthometalation with $[MeMn(CO)_5]$: M. I. Bruce, B. L. Goodall, F. G. A. Stone, *J. Chem. Soc. Chem. Commun.* **1973**, 558.
[18] In analogy to the indium and rhodium complexes, the alternative insertion into a Co–C bond should also be disfavored on thermodynamic grounds: a) H. E. Selnau, J. S. Merola, *Organometallics* **1993**, *12*, 3800; b) *J. Am. Chem. Soc.* **1991**, *113*, 4008; c) W. T. Boese, A. S. Goldman *Organometallics* **1991**, *10*, 782.
[19] The lower lying LUMO (in comparison with the other N-aryl group) could explain the regioselectivity of this second nucleophilic attack.
[20] The powder diffraction diagram contains the reflections from both compounds.
[21] The possibility that traces of isomers with *cis*-stilbenyl groups exist in solution cannot be excluded.



Synthesis and Structure of the Smallest Cyclic Cumulene; Reaction of 1,3-Diynes with Zirconocene Complexes**

Uwe Rosenthal,* Andreas Ohff, Wolfgang Baumann, Rhett Kempe, Annegret Tillack, and Vladimir V. Burlakov

For some time now we have been studying the interaction of disubstituted butadiynes with Group 4 metallocenes "Cp_2M" as a function of the metal M and the substituents of the diyne. For M = Ti the central C–C single bond of $Me_3Si-C\equiv C-C\equiv C-SiMe_3$ is cleaved, and a dimeric complex $[Cp_2Ti(\mu\text{-}\eta^1\text{:}\eta^2\text{-}C\equiv CSiMe_3)]_2$[1] containing bridged σ-π acetylide groups (type **I**) is formed. This cleavage was found to be dependent on the nature of the diyne substituents. For all other investigated disubstituted butadiynes $R^1C\equiv C-C\equiv CR^2$ ($R^1 = R^2$ = Ph, *t*Bu; $R^1 = SiMe_3$, R^2 = Ph, *t*Bu) the C_4 unit remains intact for M = Ti. This affords binuclear complexes with tetradehydro-*trans*, *trans*-butadiene moieties (μ-η(1–3), η(2–4)-*trans*,*trans*-butadiene or "zigzag butadiyne") between the Ti centers (type **II**).[2]

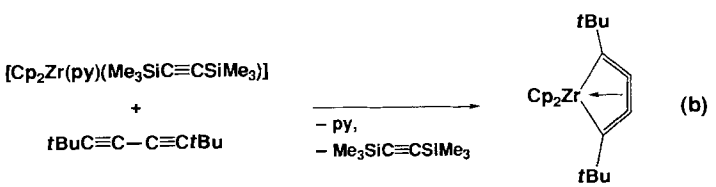
In contrast, cleavage of the diyne appears to be favored for M = Zr. When using the zirconocene synthon $[Cp_2Zr(thf)(Me_3SiC_2SiMe_3)]$[3] all butadiynes, except $tBuC{\equiv}C{-}C{\equiv}CtBu$, undergo cleavage. For $R^1 = R^2 = SiMe_3$, the reaction yields the complex $[Cp_2Zr(\mu\text{-}\eta^1{:}\eta^2\text{-}C{\equiv}CSiMe_3)]_2$, which has recently also been prepared by a different route.[4] By using unsymmetrically substituted butadiynes ($R^1 = SiMe_3$, R^2 = Ph, tBu) we were able to prepare the first complexes of type $[Cp_2Zr(\mu\text{-}\eta^1{:}\eta^2\text{-}C{\equiv}CR^1)(\mu\text{-}\eta^1{:}\eta^2\text{-}C{\equiv}CR^2)ZrCp_2]$. Notably, the σ-π acetylide bridges connecting the two Zr centers differ in these complexes.[5] Reaction with di-*tert*-butyl-1,3-butadiyne yields product mixtures that are difficult to separate and do not contain any product due to cleavage.

Employing the alkyne zirconocene complex $[Cp_2Zr(py)(Me_3SiC_2SiMe_3)]$[6] (py = pyridine) as a zirconocene synthon yielded novel zirconocene complexes in a surprising array of reactions. These transformations clearly show that in treating complexes of type $[Cp_2Zr(L)(Me_3SiC_2SiMe_3)]$ (L = thf or py) with diynes the nature of the ligands L has a decisive influence on the course of the reaction.

When using $Me_3Si{-}C{\equiv}C{-}C{\equiv}C{-}SiMe_3$ the binuclear complex $[Cp_2Zr(\mu\text{-}\eta^1{:}\eta^2\text{-}C{\equiv}CSiMe_3)]_2$ is formed only as a by-product. Zirconocene complex **1** is the main product, which results from the unusual coupling of two diyne molecules [Eq. (a)]. It was also recently obtained by treating the same



1

butadiyne with di-*n*-butylzirconocene (precursor to the Cp_2Zr synthon $[Cp_2Zr(n\text{-butene})]$[8]).[9] It crystallizes as yellow prisms that melt in an argon atmosphere at 187–188 °C.[7]

The 2,4,7-tris(trimethylsilyl)-3-(trimethylsilylethynyl)zircona cyclohepta-2,4,5,6-tetraene **1** contains the smallest cyclic cumulene yet synthesized (seven-membered).[10] Previously only the organic cumulene cyclonona-1,2,3-triene[11] had been isolated and a cyclohexa-1,2,3-triene detected in situ.[12]

On treatment of $[Cp_2Zr(py)(Me_3SiC_2SiMe_3)]$ with $tBuC{\equiv}C{-}C{\equiv}CtBu$, the complex **2**, in which only one diyne is complexed by zirconocene, is formed instead of the expected cleavage or coupling product [Eq. (b)].

2

Complex **2** crystallizes as light green needles, which melt with decomposition at 190–192 °C. They are sensitive to oxygen and moisture. In the IR spectrum of **2**, no absorption is observed in the region characteristic of the stretching vibrations for coordinated (1700–1800 cm^{-1}) or free C–C triple bonds (2050–2200 cm^{-1}). The ^1H and ^{13}C NMR spectra of **2** confirm a highly symmetrical coordination of the butadiyne.[13] Relative to the free diyne (δ = 86.2 ($C{\equiv}\underline{C}tBu$), 65.2 ($\underline{C}{\equiv}CtBu$), the signals for the alkyne C atoms in **2** are shifted downfield (δ = 186.4 and 105.5, respectively); they are also not as prominent as those in the binuclear Ti complex of type **II** (δ = 234.4 and 125.3, respectively).[2] The mass spectrum shows a molecular ion peak (M^+) at m/z = 382, indicative of a mononuclear complex.

The result of the X-ray structure analysis[14] for **2** is shown in Figure 1 and identifies the compound as a highly strained cumulene. The bond lengths for C1–C2 (1.28(1) Å), C2–C3 (1.31(1) Å), and C3–C4 (1.29(1) Å) are equivalent and confirm an identical bond order (double bond[15]). The atoms Zr, C1, C2, C3, and C4 are almost perfectly coplanar, and even the tertiary C atoms of the tBu substituents are bent out-of-plane by only 0.02(1) Å. Accordingly, all four ring C atoms possess p orbitals perpendicular to the plane of cumulene; in addition, the sp-hybridized C atoms (C2, C3) also possess p orbitals lying in-plane. The C2=C3 double bond is therefore suitable for coordination by the zirconium center. This results in a shortening of the distance between the β-C atoms and the zirconium center, which reduces the deviation of the cumulene unit in **2** from linearity. Nevertheless, the cumulene remains highly strained (the bond angles C1–C2–C3 of 150.0(5)° and C2–C3–C4 of 147.2(5)° differ markedly from 180°) and is coordinated to the zirconium center by σ bonds to carbon atoms C1 and C4.

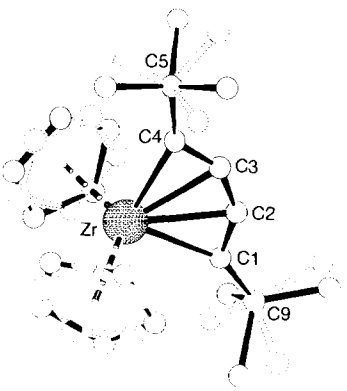


Fig. 1. Structure of **2** in the crystal.

A comparison of the data listed in Table 1 supports the description of **2** as a cyclic cumulene. Distances and angles of the

[a] **A** = 1,2,3-cyclopentatriene, **B** = 1,2,3-cyclohexatriene, C = 1,2,3-cycloheptatriene. [b] Calculated [11].

ZrC_4 unit in **2** are comparable to those reported for the cumulene unit in **1** and are also in accord with values calculated for cyclic cumulenes (**A**, **B**, and **C**).[11]

The cyclic structure of **2**, in principal, resembles that found in metallacyclopentadienes (for example, as reported for zirconi-

um),[16] in which the ring atoms are also coplanar. However, in **2** the ring strain is increased by the central double bond.

In summary, *t*BuC≡C–C≡C*t*Bu and $Me_3SiC{\equiv}C{-}C{\equiv}CSiMe_3$ react completely differently with zirconocene complexes. The latter cleaves[5] or couples [Eq. (a), ref. [9]] when treated with "Cp_2Zr". In contrast, the less reactive *t*BuC≡C–C≡C*t*Bu remains intact to yield the mononuclear complex **2**. One possible explanation for these differences in reactivity lies in the different electronic influences the substituents exert on the butadiyne system. For R = $SiMe_3$ a withdrawal of electron density from the central C atoms through dπ(Si)–pπ(C) interactions is conceivable; this situation is described by the limiting structure $Me_3\overset{(-)}{Si}{=}C{=}\overset{(+)}{C}{-}\overset{(+)}{C}{=}C{=}\overset{(-)}{Si}Me_3$. For R = *t*Bu the central double bond (essential for coordination as a cumulene) is stabilized in the complex. Coordination is therefore favored over cleavage or coupling (as observed for R = $SiMe_3$).

Experimental Procedure

All reactions were conducted under anaerobic and anhydrous conditions.

1: To an orange solution of [$Cp_2Zr(py)(Me_3SiC_2SiMe_3)$] (400 mg, 0.85 mmol) in *n*-hexane (20 mL) was added a solution of bis(trimethylsilyl)-1,3-butadiyne (330 mg, 1.7 mmol) in *n*-hexane (10 mL), and the mixture was stirred for 48 h at room temperature. The solvent was removed under vacuum, the residue redissolved in *n*-hexane and filtered through a frit, and the filtrate was then allowed to crystallize in the cold. Yellow crystals of **1** formed and were washed with cold *n*-hexane and dried under vacuum. Yield: 210 mg (51%), m.p. 187–188 °C, correct elemental analysis.

2: At room temperature, a solution of di-*tert*-butyl-1,3-butadiyne (183 mg, 1.13 mmol) in *n*-hexane (10 mL) was added to a stirred solution of [$Cp_2Zr(py)(Me_3SiC_2SiMe_3)$] (532 mg, 1.13 mmol) in *n*-hexane (15 mL). The solution's color changed from dark red to green. After 24 h all volatile components were removed under vacuum and *n*-hexane was added. Following filtration, **2** crystallized upon cooling in form of light green needles; these were washed with cold *n*-hexane and dried under vacuum. Yield: 281 mg (65%, m.p. 190–192 °C (decomp.), correct elemental analysis.

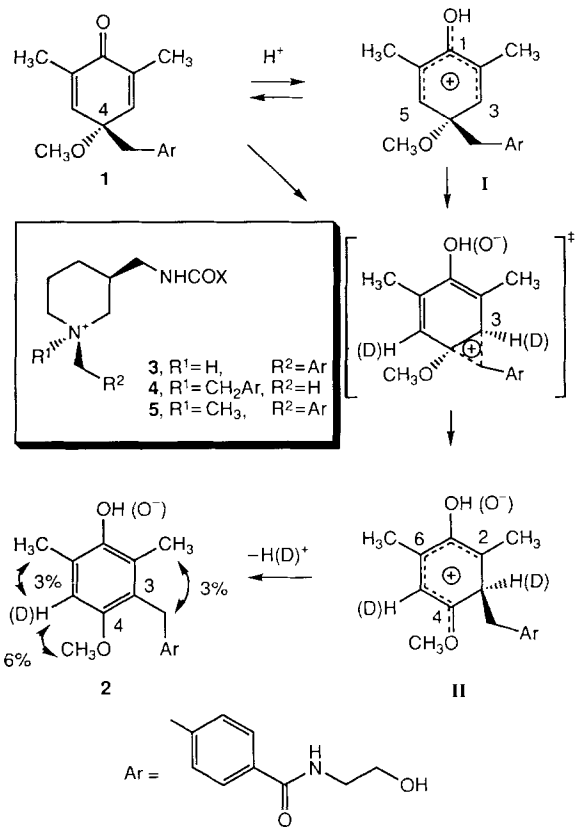
An Antibody-Catalyzed 1,2-Rearrangement of Carbon–Carbon Bonds**

Yuanwei Chen, Jean-Louis Reymond,* and Richard A. Lerner*

Catalytic antibodies are generated by immunization with stable transition state analogues of a chemical reaction. This technique provides rapid and practical access to new protein catalysts, and has been successfully applied to a number of chemical transformations.[1] However, only a few reactions involving C–C bonds have been catalyzed by antibodies.[2] These include the Diels–Alder reaction,[3] the Claisen and the oxy-Cope rearrangements,[4] and decarboxylations.[5] Herein we report on the first antibody-catalyzed 1,2-rearrangement of C–C bonds, namely the dienone–phenol rearrangement.

Many rearrangements of C–C bonds are nucleophilic 1,2-shifts, in which an electronic sextet formed on an atom A attached to a carbon atom induces an adjacent C–C bond to move with its electron pair to that center to fill its valence shell. A carbenium ion is left behind, which is then stabilized by donation of an electron pair from one of its substituents (Scheme 1).



Scheme 1. Nucleophilic 1,2-shift of a C–C bond. The atom A has an electronic sextet and may be positively charged (A = carbon, oxygen) or neutral (A = nitrogen).

This mechanism is of extremely broad scope and encompasses many important synthetic transformations.[6] When A is oxygen or nitrogen, the reaction is an oxidation. Examples of this are the Baeyer–Villiger and Beckmann rearrangements of ketones and oximes, or the Curtius and Hofmann degradations of carboxylic acids. When A is carbon, the reaction is a rearrangement, as is the case in the pinacol, dienone–phenol, or Wagner–Meerwein reactions.

The dienone–phenol rearrangement is the acid-catalyzed transformation of a 4,4-disubstituted cyclohexadienone into a 3,4-disubstituted phenol.[7] In the case of compound **1**, the benzyl group migrates preferentially to give phenol **2** (Scheme 2).

Scheme 2. Mechanism of dienone–phenol rearrangement of **1** to **2**; transition state analogues **3**–**5** were used as haptens. Nuclear Overhauser effects observed for **2** confirm that the benzyl group migrated to C-3. X represents the link to the carrier protein.

The reaction mechanism involves preequilibrium protonation of the carbonyl oxygen by the acid catalyst to form **I**, followed by rate-determining migration of the benzyl group to form **II**. Proton abstraction from C-3 finally leads to aromatization and regeneration of the acid catalyst. Two important structural and electronic changes occur during the benzyl group migration: 1) carbon atoms C-3 and C-4 change their hybridization, forming a three-membered ring with the migrating group in the transition state; 2) the positive charge, which is delocalized at C-1, C-3, C-5, and the carbonyl oxygen atom in intermediate **I**, becomes localized within the three-membered ring of the transition state. We reasoned that the piperidinium haptens **3**–**5** could be considered as analogues of the transition state in this reaction, because, with the ammonium center in the position corresponding to the homobenzylic position of the migrating group, they mimic the charge distribution in the transition state. The structural features common to both haptens and transition state are the most strongly immunogenic elements of haptens **3**, **4**, and **5** and were thus expected to shape the immune response. It was hoped that the resulting antibodies might catalyze the rearrangement of **1** to **2**.

Dienone **1** was obtained as a minor product in the alkylation of 4-methoxy-2,6-dimethylphenol.[8] When treated with aqueous acid, **1** was quantitatively converted to phenol **2**. Fourteen anti-**3**, twenty-two anti-**4**, and twenty-one anti-**5** antibodies[9] were assayed for catalysis of the rearrangement of **1** to **2** at pH 5.75 and 37 °C. One anti-**3** and one anti-**4** antibody were found to catalyze the reaction. Catalysis followed Michaelis–Menten kinetics. Quantitative inhibition was observed on addition of the respective haptens, thus confirming that the catalytic reaction was taking place at the antibody binding site. Antibody 62C7 (anti-**3**) was characterized in detail (Fig. 1, Table 1).

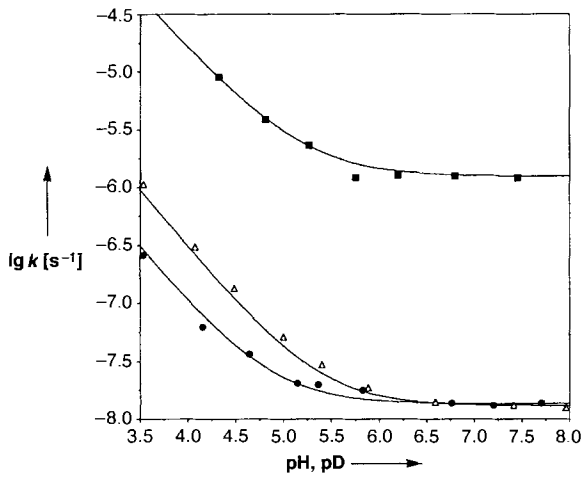

Fig. 1. Plot of lg$k$ vs. pH for the rearrangement of **1** to **2**: catalyzed by antibody 62C7 (anti-**3**) (■), and background reactions in H_2O (●) and D_2O (△). The lines were calculated from the equations $k_{cat} = k^0_{cat} + k_{cat,H}\cdot[H_3O^+]^{0.92}$; $k(H_2O) = k^0 + k_H\cdot[H_3O^+]$; $k(D_2O) = k^0 + k_D\cdot[D_3O^+]$.

Table 1. Isotope effects in antibody-catalyzed and background rearrangements of **1** to **2** [10].

Substrate	pH	K_m [μM]	$k_{cat.}$ [s^{-1}]	$k_{uncat.}$ [s^{-1}]	$k_{cat.}/k_{uncat.}$
1	5.75	670	1.22×10^{-6}	1.51×10^{-8}	80
[D_2] **1**	5.75	770	1.37×10^{-6}	1.71×10^{-8}	80
1	7.07	1200	1.25×10^{-6}	1.38×10^{-8}	90
1 (D_2O)	7.07 (pD)	1300	1.25×10^{-6}	1.31×10^{-8}	90

Below pH 5.75, both the 62C7-catalyzed and background reactions proceed with hydronium catalysis ($k_{cat,H^+} = 0.176\ M^{-1}s^{-1}$, $k_{H^-} = 1.51\times10^{-3}\ M^{-1}s^{-1}$). The latter exhibits a large inverse-solvent isotope effect ($k_{H^+}/k_{D^+} = 0.32$), consistent with preequilibrium protonation of **1** to form **I**.[10, 11] Above pH 5.75, a pH-independent pathway with a solvent isotope effect of about 1 predominates ($k^0_{cat} = 1.23\times10^{-6}\ s^{-1}$, $k^0 = 1.33\times10^{-8}\ s^{-1}$; Fig. 1, Table 1).[10, 12] These results point to a spontaneous rearrangement **1** to the conjugate base of intermediate **II** and of the complex [Ab·**1**] (Ab = antibody) to the conjugate base of the complex [Ab·**II**]. Importantly, a small inverse secondary isotope effect is observed in all cases at C-3 of the dienone ($k_{cat,H}/k_{cat,D} = 0.89$ at pH = 5.75, $k_H/k_D = 0.88$–0.94 from pH = 2.93 to 9.54). This indicates that the rate-determining step is the C–C bond migration itself involving rehybridization from sp^2 to sp^3 at C-3.[11] The C-3–H bond is ultimately broken during the formation of phenol **2**. This step is however not rate determining, since a large primary isotope effect at C-3 would then have been expected.[10]

The pH profile and isotope effects described above demonstrate that the antibody 62C7 catalyzes both the oxonium-promoted and the spontaneous rearrangement of **1** to **2** with similar efficiency and without altering the mechanism. Here, 62C7 is

clearly not acting as a simple acid catalyst. Since both pathways involve the localization of a positive charge near the rearranging C–C bond, the catalytic effect of 62C7 might result from selective stabilization of the charge distribution in the transition state.[13] The catalytic effect does not change significantly between pH 5 and 8. Stabilization of a positive charge could be mediated either by a carboxylate with a pK_a of less than 5 or by aromatic residues.[14]

Using electrostatic complementarity to the transition state as a guiding principle for hapten design, we have developed the first antibody-catalyzed 1,2-rearrangement of C–C bonds. Since formation of a transient positive charge in the migrating bond is a general feature of nucleophilic 1,2-shifts, the same principle should be applicable to the design of transition state analogues for other rearrangement reactions. We are now investigating improved haptens containing additional features of the transition state, such as a cyclopropane moiety which mimics the geometry of the bond migration.

Experimental Procedure

4-Methoxy-2,6-dimethylphenol was obtained in 87% yield by heating 2,6-dimethylhydroquinone with conc. H_2SO_4 in methanol at reflux [8a]. 4-Methoxy-2,6-dimethyl[3,5-D_2]phenol (96% D_2, 85% yield) was obtained by using D_2SO_4 and [D_1]methanol. Treatment with *N*-hydroxyethyl-4-chloromethylbenzamide and sodium hydroxide in refluxing water gave **1** (2.5%) [8b], and the O-alkylation (38%) and 2-alkylation (25%) products. Compound **1** was purified by preparative HPLC (>98% purity, reverse-phase C-18, H_2O/CH_3CN gradient). **1**: M.p. 130.0–131.0 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.66, 7.16 (2d, ^3J = 8.2 Hz, 2 × 2H), 6.88 (t, ^3J = 5.3 Hz, 1H), 6.45 (s, 2H), 3.78 (t, ^3J = 4.7 Hz, 2H), 3.58 (dt, ^3J = 4.7 Hz, 5.3 Hz, 2H), 3.15 (s, 3H), 2.97 (s, 2H), 1.84 (s, 6H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 186.4, 168.3, 145.4, 139.5, 137.9, 132.5, 130.8, 126.5, 75.4, 62.1, 52.8, 46.3, 42.7, 15.8, 15.7.

2: M.p. 147.0–148.0 °C; ^{1}H NMR (500 MHz, CD_3CN): δ = 7.66, 7.16 (2d, ^3J = 8.3 Hz, 2 × 2H), 7.08 (bs, 1H), 6.67 (s, 1H), 5.64 (s, 1H), 4.03(s, 2H), 3.70 (s, 3H), 3.59(m, 2H), 3.41 (m, 2H), 3.15 (t, ^3J = 4.5 Hz, 1H), 2.21, 2.06 (2s, 2 × 3H); ^{13}C NMR (125 MHz, CD_3CN): δ = 168.6, 152.1, 147.6, 146.2, 132.8, 129.1, 128.0, 126.1, 125.7, 123.8, 112.0, 61.6, 56.6, 43.1, 32.2, 17.0, 12.9.

Assay conditions: 50–1500 μM substrate **1**, 8 μM antibody in 100 mM NaCl, 50 mM either bis-tris(bis(hydroxyethyl)iminotris(hydroxymethyl)methane) or 1,3-bis-[tris(hydroxymethyl)methylamino]propane, 37 °C. Product formation was followed by reverse-phase HPLC (Vydac C-18 218TP54, 0.45 × 22 cm, 1.5 mL min^{-1}, t_R(**1**) = 5.02 min, t_R(**2**) = 7.14 min; 28% CH_3CN, 72% H_2O, and 0.1% CF_3COOH). The pD (98% D_2O) values were obtained by adding 0.4 to the pH-electrode reading.

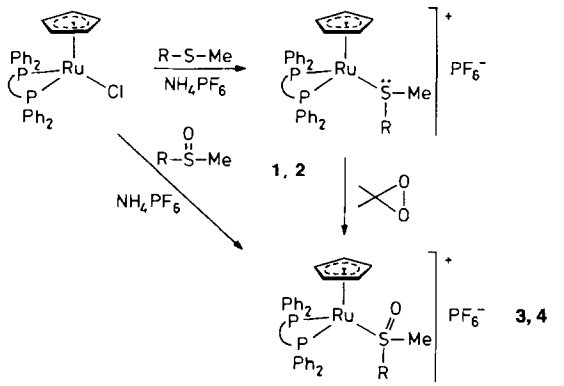
Oxidation of Metal-Coordinated Thioethers with Dimethyldioxirane—A New Stereoselective Synthesis of Chiral Sulfoxides**

Wolfdieter A. Schenk,* Jürgen Frisch, Waldemar Adam,* and Frank Prechtl



Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

Enantiomerically pure sulfoxides RS(O)R′ play an eminent role as intermediates and final products.[1] Nucleophilic substitution at diastereomerically pure sulfinic acid esters or amides is especially suitable for their synthesis;[2] the stereoselective oxidation of prochiral thioethers is another attractive method. When microorganisms or isolated enzymes are employed, high expectations regarding yield and selectivity are often not fulfilled.[3] However, oxidation of alkyl aryl sulfides with enantiomerically pure oxaziridines[4] and especially with *t*BuOOH in the presence of asymmetric titanium catalysts, methods developed by Kagan et al.[5] and Uemure et al.[6] are well proven. Dialkyl sulfides, on the other hand, are generally oxidized with only poor enantioselectivity.[4–6] We report here on a new methodology for solving this selectivity problem. The prochiral thioether is first coordinated to an enantiomerically pure transition metal complex fragment, which is then oxidized with a reactive oxygen transfer reagent.

It has been known for some time that the three-coordinate sulfur in thioether complexes is still susceptible to electrophilic attack, for example, by $[Me_3O]^+$.[7] Dimethyldioxirane (DMD) has proven to be an exceptionally effective, predominantly electrophilic oxygen transfer reagent,[8] which can also be used in the oxidation of organometallic substrates.[9] Therefore, we first tested whether the readily available thioether complexes **1a**, **b** and **2a**, **b** can be oxidized by DMD in acetone (Scheme 1).[10] Indeed, the sulfoxide complexes **3a**, **b** and **4a**, **b** were obtained in high yields. The identity of the products was established spectroscopically and by independent synthesis. By crossover experiments it was shown that the reaction does *not* proceed according to the following reaction sequence: a) dissociation of the thioether, b) oxidation of the uncoordinated thioether, and c) coordination of the resulting sulfoxide. Thus, oxidation of an

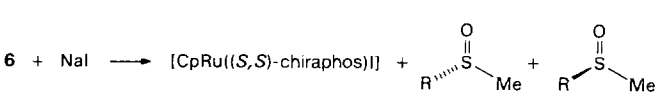
[**] Sulfur(IV) Compounds as Ligands, Part 21. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347 "Selective Reactions of Metal-Activated Molecules") and the Fonds der Chemischen Industrie. Part 20: W. A. Schenk, A. Khadra, C. Burschka, *J. Organomet. Chem.* **1994**, *468*, 75.



Scheme 1. **1a**–**4a**: R = Ph; **1b**–**4b**: R = CH_2Ph. The bidentate phosphane ligand is bis(diphenylphosphino)methane (dppm) in **1** and **3**, and bis(diphenylphosphino)ethane (dppe) in **2** and **4**.

equimolar mixture of **1a** and **2b** with DMD gave the sulfoxide complexes **3a** and **4b**. No crossover products **3b** and **4a** were formed. Similarly only **3b** and **4a** were obtained from a mixture of **1b** and **2a**, and no detectable amounts ($\leq 2\%$, ^{31}P NMR spectrum) of the crossover products **3a** and **4b** were found.

Scheme 2. **5a**, **6a**: R = Ph; **5b**, **6b**: R = CH_2Ph; **5c**, **6c**: R = *i*Pr.

The oxidation with DMD can be applied without problems to the (*S*,*S*)-chiraphos (chiraphos = 1,2-dimethyl-1,2-ethanediyl-bis[(diphenyl)phosphane]) complexes **5a–c** (Scheme 2). The sulfoxide complexes **6a–c** were thus obtained in nearly quantitative yields, and their identity was corroborated by independent synthesis from [CpRu{(*S*,*S*)-chiraphos}Cl].

b	CH_2Ph	≤1 (+)	≥99 (-)
c	*i*Pr	93 (+)	7 (-)

Scheme 3.

The bound sulfoxides were decomplexed in quantitative yields with sodium iodide in acetone. The chiral metal fragment was recovered in a form which would allow it to be recycled (Scheme 3). Separation of the sulfoxides by HPLC on a chiral column confirmed the diastereoselectivities determined by NMR spectroscopy and the stereospecificity of the cleavage reaction. Thus, for example, enantiomerically pure (*S*)-**7b** was obtained from (R_S)-**6b** with retention of configuration at sulfur. The absolute configurations of **7a**[5a] and **7b**[2a] follow from the sign of the specific rotation. The positive sign of the specific rotation for **7c** indicates an *R* configuration by analogy with (*S*)-MeS(O)*n*Pr ($[\alpha]_D = -139$) and (*R*)-MeS(O)*i*Bu ($[\alpha]_D = +138$).[2a]

The high diastereoselectivity of the oxygen transfer is kinetic in origin. The sulfur atom in thioether complexes usually undergoes rapid pyramidial inversion;[11] for example, only at −40 °C can separate NMR signals be observed for the two diastereoisomers of **5b**, which are nearly equal in energy (18% *de*). Each diastereoisomer can exist as three different rotamers with respect to the Ru–S bond. According to the NOE difference spectra (NOE = nuclear Overhauser effect; irradiation of the Cp resonance frequencies causes comparable enhancement of the SCH_3 and SCH_2 signals for both diastereomers of **5b**), the energetically preferred rotamer is that with both substituents at sulfur oriented towards the cyclopentadienyl ring. In this orientation, the lone pair at sulfur is sterically shielded by the aryl groups of the chelating phosphane.[12] As a result, the oxygen atom must be preferentially transferred to one of the other two rotamers of (R_S)-**5b**. The diastereoselectivity of the oxidation therefore depends on the difference in energy between the two higher energy rotamers, which were not observed in the NMR spectra, as well as on the difference in their reactivities. Since a large number of C_2-symmetric bidentate phosphane ligands are known, many of which are commercially available, our results open up a novel route for the enantioselective oxidation of thioethers.

Experimental Procedure

All experiments were carried out with purified solvents and under an inert atmosphere. ^{31}P NMR spectra were recorded at 162 MHz in [D_6]acetone at 25 °C, using 85% H_3PO_4 as the reference.

1, **2**: A solution of 0.25 mmol [CpRu (dppm)Cl] or [CpRu(dppe)Cl], 50 mg NH_4PF_6 (0.30 mmol), and 1.00 mmol thioether in 10 mL of methanol was heated for 3–4 h under reflux. The mixture was then concentrated to dryness and the residue recrystallized twice from dichloromethane/diethyl ether. The products were thus obtained as yellow crystalline powders in about 90% (**1a, b**) and 75% (**2a, b**) yield (correct elemental analyses). **1a**: M.p. 173–175 °C; ^{31}P NMR: $\delta = 7.7$. **1b**: M.p. 192–197 °C; ^{31}P NMR: $\delta = 8.8$. **2a**: M.p. 164–167 °C; ^{31}P NMR: $\delta = 73.7$. **2b**: M.p. 218–220 °C; ^{31}P NMR: $\delta = 72.8$.

3, **4**: a) The independent synthesis of **3** and **4** was achieved by an analogous procedure starting from the chloro complex and sulfoxide in 80–85% yield. b): To a solution of 0.15 mmol thioether complex in 3 mL of acetone at 0 °C was added slowly a solution of 0.60 mmol DMD in acetone [10]. After 45 min all volatiles were removed under vacuum and the residue recrystallized from acetone/diethyl ether. The products were thus obtained as light yellow crystalline powders (correct elemental analyses) in yields >90%. No thioether complex could be detected in the NMR spectra of the crude products. **3a**: M.p. 120–124 °C; ^{31}P NMR: $\delta = 8.5, 5.0$, J (P,P) = 85 Hz. **3b**: M.p. 214–217 °C; ^{31}P NMR: $\delta = 8.0, 7.7$, J (P,P) = 85 Hz. **4a**: M.p. 171–175 °C; ^{31}P NMR: $\delta = 78.9, 69.9$, J (P,P) = 20 Hz. **4b**: M.p. 162–165 °C; ^{31}P NMR: $\delta = 73.6, 72.9$, J (P,P) = 22 Hz.

5: The synthesis was achieved following the procedure given for **1** and **2**; the products were obtained as yellow crystalline powders in >95% yield (correct elemental analyses). **5a**: M.p. 148–153 °C; ^{31}P NMR: $\delta = 82.1, 63.8$, J (P,P) = 41 Hz. **5b**: M.p. 212–217 °C; ^{31}P NMR: $\delta = 82.2, 66.8$, J (P,P) = 40 Hz. **5c**: M.p. 187–189 °C; ^{31}P NMR: $\delta = 81.4, 64.4$, J (P,P) = 41 Hz.

6: a) The independent synthesis was achieved starting from the chloro complex and sulfoxide and following the procedure given for **1** and **2**; **6a–c** were thus obtained as pale yellow crystalline powders in 85–90% yield (correct elemental analyses). (R_S)-**6a**: (S_S)-**6a** = 93:7 (86% *de*); (R_S)-**6a**: ^{31}P NMR: $\delta = 81.8, 60.3$, J (P,P) = 36 Hz; (S_S)-**6a**: ^{31}P NMR: $\delta = 79.1, 62.3$, J (P,P) = 36 Hz. (R_S)-**6b**: (S_S)-**6b** = 50:50 (0% *de*); (R_S)-**6b**: ^{31}P NMR: $\delta = 80.9, 61.2$, J (P,P) = 37 Hz; (S_S)-**6b**: ^{31}P NMR: $\delta = 80.9, 61.8$, J (P,P) = 36 Hz. (R_S)-**6c**: (S_S)-**6c** = 12:88 (76% *de*). R_S-**6c**: ^{31}P NMR: $\delta = 78.6, 60.4$, J (P,P) = 37 Hz; (S_S-**6c**): ^{31}P NMR: $\delta = 80.6, 57.8$, J (P,P) = 37 Hz. b) The oxidation of **5a–c** to **6a–c** with DMD was carried out as described above. The extent of reaction and the diastereoisomeric ratios were determined from the NMR spectra of the crude reaction mixtures. **6a**: Yield 95%, (R_S)-**6a**: (S_S)**6a** = 73:27 (46% *de*). **6b**: Yield 90%, (R_S)-**6b**: (S_S)-**6b** ≥99:1 (98% *de*). **6c**: Yield 95%, (R_S)-**6c**: (S_S)-**6c** = 7:93 (86% *de*).

Removal of the sulfoxide: The sulfoxide complex (0.10 mmol) and 75 mg sodium iodide (0.50 mmol) were heated for 15 h under reflux in 5 mL of acetone. The mixture was then concentrated. The residue was taken up into 2 mL of dichloromethane and chromatographed on silica. [CpRu{(S,S)-chiraphos}I] was

eluted first with dichloromethane and then the sulfoxide with acetone. Upon removal of the solvent, the product was obtained in pure form and in quantitative yield (NMR). The enantiomeric ratio was determined by HPLC (Chiracel OD column, hexane/2-propanol 9:1, UV and optical rotation detector).

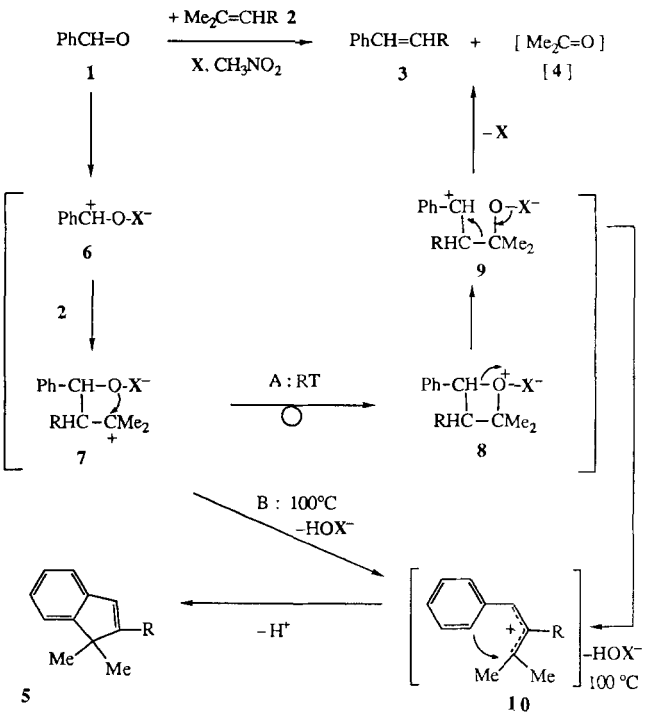
Acid-Catalyzed Olefination of Benzaldehyde

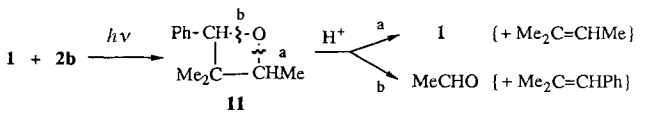


Henk-Peter van Schaik, Robert-Jan Vijn, and Friedrich Bickelhaupt*

Olefinations of carbonyl compounds are usually performed under alkaline conditions. The reaction starts with the nucleophilic attack of a negative carbon atom on a carbonyl group. This applies to the classical Wittig[2] reaction and its variants.[2] We present here an acid-catalyzed olefination, namely the reaction of benzaldehyde with olefins catalyzed by a solid Lewis acid. This reaction is particularly interesting not only because of the acid catalysis. First, it is a one-pot reaction with a surprising, and to our knowledge hitherto unknown, reaction mechanism. Second, in spite of having certain inherent limitations, this reaction is attractive from a preparative point of view because the carbon atom used for the olefination of the carbonyl group comes from a simple olefin, that is, from an inexpensive raw material. The principle of this reaction is shown in Scheme 1. In

Scheme 1. Reaction of benzaldehyde (**1**) with **2a** (15% **3a** at 60% aldehyde conversion) and **2b** (30% **3b** at 25% aldehyde conversion). RT=room temperature.

a typical experiment, benzaldehyde (**1**), one equivalent of alkene **2**, and the solid Lewis acid catalyst EPZ-10[3] were stirred in nitromethane for 44 hours at room temperature. From this reaction styrene (**3a**) (15%) or β-methylstyrene (**3b**) (30%) were obtained; these yields are based on conversion rates of 60 and 25%, respectively. At higher temperatures or longer reaction times, better conversions were obtained; however, the formation of by-products also increased. As known from the literature,[4] **3a** dimerized to (*E*)-1,3-diphenylbut-1-ene. At higher temperature (100 °C) indenes **5a** (< 1%) or **5b** (10%) and increased amounts of polymeric products were formed (Scheme 2).



Scheme 2. Postulated mechanism of product formation. X corresponds to the catalyst EPZ-10.

The, at first glance, surprising formation of **3** can easily be explained by using well-known mechanistic principles (Scheme 2). It is assumed that the acidic catalyst **X** and **1** generate the intermediate **6**, which adds to **2** leading to the formation of **7**; this corresponds to the first step of the Prins reaction.[5] In the continuation of the Prins reaction, except for some special

cases,[6] the ring closure to give the oxetane does not seem to play a major role; however, in the case of **7** the formation of the (complexed) oxetane **8** (Scheme 2, route A) is the simplest hypothesis.[7] There are some examples[8] in the chemistry of oxetanes[6] for the subsequent acid-catalyzed ring opening. They show, as expected, that the most stable carbocation is formed after the cleavage of the four-membered ring. Accordingly, **8** should open to give the intermediate **9** with a cationic benzylic group, which produces **3a** or **3b** by a Grob fragmentation.[9] The majority of these reaction steps are probably reversible. Thus, for example, it is known that oxetane **11**, which is made by photoaddition of **1** to **2b** and whose structure is regioisomeric with that of **8b**, can be cleaved by acid to give acetaldehyde as well as **1**[8a] (Scheme 3). The olefination is, however, not

Scheme 3. Fragmentation of oxetane **11** [8a].

dominated exclusively by the thermodynamically determined position of equilibrium, since model calculations for the reaction **1** + **2** → **3** + **4** (Scheme 1) indicate strongly negative reaction enthalpies (ΔH_R) and Gibbs energies (ΔG_R) (with **2a**: $(\Delta H_R) = -4.5$; with **2b**: $(\Delta H_R) = -5.2$; $(\Delta G_R) = -4.6$ kcal mol^{-1}) that should lead to an almost complete displacement of the equilibrium to the right-hand side. The formation of **5** under extreme conditions seems to proceed via the allyl cation **10**, which can be generated (in a multistep process) from **7** (Scheme 2, route B) or from **9**.

Acetone (**4**), which along with **3** was expected to be the second fragmentation product, was not detected, presumably because under these reaction conditions acetone rapidly reacts to form the aldol condensation product, benzalacetone, which has been identified in the reaction mixture (Scheme 1). From this, the first limitation of the new olefination process can be derived directly: the carbonyl compound to be olefinated may not contain any α-hydrogen atoms, since otherwise, the aldol condensation dominates. Furthermore, the cation formed by protonation of the carbonyl compound must not be *too* stable; for instance, no reaction was observed between benzophenone and **2a** even at 100 °C, presumably because the reaction corresponding to the conversion **6** → **7** would be thermodynamically unfavorable for the intermediate with a cationic diphenylhydroxymethyl unit. The same applies to the olefin **2** used in the process whose nucleophilicity may be neither too low nor too high. We draw this conclusion from the observation that benzaldehyde did not react either with 1-octene or with 1,1-diphenylethene. In the case of 1-octene, the attack of the olefin on **6** leading to the formation of **7** is probably too unfavorable; for 1,1-diphenylethene, the Lewis acid could either react directly with the olefin to form a stable zwitterion, or **7** (with the cationic diphenylmethyl group!) is so stable that ring closure to give the oxetane **8** does not occur.

Further studies on the mechanism, as well as the optimization and limitations of the new reaction sequence, are in progress.

Experimental Procedure

In a typical experiment **1** (20 mmol) and EPZ-10 (1 g) [3] (heated for about 15 h in an oven at 130 °C) were stirred in nitromethane (20 mL) under nitrogen at room temperature. **2** (20 mmol) was added and the mixture stirred for an additional 44 h; in the case of **2a**, a reflux condenser filled with acetone/dry ice was applied. After completion of the reaction, the catalyst was separated by filtration. The yield in the filtrate was determined by GC/MS analysis with nitrobenzene as an internal standard. The identity of the products was confirmed by ^{1}H NMR spectroscopy of samples purified by preparative gas chromatograhy: **3a** (authetic sample); **3b** [10]. **5a** [11] (because the yield was less than 1% identification by mass spectrometry only was possible); **5b** [12], (*E*)-1,3-diphenyl-1-butene [4a], benzalacetone (authetic sample).

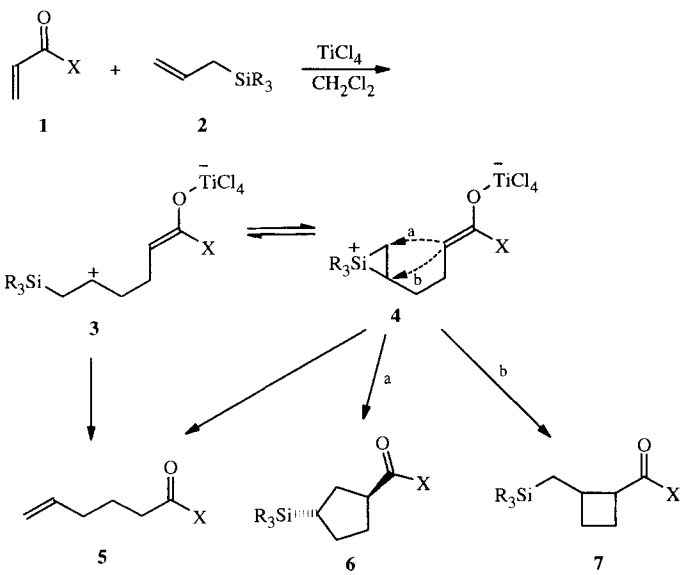
Lewis Acid Promoted [2+2] Cycloaddition of Allylsilanes and Unsaturated Esters: A Novel Method for Cyclobutane Construction**



Hans-Joachim Knölker,* Gerhard Baum, and Regina Graf

The [3+2] cycloaddition of allylsilanes, which was first described by us four years ago,[1] has been established as an efficient method for the stereoselective construction of five-membered ring systems.[2–4] The major achievement was the suppression of the classical Sakurai reaction[5] by using bulky substituents at the silicon atom of the allylsilane.[2] We report herein a novel mode of reactivity for allylsilanes and α,β-unsaturated carbonyl compounds in the presence of a Lewis acid, the

[**] Cycloadditions of Allylsilanes, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft (Gerhard-Hess-Förderpreis) and the Fonds der Chemischen Industrie. Part 5: [13].

[2+2] cycloaddition of allylsilanes and α,β-unsaturated esters. The three types of reactions of allylsilanes with unsaturated carbonyl compounds can be rationalized as presented in Scheme 1.

Scheme 1. Possible reactions for the α,β-unsaturated carbonyl compound **1** and allylsilanes **2** in the presence of $TiCl_4$: Sakurai reaction (product **5**; R = Me; X = H, alkyl), [3+2] cycloaddition (product **6**; R = Ph, *i*Pr; X = alkyl), and [2+2] cycloaddition (product **7**; R = Ph, *i*Pr; X = Oalkyl).

Nucleophilic attack of the allylsilane **2** is initiated by the Lewis acid and takes place at the β position of the conjugated carbonyl system **1**. The positive charge of the resulting β-silyl cation **3** is stabilized by internal nucleophilic neighboring group participation of the silicon atom, and a bridged nonclassical pentavalent silicon cation (= siliranium ion) **4** is generated. The pentavalency of silicon in the siliranium ion is possible because of its d orbitals.[6] This contribution to the β-effect of silicon has been termed "non-vertical stabilization" by Traylor.[7] Intermolecular nucleophilic attack at the silicon atom of the cationic intermediate either in its open form **3** or in the form of the siliranium ion **4** provides the Sakurai product **5** after hydrolysis and workup.[5] Sterically demanding substituents inhibit the nucleophilic attack at the silicon atom of either cationic species and thus favor cyclization by intramolecular nucleophilic attack of the titanium enolate. In the case of α,β-unsaturated ketones nucleophilic attack of the titanium enolate occurs at the primary carbon atom of the siliranium ion **4** (pathway a, 5-*exo-tet* cyclization)[8] and thus results in a [3+2] cycloaddition of the allylsilane involving a cationic 1,2-silyl shift to the silylcyclopentane **6**.

Herein we describe cyclizations that are inititated by nucleophilic attack of the titanium enolate at the secondary carbon atom of the intermediate siliranium cation (pathway b, 4-*exo-tet* cyclization)[8] which afford the silylmethylcyclobutanes **7**. Two points are worth noting in this context and should be mentioned in order to avoid any confusion. First, allyltrimethylsilanes failed to give conjugate additions in the Lewis acid ($TiCl_4$) promoted reaction with α,β-unsaturated carboxylic acid esters.[5a] Secondly, all proposed silylmethylcyclobutanes reported as by-products from the Lewis acid promoted reaction of conjugated enones[9] were reassigned as silylcyclopentanes.[10] These reassignments are not challenged by the present findings, which describe for the first time[11] that allylsilanes having bulky substituents at the silicon atom undergo Lewis acid promoted [2+2] cycloadditions with α,β-unsaturated esters leading to silylmethylcyclobutanes.

Initially, we investigated the [2+2] cycloaddition of the allylsilanes **2** and the methyl acrylates **8**. The cycloadditions of allyltriphenylsilane (**2a**) and allyltriisopropylsilane (**2b**) with methyl acrylate (**8a**) afforded irrespective of the temperature a mixture of the diastereomeric silylmethylcyclobutanes *anti*-**9** and *syn*-**9** (*syn* and *anti* specify the position of the silylmethyl side chain relative to the methoxycarbonyl group) and minor amounts of silylcyclopentane **10** (Table 1). However, the range of products

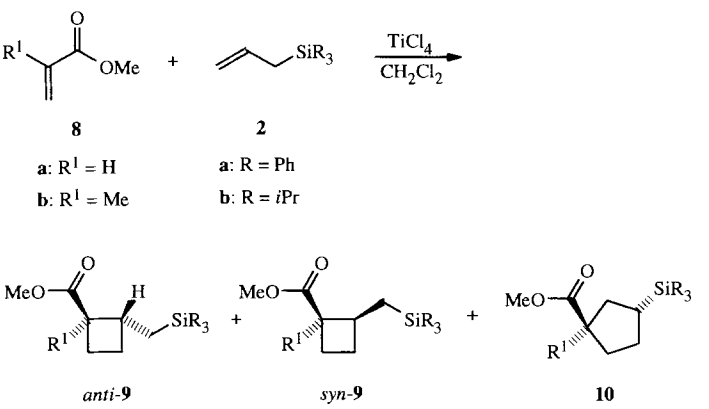

Table 1. Results of the cycloadditions of allylsilanes **2** and methyl acrylates **8**.

Products	R^1	R	Reaction conditions	Yield [%]	Product ratio [a] *anti*-**9**:*syn*-**9**:**10**
9a, **10a**	H	Ph	25 °C, 1 d → 40 °C, 1 d	46	9.8:12:1
9b, **10b**	H	*i*Pr	−40 °C → 0 °C, 19 h	100	9.5:11.9:1
9b, **10b**	H	*i*Pr	40 °C, 3 h	97	1.7:6.3:1
9c, **10c**	Me	Ph	25 °C → 40 °C, 4 d	69	9:2.5:1
9d, **10d**	Me	*i*Pr	−78 °C → −20 °C, 19 h	40	8.6:1:1.1
9d, **10d**	Me	*i*Pr	−78 °C → 40 °C, 19 h	57	5.4:1:13

[a] The product ratios were determined by NMR spectroscopy.

in the reaction of **8a** with allyltriisopropylsilane (**2b**) was significantly dependent on the temperature during the cycloaddition. Addition of **2b** to the titanium tetrachloride complex of **8a** at −40 °C and subsequent reaction at 0 °C for 19 h quantitatively provided the diastereomers *anti*-**9b** and *syn*-**9b** (1:1.25) together with small amounts of **10b**. When the reaction was performed in refluxing dichloromethane, a mixture of *anti*-**9b**, *syn*-**9b**, and **10b** was obtained in a ratio of 1.7:6.3:1 (97% yield). Therefore, it can be concluded that higher reaction temperatures favor both the cyclization of intermediate **4** (X = Oalkyl) to the *syn*-configurated silylmethylcyclobutane over the *anti* product, and the formation of the silylcyclopentane product (cyclization according to pathway a). The same trend was observed in the cycloaddition of allyltriisopropylsilane (**2b**) and methyl methacrylate (**8b**). In this case the regioselectivity for the cyclization of the intermediate siliranium ion is reversed in favor of the cyclization leading to the corresponding cyclopentane derivative (path a). Reaction at 40 °C provided the silylcyclopentane **10d** and the two diastereomers of silylmethylcyclobutane **9d** in a ratio of 2:1. Also for this example a higher proportion of the *syn*-silylmethylcyclobutane isomer was obtained at a higher temperature.

Structural assignments of the silylmethylcyclobutanes **9** and the silylcyclopentanes **10** are based on the ^{13}C NMR data (Table 2). The signals for the C atom α to the silicon atom (αSi-CH) appear for the silylcyclopentanes **10** at roughly $\delta = 23$.

Table 2. Selected ^{13}C NMR data (100 MHz, $CDCl_3$, δ values) of the silylmethylcyclobutanes **9**, **12**, and **15** [a].

	anti		*syn*	
Cyclobutane	αSi-CH_2	βSi-CH	αSi-CH_2	βSi-CH
9a	16.0	34.3	20.3	36.3
9b	11.9	34.7	17.3	37.1
9c	14.9	37.6	16.2	42.6
9d	9.9	37.7	[b]	43.1
12	11.6	49.4	17.3	49.7
15	10.2; 13.3 [c]	31.4; 35.2 [c]	13.6 [d]	40.7 [d]

[a] Relevant ^{13}C NMR data of further products for comparison: **10a**: 22.9 (αSi-CH); **10b**: 22.4 (αSi-CH); **10c**: 23.3 (αSi-CH); **10d**: 23.5 (αSi-CH); acid of *anti*-**9c**: 14.7 (αSi-CH_2), 37.6 (βSi-CH); **14**: 12.6 (αSi-CH_2), 38.8 (βSi-CH). [b] No assignment possible because of overlap with the signal of the triisopropylsilyl group. [c] *anti,syn*-**15** (major isomer). [d] *syn,syn*-**15** (minor isomer).

The NMR signals of αSi-CH groups in this type of compound generally show up in the region of $\delta = 20-25$.[2, 3, 10] The ^{13}C NMR signals of the αSi-CH_2 groups in the silylmethylcyclobutanes described here are, as expected, significantly shifted to higher field, while the signal of the βSi-CH group appears in the normal region. As anticipated, the signals of the *anti*-silylmethylcyclobutanes are shifted towards higher field relative to their *syn* isomers, in which the silylmethyl group is on the same side of the four-membered ring as the methoxycarbonyl group. For an unambiguous confirmation of the relative configuration we required an X-ray analysis. In contrast to the triphenylsilylcyclopentanes, which crystallize very easily,[2] most of the silylmethylcyclobutanes described here were obtained as oils. However, saponification of the triphenylsilylmethylcyclobutanes **9c** (KOH, H_2O, reflux, 1 d, 92%) afforded the corresponding acids from which the major diastereoisomer exhibiting the *anti* orientation was easily crystallized. Single crystals of the acid of *anti*-**9c** were suitable for an X-ray crystal structure determination, and the four-membered ring with the *anti* configuration of the side chain was unequivocally confirmed (Fig. 1).[12] The racemic acid of *anti*-**9c** crystallized diastereospecifically; dimers formed by hydrogen bonding are composed exclusively of the two opposite enantiomers (Fig. 2). Comparison of the ^{13}C NMR data of the acid of *anti*-**9c** with those of the other silylmethylcyclobutane derivatives confirms the structural assignments made above (cf. Table 2).

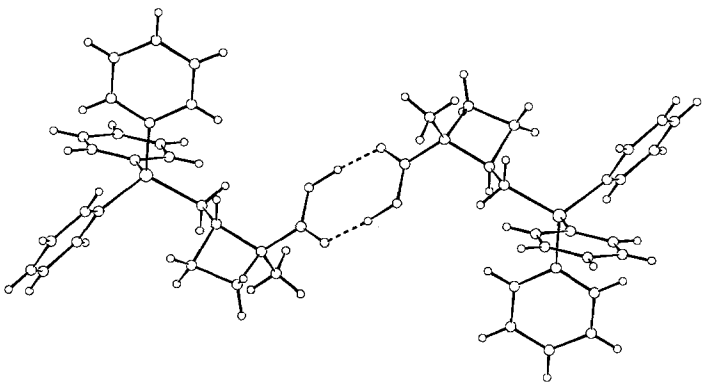

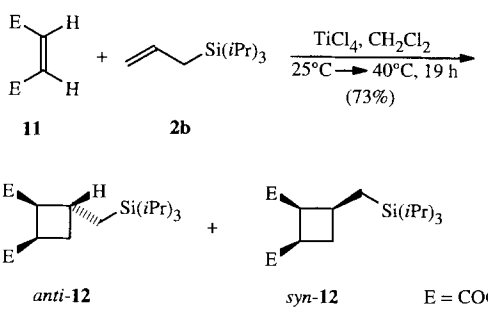

Fig. 2. Arrangement of the dimer formed by the acid of *anti*-**9c** in the crystal. Selected distances [Å] and angles [°]: O1-H1 1.16(6), O2-H1 1.47(6), O1-O2 2.619(3); O1-H1-O2 173(5).

Addition of allyltriisopropylsilane (**2b**) to the titanium tetrachloride complex of dimethyl maleate (**11**) at room temperature and subsequent reaction at 40 °C for 19 h afforded in 73% yield a mixture of the diastereomers *anti*-**12** and *syn*-**12** in a ratio of

4:1. In this case lower reaction temperatures favored the formation of the *syn* diastereomer (25 °C, 5 d, 61% yield; *anti*-**12**/*syn*-**12** = 1:1.3). Structural assignments were again based on the ^{13}C chemical shift of the CH_2 group α to silicon, which is significantly shifted downfield for the *syn* diastereomer (Table 2).

We recently described a remarkable extension of the [3+2] cycloaddition methodology of allylsilanes—the direct synthesis of bicyclo[3.3.0]octanes by the domino [3+2] cycloaddition of allylsilanes and 3-butyn-2-one.[13] This process generates four C–C σ-bonds in a one-pot reaction. Thus we expected that direct access to the bicyclo[2.2.0]hexane framework should be feasible by a domino [2+2] cycloaddition of allyltriisopropylsilane (**2b**) and propynoic ester **13**. In this reaction the two four-membered rings would be formed sequentially, the first by a [2+2] cycloaddition of **2b** to the Lewis acid complex of **13**, and the second by a [2+2] cycloaddition to the Lewis acid complex of the intermediate cyclobutenecarboxylic acid ester formed in the first step.

Addition of three equivalents of allyltriisopropylsilane (**2b**) to the titanium tetrachloride complex of methyl propynoate (**13**) at −78 °C and subsequent reaction at −20 °C for 19 h selectively provided the cyclobutene **14** in 98% yield (Table 3). After reac-

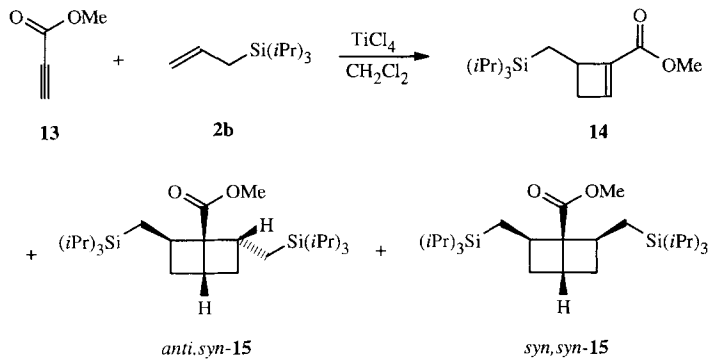

Table 3. Cycloaddition of allylsilane **2b** and methyl propynoate (**13**).

Reaction conditions	**14**, Yield [%]	**15**, Yield [%]
3 equiv **2b**, −78 °C → −20 °C, 19 h	98	–
4 equiv **2b**, −78 °C → 25 °C, 5 d	45	46 [a]
3 equiv **2b**, 25 °C → 40 °C, 19 h	34	64 [a]

[a] *anti,syn*-**15**: *syn,syn*-**15** = 3:1. Traces of the Sakurai product and a cyclopentane derivative were also detected.

tion at room temperature for five days, **14** and the bicyclo[2.2.0]hexane **15**, the product of the domino reaction, were formed in approximately equal amounts. Cycloaddition of **2b** with **13** in dichloromethane at reflux for 19 h provided **15** and **14** in yields of 64% and 34%, respectively. Bicyclo[2.2.0]hexane **15** was obtained as a mixture of the *anti,syn* and the *syn,syn* diastereomers in a 3:1 ratio. The two diastereomers are easily distinguished by their ^{13}C NMR spectra. The major isomer *anti,syn*-**15** shows two signals for the αSi-CH_2 groups, one *anti* to the methoxycarbonyl group at $\delta = 10.2$ and one *syn* at $\delta = 13.3$. The minor isomer *syn,syn*-**15** is symmetrical and therefore exhibits only one signal for the αSi-CH_2 group in the region typical for the *syn* diastereoisomer ($\delta = 13.6$). Thus, this product was assigned the *syn,syn* configuration with both silylmethyl groups on the same side as the methoxycarbonyl group.

Experimental Procedure

15: A solution of methyl propynoate (**13**) (337 μL, 339 mg, 4.03 mmol) in dry dichloromethane (5 mL) was added to a stirred solution of titanium tetrachloride (490 μL, 840 mg, 4.43 mmol) in dry dichloromethane (5 mL) at room temperature. To this mixture was added a solution of allyltriisopropylsilane (**2b**) (2.92 mL, 2.40 g, 12.08 mmol) in dry dichloromethane (5 mL). The reaction mixture was refluxed for 19 h and then quenched by addition of an aqueous solution of ammonium chloride. The organic layer was separated, the aqueous layer was extracted three times with dichloromethane, and the combined organic layers were dried over magnesium sulfate. Evaporation of the solvent and flash chromatography (hexane/ether 15:1) of the residue on silica gel provided the bicyclo[2.2.0]hexane **15** (1.24 g, 64%) and the cyclobutene **14** (387 mg, 34%) both as colorless oils.

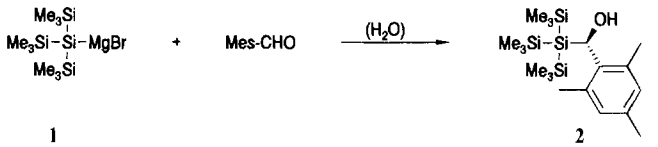
The Formation and an Unusual Dimerization of 2-Mesityl-1,1-bis(trimethylsilyl)silene**



Clemens Krempner, Helmut Reinke, and Hartmut Oehme*

The reaction of tris(trimethylsilyl)silylmagnesium bromide **1** with aldehydes and ketones makes accessible 1-hydroxyalkyltris(trimethylsilyl)silanes, which have proven useful as precursors for the synthesis of silenes by a modified Peterson mechanism. Recently we have reported the formation of 2-*tert*-butyl-1,1-bis(trimethylsilyl)silene by the base-initiated elimination of trimethylsilanolate from 2,2-dimethyl-1-tris(trimethylsilyl)silylpropanol and its head-to-head cyclodimerization to the corresponding 1,2-disilacyclobutane.[1]

The reaction of 2,4,6-trimethylbenzaldehyde and **1**, which is prepared from $(Me_3Si)_3SiLi \cdot 3THF$[2] and magnesium bromide in ether and is used in situ, yields mesityltris(trimethylsilyl)silylmethanol **2**. The identity of **2** has been established by spectroscopic and mass spectrometric means.

1 2

If strong bases are added to **2**, trimethylsilanolate is eliminated which, after aqueous workup, can be identified by gas chromatography as hexamethyldisiloxane. The result of this reaction is strongly dependent on the base used for deprotonation, the solvent employed, and the reaction conditions. For example, the deprotonation of **2** with methyllithium in ether at $-78\,^{\circ}C$ leads to a colorless, crystalline, air-stable compound, which was identified by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy, mass spectrometry, and an X-ray crystal structure analysis as (*E*)-1,2,3,8a-tetrahydro-1-mesityl-5,7,8a-trimethyl-2,2,3,3-tetrakis(trimethylsilyl)-2,3-disilanaphthalene **4** (see Scheme 1, Fig. 1).[3] The crystal

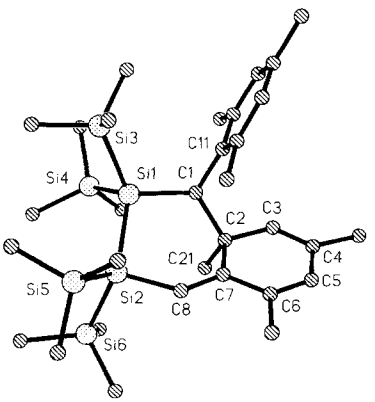
structure analysis yielded an interesting boat conformation for the disilacyclohexene fragment, in which the plane defined by Si1, Si2, and C8 is tilted by 16.8° and the plane defined by C1, C2, and C7 by 43.6° with respect to the plane defined by Si1, C1, C7, and C8.

We interpret the formation of **4** as the result of a head-to-head cyclodimerization of the unstable silaethene (silene) **3**, which undergoes an unusual [2+4] reaction in which the silene acts as



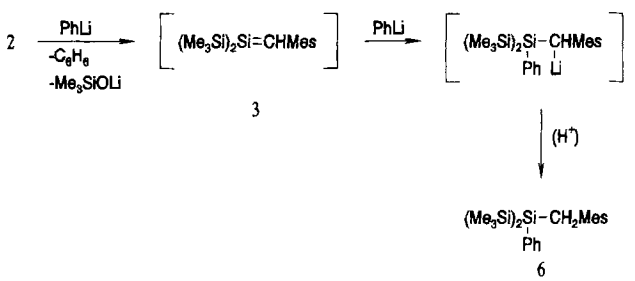


Fig. 1. Structure of **4** in the crystal (H atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: Si1-Si2 236.9(1), Si1-Si3 237.6(1), Si1-Si4 238.4(1), Si2-Si5 237.1(1), Si2-Si6 238.0(1), Si1-C1 195.6(2), C1-C2 159.0(2), C2-C3 150.7(3), C2-C21 154.9(2), C2-C7 154.6(3), C7-C8 134.8(3), C8-Si2 187.3(2); Si1-Si2-C8 101.18(7), Si2-Si1-C1 104.01(6), Si1-C1-C2118.52(12), C1-C2-C3 118.84(14), C2-C7-C8 122.46(16), C7-C8-Si2 131.82(15), C21-C2-C7 105.03(15), Si3-Si1-Si4 101.62(4), Si5-Si2-Si6 104.68(4).

the monoene as well as by utilizing the aromatic substituent the diene (see Scheme 1). The groups of Brook[4] and Ishikawa[5] have identified radical intermediates for the dimerization of similar silenes. Based on these results we assume an initial Si–Si linkage and the formation of a diradical, which then stabilizes and yields **4**. The current results do not allow the exclusion of an alternative mechanism, namely the addition of the lithium silanide **5** to the Si=C bond of silene **3** and subsequent ring formation in the sense of a nucleophilic substitution of the trimethylsiloxy unit. The intermediate formation of the silene **3** can be proven by the reactions of **2** with an excess of organolithium compounds, which yield the corresponding 2-alkyl- or 2-aryltrisilanes. For instance, the reaction of **2** with an excess of phenyllithium leads to 1,1,1,3,3,3-hexamethyl-2-(2,4,6-trimethylphenylmethyl)-2-phenyltrisilane **6** in 92% yield. The nucleophilic addition of phenyllithium to **3** leads to an organolithium intermediate, which is transformed into **6** by the aqueous workup.

The dimerization behavior of **3** is unusual insofar as, in the absence of scavenger reagents, sterically encumbered unstable silenes usually dimerize in a head-to-head fashion, yielding 1,2-disilacyclobutanes.[6] Silene **3** is therefore also fundamentally different from the 2-mesityl-2-trimethylsiloxy-1,1-bis(trimethylsilyl)silene prepared by Brook and co-workers.[7] This compound is stable in solution for extended periods and reacts under photolysis conditions to yield a substituted dihydrobenzocyclobutene. A [2+4] reaction similar to the synthesis of **4** has been discussed by Fink et al. for the dimerization of 1-mesityl-2,3,4-tri-*tert*-butyl-1-silacyclobutadiene.[8]

The initially unexpected [2+4] reaction of **3** becomes more obvious when one considers the steric demands of the mesityl group and the weak C–C bonds in the 1,2-disilacyclobutanes formed by the dimerization of sterically hindered silenes.[9] Silenes with allyl groups avoid the formation of four-membered rings and prefer a linear dimerization by a H transfer.[5, 10] For many silenes, for example 2-*tert*-butyl-1,1-bis(trimethylsilyl)silene,[1] there is apparently no alternative to the [2+2] cyclodimerization. For **3** the [2+4] addition is a viable pathway to avoid the steric hindrance stemming from the formation of a four-membered ring, while dimerization would lead to a 1,2-disilacyclobutane with a sterically congested C–C bond.

A completely different scenario is found for the reaction of **2** in THF. The addition of MeLi to a THF solution of **2** at −70 °C leads to a rapid 1,3-Si,O-trimethylsilyl migration, forming the lithium silanide **5**, which yields mesityltrimethylsiloxybis(trimethylsilyl)silylmethane (**7**) upon protonation (see Scheme 1). This transformation proceeds particularly smoothly, in THF as well as ether, when sodium hydride is used as base, yielding **7** quantitatively. Compound **5** and its sodium analogue are apparently unable to form a silene in THF; compound **4** could not be found in the reaction mixture.

If **2** is deprotonated with MeMgBr in THF 2,4-dimesityl-1,1,3,3-tetrakis(trimethylsilyl)-1,3-disilacyclobutane **8** is formed in addition to **7** (see Scheme 1). Dimer **8** can also be prepared by the in situ reaction of **1** and mesitylaldehyde in THF. The proposed structure is supported by NMR and mass spectrometry data and an X-ray crystal structure analysis, which showed the presence of a slightly bent four-membered ring (see Fig. 2).[11]

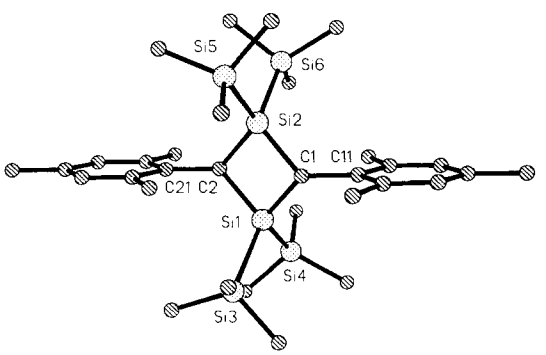

Fig. 2. Structure of **8** in the crystal (H atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: Si1-C1 194.3(4), Si1-C2 194.3(4), Si1-Si3 239.2(2), Si1-Si4 237.7(2), Si2-C1 194.1(3), Si2-C2 194.5(4), Si2-Si5 238.3(2), Si2-Si6 238.1(2), C1-C11 151.6(5), C2-C21 151.1(5); C2-Si1-C1 90.11(15), C2-Si2-C1 90.10(15), Si1-C1-Si2 89.91(15), Si1-C2-Si2 89.79(15).

The two planes each containing the Si atoms and one C atom of the ring intersect at an angle of 3°. This four-membered ring structure leads to a relatively short distance between Si1 and Si2 (274.4 pm).

The cyclobutane **8** is formally the head-to-tail cyclodimerization product of the silene **3**. Apparently the change of solvent for the deprotonation of **2** from ether to THF also leads to a fundamental change in the course of the reaction. The formation of **4** from **2** and MeLi in ether is likely to proceed through an intermediate silene. As will be reported elsewhere, this intermediate leads to the expected products upon reaction with 2,3-dimethylbutadiene and nucleophiles. On the other hand, we assume that **8** is the result of an intermolecular elimination of trimethylsilanolate from a magnesium silanide similar to **5**. Bimolecular reactions of this type have been identified in similar cases.[12]

Experimental Procedure

2: Within 30 minutes a solution of 2.37 g (0.016 mol) of 2,4,6-trimethylbenzaldehyde in 30 mL of ether was added dropwise, at −70 °C, to a solution of **1**, prepared from 7.3 g (0.016 mol) of $(Me_3Si)_3SiLi \cdot 3THF$ and an equimolar amount of $MgBr_2$ in 80 mL of ether. The mixture was stirred for 3 h at −70 °C and subsequently subjected to an aqueous workup. After solvent removal, volatile impurities were removed from the crude product by vacuum sublimation. The residue was recrystallized twice from acetonitrile. Yield 4.06 g (66%); m.p. 119–120 °C; IR (Nujol mull): $\tilde{\nu}_{OH} = 3507.2\ cm^{-1}$; ^1H NMR (250 MHz, [D$_6$]acetone): $\delta = 0.12$ (s, $SiCH_3$, 27H), 2.17 (s, Ar-*p*-CH_3), 3H), 2.35 (br s, Ar-*o*-CH_3, 6H), 3.72 (d, $^3J = 4.1$ Hz, OCH, 1H), 5.64 (d, $^3J = 4.4$ Hz, COH, 1H), 6.75 (br s, ArH, 2H); ^{13}C NMR (62.9 MHz, [D$_6$]acetone): $\delta = 2.13$ ($SiCH_3$), 20.76 (Ar-*p*-CH_3), 21.53, 23.44 (Ar-*o*-CH_3), 62.75 (COH), 129.34, 131.02, 133.45, 135.61, 137.89, 140.99 (aromatic C); ^{29}Si NMR (59.6 MHz, $CDCl_3$): $\delta = -11.94$ ($SiCH_3$), −71.26 (*Si*($SiMe_3$)$_3$); MS (CI, isobutane): *m/z* (%): 397 (1.5) [$M^+ - 1$], 379 (100) [$M^+ - OH$], 307 (7) [$M^+ - Me_3SiOH$].

4: To a solution of 0.5 g (1.26 mmol) of **2** in 20 mL of ether at −78 °C was added an equimolar amount of MeLi (1.6 M). The mixture was stirred at −78 °C for 1 h and subsequently allowed to warm to room temperature over a period of 2 h. After hydrolytic workup and solvent removal, a residue was obtained that was recrystallized twice from acetone. Yield 0.27 g (70%); m.p. 152–154 °C; ^1H NMR ([D$_6$]benzene): $\delta = 0.07$ (s, $SiCH_3$, 9H), 0.52, 0.52, 0.55 (3s, $SiCH_3$, 27H), 1.49, 1.56, 2.06, 2.16, 2.34, 2.47 (6s, CH_3, 6 × 3H), 3.87 (s, Si*CH*Mes, 1H), 5.14, 5.65, 6.37 (3s, olefinic H, 3 × 1H), 6.76, 6.82 (2s, aromatic H, 2 × 1H); ^{13}C NMR ([D$_6$]benzene, DEPT, C,H-COSY): $\delta = 1.93$, 2.33, 2.56, 3.04 ($SiCH_3$), 20.67, 21.09, 21.14, 23.14, 26.02, 37.94 (CCH_3), 37.53 (SiCHMes), 45.21 (8a-C), 119.61, 125.31, 136.15 (olefinic CH), 129.36, 130.92 (aromatic CH), 125.46, 133.14, 134.18, 135.51, 137.43, 141.63, 160.93 (quarternary, olefinic, and aromatic C); ^{29}Si NMR ([D$_6$]benzene): $\delta = -94.70$, −87.10 (*Si*$SiMe_3$), −12.44, −11.83, −11.26, −10.22 ($SiMe_3$); MS (70 eV): *m/z* (%): 612 (7) [M^+], 597 (4) [$M^+ - CH_3$], 539 (14) [$M^+ - SiMe_3$], 348 (100) {[$Me_3Si]_2Si)_2$}$^+$.

6: A solution of 0.5 g (1.26 mmol) of **2** in 20 mL of ether was added dropwise to a five-fold molar excess of PhLi in 10 mL of ether at room temperature. After 4 h of stirring the solution was worked up hydrolytically. Compound **6** was obtained from the organic phase by Kugelrohr distillation (0.1 Torr, 175 °C). Yield 0.45 g (92%); m.p. 76 °C; ^1H NMR ($CDCl_3$): $\delta = 0.02$ (s, $SiCH_3$, 18H), 2.02 (s, Ar-*o*-CH_3, 6H), 2.18 (s, Ar-*p*-CH_3, 3H), 2.49 (s, $SiCH_2$, 2H), 6.70 (s, Mes-H, 2H), 7.20–7.24, 7.37–7.41 (2m, Ph-H, 5H); ^{13}C NMR ($CDCl_3$, DEPT): $\delta = -0.18$ ($SiCH_3$), 13.75 ($SiCH_2$), 20.70 (Ar-*p*-Me), 21.56 (Ar-*o*-Me), 127.72, 127.80, 128.63, 135.04 (aromatic CH), 133.24, 134.78, 135.88, 138.58 (aromatic C); ^{29}Si NMR ($CDCl_3$): $\delta = -42.56$ (Ph-Si), −15.38 ($SiMe_3$); MS (70 eV): *m/z* (%): 383 (8) [$M^+ - H$], 369 (10) [$M^+ - CH_3$], 307 (100) [$M^+ - Ph$].

7: To a solution of 0.5 g (1.26 mmol) of **2** in 25 mL of THF were added 0.06 g (2.5 mmol) of NaH, and the mixture was stirred for 1 h at room temperature. After aqueous workup and solvent removal, an oil was obtained that was purified by Kugelrohr distillation (0.1 Torr, 140 °C). Yield 0.47 g (93%); IR (capillary): $\tilde{\nu}_{SiH} = 2043.4$, 2088.4 cm^{-1}; ^1H NMR ([D$_6$]benzene): $\delta = 0.01$, 0.11, 0.26 (3s, $SiCH_3$, 3 × 9H), 2.10 (s, Ar-*p*-CH_3, 3H), 2.25 (s, Ar-*o*-CH_3, 3H), 2.69 (s, *o*-CH_3, 3H), 3.97 (d, $^3J = 5.43$ Hz, SiH, 1H), 5.55 (d, $^3J = 5.9$ Hz, CH, 1H), 6.67, 6.78 (2s, aromatic H, 2H); ^{13}C NMR ([D$_6$]benzene, DEPT): $\delta = 0.94$, 1.22, 1.33 ($SiCH_3$), 21.54, 21.76, 22.85 (Ar-CH_3), 63.83 (CHOSi), 129.80, 132.03 (aromatic CH), 132.75, 136.26, 138.90, 139.60 (aromatic C); ^{29}Si NMR ([D$_6$]benzene): $\delta = -58.4$ (SiH, $J_{SiH} = 162.8$ Hz), −14.61, −15.33 (Si*Si*Me_3), 17.09 ($OSiMe_3$); MS (CI, isobutane): *m/z* (%): 395 (0.2) [$M^+ - 1$], 381 (0.6) [$M^+ - CH_3$], 307 (4) [$M^+ - OSiMe_3$], 221 (100) [$Me_3SiOCHMes^+$].

8: To a solution of 0.5 g (1.26 mmol) of **2** in 10 mL of THF at 0 °C was added an equimolar amount of methylmagnesium bromide (prepared from MeLi and $MgBr_2$). The mixture was stirred for 5 h while cooling on ice and subsequently subjected to an aqueous workup. After solvent removal an oil was obtained that was dissolved in acetone. Cyclobutane **8** slowly crystallized from this solution and was recrystallized once from acetone. Yield 0.053 g (14%); m.p. 240–241 °C; ^1H NMR ($CDCl_3$): $\delta = 0.07$ (s, $SiCH_3$, 36H), 2.18 (s, Ar-*p*-CH_3, 6H), 2.45 (s, Ar-*o*-CH_3, 12H), 3.87 (s, ring CH, 2H), 6.70 (s, Ar-H, 4H); ^{13}C NMR ($CDCl_3$, DEPT): $\delta = 0.68$ ($SiCH_3$), 14.91 (Ar-*p*-CH_3), 20.59 (ring C), 24.25 (Ar-*o*-CH_3), 128.74 (Ar-*o*-*C*), 132.29, 134.46, 136.09 (Ar-*ipso*-*C*, Ar-*m*-*C*, Ar-*p*-*C*); ^{29}Si NMR ($CDCl_3$): $\delta = -12.25$ (Si*Si*Me_3), −6.10 (*Si*$SiMe_3$); MS (CI, isobutane): *m/z* (%): 613 (60) [$M^+ - H$], 612 (28) [M^+], 597 (8) [$M^+ - CH_3$], 539 (72) [$M^+ - SiMe_3$], 493 (100) [$M^+ - Mes$].

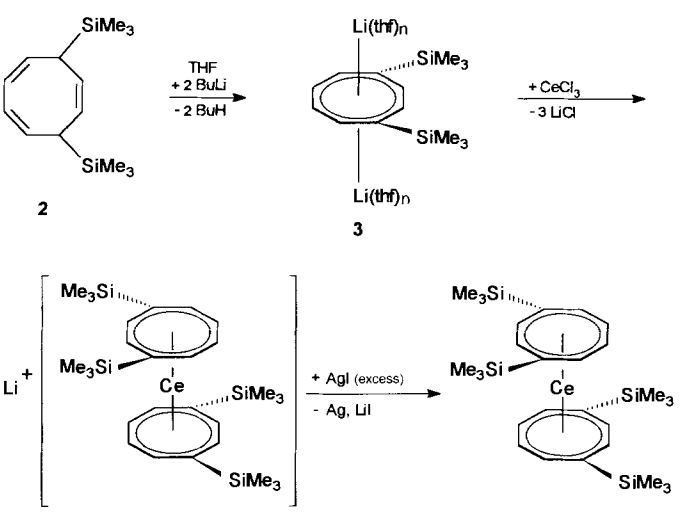
An Efficient Access to Organocerium(IV) Complexes: Synthesis and Structure of Bis[1,3,6-tris(trimethylsilyl)cyclooctatetraene]cerium(IV)**

Ulrike Kilimann, Regine Herbst-Irmer, Dietmar Stalke, and Frank T. Edelmann*



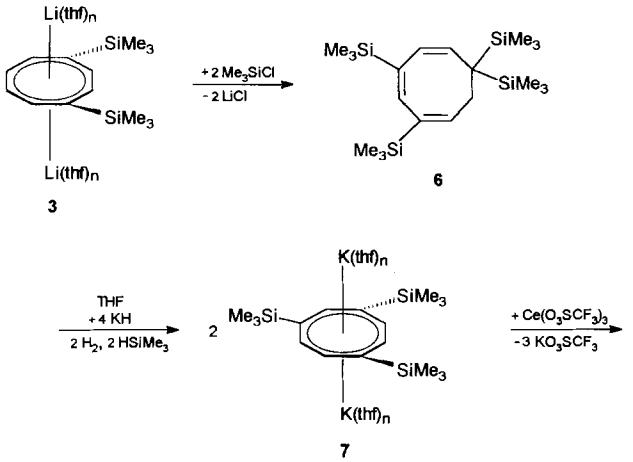
Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

The synthesis of stable organometallic compounds containing tetravalent cerium is one of the challenges in the field of preparative organo-f-element chemistry.[1] The main reason why numerous attempts at the synthesis of organocerium(IV) complexes have failed is the strong oxidizing effect of the cerium(IV) ion (E^0 for Ce^{3+}/Ce^{4+} in HCl: +1.28 V; in 8 M $HClO_4$: +1.87 V[2]). Thus, in reactions with organometallic reagents such as NaC_5H_5, the cerium(IV) reagents $(NH_4)_2[Ce(NO_3)_6]$ or $[pyH]_2[CeCl_6]$ (pyH = pyridinium cation) are reduced without exception to cerium(III) products. A series of complexes of the type $[(C_5H_5)_3CeX]$ and $[(C_9H_7)_2CeX_2]$ (X = H, BH_4, Cl, N_3, CN, NCO, NO_2, NO_3, OR, O_2CR, SR, NH_2, alkyl, aryl) described in the 1970s[3–6] were all found to have been wrongly characterized.[1] Also, for "$[(C_5H_5)_4Ce]$"[3] it was demonstrated that this compound was in fact $[(C_5H_5)_3Ce(thf)]$.[7] Bis(cyclooctatetraene)cerium(IV) (**1**), also known as bis([8]annulene)-cerium(IV) or "cerocene", which is of considerable theoretical interest,[8, 9] and its 1,1′-dimethyl derivative $[Ce(C_8H_7Me)_2]$[10] are among the few fully characterized organocerium(IV) complexes. Complex **1** was discovered in 1976 by Cesca et al.;[11] however, because of its pyrophoric nature and its poor solubility in organic solvents, unsubstituted **1** is not very attractive for reactivity studies. We describe here an efficient entry to soluble bis(cyclooctatetraene)cerium(IV) complexes, which for the first time allows an extensive study of this interesting class of compounds.

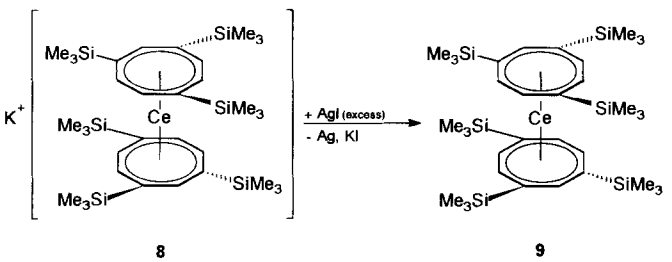
$[Ce(\eta^8\text{-}C_8H_8)_2]$ **1**

For the reasons mentioned above the controlled oxidation of cerium(III) precursors appeared to be a more suitable route for the synthesis of new cerium(IV) complexes than starting from $(NH_4)_2[Ce(NO_3)_6]$ or $[pyH]_2[CeCl_6]$. In our synthesis concept substituted cyclooctatetraene ligands should sterically shield the cerium atom and thus protect it from decomposition reactions. As in many cyclopentadienyl complexes, for example those with 1,3-bis(trimethylsilyl)cyclopentadienyl ligands,[12, 13] bulky trimethylsilyl substituents should be particularly suitable for this purpose.

Following a suggestion by Cloke et al.,[14] initially the dianion of 1,4-bis(trimethylsilyl)cyclooctatetraene was prepared. Its lithium salt **3** is readily accessible by metalation of 1,4-bis(trimethylsilyl)cyclooctatriene (**2**) with *n*-butyllithium.[13] The starting material **2** can be obtained in a one-pot reaction from 1,5-cyclooctadiene.[15] The reaction of **3** with anhydrous cerium trichloride in a molar ratio of 2:1 leads to the bright green anionic sandwich complex **4**, which because of its extreme sensitivity to oxidation was not isolated but immediately converted to the neutral cerium(IV) derivative. The desired oxidation to yield **5** occurs smoothly and under mild conditions with



an excess of silver iodide as oxidizing agent. Bis[1,4-bis-(trimethylsilyl)cyclooctatetraene]cerium(IV) (**5**) is the first readily accessible derivative of **1**, which is sufficiently soluble to allow reactivity studies. Spectroscopically pure, diamagnetic **5** is obtained as a deep purple oil, which thermally decomposes only above 226 °C. In contrast to the pyrophoric parent compound **1**,[11] compound **5** can be handled in air for short periods of time. In the EI mass spectrum the molecular ion appears as the highest mass peak with 6% relative intensity.



The synthesis of a crystalline derivative of **1** was achieved by using the new sterically demanding ligand 1,3,6-$(Me_3Si)_3C_8H_5^{2-}$. Compound **3** prepared in situ reacted with two

equivalents of chlorotrimethylsilane in Et_2O/THF selectively to give 1,3,6,6-tetrakis(trimethylsilyl)cyclooctatriene (**6**),[15] which can be isolated as colorless, sublimable needles in 52% yield. The substitution pattern of **6** is confirmed unequivocally by the NMR data. The presence of two trimethylsilyl groups on one carbon atom of the cycle initially made the desired derivatization to give the substituted cyclooctatetraene dianion appear impossible (1,2,4,4-tetrakis(trimethylsilyl)cyclopentadiene cannot be metalated at the cyclopentadiene ring[16]).

Indeed, **6** proved to be completely inert towards *n*-butyllithium. Surprisingly, the metalation was achieved with potassium hydride; however, a notable reaction was only observed in boiling THF. In addition to the expected deprotonation, a trimethylsilyl group is eliminated in the form of trimethylsilane. This leads to the dipotassium salt of the 1,3,6-*tris*(trimethylsilyl)cyclooctatetraene dianion **7** (37%). The latter is isolated as a colorless, microcrystalline powder of the composition $[K_2(thf)_3][C_8H_5(SiMe_3)_3]$ and spectroscopically characterized. Subsequent reaction with cerium triflate (molar ratio 2:1) led to the extremely air-sensitive dark green anionic complex **8**, which was oxidized in situ with silver iodide to give bis[1,3,6-tris(trimethylsilyl)cyclooctatetraene]cerium(IV) (**9**). This forms permanganate-colored crystals with a low melting point (m.p. = 38 °C), which are stable in air for a short period of time and very soluble in nonpolar solvents such as pentane, hexane, or toluene. Complex **9** can be vaporized without decomposition; in the EI mass spectrum it exhibits the molecular peak with 14% relative intensity.

Deep purple single crystals of **9** were obtained from acetonitrile. The single-crystal X-ray structure analysis[17] confirms the presence of a neutral cerium(IV) complex (Fig. 1). The two annulene rings are η^8-coordinated to the cerium atom. The Ce1–C distances range from 267.0 to 275.1 pm and are comparable with those of related complexes.[10] The two C_8 rings in **9** are not coplanar. The ring centroid-Ce-ring centroid angle is

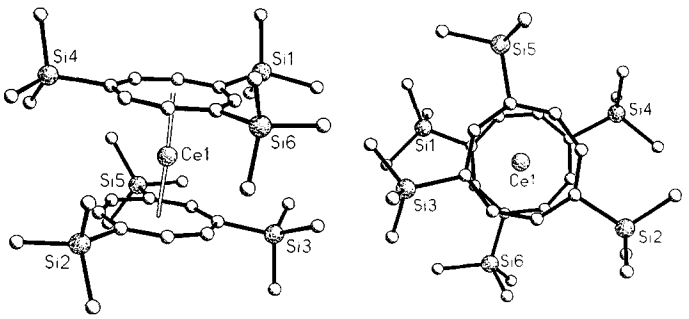

Fig. 1. Side view (left) and top view (right) of **9**; mean bond lengths [pm] and bond angles [°]: Ce1–C (mean) 270.4(7) (267.0(6)–275.1(7)), Ce1–ring centroid 197.6(6) and 197.7(6); ring centroid-Ce1-ring centroid 176.1(3).

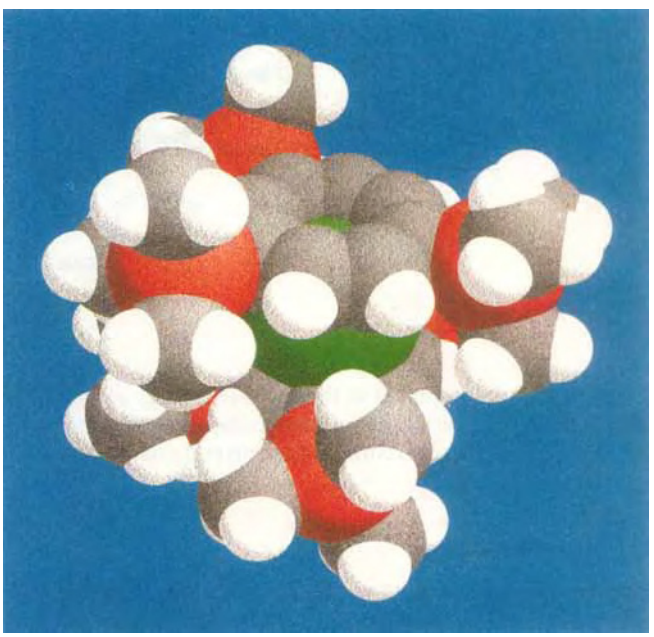
176.1° and is thus almost identical with the corresponding value in the anionic Yb^{II} derivative $[Yb(C_8H_8)_2]^{2-}$ (177°).[18] The nonlinear coordination of the metal atom in **9** is probably due to steric reasons. The more open side of **9** is the one at which the Me_3Si groups of Si1 and Si3 (Fig. 1 right) are closest to each other (521.4 pm). In comparison, for example, the Si2···Si4 distance on the closed side is 30 pm longer. All other Si···Si distances range from 570 to 590 pm.

The high solubility of **9** can be attributed to the Me_3Si groups, which interlock like a set of cog wheels (Fig. 2) and surround the metal atom with an organic shell.



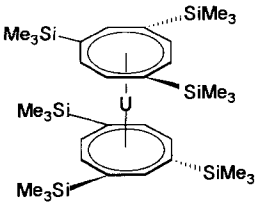


Fig. 2. Space-filling model of **9**.

In order to determine the rotation barrier in sandwich complexes with the 1,3,6-$(Me_3Si)_3C_8H_5^{2-}$ ligand, the uranium complex **10**, analogous to **9**, was synthesized and its variable-temperature ^1H NMR spectra were analyzed. Dark green **10** is readily obtained from the reaction of anhydrous uranium tetrachloride with two equivalents of **7**. This complex is also stable in air for a short period of time, whereas the unsubstituted parent compound $[U(C_8H_8)_2]$ is highly pyrophoric.[19] In the EI mass spectrum of **10** the molecular peak appears with 100% relative intensity. The energy barrier for the rotation of the two sub-

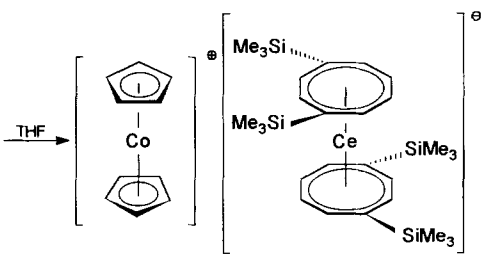
10



stituted cyclooctatetraene rings can be determined ($\Delta G^{\neq} = 18\ kJ\,mol^{-1}$) from the coalescence of the $SiMe_3$ signals in the temperature-dependent ^1H NMR spectrum of **10**.

This value seems surprisingly low when compared with the rotation barrier of $34.7\ kJ\,mol^{-1}$, which was determined by Streitwieser et al. for bis[1,4-bis(*tert*-butyl)cyclooctatetraene]-uranium.[20] Our explanation for this difference is that the substituted cyclooctatetraene ligands in **10** do not undergo a complete rotation but only oscillate. The same phenomenon was already detected by NMR spectroscopy by Okuda for 1,1′,2,2′,4,4′-hexakis(trimethylsilyl)ferrocene.[21, 22] The rotation barrier here is as high as that for 1,1′,3,3′-tetrakis-(trimethylsilyl)ferrocene ($11.0\ kJ\,mol^{-1}$), which contains only four silyl groups.

The ready availability of soluble cerium(IV) complexes opens up very promising perspectives for novel electron transfer reactions. The redox reaction of **5** with cobaltocene serves as a first example. This reduction leads to the saltlike Ce^{III} compound **11**, in which both the cation and the anion are sandwich complexes. The green cobaltocenium salt **11** can be characterized spectroscopically without any problems.

$$[\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2Ce] \;+\; [(C_5H_5)_2Co]$$

5

11

The further development of the redox chemistry of **5** and **9** as well as possible applications of these complexes as soluble oxidizing agents in organic synthesis are currently under investigation.

Experimental Procedure

Synthesis and characterization: All work was carried out under a purified N_2 atmosphere.

5: **2** (6.1 g, 24.4 mmol) [14] in THF (50 mL) was treated dropwise with *n*BuLi (48.8 mmol) at −30 °C. The mixture was allowed to warm to room temperature and stirred for 1 h. To the resulting brown solution was added a suspension of $CeCl_3$ (3.0 g, 12.2 mmol) [23] in THF (30 mL) at 0 °C. This led to a dark green solution which was again allowed to warm to room temperature, stirred for two days, filtered through a layer of Celite, and the filtrate was treated with AgI (5.6 g, 24.0 mmol). In addition to the formation of elemental Ag, the solution immediately turned deep purple. The reaction mixture was stirred for 12 h with exclusion of light, and evaporated. The residue was treated with hexane (50 mL), and carefully filtered. Removal of the solvent under vacuum afforded **5** (3.1 g, 40%) as a deep purple, oily product. Correct elemental analysis; m.p. 226 °C (decomp), ^1H NMR (250.1 MHz, C_6D_6): $\delta = 6.13$ (m, $^3J(H,H) = 7$ Hz, 2H, ring-H), 5.98 (m, 2H, ring-H), 5.92 (m, $^3J(H,H) = 11$ Hz, $^4J(H,H) = 3$ Hz, 2H, ring-H), 5.88 (m, $^3J(H,H) = 7$ Hz, 2H, ring-H), 5.83 (m, 2H, ring-H), 5.72 (m, $^3J(H,H) = 11$ Hz, $^4J(H,H) = 3$ Hz, 2H, ring-H), 0.08 (s, 18H, $SiMe_3$), 0.07 (s, 18H, $SiMe_3$); ^{29}Si NMR (49.7 MHz, [D$_8$]toluene): $\delta = -5.44$ (s), −5.43 (s); MS (EI): *m/z*: 636 ([M^+], 6%), 388 ([$Ce[C_8H_6(1,4\text{-}SiMe_3)_2^+]$], 52%), 249 ([$C_8H_6(1,4\text{-}SiMe_3)_2^+$], 4%), 73 ([$SiMe_3^+$], 100%); IR (KBr, pure substance): $\tilde{\nu}[cm^{-1}] = 1578$ m, 1310 m, 1249 vs, 1102 s, 1080 m, 1004 m, 975 m, 929 s, 880 s, 839 vs, 751 s, 715 m, 633 s, 565 m, 511 m, 447 m, 372 m.

6: *n*BuLi (239.6 mmol) was added dropwise to a solution of **2** (30 g, 119.8 mmol) [14] in THF (200 mL) at −30 °C. Subsequently the solution was allowed to warm to room temperature and stirred for a further 12 h. The resulting deep brown solution was added dropwise to a solution of Me_3SiCl (26.0 g, 239.6 mmol) in Et_2O (150 mL) at −10 °C. The mixture was allowed to react at −10 °C for 10 min, then for 12 h at room temperature, filtered carefully, and the filtrate was evaporated to dryness under vacuum. The crude product was treated with dry MeOH (250 mL) and filtered while hot to remove the insoluble material. Cooling to −20 °C afforded pale yellow, needlelike crystals of **6** (24.7 g, 52%), m.p. 87 °C, correct elemental analysis; ^1H NMR ($CDCl_3$, 400.1 MHz): $\delta = 6.15$ (ddd, $^3J(H,H) = 9$ Hz, $^4J(H,H) = 1$ Hz, $^4J(H,H) = 1$ Hz, 1H, ring-H), 5.51 (dd, $^3J(H,H) = 11$ Hz, $^3J(H,H) = 9$ Hz, 1H, ring-H), 5.43 (dd, $^3J(H,H) = 13$ Hz, $^4J(H,H) = 1$ Hz, 1H, ring-H), 5.22 (ddd, $^3J(H,H) = 11$ Hz, $^4J(H,H) = 1$ Hz, $^4J(H,H) = 1$ Hz, 1H, ring-H), 5.18 (ddd, $^3J(H,H) = 13$ Hz, $^4J(H,H) = 1$ Hz, $^5J(H,H) = 1$ Hz, 1H, ring-H), 4.27 (ddd, $^3J(H,H) = 9$ Hz, $^3J(H,H) = 9$ Hz, $^4J(H,H) = 1$ Hz, 1H, ring-H), 0.10 (s, 9H, $SiMe_3$), 0.04 (s, 9H, $SiMe_3$), 0.03 (s, 9H, $SiMe_3$), −0.03 (s, 9H, $SiMe_3$); ^{13}C NMR ($CDCl_3$): $\delta = 145.6$ (s, ring-C), 143.1 (t, $^1J(^{13}C,^{29}Si) = 66$ Hz, ring-C), 133.1 (s, ring-C), 131.0 (s, ring-C), 129.0 (s, ring-C), 126.2 (s, ring-C), 37.4 (t, $^1J(^{13}C,^{29}Si) = 43$ Hz, ring-C), 29.9 (t, $^1J(^{13}C,^{29}Si) = 53$ Hz, ring-C), −1.3 (t, $^1J(^{13}C,^{29}Si) = 52$ Hz, $SiMe_3C$), −1.4 (t, $^1J(^{13}C,^{29}Si) = 52$ Hz, $SiMe_3C$), −1.5 (t, $^1J(^{13}C,^{29}Si) = 52$ Hz, $SiMe_3C$), −3.1 (t, $^1J(^{13}C,^{29}Si) = 51$ Hz, $SiMe_3C$); ^{29}Si NMR ($CDCl_3$): $\delta = -5.3$ (s, $SiMe_3$), 2.0 (s, $SiMe_3$), 2.4 (s, $SiMe_3$), 2.6 (s, $SiMe_3$); MS (EI): *m/z*: 394 ([M^+], 34%), 321 ([$M-SiMe_3^+$], 60%), 233 ([$M-2SiMe_3CH_3^+$], 54%), 73 ([$SiMe_3^+$], 100%); IR (KBr, Nujol): $\tilde{\nu}[cm^{-1}] = 1578$ m, 1310 m, 1249 vs, 1102 s, 1080 s, 1004 m, 975 m, 929 s, 880 s, 839 vs, 751 s, 715 s, 686 s, 633 s, 565 m, 511 m, 447 m, 372 m.

7: **6** (2.5 g, 6.3 mmol) and KH (0.8 g, 20.0 mmol) were heated under reflux in THF (50 mL) for 2 days. Subsequently, excess KH was filtered off, the orange solution evaporated to dryness, and the residue taken up in hexane (40 mL) and stirred for for 3 h. The solid precipitate was separated and dried under vacuum. A white, microcrystalline powder **7** (1.57 g, 37%) was obtained. Correct elemental analysis; m.p. 247 °C (decomp); ^1H NMR (250.1 MHz, [D$_8$]THF): $\delta = 6.39$ (m, 1H, ring-H), 6.34 (m, 1H, ring-H), 6.30 (m, 1H, ring-H), 6.23 (m, 1H, ring-H), 6.18 (m, 1H, ring-H), 3.62 (m, 12H, THF), 1.79 (m, 12H, THF), 0.32 (s, 18H, $SiMe_3$), 0.27 (s, 9H, $SiMe_3$); ^{29}Si NMR ([D$_8$]THF): $\delta = -2.3$ (s), −3.2 (s, half intensity); MS (EI): *m/z*: 320 ([$C_8H_5(SiMe_3)_3^+$], 8%), 247 ([$C_8H_5(SiMe_3)_2^+$], 42%), 73 ([$SiMe_3^+$], 100%); IR (KBr, Nujol): $\tilde{\nu}[cm^{-1}] = 1734$ m, 1532 m, 1304, 1240 vs, 1216 m, 1081 vs, 1046 vs, 975 s, 924 m, 889 m, 870 s, 824 vs, 740 vs, 672 m, 633 m, 567 m, 511 m.

9: 7 (2.5 g, 3.6 mmol) in THF (50 mL) was treated with a suspension of $Ce(O_3SCF_3)_3$ (1.1 g, 1.8 mmol) [24] in THF (30 mL) at 0 °C and stirred. The solution turned bright green. Subsequently, the mixture was allowed to react for a further 12 h under reflux, then AgI (0.9 g, 3.8 mmol) was added at room temperature, which caused an immediate color change to purple. After stirring the mixture for 1 h with exclusion of light, the solvent was evaporated, the residue taken up in hexane (50 mL) and filtered. The filtrate was evaporated to dryness and the residue was treated with MeCN (50 mL). Crystallization at room temperature afforded **9** (0.5 g, 33%) as a microcrystalline, deep purple solid. Correct elemental analysis; m.p. 38 °C; ^1H NMR (250.1 MHz, C_6D_6): $\delta = 6.43$ (d, $^3J(H,H) = 12$ Hz, 4H, ring-H), 6.00 (d, $^3J(H,H) = 12$ Hz, 4H, ring-H), 5.61 (s, 2H, ring-H), 1.11 (s, 18 H, $SiMe_3$), 0.99 (s, 36H, $SiMe_3$); ^{29}Si NMR (C_6D_6): $\delta = -1.74$ (s), −3.09 (s, half intensity); MS (EI): *m/z*: 780 ([M^+], 14%), 708 ([$M-SiMe_3^+$], 2%), 460 ([$CeC_8H_5(SiMe_3)_3^+$], 100%), 386 ([$CeC_8H_5(SiMe_3)_2^+$], 8%), 73 ([$SiMe_3^+$], 38%).

10: UCl_4 (0.7 g, 1.8 mmol) [25] in THF (30 mL) was added to a solution of **7** (2.5 g, 3.6 mmol) in THF (50 mL) at 0 °C. The solution was then stirred for 3 h at room temperature, concentrated, treated with hexane (30 mL), and stirred for a further 12 h. Subsequently, the mixture was filtered while hot and concentrated to 10 mL. Cooling to −20 °C afforded green crystals of **10** (0.4 g, 28%). Correct elemental analysis; m.p. 110 °C (decomp); ^1H NMR (250.1 MHz, [D$_8$]THF): $\delta = 0.03$ (m, 10H, ring-H), −7.30 (br. s, 36H, $SiMe_3$), −9.10 (s, 18H, $SiMe_3$); ^{29}Si NMR ([D$_8$]THF): $\delta = -120.7$ (s); MS (EI): *m/z*: 878 ([M^+], 100%), 806 ([M^+-SiMe_3], 3%), 732 ([$M^+-2SiMe_3$], 5%), 558 ([$UC_8H_5(SiMe_3)_3^+$], 51%), 73 ([$SiMe_3^+$], 44%); IR (KBr, Nujol): $\tilde{\nu}[cm^{-1}] = 1260$ vs, 1249 s, 1090 vs, 1019 vs, 836 s, 801 vs, 747 m, 638 m.

11: **5** (2.0 g, 3.1 mmol) and Cp_2Co (0.6 g, 3.1 mmol) [26] were dissolved in THF (40 mL) and stirred for 3 h. The initially purple solution turned red-brown. The mixture was filtered over a thin layer of Celite and the filtrate was evaporated to dryness. The residue taken up in hexane (50 mL), and the green precipitate was isolated and dried. Compound **11** (0.2 g, 7%) was obtained as a pyrophoric, extremely air-sensitve solid. Correct elemental analysis; m.p. 142 °C (decomp); ^1H (250.1 MHz, [D$_8$]THF): $\delta = 6.21-5.79$ (m, 12H, ring-H), 1.30 (s, 5H, C_5H_5), 1.05 (s, 18H, $SiMe_3$), 0.90 (s, 5H, C_5H_5), 0.08 (s, 18H, $SiMe_3$); ^{29}Si NMR ([D$_8$]THF): $\delta = -2.4$ (s), −5.3 (s); MS (EI): *m/z*: 248 ([$C_8H_6(1,4\text{-}SiMe_3)_2^+$], 16%), 189 ([$Co(C_5H_5)^+_2$], 50%), 124 ([$Co(C_5H_5)^+$], 11%), 73 ([$SiMe_3^+$], 100%); IR (KBr, Nujol): $\tilde{\nu}[cm^{-1}] = 1413$ m, 1306 m, 1261 vs, 1248 m, 1092 vs, 1037 vs, 980 m, 937 m, 861 m, 836 s, 800 vs, 750 m, 688 m, 637 m, 436 m.

[17] Crystal data of **9**: $[(Me_3Si)_3C_8H_5]_2Ce$, $M = 781.51$, orthorhombic, space group $Pna2_1$, $a = 2232.2(4)$, $b = 1647.6(3)$, $c = 1132.3(2)$ pm, $V = 4.163(1)$ nm^3, $Z = 4$, $\rho_{calcd} = 1.247$ Mg m^{-3}, $F(000) = 1640$, $\lambda = 71.073$ pm, $T = -120$ °C, $\mu(Mo_{K\alpha}) = 1.286$ mm^{-1}, crystal dimensions: $0.6 \times 0.6 \times 0.4$ mm, $4° < 2\theta \leq 50°$; of 5491 measured reflections, 5084 were independent and 5080 were used for the refinement of 388 paramters; maximum residual electron density: 1572 e nm^{-3}, $R1(F > 4\sigma(F)) = 0.039$, $wR2 = 0.115$ (all data) with $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR2 = (\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2)^{0.5}$. The data were collected on a Stoe-Huber diffractometer. The intensity measurements were carried out on a rapidly cooled crystal in the oil drop [26] by the $2\theta/\omega$ method. Semiempirical absorption corrections were carried out on all data. The structure was solved by Patterson and Fourier methods (SHELXS-90) [27] and refined with the least squares method on F^2 [28]. The refinement of the inversion twin parameter [29] ($x = 0.00(2)$ for $x = 0$ for the correct absolute structure and $x = +1$ for the inverted structure) confirmed the absolute structure of **9**. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

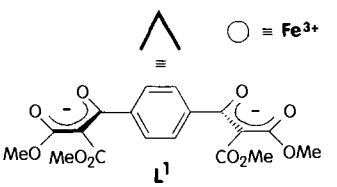
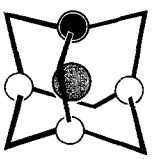
Mixed-Valence, Tetranuclear Iron Chelate Complexes as Endoreceptors: Charge Compensation Through Inclusion of Cations**

Rolf W. Saalfrank,* Roman Burak, Alexandra Breit, Dietmar Stalke, Regine Herbst-Irmer, Jörg Daub, Michael Porsch, Eckhard Bill, Markus Müther, and Alfred X. Trautwein



Dedicated to Professor Helmut Ringsdorf on the occasion of his 65th birthday

An essential prerequisite for the rapid development of endohedral chemistry, that is chemistry within cages, is easy access to host molecules of variable internal diameter.[2] In this context we have recently reported the tetranuclear adamantanoid Fe^{III} spacer-complex $[Fe_4L^1{}_6]$ **1**.[1] Complex **1** is endowed with a substantial cavity, which should, in principle, be suitable for the uptake of guest molecules. Our attempts to obtain the spacer-free metallospherand core unit $[Fe_4L^2_6]$ in analogous manner have thus far given rise to products which could not be characterized unambiguously.



In contrast, we have obtained for the first time, the tetranuclear, mixed-valence ammonium inclusion complexes $[NH_4 \subset Fe_4L^2_6]$ **2** and $[NH_4 \subset Fe_4L^3_6]$ **3** in a one-pot reaction.[3] Complexes **2** and **3** are formed by spontaneous self-assembly[1, 4–7] from the reaction of dialkyl malonates with methyllithium/iron(II) chloride and oxalyl chloride at −78 °C in tetrahydrofuran, followed by workup with aqueous ammonium

[**] "Adamantanoid" Chelate Complexes, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We thank Prof. Dr. F. Vögtle and Dr. S. Schuth, Universität Bonn, and Prof. Dr. K.-P. Zeller, Universität Tübingen for the measurement of the FAB mass spectra. Part 3: ref. [1].

chloride. The bis(bidentate), spacer-free bridging ligands L^2 and L^3 are formally obtained by coupling of two dialkyl malonate monoanions with oxalyl chloride to form H_2L^2 and H_2L^3, respectively, followed by double deprotonation.

The microanalytical data and FAB mass spectra of **2** and **3** gave the first indications that these products might constitute host–guest systems. The molecular- and fragment ion peaks of **2** and **3** are, in each case, 18 mass units greater, as expected for the inclusion of an ammonium ion.

For a definitive characterization of **2** and **3**, we have carried out crystal structure analyses on both complexes.[8] The results of these show that **2** and **3** are present in the crystal as neutral, tetranuclear, mixed-valence chelate complexes with an endohedrally complexed cation for charge compensation (Fig. 1). The

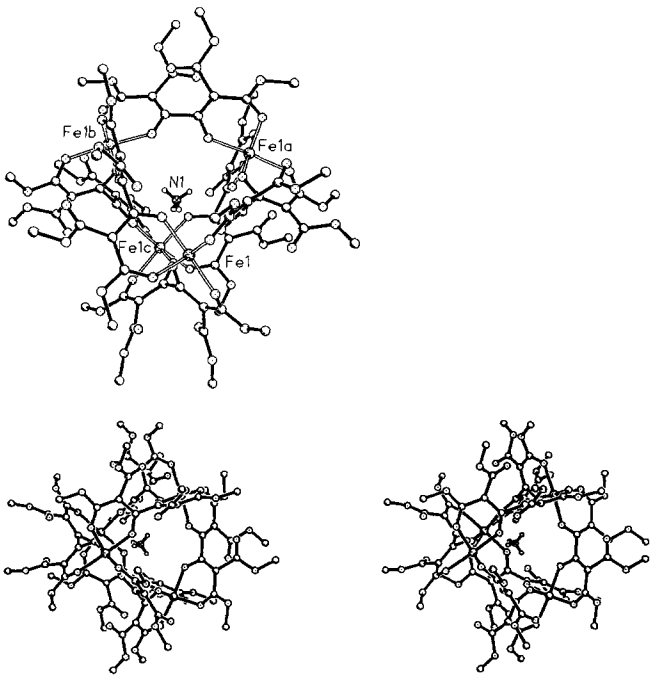

Fig. 1. Top: Structure of **2** in the crystal (view along the crystallographic C_3 axis: H atoms of the NH_4^+ ion plain, O atoms dotted, C atoms shaded). Bottom: Stereoview of **2** along the crystallographic C_3 axis. Water of crystallization is not depicted for reasons of clarity.

receptor nucleus of **2** and **3** consists in each case of a regular tetrahedron with corners defined by one Fe^{II} and three Fe^{III} ions. The six edges of the tetrahedron are each formed by the bis(bidentate), doubly negatively charged bridging ligands L^2 or L^3. Each of the four iron ions is octahedrally coordinated by six oxygen atoms.[13] In the center of the iron tetrahedron there is an ammonium ion which serves presumably as a template for the formation of **2** and **3**, thereby becoming enclosed during the construction of these systems.
