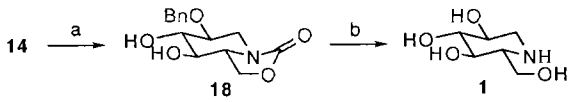
The primary silyl ether was deprotected by treatment of the cycloadduct **8** with hydrogen fluoride–pyridine (Scheme 3). Reprotection of the alcohol **9** as a methyl carbonate followed by reductive N–O bond scission led to the methyl carbamate **10** as a result of acyl migration. Formation of the crystalline cyclic carbamate **11** was promoted by stirring in toluene (bath temperature 120 °C) with sodium hydroxide and 4 Å molecular sieves. A variety of reagents was explored to effect elimination of the



Scheme 3. Formation and dehydration of the alcohol **11**. a) HF–pyridine, THF, ca. 20 °C (90%); b) MeOCOCl, NaH, THF, ca. 20 °C, then Zn, AcOH–EtOH–H_2O, 60 °C (99%); c) NaOH, 4 Å molecular sieves, toluene, 120 °C (bath temperature) (77%); d) $Ph_2S[OC(CF_3)_2Ph]_2$ (Martin sulfurane), CH_2Cl_2, ca. 20 °C (96%).

secondary alcohol **11** to an exocyclic alkene. All the common reagents showed disappointing yields and selectivities. However, the Martin sulfurane[10] was found to exhibit an exceptionally regio- and stereocontrolled elimination to provide the more substituted alkene **12**. The reaction is believed to follow an E_2 pathway, and proceeds by way of a charged leaving group.[10] Consequently, it is presumed that the selectivity arises from the kinetic acidity of the equatorial proton that is antiperiplanar to the electron-deficient C–N(C=O) bond of the piperidine ring.[19]

Oxidative cleavage of the alkene **12** was best achieved by ozonolysis followed by a reductive workup employing triphenylphosphane (Scheme 4). Reduction of the resulting ketone **13** with a variety of hydride reagents was complicated by 1,2-silyl migration in the alkoxide intermediate. For instance, reduction with sodium borohydride furnished a mixture of four alcohols **14**–**17** (22%, 15%, 36%, and 10%, respectively). A more stereoselective reduction was observed with sterically demanding sources of hydride. With L-Selectride only the axial isomers **16** (37%) and **17** (7%) were observed. A satisfactory route from the ketone to the equatorial alcohol **14** (45% yield) was achieved with DIBAL-H. However, ozonolysis of the alkene **13** followed by direct treatment of the ozonide with DIBAL-H at -78 °C afforded the alcohol **14** in a single step (43%). To our knowledge this is the first example of the reduction of an ozonide directly to an alcohol with DIBAL-H. Clearly, chelation of DIBAL-H to the α-siloxy group plays an important part in controlling this selectivity. Deprotection of the alcohol **14** in a three-stage sequence (Scheme 5) involving desilylation (to **18**), hydrogenolysis, and aqueous hydrolysis gave deoxynojirimycin (**1**), which was identical in all respects to an authentic sample.[2b, 20, 21]

Scheme 4. Ozonolysis of alkene **12** and hydride reduction. a) Ozone, CH_2Cl_2, -78 °C, then PPh_3, ca. 20 °C (66%); b) Reduction (see text).

Scheme 5. Synthesis of deoxynojirimycin (**1**). a) Tetrabutylammonium fluoride, THF, ca. 20 °C (62%); b) H_2, Pd/C, HCl, MeOH, ca. 20 °C, then KOH, MeOH – H_2O, reflux (43%).

In summary, a concise enantioselective synthesis of deoxynojirimycin has been achieved in twelve steps from achiral starting materials in which a (*Z*)-boron enolate of an Evans oxazolidinone was used to control both simple and induced diastereoselectivity.[22] The method lends itself to the stereocontrolled syntheses of potentially important biologically active molecules. Work is now underway to extend this methodology to the synthesis of other biologically interesting polyhydroxylated piperidines and indolizidines.

Experimental Procedure

Conversion of **12** into **14**: Ozone was bubbled through a stirred solution of the alkene **12** (21.8 mg, 0.041 mmol) in CH_2Cl_2 (20 mL) at −78 °C for 5 min. At this point saturation was evident by the blue color of the reaction mixture and by the dark brown color of potassium iodide solution receiving the exhaust gases from the reaction. Nitrogen was bubbled through the reaction for 10 min to flush out the excess ozone before the addition of DIBAL-H (1 M in dichloromethane, 0.4 mL, 0.4 mmol). After being stirred for 1 h at −78 °C, the reaction was quenched with methanol (2 mL) and allowed to warm to ca. 20 °C. The reaction mixture was poured into a vigorously stirred emulsion of ethyl acetate (100 mL), saturated aqueous ammonium chloride (50 mL), and saturated aqueous sodium potassium tartrate (50 mL). Stirring was continued for 1 h, at which point the two phases were separated and the aqueous phase extracted with ethyl acetate (50 mL). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated to dryness on a rotary evaporator. The residue was filtered through a short column of silica gel (eluting with 50% EtOAc/hexane) and purified by high-pressure liquid chromatography (eluting with 40% EtOAc/hexane) to give the alcohol **14** (9.2 mg, 43%) as a colorless gum; R_f 0.20 (30% EtOAc/hexane); (calcd for $C_{30}H_{35}NO_5Si$: C 69.6, H 6.8, N 2.7; found: C 69.3, H 7.0, N 2.6); $[\alpha]_D^{20} = -15.8$ ($c = 1.64$ in $CHCl_3$); IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 3580 w (OH), 1775 s (C=O); ^1H NMR (400 MHz, $CDCl_3$, 20 °C, TMS): $\delta = 1.01$ (s, 9H; $(CH_3)_3C$), 2.20 (d, $^3J = 2.6$ Hz, 1H; OH), 2.58 (dd, $^3J = 10.2$, 13.3 Hz, 1H; NCH*H*), 3.38 (ddd, $^3J = 3.8$, 7.8, 9.4 Hz, 1H; NCH), 3.46–3.53 (m, 2H; BnOC*H* and HOCH), 3.63 (t, $^3J = 8.7$ Hz, 1H; SiOCH), 4.08 (dd, $^3J = 5.6$, 13.3 Hz, 1H; NC*H*H), 4.18 (dd, $^3J = 3.8$, 9.1 Hz, 1H; NCHCH*H*), 4.23 (d, $^3J = 11.2$ Hz, 1H; PhCH*H*), 4.32 (dd, $^3J = 7.9$, 8.9 Hz, 1H; NCHC*H*H), 4.40 (d, $^3J = 11.2$ Hz, 1H; C*H*HPh), 6.99–7.01 (m, 2H; 2 of 3 × Ph), 7.24–7.27 (m, 3H; 3 of 3 × Ph), 7.31–7.46 (m, 6H; 6 of 3 × Ph), 7.62–7.71 (m, 4H; 4 of 3 × Ph); ^{13}C NMR (100.6 MHz, $CDCl_3$, 20 °C, TMS): $\delta = 19.6$ (s), 27.1 (q), 42.7 (t), 57.5 (d), 66.5 (t), 71.8 (t), 74.4 (d), 76.9 (d), 79.0 (d), 127.65 (d), 127.69 (d), 127.81 (d), 127.97 (d), 128.19 (d), 129.85 (d), 130.00 (d), 132.9 (s), 133.5 (s), 135.7 (d), 135.9 (d), 137.6 (s), 156.8 (s); MS (Chemical Ionization): *m/z* (%) 535 (22) [($M^+ + NH_4$)], 518 (32) [($M^+ + H$], 440 (86), [($M^+ - Ph$)], 108 (100) [($PhCH_2OH^+$)], 91 (75) [($PhCH_2^+$)]; ($M^+ + H$) calculated for $C_{30}H_{36}NO_5Si$ 518.2363; found 518.2364.

$[Mn_4Te_4(SC_3H_7)_4]^{4-}$ and $[Mn_4Te_4(SeC_3H_7)_4]^{4-}$: Novel Heterocubane Clusters of Manganese**

Hans-Oscar Stephan and Gerald Henkel*

Dedicated to Professor Wilhelm Preetz on the occasion of his 60th birthday

Sulfido(thiolato) transition metal complexes are biologically relevant as models for the active sites of metalloproteins such as ferredoxins and nitrogenases, and for this reason they have been the subject of investigation for some time now.

To date, the following compounds have been isolated with divalent metal ions: compounds with adamantane-type structures, for example $[Zn_{10}S_4(SPh)_{16}]^{4-}$ and $[Cd_{17}S_4(SPh)_{28}]^{2-}$; complexes of the formula $[M_3S(SR)_6]^{2-}$ with an incomplete mixed metal–sulfur cubane structure (M = Fe, Co) or an incomplete sulfur cubane structure (M = Ni); and the cobalt–sulfur complex $[Co_8S_6(SPh)_8]^{n-}$ ($n = 4$, 5) with a complete metal cubane structure.[1] With the exception of the Ni complexes, the metal centers in all these compounds—just as in the mixed-cubane clusters $[Fe_4S_4(SR)_4]^{n-}$ ($n = 1-3$)[2, 3] and in the $[Fe_6S_6(SR)_6]^{3-}$[4] clusters with a metal-deficient cubane structure—are tetrahedrally coordinated; however, the metals listed here have fractional oxidation numbers that lie between two and three.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, and the Fonds der Chemischen Industrie.

In spite of intensive research, it was not possible until now to isolate heterocubane clusters of the composition $[M_4X_4(SR)_4]^{4-}$ (X = S, Se, Te), in which the metal atoms are exclusively divalent—not even by the attempted replacement of the sulfide ions by selenide or telluride ions. We were recently able to show with the synthesis of $[Mn_4Te_4(Te\mathit{i}C_3H_7)_4]^{4-}$,[5] however, that the oxidation state + 2 can be stabilized in heterocubane clusters by a complete tellurium ligand environment. With compounds **1** and **2**, we have now succeeded in synthesizing and characterizing the first sulfur- and selenium-containing heterocubane clusters with divalent metal ions, and at the same time also the first chalcogenido(thiolato) and chalcogenido(selenolato)manganese complexes.

$[Mn_4Te_4(S\mathit{i}C_3H_7)_4]^{4-}$ **1** $[Mn_4Te_4(Se\mathit{i}C_3H_7)_4]^{4-}$ **2**

The reaction of mixtures of $\mathit{i}C_3H_7XNa$ (X = S, Se) and $MnBr_2$ (molar ratio 3:1) with $(SiMe_3)_2Te$ in acetonitrile leads to the formation of **1** or **2**, which can be isolated as **3** and **4**, respectively, after the addition of $[Et_4N]Br$.

$(Et_4N)_4[Mn_4Te_4(S\mathit{i}C_3H_7)_4]\cdot 2\,MeCN$ **3**

$(Et_4N)_4[Mn_4Te_4(Se\mathit{i}C_3H_7)_4]\cdot 1.5\,MeCN$ **4**

According to the results of the crystal structure analyses,[6] **1** and **2**[7] are discrete complex ions (Fig. 1). Their Mn_4Te_4 frameworks are constructed from Mn_4 and Te_4 tetrahedra which are intertwined in such a way that the corners of one tetrahedron lie above the centers of the faces of the other. Since the edges of these tetrahedra differ in length, distorted Mn_4Te_4 cubes are formed with idealized T_d symmetry. The average Mn–Te distances are 2.783 Å (**1**) and 2.768 Å (**2**) with a difference of 0.015 Å. The differences in the Mn···Mn and Te···Te distances are of a similar magnitude: On going from **1** to **2**, they are shortened by 0.022 Å to 3.282 Å and by 0.019 Å to 4.387 Å, respectively. The terminally coordinated $\mathit{i}C_3H_7X^-$ ligands are bonded at distances of 2.413 Å (X = S; **1**) and 2.537 Å (X = Se; **2**) and are thus each 0.029 Å shorter than the corresponding distances in $[Mn(SPh)_4]^{2-}$[8] and $[Mn(SePh)_4]^{2-}$.[9]

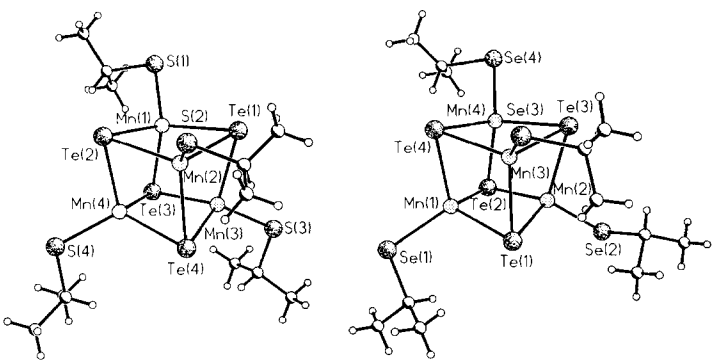

Fig. 1. Left: Structure of the complex anion **1** in crystals of **3**. Important distances [Å] and ranges of angles [°]: Mn···Mn 3.241(1)–3.422(1), Mn(1)-S(1) 2.412(2), Mn(2)-S(2) 2.397(2), Mn(3)-S(3) 2.441(2), Mn(4)-S(4) 2.403(2), Mn(1)-Te(1) 2.782(1), Mn(1)-Te(2) 2.773(1), Mn(1)-Te(3) 2.796(1), Mn(2)-Te(1) 2.773(1), Mn(2)-Te(2) 2.763(1), Mn(2)-Te(4) 2.805(1), Mn(3)-Te(1) 2.791(1), Mn(3)-Te(3) 2.785(1), Mn(3)-Te(4) 2.804(1), Mn(4)-Te(2) 2.755(1), Mn(4)-Te(3) 2.766(1), Mn(4)-Te(4) 2.799(1); Te-Mn-Te 100.5(1)–107.5(1), Te-Mn-S 103.3(1)–121.7(1), Mn-Te-Mn 70.7(1)–75.9(1). Right: Structure of the complex anion **2** in crystals of **4** [7]. Important distances [Å] and ranges of angles [°]: Mn···Mn 3.214(4)–3.358(4), Mn(1)-Se(1) 2.538(4), Mn(2)-Se(2) 2.538(4), Mn(3)-Se(3) 2.542(4), Mn(4)-Se(4) 2.532(4), Mn(1)-Te(1) 2.747(4), Mn(1)-Te(2) 2.802(4), Mn(1)-Te(4) 2.776(4), Mn(2)-Te(1) 2.755(4), Mn(2)-Te(2) 2.763(4), Mn(2)-Te(3) 2.777(4), Mn(3)-Te(1) 2.754(4), Mn(3)-Te(3) 2.758(4), Mn(3)-Te(4) 2.776(4), Mn(4)-Te(2) 2.778(4), Mn(4)-Te(3) 2.765(4), Mn(4)-Te(4) 2.778(4); Te-Mn-Te 102.1(1)–107.0(1), Te-Mn-Se 107.5(1)–120.0(1), Mn-Te-Mn 71.3(1)–74.4(1).

The Mn_4X_4 units in **1** and **2** are slightly distorted. Their symmetry does not deviate in a systematic manner from the point group T_d, unlike the cubane frameworks of many structurally related iron complexes. The values of the Mn–Te bond lengths are spread over typical ranges about common average values (2.755–2.805 Å in **1**; 2.747–2.802 Å in **2**).

The formation of mixed $M^{2+}/X^{2-}/YR^-$ complexes with $[M_4X_4]^0$ frameworks is unexpected due to the high overall charge of four electrons, since other spatial arrangements would permit a smaller formal charge per metal atom. Examples for this are the metal cubanes $[M_8S_6L_8]^{n-}$ (M = Co, L = SPh, n = 4, 5;[10] M = Fe, L = I, n = 4[11]) and the adamantane-type compounds $[M_{10}S_4(SPh)_{16}]^{4-}$ (M = Zn, Cd),[12] $[Cd_{17}S_4(SPh)_{28}]^{2-}$,[13] and $[Cd_{32}S_{14}(SPh)_{36}(dmf)_4]$.[14] The surprising stability of **1** and **2** presumably results from the specific electronic and steric properties of the tellurido ligands, and the circumstance that manganese in a tetrahedral chalcogenide environment can at most be divalent. Indeed, as yet we have been unable to replace the telluride ions by selenide or sulfide ions.

An important difference to the structurally analogous iron complexes lies in the unexpectedly long metal–metal distances in **1** and **2**, which are about 0.5 Å longer than the comparable distances in $[Fe_4Te_4(S\mathit{i}C_3H_7)_4]^{2-}$ (2.808 Å) and $[Fe_4Te_4(S\mathit{i}C_3H_7)_4]^{3-}$ (2.815 Å).[5] An expected value for the Mn···Mn distances can be estimated by extrapolating the Fe···Fe contacts in the hypothetical anion $[Fe_4Te_4(S\mathit{i}C_3H_7)_4]^{4-}$ (2.822 Å), and subsequently adding the difference of 0.242 Å which occurs in the metal–metal distance in simple thiolato complexes $[M_2(SEt)_6]^{2-}$ on going from Fe (2.978 Å) [15] to Mn (3.220 Å).[16] The value obtained in this way is 3.064 Å. The observed Mn···Mn distances are in fact 0.281 Å (**1**) and 0.240 Å (**2**) longer than this value and therefore rule out any significant Mn–Mn bonding. This finding contradicts the generally accepted MO models for complexes of the composition $[M_4S_4(SR)_4]^{n-}$. According to these models, when the number of cluster valence electrons lies between 45 and 60, all six of the bonding molecular orbitals (MO) of the M_4 cluster are fully occupied, and the valence electrons in excess of the number 45 are distributed among the eight nonbonding MOs.[17]

The cause of this change in the properties is possibly due to the energetic order of the bonding and nonbonding orbitals being swapped on going from iron to manganese. In this case, an average Mn–Mn bond order of 1/3 can be predicted, which is consistent with the observed conditions.

Cyclic voltammetric measurements on **3** and **4** show that the complex anions **1** and **2**, respectively, do not undergo reversible or quasi-reversible electronic transitions. The current–voltage curves are dominated by the redox behavior of the tellurido ligands, which are oxidized to ditelluride ions and subsequently to polytelluride ions.

Experimental Procedure

All manipulations were carried out in a glove box under an inert atmosphere (N_2). **3**, **4**: $MnBr_2$ (1.07 g, 5 mmol) was dissolved in MeCN (30 mL), and $NaS\mathit{i}C_3H_7$ (1.47 g, 15 mmol) or $NaSe\mathit{i}C_3H_7$ (2.17 g, 15 mmol) was added. $(Et_4N)Br$ (1.05 g, 5 mmol) was added and the mixture was then stirred for about 15 h. The reaction solution was filtered and $(SiMe_3)_2Te$ (5 mmol) in MeCN (20 mL) was added dropwise. The resulting deep red solution remained clear and was stirred 48 h before being evaporated under reduced pressure to about 7 mL. Subsequent layering with diethyl ether led to the desired products, after the solutions had been left to stand

for several days. Yields: **1**: 1.3 g (0.84 mmol, 67%); **2**: 580 mg (0.33 mmol, 27%); correct C, H, N, S analyses; UV/VIS (MeCN): λ_{max} [nm] (ε) = 504 (151) for **1**; 500 (256) for **2**.

Structure of a Mixed Phosphate/Phosphonate Layered Zirconium Compound from Synchrotron X-Ray Powder Diffraction Data**

Damodara M. Poojary, Baolong Zhang, and Abraham Clearfield*

Despite new developments in instrumentation and methods, structure determination from powder diffraction data is still not a routine procedure. Until now the most complex structures solved by this method include those of the β-Ba_3AlF_9,[1] the trivalent metal phosphites $(M_2HPO_3)_3 \cdot 4H_2O$ (M = Ga, Al, Fe),[2, 3] $(AlPO_4)_3 \cdot CH_3NOH$,[4] and $[\{HgRu(CO)_4\}_4]$.[5] β-Ba_3AlF_9 and gallium phosphite contain 29 atoms (including H atoms) in the asymmetric unit. The structure of the former compound was solved from conventional powder diffraction data while a combination of neutron and synchrotron data were used for the solution of the Ga compound. Here we report the X-ray powder structure analysis of a new layered compound (**1**) in which one of the phosphate groups contains a large organic complexant.

$$[Zr_2(PO_4)\{O_3PCH_2N(CH_2CO_2H)_2\}\{O_3PCH_2N(CH_2CO_2H)(CH_2CO_2)\}(H_2O)_2]$$
1

Layered zirconium phosphate compounds are of interest because of their practical application in areas such as ion exchange, catalysis, and intercalation chemistry. Most of the zirconium phosphate compounds studied thus far are structurally related to either $Zr(HPO_4)_2 \cdot H_2O$ (α-ZrP)[6] or to $Zr(PO_4)(H_2PO_4) \cdot 2H_2O$ (γ-ZrP).[7, 8] Since these Zr compounds are difficult to obtain as a single crystal, their structures can be determined only from their powder diffraction data. Using powder methods, we have determined the structures of a number of layered compounds and discovered some new phosphatozirconium layer types different from those of α- and γ-ZrP.[9, 10] Compound **1** is a mixed phosphate/phosphonate layered compound with an unusual Zr/P ratio of 2/3.

Preliminary X-ray powder data were collected on a Rigaku rotating anode automated diffractometer ($Cu_{K\alpha}$ radiation; 50 kV, 180 mA). The pattern was indexed by Ito methods.[11] The systematic absences were consistent with the space group $P2/c$ or Pc. Integrated intensities were extracted from the profile, and a Patterson map was computed using unambiguously indexed low angle reflections. The positions of the Zr atom and the P atoms located from this map were then entered into the program GSAS[12] for Rietveld refinement. A series of Fourier maps revealed the positions of the oxygen atoms that complete the coordination of the metal atom and the P atoms, but no atoms of the phosphonatomethyliminodiacetic acid group, $O_3PCH_2N(CH_2CO_2H)_2$ (PMIDA) could be located. To improve the quality of the data and to locate the light atoms, we collected Synchrotron powder diffraction data on beam line X7A at the National Synchrotron Light Source using a Ge(111) monochromator and Ge(220) analyzing crystal. The sample was

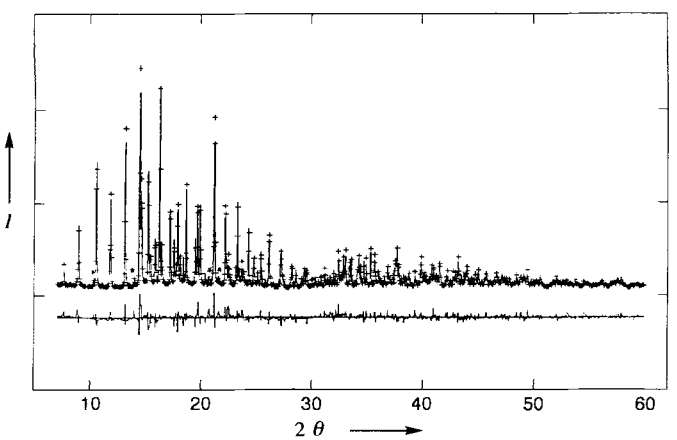

Fig. 1. Superimposed observed and calculated diffraction profiles (top, X-ray intensity versus 2θ) and their difference (bottom).

The metal coordination and the atom labeling are given in Figure 2, and the arrangement of the layers in the lattice in Figure 3. The structure contains both phosphate and phosphonate groups. The phosphorus atom of the phosphate is located on a twofold axis, while that of the phosphonate is in a general position thus giving a Zr/P ratio of 2:3. The phosphate group is situated nearly in a plane (atoms P2, O4, O5) at $x = 0$ and bridges four zirconium atoms which are arranged slightly above and below this plane. Also, all three oxygens (O1, O2, and O3) of the phosphonate group are involved in binding to metal atoms. The octahedral coordination of a single metal atom is completed by an oxygen atom from each of two phosphate groups, three oxygen atoms of phosphonate groups, and an oxygen of the water molecule.

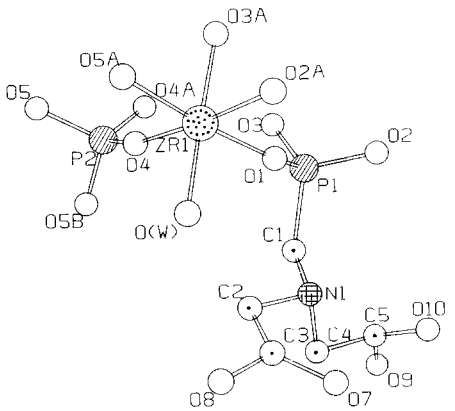

Fig. 2. Schematic representation of the structure of **1** showing the coordination about the zirconium atom and the numbering scheme. Selected bond lengths [Å] and angles [°]: Zr1-O1 2.083(5), Zr1-O2 2.042(6), Zr1-O3 2.070(5), Zr1-O4 2.029(5), Zr1-O5 2.015(6), Zr1-O(W) 2.012(6); average values for P-O 1.55(1), O-Zr-O 90 (*trans*: 177), O-P-O 110(1).

The carboxylate oxygens of the PMIDA group are not involved in metal binding; instead they are positioned near the center of the metal phosphate layers. The carboxylate groups from the neighboring layers are linked to each other by hydrogen bonds. One such bond is between O7 of the C3-carboxylate and O10 of the C5-carboxylate group of the adjacent layer (O7 $\cdots$ O10 = 2.82(3) Å). The other hydrogen bond involves two O8 oxygen atoms (O8 $\cdots$ O8′ = 2.54(1) Å) related by a twofold axis at $\frac{1}{2}, y, \frac{1}{4}$. On the basis of this symmetry restriction and the charge requirement, we postulate that these two oxygens share a proton. In other words, there exists only one proton for two of the C3-carboxylate groups while the C5-carboxylate group is fully protonated. This feature may be better explained if we reduce the symmetry to the noncentric space group, *Pc*. In this space group, the structure contains two independent PMIDA groups, and the charge balance is achieved by deprotonation of a carboxylate group in one of the PMIDA groups. This explanation agrees well with the results from ^{31}P MAS NMR spectrum, which shows a doublet for the phosphonate groups rather than a single resonance. However, the refinement of the structure in *Pc* (37 atoms) did not converge, possibly due to the limited number of observed reflections. The PMIDA group also appears to interact with the coordinated water molecule through its oxygen atom, O9 (O9 $\cdots$ O(W) = 2.96(2) Å). The P1–C1 bond distance of 1.80(1) Å agrees well with that found for other phosphonate structures.[13–15] The carbon atoms C1, C2, and C4 are in a regular tetrahedral environment C2–C3 = 1.51(1), C4–C5 = 1.52(1) Å). The average C-N-C bond angle is 111(1)° and the N–C distance 1.48(1) Å. The carboxylate groups are nearly planar with an average bond angle of 119(1)°, and the average of the C–O bond distances in these groups is 1.36(1) Å.

To the best of our knowledge this is the first example of a mixed phosphate/phosphonate system that has been structurally characterized. Despite the unusual Zr/P ratio of 2:3 the title compound shows some similarities with the well-known α- and γ-zirconium phosphates. The bridging nature of the phosphate in this compound is similar to that observed for γ-ZrP, while the binding of the phosphonate resembles that in α-ZrP. The γ-structure contains an additional H_2PO_4 group, which links to only two metal atoms. Compound **1** is the first zirconium phosphate layer compound that has been observed to contain a metal-coordinating water molecule, although this frequently occurs with other metal atoms.[15, 16] Intercalation and ion exchange reactions of **1** are under investigation.

Experimental Procedure

H_2PMIDA (2.27 g, 10 mmol), [16]) was dissolved in 5N ammonium hydroxide (30 mL). The pH was adjusted to 1 by adding HCl, and this solution was then mixed with 85% phosphoric acid (0.68 mL, 10 mmol). A solution of $[ZrFA_6]^{2-}$ was prepared by dissolving $ZrOCl_2 \cdot 8H_2O$ (3.22 g, 10 mmol) in distilled water (20 mL) and HF (1 mL). The metal and the PMIDA solutions were mixed in a Teflon flask fitted with a Teflon condensor and heated in an oil bath at 60 °C for a week. The white crystalline powder was filtered hot, rinsed with distilled water, and dried at 60 °C in an oven for one day.

Unusually Large Isotope Effects on NMR Chemical Shifts of Paramagnetic Organometallic Compounds**

Robert A. Heintz, Thomas G. Neiss, and Klaus H. Theopold*

NMR spectroscopy applied to paramagnetic molecules typically suffers from so-called isotropic shifts and more or less severe line broadening.[1] The former invalidate the empirical correlation between resonance frequency and chemical environment, and the latter obscures internuclear coupling and sometimes even prevents detection of resonances. Despite these obvious drawbacks, paramagnetism may yet hold advantages even for NMR spectroscopy. We report here the observation of unusually large isotope effects on both ^{1}H and ^{13}C NMR chemical shifts of a paramagnetic organometallic complex (Paramagnetic Isotope Effect on Chemical Shift, PIECS). This phenomenon appears to be widespread[2] and may prove to be a useful tool for the investigation of structure and reactivity of molecules with unpaired electrons.

As part of our investigation of paramagnetic organometallic chromium complexes,[3] we have previously reported the synthesis and structural characterization of $[\{Cp''Cr(\mu_3\text{-}H)\}_4]$ (**1**; see Scheme 1, $Cp'' = \eta^5\text{-}C_5Me_4Et$).[4] Variable-temperature magnetic susceptibility measurements carried out with a Faraday balance showed **1** to have a temperature-dependent effective magnetic moment. At ambient temperature **1** exhibited $\mu_{eff} = 3.5\ \mu_B$, and cooling led to a decrease in the magnetic moment, as expected for antiferromagnetic coupling of the metal centers. Despite its sizable magnetic moment, **1** exhibits rather distinct ^{1}H and ^{13}C NMR spectra.

In an attempt to gauge its thermal stability, a C_6D_6 solution of **1** in a sealed NMR tube was heated to 50 °C and periodically monitored by NMR spectroscopy. After two days, the ^{1}H NMR spectrum displayed two new resonances (at $\delta = 7.5$ and 6.9), very similar in appearance to the resonances attributed

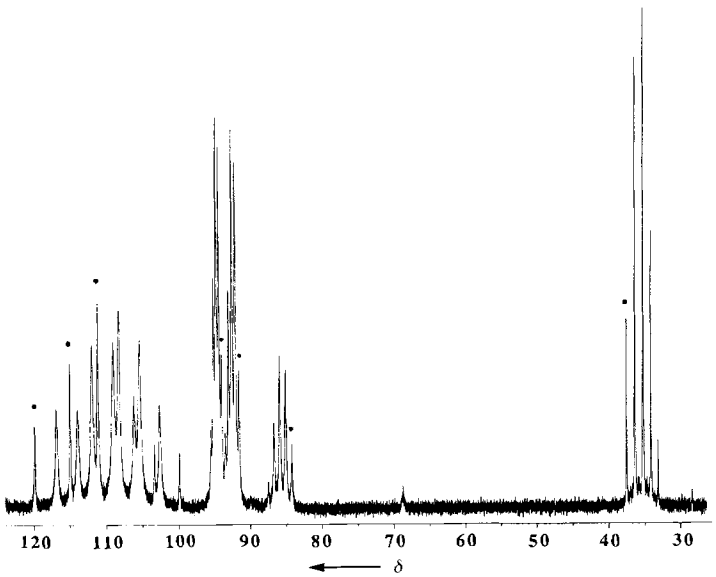

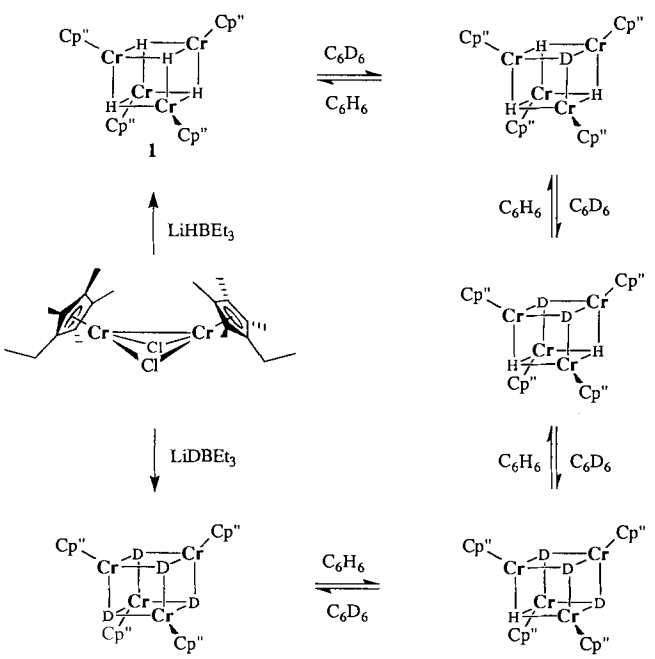

Fig. 1. ^{13}C NMR spectrum (125.8 MHz, 298 K, [D_8]toluene) of a statistical mixture of isotopomers of the general composition [$Cp''_4Cr_4(\mu_3\text{-}H)_{4-n}(\mu_3\text{-}D)_n$] ($n = 0$–4). Filled circles indicate the resonances of unlabeled [$Cp''_4Cr_4(\mu_3\text{-}H)_4$].

to the ring-bound methyl groups of **1**, and an upfield shoulder to the resonance caused by the methylene group. Further heating led to the appearance of additional resonances until, after four weeks, the low-field part of the spectrum ($\delta = 6$–8) exhibited at least seven broad and overlapping peaks of various intensities. The ^{13}C NMR spectra of the sample revealed a parallel evolution; each of the seven original resonances of **1** split up into a group of several peaks. Figure 1 shows such a

Scheme 1.

^{13}C NMR spectrum. Close examination revealed that each of the seven original singlets had been transformed into a set of five resonances in the approximate proportions 13:30:33:19:5. We propose that this spectrum results from a mixture of isotopomers of the constitution [$Cp''_4Cr_4(\mu_3\text{-}H)_{4-n}(\mu_3\text{-}D)_n$] (i.e. [$D_0$]-**1**, [$D_1$]-**1**, ... [$D_4$]-**1**) formed by H/D exchange with the deuteriated solvent (Scheme 1). The results of several experiments support this hypothesis. After prolonged heating of **1** in C_6H_6, followed by removal of the solvent, and addition of C_6D_6, NMR analysis showed only the seven original singlets of **1**. Reaction of [{Cp″Cr(μ-Cl}$_2$] with Li[DBEt$_3$] (95% D) yielded a sample of **1** featuring two sets of seven resonances in the ^{13}C NMR spectrum. The most intense set of resonances had the same chemical shifts as the lowest field signals in Figure 1; they presumably belong to the completely deuteriated [D_4]-**1**. The minor set of resonances had intermediate chemical shifts and was consistent with the spectrum expected of [D_3]-**1**, which results from residual hydride in the deuteride reagent. Exposure of this mixture to an excess of H_2 (1 atm, several days) restored the spectrum of [D_0]-**1**. Finally, treatment of **1** with a stoichiometric amount of D_2 yielded a sample with a ^{13}C NMR spectrum much like that shown in Figure 1. The H/D exchange is most facile with H_2 (D_2) gas; it proceeds more slowly with benzene or toluene, and apparently not at all with saturated hydrocarbons (e.g. cyclohexane).

The observed isotope effects on the ^{13}C chemical shifts of **1** range from $\Delta\delta = 0.37$ to 3.06 per H/D substitution (see Table 1)! The ring carbons, which are directly bonded to the

spin-carrying chromium atom, show the biggest effect; the corresponding resonances of [D_0]-**1** and [D_4]-**1** differ by up to $\Delta\delta = 11.7$. The signal for the methyl carbon of the ethyl substituent (four bonds from the nearest hydride ligand) shows the next biggest effect, while the signals for methyl groups directly attached to the ring are least shifted. Subsequent H/D substitutions consistently attenuate the shift; thus the incorporation of the fourth deuterium has only roughly 90% of the effect of the first one. The effect is slightly less pronounced in the ^1H NMR spectrum. While the signals for protons of the ethyl group show only modest shifts, those of the ring-bound methyl groups suffer upfield shifts of $\Delta\delta = 0.2$–0.45 per H/D substitution. These isotope effects are at least an order of magnitude larger than comparable shifts observed for diamagnetic molecules.[5] While we believe this to be the first observation of paramagnetically induced isotope shifts in ^{13}C NMR spectroscopy, a few reports exist about analogous effects in ^1H NMR spectroscopy.[2] It is likely that other NMR-active nuclei will show similar effects, and their discovery is limited only by the usual requirements for the detection of reasonably sharp NMR resonances of paramagnetic molecules (i.e. fast electron relaxation).

What causes these unusually large isotope shifts in **1**? In general, isotropic shifts consist of two contributions, namely the Fermi contact shift and the dipolar shift.[1] Without any independent measure of the magnetic anisotropy of **1**, the separation of these two effects is impossible. However, both depend on the magnitude of the magnetic susceptibility, and we believe that in this particular case the isotopic substitution may actually affect

the susceptibility of the complex. Due to the lower zero-point energy of Cr–D bonds, they are expected to be slightly shorter than Cr–H bonds. H/D substitution in **1** may therefore lead to small changes in the H(D) positions, and possibly even to contraction of the Cr–Cr distances. Such structural changes should affect the coupling constant J of the antiferromagnetic interaction (i.e. $|J_{[D_0]\text{-}\mathbf{1}}| < |J_{[D_4]\text{-}\mathbf{1}}|$), leading to a shift in the relative population of the various spin states and hence the average susceptibility. Some support for this proposal is provided by the observation that the direction of the isotope shifts induced by deuteriation in all cases parallels the effects of a decrease in temperature. While χ_m of solid **1** decreases upon cooling, the ^{13}C NMR resonances of the ring carbons and the methyl group of the ethyl substituent move upfield, and those of the methylene carbon and the ring-bound methyl groups shift downfield. Examination of Table 1 reveals shifts in the same directions brought about by progressive deuterium incorporation. According to our proposal, both cooling and deuteriation are expected to shift the spin equilibrium toward lower average spin multiplicity, and the parallel effects on the chemical shifts are consistent with this notion.

Whatever the mechanisms responsible for PIECS, they seem to occur with some regularity, and they can be very large. The following demonstrates how this phenomenon can be put to good use. Note, that the mixed isotopomers [D_1]-**1**, [D_2]-**1**, and [D_3]-**1** each feature two sets of chemically inequivalent Cp″ ligands. Thus, one might have expected a total of eight resonances in Figure 1 for each kind of carbon atom. One possible explanation for the observation of one resonance only for each isotopomer is the occurrence of a fluxional process. Such a process might be frozen out at lower temperature. Accordingly, Figure 2 shows the temperature dependence of one set of ^{13}C NMR resonances. Upon cooling, the three intermediate resonances broaden, collapse, and eventually reemerge to give a total of at least seven peaks. The estimated rate constant for the exchange process at the coalescence temperature is $k_{248\ K} = 120\ s^{-1}$, and substitution of this value into the Eyring equation yields $\Delta G^{\ddagger} = 12$ kcal mol^{-1}. Previously determined activation barriers for fluxional processes involving hydride migration in metal clusters range from 3 to 19 kcal mol^{-1}[6] and encompass the value found for **1**. This straightforward detection and kinetic characterization of the hydride migration in **1** would have been impossible for a diamagnetic analogue, in other words in the absence of PIECS.

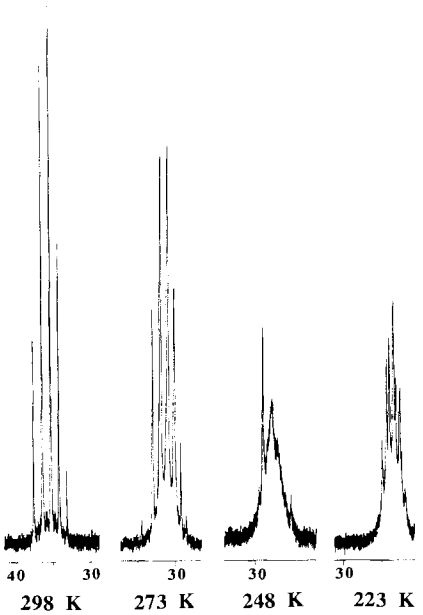

Fig. 2. Temperature dependence of the ^{13}C NMR resonances attributed to the methyl groups of the ethyl substituents of $[Cp''_4Cr_4(\mu_3\text{-}H)_{4-n}(\mu_3\text{-}D)_n]$ ($n = 0$–4).

A number of examples suggest that NMR spectra of paramagnetic compounds frequently exhibit unusually large isotope effects on chemical shifts. Under favorable circumstances, these isotope shifts may facilitate experiments on paramagnetic complexes (e.g. labeling studies, dynamic NMR studies, etc.), which cannot be done with diamagnetic molecules.

Experimental Procedure

1: To a stirred suspension of 1.004 g (8.17 mmol) of $CrCl_2$ in 60 mL of THF was added 1.271 g (8.14 mmol) of $EtMe_4C_5Li$. The reaction was allowed to stir for 2 h at room temperature. To this solution was slowly added 8.1 mL (8.1 mmol) of $LiHBEt_3$ (1.0 M in THF) by syringe. The mixture was stirred for another 30 min, and then the THF was removed under vacuum. The resulting sticky brown solid was extracted with pentane and the extract filtered. The pentane solution was concentrated and cooled to $-30\,^{\circ}C$ to yield 0.991 g (1.22 mmol, 60%) of **1**. ^1H NMR (C_6D_6): $\delta = 7.9$ (s, 6H), 7.3 (s, 6H), 3.4 (s, 2H), 1.1 (s, 3H); ^{13}C NMR (C_6D_6): $\delta = 119.9, 115.0, 111.2, 94.0, 91.6, 84.3, 37.6$; IR (KBr): $\tilde{\nu} = 2960$ (s), 2901 (s), 2868 (s), 2714 (w), 1448 (s), 1365 (s), 1303 (w), 1018 (m), 945 (w), 551 (s) cm^{-1}. Analysis calculated for $C_{44}H_{72}Cr_4$: C 65.65; H 8.97. Found: C 65.55; H 8.88. μ_{eff}(299 K) = 3.50 μ_B (1.75 μ_B/Cr).

[D_4]-**1**: The procedure was the same as described above, except $LiDBEt_3$ (95% D) was used. A mixture of $[Cp''_4Cr_4(\mu_3\text{-}D)_4]$ ([D_4]-**1**, ca. 80%) and $[Cp''_4Cr_4(\mu_3\text{-}D)_3(\mu_3\text{-}H)]$ ([D_3]-**1**, ca. 20%) was obtained. ^1H NMR (C_6D_6): [D_4]-**1**: $\delta = 6.8$ (s), 6.2 (s), 3.1 (s), 1.1 (s); [D_3]-**1**: $\delta = 7.0$ (s), 6.4 (s), 3.1 (s), 1.1 (s); ^{13}C NMR (C_6D_6): [D_4]-**1**: $\delta = 108.9, 103.7, 100.5, 95.4, 93.4, 87.6, 33.7$; [$D_3$]-**1**: $\delta = 111.7, 106.7, 103.2, 95.1, 93.0, 86.8, 34.8$ ppm.

Hf_3Te_2: A New and Remarkable Layered Compound**

Robert L. Abdon and Timothy Hughbanks*

Binary, early-transition-metal chalcogenides of surprisingly simple composition continue to be found. Recent attention to this chemistry and advances in synthetic methodology have produced Ta_3S_2,[1,2] Ta_6Te_5,[3] Ta_2Te_3,[4] and Ta_2Se.[5] Investigations of tantalum- and niobium-rich chalcogenides have yielded novel layered materials with structures related to the body-cen-

tered cubic (bcc) metals. Ta_2Se can be regarded as an insertion phase containing four layers of bcc-like tantalum sandwiched between layers of selenium. An isostructural sulfide exists in the ternary compound $Ta_{1.60}Nb_{0.40}S$.[6, 7] At the composition $Ta_{1.64}Nb_{0.86}S$ (M_5S_2) five layers of bcc metal are found between the sulfide layers.[8] Mixed tantalum/niobium sulfides having higher niobium content have been prepared,[9, 10] but their structures are similar to the niobium-rich sulfides $Nb_{21}S_8$ and $Nb_{14}S_5$, which are less closely related to the bcc-metal structure.

Preparative investigations of hafnium-rich tellurides incorporating later 3d transition metals have produced Hf_8MnTe_6 and Hf_8FeTe_6.[11] These materials are structurally related to the condensed cluster Ta compounds $Ta_{11}M_2Se_8$, Ta_8MSe_8, and $Ta_9M_2S_6$.[12–14] In our attempts to prepare related, ternary compounds of hafnium and tellurium, the binary phase Hf_3Te_2 was discovered. This remarkable material is the only reduced, binary hafnium telluride, and like Ta_2Se, it has a simple structure and composition.

We prepared Hf_3Te_2 by direct reaction of stoichiometric amounts of the elements (Hf 96.9%, including 2.9% Zr, and Te 99.99%; Johnson Matthey) in sealed Nb capsules, which were in turn sealed in evacuated and flame-baked silica tubes. The temperature of the reaction vessel was increased uniformly to 1000 °C over 5 days, and the product was isolated in quantitative yield after 10 more days at this temperature. Attempts to grow single crystals by vapor phase transport with $TeCl_4$ repeatedly produced only microcrystalline powders. However, by employing KCl as a flux (molar ratio, 2 KCl: 1 Hf_3Te_2) and cycling the reaction temperature between 950 °C and 1000 °C repeatedly over a two-week period, black, square crystals suitable for single-crystal X-ray studies were obtained (Table 1).[15] No contamination by niobium was detected in elemental analysis of the product.

Table 1. Structural parameters for Hf_3Te_2: space group $I4/mmm$ (no. 139), $Z = 2$; $a = 3.6837(3)$ Å, $c = 17.901(2)$ Å.

Atom	x	y	z	U (equiv) [Å$^2 \times 10^3$]
Hf1	0	0	0	7 (1)
Hf2	1/2	1/2	0.0962	7 (1)
Te1	0	0	0.1690	7 (1)

As in Ta_2Se and the mixed Ta/Nb sulfides, Hf_3Te_2 is formally an insertion phase related to that of bulk body-centered cubic metal. After every three layers of hafnium, two layers of tellurium are inserted. The result is a layered structure in which slabs are made up from three square nets of hafnium sandwiched between two layers of tellurium (Fig. 1). These Te-Hf_3-Te sandwiches are stacked, with only weak interlayer interactions, to form the full three-dimensional structure. Within the slabs, the more oxidized metal centers (Hf2) are those bound to four tellurium atoms at the exterior of the layer. Each of these metal atoms forms four bonds to the hafnium atoms (Hf1) in the central net (3.1229(4) Å) and one longer bond through the slab (3.4454(12) Å) to a symmetry-equivalent atom. Each tellurium is five-coordinate with respect to hafnium atoms in the same slab (Te1–Hf2, $4 \times 2.9120(5)$; Te1-Hf1, $1 \times 3.0245(9)$ Å). Guinier powder films show two very weak lines, suggesting the possibility of a ($\sqrt{2}a \times \sqrt{2}b$) superlattice. The existence of this superlattice could not be detected in the single crystal study, and currently is under investigation.

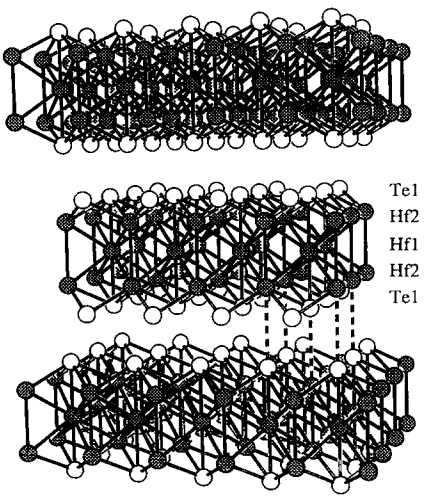

Fig. 1. The Hf_3Te_2 structure viewed approximately along the {110} direction. Hf atoms are shown as dotted circles and Te as open circles. Only interatomic distances less than 3.6 Å are shown as bonds.

The electronic band structure of Hf_3Te_2 was calculated with the extended Hückel method.[16] The Fermi level lies just below a pronounced minimum in the total density of states (DOS) diagram (Fig. 2a). Projected DOS diagrams show that the energy levels between -15.0 and -10.5 eV are primarily localized on Te (Fig. 2b), while the higher levels have mainly Hf d and s character (Fig. 2c). The mixing of Hf-based orbitals into the Te-based manifold gives evidence for significant Hf–Te covalency. Crystal orbital overlap populations (COOPs)[17] yielded a valence electron concentration (VEC) that indicates that all levels with strongly Hf–Hf bonding character are filled (Fig. 3). At the same time, these levels have only moderately antibonding Hf–Te character. Isoelectronic Zr_3Te_2 adopts a defect-WC structure, as do the other known Group IV chalcogenides of the same composition.[18–20] Although these calculations rationalize the structure of Hf_3Te_2, the underlying factors controlling the choice between structural types for isoelectronic compounds remain unclear.

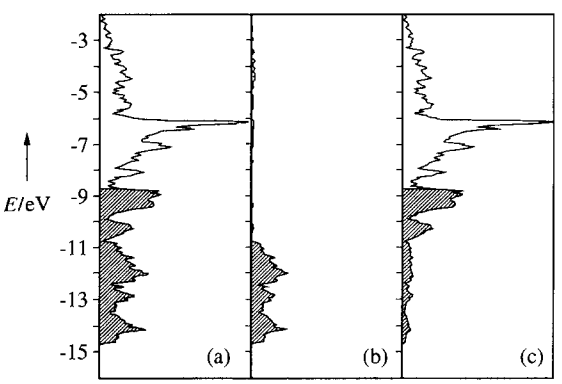

Fig. 2. a) Total density of states (DOS) diagram for Hf_3Te_2. The energy range includes the Te 5p bands and the Hf d and s bands. b) Tellurium contribution to the DOS. c) Hafnium contribution to the DOS. Filled levels are shaded.

The title compound belongs to a broader class of chalcogenides having a structure based on the stacking of 4^4 nets of atoms. The transition from three-dimensional to two-dimensional structures in these materials is determined by the lattice

constant *a* and the size of the chalcogenide. In ZrGeTe (PbFCl type), the stacking sequence of the nets is Te-Zr-Ge_2-Zr-Te. The larger *a* dimension of 3.866 Å reduces steric crowding in the Te nets and permits much shorter Zr–Te contacts between adjacent layers. On the other hand, isostructural ZrSiTe has a significantly shorter *a* axis (3.692 Å) that precludes such interlayer Zr–Te bonding.[21, 22] In Hf_3Te_2 the *a* dimension is only 3.6837(3) Å, slightly shorter than that of ZrSiTe. The Hf–Te contacts between adjacent layers in Hf_3Te_2 are 4.195 Å, too long for significant Hf–Te bonding. The Te–Te distances between adjacent layers of 3.785 Å suggest that the structure is highly two-dimensional, with van der Waals interactions between the slabs.

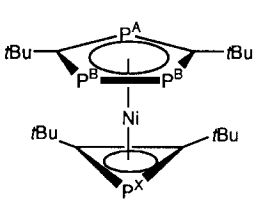
Synthesis and Characterization of the First Compounds Containing a Stable Phosphirenyl Cation: Crystal and Molecular Structure of $[Ni(\eta^3\text{-}PC_2tBu_2)(\eta^5\text{-}P_3C_2tBu_2)W(CO)_5]$**

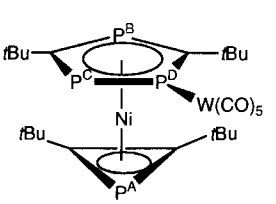
Anthony G. Avent, F. Geoffrey N. Cloke, Kevin R. Flower, Peter B. Hitchcock, John F. Nixon,* and David M. Vickers

Phosphirenium salts **1**[1–3] do not exhibit aromatic behavior[4] presumably because the 3dπ-2pπ interaction between the phosphorus atom and the C=C double bond is weak as in the isoelectronic silirene.[5] On the other hand it has been proposed[6] that a strong 3pπ-2pπ interaction might be expected between the electron-deficient phosphorus atom and the double bond in the phosphirenyl cation **2** which represents the simplest

1



2



2π-aromatic species containing phosphorus. To date, however, all attempts to synthesize this type of compound have been unsuccessful,[7, 8] for example treatment of the chlorophosphirene ring ClPC(Ph)=CPh with metal salts containing the $[BF_4]^-$ or $[BPh_4]^-$ ions led only to the fluoro- or phenyl-substituted phosphirenes XPC(Ph)=CPh (X = F, Ph), respectively.

Theoretical calculations on silirenyl cations[9] suggest that, if synthesized, they would not be aromatic; on the other hand it has been proposed that phosphirenyl cations would receive some extra stabilization by cyclic delocalization if the destabilizing *n*-π interaction were suppressed by P complexation.[6, 10]

We describe herein the first synthesis of the phosphirenyl cation **2**, (R=*t*Bu) as a ligand in the red-orange nickel complex **3**, whose structure has been elucidated by mass spectrometric and multinuclear NMR studies and confirmed by a single-crystal X-ray structural study on its $[W(CO)_5]$ adduct **4**.

[**] We thank the Engineering and Physcial Sciences Research Council for their continuing support of our work.

molybdenum vapor with the phosphaalkyne tBuC≡P afforded tris-(η^4-2,4-di-*tert*-butyl-1,3-diphosphacyclobutadiene)molybdenum(0), [Mo(η^4-P_2C_2tBu$_2$)$_3$]. Extension of this synthetic approach to other transition metals gives the known pentaphosphaferrocene [Fe(η^5-P_2C_3tBu$_3$)(η^5-P_3C_2tBu$_2$)][12] and the new paramagnetic chromium and vanadium analogues.[13]

The reaction of tBuC≡P with nickel atoms at 77 K, however, affords two red-orange products, **3** and **5**, both of molecular

[Ni(η^4-P_2C_2tBu$_2$)$_2$] **5**

formula NiP_4C_4tBu$_4$. Complex **5** was identified as bis(η^4-2,4-di-*tert*-butyl-1,3-diphosphacyclobutadiene)nickel(0), which was previously reported by Binger et al.[14] using a different synthetic route.

The structure of the isomeric nickel complex **3** was deduced to be [Ni(η^3-PC_2tBu)(η^5-P_3C_2tBu)], which contains the novel phosphirenyl cation $(PC_2t\text{Bu}_2)^+$ as ligand, from 1) its characteristic mass spectrum, which exhibits a parent ion at $m/z = 458$ showing the typical isotopic pattern, and peaks consistent with the expected fragmentation, the strongest peak at $m/z = 320$ corresponding to the loss of tBuC≡CtBu from the parent compound, and 2) from its ^{1}H, ^{31}P{^{1}H}, and ^{13}C{^{1}H} NMR spectra, in particular, the multiplet at $\delta = 178.9$ in the ^{13}C NMR spectrum which analyses as the A part of an AMXY spin system (Table 1) and is characteristic of the ring carbon of the P_3C_2 moiety. The ^{31}P{^{1}H} NMR spectrum analyses as an AB_2X spin system, the AB_2 part being assigned to the P_3C_2 ring. Since the ^{1}H and ^{13}C{^{1}H} NMR spectra establish two chemically equivalent CtBu fragments, the presence of the three-membered PC_2 ring is confirmed. Of special significance is the chemical shift of the P^X resonance in the three-membered ring, which lies very close to that observed for the fully characterized, structurally related complex [Ni(η^3-P_3)(η^5-C_5H_3tBu$_2$)].[15]

Table 1. Selected spectroscopic and analytical data for compounds **3** and **4** [a].

3: ^{1}H NMR: $\delta = 1.45$ (d, $^4J_{PXH} = 0.9$ Hz, 18H, C(CH$_3$)), 1.14 (s, 18H, C(CH$_3$)); ^{31}P{^{1}H}-NMR: AB_2X, $\delta = 155.4$ (P^A), 145.1 (P^B), −161.2 (P^X), $J_{PAPB} = 51.8$, $J_{PAPX} = 5.1$, $J_{PBPX} = 16.0$ Hz; ^{13}C{^{1}H}-NMR: $\delta = 32.4$ (s, C(*C*H$_3$)), 32.9 (d, $J_{CPX} = 4.3$ Hz, C(*C*H$_3$)), 36.8 (A part of AMXX′, $J_{AM} = 9.3$, $J_{AX} + J_{AX'} = 9.2$ Hz (A = C(CH$_3$), M = P^A, XX′ = P^B), 40.0 (A part of AMXX′, $J_{AM} = 18.5$, $J_{AX} + J_{AX'} = 12.4$ Hz, A = *C*(CH$_3$), M = P^A, XX′ = P^B), 94.6 (d, $J_{CPX} = 70.0$ Hz, ring-C), 178.9 (A part of AMXY, $J_{AM} = 78.7$, $J_{AX} + J_{AY} = 104.4$ Hz, $\Delta\delta_{XY} = 31.6$) [b]; MS (70 eV) m/z(%) 458 (14) [M^+], 358 (5) [$M^+ - C_5H_9P$].

4: ^{1}H NMR (318 K): $\delta = 1.12$ (s, 18H, C(CH$_3$)$_3$), 1.38 (s, 18H, C(CH$_3$)$_3$); (248 K): $\delta = 1.08$ (s, 18H, C(CH$_3$)$_3$), 1.26 (s, 9H, C(CH$_3$)$_3$), 1.47 (s, 9H, C(CH$_3$)$_3$); ^{31}P{^{1}H} NMR (253 K): $\delta = -144.7$ (d, $^2J_{PAPD} = 22.3$ Hz, P^A), 86.6 (ddd, $^1J_{PDW} = 226.5$, $^1J_{PDPC} = 439.3$, $^2J_{PDPB} = 52.7$, $^2J_{PDPA} = 22.3$ Hz, P^D), 129.9 (dd, $^1J_{PCPD} = 439.3$, $^2J_{PCPB} = 46.6$ Hz, P^C), 149.1 (dd, $^2J_{PBPD} = 52.7$ Hz, P^B); ^{13}C{^{1}H} NMR (253 K): $\delta = 31.4$ (s, C(*C*H$_3$)), 31.9 (s, C(*C*H$_3$)), 32.1 (s, C(*C*H$_3$)), 32.3 (s, C(*C*H$_3$)), 35.5 (dd, $^3J_{CP} = 5.4$, $^3J_{CP} = 11.0$ Hz, C(CH$_3$)), 35.9 (dd, $^3J_{CP} = 8.9$, $^3J_{CP} = 8.9$ Hz, C(CH$_3$)), 39.57 (dd, $^1J_{CP} = 15.9$ Hz, C(CH$_3$)), 39.61 (dd, $^1J_{CP} = 22.2$ Hz, C(CH$_3$)), 97.7 (d, $^1J_{CP} = 69.6$ Hz, ring-C), 100.9 (d, $^1J_{CP} = 71.1$ Hz, ring-C), 159.9 (ddd, $^1J_{CP} = 83.6$, $^1J_{CP} = 64.3$, $^2J_{CP} = 9.5$ Hz, ring-C), 176.4 (dd, $^1J_{CP} = 78.9$, $^1J_{CP} = 91.8$ Hz), 196.4 (d, $^2J_{CPD} = 2.5$, $^1J_{CW} = 126.6$ Hz, *cis*-CO), 198.8 (d, $^2J_{CPD} = 31.0$ Hz, *trans*-CO); MS (70 eV) m/z(%) 782(17) [M^+]; elemental analysis: found: C 38.72, H 4.71; calcd.: C 38.35, H 4.63.

[a] ^{1}H: 500 MHz, [D$_8$]toluene; ^{13}C{^{1}H}: 125.76 MHz, [D$_8$]toluene; ^{31}P{^{1}H}: 202.6 MHz, [D$_8$]toluene. [b] For all AMXX′ spin systems $J_{XX'}$ is assumed to be large.

Although it has not yet been possible to obtain single crystals of **3** suitable for an X-ray crystallographic study, treatment of **3** with [W(CO)$_5$(thf)] readily afforded dark red crystals of its [W(CO)$_5$] adduct **4**. Variable-temperature ^{31}P{^{1}H} and ^{1}H NMR studies on **4** established that the [W(CO)$_5$] fragment is η^1-ligated to one of the P atoms of the P–P unit in the P_3C_2 ring; this is similar to that previously established in the complexes [Fe(η^5-P_3C_2tBu$_2$)$_2$W(CO)$_5$] and [Fe(η^5-P_3C_2tBu$_2$)(η^5-P_2C_3tBu$_3$)W(CO)$_5$].[16]

The ^{31}P{^{1}H} NMR spectrum of **4** at room temperature is deceptively simple (Table 1) because the [W(CO)$_5$] moiety undergoes an *intra*molecular exchange between the adjacent P^C and P^D nuclei of the P_3C_2 ring, as previously observed in related systems.[17–19] On cooling the sample to −20 °C this dynamic process is suppressed, and the ^{31}P{^{1}H} NMR spectrum reveals the expected four different types of phosphorus environments with only the signal of the P^D atom exhibiting ^{183}W satellites ($J_{PW} = 226.5$ Hz). Interestingly there is a significant ^2J coupling between the P^A atom of the three-membered ring and the tungsten-substituted P^D atoms in the five-membered ring (vide infra).

Complexes **3** and **4** can thus be formally considered as Ni^0 compounds in which the triphosphacyclopentadienyl anion is η^5-ligated and the phosphirenyl cation is η^3-ligated to the metal center. The stabilizing effect of the electron-rich 3d^{10} Ni center on the phosphirenyl cation would be consistent with the results of INDO-SCF-MO calculations on [Ni(η^3-C_3H_5)(η^5-C_5H_5)] which indicate that there is a substantial transfer of charge from the metal center to the η^3-cyclopropenyl group.[20]

The molecular structure[21] of **4** (Fig. 1) confirms the presence of the three-membered phosphirenyl ring system and that the

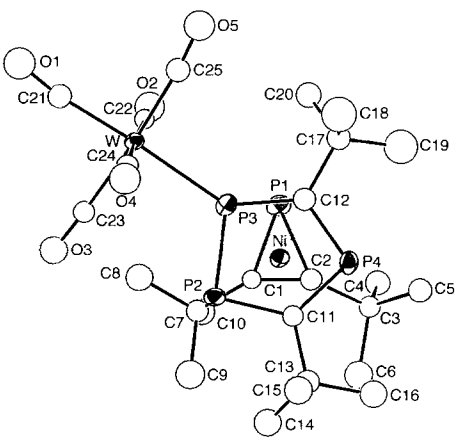

Fig. 1. Molecular structure of **4**. Selected bond lengths [Å] and bond angles [°]. M1 and M2 are the centroids of the three- and five-membered rings, respectively. Ni-P1 2.207(5), Ni-P2 2.397(5), Ni-P3 2.354(5), Ni-P4 2.354(5), Ni-C1 2.02(2), Ni-C2 2.04(2), Ni-C11 2.24(2), Ni-C12 2.12(2), Ni-M1 1.860, Ni-M2 1.692, W-P3 2.517(5), P1-C1 1.78(2), P1-C2 1.82(2), P2-P3 2.111(7), P2-C11 1.74(2), P4-C12 1.76(2), C1-C2 1.33(3); M1-Ni-M2 176.0, P3-W-C21 176.7(7), C1-P1-C2 43.3(8), P3-P2-C11 96.4(7), P2-P3-C12 101.6(7), C11-P4-C12 99.6(9), P1-C1-C2 70(1), P1-C2-C1 67(1).

two ring systems lie essentially parallel to each other (dihedral angle about 4°). The Ni–P and Ni–C bond lengths to the three-membered PC_2 ring are significantly shorter than the corresponding distances to the five-membered P_3C_2 ring, which parallels the behavior previously observed[22] for the complex [Ni(η^3-C_3Ph_3)(η^5-C_5H_5)]. The short C1–C2 bond (1.33(3) Å) in the $PC_2t\text{Bu}_2$ ring of **4** implies significant double bond character, as was found[23] in the unsymmetrically ligated η^3-cyclopropenyl cation in [Ni(η^3-C_3Ph_3)(PPh$_3$)$_2$] PF_6. Calculations by Maclagen on the the parent phosphirenyl cation $PC_2H_2^+$ show optimized geometries of C–C (1.340 Å) and P–C (1.703 Å) at the HF/6-31G* level, and C–C (1.350 Å) and P–C (1.728 Å) at the MP3/6-31G* level.[24] The aromatic character of the free phosphirenyl cation is corroborated by recent ab initio calculations by Laali et al, who have also obtained low-temperature

NMR evidence for a persistent phosphirenyl cation in a compound formulated as $(PhtBuC_2P)^+[B(OSO_2CF_3)_4]^-$.[25]

In **4**, the slightly shorter C–C bond length (1.33(3)Å) and the elongated P–C bonds (1.78(2)Å and 1.82(2)Å) would suggest incomplete delocalization when compared with the theoretical models of the free ligand, although the effect of a bound transition metal fragment on the latter is not clear. The Ni–P1 bond (2.207(5)Å) in **4** lies close to the average Ni–P bond length found by Scherer et al.[15] in $[Ni(\eta^3\text{-}P_3)(\eta^5\text{-}C_5H_3tBu_2)]$. It is noteworthy that in **4** the P1 atom in the three-membered ring lies closest to P3 in the five-membered ring, suggesting that the large $^2J_{PP}$ coupling constant between these nuclei may have a through space component similar to that previously observed for $[Fe(\eta^5\text{-}P_3C_2tBu_2)_2]$.[12]

Experimental Procedure

3: Electron beam (400 W) vaporized nickel (0.99 g) was cocondensed with an excess of *t*BuCP (20 g) at 77 K over a period of 2.5 h. The residue was washed from the belljar with petroleum ether (40–60°) and filtered through a celite pad to remove colloidal metal. Removal of solvent in vacuo afforded a dark oil. Extraction of the oil into petroleum ether (40–60°) followed by chromatographic workup on alumina (4% m/m H_2O) with petroleum ether (40–60°) as eluent afforded **3** as an oil (ca. 0.2 g, 3%) and **5** (0.2 g, 3%) analytically pure, after recrystallization from pentane. For spectroscopic data see Table 1.

4: To $[W(CO)_5(thf)]$ generated in situ from $[W(CO)_6]$ (0.10 g) in THF (25 mL) was added **3** (ca. 0.05 g) and the mixture stirred for 4h. The solvent was removed in vacuo to yield a dark oil. Extraction of the oil into petroleum ether (40–60°) followed by chromatographic workup on Kieselgel 60 GF_{254} with petroleum ether (40–60°) as eluent afforded **4** as a microcrystalline powder on removal of solvent. Recrystallization from pentane (223 K) afforded analytically pure **4** (0.05 g, 58%), see Table 1 for spectroscopic data.

Phase Transitions in Self-Assembled Monolayers Detected by Electrochemistry**

Antonella Badia, Roberta Back, and R. Bruce Lennox*

Self-assembled monolayers (SAMs) of *n*-alkanethiols (RSH) on metals have been used both as models for organic surfaces and as modulators of metal surface properties.[1] These SAMs are prepared under readily accessible laboratory conditions, and the strong interaction between the metal substrate (Au, Pt, Ag, Cu, Hg, etc.) and the sulfur atom provides a monolayer film that is sufficiently stable to desorption to allow spectroscopic, diffraction, and electrochemical experiments to be performed with a minimum of precautions.[1] Grazing-angle FT-IR studies and grazing incidence diffraction experiments of a typical $n\text{-}C_{18}H_{37}S$ monolayer on a Au(111) surface show that molecular ordering is present.[2, 3]

One key aspect of SAMs that has so far eluded detailed description concerns the question of film thermodynamics and, more specifically, the nature of film phases. A very recent X-ray diffraction study has shown that 2D structural phase transitions may be observable in SAMs.[4] This reveals that, like Langmuir and Langmuir-Blodgett films,[5] SAMs do indeed have a complex phase behavior. Contact angle/wetting studies hint at rearrangement processes in RS–Au monolayers,[6] while temperature dependent FT-IR studies reveal only gradual changes,[7] and not the discontinuities expected from first-order processes. We have addressed the important problem of phase properties of SAMs by using the electron transfer process between a water-soluble redox species and an RSH-modified Au electrode as a probe of the monolayer film structure. We have discovered that phase transitions do, in fact, occur and that film preparation protocols play a crucial role in their formation.

Electrochemical thermograms for RS–Au electrodes (R = $n\text{-}C_{16}H_{33}$ to $C_{20}H_{41}$) were obtained over an approximate temperature range of 10 to 65 °C. Electrodes which exhibit striking discontinuities in the electrochemical thermograms were prepared by a variation on the conventional preparation protocols.[1, 8] Specifically, polycrystalline Au electrodes were immersed in thiol solutions and kept at 23 ± 2 °C for prolonged periods (days to weeks). Conventional protocols usually employ much shorter times (minutes to hours), a variety of heating/annealing procedures, and reimmersion in thiol solution after each experiment, or cosurfactants in the thiol solution.[9]

One of the most interesting properties of RS monolayers is their ability to attenuate the rate of electron transfer between a water-soluble redox couple and the underlying metal electrode.[2e, 9a–c, 10] The transmonolayer electron transfer mechanism has been studied with several soluble or monolayer-bound redox couples and a variety of electrochemical techniques.[2c, 9–11] The electrodes discussed here were thoroughly blocked: the capacitance values were reduced, the $[Fe(CN)_6]^{3-}$ reduction currents greatly attenuated relative to bare Au electrodes, and the features in cyclic voltammograms that are diagnostic of pinholes or bare patches in the films were absent.

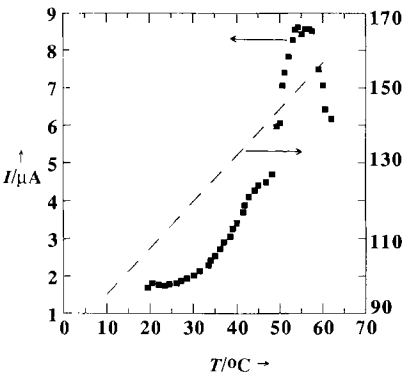
The temperature dependence of the iron(III) cyanide reduction current, observed at constant overpotential, for a representative $C_{18}H_{37}S$–Au electrode is shown in Figure 1. The reduction of $[Fe(CN)_6]^{3-}$ at a clean bare electrode increases montonically with increasing temperature (Fig. 1, dashed line),



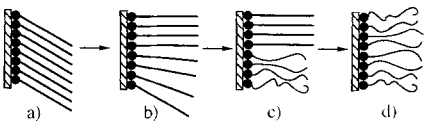


Fig. 1. Electrochemical thermograms (plot of current I vs. temperature T) for $[Fe(CN)_6]^{3-}$ reduction at bare Au (dashed line) and $C_{18}H_{37}S$–Au (■) electrodes obtained by cyclic voltammetry (0.020 M $K_3[Fe(CN)_6]$, 0.1 M KBr, scan rate $v = 20$ mVs^{-1}), temperature corrected overpotential $\eta = -250$ mV.

as is expected for an activated process.[12] For each chain length studied, the modified Au electrode, however, exhibits a pronounced current maximum. In all cases except the nineteen-carbon chain, a distinct shoulder on the low temperature side of the maximum is also observed. Clearly, these substantial current changes reflect temperature-induced modification of the SAM as a barrier to electron transfer. Previous studies suggest that the overall rate-limiting step in the case of well-blocked RS–Au electrodes is electron tunneling[1d, 9a, b, 10d, e, 11f] although some data is also consistent with a permeation mechanism.[9a, 10a, b, e, g, 13] Current derived exclusively from a through-bond tunneling mechanism, for example, should be either temperature-independent or should increase with increasing temperature, depending on whether there is an activation component to the electron transfer[12a] On the other hand, current derived from permeation of the redox couple into the monolayer would exhibit a complex temperature dependence, as it would depend on the relationship between film structure, the solvent–monolayer partition coefficient, the diffusion coefficient of the redox couple in the monolayer, and interfacial resistances. The data in Figure 1 is clearly inconsistent with tunneling, but is qualitatively consistent with a complex permeability-linked process.

Our experiments with SAMs prepared under prolonged immersion in the thiol solution exhibit striking parallels to the temperature-dependent permeability profiles of phosphatidylcholine lipid vesicles to Na^+, K^+, H_2O.[14] Bilayer lipid vesicles have been extensively characterized by calorimetric and spectroscopic techniques and are known to undergo a series of phase transitions, the two most prominent being a gel/liquid-crystal transition (at $T = T_m$) and an untilting/rippling transition (at $T = T_p$).[15] This untilting transition preceeds T_m by 3–6 °C, depending on the alkyl chain length. Large anomalous increases in transmembrane permeability are observed at $T_m \pm 5$ °C.[14] These large current fluxes are attributable to transient dislocations or grain boundaries found at the interface between domains of the coexisting gel and liquid-crystalline phases. These boundaries provide a low energy barrier to ion and solute diffusion across the membrane. Recent theoretical studies support

Scheme 1. Sketch of physical interpretation of the phase transitions in SAMs. a) Close-packed, b) coexistence of tilted and untilted chains, c) coexistence of melted and unmelted chains, d) melted chains.

this experimentally based description.[16] The current maxima described here are thus believed to arise from regions where diffusion is facilitated in the monolayer at coexistence boundaries between ordered and disordered alkyl chain domains (Scheme 1). It is interesting to note that evidence for electron tunneling in the well-studied lipid vesicle systems is decidedly lacking and that permeation processes are in fact responsible for current generation in these systems.[17]

The temperatures at which the current maxima (T_m^e) and shoulders (T_p^e) are observed in the electrochemical thermograms correlate (1:1) with T_m values (measured by calorimetry) of di-*n*-acylphosphatidylcholines of equivalent chain length (Fig. 2A, slope = 1.0).[15] This correlation arises because the underlying Au substrate dictates that the RSH chain packing

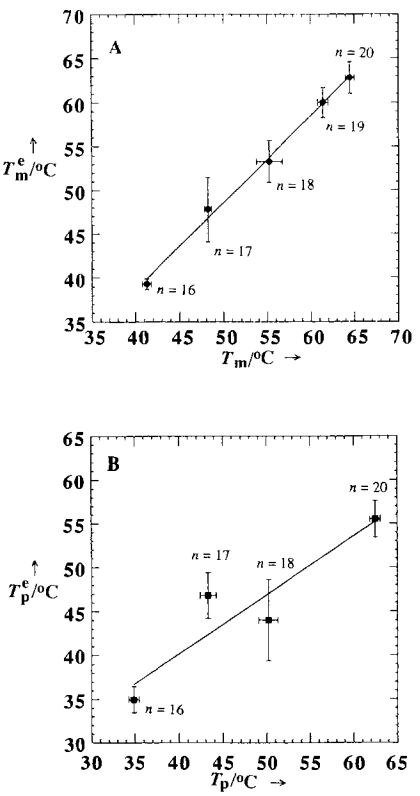

Fig. 2. A) Relationship between the electrochemically determined temperature T_m^e for $C_nH_{2n+1}S$/Au ($n = 16$–20) and T_m of the gel/liquid-crystal phase transitions of di-*n*-acylphosphatidylcholines measured by DSC. Error bars represent standard deviations reported here (T_m^e) and in the literature [15] (T_m). Slope = 1.0, correlation coefficient $r = 0.998$. B) Pretransition observed in the electrochemical thermograms of the modified electrode (T_p^e) vs. the pretransition of phosphatidylcholines (T_p). T_p^e has not been observed for $C_{19}H_{37}S$–Au, nor has T_p been reported for corresponding phospholipid [15]. Slope = 0.67, correlation coefficient $r = 0.920$.

configuration and density are very similar in the two cases. The underpotential deposition of Pb[10c] established the surface composition of our bulk Au electrodes to be 70% Au(110) and 30% Au(111); consequently the areas occupied by the chains

are 46.9 Å^2 and 43.5 Å^2,[3c] respectively. *n*-Dicylphosphatidylcholines, by comparison, occupy 43–48 Å^2 in their condensed phase.[15] Clearly, the phosphatidylcholine headgroup and the Au lattice serve the same purpose – to enforce a defined packing density on the alkyl chains. The surface packing of chains in a RS monolayer on a Au(100) surface is 18% more dense.[3c] Because phosphatidylethanolamine lipids are packed tighter and have higher T_m's than phosphatidylcholines, we expect an RS monolayer on Au(100) to exhibit higher T_m^e's than those shown in Figure 2.

The T_p^e for the monolayer also correlates with phosphatidylcholine data, but (given the scatter in the data) may be attenuated to about 70% of the lipid T_p value (Fig. 2B, slope = 0.67). This may arise because the position of the headgroup is fixed in the SAMs where the Au–S bond eliminates the possibility of vertical motion of the alkyl chains necessary for a periodic rippling of the surface. The current increase at T_p^e is caused by enhanced permeability along tilt/untilt boundaries in the monolayer.

The experimental observation of thermally induced changes in RS–Au monolayers depends upon two conditions. Firstly, only if contact times between electrode and monolayer-forming solutions are prolonged (from days to weeks) will the features shown in Figure 1 arise. Chain ordering is apparently a very slow process[1d, 18] and may also be accompanied by RSH-assisted Au reconstructions. Dissolution of Au surface features or reconstructions of the binding sites of the sulfur on the Au are also possible.[19, 20] Secondly, the thermal history of the electrode is important. The complex behavior does not arise for many as prepared electrodes and all annealed electrodes. These share another form of temperature dependence, to be described elsewhere in a detailed description of the electrochemistry.[21] Preliminary studies show that kinetics are important in these systems. Figure 3 shows the behavior of a $C_{16}H_{33}S$–Au electrode under a heat-cool-reheat cycle. These annealed electrodes do not re-exhibit a maximum (as in Fig. 1) unless subjected to prolonged cooling at about 5 °C.

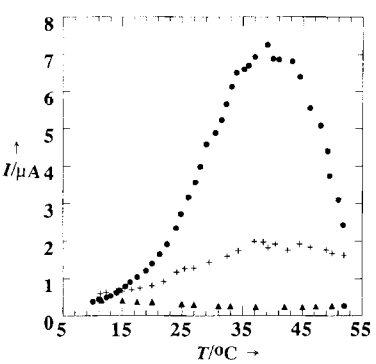

Fig. 3. Electrochemical thermogram (see Fig. 1 caption for experimental details) showing a heat-cool-reheat cycle for a $C_{16}H_{33}S$–Au electrode. The $C_{16}H_{33}S$–Au electrode was cycled as follows: • initial heating curve of the electrode modified at 23 ± 2 °C; ▲ the electrode was cooled to 15 °C, removed from the electrochemical cell, and held at about 5 °C in air for 18 h; + $C_{16}H_{33}S$–Au electrode was subjected to a second heating cycle.

We conclude that SAMs which have been prepared under conventional conditions or have been annealed may be viewed as assemblies of disordered chains with short range order (as reported by FT-IR). However, the order is insufficient to manifest phase transitions. Interestingly, order/disorder transitions are predicted by molecular dynamics simulations,[22] and a recent analysis shows that a domain must be a minimum size to manifest a phase co-existence region.[23, 24]

The film discontinuities responsible for the electrochemical thermogram features (Fig. 1) are intrinsic to SAMs that have been prepared under the experimental conditions described. The film discontinuities reported here are *not* the ill-defined pathological defects frequently invoked as disclaimers of film imperfection. These latter generic defects are synonomous with thin patches, defect regions commensurate with Au substrate defect structures, or regions where a coadsorbate is clustered. The sites of enhanced passive diffusion responsible for maxima as in Figures 1 and 2 are clearly thermodynamically controlled. This is apparent, because they exist at defined temperatures and are determined solely by the chain length of the alkane thiol adsorbate. Correlation with lipid thermotropic behavior suggests that the lattice spacing imposed by the Au substrate determines the chain packing density. Our studies suggest that order/disorder phase transitions are possible in SAMs. It is clearly more correct (and interesting) to consider RS–Au monolayers as structures with both rich phase properties and complex reorganization kinetics than to view them as "defect-free" hydrocarbon slabs.

Experimental Procedure

n-Octadecanethiol ($C_{18}H_{37}SH$; Aldrich, 98%) was recrystallized three times from ethanol. *n*-Hexadecanethiol ($C_{16}H_{33}SH$), heptadecanethiol ($C_{17}H_{35}SH$), nonadecanethiol ($C_{19}H_{39}SH$), and icosanethiol ($C_{20}H_{41}SH$) were synthesized by standard procedures. Their purity was monitored by ^1H and ^{13}C NMR spectroscopy, thin layer chromatography, mass spectrometry (NH_3, CI), and melting point determination by differential scanning calorimetry (DSC). The melting point measurements by DSC are particularly useful in detecting the presence of trace amounts of homologous hydrocarbons.

Bulk polycrystalline Au electrodes (0.020 cm^2 geometric area; BAS, West Lafayette, IN) were mechanically polished (Buehler, Ecomet II polisher) on microcloth pads with alumina (Buehler) slurries of decreasing particle size (1.0, 0.3, and 0.05 μm). The polished electrodes were sonicated in H_2O to remove any residual polishing alumina from the Au surface. The sonicated Au electrodes were then rinsed copiously with H_2O and subsequently with absolute ethanol, and were immediately immersed in RSH solutions. The Au substrates were immersed in 5 mL argon-saturated ethanol solutions (to prevent the formation of thiol multilayers) of the thiol in sealed glass vials (2–5 mM RSH) at 23 ± 2 °C for days to weeks [25]. The RSH-modified electrodes were rinsed copiously with ethanol, followed by H_2O, immediately prior to the electrochemical experiments.

The RS–Au working electrode was introduced into a degassed, thermostated (Haake G circulating bath) 150 mL cell containing 0.1 M KBr electrolyte (Anachemia) and 0.020 M $K_3[Fe(CN)_6]$ (BDH). Deionized H_2O (18 MΩcm^{-1}) was obtained from a Milli-Q water system (Millipore; 3 bed ion-exchange/1 bed organic removal cartridge unit) connected to distilled water. The counter electrode was a Pt wire (Aldrich), and all potentials are referred to a Ag/AgCl electrode (BAS; 3 M NaCl). Currents were obtained from cyclic voltammograms (BAS 100B electrochemical analyzer) at 20 mVs^{-1} between +500 mV and −150 mV. Typical heating rates of 0.2 to 0.3 °Cmin^{-1} were used for all experiments. The $[Fe(CN)_6]^{3-}$ reduction current reported at each temperature was measured from the cathodic segment of the cyclic voltammogram at $\eta = -250$ mV for $[Fe(CN)_6]^{3-/4-}$ at that temperature.

Synthesis of the First Microporous Aluminum Phosphonate with Organic Groups Covalently Bonded to the Skeleton**

Kazuyuki Maeda,* Yoshimichi Kiyozumi, and Fujio Mizukami

Zeolites and similar microporous solids are important materials for adsorbents and catalyst systems and can be used as ion exchangers and for many other applications.[1] Therefore, great effort has been made to develop new microporous crystalline materials.[1, 2] Among them, compounds of the family of aluminophosphates (ALPO) adopt a great variety of structures depending on the synthesis conditions, in particular, on the organic additives used as the structure-directing agent.[3] In these microporous solids, however, the wall of the channel is generally composed of oxygen atoms, which are larger than aluminum and phosphorus atoms.[4] The character of the micropore, therefore, is fundamentally determined by the arrangement of the oxygen atoms, but also from the elements incorporated in the framework. In this study we wanted to develop a new family of microporous aluminophosphonates whose channel walls are modified by the introduction of organic groups directly attached to the phosphorus atoms.

A zirconium phosphite–diphosphonate, a microporous inorganic–organic polymer has been reported previously.[5] The proposed structural model of this compound is based on zirconium phosphite layers partly pillared by organic groups.[5] The structure of the novel microporous aluminum methylphosphonate AlMepO-β prepared by us differs from this structure: it is based on a three-dimensional inorganic framework, in which organic groups are covalently bonded to the skeleton.

AlMepO-β was obtained as needlelike crystals in a hydrothermal reaction in which no structure-directing agent was used; however, cationic or neutral amines are usually necessary for synthesis of ALPOs.[3] The elemental analyses of AlMepO-β synthesized in this way gave the following composition; C 10.5, H 3.2, Al 15.2, P 27.6%. The P/Al ratio calculated from the elemental analyses is 1.58 and the H_2O/Al ratio is estimated to be 0.5 from both the elemental analyses and thermogravimetry. The values obtained correspond fairly well with the ideal composition of the neutral salt of aluminum methylphosphonate, $Al_2(CH_3PO_3)_3 \cdot H_2O$ (C 10.2, H 3.1, Al 15.2, P 26.3%).

The powder X-ray diffractogram of AlMepO-β (Fig. 1, bottom) showed a characteristic pattern with a strong reflection at

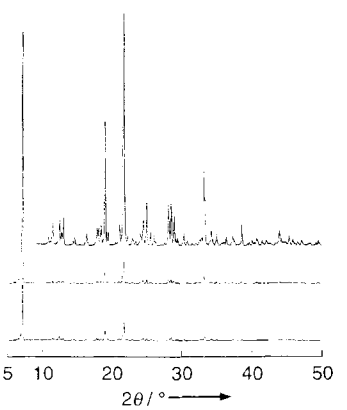

Fig. 1. X-ray powder diffraction pattern of AlMepO-β (bottom) and AlMepO-β dehydrated at 500 °C for 6 h (middle and top (× 10)).

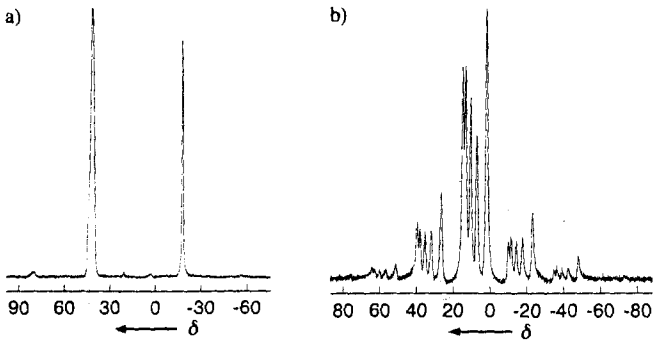
[**] We thank Dr. J. Akimoto, National Institute of Materials and Chemical Research, Tsukuba, Japan, for the X-ray diffraction measurement of the single crystal.

7.2° ($d = 12.3$ Å). The reflections were indexed to a rhombohedral unit cell; a few lines were attributed to impurities. The cell dimensions were refined to give $a = b = 24.72(2)$, $c = 25.33(2)$ Å (hexagonal axes).[6] Since AlMepO-β degassed at 500 °C under vacuum for 6 h also gave an essentially identical diffraction pattern (Fig. 1, middle), it can be concluded that AlMepO-β is not a layered compound intercalating water, but a microporous solid with a three-dimensional framework which adsorbs water. From the above compositional formula and the density (1.65 g mL^{-1}) of a crystal, the number of $Al_2(CH_3PO_3)_3 \cdot H_2O$ units per unit cell, which should be crystallographically meaningful, is estimated at 36. The framework density, the number of tetrahedrally surrounded atoms (T) per 1000 Å^3, is generally used to discriminate microporous phases from densely packed phases. A microporous phase is present in most cases if the framework density is smaller than 20–21 T per 1000 Å^3.[7] The calculated framework density of AlMepO-β (13.5 T per 1000 Å^3),[8] which is as small as that for the known aluminophosphates VPI-5 (14.2) and MAPSO-46 (13.7),[7] supports a microporous structure, although there should be methyl groups in the cavities.

The ^{27}Al MAS-NMR spectrum of AlMepO-β (Fig. 2a) shows two sharp signals at $\delta = -17.6$ and 41.2, which are assigned to six- and four-coordinate aluminum centers, respectively (ratio of 1:3). The chemical shift of $\delta = 41.2$ lies in the range of signals reported for aluminophosphates[9, 10] whose (AlO_4) units are surrounded by four phosphate units. Also the position of the signal at $\delta = -17.6$ corresponds to those reported for six-coordinate aluminum atoms in ALPOs, which are coordinated to water molecules.[9] Because dehydration of AlMepO-β by evacuation at 400 °C did not change the intensity ratio of the two peaks, we can conclude that the observed six-coordinate aluminum centers are indeed present in the framework structure.



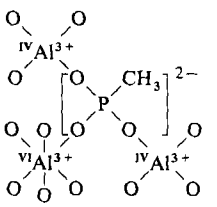


Fig. 2. ^{27}Al MAS-NMR spectrum (a) and ^{31}P MAS-NMR spectrum (b) of AlMepO-β.

The ^{31}P MAS-NMR of AlMepO-β showed five sharp signals at $\delta = 1.5, 6.9, 10.3, 13.1$, and 14.7 (intensity ratio ca. 2:1:1:1:1; Fig. 2b), while that of methylphosphonic acid gave a broad signal at $\delta = 37.6$. The number of the signals suggests that the number of the crystallographically independent atoms is at least five, probably six. In various microporous aluminophosphates, a phosphate group connected with four aluminate units generally gives rise to peaks in the range $-23 \geq \delta \geq -34$,[11] which is typical for tetrahedrally coordinated phosphorus oxide. The difference in chemical shifts of these phosphates ($-23 \geq \delta \geq -34$) and those of AlMepO-β ($1 \leq \delta \leq 15$) almost correspond to the shift of the signal to lower field ($\Delta\delta = 37.6$) caused by the substitution of a hydroxy group for a methyl group in phosphoric acid.

The ^{13}C CP/MAS NMR spectrum, which showed a cluster of incompletely resolved peaks ($11 \leq \delta \leq 14$) in the region of the chemical shift of methylphosphonic acid [$\delta = 11.3$ (d, ^1J(C,P) = 140 Hz)], also supports the proposal that the methyl groups in AlMepO-β remain bonded to the phosphorus atom. From the above NMR results and elemental analysis, it is reasonable to propose that two of the O atoms of the CH_3PO_3 unit are bound to two Al centers with coordination number four and that one O atom is bound to a six-coordinate Al center. All AlO_n groups are only surrounded by CH_3PO_3 units (Scheme 1). AlMepO-β is a new network, in which three AlO_n groups are coordinated to the P atoms, and formal AlO_4 and AlO_6 groups are included.

Scheme 1. Postulated repeat unit of the structure of AlMepO-β.

The nitrogen adsorption isotherm for AlMepO-β degassed at 400 °C for 6 h shown in Figure 3 is classified as Langmuir type (the type 1 of the IUPAC classification[12]) and is typical of microporous substances.[13] The micropore volume of the sample is estimated to be 0.117 cm^3 g^{-1} based on the DR plot,[14] and the BET specific surface area is calculated at 297 m^2 g^{-1}; for the latter the values of the low-pressure region of the isotherm ($p/p_0 < 0.04$) were used.[15]

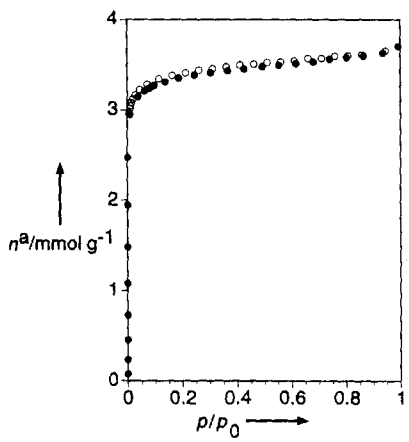

Fig. 3. Nitrogen adsorption isotherm of AlMepO-β degassed at 400 °C for 6 h; •: adsorption branch, o: desorption branch.

Recently Huo et al. revealed that micellar, cubic, and hexagonal phases of periodic surfactant/inorganic composites can be obtained for various combinations of inorganic species and surfactants.[16] They also suggested that a monoalkylphosphate used as a surfactant could be a part of the frameworks in compounds with Zn or Al. Among the three phases, the hexagonal one MCM-41[17] contains unidimensional channels stuffed with surfactants. Accordingly, we presume that AlMepO-β possesses channels lined by methyl groups, since the steric hindrance between the organic groups should be minimized in a larger pore. This assumption is supported by a water adsorption isotherm of AlMepO-β, which shows the hydrophobic character.[18] At present, further detailed structural analyses including crystallographic studies are in progress.

The sizes and shapes of micropores bordered by organic groups can be varied by changing the phosphonic acids and the synthesis conditions. Such porous materials with ordered structures of organic functional groups not only will serve as sorption media and separation materials, but also may find unique electric or optic applications.

Experimental Procedure

Typical synthesis: Pseudo-boehmite powder (PURAL SCF from Condea Chemie; 74.4 wt.% Al_2O_3, 25.6 wt.% water) and methylphosphonic acid (Aldrich, 98 wt.%) were dispersed in water ($Al:P:H_2O = 1:1.5:40$) by stirring at ambient temperature for 1 h. Subsequently, the mixture was hydrothermally treated at 160 °C for 48 h under an autogenous pressure using an autoclave with a Teflon sleeve in a thermostated oven. The air-dried crystals were subjected to elemental analyses and ICP analyses (Al and P). The density of a single crystal was determined pycnometrically.

[6] The rhombohedral lattice was confirmed initially by a single-crystal X-ray diffraction, and the lattice parameters were approximately determined. The reflections from the small crystals were not strong enough to be used in the refinement of the lattice parameter. Accordingly, the refinement was based on the nine best resolved peaks ($2\theta = 18-30°$) in the powder X-ray diffractogram.

1-Oxa-3,5,7,9-tetraazadecapentaene, a Model Oligonitrile with a Helical Structure in the Crystalline State**

Martin Buhmann, Manfred H. Möller, Ute Rodewald, and Ernst-Ulrich Würthwein*

Dedicated to Professor C. Reichardt on his 60th birthday

Polyacetylenes (polyenes) have become important recently as advanced materials on account of their special electrical and optical properties. However, to our surprise, hardly any linear polynitriles have been investigated. Their defined unsaturated chains with carbon and nitrogen atoms in an alternating sequence[1] contain polar C=N bonds, together with the free electron pairs on the nitrogen atoms; both should lead to interesting physical and chemical properties not feasible in the polyacetylenes. Pursuing a systematic concept we have developed new routes in organic chemistry for the controlled synthesis of oligonitriles with defined chain lengths. In two recent publications we have reported on 1-oxa-3,5-diazahexatrienes[2] and 1-oxa-3,5,7-triazaocatetraene;[3] here we publish our results on the longest yet synthesized of this type of compound with ten chain atoms, a 1-oxa-3,5,7,9-tetraazadecapenta-1,3,5,7,9-ene. To enable further chain lengthening, all these molecules contain a terminal carbonyl group,[4] which should hardly influence the electronic system of the oligonitrile.

Target molecule **1** is easily synthesized by the reaction of the lithiated 1,3-diazabutadiene **2**-H[5] with the 1,3,5-oxoniadiazine salt **3**[6] at −78 °C, followed by purification by flash chro-

matography and recrystallization (in addition about 10% of 2,4,6-triphenyl-1,3,5-triazine is formed). The constitution of **1** was clearly established by means of IR and ^{13}C NMR spectroscopy (Table 1). In solution at room temperature **1** shows a single set of sharp NMR signals; the presence of several isomers or ring-chain tautomers like those we observed with the shorter homologues[2, 3] can therefore be excluded for the NMR time scale available to us.

Table 1. Selected spectroscopic and analytical properties of **1**[a].

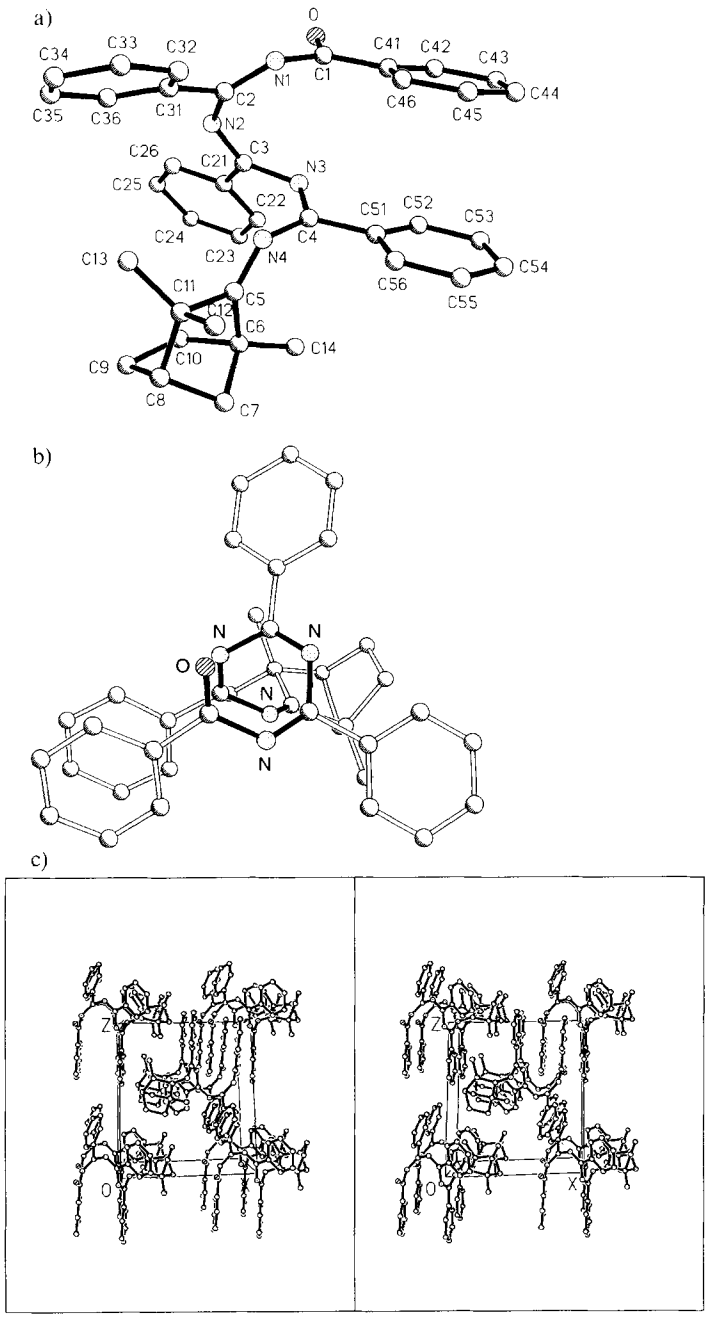

Fig. 1. XS plot [14] of the structures of isomers **1a** (a) and **1b** (viewed down the helix axis, b) in the crystalline phase. The stereoplot (c) shows the crystal packing of **1** (view onto the x,z plane).

cules of **1** in a unit cell, one of which is present uniquely as an (*P*)-helix with a (*Z*)-configurated N4=C5 bond (isomer **1a**) and the other is disordered: an (*M*)-helix with an (*E*)-N4=C5 bond (68%, isomer **1b**) is overlapped by 32% of an (*M*)-helix with a (*Z*) N4=C5 bond (isomer **1c**). The 3_1-helical structures in the oligonitrile part of all three isomers **1a–c** are formed by the all-(*Z*)-configurated C=N bonds with *gauche* C–N conformations of identical sense in which isomer **1a** has the opposite helical sense to isomers **1b** and **1c**. All the isomers contain an (*R*)-trimethylnorbornylidene group as a consequence of the synthetic method and are therefore diastereoisomeric. The isomerism and the disorder are an indication to us that the importance of the configuration of the trimethylnorbornylidene as an almost spherical end group should not be overemphasized. Apparently, different configurations find sufficient space in the crystal lattice. A dependence of the helical sense on the absolute configuration of the trimethylnorbornyl group does not, therefore, exist; rather, if the configuration of the trimethylnorbornylidene residue and the N4=C5 bond is neglected, the helices are present as mirror images. The pitch of the helices is 3.4–4.3 Å; the two phenyl groups on C1 and C4 are also about the same distance apart (3.5–3.8 Å); in graphite[8] there are corresponding separations between two layers, and similar electronic interactions may be expected here.

The preference for a three-dimensional structure over a planar all-*trans* configuration can be explained by looking at simple model compounds. 1,3-Diazabutadiene, according to experimental and quantum mechanical investigations[9, 10] is present in a preferred *gauche* conformation of the central C–N single bond; in this way a low dipole moment can be achieved by bond dipole compensation. The (*Z*) configuration of the C=N bonds is already favored in the shorter oligonitrile model compounds.[2, 3] The combination of these two structural elements leads inevitably to tertiary structures with helical elements.

By means of ab initio quantum mechanical calculations (MP3/6-31G*//6-31G*)[11] on isomers of 1-oxa-3,5,7,9-tetraazadecapenta-1,3,5,7,9-ene as a model compound (that is, without considering the phenyl groups), we searched for evidence of an energetic preference for the helical structure in isolated molecules in the gas phase (Fig. 2). No evidence was

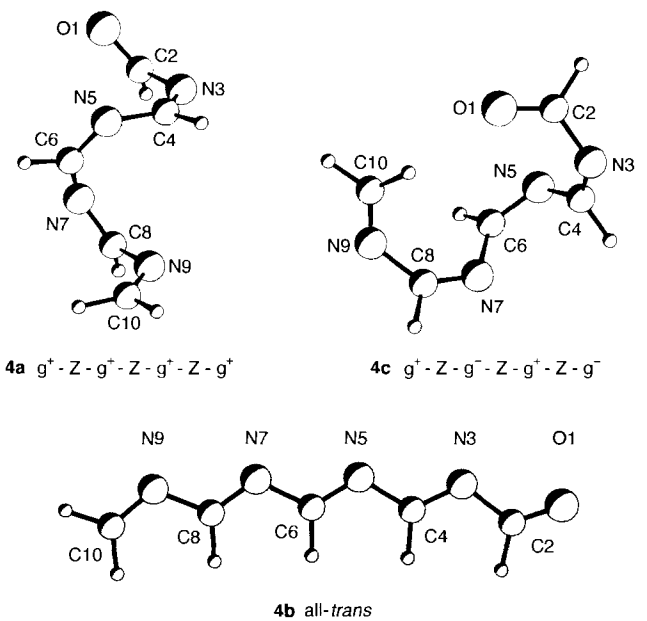

Fig. 2. Structures **4a–c** calculated by ab initio methods (6-31G*//6-31G*).

found; instead the helical structure **4a** is of relatively high energy (E_{rel}(**4a**) = 7.56 kcal mol^{-1}) and exhibits a high dipole moment (8.02 Debye) whose vector lies approximately in the direction of the axis of the helix. The calculated pitch (4 Å) corresponds with that determined for **1** by X-ray analysis. Even higher in energy, as expected, is the planar and—because of the unequal C-N-C and N-C-N bond angles—bow-shaped all-*trans* configurated isomer **4b** (E_{rel}(**4b**) = 10.1 kcal mol^{-1}, μ = 11.79 Debye).[12] The lowest energy isomer is calculated to be the all-(*Z*) configuration with alternating (+)-*gauche* and (−)-*gauche* conformations about the C–N bonds (E_{rel}(**4b**) = 0.00 kcal mol^{-1}; E_{tot}(MP3/6-31G*//6-

31G* = −486.86848 Hartree); the best dipole moment compensation is achieved through the short helical sections with opposed senses in this isomer ($\mu = 1.92$ Debye). According to these results the tertiary structure determined by X-ray crystallography is the result of intra- and intermolecular packing effects in which the bulkiness of the phenyl groups on C1 and C4 plays an important role. In the packing diagrams of **1** (Fig. 1c) these phenyl rings are arranged parallel to the *y*,*z* plane. Thus a particularly favorable packing of the helices (3_1-helices, Fig. 1b), which resemble three bladed propellers seen from the top, can be achieved. The crystal structures and model quantum mechanical calculations for the shorter homologues (similarly without taking the phenyl groups into account) agree very well.[12, 3]

From the diversity of the established structures a high intramolecular flexibility may be deduced. In our earlier studies we estimated low barriers for rotation around the C–N bonds (about 4–5 kcal mol^{-1});[10] also (*E*)/(*Z*) isomerization of the C=N bonds seems possible, during which transition states with a zwitterionic cumulene structure are traversed (about 20 kcal mol^{-1} activation energy for 1,3-diazabutadienes,[9] and 12 kcal mol^{-1} for *N*-acylimines[13]). This may also explain the discrepancy between the single set of signals found in the NMR spectra for a solution and the complex X-ray results.

The X-ray and quantum mechanical results also supply a convincing explanation for the electronic spectra of **1**; since there is clearly no extended π-electron system present ($\lambda_{max} < 270$ nm) but a sequence of strongly twisted amidine units and an amide unit, no long-wavelength π–π* absorption bands appear; the π–π* transitions are hidden by arene bands.

Experimental Procedure

1: *n*-Butyllithium solution (1.6 M, 2.7 mL, 4.4 mmol) was slowly added to a solution of *N*,*N*-(1,3,3-trimethylbicyclo[2.2.1]hept-2-ylidenebenzamidine [5] (2-H, 1.11 g, 4.4 mmol) in THF (15 mL) at −78 °C. After 5 min a suspension of 2,4,6-triphenyl-1,3,5-oxadiazinium pentachlorostannate (**3**, 2.65 g, 4.4 mmol) in THF (50 mL) was added dropwise, and the reaction mixture was stirred at −78 °C. The reaction mixture was allowed to warm to room temperature over approximately 12 h. After 27 h the mixture was cooled to 0 °C, and the cloudy, yellow solution was shaken with 40 mL of ice cold 1 N sodium hydroxide solution. The aqueous solution was extracted twice with dichloromethane (20 mL). The combined organic phases were dried over magnesium sulfate, and the solvent removed under vacuum. The residue was taken up in a little dichloromethane, filtered, and worked up by flash chromatography (petroleum ether/diethyl ether 2/1, **1**: $R_{f(DC)} = 0.24$). The yellow residue thus obtained was recrystallized from diethyl ether. Yield 0.84 g (34%) **1**, pale yellow crystals; m.p. 155 °C.

Tether-Directed Remote Functionalization of Buckminsterfullerene: Regiospecific Hexaadduct Formation**

Lyle Isaacs, Richard F. Haldimann, and François Diederich*

Following the development of a great variety of methods for monofunctionalization,[1] the regiospecific formation of covalent polyadducts has become the frontier in the chemistry of buckminsterfullerene C_{60}.[2] Reversible reactions with transition metal complexes[3] or halogens[4] yield the thermodynamically most stable isomer or an isomer that selectively crystallizes out of the reaction mixture. Alternatively, mixtures of many possible multiple adducts are produced by successive, irreversible reactions at the C_{60} sphere. Purification is then achieved by tedious, scale-limiting HPLC separation of the isomeric mixtures or by recrystallization, when possible.[2] In an attempt to develop a more rational approach to the production of one desired regioisomer in multiple functionalization reactions, we turned to the tether-directed remote functionalization of C_{60}, a concept that was introduced by Breslow for the regioselective functionalization of steroids and long-chain alkanes.[5] Here, we describe the application of remote functionalization to the regiospecific formation of bis- and trisadducts of C_{60}. With a trisadduct as the starting material, formation of a hexaadduct with the six functional groups aligned in pseudooctahedral positions on the C_{60} surface (positions *a*–*f* in Fig. 1) is readily achieved. This unique functionalization pattern has previously only been described for transition metal complexes.[3, 6] All compounds are isolated in pure form without the application of HPLC methods.

[**] This work was supported by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung.

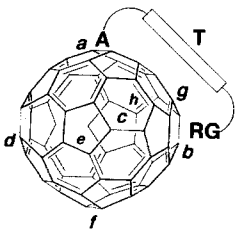

Fig. 1. Schematic depiction of the tether-directed remote functionalization of C_{60}. The bonds a–f (in red) represent the six pseudooctahedrally disposed double bonds on the C_{60} sphere; bonds g and h (in green) do not react with the reactive group for steric reasons. A = anchor, T = tether, RG = reactive group.

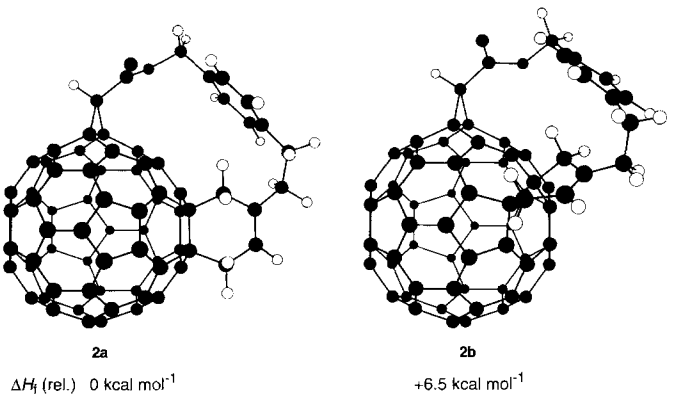
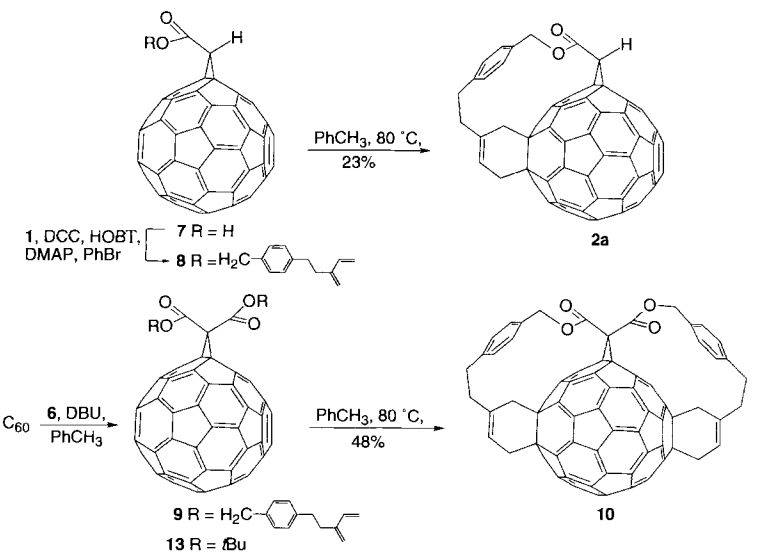
First, we targeted the regiospecific production of an equatorial bisadduct of C_{60} (Fig. 1) using a reactive group anchored by a tether to the fullerene. As the anchor, we chose the carboxylate of the methanofullerene carboxylic acid **7**[7] (Scheme 2) and as reactive group, a 2-substituted 1,3-butadiene known to undergo irreversible Diels–Alder reactions with C_{60} at 6-6 bonds (bonds between two fused six-membered rings).[8] The choice of the tether between anchor and reactive group was critical for the regioselective attack. Its size and shape were chosen to favor attack at the equatorial bond b (Fig. 1) over attack at the other possible reactive 6-6 bonds g and h located in the same hemisphere in somewhat closer proximity to the anchor bond a (Fig. 1). PM3 computational studies[9] show that the chosen 4-substituted benzyl alcohol tether in **1** (Scheme 1) would lead to a preference for the targeted bisadduct **2a** over regioisomer **2b**. The heat of formation of **2a** is calculated to be 6.5 kcal mol^{-1} lower than that of the lowest energy conformer of **2b** (Fig. 2). A close examination of the calculated geometry of **2b** shows that the tether is too short in the conformer shown and too long in the higher energy conformer in which the double bond of the cyclohexene boat is oriented towards the anchor. This mismatch of the tether length leads to distortions in the bridging benzene ring and also to skewing of the ester group, which both increase the heat of formation. The different symmetries of **2a** (C_s) and **2b** (C_1) should make it easy to identify by ^{13}C NMR spectroscopy the bisadduct formed.





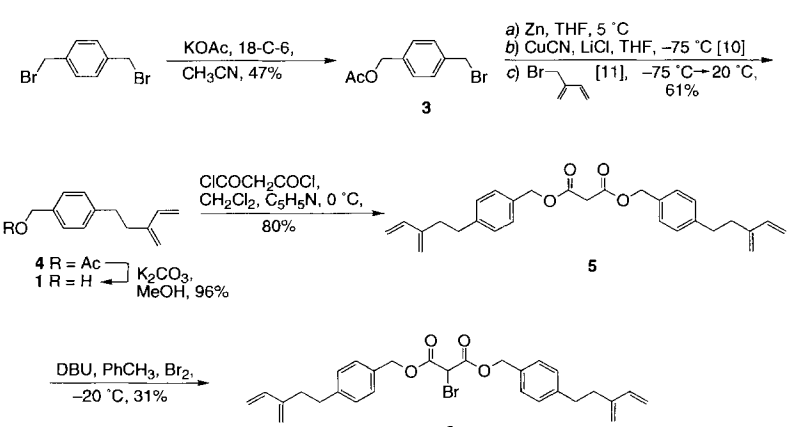


Fig. 2. PM3-calculated structures and heats of formation for the two possible regioisomeric bisadducts **2a** and **2b**.

Scheme 2. Synthesis of the bis- and trisadducts **2a** and **10**. DCC = dicyclohexylcarbodiimide, HOBT = 1-hydroxybenzotriazole, DMAP = 4-dimethylaminopyridine.

The synthesis of **1**, which contains both tether and reactive group, is shown in Scheme 1. Reaction of **1** with **7** (Scheme 2) under dicyclohexylcarbodiimide (DCC) coupling conditions[7] afforded the intermediate wine-red methanofullerene **8**, which was purified by flash chromatography (SiO_2, toluene/hexane 2/1) and identified in solution by the two diagnostic UV/VIS absorption bands of a monoadduct at λ_{max} = 429 and 692 nm. Further characterization was not attempted owing to the rapid polymerization of **8** upon evaporation to dryness. However, heating of a solution of **8** (ca. 0.1 mM) in toluene to 80 °C led to a color change from wine-red to yellow-orange. Flash chromatography (SiO_2, toluene/hexane, 2/1) followed by recrystallization (CS_2/hexane) afforded the isomerically pure bisadduct **2a** in 23% yield, which was fully characterized spectroscopically (Table 1). The presence of 32 signals for the fullerene C atoms in the ^{13}C NMR spectrum demonstrates conclusively that the Diels–Alder reaction occurred at the equatorial double bond b (Fig. 1) with formation of the C_s-symmetrical isomer. The bisadduct, like the other highly functionalized fullerenes described below, is air- and light-sensitive and must be stored under argon in the dark. One other fullerene product (ca. 5% yield) was also present in the reaction mixture, but matrix-assisted laser desorption–ionization time-of-flight mass spectrometry (MALDI-TOF MS)

Scheme 1. Synthesis of the "tether–reactive group" fragments **1** and **6**. 18-C-6 = [18]crown-6, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

[a] All new compounds in Scheme 1 were fully characterized by ^{1}H and ^{13}C NMR, FT-IR, and EI-MS data, as well as by elemental analysis or high-resolution MS. [b] MALDI-TOF MS spectra were measured with 2,5-dihydroxybenzoic acid or 2-(4-hydroxyphenylazo)benzoic acid as the matrix.

showed it to be a by-product due to oxidation[2d] of **2a** rather than a regioisomeric bisadduct. The rather low isolated yield of **2a** is a reflection of the difficulties encountered with its chromatographic separation from its oxidation product.

For the regiospecific formation of a trisadduct resulting from double Diels–Alder addition to the two equatorial double bonds *b* and *d* (Fig. 1), the doubly tethered system **6** was prepared (Scheme 1) and anchored to C_{60} by the versatile α-bromomalonate alkylation method introduced by Bingel.[12] Addition of **6** to C_{60} (2 equiv) in toluene with DBU as base gave methanofullerene **9**. Following flash chromatography (SiO_2, toluene/hexane, 1/1 then 2/1) to recover the excess C_{60}, the identity of **9** was established by ^{1}H NMR and UV/VIS spectroscopy. The ^{1}H NMR spectrum showed all expected resonances for tether and reactive groups, and the electronic absorption spectrum contained the two diagnostic monoadduct bands at λ_{max} = 429 and 690 nm. Heating of a solution of **9** in toluene (ca. 0.07 mM) at 80 °C for 83 h resulted in a color change from wine-red to yellow-orange. Flash chromatography (SiO_2, toluene) afforded a single trisadduct (48% yield based on **6**), which was assigned the C_{2v}-symmetrical structure **10** on the basis of its spectroscopic data (Table 1). The ^{1}H NMR spectrum of **10** is similar to that of **2a**, except that the signal corresponding to the methine resonance in the methano bridge is absent. The ^{13}C NMR spectrum shows the expected 17 resonances for the fullerene C atoms in a C_{2v}-symmetrical molecule.

The fact that we had access to relatively large quantities (ca. 100 mg batches) of trisadduct **10**, prompted us to test the regioselectivity of further reactions on the fullerene sphere. The regioselectivity observed by Hirsch et al.[2b] in the formation of a trisadduct (*a*,*b*,*c*-functionalized, Fig. 1) from an equatorial bisadduct (*a*,*b*-functionalized) made us optimistic that further functionalization of **10** would lead to regioisomerically pure tetra- through hexaadducts. When a 1 mM solution of **10** in chlorobenzene was reacted with five equivalents of diethyl α-bromomalonate and DBU at room temperature (Scheme 3), the

Scheme 3. Synthesis of the tetra- and hexaadducts **11** and **12**.

C_s-symmetrical bright red tetraadduct **11** functionalized at the *a*,*b*,*c*,*d* bonds was selectively obtained in 72% yield. The ^{1}H NMR spectrum of **11** shows two sets of ethyl ester resonances, and the presence of 32 fullerene-core resonances in the ^{13}C NMR spectrum supports the assigned molecular symmetry (Table 1). When an 18 mM solution of **10** was reacted with a tenfold excess of the reagents, flash chromatography (SiO_2, CH_2Cl_2) allowed the isolation of the bright yellow hexaadduct **12** in 73% yield. The overall yield of **12** was a remarkable 35% based on C_{60}.

In the MALDI-TOF mass spectrum of **12**, the expected molecular ion appears as the base peak at m/z = 1637, in addition to weaker peaks resulting from the fragmentation of the ethyl malonates. In accord with the proposed C_{2v}-symmetrical structure, the ^{1}H NMR spectrum contains three nonequivalent ethoxy groups, and the ^{13}C NMR spectrum shows 17 resonances for the fullerene core C atoms. Hexaadduct **12** is highly soluble and dissolves readily in chlorinated and aromatic solvents; more than 40 mg can be dissolved in 1 mL of $CHCl_3$.

The change in the extent of conjugation in the fullerene chromophore when passing from a mono- to a hexaadduct is readily apparent from the visual color changes. Accordingly, the electronic absorption spectra change dramatically (Fig. 3). Compared to C_{60}, compound **13** (Scheme 2), which is typical of methanofullerene monoadducts, shows much less fine structure in the 400 to 700 nm range, and a hypsochromic shift of λ_{max} for the broad, long-wavelength band to about 500 nm is observed. Two additional diagnostic bands appear at about λ_{max} = 430 and 700 nm. The characteristic peak at λ_{max} = 700 nm in the spectrum of **13** is no longer observed for the bisadduct **2a**, and the broad band in the visible region is further hypsochromically shifted to λ_{max} = 449 nm. Trisadduct **10** exhibits little fine structure in its electronic absorption spectrum, and the characteristic band at λ_{max} at about 430 nm, present in the mono- and bisadducts, is not observed. However, a new strong band appears at the surprisingly long wavelength of λ_{max} = 498 nm. The spec-

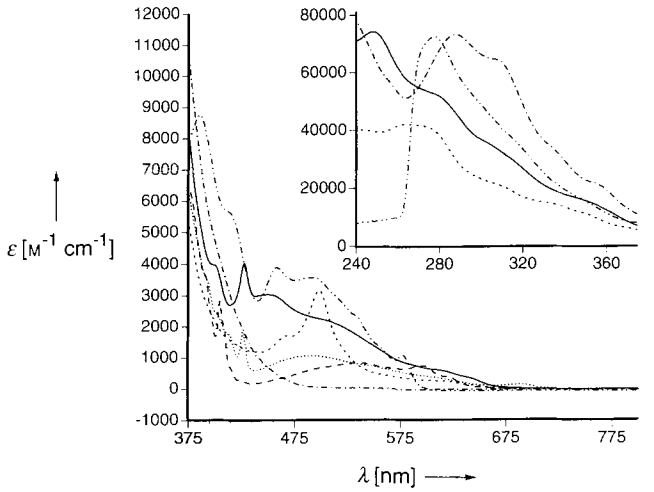

Fig. 3. Electronic absorption spectra of C_{60} (---), **2a** (—), **10** (-----), **11** (·····), **12** (-·-·-), and **13** (····) in CH_2Cl_2.

trum of the tetraadduct **11** is much more intense and structured than that of **10**; no absorption is observed beyond 600 nm in the spectrum of **11**. Hexaadduct **12** has a π system composed of eight benzene-type rings placed in the corners of a cube; each ring is connected to three neighboring rings by biphenyl-type *meta* bonds. Absorption above 475 nm is no longer observed; this is consistent with a drastic reduction in π conjugation as compared to the precursor molecules.

The described tether-directed remote functionalization methodology should provide a versatile entry into the unexplored area of multiply and differentially functionalized buckminsterfullerenes, which may prove to be useful in chemical, materials, and biomedical applications.

Experimental Procedure

Trisadduct **10**: To a solution of C_{60} (264 mg, 0.367 mmol) and **6** (96 mg, 0.183 mmol) in toluene (155 mL) was added DBU (29 mg, 0.187 mmol) in toluene (5 mL) over 5 min. After 2.75 h, the reaction mixture was concentrated to 100 mL, diluted with hexane (100 mL), and chromatographed (SiO_2). Unreacted C_{60} was recovered with a 1:1 mixture of toluene/hexane as eluent; the monoadduct **9** was eluted with a 2:1 mixture. The resulting solution was concentrated on a rotary evaporator to remove the hexane and then diluted to 1.5 L with toluene. The solution was thoroughly deoxygenated by bubbling Ar through the solution for 1.5 h and then heated at 80 °C for 83 h. The reaction mixture was concentrated and loaded onto a column (SiO_2), which was eluted with toluene. Recrystallization from $CHCl_3$/MeOH followed by drying at 25 °C/10^{-1} Torr gave **10** (102 mg, 48% yield) as a black solid.

Hexaadduct **12**: A solution of diethyl α-bromomalonate (42.1 mg, 0.176 mmol) in anhydrous chlorobenzene (0.45 mL) was added under argon to trisadduct **10** (20.5 mg, 0.0176 mmol), and DBU (26.8 mg, 0.176 mmol) in anhydrous chlorobenzene (0.55 mL) was subsequently added to the suspension. After 5 min, a bright red, homogeneous reaction mixture was obtained. After 2 h, the mixture was loaded onto a SiO_2 column and eluted with CH_2Cl_2. The bright yellow product was collected and concentrated to dryness. Recrystallization from CH_2Cl_2/pentane gave, after drying at 25 °C/10^{-1} Torr, **12** (21.1 mg, 73% yield) as a yellow solid.

Polar Superstructures Stabilized by Polymeric Oxometal Units: Columnar Liquid Crystals Based on Tapered Dioxomolybdenum Complexes**

André G. Serrette and Timothy M. Swager*

The design of molecule-based materials requires the controlled assembly of specific superstructures that effectively transform discrete molecular properties into collective material properties. Liquid crystalline (mesomorphic) materials are the best examples of designed supermolecular materials, and the cooperative physical properties of these materials have led to numerous technological applications. The continued development of liquid crystal based technologies requires new types of mesomorphic materials that integrate novel structural elements and physical properties. To this end, liquid crystals and transition metals have been combined to give metallomesogens, materials with new properties.[1] In this report we describe columnar mesomorphism in a new class of metallomesogen based upon dioxomolybdenum complexes with tapered structures. The polymeric $(\cdot\cdot Mo{=}O\cdots Mo{=}O\cdot\cdot)_n$ units in these materials provide a strong organization force that directs the assembly process and stabilizes the mesophase.

Thermotropic columnar liquid crystalline phases of disc-shaped molecules have been extensively studied. However, in recent years the structural diversity of materials displaying a columnar mesophase has grown to include hemi-disc,[2] phasmidic,[3] bowlic,[4] octahedral,[5] and tapered mesogens.[6] Of these columnar materials, the stabilization of mesophases based upon tapered materials is most demanding, requiring the simultaneous assembly of four molecular units to produce the

disc-shaped units which combine to give columnar superstructures. The group of Percec has studied this assembly process and has pointed out the similarities with the association of proteins to form the tobacco mosaic virus.[6a-e] Previous investigations found that the organization of tapered units into columnar mesophases requires strong organizational forces such as the complexation of ions by crown ethers, the segregation of hydrophobic and hydrophilic groups, hydrogen bonding, charge transfer interactions, and the tethering of the mesogens to a polymer.[6]

In an effort to design new types of ferroelectric materials, we are investigating metallomesogen assemblies based upon polar polymeric $(\cdots M{=}O\cdots M{=}O\cdots)_n$ structures.[7] We are particularly interested in hexagonal columnar phases in which the polymeric structure manifests an axial supermolecular dipole along the column's axis. In such a material the hexagonal symmetry leads to dipolar frustration which prevents the antiparallel (antiferroelectric) dipolar order generally observed in achiral polar liquid crystals.[8] Hence, a hexagonal array of dipoles must exhibit either random (paraelectric) dipolar order or a polar (ferroelectric) organization.

We have synthesized the tapered complexes (pyridinediyl-2,6-dimethanolato)dioxomolybdenum **1**, which were designed to form polymeric structures (Scheme 1).[9] When the side chains

Scheme 1. a) 5.0 equiv Na_2CO_3, cat. NaI, acetone, reflux, 2 days, 84–86%. b) (1) 5.5 equiv $NaBH_4$, THF/MeOH (4/1), 0 °C 1 h, 25 °C 2 h, reflux 14 h; (2) 8.0 equiv Na_2CO_3, H_2O, reflux, 2 h, 66–73%. c) 1.0 equiv $[MoO_2(acac)_2]$, $CHCl_3$/MeOH (1/4), reflux, 3 h, 81–83%.

are sufficiently long ($n > 8$), **1** exhibits enantiotropic liquid crystalline behavior (Table 1). The optical textures viewed with a polarizing microscope (Fig. 1) are characteristic of hexagonal

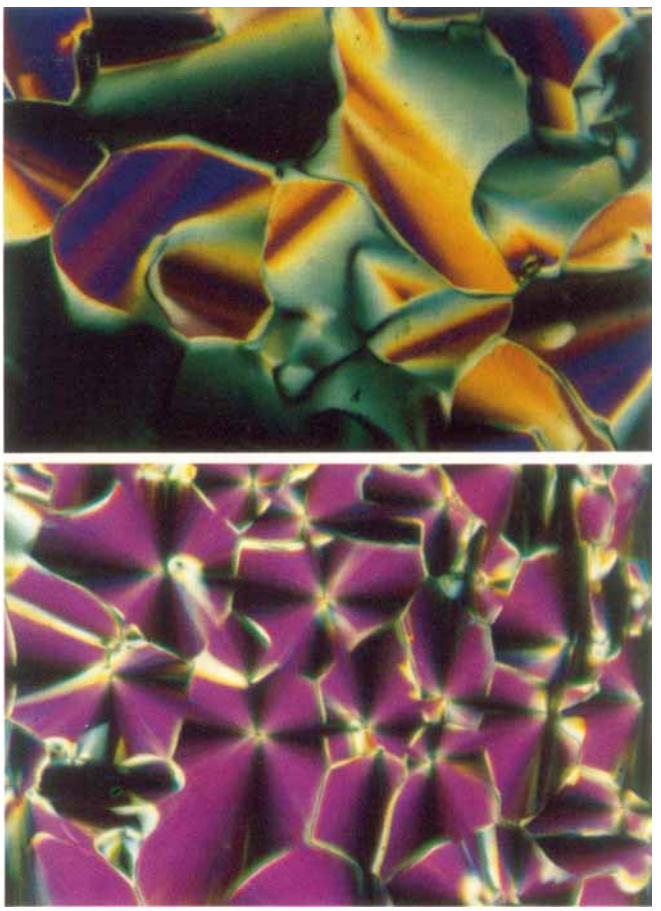

Fig. 1. Optical textures of **1**, $n = 10$, which are typical of hexagonal columnar phases. Top: A relatively thin sample at 121 °C which shows linear birefringent defects and areas of uniform extinction. Bottom: A thicker sample which displays a fan texture at 125 °C.

columnar phases (Φ_h)[10] and display linear birefringent defects, large areas of uniform extinction, and fan domains. Similar to classical discotic phases, the mesophase of **1** mesophase is optically negative. X-ray diffraction (XRD) from the mesophase (Table 2) reveals one strong low-angle peak, two weaker peaks at somewhat higher angle, and a broad halo at wide angle. The low-angle peaks are the (100), (110), and (200) reflections of a hexagonal lattice, and the d-spacing scales as $1:(1/3)^{1/2}:1/2$,

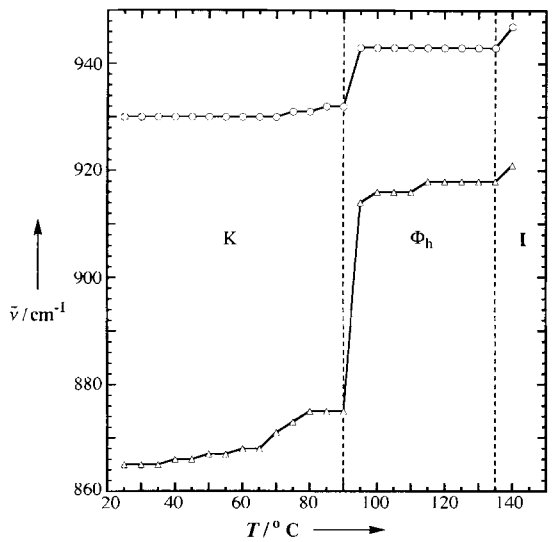
respectively. The presence of a single broad halo at wide angle indicates that there are only weak liquidlike interactions between the mesogens. Consistent with a highly disordered phase, the mesophase-to-isotropic transition enthalpies are small (0.2–0.4 kcal mol^{-1}, Table 1), and the mesophases have qualitatively high fluidity. The Φ_h phase was observed to supercool slightly (3.6–3.8 °C) for the $n = 12$ and 14 compounds. The stability range of the Φ_h phases is 25–45 K, and the phases at lower temperature are labeled as crystalline (K) since the Φ_h-to-K transition has a greater tendency to supercool. However, we do find that these crystal phases are still very disordered, and XRD shows them to have similar diffraction patterns and lattice constants within 1.3% of those exhibited by the Φ_h phase. These similarities between the K and Φ_h phases are also reflected in the fact that most of the Φ_h-to-K transition enthalpies are small.

As mentioned earlier, the organization of tapered mesogens into a columnar mesophase requires a greater thermodynamic driving force than the dipolar attractions that stabilize most liquid crystalline phases.[6] Alone, the pyridinediyl-2,6-dimethanol ligands do not display liquid crystalline behavior. Therefore the ability of **1** to exhibit a stable columnar mesophase arises from the dioxomolybdenum functionality and its tendency to form polymeric $(\cdots Mo{=}O\cdots Mo{=}O\cdots)_n$ structures. Because the dioxomolybdenum unit displays characteristic symmetric and asymmetric Mo=O stretching bands that shift to lower energy in a polymeric structure,[9, 11] the degree of polymeric association could be determined by variable-temperature infrared spectroscopy (VT-IR). As shown for **1**, $n = 14$, in Figure 2, the respective symmetric and asymmetric vibrational



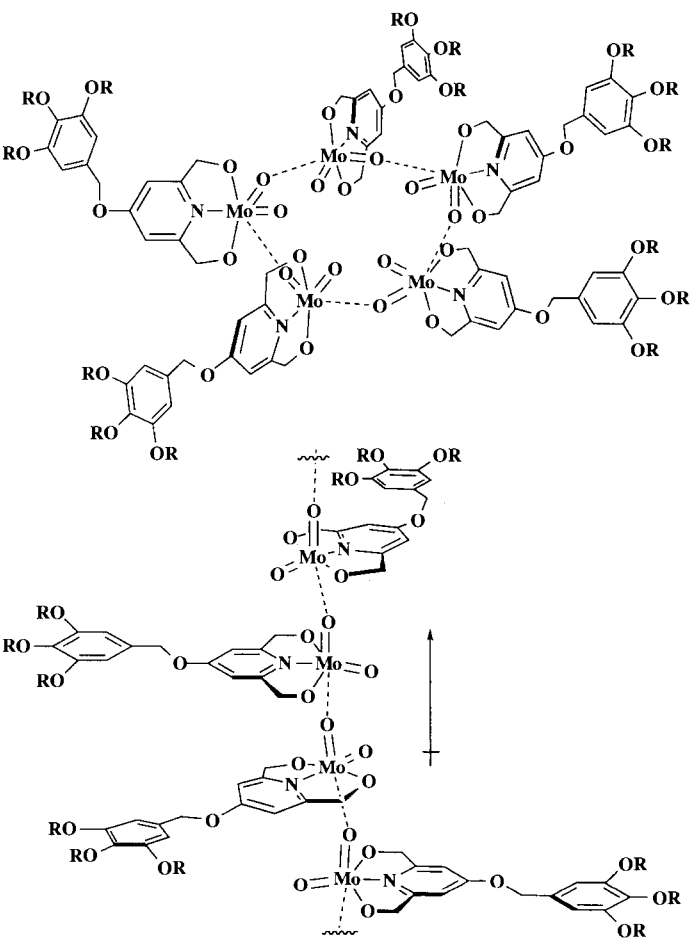


Fig. 2. Plot of the $Mo(O)_2$ stretching frequencies as a function of temperature for **1**. $n = 14$. The circles and triangles are assigned to the $Mo(O)_2$ symmetric and asymmetric stretching modes respectively. A small shift in the I → Φ_h transition indicates that a weakly polymeric structure is formed. The large shift in the Φ_h → K transitions indicates that a strong polymeric structure with strong interactions results.

modes of the $Mo(O)_2$ units in the isotropic phase are observed at 946 cm^{-1} (^{18}O: 893 cm^{-1}) and 921 cm^{-1} (^{18}O: 876 cm^{-1}), and are indicative of a monomeric structure. Upon entering the mesophase, both of these bands shift to slightly lower energy by 4 to 6 cm^{-1}, suggesting the formation of a polymeric structure held together by weak interactions. Further cooling into the crystal phase produces a dramatic shift of both infrared modes to lower energy. The shift of the asymmetric band is greatest at about 50 cm^{-1}, and the shift in the symmetric band is about 13 cm^{-1}. The greater shift of the asymmetric band in both phases is also suggestive of a polymeric structure.

The supermolecular structure of the mesophase of **1** may be deduced from the molecular shape, the lattice dimensions of relative to the molecule's size, and the previously described IR data, which suggest a polymeric or associated structure held together by weak forces. The most reasonable organization whereby a tapered mesogen can produce a columnar phase is one in which the molybdenum head groups are positioned near the center of the column. The effective size of the mesogenic core of **1** in the Φ_h phase can be determined from a plot of the intercolumnar spacing a vs. side-chain length n which yields a straight line. A linear regression of this plot ($R = 0.9995$) gives a slope of 1.03 Å per n and an intercept of 26.1 Å, which is about twice the size of the mesogenic core (i.e. **1**, $n = 0$).[12] This extrapolated value is consistent with a structure in which the molecules extend radially from the center of the column. The VT-IR spectra show only small shifts of the Mo=O bands in the liquid crystalline phase. However, the fact that the crystal phase exhibits a strong polymeric association with a similar structure supports the presence of a weakly associated polymer in the mesophase. On the basis of the IR data alone we cannot discount the possibility of oligomeric macrocyclic (rosette) assemblies (Scheme 2, top). A macrocyclic structure would most

Scheme 2. Possible structures of the Φ_h phase of **1**. The rosette structure (top) is unlikely considering the arguments given in the text. The more likely structure (bottom) has a polymeric $(\cdots Mo{=}O\cdots Mo{=}O\cdots)_n$ assembly which stabilizes the columnar superstructure and manifests a dipole (arrow) along the column's axis.

closely resemble the structures previously proposed for other tapered liquid crystalline materials.[6] However, in the present case, the macrocyclic structure is unreasonable since it would orient the polar oxo groups not assembled in the polymer inward, which generates strong repulsive forces at the column's core. Additionally, macrocyclic association would require the planes of all of the pyridine rings to be oriented along the column's axis. This organization would be highly unusual for a thermotropic liquid crystal since it does not allow for optimal dipolar interactions between neighboring aromatic rings. Thus, we propose that **1** displays the superstructure shown at the bottom of Scheme 2 with the $(\cdots Mo{=}O\cdots Mo{=}O\cdots)_n$ polymeric chain oriented along the column's axis. This organization gives rise to supermolecular dipoles along the columns axis which are frustrated by the hexagonal symmetry of the mesophase. The fluid nature should allow for a facile reorientation of these dipoles, and the electrical properties of these novel materials will be the subject of future reports.

A Novel Type of Stereoisomerism in Calix[4]arene-Based Carceplexes

Peter Timmerman, Willem Verboom, Frank C. J. M. van Veggel, John P. M. van Duynhoven, and David N. Reinhoudt*

Carcerands are well known for the ability to trap guest molecules in their interior.[1, 2] During synthesis they form carceplexes by capturing guest molecules from the medium that cannot leave the cavity without the rupture of at least one covalent bond of the host.[3–6]

All carcerands hitherto synthesized have D_{4h} symmetry. Different orientations of the guest molecule inside such cavities do not lead to diastereomeric structures due to the overall symmetry of the carceplex. In a previous paper we reported the first carceplex constructed from both a calix[4]arene and a resorcinol unit (**2**), which has C_{4v} symmetry.[7] This carceplex containing one molecule of *N*,*N*-dimethylformamide (DMF) inside the cavity[8] was isolated in 27% yield as a by-product in the synthesis of an organic molecule with a rigid cavity of nanometer dimensions.[7] Here we report two new carceplexes (**3** and **4**) and describe their synthesis, structure, and dynamic behavior. These carceplexes exhibit a novel type of stereoisomerism as a result of different orientations of the guest molecule inside the cavity.

When a solution of **1**, which was prepared as described previously,[7] in *N*,*N*-dimethylacetamide (DMA) was added over 8 hours to a solution of CsF, Cs_2CO_3, and KI in DMA at 80 °C, and the mixture stirred for a further 16 hours at this temperature, carceplex **3** was isolated without further purification in essentially quantitative yield. The ^{1}H NMR spectrum of **3** (Fig. 1) is consistent with C_{4v} symmetry, indicating that rotation of the guest DMA molecule about the molecular axis is fast on the ^{1}H NMR (chemical shift) time scale.[9] All guest proton signals exhibit dramatic upfield shifts as a result of the shielding effect of the aromatic rings. Similar upfield shifts of guest proton signals have been frequently observed for the "Cram" carcerands.[4, 5] The spectrum of **3** shows two broad singlets at $\delta = -1.0$ and -2.0, representing the *N*-methyl group *cis* to the carbonyl group that normally resonates at $\delta = 2.8$, and the methyl group of the acetyl unit, which resonates $\Delta\delta = 4.0$ up-

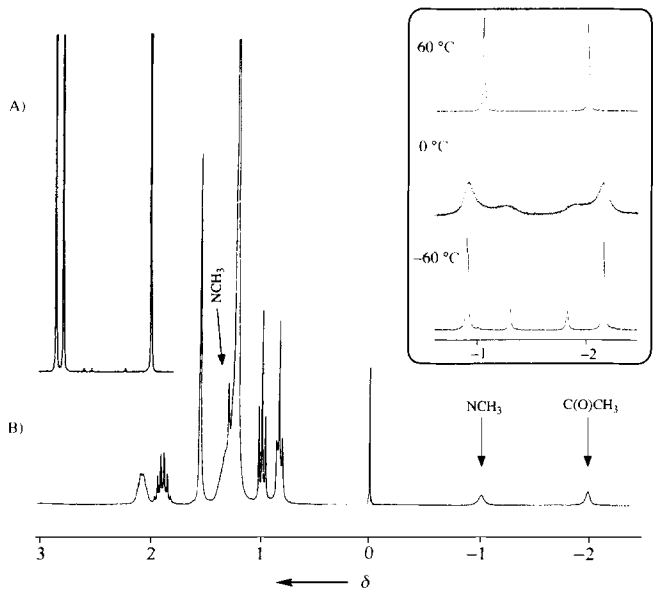

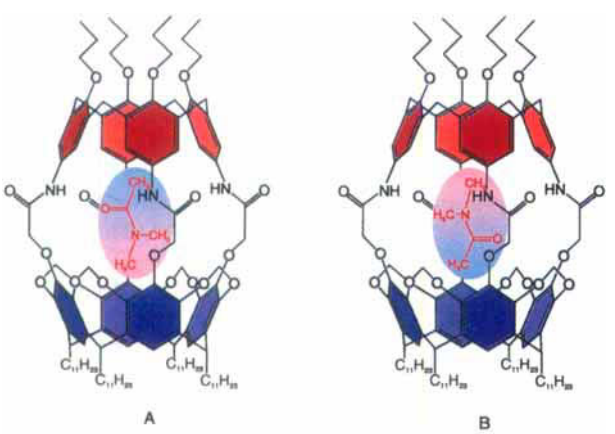

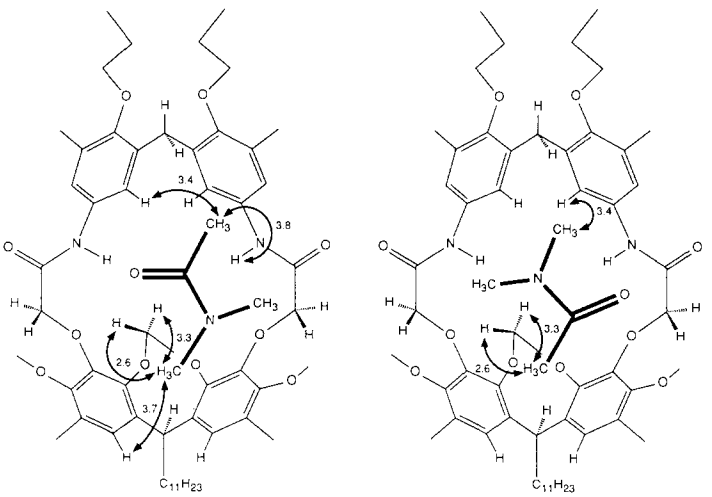

Fig. 1. ^{1}H NMR spectra (250 MHz) of DMA (A) and carceplex **3** (B) in $CDCl_3$ at room temperature; the framed inset shows sections of the ^{1}H NMR spectra (400 MHz) of **3** at different temperatures.

field from its normal position at $\delta = 2.0$, respectively.[10] The methyl group *trans* to the carbonyl resonates at $\delta \approx 1.3$ (obscured by the multiplet of the undecyl chains), which is only $\Delta\delta = 1.6$ upfield from its normal position. Apparently, it is not located close to the aromatic rings of the cavity.

Cooling the sample causes the ^{1}H NMR signals to decoalesce at 0 °C (Fig. 1). At temperatures below −30 °C the broad signals are split into two sets, one of two small, equally intense singlets at $\delta = -1.3$ and -1.8, flanked by the larger singlets of the other at $\delta = -0.9$ and -2.2 also with equal intensity. 2D EXSY experiments revealed that the large singlet at $\delta = -0.9$ shows exchange with the small singlet at $\delta = -1.3$, while the other large singlet at $\delta = -2.2$ exchanges with the small singlet at $\delta = -1.8$. Apparently, calix[4]arene-carceplex **3** switches between two isomeric states **A** and **B** in which the DMA molecule

occupies different orientations inside the cavity of **3**. The structures of **A** and **B** were determined by NOESY experiments (see Fig. 2). The acetyl group's methyl protons in isomer **A** (large singlet at $\delta = -2.2$) exclusively show NOE connectivities with protons that are located in the upper region of **3**, such as the NH protons and the aromatic protons of the calixarene *ortho* to these amide groups (Scheme 1, left), while the protons of the *N*-methyl *cis* to the carbonyl group (large singlet at $\delta = -0.9$) show NOEs with protons located in the lower region of **3**, like the protons of the methylenedioxy bridge pointing inwards or outwards and the aromatic protons of the resorcinol moiety close to the undecyl chains. The set of small singlets of **B** at $\delta = -1.3$ and -1.8 shows opposite NOEs (Scheme 1, right). The protons giving rise to the singlet at $\delta = -1.8$ exclusively show NOE connectivities with protons located at the lower regions of **3**, and those assigned to the singlet at $\delta = -1.3$ with protons located in the upper part of **3**. The relevant intermolecular distances in the two isomers were determined semiquantitatively[11, 12] by using the initial rate approximation.[13]

Scheme 1. Orientation of the guest DMA in the major isomer **A** (left) and in the minor isomer **B** (right) of **3**. The arrows link protons that give rise to NOEs; the numbers give the intermolecular distances.

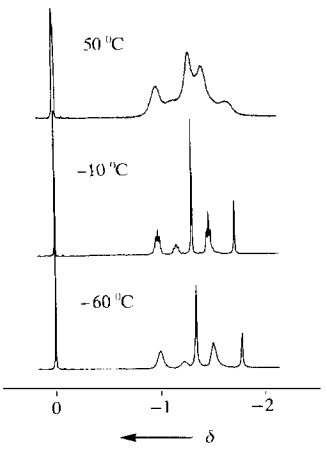
The type of stereoisomerism observed here, which is very similar to that observed in certain rotaxanes,[14] is novel, because it is based on different orientations of two molecular components that are *not* covalently attached. Since no official nomenclature exists for this type of stereoisomerism, we tentatively propose the name *carceroisomerism* (referring to the hindered rotation of a molecule inside the cavity of a carcerand).

The two isomers (carceromers) **A** and **B**, which are not equally abundant ($\Delta G = 0.7$ kcal mol^{-1} at −60 °C in $CDCl_3$),[15a] show fast exchange on the ^{1}H NMR time scale above room temperature, but give rise to separate signals below −30 °C. The activation enthalpy ($\Delta H^{\neq}$) for isomerization was calculated to be 13 ± 1 kcal mol^{-1} from ^{1}H NMR line shape analysis.[16a]

Another important point is evident from the NOESY spectrum of carceplex **3**: protons belonging to the host give rise to distinctly different resonances in the two isomers. This is most clear for the protons of the methylenedioxy bridges that point into the cavity. These protons resonate at $\delta = 4.0$ in the major isomer **A** and have an NOE with the large singlet of the methyl group *cis* to the carbonyl group ($\delta = -0.9$). In the minor isomer the resonance for these methylene protons is slightly shifted downfield to $\delta = 4.1$. This signal gives an NOE exclusively with the small singlet of the acetyl's methyl group at $\delta = -1.8$, which unambiguously proves that this resonance belongs to the minor isomer **B**.

When the reaction of **1** with CsF, Cs_2CO_3, and KI was carried out in 1-methyl-2-pyrrolidinone (NMP) under the same conditions as used for DMA, carceplex **4** was isolated in 50% yield.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2222-2346 $ 10.00+.25/0



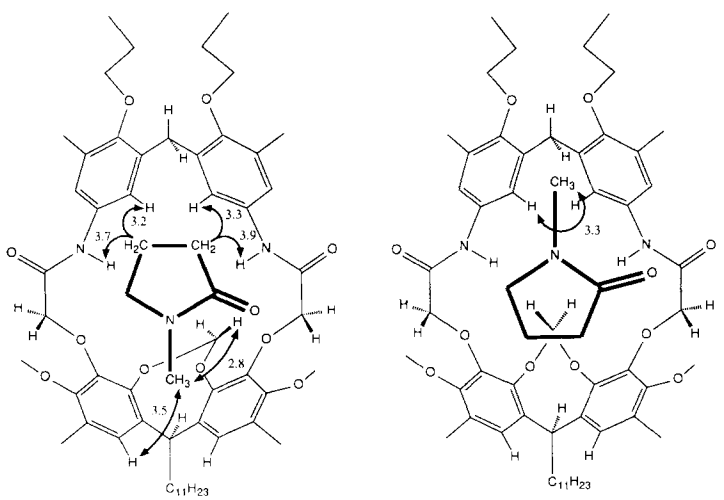


Fig. 2. Sections of the ^{1}H NMR spectra of carceplex **4** at different temperatures.

The presence of unequal amounts of two isomers can be most clearly observed at $-10\,^{\circ}C$ (see Fig. 2). The two singlets at $\delta = -1.3$ and -1.7 represent the methyl groups of incarcerated NMP in the major and minor isomer, respectively ($\Delta G = 0.4$ kcal mol^{-1} at $-60\,^{\circ}C$ in $CDCl_3$).[15b] DQ-COSY and NOESY experiments revealed that the multiplet at $\delta = -1.0$ arises from the 4-CH_2 group of NMP in the major isomer. The corresponding chemical shift for the minor isomer is -1.5 and is obscured by the triplet of the 3-CH_2 group of NMP in the major isomer. The small triplet at $\delta = -1.2$ is assigned to the 3-CH_2 group of NMP in the minor isomer. The 5-CH_2 groups of NMP in both isomers resonate at much lower field ($\delta \approx 1.4$ and 1.5), since they are not located close to the aromatic rings of the cavity.

From a systematic evaluation of the NOEs between host and guest protons, the structure of both isomers could be easily determined (Scheme 2).[17] The *N*-methyl group of NMP in the major isomer is located in the lower part of carceplex **4** as it shows strong NOE connectivities only with the protons of the methylenedioxy bridges and the aromatic protons of the resorcinol moiety close to the undecyl chains. In the minor isomer this methyl group is located in the upper part of the cavity, since it exclusively exhibits NOEs with NH and with the aromatic protons of the calixarene ortho to the amide groups. The 3- and 4-CH_2 groups both give strong NOEs with NH and the protons of the calixarene ortho to the amide groups in the major isomer, whereas these protons in the minor isomer give NOEs exclusively with the protons of the methylenedioxy bridges and with the aromatic protons of the resorcinol moiety close to the undecyl chains. All relevant intermolecular distances between host and guest protons in the two isomers were determined semiquantitatively[11, 17] with the initial rate approximation.[13]

Scheme 2. Orientation of the guest NMP in the major isomer (left) and in the minor isomer (right) of **4**. The arrows link protons that give rise to NOEs; the numbers give the intermolecular distances.

Warming a sample of **4** to 50 °C causes the NMP resonances to coalesce. This coalescence, which is related to isomerization of the two carceromers, takes place at a much higher temperature for **4** than for **3** (DMA carceplex). The activation enthalpy $\Delta H^{\ddagger}$ of 16 ± 1 kcal mol^{-1}[16b] for the rotation is 4 kcal mol^{-1} higher than for **3**.[18] This is primarily because NMP is one carbon atom larger, but the cyclic structure of NMP also renders this molecule much more rigid than DMA, which may also contribute to a higher energy barrier for carceromerization.

When the sample is cooled to $-60\,^{\circ}C$, the guest proton signals broaden markedly. This broadening is most probably related to rotation of the guest molecule about the C_4 axis of the carcerand, a process that becomes progressively slower with larger guest molecules.

The energy barriers for isomerization in carceplexes **3** and **4** is much higher than that for carceplex **2**. Even at $-60\,^{\circ}C$ an averaged ^{1}H NMR spectrum for the isomers of carceplex **2** is observed.

The type of stereoisomerism observed in carceplexes **3** and **4** constructed from calix[4]arene and resorcinol units provides a novel type of molecular switch, with potential applications in the fields of data storage and molecular electronics.[21]

[8] No exchange of the guest DMF for deuterated solvent DMF was observed after heating a solution of **2** in [D$_7$]DMF for 1 hour at 100 °C, which unambiguously proves that the guest molecule is trapped inside the cavity.
[9] The molecular axis is defined as the axis connecting the centers of the calix[4]arene and resorcinol moieties.
[10] Conclusive evidence for the identity of the methyl groups was found by heating a solution of **3** in [D$_5$]nitrobenzene. Above 100 °C the singlet at $\delta = -1.0$ coalesces as a result of the hindered rotation about the C–N bond, a process that is slow on the ^{1}H NMR time scale at room temperature, but fast at temperatures above 100 °C. In this way the singlet at $\delta = -2.0$ was assigned to the methyl group of the acetyl unit and the singlet at $\delta = -1.0$ to the *N*-methyl group *cis* to the carbonyl group.
[11] All intermolecular distances between protons of host and guest vary between a minimum and maximum value because of fast rotation of the guest molecule about the C_4 axis of the host. Since NOEs between two protons are inversely proportional to the sixth power of the intermolecular distance, short distances contribute much more to the NOE than large distances. For this reason the calculated distances between two protons should be interpreted as the upper limit for the minimum distance between those protons rather than an averaged distance.
[12] For the two isomers **A** and **B** of carceplex **3** the intermolecular distances in Å (± 0.2 Å) in Scheme 1 have been determined (only parts of the structures are shown for clarity).
[13] R. R. Ernst, G. Bodenhausen, A. Wokaun in *International Series of Monographs on Chemistry, Vol. 14* (Eds.: R. Breslow, J. B. Goodenough, J. Halpern, J. S. Rowlinson), Clarendon, Oxford, **1987**, Chapter 9.
[14] R. A. Bissell, E. Córdova, A. E. Kaifer, J. F. Stoddart, *Nature* **1994**, *369*, 133–137.
[15] A systematic search using Quanta/CHARMM Version 3.3 was carried out in order to find as many local minima as possible that correspond to different orientations of the guest molecule inside the cavity. The search was performed

by rotation of the guest about the x (0–60°), y (0–330°) and z axes (0–330°) in steps of 30° each, followed by energy minimization (conjugate gradient) until the root mean square (RMS) of the gradient was less than 0.01. Visual inspection of the minimized structures revealed that they correspond to several different orientations of the guest inside the host. The lowest energy structure of each orientation was minimized further with ABNR (ABNR = adopted basis set Newton–Raphson) until the RMS of the gradient was less than 0.001. a) For carceplex **3** seven energy minima with different orientations of DMA inside the cavity were found. Molecular Dynamics Simulations at 300 K revealed that all orientations isomerize to either of the two lowest energy orientations within 100 psec. The two lowest energy orientations are structurally identical (within the experimental error of the NOE measurements) with the two isomers **A** and **B** found experimentally. The internal energy (ΔE) of the major isomer was calculated to be 1.7 kcal mol^{-1} lower than that of **B**. This energy difference [E (isomer **B**) − E (isomer **A**)] is slightly higher than the experimentally determined Gibbs free energy difference (ΔG) of 0.7 kcal mol^{-1}. b) For carceplex **4** six minima with different orientations of NMP inside the cavity were found. Also here the two lowest energy orientations were structurally identical (within the experimental error of the NOE measurements) with **A** and **B** [17]. In this case the major isomer was calculated to be 1.3 kcal mol^{-1} lower in energy. Again ΔE is higher than the experimental determined ΔG of 0.4 kcal mol^{-1}.

[16] The isomerization of **3** and **4** was studied using the computer simulation program Conjugate Peak Refinement ("TRAVEL") [19]. For a given isomerization process this program finds saddle points on the adiabatic potential energy surface. CHARMM Version 22g3 was used for the TRAVEL studies. a) In case of **3**, an activation energy for interconversion between the two lowest energy structures of 9.8 kcal mol^{-1} was calculated [20], which is 3.2 kcal mol^{-1} lower than the experimentally determined activation enthalpy. b) In case of **4**, an activation energy for interconversion between the two lowest energy structures was calculated at 12.4 kcal mol^{-1} [20], which is 3.6 kcal mol^{-1} lower than the experimentally determined value.

[17] The intermolecular distances in Å (±0.2 Å) in Scheme 2 have been determined for the two isomers of **4** (only parts of the structures are shown for clarity).

[18] Attempts to determine the activation enthalpy for interconversion using ^{1}H NMR line shape analysis were hampered by the complexity of the spectrum. The activation enthalpy was therefore determined by measuring the exchange rate by EXSY (at five different temperatures).

[19] S. Fischer, M. Karplus, *Chem. Phys. Lett.* **1992**, *194*, 252–261.

[20] A physically realistic activation energy for interconversion was only found when one (in case of **3**) or two (in case of **4**) of the higher energy structures were used as intermediates.

Corrigenda

In the communication "Spectroscopic Studies of Anhydroretinol, an Endogenous Mammalian and Insect *retro*-Retinoid" by F. Derguini, K. Nakanishi, J. Buck, U. Hämmerling, and F. Grün (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1837–1839) an editorial error was made in the description of the UV/VIS spectrum of the all-*trans*-anhydroretinol **4**. A weak band at $\lambda = 262$ nm was incorrectly attributed to *cis* double bonds. This absorption actually arises from bending of the conjugated system induced by sterid hindrance. Because this bending is enhanced by the *cis* double bonds of sterically hindered *cis* isomers, it is called the "*cis*-band". This term does not necessarily imply the presence of a *cis* double bond.

In the review "Otto Roelen, Pioneer in Industrial Homogeneous Catalysis" by B. Cornils, W. A. Herrmann, and M. Rasch (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 2144–2163), the names of two of the authors were assigned to the wrong photographs. The central picture is of W. A. Herrmann and the right-hand picture is of M. Rasch.

Observing and Applying Secrets of the Cell

Gene Regulation in Eukaryotes. By *E. Wingender*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 430 pp., hardcover DM 178.00, $ 120.00.—ISBN 3-527-28460-5/1-56081-706-2

Anyone who is concerned on an everyday basis with the subject of eukaryotic gene regulation will appreciate how demanding a task Edgar Wingender has set himself in writing a monograph on this highly topical theme. It is obviously very difficult to take into account all the new research results that are continually appearing. It is greatly to the credit of the author and publishers that this book covers even work that has been published very recently.

The material is arranged in a way that progresses from the general to the specific, skillfully introducing the reader to the secrets of cellular processes in eukaryotic organisms. The first chapter reveals the complexity of the regulation scenario in a eukaryotic cell. Chapters 2 to 4 describe in detail the 'principal characters' involved in gene regulation, the three RNA polymerases. As in most stage productions, the effectiveness of the main actor depends on his interaction with the supporting players. The author goes on to describe the indispensable transcription factors which play the supporting roles, pointing out also that the same actor can appear in several different productions. Thus, for example, zinc finger proteins have essential roles in gene regulation in molds, insects, and vertebrates. The author discusses widely varied but precisely chosen examples in which the zinc finger ribbon motif controls the regulation of cell processes. Here the RNA polymerases are cast in ever more exciting and important roles.

Another class of transcription factors has as its common feature a homeobox which is homologous to the 'helix–turn–helix' DNA ribbon motif of the regulatory proteins in prokaryotes. In the chapter on these the author shows that as well as homeobox proteins there are other types of transcription factors, such as the 'helix–loop–helix' and 'leucine zipper', which can, for example, interact cooperatively so as to enable a *Drosophila* embryo to undergo differentiation.

Virtually every aspect of gene regulation is mentioned, including such topics as signal transduction via a 'second messenger', and steroid receptors which come into direct contact with the promotors of the genes concerned. Not only the specialist but also the reader approaching the subject for the first time will benefit from the book. It is unlikely that one would want to read through the book from beginning to end, and probably that is not what the author intends. Instead he has put together a compendium on the subject of gene regulation in eukaryotes, so that each reader can satisfy his or her thirst for knowledge in the relevant areas of this currently very important field. For example, if one looks in the index under 'GCN4', one is directed to an informative account of the importance of this yeast transcription factor, including also a mention of transcription factors that function similarly in other eukaryotes (in this case the vertebrate proto-oncogene c-jun). At the end of of each section within a chapter there is a useful summary which enables the reader to consolidate the foregoing material. Another excellent idea is that of the gray 'boxes' which are placed at appropriate points in the text to give background information on, for example, c-Raf1, c-Mos, Ras, EGF, and thyroid hormones. The list of abbreviations, although not exhaustive, is also a useful aid. I found only a few shortcomings, such as inconsistencies between figures and legends (e.g., Figs. 9, 10), repetition of the information about Raf1 (cf. pp. 69, 249), and the inaccurate description of the uvrABC endonuclease as an enzyme rather than a multienzyme complex, but these do not detract significantly from the high standard of the book. The plain and straightforward style of the text does not rob the subject of eukaryotic gene regulation of any of its splendor. The book should be in every library where students of molecular genetics and related subjects occasionally spend time (or ought to do so).

As with every theatrical production, it is the audience who determine whether it is a success. The same will also apply to this book, and therefore I recommend you to buy it and visit the show!

Biotechnology. Vol. 2. Genetic Fundamentals and Genetic Engineering. Edited by *H.-J. Rehm* and *G. Reed*. VCH Verlagsgesellschaft, Weinheim, 1993. XIII, 880 pp., hardcover DM 490.00.—ISBN 3-527-28312-9

"This is, consequently, the first book which deals comprehensively with all aspects of genetics in biotechnology..." This sentence on the first page of the book reviewed here describes the ambitious goal that the 32 authors have set themselves; the claim to have achieved it is at least partly justified. The idea of collecting together in a single volume all the knowledge of microbial and molecular genetics that is relevant to biotechnology undoubtedly addresses a real gap in the literature. The very rapid growth of knowledge in the areas of genetic fundamentals and genetic engineering during the 1970s played a key role in the development of biotechnology, and these sciences continue to provide the main nucleus for innovation.

However, this aspect is only brought out to a limited extent in this volume, which instead follows the overall concept of the twelve-volume work, with a greater emphasis on 'classical' biotechnology than on its molecular genetic aspects.

The main subject matter of this volume is divided into three areas. First, classical

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

genetics (181 pp.) is treated in five chapters, covering mutagenesis, genetic exchange processes in prokaryotic and lower eukaryotic organisms, and cell fusion and gene-mapping in animals and plants. Molecular genetics (178 pp.) is treated in four chapters: structure and function of DNA, principles of gene expression, DNA sequencing, and DNA synthesis. The section on genetic engineering deals first with microorganisms (170 pp.), with five chapters covering gram-negative and gram-positive bacteria, yeast cells and yeast plants, and an introduction to practical methods based on *Escherichia coli* as an example. There are then two chapters on plant systems (122 pp.) and two on animal systems (170 pp.), each topic being divided into work with cells and with transgenic organisms. The volume ends with 19 pages on safety aspects of biotechnology.

The task of covering "all aspects of genetics in biotechnology", from the basic principles of classical microbiology and genetics to the latest methods of genetic engineering, is an enormous undertaking, and some compromises are unavoidable. One such compromise is the omission of borderline topics. Among those that have been sacrificed are the use of 'bioinformation technology' for projects on gene-mapping and sequencing, the use of PCR (polymerase chain reaction) and other analytical methods of genetic engineering to identify individuals, groups of organisms, and complex populations, and the in-vitro molecular genetics techniques of 'evolutionary biotechnology'. Biodiversity and the conservation of genetic resources, which constitute the genetic foundations of biotechnology, are also not discussed. The chapter on safety aspects of biotechnology is confined to a discussion of administrative measures, and contains no mention of the experimental findings accumulated over many years, e.g., from the 'worst case' experiments carried out in the 1980s, or from the many studies of releases into the environment.

The heterogeneity often found in multiauthor works has been avoided in an exemplary way in this volume, except for the figures, which vary greatly in quality. In contrast to the mainly black-and-white photographs and diagrams, many of which are good, there are a few partly colored figures whose information content is unconvincing. Compromises are also evident in the subject index, to the detriment of the book. The quality of the index is especially important in a reference work such as this. It is very annoying to find that, although the index lists general methods of gene transfer treated in the chapter on plant cells, other applications are not mentioned or are very difficult to find. Examples of this are the use of liposomes (only listed in the index under "DNA uptake by sperms"), electroporation (two incorrect entries in the index), biolistics (not in the index), and antisense-RNA and antisense-ribozymes (here "antisense" only occurs in the index as a subsidiary term under "ribozyme", and it is left to chance whether the reader finds the figure on page 637 in which this technique is explained).

However, shortcomings such as these do not greatly detract from the usefulness of this information-packed and otherwise cleverly assembled collection of review articles. Such diverse readers as biology students, laboratory administrators, and research specialists will all gain much from referring to this volume—provided that their library has not already lent it out! Those who might consider buying their own copy, despite its price, should note its particular advantage in being thoroughly readable and written in such a clearly understandable way that one could almost recommend it as a textbook. However, it could only be used for this purpose by advanced students, because it contains a great wealth of detailed information.

Owing to the increasingly wide use of the methods of biotechnology, its rapid pace of development, and not least the introduction of legislation to control genetic engineering, there is an urgent need for a readily understandable, applications-orientated, and up-to-date reference source on the subject. Although this volume has occasional shortcomings, it is certainly a very welcome contribution to meeting this need.

One Hundred Years Lock-and-Key Principle**

Albert Eschenmoser*

When we look at modern organic chemistry and ask ourselves where we are going, then the spirit of no other organic chemist of the past appears to be nearer to our present-day thinking than that of Emil Fischer. In saying this, I refer, of course, to Fischer's legacy of the "lock-and-key" concept, an idea which – together with Pauling's later extension to transition states – constitutes the foundation on which all our modern structural modeling of the selectivity of intermolecular communication in chemistry and biology rests. Rightly, therefore, this symposium commemorates the concept's centenary, and the organizers are to be congratulated for their insight and initiative.

By the spirit of Emil Fischer, however, I also mean (and perhaps above all) Fischer's attitude as an organic chemist towards biology. It is the attitude that made and continues to make the biological world the major and deepest source of inspiration for research in organic chemistry, be it in a direct or an indirect way, or just as a reference for achievement. Organic chemistry has returned to this attitude only relatively recently after a period of splendid isolation in organo-chemical self-complacency for more than half a century after Emil Fischer's time.

Today, we marvel at Fischer's foresight in choosing the research fields in which he decided to spend his lifetime as a scientist, fields in which he created an oeuvre that makes him today the unique pioneering figure for organic chemistry, biochemistry, and molecular biology alike. His focus on the basic structural and synthetic chemistry of carbohydrates, nucleotides, and polypeptides, the three families of organic matter that later were recognized as the three pillars on which the living world is built, his interest in and practical use of enzymes as chemical catalysts, and his concern about their mode of action all differentiate him from the natural-products chemists of the self-complacency period, when the recurring pleasures of successful constitutional analyses and syntheses of nicely crystallizing low molecular weight objects, beautiful colors of pigments, fine odors of terpenes, and interesting biomedical properties of alkaloids lured the chemists away from proteins and nucleic acids, from those constitutionally repetitive and "nasty" materials that later revealed themselves as the most important part of the task originally assigned to the chemistry that was named organic, namely, the task of studying the substances produced by living organisms.

If Emil Fischer lived in our time, and if he happened not to be a biologist, he would quite probably be a practitioner of what today is called supramolecular chemistry, judging by the pronounced flair he had for structure and synthesis. In this field of chemical enterprise chemists set out to systematically conquer through synthesis new domains of the structure space of organic matter.

Let us call to mind that the portion of sequence space occupied by DNA and proteins during biological evolution is infinitesimally small compared to the overall size of these structure spaces; and the structure space of organic matter as a whole is infinitely greater than the space within which living matter is evolving. Clearly, moving within a structure space, be it by Nature herself or by synthetic chemists, demands the process of *selection*—selection of structures based on specific criteria. In this context we can distinguish two types of selection: post-synthesis and pre-synthesis selection. Darwinian selection is the prototypical example of the first, but also a chemist's discovery of an unexpected structure with an unexpected property that is put to good use is an example. The second type of selection represents—at least in traditional thinking—the molecular scientist's dream: it is the construction of a specific object based on theory; that is, the scientist selects the object to be synthesized in advance. Selection criteria are always utilitarian, be it fitness for survival, or for technological, scientific, or cultural application. In the supramolecular chemist's space walks, utility is connected with a given structure's specific properties; such properties manifest themselves in the transfer of information from the structure to a receiver, most often another molecular or supramolecular structure. And thus, mutual and strictly selective molecular recognition—Fischer's **lock and key**—is the central issue.

Therein lies that underlying dichotomy in structure space exploration in chemical research: post-synthesis selection (discovery) versus pre-synthesis selection (design). The recent sudden rise of encoded combinatorial synthesis within chemistry should make us reflect: we witness the transplant of a principle of synthesis from the heart of biology into the center of chemistry. An exciting period is ahead of us in which we shall be able to watch and compare the power of the two selection modes in chemical synthesis and their impact on the evolution of chemistry.

100 Years "Schlüssel-Schloss-Prinzip": What Made Emil Fischer Use this Analogy?**

Frieder W. Lichtenthaler*

Emil Fischer's famous lock-and-key analogy (Schlüssel-Schloss-Prinzip) for the specifity of enzyme action has provided successive generations of scientists with a mental picture of molecular recognition processes, and thus has shaped to a marked degree the development not only of organic chemistry, but, through its extension to basic live processes, that of biology and medicine as well. The hundredth anniversary of the first use of this most fertile metaphor provides a welcome opportunity not only for highlighting its paramount importance, but for gaining an understanding and appreciation of the creative processes involved, of the constructive reasoning and the thought patterns underlying the fundamental insight. Accordingly, this account attempts to trace how Fischer was led to the lock-and-key analogy, based on the state of knowledge and the views prevailing at the time. It reveals that Fischer, who had a pronounced tendency against any sort of theoretical speculation, refrained from taking this metaphor any further, that is to the obvious extensions of what turns the key, and what kind of doors are then opened. Except for a small refinement -the differentiation of main key and special keys to account for the fact that some yeasts can ferment a larger number of hexoses than others—he rather expounded on the scope of the lock-and-key picture: "I am far from placing this hypothesis side by side to the established theories of our science, and readily admit, that it can only be thoroughly tested, when we are able to isolate the enzymes in a pure state and thus investigate their configuration." Others, most notably P. Ehrlich und F. Lillie, by introduction of the concept of stereocomplementarity into medicine and biology, induced the lock-and-key analogy to become something of a dogma for explaining principal life processes.

Ich halte Lehre und Studium der historischen Entwicklung der Wissenschaft für unentbehrlich.... Unsere Lehrbücher versagen darin.
Richard Willstätter[1]

Emil Fischer's famous lock-and-key analogy for the specifity of enzyme action has provided successive generations of scientists with their mental picture of molecular recognition processes, and, thus has shaped to a marked degree the development not only of organic chemistry, but, by extension to basic life processes, that of biology and medicine as well.

Fischer's seminal paper in which he first used the lock-and-key metaphor appeared in *Berichte der Deutschen Chemischen Gesellschaft* of 1894.[2] Thus, a century has passed away since and accordingly, this provides a unique opportunity to commemorate the 100th anniversary of this most fertile hypothesis—not only for historical purposes or for keeping pivotal facts from oblivion, but for gaining an understanding and appreciation of the creative processes involved, of the thought patterns underlying the fundamental insight, and the constructive reasoning that eventually led to it. A comprehension of these factors appears to be required to get a true measure of the magnitude and significance of Fischer's basic contribution.

Any attempt—after a 100 years—to trace what led Fischer to the lock-and-key analogy, must go back to the state of knowledge and the views pevailing at the time, that is around 1890, and to the scientific school from which Fischer emerged. In 1871, he had entered the University of Bonn, where he attended lectures by A. Kekulé and R. Clausius, yet, in the following year transferred to the University of Strassburg to study with Adolf Baeyer, earning his doctorate with him in 1874 at the age of 22. A year later, while working already independently in Baeyer's laboratory, he accidentally discovered phenylhydrazine[3] which was to become the key reagent for his exploration of the sugars, when, ten years later, he finally applied it to the then existing sugars.[4]

The research school of Adolf Baeyer (1835–1917[5]), from which Fischer emerged—first in Strassburg, and then for 40 years after 1875 at the University of Munich—was a major "forge" of talent. A group photograph[6] of 1878 (Fig. 1)

[**] Based on a Commemorative Lecture presented at the European Research Conference "Supramolecular Chemistry: 100 Years Schloss-Schlüssel-Prinzip", Mainz, August 12, 1994.

Fig. 1. Photograph of the Baeyer group in early 1878 at the laboratory of the University of Munich (room for combustion analysis), with inscriptions from Fischer's hand [6].

attests to that almost literally: the unusually wide hood in the background is certainly more reminiscent of a forge than of a laboratory. In the center Adolf Baeyer, wearing a prominent hat; since several others also wear headgear, we may deduce that in the winter of 1878 the heating was deficient in that laboratory. To the right of Baeyer the 25-year-old Emil Fischer, in a peaked cap and strikingly self-confident three years after his Ph.D.; to the left Jacob Volhard (1834–1910), who was in charge of the analytical division in Baeyer's institute, and whose successor Fischer was to become in Munich a year later (1879), and at the University of Erlangen in 1882.

Fischer, at Munich, pursued several classical organic research topics: the phenylhydrazones of acetaldehyde, benzaldehyde, and furfural were unequivocally characterized and structurally

Frieder W. Lichtenthaler, born 1932 in Heidelberg, studied chemistry at the University of Heidelberg from 1952–1956 and received his doctorate there in 1959 under F. Cramer for research on enol phosphates. The following three years he spent as a postdoctoral fellow at the University of California, Berkeley, with Hermann O. L. Fischer—the only of Emil Fischer's sons who survived the first World War. He subsequently worked as an assistant at the Technische Hochschule Darmstadt, where he acquired his "Habilitation" in 1963, was appointed associate professor in 1968, and was promoted to full professor in 1972. His research activities center on the generation of enantiopure building blocks from sugars, their utilization in the synthesis of oligosaccharides and complex non-carbohydrate natural products, the computer simulation of chemical and biological properties of sugars, and studies towards the utilization of carbohydrates as organic raw materials.

secured;[7] over a number of years (1876–1880) he did extensive investigations on rosaniline dyes with his cousin Otto Fischer (Fig. 1, far left, sitting),[8] and in 1881 he started work on purines, investigating the structure of caffeine,[9] research that eventually led to his classification of the purines. In 1882 at the age of 30, he moved from Munich to Erlangen, accepting the chair of chemistry at that university, and there he was intensely occupied with the conversion of phenylhydrazine into N-heterocycles,[10] which led to the Fischer indole synthesis.[11] It was in Erlangen in 1884, that is after having left Baeyer's sphere of influence for over two years, that he began his studies on sugars, by reaction of those that were known at the time (glucose, fructose, galactose, maltose, sucrose, and lactose) with phenylhydrazine.[3, 12] The hydrazones and osazones obtained thereby have not only rendered invaluable service for the identification and isolation of the then existing sugars, but also have been instrumental in the preparation of new ones. In 1888 Fischer had moved to the University of Würzburg by then—he discovered a new hexose in this way:[13] gentle oxidation of mannitol with nitric acid gave a mixture which could not be characterized as such, but on exposure to phenylhydrazine afforded a crystalline phenylhydrazone, isomeric with the one generated from glucose (Fig. 2). By the acid hydrolysis of this product, an as yet unknown hexose was obtained, which he named mannose.

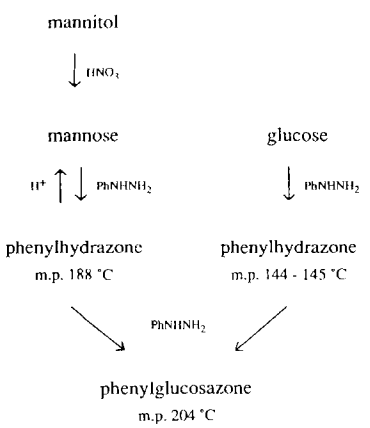

Fig. 2. Synthesis of mannose from mannitol in 1888 [13] soon thereafter to be discovered in nature [16].

It is in this stage of Fischer's purely chemical-synthetic studies of sugars, in the first of four papers with Hirschberger on mannose,[13–15] that we find, rather unpreparedly, the lapidary sentence:[13] "Mannose is avidly fermented by beer yeast at room temperature even in strongly diluted aqueous solution." For Fischer, however, it was not a peculiar, remote thing to incorporate yeast into his investigations, since he had developed a curiosity in yeast fermentation as a youth already – sparked by the entrepreneurship of his father. Laurens Fischer was a successful businessman, and in 1870—Emil was 18 by then—he invested a large amount of money in the foundation of a beer brewery in Dortmund, an enterprise that was later turned into a stock company, the "Dortmunder Aktienbrauerei" of today; Laurens Fischer was chairman of the board for several decades.

In the winter of 1876/1877, Emil Fischer spent three months at the University of Strassburg on Baeyer's suggestion obviously, since he held the position of an assistant at his Munich institute to acquire more expertise in quantitative analysis in the laboratory of Prof. Rose. A delightful passage of Fischer's autobiography elaborates on his encounter with yeast there:[17]

"During the winter semester of 1876/1877 I again was in Strassburg, and there, through Dr. Albert Fitz, a wealthy winegrower from the Palatinate, was introduced to the book of Pasteur "Etudes sur la bière", that had just appeared. Therein, this ingenious researcher had laid down his experiences on the contamination of beer-yeast by other microorganisms and their harmful effect on the quality of the beer. When I reported on this to my father, he urged me to study this subject very thoroughly, which I gladly did since it interested me scientifically. A fine microscope was immediately acquired, and with the help of Dr. Fitz and the botanist Prof. de Bary I made studies on moulds, sprouts, and yeasts, from which I later profited immensely in my investigations of the sugars. For the time being, however, I had to make practical use of this new knowledge.

Accordingly, I moved with my microscope to Dortmund for several weeks, to train the workers of the brewery in the new identification procedures. Presumably, I was the first chemist in Germany who attempted this, and have to admit, that I was met with substantial distrust by the men. They made every effort to lead me astray with false statements on the origin and the quality of the yeast under examination. They became more serious-minded though after I could find out, with the help of the microscope, those yeast types that were spoiled. Yet, I did not succeed in instructing any of the men in the correct use of the microscope."

Through these activities, Fischer obviously had developed a keen interest in the subject, because he remarks: "The chemistry of yeasts interested me so highly, that I certainly would have done own research in this field had I stayed longer in Strassburg."[17]

Seen in this context, it was a quite obvious move for Fischer (Fig. 3) to test whether the newly prepared hexose, of which the

Fig. 3. Emil Fischer (1852–1919) in 1889 [18].

set of reactions summarized in Figure 2 had shown it to be the 2-epimer of glucose, would also be fermented by yeast. Similarly, when racemic sugars became available by his investigations of the formose reaction, it became standard practice to expose them to "ordinary beer yeast" for evaluation of their fermentability. Thus, besides proving that D-mannose indeed formed ethanol on yeast fermentation (Fig. 4),[15] it was estab-

D-mannose	⟶	CO_2 + ethanol	[13,15]
D,L-fructose	⟶	L-fructose	[19,20]
D,L-mannose	⟶	L-mannose	[20]
D,L-glucose	⟶	L-glucose	[21]
D,L-galactose	⟶	L-galactose	[22]
D-gulose	—X⟶		[23]
L-gulose	—X⟶		[24]
D-*manno*-heptose	—X⟶		[25]
D-*gluco*-heptose	—X⟶		[26]

Fig. 4. Fischer's early observations (1888–1892) on the fermentation of sugars with beer yeast [27].

lished that in the case of racemic glucose, mannose, galactose, and fructose, only the D component was devored, allowing the isolation and characterization (as hydrazones and osazones) of the corresponding L-sugars.

The study of the fermentation of these sugars was a by-product of his synthetic work, until, at the end of 1891, he had proceeded so far as to have reached the goal: the relative configurations of the sugars had been unravelled. This proof not only put carbohydrate chemistry on a rational basis but—more importantly for that time—provided unequivocal proof for the validity of the Le Bel–van't Hoff theory of stereoisomerism.[28] It became the basis for the sugar family tree (Fig. 5) as it is—100 years later—in our textbooks today.

The completion of this most remarkable, classic piece of work, accomplished by ingeniously planned organic syntheses and brilliant mathematical reasoning had brought order and clarity to the field. To Fischer it was the incentive for now venturing into topics of much higher complexity, that is into biological phenomena:[29]

> "After the classification of the monosaccharides has essentially been concluded by the establishment of their configurational formulae, it is now obvious to utilize the experiences, which have led to this goal, for the purposes of biological research."

Following the early observations on the fermentability of sugars (Fig. 4), which had more the character of orientative tests than carefully planned experiments, Fischer apparently realized that the ordinary brewer's yeast ("gewöhnliche Brauereihefe") he had been using was not pure, and that therefore the results could be misleading. So he made, together with Hans Thierfelder,[30] a comparative study of natural and synthetic monosaccharides with respect to their behavior towards various families of yeast. This resulted in a landmark paper in the "*Berichte*" of 1894.[31] Fischer, thereby, was in the fortunate position, that his sugar studies had left him with a rich stock of rare sugars—nowhere else in chemistry was such a fine inventory of isomers available—yet some of these were only accessible in small amounts.[31]

> "Since the preparation of the artifical sugars is in part quite laborious and the experiments had to be varied frequently we have used a small fermentation tube of the form shown below to save material" (Fig. 6).

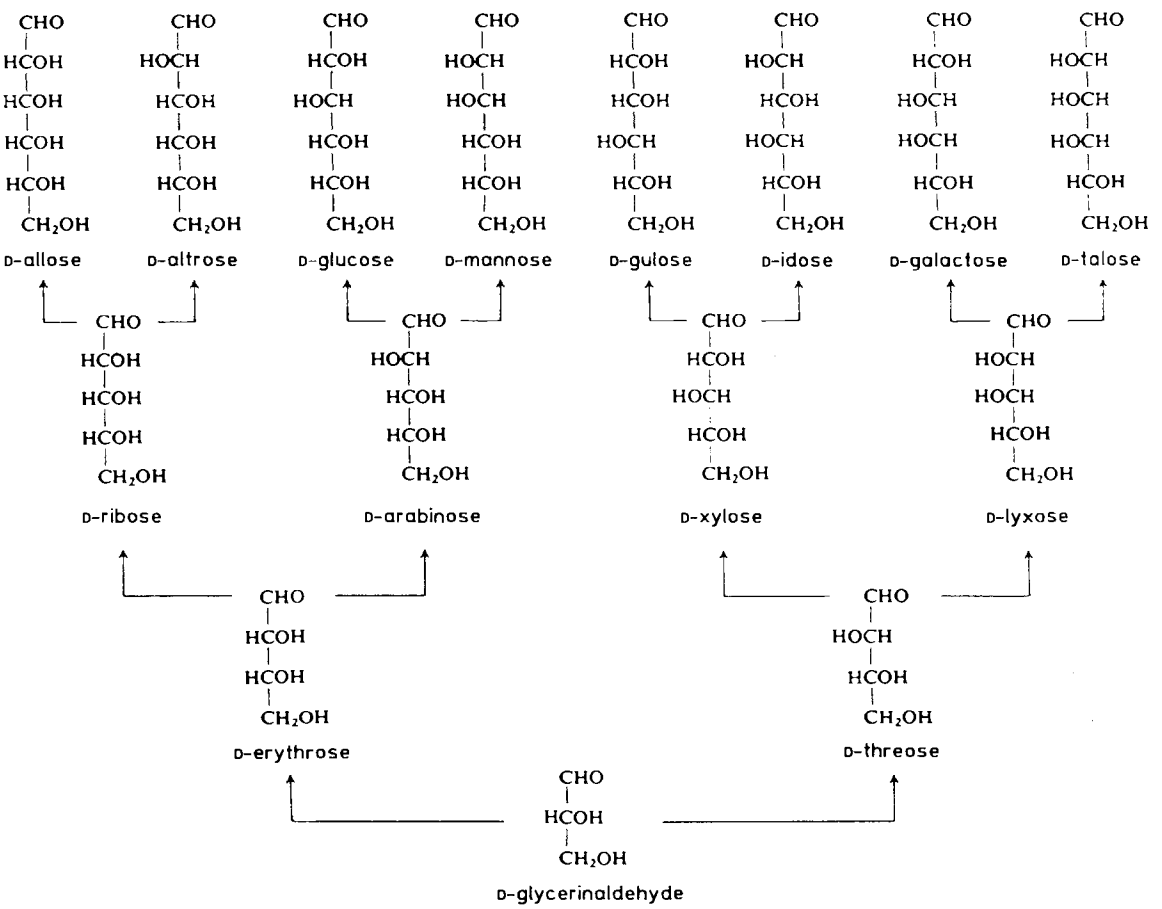

Fig. 5. The sugar family tree of D-aldoses.

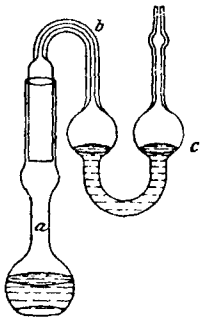

Fig. 6. Semimicro scale assay for the fermentation of sugars by yeasts [31] in original size. a = Fermentation flask, b = S-trap for CO_2 generated, c = aqueous $Ba(OH)_2$. Example: 70 mg sugar in 0.35 mL H_2O, 0.35 mL aqueous yeast abstract; sterilization, addition of 13 mg of a pure yeast species; 3–10 d at 24–28 °C.

This microscale fermentation assay was quite elaborate for the time, allowing one to work with 70 mg of sugar; the bulb holding the sample has a volume of about 1 mL only. It is interesting to perceive today Fischer's keen sense for meticulous observations:[31]

"In all cases, even when the sugar is not fermented, a small amount of carbon dioxide evolves, which covers the surface of the barium hydroxide with a thin layer of carbonate. Since this phenomenon occurs even when no sugar has been added to the solution, it is obviously caused by the small amount of carbohydrate present in the yeast itself or the extract.

The situation is quite different, when the material is readily fermentable: the barium hydroxide is not only becoming strongly turbid, but is neutralized.

Intermediate cases are these, where material has to be brought into a fermentable state first, as with the glucosides; fermentation proceeds slowly ...., yet here too, the amount of carbon dioxide developed is always large enough, that one cannot be in doubt about the real occurrence of fermentation."

Observations of this sort led to the data collected in Scheme 1, a reproduction from the first[31] of four papers to appear on the subject in the second half of 1894:[2, 29, 31, 32] *d*-mannose, *d*-fructose, and, to a lesser extent *d*-galactose resemble *d*-glucose, as does sucrose ("Rohrzucker") and maltose, whilst one of the yeasts ("Milchzuckerhefe") fermented sucrose and lactose ("Milchzucker"), yet left maltose untouched. All of the yeasts were indifferent towards a variety of synthetic sugars.

Fischer seemed to be particularly intrigued by the fact, that *d*-talose, the 2-epimer of galactose, was not fermented (Fig. 7), since he notes:[31]

"*d*-Talose relates configurationally to *d*-galactose as does *d*-mannose to *d*-glucose. As *d*-galactose already ferments less readily than the two others, any further small change in geometry eliminates fermentability altogether."

[31]). ††† denotes no reduction of the Fehling's solution after 8 days, thus complete fermentation. †† denotes very weak reduction after 8 days, thus almost complete fermentation. † denotes significant reduction after 8 days, but undoubted fermentation. – denotes no fermentation.

Considerations such as these led to the cautious rationalization, "that the yeast cells with their asymmetrically formed agent are capable of attacking only those sugars of which the geometrical form does not differ too widely from that of *d*-glucose."[31]

On extending this inquiry to natural and artificial glucosides, Fischer found that these materials arrange themselves into distinct groups with respect to their behavior towards air-dried yeast extract and the aqueous extract of bitter almonds ("invertin" and "emulsin", respectively). Although both were later shown to be crude mixtures of enzymes, the former only cleaved α-glucosidic linkages, whereas the other, just as specifically, only hydrolyzed β-glucosides (Table 1).

The second of these four 1894 papers on yeast fermentation carries the unassuming title "influence of the configuration on

545. Emil Fischer: Einfluss der Configuration auf die Wirkung der Enzyme.

[Aus dem I. Berliner Universitäts-Laboratorium.]
(Vorgetragen in der Sitzung vom Verfasser.)

Das verschiedene Verhalten der stereoisomeren Hexosen gegen Hefe hat Thierfelder und mich zu der Hypothese geführt, dass die activen chemischen Agentien der Hefezelle nur in diejenigen Zucker eingreifen können, mit denen sie eine verwandte Configuration besitzen[1]).

Diese stereochemische Auffassung des Gährprocesses musste an Wahrscheinlichkeit gewinnen, wenn es möglich war, ähnliche Verschiedenheiten auch bei den vom Organismus abtrennbaren Fermenten, den sogenannten Enzymen, festzustellen.

Das ist mir nun in unzweideutiger Weise zunächst für zwei glucosidspaltende Enzyme, das Invertin und Emulsin, gelungen. Das Mittel dazu boten die künstlichen Glucoside, welche nach dem von mir aufgefundenen Verfahren aus den verschiedenen Zuckern und den Alkoholen in grosser Zahl bereitet werden können[1]). Zum Vergleich wurden aber auch mehrere natürliche Producte der aromatischen Reihe und ebenso einige Polysaccharide, welche ich als die Glucoside der Zucker selbst betrachte, in den Kreis der Untersuchung gezogen. Das Ergebniss derselben lässt sich in den Satz zusammenfassen, dass die Wirkung der beiden Enzyme in auffallender Weise von der Configuration des Glucosidmoleküls abhängig ist.

Versuche mit Invertin.

Das Enzym lässt sich bekanntlich aus der Bierhefe mit Wasser auslaugen und soll aus der Lösung durch Alkohol unverändert gefällt werden. Aus den später angeführten Gründen habe ich auf die Isolirung desselben verzichtet. Die nachfolgenden Versuche sind vielmehr direct mit einer klar filtrirten Lösung angestellt, welche durch 15stündige Digestion von 1 Theil lufttrockener Bierhefe (Saccharomyces cerevisiae, Typus Frohberg, Reincultur) mit 15 Theilen Wasser bei 30—35° bereitet war.

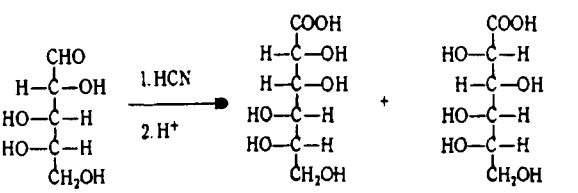
Fig. 8. Title page of the second [2] of Fischer's four landmark papers in 1894 on the influence of the configuration on the action of enzymes.

the action of enzymes" (Fig. 8), reporting some of these results in a very sober, purely scientific diction.[2] Towards the end—as usually found in the majority of Fischer's publications—he gives clear indications on what he is to do next: incorporation of other enzymes into the study, such as glucase, ptyalin, myrosin, and the ferments of pancreas, and their extension to the rare oligosaccharides, as for example isomaltose, turanose, melibiose and melitriose (Fig. 9). Then, very much towards the end of this paper, in the coda quasi, in musical terms, Fischer tries to sum up and rationalize the observations available. The resulting section contains the crucial metaphor:

> "The restricted action of the enzymes on glucosides may therefore be explained by the assumption that only in the case of similar geometrical structure can the molecules so closely approach each other as to initiate a chemical action. To use a picture I would like to say that enzyme and glucoside have to fit together like lock and key in order to exert a chemical effect on each other. The finding that the activity of enzymes is limited by molecular geometry to so marked a degree, should be of some use in physiological research. Still more important though appears to me the proof, that the previously assumed difference between the chemical activity of a cell and the mode of action of chemical reagents is, factually, non-existent."[2]



Emil Fischer left many contributions of great brilliance in the annals of science:

- the unravelment of the sugar configurations as the classical piece of exact mathematical reasoning in any experimental science[12]
- the classification of purines[33] and the synthesis of the first nucleosides[34]
- the laying of the chemical and biological foundation of protein chemistry by his extensive work on amino acids, peptides, and proteins,[35]
- the first unifying concept on the structures of the complex natural products depsides and tannins.[36]

But here, an analogy, a metaphor, almost casually thrown in at the end of a paper, develops a life of its own, to become one of the most frequently invoked concepts of the past 100 years. Apparently, the lock-and-key analogy met a conceptual need of the time, for within a very short period it formed an interface between chemistry, biology, and medicine—very much to the surprise of Fischer himself, since he did not expound on it. Particularly, he refrained from going any further—at least in print—although I am sure, in his thoughts, he must have taken this picture to the obvious questions, what turns the key, and what kind of doors are then opened. The only extension to be found in print, in an extensive 43-page review on his investigations on sugars of 1894, is a small refinement:[29]

> "The action of enzymes involves a far-reaching chemical process which takes place readily or not at all. Here, apparently, the geometrical structure exerts such a profound influence on the playing of the chemical affinities, that it appeared legitimate to me to compare the interacting molecules with key and lock.
> If one wants to do justice to the fact, that some yeasts can ferment a larger number of hexoses than others the picture may be completed by the differentiation of main key and special keys."

It was obvious to apply the concept of lock-and-key complementarity to the question of asymmetric synthesis in plants, most notably to the process of assimilation. Along the way of the gradually unfolding interrelationships between the sugars, Fischer, in 1889, had made another key discovery that was to have major bearing on biological questions. He uncovered the phenomenon of asymmetric synthesis:[37] the cyanohydrin extension of natural L-arabinose does not only give L-mannonic acid on hydrolysis, as Kiliani had previously shown,[38] but a second product, the 2-epimeric L-gluconic acid, as evidenced by their distinctly different, well-crystallizing phenylhydrazides:

L-arabinose L-mannonic acid L-gluconic acid

2992

von Leuchtbacterien beweisen will, ist wohl geeignet, ernste Bedenken gegen die Zuverlässigkeit des Resultats zu erwecken. In der That ist denn auch Beyerinck's Ansicht von Schnurmans Stekhoven [1]) sehr bestimmt bestritten worden. Letzterer kommt vielmehr zu dem Schluss, dass das Enzym der Kefirhefe zwar den Rohrzucker und die Raffinose, aber nicht den Milchzucker zerlege. Die Frage, wer hier Recht hat, lässt sich leicht entscheiden, wenn man den Versuch mit reiner Kefirhefe so anstellt, wie er oben für die Kefirkörner beschrieben ist. Ich werde denselben ausführen, so bald mir eine genügende Menge der Hefe zur Verfügung steht.

Ferner beabsichtige ich, noch einige verwandte Enzyme, wie die Glucase, das Ptyalin, Myrosin und die Pancreasfermente zum Vergleiche heranzuziehen und die Versuche auch auf die selteneren Polysaccharide, wie Isomaltose, Turanose, Melibiose, Melitriose, Trehalose, Melezitose, die künstlichen Dextrine etc. zu übertragen. Zweifellos werden sich dann noch mehr solcher Gegensätze zeigen, wie sie zwischen dem Invertin und Emulsin jetzt festgestellt sind.

Aber schon genügen die Beobachtungen, um principiell zu beweisen, dass die Enzyme bezüglich der Configuration ihrer Angriffsobjecte ebenso wählerisch sind, wie die Hefe und andere Mikroorganismen. Die Analogie beider Phänomene erscheint in diesem Punkte so vollkommen, dass man für sie die gleiche Ursache annehmen darf, und damit kehre ich zu der vorher erwähnten Hypothese von Thierfelder und mir zurück. Invertin und Emulsin haben bekanntlich manche Aehnlichkeit mit den Proteïnstoffen und besitzen wie jene unzweifelhaft ein asymmetrisch gebautes Molekül. Ihre beschränkte Wirkung auf die Glucoside liesse sich also auch durch die Annahme erklären, dass nur bei ähnlichem geometrischem Bau diejenige Annäherung der Moleküle stattfinden kann, welche zur Auslösung des chemischen Vorganges erforderlich ist. Um ein Bild zu gebrauchen, will ich sagen, dass Enzym und Glucosid wie Schloss und Schlüssel zu einander passen müssen, um eine chemische Wirkung auf einander ausüben zu können. Diese Vorstellung hat jedenfalls an Wahrscheinlichkeit und an Werth für die stereochemische Forschung gewonnen, nachdem die Erscheinung selbst aus dem biologischen auf das rein chemische Gebiet verlegt ist. Sie bildet eine Erweiterung der Theorie der Asymmetrie, ohne aber eine directe Consequenz derselben zu sein; denn die Ueberzeugung, dass der geometrische Bau des Moleküls selbst bei Spiegelbildformen einen so grossen Einfluss auf das Spiel der chemischen Affinitäten ausübe, konnte meiner Ansicht nach nur durch neue thatsächliche Beobachtungen gewonnen werden. Die bis-

2993

herige Erfahrung, dass die aus zwei asymmetrischen Componenten gebildeten Salze sich durch Löslichkeit und Schmelzpunkt unterscheiden können, genügte dafür sicher nicht. Dass man die zunächst nur für die complicirten Enzyme festgestellte Thatsache bald auch bei einfacheren asymmetrischen Agentien finden wird, bezweifle ich ebensowenig wie die Brauchbarkeit der Enzyme für die Ermittlung der Configuration asymmetrischer Substanzen.

Die Erfahrung, dass die Wirksamkeit der Enzyme in so hohem Grade durch die moleculare Geometrie beschränkt ist, dürfte auch der physiologischen Forschung einigen Nutzen bringen. Noch wichtiger für dieselbe aber scheint mir der Nachweis zu sein, dass der früher vielfach angenommene Unterschied zwischen der chemischen Thätigkeit der lebenden Zelle und der Wirkung der chemischen Agentien in Bezug auf moleculare Asymmetrie thatsächlich nicht besteht. Dadurch wird insbesondere die von Berzelius, Liebig u. A. so häufig betonte Analogie der »lebenden und leblosen Fermente« in einem nicht unwesentlichen Punkte wieder hergestellt. —

Bei der Ausführung obiger Versuche habe ich mich der eifrigen und geschickten Beihülfe des Hrn. Dr. Paul Rehländer erfreut. Ferner bin ich für die Ueberlassung von reingezüchteten Hefen den HH. Dr. H. Thierfelder, Prof. M. Delbrück und Dr. O. Reinke zu grossem Danke verpflichtet.

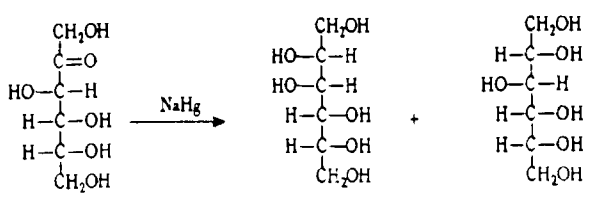

Fig. 9. Final section of Fischer's seminal 1894 paper [2] in which the lock-and-key metaphor was first used.

As it turned out, this is the first example of an asymmetric synthesis recorded in the literature, on which Fischer commented in the following way:[39]

"The simultaneous formation of the two stereoisomeric products on the addition of hydrogen cyanide to aldehydes, which was observed here for the first time, is quite remarkable in theory as well as in practice."

This first example of an asymmetric synthesis was soon to be followed by a second case, since sodium amalgam reduction of D-fructose gave rise to two stereoisomeric products, namely D-mannitol and D-sorbitol.[40] Fischer clearly realized the basic importance of this result:

"The reduction of fructose is the second reaction in the sugar group, which generates two stereoisomeric products due to the formation of an asymmetric carbon atom. The same phenomenon will undoubtedly be observed much more frequently in the future, and most probably will be generally found with all compounds that are asymmetric a priori."

D-fructose D-mannitol D-sorbitol

Four years later, in one of these 1894 papers,[29] the biological significance of these sober chemical findings had been fully realized and applied to assimilation by invoking the lock-and-key concept:

"It seems to me that this concept offers a simple solution for the enigma of natural asymmetric synthesis. According to the plant physiologists, carbohydrate formation takes place in the chlorophyll granule, which itself consists entirely of optically active substances. I can imagine that the formation of carbohydrates is preceeded by the generation of a compound

of carbonic acid or formaldehyde with those substances; and that then, due to the already existing asymmetry of the entire molecule, the condensation to the sugars takes place in an asymmetric fashion too.
Their asymmetry can thus be readily explained by the nature of the material from which they were produced. Of course, they also provide the material for new chlorophyll granules which, in turn, produce active sugar. In this manner, the optical activity propagates from molecule to molecule, as life itself does from cell to cell. Hence, it is not necessary to attribute the formation of optically active substances in the plant to asymmetric forces outside the organism, as Pasteur had supposed. The origin rather lies in the structure of the chlorophyll granule that generates the sugar, and with this conception the difference between natural and artificial synthesis is completely eliminated."

In a lecture of 1894 on "The chemistry of carbohydrates and their importance for physiology" he again advocated this view in more general form:[41]

"Whoever wants to conclusively elucidate the process of assimilation, will have to tackle the more special question, why the plant exclusively generates optically active sugar whilst chemical synthesis leads to the inactive products. This contrast appeared so fundamental to Pasteur, who created the precept of molecular asymmetry, that he considered the generation of active substances to be a privilege of the organism. The progress of science has deprived the highly respected lifeforce of even this last hiding-place; for we are now in a position to artificially prepare such active substances without any assistance from a living organism."

With these words, Fischer had clearly repudiated the accepted view of the time—asserted by Pasteur—that fermentation is inextricably tied to living cells, wherein a "vis vitalis" was supposedly operating. Eduard Buchner is usually credited to have demonstrated in 1897[42] that fermentation can occur outside living cells, thus unequivocally refuting Pasteur's view. The above passage of Fischer in 1894 proves, that he had arrived at this conclusion already three years earlier.

In 1894, when Fischer first used the lock-and-key analogy to illustrate enzyme specifity, he was 42. He lived for another 25 years, during which time he published the imposing number of over 400 further papers.[43] However, he referred to the lock-and-key concept only in another three: in his Nobel lecture in 1902, rather incidentally,[44] in his Faraday lecture at the University of London in 1907,[45] also quite cursorily, and, at the end of an extensive, 28-page review of 1898, with the momentous title "Significance of Stereochemistry for Physiology." Therein,[46] Fischer apparently felt that he had to state the scope of the analogy he had proposed, because others were taking it too far:

"The reasons for these phenomena are in all probability to be found in the asymmetric structure of the enzyme molecule. Although one does not know these substances in a pure state, their similarity with proteins is so close and their generation from these so probable, that they have undoubtedly to be considered as optically active, and, hence, asymmetric molecular forms.
This had led to the hypothesis, that there must be a similarity in the molecular configuration between the enzymes and their object of attack, if reaction is to take place. To make this thought more perspicuous, I have used the picture of lock and key.
I am far from placing this hypothesis side by side to the established theories of our science, and readily admit, that it can only be thoroughly tested, when we are able to isolate the enzymes in a pure state and thus investigate their configuration."[46]

Paul Ehrlich, for example, from 1897 on, introduced the lock-and-key complementarity into the then young discipline of immunology through his so-called "side chain theory of immunity", as illustrated in a publication from 1900[47] (Fig. 10): each cell possesses a number of side chains, which bind toxins in a lock-and-key type manner. The binding of such toxins causes the overproliferation of that particular side chain some of which are set free from the cells as antibodies. In the case of diseases that leave immunity there are so many free "side chains" (antibodies) in the blood that appreciable fixations at the cell cannot occur.

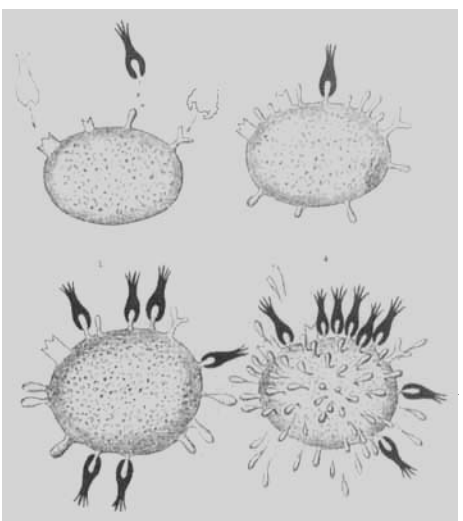

Fig. 10. Ehrlich's side chain theory of immunity as illustrated in 1900 [47].

The lock-and-key complementarity also gained headway in embryology, particularly from 1914 on, when Lillie, at the University of Chicago, invoked it to describe recognition between sperm and cells.[48] He crystallized his ideas on the interaction of the components involved into an explicit lock-and-key diagram (Fig. 11), a dangerously elaborate concept in view of the few secure experimental data available then.

Accordingly, Ehrlich had brought stereocomplementarity from the realm of chemical reactions in solution to reactions on the cell surface, whilst Lillie and others[49] extended it to cell–cell interactions. So, the first two decades following Fischer's use of the lock-and-key analogy saw a rather free, uncontrolled proliferation of the concept from chemistry into medicine and biology—and, along the way, its use became more and more speculative.

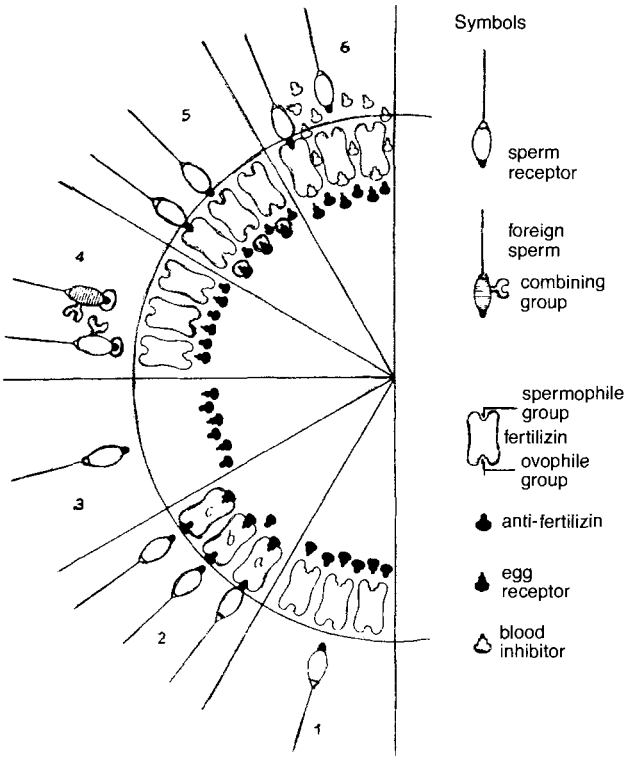

Fig. 11. Lillie's theory of fertilization as diagrammed in 1914 [48]: segment 1 shows the situation before fertilization; in segment 2, the sperm receptor binds to the spermophile group of "fertilizin", activating the ovophile group to bind to the egg receptor. Molecules of antifertilizin combine competitively with this site on other fertilizin molecules to forbid the binding of other sperm. The other segments refer to experiments not relevant to the discussion here.

The passage of time corrects many a distortion of perspective. Both theories survived only insofar as they allowed recognition of the complex relationship in very general terms, and hence, had a favorable influence on the concretization of research activities. Wherever they were used for too detailed analyses, they failed, obviously because the ground of scientifically established facts was left too far behind in the quest to explain phenomena much too complex as to yield to rationalization or comprehension at the time.

Unlike these theories from Ehrlich, Lillie, and others along similar veins,[49] Fischer's lock-and-key analogy still stands in the annals of science—a 100 years later—as a most fertile concept. Maybe, because it was unspecified in its details, thus leaving ample room for the imagination of chemists, biologists, and medical researchers alike.

Fischer had an unfailing intuitive perception for identifying important areas of research in organic chemistry and brought unsurpassed creativity to the conception of experiments and their skilful execution. The most striking feature of Fischer's scientific personality may be found in his pronounced tendency against any sort of theoretical speculation. Two instances may document this attitude further, one concerning the Walden inversion, to which Fischer had contributed[50] and which was controversially discussed around 1912. In a letter to T. W. Richards,[51] Fischer writes:

"I do not derive much pleasure from theoretical things. The occupation with the Walden inversion was rather a digression and recuperation from the extensive work on proteins. Moreover, so many limited heads have now jumped on this question, that the delight thereon is spoiled completely."

The second example refers to the question still open around 1914 on the ring sizes of the fructose and glucose portions of sucrose (formulations see Fig. 12), and how these sugars are

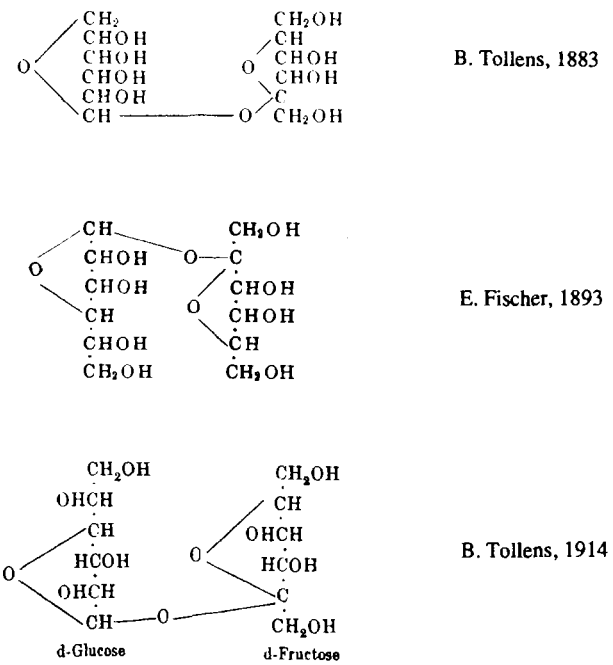

Fig. 12. Structural representations of sucrose by Tollens [53, 55] and Fischer [54].

linked. Fischer clearly states his position,[52] which may rightfully be extended to the lock-and-key picture:

"We know nothing definite on the mode, how the fructose residue is linked in cane sugar, thus leaving huge room for speculation. I, however, gladly renounce to use it."

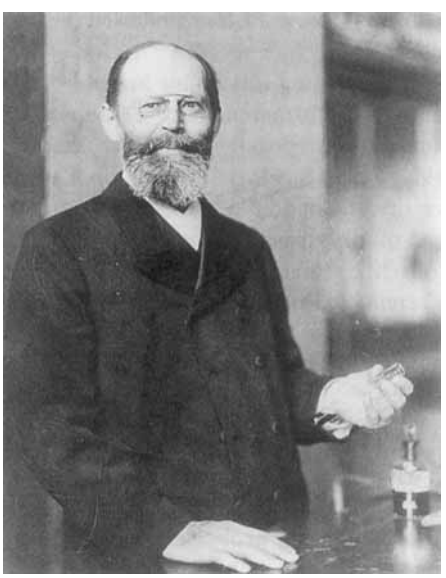

Fig. 13. Emil Fischer around the turn of the century.

In concluding this centennial tribute to one of the really great figures of our science (Figs. 13, 14) and to the lock-and-key concept with which he had a major influence on interrelating chemistry, biology, and medicine, I would like to cite a passage from his 1907 Faraday lecture at the University of London, entitled "Synthetic Chemistry in Relation to Biology", in which he clearly states his conviction to give in one's theoretical reasonings expression only to observed facts:[45]

> "The separation of organic chemistry from biology was necessary during the past century while experimental methods were being elaborated; now, that our science is provided with a powerful armory of analytical and synthetical weapons, chemists can once more renew the alliance both to its own honor and to the advantage of biology. The prospect of obtaining a clearer insight into the wondrous series of processes which constitute animal and vegetable life may well lead organic chemistry and biology to work with definite purpose to a common end.
> In order, as far as possible, to avoid mistakes in this difficult task and to shield ourselves from the disappointment which is the inevitable consequence of exaggerated hopes, we cannot do better than strive to imitate the great example of Faraday, who always, with rare acumen, directed his attention to actual phenomena without allowing himself to be influenced by preconceived opinion, and who in his theoretical conceptions gave expression only to observed facts."

This attitude with respect to the interpretation of experimental results applies to our science today as much as it did a 100 years ago. Especially in the field of molecular recognition which is in a very active phase of its development, we should comply with it most rigorously, as it gives us an unfailing measure of how far we should go with our interpretations today, and what we should leave for the next 100 years.

[6] a) The original and numerous other photographs are contained in the Collection of Emil Fischer Papers, housed in the Bancroft Library at the University of California, Berkeley. This scientific bequest consists of 34 boxes of material: lab notes, manuscripts, drafts of his autobiography "Aus meinem Leben", and about 5000 letters, that reached Fischer during his 40-year scientific career; for example, 157 letters during 1889–1915 from his teacher A. von Baeyer, others from F. Beilstein (11), A. Hantsch (56), F. Haber (35), J. H. van't Hoff (31), A. W. Hofmann (5), A. von Kekulé (6), H. Kiliani (16), V. Meyer (46), W. Nernst (67), B. Tollens (20), P. Walden (13), O. Wallach (46), and R. Willstätter (33); Fischer's intense interaction with industry is documented by 181 letters from C. Duisberg (from 1895–1919), from Bayer (271), BASF (54), Boehringer Mannheim (116), Hoechst (50), and Merck (33). The papers eventually reached Berkeley through Fischer's son, Hermann Otto Laurens Fischer [6b] who carried this collection through all the stations of his unusually cosmopolitan career: Privatdozent in Berlin, Professor of Pharmaceutical Chemistry in Basel, Director of the Banting Institute, Toronto, and Professor of Biochemistry at the University of California Berkeley; b) F. [27] a) In the Figures 4 and 5 the affiliation of the individual sugars to the D- or L-series has already been made. It should be noted though, that Fischer only introduced the symbols *d* and *l* as late as 1890 [27b] (cf. Scheme 1 and Fig. 7), deriving their meaning from the sign of rotation. Rosanoff in 1906 [27c], and Wohl and Freudenberg in 1923 [27d] brought the use of the *d* and *l* symbols on a logical, genetic basis by selecting the enantiomeric glyceraldehydes as points of reference, such that any sugar belongs to the *d*-series, if it can be derived from *d*-glyceraldehyde by successive Kiliani-Fischer syntheses. The present use of the D- and L-notation [27e] started around 1940; b) E. Fischer, *Ber. Dtsch. Chem. Ges.* **1890**, *23*, 370–394; c) M. A. Rosanoff, *J. Am. Chem. Soc.* **1906**, *28*, 114–121; d) A. Wohl, K. Freudenberg, *Ber. Dtsch. Chem. Ges.* **1923**, *56*, 309–313; e) Rules of Carbohydrate Nomenclature, No. 4 and 5 in *The Carbohydrates, Vol. IIB* (Eds.: W. Pigman, D. Horton), Academic Press, New York, **1970**, p. 809ff.
[28] Aside of ref. [12], there are several pertinent accounts of Fischer's conquest of the sugar configurations, for example C. S. Hudson, "Emil Fischer's Discovery of the Configuration of Glucose", *J. Chem. Educ.* **1941**, *18*, 353–357; "Emil Fischer and His Contribution to Carbohydrate Chemistry". K. Freudenberg, *Adv. The Key–Lock Theory and the Induced Fit Theory

Daniel E. Koshland, Jr.

It is a great pleasure for me to contribute to this symposium honoring the great scientist Emil Fischer. My graduate thesis required me to synthesize [1-^{14}C]glucose, which introduced me to the famous Fischer–Kiliani synthesis of glucose and mannose from arabinose and HCN.[1] I was also particularly intrigued with his classic key–lock (or template) theory of enzyme specificity,[2, 3] which like all great theories seemed so obvious once one understood it.

This symposium in his honor allows me to pay tribute to Fischer's great contributions to biochemistry varying from natural products chemistry to the key–lock theory, to review some of the history and significance of our induced fit theory, to illustrate the ramifications of those theories in our present era of protein–ligand interactions, and to discuss recent work in our laboratory which is helping to clarify conformational changes and their function. These theories have assumed again a central role in modern health research where the need for drug design requires taking into account the complementarity of fit of Fischer's principle and the flexibility and regulatory implications of the induced fit theory.

The induced fit theory is no more a refutation of Fischer's key–lock principle than the Heisenberg atom was of the Bohr atom or the modern DNA sequences are of the one gene–one enzyme hypothesis. A new theory must explain all the existing facts that pertain to it at the time of its enunciation. Gradually the new theory becomes accepted and then acquires anomalies due to the new facts uncovered after its enunciation. That in turn generates a newer theory which elicits new techniques to test it and its predictions. These new techniques then uncover facts which eventually require further new theories and so on. The new theories are built on components of the old principles. It is said that each scientist stands on the shoulders of the giants who have gone before him. There can be no more honored place than to stand on the shoulders of Emil Fischer.

Limits of the Key–Lock Theory

My first inkling that the Fischer key–lock model needed modification really arose from my consideration of the role of water in biological reactions. I was preparing a lecture for a scientific meeting and decided to consider why some proteins were kinases and others ATPases. The more I thought about the protein, the more astonishing it seemed that water could be prevented from reacting at the active site of a kinase.

In hexokinase, which I took as a typical kinase, the OH group of water was known to be as good a nucleophile as the OH group of a sugar. If glucose is bound very tightly then it could exclude water, and a basic group on the protein would generate a glucosyl oxyanion nucleophile which could attack the ATP. But glucose would not normally saturate the site and could in many physiological circumstances fall to very low levels. Water, at 55 M, would fill up an empty site, and therefore water would be constantly competing with glucose in the nucleophilic attack on ATP. The existence of kinases in the absence of substrate or with only partially filled template type active sites would result in great ATPase activity and an enormous waste of energy.

Once I started thinking along these lines other anomalies came to mind. One example was "noncompetitive inhibition", which was explained by saying that the inhibitor blocked enzyme action but did not affect the binding of the substrate. No key–lock concept was available to explain such a result.

The key–lock (or template principle) could explain why smaller sugars might not react: they would not be attracted to the active site strongly enough to form significant amounts of the ES complex. However, we found that α-methylglucoside was not a substrate but was a tightly bound competitive inhibitor of the enzyme. Thus it was tightly bound, could fit into the site, had the right chemical stereochemistry, but did not react. ("Substrate analog" was used for those chemicals whose chemistry is similar to a substrate but fail to react on the enzyme's surface as in α-methylglucoside, a substrate analog of the enzyme amylomaltase.)

Other reactions raised the same question of smaller chemically logical molecules that nevertheless did not react. And there were also cases in which a bigger substrate analog did not react. As another example, we found that cyclohexaamylose was an inhibitor of β-amylase (an enzyme that cleaved glucosyl bonds in long amylose chains). One could try to explain this on the basis of the key–lock principle by saying that the cyclic amylose was too big and couldn't bind, but we showed it did, in fact, bind (and tightly) but failed to react.[4]

Introduction of the Induced Fit Theory

So the induced fit theory[5] was proposed in the following terms "a) the precise orientation of catalytic groups is required for enzyme action, b) the substrate causes an appreciable change in the three-dimensional relationship of the amino acids at the active site, and c) the changes in the protein structure caused by the substrate will bring the catalytic groups into the proper alignment, whereas a nonsubstrate will not."

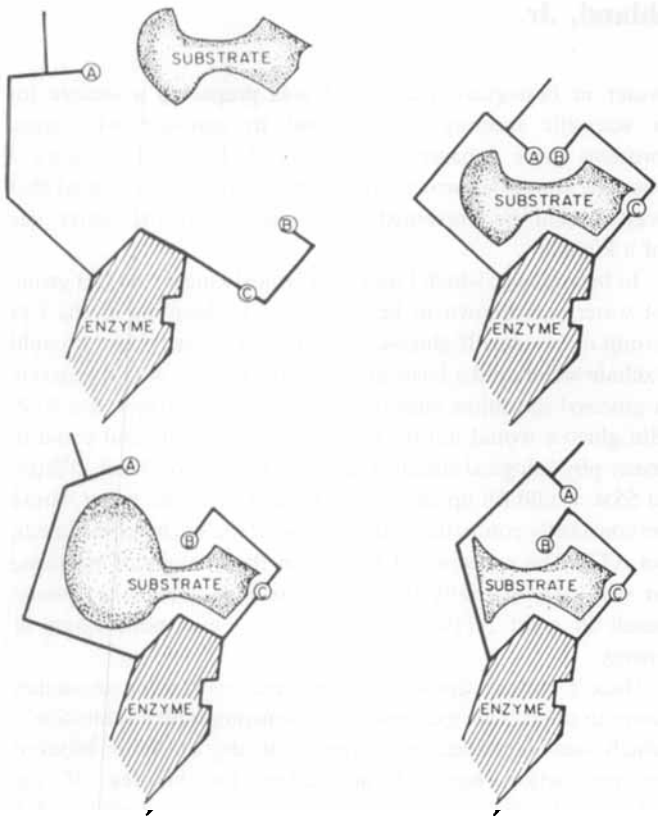

Fig. 1. Schematic model of the induced fit mechanism. Black lines indicate protein chains containing catalytic groups A and B and binding group C. Upper left: substrate and enzyme dissociated. Upper right: substrate with induced change of protein chains to bring A and B into proper alignment for reaction. Lower left: bulky group added to substrate prevents proper alignment of A and B. Lower right: deletion of a group eliminates buttressing action on the chain containing A, so the thermodynamically stable complex has incorrect alignment of A and B.

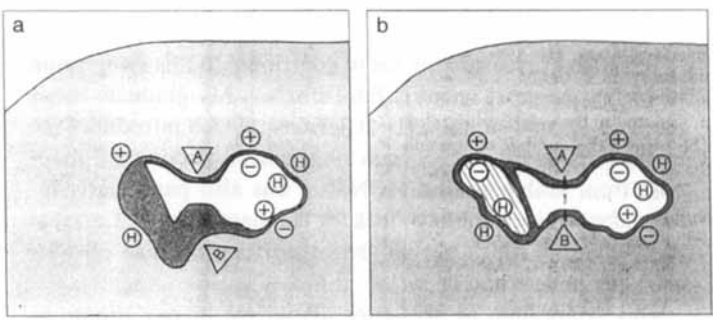
Pictures to illustrate this concept and how it could explain the previous anomalies are shown in Figure 1 taken from papers published at the time.[6] The theory of Emil Fischer was deep in the hearts of scientists and journal editors, so I had great difficulty getting the original ideas published or convincing skeptics, but we did obtain more evidence from my own laboratory, and soon others joined in. One of the predictions that results from the assumption of a flexible enzyme, namely that a small nonreactive molecule could make up for a structural deficiency in a nonsubstrate (Fig. 2), was established for us by two



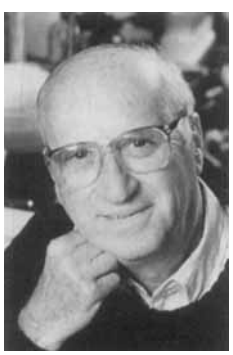


Fig. 2. Activator molecules can, according to the flexible model of enzyme action, help to make a deficient molecule act as a substrate by altering the shape of the enzyme. For example, in the case of a molecule (unshaded) that by itself is too small to induce the proper alignment of catalytic groups, A and B [shown in a)], a second molecule (shaded) can bind immediately adjacent to the deficient molecule [shown in b)] or (not shown here) to a more distant site, thereby inducing a stable shape with the proper alignment of catalytic groups.

laboratories. Sols et al. showed that xylose, a pentose (similar to glucose but lacking the 6-CH_2OH group), made hexokinase a better ATPase,[7a] and Murachi et al.[7b] showed that the nonsubstrate for trypsin, glycine ethyl ester, could react appreciably if ethylamine was added to the incubation mixture. These "regulatory" molecules which did not themselves undergo chemical changes could induce the further conformational changes in an enzyme needed for reaction (as illustrated in Fig. 2).

These indirect chemical assays added to the credibility of the hypothesis, but we needed direct evidence for the predicted induced conformational change in the protein (a proof which was easy later when protein crystallography became available). So Yankeelov and I said we must get a result with protein reactivity

Daniel E. Koshland was born in New York City in 1920. He earned his B. S. degree from the University of California, Berkeley, in 1941, and Ph. D from the University of Chicago in 1949. After two postdoctoral years at Harvard he joined the staff of Brookhaven National Laboratory, and later also of Rockefeller University. In 1965 he joined the faculty of the University of California, Berkeley, where he is currently Professor of Biochemistry and Molecular Biology. He became Editor of Science in 1985. Among his honors are the National Medal of Science, the Edgar Fahs Smith and Pauling Awards of the American Chemical Society, the Rosenstiel Award of Brandeis University, the Waterford Prize, and the Merck Award of the American Society of Biochemistry and Molecular Biology. Included in his fields of interest are the role of conformational changes in enzyme regulation and the elucidation of the catalytic power of enzymes. He demonstrated that bacteria have short-term memory and that purified mammalian cell lines show rudimentary memory. His recent work has emphasized the chemical mechanism of short-term and long-term memory, and the structure–function relationship of receptors.

that tested the key–lock template hypothesis and induced fit. We argued that adding a ligand to a template type enzyme can bury groups but it cannot expose them, whereas an induced fit conformational change could bury some groups and expose others. We picked the enzyme phosphoglucomutase (whose reaction had similarities to hexokinase, and thus we expected it to be an induced fit enzyme)[8] and used the reactivity of its SH group as a test. The experiment illustrated in Figure 3 gave the result we wanted.[8] Ligand binding induced the exposure of an SH group, a result incompatible with the key–lock theory. We likened it to the flexibility of a "hand in glove", which included Fisher's idea of a fit but added the flexibility concept.

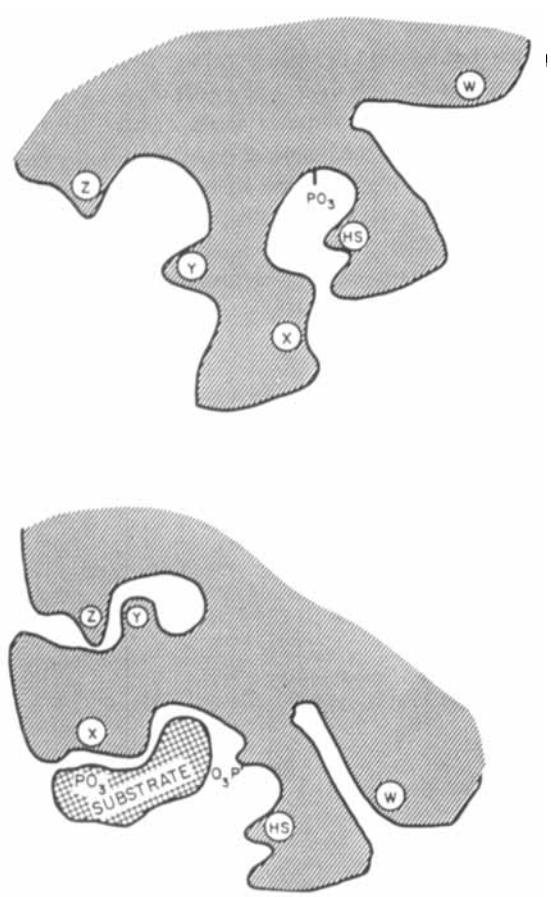

Fig. 3. Schematic illustration of flexibility in the action of phosphoglucomutase. The upper part of the figure represents the enzyme molecule in the absence of substrate. The lower part of the figure represents the change in conformation leading to exposure of –SH and burying of X, Y, Z, and W.

Further support came when the structures of lysozyme[9] and ribonuclease[10] were published because there were definite conformational changes; however, these were small and did not impress many. (Many biologists forgot that C–C and C–O bonds are only 1.5 Å long, so small changes can easily disrupt a catalytic alignment needed to catalyze changes in the bonds.) Then Steitz et al. with carboxypeptidase[11] and Steitz et al. with hexokinase[12] showed conformational changes that were breathtakingly large and highly convincing. Steitz showed that the engulfing of the substrate glucose by hexokinase occurred precisely as the induced fit predicted, thus giving visual proof that ligand-induced conformational changes were real and significant.[12]

Today almost every enzyme has been shown to undergo significant ligand-induced changes. A recent review by Gerstein, Lesk, and Chothia[13] divides these changes into "hinge domain" and "shear" motions and lists 42 enzymes that illustrate major conformational changes. The enzymes that show the least conformational changes are the hydrolases such as the proteases and nucleases—and they are precisely those one might expect to fall in this category, since they do not need to exclude water. The finding of extensive conformational changes in many enzymes is logical, since most enzymes exist in a cytoplasm with many pathways that contain many smaller substrate analogs, for example trioses, which must be prevented from reacting at sites of larger analogous substrates, for example hexoses. If the specificity failed to exclude smaller analogs, poor yields and bad side reactions would occur.

The question then arises as to how big the conformational changes have to be in order to be considered "significant". Some recent evidence indicating some answers to this problem is discussed below.

Isocitrate Dehydrogenase and Small Conformational Changes

We have recently been studying isocitrate dehydrogenase to obtain some clues to the size and significance of conformational changes. We found, for example, that the enzyme was inactivated by phosphorylation,[14] but this phosphorylation, unlike the case of glycogen phosphorylase,[15] involved phosphorylation right at the active site with little resulting change in conformation of the protein.[16–19] We also found very little change in conformation induced by the substrate isocitrate on binding to the protein and were about to conclude that the enzyme was one of those that approximated the Fischer key–lock model. However, we did one more experiment and tested the protein in the presence of the product, α-keto glutarate.[20] In that case the ligand-induced conformational changes were wide spread. Many atoms moved though each movement was rather small. The protein did not fit into the "hinge domain" category of Gerstein, Lesk, and Chothia nor even into the "shear" category, but rather into what might be called a "spider web" category, that is, small interconnected changes occurring over an extensive surface. The changes in each atom were less than an angström but many atoms moved, which suggested that subtleties in alignment were capable of turning an enzyme off or on.

We have also measured the changes in the aspartate receptor of chemotaxis in collaboration with Sung Hou Kim et al.[21] This case fits the shear model more closely, as we postulate that the small changes at the binding site for aspartate can cause a sliding of one helix past another.[22–24] The changes that are generated in the cytoplasmic domain are relatively small – maybe an average change of 0.5 Å—but the conformational change is transmitted from one side of the dimer to the other. In addition we have shown that the receptor shows negative cooperativity[25, 26] in which binding of the first aspartate to a dimer completely blocks aspartate binding to a second aspartate site. The two sites are initially identical, but the ligand-induced changes in the second site reduce the size of the second site so it becomes too small to bind aspartate. The changes are quite

Table 1. Distances between side chains in binding sites in the *Salmonella* aspartate receptor–ligand binding domain.

Amino acids	Separation [Å] in unbound receptor[a]	Separation [Å] in empty site of Asp-bound receptor[a]	Reduction in distance [Å]
Ser-68, Thr-154	8.9	8.1	0.8
Tyr-149, Arg-73	6.9	6.0	0.9
Tyr-149, Arg-64	4.1	3.2	0.9
Phe-150, Arg-73	4.8	3.5	1.3
Ser-68, Arg-69	7.4	6.6	0.8

[a] Distance between closest non-hydrogen atoms.

small in Å (Table 1) but are enough to prevent binding of the aspartate molecule.[26]

Our conclusion is that big movements are important but so are small ones. The important feature from the induced fit theory is that the alignment of catalytic groups and binding groups must be optimized for the transition state, and the attainment of the state is unfavorable energetically unless it is supplied with the energy of the substrate binding. If the protein movements were easy to attain, they would occur spontaneously often enough to have little effect on catalysis. However, a small movement can also be energetically unfavorable, as in the shift of a ferrous atom 0.7 Å into and out of the plane of the heme in hemoglobin.[27] When the small movement needed for catalysis, in the case of an enzyme, is generated by the binding of the substrate, enzyme action occurs.

A second conclusion is that the conformation of the protein is undoubtedly selected during evolution to optimize both the unliganded state and the liganded state. Allosteric sites are often distant from the active site by 20 Å or more, and the conformational changes are far larger than can be explained by a distortion that propagates from one site to another by pure chemical torsions. Those nonbonded forces dampen out too rapidly. Therefore, the conformational change induced by the substrate binding has a long-range effect because it generates and catalyzes the transition from one evolutionarily selected conformation to another.

Summary and Outlook

The basic concept of Emil Fischer's key–lock theory, which explained enzymatic properties of specificity and action for 60 years, required modification to explain discrepancies such as the lack of hydrolytic activity of kinases, noncompetitive inhibition, and other apparent inconsistencies. The new theory, the induced fit theory, incorporated Fisher's concepts of the complementarity of enzyme and substrate but introduced the concept of a flexible enzyme, likened to the fit of a hand in a glove. The flexible enzyme concept not only explained the discrepancies but set the stage for further understanding of *regulation*, *cooperativity*, and *specificity* as described in papers by Pardee,[28] Monod,[29] and our own laboratory, as well as many others. Thus the great work of Emil Fischer lives on in an extension of the theory and application to new problems of chemistry and biochemistry that were impossible to visualize in the 1900s. The new studies focus on the importance of conformational changes, both large and small, and the manner in which they control enzymatic reactions. The findings from modern X-ray crystallography that essentially all enzymes undergo conformational changes induced by substrate binding has made the induced fit theory universally accepted in textbooks and by scientists.

These theories are of increasing importance because of the rise in drug-resistant strains of organisms. Computer-assisted drug design is what we and many others are now developing to prevent the ravages of the new virulent organisms. For that purpose the key–lock theory with a relatively rigid enzyme would be an easier basis for computer designs, but unfortunately the evidence that induced fit theory is closer to reality means that computer programs will have to be a little more sophisticated. However, the modern computer seems clearly up to the challenge, and a rigid enzyme is a good starting point for initial assumption. The flexibility can then be built into subsequent calculations. Moreover, the flexible enzyme allows binding to a "regulatory" or "allosteric" site, which may be a better target for drug therapy in many cases. The finding that very small changes can "turn on" or "turn off" an enzyme is very encouraging in this regard.

This work received financial support from the National Institutes of Health and the National Science Foundation.

Fine Feathers Make Fine Birds: The Heck Reaction in Modern Garb

Armin de Meijere* and Frank E. Meyer

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

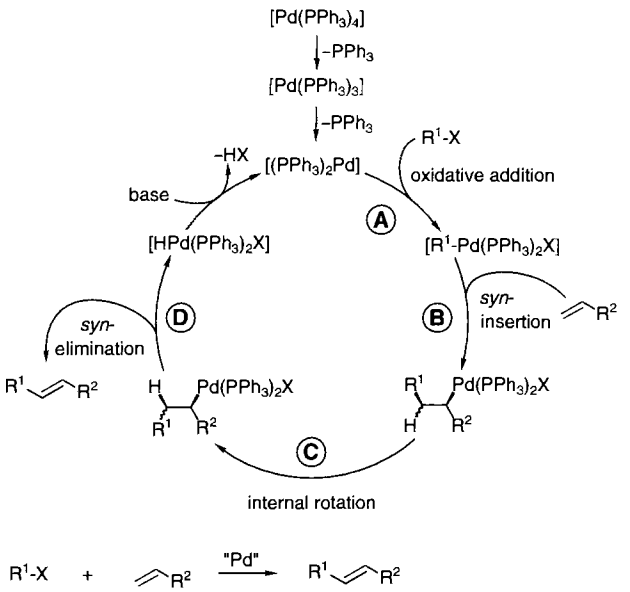
The palladium-catalyzed coupling of haloarenes and haloalkenes with alkenes, which was discovered by Richard F. Heck in the late sixties, has been a topic of fluctuating interest; however, in the last six years activity in this area has flourished. Careful choice of substrates and skillful tailoring of reaction conditions lead to impressive sequences consisting of even different reaction types that occur not only in a consecutive mode, but also in a single operation. The well-established Heck reaction, together with other mechanistically related palladium-catalyzed transformations with arene, alkene, and alkyne derivatives, opens the door to a tremendous variety of elegant and highly convergent routes to structurally complex molecules. The reaction is not disturbed by heteroatoms such as oxygen and nitrogen (nor by sulfur and phosphorus with some limitations). The spectrum of recent achievements starts with a range of chemoselective and regioselective monocouplings of highly functionalized substrates with unsymmetrical and multisubstituted reaction partners. Other advances include cascade reactions in which three, four, five, and even eight new C–C bonds are formed to yield oligofunctional and oligocyclic products with impressive molecular complexity. Even the enantioselective construction of complex natural products with quaternary stereocenters has been achieved with Heck reactions in key steps, as exemplified by the synthesis of crinan, picrotoxinin, and morphine. Today, the Heck reaction is indispensible in the arsenal of synthetic methods available to organic chemists. Certainly it is only a matter of time before the Heck reaction is applied in industrial syntheses.

1. Introduction

Like other fields, organic chemistry is subject to fashions. One of the latest fascinating trends is the rapidly developing field of fullerene chemistry.[1] But just as fashions may disappear into the back of the closet after only a short time, relevant discoveries in organic chemistry have often enough slipped into the realm of oblivion or at least have not received the broad attention that their potential would call for.

An example of an important new type of reaction that has been subject to these ups and downs in attention is the palladium-catalyzed arylation or alkenylation of alkenes known as the Heck reaction. Although the reaction was discovered as early as the late sixties by R. F. Heck[2] and initially received much attention as a new method for C–C bond formation, the Heck reaction was not applied and developed in the seventies and eighties to the extent that important synthetic reactions typically are. Only a few research groups continued to explore the scope and limitations of the method.[3]

Since synthetic strategies have become directed increasingly toward both efficiency *and* stereoselectivity, concepts in the past decade have been devised to sequentially form several carbon–carbon bonds in a single synthetic step—if possible, even diastereo- and enantioselectively.[4] Convincing initial success was achieved with radical-initiated cascade cyclizations,[5] but soon metal-mediated and metal-catalyzed reactions were specifically employed.[6] During the mid-eighties many groups recognized that the Heck reaction was underdeveloped and far from being exploited to its full synthetical potential. But this classic reaction experienced a renaissance soon after answers had been found to some important questions regarding the mechanism, the control of substrate selectivity as well as regio- and stereoselectivity, and the increase in efficiency. Now, scarcely a week passes without interesting new publications in this field. In view of this rapid development it would certainly appear reasonable to summarize what the "heck" has been going on recently behind so many laboratory doors.



2. A Brief Description: Mechanism, Methods, and New Possibilities

2.1. Mechanism

Even at an early stage in the development of this catalytic reaction into a facile method for the preparation of alkenyl- and aryl-substituted alkenes, reasonable concepts for the mechanism of the Heck reaction emerged, which could serve at least as a working hypothesis (Scheme 1).[3]

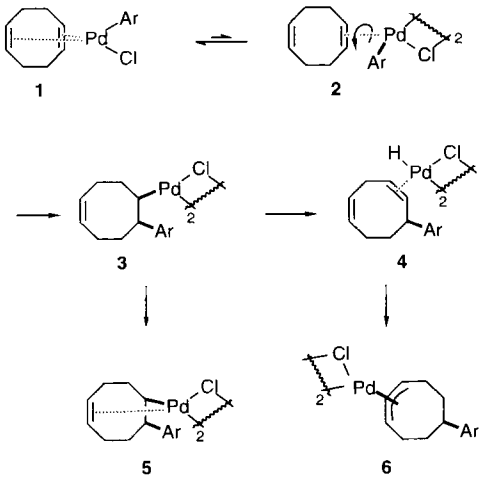
Scheme 1. Mechanism of the Heck reaction. R^1 = alkenyl, aryl; R^2 = aryl, alkyl, alkenyl, CO_2R', etc; R' = alkyl; X = I, Br, (Cl), OSO_2CF_3.

Today, a coordinatively unsaturated 14-electron palladium(0) species, usually coordinated with weak donor ligands (tertiary phosphanes), is assumed to be the catalytically active complex. This complex is normally generated in situ. Tetrakis(triphenylphosphane)palladium(0)[7] which occurs as a tris(triphenylphosphane)palladium(0) complex in solution, is frequently employed.[8] After the endergonic loss of a second phosphane ligand[9] the catalytically active species bis(triphenylphosphane)palladium(0) is generated. However, palladium(II) salts such as palladium acetate or bis(triphenylphosphane)palladium dichloride, which are reduced in the reaction medium, are more commonly used.[10] Bis(triphenylphosphane)palladium(0) is a well-characterized compound, accessible by both chemical[11] and electrochemical[12] routes.

In the first step of the catalytic cycle (A in Scheme 1) haloalkenes and haloarenes are commonly assumed to oxidatively add to bis(triphenylphosphane)palladium(0), generating a σ-alkenyl or σ-arylpalladium(II) complex. This reaction should lead to the thermodynamically stable[12, 13] *trans*-σ-alkenyl- or -arylpalladium(II) complex in several steps,[14a, 15, 16] probably via a *cis*-σ-alkenyl- or -arylpalladium(II) intermediate.[15a, c, d]

In the next step an alkene molecule is coordinated, probably after elimination of another phosphane ligand.[17] After both ligands have adopted the *cis* orientation necessary for insertion of the alkene into the σ-alkenyl or σ-aryl C–Pd bond, rotation of the alkene leads to in-plane coordination of the alkene. Finally, the alkene inserts into the σ-alkenyl- or -arylpalladium bond[18] to give a σ-alkylpalladium complex via a four-center transition state (step B).

The rearrangement of complex **1** via σ complex **3** to σ,π complex **5** and the π-allyl complex **6** is an example of a double bond insertion into a σ-aryl C–Pd bond (Scheme 2).[19]

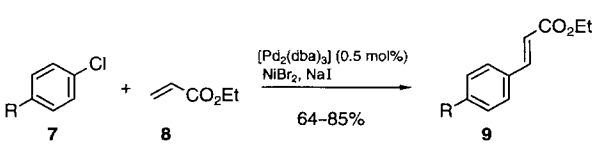


After the *cis*-addition of the alkene, the reaction-terminating β-hydride elimination (step D)[20] can generally occur only after internal rotation (step C) of the generated alkylpalladium species. In this way, the essential *syn* orientation of a β hydrogen is provided for elimination. The catalyst is regenerated after reductive elimination of HX in presence of the base.[21]

2.2. Further Developments

Applications of the Heck reaction in natural product syntheses were until recently[22, 24f] rather limited,[23] despite the potential of this reaction for the arylation and alkenylation of alkenes. This was surely due to the lack of regioselectivity frequently encountered in couplings with unsymmetrical alkenes,

Armin de Meijere, born 1939 in Homberg (Niederrhein), studied chemistry at the Universities of Freiburg and Göttingen and obtained his doctorate at the University of Göttingen with a thesis entitled "The Conformations of the Lower Bicycloalkyls" under the guidance of Prof. Dr. Wolfgang Lüttke. He spent two years as a postdoctoral fellow with Prof. Kenneth B. Wiberg at Yale University in New Haven, CT (USA), and obtained his "Habilitation" in 1971 at the University of Göttingen. He became full professor of organic chemistry at the University of Hamburg in 1977, and returned to the University of Göttingen as a professor of organic chemistry in October 1989. He has served as a member of the Academic Senate at the University of Göttingen, as a dean of the chemistry department in Hamburg, and as the Director of the Institute of Organic Chemistry. Over the years, he has been visiting professor at the University of Wisconsin in Madison, Wisconsin, the IBM Research Laboratory in San José, CA, the Technion in Haifa, Israel, Princeton University in Princeton, NJ, and the University of Aix-Marseille III. He received a fellowship from the Studienstiftung des Deutschen Volkes, obtained the award "Dozentenstipendium" from the Fonds der Chemischen Industrie in 1972, and was elected a member of the Norwegian Academy of Sciences and Letters in 1992. He is editor or member of the editorial board of a number of scientific journals and books. His scientific achievements have been published in over 280 original publications, review articles, and chapters in books. His current research interests include the development of new small-ring building blocks and their application in the synthesis of natural and non-natural compounds; new highly strained polycyclic compounds with interesting properties; application of organometallic complexes and catalysts in organic synthesis; palladium-catalyzed sequential reactions; and carbon compounds and organometallic complexes with unconventional chemical and physical properties.



Scheme 2. Ar = C_6F_5.

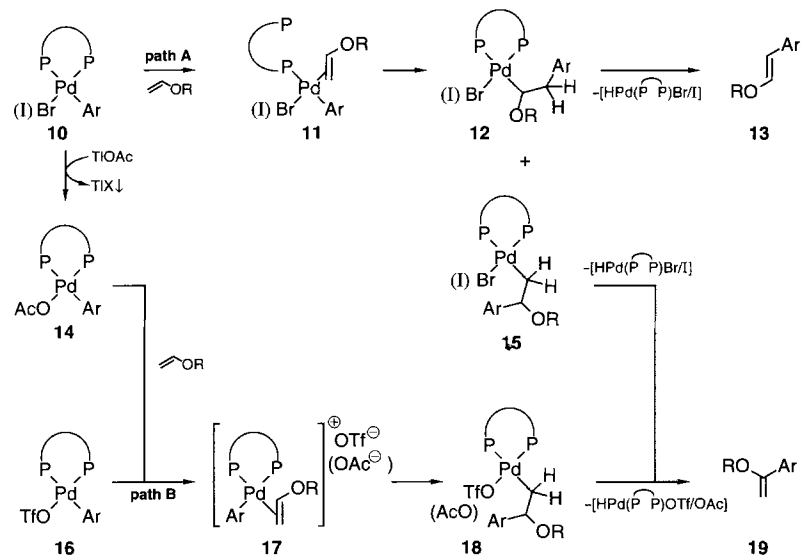
and the observed isomerizations of the products generated after β-elimination. A further handicap was the restriction of coupling substrates to aryl and alkenyl bromides and iodides. Consequently, there was great interest in the development of coupling substrates that are both more economical and preparatively more easily accessible, and if possible reactive even at lower reaction temperatures.

The nature of the leaving group X also affects the addition rate (ArI > ArBr ≫ ArCl),[24, 25] because the oxidative addition of haloarenes (haloalkenes) to palladium(0) is in many cases the rate-determining step.[12b, 24] Common reaction temperatures lie in the range of 70 to 100 °C, though chloroarenes are practically unreactive under these conditions.[25a, 26]

Meanwhile it has been shown that Heck reactions can be performed at room temperature with aryl diazonium salts,[27] *N*-nitroso-*N*-aryl acetamides,[28] and hypervalent iodo compounds.[29] Interestingly, even haloarenes and haloalkenes react at room temperature when high pressure[30] is applied or phase-transfer catalysts such as tetrabutylammonium chloride[31] are added (conditions according to Jeffery's protocol). Benzyl halides[32] and benzoyl chlorides[33] have also been employed in coupling reactions with alkenes. Further developments are directed towards the use of low-cost chloroarenes that normally do not undergo oxidative addition to palladium(0) under Heck conditions. Some initial successful attempts have been reported on the application of high pressure,[30] the deployment of basic ligands that facilitate oxidative addition,[34] the immediate generation of the catalytically active palladium species,[35] and the nickel dibromide/sodium iodide assisted activation of substituted chloroarenes (Scheme 3).[36]

Alkenyl sulfonates have become important as haloalkene substitutes and are normally easily prepared from the corresponding carbonyl compounds.[37] While the use of alkenyl mesylates and alkenyl tosylates is largely unexplored,[38] many successful reactions with alkenyl trifluoromethanesulfonates

Scheme 3. R = H, COMe, OMe, Me, CN; dba = dibenzylidenacetone.



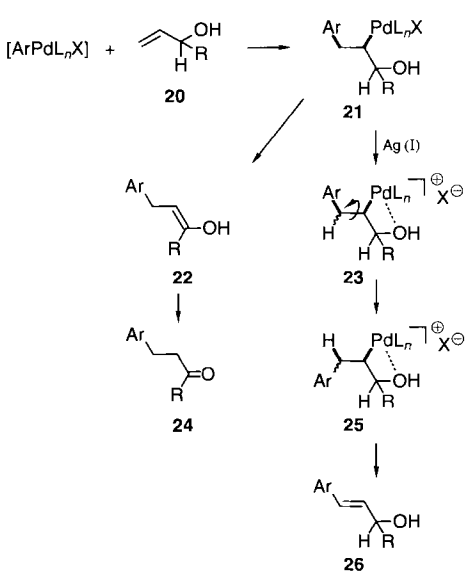
(alkenyl triflates), starting with the early works by Cacchi et al.[39] and Stille et al.,[23m, 40, 41] have demonstrated the advantages of this leaving group. The previously observed inhibition of the reaction following facile oxidative addition of alkenyl triflates to palladium(0) can be prevented by adding lithium chloride to the reaction mixture.[40] Addition of metal halides or tetrabutylammonium halides can also facilitate Heck couplings.[23h, 31, 41a, 42] Detailed studies by Amatore et al.[12a, 43] confirmed the early assumption[40b, c] that halide ions stabilize coordinatively unsaturated and low-valent palladium species. In many cases the Heck reaction is also accelerated by silver(I)[44] and thallium(I) salts.[23a, 45]

Initially, dipolar aprotic solvents such as dimethylformamide (DMF), *N*-methylpyrrolidone (NMP), dimethyl sulfoxide (DMSO), and acetonitrile were common. But ever since the pioneering work by Beletskaya et al.[46] many alkene arylations are also known to proceed superbly in aqueous solution. Thus, excellent results were achieved with water-soluble triarylphosphane ligands in water-containing acetonitrile.[47a] In fact, water accelerates the reaction, especially in the presence of quaternary ammonium salts.[47b]

According to the studies of Hallberg et al.,[48] Teranishi et al.,[49] Choudary et al.,[50] and Zhuangyu et al.[51] the typically homogeneous reaction can also be performed with polymer-bound palladium catalysts. Early investigations concerning intermolecular arylations of unsymmetrically substituted alkenes often revealed only poor regioselectivities,[3a, 52] especially with acyclic enol ethers.[53] In recent years, however, suitable conditions have been developed for the selective α- or β-arylation of enol ethers[54] and enamides.[55] In these arylations the regiochemistry is determined by the decomposition of π complex **11** (Scheme 4, path A)[19] to give either the σ complexes **12** or **15**, or a mixture of both. Although the metal center may be regarded upon insertion as an electron acceptor and the migrating carbon atom as a nucleophile, merely a minor charge separation is actually involved. Therefore, the regioselectivity of insertion is commonly explained by steric considerations.[56, 87b] Nevertheless, electronic effects do indeed play a major role in arylations of acyclic enol ethers.[54b, 57]

Thus, reactions of acceptor-substituted aroyl chlorides provide β-arylalkenyl ethers in good yields.[58a, d] Also, high β-selectivities are achieved in arylations of modified alkenyl ethers, for example 2-(dimethylaminoethyl)-,[58b] 2-(diphenylphosphanoethyl)-, and 2-(diphenylphosphanophenyl)alkenyl ethers.[58c]. On the other hand, the extent of α-alkenylation was improved considerably by using alkenyl triflates.[59] In contrast to previous findings,[60] Cabri et al.[45a, 61] achieved excellent α-regioselectivities with bidentate ligands such as 1,3-bis(diphenylphosphano)propane (DPPP)[45d, 61b, d] and 2,2′-dipyridyls.[61c] Aryl and aroyl halides also give exclusively α regioisomers[61a, d] in presence of thallium(I) acetate.

According to Cabri et al.[61a, d] and Hayashi et al.,[62] the drastic effect that the leaving group on the arene and the addition of silver(I) or thallium(I) salts have on regioselectivity arises from the competition of two different coordination–insertion steps in the Heck reaction. If, after oxidative addition, the counterion in complex **10** is halide, one of the two phosphorus atoms in the bidentate ligand will dissociate from palladium, and an alkene molecule will coordinate instead giving the neutral

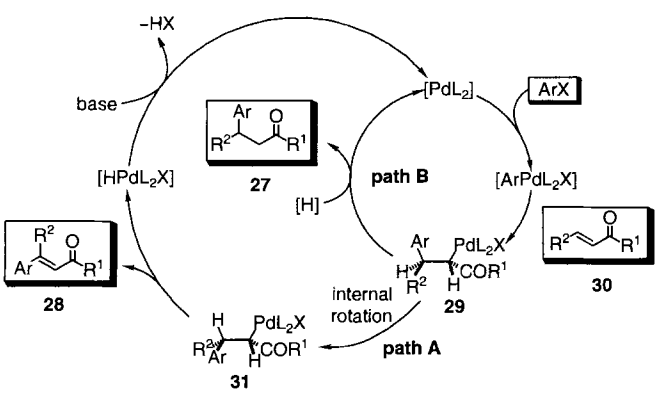


Scheme 4. Ar = aryl; Tf = triflate = CF_3SO_2; P⌒P = diphosphane ligand.

complex **11** (path A in Scheme 4). In **11** the π system of the coordinated enol ether is only slightly polarized, and the electronic effect on the subsequent insertion is subtle, therefore leading to higher preference for β attack. Upon addition of thallium(I) acetate or silver salts to the reaction mixture, the halide ion in complex **10** is presumably replaced by weaker ligands such as acetate to give complex **14**.[63]

In palladium(II) complexes **14** and **16** weak ligands[64] like triflate and acetate readily dissociate giving the cationic complex **17** (path B in Scheme 4). Coordination of the enol ether in these cationic complexes causes a significant polarization of the π system, resulting in a much more directed migration of the aryl residue and an increased proportion of α-substituted product.

The regioselectivity of Heck reactions with unsymmetrical alkenes can therefore be manipulated by specific variation of components in the "catalyst cocktail". But the impact of silver(I) and thallium(I) salts on Pd-catalyzed reactions extends beyond just increasing regioselectivities and enhancing reaction rates.[44a, b, 65] Without these additives, arylations of allyl alcohols **20** afford aldehydes and ketones **24**[66] rather than the β-aryl allylic alcohols **26** (Scheme 5). This may be explained by a faster or more selective β-hydride elimination in intermediate **21**, leading to enol **22**. Similarly, elimination to give allylic alcohol **26** followed by

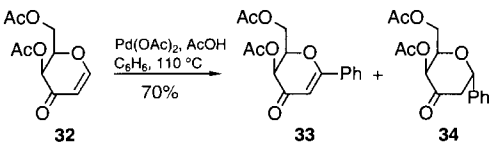


Scheme 5. Ar = aryl; L = ligand; X = halogen; R = alkyl.

readdition of the hydridopalladium species to the double bond[67] and subsequent β-hydride elimination to give the more stable enol **22** also provides a suitable explanation. This type of isomerization consisting of a sequence of β-hydride eliminations, readditions, and renewed elimination is not restricted to allylic alcohols.[68]

These types of Pd-catalyzed isomerizations are suppressed by addition of silver(I) salts.[44] Thus, in the presence of silver carbonate, allylic alcohols can be arylated and alkenylated in palladium-catalyzed reactions.[69] With triflates couplings are achieved without accompanying isomerization, even in the absence of silver salts.[70] The formation of cationic palladium complex **23** is attributed to either silver ion assisted dissociation of **21** or spontaneous dissociation of the triflate leaving group. β-Elimination leading to enol **22** is hindered by the chelating hydroxyl group.[69c, 70] Because of the shortened lifetime of the eliminated hydridopalladium species, its readdition to **26** does not take place.

The complete control of regiochemistry in this example is also impressive. Iodoarenes give, in the presence of phase-transfer catalysts, β regioisomers **22** and **24**.[69] Complementary α-aryl allylic alcohols may be obtained by using aryl triflates and DPPP as a bidentate ligand.[61d] Furthermore, the desilylation reactions in alkenylations with alkenyltrimethylsilanes frequently observed under classical Heck conditions can be avoided by employing alkenyl triflates or iodoalkenes and by adding silver salts.[65, 71]

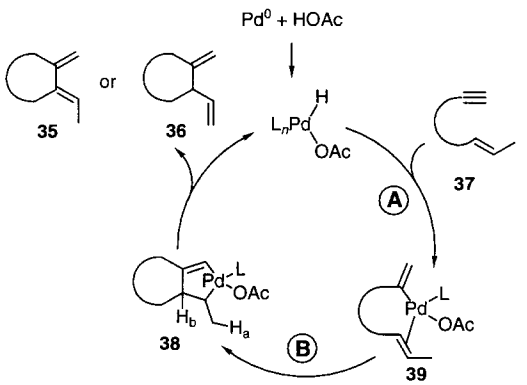


In arylations of β-substituted α,β-unsaturated enones **30** (Scheme 6) varying amounts of different products are frequently

Scheme 6. X = Br, I; R^1 = alkyl, aryl, H; R^2 = alkyl, aryl.

obtained, on account of two competing processes at the stage of alkylpalladium species **29**. On one hand, *syn* β-elimination of $[HPdL_nX]$ (vinylic substitution) may yield the expected Heck reaction product **28** (path A), but the palladium residue in **29** is much more often observed to be protolytically cleaved (path B), giving rise to **27**,[72] the product of 1,4-addition to **30**. In the absence of appropriate reducing agents only low conversions are observed, since palladium leaves the catalytic cycle as Pd^{II}. In contrast to these findings, vinylic substitution is entirely suppressed by 1,4-addition in the presence of trialkylammonium

formate.[73] But β-arylations proceed favorably at least with acyclic α,β-unsaturated enones in the presence of sodium acetate[74] under the conditions developed by Jeffery.[74] However, analogous results cannot be obtained with cyclic α,β-unsaturated enones, as is evident in the arylation of dihydro-γ-pyrone **32** with benzene in the presence of an equimolar amount of palladium acetate.[75] Different reaction conditions lead to varying amounts of both **34**, the product of 1,4-addition, and **33**, that of vinylic substitution (Scheme 7).



32 **33** **34**

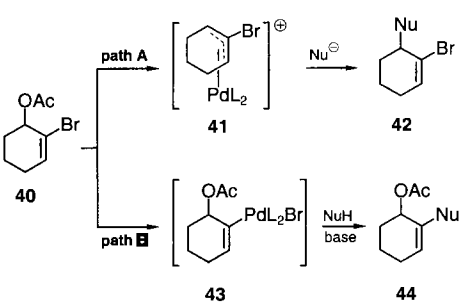
Scheme 7.

Although some of the initial major problems of the Heck reaction (i.e. lack of regioselectivity, product isomerizations, high reaction temperatures, and restriction of substrates to bromides and iodides) have been overcome or almost unraveled, it must be recognized that some of these achievements were literally quite costly. Indeed, the equimolar amounts of silver and thallium salts frequently employed in those first studies are not exactly what one would call inexpensive.

In the mid-eighties Trost et al.[76a] found a both simple and ingenious way out of this dilemma by developing palladium-catalyzed enyne cyclizations[76] (Scheme 8). The atom economy[77]

Scheme 8.

of this reaction equals that of the Diels–Alder reaction.[78] The cycloisomerization of 1,6-enynes **37** to 1,2-dimethylenecycloalkanes **35** or 1-methylene-2-ethenylcycloalkanes **36** is performed with palladium acetate in the presence of acetic acid and phosphane ligands.

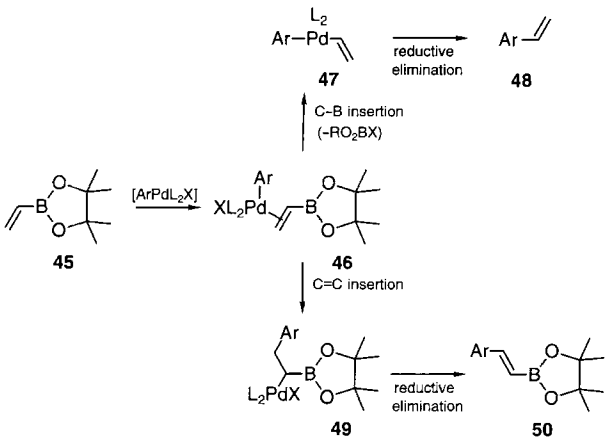


Unlike the Heck reaction, the initial step here is not an insertion of the Pd^0 species into an alkenyl carbon–halogen bond. Instead, acetic acid is oxidatively added to palladium(0), generating a hydridopalladium species.[79] The catalyst then adds to the terminal alkynyl group in enyne **37** with remarkable regio- and chemoselectivity and coordinates the alkenyl group (step A). It is yet unclear how the next intermediate, σ complex **38**, is generated (step B). β-Elimination of H_a or H_b in **38** yields 1,2-dimethylenecycloalkane **35** or the Alder–ene product **36** and regenerates the catalyst [HPdOAc].[80]

Although comparable with the Heck reaction in terms of products and individual mechanistic steps, cycloisomerizations of 1,6-enynes offer an interesting alternative from an economic standpoint. The arduous task of introducing halogen or pseudohalogen substituents to alkenyl groups is not necessary, and difficulties arising from the coordination of halide ions by the catalytically active species can be avoided. Unfortunately, this reaction is still restricted to intramolecular applications, and the initial step of the catalytic cycle, regioselective addition of [HPdOAc] to the terminal alkyne, primarily generates exo-methylenecycloalkanes.

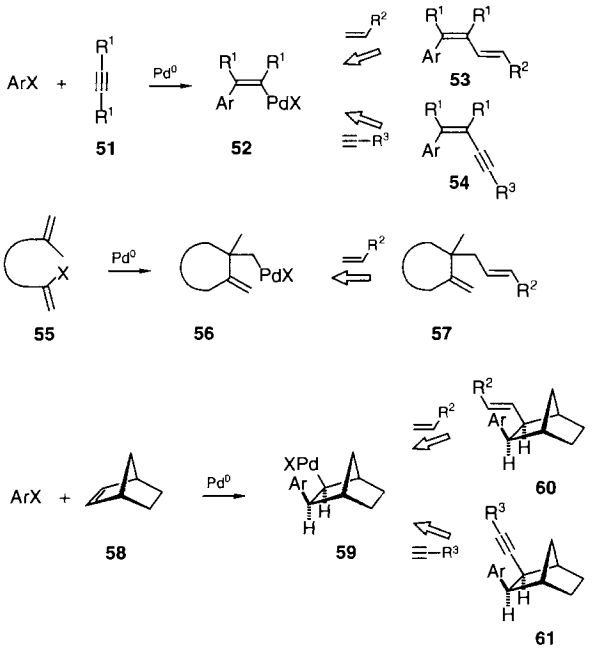
2.3. Variety is the Spice of Life: Ideas and New Concepts

Palladium complexes are of eminant importance in organic synthesis because of the diversity of chemical transformations they catalyze. In addition to Heck reactions and hydrogenations of unsaturated compounds,[81] reactions such as nucleophilic substitutions via π-allylpalladium complexes,[82] the chloroacetoxylation of dienes,[83] couplings with terminal and heteroatom-substituted acetylenes,[84] and stereoselective cross-couplings belong to the modern synthetic chemist's unrelinguishable arsenal of methods.



Many parallels in individual mechanistic steps of all these reactions may be perceived and give rise to interesting questions. For example, how do substrates like cyclohexene **40** behave upon reaction with nucleophiles in the presence of a palladium(0) complex (Scheme 9)?[85] The presence of both a vinyl

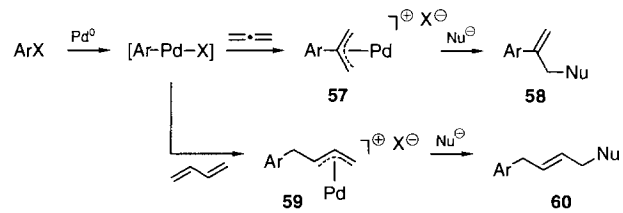
Scheme 9.



bromide and an allyl acetate group should enable the generation of both a π-allylpalladium complex **41** and σ-alkenylpalladium species **43**, respectively. How do haloarenes react in the presence of Pd^0 complexes with substrates such as ethenyl boronate **45**, which have the potential to react according to a Heck or a Suzuki coupling[22g] (Scheme 10)?[86] Results showed that cyclohexene **40** reacts chemoselectively via cyclohexenylpalladium complex **43** (path B), and ethenyl boronate **45** gives a mixture of styrene **48** and styrylboronate **50**.

Palladium-catalyzed reactions also play an important role in sequential reactions, which are rapidly increasing in popularity. Palladium catalysts initiate reaction cascades in which several carbon–carbon bonds are formed in a single synthetic operation.[4] Heck reactions and mechanistically related transforma-

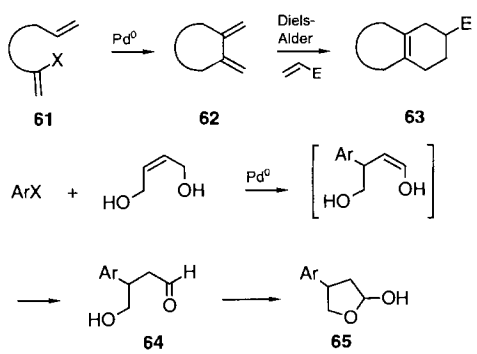
Scheme 10.



tions with substrates that for steric reasons do not allow termination of the catalytic cycle by the common β-hydride elimination have exceptionally high potential for reaction cascades (Scheme 11).

Scheme 11. Palladium-catalyzed sequential reactions I; R^1 = aryl, $(alkyl)_2COH$, $SiMe_3$; $R^2 \neq$ alkyl; R^3 = alkyl, aryl, CO_2alkyl, $SiMe_3$.

Such a situation arises on addition of a haloarene to disubstituted alkyne **51** in the presence of Pd^0.[87] This addition yields the sufficiently stable and therefore long-lived alkenylpalladium species **52**, which is thus able to undergo further reaction and which also could have been generated by oxidative addition of an appropriate alkenyl halide to palladium(0). β-Hydride elimination is also suppressed in an alkylpalladium halide intermediate of type **56**, which is generated by intramolecular addition of an alkenyl halide to a 1,1-disubstituted double bond as in diene **55**.[32] It can also be advantageous that reductive elimination of [HPdX] typically only occurs if the palladium and hydrogen atoms have a *syn* orientation. Upon addition of arylpalladium halide to the double bond of rigid bicyclic norbornene **58**, alkylpalladium species **59** is generated, which cannot undergo β-hydride elimination. Just like **52** and **56**, intermediate **59** can undergo subsequent intra- and intermolecular reactions with carbon nucleophiles and alkenes.[88] These are only three examples of the formation of two new C–C bonds in a simple two-step sequence.

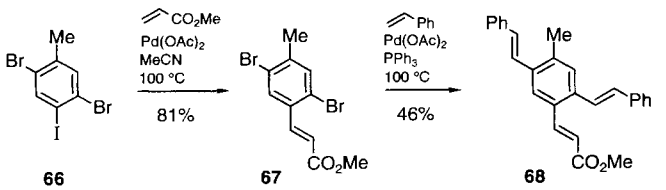


The addition of arylpalladium complexes to polyunsaturated systems such as allenes[89] and 1,3-dienes[90] initiates yet another type of reaction cascade in which two bonds are formed consecutively. The π-allylpalladium complexes **57** and **59** thus generated typically react with various nucleophiles leading to substitution products **58** and **60**, respectively (Scheme 12).

Scheme 12. Palladium-catalyzed sequential reactions II.

In both types of cascades the initial steps are the same as those in the Heck reaction, but in the course of the transformation characteristics of a different reaction type come to fore. The considerable synthetic potential of palladium-catalyzed sequential reactions becomes apparent in these examples. By careful choice of substrate and reaction conditions, several even quite different reaction steps can be performed in a single synthetic operation.

In yet another conceptional approach palladium-catalyzed reactions generate structural elements that can undergo consecutive reactions,[4a] thus allowing additional bond formations.[91] In this context it would appear favorable to assemble 1,3-dienic systems **62** by subjecting bromodienes **61** to a Heck reaction. Subsequently, these 1,3-dienes **62** can serve as reaction partners in Diels–Alder reactions, performed either in the same or in a consecutive synthetic operation (Scheme 13).[92] Haloarenes can be linked to 1,4-butenediol in palladium-catalyzed reactions to yield γ-hydroxyaldehydes **64**, which can react further intramolecularly to provide the corresponding substituted hemiacetals **65**.[93]

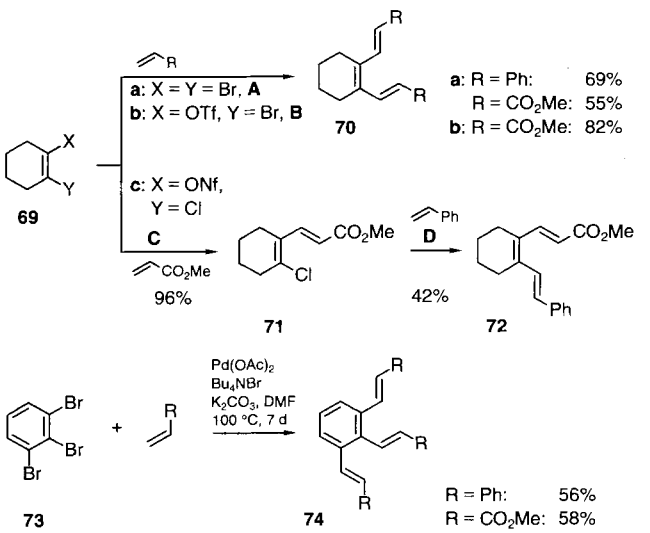


Scheme 13. X = Br, I; E = CO_2alkyl.

During the past six years these astonishingly simple concepts have revealed totally new perspectives for palladium-catalyzed reactions, which have been demonstrated in a whole host of synthetic applications. Thus, in the 25 years following its discovery, the Heck reaction has evolved from a simple alkenylation or arylation of alkenes to an integral part of tunable sequences consisting of various successive transformations in cascade reactions.

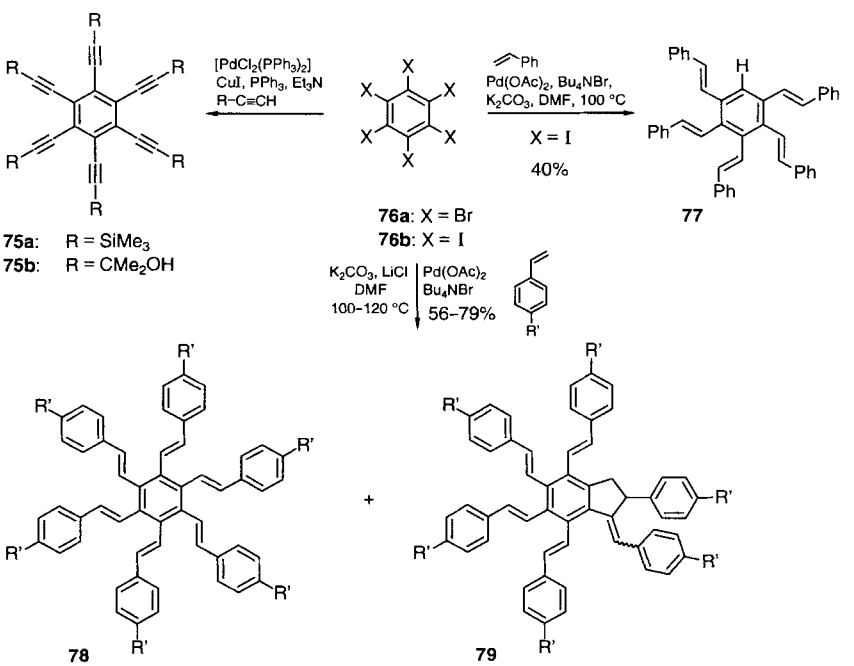
3. Heck Couplings with Oligohaloarenes: How Many Are Possible?

Since palladium-catalyzed alkenylations of haloalkenes and haloarenes often proceed in excellent yields, it would appear obvious to also apply this coupling to appropriate oligohalogen derivatives.[94] Heck et al.[95] reported on the twofold coupling of *ortho*- and *para*-diiodobenzene with alkenes at a very early stage. Bromoiodoarenes can also be coupled consecutively to two different alkenes, as was shown in the sequential reaction of 2,5-dibromo-3-iodotoluene (**66**) with methyl acrylate and styrene (Scheme 14).[96] Discrimination is possible with appropriate reaction conditions. When triphenylphosphane is not added, only iodide is replaced by acrylate, whereas upon addition of triphenylphosphane the dibromo derivative **67** reacts with two equivalents of styrene to give **68** (Scheme 14).



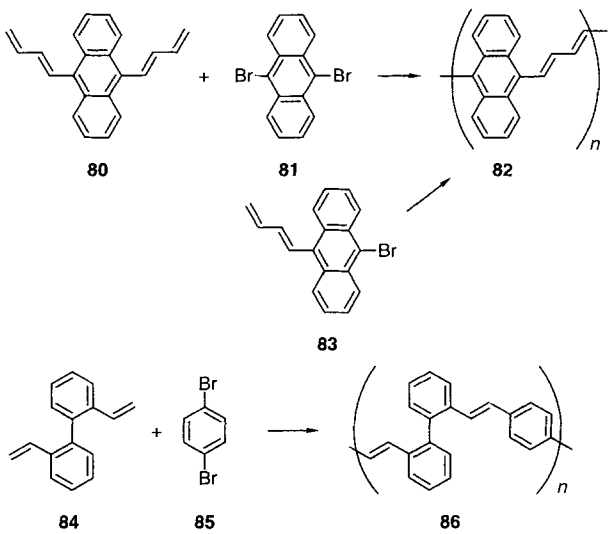
66 **67** **68**

Scheme 14.



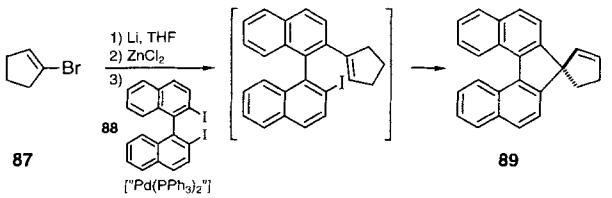
The scope of selectivity control in these multiple couplings can be extended with triflate leaving groups in the multifunctional substrates. The successive coupling of 2-chlorocyclohexenyl nonaflate (**69c**) with methyl acrylate and styrene to yield **72** is a typical example. In contrast, dibromide **69a** and bromotriflate **69b** react with styrene or acrylate under similar conditions to immediately give **70** (Scheme 15).[97]

Although the synthesis of hexaalkynylbenzenes **75** from hexabromobenzene (**76a**) was described some time ago (see Scheme 16),[98] hexaalkenylbenzenes other than hexaethenylbenzene were unknown.[99] Exchange of more than two vicinal halogen substituents on an arene by alkenyl groups failed to take place under Heck's original conditions.[95] However, Jeffery's[31] modified reaction conditions allow the replacement of three, four, five, and even six vicinal halogen substituents by styryl groups.[97, 100] For example, reaction of 1,2,3-tribromobenzene (**73**) with three equivalents of styrene smoothly yields 1,2,3-tristyrylbenzene (**74**) (Scheme 15). Hexaiodobenzene (**76b**) gave pentastyrylbenzene (**77**) in only 40% yield as the major product, apparently because of a side reaction involving protiodepalladation of the (aryl)iodopalladium intermediate.[100] In contrast, hexabromobenzene (**76a**) gave sixfold coupled products **78** with styrene and a whole host of *para*-substituted styrenes in good yields (Scheme 16). However, it proved to be extremely difficult to separate hexastyrylbenzenes **78** from isomers **79**, which were generated in further palladium-catalyzed reactions of *ortho*-dialkenylbenzenes.[101]



Scheme 15. A: $Pd(OAc)_2$, PPh_3, Et_3N, DMF, 90 °C, 40 h; B: as A but 65 °C, 4 h; C: as A but 60 °C, 24 h; D: $Pd(OAc)_2$, PPh_3, MeCN/THF (3/1), 10 kbar, 60 °C, 3 d. Nf = $C_4F_9SO_2$.

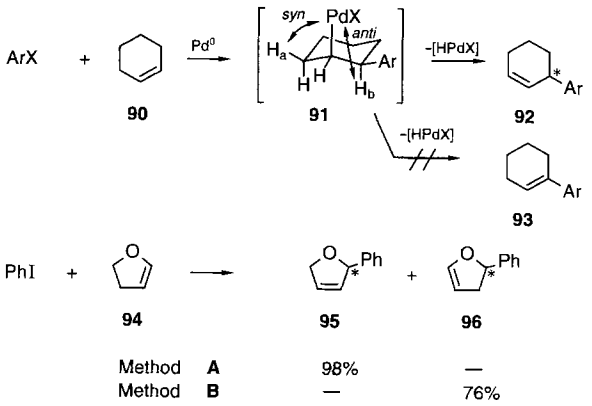
Multiple couplings of *para*-dibromoarenes with dialkenylarenes are also of interest for the synthesis of extended π systems. For example, 9,10-dibromoanthracene (**81**) and 9,10-bis(buta-



Scheme 16. R' = H, F, CH_3, OCH_3, OC_7H_{15}, $OC_{16}H_{33}$.

dienyl)anthracene (**80**) give oligomers **82** with an average degree of polymerization of 12. These oligomers can also be constructed from the bifunctional monomer **83** (Scheme 17).[102] The analogous coupling of 2,2'-diethenylbiphenyl (**84**) with *para*-dibromobenzene (**85**) led to oligomeric stilbenes **86** with an average degree of polymerization of 15. Compounds **86** are interesting owing to their potential in photochemically induced reactions.

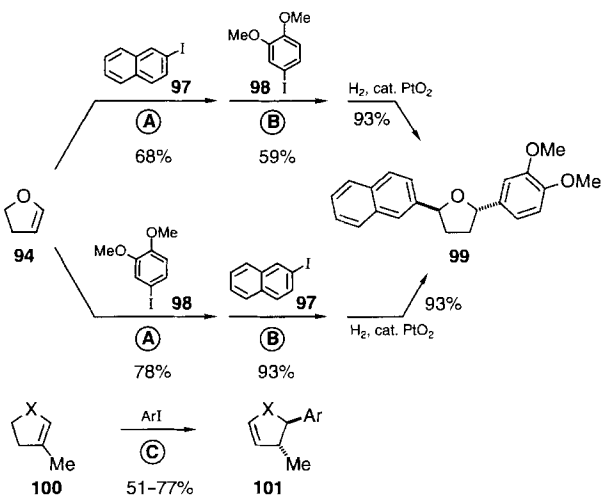
Scheme 17.



Palladium-catalyzed cross-couplings of dihaloarenes with unsaturated organozinc compounds, followed by an intramolecular Heck reaction offer a yet unexplored area. The interesting spiro compound **89**, for example, is available from 2,2'-diiodo-1,1'-binaphthyl (**88**) and 1-bromocyclopentene (**87**) (Scheme 18).[103]

Scheme 18.

4. Heck Reactions with Cyclic Alkenes: Key to the Construction of Stereogenic Centers



For a long time palladium chemists paid little attention to the intermolecular carbopalladation of cyclic alkenes, because at the high temperatures required, mixtures of double-bond isomers were frequently obtained.[104] But the reaction was never completely ignored, since it offered a possibility of creating new stereogenic centers by linking two sp^2 centers. For example, cis-addition of an arylpalladium species to cyclohexene **90**, followed by syn-elimination of hydrogen atom H_a in intermediate **91** produces 3-arylcyclohexene **92**, but not 1-arylcyclohexene **93**. Elimination of hydrogen atom H_b in the *anti* position does not take place (Scheme 19).

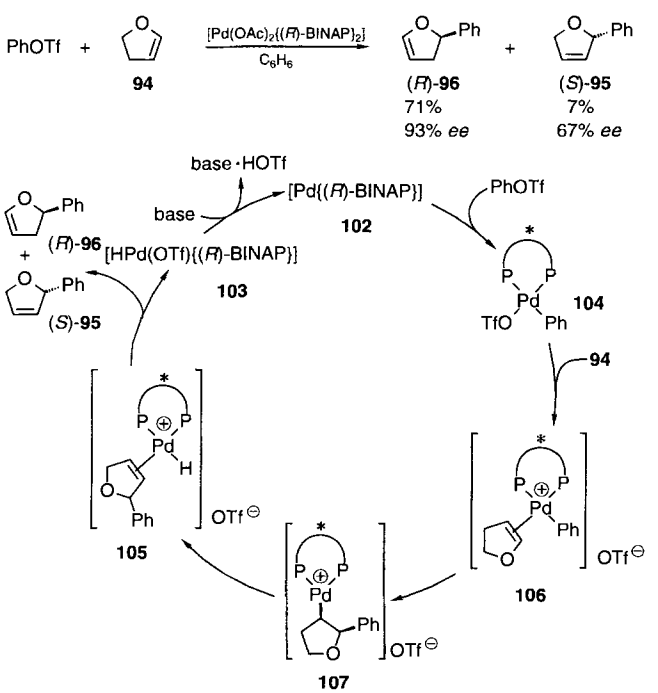
Scheme 19. X = I, Br, OSO_2CF_3. A: 3–4% $Pd(OAc)_2$, 9% PPh_3, 2 equiv Ag_2CO_3, MeCN, 80 °C; B: 2.5% $Pd(OAc)_2$, 1 equiv nBu_4NCl, 3 equiv KOAc, 2.5% PPh_3, DMF.

Thorough studies by Larock et al.[42c–f,l,n,105] led to the development of several experimental procedures with which undesired regioisomer formation can be avoided under very mild conditions.[106] In an impressive example, phenylation of 2,3-dihydrofuran (**94**) in the presence of silver carbonate provides 2-phenyl-2,5-dihydrofuran (**95**).[44,65] In contrast, reaction under Jeffery's[31] conditions affords solely the thermodynamically more stable 2-phenyl-2,3-dihydrofuran (**96**) (Scheme 19).[42n]

When conditions **A** and **B** are applied successively, two different arenes, for example 2-iodonaphthalene (**97**) and 3,4-dimethoxyiodobenzene (**98**), can be introduced to dihydrofuran (**94**) with *trans* stereoselectivity (Scheme 20). Upon catalytic

Scheme 20. X = O, NCO_2Et. A: 3–4% $Pd(OAc)_2$, 9% PPh_3, 2 equiv Ag_2CO_3, MeCN, 80 °C, 24 h; B: 2.5% $Pd(OAc)_2$, 1 equiv nBu_4NCl, 3 equiv KOAc, 2.5% PPh_3, DMF, 80 °C, 24 h; C: 2–6% $Pd(OAc)_2$, 4–12% PPh_3, Et_3N, DMF, 60–80 °C, 3–4 d.

hydrogenation the resulting product gave the *trans*-bisarylte-trahydrofuran **99** in excellent overall yields.[105b] This three-step sequence allows an exceptionally efficient and attractive approach toward potential antagonists of the platelet activating factor.[107] Similar twofold Heck reactions have also been performed with cyclopentene.[108]

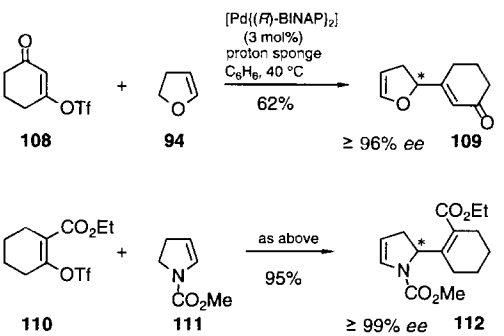


The diastereoselective construction of two stereocenters is also achieved in coupling reactions of 4-substituted 2,3-

dihydrofurans **100** (X = O) and 2,3-dihydropyrroles **100** (X = NCO_2Et). Arylations give exclusively *trans*-configurated products **101** (X = O, NCO_2Et) in good yields.[109]

4.1. The Ultimate Refinement: Heck Reactions with Intermolecular Asymmetric Induction

It is hardly necessary to point out the relevance of asymmetric synthesis in the preparation of chiral compounds. Transition metal induced reactions are increasingly important in the array of methods for the enantioselective construction of new asymmetric centers. Catalytic processes, in which chiral information is transferred from a small portion of the chiral auxiliary in the catalyst to a large portion of the prochiral substrate, are rapidly developing into extremely valuable methods.[110] Among these there are, however, only a few examples of reactions for the catalytic and enantioselective formation of carbon–carbon bonds.[110]

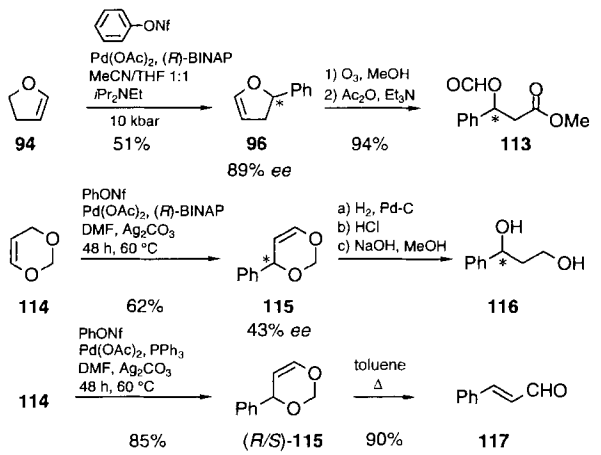


Subsequent to first reports by Overman et al.[111] and Shibasaki et al.[112] on intramolecular asymmetric Heck reactions, Hayashi et al. systematically investigated the ligand-induced asymmetric arylation of dihydrofurans.[10, 113] Whereas coupling with iodoarenes gave only low enantiomeric excesses in the presence of the C_2-symmetrical phosphane ligand (*R*)-1,1′-binaphthalene-2,2′-diylbis(diphenylphosphane) ((*R*)-BINAP), the coupling reaction of 2,3-dihydrofuran (**94**) with phenyl triflate afforded (*R*)-2-phenyl-2,3-dihydrofuran ((*R*)-**96**) with up to 93% enantiomeric excess and up to 71% yield (Scheme 21). In the reaction with iodobenzene, the BINAP ligand apparently dissociates from the intermediate phenylpalladium iodide complex to a certain extent. In contrast, when phenyl triflate is employed in the coupling, the labile triflate ligand dissociates more easily from intermediate **104**, thus generating the cationic complex **106**. Here, the BINAP ligand is much more tightly bound, and asymmetric induction is possible during the addition step leading to **107**.

Scheme 21. BINAP = P⌒P = 1,1′-binaphthalene-2,2′-diylbis(diphenylphosphane).

Quite interestingly, the minor product 2-phenyl-2,5-dihydrofuran (**95**) has the opposite, (*S*), configuration. However, this compound is produced with significantly less enantiomeric excess. It is possible that this is caused by a kinetic resolution effect in the alkene complex **105**; the π-bound palladium hydride in the complex leading to **96** could add again to the double bond (Scheme 21). Base influence is also noteworthy, and the highest enantiomeric excesses were achieved with 1,8-bis(dimethylamino)naphthalene ("proton sponge").[113c]

Regioselectivity and enantioselectivity were even better in reactions of alkenyl triflates with 2,3-dihydrofuran (**94**) and 2,3-dihydropyrroles such as **111**. Under optimized conditions, reactions with **108** and **110** yielded exclusively regioisomers **109** and **112** with enantioselectivities exceeding 96% and 99%, respectively (Scheme 22).



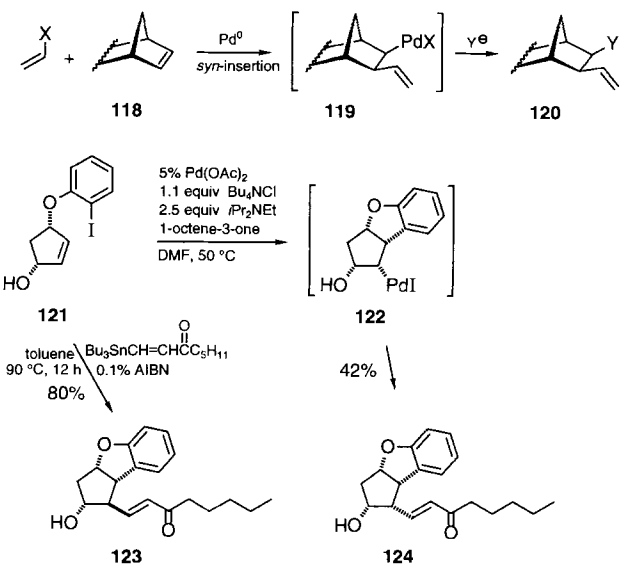
Scheme 22.

Whereas Hayashi et al. obtained good results for intermolecular reactions only with triflates, Shibasaki et al. achieved comparable inductions in intramolecular reactions of iodoalkenes by adding silver salts.[112, 114] These findings support the hypothesis that the generation of a cationic alkenylpalladium complex **106** has a favorable effect on the enantioselectivity (Scheme 21). Nevertheless, Ashimori and Overman[115] obtained good enantioselectivities even with neutral intermediate complexes and halide ligands in the presence of tertiary amines. These and other results[21] suggest a closer investigation of the influence of tertiary amines, which is certainly not just that of a simple base.

4.2. Degradation for Construction—An Interesting Concept

Reiser et al. recently reported[116] on the coupling reactions of aryl nonaflates with 2,3-dihydrofuran (**94**) under high pressure. Enantioselectivities were significantly higher than those obtained in analogous reactions under atmospheric pressure. The enantiopure 2-phenyl-2,3-dihydrofurans (**96**) can be cleaved by ozonolysis, and the resulting aldol derivatives **113** were obtained without loss of chiral information (Scheme 23).[117] A similar reaction sequence[118] is encountered in the enantioselective Heck arylation of 4*H*-1,3-dioxine (**114**), subsequent

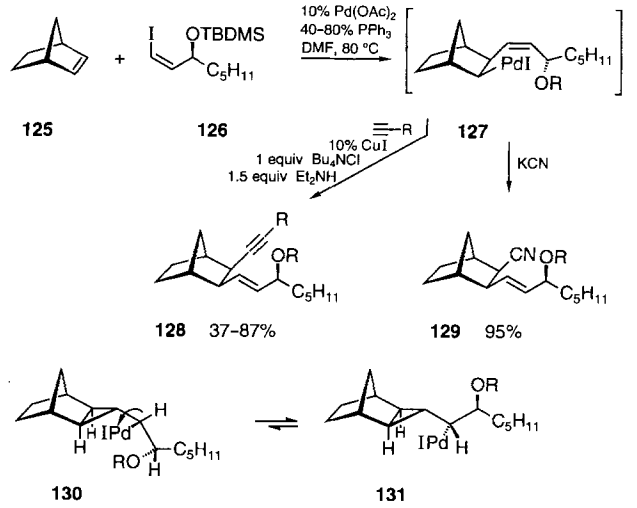
Scheme 23. Nf = nonaflate = $C_4F_9SO_2$.



catalytic hydrogenation of phenyldioxine **115**, and acidic cleavage yielding diol **116** (Scheme 23). Although only moderate enantiomeric excess is achieved,[118b] experience shows that a further increase is likely. Another interesting reaction of phenyldioxine **115** is its thermal [4 + 2] cycloreversion to give cinnamic aldehyde **117**. This high-yielding reaction sequence formally corresponds to the β-formyl vinylation of haloarenes, and is thus an alternative to the straightforward arylation of α,β-unsaturated aldehydes under Jeffery's conditions.[31]

4.3. Multiple-Component Reactions: Entropy as the Only Opponent

The concept of stereoselective construction of stereogenic centers by means of Heck reactions becomes even more efficient and elegant when carbopalladations are performed with bridged cycloalkenes such as **118**. In the initially formed halo(β-vinylbicycloalkyl)palladium complex **119** there is no hydrogen atom with a *syn* orientation with respect to the palladium substituent. Therefore, the σ complex has an unusually long lifetime and may undergo intermolecular reaction with a nucleophilic coupling substrate (Scheme 24). In this way two new stereogenic centers can be generated in a single synthetic operation. Three-component couplings like these are suitable for prostaglandin synthesis. The same sequence consisting of carbopalladation and substitution allows the *cis*-selective introduction of two substituents. This differs not only from the previously developed domino reactions (γ-addition of cuprates to cyclopentenones and subsequent alkylation of the resulting enolates[119]), but also from radical domino cyclizations.[120]

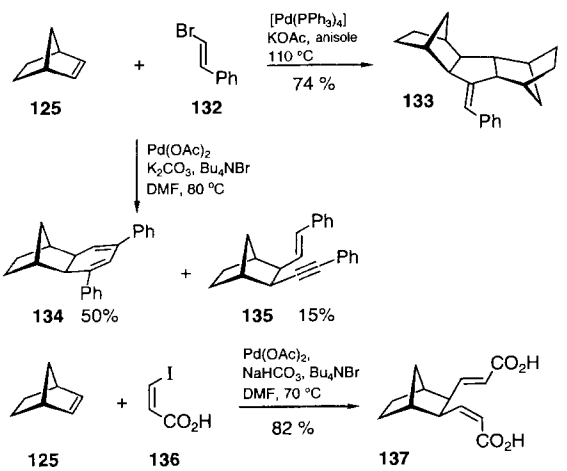


The palladium-induced asymmetric synthesis of the benzoprostacyclin derivative **124** from aryl ether **121** and 1-octen-3-one is an impressing application of this principle. Complementarily, radical-induced cyclization gives the epimeric benzoprostacyclin **123** (Scheme 24).[121]

Torii, Okumoto, et al.[122] have conducted decisive investigations concerning palladium-catalyzed stereoselective intermolecular three-component couplings. In view of the preparation of prostaglandin H (PGH) analogues with 2,3-disubstituted norbornane skeletons, they focused their attention on

Scheme 24. X = I, Br, OSO_2CF_3; Y = nucleophile (e.g. CN); AIBN = 2,2'-azobisisobutyronitrile.

diastereoselective additions to C_s-symmetric norbornene **125** (Scheme 25). Based on early studies by Catellani and Chiusoli[123] as well as by Larock et al. (application of halo-

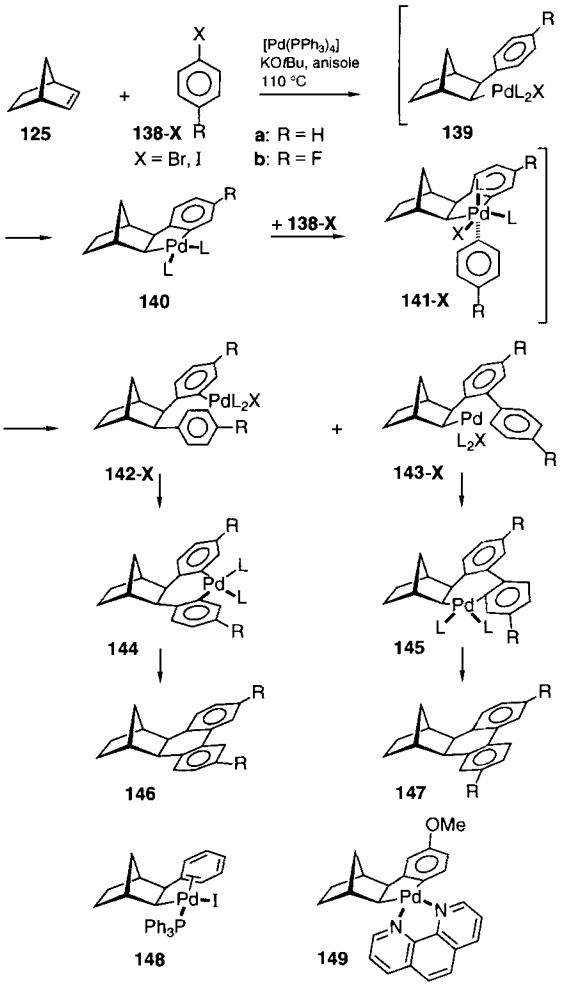


Scheme 25. R = TBDMS = tBuMe$_2$Si.

(alkenyl)mercury compounds as coupling partners[88a, c, 124]), Torii, Okumoto et al. used chiral iodoalkenes **126**. After addition to norbornene (**125**) the alkylpalladium intermediate **127** was captured either with cyanide or terminal alkynes.[122] Not only was *cis*-diastereoselective bis-*exo* coupling observed, but also enantiofacial differentiation of the *meso* substrate norbornene. This asymmetrically induced desymmetrization in the sequential formation of two new carbon–carbon bonds is accompanied by *cis*/*trans* isomerization of the side-chain double bond. A cyclopropylmethylpalladium intermediate **130** is postulated to explain the formation of the more stable *trans* alkene. Rotation about the C–C bond adjacent to Pd leads to the favored conformer **131**, which opens to give the thermodynamically more stable *trans*-alkenyl derivative. Cyclopropane deriva-

tives containing a norbornane skeleton derived from tricyclo[3.2.1.$0^{2,4}$]octane intermediates **130**/**131** have meanwhile been isolated and characterized.[88d, 125]

Halo(norbornyl)palladium intermediates of type **119** (Scheme 24) formed in alkenylations or arylations of norbornene have been identified by reduction with formate,[42b, 125] and also by couplings with organotin compounds[126] and boronates.[127] At least the first step of the domino couplings involving norbornene (**125**) and β-bromostyrene (**132**) proceed analogously and yield **133** and **134**, respectively (Scheme 26). It is not clear why, depending on the selected reaction conditions, two molecules of norbornene react with bromostyrene to give pentacycle **133** with a new five-membered ring,[128] or alternatively only one molecule of norbornene (**125**) reacts with two molecules of **132** to give cyclohexadiene **134**.[129]



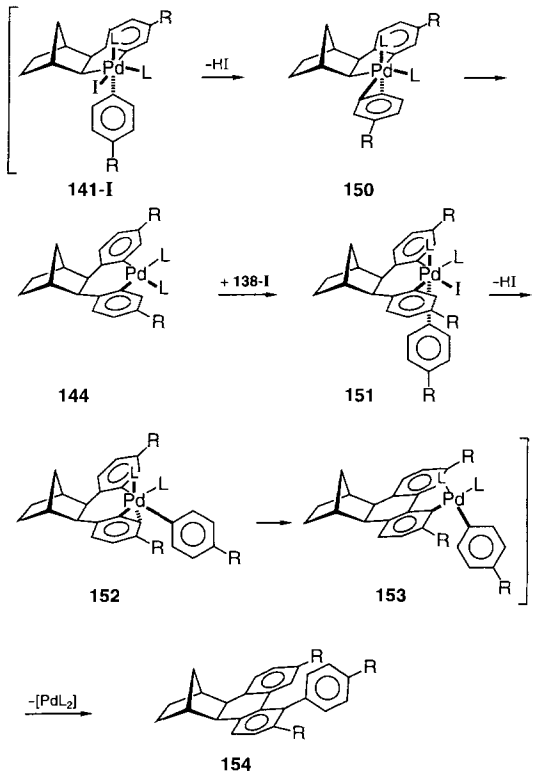
Scheme 26.

Even more puzzling is the finding that *cis*-3-iodoacrylic acid (**136**) reacts under analogous conditions to yield neither the first nor the second kind of product, but the twofold coupled *exo,exo* product **137** with one *cis*- and one *trans*-configurated acrylic acid group.[129] A cyclopropylmethylpalladium intermediate like **131** probably plays a key role in this reaction.

Although the development of palladium-catalyzed multicomponent couplings is still in its infancy, the enormous synthetic potential inherent in this reaction principle is apparent even at this early stage.

4.4. When Heck Reactions Stall: Palladacycles as Intermediates

Some of the above-mentioned palladium-catalyzed sequential couplings with norbornene are not in accord with the common scheme of the Heck reaction. Even haloarenes can react with norbornene to give domino coupling products, provided that other substrates such as alkynes or reducing agents are absent. Thus, upon reaction of iodo- or bromoarenes **138-X** with norbornene (**125**) (in the presence of [Pd(PPh$_3$)$_4$], KO*t*Bu, and anisole at 110 °C), Catellani and Chiusoli obtained the norbornane-annelated 9,10-dihydrophenanthrenes **146** and **147** (Scheme 27).[130] Different reaction conditions (Pd(OAc)$_2$, K_2CO_3, Bu_4NBr, DMF, 80 °C) led to norbornane-annelated

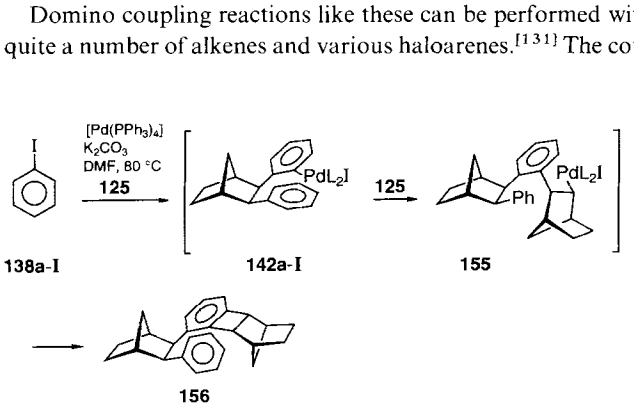


Scheme 27.

4-aryl-9,10-dihydrophenanthrenes **154** exclusively, which apparently were formed from three molecules of **138-X** with one molecule of norbornene (**125**)[131] (see Scheme 28). Both reactions are likely to proceed identically in the first steps. After oxidative addition of the aryl halide to palladium and *exo-syn*-addition of the resulting (aryl)halopalladium complex to **125**, the norbornylpalladium intermediate **139** cyclizes to give palladacycle **140** since it has no coupling partner (Scheme 27). Oxidative addition of another molecule of aryl halide to intermediate **140** gives palladium(IV) complex **141-X**.[132] The structure of intermediate **139** has been corroborated by X-ray structure analysis of complex **148**.[133] The observed η^2-complexation of the phenyl group in **148** provides support for *ortho* activation en route to complex **141-X**. Furthermore, Chiusoli et al.[134] have demonstrated that the well-characterized Pd^{II} complex **149** undergoes facile oxidative additions with a number of reagents.[135]

Reductive elimination in **141-X** can take two directions, leading to Pd^{II} complexes **142-X** and **143-X**, respectively. Repeated *ortho*-CH activation and reductive elimination (via **144**

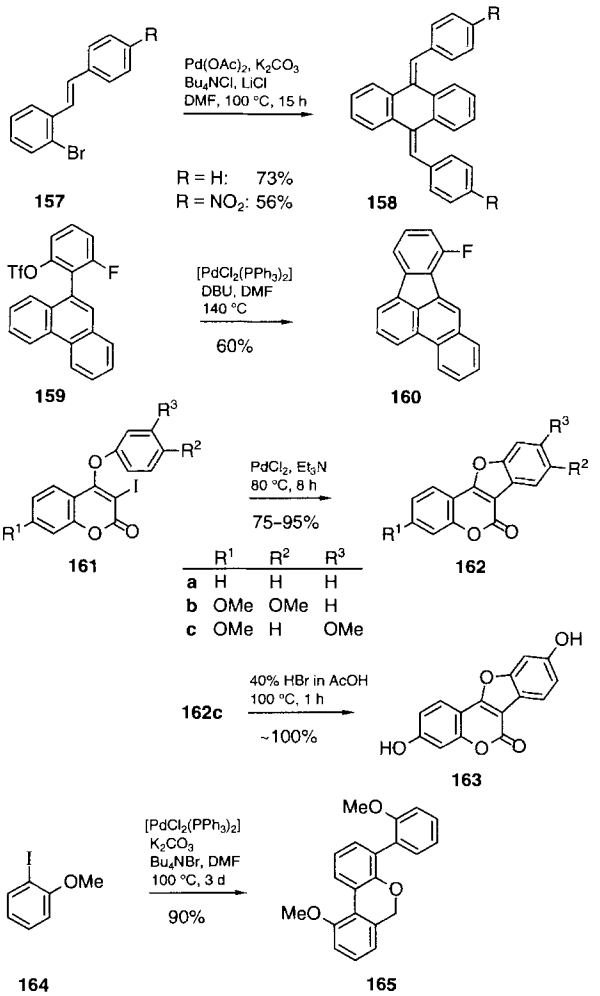
and **145**) lead to the isomeric products **146** and **147**. Dehydroarene complex **150** can be proposed as an intermediate in the second *ortho*-CH activation (**141-I** → **144**) (Scheme 28). Certain



Scheme 28.

conditions lead to a four-component reaction at the stage of the seven-membered palladacycle **144**; oxidative addition of another molecule of iodoarene **138-I** yields the Pd^{IV} complex **151**. Repeated generation of an aryne complex **152**, followed by reductive elimination to give palladium(II) complex **153**, and final reductive elimination regenerates the catalytically active palladium(0) species and provides the 4-aryldihydrophenanthrene derivative **154** (Scheme 28).[131c]

Under yet another set of conditions ($[Pd(PPh_3)_4]$, K_2CO_3, DMF, 80 °C) intermediate **142a-I** reacts with norbornene (**125**) and affords benzocyclobutene **156** apparently via **155** (Scheme 29).[136a]



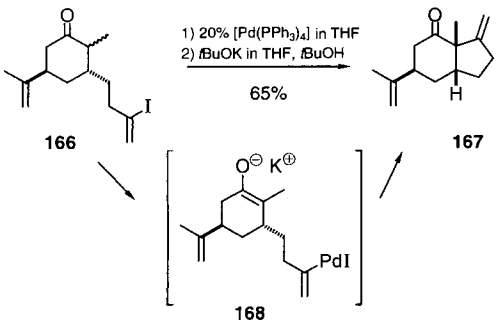
Domino coupling reactions like these can be performed with quite a number of alkenes and various haloarenes.[131] The cou-

Scheme 29.

pling products derived from norbornene and dicyclopentadiene can serve as precursors for diverse polycyclic aromatic compounds.[131c]

By slightly modifying the reaction conditions and the medium the chemistry of palladacycles can be made to proceed selectively, and therefore provides a wealth of interesting perspectives (Scheme 30).[136b] Examples include the dimerization of *ortho*-

Scheme 30. DBU = diazabicycloundecane.

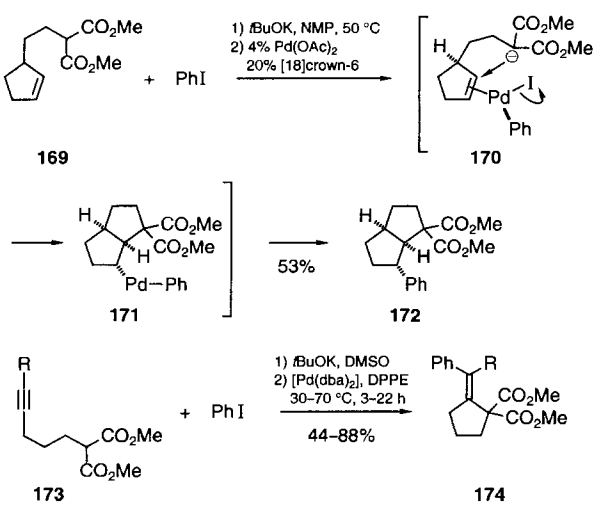


bromostilbenes **157** to give (*Z*)-9,10-dibenzylidenedihydroanthracenes **158**,[100] the synthesis of benzofluoroanthrenes **160** from aryl triflate **159**[137] and of coumestan **162** and coumestrol (**163**) from 4-aryloxy-3-iodo-2*H*-1-benzopyran-2-ones **161**,[138] and the CH activation of *ortho*-methoxy groups as in 2-iodoanisole (**164**) reported by Dyker,[139] leading elegantly to 6*H*-dibenzo[*b*,*d*]pyrans like **165** (Scheme 30).

5. Palladium-Catalyzed Reactions with Nucleophilic Substrates

5.1. Soft Nucleophiles as Reaction Partners

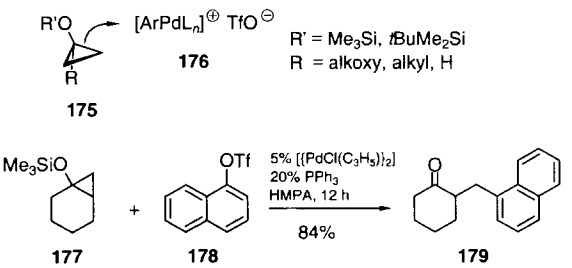
The complexes generated by oxidative addition of haloarenes and haloalkenes to palladium(0) are electrophilic at the substi-



tuted metal center, and can therefore react with carbon nucleophiles other than alkenes, especially with enolate and homoenolate ions, to form new C–C bonds. As Takahashi et al.,[140] Ciufolini et al.,[141] and Piers et al.[142] have shown, palladium-catalyzed intramolecular and intermolecular arylations and alkenylations can be achieved with soft enolate anions. Even quaternary carbon centers may be constructed in this way. The methylenecyclopentane annelation developed by Piers et al. and demonstrated with iodoalkene **166** in Scheme 31 is an interesting alternative to other methods for annelations with five-membered rings.[142] In the mechanism it is assumed that intermediate **168** undergoes an intramolecular nucleophilic substitution, leading to a six-membered palladacycle. Bicycle **167** is subsequently formed by reductive elimination.

Scheme 31.

The formation of substituted cyclopentanes such as **172** and alkylidenecyclopentanes **174** has been investigated fairly thoroughly. These studies focused on intermolecular reactions between iodoarenes and substituted enolates of malonic ester that contain double or triple bonds in the 4'-position (Scheme 32).[143] The results indicate that the electrophilicity of the double or triple bond is enhanced by coordination to the σ-arylpalladium species, and attack of the enolate ion is facilitated (Scheme 32).

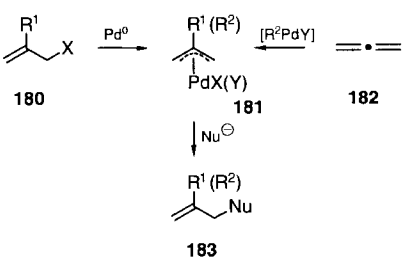


Utimoto, Nozaki, et al.[144] reported at a very early stage on the palladium(II) activation of triple bonds towards nucleophilic

Scheme 32. R = H, CH_3, C_3H_5, CH_2OTHP, $(CH_2)_2OTHP$; NMP = *N*-methylpyrrolidone; DPPE = 1,2-bis(diphenylphosphano)ethane.

attack with carboxylate ions. This method has recently seen a growing number of applications.[145]

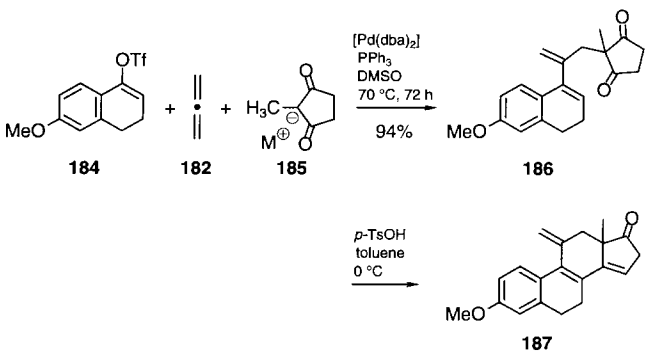
Nakamura, Kuwajima et al.[146] have shown that donor-substituted cyclopropane derivatives **175** can be also activated, by cationic arylpalladium complexes **176**, in particular (Scheme 33). The products of a formal arylation of homoenol-



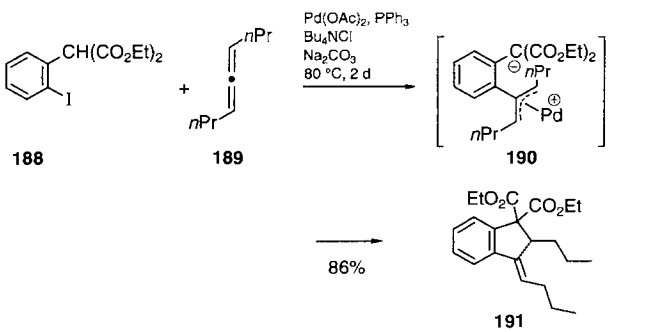
Scheme 33. HMPA = hexamethylphosphoric triamide.

ates are obtained in good yields in the presence of (allyl)chloropalladium, as in the reaction of silyloxycyclopropane **177** with aryl triflate **178**.

5.2. An Unusual Combination: Heck Reactions and π-Allylpalladium Complexes



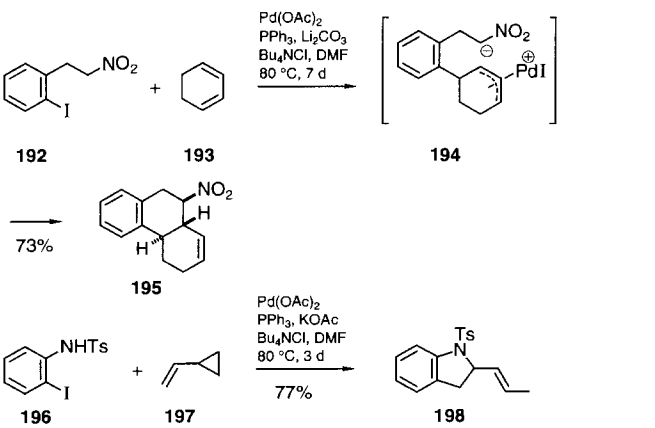
Palladium-catalyzed substitutions of allylic esters **180**, which proceed via π-allylpalladium complexes such as **181**, are well established in the meantime (Scheme 34).[82] In contrast, the



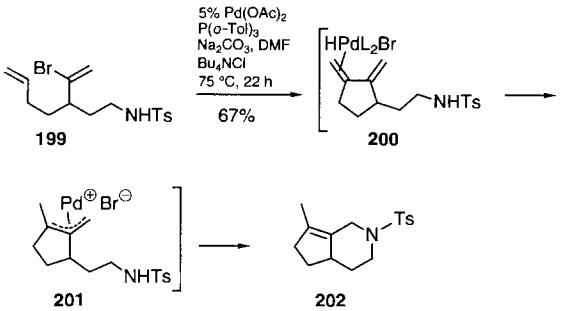
Scheme 34. R^1 = H, alkyl; R^2 = aryl, alkenyl; X = OCOalkyl; Y = I, Br, OSO_2CF_3; Nu = nucleophile.

potential of reactions proceeding through π-allylpalladium intermediates, generated by adding haloarenes, haloalkenes, or the corresponding triflates to allenes **182** and substituted allenes under Pd catalysis, has scarcely been tapped (Scheme 34). π-Allylpalladium intermediates generated in this way have been utilized elegantly by Gore et al.[89, 147] in three-component reactions. For example, allene (**182**), the enol triflate of 6-methoxytetralone (**184**), and the enolate of 2-methylcyclopentane-1,3-dione (**185**) give **186** smoothly and in very good yield (Scheme 35). The steroid skeleton **187** is obtained in just one more step.[148]

In the presence of a palladium catalyst and a base, haloarenes such as **188** containing a CH-acidic group in *ortho* position react regioselectively in inter–intramolecular reactions with allenes such as **189**, giving high yields of annelated arenes like **191** with five-membered rings (Scheme 36).[149] Treatment of 1,3-dienes,[42q, 150] 1,4-dienes,[151] methylenecyclopropanes, and



Scheme 35.

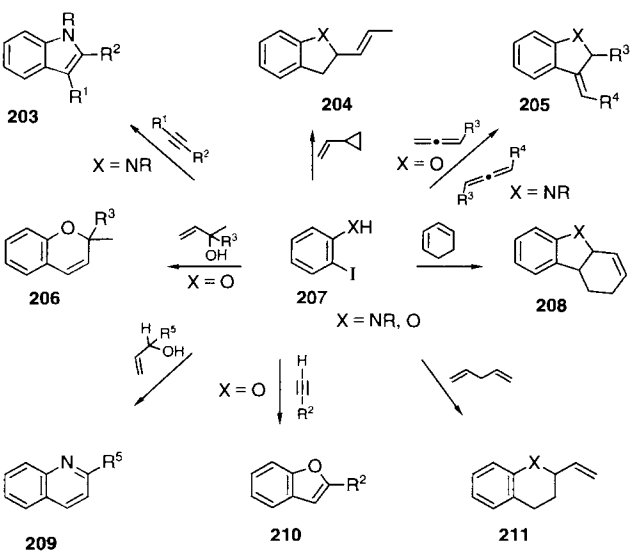


Scheme 36.

ethenylcyclopropanes with arylpalladium intermediates leads to π-allylpalladium complexes, which can be trapped with a variety of nucleophiles. Larock et al. showed that 1,3-cyclohexadiene (**193**)[42q] and *ortho*-(2′-nitroethyl)iodobenzene (**192**) react in the presence of palladium acetate via π-allyl complex **194** to afford the *trans*-configurated tricycle **195** (Scheme 37). Ethenylcyclopropane (**197**) and substituted 2-iodoaniline **196** are transformed analogously into dihydroindole **198**.[152a]

Scheme 37.

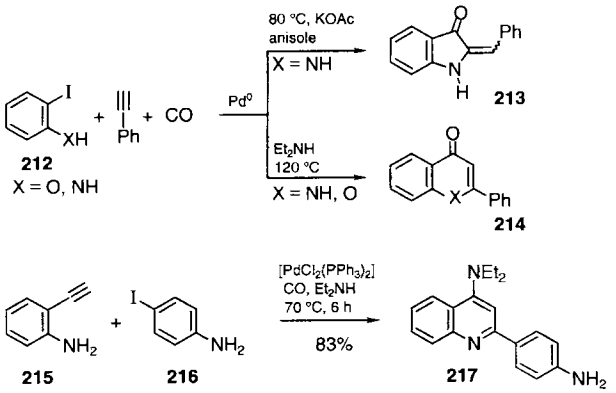
Weinreb et al. presented an interesting new approach to nitrogen heterocycles,[153] based on early findings by Heck et al. that coupling reactions of haloalkenes with alkenes in the presence of secondary amines give allylamines.[154] The palladium-catalyzed cyclization of bromo-1,6-diene **199** initially gives 1,3-diene **200**. Readdition of the eliminated halohydridopalladium leads to the π-allylpalladium complex **201**, which then undergoes intramolecular nucleophilic substitution, yielding bicycle **202** (Scheme 38).



Scheme 38. Tol = tolyl; Ts = tosyl = $CH_3C_6H_4SO_2$.

Interestingly, π-allyl complexes are not generated in palladium-catalyzed arylations of ethenylepoxides, ethenyl oxetanes, or 4-alkenyl-2-azetidinones. Rather, substituted allyl alcohols,[155] homoallyl alcohols,[156] and 5-aryl-3-alkenamides[157] are formed.

5.3. New Routes to Heterocycles: Pd-Catalyzed Heteroannelations



Given the tremendous variety of naturally occurring heterocycles, the development of elegant and efficient synthetic routes to these substances is a desirable goal. Palladium-catalyzed reactions have revealed almost unlimited horizons in this field, which have been documented in a myriad of publications. The array of palladium-catalyzed annelation reactions that *ortho* hetero-substituted iodoarenes **207** can undergo with 1,2-,[149] 1,3-,[42q, 150b] and 1,4-dienes[151] and ethenylcyclopropanes[152] is exemplary (Scheme 39). These reactions, which lead to substi-

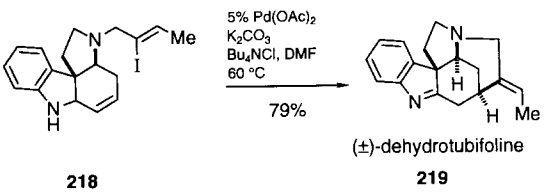
Scheme 39. R = H, Me, Ac, Ts; R^1 = alkyl, alkenyl, aryl, CH_2OH; R^2 = alkyl, aryl, CH(OH)aryl, trimethylsilyl, *tert*-butyldimethylsilyl for X = NR; R^3 = alkyl; R^4 = H, alkyl; R^5 = alkyl, aryl.

tuted dihydrobenzofurans and dihydroindoles, also proceed via intermediate π-allylpalladium complexes. Transformations with terminal and internal alkynes afford monosubstituted and disubstituted benzofurans **203**, **210** (X = O)[158] and indoles **203**, **210** (X = N),[159] respectively, in good yields. When allylic alcohols are employed as coupling partners, 2,2-disubstituted chromenes **206**[160] and quinolines **209** are obtained.[161]

New strategies for the annelation of benzene derivatives with five- and six-membered rings rely on the carbonylative coupling of iodo- and bromoarenes with aminophenols[162] and of terminal alkynes with iodophenoles and iodoanilines.[163, 164] In these reactions it is irrelevant whether the heteroatom is at the *ortho* position of the iodoarene **212** or whether it is part of the aryl alkyne as in **215** (Scheme 40).[164] *ortho*-Iodoanilines and *ortho*-iodophenols react with carbon monoxide and phenyl-

Scheme 40.

acetylene in the presence of diethylamine to give 2-substituted 1,4-dihydro-4-oxoquinolines and flavones **214**, respectively. In contrast, *ortho*-iodoaniline yields indoxyl derivatives **213** in anisole, when potassium acetate is used as base.[165] A tremendous number of possible combinations of aryl or alkenyl halides with alkynes or alkenes and alcohols or amines are possible, and their reactions under palladium catalysis lead to a variety of heterocycles.[166]

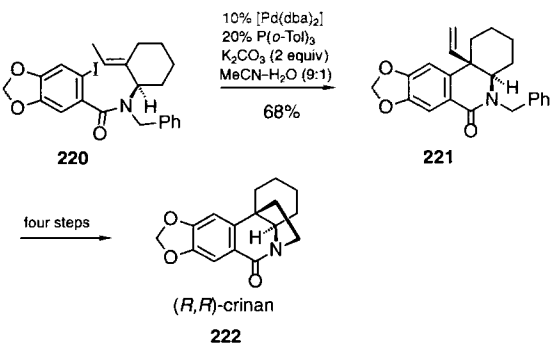


The reaction of 4-iodoaniline (**216**) and (2-aminophenyl)-acetylene (**215**) in diethylamine and exposed to a carbon monoxide atmosphere yields 2-(4′-aminophenyl)-4-diethylaminoquinoline (**217**) in a single synthetic operation.[164]

6. Intramolecular Heck Reactions with Alkenes

6.1. Applied Intramolecular Heck Reactions

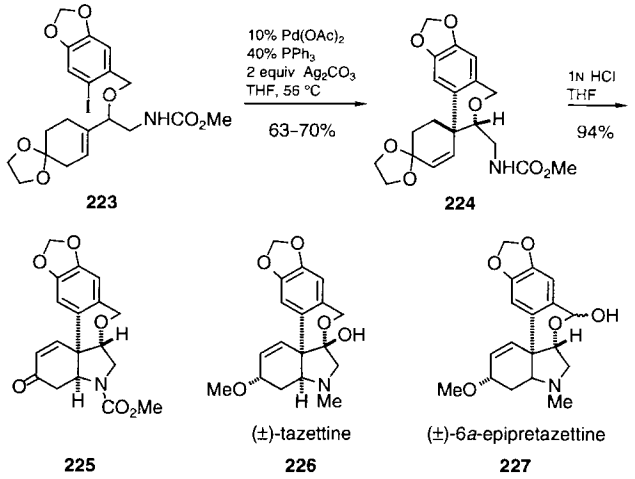
For a long time applications of the Heck reaction in the construction of cyclic systems were focused on the preparation of heterocyclic compounds from appropriately substituted haloarenes.[153b, 167] It was not realized until only recently that even complicated ring systems with numerous different functionalities may also be assembled.



Efforts to develop a generally applicable and stereocontrolled synthesis of *Strychnos* alkaloids led Rawal et al.[168] to the preparation of (±)-dehydrotubifoline (**219**) (Scheme 41). Ring

Scheme 41.

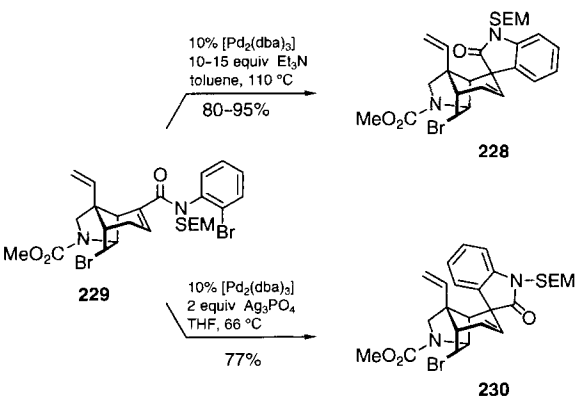
closure of **218** was performed under palladium catalysis in the presence of K_2CO_3 and Bu_4NCl with subsequent enamine–imine tautomerization. The ethylidene group typical for many *Strychnos* alkaloids retains its defined configuration in this transformation.



The Heck reaction may even be applied in the construction of tetrasubstituted carbon centers, which are often accessible otherwise only with great difficulty.[42a, p, 44a] Following this strategy, Grigg et al.[42a, p] and in particular Overman et al.[169] have developed new, impressive regioselective and stereoselective routes to a number of complex heterocyclic natural products. (*R,R*)-Crinan (**222**)[23i], an alkaloid from plants in the *Amaryllidaceae* family, has been prepared in a total synthesis in which the key step is the regioselective formation of the central heterocyclic ring (Scheme 42). This was accomplished by an in-

Scheme 42.

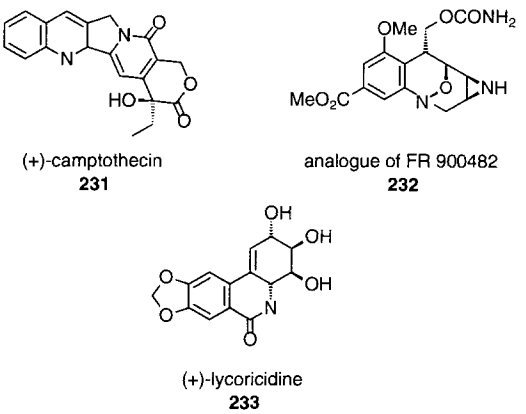
tramolecular 6-*exo-trig* reaction of the iodoarene moiety in **220** with the exocyclic double bond on the cyclohexane ring. Interestingly, high yields and high stereoselectivities are possible only when the reaction mixture contains 10% water[47, 170] and when sterically demanding phosphanes are added.[23i]



In the syntheses of two other *Amaryllidaceae* alkaloids, tazettine (**226**) and 6*a*-epipretazettine (**227**), the key steps also followed the same principle (Scheme 43).[171] The common precursor is tetracycle **225**. Palladium-catalyzed intramolecular insertion of the iodoarene moiety into the double bond of the appended cyclohexene ring in **223** and subsequent acid-catalyzed rearrangement leads to the 2-benzopyrano[3,4-*c*]hexahydroindole subunit in **225**. Excellent stereoselectivity was observed and the cyclization proceeded as a 6-*exo-trig* ring closure. Compound **225** was thus prepared in 90% yield (63–70% after recrystallization), and provided access to 6*a*-epipretazettine and other related compounds. It should be noted that the intramolecular Heck reaction in **223** required stoichiometric amounts of silver salts. In the formation of tetracycle **225**, which has the relative configuration of the 6*a*-epipretazettines, the

Scheme 43.

Pd–C σ bond and the alkene π bond must be eclipsing in a transition state with a boat conformation.

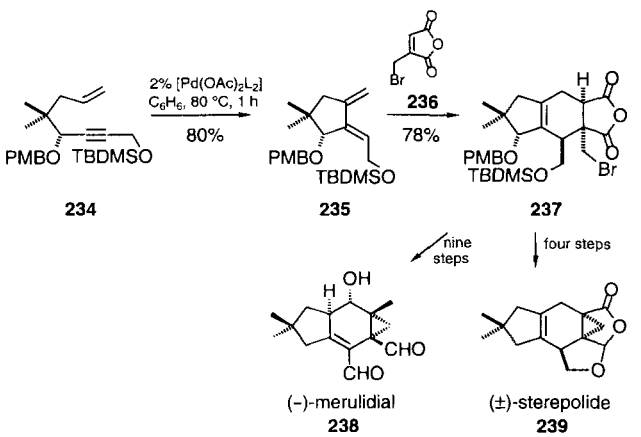


The syntheses of heteropentacycles **228** and **230** by Overman et al.[169, 172] constitute a highlight in the stereoselective construction of compounds containing quaternary carbon centers with sterically demanding substituents (Scheme 44). The dra-

Scheme 44. SEM = $CH_2OCH_2CH_2SiMe_3$.

matic influence of silver salts and various ligands on the stereoselectivity of intramolecular Heck reactions has been impressively demonstrated with the cyclization of tetracyclic acryloyl-2-bromoanilide **229**. In the transition state leading to **228** the 1,3-diaxial interactions between the vinyl group and the oxoindole group make the generation of the pentacyclic oxoindole appear rather unexpected. Additionally, 1,3-diaxial interactions between the ethano bridge and the ligands of the coordinated square-planar alkylpalladium complex (after insertion of the bromoarene moiety) must be allowed for. Formation of pentacycle **228** is greatly favored when the reaction is performed without phosphane ligands. On the other hand, when silver salts are added to the reaction mixture, an almost total reversion of stereoselectivity is observed, thus favoring formation of **230**. The more polar transition state, which is reached via a cationic complex, is favored if the attack occurs from the side of the angular vinyl group. In this way additional coordination of palladium in the complex is facilitated by the vinyl group.

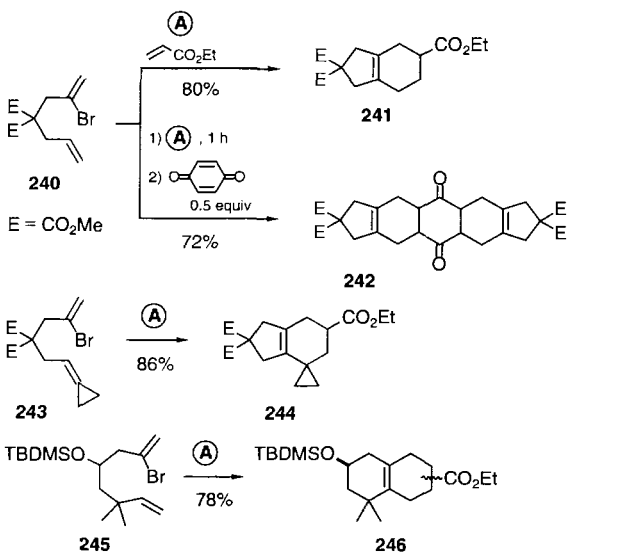
Further examples for natural product syntheses in which intramolecular Heck reactions are important key steps include those of (+)-camptothecin (**231**),[173] the congener **232** of FR 900482,[174] and (+)-lycoricidine (**233**)[23a, 175] (Scheme 45).



Scheme 45.

Early on, efforts were made to apply palladium-catalyzed alkenylations and especially arylations of double bonds to the synthesis of heterocycles, and these reactions are meanwhile widely applied. However, it took quite a long time before exhaustive and detailed studies were undertaken on the analogous preparations of pure carbocycles. The pioneering work was done by Grigg et al.[42g, 45b, 176a–c] and Negishi et al.[176e–i] in studies of the regioselectivity in cyclizations of acyclic 1- and 2-bromo(or -iodo-)dienes. Although *n-exo-trig* ring closures[177] were found to be generally favored, double bond isomerizations following cyclization often remained a major difficulty. This problem was solved later by adding silver(I) and thallium(I) salts.[44, 45b, 176c]

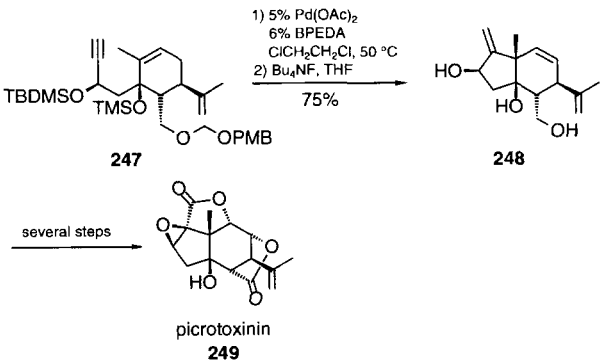
At the same time Trost et al. developed cycloisomerizations for 1,6-enynes[76] under mild conditions for the construction of carbo- and heterocycles with high regioselectivities and in very good yields. In view of possible synthetic applications, both cycloisomerizations of 1,6(7)-enynes and the selective intramolecular Heck coupling of 2-bromo(or -iodo-)-1,6(7)-dienes to give 1,2-bis(exomethylene)cycloalkanes rapidly gained interest. The latter are suitable substrates for subsequent Diels–Alder reactions.[76a, 92, 176a–c, 178]



For example, this sequence consisting of a palladium-catalyzed cycloisomerization followed by a Diels–Alder reaction was applied in the syntheses of (±)-sterepolide (**239**)[179] and (−)-merulidial (**238**) (Scheme 46).[180] Both the cycloisomerization of enyne **234** and the Diels–Alder reaction of diene **235** with bromomethyl malonic anhydride (**236**) proceed in good yields. In this synthesis it was essential that formation of the 1,4-diene be suppressed. This was possible with the trialkylsilyloxymethyl group on the alkyne moiety, and the desired 1,3-diene was formed almost exclusively. Analogous Heck reactions performed with corresponding 2-bromo-1,6-dienes having an allylic alcohol function lead preferentially to γ,δ-unsaturated car-

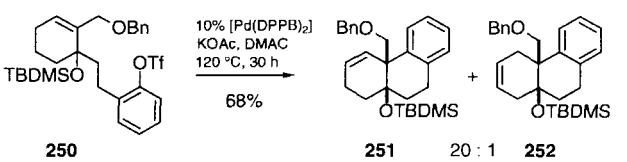
Scheme 46. PMB = *para*-methoxybenzyl; L = P(*o*-Tol)$_3$.

bonyl compounds in the absence of silver(I) or thallium(I) salts.[176d]



This sequence is normally conducted in two steps, but may also be performed in a one-pot procedure without isolating the intermediate diene, by adding an external dienophile[92] or by making use of a dienophile already present in the intermediate. The intra–intermolecular sequence consisting of Heck and Diels–Alder reactions is feasible only with dienophiles that cannot oxidize the applied catalyst. For example, 2-bromo-1,6-diene **240** reacts smoothly in a one-pot procedure to give bicycle **241** in good yield (Scheme 47). On the other hand, in reactions

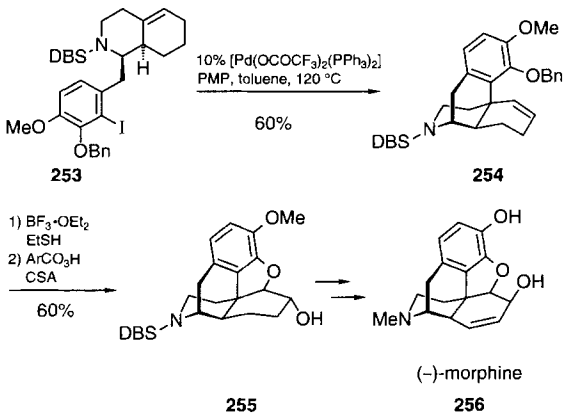
Scheme 47. E = CO_2Me; A: 3% $Pd(OAc)_2$, 8% PPh_3, 1.2 equiv Ag_2CO_3, MeCN, 90 °C, 45 min.



with dienophiles like *para*-benzoquinone, the 1,3-diene must be preformed prior to the addition of the dienophile. Palladium-catalyzed 1,6-enyne cyclizations[76] and subsequent Diels–Alder reactions are also feasible in a one-pot procedure.[92] However, in certain cases bromodienes succeed even when the analogous enyne cycloisomerizations fail. This is demonstrated by bromodiene **243** containing a terminal methylenecyclopropane group, and compound **245**, which both cyclize to form a five- and a six-membered ring, respectively.[181] It is only a matter of time until the combination of metal-catalyzed cyclization and thermal cycloaddition sees its first application in natural product synthesis.

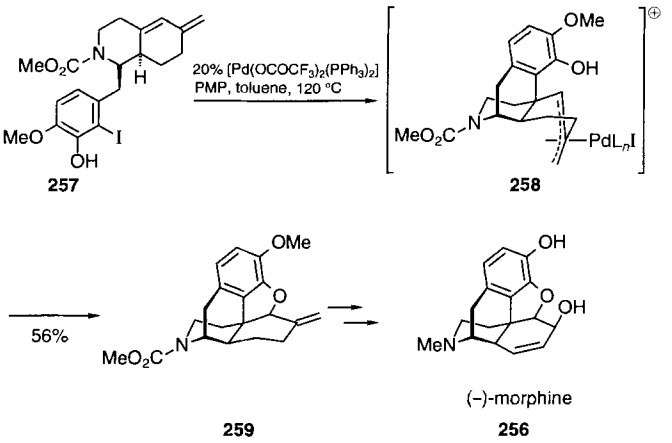
Palladium-catalyzed cycloisomerization is by no means restricted to the preparation of 1,2-bis(exomethylene)cycloalkanes. Other applications include the total syntheses of (−)-dendrobine[182] and picrotoxinin (**249**) (Scheme 48).[76c, 183] The skeleton **248** of **249** was obtained from enyne **247** in very good yield.

Scheme 48. BPEDA = *N*,*N*′-bis(phenylmethylene)-1,2-ethylenediamine; TMS = Me_3Si.



In research directed toward the synthesis of complex cardenolides, Overman et al. examined intramolecular Heck cyclizations with model reactions of triflate **250**, and obtained carbocycles **251** and **252** with the desired *cis* annelation (Scheme 49).[184a]

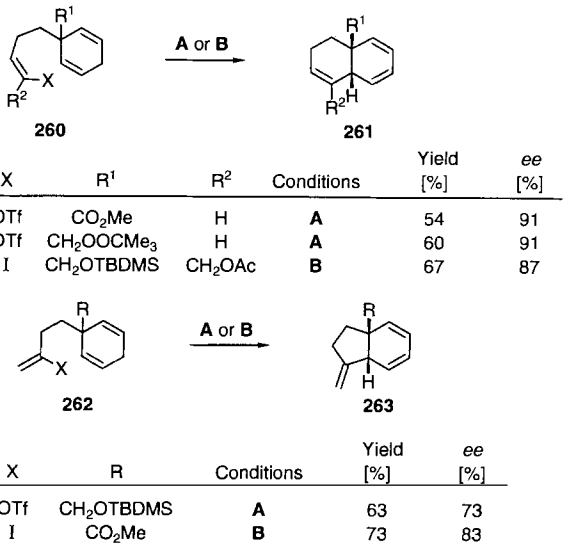
Scheme 49. DPPB = 1,4-bis(diphenylphosphano)butane. DMAC = *N*,*N*-dimethylacetamide; Bn = benzyl.



The syntheses of (−)- and (+)-morphine by Overman et al.[184b, 185] constitute further impressive examples, as both enantiomers were prepared for the first time without separation of the diastereomeric intermediates. Again, intramolecular Heck reactions play an important role in Overman's construction of the morphine skeleton. In an initial attempt, an active catalyst obtained from $[Pd(OCOCF_3)_2(PPh_3)_2]$ was used to convert iodoarene **253** into the unsaturated morphinane **254** (Scheme 50). Selective cleavage of the benzyl ether and cyclization of the camphor sulfonate of **254** with 3,5-dinitroperoxybenzoic acid finally yielded pentacycle **255**, which was then transformed via (−)-dihydrocodeinone into (−)-morphine (**256**).[184b]

If, on the other hand, iodoarene **257** is cyclized under palladium catalysis, pentacyclic skeleton **259** is formed directly. In this reaction intramolecular arylation of the 1,3-dienic moiety gives

Scheme 50. DBS = dibenzosuberyl; PMP = 1,2,2,6,6-pentamethylpiperidine; CSA = camphorsulfonic acid; Ar = 3,5-dinitrophenyl.

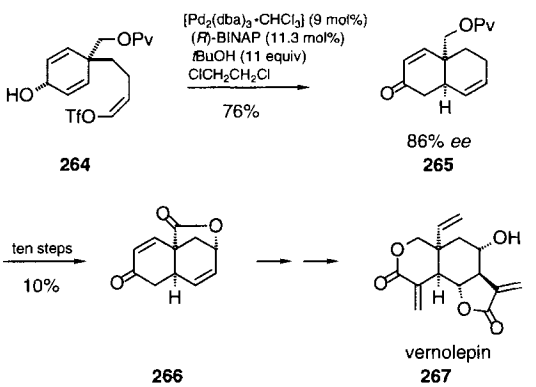


π-allylpalladium complex **258**, the phenolic hydroxy function of which is captured in an intramolecular reaction yielding **259**, a precursor to morphine (Scheme 51).[184c, 185]

Scheme 51.

6.2. Tailored Intramolecular Asymmetric Heck Reactions

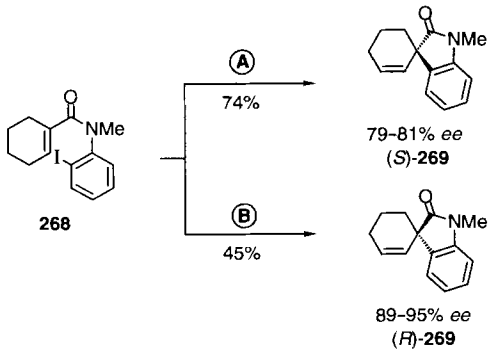
The enormous potential of intramolecular Heck reactions has been demonstrated impressively in elegant syntheses of even the most complicated natural product skeletons. Addressing the question of whether these reactions may be performed enantioselectively, Shibasaki et al.[112, 114] and Overman et al.[111, 115] examined the intramolecular Heck reactions of monocyclic iodoalkenes **260** and alkenyl triflates **262** using catalysts that contained chiral ligands (Scheme 52); decalins **261**[114c] and hydroindane derivatives **263**[114d] were obtained with excellent enantioselectivities. Complementary to the asymmetrically induced intermolecular arylations and alkenylations with triflates by Hayashi et al. (see Schemes 21 and 22), reasonable intramolecular inductions were also achieved with iodides upon the addition of silver salts (Scheme 52). With terminal allylsilane groups, these intramolecular reactions regioselectively led to tetrahydroisoquinoline and tetrahydro-1*H*-3-benzazepines with up to 90% enantiomeric excess.[186]



X	R^1	R^2	Conditions	Yield [%]	*ee* [%]
OTf	CO_2Me	H	**A**	54	91
OTf	CH_2OOCMe_3	H	**A**	60	91
I	$CH_2OTBDMS$	CH_2OAc	**B**	67	87

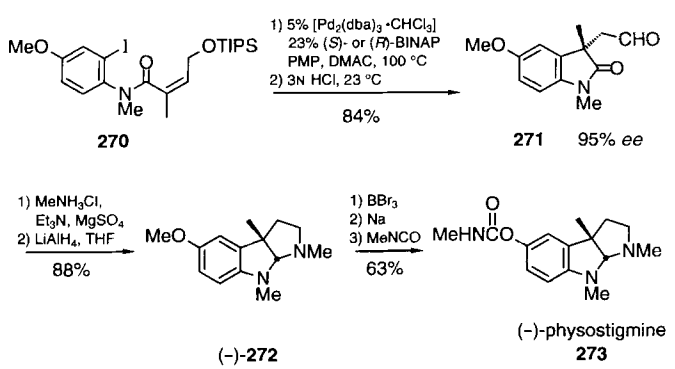
X	R	Conditions	Yield [%]	*ee* [%]
OTf	$CH_2OTBDMS$	**A**	63	73
I	CO_2Me	**B**	73	83

Scheme 52. A: 5% $Pd(OAc)_2$, 10% (*R*)-BINAP, 2 equiv K_2CO_3, benzene or toluene, 60 °C, 49–55 h. B: 10% $[PdCl_2\{(R)\text{-BINAP}\}]$, 2 equiv Ag_3PO_4, 2.2 equiv $CaCO_3$, *N*-methylpyrrolidone, 60 °C, 100 h.



Shibasaki et al. soon applied asymmetric Heck reactions to natural product synthesis.[114g] Cyclization of triflate **264** yielding enone **265** with 86% enantiomeric excess established convenient access to enantiomerically pure **266**, a key intermediate in Danishefsky's synthesis[187] of vernolepin (**267**) (Scheme 53).

Scheme 53. Pv = pivaloyl = $COC(CH_3)_3$.

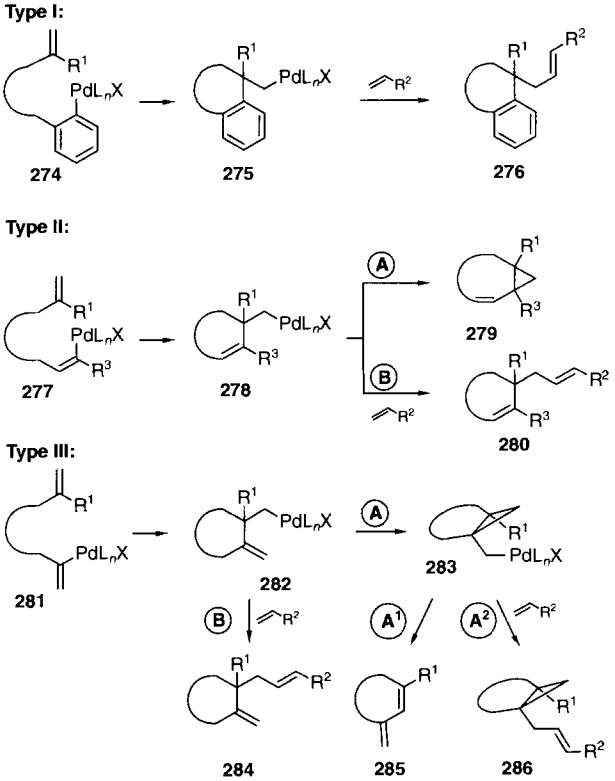


Key intermediates for the synthesis of capnellenols[114b, f] were constructed by asymmetrically induced Heck reaction/anion capture processes,[188] and in the synthesis of (−)-eptazocin a key reaction was the asymmetrically induced generation of a quaternary benzylic carbon center.[114i]

Overman et al.[111, 185] and Grigg et al.[189] first rose to the challenge of the catalytic asymmetric construction of quaternary carbon centers. Amazing results were obtained in the preparation of spirooxoindoles (*S*)-**269** and (*R*)-**269** from **268** (Scheme 54); each product enantiomer was obtained selectively by careful choice of reaction conditions and, remarkably, by applying the exact same enantiomer of the chiral phosphane ligand.[115] It should be noted that despite the absence of silver salts in the latter reaction, very good enantioselectivity was achieved even with an iodoarene.

Scheme 54. A: 5% $[Pd_2(dba)_3]$, 10% (*R*)-BINAP, 2 equiv Ag_2CO_3, $MeCONMe_2$, 60–80 °C. B: 10% $[Pd_2(dba)_3]$, 20% (*R*)-BINAP, 5 equiv 1,2,2,6,6-pentamethylpiperidine, $MeCONMe_2$, 80–100 °C.

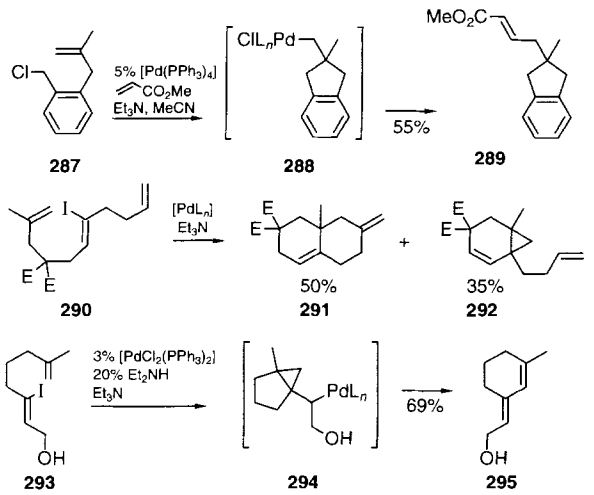
These studies culminated in the synthesis of both enantiomers of physostigmine (**273**) (Scheme 55).[190] Palladium-catalyzed cyclizations of iodoarene **270** using (*S*)- and (*R*)-BINAP as



Scheme 55. TIPS = iPr_3Si.

ligands afforded oxoindoles (*S*)-**271** and (*R*)-**271**, respectively, with enantiomeric excesses greater than 95% in each case. After cyclizing condensation of **271** with methylamine, reduction of the products with lithium aluminum hydride furnished (+)- and (−)-esermethole (**272**), respectively. Three further known steps[191] finally completed the syntheses of both (+)- and (−)-physostigmine (**273**) (Scheme 55).

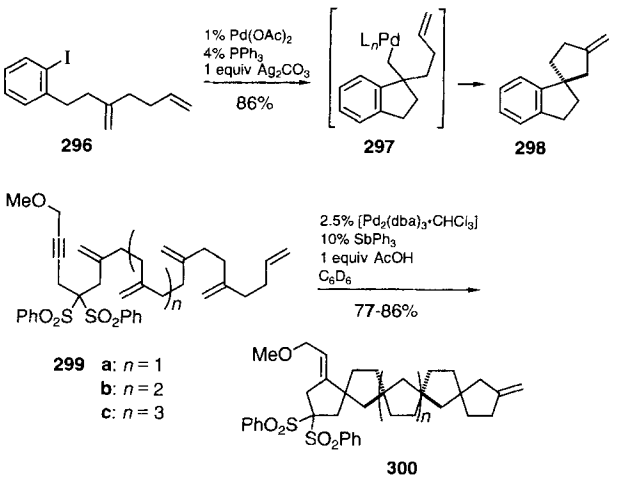
6.3. Obstacles with a Bonus: Neopentylpalladium Intermediates



Intramolecular Heck reactions can be extended considerably in scope, when the primary insertion is forced to occur regioselectively at a 2,2-disubstituted double bond, such that β-hydride elimination cannot take place. Three versions of this type of reaction can be distinguished, which depend on the structure of the aryl halide or alkenyl halide initiating the cyclization (Scheme 56). If the initiator is an aryl halide (or benzyl halide) such as the precursor to **274** (type I),[192] then a neopentylpalladium intermediate **275** is generated which reacts intermolecularly with alkene to form an allyl-substituted bicycle **276** in a typical Heck reaction. Intramolecular reaction with the double bond of an alkenyl side chain may also take place, thus forming a further ring.

Scheme 56. R^1 = alkyl; R^2 = aryl, CO_2alkyl, CN, $SiMe_3$; X = I, Br, OSO_2CF_3.

Application of initiating haloalkenes like the precursor to **277** (type II) causes a somewhat more complex reaction course.[193] Even without an additional alkenyl side chain, the generated neopentylpalladium intermediate **278** can react intramolecularly to give alkenylcyclopropane **279** in a 3-*exo-trig* cyclization followed by β-hydride elimination of the (cyclopropylmethyl)palladium intermediate (path A). Alternatively, intermediate **278** may couple intermolecularly with an added alkene to give **280**, or intramolecularly with another alkenyl group in the molecule giving an additional ring (path B). Path A branches further if the double bond of the former haloalkene remains exocyclic after initial cyclization, as in the case of the conversion of **281** to the neopentylpalladium intermediate **282** (type III in Scheme 56). Even after the 3-*exo-trig* ring closure of **282** yielding **283**, the palladium remains in a neopentyl position. Elimination of hydridopalladium halide (or triflate) occurs only with opening of the three-membered ring in a cyclopropylmethyl–homoallyl rearrangement, thus yielding diene **285** (path A^1). On the other hand, allylcyclopropane **286** can be formed by the intermolecular coupling of **283** with an alkene (path A^2). Incidentally, compound **285** is the formal product of a 6-*endo-trig* cyclization of intermediate **281**.

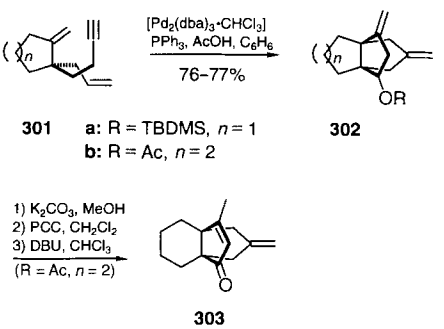


In the long run, kinetics will always determine which path is available for the neopentylpalladium intermediates. The cyclization of benzylic halide **287** in the presence of methyl acrylate gives product **289** according to a type I reaction.[32a] On the other hand, in type II reactions, even the intramolecular capture of the butenyl side chain in iodotriene **290** is only roughly twice as rapid as the 3-*exo-trig* cyclization yielding cyclopropane derivative **292** (Scheme 57).[193] The formation of the formal 6-*endo-trig* product **295** from iododiene **293** is an example of a

Scheme 57. E = CO_2Et.

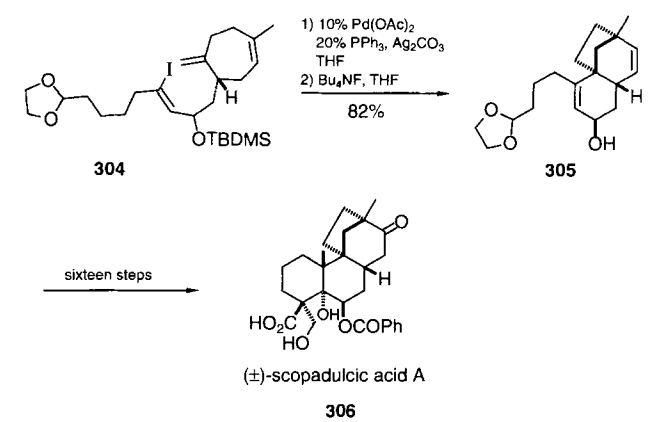
cyclopropylmethyl–homoallyl rearrangement in a type III reaction.[193]

Little attention has been paid so far to the effect of ligands and halide ions on the course of these reactions.[194] Since Overman et al.[192] succeeded in obtaining spirocycle **298** from iodoarene **296** in good yield (Scheme 58), numerous examples of



Scheme 58.

neopentylpalladium intermediates used in the formation of complex spirocycles have been published.[45a, 176c, 195] The current record for the maximum number of cyclizations performed in one step is held by the cycloisomerization cascade of heptaenyne **299c**, which finally results in the hexaspiro compound **300c**.[196]

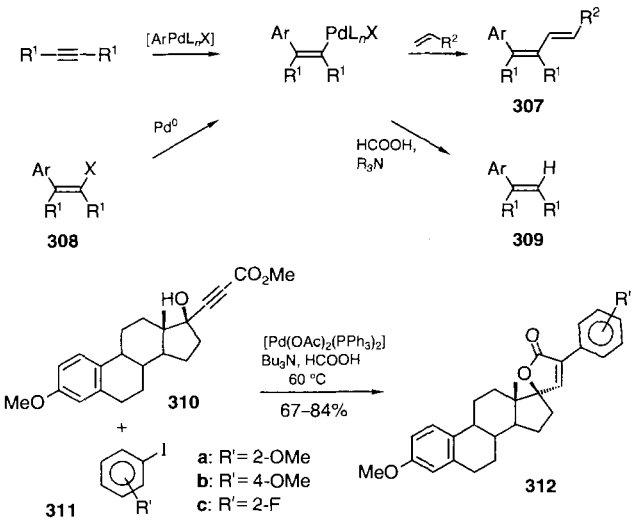


Neopentylpalladium intermediates generated in cycloisomerization reactions from suitable precursors such as **301** can also successfully lead to propellanes **302** (Scheme 59).[198] Hydrolysis, oxidation, and isomerization of the double bond transforms acetoxy derivative **302b** to the enone **303**.

Polyene cyclizations are generally suitable for the synthesis of bridged oligocycles.[193, 195c] The first total synthesis of scopadulcic acid A (**306**), recently reported by Overman et al., is

Scheme 59. PCC = pyridinium chlorochromate.

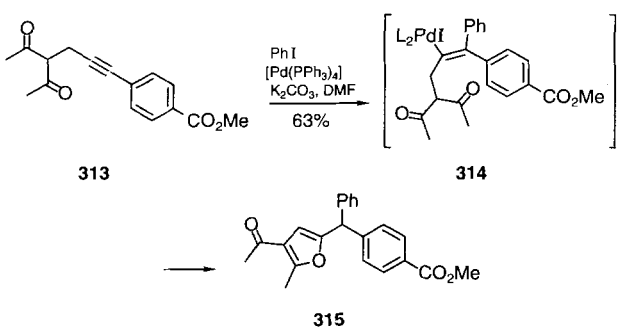
one of the most convincing demonstrations of the synthetic potential of this method (Scheme 60).[197] The bicyclononane subunit in the tetracyclic skeleton of **306** was constructed in a diastereoselective cyclization of 5-methylenecycloheptene **304**, which led to tricycle **305**.



Scheme 60.

7. Chemical Relay Stations: Palladium-Catalyzed Additions to Triple Bonds

7.1. A Domino Sequence Consisting of Intermolecular Addition and Subsequent Intramolecular Reaction

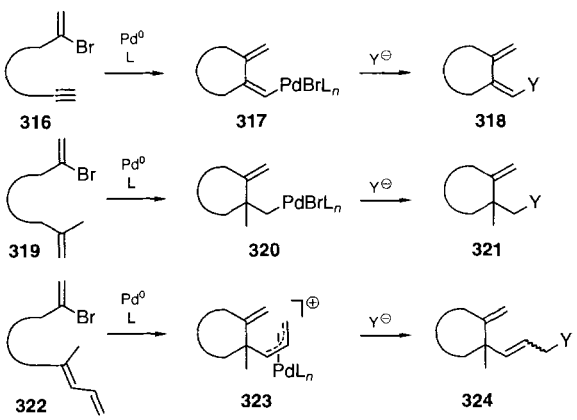


After Cacchi et al. had shown that iodoarenes and α,β-unsaturated carbonyl compounds undergo palladium-catalyzed 1,4-additions in the presence of tertiary amines and formic acid,[73] disubstituted alkynes were allowed to react with iodoarenes under identical conditions (Scheme 61).[87a, b, 198] (Aryl)iodopalladium, generated by oxidative addition of iodoarene to palladium(0), adds to the alkyne, thus creating an intermediate which formally could also have been generated by oxidative addition of the appropriately substituted haloalkene **308** to Pd^0. The intermediate can then react with alkenes to yield dienes **307** or be protiodepalladated, giving rise to **309**. Thus, the alkyne acts as a relay through which the ability of forming carbon–carbon bonds is passed on; in other words, the reactivity of the alkyne to nucleophiles is "switched on" by the addition of the arylpalladium species. Regioselectivity of the addition to

Scheme 61. R^1 = alkyl, aryl, $SiMe_3$; $R^2 \neq$ alkyl.

the alkyne is mainly determined by steric factors. Thus the aryl group is directed preferentially to the sterically less encumbered position.[187b, 198a] This reaction offers interesting possibilities, since arylation of 4-hydroxy-2-alkynoic acid esters such as **310** with iodoarene **311** yields a trisubstituted acrylic ester, which then lactonizes to the substituted butenolide **312** (Scheme 61).

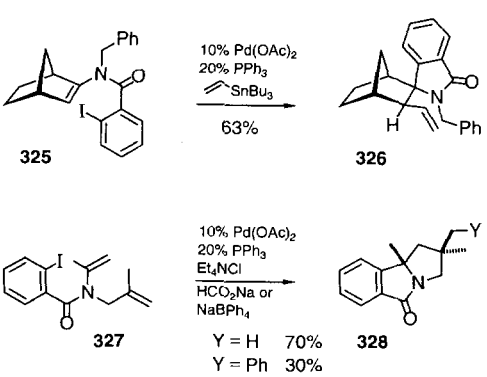
Palladium-catalyzed additions to triple bonds thus afford intermediates capable of forming of further C–C or C–X bonds according to the domino principle. A sequential reaction of this kind is illustrated by the arylation of alkyne **313** with iodobenzene (Scheme 62). The alkenyliodopalladium intermediate **314**



Scheme 62.

is attacked intramolecularly by the enolate ion formed through action of the base. β-Hydride elimination and double bond migration afford trisubstituted furan **315**.[199] Further studies on the preparation of functionalized butenolides,[200a] substituted γ-methylene-γ-butyrolactones,[200b] and substituted 5-alkenyl-2-furanones and 2-alkenyltetrahydrofurans[200c] underline the far-reaching ramifications for synthesis based on this reaction scheme.

7.2. The Sequence Consisting of Cyclization and Anion Capture[201]

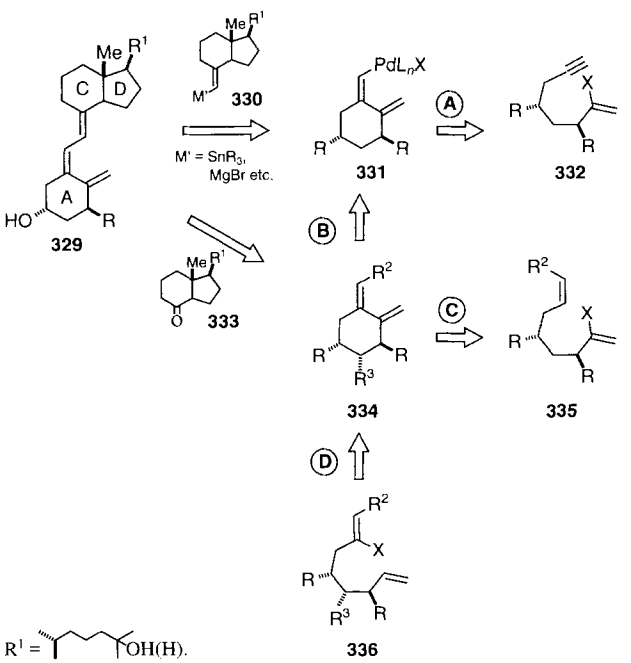


The double bond shifts frequently observed in products of intramolecular Heck reactions can be avoided in intramolecular additions to triple bonds by conducting the reaction under reducing conditions (formic acid/trialkylamine). The scope of this method is, however, by no means restricted to the formation of formal Heck cyclization products by hydride capture.[42i, j] For instance, alkenylpalladium intermediate **317**, generated in the *n-exo-dig* cyclization of bromoenyne **316**, may also be trapped by various "anionic" reagents Y^- (Scheme 63). The pioneering

Scheme 63. Y = H, alkyl, alkenyl, Ph, CN, NR_2, CO_2R; R = alkyl.

work in this field done primarily by Grigg et al. revealed the possibility of a stereospecific group transfer of organotin,[202] -zinc, and -boron compounds,[195a, 203] as well as organoaluminum and -zirconium compounds.[204] Furthermore, intermediates such as **317** may also be captured by oxygen, nitrogen, and carbon nucleophiles.[205] This process is not restricted to just alkenylpalladium species, but can be applied to neopentylpalladium intermediates **320** and π-allylpalladium complexes **323** as well.[42j, 195a, 202, 204]

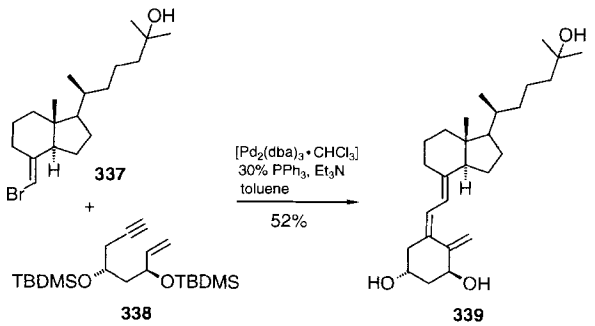
A frequently encountered problem related to these palladium-catalyzed domino Heck cross-coupling reactions lies in the relative rate of the carbopalladation step in comparison to the rate of group transfer. In reactions involving organozinc compounds the two steps often proceed with comparable rates, thus giving rise to product mixtures. In contrast, coupling reactions with organotin and organozirconium compounds[202, 204] are much more specific, as can be demonstrated by the preparation of spirocycle **326** by reaction of amide **325** with tributylvinylstannane (Scheme 64).[202]



Scheme 64.

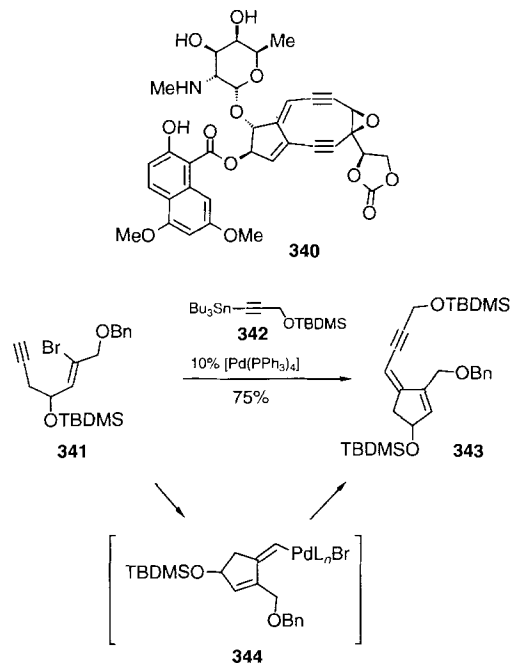
Even multiple cyclizations may be performed easily; anion capture with sodium formate or sodium tetraphenylborate occurs only after completion of the cyclization sequence. Grigg et al. performed various transformations in this manner, for example the conversion of iodoarene **327** into tricycle **328** (Scheme 64).[32c, 45a, 195b, e]

7.3. Relay Stations at Work: The Skeleton of Vitamin D and the Enediyne Ring of the Neocarzinostatin Chromophore



A particular challenge in the synthesis of the hormonally active form of vitamin D_3, 1α,25-dihydroxyvitamin D_3 (**329**; R = OH, $R^1 = CH(CH_3)(CH_2)_3OH$) (Scheme 65), remains the stereoselective preparation of the triene substructure. In the meantime several solutions to this particular problem have been published, each of which has palladium-catalyzed reactions in key steps.

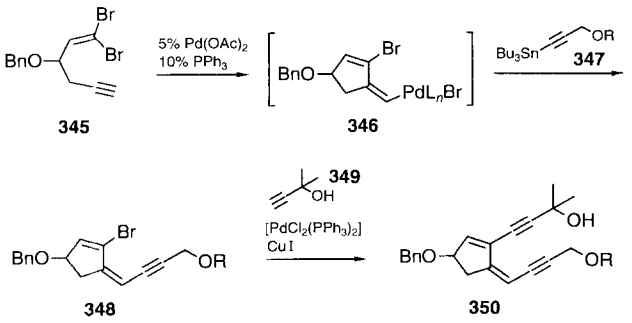
Scheme 65. R = OTBDMS, OCH_2OCH_3, OH, H; $R^2 = CO_2Me$, CH_2OH; X = Br, I.



The approaches of Shimizu et al.[206] and Crich et al.[207] (path C), and Mouriño et al.[208] and Takahashi et al.[209] (path D) rely on intramolecular Heck reactions with halodienes **335** and **336**, respectively, for the stereoselective construction of ring A in intermediate **334**. Subsequently, following Kocienski's[210a] protocol, **334** is linked to ketone **333** by a Wittig reaction. The strategy applied by Nuss et al.[211] is even shorter and more elegant. A palladium-catalyzed cyclization–carbonylation sequence is applied to 2-bromo-1,7-enyne **332** in a one-pot procedure to yield cyclic diene **334** via alkenylpalladium species **331** (path A, B) which can then be further transformed according to well-established methods.[210b–c] Intermediate **331** can be trapped directly with metal derivative **330** (alkenylstannane, alkenylmagnesium halide), thus providing the target molecule **329** in a very short sequence indeed (Scheme 65).

Trost et al.[212] demonstrated an elegant and highly convergent reaction cascade in the total synthesis of calcitriol (**339**) (Scheme 66). In this sequence the palladium-catalyzed intermolecular addition of bromoalkene **337** to the terminal alkyne **338** is followed by intramolecular carbopalladation and β-hydride elimination. Desilylation of the cyclized product led directly to calcitriol (**339**) in 52% yield.

Scheme 66.

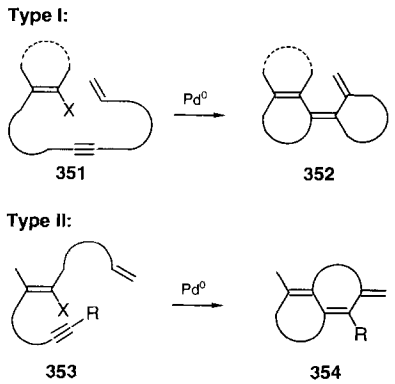


The synthesis of the enediyne ring in the neocarzinostatin chromophore (**340**) is yet another interesting problem that can be tackled successfully with sequential carbometallation/anion capture reactions (Scheme 67). In a first approach Nuss et al.[213a] started with 2-bromo-2,6-enyne **341** which was cyclized to give the alkenylpalladium species **344** and subsequently coupled with stannane **342**, thus yielding dienyne **343**. The second triple bond can be introduced in several subsequent steps.[213b]

Scheme 67.

Sequences published by Torii, Okumoto, et al.[214a] and by Nuss et al.[214b] utilizing 1,1-dibromoalkene **345** as a building

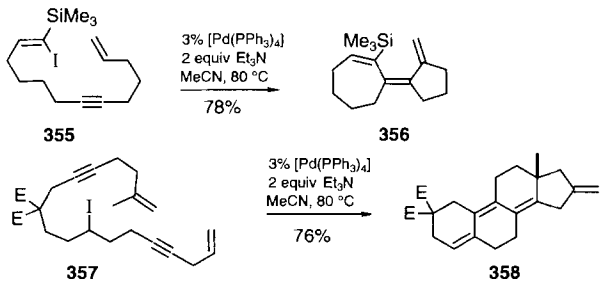
block are even more elegant (Scheme 68). The (*Z*) bromine–vinyl carbon bond reacts preferentially with palladium(0) by oxidative addition, and the resulting intermediate cyclizes to give **346**, which undergoes a selective coupling reaction with



Scheme 68.

stannane **347**. In a second palladium-catalyzed step the bromo substituent, which was originally in the (*E*) position in **345**, is replaced by propargylic alcohol **349**, thus providing the required precursor **350** for the enediyne ring. In spite of uncertainties concerning the mechanism of the cyclization of 1,5-enynes containing a 1,1-dibromovinyl terminus, it may be expected that future efforts in the applications of bifunctional reagents will reveal many new synthetic routes.

7.4. Zip It Up: Carbooligocycles from Cascade Reactions

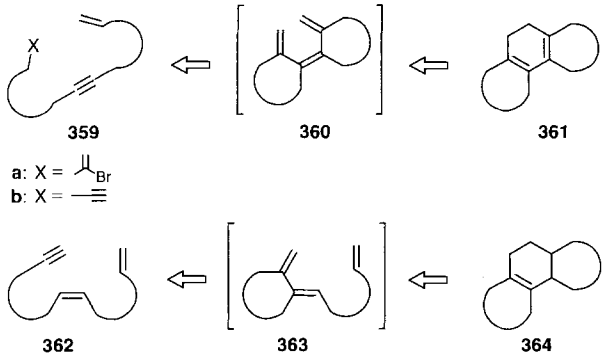


Alkenylpalladium intermediates generated by intramolecular addition of a haloalkene to a triple bond may also be captured by alkenes, either intermolecularly or intramolecularly. Thus, depending on the positions of double and triple bonds in the acyclic precursor, bicycloalkylidenes **352** (type I in Scheme 69)

Scheme 69. R = alkyl, aryl, CO_2alkyl; X = I, Br, OSO_2CF_3.

or annelated ring systems **354** (type II) may be formed. Type I reactions are initiated not only in substrates containing a haloalkenyl unit such as in **351** or **353**, but are also initiated reductively by addition of a hydridopalladium complex (generated in situ) to a terminal triple bond. The latter was demonstrated for the first time by Trost et al. with the reductive cyclization of 1,6-diynes.[215]

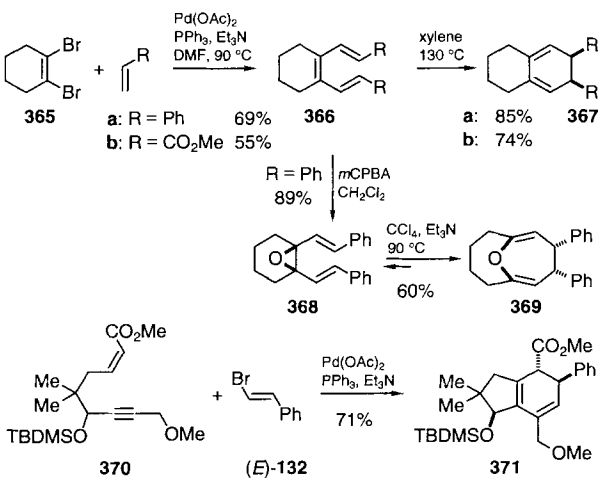
An example of a type I reaction is the straightforward cyclization of iododienyne **355** to (methylenecyclopentylidene)-cycloheptane **356** (Scheme 70).[216a] This is not the only demonstration that palladium-catalyzed cyclizations—in contrast to similar radical-initiated reactions—provide easy access to seven-membered rings as well as five- and six-membered rings.



Scheme 70. E = CO_2Et.

Acyclic precursors such as **357** can be subjected to a continuous sequence of more than two carbopalladation steps, thus forming three or more rings. The term "crochet-type reactions" was introduced for carbocation-initiated cyclization cascades[217] because of the analogy with interlinked crochet stitches (see also Scheme 58). In other work Negishi et al. designated their own Pd-catalyzed polycyclizations of acyclic molecules as "zipper" cyclizations, since the two dienoligoyne chains connected by a head piece are multiply linked just like the two sides of a zipper.[216b] The one-step construction of the steroid skeleton **358** through tetracyclization of acyclic precursor **357**[216c] is a good example (Scheme 70). Interestingly, the neopentylpalladium intermediate generated after the third cyclization does not undergo a 3-*exo-trig* cyclization to produce a three-membered ring. Instead, a 5-*exo-trig* ring closure with participation of the terminal double bond predominates (Scheme 70).

7.5. Tactical Combinations: Palladium-Catalyzed Polycyclizations and Intramolecular Reactions

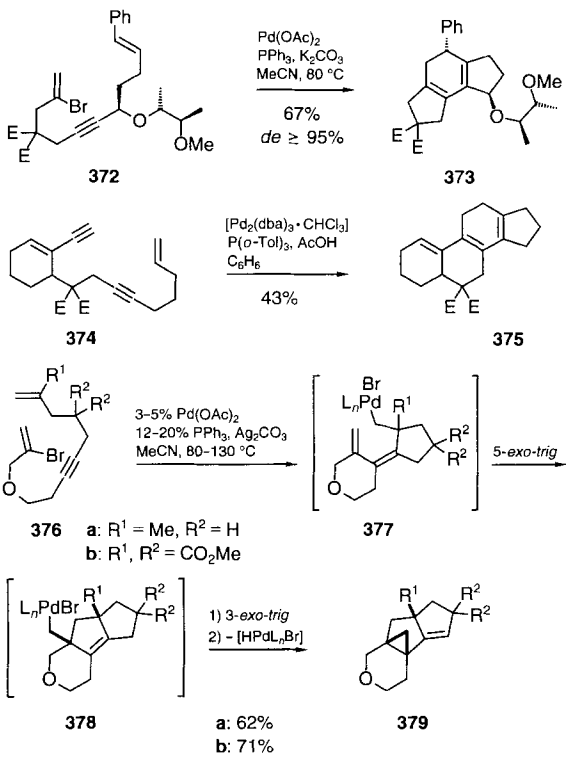


New perspectives for multiple cyclizations may arise when a palladium-catalyzed cyclization sequence leads to a molecule with more than two double bonds in an arrangement that would allow a subsequent thermal intramolecular reaction. Electrocyclic reactions and Diels–Alder reactions are the primary candidates for this second reaction. (*E,Z,E*)-1,3,5-Trienes **360** may be expected from the palladium-catalyzed biscyclizations of 2-bromodienynes **359a** or enediynes **359b**. Subsequent disrotatory electrocyclization of **360** leads to bisannelated cyclohexadienes **361** under comparatively mild conditions (Scheme 71). Alternatively, substituted dienynes **362** are transformed into bis(exoalkylidene)cycloalkanes **363** by palladium-catalyzed cycloisomerization; subsequent intramolecular [4 + 2] cycloaddition then yields bisannelated cyclohexenes **364** (Scheme 71).

The combination of Heck reaction and subsequent electrocyclization was realized for the first time in the preparation of (*E,Z,E*) trienes **366**, in which vicinal dibromides like **365** were

Scheme 71.

coupled with monosubstituted alkenes (Scheme 72).[97, 100, 218] The anticipated electrocyclization did not occur under the applied Heck coupling conditions (90 °C) but at slightly elevated temperature (130 °C) in refluxing xylene.

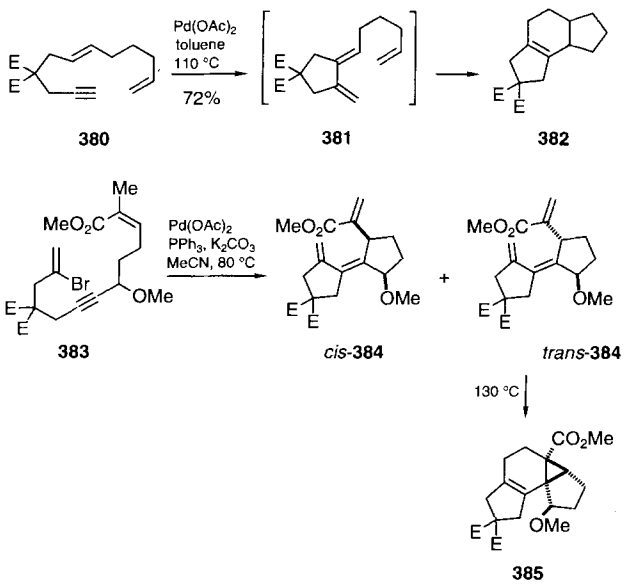


Scheme 72. *m*CPBA = *meta*-chloroperbenzoic acid.

In contrast to these findings, Trost et al.[212b] isolated the bicyclic product **371** from the Heck reaction of enyne **370** with *β*-bromostyrene ((*E*)-**132**) under standard conditions. In this sequence carbopalladation of the triple bond followed by 5-*exo*-*trig* ring closure and subsequent *β*-hydride elimination is assumed; the resulting (*E*,*Z*,*E*) triene is finally transformed into the annelated cyclohexadiene **371** by disrotatory ring closure. The rotaselectivity responsible for the production of only one diastereomer has been explained by interactions between the silyloxy and methoxymethyl substituents (Scheme 72).

Since (*E*,*Z*,*E*) trienes **366** are isolable, they are conducive to diverse applications. Selective epoxidation of the central double bond is feasible, thus yielding dialkenyloxiranes **368**, which can undergo Cope rearrangement at 90 °C.[100] Indeed, the formation of the bridged 1,6-oxacyclodeca-1,5-diene **369** from **366** corresponds to a ring expansion by four carbon atoms (Scheme 72).

In two independent developments[196b, 219, 220] a purely intramolecular reaction cascade was devised, in which two successive Heck reactions yielded a triene, which underwent subsequent 6π electrocyclization. In the first case the sequence is initiated by insertion of palladium into an alkenyl carbon–halogen bond. For unsubstituted dienynes it proved essential to add silver salts to suppress rearrangement products during triene formation.[220a] The disrotatory 6π electrocyclization of terminally substituted 1,3,5-hexatrienes such as that formed from **372** proceeds with remarkable rotaselectivity.[220b, c] Enantiomerically pure 2-bromodienyne **372** thus yielded virtually enantiopure bisannelated cyclohexadiene **373** in good yields (Scheme 73).



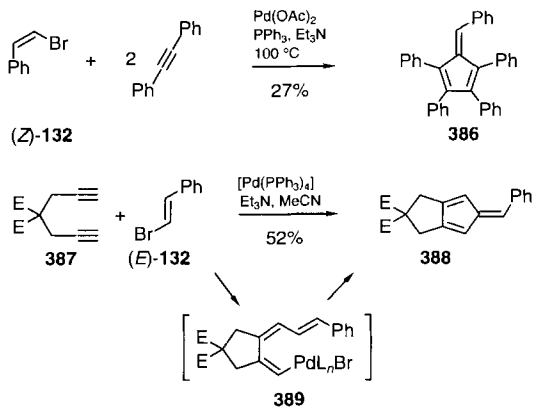
Scheme 73. E = CO_2Et.

The cycloisomerizations of enediynes such as **374** developed by Trost et al. are complementary to these findings, and in part superior. These reactions proceed through an analogous sequence of intermediates, leading to bisannelated cyclohexadienes like **375**.[219] Silver salts may be omitted, as the initial step consists of a chemoselective addition of a hydridopalladium complex (generated in situ) to the terminal triple bond. Moreover, substrates are generally more easily accessible, since haloalkenes are not required. Combined palladium-catalyzed biscyclizations and 6π electrocyclizations have meanwhile matured to such a degree[196b] that it will certainly be only a question of time before this method is applied in natural product synthesis.

An even greater increase of structural complexity in a single synthetic operation may be achieved in palladium-catalyzed transformations of bromodienynes **376**, containing a terminal double bond which is disubstituted at the penultimate carbon atom (Scheme 73). The neopentylpalladium intermediate **377** generated in the second cyclization step undergoes predominantly a 5-*exo*-*trig* cyclization. The resulting intermediate **378** cyclizes once more in a 3-*exo*-*trig* mode before *β*-hydride

elimination yields **379**. Tetracycle **379** is formed with complete diastereocontrol in yields of up to 71%.[220a]

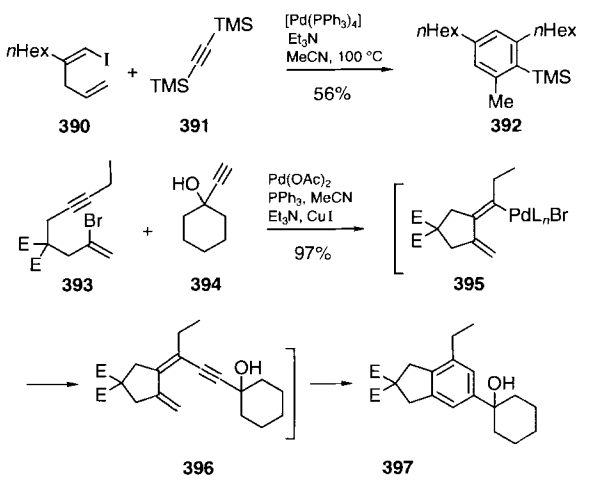
As already mentioned, palladium-catalyzed cycloisomerizations and intramolecular Heck reactions are ideal tools for the construction of bis(exoalkylidene)cycloalkanes,[92] which can continue the reaction cascade in subsequent Diels–Alder reactions, which may even proceed intramolecularly. A nice example of a solely intramolecular sequence is given by the cycloisomerization of dienyne **380**, resulting in the bisannelated cyclohexene **382** (Scheme 74). It should be emphasized that the regiocontrolled formation of conjugated diene **381** is due to the presence of the terminal double bond.[76b,d] Alternatively, the reductive cyclization of 1,6-diynes[215a] may be used to synthesize the 1,3-diene units necessary for intramolecular or intermolecular Diels–Alder reactions. Subsequent to biscyclization of 2-bromodienyne **383** under Heck conditions, an intramolecular Diels–Alder reaction also terminates the reaction sequence leading to the highly strained tetracycle **385** (Scheme 74).[220c]



Scheme 74. E = CO_2Et.

7.6. A New Twist on Arene Chemistry: {2+2+2} Assembly of Benzene Derivatives

The efficiency of organometallic reactions manifests itself in numerous transition metal catalyzed and transition metal mediated cyclotrimerizations of alkynes to benzene derivatives.[221] It was merely a question of time before palladium-catalyzed reactions were also applied. However, the first concepts were not amenable to synthetic applications.

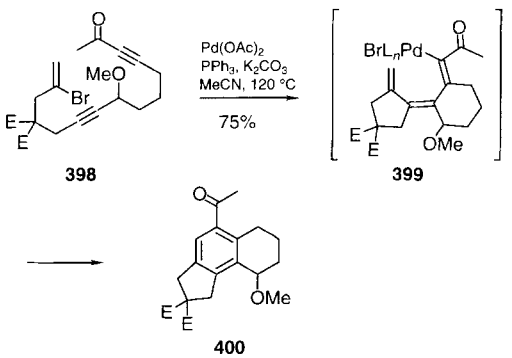


Purely intermolecular {2+2+2} cyclotrimerizations indeed led to benzene derivatives,[222] but the trimerization of unsymmetrically disubstituted alkynes yielded mixtures of at least two regioisomers. Because of this and also the stoichiometric formation of cyclobutadienylpalladium complexes, the synthetic utility of this strategy was extremely limited. Intermolecular Heck reactions were tested with (*Z*)-β-bromostyrene ((*Z*)-**132**) and

Scheme 75. E = CO_2Et.

diphenylacetylene (Scheme 75). The stoichiometry of the reaction no longer created problems, but pentaphenylfulvene (**386**) was obtained in poor yield instead of the anticipated benzene derivative.[223] (*E*)-Bromostyrene ((*E*)-**132**) undergoes a similar transformation upon reaction with diyne **387** under Heck conditions.[224] The 5-*exo-trig* ring closure of the intermediate alkenylpalladium derivative **389** is apparently favored kinetically over a 6-*endo* attack (Scheme 75).

The first promising results were obtained in the palladium-catalyzed reaction of 1-iododiene **390** with alkyne **391** (Scheme 76). Intermolecular addition of the alkenylpalladium intermediate to the triple bond takes place before ring closure occurs, yielding the tetrasubstituted benzene derivative **392**.[216a] Undoubtedly, this approach relies on the tendency of palladium-catalyzed cyclizations to follow Baldwin's rules.[177] Thus, a 4-*exo-trig* ring closure is disfavored kinetically to such an extent that intermolecular addition to the alkyne dominates and is eventually followed by a 6-*exo-trig* ring closure.



Scheme 76. E = CO_2Et.

Torii, Okumoto et al.[225] have demonstrated the most convincing strategy for the intermolecular trapping of 1,3-dienylpalladium intermediates (generated in situ) with alkynes. Intramolecular cyclization of 2-bromoenyne **393** initially leads to alkenylpalladium species **395**, which is then intermolecularly

coupled with a terminal alkyne **394** to yield dienyne **396**. Spontaneous rearrangement of **396** affords the monoannelated benzene derivative **397** (Scheme 76). Later studies[224, 226] underline the scope of this method and show that diyne cycloisomerizations may also serve as initiators for such sequences.[224a]

The potpourri of palladium-catalyzed preparations of benzene derivatives was completed by a further variant, proceeding entirely intramolecularly (Scheme 77).[227] The acyclic precursor **398** containing a second triple bond leads to the alkenylpalladium species **399** after two successive *n-exo-dig* cyclizations. Yet another ring closure occurs and, after subsequent β-hydride elimination, the angularly bisannelated benzene derivative **400** is formed. It still is unclear whether the last step of this sequence is a direct Heck coupling, or if electrocyclization of **399** first takes place, followed by β-hydride elimination. Needless to say analogous cycloisomerizations of triynes give similar results.[224a]

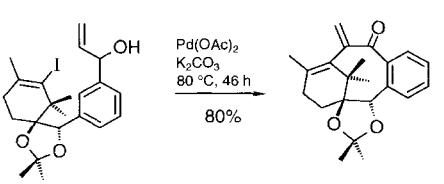
398 **399** **400**

Scheme 77.

8. Summary and Outlook

Although a reasonable working hypothesis has been established for the mechanism of the palladium-catalyzed arylation and alkenylation of alkenes, the Heck reaction, individual steps are far from being completely understood. Nevertheless, insight into the factors determining these reactions has contributed significantly to the further development and improvement of these methods. Numerous related procedures have emerged from the classic Heck reaction. Chemoselective and regioselective couplings are now possible with the appropriate catalyst cocktail. Indeed, even ligand-controlled enantioselective intermolecular and intramolecular couplings of highly functionalized aryl and alkenyl derivatives with unsymmetrical and oligosubstituted alkenes, cycloalkenes, and unsaturated heterocycles are possible. Oligo couplings and even multiple couplings proceed with astonishing yields, both intermolecularly and intramolecularly.

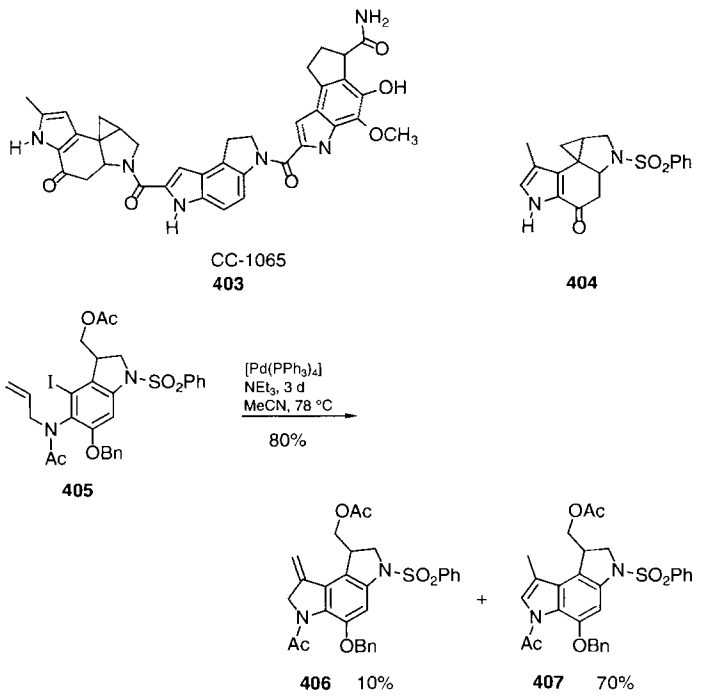
Reaction cascades have resulted from the skillful combination of the Heck reaction or its initial steps with other palladium-catalyzed procedures such as nucleophilic substitutions (via π-allylpalladium complexes) or thermally controlled transformations like Diels–Alder reactions and 6π electrocyclizations. In these cascades, not just one new C–C bond is formed specifically; two, three, four, and even more new bonds can be formed in a single step. The increase in molecular complexity, accepted nowadays as a measure for the efficiency of a synthetic manipulation, is impressive in these sequential reactions.



Procedures in which initially formed arylpalladium or alkenylpalladium species are added to a triple or a double bond either (re)generating an alkenyl-, neopentyl-, or even a π-allylpalladium intermediate have proven to be particularly useful for the development of cascade reactions, as these intermediates cannot be removed or at least not so rapidly from the reaction by β-hydride elimination. Instead, they again react with triple bonds and double bonds or with other neutral and anionic nucleophiles. Thus, a triple bond in a molecule behaves like a relay, producing a new reactive intermediate upon the addition of a palladium species.

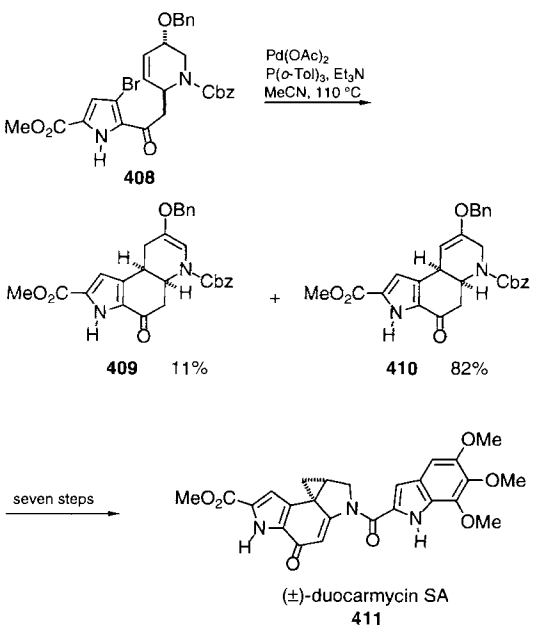
Up to now, the various possibilities arising from the domino-like combination of several Heck reaction steps with other processes have yet not been exploited to the fullest extent, in spite of numerous successes. In this area chemists' imaginations can run wild. Indeed, the opportunities for the elegant and highly convergent construction of complex natural and non-natural products justify increasing research efforts in this field of palladium-catalyzed bond-forming methods (Heck reactions as well as mechanistically related processes). The anticipation and excitement amongst chemists is a result of a myriad of new discoveries in the recent past. Certainly, the Heck reaction will never again fall into oblivion, since it promises solutions to future preparative challenges. Yet there are still some hurdles to be overcome before a broad application can be realized, especially on an industrial scale. As with almost every new application, selectivity problems will have to be unraveled by carefully matching reaction partners and fine-tuning reaction conditions. Expansion of the spectrum of starting materials, especially to inexpensive chloroarenes and chloroalkenes, remains a desirable goal. In view of a practical industrial application, improvements in catalyst efficiency and catalyst recycling are essential.[35] It remains to be seen whether all these expectations can be met.

Addendum



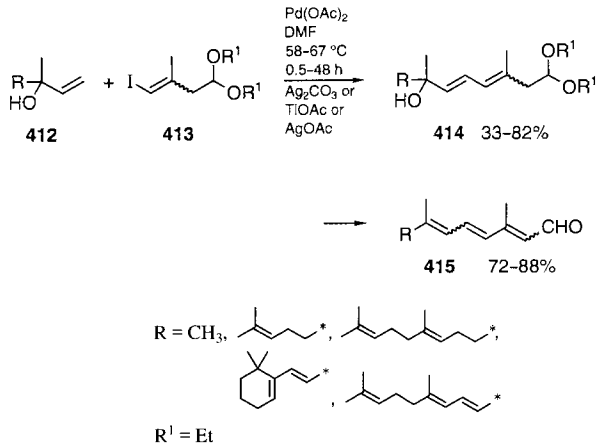
Many new studies have been published since the completion of the final version of this review almost a year ago. These findings have contributed substantially to establishing the Heck reaction in natural product synthesis and have reported progress in catalytically performed asymmetric synthesis.

A short reaction sequence has been demonstrated by Masters et al.,[228] who applied an intramolecular Heck reaction as a key step in the construction of the highly functionalized tricycle **402**, containing the basic tricyclic skeleton of taxol (Scheme 78).



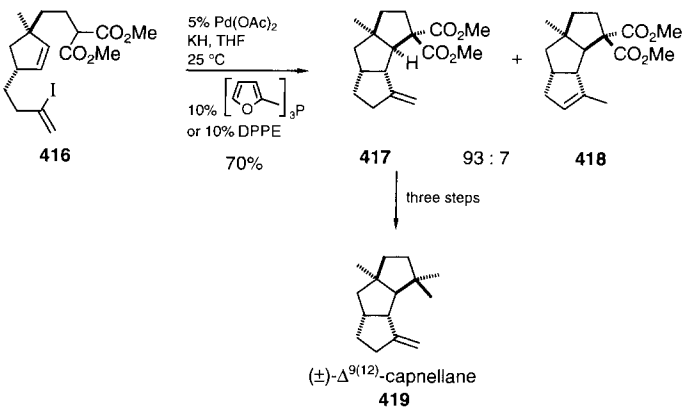
401 **402**

Scheme 78.



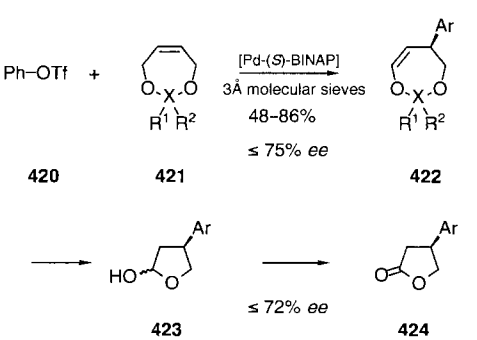
Scheme 79.

Tietze et al.[229] marked progress along a new route to the antitumor antibiotic CC-1065 (**403**) with the successful synthesis of the protected subunit **404** (Scheme 79). One of the two pyrrole rings in the precursor **407** to (±)-N^2-(phenylsulfonyl)-CPI (**404**) may also be obtained by an intramolecular Heck reaction of bicycle **405** (Scheme 79). Natsume et al.[230] applied an intramolecular Heck reaction in a key step of the total synthesis of the antitumor antibiotic (±)-duocarmycin SA (**411**; Scheme 80).



Scheme 80.

An example of a new intermolecular application is the vinylation of tertiary allyl alcohols **412**, giving access to isoprenoid aldehydes **415** (Scheme 81).[231] These results were obtained in the laboratories of Rhône-Poulenc, once again underlining revived interest even in industry in this catalytic transformation.



Scheme 81.

Balme et al.[232] reported an interesting new synthesis of the triquinane sesquiterpene (±)-$\Delta^{9(12)}$-capnellane (**419**) (Scheme 82). Biscyclization of the cyclopentene derivative **416** gave tricycle **417** (by-product **418**), which was converted into target molecule **419** in three further steps.

Scheme 82.

The enantioselective arylation of 4,7-dihydro-1,3-dioxepines **421** to yield **422** opens a new chapter in the asymmetric synthesis of γ-butyrolactone derivatives **424** (Scheme 83), which are then accessible in two additional steps via hemiacetal **423**. In this publication Shibasaki et al.[233] also discuss the effect of molecular sieves on reaction rates of asymmetric arylations.

Scheme 83. X = C, Si; R^1,R^2 = CH_3, *t*Bu, H, $(CH_2)_5$.

Studies undertaken by Fuchs et al.[234] Xu et al.,[235] and Pietrusiewicz et al.[236] revealed new substrates for Heck reactions with successful applications of vinylsulfones, phenylvinylphosphinates, and dienylphosphine oxides. Attention should also be drawn to the increasing importance of new ligand classes, especially 1,10-phenanthroline and its derivatives,[237] which have been successfully applied in directing palladium-catalyzed reactions. A myriad of interesting new papers[238–251] have been published in addition to those referred to in this short and somewhat arbitrary selection. And this flood does not promise to end soon.

The authors' own work mentioned in this review was supported financially by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Studienstiftung des Deutschen Volkes, the Alexander-von-Humboldt-Stiftung, the German Academic Exchange Service, and the Fonds der Chemischen Industrie, as well as the companies BASF, Bayer, Degussa, Hoechst, and Hüls AG through generous gifts of chemicals. The authors thank Stefan Beusshausen for preparing the schemes and Dr. Burkhard Knieriem for his careful proofreading of the manuscript in various stages. Our ongoing collaboration with Prof. Dr. Philip J. Parsons, University of Reading, was made possible by a grant within the Academic Research Collaboration (ARC) Programme administered by the German Academic Exchange Service and the British Council.

Dendrimers: From Generations and Functional Groups to Functions

Jörg Issberner, Rolf Moors and Fritz Vögtle*

Introduction

When a new idea in science is particularly appealing or "contagious", activity in that area may rapidly reach epidemic proportions.[1] A recent example is the development of dendrimer research in the past few years. A CAS online search shows that the number of publications in this field has increased nearly exponentially over the past decade, and the limit has not yet been reached (Fig. 1).[2-6]

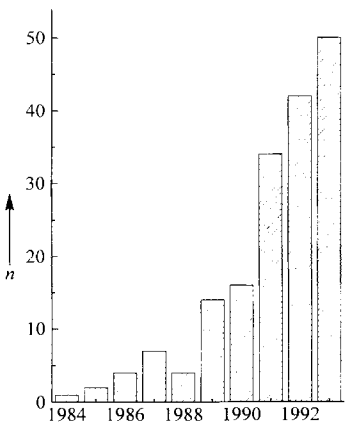

Fig. 1. Number n of publications about dendrimers in the last decade [7].

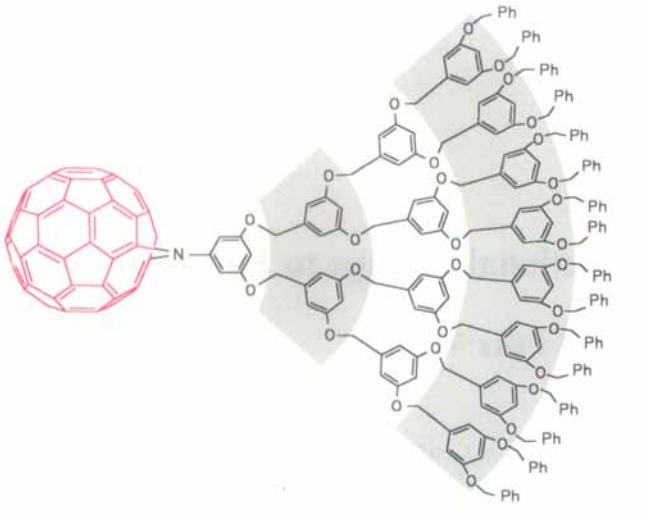
Up until now the primary goal was the synthesis of dendrimers with high molecular mass and as many generations as possible. Poly(amidoamines) (PAMAM),[6c] polypropylenamines,[8] and silicon dendrimers[9] set "records" for the number of generations, whereas the polyacetylene dendrimer prepared by Moore et al.[10] with the formula $C_{1398}H_{1278}$ and a mass of 18079.53 g mol^{-1} represents the "heavyweight champion" for pure hydrocarbon dendrimers. In the past two years, however, the emphasis has changed, and the synthesis of large, complex molecules has become less important. A first indication of new trends in dendrimer research was, for example, a report in 1991 by Newkome et al.[11] on a chiral dendrimer. In 1992 Shinkai et al. described a "crowned arborol" capable of complexing metal ions with the crown ether units at the periphery of the molecule.[12] We ourselves developed a reversibly photoswitchable dendrimer containing terminal azobenzene units.[13]

These first examples of cascade molecules with functional components point out the new directions in dendrimer research: properties are modified increasingly with functional centers. Not the dendrimer itself but the multiplication of functional components attached to a dendritic skeleton moves into the forefront, and new materials with specific properties (redox, ligand, and liquid crystalline properties, biochemical activity...) are anticipated. Industry has also shown increasing interest in functional cascade molecules for applications in diverse areas such as medical engineering,[14d-j] agrochemistry,[14c] and the development of photocopier toners,[14a,b] as documented by many patents.[14a-c,e,i] Furthermore the potential of dendrimers in pharmaceutical and medical applications,[14f] diagnostic imaging,[14c] and radiation therapy[14g,h] is frequently discussed. Oligoamines[15] were screened for anticancer properties.[16] Recent results and examples for new functional cascade molecules are presented in more detail below.

Dendrimers in Organic and Organometallic Chemistry

The preparation of the first fullerene dendrimer by Fréchet, Wudl, et al. spans two topical areas of supramolecular chemistry.[17] C_{60} and a dendritic benzylic bromide were linked by Williamson ether synthesis. More recently Fréchet et al. obtained the fullerene dendrimer **1** analogously by reaction with a dendritic azide (Scheme 1).[18]



Shinkai et al. reported the synthesis of potentially complexing arborols bearing crown ether units in the core and along the periphery.[12] They provided evidence that these "crowned arborols" **2** not only form complexes with metal ions, but are also able to solubilize myoglobin in organic solvents.

The synthesis of dendrimers **3** with a complexing inner core (hexacyclen = hexaaza[18]crown-6) succeeded in Bonn; hexacyclen was linked with a branching unit which was obtained in a convergent manner.[19] A dendritic imine (multisalen dendrimer) forms the trinuclear complex **4** with cobalt salts.[15]

In most cases the functional units are located on the dendrimer surface, but dendrimers like **3** are now accessible containing a nucleus capable of performing special functions (lu-

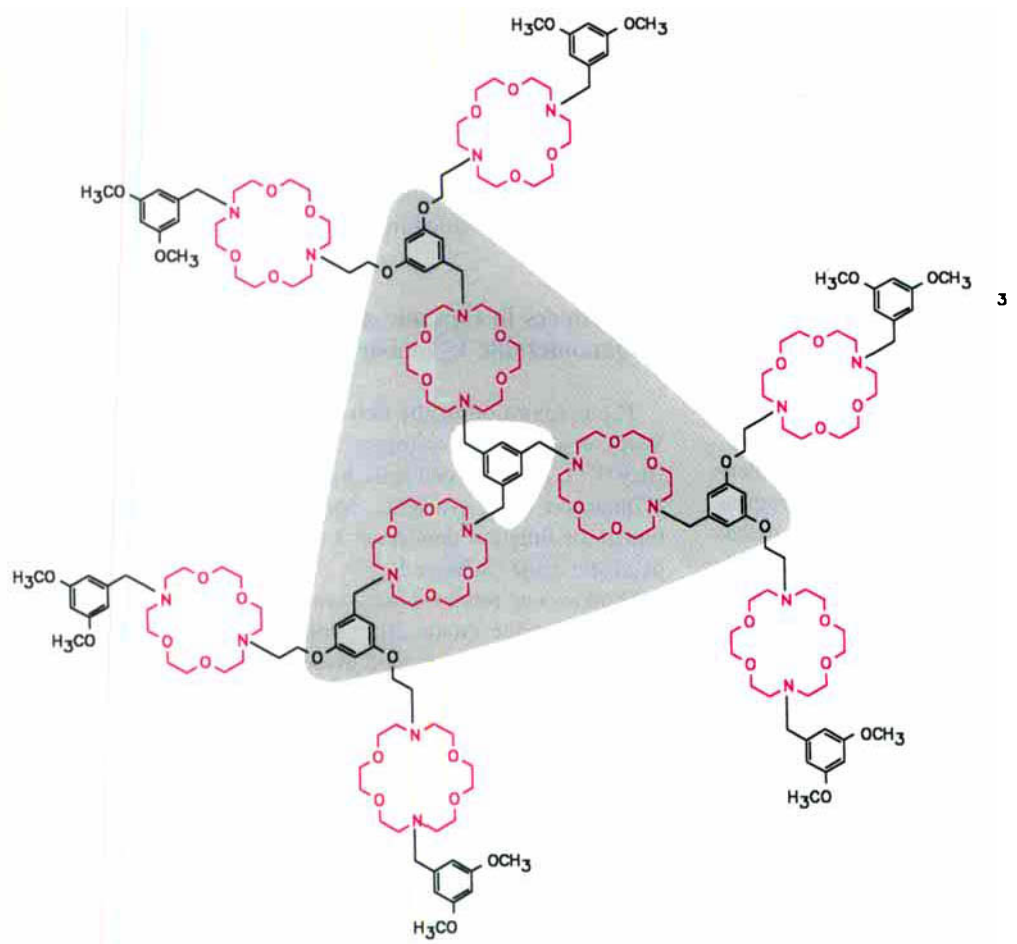
Scheme 1. Fullerene-containing dendrimer [18]. Functional units in all formulas are red; every second generation (from the inside to outside, the first, third, fifth etc). is shaded in gray.



minescence, complexation) which are influenced to some extent (sterically or electronically) by the periphery. Inoue et al. were the first to describe a dendrimer with a metal porphyrin at its center.[20] The convergent synthetic method of Fréchet[17] was used to prepare a dendrimer in which the photoactive metal porphyrin center is sterically shielded. Diederich et al.[21] investigated the influence of the surface groups on the electrochemical behavior of metal porphyrins. Following a divergent synthesis devised by Newkome et al.,[2] they prepared the third-generation porphyrin dendrimer **5**, which has a molecular weight of over 19000. The redox chemistry of **5** strongly contrasts that of non-dendritic zinc porphyrins. The porphyrin nucleus is shielded by a core of electronegative oxygen atoms such that reduction by electrons from the outside is hindered, and conversely oxidation is facilitated. Such structures suggest the development of a "molecular energy collector" with included metal ions for energy absorption. The spontaneous emission of stored energy as light would correspond to an amplification of light intensity (light harvesting effect).

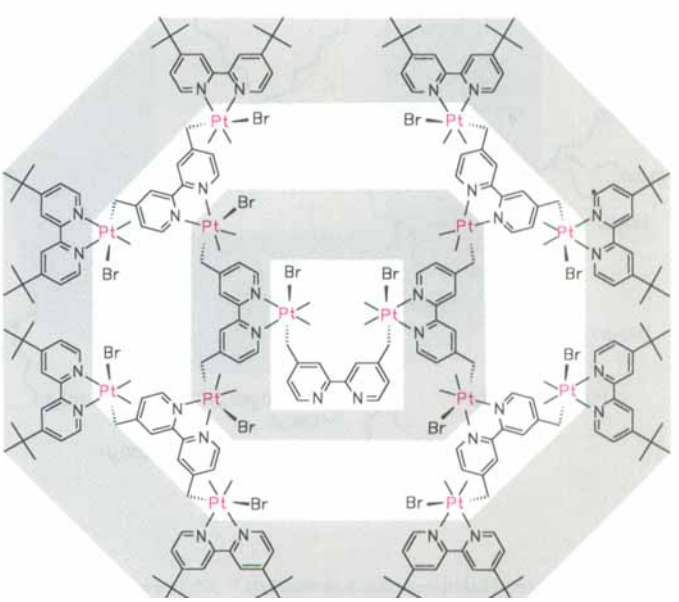
4

2

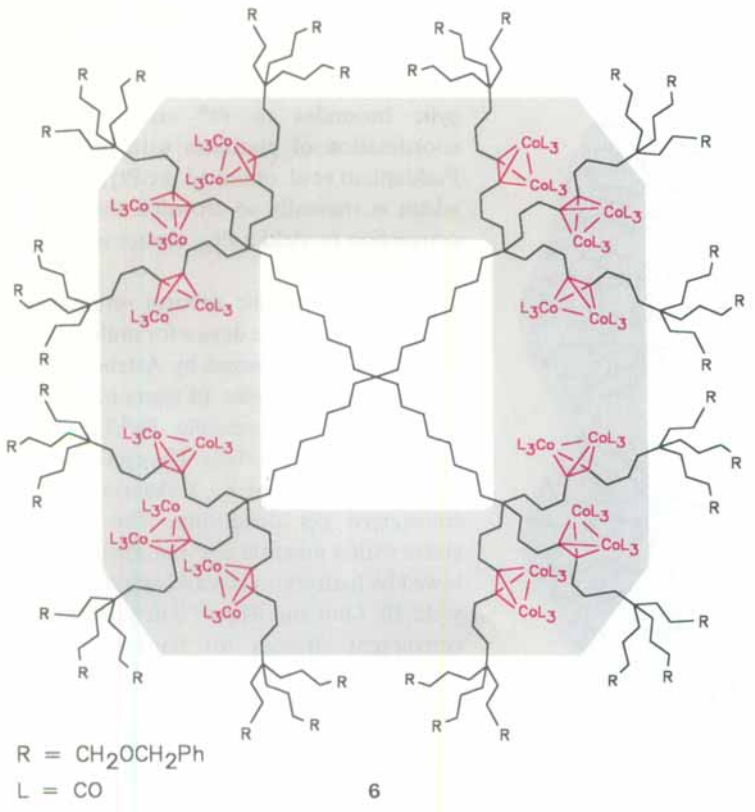
5

The first studies on dendritic metal and nonmetal complexes demonstrate that dendrimers/arborols can be attached to metal centers for the preparation of "supramolecular aggregates".[22–26] The controlled complexation of metal ions at specific binding sites in dendrimer cavities was achieved by Newkome et al., who prepared a dendrimer framework containing triple bonds, which could be complexed by dicobalthexacarbonyl units (**6** in Scheme 2).[27]

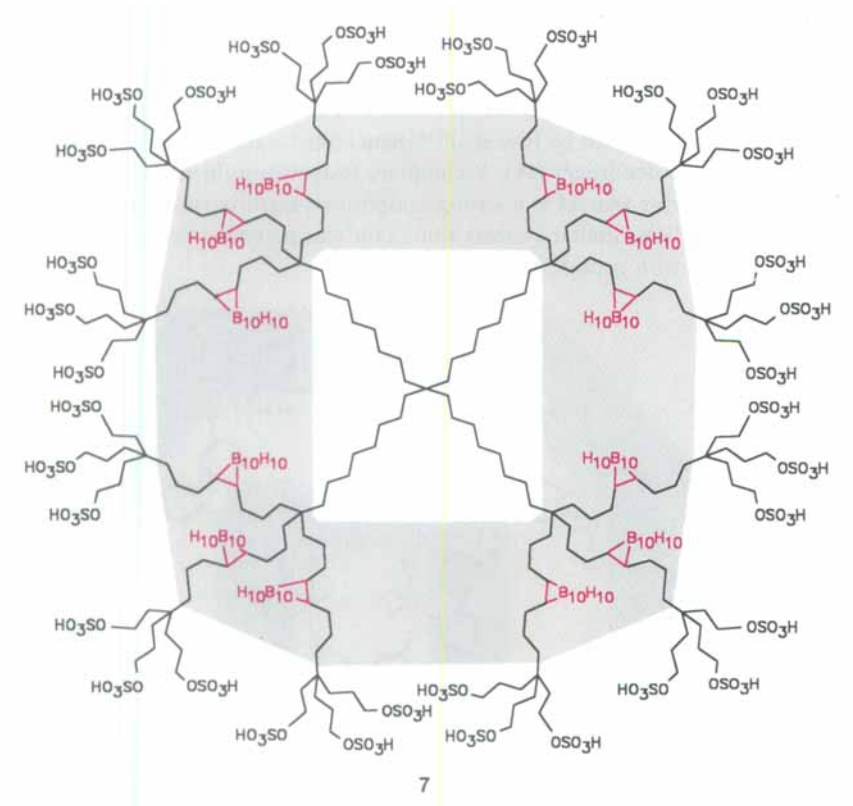
A second site-specific reaction within a cascade molecule was reported by Newkome et al. The triple bond containing dendrimer described previously was treated with decaborane $B_{10}H_{14}$. The dendrimer obtained, "boron supercluster" **7**, bears covalently bound borane at defined sites inside the dendrimer.[28, 29] This is not just the complexation of a borane cluster, but an actual reaction with the dendrimer to give a carborane.[29] In this way up to twelve borane clusters can be fixed within a dendrimer. The resulting water-soluble carboranes may find application in catalysis[28, 30] and boron neutron-capture therapy in cancer treatment.[31]



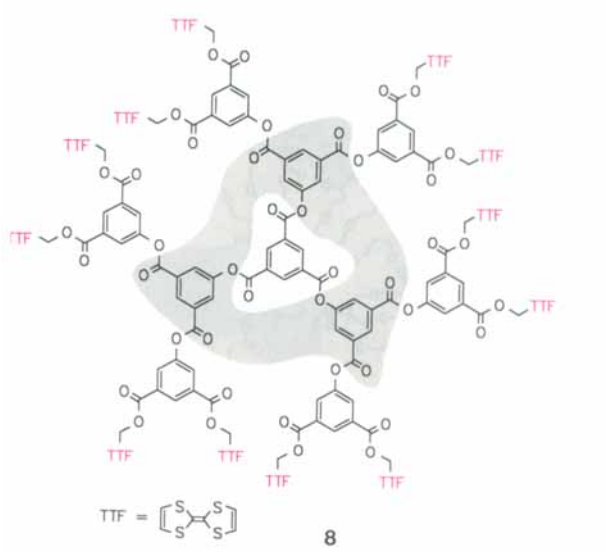
An example of redox-active dendrimers was given by Bryce et al.,[32] who connected benzene tricarboxylic acid trichloride to dendritic tetrathiafulvalene (TTF) as a functional component in **8** (Scheme 2). The cyclic voltammogram of **8** indicates formation of a multiply positively charged species in which the tetrathiafulvalene units do not interact. These new redox-active species may be useful as organic conductors and for the investigation of charge-transfer interactions.



Puddephatt et al.[26] described the synthesis of metal ion containing dendrimers by coordinating bipyridine derivatives to transition metals, which resembles the synthetic strategy developed by Balzani et al.[24] In a convergent synthesis, in other words by repetition of alternating steps (oxidative addition of benzylic bromides to Pt^{II} and subsequent coordination of platinum with bipyridine) Puddephatt et al. obtained the Pt_{14} cluster **9**, which is sterically so crowded that further conversion to yield a Pt_{30} cluster is not possible.[26a]

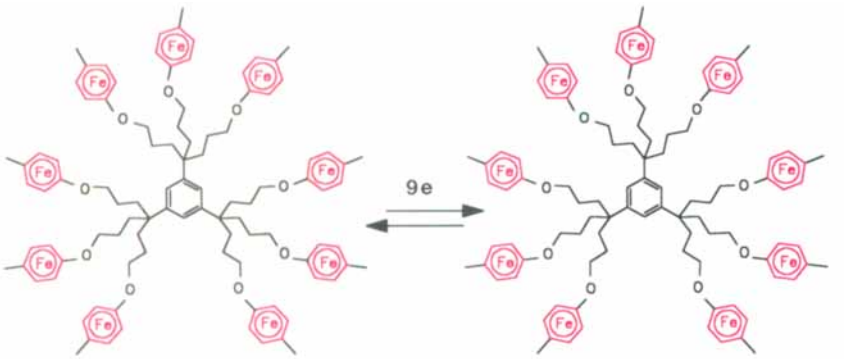


An organometallic arborol serving as a molecular electronic device for multielectron transfer was synthesized by Astruc et al.[23] The nonairon complex **10** bears nine quasi-equivalent and reversible Fe^{II}/Fe^{I} redox equivalents on its surface. The cyclic voltammogram shows that 8 ± 1 electrons can be transferred per dendrimer. The synthesis starts with a ninefold one-pot allylation followed by hydroboration and etherfication to yield **10**. Liao and Moss[33] demonstrated a convergent strategy for hanging organometallic units to the branches of a dendrimer in their synthesis of a molecule with twelve dicarbonylcyclopentadienyl metal complex fragments. Owing to the stability of the metal complexes to oxygen, a convergent strategy was possible.



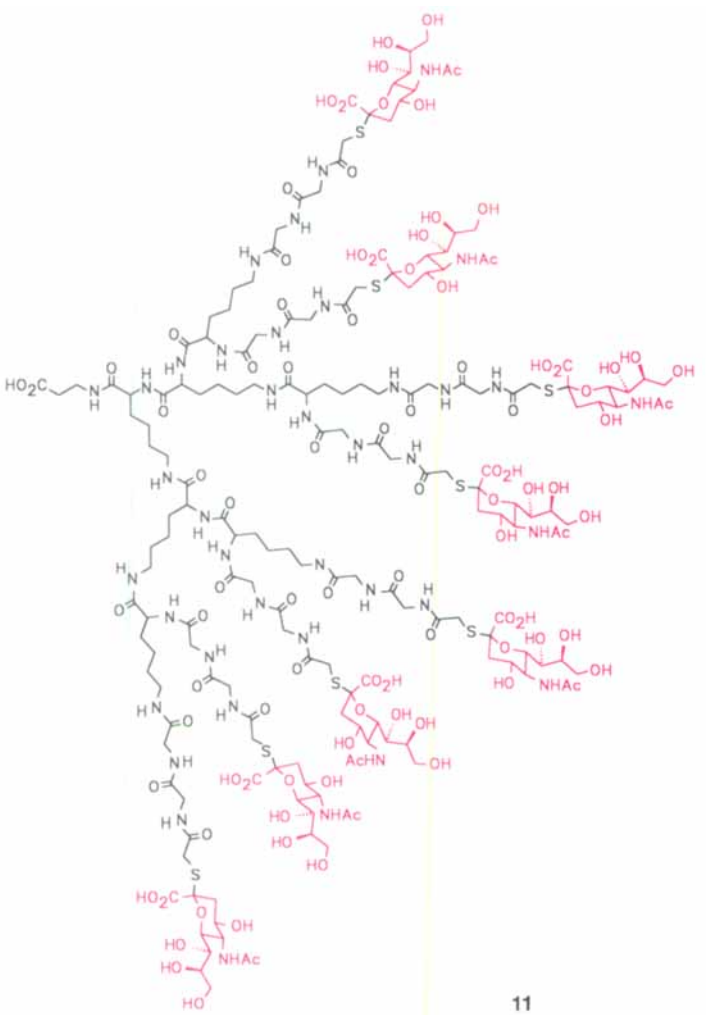
Biochemically Active Dendrimers

The connection of natural products or drugs to a dendritic skeleton is also very promising. The first successful results were published by Roy et al.[34] who linked eight sialinic acid units to a dendrimer (**11**). Preliminary tests with influenza A virus indicate that **11** is a strong inhibitor of erythrocyte hemagglutination. Similar systems among the star polymers were synthesized with peptide residues.[35]



Scheme 2. Examples of functional cascade molecules [27–32]. In **6** and **7** the functional units are located at the inside of the dendrimer; in **8** the functional units (TTF) are along at the periphery of the dendrimer.

Even nucleic acids can be constructed in a dendritic way, as Hudson and Damha showed.[36] In an automated procedure the nucleic acid chains were first prepared and then connected in a divergent manner to give a cascade molecule containing 87 nucleic acid residues and having an approximate molecular weight of 25000. It was necessary to use longer branches for the inner core of the dendrimer than for the periphery. Recently Rao and Tam proved that even peptides can be connected in a dendritic manner.[37] An octameric peptide dendrimer, which could be useful as a synthetic protein, was detected by laser desorption mass spectrometry.



First investigations with cell cultures showed that dendrimers functionalized with amino groups support the transfection of mammalian cells by plasmids.[14d] The controlled synthesis, low toxicity, and pH buffering effect of dendrimers are the main criteria making dendrimers suitable for gene-transfer experiments.

Chiral Dendrimers

Seebach et al.[38] met the challenge of synthesizing chiral dendrimers to investigate the influence of chiral building blocks on the chirality of the whole molecule and to determine whether enantioselective complexation is possible. They achieved dendrimers with a chiral nucleus as well as dendrimers with additional chiral branches. The optical activity of dendrimers with only a chiral nucleus decreases with increasing size of the dendrimer whereas the optical activity of dendrimers that are "fully chiral" correspond to the optical activity of the nucleus. These dendrimers also form quite stable clathrates.

10a $Fe=(CpFe^{II})^+ PF_6^-$ 10b $Fe=CpFe^{I}$

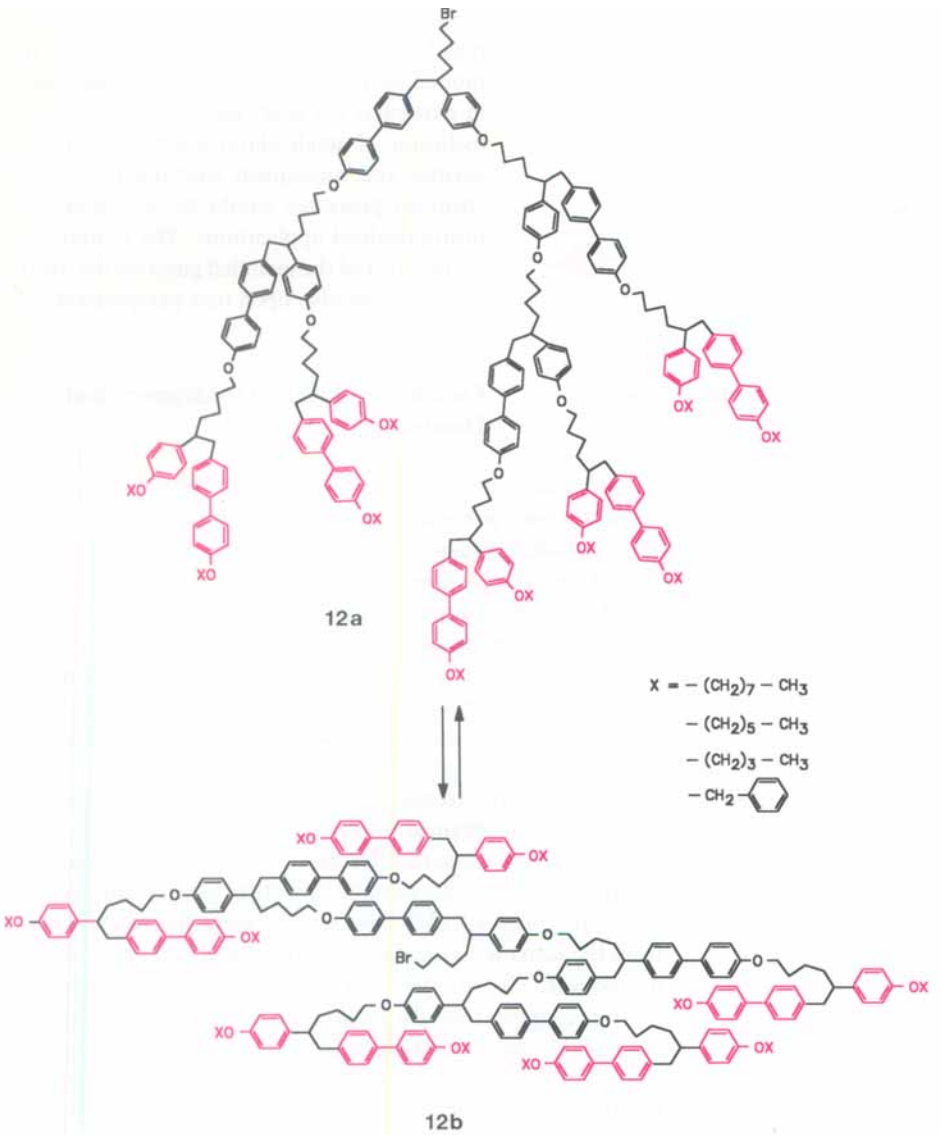
11

A few recent publications have focused on the synthesis of chiral dendrimers by linking chiral units to dendrimer components.[39,40] J. A. Kremers and E. W. Meijer reported on the construction of chiral dendrimers with nonchiral building blocks. They connected four dendrimer branches differing only in the number of generations (generations 0–3) to a pentaerythritol core.[41a] Recent results of Meijer et al. show that dendrimers with chiral terminating units have low or vanishing optical activity with increasing generation number.[41b]

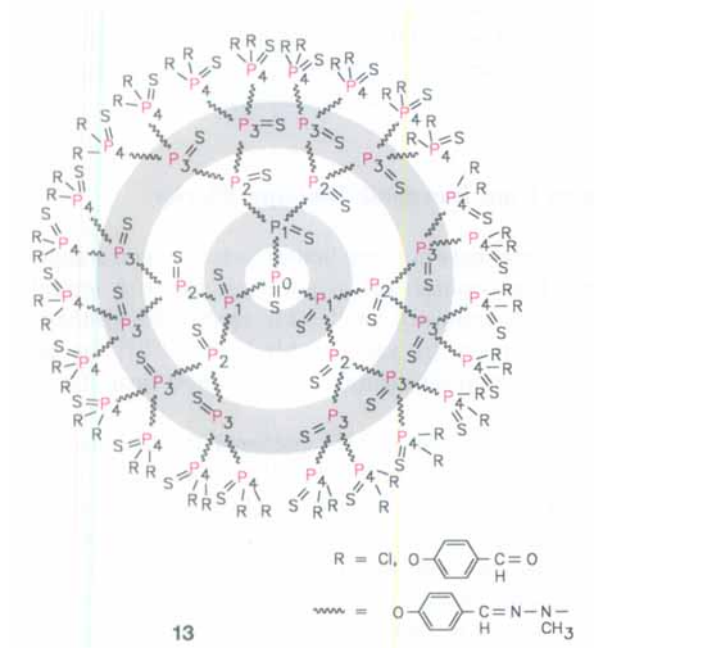
The porous structure of dendrimer with cavities[42] is important for properties like monodispersity and defined surface geometry, in particular for host–guest interactions. The inclusion of small chiral guests within these cavities and subsequent controlled release by chemical processes would be very useful for future medical applications. The examination of the effect of the included guest on the overall chirality may also open new perspectives.

Liquid Crystalline Dendrimers and Dendrimer Layers

The synthesis of liquid crystals is an aspect of dendrimer chemistry with potential industrial applications. Because of the round, flattened shape of many dendrimers, for example, they should be able to form discotic phases.[43] Dendrimers with liquid crystalline properties were reported by different research groups.[44] Kim proposed the synthesis of liquid crystalline polyamides, which he had obtained previously by polymerization, by a more directed, repetitive route. He wanted to optimize the clarification points, which are considerably greater than 100 °C for the polymers.[45]



The first thermotropic liquid crystalline dendrimer based on ethers (**12**) was obtained by Percec and Kawasumu.[46,47a] Because of the conformative flexibility of the molecule, **12a** exists in equilibrium with the nematic form **12b**, which exhibits liquid crystalline properties.[45b] The temperature for the transition from the nematic to the isotropic state for X = *n*-octyl, *n*-hexyl lies between 20 and 50 °C. The low transition temperatures for the change from the solid state to the liquid crystalline state make these dendrimers attractive for applications. The control of the transition temperatures seems to be realizable in the future, especially through the stepwise synthesis of dendrimers.



Recently S. Watanabe and S. L. Regen reported the use of dendrimers as building blocks for multilayers.[58] A silicon wafer was coated with $[PtCl_4]^{2-}$ and then treated with the polyamidoamine dendrimer PAMAM (generation 6). Repetition of these coating steps leads to multilayers.

Dendrimers from Inorganic Building Blocks

Recent advances have not been limited to research on organic dendrimers. The synthesis of cascade molecules is a topical area in inorganic chemistry too.[48] The remarkable synthesis of silicon dendrimers by van der Made et al.,[9a,b] for instance, displays impressive simplicity and almost quantitative yield.

Not long ago Majoral et al.[49] prepared the first neutral phosphorus-containing dendrimer **13**.[49] The fourth-generation dendrimer **13** was obtained by reacting $SPCl_3$ and the sodium salt of *para*-hydroxybenzaldehyde and $H_2N-N(Me)P(S)CCl_2$. Analogous reactions with $OPCl_3$ instead of $SPCl_3$ are also possible. The only by-products are NaCl and water, and the dendrimer is formed in almost quantitative yield. Brunner and

Bublak synthesized optically active "inorganic" dendrimers by reaction of optically active metalated pyridamides with 1,2-bis(dichlorophosphino)ethane.[51]

Methods for Analyzing Dendrimers

The analysis of dendrimers has been optimized decisively in the last years. EPR analysis[52] and light scattering experiments[53] have been developed, and new references have emerged for size exclusion chromatography. Until recently common polymers were used as standards for mass detection, but now the dendrimers themselves can serve as standards.[54] Molecules prepared through a repetitive synthesis[55] have well-defined molecular weights which distinguish them from polymers of comparable weight. Another property of many dendrimers is their spherical shape[56] which contrasts that of the more ellipsoidal polymers.

Cavities in Dendrimers

In addition to forming clathrates (see above), dendrimers have been found to encapsulate guest molecules inside their cavities ("dendritic box", "container dendrimers").[57] Suitable methods for inclusion of even large molecules (dyes, spin markers, fluorescence markers) have been developed. After a guest is bound in a defined generation of the dendrimer, the next generation is covalently linked, and the now-closed core binds the guests in the dendrimer cavities either irreversibly or reversibly depending on the size of the guest. Thus dendrimers are clearly supramolecular hosts. If the generation that closes the cavities containing guests is connected to the dendrimer through supramolecular interactions (e.g. hydrogen bonding), this linkage could be broken more easily later. Thus even without guests, dendrimers can be supramolecules. Dendrimers that release guests on changes in pH have been synthesized and hold promise for the targeted application of pharmaceuticals (drug release, drug targeting).

Summary

The variety of the examples listed above documents the status that dendrimer chemistry has attained during the past few years. In this compilation of recent results the trend towards function-

al and application-oriented molecules including biochemically active, photoswitchable, and polymerlike dendrimers is particularly apparent. Dendrimers could have advantages over polymers with regard to viscosity properties and application in high-resolution lithography. Increasing industrial research on dendrimers and the commercial availability of PAMAM[4, 6] and polyamine dendrimers[8] should stimulate further investigations in this field.

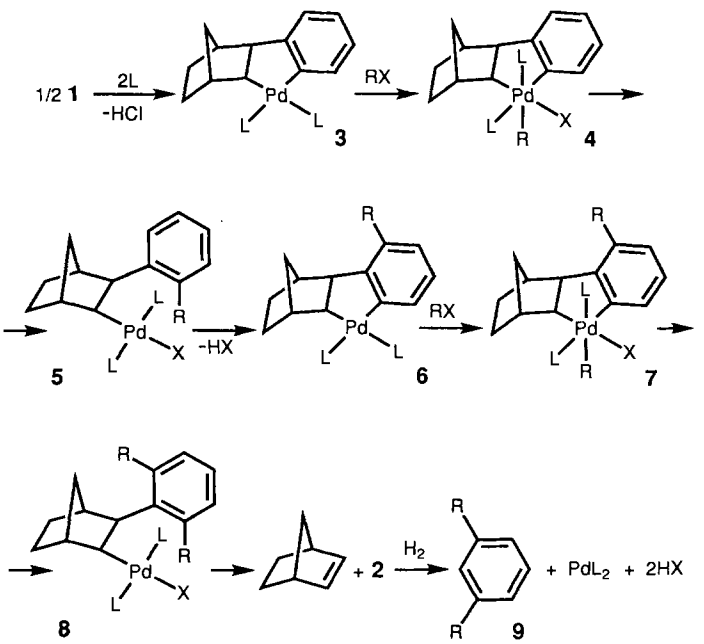
Palladacycles as Intermediates for Selective Dialkylation of Arenes and Subsequent Fragmentation**

Marta Catellani* and Maria Chiara Fagnola

The chemistry of palladium(II) and (IV) metallacycles has attracted much interest in the past years.[1] In particular the metallacycles containing alkyl and arene units recently isolated by us[2] lend themselves to rather complex reactions.[3] We now wish to report an unprecedented reaction sequence of oxidative addition, aromatic substitution, and reductive elimination steps, which ends with spontaneous fragmentation and elimination of the aliphatic part of the metallacycle (Scheme 1).

Scheme 1. X = Br, I; R = alkyl, benzyl; L = DMF, methyl isonicotinate.



The arylnorbornylhalopalladium complex **1** dissolved in *N*,*N*-dimethylformamide (DMF) reacts with an alkylating agent via metallacycle **3** to form a Pd^{IV} complex (**4**), which spontaneously undergoes reductive elimination to form complex **5**. Complexes of the type **3**–**5** had been previously trapped with phenanthroline as ligand (2L) and fully characterized.[4] Once complex **5** is formed, conditions become favorable for a new ring closure to form complex **6**, which again undergoes oxidative addition to give a Pd^{IV} species (**7**) analogous to **4**, followed by another reductive elimination reaction leading to complex **8**. At this point fragmentation occurs spontaneously by norbornene elimination with formation of the *meta*-dialkylated arylpalladium complex (**2**), which gives arene **9** by treatment with hydrogen or $NaBH_4$.

The position of ligands in the octahedral intermediates **4** and **7** has been inferred from the structure of the complexes containing the bidentate phenanthroline ligands 2L. We cannot exclude, however, a different arrangement still preserving the essential mutually *cis* positions of the R and aryl groups. The four-coordinate square-planar intermediates **5** and **8** are *cis* in the phenanthroline derivative, but in the present case we assume a *trans* arrangement in view of the *trans* structure of the final complex **2**.

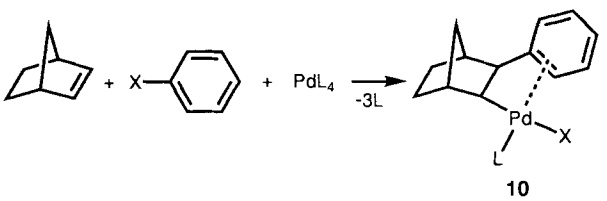
[**] This work was supported by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST, Rome) and the Consiglio Nazionale delle Ricerche (CNR, Rome). Mass spectrometric and NMR spectroscopic facilities were provided by Centro Interfacoltà dell'Università di Parma.

In spite of the many steps involved, the reaction occurs simply by treatment of complex **1** (*cis*, *exo*) in DMF with an alkyl or benzyl halide in 1:2 molar ratio under nitrogen at room temperature for 7 h. Beside the *meta*-dialkylated benzene derivative (**9**), small amounts of 2-phenylnorbornanes mono- and dialkylated at the arene ring were obtained by passing hydrogen through the solution. These compounds derive from hydrogenolysis of complexes **5**–**8**, which are present in the final solution after complete conversion of **1**. Although the selectivity of **9** still is high (84–87%), the presence of these species supports the pathway shown in Scheme 2. The formation of nor-



Scheme 2. A possible mechanism for selective dialkylation. X = Br, I; R = alkyl, benzyl; L = DMF, methyl isonicotinate.

bornene was established by mass spectrometry. Similar results were obtained on starting with the palladacycle complex **3** (L = methyl isonicotinate). As further evidence of the proposed mechanism, complex **2** was isolated by addition of the ligand (methyl isonicotinate) at the end of the reaction and removal of the solvent under vacuum and characterized by ^1H NMR spectroscopy.

Fragmentation of **8** to **2** does not occur if the aromatic moiety of phenylnorbornane is not disubstituted; the unexpected cleavage of a C–C bond between aliphatic and aromatic carbon atoms therefore appears to be driven by steric factors. The use of phenanthroline as ligand L does not lead to C–C bond cleavage; instead the reaction proceeds only to the stage of monoalkylation.[4] The fragmentation reported here corresponds to a deinsertion reaction that has been observed in the case of decarbonylation (reversible insertion),[5] but is rather unusual with olefinic compounds. Two related examples deserve

to be mentioned: one by Porri et al., who converted methallylnorbornylnickel acetate into methallylnickel bromide and norbornene by exchange of the acetate with a bromide anion,[6] the other by Maitlis et al., who achieved the elimination of styrene by adding HCl to a 2-pentamethylcyclopentadienyl-2-phenylethylpalladium chloride.[7] In our case, however, elimination is not caused by anion exchange or HCl addition but occurs spontaneously to form an *o,o*-disubstituted aryl group which stabilizes complex **2**[8] with respect to **8**. The elimination of cyclopentadiene from a ruthenacycle containing norbornene[9] is entirely at variance with the behavior reported here, since a retro-Diels–Alder and not a deinsertion reaction is involved in liberation of cyclopentadiene.

Since aryl bromides or iodides are known to react with norbornene in the presence of Pd^0 to give arylnorbornylpalladium complexes of type **10**[10] (Scheme 3), the function of norbornene in the overall process that involves norbornene insertion and deinsertion can be viewed that of a protecting group. It assists in the oxidative addition of alkyl halides and disubstitution of arenes through intermediate palladacycles and is finally expelled.

10

Scheme 3. X = Br, I; L = PPh_3.

Although the reaction is general for alkyl and benzyl halides, *p*-fluorobenzyl bromide proved to be appropriate for our study because it led in good yield to the formation of fluorinated products, which is useful for NMR determinations. Incidentally product **9** (R = *p*-fluorobenzyl) turns out to be an intermediate for the synthesis of polyether–polyketones.[11] Other alkyl halides also react with high yield. It is remarkable that no β-elimination of hydrogen occurs owing to the unfavorable stereochemistry. Thus this general drawback of many metal-catalyzed reactions[12] is absent in the present process.

Experimental Procedure

To complex **1** [10b] (0.100 g, 0.32 mmol) dissolved in anhydrous DMF (8 mL) are added K_2CO_3 (0.090 g, 0.65 mmol) and *p*-fluorobenzyl bromide (0.122 g, 0.64 mmol). The mixture is stirred at room temperature for 7 h under nitrogen. Hydrogen is then bubbled through the solution to precipitate palladium black. After conventional workup and purification by column chromatography with hexane/ethyl acetate as eluent, compound **9** (R = *p*-fluorobenzyl) [13] is obtained in 87% yield together with a small amount of mono- and dialkylated phenylnorbornanes. If instead of passing hydrogen through the reaction mixture, methyl isonicotinate (0.088 g, 0.64 mmol) is added, and DMF is removed under vacuum, complex **2** (L = methyl isonicotinate) [13] is obtained. After filtration through Celite, recrystallization from a mixture of chloroform and hexane gives light orange crystals in 63% yield. Analogously, carrying out the reaction with ethyl iodide as halide (0.100 g, 0.64 mmol) leads to compound **9** (R = ethyl) in 84% yield.

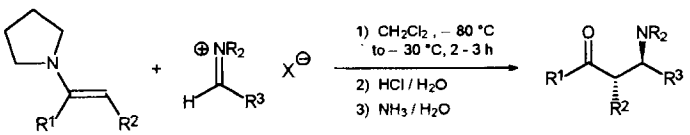
Diastereomerically Pure Mannich Bases from the Addition of Enamines to Ternary Iminium Salts**

Nikolaus Risch* and Michael Arend



β-Amino carbonyl compounds are an attractive class of substances and are useful polyfunctional synthetic units in a variety of applications, for example, the synthesis of pharmaceutical, plant-protection, and natural products.[2] Efficient access to stereochemically pure Mannich bases, apart from β-amino acids and their derivatives, has hardly been developed until now.[3]

Our method of reacting (*E*)-enamines **1** (derived from aldehydes or ketones) with preformed ternary iminium salts **2** has fundamental advantages over the classic Mannich reaction[2] (Scheme 1). The reaction can be carried out in aprotic solvents, and the high iminium ion concentration guarantees high reaction rates even at low temperatures.

Because of the mild reaction conditions, no unwanted byproducts were formed. Good to excellent yields of almost stereochemically pure β-amino aldehydes or β-amino ketones *anti*-**3** were obtained (Table 1), which were generally crystalline. Ternary iminium salts **2** have long been known and are readily accessible,[4a] but have, surprisingly, in contrast to the methylene iminium salts such as Eschenmoser's salt, hardly

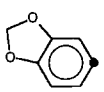
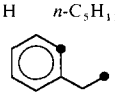
[**] Stereoselective Synthesis of Mannich Bases, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 1: [1].





1 2 *anti*-3

Scheme 1. Diastereoselective addition of (*E*)-enamines **1** to ternary iminium salts **2**.

found any applications up until now.[4] Their use allows the scope of the classic Mannich reaction to be extended from amino*methyl*ation to amino*alkyl*ation. In addition, it should be emphasized that our method uses inexpensive, readily available chemicals and can be applied to sensitive substrates (mild reaction conditions).

Surprisingly, our investigations to date have shown (Table 1) that the stereoselectivity of addition is not influenced by the type of (*E*)-enamine or ternary iminium salt used. Variation in R^3, NR_2, and X^- always led to comparable results: with one exception (Table 1, entry 6), the ^1H NMR spectra of the crude products only show the signals for a single diastereoisomer. Similarly, changing the reaction medium from CH_2Cl_2 to the more strongly complexing THF had, at least at low temperatures, no obvious influence on the stereochemistry of the reaction. The fact that the reaction was less stereoselective under reflux in THF than in CH_2Cl_2 is probably explained by the higher temperature (due to the higher boiling point of THF) (Table 1, entry 1c). One product (Table 1, entry 2) was unambiguously assigned the *anti* configuration by comparing its NMR data to those reported in the literature for an authentic sample (X-ray structure analysis available).[3b, c] On the basis of the NMR spectra and considering that the probability of a total reversal of the stereochemical progress of the reaction as a result of the changes made is small, we assume that the other Mannich bases also have the *anti* configuration.

[a] Tetrachloroaluminates are easily accessible (by reaction of the iminium chloride with $AlCl_3$ in CH_2Cl_2 at 0 °C; the tetrachloroaluminates are finally precipitated with Et_2O), only slightly hygroscopic, and therefore especially easy to handle (similar to methylene iminium tetrachloroaluminates) [5]. Because of the formation of an $Al(OH)_3$ precipitate during workup, however, they are less suitable for the preparation of Mannich bases in multigram quantities. Here, better results are obtained by using the freshly prepared iminium chlorides. [b] The diastereoisomeric ratios were always determined for the crude products by means of ^1H or ^{13}C NMR spectroscopy (integration of the signals for CHN protons). [c] Similar results (92%, >99% *ds*) were obtained in THF. Under reflux conditions (10 min), the Mannich base was obtained in 78% yield with 94% *ds* (in THF: 87%, 82% *ds*). Analogous results were obtained with the corresponding chloride and perchlorate. The reaction failed in Et_2O, probably because the iminium salt is practically insoluble in this solvent.

The scope of the method, the consistently high yields, and the excellent *de* values, which are only achieved in exceptional cases—if at all—by other methods, demand that the mechanism of the reaction be examined. The results can basically be explained by a similar model to that described by Seebach et al., namely, a transition state stabilized by electrostatic forces analogous to that formed in the aldol addition.[3e] However, a mechanism of the polar [2s + 2s]-cycloaddition type, such as has already been postulated for numerous reactions between very electron-rich and very electron-poor alkenes,[6] cannot, a priori, be excluded. Evidence in favor of this mechanism includes the fact that the reaction between ynamines and iminium salts is thought to proceed via a four-membered cyclic intermediate.[7]

Elucidation of the mechanism will also give further impetus to the extension of our method to an enantioselective variant,[1] the synthesis of primary and secondary Mannich bases, and the use of (*Z*)-enamines and quaternary iminium salts. It would also be interesting to investigate whether a third stereogenic center can be formed selectively by diastereoselective reactions (e.g., reduction or addition of organometallic compounds) at the prochiral carbonyl group.

Experimental Procedure

anti-3: The reaction was carried out under argon and anhydrous conditions. A solution of the (*E*)-enamine **1** (2.5 mmol) in anhydrous CH_2Cl_2 (2.5 mL) was cooled to −80 °C. The iminium salt **2** (2.5 mmol) was then added in one portion with stirring. The mixture was stirred and the temperature allowed to rise to −30 °C over 2–3 h. In order to ensure a good yield in all cases, it is advantageous to store the reaction mixture at this temperature in a refrigerator for ca. 15 h before workup. Aqueous hydrochloric acid (5 mL, conc. HCl/water 1/1) was then added. The mixture was stirred for ca. 10 min and then extracted several times with Et_2O. Dilute ammonia (25 mL, 25% NH_3/H_2O 1/4) was added with vigorous stirring, and the Mannich base *anti*-**3** was extracted with CH_2Cl_2 or Et_2O (3 × 50 mL, 1 min each time) [8]. The combined organic phases were dried over Na_2SO_4. The solvent was finally removed in a rotary evaporator without heating.

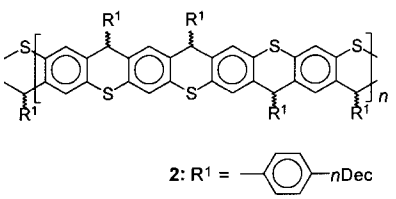
[8] Some Mannich bases of the type *anti*-**3** tend to decompose, to varying extents, in aqueous alkaline solutions. However, this can be almost entirely avoided by rapid workup.

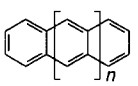
Ladder Polymers with a Heteroacene Skeleton**

Torsten Freund, Ullrich Scherf, and Klaus Müllen*



Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

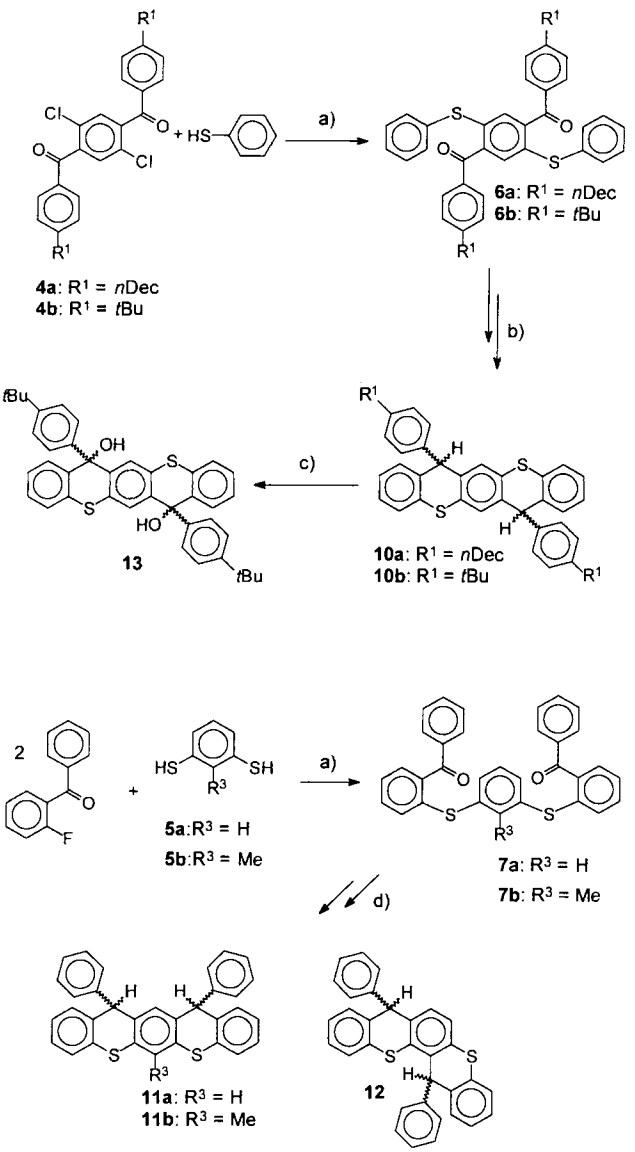
The synthesis of macromolecular ladder structures of type **1** is a particular challenge for polymer chemistry. With ladder polymers such as these it is possible to compare the form and persistence length of double-stranded polymers with that of their linear analogues.[1] Moreover, in the presence of extended π-conjugation two-dimensional structures have electronic advantages, for example, a lower band gap.[2]



1

Here we describe the synthesis of the high molecular mass heteroacene **2** (*n*Dec = *n*-decyl), which is completely soluble in organic solvents and which, according to spectroscopic investigations, exhibits a defect-free ladder structure. Studies on oligomeric model compounds are particularly important for the investigation into the formation of the polymer and also the subsequent generation of extended π-conjugation in the acene.

2: R^1 = *n*Dec

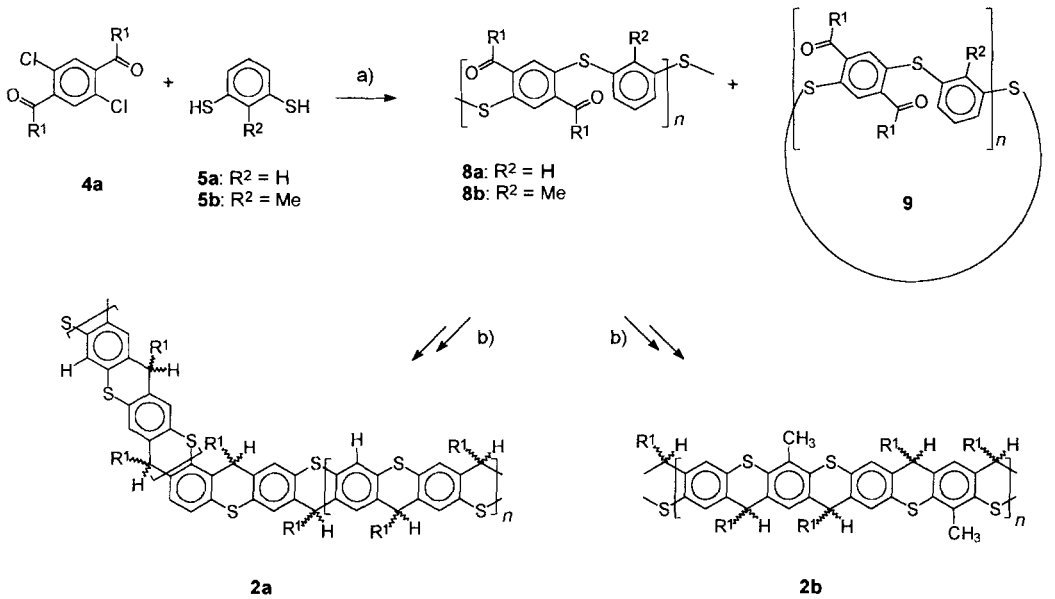


3

In principle, there are two methods available for the synthesis of double-stranded polymers: a "concerted" route with repetitive cycloadditions and a multistep route, in which the linear precursor can undergo polymer-analogous cyclization reactions. In the case of acenes **3** the repetitive Diels–Alder cycloaddition is the preferred method,[3] whereas for the sulfur-containing "polyhydroacene" **2** a multistep synthetic route is required. The starting compound was the terephthalophenone **4a** (see Scheme 2),[4] which can be converted into single-stranded poly(phenylenesulfide)s with benzoyl substituents by nucleophilic aromatic substitution with 1,3-benzenedithiol ("dithioresorcin") (**5a**) or 2-methyl-1,3-benzenedithiol (**5b**). Subsequent cyclization in a sequence of Friedel–Crafts reactions should then yield ladder structures. The phenyl substituents in **4** function as stabilizing substituents on the perimeter of the acene, while the *n*-alkyl groups are essential to achieve sufficient solubility of the rigid polymer backbone.

In model reactions (Scheme 1) **4a** and **4b** can be treated with thiophenolate to give **6a** and **6b** (each in 95% yield), respectively. The diketones **7a** and **7b** are obtained analogously from 2-fluorobenzophenone and the dithioresorcins **5a** and **5b**.[5, 6]

Phenylenesulfide formation of **6**, which proceeds without any detectable side reactions, suggests polycondensation of **4a** with **5a** (Scheme 2). Thus, the dithiolate formed by deprotonation with potassium carbonate in dimethylacetamide replaces both chlorine atoms in **4a** at 120 °C. In this way poly(phenylenesulfide) **8a** is accessible, for example, with molecular weights $M_n = 150000$ and $M_w = 670000$, determined by membrane osmometry and light-scattering, respectively.



Scheme 1. a) K_2CO_3/dimethylacetamide, 120 °C; b) 1. $LiAlH_4$/THF; 2. $BF_3 \cdot OEt_2/CH_2Cl_2$; c) DDQ/THF 0.5% H_2O; d) **7a**: 1. $LiAlH_4$/THF; 2. $BF_3 \cdot OEt_2/CH_2Cl_2$, **7b**: 1. $LiAlH_4$/THF; 2. $SnCl_4/CH_2Cl_2$.

If polymer **8** is precipitated by pouring the reaction mixture into 10% acetic acid, the gel permeation chromatograms show a bimodal distribution. The maximum in the low molecular mass range is attributed to the formation of cyclic oligomers **9**, which could be shown to contain up to eight repeating units by FD-mass spectrometry. The macrocyclic oligomers **9** can, however, be easily removed from the crude material (dissolved in dichloromethane) by fractional precipitation with acetone. In this way polymer samples of **8a** with narrower molecular mass distribution and number average molecular weights M_n = 50000–110000 are obtained; these samples can be used for investigations into the molecular weight dependence of the subsequent polymer-analogous Friedel–Crafts reactions.

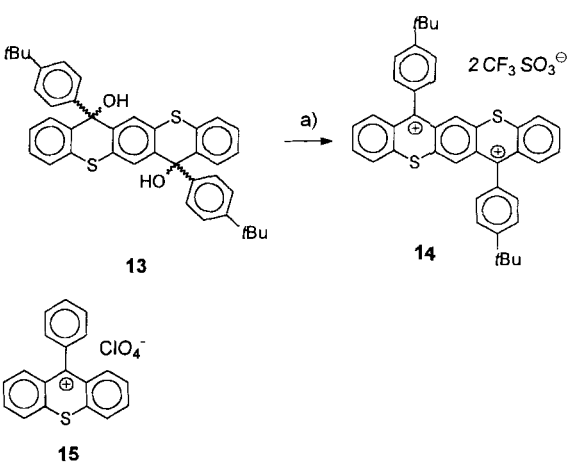
Scheme 2. a) K_2CO_3/dimethylacetamide, 120 °C; b) 1. $LiAlH_4$/THF; 2. $SnCl_4/CHCl_3$. $R^1 = p\text{-}C_6H_4\text{-}n\text{-}C_{10}H_{21}$.

Dithiol **5b** reacts with diketone **4a** to give the poly(phenylene-sulfide) **8b** (see Scheme 2). In contrast to **8a**, neither a bimodal distribution in the GPC elution profile nor the presence of cyclic oligomers in the FD-mass spectrum could be detected. The isolated material also shows a lower molecular weight and a lower polydispersity ($M_n = 65000$ and $M_w = 140000$) than that of **8a**.



The Friedel–Crafts cyclization route towards ladder structures was initially investigated by using the model compounds **6a**, **6b**, **7a**, and **7b** (see Scheme 1). It was shown that the cyclization of the diketones is significantly inferior to the analogous reaction of the diols. This result confirms observations in the synthesis of ladder-type polyphenylenes.[7] The reaction of the diols obtained from **6a** and **6b** ($LiAlH_4$ in THF) with $BF_3 \cdot OEt_2$ in dichloromethane gave a quantitative yield of **10a** and **10b** as a mixture of the respective diastereomers.

In principle, unlike the cyclization of **6**, regioisomers can be formed by the cyclization of **7**. Although the isomer mixture precipitated after reduction of **7a** and subsequent Friedel–Crafts alkylation with $BF_3 \cdot OEt_2$ in dichloromethane no longer contains any uncyclized diarylmethanol units (^1H and ^{13}C NMR evidence), the bent structures **12** (as a mixture of diastereomers), formed by Friedel–Crafts alkylation in the 2-position of the benzenedithiol group, were detected in addition to the linear annelated systems **11a**. After column chromatography (alumina, CH_2Cl_2/petroleum ether 4:1) and crystallization (CH_2Cl_2/hexane) a pure *cis* isomer of **12** was obtained and its structure determined by crystallography. Thus, it is understandable that 2-methyl-1,3-benzenedithiol (**5b**) is always used as a bifunctional nucleophile, rather than **5a**, to avoid formation of bent substructures during ring closure on route to acenes. Indeed, reaction of the diol obtained from **7b** with $SnCl_4$ in dichloromethane results in a *cis-trans* mixture of diastereomers of the *linear annelated* structure **11b** (see Scheme 1).[8]

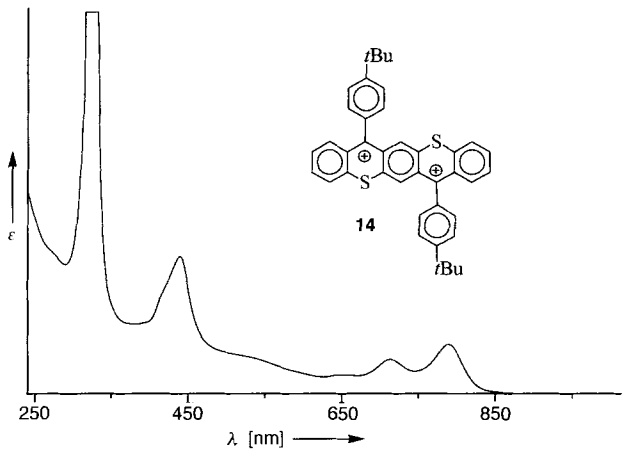
The reduction of the polymers **8a** and **8b** to the corresponding polyalcohols with $LiAlH_4$ in THF was quantitative in both cases. Cyclization (see Scheme 2) was also carried out with three equivalents of $SnCl_4$ per reactive group using chloroform as the preferred solvent. This reaction can be conducted in gram-quantities; a polymer concentration of about 4 g polyalcohol per liter of chloroform was chosen, which guarantees that the reaction can take place in an homogeneous medium. Degradation of the polymer does not take place, either during the reduction or during the subsequent ring closure. According to NMR spectroscopic analysis, cyclization products of similar structure are obtained independent of the molecular weight of the sample. The NMR signals of the methine bridges are shown to be of particular diagnostic value, as already seen for the model reactions leading to **10**, **11**, and **12**. No indication of incomplete polymer-analogous cyclization is observed.[9, 10]

The multistep sequences described thus lead to a high molecular weight, completely cyclized, and soluble ladder polymer **2b**. This product should now permit the desired comparison of the form behavior and the persistence length of one- and two-dimensional structures, for example, on the basis of light-scattering and viscosity measurements.[11]

Furthermore, polymer **2b** and model compound **10** are suitable precursors for the preparation of heteropolyacenes with extended conjugated π-electron systems by dehydrogenation or ionization methods. The reaction of **10b** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (*DDQ*) in THF in the presence of 0.5 vol.% water led to diol **13** in 96% yield (see Scheme 1). Treatment of **13** with trifluoromethanesulfonic acid in dichlormethane or acetonitrile (Scheme 3) gave a quantitative

Scheme 3. a) Trifluoromethanesulfonic acid/CH_2Cl_2 or CH_3CN.

yield, within seconds, of the stable dication **14**, which was characterized by NMR and electronic absorption spectroscopy (Fig. 1; see also Experimental Procedure). A close relationship of dication **14** with the isoelectronic pentacene could be demonstrated by the electronic absorption spectrum.[11] The longest wavelength absorption of **14** shows, in contrast to that of 9-phenylthioxanthenylium perchlorate (**15**) ($\lambda_{max} = 515$ nm),[12] a



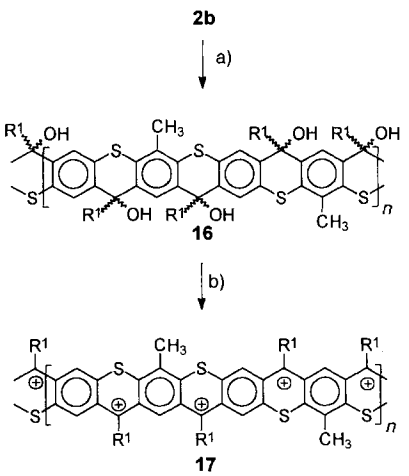


Fig. 1. UV/VIS spectrum of the dication **14**.

marked bathochromic shift, which can be assigned to the smaller band gap of the higher homologue **14**.

Polymer **2b** can be converted, analogous to the formation of **13**, into the polyalcohol **16** by treatment with DDQ in THF/0.5 vol.% H_2O (Scheme 4). The lack of a ^{1}H NMR signal at

Scheme 4. a) DDQ/THF/0.5% H_2O; b) 1. Trifluoromethanesulfonic acid/CH_3CN; 2. Washing with anhydrous CH_3CN. $R^1 = p$-C_6H_4-n-$C_{10}H_{21}$.

$\delta = 5.27$, which stems from the methine bridge in **2b**, substantiates the complete conversion. Characterization of the polycation **17** (analogous to **14**) is prevented by its low solubility (e.g., in dichloromethane, acetonitrile, nitromethane, or trifluoroacetic anhydride). Thus, **16** (in THF) was poured into a thin film from THF solution and this was ionized by using trifluoromethanesulfonic acid in acetonitrile. After washing the product with dry acetonitrile an electronic absorption spectrum was obtained that, based on the longest wavelength absorption at 978 nm, reveals the presence of extended π-conjugated cationic subunits. Examination of the extent of the conversion in the immobilized phase and a more detailed characterization of the ionic polyacene structure **17** will be reported elsewhere.

Experimental Procedure

Dication **14**: 10 mg of a mixture of diastereomers of diol **13** was dissolved in CD_2Cl_2 (1 mL) and treated with one drop of trifluoromethanesulfonic acid. ^{1}H NMR (500 MHz, CD_2Cl_2, 263 K): $\delta = 9.72$ (s, 2H), 8.75 (d, ^3J(H,H) = 8.4 Hz, 2H), 8.75 (m, 4H), 8.57 (m, 4H), 8.18 (t, ^3J(H,H) = 7.8 Hz, 2H), 7.94 (d, ^3J(H,H) = 7.9 Hz, 4H), 7.67 (d, ^3J(H,H) = 7.9 Hz, 4H), 1.54 (s, 18 H); ^{13}C NMR (125 MHz, CD_2Cl_2, 263 K): $\delta = 175.2$, 157.8, 154.1, 142.8, 139.4, 138.8, 137.8, 132.9, 131.7, 131.5, 131.2, 130.6, 128.3, 127.0, 35.6, 30.9. UV/VIS spectrum of **14**: c(**13**) = 2.9×10^{-5} M in 0.05 M trifluoromethanesulfonic acid in acetonitrile: λ_{max} (ε [L mol^{-1} cm^{-1}]) = 323 (64200), 439 (12100), 648 (1280), 706 (2920), 778 (4530).

[4] Diketones **4a** and **4b** were prepared, according to ref. [7], from 2,5-dichloro-*p*-xylene, which was oxidized with $KMnO_4$ in pyridine to give 2,5-dichloroterephthalic acid (72% yield). The bis-acid chloride obtained with $SOCl_2$ in benzene (85%) then gave **4a** (69% yield) or **4b** (75% yield), respectively, in a Friedel–Crafts acylation with 1-phenyldecane or with *tert*-butylbenzene.

[5] Compound **6b** was synthesized from 2-methylresorcin, according to ref. [6].

[6] H.-J. Kurth, U. Kraatz, F. Korte, *Chem. Ber.* **1973**, *106*, 2419.

[8] The trityl protons of **11b** show signals at $\delta = 5.55$ and $\delta = 5.50$. The signal for the corresponding carbon atom appears at $\delta = 53.5$ and is not split, in spite of the diastereomer formation observed in the ^{1}H NMR spectrum.

[9] In the ^{1}H NMR spectrum of **2a** the protons of the methine bridges show the signal expected for a triphenylmethane structure at $\delta = 5.25$, as well as an extra signal at $\delta = 5.95$. This result, however, is not attributed to the presence of uncyclized diphenylmethanol groups, since the signals of the alcohol structures at $\delta = 72.8$ in the ^{13}C NMR spectrum have completely disappeared and new signals have appeared at $\delta = 52.0$ and $\delta = 49.0$. Taking into account that the proton of the methine bridge formed by cyclization at the 2-position of the dithioresorcin subunit in the model compound **12** shows a resonance signal at $\delta = 6.0$, it becomes evident that cyclization of the polyalcohol leads to a product **2a**, in which bent substructures also exist. On the other hand, the cyclization of the polyalcohol obtained from **8b** gave, as expected, an exclusively linear annelated product **2b**, the NMR spectrum of which shows only a single signal for the trityl protons at $\delta = 5.27$ and the corresponding ^{13}C NMR signal at $\delta = 52.9$. Even at a signal-to-noise ratio $S/N = 150$ for the ^{1}H NMR signal of the methine bridge, no signals were detected in the range $5.8 > \delta > 6.3$, as would be expected for an incompletely cyclized diphenylmethanol structure. Nevertheless, in the electronic absorption spectrum a band with low intensity was found at $\lambda_{max} = 602$ nm, which can be attributed to partial dehydrogenation during cyclization and thus formation of quinodimethane subunits. This assignment is based on a comparison with the corresponding model compounds and related polymers [10]. The fraction of such structures, which are not detectable in the NMR and IR spectra, is below 1%.

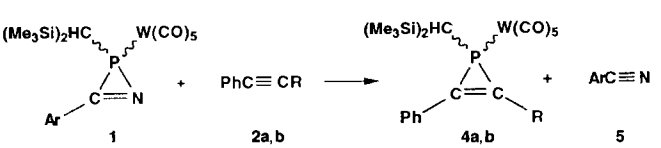
Thermally Induced Ring Cleavage of a 2*H*-1,2-Azaphosphirene Tungsten Complex**

Rainer Streubel,* Annette Kusenberg, Jörg Jeske, and Peter G. Jones

Dedicated to Professor Reinhard Schmutzler on the occasion of his 60th birthday

Because of their ability to generate 1,3-dipoles as reactive intermediates on ring-opening, unsaturated three-membered heterocycles are of great preparative interest for the generation of five-membered heterocycles.[1] Of three-membered heterocycles possessing the structural element C=N, only the 2*H*-azirenes have been extensively investigated with respect to their ring-opening reactions.[2-4] Thus 2*H*-azirenes with an sp^3-hybridized carbon in the 2-position predominantly display reactions, thermal and photochemical, in which the first step is the breaking of one ring bond (route a and b).[2] In contrast, the 2-methylene-2*H*-azirenes, which have an sp^2-hybridized atom at the 2-position, undergo photochemical reactions that result in ring cleavage (route c)[3] (Scheme 1).



Scheme 1. Schematic representation of the ring-opening reactions of 2*H*-azirenes (the substituents are unspecified; for the 2-methylene-2*H*-azirenes the bonds at the 2-position are formed to the same atom).

We report here the first example of a thermally induced ring cleavage of the 2*H*-1,2-azaphosphirene tungsten complex **1**[5] in the presence of acetylene derivatives and in the presence of benzaldehyde.

The tungsten complex **1** is thermally labile in toluene in the presence of phenylacetylene (**2a**) or diphenylacetylene (**2b**), and the corresponding 1*H*-phosphirene tungsten complexes **4a** and **4b**, respectively, are formed. Since five-membered heterocycles, for example as products of the reaction between **2a,b** and a conceivable 1,3-dipole generated from **1**, were not observed, the assumption of a terminal phosphanediyl tungsten complex **3** as

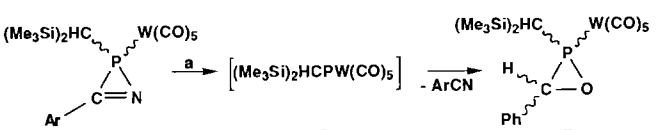
$[(Me_3Si)_2HCPW(CO)_5]$ **3**

an intermediate seems plausible (cf.[6]). The other product of this reaction, *p*-toluonitrile **5** (Scheme 2), can be identified in the solution by its characteristic C–N valence band in the IR spectrum.[7] The 1*H*-phosphirene tungsten complexes **4a,b** show

Scheme 2. **1, 5:** Ar = *p*-tolyl; und **2a, 4a:** R = H; **2b, 4b:** R = Ph.

NMR spectroscopic data characteristic of this type of compound and this substitution pattern of the ring carbon atoms (Table 1) (cf.[8]). The IR spectroscopic and mass spectrometric data[9] also support the proposed nature of **4a,b**.

Table 1. Selected spectroscopic data of **4a,b** and **7** [a].



4a: ^{1}H NMR: δ = 0.07 (s, 9 H; $SiMe_3$), 0.25 (s, 9 H; $SiMe_3$), 0.58 (d, ^2J(H,P) = 2.41 Hz, 1 H; PC*H*), 7.48 (m, 3 H; Ph), 7.68 (m, 2 H; Ph), 8.40 (d, ^2J(H,P) = 21.6 Hz; C=C*H*); ^{13}C {^{1}H} NMR: δ = 1.56 (d, ^3J(C,P) = 3.09 Hz; $SiMe_3$), 1.86 (d, ^3J(C,P) = 3.74 Hz; $SiMe_3$), 27.75 (d, ^1J(C,P) = 27.24 Hz; P*C*H($SiMe_3$)$_2$), 124.66 (d, ^1J(C,P) = 6.48 Hz; P*C*H=C), 128.07 (d, ^2J(C,P) = 6.09 Hz; *i*-C), 129.11 (s; *m*-C), 129.24 (d, ^3J(C,P) = 2.64 Hz; *o*-C), 130.82 (s; *p*-C), 145.82 (d, ^1J(C,P) = 17.86 Hz; P*C*=CH), 197.18 (dd, ^2J(C,P) = 8.49 Hz; ^{1}J(C,W) = 108.03 Hz; *cis*-CO), 198.93 (d, ^2J(C,P) = 31.11 Hz; *trans*-CO); ^{31}P {^{1}H} NMR: δ = −136.75 (d, ^1J(P,W) = 272.08 Hz).

4b: ^{1}H NMR: δ = 0.07 (s, 9 H; $SiMe_3$), 0.13 (s, 9 H; $SiMe_3$), 0.27 (d, ^2J(H,P) = 2.98 Hz, 1 H; PC*H*($SiMe_3$)$_2$), 7.33 (m, 6 H; Ph), 7.52 (m, 4 H; Ph); ^{13}C {^{1}H} NMR: δ = 1.06 (d, ^3J(C,P) = 2.87 Hz; $SiMe_3$), 1.74 (d, ^3J(C,P) = 3.18 Hz; $SiMe_3$), 27.89 (d, ^1J(C,P) = 30.28 Hz; P*C*H($SiMe_3$)$_2$), 128.82 (d, ^3J(C,P) = 3.42 Hz; *o*-C), 128.97 (s; *m*-C), 129.18 (d, ^2J(C,P) = 6.22 Hz; *i*-C), 129.99 (s; *p*-C), 136.04 (d, ^1J(C,P) = 12.48 Hz; P(Ph)*C*=), 197.38 (dd, ^2J(C,P) = 8.30 Hz; ^1J(C,W) = 91.78 Hz; *cis*-CO), 198.58 (d, ^2J(C,P) = 30.36 Hz; *trans*-CO); ^{31}P {^{1}H} NMR: δ = −134.60 (d, ^1J(P,W) = 268.64 Hz).

7: ^{1}H NMR: δ = 0.31 (s, 9 H; $SiMe_3$), 0.37 (s, 9 H; $SiMe_3$), 0.88 (d, ^2J(H,P) = 6.16 Hz, 1 H; PC*H*($SiMe_3$)$_2$), 4.34 (d, 1 H, ^2J(H,P) = 2.05 Hz; PhC*H*), 7.47 (m, 3 H; Ph), 8.10 (m, 2 H, Ph); ^{13}C {^{1}H} NMR: δ = 1.66 (d, ^3J(C,P) = 4.26 Hz; $SiMe_3$), 1.97 (d, ^3J(C,P) = 2.29 Hz; $SiMe_3$), 32.49 (d, ^1J(C,P) = 18.96 Hz; P*C*H($SiMe_3$)$_2$), 59.71 (d, ^1J(C,P) = 27.33 Hz; P*C*O), 125.64 (d, ^2J(C,P) = 3.54 Hz; *i*-C), 128.14 (d, ^3J(C,P) = 2.64 Hz; *o*-C), 128.58 (d, ^4J(C,P) = 2.31 Hz; *m*-C), 135.28 (s; *p*-C), 194.85 (dd, ^2J(C,P) = 7.24 Hz; ^1J(C,W) = 125.47 Hz; *cis*-CO), 196.97 (d, ^2J(C,P) = 35.52 Hz, *trans*-CO); ^{31}P {^{1}H} NMR: δ = 40.44 (d, ^1J(P,W) = 308.22 Hz).

[a] All spectra in $CDCl_3$, 25 °C; ^{1}H NMR: 200 MHz, ^{13}C NMR: 50.3 MHz, ^{31}P NMR: 81.0 MHz; the deuterated solvents were used as internal, 85% H_3PO_4 as an external standard.

In order to test further the above interpretation of the reaction of the 2*H*-1,2-azaphosphirene tungsten complex **1** with **2a,b**, the reactivity of **1** with respect to the dipolarophile benzaldehyde **6** was investigated. Complex **1** was treated with a large excess of benzaldehyde (molar ratio 1:20) in toluene at 45 °C. The formation of the corresponding oxaphosphirane tungsten complex **7** again points to the phosphanediyl tungsten complex **3** as the reactive species[10] (Scheme 3). Further confir-

Scheme 3. **1, 7:** Ar = *p*-tolyl. Proposed reaction sequence leading to formation of the oxaphosphirane tungsten complex **7**. a) PhCHO **6**/toluene.

mation of this interpretation is provided by the failure, under these reaction conditions, to observe the formation of [3 + 2] cycloaddition products of a phosphorus analogue to a 1,3-dipolar nitrile ylide with benzaldehyde. It is particularly interesting that the exclusive stereoselective formation of the *RS*/*SR* diastereomer of the oxaphosphirane tungsten complex **7** is observed. This is probably the first example of an effective steric control of a [2 + 1] cycloaddition of a terminal phosphanediyl complex.[11]

The ^{31}P NMR spectroscopic data of **7** (Table 1) show a significant low-field shift for the resonance of the phosphorus atom

[**] Reactions of 2*H*-1,2-Azaphosphirene Complexes, Part 2. This work was supported by the Fonds der Chemischen Industrie and by BASF AG, Ludwigshafen. Part 1: [5].

at $\delta = 40.44$, compared to the only oxaphosphirane complexes previously known ($\delta = 2.9$ and 3.8).[12] This unusual finding prompted us to investigate the nature of complex **7** more closely by a single-crystal X-ray analysis (Fig. 1).[13]

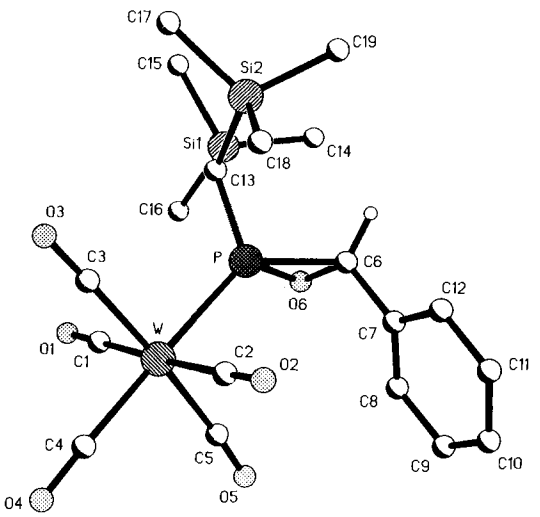

Fig. 1. Structure of compound **7** in the crystal (all H atoms except H6 have been omitted for clarity). Selected bond lengths [pm] and angles [°]: P1-O6 166.8(6), P1-C6 180.2(7), O6-C6 148.0(9), W-P1 246.2(2), P1-C13 179.4(6), C6-C7 149.6(9); O6-P1-C6 50.3(3), O6-C6-P1 60.1(3), O6-P1-C13 107.8(3), C13-P1-C6 108.6(3), C6-O6-P1 69.6(3), O6-C6-C7 116.8(6), C7-C6-P1 122.8(5).

Figure 1 shows for **7** a three-membered P-C-O ring system that is somewhat different from that in the only other known structure of an oxaphosphirane complex;[12] the P1–C6 bond is slightly longer, 180.2(7) vs. 177.8(6) pm,[12] as is the P1–O6 bond, 166.8(6) vs. 165.7(4) pm,[12] whereas the C–O ring bond length remains constant at 148.0(9) pm (cf. C–O 148.0(7) pm[12]). It is notable that the sum of the angles C6-P1-W1, C13-P1-W1, and C13-P1-C6, 357.8°, is close to 360° (cf.[12]). In view of the very similar bond lengths and angles in the phosphanediyl tungsten moieties of **1**[5] and **7**, any structure/reactivity relationships in the ring systems of **1** and **7** remain to be demonstrated.

The cleavage of the 2*H*-1,2-azaphosphirene ring system in **1** and the interesting comparison with the 2-methylene-2*H*-azirenes will form the basis of further investigations.

Experimental Procedure

General preparation of **4a,b**: A solution of **1** (1 mmol) in toluene (3 mL) was treated under nitrogen at room temperature with phenylacetylene **2a** (0.3 g, 2 mmol) or diphenylacetylene **2b** (0.4 g, 2 mmol) and stirred for 2 or 2.5 h, respectively, at 75 °C. The pale brown reaction mixtures were evaporated to dryness under reduced pressure and the products separated by column chromatography on silica (−10 °C, hexane). The eluates were concentrated to about 5 mL under reduced pressure and cooled to −30 °C. The solids thus obtained were washed with a little pentane and freed from residual solvent under high vacuum (10^{-3} mbar). **4a**: Pale yellow powder, yield: 67%, m.p. = 104 °C (decomp.); **4b**: pale yellow powder, yield: 44%, m.p. = 112 °C (decomp.).

7: **1** (0.5 g, 0.75 mmol) in toluene (4 mL) was treated with benzaldehyde (1.5 mL, 15 mmol) and stirred for 9 h at 45 °C. The yellow-brown solution thus obtained was evaporated to dryness under reduced pressure. Subsequent column chromatography on silica (−30 °C, hexane/ether 9:1) afforded **7** as a yellow powder (yield: 56%). Recrystallization from pentane at +6 °C gave pale yellow crystals, yield: 26%, m.p. = 114 °C (decomp.).

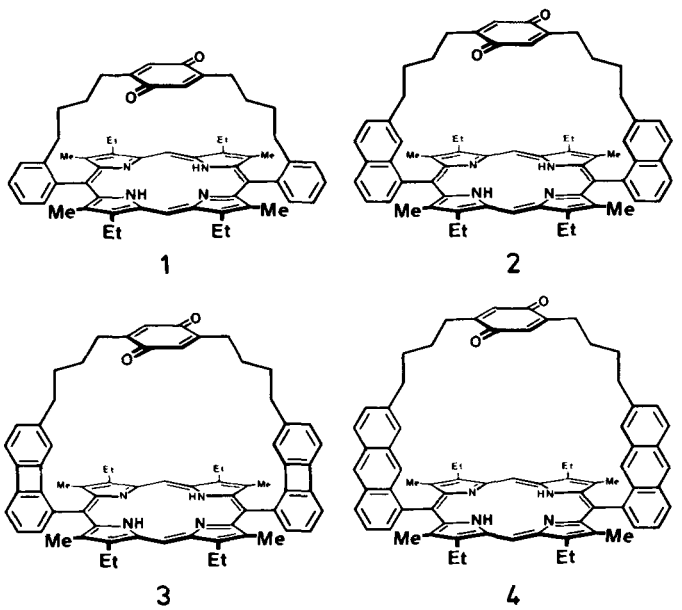
[13] Crystal structure analysis of **7**: $C_{19}H_{25}NO_6PSi_2W$, triclinic, space group $P\bar{1}$, $a = 894.3(3)$, $b = 1070.0(3)$, $c = 1400.0(3)$ pm, $\alpha = 87.39(2)$, $\beta = 88.62(2)$, $\gamma = 68.27(2)°$, $U = 1.2431(6)\ nm^3$, $Z = 2$, $\mu = 4.9\ mm^{-1}$, $T = -100$ °C. A colorless tablet 0.8 × 0.32 × 0.1 mm was mounted in inert oil (type RS 3000, Riedel de Haën). A Siemens R3 diffractometer with $Mo_{K\alpha}$ radiation was used to collect 8113 intensities to $2\theta_{max}$ 55°, of which after an absorption correction (Ψ-scans) 5200 independent reflections were used for all calculations (program SHELXL-93: G. M. Sheldrick, University of Göttingen, **1993**). The structure was solved with the heavy atom method and refined anisotropically on F^2. H atoms were included by using a riding model. The final $wR(F^2)$ was 0.115, with a conventional $R(F)$ 0.043 for 262 parameters and 108 restraints. The maximum residual electron density was 2800 e nm^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the deposition number CSD-401280.

Porphyrin–Quinone Cyclophanes with Gradually Varied Donor–Acceptor Distances**

Heinz A. Staab,* Achim Feurer, and Ralf Hauck



Porphyrin–quinone cyclophanes of type **1** represent especially suitable systems for the investigation of photoinduced electron transfers since the donor and acceptor components are fixed in well-defined spatial orientations. Whereas all other structural parameters remained constant, the electron affinity of the quinone unit and the donor strength of the porphyrin system were varied over a wide range.[1, 2] The cyclophane concept realized in **1** and its doubly bridged analogues[3] was extended to triads of the type porphyrin-quinone(1)-quinone(2) and porphyrin(1)-porphyrin(2)-quinone for the study of multi-

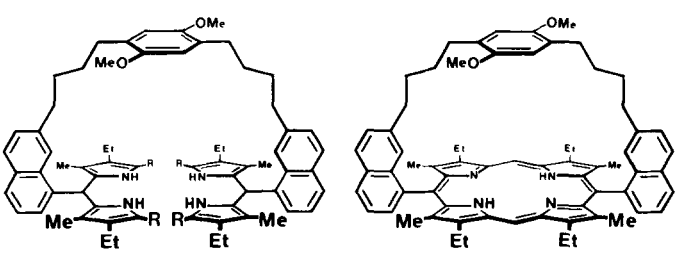
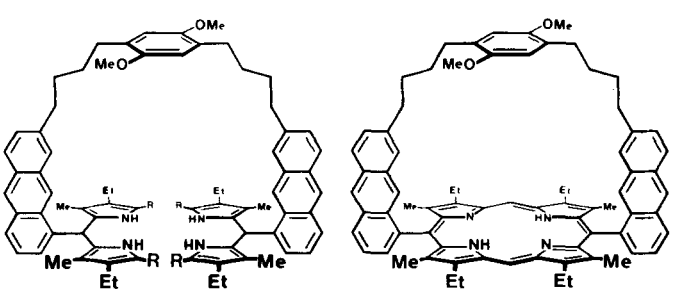
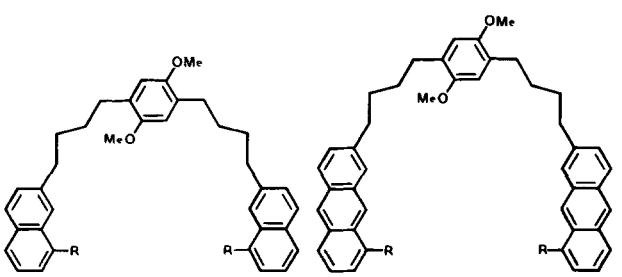
[**] Photoinduced Electron Transfer in Porphyrin–Quinone Cyclophanes, Part 13. Part 12: [4b].

step electron transfer reactions.[4] We now used such porphyrin–quinone cyclophanes for experimental studies of the distance dependence of electron transfer.[5]



X-ray structure analyses of compounds of type **1** showed[1, 6] that for steric reasons the ring planes of the phenyl substituents in the 5- and 15-positions of the porphyrin units are approximately perpendicular to the plane of the porphyrin system. Thus the linkage of the tetramethylene-quinone-tetramethylene bridge to the *ortho* positions of these phenyl rings has a corresponding spatial orientation. When the phenyl groups of **1** are replaced with 1-naphthyl (**2**), 1-biphenylenyl (**3**), and 1-anthryl groups (**4**), we anticipated that these aryl units would also be positioned





roughly perpendicular to the plane of the porphyrin system, and that the bonds in the 7-positions of these arenes would be oriented parallel to the *ortho* bonds of the phenyl rings of **1**. The same quinone bridge as in **1** attached to the 7-positions of these larger arene spacers would thus be shifted parallel. As a result the porphyrin–quinone distances in the series of compounds **1**–**4** would increase stepwise from about 350 to 900 pm, assuming analogous conformations within the bridges. We report here on the syntheses and properties of **2** and **4** and compare them to those of **1**;[1] the biphenylene system **3** requires a different synthetic route, which so far was used successfully only for cyclophanes having porphyrin units with a different substitution pattern.[7]

The main task in the synthesis of porphyrin–quinone cyclophanes **2** and **4** was the construction of the dialdehydes **7** and **10**, which contain the carbon skeleton of the bridge and the two lateral arene units with substitution patterns suitable for the subsequent porphyrin synthesis. The synthesis of the porphyrin cyclophane system should then be possible in analogy to the preparation of cyclophanes of type **1**.[1]

Reaction of methyl 7-bromomethyl-1-naphthoate[8] with triphenylphosphane provided the corresponding triphenylphosphonium bromide (quantitative yield). Subsequent Wittig reaction with (*E*,*E*)-1,4-bis(2-formyl-1-ethenyl)-2,5-dimethoxybenzene[3] led to 1,4-bis[4-(8-methoxycarbonyl-2-naphthyl)-1,3-butadienyl]-2,5-dimethoxybenzene (mixture of *Z*/*E* isomers, 90–95% yield).[9] Catalytic hydrogenation (Pd/C, methanol/ethyl acetate, 1:1) afforded 1,4-bis[4-(8-methoxycarbonyl-2-naphthyl)butyl]-2,5-dimethoxybenzene (**5**) (90% yield).[9] Compound **5** was reduced with lithium aluminum hydride (THF; 95% yield) to furnish the bis(hydroxymethyl) compound **6**, which was oxidized with pyridinium chlorochromate (celite/magnesium sulfate, dichloromethane; 70–90% yield) to give dialdehyde **7** (m.p. 126–128 °C).[9] The reaction of dialdehyde **7** with 2-benzyloxycarbonyl-3-ethyl-4-methylpyrrole led to the corresponding bis(dipyrrylmethyl) compound **11** (conc HCl, ethanol, 3 h at reflux; 90–95% yield). After hydrogenolysis to **12** (Pd/C, THF, 20 °C; almost quantitative yield), the synthesis was completed by closure of the porphyrin ring in analogy to the synthesis of **1**[1] (triethyl orthoformate, trichloroacetic acid; then dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ)). Purification by chromatography (MPLC, silica gel, hexane/ethyl acetate) and recrystallization from methanol/dichloromethane provided **13** in two crystal modifications with melting points of 289–291 and 325–329° (12% total yield).[9] Subsequent ether cleavage (boron tribromide, dichloromethane) and oxidation with DDQ afforded the corresponding porphyrin–quinone cyclophane **2** (violet crystals; m.p. 314–317 °C, 80% yield).[9]

The porphyrin–quinone cyclophane **4** containing the anthracene spacer was prepared by a reaction sequence resembling that of the synthesis of **2**. Bromination of methyl 7-methylanthracene-1-carboxylate[10] with *N*-bromosuccinimide (NBS) was followed by reaction with triphenylphosphane to give the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2323-2429 $ 10.00+.25/0

phosphonium salt[9] (61% yield). Subsequent Wittig reaction with 1,4-bis(2-formylethyl)-2,5-dimethoxybenzene[3] afforded the corresponding diene,[9] which was converted to **8**[9] by catalytic hydrogenation (Pd/C, THF, 80% yield). Diester **8** was reduced (lithium aluminum hydride, THF, ca. 95% yield) to furnish the bis(hydroxymethyl) compound **9**,[9] oxidation of which (DMSO, oxalyl dichloride, THF, −75 °C) provided dialdehyde **10** (m.p. 184–186 °C)[9] in almost quantitative yields. Condensation of **10** with 2-benzyloxycarbonyl-3-ethyl-4-methylpyrrole (*p*-toluenesulfonic acid monohydrate, benzene, 48 h, 80 °C, under argon) afforded the corresponding bis(dipyrrylmethyl) compound **14** (53% yield);[9] hydrogenolysis (Pd/C, THF, 24 h, 20 °C) then led to tetracarboxylic acid **15** (72% yield) (in part hydrogenated at the 9,10-positions of the anthracene units). The closure of the porphyrin ring was completed according to the method employed successfully with **1** and **2**[1] (triethyl orthoformate, trichloroacetic acid, dichloromethane; 22 h, 20 °C). Subsequent dehydrogenation with tetrachloro-1,4-benzoquinone and purification by chromatography (MPLC, silica gel, toluene/ethyl acetate, 20:1) provided the porphyrin cyclophane **16** (4.6% yield; recrystallization from methanol/dichloromethane gave violet crystals, m.p. 271–275 °C).[9] The porphyrin–quinone cyclophane **4** was obtained from **16** by ether cleavage (boron tribromide, dichloromethane, 2 h at 20 °C) and then oxidation of the hydroquinone with tetrachloro-1,4-benzoquinone; chromatography (HPLC, silica gel, toluene/ethyl acetate, 30:1) and recrystallization from methanol/dichloromethane provided **4** in the form of a violet microcrystalline powder (m.p. > 350 °C; 19% yield).[11]

In the series of porphyrin–quinone cyclophanes **1**–**4** completely identical conformational relationships in the quinone bridges corresponding to an exactly parallel shift could not be assumed a priori, since with increasing length of the arene spacer the probability of other conformations becomes greater. However, it was evident from the ^{1}H NMR spectra that the quinone–porphyrin distances increased stepwise as desired. The signal of the protons on the quinone ring in **1** is shifted to considerably higher fields ($\delta = 4.15$, s, 2H) as compared to those of simple 2,5-dialkyl-1,4-benzoquinones ($\delta \approx 6.60$) owing to the anisotropy effect of the porphyrin system. The signal arising from the quinone protons in **2**, the cyclophane with naphthalene spacers, is observed at $\delta = 4.92$ (s, 2H), and that of the anthracene analogue **4** at $\delta = 5.96$ (s, 2H; all spectra in CD_2Cl_2, 303 K). This marked reduction in the ring current effect of the porphyrin units provides clear indication of the increasing porphyrin–quinone distance in this series. However, these data correspond to the time average and cannot be assigned to specific conformations which interconvert rapidly on the ^{1}H NMR timescale. Low-temperature ^{1}H NMR spectra[6] of compounds of type **1** demonstrate that the most stable conformations are not the C_2-symmetric structures with parallel and centered quinone and porphyrin rings. Instead, two equivalent mirror-image conformations exist in which the bridges are arranged unsymmetrically; the swinging of the bridges back and forth corresponds to interconversion of the two conformations ("swinging bridge process"). X-ray structure analyses for compounds in this series also displayed these unsymmetrical conformations, in which the quinone rings are tilted toward the average porphyrin plane by roughly 25° and the vertical distances between the center of the quinone ring and the average porphyrin plane are approximately 450 pm.[6]

Similar conformations can be assumed for porphyrin–quinone cyclophane **2** with naphthalene spacers. ^{1}H NMR spectra recorded at low temperatures (down to 145 K) show broadened but unresolved signals for the NH and methine protons of the porphyrin system, as a result of the expected low energy barriers for the swinging bridge process. The X-ray structures of a derivative of **2** with two chloro substituents on the quinone ring and of **13**, the immediate non-quinoid precursor of **2**, are in principle very similar to that of **1**. However, the tilt of the central rings in the bridges is greater (49 and 56°, respectively), and the distances from the center of these rings to the average porphyrin plane increase to 503 and 516 pm, respectively.[12]

The arrangement and distance between the quinone and porphyrin units in the porphyrin–quinone cyclophane **4** with anthracene spacers could not be determined by either low-temperature ^{1}H NMR studies nor by X-ray structure analysis. Calculations of the conformations based on molecular dynamics (MD) simulations, and determination of the geometries of the lowest energy conformations, which in the case of **1** agree quite well with the experimentally determined conformations, indicate that **4** has an extended quinone–porphyrin arrangement with a vertical distance of 952 pm between the quinone center and the porphyrin plane (Fig. 1).[13]

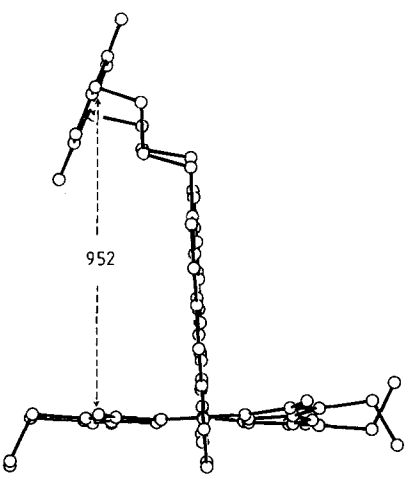


Fig. 1. Lowest energy conformation calculated for **4** (for details on MD simulation see ref. [13]).

UV spectra of porphyrin–quinone cyclophanes **1**, **2**, **4**, and their non-quinoid precursors, as well as the simple 2,8,12,18-tetraethyl-3,7,13,17-tetramethyl-5,15-diphenylporphyrin all show very similar, typical porphyrin absorptions (Soret and Q-bands). The intensities of the emission bands at 630 and 700 nm are, however, dependent on the rate of the photoinduced electron transfer, which leads to radiationless deactivation of the first excited singlet state of the porphyrins competing with fluorescence emission. Comparable values for the emission intensities of the porphyrin–quinone cyclophanes can be obtained from the relative quantum yields φ_{rel} of the fluorescence by comparing the fluorescence intensities of these compounds to those of their immediate non-quinoid precursors. Comparison of the spectra of compounds of type **2** with those of the analogously substituted systems **1**[1] reveals a slight increase of φ_{rel} of fluorescence only marginally outside of the limits of error; in other words, the replacement of the benzene unit by the naphthalene spacer has a rather small effect [$\varphi_{rel} \approx 3 \times 10^{-3}$ (in toluene), 2×10^{-3} (dichloromethane)]. In contrast, for **4** the rate of electron transfer (corresponding to $\varphi_{rel} \approx 0.5$ in toluene) decreases drastically. The magnitude here is in agreement with that found by time-resolved measurements of the fluorescence lifetimes,[14] which appear to correspond to a superposition of

two or three decay times (electron transfer in different conformations?) [**1**: 2 ps (95%); **2**: 3 ps (69%), 25 ps (17%); **4**: 2.4 ns (19%), 5.6 ns (81%); in toluene]. According to these preliminary results the photoinduced electron tranfer becomes slower on going from **2** to **4** by roughly three orders of magnitude. Thus cyclophane **3**, with an intermediate transannular distance, is of particular interest. A systematic investigation of the solvent dependence of the rates of electron tranfer in **1**–**4** seems necessary, since principally different types of solvation cannot be excluded.

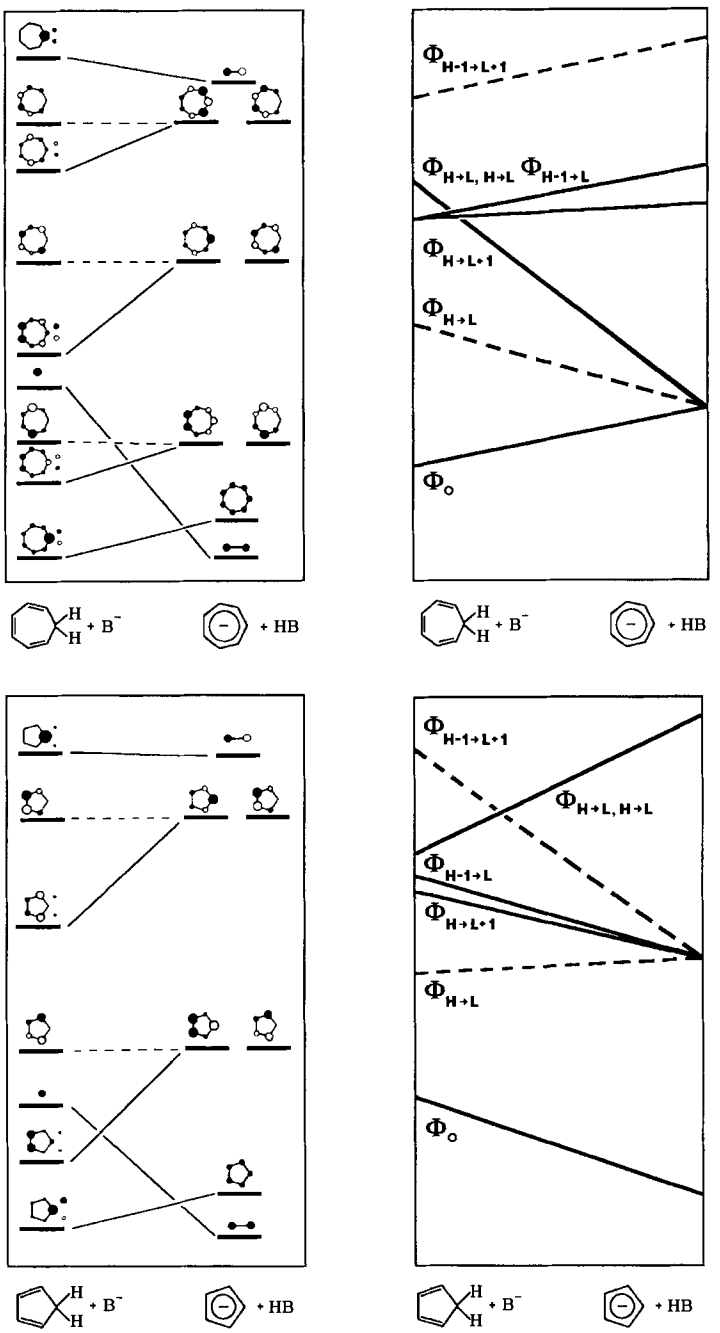
Excited-State Carbon Acids: Theoretical Studies of Suberene and Cycloheptatriene

Hans-Martin Steuhl and Martin Klessinger*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

Cyclopentadienyl and cycloheptatrienyl anions in the ground state have a cyclic array of $4N + 2$ and $4N$ π electrons and are expected to be aromatic and antiaromatic, respectively. The hypothesis[1] that in the excited singlet state, ground-state antiaromatic carbanions are stabilized relative to ground-state aromatic carbanions is supported by the recent finding that suberene (**1**) has a much greater propensity to undergo heterolysis of the benzylic C–H bond than fluorene (**2**).[2, 3] Correlation diagrams, as shown in Figure 1 for the deprotonation of the parent hydrocarbons cyclopentadiene (**3**) and cycloheptatriene (**4**), also support this hypothesis.



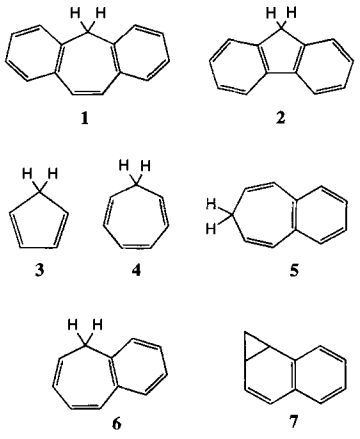


Fig. 1. a) Natural orbital correlation diagrams and b) configuration correlation diagrams for the deprotonation of cycloheptatriene (top) and cyclopentadiene (bottom).

However, while **1** in the excited singlet state is deprotonated by water as base and yields the transient suberenyl anion, on irradiation of **4** a suprafacial [1,7] sigmatropic H-shift[4] and formation of bicyclo[3.2.0]hepta-2,6-diene by intramolecular cyclization[5] occurs. Similarly, the benzo derivatives **5** and **6** showed no evidence for carbon-acidic behavior; instead these compounds reacted exclusively by a very efficient photorear-

rangement to give **7** in good yield.[6] The flexibility of **5** and **6** has been mentioned as a possible cause for the difference in photochemical reactivity between these molecules and **1**;[1, 6] the geometric structure or the electronic structure of the excited states could be stated as alternative reasons. To decide between these possibilities and to understand the excited-state carbon-acidic behavior of suberene, we carried out semiempirical MNDOC-CI calculations[7] for the ground and excited states of **1** and **4**, as well as for their anions.

Optimized structures are shown in Figure 2. While **4** is calculated to be planar or nearly planar in the lowest three singlet states S_0, S_1, and S_2,[8] **1** is far from planar in all three states. As a consequence of this nonplanar structure, the two methylene hydrogens of **1** differ considerably with respect to their chemical surroundings as well as to their charge. But the excited state structures of **1** turn out to be rather flexible, the difference in energy between the planar form and the equilibrium conformation being less than 4 kcal mol^{-1} for the S_1 state. A rough estimate of the ground- and excited-state acidity of **1** and **4** from calculation of the ground- and excited-state heats of formation of the corresponding carbanions yields ΔpK_a values of comparable magnitude (ΔpK_a(**1**) = − 52, ΔpK_a(**4**) = − 47). Therefore, the structure and acidity of the excited states cannot explain the different photochemical behavior of **1** and **4**.

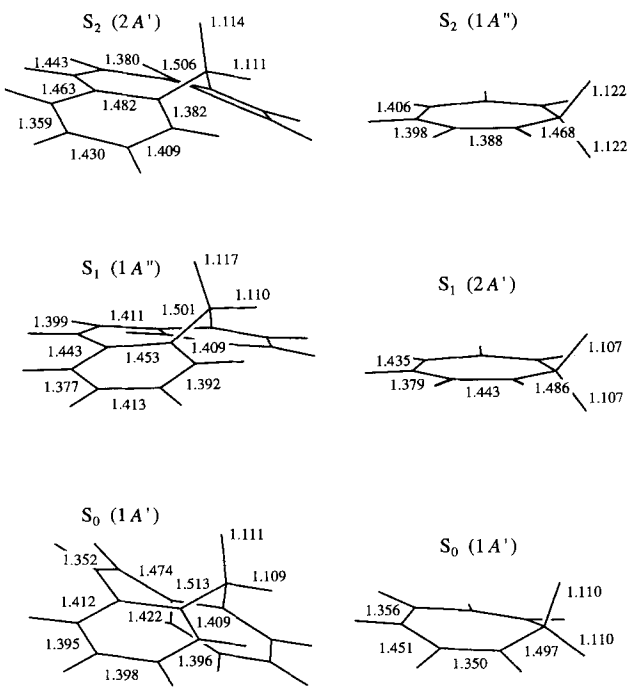

Fig. 2. Optimized structures for the ground and the lowest excited singlet state of suberene (**1**) (left) and cycloheptatriene (**4**) (right). MNDOC-CI results obtained including all single and double excitations with respect to the leading configurations (cf. Table 1) within the active space HOMO−4 to LUMO + 4 for **1** and HOMO−2 to LUMO + 2 for **4**. For the optimization of the excited A' state of **1** the CI had to be further truncated by choosing an excitation index 9/9 [7b]. Vibrational analysis confirmed all stationary points to be true minima.

However, a closer look at the excited-state wave functions in Table 1 reveals that the electronic structure of the lowest excited singlet state of **1** is very different from that of **4**. While for **4** the lowest excited singlet state has the same symmetry as the ground state (A' in C_s), it has a different symmetry (A'') for **1**. The order of vertically excited states, on the other hand, is the same: the A'' state (S_1) lies below the A' state (S_2) for both molecules (Table 1). Therefore, on excited-state relaxation a crossing of states must occur for **4**. This is shown in Figure 3, where the energy of the three lowest singlet states of **1** and **4** is shown as a function of the geometry. Thus, the different photochemical behavior of cycloheptatriene (**4**) and its derivatives on the one hand and of suberene (**1**) on the other is simply due to the fact that excited states of different electronic nature are involved in the photoreactions of these molecules. While in a very short time after vertical excitation into the HOMO → LUMO (H → L) excited A'' state, cycloheptatriene (**4**) will find itself in an excited A' state that may be described by a mixture of the configurations $\Phi_{H\to L,H\to L}$, $\Phi_{H\to L+1}$, and $\Phi_{H-1\to L}$, suberene (**1**) relaxes to the HOMO → LUMO excited A'' state. Only this state is capable of exhibiting excited-state carbon-acidic behavior, as is evident from the correlation diagram shown in Figure 1.

Table 1. Vertical and adiabatic excitation energies [kcal mol^{-1}] of suberene **1** and cycloheptatriene **4** [a].

Excited state[b]	Wave function[c]	**1** ΔE_{vert}	**1** ΔE_{ad}	**4** ΔE_{vert}	**4** ΔE_{ad}
A''	$\Phi_{H\to L}$	98.8	87.5	91.0	84.0
A'	$\Phi_{H\to L,H\to L}$, $\Phi_{H\to L+1}$, $\Phi_{H-1\to L}$	102.1	94.1	91.4	69.2

[a] MNDOC-CI results using the optimized structures and all single and double excitations with respect to all five reference configurations (Φ_0, $\Phi_{H\to L}$, $\Phi_{H\to L,H\to L}$, $\Phi_{H\to L+1}$ and $\Phi_{H-1\to L}$) within the active space specified in the legend of Figure 2 (**1**: 1439 configurations, **4**: 126 configurations). [b] The calculated ground state energies are ΔH_f(**1**) = 138.6 and ΔH_f(**4**) = 65.8 kcal mol^{-1}. [c] Leading contributions to the CI wave function.

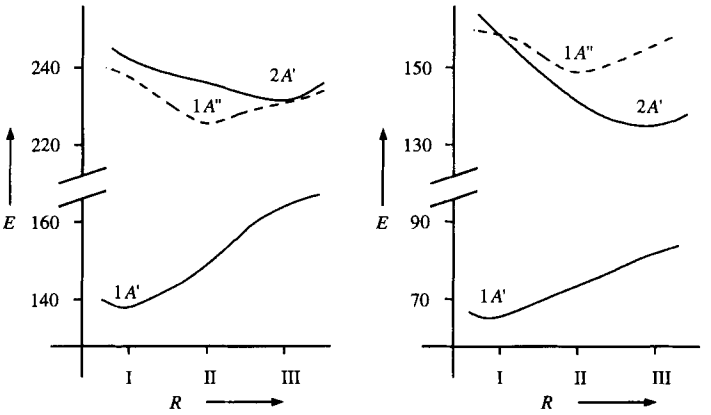

Fig. 3. Energies E [kcal mol^{-1}] of the first three singlet states of suberene (**1**) and cycloheptatriene (**4**) as a function of excited-state relaxation (R). Energies were calculated at the geometries of the $1A'$ ground state (I) and of the $1A''$ (II) and $2A'$ (III) excited states, respectively.

Thus, suberene (**1**) exhibits the expected photochemical reactivity, whereas for cycloheptatriene (**4**) it is not observed, because due to a conical intersection, a fast transition takes place into

the A' state, the characteristic reaction of which is a very efficient [1,7] hydrogen shift. This is in perfect agreement with the observation that though the optically prepared excited state of **4** depopulates within about 25 fs,[11] ground-state **4** is produced only 26 ps after excitation.[12] It also confirms the model proposed to explain this dramatic difference of three orders of magnitude.[12] In addition, this is an indication that in spite of the limitations of semiempirical results as far as absolute accuracy is concerned, the energy difference of merely 0.4 kcal mol^{-1} obtained for the vertical excitation energies of **4** may be significant.

The excited-state acidic behavior observed for **1** might be due to the fact that the photoreactions observed for **4**–**6** are not operative in **1** because they are energetically unfavorable, since the intermediate cannot irreversibly rearomatize to a stable product.[13] This argument, however, is difficult to reconcile with the experimental observation that the [1,7] H shift occurs from a totally symmetric state and the fact that in **1** there is no low-lying state of this symmetry.

Further investigations into the structural and electronic prerequisites for excited-state carbon-acidic behavior are under way.

"Free" $[Fe(tpp)]^+$ Cation: A New Concept in the Search for the Least Coordinating Anion**

Zuowei Xie, Robert Bau, and Christopher A. Reed*

The search for the least coordinating anion is a major thrust of contemporary chemistry.[1, 2] Coordinatively unsaturated cations such as the silylium ion, R_3Si^+, cannot be isolated in condensed media because of the coordinating nucleophilicity of even the best available counterions.[3] $[Fe(tpp)]^+$, the tetraphenylporphyrinatoiron(III) cation, is another long sought after cation[4] and its geometry has become a yardstick for measuring progress towards the noncoordinating anion ideal. In arene solvents, all anions investigated to date either coordinate to or react with iron to form five-coordinate complexes of the type [Fe(tpp)Y]. We now report that $[Fe(tpp)]^+$ can be isolated from arene solvents with no coordination by the anion. The counterion is a novel complex ion formed from Ag^+ and two equivalents of the least coordinating carborane anion currently known, $Br_6CB_{11}H_6^-$. This introduces a conceptually new strategy for preparing weakly coordinating anions.

Treatment of [Fe(tpp)Br] with one equivalent of $Ag(Br_6CB_{11}H_6)$[5] in dry *p*-xylene at 100 °C, removal of the AgBr precipitate, and vapor diffusion of *n*-hexane gave purple crystals of **1** suitable for X-ray structure determination.[6]

$[Fe(tpp)][Ag(Br_6CB_{11}H_6)_2]\cdot 4(p\text{-xylene})$ **1**

As the stereoscopic view of the packing in the crystal shows (Fig. 1), the crystal structure consists of well-separated, alternating layers of $[Fe(tpp)]^+$ cations and $[Ag(Br_6CB_{11}H_6)_2]^-$ anions. The apparent voids in the structure are filled by several interspersed *p*-xylene solvent molecules (not shown). The complementary sizes of the anion and cation probably contribute to the stabilization of the layered ionic lattice.

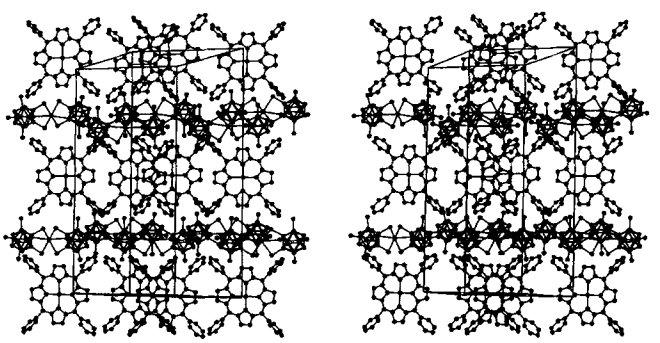

Fig. 1. Stereoscopic view of the packing diagram for **1**. Solvent molecules are omitted for clarity.

The anion (Fig. 2) is a novel variant of the $[AgX_2]^-$ type where X is the icosahedral carborane 7,8,9,10,11,12-hexabromo-*closo*-$CB_{11}H_6^-$. Each carborane is η^3-coordinated to silver through three bromine atoms giving overall octahedral coordination around silver. The generally recognized high affinity of silver(I) for halide ligands may contribute to the stability of this complex ion. Its weak coordinating ability must be related to the

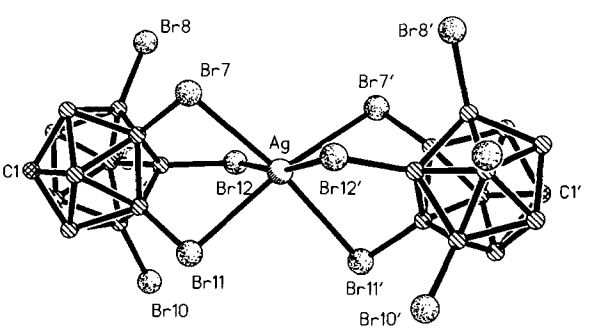

Fig. 2. Perspective view of the anion in **1**: Ag–Br7 = 2.882(3), Ag–Br11 = 2.891(3), Ag–Br12 = 2.865(3) Å.

effective charge reduction brought about by complexation of $Br_6CB_{11}H_6^-$ to Ag^+. By taking the current least coordinating carborane anion,[3, 5] and halving its overall charge, we have lowered its electrostatic attraction to the $[Fe(tpp)]^+$ cation. This is a new concept for lowering the nucleophilicity of an anion and may become an important new general strategy for synthesizing anions that are less coordinating than any presently known.

The $[Fe(tpp)]^+$ cation is shown in Figure 3 along with the two closest approaching solvent molecules. The iron atom lies nearly

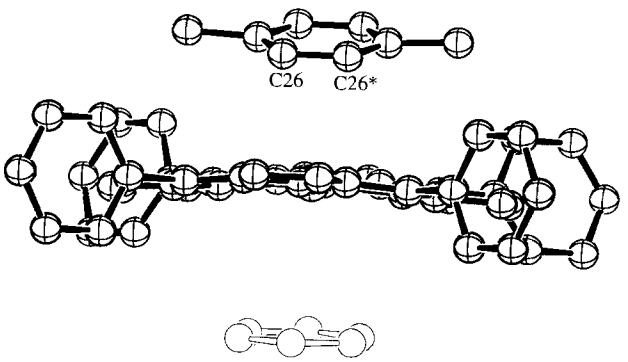

Fig. 3. Perspective view of the $[Fe(tpp)]^+$ cation in **1** with the two closest solvent molecules. The lower *p*-xylene is not well defined crystallographically. Only its arene plane is shown.

in the mean plane of the porphyrin, the Fe–N distances are short (average 1.97(2) Å), and the porphyrin core is slightly ruffled. The porphyrin dimensions are not very different from those of $[Fe(tpp)(FSbF_5)] \cdot C_6H_5F$ (center-to-N distance = 1.974 Å)[7, 8] suggesting that the two closely approaching solvent molecules play a significant role in compensating for the positive charge.

The nature of the solvent interactions can be seen in the side-on view of Figure 3 and the plane projection of Figure 4. The upper *p*-xylene molecule is the more important of the two. It is closer to the porphyrin and is crystallographically well defined by using rigid body refinement procedures. The lower *p*-xylene molecule is about 0.2 Å more distant and, like the other disordered solvent molecules in the lattice, is not well defined crystallographically. Only its arene plane is well defined so we have represented it by an open-bond hexagon. The solvent molecules have many of the general features of π-arene solvates of a number of metalloporphyrins[7, 9, 10] some of which have been shown to have small but demonstrable effects on the coordination geometry.[9] These features include electron-rich carbon atoms relatively close to the metal but not directly over it, a C–C bond approximately straddling a pyrrole N atom, and small dihedral angles between the solvent and porphyrin planes. Some of these features are accentuated in **1**. The dihedral angle of the mean porphyrin plane to the closer, well-defined *p*-xylene plane is 13°, to the other, 5°. The closest approach of a solvent atom to the mean plane of the porphyrin is 2.89 Å to C26. This can be compared to 3.04 Å in [Mn(tpp)]·toluene.[11] The closest Fe–C distance is 2.94 Å to C26, about 0.2 Å shorter than the sum of the covalent radius of Fe^{III} and the van der Waals half-thickness of an arene. The iron atom is drawn 0.07 Å out of the mean plane of the porphyrin core towards the closer, more tilted *p*-xylene.

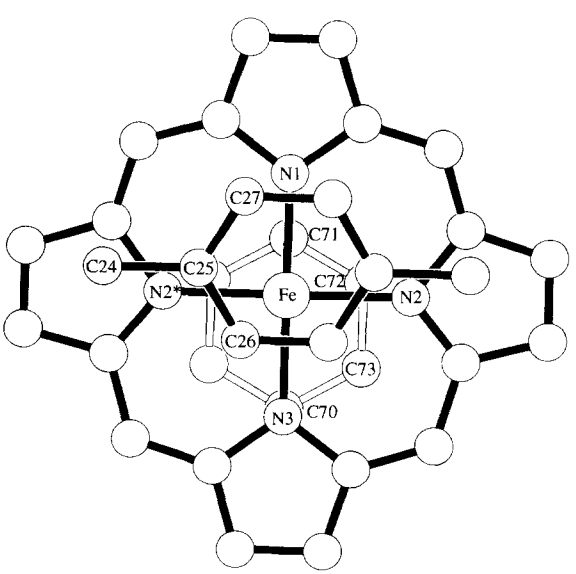

Fig. 4. Projection of the well-defined (front) and less well-defined (hexagon in rear) *p*-xylene molecules onto the mean porphyrin plane.

Thus, the isolation of $[Fe(tpp)]^+$ has been achieved for the first time by providing a) π-donor solvent stabilization of the cation, b) a new least coordinating anion, and c) favorable lattice energetics. The close approach of arene solvent molecules to $[Fe(tpp)]^+$ blurs the distinction between axial ligand and solvate and suggests a continuum between these definitional ideals. Indeed as modern chemistry explores the nature of weak interactions, a vacant coordination site in cationic complexes is becoming increasingly an operational definition rather than a persistent reality.

$[(Cp^{**}CoH)_2$-μ-$\{\eta^2:\eta^2$-*cis*-μ-$[(C_2H_5)_2Al-CH=CH-Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2-C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds**

Jörg J. Schneider,* Carl Krüger, Matthias Nolte, Ingo Abraham, Teja S. Ertel, and Helmut Bertagnolli

Dedicated to Professor Borislav Bogdanović on the occasion of his 60th birthday

To date, only a few heteronuclear organometallic compounds with transition metal–aluminum bonds are known.[1] In contrast, intermetallic phases such as Co_2Al_5 (Al–Al 2.88, Co–Al 2.43 Å) and Co_2Al_9 (ninefold coordinated Co centers, Al–Al 2.83, Co–Al 2.47 Å) are well characterized.[2] This indicates that compounds with Co–Al bonds are, in principle, stable. The structures of organometallic compounds with this combination of elements could not be determined until now, although the syntheses of $[Co_3(CO)_9Al]$[3] and $[(CO)_3(PMe_3)CoAl\{(NMe_2)(CH_2)_3\}(CH_2tBu)]$[1e] have been reported. Direct Ni–Al interactions have been discussed for the Ni^0-catalyzed alkylaluminum/alkene exchange reaction (nickel effect).[4, 5] Our investigations into the synthesis of homonuclear hydridocobalt cluster compounds show that aluminum bonds directly to alkenyl complex fragments with Group 8 transition metals. In the course of the synthesis, cobalt–aluminum clusters are formed as intermediates. We report here on their structural characterization by means of single-crystal structure analyses and EXAFS spectroscopy. Shortly after our work had been submitted, Schnöckel et al. had success with the first structure determination of a cluster with Ni–Al bonds.[6]

The aluminum hydride **1** reacts slowly with **2** at 60–70 °C to form ethylene and ethane. During the subsequent alcoholysis with methanol or ethanol at −78 °C in pentane, the reaction solution changes color immediately from brown to blackish red. The workup and the fractional crystallization of the reaction mixture leads to the paramagnetic clusters **3** and **4**, as well as the diamagnetic **5**.[7]

$$[Cp^*Co(\eta^2\text{-ethene})_2] + [(C_2H_5)_2AlH] \xrightarrow[-C_2H_5]{70\,^\circ C,\ CH_3C_6H_5} \xrightarrow[C_2H_5OH]{-78\,^\circ C} [(Cp^*Co)_2H_3] + [(Cp^*Co)_3H_4] + [(Cp^*Co)_4H_4]$$

2 **1** **3** **4** **5**

The aprotic workup of the reaction mixture of **1** and **2** in the absence of alcohol (pentane extraction, fractional crystallization of the raw product from ether/pentane) resulted in a 20–30% yield of reddish brown crystals with the analytical composition of **6** as well as unconverted starting material.

[**] We thank one of the reviewers for his valuable comments, the Fonds der Chemischen Industrie for financial support, and the Deutsche Forschungsgemeinschaft (Heisenberg Fellowship to J.J.S.). The single-crystal X-ray structure analyses were carried out by C. K. and M. N., the EXAFS analyses by I. A., T. S. E. and H. B. Abbreviations: Cp* = η^5-pentamethylcyclopentadienyl, Cp** = η^5-1,2,3,4-tetramethyl-5-ethylcyclopentadienyl.

A ^{13}C NMR spectrum of **6** with a complete signal set could not be obtained because of the low solubility of the substance. In order to solve the structure of this compound, we attempted to improve the solubility and the crystallization behavior by varying the Cp ligand.

Reaction of the corresponding Cp** starting material **7** with **1** under the same reaction conditions as for the synthesis of **6** led to the analogous compound **8**. The yields of the crystalline product **8** were also between 20–30%. Compounds **6** and **8** gave comparable spectroscopic data. In the mass spectrometer, both decomposed on evaporation in the temperature range 130–150 °C; consequently mainly fragment ions could be observed in the spectra. The most intense signals (100%) in the mass spectra of **6** and **8** are found at *m/z* 527 and 555, respectively. The molecular ions had only low intensity. The sudden formation of ethane could be detected at the beginning of the evaporation of both compounds. The ^1H NMR spectra of **6** and **8** confirm the presence of two hydridic hydrogen atoms; their signals lie in the shift region typical for transition metal hydrides at $\delta = -17.90$ for **6** and $\delta = -18.02$ for **8**. In the IR spectrum of **8** the very broad Co–H stretching vibration lies at 1810 cm^{-1} ($\tilde{\nu}_{1/2}$ = 40 cm^{-1}). A clear designation of the Co–H stretching vibration is not possible for the Cp* derivative **6**. The ^1H NMR signals at $\delta = 1.85$ for **8** and at $\delta = 1.90$ for **6** can be attributed to protons on a C_2 alkene unit. The protons of the various ethyl groups of **8** appear in the ^1H NMR spectrum as three signal groups (each as the expected quartet and triplet).

The molecular structure of the Cp** derivative **8** was solved by means of a crystal structure analysis[8] (Fig. 1). We assume that the Cp* compound **6** has a corresponding structure. In **8**, two 15VE (Cp**CoH) complex fragments, each of which is η^2-bonded to the π-system of the bridging C_2 unit, are connected through a dialuminioethene unit over a twofold axis. One terminal ethyl group of each $[Al(C_2H_5)_2]$ unit is disordered in the crystal. The positions of the hydridic protons on the Co atoms were determined during the resolution of the structure and refined. The nonbonding distance of 3.503 Å between the two Al atoms is very large, even larger than the Co–Co distance

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2323-2435 $ 10.00+.25/0

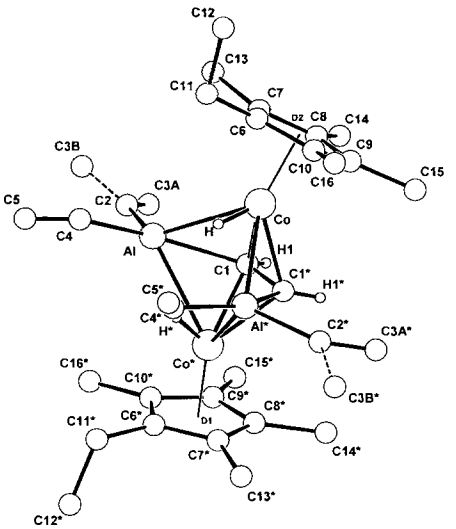

Fig. 1. Molecular structure of **8** in the crystal. Hydrogen atoms on the Cp** rings and on the ethyl groups are not shown. The positions of the carbon atoms C2 and C3 on Al and Al* are disordered (dashed lines). Selected distances [Å] and angles [°]: Co-Al 2.604(1), Co-Al* 2.591(2), Co-C1 1.992(4), Co-Cl* 1.986(4), Al-C1 2.088(4), Co-C6 2.030(4), Co-C7 2.052(4), Co-C8 2.065(5), Co-C9 2.080(5), Co-C10 2.050(4), C1-C1* 1.363(5); C1*-Co-Al 52.1(1), C1*-Co-H 88(2), C1*-Co-Al 81.8(1), Al*-Co-H 47(2), Co-Al-H 57(2), Co*-Al-C1 48.7(1), C1-Al-Co 48.7(1), C1*-C1-Co 70.2(2), Co*-C1-Co 114.2(2), Al-C1-Co 79.3(1).

(Co–Co* 3.338 Å). Because of the absence of an Al–Al bond, the C_2 unit in **8** can be described as a *cis*-dimetalated olefin.[9]

The reaction of **1** with **2** or **7** can be formally considered as the addition of a Lewis acid complex to a coordinatively unsaturated hydrocarbon. This reaction type presents a route to dimetallacycloalkenes.[10] Until now, two structurally characterized examples of this class of compounds existed which contain aluminum.[11] In these, the Al–Al distances of 3.37 Å[11a] and 3.47 Å[11b] are of the same order of magnitude as that in **8**, and are also to be regarded as nonbonding. The length of the olefinic C=C bond in **8** (1.363(5) Å) is comparable with that of other dimetalated olefins[9, 10, 11a] and also only slightly different from that in free ethene (1.34 Å). This would indicate a stronger contribution of the alkene-$\sigma \rightarrow$ donor portion than that of the metal-$\sigma \rightarrow \pi$-acceptor portion to the bond of the Co-dimetallioalkene molecular fragment, which ultimately leads to the short μ-η^2:η^2-coordinated C=C bond in **8**. An almost ideal planar ordering of all four atoms C1, C1*, Al, and Al* was determined for the dialuminioolefin unit in **8** (maximum deviation from the best plane less than $\pm 1.6 \times 10^{-3}$ Å). This indicates that no significant rehybridization of the sp^2 carbon atoms C1 and C1* towards sp^3 hybridization occurs in the formation of the dialuminioethene unit.[12] The Co–Al distances of 2.604(1) Å and 2.598(1) Å in **8** are surprisingly very long in comparison to the Co–Al contacts in **9** (2.336(1), 2.333(1) Å). The atomic distances of both the Co atoms to the C atoms C1 and C1* of the *cis*-dialuminiometalated bridging ethene ligands in **8** are 1.989 Å on average. They are thus clearly shorter than the corresponding Al–C distances to the π bonds of the *cis*-dimetalated olefin units (2.35 Å) in dimeric 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene.[11a] Structurally characterized complexes of μ-η^2:η^2-bridging alkene ligands, as first observed in **8** for cobalt compounds, were very rare until now (M = Zr,[13] Hf,[14] Sm[15]). An example of a C_2 carbon fragment as a σ-μ-π bridge for four metal atoms is as yet unknown.

When important structural parameters from single-crystal structure analyses are missing, an alternative method for obtaining valuable information on characteristic M–M atomic distances in organometallic complexes is EXAFS spectroscopy. No structural data for **6** is available from single-crystal structure analyses at present. An analysis of the Co-K EXAFS spectra[16] of polycrystalline samples of **6** and **8** show, however, that an analogous structure can be assumed for both. The Fourier transforms of the k^3-weighted $\chi(k)$ functions reveal two coordination shells for the Co atoms in **6** and **8**. The first coordination shell is formed from C atoms at a distance of 2.06(1) Å, the second coordination shell from Al atoms at a distance of 2.56(3) Å (**6**) and 2.59(3) Å (**8**). The Co–Cp_{ring} distances and the Co–Al distances in **6** and **8** determined by the EXAFS method agree very well with those determined in **8** by the single-crystal structure analysis.

The attack of the organoaluminum component on the organocobalt starting materials **2** and **7**, and the π-precoordination of the ethene ligands on the cobalt center are possibly crucial for the formation of the new complex types **6** and **8**. The CH acidity of the protons of the coordinated ethene is greatly increased in this way, and these ligands can thus be eliminated more easily in a consecutive reaction.

A second organometallic component **9** is additionally formed in low yield (< 2%) in the form of red crystals from the product mixture of the reaction of **1** with **2**. In addition to the mass spectroscopic identification, **9** was also characterized by a crystal structure analysis (Fig. 2).[8] We have not yet been able

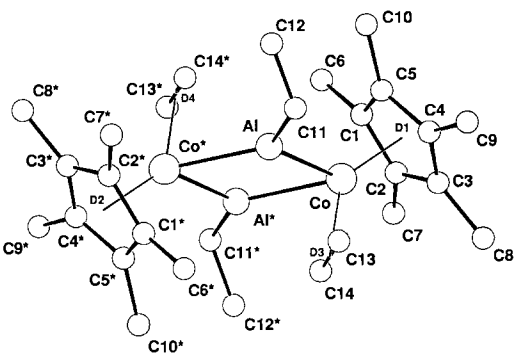

Fig. 2. Molecular structure of **9** in the crystal. Hydrogen atoms not shown. Selected distances [Å] and angles [°]: Al-Al* 2.663(3), Co-Al 2336(1), Co-Al* 2.333(1), Al-C(11) 1.976(3); Co*-Al-Co 110.4(1), Al*-Co-Al 69.6(1), Co-Al-C(11) 123.8(1), Co*-Al-C(11) 125.7(1), C(13)-Co-Al 68.9(1), Al-C(11)-C(12) 119.1(3).

to investigate an analogous product to **9** in the case of the reaction of the Cp** derivative **7**. Formally the two 16VE [Cp*(η^2-ethene)Co] units in **9** are linked by [Al(C_2H_5)] groups. The four-membered ring in **9** is planar, and **9** crystallizes around an inversion center C_i. Due to the space group symmetry, all ligands on the metal atoms are thus arranged as *trans* pairs. No bond exists between the two Co atoms (Co–Co* 3.835(0) Å). The Co–Al distances are 2.336(1) and 2.333(1) Å, and are thus significantly shorter than the distances in **6** and **8**. Comparable data for organometallic compounds do not exist as yet, as **6**, **8**, and **9** are prototypes for such Co–Al clusters. The distance between the two aluminum atoms in **9** of 2.663(3) Å fits reasonably well into the range of Al–Al distances that have already been determined for dimeric alkylaluminum compounds and lies in the region of a bonding Al–Al interaction.[18]

The reaction that leads to the buildup of the heterodinuclear cluster **9**, can be considered as a bimolecular elimination.[23] Al–C bond cleavage occurs at the Co center, resulting elimination of ethane and the formation of Al–Co bonds.

Experimental Procedure

6, **9**: Compound **2** (2.57 g, 10.3 mmol) was dissolved in toluene (100 mL). **1** (1.9 mL, 17 mmol) was added and the mixture stirred at 70 °C for 12 h. The solvent was removed from the resulting reddish brown solution under reduced pressure, and the oily semicrystalline residue extracted first with pentane, then with ether. The greater part of both extracts consisted of red crystals of **6** (pentane, −30 °C); 360 mg (24.2%). MS (EI, 70 eV, evaporation temperature 140 °C), 557(32), 527(100), 471(22), 386(28), 353(28), 264(23), 133(15), 57(26), 28(28), 27(63). – ^{1}H NMR (200 MHz, C_6D_6, 27 °C, TMS): $\delta = -17.9$ (s, 2H), 0.50 (q, 4H), 0.93 (q, 4H), 1.62 (s, 30H), 1.62 (t, 6H, COSY), 1.72 (t, 6H), 1.90 (s, 2H, HC=). – ^{13}C NMR (100 MHz, C_6D_6, 27 °C, TMS): $\delta = 10.1$ (Cp*), 12.47, 12.52, 90.2 (Cp*). – IR (KBr): $\tilde{\nu}$[cm^{-1}] = 525(s), 580(s, br), 620(s), 890(vs), 945(m), 980(m), 1025(s), 1085(s), 1380(vs), 1405(m), 1460(vs, br), 2850, 2910(vs). In addition to this, a few reddish orange crystals of **9** were isolated from the mother liquor. MS (EI, 70 eV, evaporation temperature 160 °C), *m/z* (%): 556(59) [M^+], 528(100), 500(49), 440(41), 377(52), 353(27), 264(32), 27(77). After prolonged cooling at −78 °C, starting material **2** (1.3 g, 5.2 mmol) also crystallized from the pentane extract.

8 was synthesized analogously to **6** by reaction of **7** with **1** (stoichiometry 1:1). Reddish brown crystals of **8** were obtained from the crude oily reaction product by dissolving in diethylether/acetonitrile (3:1) and then cooling slowly, first to 0 °C then to −30 °C. Still more **8** can be obtained, in total up to a yield of approx. 30%, by prolonged cooling of the mother liquor at −30 °C. 555(100), 530(15), 499(45), 278(34), 57(19), 30(12), 28(47). – ^{1}H NMR (200 MHz, C_6D_6, 27 °C, TMS): $\delta = 2.33$ (q, 4H, CH_2 on Cp**), 1.85 (s, 2H, HC=), 1.69 (t, 6H), 1.61 (s, 12H, CH_3 on Cp**), 1.54 (s, 12H, CH_3 on Cp**), 1.54 (t, 6H, COSY-assignment), 0.87 (q, 4H), 0.69 (t, 6H), 0.46 (q, 4H), −18.01 (s). – ^{13}C NMR (100 MHz, C_6D_6, 27 °C, TMS) $\delta = 10.0$, 12.52, 12.56, 14.3, 19.1, 37.7, 89.7, 90.6, 95.5. – IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2990–2840 (vs), 1820 (m, Co-H), 1480 (m), 1450 (vs), 1405 (s), 1380 (s), 1370 (s), 1305 (m), 1090 (vs), 1050 (s), 1030 (s), 980 (s, br), 950 (s), 910 (s), 895 (vs), 625 (vs), 580 (s), 530 (s), 500 (s). Satisfactory elemental analyses for C, H, Al, and Co were obtained for **6** and **8**.

Antenna Effect in Multichromophoric Cyclodextrins**

Ludovic Jullien, Josette Canceill, Bernard Valeur,* Elisabeth Bardez, and Jean-Marie Lehn*

By analogy with the antennae pigments of photosynthetic units,[1] a *photochemical antenna* consists of an assembly of chromophores such that 1) the photon-harvesting efficiency is high owing to a large overall cross-section for light absorption and 2) excitation energy is conveyed from the chromophores (directly or after hops from chromophore to chromophore) to an energy acceptor, which converts the absorbed light energy. This acceptor can be a light-emitting species (a lanthanide ion or an organic fluorophore), so that the incident light is converted into light at higher wavelengths; an example is provided by complexes between lanthanide ions and polypyridine ligands,[2] which are promising fluorescent labels for chemical and biological purposes. Other antenna-based photochemical molecular devices can be designed;[3] polynuclear metal complexes have received special attention in this context.[4] The antenna effect has also been studied in light-harvesting polymers having chromophores substituted at intervals along the chains.[5, 6] In the multichromophoric β-cyclodextrins (β-CD) reported to date, the position of the chromophores is much better spatially defined, which is a distinct advantage for the understanding of the energy hopping process.[7, 8] In the course of our work on these systems, we have prepared a new multichromophoric β-CD to mimic the antenna effect occurring in photosynthetic units. We report here on the very efficient energy transfer from seven 6-carboxy-2-naphthyl antenna chromophores to a merocyanine, DCM-OH, included in the cavity (Fig. 1).

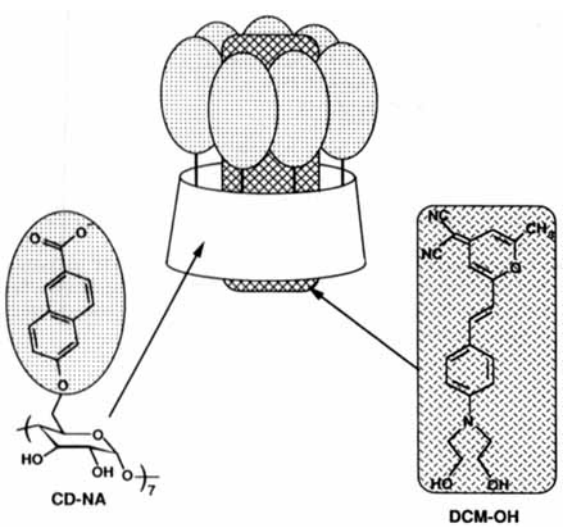

Fig. 1. Schematic representation of the complex between the heptanaphthoate β-cyclodextrin (CD-NA) and the merocyanine DCM-OH.

[**] This work was supported by the Centre National de la Recherche Scientifique (CNRS). The authors thank Dr. R. Pansu, Ecole Normale Supérieure, Cachan, for his help in the fluorescence decay experiments.

The photosensitive β-CD (CD-NA) was dissolved in a buffer at pH 10, so that the chromophores were in the naphthoate form. The absorption and fluorescence spectra are shown in Figure 2. The fluorescence spectrum consists of two bands. The

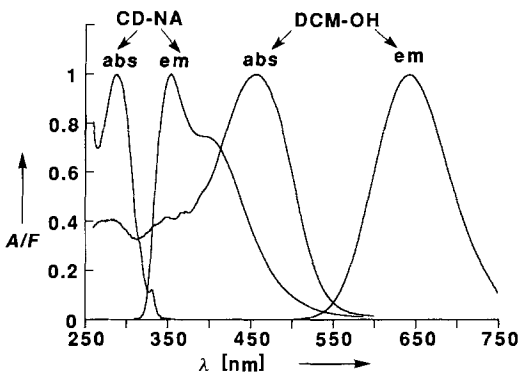

Fig. 2. Absorption and fluorescence spectra of CD-NA and DCM-OH in a buffer at pH 10 containing 5% (v/v) of ethanol; for the sake of clarity, all spectra have been normalized to the same height at the maximum. The molar extinction coefficients at the maximum are 4.35×10^4 and $3.15 \times 10^4\,\text{M}^{-1}\text{cm}^{-1}$ for CD-NA and DCM-OH, respectively; at 300 nm (excitation wavelength), the values are 3.43×10^4 and $1.83 \times 10^4\,\text{M}^{-1}\text{cm}^{-1}$, respectively.

first one with a maximum at 355 nm is similar to the fluorescence spectrum of 2-methoxy-6-naphthoic acid, which at pH 10 is in the naphthoate form. The second band with a maximum at 405 nm is not observed in this model compound under the same conditions; moreover, the excitation spectrum of CD-NA was found to be independent of the observation wavelength (either 355 or 405 nm) and identical to the absorption spectrum. Therefore, the band at 405 nm is assigned to intramolecular excimer formation. Excimers were also identified in β-CD labeled with naphthoyloxy chromophores,[7] but not in those labeled with naphthalene-6-sulfonate residues.[9]

Among dyes that are likely to form an inclusion complex with the cyclodextrin, DCM-OH (4-dicyanomethylene-2-methyl-6-*p*-diethanolaminostyryl-4*H*-pyran),[10] a derivative of the well-known laser dye DCM (4-dicyanomethylene-2-methyl-6-*p*-dimethylaminostyryl-4*H*-pyran), was chosen for the following reasons: 1) good overlap is observed between the absorption spectrum of DCM-OH and the emission spectrum of the naphthoate chromophores (see Fig. 2); 2) its elongated form fits well in the CD-NA interior, and its length is approximately equal to the depth of the cavity plus the length of the linked chromophores; and 3) it is essentially hydrophobic, but partially hydrophilic thanks to the two terminal hydroxyl groups (DCM-OH is fairly soluble in water containing a small amount of ethanol). On the basis of the last two features, efficient complexation of DCM-OH with CD-NA is expected.

Several 2.9 μM solutions of CD-NA in the pH 10 buffer containing 5% (v/v) of ethanol and various amounts of DCM-OH were prepared. The fluorescence of the naphthoate residues (excited at 300 nm) decreases as the concentration of DCM-OH increases. The quenching process can be explained in terms of transfer of excitation energy from the naphthoate residues to DCM-OH; this is confirmed by the concomitant increase in fluorescence intensity of the latter. The contribution of the directly excited DCM-OH molecules (at 300 nm) to this increase was found to be only a small fraction of the overall DCM-OH fluorescence. The evolution of the whole fluorescence spectrum is shown in Figure 3.

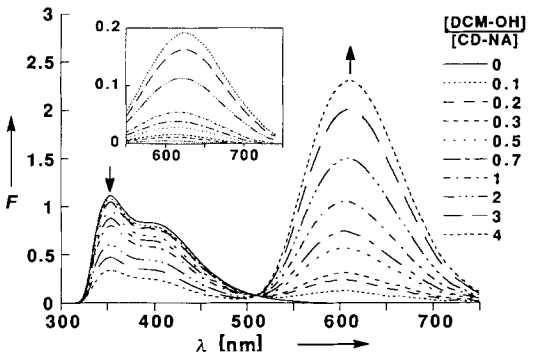

Fig. 3. Evolution of the fluorescence spectrum of a CD-NA solution on addition of DCM-OH in a concentration ratio [DCM-OH]/[CD-NA] = 0 to 4 (solvent: buffer at pH 10 containing 5% (v/v) of ethanol). Excitation wavelength: 300 nm. Insert: contribution from DCM-OH molecules directly excited at 300 nm (this contribution was obtained by measuring the fluorescence spectra upon excitation at 400 nm where CD-NA does not absorb and by multiplication with the ratio of the absorbances at 300 and 400 nm).

The fluorescence decay curves of CD-NA (2.9 μM) upon excitation by a laser pulse at 300 nm were recorded at 355 nm (the time-resolution of the instrument was about 100 ps). In the absence of DCM-OH, the decay is biexponential owing to emission from both monomer and excimer. In the presence of fourfold excess of DCM-OH, the decay was found to be superimposable on the latter (after normalization at the same height at the maximum in order to compensate for the large decrease in fluorescence intensity in the presence of DCM-OH). This means that the efficiency of transfer from the naphthoate chromophores to DCM-OH is very close to 1, and the observed fluorescence at 355 nm is solely due to CD-NA molecules containing no DCM-OH molecule. Considering the very short distances between the naphthoate residues and DCM-OH, both the Förster mechanism (dipole–dipole interaction) and the Dexter mechanism (exchange interaction) are likely to be involved in such a highly efficient energy transfer.

The association of DCM-OH with CD-NA deserves further attention. Information on the complex is provided by fluorescence and circular dichroism spectra. The fluorescence spectrum of DCM-OH is blue-shifted by around 40 nm upon addition of CD-NA, which shows that the averaged microenvironment of DCM-OH is less polar in the complex with CD-NA than in the buffer. More precisely, since the dipole moment of DCM and DCM-OH is much larger in the excited state than in the ground state, a blue shift is due to a reduction of the relaxation of the solvent molecules around the large dipole created upon excitation. Furthermore, the circular dichroism spectrum of DCM-OH in the presence of CD-NA exhibits a positive band in the 380–550 nm range which means[11] that the transition dipole moment of DCM-OH (which is directed along the long axis of the molecule) lies in a cone whose axis is parallel to the symmetry axis of the cyclodextrin.

The stoichiometry of the complex was demonstrated to be 1:1 by means of a Job plot:[12] the variations in fluorescence intensity at 355 nm as a function of the ratio [DCM-OH]/([DCM-OH] + [CD-NA]) at constant [DCM-OH] + [CD-NA] passes through a maximum at 0.5. The most accurate stability constant for the complex was obtained by analysis of the variations in fluorescence intensity at 355 nm as a function of the concentration in DCM-OH. After suitable corrections for inner-filter effects and taking into account the transfer efficiency of 1, a nonlinear least-squares analysis leads to a stability constant of $(1.2 \pm 0.2) \times 10^5$ for the equilibrium (a). Compared to previously

$$\text{CD-NA} + \text{DCM-OH} \rightleftharpoons [\text{DCM-OH} \subset \text{CD-NA}] \quad \text{(a)}$$

reported data on complexes with β-CD molecules,[13] this value is quite high. This can be interpreted in terms of an additional contribution from the naphthoate chromophores: the usual hydrophobic effects operating between the etherlike cyclodextrin walls and lipophilic guests are reinforced by the naphthalene rings of the appended chromophores.

In conclusion, β-cyclodextrins bearing seven naphthoate chromophores form highly stable 1:1 complexes with a merocyanine dye. The antenna effect (i.e., the transfer of excitation energy from the chromophores to the merocyanine) takes place with an efficiency close to 1. It represents a very efficient light conversion process by an absorption–energy-transfer–emission (A–ET–E) sequence in a supramolecular photochemical device.[14] Further studies aimed at the characterization of the excited-state processes are in progress. Other energy acceptors included in the cavity are being considered; special attention is paid to photoreactive acceptors with a view to converting light energy into chemical energy as in natural photosynthetic systems.

Experimental Procedure

CD-NA was prepared from methyl 6-hydroxy-2-naphthoate and heptakis(2,3-di-*O*-acetyl-6-deoxy-6-iodo)cyclomaltoheptanose by nucleophilic substitution [15]. Details of the experimental procedure will be published elsewhere. DCM-OH was synthesized by Dr. J. Bourson according to the general procedure described in ref. [16]. The Britton–Robinson buffer at pH 10 (ionic strength of 0.1 M) was prepared according to ref. [17]. The UV/Vis absorption spectra were obtained with a Kontron Uvikon-940 spectrophotometer. Corrected fluorescence spectra were recorded on a SLM 8000 C spectrofluorometer. All the experiments were performed at 25 °C.

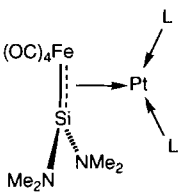
Platinum–Iron Silylene Complexes and Metal-Promoted Substituent Exchange between $Si(NMe_2)_3$ and $P(OEt)_3$ Ligands**



Ulf Bodensieck, Pierre Braunstein,* Werner Deck, Thierry Faure, Michael Knorr, and Christine Stern

The considerable current interest in metal silylene complexes results largely from the need to gain a better understanding of their occurrence, reactivity, and possible role as intermediates in a number of important rearrangements[1] or catalytic reactions, such as the polymerization of silanes or the dehydrogenative coupling of silanes to disilanes.[2]

We reasoned that heterometallic silylenes would represent an important new class of complexes in which the reactivity of the metal–silicon bond could be tuned by varying the nature of the other metal fragment. On the other hand, tris(amino)silyl derivatives of the transition metals should display interesting reactivity patterns, in particular owing to the basicity of the nitrogen atoms. The amino substituents would be expected to have a considerable influence on the properties of the iron–silicon bond. However, the reactivity of tris(amino)silanes towards transition metals has not yet been examined, although tris(amino)silyl complexes have been obtained indirectly.[3] We now attempt to combine these two facets of silicon/transition metal chemistry and report here on the stabilization of a (dimethylamino)silylene complex by an electron-acceptor metal fragment, which leads to formation of heterobimetallic silylene complexes, as well as on an unprecedented iron carbonyl promoted substituent exchange between phosphite and aminosilyl ligands.

In pioneering work, G. Schmid et al. reported the synthesis of the first base-stabilized silylene complex $[Fe(CO)_4\{SiMe_2(NEt_2H)\}]$.[4] We have now synthesized the amine-stabilized bis(dimethylamino)silylene complex **2** by oxidative addition of the Si–H bond of $HSi(NMe_2)_3$ to the photochemically generated $Fe(CO)_4$ species. The hydrido, tris(dimethylamino)silyl complex **1** is the most likely primary product, but is unstable owing to proton migration to the more basic nitrogen atom. However, if tautomer **1** were present in small amounts in the reaction mixture, one could exploit the Fe–H functionality for oxidative addition to a low-valent metal complex with the aim of generating a heterobimetallic complex. This was indeed possible with the isoelectronic system $[HFe\{Si(OMe)_3\}L_4]$ in which the methoxy groups are much less basic than the dimethylamino groups of **1**.[5]

3a L = PPh_3
3b L = $P(p\text{-Tolyl})_3$
3c L_2 = dppe

Reaction of **2** with $[Pt(C_2H_4)(PR_3)_2]$ (R = Ph, *p*-tolyl) resulted in displacement of the dimethylamine ligand from **2** and the Pt-bound ethylene ligand and yielded new complexes, which were assigned the structures **3a,b** on the basis of analytical and spectroscopic data (Table 1). The

[**] Part of the planned dissertation of C. Stern. We would like to thank Prof. Dr. H. Vahrenkamp for access to the X-ray diffractometer in Freiburg. We are grateful to the Ministère de l'Enseignement Supérieur et de la Recherche (Paris) for a post-doctoral grant to U. B., to the Centre National de la Recherche Scientifique, the Commission of the European Communities (contract CHRX-CT93-0277), and the Alexander von Humboldt-Stiftung (award to P. B.) for financial support, and Johnson Matthey PLC for a generous loan of $PtCl_2$.

$^{31}P\{^1H\}$ NMR spectra of **3a,b** show an AX pattern, which is indicative of two chemically different P nuclei ($^2J(PP) = 4.0$ and 2.5 Hz, respectively; these values are typical for a *cis* arrangement) and is observed for L_2Pt^0 or L_2Pd^0 fragments coordinated to unsymmetrical olefins.[6]

It thus appears that an oxidative addition process does not occur, but rather that the amine ligand in **2** is displaced—more readily than anticipated—to give a silylene complex **3**. The latter is stabilized by an electron-acceptor fragment (i.e. PtL_2) instead of an electron-donor group, as observed so far.[7] It should be noted that base-free silylene complexes have only recently been synthesized and structurally characterized.[8a–e] Bearing in mind the isolobal analogy between $Fe(CO)_4$ and SiR_2, we can relate these molecules to the first platinum η^2-disilene complexes reported recently.[8f] The ^{29}Si NMR chemical shift of **3a** ($\delta = 113.9$) is consistent with a silylene complex, and the $^2J(Si,P_{trans})$ coupling constant of 136.4 Hz indicates that the PtL_2 fragment does not rotate. The Fe–Si–Pt system in **3a** is remarkably stable, since reaction with 1,2-bis(diphenylphosphino)ethane (dppe) led only to displacement of the PPh_3 ligands to give **3c**. In the absence of a crystal structure, we cannot comment on the extent to which the resonance forms **A** and **B** contribute to the actual structure of complexes **3**.

Since electron-donor substituents at Fe should stabilize the Fe–Si double bond, we set out to prepare the phosphite derivative **4**. However, the photochemical reaction of $[Fe(CO)_4\{P(OEt)_3\}]$ with $HSi(NMe_2)_3$ yielded, after workup, a new complex **5** with a singlet in its $^{31}P\{^1H\}$ NMR spectrum at

$\delta = 196.8$. The ^1H NMR spectrum was unexpected: the NCH_3 protons appeared as a singlet and a doublet in a 1:2 ratio, and the CH_2CH_3 protons as two triplets in a 1:2 ratio. An X-ray diffraction study (Fig. 1) allowed full elucidation of the structure of **5** and showed that an unprecedented ligand rearrangement had taken place: two ethoxy groups from the phosphite

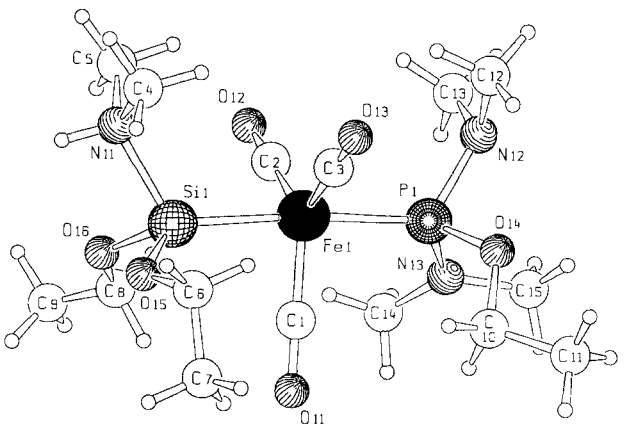

Fig. 1. The crystal structure of one molecule of **5** [13c]. Selected bond lengths [Å] and angles [°]: Fe1–C1 1.747(7), Fe1–C2 1.761(8), Fe1–C3 1.764(7), Fe1–P1 2.186(2), Fe1–Si1 2.218(2), Si1–O15 1.666(5), Si1–O16 1.652(5),Si1–N11 1.916(5), P1–O14 1.618(5), P1–N12 1.695(6), P1–N13 1.661(6); C1-Fe1-C2 120.7(3), C1-Fe1-C3 117.8(3), C2-Fe1-C3 121.2(3), P1-Fe1-Si1 173.4(1), O15-Si1-O16 99.7(2), O15-Si1-N11 95.8(2), O16-Si1-N11 93.9(2), N12-P1-N13 101.8(3), O14-P1-N12 95.2(3), O14-P1-N13 104.1(3).

ligand exchanged with two NMe_2 substituents on the silicon atom; this resulted in the formation of a $HNMe_2$-stabilized (diethoxy)silylene complex.[9] The asymmetric unit of **5** comprises two independent but similar molecules of **5**, which are connected through hydrogen bonds (Fig. 2). The coordination

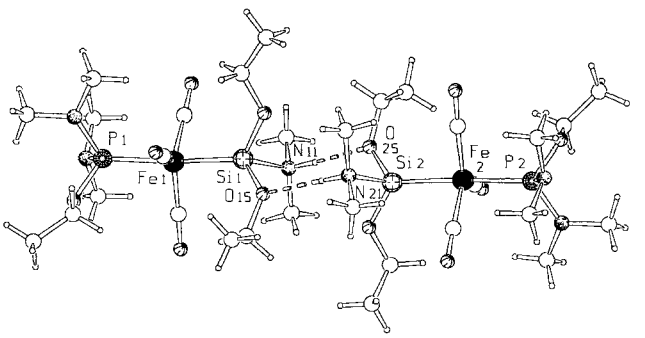

Fig. 2. The pseudo-dimer of **5** resulting from the hydrogen bonds between the molecules [13c].

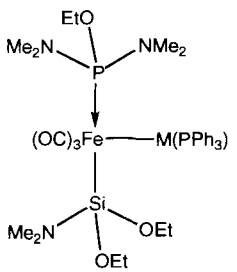
about the Fe atom is trigonal bipyramidal with a *trans* arrangement of the P-Fe-Si atoms. The metal–Si bond length of 2.218(2) Å [2.216(2) Å in the second molecule] is one of the shortest reported for Fe–silylene complexes.[7] One of the NMe_2 groups attached to P is planar, whereas the other is pyramidal. This is indicative of some π bonding between N and P atoms.[10] In addition, there are mutual hydrogen bonds between two molecules in the solid state, involving the amine H atom of one molecule and the O atom of a SiOEt group of the other molecule. The corresponding distances [N(11)···O(25) = 2.871(7) and N(21)···O(15) = 2.959(7) Å] are consistent with strong interactions;[11] these generate an almost centrosymmetric dimer with a chairlike arrangement of the resulting six-membered ring. The hydrogen bonds contribute significantly to the stabilization of **5** and explain its low solubility in hexane. Accordingly, in donor solvents like THF, the stability of **5** is drastically reduced.



Irradiation or heating of a mixture of $P(OEt)_3$ and $HSi(NMe_2)_3$ did not lead to scrambling of their substituents. The reac-

tion of **2** with $P(OEt)_3$ under similar conditions (*hv*, 4 h, −22 °C) afforded **5** in only 14% yield. These experiments show that the oxophilicity of silicon is sufficient to allow the selective transfer of two OEt substituents from P to Si, but that this reaction requires prior coordination to the metal, preferably of the phosphite ligand. Whether other metals are capable of promoting this reaction, which connects the isosteric pairs M←P/OR and M−Si/NR_2 (or M←P/NR_2 and M−Si/OR) and transforms $P(OEt)_3$ and -$Si(NMe_2)_3$ into $P(OEt)(NMe_2)_2$ and -$Si(OEt)_2(NMe_2)$, is under investigation.

Deprotonation of **5** by KH in THF yielded the metalate complex **7** [$\tilde{\nu}$(CO) (THF) = 1807 (s), 1841 (vs), 1921 (w) cm^{-1};

$K[Fe(CO)_3\{P(OEt)(NMe_2)_2\}\{Si(OEt)_2(NMe_2)\}]$ **7**

$^{31}P\{^1H\}$ NMR(CD_2Cl_2, 25 °C): δ = 207.2], which was reacted with M^I complexes (M = Cu, Ag, Au) to afford the heterobimetallic complexes **6a–c**. The two doublets with $^3J(PP)$ = 12 Hz observed in the $^{31}P\{^1H\}$ NMR spectrum of **6c** confirm the presence of a metal–metal bond. The ^1H NMR data indicate that the substituents of the Fe-bound P and Si ligands have not exchanged further. However, there is a notable shift of the $SiNMe_2$ resonance compared to that of **5**, which is consistent with the change in the nature of the Fe–Si bond in moving from silylene in **5** to silyl in **6**. The IR and $^{31}P\{^1H\}$ NMR data for these complexes are similar to those for complexes such as $[(OC)_3(Ph_3P)\text{-}\{(MeO)_3Si\}Fe\text{-}Au\text{-}(PPh_3)]$.[12] These results indicate that deprotonation of the Si-bound nitrogen atom of **5** restores sufficient basicity to the Fe atom in **7** for the formation of stable (dialkoxy)aminosilyl heterobimetallic complexes.

6a M = Cu
6b M = Ag
6c M = Au

Experimental Procedure

2: A mixture of $[Fe(CO)_5]$ (2.35 g, 12.0×10^{-3} mol) and $HSi(NMe_2)_3$ (3.80 mL, 20.0×10^{-3} mol) in hexane (500 mL) was irradiated with a 150 W lamp for 4 h at −20 °C. A white powder precipitated during irradiation. The solvent was decanted, and the solid collected and dried in vacuo. Yield: 2.77 g (70% based on $[Fe(CO)_5]$.

3a,b: A solution of **2** (1.20×10^{-3} mol) in toluene (20 mL) was added dropwise to a stirred solution of $[Pt(C_2H_4)(PR_3)_2]$ (for **3a**: R = Ph, **3b**: R = *p*-tolyl; 1.20×10^{-3} mol) in toluene (30 mL) at −45 °C. The yellow solution was allowed to warm to room temperature and after completion of the reaction (4 h, monitored by IR) it was evaporated to dryness. Addition of hexane caused precipitation of a yellow product which was filtered off and dried in vacuo. Isolated yield: 1.02 g of **3a** (85%) and 1.02 g of **3b** (78%).

3c: A solution of dppe (0.12 g, 0.30×10^{-3} mol) in toluene (20 mL) was added dropwise to a stirred solution of **3a** (0.30 g, 0.30×10^{-3} mol) in toluene (30 mL) at −45 °C. The orange-yellow solution was slowly evaporated to dryness. Addition of hexane caused precipitation of solid material identified as a mixture of **3c** (80%), $[Pt(dppe)_2]$ (20%), and free PPh_3.

5: A sample of $[Fe(CO)_4\{P(OEt)_3\}]$ (4.0 g, 12.0×10^{-3} mol) and $HSi(NMe_2)_3$ (3.80 mL, 20.0×10^{-3} mol) in diethyl ether (500 mL) was irradiated with a 150 W lamp for 4 h at −20 °C. Concentration and addition of hexane at −20 °C yielded pale brown crystals. Yield: 3.93 g (70% based on $[Fe(CO)_4\{P(OEt)_3\}]$).

6a–c: A solution of **7** in THF (20 mL) was prepared in situ from **5** (0.80×10^{-3} mol) and KH (in excess). This was filtered and added to a stirred suspension of $[MX(PPh_3)]$ (for **6a**: M = Cu, X = Cl; **6b**: M = Ag, X = NO_3; **6c**: M = Au, X = Cl; 0.80×10^{-3} mol) in THF (10 mL) at −45 °C. The mixture was slowly evaporated to dryness. Addition of hexane caused the precipitation of **6a** and **6c**. Complex **6b** was too labile to be isolated in the solid state and was only characterized in solution. Yield: 0.49 g of **6a** (78%) and 0.41 g of **6c** (55%).

[9] Crystals of **5**, $C_{15}H_{34}FeN_3O_6PSi$, were grown from a ether/hexane solution of the compound. Data were collected at −90 ± 2 °C. The compound crystallizes in space group $P2_1/a$, a = 15.302(8), b = 17.129(3), c = 18.42(2) Å; β = 109.38(4)°, V = 4556(5) Å^3; Z = 8; μ_{calcd} = 0.818 mm^{-1}; $F(000)$ = 1984. A total of 8180 unique reflections were measured in the range $6.02 \le 2\theta \le 52.58°$, of which 8062 were used for refinement and 5208 with $I > 2\sigma(I)$. The structure was solved by direct methods (hydrogen atoms were introduced in calculated positions) [13a]. Least squares refinement was performed by means of the full matrix on F^2 [13b]. R (obs.) = 0.0743, wR (obs.) = 0.1869. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-380065.

The Crystal Structures of Base-Free, Monomeric Arylcopper(I) and Arylsilver(I) Compounds; Two Cases of Mistaken Identity?**

Arne Haaland,* Kristin Rypdal, Hans Peter Verne, Wolfgang Scherer, and Werner Richard Thiel

In 1988 Lingnau and Strähle reported the syntheses of two base-free arylcopper and arylsilver compounds [M(Ar)] (Ar = 2,4,6-$Ph_3C_6H_2$; M = Cu, Ag).[1] X-ray structure analysis showed that both compounds are monomeric in the crystalline phase and yielded the bond lengths Cu–C = 189.0(6) and Ag–C = 190.2(5) pm.[1] These bond lengths remain the only experimentally determined bond lengths between monocoordinate copper or silver centers and carbon, and provide important benchmarks for comparison with Cu–C and Ag–C bond lengths in more complex structures.

Base-free organocopper(I) and organosilver(I) compounds are generally polymeric in the solid phase. Thus CuMes (Mes = 2,4,6-$Me_3C_6H_2$, mesityl) forms a pentamer with a ten-membered ring composed of alternating metal atoms and carbon atoms of the bridging aryl groups, while AgMes forms a cyclic tetramer.[2] 2,4,6-Triisopropylphenylcopper and trimethylsilylmethylcopper both form tetramers in the solid phase.[3, 4]

The close similarity of the Cu–C and Ag–C bond lengths obtained by Lingnau and Strähle is surprising: In the gaseous hydrides MH(g) the Ag–H bond length of 162 pm is 16 pm longer than the Cu–H bond length of 146 pm; in the gaseous monomeric chlorides MCl(g) the Ag–Cl bond length of 228 pm is 23 pm longer than the Cu–Cl bond length of 205 pm.[5] The lengths of the element–carbon bonds in simple methyl derivatives of elements of the fourth period from Zn to Br fall in the relatively narrow range from 193 to 197 pm, while the bond lengths in analogous compounds of elements of the fifth period from Cd to I fall in the range from 211 to 216 pm. The bond between a carbon atom and an element of the fifth period is, on the average, 19 pm longer than that between a carbon atom and an element of the fourth period in the same group.[6] These correlations suggest that if the Cu–C bond length is 189 pm, the Ag–C bond length should be approximately 208 pm.

We have carried out ab initio MO calculations on $CuCH_3$ and $AgCH_3$ to see whether we could reproduce the experimental bond lengths reported by Lingau and Strähle. Structure optimization at the all-electron TZ/MP2 level yielded the bond lengths of 191 pm for Cu–C and 218 pm for Ag–C. Since relativistic effects have been neglected, the value obtained in this manner for the Ag–C bond is expected to be roughly 4 to 8 pm too large.

Before our calculations had been published, they were superseded by more accurate calculations by Bauschlicher et al.[7] Their all-electron calculations on $CuCH_3$ at the TZ + P/MCPF level yielded an optimal Cu–C distance of 193.6 pm; relativistic core potential (RCP) calculations on $AgCH_3$ at the TZ + P/MCPF level yielded an Ag–C distance of 214.6 pm.[7]

[**] This research was supported by the VISTA program of STATOIL and the Norwegian Academy of Science and Letters. We thank Prof. J. Strähle for helpful correspondence.

We therefore decided to request copies of the X-ray data deposited by Lingnau and Strähle and repeat the structure refinements.[8] Figure 1 top shows the reported structure for [Ag(Ar)]. The calculated thermal displacement parameters of

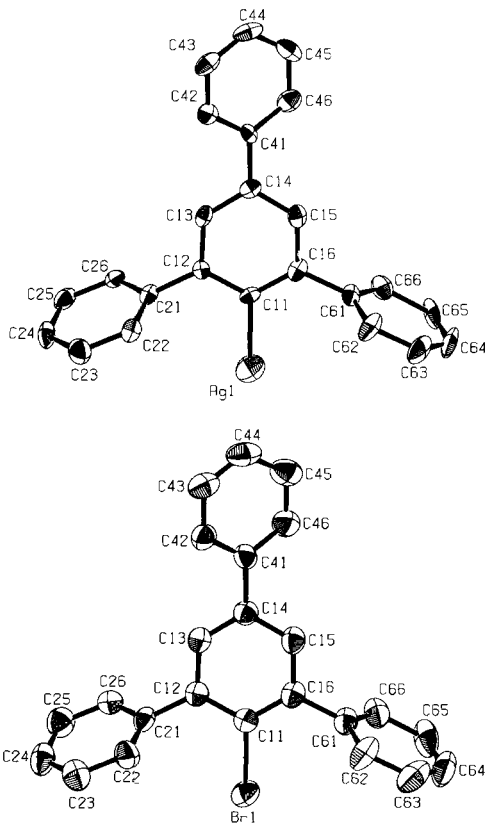

Fig. 1. Top: The published crystal structure of [Ag(Ar)] [1]. The hydrogen atoms are omitted; the thermal ellipsoids correspond to 50% probability. (PLATON drawing, measurement at ambient temperature, extinction correction and empirical absorption (DIFABS) applied. $U_{eq(C)} = 3.2 \times 10^2$ pm^2, $U_{eq(M)} = 5.8 \times 10^2$ pm,^{2}, $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.082$, $R_w = [\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2} = 0.107$). Bottom: Structure model of BrAr resulting from refinement on the data collected for [Ag(Ar)]. Thermal ellipsoids correspond to 50% probability (no extinction correction applied, weighting scheme ($w = 1/\sigma^2(F_o)$, $U_{eq(C)} = 5.1 \times 10^2$ pm^2, $U_{eq(Br)} = 5.5 \times 10^2$ pm^2, $R = \sum(||F_o| - |F_c||)/\sum|F_o| = 0.041$, $R_w = [\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2} = 0.030$)).

the carbon atoms, $U_{eq(C)} = 3.2 \times 10^2$ pm^2, are unusually small compared with the corresponding parameter of the metal atom, $U_{eq(M)} = 5.8 \times 10^2$ pm^2. Such a relationship between the thermal parameters indicates that a metal atom was incorrectly identified.[11] Obviously the electron density at the position of the silver atom in the observed Fourier map is much smaller than calculated, and the thermal parameters of the metal and carbon atoms have been adjusted by the least-squares routines to reduce the discrepancy. Lingnau and Strähle also performed an empirical absorption correction (DIFABS) and refined the secondary extinction parameter (as mentioned in the copies of the deposited crystallographic data), which resulted in further reduction of the discrepancy. Refinements of the structure without an extinction correction and using a weighting scheme $w = 1/\sigma^2(F_o)$ result in unreasonable anisotropic thermal displacement parameters, which are also indicative for poor data or an incorrect model.

Refinements based on the "Ag data" and on the assumption that the crystal consisted of pure [Cu(Ar)] (which implies a smaller electron density at the metal atom) proceeded without

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/2323-2443 $ 10.00+.25/0

difficulties to yield a significant improvement of the fit (Table 1) and a reasonable ratio of the thermal displacement parameters: $U_{eq(C)}/U_{eq(M)} = 0.88$.[11c] Refinements based on an assumed composition of BrAr (isomorphic replacement of the silver atom by bromine) provide in an even better fit (Table 1 and Fig. 1 bottom). *These results show that the data cannot have been recorded with a crystal of pure [Ag(Ar)].*

Table 1. Unit cell parameters obtained by crystal structure refinements on the data deposited by Lingnau and Strähle [1] (referred to as Ag data and Cu data) and our data for BrAr (Br data) [a].

Data set	Assumed composition	E–C bond length [b] [pm]	R (R_w)	Parameter
Ag data	[Ag(Ar)]	188(1)	0.106 (0.112)	at 18 °C: $P2_1/c$;
	[Cu(Ar)]	188.5(7)	0.051 (0.042)	$a = 1063.6(2)$,
	BrAr	189.5(5)	0.041 (0.030)	$b = 1510.5(4)$,
				$c = 1253.4(4)$ pm;
				$\beta = 113.55(2)°$;
				$V = 1846 \times 10^6$ pm^3
Cu data	[Ag(Ar)]	191(2)	0.118 (0.118)	at 18 °C: $P2_1/c$;
	[Cu(Ar)]	188.4(5)	0.043 (0.036) [c]	$a = 1065.7(4)$,
	BrAr	190.6(5)	0.046 (0.036) [c]	$b = 1508.3(9)$,
				$c = 1252.6(9)$ pm;

				$V = 1844 \times 10^6$ pm^3
Br data	[Ag(Ar)]	187(2)	0.107 (0.108)	at 23 ± 1 °C: $P2_1/c$;
	[Cu(Ar)]	187.6(6)	0.042 (0.032) [c]	$a = 1068.0(2)$,
	BrAr	189.2(5)	0.047 (0.034) [c]	$b = 1509.4(1)$,
				$c = 1251.3(2)$ pm;
				$\beta = 113.634(7)°$;
				$V = 1848 \times 10^6$ pm^3

[a] Three structure refinements were carried out with each data set, one under the assumption that the crystal consists of pure [Ag(Ar)], another under the assumption that it consists of pure [Cu(Ar)], and the third under the assumption that it consists of pure BrAr. Refinements based on the composition [Ag(Ar)] were carried out without extinction correction and using a weighting scheme $w = 1/\sigma^2(F_o)$ with isotropic thermal displacement parmeters for carbon atoms; refinements of anisotropic thermal displacement parameters yielded unreasonable results (see text). [b] Ag–C, Cu–C, or Br–C bond. [c] The atom form factors of Cu and Br are apparently too similar to allow distinction of the two elements based on X-ray data [12].

Lingnau and Strähle prepared the two aryl metal complexes from the aryl bromide BrAr, which was treated with magnesium in tetrahydrofuran to give the Grignard compound ArMgBr, which in turn was reacted with solid CuCl or AgCl to yield crystalline, colorless, and air-stable [Cu(Ar)] and [Ag(Ar)] in 65 and 52% yield, respectively. The compounds were characterized by elemental analysis for C and H, but apparently not for the metal or Br.[1]

The ^{1}H and ^{13}C NMR spectra of the two compounds in $CDCl_3$ appear indistinguishable, and identical δ values for all carbons in the two compounds were reported (Table 2).[1b] The ^{1}H spectra contain a number of lines between $\delta = 7.36$ and 7.66; a strong singlet at $\delta = 7.58$ was assigned to H-3 and H-5. The IR spectra are also very similar; both contain a band at 490 cm^{-1} which was assigned to the M–C stretching vibration.[1b] The melting points are given as 121 °C (Cu) and 116 °C (Ag).[1b] The two compounds are isotypic (Table 1).

It would therefore appear possible that Lingnau and Strähle inadvertently exchanged crystals of the arylcopper and arylsilver compounds. Another possibility might be that the Ag data were collected with a crystal containing significant amounts of the starting material BrAr.[13]

Table 2. ^{13}C NMR spectroscopic data of [Cu(Ar)] and [Ag(Ar)] (reported by Lingnau and Strähle [1b]) and of BrAr (our data).

δ ^{13}C{^{1}H} [M(Ar)] [b]	BrAr	Assignment [a]	δ ^{13}C{^{1}H} [M(Ar)] [b]	BrAr	Assignment [a]
144.13	144.11	C-12,16	141.99	141.98	C-21
139.85	139.83	C-14	139.50	139.48	C-41
129.49	129.46	C-22,26	128.87	128.85	C-43,45
128.67	128.64	C-13,15	127.94	127.92	C-23,25
127.76	127.72	C-44	127.58	127.55	C-24
126.98	126.95	C-42,46	122.11	122.08	C-11

[a] From ref. [1b]. [b] M = Cu, Ag.

At this point it may be pertinent to point out that even though organocopper and organosilver compounds generally are very sensitive to oxygen and water, [Cu(Ar)] and [Ag(Ar)] were reported to be air-stable.[1] In addition organosilver compounds are generally light-sensitive, but no such sensitivity is mentioned in ref. [1]. We decided, therefore, to prepare BrAr in order to compare its properties with those reported for the metal analogues.

We found the ^{1}H and ^{13}C NMR spectra of BrAr to be indistinguishable from those reported for [Cu(Ar)] and [Ag(Ar)][1b] (δ(^{13}C) shifts in Table 2). Even the shifts for the *ipso* C atom (C-11) in the three compounds are equal to within $\Delta\delta = 0.03$. The IR spectrum of BrAr is similar to those of [Cu(Ar)] and [Ag(Ar)] reproduced in ref. [1b]. An absorption band is found at 494 cm^{-1} for BrAr, comparable to one at 490 cm^{-1} for [Cu(Ar)] and [Ag(Ar)], which we assign to an out-of-plane skeletal vibration.[14a] The C–Br stretching vibration of aromatic hydrocarbons is usually located in the region from 1075 to 1030 cm^{-1}.[14b] We found an absorption line in the IR spectrum of BrAr at 1073 cm^{-1} which is also present in the IR spectra of [Cu(Ar)] and [Ag(Ar)].[1b] The melting points reported for [Cu(Ar)] and [Ag(Ar)] recrystallized from chloroform/ethanol mixtures fall in the range spanned by the melting points of BrAr recrystallized from different solvents (see Experimental). The crystal structures of the three compounds are isotypic (see Table 1).[15] Refinement of the crystal structure of BrAr yields a C–Br bond length of 189.2(5) pm,[14] which is comparable to that obtained for monobromobenzene by gas electron diffraction (189.8(1) pm).[17]

Finally we have compared the Cu data and the Ag data to the Br data by refining a scaling factor by least squares calculations on the reflections common to the two data sets; this is 621 reflections for Ag and Br data and 646 reflections for Cu and Br data. The Ag data yielded a scaling factor of 30.7(1.6) and an R_w value of 0.050; the Cu data yielded a scaling factor of 22.2(2.2) and an R_w value of 0.052. We feel that the agreement is too close to rule out the possibility that the three data sets were recorded with crystals having the same chemical composition.

Thus we conclude: 1) The crystal used by Lingnau and Strähle[1] to determine the molecular structure of [Ag(Ar)] did not consist of the pure compound. We suggest that the crystal consisted partly or entirely of the starting material. 2) The crystal used by Lingnau and Strähle[1] to determine the structure of [Cu(Ar)] may have consisted partly or entirely of the starting material BrAr. We suggest that the investigation should be repeated before the results of Lingnau and Strähle can be regarded as established.

Experimental Procedure

1-Bromo-2,4,6-triphenylbenzene (BrAr): 1,3,5-Triphenylbenzene (10.0 g, 32.7 mmol) was dissolved in 100 mL of CS_2 in a 250 mL two-necked flask equipped with a reflux condenser and a dropping funnel. After the addition of Fe powder

(0.1 g), bromine (5.49 g, 34.3 mmol) was added dropwise and the mixture stirred for 30 min. The solvent was removed in vacuo, the residue dissolved in diethyl ether, and the solution filtered over Al_2O_3. The crude product was recrystallized from ethanol/diethyl ether. Yield: 10.6 g (84%). The product was pure by gas chromatography (GC/MS). Elemental analysis; calcd (found): C 74.82 (73.99), H 4.45 (4.42). M.p. 128.5 °C from isopropanol (ref. [18]: 129–130 °C); 109 °C from ethanol (ref. [18]: 108 °C). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, $CDCl_3$): $\delta = 7.70$ (H-42,46), 7.65 (H-13,15), 7.60 (H-22,26), 7.54 (H-23,25), 7.50 (H-43,45), 7.49 (H-24), 7.43 (H-44). ^{13}C NMR data are listed in Table 2.

[8] The X-ray data for [Ag(Ar)] and [Cu(Ar), referred to in the text as "Ag data" and "Cu data", respectively, had been deposited at the Fachinformationszentrum Karlsruhe [1]. We received 1560 ([Ag(Ar)]) and 1772 ([Cu(Ar)]) independent reflections with $I > 3\sigma(I)$. The numbers of deposited reflections with $I > 3\sigma(I)$ is thus less than those reported by Lingnau and Strähle (1710 and 1946 reflections, respectively). We excluded two reflections of the [Cu(Ar)] data that should be systematically absent. The *R*-factors of the published and deposited data are slightly different in the case of [Ag(Ar)]. An empirical absorption correction (DIFABS) of both data sets had been performed by Lingnau and Strähle. No further corrections were made. All calculations were performed on a DECstation 5000/25 computer with the programs CRYSTALS [9] and PLATON [10].

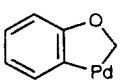
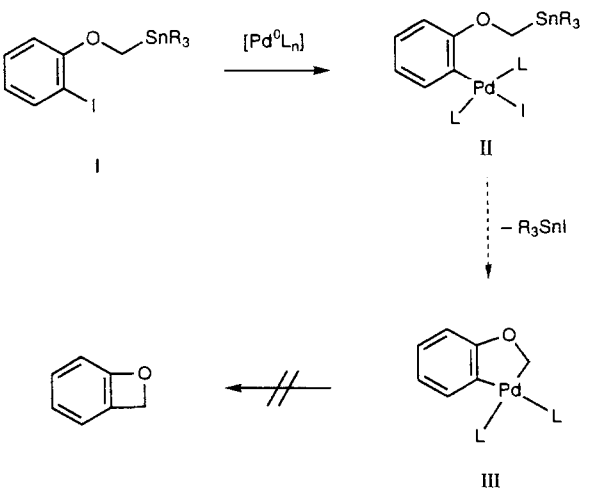
Synthesis of Oxa- and Azapalladacycles from Organostannanes**



Diego J. Cárdenas, Cristina Mateo, and Antonio M. Echavarren*

Palladium-catalyzed cascade reactions that proceed by means of successive Heck insertions expedite the construction of complex molecules in a single step.[1, 2] A number of more complex sequential reactions proceeding through palladacycles such as **1** show promise in the synthesis of complex targets.[3–5] These cascade reactions are initiated by oxidative addition of aryl halides ArX to a $[Pd^0L_n]$ complex to give $[Pd(Ar)X(L)_2]$.[3, 4] Insertion of norbornene into the Pd–C bond of the arylpalladium complex leads to formation of a labile η^2-aryl complex,[6] which reacts further by intramolecular C–H activation of the aryl ring to form complexes of type **1**.[3, 7, 8] New C–C bonds are formed by reaction of palladacycles such as **1** with alkyl halides to give hexacoordinated Pd^{IV} complexes, followed by reductive elimination.[7, 9–11]



1

Recently, a series of novel palladium-catalyzed cascade reactions leading to the formation of heterocyclic compounds were described by Dyker.[12] In the reaction with *o*-iodoanisole, palladacycle **2** was proposed as an intermediate formed by a new intramolecular C–H activation of the methoxy group.[12, 13] A milder procedure for the synthesis of these intermediate palladacycles could be conceived-based on an intramolecular Stille coupling[14, 15] of an iodoaryl stannane **I** (Scheme 1). Oxidative addition of stannane **I** to a palladium(0) complex would furnish intermediates **II**, which could undergo an intramolecular transmetalation[16] at the OCH_2–Sn bond to give the desired complexes **III**. Endocyclic restriction[17] would disfavor the alternative cleavage of the Sn–R bonds. The reductive elimination of the two

mutually *cis* organic ligands is fast in the Stille cross-coupling reaction,[14, 15] even when the elimination leads to the formation of four-membered rings.[18] However, the reductive elimination was expected to be slow in our case, owing to the high energy of the product 2*H*-benzoxete.[19] Herein we report on the successful application of this scheme to the synthesis of oxapalladacycles and an aza derivative related to **2** and the preliminary results on the reactivity of these complexes.

Oxapalladacycle **3** with two triphenylphosphane ligands was synthesized in two steps as shown in Scheme 2. Alkylation of *o*-iodophenol with stannanes **4** or **5**[20] (K_2CO_3, DMF, 70 °C, 15 h) gave **6** and **7**, respectively.[21] Reaction of these stannanes with $[Pd(PPh_3)_4]$ (1 equiv) in toluene at 45 °C for 24 h afforded **3** as an air-stable white powder. The primary oxidative-addition product of the iodoarene to the Pd^0 complex could not be isolated. The structure of **3** was established by ^1H, ^{13}C, and ^{31}P NMR spectroscopy, including heteronuclear correlation experiments (HMQC[22a] and HMBC[22b], Table 1). As expected, **3** did not undergo reductive elimination after prolonged heating in benzene at 80 °C.

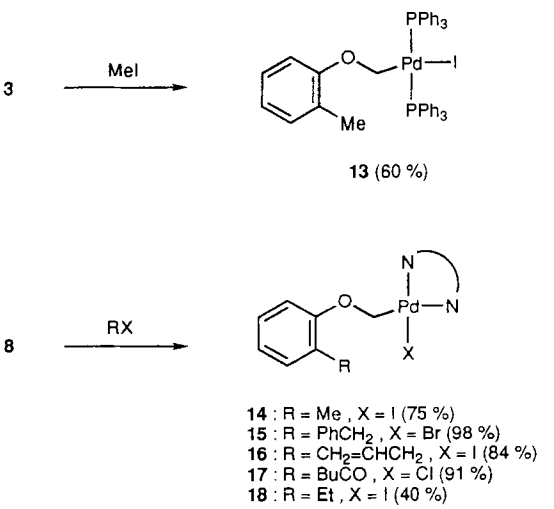
Scheme 2.

Ligand exchange with 9,10-phenanthroline (phen) (10 equiv, CH_2Cl_2, reflux) afforded **8** (Scheme 3). Reaction of **3** with *tert*-butyl- or 2,6-dimethylphenylisocyanide led to complexes **9** and **10**, respectively. The selective substitution of the phosphane *cis* to the aryl ligand reflects the higher *trans* effect of the OCH_2 ligand.[7, 23] Neither substitution of the second phosphane ligand, nor isocyanide insertion reaction[24] were observed under more severe conditions. On the other hand, the metallacycle **11** with two *cis* isocyanide ligands could be prepared from **8** by substitution of the phenanthroline ligand at 23 °C. This organometallic Pd^{II} complex is a rare example of an organopalladium derivative with four Pd–C bonds.[25]

Scheme 3.

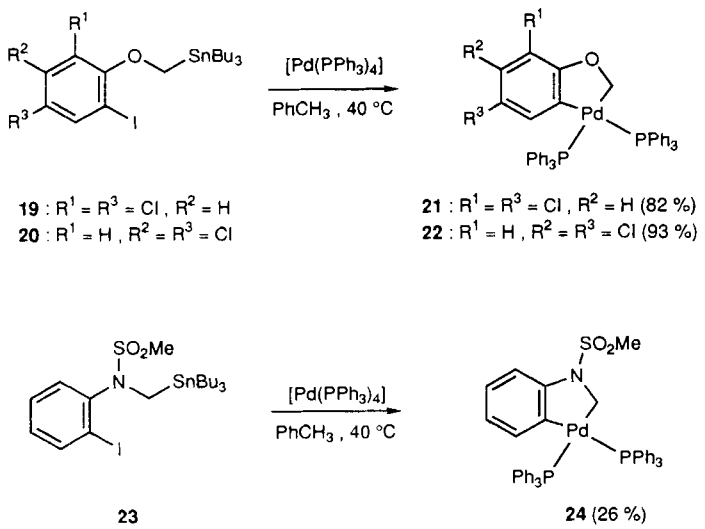


Treatment of **3** with carbon monoxide (3.5 atm, 60 °C, 15 h) failed to give any insertion product. However, dimethyl acetylenedicarboxylate smoothly reacted with **3** ($CHCl_3$, 40 °C, 1 h) by insertion into a C–Pd bond, followed by reductive elimination leading to chromene **12**. The known complex $[Pd(MeO_2CC{\equiv}CCO_2Me)(PPh_3)_2]$ was also isolated in this reaction (91 % yield).[26] Heterocycle **12** could also be obtained in almost quantitative yield by reaction of complex **9** with dimethyl acetylenedicarboxylate (23 °C, 13 h) (Scheme 3).

Oxapalladacycle **3** reacted slowly at 23 °C with methyl iodide in acetone to give **13** after 24 h (Scheme 4). Palladacycle **8** was

Table 1. Selected NMR data ($CDCl_3$) for palladacycles **3** and **24**.

3: ^1H NMR (300 MHz): $\delta = 7.50-7.35$ (m, 12H), 7.32–7.11 (m, 12H), 7.09–7.05 (m, 6H), 6.78 (m, 1H), 6.71 (ddd, $J = 7.9, 2.8, 1.6$ Hz, 1H), 6.61 (tdd, $J = 7.5, 2.5, 1.5$ Hz, 1H), 6.06 (ddt, $J = 7.6, 6.9, 1.6$ Hz, 1H), 5.18 (dd, $J = 5.6, 3.3$ Hz, 2H); $^{13}C\{^1H\}$ NMR (75 MHz; DEPT): $\delta = 174.60$ (dd, $^3J(C,P) = 7.3, 5.5$ Hz; C), 149.27 (dd, $^2J(C,P) = 100.0, 11.7$ Hz; C), 141.71 (dd, $^3J(C,P) = 8.9, 3.0$ Hz; CH), 135.20 (d, $^2J(C,P) = 13.3$ Hz, $CH(PPh_3)$), 134.19 (d, $^2J(C,P) = 13.2$ Hz; $CH(PPh_3)$), 134.03 (dd, $^1J(C,P) = 30.9$ Hz, $^3J(C,P) = 1.9$ Hz; $C(PPh_3)$), 132.10 (dd, $^1J(C,P) = 35.5$ Hz, $^3J(C,P) = 1.8$ Hz; $C(PPh_3)$), 129.84 (d, $^4J(C,P) = 2.0$ Hz; $CH(PPh_3)$), 129.47 (d, $^4J(C,P) = 1.9$ Hz; $CH(PPh_3)$), 127.99 (d, $^3J(C,P) = 9.8$ Hz; $CH(PPh_3)$), 127.76 (d, $^3J(C,P) = 9.3$ Hz; $CH(PPh_3)$), 125.30 (CH), 116.65 (dd, $^4J(C,P) = 7.9, 3.0$ Hz; CH), 107.82 (CH), 93.49 (dd, ^2J (C,P) = 90.8, 6.4 Hz; CH_2); $^{31}P\{^1H\}$ NMR (121.5 MHz): $\delta = 28.39$ (d, $J = 25.6$ Hz, 1P), 25.52 (d, $J = 25.6$ Hz, 1P).



24: ^1H NMR (300 MHz): $\delta = 7.60-7.05$ (m, 31H), 6.82–6.71 (m, 2H), 6.25 (brt, $J = 7.4$ Hz, 1H), 3.98 (dd, $J = 6.6, 4.2$ Hz, 2H), 2.76 (s, 3H); $^{13}C\{^1H\}$ NMR (50 MHz): $\delta = 154.39$ (dd, $^2J(C,P) = 105.3, 8.3$ Hz); 141.66 (brd, $^3J(C,P) = 11.4$ Hz), 135.02 (d, $^2J(C,P) = 13.4$ Hz; PPh_3), 134.03 (d, $^3J(C,P) = 13.8$ Hz; PPh_3), 132.86 (brd, $^1J(C,P) = 44.6$ Hz; PPh_3), 131.83 (brd, $^1J(C,P) = 30.7$ Hz; PPh_3), 129.97 (brs; PPh_3), 129.64 (brs; PPh_3), 128.14 (d, $^3J(C,P) = 8.6$ Hz; PPh_3), 127.81 (d, $^3J(C,P) = 9.2$ Hz; PPh_3), 124.47 (s), 122.54 (brs), 121.66 (brd, $^3J(C,P) = 9.0$ Hz), 115.82 (s), 61.62 (dd, $^2J(C,P) = 88.6, 5.4$ Hz), 33.23 (s); $^{31}P\{^1H\}$ NMR (121.5 MHz): $\delta = 27.45$ (d, $J = 25.8$ Hz, 1P), 25.84 (d, $J = 25.8$ Hz, 1P).

Scheme 4.

more reactive at 23 °C: treatment with methyl iodide, benzyl bromide, allyl iodide,[27] and pentanoyl chloride led to complexes **14**–**17**, respectively, after 1–4 h (Scheme 4). Ethyl iodide reacted more sluggishly with **8** ($CDCl_3$, reflux, 18 h) to give **18**, and starting material was recovered with 2-iodopropane and methyl *p*-toluenesulfonate.[28] The reactions with the alkyl halides probably proceed by oxidative addition to give a Pd^{IV} intermediate, which undergoes aryl–alkyl or aryl–acyl reductive elimination to yield the observed Pd^{II} complexes. The reductive elimination is very selective in these cases, leading to exclusive bond formation with the aryl ligand.[7–11] Surprisingly, reaction of **3** with (*E*)-1-iodo-2-phenylethene in acetone at 23 °C led to (*E*)-triphenylvinylphosphonium iodide and a complex mixture of palladium complexes. The vinyl phosphonium salt could be also prepared by reaction of the vinyl iodide with triphenylphosphane in the presence of catalytic amounts of $[Pd(PPh_3)_4]$.[29] On the other hand, iodobenzene and *o*-iodomethoxybenzene were not reactive with either **3** or **8** even under forcing conditions. The lack of reactivity of the palladacycles with aryl iodides suggests that a more complex reaction pathway not involving Pd^{IV} species may be operating in the formation of aryl–aryl bonds under catalytic conditions.[30]

The synthesis of **3** could be extended to the preparation of substituted oxapalladacycles. Thus, dichloroiodoaryl stannanes **19** and **20** yielded oxapalladacycles **21** and **22**, respectively (Scheme 5). The aminomethyl stannane **23** also reacted with

Scheme 5.

$[Pd(PPh_3)_4]$ to afford the novel azapalladacycle **24** (Table 1) as a white solid that slowly decomposed in $CDCl_3$. The lower yield may be due to decomposition by reductive elimination to give a 1,2-dihydrobenzazete.[31]

The synthesis of oxa- and azapalladacycles described here extends considerably the existing methods for the preparation of metallacycles. These palladacycles are new members of the little studied class of alkyl(aryl)palladium(II) complexes.[3, 8, 11] With the preparation of **3** and related palladacycles, we are now in a position to study their role in the formation of aryl–aryl bonds. In addition, investigations into the catalytic transformations of iodostannanes such as **6**, **7**, and **23** are being pursued.

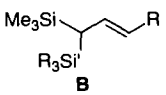
A Regioselective Palladium-Catalyzed Reduction of 3,3-Heterobimetalated Allylic Acetates—Synthesis and Reactivity of Allylic Bimetallic Compounds**

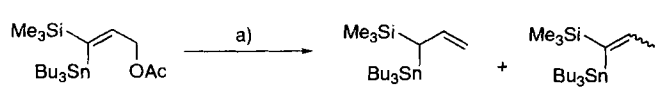


Mark Lautens* and Patrick H. M. Delanghe

Bimetallic reagents have found widespread use in organic synthesis as coupling reagents.[1] These reagents are particularly interesting when a difference in reactivity of the two metals allows selective reaction of one organometallic group.[2]

As part of our continuing interest in the synthesis and reactivity of novel homo- and heterobimetallic reagents containing tin and silicon,[3, 4] we envisioned that stannylsilyl- and disilyl-substituted allylic reagents **A** and **B** would be useful building blocks in organic synthesis.

A



B

Both allylic silanes[5] and allylic stannanes[6] have been shown to be extremely useful reagents for the regio-, diastereo-, and enantioselective construction of C–C bonds. Since allylic stannanes display a higher reactivity towards electrophiles than allylic silanes,[7] selective C–C coupling reactions of the allylic tin moiety of the bimetallic reagent were thought to be feasible. However, there is no general route to these simple bimetallic species.[2c] An appealing and straightforward approach towards **A** via the allyltrimethylsilyl anion yielded predominantly its regioisomer.[8]

The palladium-catalyzed nucleophilic displacement of the acetate unit of allylic acetates by a hydride is ideally suited to achieve this goal. Allylic acetates undergo efficient palladium(0)-catalyzed substitution reactions with a variety of nucleophiles.[9] Control of regiochemistry of the product is determined by the steric hindrance at the termini of the π-allylpalladium intermediate and by the character and size of the incoming nucleophile. Reactions of π-allylpalladium complexes with hydride as a nucleophile are also well known. The regioselectivity observed is highly dependent on the hydride reagent selected: $LiAlH_4$,[10] $Bu_3SnH(D)$,[11] $LiBHEt_3$,[12] and silicon hydrides[13] deliver the hydride at the less substituted terminus of the π-allylic ligand, while hydride generated from formate is delivered selectively to the more substituted position.[14]

When we subjected the allylic acetate **1a** to the reducing conditions of formate in the presence of palladium (2 mol%), **2a** was obtained as the sole product in high yield (Scheme 1).[4] No decomposition of the resulting silylstannyl compound was observed under the reaction conditions. This is quite surprising since allylic stannanes have been used as nucleophiles in the palladium-catalyzed allylation of allylic acetates.[15] Moreover, delivery of the hydride was highly regioselective to the more substituted carbon of the π-allylic ligand.

1a **2a** >99.5:0.5 **3a**

Scheme 1. a) 1 Mol% $[Pd_2(dba)_3]$, 8 mol% PPh_3, 3 equiv HCO_2H, 3 equiv Et_3N, dioxane, 3 h under reflux; 99% yield.

A variety of bimetalated allylic reagents can be prepared in nearly quantitative yield and excellent selectivity (Table 1, entries 1–5). With the alkyl-substituted allylic acetates **1b–d**, only the *E* isomers were obtained. The reaction was generally performed in refluxing dioxane or THF and was complete in 3–24 h. As expected, the allylic chloride **4** reacted even faster (entry 6). Disilyl-substituted allylic groups containing two different silyl moieties can also be obtained. However, while the disilyl-substituted allylic acetate **5a** (tBuMe$_2$Si, Me$_3$Si) reacted almost exclusively at the γ-position (entry 7), the sterically more encumbered substrate **5b** (iPr$_3$Si, Me$_3$Si, entry 8) gave a 2.5:1 mixture of **6b** and **7b**.

Tsuji was the first to show that the ligand plays an important role in the regioselectivity of the hydride delivery.[14c]

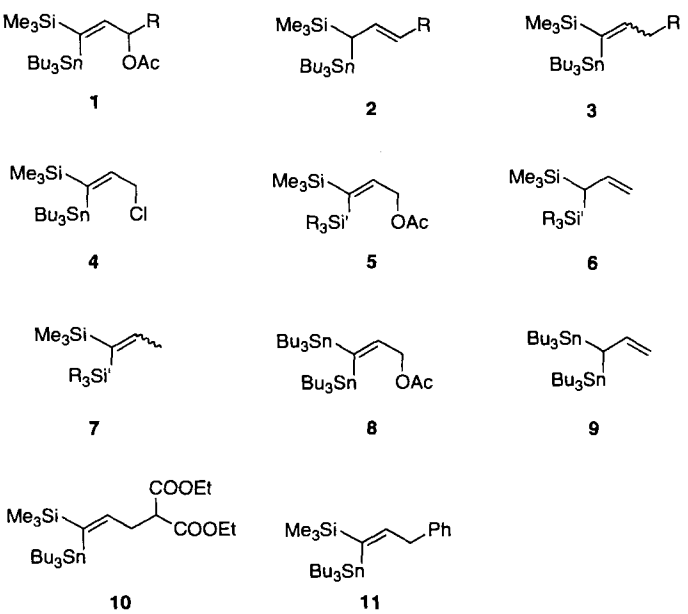


Table 1. Palladium-catalyzed nucleophilic addition to 3,3-bimetallic allylic acetates and chlorides.

No.	Substrate	Method [a]	t [h]	Product(s)	γ: α-Substitution	Yield [%]
1	**1a** (R = H)	A	3	**2a, 3a**	99.6:0.4	99
2	**1a** (R = H)	B	6	**2a, 3a**	99.6:0.4	99
3	**1b** (R = C_2H_5)	A	12	**2b, 3b**	99.6:0.4	99
4	**1c** (R = C_3H_7)	A	12	**2c, 3c**	99.4:0.6	98
5	**1d** (R = c-C_6H_{11})	A	17	**2d, 3d**	99.4:0.6	98
6	**4**	A	1	**2a, 3a**	99.6:0.4	92
7	**5a** (Si' = tBuMe$_2$Si)	A	3	**6a, 7a**	98.9:1.1	85
8	**5b** (Si' = iPr$_3$Si)	A	17	**6b, 7b**	71:29	49
9	**5b** (Si' = iPr$_3$Si)	C	24	**6b, 7b**	88:12	74
10	**8**	B	0.5	**9**	-	-
11	**1a**	D	4	**10**	<1:99	95
12	**1a**	E	4	**11**	-	-

[a] Method A: 3 equiv HCO_2H/Et_3N, 2 mol% $[Pd_2(dba)_3]$, 16 mol% PPh_3, dioxane, 100 °C; method B: 3 equiv HCO_2H/Et_3N, 2 mol% $[Pd_2(dba)_3]$, 16 mol% PPh_3, THF, 65 °C; method C: analogous to method A, except PBu_3 was used instead of PPh_3; method D: $NaCH(COOEt)_2$ was used as the nucleophile; method E: PhZnCl was used as the nucleophile.

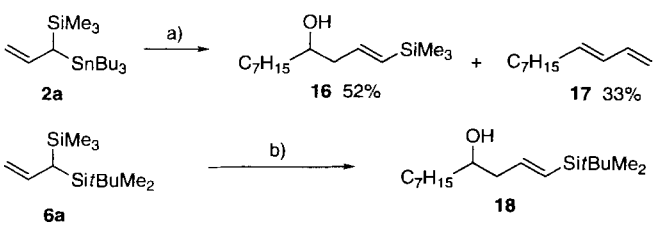
Sloan Foundation Fellow, NSERC (Canada) University Research Fellow, Bio-Mega Young Investigator, Eli Lilly Grantee. P. H. M. D. thanks the Province of Ontario for an Ontario Graduate Scholarship and the University of Toronto for a Simcoe Scholarship.

While typical ratios for hydride attack at the most versus the least substituted position were 95:5 for PPh_3, this ratio improved to 100:0 when PBu_3 was used. With most of the bimetalated allylic acetates (**1a–d** and **5a**) ratios greater than 99:1 were obtained even when PPh_3 was used as the ligand. However, increased selectivity was observed with **5b** when the ligand was changed from Ph_3P to Bu_3P (entry 9). Unfortunately, the distannyl reagent **9** could not be prepared under any of these conditions, presumably due to fast decomposition of the product.

A soft carbon nucleophile such as diethyl sodiomalonate reacted cleanly at the less hindered α-position in 95% yield to give **10** (entry 10). However, the harder phenylzinc choride did not give any of the desired product.

The effect of exchanging silicon for carbon on the regioselectivity of the hydride delivery was also studied. When the alkylstannylated allylic acetate **13** (the Me_3Si group in **1c** is replaced by an *n*-butyl group) was subjected to the same reaction conditions, the selectivity was considerably eroded, and a 71:29 mixture of **14** and **15** was obtained (Scheme 2). To understand this result, the mechanism of hydride transfer must be considered.



Scheme 2. a) 10 mol% $[Pd_2(dba)_3]$, 80 mol% PPh_3, 3 equiv HCO_2H, 3 equiv Et_3N, dioxane, 17 h at 100 °C; 99% yield.

Tsuji showed that hydride generated from formate is delivered selectively to the more substituted end of the π-allylic ligand in the palladium complex.[14] Recently, a mechanism via an η^1-palladium complex, in which the palladium is coordinated at the least hindered end of the allylic group, was put forward to explain the observed selectivity.[14d] Hydride delivery was proposed to occur intramolecularly at the more hindered terminus of the π-allylic ligand.

Since a butyl group (*A*-value = 1.9)[16] is considerably smaller than a Me_3Si (*A*-value = 2.5),[17] a higher proportion of the η^1-alkyl palladium complex is expected for substrate **1c**. However, this explanation, based exclusively on steric grounds, does not completely explain the results for the extremely hindered substrate **5b**.

We also investigated the reactivity of these bimetallic species with an aldehyde as the electrophile. Treatment of the bimetallic reagent **2a** with octanal in the presence of $BF_3 \cdot OEt_2$ gave the silylated homoallylic alcohol **16** in 52% yield (Scheme 3). No stannyl-substituted homoallylic alcohol was detected. The diene **17** was also isolated in 33% yield. This product presumably arises from a competing, Lewis acid mediated 1,3 shift of the tin substituent in **2a** to give the isomeric bimetallic reagent.[2d] Reaction of this species with the aldehyde, followed by a Peterson elimination of the 1,2-silyl alcohol gives the diene **17**.

Scheme 3. a) 1 equiv $C_7H_{15}CHO$, 1 equiv $BF_3 \cdot Et_2O$, CH_2Cl_2, 10 min at −78 °C. b) 1 equiv $C_7H_{15}CHO$, 1 equiv $BF_3 \cdot Et_2O$, CH_2Cl_2, 2 h at −40 °C; 73% yield.

High selectivity was also observed in the reaction of **6a** with an aldehyde (Scheme 3). Only the Me_3Si group in the disilyl allylic reagent **6a** reacted in the presence of $BF_3 \cdot OEt_2$ to yield the homoallylic alcohol **18** in 73% yield.

In conclusion, the palladium-catalyzed reduction of sensitive bimetallic allylic acetates proceeds with high chemo- and regioselectivity for most cases. The reactivity of these bimetallic reagents towards an electrophile shows that a selective reaction of one of the metals is possible.

Experimental Procedure

2a: To a solution of the allylic acetate **1a** (2.0 g, 4.3 mmol) and PPh_3 (90 mg, 0.34 mmol) in dioxane (15 mL) under nitrogen was added Et_3N (1.8 mL, 13.0 mmol) and HCO_2H (0.49 mL, 13.0 mmol) followed by quick addition of $[Pd_2(dba)_3]$ (39 mg, 0.043 mmol). The mixture was heated at reflux for 3 h. The black solution was diluted with hexanes, washed successively with aqueous $NaHCO_3$ and brine, dried over anhydrous $MgSO_4$, and concentrated in vacuo. The crude oil was filtered through a small plug of silica gel (elution with hexanes) to yield pure **2a** (1.73 g, 99%) as a colorless oil. ^1H NMR (400 MHz, $CDCl_3$): δ = 5.79 (ddd, J(H,H) = 16.5, 12.1, 9.8 Hz, 1H), 4.66 (dd, J(H,H) = 16.5, 2.2 Hz, 1H), 4.62 (dd, J(H,H) = 9.8, 2.2 Hz, 1H), 1.46 (m, 7H), 1.29 (sext, J(H,H) = 7.3 Hz, 6H), 0.88 (t, J(H,H) = 7.3 Hz, 9H), 0.86 (m, 6H), 0.00 (s, 9H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 139.02 (J(Sn,C) = 42.5 Hz), 109.19 (J(Sn,C) = 46.1 Hz), 29.20 (J(Sn,C) = 19.0 Hz), 27.51 (J(Sn,C) = 59.3 Hz), 22.60 (J(Sn,C) = 183.1, 174.3 Hz), 13.71, 9.99 (J(Sn,C) = 314.2, 301.0 Hz), −0.45 (J(Sn,C) = 10.3 Hz); ^{119}Sn NMR (112 MHz, $CDCl_3$): δ = −16.83; ^{29}Si NMR (80 MHz, $CDCl_3$): δ = 1.18.

18: Octanal (68 mL, 0.44 mmol) was dissolved in 0.5 mL dry CH_2Cl_2, and the flask cooled to −40 °C. $BF_3 \cdot OEt_2$ (0.88 mL, 0.5 M solution in CH_2Cl_2, 0.44 mmol) was added followed by **6a**. The reaction was stirred at −40 °C for 2 h. After aqueous workup, the crude colorless oil was purified by flash chromatography, with pentane to pentane:diethyl ether 10:1 as eluent, to yield 91 mg (73%) of **18**. ^1H NMR (400 MHz, $CDCl_3$): δ = 6.02 (ddd, J(H,H) = 18.6, 7.3, 5.9 Hz, 1H), 5.73 (ddd, J(H,H) = 18.6, 1.5, 1.1 Hz, 1H), 3.64 (m, 1H), 2.37 (dddd, J(H,H) = 13.6, 5.9, 4.4, 1.4 Hz, 1H), 2.19 (dddd, J(H,H) = 13.6, 8.7, 7.3, 1.1 Hz, 1H), 1.54 (d, J(H,H) = 3.7 Hz, 1H), 1.43 (m, 4H), 1.26 (m, 8H), 0.86 (t, J(H,H) = 7.3 Hz, 3H), 0.84 (s, 9H), 0.00 (s, 6H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 144.09, 131.59, 70.56, 45.20, 36.81, 31.83, 29.64, 29.29, 26.44, 25.65, 22.69, 16.45, 14.13, −6.05, −6.06.

Doubly Lithiated Oligosilanes: Synthesis and Structure of the First Vicinal Dilithiodisilane**

Johannes Belzner,* Uwe Dehnert, and Dietmar Stalke*

The cleavage of silicon–silicon σ bonds by alkali metals is a common method for the preparation of metalated silanes. This reaction, however, only proceeds satisfactorily if the silicon centers carry at least one aromatic substituent.[1] The same is true for the reaction of cyclic silanes with alkali metals: while peralkylated cyclosilanes are reduced by alkali metals only to the stage of radical anions,[2] aryl-substituted silacycles undergo bond cleavage to yield synthetically useful difunctional α,ω-dimetallio oligosilanes. The reactions of octaphenyltetrasilane and decaphenylcyclopentasilane with lithium have been studied extensively and have been used for the preparation of numerous organosilicon compounds.[3] To our knowledge, there are no reports about the analogous reactions of cyclotrisilanes with metals. This gap is now filled by the results of the reaction of the cyclotrisilane **1** with lithium metal, which yields, depending on the reaction conditions, either the 1,3-dilithiotrisilane **2a** or the 1,2-dilithiodisilane **3a**.

1 **2** **3**

Ar = 2-(Me_2NCH_2)C_6H_4

2a,3a: R = Li
2b,3b: R = H

The reaction of the cyclotrisilane **1** with two equivalents of lithium in 1,4-dioxane allowed the subsequent isolation of red, extremely air-sensitive crystals of **2a**, which can be smoothly protonated with cyclopentadiene to yield the trisilane **2b**. The ^1H and ^{13}C NMR spectra of **2a** are very concentration- and temperature-dependent, and hence not very useful for structural elucidation, as they primarily contain very broad, strongly overlapping signals. The ^{29}Si NMR spectrum also exhibits two strongly broadened signals at $\delta = -26.5$ and -31.8. Therefore, the identification of the reaction product as the 1,3-dilithiotrisilane **2a** is based primarily on the results of the single-crystal X-ray structure determination.[4]

The crystal structure of **2a** (Fig. 1) indicates that the concept of intramolecular side-chain coordination is, here too, particularly useful—this idea has also been successfully applied to organocopper compounds[8] and compounds containing highly coordinated silicon centers.[9] In **2a** the lithium atoms bound to silicon are coordinated by both amino groups of the neighboring $Me_2NCH_2C_6H_4$ substituents; two chelate rings are thus formed. The average Li–N bond length is 214 pm, significantly longer than that in contact ion pairs of lithium atoms and bases with nitrogen donors.[10] In addition, each lithium atom is coordinated by a single oxygen atom from a dioxane molecule.

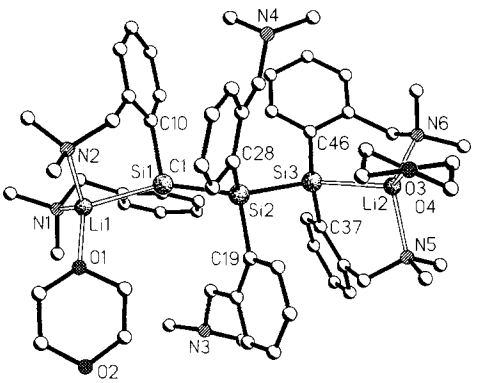

Fig. 1. Crystal structure of **2a**. Three noncoordinated dioxane molecules are omitted for clarity. Selected bond lengths [pm] and angles [°]: Si1–Si2 240.7(3), Si2–Si3 240.1(3), Si1–Li1 255(1), Si3–Li2 254(1), Li1–N1 214(1), Li1–N2 215(1), Li1–O1 197(1), Li2–N5 216(1), Li2–N6 211(1), Li2–O3 199(1); C1-Si1-C10 99.5(3), C19-Si2-C28 101.9(3), C37-Si3-C46 99.8(3), Si1-Si2-Si3 136.9(1), Li1-Si1-Si2 131.6(3), Si2-Si3-Li2 129.7(3).

The average distance between Si and Li is significantly shorter (254.3 pm) than in all other structurally characterized molecular compounds with Si–Li contacts ($[Me_3SiLi]_6$ 265 pm;[11] $[Me_3SiLi(tmeda)_{1.5}]$ 270 pm,[12] tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine; $[(Me_3Si)_3SiLi(dme)_{1.5}]$ 263 pm,[13] dme = 1,2-dimethoxyethane; $[\{(thf)_3Li\}_2(SiPh_2)_4]$ 271 pm;[14] $[(Me_3Si)_3SiLi(thf)_3]$ 264 and 267 pm;[15] $[Ph_3SiLi(thf)_3]$ 267 pm[16]). The steric demands of the six 2-(Me_2NCH_2)C_6H_4 units cause a distinct stretching of the $LiSi_3Li$ backbone, which assumes an approximately antiperiplanar conformation. The bond angles along the $LiSi_3Li$ chain are significantly larger than ideal tetrahedral angles; the central Si-Si-Si angle is widened to 136.9°.

The reaction of **1** with excess lithium in THF yields a different product: the first 1,2-dilithiodisilane **3a** is obtained in the form of deep red crystals. This compound can also be prepared by treating **2a** with lithium under the same conditions. The single-crystal X-ray structure analysis (Fig. 2) shows that both lithium atoms are coordinated to the silicon centers, as was the case in **2a**.

Compound **3a** crystallizes with two independent molecules per asymmetric unit, which only differ slightly in the orientation of the substituents (the structural parameters of the second mol-

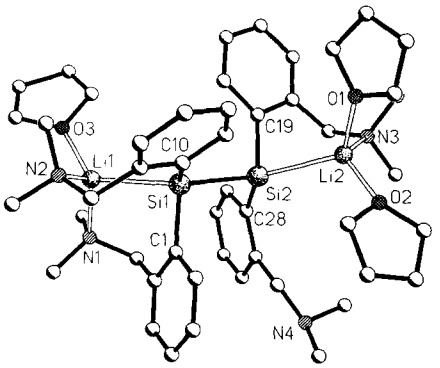

Fig. 2. Crystal structure of **3a**. Selected bond lengths [pm] and angles [°]—the values separated by a slash are those for the chemically equivalent parameter in the second, crystallographically independent molecule: Si1–Si2 238.0(2)/237.7(2), Si1–Li1 254.2(8)/255.0(8), Si2–Li2 258.9(8)/259.0(8), Li1–O3 195(1)/196(1), Li1–N1 217(1)/215(1), Li1–N2 213(1)/215(1), Li2–O1 198(1)/199(1), Li2–O2 196(1)/197(1), Li2–N3 213(1)/214(1); C1-Si1-C10 100.7(2)/99.6(2), C19-Si2-C28 102.0(2)/101.3(2), Li1-Si1-Si2 143.7(2)/143.7(2), Si1-Si2-Li2 134.9(2)/134.7(2).

ecule, not shown in the Figure, are separated from the analogous ones for the first molecule by a slash). The most striking structural feature at first glance is perhaps the different environments of the two lithium atoms: Li1 is coordinated to two Me_2NCH_2 side chains (average Li–N bond length 215.2/215.8 pm) and one thf molecule, while Li2 is surrounded by only one amino group (Li–N 212.8/213.7 pm) and two thf ligands. The two Si–Li bond lengths are not identical (Si1–Li1 254.2/255.0 pm, Si2–Li2 258.9/259.0 pm). Apparently, coordination to two amino side chains brings the Si and Li atoms closer together (cf., 254.3 pm in **2a**). The central Si–Si bond length (238.0/237.7 pm) is typical for a Si–Si single bond and is nearly identical to that in the disilane **3b** (236.4/238.6 pm).[17]

A side-on coordination of the lithium atoms to the central element–element bond,[18] such has been observed for the C–C unit in substituted dilithioethanes, is not found in **3a**. This is presumably a consequence of the intramolecular complexation.

With THF as solvent, the ^{29}Si NMR spectrum of **3a** exhibits a 1:1:1:1 quartet at $\delta = -32.8$.[19] The corresponding $^{29}Si-^{7}Li$ coupling constant (36 Hz) indicates a partially covalent character of the Si–Li bond.[20] However, the fact that the Si–Li bond length is shorter than in other lithiated silicon compounds is not reflected by a larger coupling constant ($[Me_2PhSiLi(thf)_x]$ 51 Hz;[21] $[Ph_3SiLi(thf)_3]$ 45 Hz;[16] $[(Me_3Si)_3SiLi(thf)_3]$ 37.2 Hz;[15] $[\{(thf)_3Li\}_2(SiPh_2)_4]$ 32.8, 40, and 42 Hz[14]).

These results show that the cyclotrisilane **1** is not only a valuable synthetic equivalent to silanediyls $Ar_2Si:$,[22] its reaction with lithium also opens up access to the dilithio compounds **2a** and **3a**, which in turn should be able to function as transfer agents for Si_3 and Si_2 units. Studies to determine the reactivity of these compounds are currently in progress.

Experimental Procedure

All experiments were performed with exclusion of oxygen and moisture. Where possible, the assignments of ^{1}H, ^{13}C, and ^{29}Si NMR signals to atoms of the terminal or central diaryldisilanediyl units in **2a** and **2b** are indicated by the numbers (1,3) or (2), respectively, after the element symbol. The ^{7}Li NMR spectra were calibrated externally with $LiCl/H_2O$.

2a: Lithium shavings (31 mg, 4.47 mmol) were added to a solution of **1** (1.99 g, 2.24 mmol) in dioxane (28 mL). The resulting mixture was stirred for 22 h at 25 °C. The volume of the clear red solution was reduced by about 2/3, and hexane (8 mL) added. Residual lithium was then removed by filtration. Crystallization at 4 °C yielded **2a** as bright red crystals (1.18 g, 49% yield, m.p. 50–60 °C (decomp.)), which still contained 2 equiv of dioxane per molecule of **2a** after solvent removal under high vacuum. ^{1}H NMR (250 MHz, $[D_8]THF$, 25 °C): $\delta = 1.35$ (brs, 12H; NMe_2), 1.93 (s, 24H; NMe_2), 2.3–3.4 (brs, 8H; CH_2), 3.6–4.1 (brs, 4H; CH_2), 6.4–6.9 (brs, 10H), 6.91 (t, $^{3}J = 7.5$ Hz, 4H), 7.18 (d, $^{3}J = 7.2$ Hz, 4H), 7.6–8.1 (brs, 4H; 6-H(1,3)), 8.6–8.9 (brs, 2H; 3-H(2)); ^{7}Li NMR (155.45 MHz, THF/C_6D_6 (5:1), 25 °C): $\delta = 0.90$ (s); ^{29}Si NMR (99.3 MHz, $[D_8]THF$, 25 °C): $\delta = -26.5$ (Si-2), -31.8 (Si-1,3).

2b: A solution of **2a** (1.05 g, 0.93 mmol), which still contained 2.5 equiv of dioxane, in THF (10 mL) was cooled to −78 °C and treated with cyclopentadiene (0.19 mL, 2.33 mmol). The mixture was stirred and allowed to warm to room temperature. The solvent was removed, hexane (15 mL) was added, and undissolved components were removed by filtration. Volume reduction of the filtrate yielded **2b** as hydrolysis-sensitive crystals (0.56 g, 68% yield, m.p. 171–172 °C). ^{1}H NMR (250 MHz, C_6D_6): $\delta = 1.79$ (s, 12H; NMe_2), 2.00 (s, 24H; NMe_2), 3.04 (s, 4H; CH_2), 3.25, 3.27 (AB system, $^{2}J = 14$ Hz, 8H; CH_2), 5.87 (s, $^{1}J(Si,H) = 200.5$ Hz, 2H; SiH), 6.92 (dd, $^{3}J(4,5) = 7.5$ Hz, $^{3}J(5,6) = 7.2$ Hz, 4H; 5-H(1,3)), 7.09 (dd, $^{3}J(3,4) = 7.4$ Hz, $^{3}J(4,5) = 7.5$ Hz, 4H; 4-H(1,3)), 7.22 (dd, $^{3}J(4,5) = 7.5$ Hz, $^{3}J(5,6) = 7.2$ Hz, 2H; 5-H(2)), 7.33 (dd, $^{3}J(3,4) = 7.6$ Hz, $^{3}J(4,5) = 7.5$ Hz, 2H; 4-H(2)), 7.36 (d, $^{3}J(3,4) = 7.4$ Hz, 4H; 3-H(1,3)), 7.71 (d, $^{3}J(5,6) = 7.2$ Hz, 4H; 6-H(1,3)), 7.81 (d, $^{3}J(3,4) = 7.6$ Hz, 2H; 3-H(2)), 8.60 (d, $^{3}J(5,6) = 7.2$ Hz, 2H; 6-H(2)); ^{13}C NMR (62.9 MHz, C_6D_6): $\delta = 45.15$, 45.28 (2 × NMe_2), 63.99, 64.46 (2 × CH_2), 125.98, 128.22, 128.98, 129.05, 129.50, (5 × CH), 135.54, 135.74 (C-1(1,2,3)), 138.43, 138.72 (C-6(1,2,3)), 146.04 (C-2(1,3)), 148.07 (C-2(2)); ^{29}Si NMR (59.6 MHz, C_6D_6): $\delta = -37.5$ (brs), -43.9 (d, $^{1}J(Si,H) = 203$ Hz); MS (70 eV) *m/z* (%): 890 (M^+, <1%), 297 (Ar_2SiH^+, 100).

3a: Lithium shavings (45 mg, 7.38 mmol) were added to a solution of **1** (1.09 g, 1.23 mmol) in THF (18 mL). The resulting mixture was stirred for 3 d at 25 °C. Residual lithium was removed from the clear, deep red solution by filtration, the solution volume was reduced (to ca. 3 mL), and pentane (10 mL) was added. Crystallization at −15 °C yielded **3a** in the form of dark red crystals, which contained 4 equiv of THF per molecule of **3a** (0.87 g, 53% yield, m.p. 45–50 °C (decomp.)). ^{1}H NMR (250 MHz, C_6D_6): $\delta = 1.82$ (brs, 24H; NMe_2), 2.7–3.4 (brs, 8H; CH_2), 6.8–7.1 (m, 4H; 3-H), 7.0–7.3 (m, 8H; 4,5-H), 8.36 (brs, 4H; 6-H); ^{13}C NMR (75.5 MHz, C_6D_6): $\delta = 46.14$ (NMe_2), 67.71 (CH_2), 122.44, 126.08 (C-4,5), 130.23 (C-3), 139.12 (C-6), 142.48 (C-2), 162.20 (C-1); ^{7}Li NMR (155.45 MHz, C_6D_6): $\delta = 1.36$ (s); ^{29}Si NMR (59.6 MHz, THF/C_6D_6 (5:1), 25 °C): $\delta = -32.8$ ($^{1}J(Si,Li) = 36$ Hz).

A Chiral Lewis Acid with Two "Metal" Centers: Cooperative Binding of Two Amine Molecules to a Chiral Diboronic Ester**

Kyoko Nozaki, Masanori Yoshida, and Hidemasa Takaya*

Lewis acid/Lewis base interactions are one of the most fundamental types of binding in organic chemistry. Although asymmetric reactions with chiral Lewis acid catalysts are well studied,[1] only a few reports have focused on structural aspects of the interaction of Lewis acids and Lewis bases.[2] Here, we describe the design and synthesis of a chiral Lewis acid having two "metal" centers,[3] *ortho*-bis[(4*R*,5*R*)-4,5-diphenyl-1,3-dioxa-2-borolane-2-yl]benzene (**1a**). This compound contains two dioxaborolane units that can bind two amine molecules cooperatively.[4, 5]

The chiral *ortho*-diboronate **1a** was synthesized along with the *meta* isomer **1b**, *para* isomer **1c**, and analogue **2**, which contains one Lewis-acidic center, and their binding properties with amines were examined. The interaction of *ortho*-diboronate **1a** with benzylamine is unique, as evident in ^{1}H NMR spectra. Thus a mixture of **1a** and benzylamine exhibited the following three notable features: 1) The two originally enantiotopic benzylic protons of the amine appear as a quartet with an AB pattern typical for diastereotopic protons. 2) The signals arising from the NH protons are shifted markedly downfield relative to those of the free benzylamine. 3) The signal due to the methine protons of the dioxaborolane units of **1a** remains a singlet and is only shifted slightly upfield. These results indicate that the amine is complexed with diboronate **1a** and influenced by the chiral surroundings. Since the equilibrium for the formation of the complex at 20 °C is rapid on the NMR timescale, the observed signal of the methine protons in **1a** is a singlet. In sharp contrast to the *ortho*-diboronate **1a**, *meta*- and *para*-diboronates, **1b** and **1c**, and monoboronate **2** show only small changes in their NMR spectra upon mixture with benzylamine under the same conditions, and the benzylic protons of the amine give rise to a singlet.[6] The exceptionally strong binding of **1a** with benzylamine has been demonstrated by titrations of boronates **1a**, **1b**, **1c**, and **2** with the amine (Fig. 1). Titrations of the *ortho*-diboronate **1a** show a characteristic marked saturation effect.

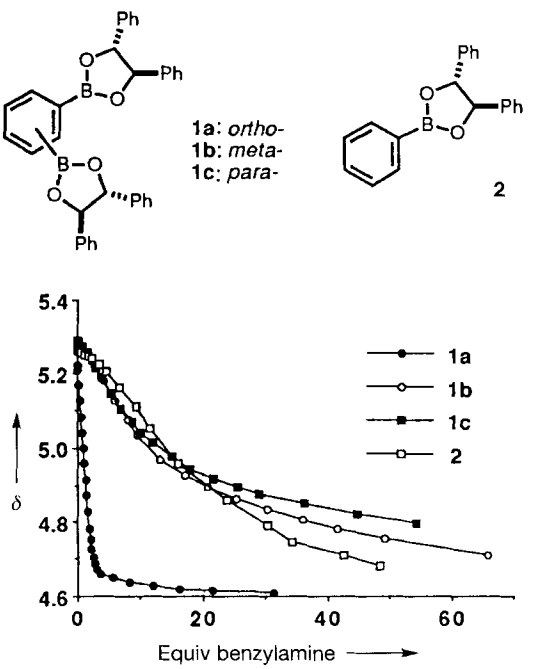

Fig. 1. Titration of boronates **1a–c** and **2** with benzylamine at 20 °C (0.10 M of **1a–c** or **2** in $CDCl_3$). Chemical shifts of the singlets due to the methine protons of the boronates (around $\delta = 5.3$) are plotted against the molar equivalents of added benzylamine.

The complexation ratio of **1a**:benzylamine = 1:2 was determined with a Job plot[7] based on ^{1}H NMR spectroscopic data (conditions: $T = 20$ °C, $[\mathbf{1a}]_{initial} + [amine]_{initial} = 0.05$ M in $CDCl_3$). Maximum complex formation occurred at $[\mathbf{1a}]_{initial}/([\mathbf{1a}]_{initial} + [amine]_{initial}) = 0.33$. Accordingly, the complexation equilibrium of **1a** with benzylamine can be described by Equations (a) and (b). Benesi–Hildebrand analysis[8] indicates that

$$\mathbf{1a} + (amine) \overset{K_1}{\rightleftarrows} \mathbf{1a} \cdot (amine) \quad (a)$$

$$\mathbf{1a} \cdot (amine) + (amine) \overset{K_2}{\rightleftarrows} \mathbf{1a} \cdot (amine)_2 \quad (b)$$

the binding of the second amine molecule to diboronate **1a** is remarkably enhanced compared to that of the first amine molecule ($K_2 \gg K_1$). The plot of $1/[amine]^2_{initial}$ vs $1/\Delta\delta_{observed}$ shows good linearity in the region where $[amine]_{initial} > 10 \times [\mathbf{1a}]_{initial}$ ($[\mathbf{1a}]_{initial} = 0.10$ M). This indicates that the contri-

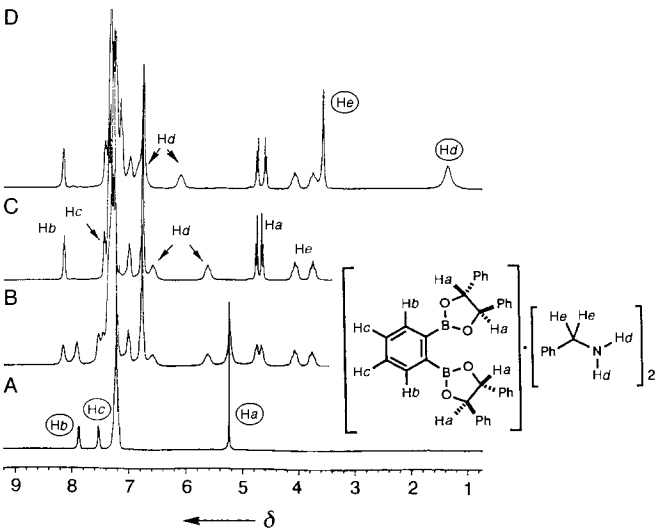
N.) both from the Ministry of Education, Science and Culture, Japan. K. N. also thanks The Asahi Glass Foundation for partial financial support.

bution of the 1:1 complex is almost negligible ($K_2 \gg K_1$). Thus the binding constant $K = 18.8\,\mathrm{M}^{-2}$ in Equation (c) can be

$$\mathbf{1a} + 2\,(\text{amine}) \overset{K}{\rightleftarrows} \mathbf{1a}\cdot(\text{amine})_2 \qquad (c)$$

calculated quite simply at 20 °C. The Hill coefficient $n_H = 1.50$ has also been estimated.

^{1}H NMR spectra recorded at −50 °C reveal that only the 1:2 complex consisting of *ortho*-diboronate **1a** and benzylamine is formed regardless of the initial ratios of the two components (Fig. 2). In spectrum C (1:2 initial ratio) complexation is so



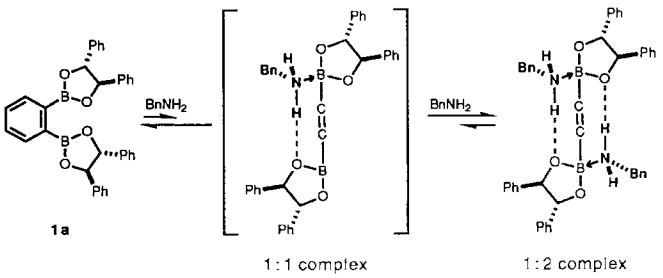


Fig. 2. ^{1}H NMR spectra of a mixture of **1a** (0.10 M) and benzylamine at −50 °C in $CDCl_3$; A: free **1a** without added amine, B: with 1.0 equiv amine (the 1:2 complex and free **1a** are present), C: with 2.0 equiv amine (only the 1:2 complex is present), D: with 4.0 equiv amine (the 1:2 complex and free amine are present). The signals with circled labels are due to free amine.

strong that only the 1:2 complex exists in solution as a single species. Spectra B and D indicate the system to be in the slow-exchange regime, since separated signals are obtained for free and bound **1a** as well as for benzylamine.[9] Thus the absence of any 1:1 complex at −50 °C again strongly suggests the cooperative binding of the two amine molecules to **1a** ($K_2 \gg K_1$).

Two significant structural features in this 1:2 complex can be observed in Figure 2, spectrum C: 1) The methine protons of **1a** (H*a*) give rise to only one AB-type quartet, indicating that the two H*a* protons on each dioxaborolane ring are magnetically nonequivalent, and that the two dioxaborolane groups are equivalent. The C_2-symmetric chiral structure of the 1:2 complex can thus be deduced. 2) A remarkable difference in chemical shift of the two NH protons of benzylamine and a significant downfield shift of one of the two NH protons strongly suggest the presence of a hydrogen bond in addition to the normal Lewis acid/Lewis base complexation.

All these results are clearly accounted for by the structural model shown in Scheme 1. The first amine molecule coordinates with one of the two boron atoms of diboronate **1a**, and at the same time, one NH proton interacts with one of the two oxygen atoms in the other dioxaborolane ring forming a hydrogen bond.[10] As a result, the two dioxaborolane units are conformationally fixed by the two-point binding and provide a suitable binding site for the second amine molecule.[11, 12] This cooperative effect can be realized only with the *ortho*-diboronate **1a**, but

Scheme 1. The central C=C group represents the phenyl unit.

not with the *meta* isomer **1b**, *para* isomer **1c**, or the monoboronate counterpart **2**.

Chiral recognition of the Lewis acid **1a** has also been examined. Titration was carried out at 20 °C for (*R*)- and (*S*)-1-phenylethylamine, and the binding constants for the 1:2 complexes have been estimated to be $K_R = 15.2\,\mathrm{M}^{-2}$ for (*R*)-1-phenylethylamine and $K_S = 18.6\,\mathrm{M}^{-2}$ for the (*S*) isomer at $[\mathbf{1a}]_{initial} = 0.10\,\mathrm{M}$. Thus, chiral recognition at 20 °C is minimal. However, the clear separation of the signals of 1-phenylethylamine suggests the possibility of using **1a** as a chiral NMR shift reagent. For example, spectra of *rac*-1-phenylethylamine (0.40 M in $CDCl_3$) with **1a** (0.10 M) at 20 °C display a pair of doublets ($PhCH(NH_2)CH_3$) and a pair of quartets ($PhCH(NH_2)CH_3$) for the amine.[13] In an analogous experiment with a sample of (*R*)-1-phenylethylamine (60% *ee*) two pairs of doublets and quartets in a ratio of 80:20 are observed.

Thus we have synthesized the chiral Lewis acid **1a** with two "metal" centers and elucidated its unique binding properties to benzylamine. Further studies on the chiral recognition of amines with **1a** and its analogues with other chiral groups on boron atoms are in progress.

Experimental Procedure

1a: (*R,R*)-Diphenyl-1,2-ethanediol (2.87 g, 13.4 mmol) was added to a chloroform solution of a 1:1 mixture of *ortho*-bis(dichloroboryl)benzene and *meta*-bis(dichloroboryl)benzene [14] (6.70 mmol total) at 0 °C. The generated HCl and the solvent were removed at 60 °C under reduced pressure. Recrystallization from CH_3CN afforded **1b** in 35% yield. The mother liquor was concentrated and purified by column chromatography on reversed-phase silica gel (Wakogel LP140C18, CH_3CN, $R_f = 0.75$). Recrystallization from ether–hexane gave **1a** in 33% yield. **1a**: m.p. 85.2–86.0 °C (ether–hexane); $[\alpha]_D^{26.0}$ −15.8 ($c = 0.79$ in $CHCl_3$); ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, TMS, 0.10 M): $\delta = 5.22$ (s, 4H), 7.12–7.33 (m, 20H), 7.47 (dd, $J = 3.3$, 5.6 Hz, 2H), 7.86 (dd, $J = 3.3$, 5.3 Hz, 2H); ^{13}C NMR (68 MHz, $CDCl_3$ 25 °C, TMS): $\delta = 87.46$, 126.09, 128.25, 128.66, 129.94, 133.84, 139.96 (carbon atoms bound to boron atoms were not observed); ^{11}B NMR (87 MHz, $CDCl_3$, 25 °C, $B(OMe)_3$): $\delta = 20.5$. Anal. Calcd for $C_{34}H_{28}B_2O_4$: C, 78.20; H, 5.40. Found C, 77.94; H, 5.44.

A Short Route to [3-^{15}N]-3′-Azido-3′-deoxythymidine (N3-Labeled AZT) via 3-Nitro-AZT**

Xavier Ariza, Valentí Bou, Jaume Vilarrasa,* Valya Tereshko, and J. Lourdes Campos

^{15}N-Labeled nucleosides are very useful for gaining insight into nucleic acid structures, drug binding phenomena, and nucleic acid/protein interactions.[1] Once these nucleosides are incorporated into DNA and RNA fragments, the changes that the corresponding ^{15}N–H bonds undergo as a consequence of hydrogen bonding or protonation/deprotonation equilibria can be directly and elegantly monitored by ^{1}H and ^{15}N NMR spectroscopy. In this context, we report here a novel, mild method for the N3-labeling of thymidines and uridines that is illustrated for the case of 3′-azido-3′-deoxythymidine (AZT, **1**), a well-studied nucleoside.[2] The procedure, which may be applied to the final product of any pyrimidine nucleoside synthesis, is based on a selective N-nitration reaction and the substitution of $^{15}NH_3$ for nitramine.[3]

Although it is known that pyrimidine nucleosides may undergo O-nitration on the sugar ring and/or nitration at C5, depending on the substrate and reaction conditions,[4] *N*-nitropyrimidine derivatives have not been reported so far, to the best of our knowledge. To achieve smooth N-nitration and avoid nucleoside hydrolysis and loss of protective groups, we took advantage of our previous experience with amide nitration under mild conditions.[5] Thus, after protecting the hydroxyl group of AZT (**1**),[6] we converted the product **2** into the *N*-nitro compound **3** by treatment with nitric trifluoroacetic anhydride (nitronium trifluoroacetate) generated in situ from appropriate amounts of NH_4NO_3 and $(CF_3CO)_2O$ in CH_2Cl_2 (Scheme 1). This N-nitration reaction gave **3** in 90% yield based on consumed starting material (81% isolated yield).

Scheme 1. a) Ac_2O/Py, 20 °C (96%); b) NO_2OCOCF_3, CH_2Cl_2, 0 °C (90%); c) $^*NH_3$ (i.e. $^{15}NH_3$), CH_3CN/H_2O, 20 °C (67%); d) conc NH_3, MeOH, 20 °C (95%); e) c and d in a one-pot reaction (75%).

5′-*O*-Acetyl-3′-azido-3′-deoxy-3-nitrothymidine (**3**) was identified by the absence of an NH signal in the ^{1}H NMR spectrum and by the large shifts of the signals for C2 and C4 in the ^{13}C NMR spectrum relative to those of **2** ($\Delta\delta = -5$ and -8, respectively). To corroborate its structure we tried to obtain suitable crystals of **3**, but it proved to be an amorphous solid. However, 3′,5′-di-*O*-acetyl-3-nitrothymidine (**4**), prepared similarly in excellent yield from thymidine, afforded good crystals from acetone/hexane. The X-ray structural analysis showed two different conformations of **4** in the asymmetric unit (Fig. 1);[7] the only significant difference between them is the torsion angles involving the 5′ substituent, specifically the O-C5′-C4′-O dihedral angle. The NO_2 group is perpendicular to the plane of the nitrogen ring, as could be expected in view of its close proximity to the two CO groups.

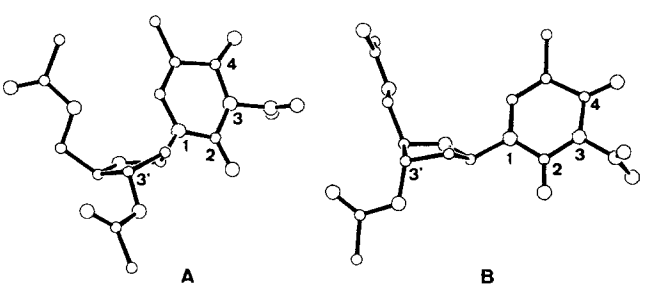

Fig. 1. Molecular structure of 3′,5′-di-*O*-acetyl-3-nitrothymidine (**4**) in the crystal (hydrogen atoms omitted for clarity); the unit cell contains two conformations **A** and **B** of **4** (C2′-*endo*/C3′-*exo*). Selected bond lengths [Å] and angles [°]: **A**: C2–O 1.183(9), C2–N3 1.40(1), N3–NO_2 1.48(1), N3–C4 1.40(1), C4–O 1.20(1); N1-C2-N3 110.5(6), O2-C2-N1 125.8(7), O2-C2-N3 123.6(7), C2-N3-C4 131.3(6), N3-C4-O4 120.6(8), C5-C4-O4 128.3(8), O-N-O 129.9(9); for **B** the values are almost identical.

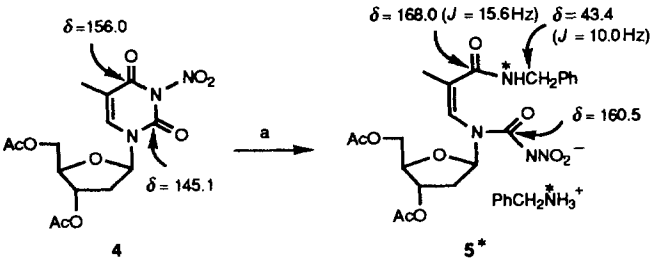

When a solution of **3**, $^{15}NH_4Cl$, and KOH in CH_3CN/H_2O was stirred at room temperature in a closed vial, a smooth reaction gave a much more polar species (according to thin-layer chromatography). After a few days, this reaction intermediate had been converted to a new compound identical to **2**, except

for the appearance of some $^1H-^{15}N$ and $^{13}C-^{15}N$ couplings in the NMR spectra. After purification by column chromatography on silica gel a 67% yield of this labeled compound (**2***) was obtained, together with small amounts of the deacetylated product **1***. The proton-coupled ^{15}N NMR spectrum of **2*** showed the expected doublet with $|^1J_{N,H}| = 90.9$ Hz at $\delta = -212.6$, referred to external conc. $H^{15}NO_3$. Deprotection of **2*** under standard conditions, either with a concentrated solution of ammonia in MeOH or with MeOH/HCl, gave almost quantitative yields of [3-^{15}N]-AZT **1*** ($|^1J_{H,N}| = 91.0$ Hz, $|^1J_{C2,N}| = 17.3$ Hz, and $|^1J_{C4,N}| = 9.9$ Hz). Compound **1*** was also obtained in 75% in a one-pot transformation from **3** (see Scheme 1) by adding a 1:1 mixture of aqueous ammonia and MeOH at the end of the labeling reaction.

To gain insight into the mechanism of the reaction of nitro derivatives **3** and **4** with ammonia, which likely involves ring opening and ring closing, we attempted to characterize the polar intermediates by NMR spectroscopy. When benzylamine was used instead of ammonia, these intermediates turned out to be kinetically stable, and their structures could be elucidated. In fact, when **3** or **4** was treated with benzylamine—at least two equivalents were necessary for complete disappearance of starting material—in $CDCl_3$ at 20 °C, we noted in both cases the formation of only one polar compound, which did not cyclize under these conditions. After confirming the assignments of the carbon atoms of **4** and its ring-opened derivative **5** by $^1H-^{13}C$ 2D NMR experiments, we monitored by $^{13}C-\{^1H\}$ NMR spectroscopy the reaction between **4** and ^{15}N-labeled benzylamine leading to the labeled compound **5*** (Scheme 2). The CO group

Scheme 2. a) $PhCH_2{}^*NH_2$, $CDCl_3$, 20 °C.

of **5*** at $\delta = 160.5$, which is related to C2 of the thymidine ring, appeared as a singlet, whereas the CO group of **5*** at $\delta = 168.0$ related to C4 showed a typical $^1J_{C,N}$ splitting. In other words, the attack of benzylamine (and presumably that of ammonia) on 3-nitrothymidines takes place mainly at the C4 position.

Experimental Procedure

3: Trifluoroacetic anhydride (0.560 mL, 4.0 mmol) was added to a suspension of finely powdered NH_4NO_3 (160 mg, 2.0 mmol) in anhydrous CH_2Cl_2 (5 mL) at 0 °C under Ar. The mixture was stirred vigorously at room temperature until the solid dissolved (ca. 1 h) and then cooled again. Compound **2** (309 mg, 1.0 mmol) was introduced, and stirring was maintained at 0 °C for 1 h. After more solvent was added, the reaction mixture was washed with cold phosphate buffer, dried, and concentrated to dryness to give almost pure product (contaminated only with small amounts of starting material). Column chromatography on silica gel (flash chromatography) eluting with CH_2Cl_2/MeOH (98/2) afforded pure **3** (287 mg, 81%); elution with CH_2Cl_2/MeOH (95/5) then provided recovered **2** (32 mg, 10%). Data of **3**: M.p. 81–83 °C (EtOAc/hexane); ^1H NMR (200 MHz, $CDCl_3$): δ = 2.00 (d, J(Me,6) = 1.2 Hz, 3H; Me), 2.14 (s, 3H; MeCO), 2.36–2.62 (m, 2H; H2′, H2″), 4.08–4.44 (m, 4H; H3′, H4′, H5′, H5″), 6.07 (dd, J(1′,2′) = 6.6 Hz, J(1′,2″) = 5.8 Hz, 1H; H1′), 7.33 (q, J(6,Me) = 1.2 Hz, 1H; H6); ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 12.8 (Me), 20.7 (MeCO), 37.7 (C2′), 60.2 (C3′), 63.0 (C5′), 82.3 (C4′), 86.8 (C1′), 110.7 (C5), 134.9 (C6), 145.0 (C2), 156.1 (C4), 170.1 (*C*OMe).

2*: *N*-Nitro derivative **3** (189 mg, 0.53 mmol) was added to a mixture of $^{15}NH_4Cl$ (145 mg, 2.66 mmol, IC Chemikalien, MSD Isotopes, 99% labeled), powdered KOH (85%, 169 mg, 2.56 mmol), acetonitrile (4 mL), and water (1 mL) in a closed vial, and the solution was stirred at room temperature for a week. Evaporation of the solvent and purification by column chromatography (silica gel, CH_2Cl_2/MeOH 95/5) afforded **2*** (111 mg, 67%) and then **1*** (14 mg, 10%) [8]. Spectral data of **2***: ^1H NMR (200 MHz, $CDCl_3$): δ = 1.94 (d, J(Me,6) = 1.2 Hz, 3H; Me), 2.15 (s, 3H; MeCO), 2.3–2.6 (m, 2H; H2′, H2″), 4.0–4.5 (m, 4H; H3′, H4′, H5′, H5″), 6.13 (t, J(1′,2′) ≈ J(1′,2″) = 6.3 Hz, 1H; H1′), 7.24 (q, J(6,Me) = 1.2 Hz, 1H; H6), 9.66 (d, J(N,H) = 90.9 Hz, 1H; NH); ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 12.6 (Me), 20.7 (MeCO), 37.5 (C2′), 60.5 (C3′); 63.3 (C5′), 81.6 (C4′), 85.5 (C1′), 111.2 (d, J(C,N) = 6.3 Hz; C5), 135.3 (C6), 150.2 (d, J(C,N) = 18.1 Hz; C2), 163.9 (d, J(C,N) = 10.0 Hz; C4); 170.2 (*C*OMe).

1*: The final mixture from the reaction of **3** (189 mg, 0.53 mmol) with $^{15}NH_4Cl$ and KOH (ca. 5 equiv of each, as above) was treated with an excess of aqueous NH_3 (30%, 15 mL) and MeOH (15 mL) at room temperature for 1 h. Removal of excess reagent and solvents in vacuo, and purification by column chromatography as above gave directly **1*** (107 mg, 75%); ^1H NMR (200 MHz, $CDCl_3$): δ = 1.91 (d, J(Me,6) = 1.2 Hz, 3H; Me), 2.3–2.6 (m, 2H; H2′, H2″), 3.75–4.05 (m, 3H; H4′, H5′, H5″), 4.42 (m, 1H; H3′), 6.08 (t, J(1′,2′) ≈ J(1′,2″) = 6.6 Hz, 1H; H1′), 7.41 (q, J(6,Me) = 1.2 Hz, 1H; H6), 9.64 (d, J(N,H) = 91.0 Hz, 1H; NH); ^{13}C NMR (50.3 MHz, [D$_6$]DMSO): δ = 12.2 (Me), 36.2 (C2′), 60.2 (C3′), 60.8 (C5′), 83.4 (C4′ or C1′), 84.0 (C1′ or C4′), 109.5 (d, J(C,N) = 6.4 Hz; C5), 136.1 (C6), 150.4 (d, J(C,N) = 17.3 Hz, C2), 163.7 (d, J(C,N) = 9.9 Hz; C4).

A Water-Soluble "Bear Trap" Exhibiting Strong Anion Complexation Properties**

Jonathan W. Steed, Ravindra K. Juneja, and Jerry L. Atwood*

Calix[*n*]arenes ($n = 4-8$) have been extensively studied in recent years[1, 2] in connection with a variety of applications in areas such as metal ion extraction,[3, 4] catalysis,[5] and enzyme modeling.[6] The vast majority of this interest has centered around the capacity of calixarenes to form molecular inclusion complexes with a wide varity of guest species,[1, 2, 7, 8] by virtue of hydrophobic cavities formed as a consequence of the conformational properties of the macrocycle.[9] Recently we have embarked upon a program of research designed to modify the electronic properties of calixarene hosts by complexation of the carbocyclic rings of the macrocycle to organotransition metal containing moieties. It is anticipated that the presence of charged metal cations bound directly to the calixarene π network will significantly reduce the electron density within the cavity and allow the incorporation of suitably sized anionic species, especially environmental contaminants such as phosphate and the phosphate residues in biologically important anions such as ATP.[10, 11] Ultimately such complexation may lead to new methods of water purification or inhibition of the conversion of ATP into ADP.

Shinkai and co-workers have already reported some neutral chromium tricarbonyl derivatives of rigidified calix[4]arene tetra-*n*-propyl ethers **1a**.[12, 13] In the present work, however, we have chosen to concentrate upon more robust, air-stable complexes containing the "(arene)Ru^{2+}" moiety which exhibit useful properties such as high positive charge and significant solubility in water.

1a: R = H, Y = *n*Pr
1b: R = Y = H
1c: R = *t*Bu, Y = H

Unsymmetrical bis(arene)ruthenium(II) complexes may be prepared conveniently[14] from the readily available chloro-bridged dimers **2**[15] by treatment with AgX ($X = BF_4$, CF_3SO_3, $\frac{1}{2}SO_4$, etc.) followed by heating in the presence of acid. Accordingly we find that refluxing a trifluoroacetic acid solution of [Ru(*p*-cymene)(acetone)$_3$]X_2 (prepared from **2b**) in the presence of a 0.25 equivalents of calix[4]arene **1b** results in the clean formation of the salt **3**-$(BF_4)_6$ (80% yield), which has a tetrametallic cation arising from the capping of each face of the macrocycle by an (arene)Ru^{2+} fragment and loss of two of the calixarene phenolic protons; the resulting cationic complex has an overall charge of 6 + . Interestingly, direct reaction of excess **2b** with **1b** in refluxing CF_3CO_2H provides the salt **4**-$[H(CF_3CO)_2]_4$ with a bimetallic cation.

2b: arene = 4-$MeC_6H_4CHMe_2$
2c: arene = C_6Me_6

$[\{Ru(p\text{-cymene})\}_4(\eta^6{:}\eta^6{:}\eta^6{:}\eta^6\text{-calix[4]arene} - 2H)](BF_4)_6$ **3**-$(BF_4)_6$

$[\{Ru(p\text{-cymene})\}_2(\eta^6{:}\eta^6\text{-calix[4]arene})][H(CF_3CO_2)_2]_4$ **4**-$[H(CF_3CO_2)_2]_4$

Salts **3**-$(BF_4)_6$ and **4**-$[H(CF_3CO)_2]_4$ were characterized by ^1H NMR spectroscopy,[16] which confirmed that the calixarene in **3** is symmetrically substituted. The observation of an AB quartet assigned to the calixarene methylenic bridges suggests that **3** and **4** both assume cone conformations in solution.[9] Both salts are significantly soluble in water and hence may be readily introduced to common water-soluble inorganic anions.

It may seem surprising that **3** should be formed in a doubly deprotonated form even though trifluoroacetic acid is used as the solvent. Previous work upon ruthenium, rhodium, and iridium π complexes with phenol ligands[17-19] has shown, however, that transition metal complexation significantly enhances the acidity of the phenolic protons (because of increased positive charge and the stability of the resulting oxocyclohexadienyl ligand), and hence it seems likely that any more highly charged species formed in the reaction readily release HBF_4 to give the observed hexacationic compounds. We have also noted similar acidity enhancements for related bimetallic pentamethylcyclopentadienyl (Cp*) rhodium and iridium complexes of **1b** and **1c** in which it has proved possible to isolate and characterize salts containing tetra-, tri-, and dicationic complexes $[(MCp^*)_2(\eta^6{:}\eta^6\text{-}p\text{-R-calix[4]arene} - nH)][BF_4]_{4-n}$ (M = Rh, Ir; $n = 0, 1, 2$; R = H, *t*Bu).[20]

The BF_4 salt of complex **3** has also been characterized by X-ray crystallography (Fig. 1).[21] The complex adopts the cone conformation in the solid state with each calixarene ring bound η^6 fashion to a (*p*-cymene)Ru^{2+} fragment (Ru–C = 2.19–2.39 Å). Bonds to the carbon atom attached to the hydroxyl functionality are significantly longer than those to the remaining five atoms of each calixarene ring (Ru–C(1) = 2.367(8) Å

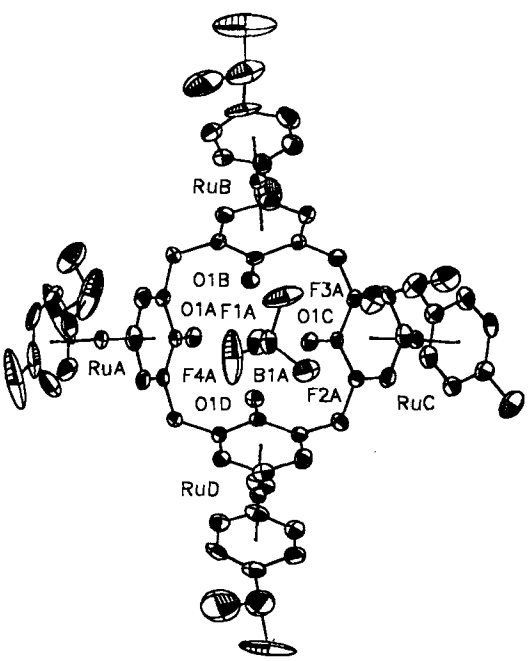

Fig. 1. X-ray crystal structure of **3** and the included tetrafluoroborate ion.

(average), Ru–C(2–6) = 2.22(1) Å (average)), consistent with a partial oxocyclohexadienyl description.[17] In contrast to previous calixarene and calixarene–metal complexes examined in the solid state,[22–25] including the bimetallic iridium(III) species in $[(IrCp^*)_2(\eta^6{:}\eta^6\text{-}p\text{-}tert\text{-butylcalix[4]arene})](BF_4)_3 \cdot Et_2O \cdot NO_2Me$,[20] **3** does not co-crystallize with a molecule of solvent or other guest within the hydrophobic cavity of the calixarene. Instead, withdrawal of electron density from the all four carbocyclic rings by the transition metal centers along with the high charge of the host molecule as a whole results in the incorporation of one of the tetrafluoroborate anions (B1A–F4A) deeply within the cavity. Three of the fluorine atoms are approximately at the level of the upper rim of the calixarene cavity, whilst F1A points directly into the bowl of the molecule. Short contacts of 3.23–3.37 Å are observed between this atom and the calixarene oxygen atoms. Distances from F1A to the centroids of the calixarene rings A and D are 3.10 and 3.15 Å, and to rings B and C 3.41 and 3.46 Å. But the remarkably short F1A···C1A and C1D distances each of 2.85 Å demonstrate the extremely deep penetration of the anion into the cavity. The tight binding of this anionic guest by the metalated host is also highlighted by the relatively small magnitude of the anisotropic thermal parameters for atoms B1A–F4A, which are similar to those of the atoms of the cation. In contrast, thermal parameters for tetrafluoroborate ions in the crystal lattice are commonly large as a result of high thermal motion and/or dynamic disorder.

The deprotonation of two of the calixarene hydroxyl groups is evidenced by the hydrogen bonding network at the base of the calixarene in which the calixarene oxygen atoms are hydrogen bonded in pairs (OA···OB and OC···OD 2.57 Å (average)); the average distance between O atoms not connected by hydrogen bonds (OA–OD and OB–OC) is 2.76 Å. This may be compared with the average distances of 2.40 and 3.14 Å in the lithium salt of the *p-tert*-butylcalix[4]arene dianion.[26]

The remaining five tetrafluoroborate ions, which exhibit larger thermal ellipsoids, occupy positions adjacent to the metal ions within the lattice and form weak hydrogen bonds (ca. 2.9 Å) to a further 1.5 molecules of water located on final difference Fourier syntheses.

Anion metathesis of **3**-$(BF_4)_6$ with $(NBu_4)I$ in nitromethane solution leads to the analogous iodo complex $[\{Ru(p\text{-cymene})\}_4(\eta^6{:}\eta^6{:}\eta^6\text{-calix[4]arene} - 2H)]I_6$ which has also been characterized by X-ray crystallography and demonstrates the inclusion of an iodide anion within the cavity of the macrocycle (I–ring centroid distances 3.60–3.78 Å). Further studies of inclusion reactions with a number of phosphate and polyphosphate anions as well as ATP are currently in progress.

The facile synthesis of **3** and **4**, coupled with our recent reports[29] of trimetallic hosts based upon cyclotriveratrylene and bi- and tetrametallic calixarenes containing rhodium and iridium confirms that bowlic host molecules may be readily modified by direct π complexation to form highly charged, air- and moisture-stable cavity-containing species capable of complexing a wide range of even highly polar guests. It is envisaged that the use of redox-active metal centers such as ruthenium(II/0) bound in close proximity to the cavity in this way will allow the design of redox-active enzyme mimics capable of reducing or oxidizing a bound substrate through electron transfer mediated by the calixarene π network.

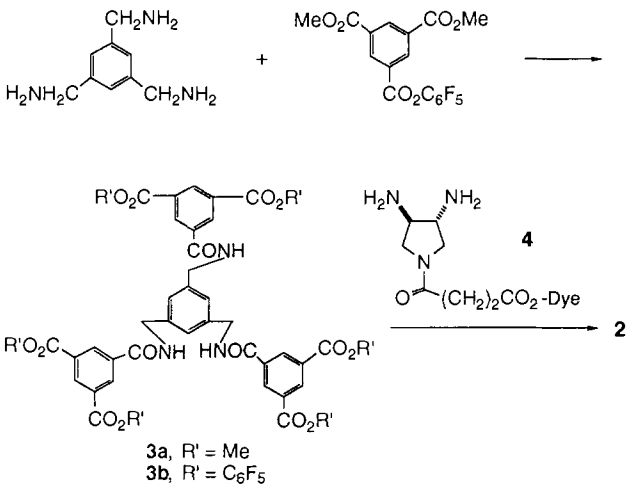
Expeditious Synthesis of a Novel C_3-Symmetric Receptor that Binds Peptides Sequence-Selectively**

Seung Soo Yoon and W. Clark Still*

One of the most exciting recent advances in molecular recognition is the development of synthetic receptors or host molecules that bind biopolymers sequence-selectively.[1] Among the most selective of these is the C_3-symmetric receptor **1**.[2] It binds a variety of biooligomers, including glycosides and both N- and C-protected peptides, with high stereochemical and functional-group selectivity. With simple peptides, for example, **1** binds L peptide residues with enantioselectivities as high as 3 kcal mol^{-1} (>99% *ee*). Though **1** is available by an optimized synthesis,[2b] we sought related receptors that could be prepared by even simpler methods and thus might find practical application to problems of separation. In this regard, **2** and its derivatives are

1a, R = H
1b, R = $OCH_2CH{=}CH_2$
1c, R = O-Dye



2, R = $CO(CH_2)_2CO_2$-Dye

attractive candidates. Receptors **1** and **2** are closely related in that their cup-shaped binding cavities have both similar dimensions and analogous patterns on their peripheries of unassociated hydrogen-bond donors and acceptors for substrate binding. In this communication, we describe a simple synthesis of **2** and its binding properties as determined by complexation with an encoded combinatorial library[7] of around 50000 acylated tripeptide substrates. As we will show, **2** is a remarkably selective receptor for peptides.

[**] We acknowledge the support of the National Science Foundation (CHE92 08254).

Our synthesis of **2** (Scheme 1) began with the coupling of three equivalents of pentafluorophenyl dimethyl trimesate to one equivalent of 1,3,5-tri(aminomethyl)benzene to provide **3a** (78% yield). Saponification of all six methyl ester groups and activation as the hexakis(pentafluorophenyl) ester then gave **3b** (30% yield). This material underwent threefold coupling with a (3*R*,4*R*)-3,4-diaminopyrrolidine linked to the dye Disperse Red 1 through a succinyl spacer;[3] three 21-membered rings were formed simultaneously, and the brilliant red receptor **2** was obtained in 26% yield. We should add that a variety of related receptors can be prepared with other 1,2-diamines. For example, reaction of commercially available (1*R*,2*R*)-1,2-diaminocyclohexane with **3b** yielded an analogous receptor (31% yield for the final tricyclization step) in which the pyrrolidine rings are replaced by simple cyclohexanes.

3a, R' = Me
3b, R' = C_6F_5

Scheme 1. Synthesis of receptor **2**.

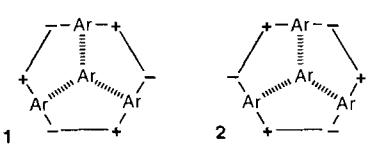
To establish the binding properties of our new receptor **2**, we treated a dye-labeled receptor with a large collection or library of potential substrates.[2d] The substrate library was synthesized on 50–80 μm Merrifield polystyrene beads in such a way that each bead carried a single library member. The binding experiment simply involved mixing red **2** with the bead-supported library and selecting those beads that turned red. Thus binding of **2** to the entire library (here ca. 50000 acylated tripeptides) could be surveyed in a single experiment.

We used the polymer-supported substrate library[2d] of general structure **5**. We prepared the library using the split

RCO–AA3–AA2–AA1–$NH(CH_2)_5CONHCH_2$–polystyrene **5**

AA*n* (*n* = 1–3) = Gly, D-Ala, L-Ala, O^3-*t*Bu-D-Ser, O^3-*t*Bu-L-Ser, D-Val, L-Val, D-Pro, L-Pro, N^4-trityl-D-Asn, N^4-trityl-L-Asn, N^5-trityl-D-Gln, N^5-trityl-L-Gln, N^6-Boc-D-Lys, N^6-Boc-L-Lys

R = Me, Et, *i*Pr, *t*Bu, *i*Bu, neopentyl (*neo*Pe), trifluoromethyl (TFM), methoxymethyl (MOM), cyclopropyl (*c*Pr), cyclobutyl (*c*Bu), cyclopentyl (*c*Pe), acetoxymethyl (AcOM), Ph, Me_2N, morpholino (Mor)



synthesis.[4] Thus, the total possible number of different substrates in the library was 15^4 (50625). To allow for determination of the structure of the substrate on any bead that bound **2**, we employed the binary encoding method that uses electron-capture gas chromatography (ECGC) to analyze tag-encoded structural information.[5]

In the binding assay, a sample of the above peptide library (10 mg, ca. 10^5 beads) was equilibrated with a 50 m > M solution of **2** in $CHCl_3$ (ca. 0.3 mL). After 24 h of agitation, approximately 1% of the beads had developed deep red-orange colorations. These beads carried peptides that bound red **2** most tightly.[6] By measuring the concentration of **2** in solution over the beads at equilibrium, we established that the assay allowed selection of beads having association constants $K_a \geq 3000$. Fifty of these most deeply colored beads were picked under a microscope (4 × magnification), and their tag-encoded structural information was decoded by ECGC. The residue types found in the peptides on these beads are listed in Table 1.

Table 1. Residues R and AA1–AA3 in acylated, protected peptide substrates that are selectively bound by **2** (no. of occurrences from 50 decoded beads in parentheses).

	D-Ala (2)	N^5-trityl-L-Gln (3)	N^5-trityl-D-Gln (3)
	Gly (1)	N^6-Boc-D-Lys (3)	N^5-trityl-L-Gln (2)
		L-Val (3)	L-Ala (2)
		N^6-Boc-L-Lys (2)	N^4-trityl-L-Asn (2)
		N^4-trityl-L-Asn (2)	D-Val (2)
		D-Val (2)	O^3-*t*Bu-L-Ser (2)
		L-Ala (1)	
		O^3-*t*Bu-L-Ser (1)	
		O^3-*t*Bu-D-Ser (1)	

In many ways, the binding selectivities of **2** are similar to those recently reported for **1**.[2d] Thus, both receptors show the highest selectivity for residues at the terminus of the peptide chain: they selectively bind certain R groups having three nonhydrogen atoms and AA3 = N^5-trityl-Gln. However, **1** binds AA3 = N^5-trityl-L-Gln, whereas **2** prefers the D isomer. This difference in enantioselection is rationalized by the enantiomeric patterns of hydogen bonding between substrate and groups at the periphery of the binding cavities of **1** and **2** (Scheme 2).

Scheme 2. Schematic representation of receptors **1** and **2**. Ar = aromatic ring; +, − indicate exposed H-bond donors and acceptors, respectively.

According to molecular modeling, these groups surround the opening to the binding cavity and are well positioned to bind substrate through intermolecular hydrogen bonds. Other donors and acceptors of **1** and **2** are unavailable for substrate binding because they project away from the opening to the binding cavity and further are involved in intramolecular hydrogen bonds.

Other selectivity differences between **1** and **2** are found at AA2 (**1** prefers L-Pro, **2** prefers Gly) and AA1 (**1** shows virtually no selectivity, **2** prefers D-Pro, L-Pro or D-Ala) residues. Interestingly, the remarkable preference of **1** for R = cyclopropyl[2d] is absent with **2**. Neither **1** nor **2** bind peptides having R = isopropyl. These and other selectivities were verified by independent binding energy measurements with **2** that showed, inter alia, that changing R = MOM to cyclopropyl or AA3 = N^5-trityl-D-Gln to N^5-trityl-L-Gln diminished binding by 1.3 kcal mol^{-1} relative to the preferred substrate MOMCO–N^5-trityl-D-Gln–Gly–L-Pro ($\Delta G_{binding} = -4.3$ kcal mol^{-1}). These results were obtained by resynthesizing selected substrate sequences and using UV spectrophotometry to quantitate the concentrations of free receptor both before and after treatment with a known quantity of the polymer-supported substrate.

We also carried out an analogous survey of **2** with a substrate library having deprotected peptide side chains (Table 2). Measurement of the concentration of **2** at equilibrium indicated that, in this case, the color assay allowed selection of substrates having $K_a \geq 5000$.

Table 2. Residues R and AA1–AA3 in acylated, deprotected peptide substrates that are selectively bound by **2** (no. of occurrences from 45 decoded beads in parentheses).

Whereas our previous studies found **1** to have similar selectivities for protected and deprotected peptide substrates, receptor **2** bound a different set of peptides with the deprotected library. It was most discriminating at the internal AA1 site where Pro was strongly preferred. In particular, **2** preferentially bound the sequences with AA3 = D-Gln, AA2 = D amino acid, and AA1 = L-Pro (40% of beads) or with AA2 = L-Gln and AA1 = D-Pro (40% of beads). The relationship between the Pro configuration at the AA1 position and both the configuration and position of the downstream Gln is particularly interesting. This novel Gln–Pro selectivity may reflect the presence of hydrogen bonding between the Gln side chain and amides at the bottom of **2**'s binding cavity—a possibility not available to **1**. The ability of **2** to selectively bind peptide spans with as many as three residues is remarkable for such a small host molecule.

These studies and others soon to be reported suggest that a variety of receptors similar in structure to **1** or **2** have significantly sequence-selective peptide binding properties and that the specific selectivity of such a receptor can be controlled by varying the details of its structure. While the full range of variations that can be tolerated without loss of binding affinity has yet to be established, we have found that the full macrotricyclic framework of **2** is necessary for peptide binding: deletion of the central aromatic linker obliterates tight peptide binding as detected by our solid-phase color assay. Given the simplicity of **2**'s synthesis, its highly selective peptide-binding properties, and the availability of many building blocks for the construction of analogues, it is likely that a variety of C_3-symmetric receptors having a range of peptide sequence selectivies can be prepared along the lines described here.

Experimental Procedure

3a: To a solution of pentafluorophenyl dimethyl trimesate (0.42 g, 1.04 mmol) and tri(aminomethyl)benzene triHCl salt (86 mg, 0.31 mmol) in 10 mL of dry *N*,*N*-dimethylacetamide (DMA) was added 0.36 mL of iPr_2NEt. After the mixture had been stirred for 8 h, it was concentrated at reduced pressure and purified by flash chromatography (silica gel, 5% MeOH in CH_2Cl_2) to give **3a** as an amorphous white solid (0.20 g, 78%). ^1H NMR ($CDCl_3$) δ = 3.90 (s, 6H), 4.38 (m, 2H), 7.10 (s, 1H), 7.30 (m, 1H), 8.61 (s, 2H), 8.70 (s, 1H); ^{13}C NMR ($CDCl_3$) δ = 165.74, 165.36, 139.11, 134.99, 132.84, 132.18, 130.77, 126.35, 52.44, 43.71; IR (neat) 3324, 2815, 1730, 1674, 1573 cm^{-1}; HR-MS (FAB) for $C_{42}H_{40}N_3O_{15}$: calcd: 827.2537 [$M + H^+$]; found: 827.2539.

2: To **3a** (0.1 g, 0.121 mmol) in THF (5 mL), MeOH (3 mL), and water (1 mL) was added a 1 N NaOH solution (0.85 mL). After stirring for 5 h, the mixture was acidified with 1 N HCl solution and extracted with EtOAc (3 × 50 mL). The extracted hexaacid was dissolved in THF (3 mL) and CH_2Cl_2 (10 mL), and C_6F_5OH (0.15 g, 0.84 mmol) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) (0.16 g, 0.84 mmol) were added. Stirring for 5 h, concentration, and flash chromatography (silica gel, 20% acetone in CH_2Cl_2) gave **3b** as an amorphous white solid (63 mg, 30%).

A solution of **3b** (44 mg, 0.025 mmol) and **4**·2CF_3CO_2H (63 mg, 0.084 mmol) in DMA (10 mL) was added with stirring to a solution of iPr_2NEt (0.19 mL, 1.09 mmol) in dry THF (200 mL) at room temperature over 20 h by syringe pump. Stirring for an additional 8 h, concentration, and flash chromatography (silica gel, 10% MeOH in CH_2Cl_2) gave **2** as an amorphous red solid (15 mg, 26%). ^1H NMR ($CD_3OD/CDCl_3$ 1/1) δ = 0.70 (t, 3H, J = 7.0Hz), 2.45 (m, 4H), 3.01 (q, 2H, J = 7.0Hz), 3.36 (br.s, 2H), 3.50 (br.s, 2H), 3.74 (m, 1H), 3.92 (m, 1H), 4.12 (m, 4H), 4.58 (m, 1H), 4.68 (m, 1H), 6.64 (d, 2H, J = 9.1Hz), 7.72 (m, 5H), 7.98 (m, 1H), 8.10 (d, 2H, J = 9.0Hz), 8.23 (m, 1H), 8.64 (m, 1H); ^{13}C NMR (1/1 = $CD_3OD/CDCl_3$) δ = 172.82, 170.20, 169.72, 169.61, 167.70, 138.51, 136.06, 133.53, 131.27, 130.54, 130.46, 129.54, 126.72, 125.92, 125.22, 124.37, 124.24, 122.31, 118.85, 112.22, 61.34, 55.74, 50.54, 45.70, 44.42, 38.28, 28.76, 28.27, 27.52, 27.22, 11.94; IR (neat) 3324, 2815, 1720, 1675, 1573 cm^{-1}; MS (FAB) *m*/*z* 2127 [$M + H^+$].

[6] Previous studies have shown that the color assay readily distinguishes substrates differing in binding energy by as little as 1.0 kcal mol^{-1}. Control experiments established that bead coloration reflects binding of the peptide and not the dye: neither the dye nor the succinylated dye stained any of the library beads under the assay conditions.

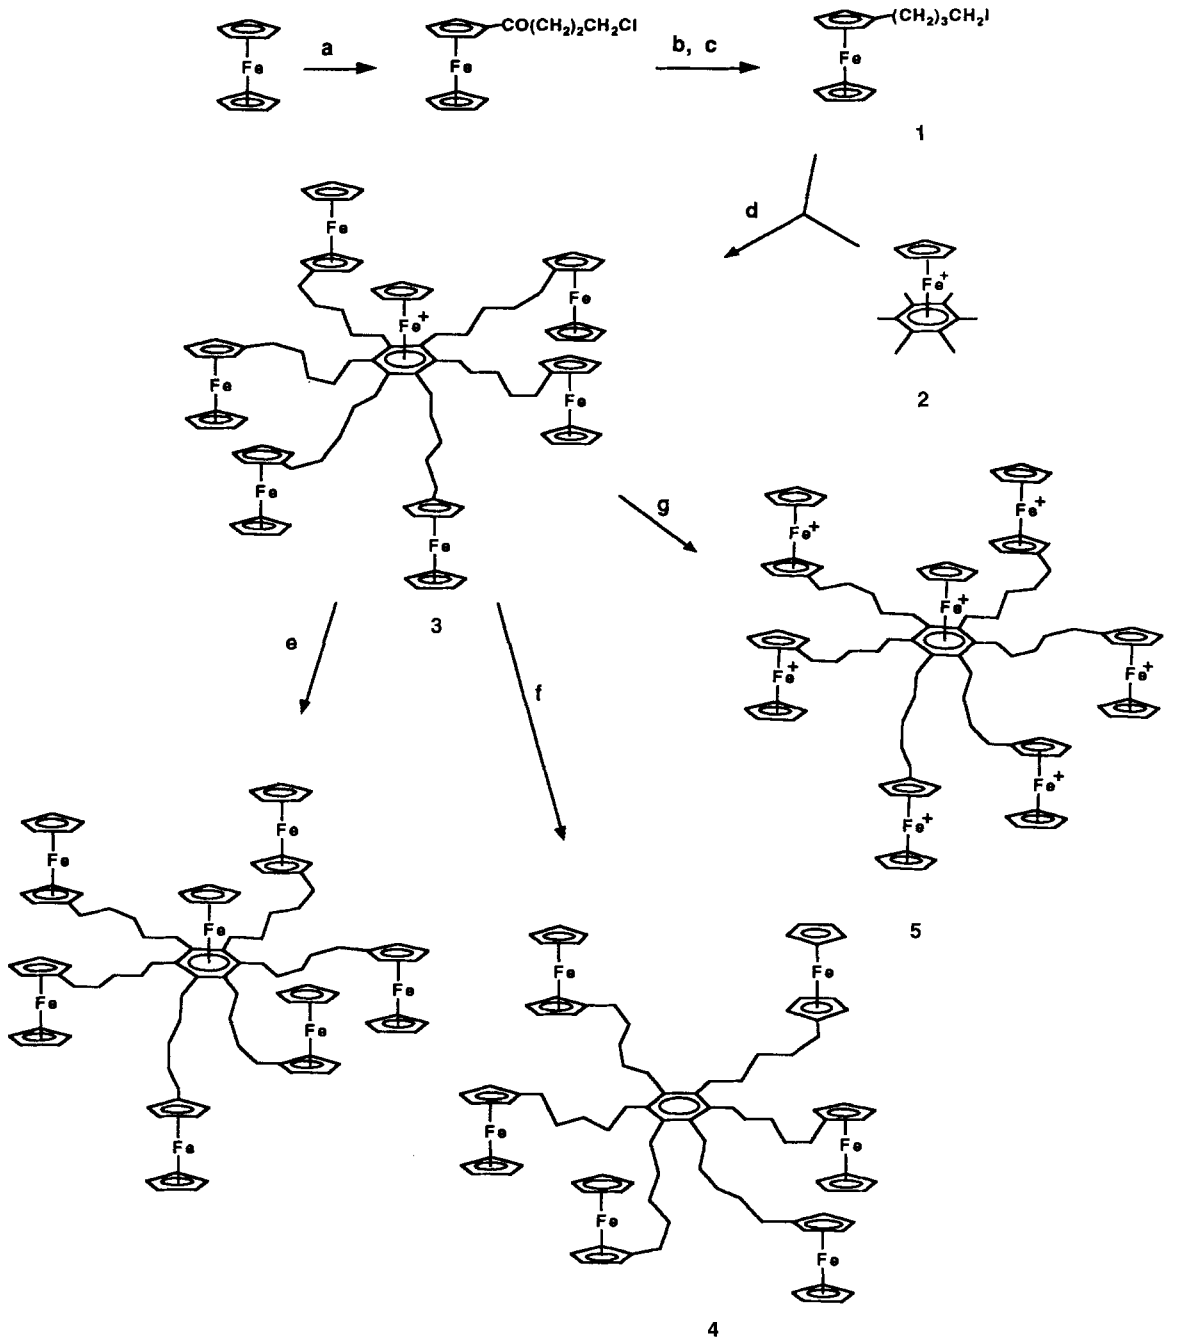
Single-Step Six-Electron Transfer in a Heptanuclear Complex: Isolation of Both Redox Forms**

Jean-Luc Fillaut, Jorge Linares, and Didier Astruc*

Dedicated to Dr. Jacqueline Zarembovitch

Polymers containing ferrocene units are useful redox catalysts for the modification of electrodes[1] and as biosensors.[2] A new generation of polynuclear compounds intermediate between mononuclear and polymeric complexes has recently appeared—the inorganic[3] and organometallic[4] molecular "trees". These well-defined molecules promise to be useful in the construction of dendrimers,[5] in molecular electronic devices,[6] and in multielectron redox catalysis.[7] $FeCp^+$ can serve as an excellent starting core for molecular trees, since polyalkylation, polyallylation, and polybenzylation of polymethyl arenes leads to various topologies.[7] The reaction of $[FeCp(C_6Me_6)]PF_6$ with excess base and an alkyl halide results in selective hexasubstitution [Eq. (a)].[7]



$$[FeCp(C_6Me_6)]PF_6 \xrightarrow[RI\ (R = alkyl)]{KOR'\ (R' = H,\ tBu)} [FeCp\{C_6(CH_2R)_6\}]PF_6 \qquad (a)$$

Since the introduction of organometallic groups on the "branches" is sometimes tedious and requires multistep synthesis,[8a] we have engaged in research aimed at grafting organometallic complexes directly on the branches in the polyalkylation process[8b] and report here our first results. We have isolated and characterized both the reduced and oxidized forms of a heptametallic hexaferrocene system.[9] The central iron units in this complex serve as an internal standard in the determination of the number of ferrocenyl groups on the branches by Mössbauer spectroscopy and cyclic voltammetry.

The 4-ferrocenylbutyl iodide (**1**) was synthesized in the form of orange-red crystals according to Scheme 1. Reaction of a threefold excess of **1** with KOH and $[Fe^{II}Cp(C_6Me_6)]PF_6$ (**2**) gives the PF_6 salt of the heptanuclear Fe^{II} complex cation **3** (orange-red microcrystals) in 65% yield. The Mössbauer spectrum of **3** at 200 K shows a ferrocene doublet with QS = 2.384 mm s^{-1} and IS = 0.487 mm s^{-1} as well as a shoulder for the $[Fe^{II}Cp(arene)]$ doublet at QS = 1.879 mm s^{-1} and IS = 0.487 mm s^{-1}. Photolysis of **3** in CH_3CN in the presence of one equivalent of PPh_3 using visible light gives $[FeCp(PPh_3)(NCMe)_2]PF_6$ and the hexanuclear neutral complex **4** (orange microcrystals) in 96% yield, which results from the selective decomplexation of the central cationic $FeCp^+$ unit. Oxidation of **3** with H_2SO_4 followed by ion exchange with aqueous NH_4PF_6 solution provides the PF_6 salt of the heptanuclear hexaferricinium complex **5** as purple-black microcrystals in 98% yield. The Mössbauer spectrum of **5** at 200 K (as well as at 4 K) shows a Fe^{II} doublet at QS = 1.95 mm s^{-1} and IS = 0.5 mm s^{-1} and a large ferricinium signal at QS = 0.164 mm s^{-1}

Boukheddaden for help with the Mössbauer spectroscopy, S. Treavett for synthetic collaboration, and Dr. F. Moulines for discussions.

Scheme 1: Reagents and conditions: a) $AlCl_3$, $ClCO(CH_2)_2CH_2Cl$ (1.0 equiv), Zn, CH_2Cl_2, 0 °C, 18 h, 72%; b) $LiAlH_4-AlCl_3$ (1.2 equiv.), Et_2O, 0 °C, 16 h, 71%; c) NaI (1.2 equiv), $CH_3COC_2H_5$, 65 °C, 3 h, 95% [10]; d) $[FeCp(C_6Me_6)]PF_6$ (0.05 equiv), KOH (1 equiv), DME, 60 °C, 60 h, 65%; e) +1e (−1.47 V vs SCE); f) *hv*, PPh_3 (1 equiv), CH_3CN, 20 °C, 3 h, 96%; g) 1. H_2SO_4 (40% in H_2O), CH_2Cl_2, 20 °C, 2 min; 2. NH_4PF_6, 98%, or −1e (+0.44 V vs SCE).

and IS = 0.476 mm s^{-1} (Fig. 1). Of particular interest is the fact that the resonance fraction is lower for the outer iron nuclei than for the central one, consistent with a larger thermal motion of the outer Cp_2Fe^+ moieties.

Examination of the electrochemical properties of the hexa- and heptanuclear iron complexes in dimethylformamide (DMF) gave insight into the number and equivalence of the outer ferrocene centers and the influence of the central [FeCp(arene)] group of **3** (Fig. 2). The voltammogram of **3** shows a relative intensity ratio of 6 ± 0.3 between the anodic and cathodic waves, confirming the presence of six ferrocene units. The ΔE_p value of the ferrocene signal, 55 mV at 0.4 Vs^{-1}, indicates that the six ferrocene moieties are electrochemically equivalent. The six ferrocene groups are also oxidized at the same potential in **3** ($E^0 = +0.44$ V vs SCE) as in **4** ($E^0 = +0.45$ V vs SCE) at a scan rate of 400 mVs^{-1}, indicating that the central cationic unit has no influence on the oxidation process. One also notes that all the waves are fully chemically reversible ($I_a/I_c \approx 1$). The formation of Fe^I in the central sandwich group, in particular, is chemically and electrochemically fully reversible on the electrochemical timescale. The diffusion coefficient of **3** is available from the Cotrell equation[1a] by using either the oxidation or the reduction wave ($D_p = 8 \pm 0.5 \times 10^{-6}$ $cm^{-2}s^{-1}$ at 20 °C).

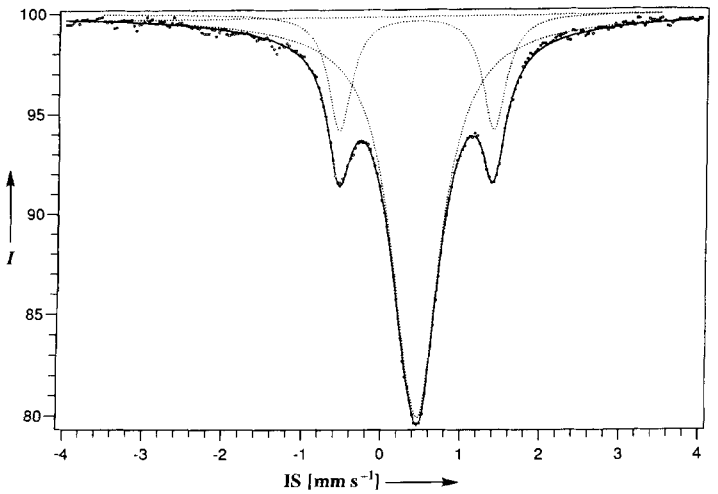

Fig. 1. Mössbauer spectrum of the mixed-valence complex PF_6 salt of **5** at 4.2 K under zero field (standard: iron metal). The shapes and parameters are similar at 78 K and 200 K (see text). The central line is due to the six outer Fe^{III} centers; the external doublet is due to the inner Fe^{II} sandwich.

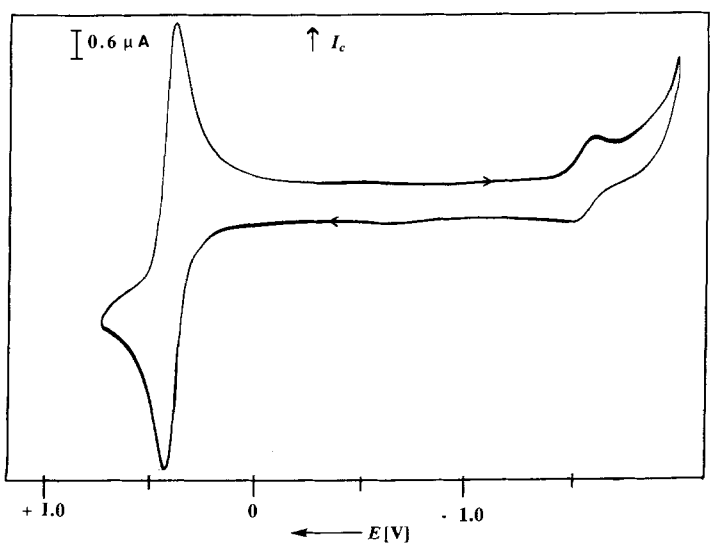

Fig. 2. Cyclic voltammogram of **3** in DMF (concentration ca. 3.4×10^{-3} mol dm^{-3}); supporting electrolyte: 0.1 mol dm^{-3} nBu$_4$BF$_4$. Pt electrode, 20 °C, scan rate 400 mV s^{-1}. Potentials were determined with reference to the SCE.

In conclusion, the $CpFe^+$-induced hexaferrocenylalkylation of C_6Me_6 opens the route to isolable mixed-valence star-shaped molecules with independent redox centers and leads to a fully reversible six-electron redox system which may be useful for multielectron redox catalysis.

Experimental Procedure

Under inert gas, a three-neck round-bottom flask equipped with a condenser was charged with [FeCp(C_6Me_6)]PF_6 (0.36 g, 1 mmol), 4-ferrocenylbutyl iodide (**1**) (6.6 g, 18 mmol), ground KOH (1.12 g, 20 mmol), and 100 mL of dimethoxyethane. The reaction mixture was stirred at 60 °C for 2.5 d under inert gas. Then, the solvent was removed under reduced pressure, and the solid residue was washed with ether (3×30 mL) to remove excess **1**. The cationic organoiron product **3** was extracted as the PF_6 salt, precipitated by addition of pentane, and recrystallized from CH_2Cl_2/ether to give 1.22 g (65 % yield) of orange-red microcrystals of **3**-PF_6, which are soluble in THF, but not in ether.

Fullerene–Oligonucleotide Conjugates: Photoinduced Sequence-Specific DNA Cleavage**

Alexandre S. Boutorine, Hidetoshi Tokuyama, Masashi Takasugi, Hiroyuki Isobe, Eiichi Nakamura, and Claude Hélène*

Oligonucleotides can be used to target either single-stranded nucleic acids such as messenger RNA or double-helical DNA.[1, 2] Oligonucleotide binding can block translation of the target mRNA (the *antisense* strategy) or transcription of the targeted gene by triple helix formation (the *antigene* strategy). Attachment of reactive substituents to oligonucleotides can induce irreversible reactions in the target sequence.[2] Hydropho-

Scheme 1.

bic substituents may also be used to improve cell uptake in biological systems.[3, 4] Recent studies on the chemistry of buckminsterfullerenes have revealed a diversity of reactions and provided access to functionalized fullerenes.[5, 6] Reports from three groups[6–8] have demonstrated that suitably modified fullerenes exhibit biological activity towards living cells,[6] enzymes,[6, 7] viruses,[8] and DNA.[6] Irradiation of a mixture of DNA and a detergent-like C_{60} carboxylic acid with low-energy light results in guanine(G)-selective strand cleavage.[6] This base-selective cleavage was ascribed to the action of singlet oxygen generated by photoactivation of the fullerene molecule, and recent experiments demonstrated that the C_{60} carboxylic acid does generate singlet oxygen in water.[9] The G-selective strand cleavage, however, took place randomly, most likely owing to nonselective hydrophobic binding of the C_{60} molecule to DNA. If this assumption is correct, the site selectivity of the G-selective cleavage should dramatically increase once a suitable recognition site is connected to the C_{60} core. Such site-selective photocleavage has been described, for example, for ellipticin and porphyrin derivatives of oligonucleotides.[10, 11] In order to further investigate this possibility, we have synthesized an organofunctional C_{60} bearing a 14-mer oligodeoxynucleotide side chain capable of binding to either a single-stranded target through Watson–Crick hydrogen-bonding interactions, or a double-stranded target by formation of Hoogsteen hydrogen bonds.[12] We report herein that photocleavage reactions do indeed take place at well-defined positions upon irradiation of the oligonucleotide–fullerene conjugate with three different targets, namely, a single-stranded DNA, a duplex DNA, and a duplex DNA with a hairpin structure.

The fullerene–oligonucleotide conjugate **7** was synthesized by alkylation of a deblocked thiol-containing oligonucleotide **6** with bromoacetate **2** (Scheme 1). The moiety **2** was prepared from the methanofullerene derivative **1**.[13] Introduction of a terminal thiol group in the deblocked oligonucleotide **3** was achieved by reaction of the cystamine **5** with the activated phosphate **4**.[14] Treatment with dithiothreitol yielded the thiol **6**, which was alkylated with **2** in pyridine to afford the fullerene–oligonucleotide conjugate **7** with a yield of 30–40%. The conjugate was colored (red-brown), soluble in water, and precipitated in ethanol or $LiClO_4$ in acetone. Purification of **7** by HPLC was not possible because of the irreversible adsorption of the conjugate on modified silica gel supports. On polyacrylamide gels this derivative formed aggregates in the wells. Electrophoresis on 1.0% agarose/0.1% triton X-100 gel revealed one homogeneous colored band migrating more slowly than unmodified oligonucleotide. This technique was used to purify the conjugate from the unreacted oligonucleotide. The sequence of the oligonucleotide is shown in Figure 1.

Three different target oligodeoxynucleotides were used to test the photosensitizing properties of the fullerene–14-mer conjugate: a single-stranded 20-mer, a duplex with 26 base pairs, and a 41-mer hairpin structure with 18 base pairs and a 5 base loop (see sequences in Fig. 1). The complex was irradiated with a 1000 W xenon lamp through a filter absorbing light at wavelengths shorter than 310 nm. The buffer (pH 6.0) contained cacodylate (10 mM), NaCl (50 mM), the target (50–100 nM), and increasing concentrations of the fullerene–14-mer conjugate (1–60 μM). The 20-mer single strand, the 41-mer hairpin, and one of the duplex strands were labeled with ^{32}P at the 5′-end by means of γ-^{32}P-ATP and T4 polynucleotide kinase (Amersham). Analysis by electrophoresis on denaturing 12% polyacrylamide gel was carried out before and after treatment with piperidine (Fig. 2).

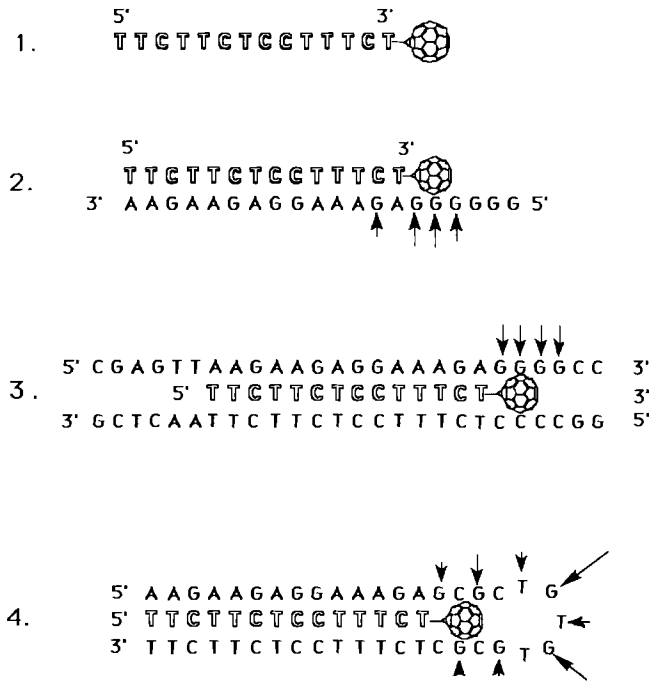

Fig. 1. Structure of oligonucleotide–fullerene conjugate (1) and its complexes with targets: 2. duplex with complementary oligodeoxynucleotide, 3. triple helix, 4. triple helix with hairpin structure. The arrows indicate cleavage sites upon irradiation with light. Lengths of the arrows correspond to intensity of photoinduced cleavage.

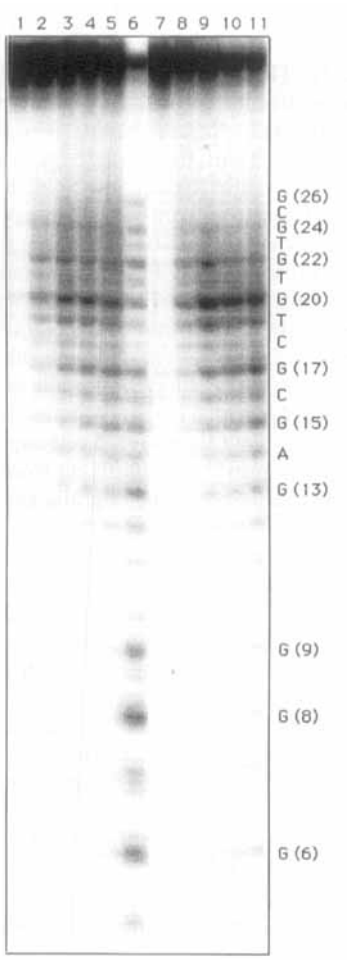

Fig. 2. Gel electrophoresis of the 41-mer hairpin-forming oligonucleotide (100 nM) (see Fig. 1, 4.) after irradiation in the presence of the 14-mer fullerene conjugate (30 μM) in cacodylate (10 mM, pH 6.0) and NaCl (50 mM) at 15 °C. The irradiation times were increased in lanes 1–5 and 7–11, respectively: 0 min (1, 7), 15 min (2, 8), 30 min (3, 9), 45 min (4, 10), and 60 min (5, 11). The two parts of the figure correspond to samples which have not been (1–5) or have been (7–11) treated with piperidine (1 M) at 90 °C for 30 min. The 41-mer was labeled at the 5′-end, and the gels were analyzed with a phosphorimager. Lane 6 indicates the sequence of guanine residues obtained after treatment with dimethyl sulfate and piperidine. The sequence in the region of cleavage and the location of guanine residues are indicated (numbering starts from the 5′-end; see Fig. 1, 4.).

The results of these experiments demonstrate that photocleavage induced by the oligonucleotide–fullerene conjugate occurred at well-defined sites in the duplex, triple helix, and triple helix with hairpin. This is in sharp contrast with the lack of site selectivity in the cleavage by the free C_{60} carboxylic acid.[6] Figure 2 shows the results obtained with the hairpin target. Cleavage was observed at guanines but also at thymine residues (with a lower efficiency). Treatment with piperidine slighthly increased the intensity of the cleavage bands. Comparison with bands generated by piperidine treatment after reaction with dimethyl sulfate (DMS) suggested that fragments obtained by photoinduced cleavage were terminated by a 3′-phosphate. They had the same mobility in the gel as 3′-phosphorylated products of DMS-induced piperidine cleavage. The cleavage sites on the three target sequences are shown in Figure 1. The most reactive guanines were those located in the loop region. With the 26 base pair duplex (devoid of hairpin structure), cleavage occurred at guanines of the purine-containing strand positioned near the 3′-end of the third oligonucleotide strand (Fig. 1). No cleavage was observed on the other strand of the duplex, which did not contain any guanines in the vicinity of the 3′-end of the third strand (the two terminal Gs could not be analyzed owing to their too close proximity to the 5′ label). On the single-stranded target photoinduced cleavage occurred at guanines near the 3′-end of the complementary oligonucleotide–fullerene conjugate (Fig. 1). In all three cases the sites of cleavage were located in the region of the target expected from the known orientation of the oligonucleotide carrying the fullerene derivative: antiparallel orientation with respect to the complementary strand in the duplex and parallel to the oligopurine target sequence in the triplex structures. The enhanced reactivity of guanines in the loop as compared to the stem of the hairpin duplex might be due to a higher accessibility to singlet oxygen in the single-stranded loop, even though the reaction might involve other mechanisms (e.g. electron transfer) resulting from folded structures.

These results indicate that the spherical fullerene terminus on the oligonucleotide chain did not hamper duplex and triplex formation. The cleavage nearly exclusively took place at guanine bases; this is consistent with singlet oxygen mediation. The same profile of site and base selectivity was observed with an oligonucleotide–chlorin conjugate (with the same oligonucleotide sequence), which was shown to generate singlet oxygen upon irradiation and to cleave nucleic acids (results not shown).

In summary, we have shown that fullerene–oligodeoxynucleotide conjugates effectively modify DNA with high site specificity by forming double and triple helices. The present results clearly indicate that fullerene–oligonucleotide conjugates are promising photoprobes for the investigation of gene transcription and mRNA translation. Design of the optimal linker moiety and conditions needed to achieve high efficiency are now under investigation. In addition, the hydrophobicity of the fullerene moiety can be exploited to enhance cell uptake for biological applications.

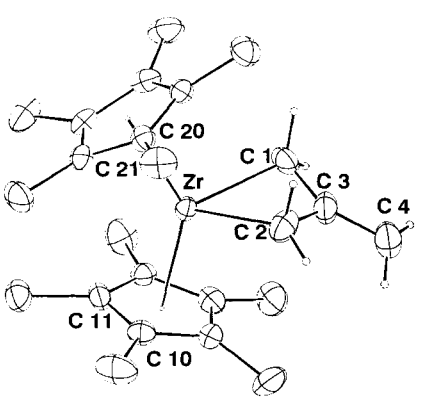
Bis(pentamethylcyclopentadienyl)(η^3-trimethylenemethane)zirconium: A New Mode of Bonding for the Trimethylenemethane Ligand

Gerhard E. Herberich,* Carsten Kreuder, and Ulli Englert

Trimethylenemethane (tmm) forms a multitude of η^4 complexes with transition metals.[1] For complexes of the early transition metals, only $[Cp^*TaMe_2(tmm)]$[2a] ($Cp^* = \eta^5$-C_5Me_5) and recently $[Cp^*Zr(tmm)(\mu\text{-}Cl)_2Li(tmeda)]$[2b] (tmeda = *N,N,N',N'*-tetramethylethylenediamine) have been described to date.

$[Cp_2^*ZrCl_2]$ reacted with $Li_2[tmm(tmeda)]$[3] to give **1**, which was obtained as deep red crystals in 45% yield. An X-ray structure analysis shows **1** to be a bent metallocene with a side-bound tmm unit (Fig. 1).[4] The angle between the C1,Zr,C2 and C1,C3,C2 planes is only 33.0(9)°; the terminal CH_2 group is bent out of the C1,C3,C2 plane by 7.8(5)°.

$[Cp_2^*Zr(tmm)]$ **1**



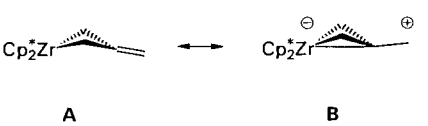


Fig. 1. Crystal structure of **1**. Metallocene angle 136.9(4)°; Zr-C(10 ··· 14) 254.1, Zr-C(20 ··· 24) 256.3 pm (average); Zr-C1 227.7(6), Zr-C2 225.8(7), Zr-C3 263.7(7), C1-C3 149(1), C2-C3 151(1), C3-C4 137.6(9) pm; C1-Zr-C2 66.7(3)°, Zr-C1-C3 86.1(4), Zr-C2-C3 86.4(4), C1-C3-C2 112.2(6), C1-C3-C4 123.4(9), C2-C3-C4 123.7(9).

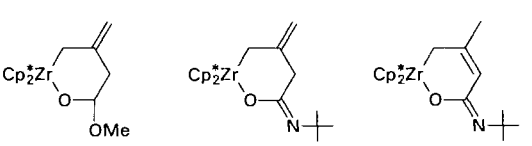
The binding of the tmm ligand to the Zr atom is unusual. The distances from the metal atom to C1 and C2 (227.7 and 225.8 pm, respectively) are very similar to those in Zr–alkyl complexes ($[Cp_2ZrMe_2]$: 228,[7a] $[Cp_2Zr(CH_2)_2SiMe_2]$: 224 pm[7b]). The distance to the central atom C3 (263.7 pm) is typical for weak interactions (compare, for example, 259.7 pm for C-2/3 in the butadiene complex $[Cp_2Zr(2,3\text{-}Me_2C_4H_4)]$[8] and 263.3–269.2 pm in the η^3-fluorenyl derivative $[CpZr(C_5H_4CMe_2C_{13}H_8)Cl]$[9]); no direct interaction exists between C4 and the Zr center (Zr ··· C4 distance = 388 pm). Thus, η^3 coordination is observed in **1**. Finally, the long C3–C4 bond (137.6(9) pm) shows that the delocalization of the π electrons of the tmm dianion is to a certain extent retained in the complex.

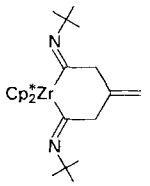
The zirconocene fragment in **1** possesses three valence orbitals with two valence electrons.[10] It is therefore able to form two strong σ bonds with C1 and C2 of the tmm ligand, as in dialkyl derivatives $[Cp_2ZrR_2]$. If the tmm ligand were not bent out of plane, the acceptor orbital of the $[Cp_2^*Zr]$ fragment would be unable to overlap with the π electron pair of the tmm ligand. Only through the observed folding is a σ interaction with C3 possible. This phenomenon has been discussed previously for enedithiolato complexes ($[Cp_2M(S_2C_2R_2)]$ where M = Ti, Mo, W),[10] and is likewise observed for the analogous zircocenes with butadiene[8] and enediolato ligands.[11] The bonding in **1** may be represented according to the valence-bond method by the resonance structures **A** and **B** (Scheme 1).



A **B**

Scheme 1.

In the NMR spectrum, the Cp* rings in **1** are equivalent, even at low temperatures (^1H NMR: −90 °C, 500 MHz; ^{13}C NMR: −90 °C, 125.7 MHz). Thus, in solution, the energy barrier for the inversion of the [Zr(tmm)] moiety can only be small ($0 \leq \Delta G^{\neq} <$ ca. 30 kJ mol^{-1}). There is no evidence of high-amplitude motion or disorder of the tmm ligand in the solid state; there are no short distances between the terminal methylene group and neighboring molecules.[12]



Upon heating, **1** decomposed with cleavage of isobutene. Protonolysis with methanol and phenol generated $[Cp_2^*Zr(OR)_2]$ (R = Me[13] or Ph[14]) and isobutene; no intermediates were detectable by NMR spectroscopy. 2-Butyne and 2,3-dimethylbutadiene did not react with **1**. On the other hand, insertions into polar double bonds were successful. Thus, methyl formate and *tert*-butyl isocyanate react with **1** at 0 °C to form the six-membered ring complexes **2** and **3**, respectively; similar behavior was found with butadiene complexes.[15] On warming, the azaenolato complex **3** with an unconjugated π electron system rearranged quantitatively to give the conjugated isomer **4**.

5

At 0 °C, **1** reacted with *tert*-butyl isonitrile in a double insertion reaction to yield the symmetric diiminoacyl complex **5**. A similar reaction is known for the cyclobutene complex $[Cp_2Zr(PMe_3)(\eta^2\text{-}C_4H_6)]$,[16] whilst the 1-sila-3-zirconacyclobutane $[Cp_2Zr(CH_2)_2SiMe_2]$ undergoes two insertion reactions with C–C coupling of two *t*BuNC molecules.[17]

Experimental Procedure

1: A cooled suspension of $[Cp^*_2ZrCl_2]$ (32.4 g, 0.75 mmol) in THF (0.6 L) and hexane (0.6 L) was treated portionwise at −80 °C with $Li_2[tmm(tmeda)_2]$ (13.8 g, 75 mmol) [3]. The mixture was warmed slowly (18 h) to 20 °C, volatiles were removed in vacuo, and the residue extracted portionwise with hexane (ca. 0.3 L) until the extracts remained colorless. The solution was again evaporated to dryness (finally under high vacuum), and the residue taken up in hexane (0.15 L). The resulting suspension was filtered through sea sand to remove insoluble solid material. Crystallization at −30 °C gave **1** (14.1 g, 45%) as dark red rods [18]; m.p. 105 °C (decomp.); MS: *m/z* (%): 414 (32, M^+), 359 (100, $Cp^*_2Zr - H$); ^1H NMR (C_6D_6): δ = 5.24 (quin, CH_2=), 1.60 (t, $2ZrCH_2$, ^4J = 1.5 Hz), 1.76 (s, 2 Cp*); ^{13}C NMR: δ = 136.9 (s, CC_3), 107.0 (tquin, 154, 6.5 Hz, CH_2=), 56.0 (tm, 133 Hz, $ZrCH_2$), Cp*: 117.5 (s), 10.9 (q, 126 Hz).

2: A solution of **1** (1.27 g) in hexane (50 mL) was treated at 0 °C with HCO_2Me (176 mg). After 2 h, all volatiles were carefully removed in vacuo. Crystallization from hexane at −30 °C gave **2** (1.09 g, 78%) as orange crystals [18]; m.p. 110–120 °C; MS: *m/z* (%): 442 (13, M − MeOH), 287 (100, $Cp^*Zr(OMe)_2^+$); ^1H NMR (C_6D_6): δ = 5.19 (dd, ^3J(5a,6) = 8.6, ^3J(5b,6) = 3.3 Hz, 6-H), 5.04 (t, ^2J(AB) = 2.8 Hz, H_A), 4.66 (dm, ^2J(AB) = 3.2 Hz, H_B) (protons of 4-CH_2= designated as H_A and H_B), 3.27 (s, OMe), 2.55 (ddm, ^2J(5a,5b) = 12.5, ^3J(5b,6) = 3.3 Hz, 5-H_b), 2.26 (ddm, ^2J(5a,5b) = 12.5, ^3J(5a,6) = 8.6 Hz, 5-H_a), 2.18 (dm, ^2J(3a,3b) = 11.0 Hz, 3-H_a), 1.84 and 1.83 (s, Cp*), 1.09 (dm, ^2J(3a,3b) = 11.0 Hz, 3-H_b); ^{13}C NMR: δ = 154.0 (s, C=CH_2), 107.0 (t, 153 Hz, CH_2=), 105.1 (d, 164 Hz, OCH), 54.0 (qd, 140, 4 Hz, OMe), 50.0 and 47.8 (t, 124 Hz, CH_2), Cp*: 119.34 (s), 119.32 (s), 11.52 and 11.47 (q, 126 Hz).

3: A solution of **1** (2.60 g) in hexane (60 mL) was treated at 0 °C with *t*BuNCO (616 mg). After 12 h the precipitated yellow powder was filtered off, and the filtrate concentrated. Further product crystallized at −30 °C as orange platelets (total yield 1.95 g, 61%) [18]; decomp. 160–180 °C; MS: *m/z* (%): 513 (67, M^+), 379 (100, MH − Cp*); ^1H NMR (C_6D_6): δ = 4.99 and 4.70 (dm, ^2J = 3.1 Hz, 4-CH_2=), 3.12 (s, 2 × 5-H), 1.76 (s, 2 Cp*), 1.70 (s, 2 × 3-H), 1.54 (s, *t*Bu); ^{13}C NMR: δ = 158.3 (s, C=CH_2), 151.8 (s, C=N), 107.0 (t, 154 Hz, CH_2=), 53.0 (t, 124 Hz, CH_2), 49.7 (t, 126 Hz, CH_2), *t*Bu: 52.8 (s, CC_3), 32.1 (q, 125 Hz, CMe_3), Cp*: 120.2 (s), 11.3 (q, 125 Hz).

4: Heating of **3** in toluene for 12 h at 60 °C generated **4**. The toluene was replaced with hexane. Further workup as described for **3** afforded **4** as yellow platelets (total yield 60%) [18]; m.p. 67–75 °C; ^1H NMR (C_6D_6): δ = 6.21 (q, ^4J = 1.0 Hz, 5-H), 2.00 (dm, ^4J = 1.0 Hz, 4-Me), 1.75 (s, 2 Cp*), 1.58 (s, *t*Bu), 1.33 (s, 2 × 3-H); ^{13}C NMR: δ = 159.2 (s, CC_3), 148.8 (s, C=N), 129.1 (d, 156 Hz, CH=), 51.5 (t, 123 Hz, CH_2), 32.1 (q, 125 Hz, 4-Me), *t*Bu: 52.7 (s, CC_3), 31.8 (q, 125 Hz, CMe_3), Cp*: 119.7 (s), 11.3 (q, 127 Hz).

5: A solution of **1** (0.51 g) in hexane (30 mL) was treated at 0 °C with *t*BuNC (200 mg). After 2 h the mixture was filtered through sea sand. Concentration of the filtrate to ca. 10 mL gave, after cooling to −30 °C, **5** (240 mg, 35%) as an ochre-colored powder, which decomposed slowly at room temperature; MS: *m/z* (%): 497 (M^+ − *t*BuNC), 360 (100, $Cp^*_2Zr^+$); ^1H NMR (C_6D_6): δ = 4.88 (s, 4-CH_2=), 3.36 (s, 3-/5-CH_2), 1.80 (s, 2 Cp*), 1.48 (s, 2 *t*Bu); $^{13}C\{^1H\}$ NMR: δ = 230.3 (Zr-C=N), 148.3 (CC_3), 109.0 (CH_2=), 58.7 (CH_2), *t*Bu: 47.5, 32.1, Cp*: 115.9, 12.7.

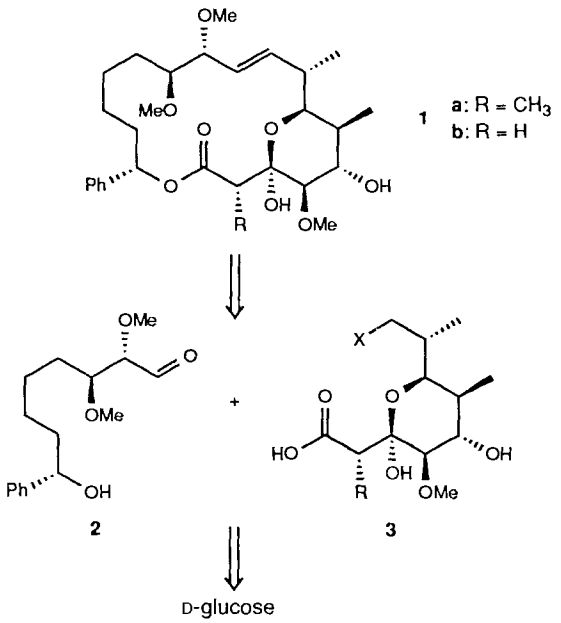
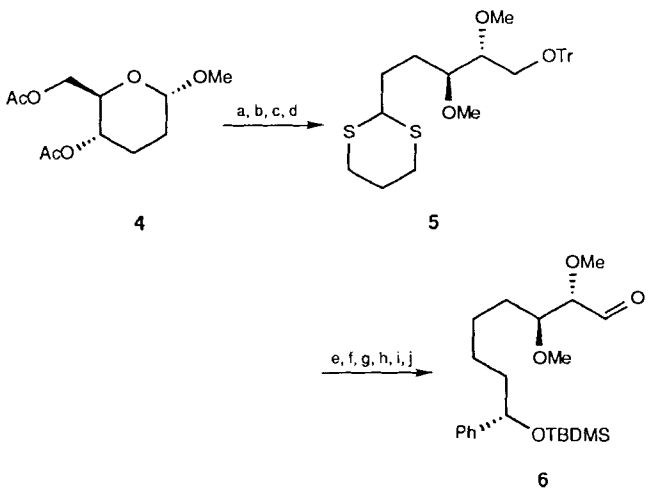
Total Synthesis of Soraphen $A_{1\alpha}$



Stephan Abel, Dominik Faber, Ottmar Hüter, and Bernd Giese*

In 1986 a new class of 18-membered macrolides called the soraphens were isolated by H. Reichenbach, G. Höfle et al. as metabolites of the microorganisms *Sorangium cellulosum*.[1] The parent compound, soraphen $A_{1\alpha}$ (**1a**), contains ten stereogenic centers, and the methyl, methoxy, and hydroxy groups of the tetrahydropyran ring occupy axial positions.[2] Due to this chemical structure as well as its antifungal activity, the novel natural product soraphen $A_{1\alpha}$ is an interesting target for synthesis.[3] Herein we report the first total synthesis of soraphen **1a** and 2-norsoraphen **1b**. The retrosynthetic analysis of **1** leads to compounds **2** and **3**, which are both available from D-glucose (Scheme 1). These building blocks were connected by a Julia olefination (**6** + **13** → **14**) as well as a subsequent lactonization (**16** → **1b**). Further key steps of the synthesis involve stereoselective chain elongation (**10** → **11**) and methylation of 2-norsoraphen **1b** resulting in soraphen (**1a**).



The synthesis of **6**, a silylated derivative of **2**, was accomplished by converting the dideoxysugar **4**[4] into the dithiane **5** and elongating the chain with Corey–Seebach methodology

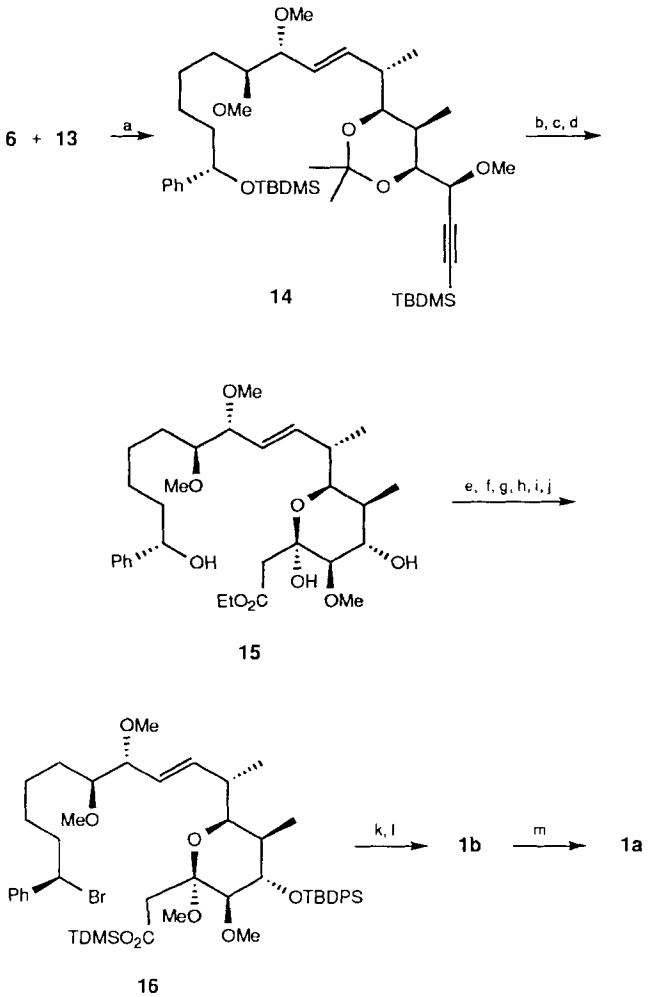
using (*R*)-phenyloxirane (Scheme 2).[5] This reaction sequence allowed the three stereogenic centers of building block **6** to be transferred directly from the starting materials.



The stereogenic centers of building block **3** were set by conversion of the functional groups of D-glucose. The six-membered ring of **3** has the framework of an L-ketose; its derivative **7**, however, can be transformed into the D-aldose **9** via the acyclic form **8** (Scheme 3). A six-membered ring framework that contains the correct steric arrangement of the functional groups as in **9** is present in aldehyde **10**, which Hanessian et al. obtained from D-glucose.[6]

The chain elongation of the aldehyde in **10** could only be achieved with the desired stereoselectivity and in high yield by using a C_2 unit. Thus the bromomagnesium salt of *tert*-butyldimethylsilylacetylene gave the chelation controlled product (**10** → **11**) stereoselectively in 87% yield.[7] The configuration of **11** was determined by crystal structure analysis.[8] It proved to be advantageous to introduce the missing carboxylic acid group and to hydrolyze the acetylene into the ketone (**14** → **15**) only after connecting the building blocks **6** and **13** by a Julia reaction.[9] To perform the latter, the acetal ring of **11** was opened with propanedithiol and the aldehyde functionality was released with methyl iodide.[10] Subsequent reduction, conversion into the phenyl thioether,[11] and oxidation with *meta*-chloroperbenzoic acid gave rise to sulfone **13**. The Julia reaction produced the (*E*)-isomer **14** selectively as shown by the coupling constant of 14.2 Hz in the ^1H NMR spectrum (Scheme 4).[12] Attempts to carry out the coupling under Wittig reaction conditions remained unsuccessful.

The coupling product **14** still lacks the carboxylic acid function of soraphen, which was introduced with ethyl chlorofor-

mate after desilylation.[13] Subsequent addition of water across the triple bond via an enamine intermediate followed by cleavage of the protecting groups resulted in the tetrahydropyran ring structure of **15**. Experiments by G. Höfle et al. on the ring-opened soraphen demonstrated that the lactonization is best effected by a substitution reaction of the cesium salt of the carboxylic acid.[14] Therefore, benzyl alcohol **15** and the bromo enamine reported by Ghosez et al.[15] were allowed to react under mild conditions and yielded bromide **16** with complete inversion. The macrocyclization of the cesium carboxylate of **16** (20 °C, 60% yield) produced the soraphen ring structure also with inversion at the benzyl group. Since the methyl group in soraphen $A_{1\alpha}$ (**1a**), that is in α-position to the lactone occupies the thermodynamically favored configuration,[16] it was introduced in the last step of the synthesis. By using two equivalents of potassium 2,6-di*tert*-butylphenoxide, the hemiketal ring of norsoraphen **1b** was opened and deprotonated to give the potassium enolate. To avoid overmethylation, the enolate ion was quenched with an excess of methyl iodide within 30 min at 0 °C. Subsequent cyclization to the hemiketal in acidic medium gave soraphen $A_{1\alpha}$ (**1a**) in 70% yield.

[16] Upon treatment of soraphen $A_{1\alpha}$ (**1a**) [2] with base (thermodynamic conditions), no change of configuration occurs at the methylated carbon α to the lactone. The crystal structure of **1a** shows that the methoxy group of the tetrahydropyran ring and the methyl group α to the lactone are in a sterically favorable position relative to each other. In the corresponding *epi* form, however, these methyl and methoxy groups are subject to 1,3-diaxial interactions. This might also be the reason why a possible dimethylation of norsoraphen **1b** can be avoided under appropriate reaction conditions.

Novel Bimetallic Model System for Cytochrome P_{450}: Effect of Membrane Environment on the Catalytic Oxidation**

Albertus P. H. J. Schenning, Dominicus H. W. Hubert, Jan H. van Esch, Martinus C. Feiters, and Roeland J. M. Nolte*

Cytochrome P_{450} catalyzes a variety of oxidation reactions, including the hydroxylation of alkanes and the epoxidation of alkenes.[1] The active site of this membrane-bound enzyme contains a heme function and a thiolate as axial ligand. The catalytic cycle involves the binding of a substrate, reduction of iron(III) to iron(II), and binding and reductive cleavage of molecular oxygen to generate what is formally an oxoiron(V) complex,

which transfers its oxygen atom to the bound substrate. The iron center accepts the electrons from NADPH, through mediation of a flavoprotein.

Because of its biological importance—this enzyme plays a crucial role in the metabolism of endogeneous chemicals and xenobiotic compounds—and also because this archetype oxidation catalyst may serve as a model for a new generation of synthetic catalysts, a great deal of research is currently focused on mimicking the action of cytochrome P_{450}.[2] Until now only a few models have been described that incorporate the important features of the natural system, namely molecular oxygen as the oxidant, a metalloporphyrin as catalyst, an electron donor, and a membrane system holding these components.[3] All models have the disadvantage of displaying very low catalytic activity.

During the course of our studies on novel supramolecular catalytic systems, we found that the rhodium complex [$Rh^{III}(\eta^5$-Cp*)(bpy)Cl_2] (Cp* = pentamethylcyclopentadienyl, bpy = 2,2′-bipyridine) is an efficient catalyst for the reduction of manganese(III) porphyrins by sodium formate.[4] We report here on a membrane-bound cytochrome P_{450} mimic that epoxidizes alkenes with good turnover numbers. The system is composed of vesicles containing an α-(aceto)-[5,10,15,20-tetrakis(2,6-dichlorophenyl)-porphyrinato]manganese(III) catalyst ([$Mn^{III}t_{2,6}$-diClPP] **1**),[5] *N*-methylimidazole as axial ligand, and an amphiphilic rhodium(III) complex (**2**)[6] in combination with sodium formate as electron donor. We found that the type of membrane has a dramatic effect on the catalytic activity of the mimic.

1 2

The manganese porphyrin **1** and the rhodium complex **2** were incorporated into positively charged dimethyl-dioctadecylammonium chloride (DODAC)[7] and negatively charged dihexadecylphosphate (DHP)[7] vesicles by the ethanol injection method.[8] Gel permeation chromatography and electron microscopy were used to show that the porphyrin and the rhodium complex were bound to the bilayers of the vesicles and that the vesicle structure was not destroyed by the incorporation procedure. The diameters of the vesicles of both amphiphiles amounted to about 4000 Å. The fluorescence spectra of H_2-$t_{2,6}$-diClPP in both DODAC and DHP vesicles ($T = 70\,^{\circ}C$) showed no effects of self-quenching when the porphyrin to lipid ratio was lower than 0.005. This indicates that below these ratios the porphyrin molecules are not aggregated.[9] The addition of water-soluble quenchers (NaI and $CuSO_4$ in the case of DODAC and DHP vesicles, respectively) to the system did not change the fluorescence spectrum of the vesicle-bound H_2-$t_{2,6}$-diClPP. Most likely the porphyrin is situated in the inner part of the vesicle bilayer. EPR studies, using [$Cu^{II}(t_{2,6}$-diClPP)] instead of **1** revealed that for both vesicle systems the orientation of the porphyrin molecules was parallel to the vesicle surface.[10] The structure of the model system is depicted in Figure 1.

First we investigated the influence of the membrane matrix on the reduction of the manganese(III) porphyrin. To this end the

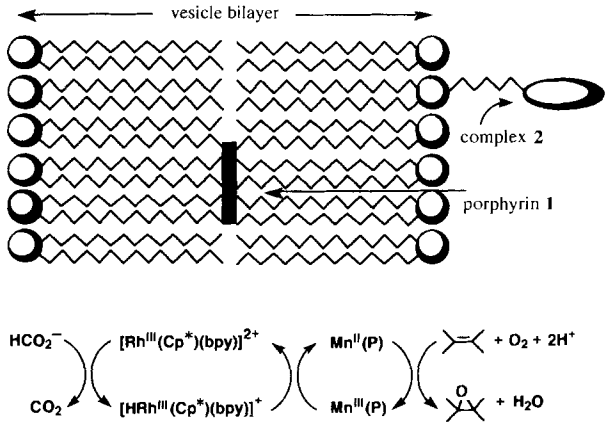

Fig. 1. Schematic representation of the cytochrome P_{450} mimic and the catalyzed reaction.

decrease in the absorption at 660 nm (Mn^{III} porphyrin) and the increase in absorption at 448 nm (Mn^{II} porphyrin) in the UV/VIS spectrum was followed as a function of time, both under an argon atmosphere and in air. The rhodium complex manganoporphyrin ratio was varied from 0.5 to 10. Under argon in DODAC as well as in DHP vesicles, the Mn^{III} porphyrin was reduced at all Rh/Mn ratios tested. The reduction rate was found to increase linearly with the Rh^{III} concentration. At a fixed Rh/Mn ratio the reduction was faster in DODAC vesicles than in DHP vesicles ([Rh]/[Mn] = 1; k_0 (DODAC) > 100 nmol $L^{-1}s^{-1}$, k_0 (DHP) = 20 ± 2 nmol $L^{-1}s^{-1}$). The reduction of Mn^{III} in DODAC vesicles also took place when the reactions were carried out in an air atmosphere. A similar result was obtained for DHP except when the Rh/Mn ratio was equal or less than 1, under which conditions reoxidation of Mn^{II} was observed. In the absence of the Rh^{III} complex or formate no reduction took place. These results indicate that the rhodium-formate system is capable of reducing the membrane-bound Mn^{III} porphyrin and presumably, as observed previously,[4] the rhodium complex acts as a redox-active phase transfer catalyst in this process. The reduction of Mn^{III} is faster in the positively charged vesicles than in the negatively charged ones because the formate concentration is higher at the bilayer/water interface of the former aggregates. The fact that in DODAC vesicles in general and in DHP vesicles with a Rh/Mn ratio higher than 1 no reoxidation of Mn^{II} takes place, indicates that the reduction of manganese is much faster than its reoxidation.

In a second series of experiments we investigated whether our membrane-bound cytochrome P_{450} mimic was able to epoxidize alkenes. The results are listed in Table 1. All substrates tested were epoxidized by the catalytic system based on DHP vesicles. The turnover numbers are higher than those obtained with the two-phase system previously published by us.[4] They are in the same range as those observed for the natural system (1 nmol product per nmol P_{450} per min).[1] Remarkable is the high stability of the catalyst during the reaction, which is in contrast with the two-phase system. The effect of the membrane environment on the catalytic epoxidation became clear when the DHP vesicles were replaced by the DODAC vesicles. In the latter membrane system no epoxidation of alkenes was observed (last two entries of Table 1). Presumably, the concentration of protons is too low to allow the formation of the catalytically active oxomanganese(V)[11] species at the positively charged interface. When the Rh/Mn ratio was increased from 1 to 10 the turnover number of the reaction decreased considerably (Table 1, entry 5). This phenomenon is possibly caused by the fact that more elec-

Table 1. Epoxidation of alkenes by the membrane-bound cytochrome P_{450} mimic [a].

Entry	Surfactant	Substrate	Product [b]	Turnover number [c]
1	DHP	α-pinene	α-pinene oxide	360
2	DHP	*cis*-stilbene	*cis*-stilbene oxide	45
3	DHP	limonene	limonene oxide	50
4	DHP	styrene	styrene oxide [d]	55
5	DHP [e]	styrene	styrene oxide	5
6	DODAC	styrene	-	0
7	DODAC [e]	styrene	-	0

[a] For reaction conditions see Experimental Procedure. The reaction was followed by GLC for 1 h. No destruction of the catalyst was found after that period. [b] The only product of the reaction was epoxide, which was gradually decomposed into other products. The decomposition processes were independent of the Rh/Mn ratio. No epoxide was formed without vesicles or when any of the components of the catalytic system were omitted. [c] Turnover number [epoxide]/1 per hour, calculated from the initial part of the conversion/time plot. α-Pinene oxide was converted (>90%) into pinocamphone within a period of one hour. Limonene oxide decomposed (±50%) into as yet unidentified products. [d] Styrene oxide and stilbene oxide were stable under the experimental conditions. [e] Rh/Mn molar ratio = 10.

trons become available due to the higher concentration of rhodium centers. As a result a side reaction can take place which produces water (the so-called non-productive pathway[11]).

In summary, we have developed a bimetallic membrane-bound cytochrome P_{450} mimic which catalyzes the epoxidation of alkenes with good turnover numbers. Current work is aimed at developing catalytic systems that display substrate selectivity.

Experimental Procedure

Reduction experiments: The desired amounts of stock solutions of **1**, **2**, *N*-methylimidazole, and DHP or DODAC in chloroform were mixed in a test tube. The solvent was evaporated under a stream of nitrogen to leave a homogeneous film. This film was solubilized in 100 μL ethanol/tetrahydrofuran (1:1, *v*/*v*) and injected in 1.25 mL water at 75 °C. The suspension was purged with argon for 30 min and injected in a cuvette containing 1.25 mL of an ethylmorpholine/sodium formate buffer at 75 °C. Final conditions: 2.4 μM of **1**, 2.4 × *n* μM of **2** (*n* = Rh/Mn molar ratio), 3.95 μM of *N*-methylimidazole, 910 μM DODAC or DHP in ethylmorpholine (50 mM)/sodium formate (250 mM) buffer (pH = 7.0), *T* = 70 °C.

Epoxidation experiments: Final conditions as above, except Rh/Mn molar ratio = 1 and [substrate] = 200 μM. Now the 100 μL solution was directly injected in a 2.5 mL buffered solution at 75 °C. Substrate was added and the reaction mixture was analyzed from time to time by taking a 0.2 mL aliquot to which was added 0.1 mL diethyl ether containing mesitylene as an internal standard. This mixture was shaken vigorously (vortex apparatus) and centrifuged. After phase separation, a 5 μL sample was taken from the diethyl ether layer and analyzed by GLC (column Chrompack, WCOT/CP-SIL5CB, temperature program 70 °C (2 min), 10 K min^{-1} 200 °C (2 min)).

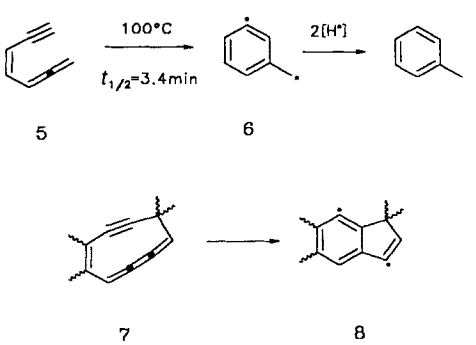
1,4-Didehydrobutadiene: The Intermediate in a New Class of Thermally Induced Intramolecular Alkyne Couplings**

Rolf Gleiter* and Joachim Ritter



Dedicated to Professor Heinz Dürr on the occasion of his 60th birthday

More than twenty years ago Bergman and co-workers discovered that enediynes such as (*Z*)-hexadiyn-3-ene (**1**) cyclize to give the corresponding 1,4-didehydrobenzenes (**2**) as short-lived intermediates.[1] This reaction occurs at 200 °C with an activation energy of 28 kcal mol^{-1} (Scheme 1).[2a] The recent discovery of the natural antitumor antibiotics calicheamicin, esperamicin, and dynemicin, which contain the cyclic enediyne unit **3**, led to an enormous increase in publications on enediyne chemistry in the last seven years.[3] A common feature in the mechanism of action of these antibiotics is the cycloaromatization of the enediyne unit **3** to give the bicyclic 1,4-didehydrobenzene **4**.

Scheme 1. Cycloaromatization of enediynes.

In the case of neocarzinostatin, the electrocyclization of an initially generated cyclic (*Z*)-cumulene-enyne **7** is proposed as the key step.[4] In related work Myers et al. found that the surprisingly facile cyclization of the open-chain cumulene **5** gives α,3-dehydrotoluene **6** and is an example of a new type of a 1,4-biradical generating reaction (Scheme 2).[5a]

Scheme 2. Cycloaromatization of cumulene-enynes.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the BASF Aktiengesellschaft (Ludwigshafen). J. R. thanks the Studienstiftung des deutschen Volkes for a doctoral fellowship.

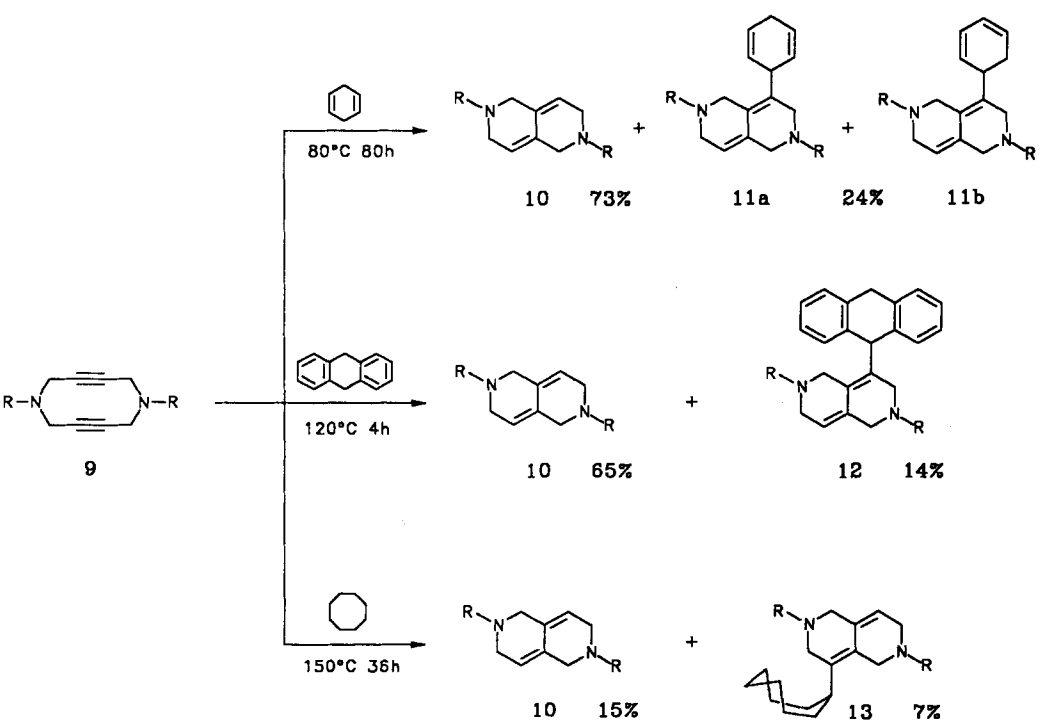
The following points concerning the two reactions should be mentioned: 1) The crucial structure parameter influencing the activation energy of the Bergman cyclization is the transannular distance c–d between termini c and d of the triple bonds. Experimental data as well as theoretical investigations reveal that at c–d distances less than about 3.2 Å the enediyne undergoes spontaneous transannular coupling at room temperature.[6] 2) Both the Bergman and the Myers cyclization proceed via a transition state in which the termini of a conjugated 6π electron species are connected.[7] For that reason the antibonding interactions between the in-plane π orbitals are compensated in part by bonding interactions of the out-of-plane π orbitals, and thus the activation energy is less than that of a nonconjugated π system. 3) In terms of thermodynamics the ease of 1,4-diradical generation depends on the energy gap between the alkyne and the diradical. While the Bergman cyclization of **1** is endothermic[2e] with a late transition state, the analogous process for allene-enyne **5** is strongly exothermic and has an early transition state.[2, 5]

One can thus conclude that the formation of a 1,4-diradical from a diyne under moderate conditions requires an electronically activated species (e.g. conjugated enediynes) with a transannular distance between the triple bonds of no more than 3.2 Å. Furthermore the C–C coupling should lead to a diradical with lower σ energy than that of the diyne, and formation of the new π system should lead to at least a partial gain in energy through aromatization or conjugation.

For some time we have been synthesizing a number of strained ten-membered cyclic diynes with c–d distances close to 3 Å.[8] These compounds have strongly split π levels and an enhanced reactivity compared to unstrained alkynes.[8a–g] Thus we wondered whether the reaction of two strongly interacting triple bonds would result in the generation of a corresponding 1,4-didehydrobutadiyne (Scheme 3).

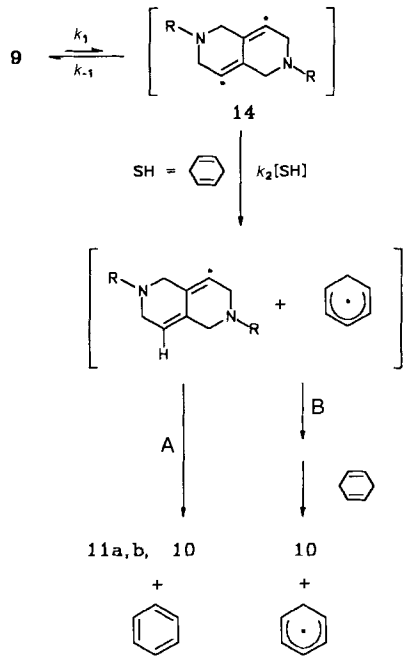
Scheme 3. A possible route to a 1,4-didehydrobuta-1,3-diene.

We report here on our investigations of thermally induced transannular alkyne couplings in 1,6-diazacyclodeca-3,8-diynes.[8e] For instance, heating *N,N'*-diisopropyl-1,6-diazacyclodeca-3,8-diyne **9** (R = *i*Pr) with various organic solvents as trapping agents affords products consistent with a butadiene-1,4-diyl intermediate (Scheme 4). With 1,4-cyclohexadiene as solvent (c(**9**) = 0.04 mol L^{-1}), the overall yield of *trans*-butadienes **10** and **11** is 97%.



In contrast to the Bergman and Myers cyclization, the reaction rate with respect to the disappearance of the starting material depends on the trapping agent (i.e. solvent). When the reaction is conducted in cyclooctane (c(**9**) = 0.024 mol) at 151 °C nearly quantitative conversion is achieved after 36 h, whereas the reaction time with the more effective hydrogen donor 9,10-dihydroanthracene amounts to only 4 h at 120 °C. The low yield (due to polymerization) for the cyclization/H-abstraction process in solvents that are apparently less effective H donors, such as cyclooctane and *n*-octane, is also consistent with the initial formation of a diradical species.

To account for the results obtained in the thermolysis of **9** we propose the following mechanism (Scheme 5) in which 1,4-didehydrobutadiene **14** occurs as an intermediate. The subsequent hydrogen abstraction from a solvent molecule may lead to a solvent cage radical pair which either results in cage or cage escape reaction products.



While the radical recombination products with 1,4-cyclohexadiene, 9,10-dihydroanthracene, and *n*-octane are difficult to separate, the only possible low molecular weight cyclooctyl recombination product **13** is obtained as an NMR-pure substance after column chromatography. The NMR data of **10**, **11a/b**, **12**, and **13** are given in Table 1.

It is evident that the reaction rate depends on the dissociation enthalpy of the relevant C–H bond of the solvent. Assuming that the rate constant for the first reaction step k_1 is very small compared to k_{-1} and k_2, we conclude that $k_{-1} \geq k_2$ [SH] should be true, where k_2 is the rate of hydrogen abstraction from a solvent molecule SH. At least in the case of cyclooctane it seems that $E_{a,-1} < E_{a,2}$.

In the course of the first reaction step the alkyne units of **9** have to be distorted in a transoid fashion to diminish the c–d distance and facilitate formation of a bond between C3 and C8. This deformation is well studied for acetylene.[9] We assume that the bending of the alkyne moieties in **9** is supported by a homoconjugative interaction between nitrogen lone pairs and the π and π* orbitals of the triple bonds. This interaction lowers the activation energy for the transannular coupling. Quantum

chemical calculations confirm this hypothesis. Formation of 1,4-didehydrobutadiene **14** leads to a σ framework of lower energy, and the π system has in part lower energy owing to generation of the bicyclic *trans*-butadiene unit with two fused six membered rings. In addition a stabilizing through-bond interaction between the two radical centers occurs. In Table 2 the enthalpy diagrams of the reactions **1** → **2**, **5** → **6**, and **9** → **14** are compared. The values given have been taken from literature[2, 5] or derived from AM1[10a] and MNDO[10b] calculations.[11]

Table 2. Comparison of the reaction enthalpies $\Delta_R H^\circ$ [kcal mol^{-1}] of the reactions **1** → **2**, **5** → **6**, and **9** → **14**; $\Delta_R H^\circ = \Delta_f H^\circ$ (diradical) − $\Delta_f H^\circ$ (alkyne). The $\Delta_f H^\circ$ values used were estimated by triplet singlet AM1/MNDO calculations for the diradicals and alkynes, respectively.

Reaction	$\Delta_R H^\circ$ (AM1)	$\Delta_R H^\circ$ (MNDO)	$\Delta_R H^\circ$ (experiment)
1 → **2**	11	12	13 ± 3 [2e]
5 → **6**	−18	−18	−15 ± 3 [5]
9 → **14**	27	24	

As mentioned previously, the Bergman and Myers cyclizations both include the electrocyclization of a conjugated 6π system to give an arene diradical. The formation of 1,4-didehydrobutadiene **14** is the first example of a related process for nonconjugated diynes in which the activation of the diyne results from homoconjugative interaction with an electron donor. Further experimental and theoretical studies on the scope and limitation of these and related systems are in progress.

[11] The $\Delta_R H^\circ$ values for the reaction **1** → **2** based on AM1/MNDO calculations (program MOLEK 9000) are in good agreement with the results of recent ab initio studies: ref. [2c, d].

Novel Rh^I Piano-Stool Complexes with New Hemilabile Ligands Ligating through Phosphane and Arene Groups: Synthesis, Characterization, and Reactivity**

Elizabeth T. Singewald, Chad A. Mirkin,*
Allison D. Levy, and Charlotte L. Stern

Ligands that are hybrids with two types of functional groups, one forming a strong bond with a transition metal and one a weak bond, have been exploited in many areas of homogeneous catalysis including olefin hydrogenation[1] and methanol carbonylation reactions.[2] Such ligands often are referred to as hemilabile ligands because the strongly binding functional groups typically are substitutionally inert and the weakly binding groups are substitutionally labile. For complexes with the late transition metals, the phosphane moiety is often chosen as the substitutionally inert group, and a group ligating through a heteroatom such as O or N is chosen as the substitutionally labile functionality. Herein, we report a new class of hemilabile ligands, **1** and **2**, which are based upon moieties containing phosphane and arene functionalities as ligating groups (Scheme 1). In the design of such ligands we drew upon the observation by others that the arene moiety can be quite labile when bound to a $(PR_3)_2Rh^I$ metal core.[3] We report the synthesis of ligands **1** and **2** and their complexation to Rh^I to form the new η^6-arene-*cis*-phosphane piano-stool complexes **3** and **4**, respectively. In addition to rich arene ligand substitution chemistry, **3** and **4** exhibit two types of novel behavior: 1) the metal-bound η^6-arene ring of the chelated ligand of **3**, but not of **4**, undergoes a fast *intramolecular* exchange with the arene ring of the monocoordinated ligand at moderate temperatures, and 2) both **3** and **4** undergo electrochemically reversible one-electron oxidation reactions to form mononuclear Rh^{II} species.

Scheme 1.

The ligands, $PhXCH_2CH_2PPh_2$ (**1**, X = O; **2**, X = CH_2) were synthesized from the reaction of $PhXCH_2CH_2Cl$ (0.020 mol) with $KPPh_2$ (0.50 M, 40 mL) in THF at 0 °C (Scheme 1). Addition of ligand **1** (1.0 mmol) to a 75 mL solution of $[(\eta^2\text{-}C_8H_{14})_2Rh(thf)_2]BF_4$[4] (0.50 mmol) in THF at −78 °C leads to the formation of **3** in 80% yield. Similarly, compound **4** forms in 75% yield from the addition of ligand **2** (1.0 mmol) to a THF solution of $[(\eta^2\text{-}C_8H_{14})_2Rh(thf)_2]BF_4$ (0.50 mmol) at −78 °C. Recrystallization of **3** and **4** at room temperature from CH_2Cl_2/diethyl ether yielded analytically pure samples of each complex.

Compounds **3** and **4** have been characterized spectroscopically and by single-crystal X-ray diffraction studies. The solid-state structures for **3** and **4** are comparable; therefore in this communication, we will limit our discussion to compound **3** (Fig. 1). The solid-state structure of **3** shows that the complex resembles a piano stool with two legs and the fulcrum at Rh. The C atoms which comprise the η^6-arene ring in **3** are essentially in a plane (mean deviation = 0.02 Å), and the distance from the center of the bound arene to the Rh atom is 1.84 Å. Although there are a few examples of structurally characterized Rh^I complexes with planar η^6-arene ligands, such ligands often adopt boat conformations when bound to Rh^I.[5] The Rh–O1 distance of 3.307(3) Å and the Rh–O2 distance of 4.185(3) Å are well outside of the normal bonding distances for Rh (about 2.2 Å).[1]

Spectroscopic data for **3** and **4** in CD_2Cl_2 at 25 °C are comparable and consistent with the formulated piano-stool structures for these complexes in solution. For example, the ^1H NMR spectrum of **3** in CD_2Cl_2 shows characteristic upfield resonances for the H atoms *ortho* to the O atom in the η^6 coordinated arene at $\delta = 6.75$, at $\delta = 6.88$ for the *meta* H atoms, and at $\delta = 4.63$ for the *para* H atom. These assignments have been confirmed by a 2D COSY experiment and a CH correlation study. The resonance at $\delta = 4.63$ for the *para* H atom of the bound arene is remarkably far upfield for coordinated arene ligands. This phenomenon seems to be common to

this class of compounds, since **4** also exhibits a resonance in this region ($\delta = 4.68$) for the *para* H atom of its η^6 bound arene ligand.

Compound **3** undergoes an intramolecular exchange reaction between the η^6 bound arene and free arene at moderate temperatures (10–30 °C) in CD_2Cl_2 (Fig. 2). This process, which is

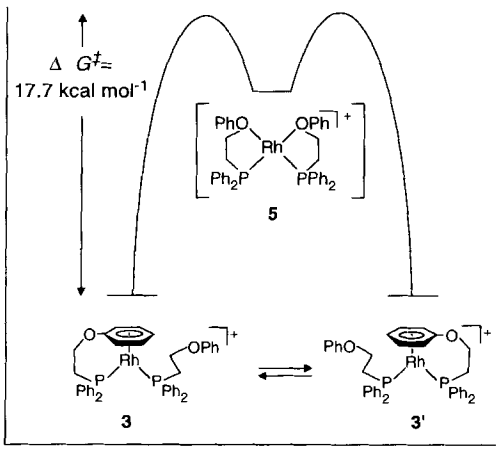

Fig. 2. Energy diagram depicting the exchange reaction between the energetically degenerate compounds **3** and **3'**. Compound **5** is a proposed intermediate; its position within the energy diagram is arbitrarily depicted. The *x* axis represents the reaction coordinate and the *y* axis the energy.

slow even at elevated temperatures (76 °C in [D_8]dioxane) in both the one-dimensional ^1H and ^{31}P NMR experiments, may be detected by a two-dimensional ^1H NMR exchange spectroscopy (EXSY) experiment[6] (Fig. 3). The EXSY experiment confirms that the two ligands undergo dynamic chemical exchange as indicated by the crosspeaks for the *para*-H atoms of the chemically exchanging arene rings, which are at $\delta = 4.63$ and $\delta = 7.00$ for the Rh-bound and unbound forms, respectively. This observation is consistent with a degenerate exchange of the two chemically inequivalent arene ligands in **3**, which is depicted by the interconversion of **3** and **3'** (Fig. 2). The activation parameters $\Delta G^{\neq} = 17.7$ kcal mol^{-1}, $\Delta H^{\neq} = 19.6$ kcal mol^{-1}, and $\Delta S^{\neq} = 6.10$ cal mol^{-1} K^{-1} at 293 K have been determined for this process by performing a variable-temperature (283–303 K) EXSY experiment and modeling the data according to the Eyring equation.[7] Although such reversible ring exchange reactions have never been reported for $Rh^I(PR_3)_2$ fragments, ring exchange reactions have been detected for polyarene complexes of $Cr(CO)_3$, albeit under very forcing conditions (for example, 170 °C, under pressure in C_6D_6).[8] Significantly, under conditions comparable to those used for **3**, compound **4** does not undergo the exchange reaction on a time scale that may be detected by the EXSY experiment.

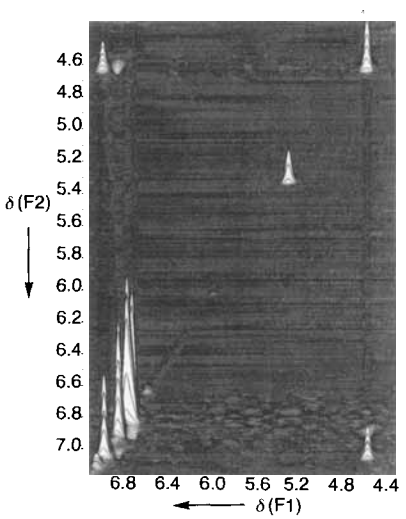

Fig. 3. 2D EXSY spectrum of **3** in CD_2Cl_2 at 30 °C.

Why does **3**, but not **4** undergo fast intramolecular exchange on the EXSY time scale? One explanation is the exchange reaction for **3** is facilitated by its ether groups, which serve as "internal solvent" molecules and allow for the formation of a relatively low energy transition state. Indeed, based on our past work and the work of others, square-planar *cis*-phosphane *cis*-ether complex **5** (Fig. 2) is a reasonable intermediate in the equilibration of **3** and **3'**;[1, 9] thus far, however, it has eluded spectroscopic detection. Since compound **4** does not possess ether moeities, it does not have such a route available to it and would be expected to have a higher energy transition state and a larger energy barrier for arene–arene exchange.

The Rh-bound arene ligand in **3** not only may be displaced intramolecularly, but also intermolecularly with more strongly coordinating ligands such as CO and CH_3CN (Scheme 1). The reaction with CH_3CN demonstrates the extreme lability of the arene–Rh linkage. The addition of four equivalents of CH_3CN to a CD_2Cl_2 solution of compound **3** (32 mg, 0.04 mmol) at −45 °C resulted in clean and quantitative conversion into the *cis*-CH_3CN adduct, **6**. The compound was assigned as the *cis* adduct rather than the *trans* adduct on the basis of the coupling constant ($J_{Rh,P} = 170.5$ Hz).[10] Significantly, the process is reversible, and vacuum evaporation of the solvent from the CD_2Cl_2 solution of **6** leads to quantitative reformation of **3**.

Compound **3** in CH_2Cl_2 also cleanly reacts with CO (1 atm) to form the tricarbonyl complex **7**. However, upon removal of the solvent and CO atmosphere, **7** slowly (4 h at 10^{-5} Torr and 25 °C) loses one CO ligand to form the dicarbonyl complex **8**. Under these conditions, there is no evidence for formation of the *cis* isomer. Addition of CO (1 atm) to a CH_2Cl_2 solution of **8** causes quantitative reformation of the tricarbonyl complex **7**. Interconversions between di- and tricarbonyl complexes containing the $Rh^I(PR_3)_2$ moiety comparable to **7** and **8** have been reported by others.[9]

Another unusual feature of the isoelectronic compounds **3** and **4** is that they each exhibit a reversible electrochemical reaction in CH_2Cl_2/0.1 M nBu$_4$NPF$_6$. The $E_{1/2}$ values for **3** and **4** are 580 mV and 530 mV vs. ferrocene/ferrocenium (Fc/Fc^+), respectively, and show that from an electronic standpoint the two arene ligands **1** and **2** are similar. Furthermore, the steric difference between the O and CH_2 groups in **3** and **4**, respectively, would be expected to be minimal. Therefore, the fluxionality observed in **3**, but not **4**, most likely is due to the ability of **3** to form an intermediate such as **5** that is not chemically possible for **4** (Fig. 2).

Significantly, cyclic voltammetry and rotating disk electrode experiments performed on **3** and **4** (referenced to Fc/Fc^+) show that the observed electrochemical transformations are one-electron oxidations, which suggest that the synthesis of mononuclear Rh^I η^6-arenediphosphane complexes followed by oxidation will provide a reasonable avenue to stable, isolable mononuclear Rh^{II} piano-stool complexes. Although there are many examples of binuclear Rh^{II} complexes and a few examples of mononuclear organometallic Rh^{II} complexes, there are no reported examples of mononuclear Rh^{II} bisphosphane η^6-arene piano-stool complexes.[12]

Experimental Procedure

All NMR spectra were recorded on a Varian Gemini 300 MHz spectrometer at 20 °C unless otherwise noted. The ^{31}P NMR spectra were referenced to external 85% H_3PO_4. Silica gel (60 Å, 230–400 mesh ASTM) was purchased from Baxter Scientific Products; **1** and **2** were isolated by column chromatography on silica gel with 15% diethyl ether in pentane as the eluent. In each case, the ligand was the only fraction collected. Analytically pure samples were obtained by recrystallization at −20 °C in ethanol (yields: **1**, 70%; **2**, 76%).

1: ^1H NMR (C_6D_6): $\delta = 2.41$ (t, $J(H,H) = 7.7$ Hz, 2H; CH_2P), 3.92 (q, $J(H,H) = J(P,H) = 7.7$ Hz, 2H; CH_2O), 7.40–6.71 (m, 15H; Phs); ^{31}P NMR (C_6D_6): $\delta = -21.8$ (s); MS(EI): (70 eV, 190 °C) *m/z*: 306 [M^+]; anal. calcd. for $C_{20}H_{19}OP$: C 78.42, H 6.25; found: C 78.52, H 6.44.

2: ^1H NMR ($CDCl_3$). $\delta = 1.79$ (m, 2H; $CH_2CH_2CH_2$), 2.09 (dt, $J(H,H) = 7.2$ Hz, $J(P,H) = 4.7$ Hz, 2H; CH_2P), 2.76 (t, $J(H,H) = 7.4$ Hz, 2H; CH_2Ph), 7.43–7.15 (m, 15H; Phs); ^{31}P NMR ($CDCl_3$) $\delta = -15.2$ (s); MS(EI): (70 eV, 190 °C) *m/z*: 304 [M^+]; anal. calcd. for $C_{21}H_{21}P$: C 82.87, H 6.95; found: C 82.62, H 7.07.

Crystal data for **3**: $C_{40}H_{38}O_2P_2RhBF_4$, $0.42 \times 0.26 \times 0.33$ mm, monoclinic, space group = $P2_1/c$, $a = 10.595(3)$, $b = 17.116(5)$, $c = 19.564(5)$ Å, $V = 3545(3)$ Å^3, $\varrho_{calcd} = 1.503$ g cm^{-3}, $2\theta_{max} = 23.9°$, $\mu(Mo_{K\alpha}) = 6.17$ cm^{-1}, $\lambda = 0.71069$ Å, $F(000) = 1640$. Data were collected on an Enraf-Nonius CAD-4 diffractometer at -120 ± 1 °C using the ω-θ scan technique ($2\theta \leq 54.0°$). The data were corrected for Lorentz and polarization effects. In addition, an analytical absorption correction was applied with transmission factors ranging from 0.80–0.86 and a correction for secondary extinction was applied (coefficient = 0.42235×10^{-7}). The structure was solved by Patterson methods (SHELXS-86). Of the 6466 reflections, 5133 with $I > 3.00\,\sigma(I)$ were used in refinement. Refinement of 452 variable parameters (TEXAN 5.0) converged with the residuals of $R = 0.033$ and $R_w = 0.043$ [13].

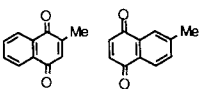
Homogeneous Catalytic Oxidation of Arenes and a New Synthesis of Vitamin K_3**

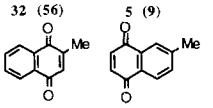
Waldemar Adam,* Wolfgang A. Herrmann, Jianhua Lin, Chantu R. Saha-Möller, Richard W. Fischer, and João D. G. Correia

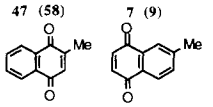
The selective oxidation of arenes is a great challenge for research in catalysis. The oxidants of choice are molecular oxygen and hydrogen peroxide.[1] The preparation of quinones usually requires the direct oxidation of arenes by chromic acid/sulfuric acid.[2] Surprisingly, we have now found that methyltrioxorhenium (MTO) efficiently catalyzes the oxidation of arenes by hydrogen peroxide.[3] This reaction is the key to a much improved synthesis of vitamin K_3, which is of appreciable commercial value as supplement in animal feed.[4]

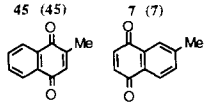
In acetic acid and in the presence of catalytic amounts of CH_3ReO_3 (2 mol%), 2-methylnaphthalene (**1**) is oxidized by hydrogen peroxide preferentially to the 1,4-quinone **2** (vitamin K_3, "menadione"). At 40 °C and after 4 h the conversion amounts to 81% (quinone yield 67%); in the absence of CH_3ReO_3 under otherwise identical conditions less than 2% conversion takes place. The high regioselectivity is particularly noteworthy: the isomeric 2-methylnaphthoquinones **2** and **3** are

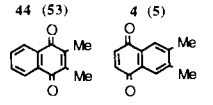
1 **2** **3**

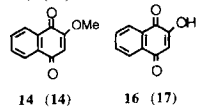


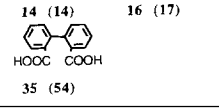












formed in a 7:1 ratio (85% yield of **2**) depending on the reaction conditions and H_2O_2 concentration (10–85% by weight). In the industrial synthesis of vitamin K_3 with chromic acid yields

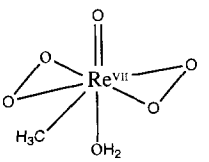
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Peroxidchemie: Mechanistische und präparative Aspekte des Sauerstofftransfers", and Sonderforschungsbereich 347 "Selektive Reaktionen metallaktivierter Moleküle"), the Bayerische Forschungsstiftung, the Fonds der Chemischen Industrie, the Alexander-von-Humboldt-Stiftung (postdoctoral fellowship for J.L.) and the European Community (postdoctoral fellowship for J.D.G.C.).

of 38–60% are achieved; however, in this stoichiometric oxidation about 18 kg of chromium-containing waste is produced per kg of product.[5a, b] The maximum regioselectivity for the oxidation with H_2O_2 under Pd^{II} catalysis is 66%.[5c] The analogous reaction with 2,3-dimethylnaphthalene provides a 59% yield of 1,4-naphthoquinone and a 1% yield of 5,8-naphthoquinone (conversion 94%, 40 °C, 4 h, 83 wt% H_2O_2 in acetic acid). Phenanthrene is converted under the same conditions into diphenyl-2,2′-dicarboxylic acid in 54% yield (Table 1).

Table 1. Oxidation of arenes with methyltrioxorhenium (MTO) and H_2O_2 [a].



Arene	t [h]	T [°C]	Conversion [%]	M.B. [b] [%]	Products and yields [%] [c]	Selectivity [%]
1	4	20	56	81	 32 (56) 5 (9)	86
1	4	40	81	73	 47 (58) 7 (9)	86
1	4	70	100	52	 45 (45) 7 (7)	86
1	8	40	83 [d]	65	 44 (53) 4 (5)	91
2,3-dimethylnaphthalene	4	40	94 [e]	62	 56 (59) 1 (1)	98
2-methoxynaphthalene	3	20	97	33	 14 (14) 16 (17)	
phenanthrene	5	40	64	71	 35 (54)	

[a] Arene:85% H_2O_2:MTO = 1:7:0.02 (mol ratio) in acetic acid, N_2 atmosphere. [b] M.B. = mass balance of isolated, characterized product and recovered starting material. [c] Yield of isolated product; yields in parenthesis were corrected for conversion of starting material; error ± 4% of stated value. [d] 35% H_2O_2 and acetic anhydride as solvent. [e] Arene:85% H_2O_2:MTO = 1:9:0.02 (mol ratio).

Since water acts as an inhibitor, concentrated H_2O_2 (85%) is preferred. Alternatively, commercially available 35% H_2O_2 in acetic anhydride can be employed; a considerably higher regioselectivity (**2**:**3**) of 10:1 was obtained with this system. The conversions improve for electron-rich arenes. Thus, with 2-methoxynaphthalene at 20 °C and after 3 h up to 97% conversion was achieved. Unfortunately, electron-rich arenes tend to undergo more side reactions, especially overoxidation, and thus the mass balance is quite poor.

Although the binary rhenium oxides ReO_3 and ReO_2 do not catalyze the oxidation of olefins,[6] they can be used instead of CH_3ReO_3 in the oxidation of arenes. These rhenium oxides also activate the oxidant H_2O_2 even at room temperature; with these catalysts the yield of vitamin K_3 amounts to 53% with a regioselectivity of 4:1 (85% H_2O_2 in acetic acid, 4 h, 51% conversion). When the formation of a *para*-quinone is not possible for structural reasons, then hydroxylation occurs instead. Thus, 4-hydroxymesitylene is produced in 73% yield when mesitylene is treated with 85% H_2O_2 in acetic acid in the presence of Re_2O_7 as catalyst (20 °C, 4 h). Without the catalyst, mesitylene does not react under these conditions. These simple rhenium oxides are active in acetic acid and acetic anhydride but not in solvents such as *tert*-butyl alcohol and THF.

Control experiments indicate that this oxidation of arenes proceeds via metal peroxides. The isolated bis(peroxo)rhenium complex **A**[6b, 7] derived from MTO and H_2O_2 reacts with 2-methylnaphthalene *quantitatively* to give 1,4-naphthoquinone **2** in high regioselectivity (>10:1) in acetic acid at 20 °C and 4 h. Analogous to the epoxidation of olefins, the bis(peroxo) complex **A** transfers only *one* of the peroxide oxygen atoms to the arene substrate. When instead of the bis(peroxo) complex **A** the double molar amount of peroxyacetic acid is used, only 29% conversion and an 8% yield of quinone is achieved, even after 4 h at 40 °C. To assure that the consumed peracid is replenished according to Equation (a), the oxidation was conducted with catalytic amounts of the strong acid CF_3CO_2H, since it is known that MTO catalyzes equilibrium (a).[9] MTO serves as a strong Lewis acid.

A

$$CH_3CO_2H + H_2O_2 \rightleftharpoons CH_3CO_3H + H_2O \quad (a)$$

The method described here allows an economic synthesis of vitamin K_3 and related quinone derivatives. The yields and regioselectivities of the oxidation system MTO/H_2O_2/CH_3CO_2H can certainly be optimized, as the stoichiometric control experiment with the bis(peroxo) complex **A** demonstrates. Mechanistic details like those recently reported for the Baeyer–Villiger oxidation should also be clarified.[8] The Re–C bond must not necessarily remain intact in all catalytic oxidations with the methyltrioxorhenium, although the stoichiometric, direct oxidation with **A** speaks for it in the present case. The relatively low amount of H_2O_2 decomposition is an advantage of the MTO/H_2O_2/CH_3CO_2H/arene system. For ReO_3 and Re_2O_7 as much as 20% decomposition may take place when a sevenfold excess of 85% H_2O_2 is employed.

Experimental Procedure

Vitamin K_3: To a solution of 10.0 g (70.3 mmol) of 2-methylnaphthalene (**1**) and 349 mg (1.40 mmol) of MTO [6b] in 150 mL of acetic acid was added dropwise at room temperature 14.3 mL (0.49 mol) of 85% H_2O_2. The reaction mixture was allowed to stir at 40 °C for 4 h under a N_2 atmosphere, before 100 mL of water was added. The mixture was extracted with CH_2Cl_2 (3 × 200 ml). The combined organic phases were washed with 150 mL of water, dried over Na_2SO_4, and concentrated at 20–40 °C/10–20 Torr. The conversion was 81% (GC/MS). The quinone products **2** and **3** were separated from the starting material by column chromatography (silica gel 32–63 μm mesh). Total yield 6.56 g (67% with respect to converted **1**). Recrystallization of the chromatographed product from ethanol afforded the quinone **2** in >98% purity (NMR) and in 58% yield (5.65 g). This method may be applied to other arenes. Depending on the reactivity of the arene, temperatures of 20–70 °C and H_2O_2 concentrations of 10–85% may be employed.

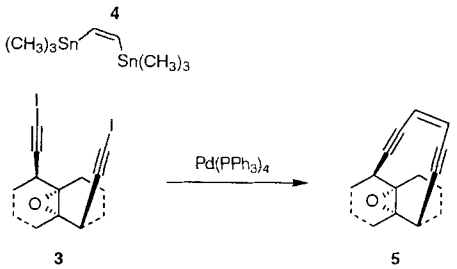
Enediyne Quinone Imines: Truncated, Biologically Active Dynemicin Congeners**

Matthew D. Shair, Taeyoung Yoon, Ting-Chao Chou, and Samuel J. Danishefsky*

The novel enediyne antibiotic dynemicin A (**1**)[1] has stimulated a range of interesting research including DNA cleavage studies,[2] the design of new prodrug constructs,[3a, b, c] and the development of novel methodology directed at total synthesis.[3a, 4] The prevailing assumption[5a, b] concerning the ignition mechanism for the drug to operate as a diyl presupposes reduction of the quinone ring to the hydroquinone. In this way, the lone pair on nitrogen is unleashed to participate in mediating solvent attack on the epoxide (Scheme 1). The opening of this epoxide



Scheme 1. Mode of action of dynemicin A. a) Reduction, b) Bergman cyclization, c) DNA cleavage through H atom abstraction. Nuc = nucleophile.

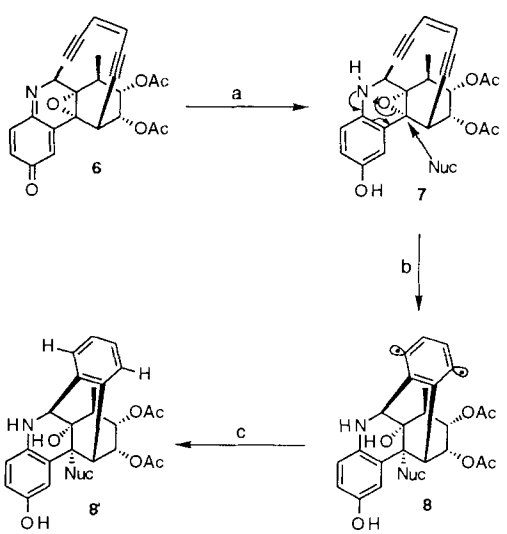
[**] This work was supported by the National Institutes of Health (Grant CA 28824). A predoctoral fellowship from Memorial Sloan-Kettering Cancer Center to M.D.S. is gratefully acknowledged. We thank Professor A. G. Myers for an advanced copy of his manuscript in which related developments are described.

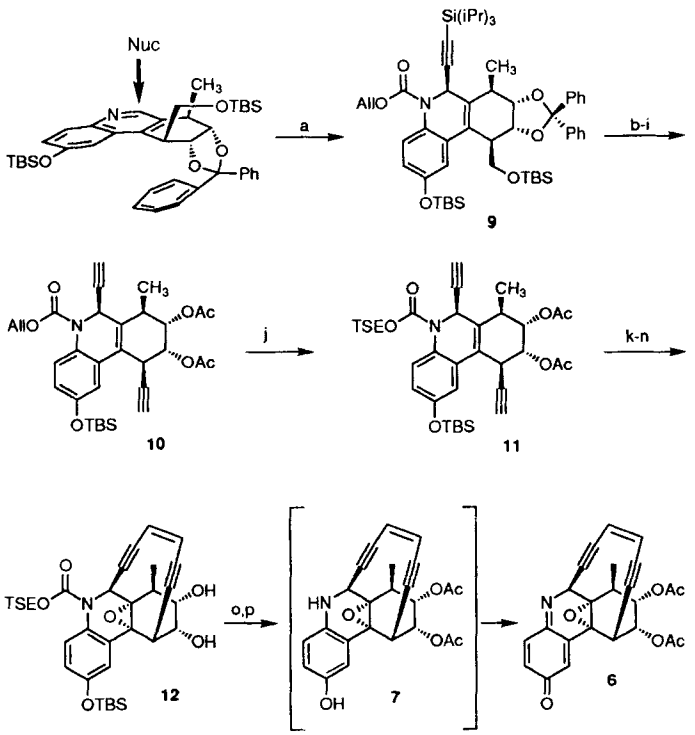


is seen to be a critical prophase in fostering the Bergman (enediyne → 1,4-diyl) transformation.[6] The cytotoxicity of the drug is perceived to arise from the DNA cutting tendency of diyl **2** or its quinone counterpart.[2] The dihydroxynaphthaquinone sector is seen to provide noncovalent contacts for intercalating and directing the drug to its oligonucleotide target.[5b, 7a, b, c]

Recently, we described the synthesis of intermediates generalized as **5** (Scheme 2) by cross coupling of diiodoalkynes of type **3**

Scheme 2. General approach to the palladium-mediated formation of enediynes.

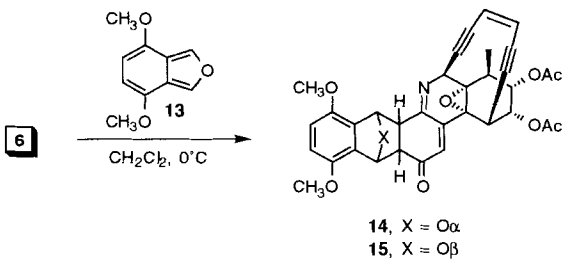
to *cis*-distannylethylenes such as **4** mediated by tetrakis(triphenylphosphane)palladium(0)[8, 9]. Given this capability, we directed our attention to the synthesis of quinone imines such as **6** (Scheme 3). The hope was that such structures might suffer



Scheme 3. Proposed mode of action of quinone imine **6**. a) Reduction, b) Bergman cyclization, c) DNA cleavage through H atom abstraction.

reductive activation like dynemicin to set off the cascade **6** → **7** → **8**. It was further perceived that **6** would be accessed by oxidation of a transient hydroisoquinoline precursor such as **7**. Since a system such as **7** is likely to be vulnerable to epoxide opening (and thence to subsequent 1,4-diyl formation), it must be generated under mild conditions from a readily deprotectable carbamate precursor. Given the favorable experiences of our laboratory with unveiling of amines in unstable molecules via (trimethylsilyl)ethoxycarbonyl (TEOC) carbamates,[10a, b] we turned to this protecting group.

We would be unable to carry the TEOC group from the start of the synthesis since it would be necessary to desilylate at several stages along the way while the urethane would remain intact. Accordingly, we prepared the allyl carbamate **9**[8, 11]



(Scheme 4). Following our recently developed protocol,[8, 9] compound **9** was converted to **10**. Given the eventual need for the palladium-mediated cross coupling reaction, the allyl carbamate was cleaved at the stage of **10** and a TEOC group installed as shown in **11**.[12] Diyne **11** was converted to **12**, and after acylation, the two silyl protecting groups were removed with tetra-*n*-butylammonium fluoride. Rapid oxidation of the resultant fleeting intermediate **7** with $PhI(OAc)_2$ furnished quinone imine **6**. *The conversion of 7 to 6 is to our knowledge, the first example of this type of oxidation of such an epoxy enediyne system, in which the nitrogen is not conjugated to a carbonyl group.*

TIPS = triisopropylsilyl, All = allyl, DMSO = dimethyl sulfoxide, TBAF = tetra-*n*-butylammonium fluoride, TBS = *tert*-butyldimethylsilyl, DMAP = 4-dimethylaminopyridine, TSE = (trimethylsilyl)ethyl, TEOC = (trimethylsilyl)ethoxycarbonyl, *m*CPBA = *meta*-chloroperbenzoic acid, NIS = *N*-iodosuccinimide, DMF = dimethylformamide.

With a view toward synthesizing dynemicin, or analogues thereof, we have examined the dienophilicity of the quinone imine linkage, in the presence of the bridging enediyne linkage (Scheme 5). The concept was tested with quinone imine **6** and isobenzofuran **13**.[13] In the event, cycloaddition occurred at 0 °C in methylene chloride to furnish an 86% yield of two products formulated as **18** and **19** in a ratio of 2.5:1.[14] Application of cycloadditions to quinone imines to reach dynemicin systems are currently in progress.

While total synthesis remains a major focus in our research directed at these enediyne quinone imines, we have begun to evaluate the biological effects of the transformation **6** → **7** → **8** (Scheme 3). Some promising findings have been obtained.

Scheme 5. Cycloaddition of quinone imine **6** with isobenzofuran **13**.

Compound **6** manifests broad cytotoxicity against a variety of tumor cell lines with an IC_{50} of roughly 5×10^{-4} μM (Table 1). Its potency is considerably greater than that of the widely used drug mitomycin C. For instance, with human promyolytic leukemia cell lines the potency of **6** relative to that of mitomycin C as measured by relative IC_{50} values is approximately 83:1. In acute lymphoblastic T cells (CCRF-CEM), the ratio is about 280:1. In corresponding comparisons with methanesulfonyl-4-(9-acridinylamino)-*m*-anisidide (*m*AMSA)[15] with the same lines, **6** is 70 and 400 times as potent, respectively.

Table 1. Comparison of the cytotoxicity of **6** with that of mitomycin C and *m*AMSA for human promylocytic leukemia cells **A** and human acute lymphoblastic T cells (CCRF-CEM) **B**.

Compound	IC_{50} [μM] for **A**	IC_{50} [μM] for **B**
6	0.00058	0.0005
mitomycin C	0.0484	0.140
*m*AMSA	0.0388	0.199

The properties of compound **6** as a DNA damaging agent have been examined using pBR322 DNA (Fig. 1). Reductive activation with NADPH and dithiothreitol (DTT) were compared, and the former method was found to be more effective. In the nicking assay as well, compound **6** outperformed mitomycin C. Curiously enough, at higher concentrations (500 μM) and under activation by NADPH compound **6** leads to signifi-

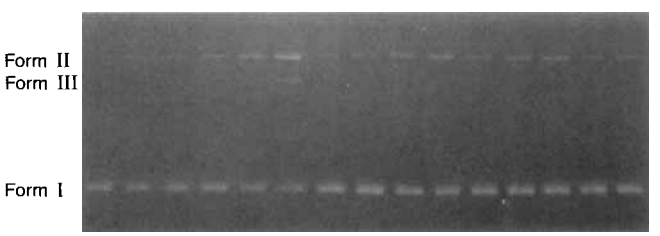


Fig. 1. Cleavage of pBR322 DNa. DNA was incubated in tris(hydroxymethyl)aminomethane (Tris)/HCl buffer (pH 7.5) for 60 min at 37 °C in the presence and absence of NADPH or dithiothreitol (DTT). The reaction mixtures were analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Track 1: DNA alone; track 2: DNA + NADPH; track 3: DNA + quinone imine **6** (5 μM); track 4: DNA + NADPH + quinone imine **6** (5 μM); track 5: DNA + NADPH + quinone imine **6** (100 μM); track 6: DNA + NADPH + quinone imine **6** (500 μM); track 7: DNA + DTT; track 8: DNA + DTT + quinone imine **6** (5 μM); track 9: DNA + DTT + quinone imine **6** (100 μM); track 10: DNA + DTT + quinone imine **6** (500 μM); track 11: DNA + mitomycin C (5 μM); track 12: DNA + NADPH + mitomycin C (5 μM); track 13: DNA + NADPH + mitomycin C (500 μM); track 14: DNA + DTT + mitomycin C (5 μM); track 15: DNA + DTT + mitomycin C (100 μM).

cant amounts of nonhelical DNA. Given the lack of an apparent intercalating arm, the double-stranded cleavage is noteworthy.

In addition to the in vitro study, a preliminary examination of **6** in various mouse models has been conducted. Compound **6** (0.1–0.5 mg kg^{-1}, i.p. (QD × 5) reduced tumor volume by 42–63% in mice bearing B-16 melanoma or sarcoma 180.[16] In each case where a comparison was drawn, compound **6** outperformed mitomycin C in reduction of tumor mass. That the antitumor properties of **6** arise from diyl intermediate **8** is assumed, but certainly not proven, particularly in the in vivo experiment.

Future studies involving this novel class of enediyne quinone imines will be directed with a view toward their application in the total synthesis of dynemicin A (and congeners thereof) as well as their amenability toward possible development as drugs.

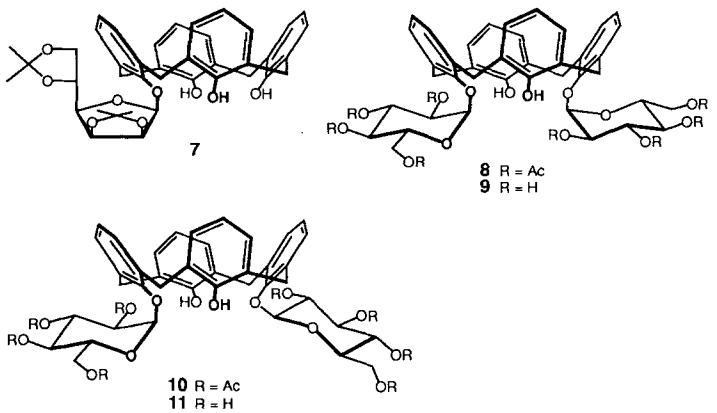
Sugar Calixarenes: Preparation of Calix[4]arenes Substituted at the Lower and Upper Rims with *O*-Glycosyl Groups**

Alberto Marra, Marie-Christine Scherrmann, Alessandro Dondoni,* Alessandro Casnati, Patrizia Minari, and Rocco Ungaro*

Peptide–carbohydrate and carbohydrate–carbohydrate interactions play an important role in biological processes.[1] In order to better understand these interactions and to develop biologically active compounds based on molecular recognition,[2] various synthetic receptors for the specific recognition of peptides[3] and carbohydrates[4, 5, 6] have been synthesized. For example, resorc[4]arenes,[4] cholaphanes,[5] and glycophanes[6] have been used for carbohydrate recognition. Calixarenes[7] represent a class of macrocyclic compounds whose sizes and shapes have been exploited mainly for the recognition of metal ions and apolar organic molecules.[8] Water-soluble nonionic calixarenes[9] are interesting because of their potential use as enzyme mimics and molecular receptors in aqueous solution of highly polar organic molecules, such as amino acids and carbohydrates. In this paper we describe the preparation and complete characterization of well defined sugar calixarenes, which were obtained in good yields by mono- and poly-O-glycosylation of **1** at the phenolic groups (lower rim) and of **2** and **3** at the hydroxymethylene groups (upper rim). Although only the tetrasugar derivative **13** proved to be water-soluble, all these O-glycoside compounds are of interest because they are the first calixarene derivatives bearing chiral polyhydroxylated residues.



We first addressed the issue of glycosylating the lower rim by Mitsunobu reaction at the phenolic groups.[10, 11] Thus, treatment of calix[4]arene **1** with 1.1 equiv of α-D-mannofuranose diacetonide **4**[12] under standard Mitsunobu conditions (1.5 equiv of diethyl azodicarboxylate (DEAD) and PPh_3,

[**] We thank Dr. M. Hamdan, Glaxo Research Center, Verona (Italy), for mass spectral determinations.

toluene, 70 °C, 30 min) afforded the monoglycosylated adduct **7** in 71% yield (isolation by flash chromatography on silica gel). The use of 4.4 equiv of **4** and more forcing conditions (refluxing toluene, 3 h) produced a complex mixture of compounds in which mono- and bisglycosides were not present. Indicative of the β-glycosyl linkage[13] in compound **7** was the $J_{1,2}$ value of 3.0 Hz in its ^{1}H NMR spectrum ([D$_6$]DMSO, Table 1). The cone conformation of the macrocycle was assigned on the basis of the chemical shifts and the multiplicity pattern of the proton signals,[7, 14] along with the chemical shifts of the carbon atoms[15] of the methylene bridges. The complete deprotection of the sugar calixarene **7** could not be achieved, since only monodeacetonization (4:1 AcOH:H_2O, room temperature, 6 h; pyridinium *p*-toluenesulfonate (PPTS), MeOH, 90 °C, 1 h) or substantial decomposition (4:1 AcOH:H_2O, 100 °C, 30 min) took place.

The Mitsunobu glycosylation of **1** with 2.2 equiv of tetraacetyl-α,β-D-glucopyranose (**5**)[16] in toluene at room temperature for 1 h afforded, after flash chromatography (4:1 diethyl ether:cyclohexane), an approximately 1:1 mixture of α,α-bisglucoside **8** and α,β-bisglucoside **10** together with several by-products in 50% overall yield.[17] Separation by HPLC (silica gel, 6 μm, 60 Å; 72:28 cyclohexane:ethyl acetate; detection at 280 nm) and crystallization from diethyl ether gave the individual bisadducts in pure form (15% each). The ^{1}H and ^{13}C NMR spectra of these compounds (Table 1) clearly indicated the configuration of the anomeric carbons and the cone conformation[7] of the macrocycle. Moreover, the diametrical 1,3-functionalization in **8** was demonstrated by the presence of only two kinds of diastereotopic carbons for the four ArCH$_2$Ar methylenes in its ^{13}C NMR spectrum.[18] The same assignment of the substitution pattern could not be deduced for **10**, since an

[a] ^{1}H and ^{13}C NMR spectra were recorded at 300 and 75 MHz, respectively.

α,β-bisglycoside should, in any case, show signals due to four different methylene bridges in its NMR spectra. The 1,3-disubstitution pattern of **10** was tentatively assigned by analogy with the isomer **8**.[19] Upon deacetylation with sodium methoxide in methanol, both **8** and **10** provided the corresponding unprotected calix[4]arene glucosides **9** and **11**; however, these compounds proved to be insoluble in water.

For O-glycosylation at the upper rim, we planned to use the symmetrical bishydroxymethylene-substituted calix[4]arene **2**[20] whose cone structure is blocked by four *O*-propyl groups at the lower rim. Moreover, aiming at a totally stereoselective glycosylation,[21] we chose to employ a sugar bearing a participating group at C-2 as glycosyl donor. The stable and readily available ethyl 1-thio-tetrabenzoyl-β-D-galactoside (**6**)[22] (2.4 equiv) was reacted[23] for 30 min at room temperature with the acceptor **2** in the presence of copper(II) triflate (2.4 equiv), acetonitrile, and 4 Å molecular sieves. After quenching with excess Et_3N and evaporation of the solvent, the reaction mixture was filtered through a short column of silica gel (1:1 cyclohexane:ethyl acetate). The solution was concentrated and the residue was treated with sodium methoxide in methanol to afford crude β-linked *O*-galactosyl calixarene **12**. This compound was isolated in pure form (65% yield from **2**) by chromatography on a column of Sephadex LH-20 (1:1 CH_2Cl_2:CH_3OH). In a similar way the calixarene **3**[24] bearing four hydroxymethylene groups, upon treatment with 6 equiv of donor **6**, was transformed into the β-linked derivative **13** in 60% isolated yield. Unlike the bisgalactoside **12**, the tetragalactoside **13** proved to be water-soluble up to 5 mM at room temperature.

12

13

In conclusion, we have described two approaches for the introduction of sugar moieties at either rim of calix[4]arenes. The resultant sugar calixarenes as well as other compounds obtained by these methodologies should provide an entry into molecular recognition of polar chiral substrates, especially carbohydrates, both in water and in organic media.

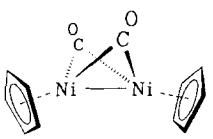
$[(CpNi)_2(Cp^*Al)_2]$: Cp*Al as a Bridging Two-Electron Ligand**

Carsten Dohmeier, Harald Krautscheid, and Hansgeorg Schnöckel*

Dedicated to Professor Gerhard Fritz on the occasion of his 75th birthday

Nearly 40 years ago Ziegler and Holzkamp reported the so-called "nickel effect".[1] They discovered that nickel compounds have a remarkable influence on the high pressure polymerization of ethylene in the presence of $[Et_3Al]$. These results initiated intense investigations of the Ziegler–Natta catalysts.



Compounds with direct bonds between the metal atoms of the catalyst components (Al–transition metal) have rarely been described.[2] To our knowledge, no molecular compounds containing the Ni–Al unit have yet been characterized by diffraction methods,[3] even though this type of compound has been discussed in connection with the "nickel effect".[4] Within the scope of our investigations concerning the reactivity of aluminium(I) compounds, we have found a simple route to molecules of this type.

With $[(Cp^*Al)_4]$ as a reducing agent, $[Cp_2Ni]$ can be transformed to the reddish brown complex **1**, which is only slightly

$[(CpNi)_2(Cp^*Al)_2]$ **1**

sensitive towards air and moisture. The diamagnetic nature of **1** is substantiated by sharp ^1H and ^{13}C NMR resonances observed in the range typical for diamagnetic compounds. The unexpectedly high thermal stability of **1** can be deduced from its mass spectrum where the molecular ion is also the base peak.

The spectroscopic results indicate a structure for **1** that can be derived from the well-known carbonyl complex **2**[5] by replacing the CO ligands by Cp*Al units. This proposal is confirmed by the X-ray structure analysis (Fig. 1).[6]

2

The four metal atoms form two three-membered Ni_2Al rings at a dihedral angle of 104.76(9)°. The "substitution" of two Cp*Al units in the tetrahedral compound **3**[7] for two CpNi fragments therefore caused the opening up of one edge of the tetrahedron. This

$[(Cp^*Al)_4]$ **3**

result was expected, since, compared to Cp*Al, every CpNi unit (isolobal with CH) contributes one more electron to the Ni_2Al_2 framework. This interpretation suggests that the Ni and Al atoms are connected by two-center two-electron bonds. Consequently the Al–Al interaction is noticable reduced: compared to that in **3**, the Al···Al distance in **1** (302.4(3) pm) is enlarged by approximately 26 pm, and the planes of the Cp* rings are nearly perpendicular to the Ni_2Al planes; this geometry differs from that of the tetrahedron.

The Ni–Al bonds in **1** (227.4(2)–228.3(2) pm) are about 16 pm shorter than in the intermetallic compound NiAl (CsCl type).[8] Surprisingly, the bond in the diatomic NiAl molecule in the gas phase is also slightly longer than that in **1**.[3] As expected, the Ni···Al distances determined for compounds with the structural unit $Ni(\mu H)Al$ are significantly longer (e.g., 273 pm in ref. [9]). A more detailed discussion of the Ni–Al bonding in **1** is not possible because there are as yet no additional experimental or theoretical data of comparable compounds available.

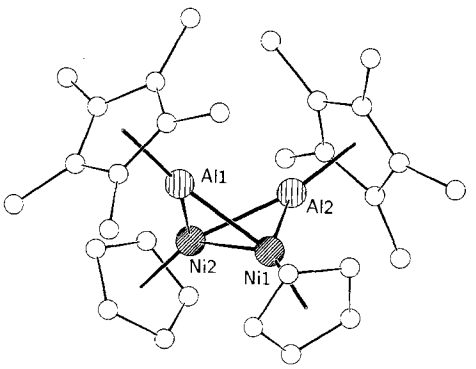


Fig. 1. Molecular structure of **1** (H atoms have been omitted for clarity). Selected bond lengths [pm] (d_{min}, d_{max}, $\bar{d}$) and angles [°]: Ni1–Ni2 248.6(2), Al1···Al2 302.4(3), Al–Ni 227.4(2), 228.3(2), 227.8, Al–C_{Cp} 224.1(7), 226.8(7), 225.3, Ni–C_{Cp} 208.2(8), 218.7(8), 213.1; Ni1–Al1–Ni2 66.04(7), Al2–Ni1–Al1 83.22(8), Al2–Ni2–Ni1 56.91(7), Ni1–Al1–Al2 48.35(7).

The Ni–Ni bond in **1** (248.6(2) pm) is relatively long compared to that in **2** (ca. 236 pm). Similarly, the average Ni–C_{Cp} distance of 213.1 pm is about 4 pm longer than that in **2**.[10] The most probable explanation for these results lies in the different polarities in the butterfly frameworks of **1** and **2**: based on the relative electronegativities, a polarity $Ni^{\delta+}-C^{\delta-}$ is expected for the Ni_2C_2 frame in **2** and $Ni^{\delta-}-Al^{\delta+}$ for Ni_2Al_2 in **1**. This interpretation is consistent with the observation that the average Al–C_{Cp} distances in **1** (225.3 pm) are significantly shorter than in **3** (233.4 pm). Similar short distances between Al and η^5-coordinated Cp* ligands were found for aluminum(III) compounds.[11] The ^{27}Al NMR resonance recorded for **1** ($\delta = +30$) confirms the polarity, since the Al nuclei in **1** are significantly deshielded compared to those in **3** ($\delta = -80$ ppm).

The straightforward synthesis of **1** demonstrates, once more, the high synthetic potential of **3**,[12] which reacts like an electron-rich, selective carbenoid.[13] Compound **1** and its derivatives might be important for the elucidation of the mechanistic details of the "nickel effect" and, furthermore, as single-source precursors for the deposition of bimetallic films by CVD.[14] The properties of **1** as well as the syntheses of other transition metal complexes of Cp*Al are the subject of our current investigations.

Experimental Procedure

1: A solution of 90 mg of $[Cp_2Ni]$ (0.477 mmol) in 3 mL of toluene was slowly added to 46 mg of **3** (0.071 mmol) suspended in 5 mL of toluene at 25 °C. The resulting green solution was heated at 50 °C for 50 h; the color gradually turned to reddish brown. Toluene and the excess of $[Cp_2Ni]$ were removed under vacuum (ca. 10^{-2} mbar) at 50 °C. The residue was suspended in a small amount of *n*-pentane. The resulting reddish brown solution was separated from a colorless compound by filtration [15]. The solution was cooled to 4 °C, and the product **1** was obtained as reddish brown crystals (ca. 40 mg, 72%). The ratio of consumed [Cp*Al] to $[Cp_2Ni]$ was 3:2.

The ESR spectrum of a solution of **1** in benzene exhibits no signal. NMR spectra (300 MHz, C_6D_6, 298 K, Bruker AMX 300): ^1H NMR: $\delta = 5.26$ (10H, Cp), 1.84 (30H, Cp*); ^{13}C NMR: $\delta = 115.3$ (Cp*), 84.4 (Cp), 11.3 (Cp*); ^{27}Al NMR: $\delta = +30$ ($\omega_{1/2} = 1800$ Hz); MS (EI, 70 eV, 155 °C): *m/z* (%): 570 (100) [M^+], 434 (23) [$M^+ - Cp^*H$], and further fragments of lower intensity.

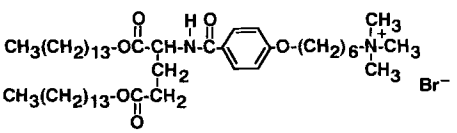
Sheldrick, D. Stalke, A. Kuhn, *Angew. Chem.* **1993**, *105*, 1828; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1729.

[12] There are two different synthetic routes for the preparation of **3** [7, 11c]. Chemical and physical properties of the two products differ markedly. We will soon report on the reasons for these observations.

[13] For example, cycloadditions (H. Schnöckel, C. Dohmeier, unpublished), insertion into element–element bonds [11a, 11c], and oxidative additions (C. Dohmeier, H. Schnöckel, C. Robl, U. Schneider, R. Ahlrichs, *Angew. Chem.* **1993**, *105*, 1714; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1655).

[14] For CVD (chemical vapor deposition), compare, for example, R. A. Fischer, W. Scherer, M. Kleine, *Angew. Chem.* **1993**, *105*, 778; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 748; and references therein; B. Fraser, L. Brandt, W. K. Storall, H. D. Kaez, S. I. Khan, F. Maury, *J. Organomet. Chem.* **1994**, *472*, 317).



[15] The molar ratio and NMR spectroscopic results of the colorless compound are consistent with the formula [AlCp*Cp_2]. However, this could not be confirmed by mass spectroscopy because of the low volatility of the compound. The yield of **1** is calculated for the reaction 3[Cp*Al] + 2[Cp_2Ni] → **1** + [AlCp*Cp_2].

Mesoscopic Sheets of a Cyano-Bridged Cu–Ni Coordination Complex: Template Synthesis at the Interlayers of Cast Multibilayer Films**

Nobuo Kimizuka, Toyokazu Handa, Izumi Ichinose, and Toyoki Kunitake*

Controlled synthesis and organization of inorganic clusters in diminishing dimensions lie at the heart of mesoscopic science. Conversion of inorganic precursors into desired clusters must be conducted *under mild conditions*, since traditional solid-state synthetic techniques allow little control over such metastable microstructures.[1, 2] Synthetic bilayer membranes display physicochemical characteristics similar to those of biomembranes. Their aqueous dispersions are, in many cases, transformed to self-supporting, multilayered films upon casting on solid substrates. The cast films provide two-dimensional matrices for the preparation of mesoscopic clusters such as quantum-sized CdS particles.[3] Very recently, organization of lead halide aggregates with quantized electronic states was achieved in two-dimensional space through electrostatic interactions with the regularly positioned cationic head groups of the bilayer.[4] These template syntheses have been limited to clusters containing a single type of metal. It is desirable to extend these techniques to the synthesis of heterometallic complexes.[5] We report here on a novel stepwise synthesis of cyano-bridged bimetallic aggregates. These coordination compounds should be of great interest, since their structural characteristics are often associated with novel properties such as molecular magnetism[6] and functional mixed valencies.[6, 7]

Tetracyanonickelate ion $[Ni(CN)_4]^{2-}$ was chosen as a μ-cyano precursor, and copper(II) ion was selected as the second metal component. The stepwise synthesis of the $[Ni(CN)_4]^{2-}$–Cu aggregate at the molecular interlayer was achieved by successively dipping a cast film of **1** first in an aqueous solution of the

1

cyanonickel complex (→**1**-Ni film), and then in an aqueous solution of copper nitrate (→**1**-Ni-Cu film). Incorporation of the cyanonickelate into the film of **1** was confirmed by the appearance of a ν_{CN} band at 2120 cm^{-1} in the IR spectrum. Atomic absorption analysis gave a Ni content corresponding to a **1**:Ni ratio of 2.7:1, which indicates essentially quantitative exchange of bromide ion. Similar stoichiometric exchanges have been reported for lead halide clusters,[4] porphyrins,[8] and myoglobin.[9]

After the second dipping, the resulting **1**-Ni-Cu film showed a group of CN stretching bands at 2195, 2185, and 2175 cm^{-1}, which were shifted to higher wavenumbers from those observed

[**] Contribution No. 996 from the Department of Chemical Science and Technology. We thank Prof. Fumiyuki Nakashio for access to a Seiko SAS 760 instrument for atomic absorption analyses.

for the **1**-Ni film (2120 cm^{-1}). These shifts[10] indicate that the nitrogen atoms of the preorganized cyanonickelate coordinate to the subsequently introduced copper ion, and a cyano-bridged Ni–Cu aggregate forms. The **1**:Ni:Cu ratio estimated from the Ni and Cu contents is 3.4:1.6:1. The presence of an excess of $[Ni(CN)_4]^{2-}$ relative to copper(II) implies that the complex formed is negatively charged. The overall charge of the film appears to be balanced by NO_3^- ions, since a NO stretching band for uncoordinated NO_3^- is observed at 1380 cm^{-1}.

X-ray diffraction patterns of the **1**-Ni-Cu film gave a series of reflections up to 10th order that correspond to a long spacing of 42.8 Å. Therefore, the ordered multibilayer structure remains intact during the stepwise formation of the aggregate. This long spacing is shorter than that of the cast film of **1** alone (d = 66.6 Å). The molecular orientation in the bilayer must have undergone considerable alteration owing to the electrostatic interactions between the cationic bilayer and the anionic Ni–Cu aggregates. A similar change in long spacing was observed for a **1**-$PbBr_4^{2-}$ cast film.[4]

Figure 1 shows ESR spectra of the copper(II) ions in the **1**-Ni-Cu cast film. The cyanonickelate moiety is diamagnetic. In

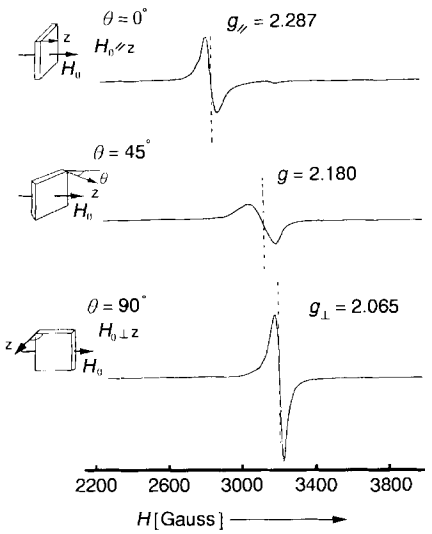

Fig. 1. ESR spectra of a **1**-Ni-Cu film at room temperature; modulation amplitude 12.5 G; microwave frequency 9.208 GHz. θ is the angle between normal of the planes of the film and the applied magnetic field.

recording these spectra the normal of the plane of the film (z axis) was set at angles of 90, 45, and 0° to the applied magnetic field H_0. The hyperfine coupling of the Cu nucleus (I_{Cu} = 3/2) is lost in the aggregate because of spin–spin interactions. A similar observation was reported for the Hofmann-type clathrate $[Cu(NH_3)_2Ni(CN)_4] \cdot 2C_6H_6$.[11] The ESR signals of the **1**-Ni-Cu film at θ = 0° are predominantly of the parallel component ($g_{\parallel}$ = 2.287) and at θ = 90° solely of the perpendicular component ($g_{\perp}$ = 2.065). These g values suggest that the copper ion has square-planar (N coordination) or elongated octahedral coordination (with axial water ligands). The observed angular dependence clearly indicates that the $d_{x^2-y^2}$ orbital of the copper ion is oriented parallel to the bilayer surface. The spectrum observed at θ = 45° has a signal located between these signals (g = 2.180), in contrast to the previous observations of oriented copper chelates[12] and myoglobin.[9] In the latter cases, the $g_{\parallel}$ and $g_{\perp}$ components coexisted in the spectra and showed complementary intensity changes upon variation of the film orientation.

Figure 2 compares the angular dependence of the observed g value with the theoretical angular dependence of the axially symmetric g-factor for a single crystal.[13] The satisfactory agreement clearly indicates that the bimetallic coordination

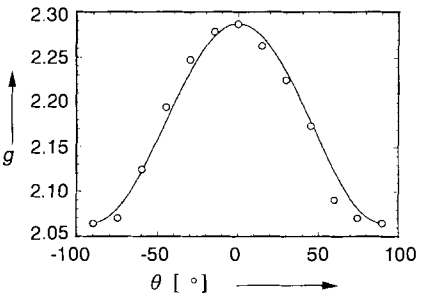

Fig. 2. Values of g (o) as a function of angle θ. The solid line is a theoretical curve obtained by using the following equation [13]: $g^2 = g_{\parallel}^2 \cos^2\theta + g_{\perp}^2 \sin^2\theta$.

compound has a highly oriented two-dimensional structure with long-range order. The copper(II) ions adopt a uniform orientation in the plane without substantial orientational fluctuation[12] in the direction of z axis of the film. When a powdered cast film was used, ESR spectra merely showed the coexistence of the $g_{\parallel}$ and $g_{\perp}$ components without angular dependence.

The stepwise synthesis of the μ-cyano adduct is depicted schematically in Figure 3. It is obvious that the adducts are suffi-

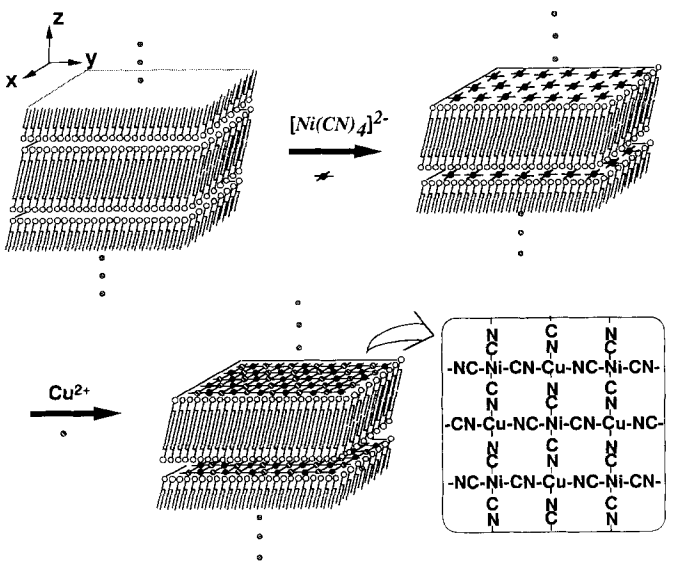

Fig. 3. Idealized representation of the stepwise synthesis of a μ-cyano Ni–Cu aggregate. Top left: cast film of **1**; top right: **1**-Ni film; bottom: **1**-Ni-Cu film and a section of the μ-cyano Ni–Cu aggregate.

ciently large such that orientational fluctuation does not arise in spite of probable undulation of the bilayer surface. The size and shape of the adduct cannot be determined definitely, although the observed Ni:Cu ratio (3:2) is in agreement with an 8 × 8 square-planar lattice.

In conclusion, a highly oriented, bimetallic aggregate was synthesized for the first time by taking advantage of a bilayer template. The repeated dipping process offers a novel approach to the production of bimetallic aggregates with unique electro-optical or quantum-based electronic properties.

Experimental Procedure

Multibilayer cast films were prepared by casting aqueous bilayer dipersions of **1** onto quartz plates or fluoropore membrane filters as described previously [3, 4]. Cast films of **1** were first dipped in an aqueous solution of potassium tetracyanonickel (100 mM) for 5 d at room temperature to effect exchange with bromide ion. The resulting **1**-Ni films were rinsed with deionized water, then dipped in an aqueous solution of copper nitrate (100 mM) for 5 d, and finally dipped in pure water for 10 min to remove unreacted copper ion (**1**-Ni-Cu film). Atomic absorption analysis of Ni and Cu was conducted for the cast films, after they had been dispersed by ultrasonication in aqueous hydrogen chloride (0.1 N) containing 0.25% sodium hypochlorite.

Sterically Strained Porphyrins—Influence of Core Protonation and Peripheral Substitution on the Conformation of Tetra-*meso*-, Octa-β-, and Dodeca-Substituted Porphyrin Dications**

Mathias O. Senge,* Timothy P. Forsyth, Liem T. Nguyen, and Kevin M. Smith

The study of nonplanar porphyrin conformations is currently under active scrutiny with regard to the possible role different macrocycle conformations play in biological processes such as respiration, electron transfer, photosynthesis, and enzyme catalysis.[1a] The synthesis of porphyrins bearing large and sterically interacting substituents at the porphyrin periphery has been used successfully to yield tetrapyrroles with significantly distorted macrocycles.[1, 2] Such compounds were mostly characterized by steric overload of the porphyrin periphery, for example, dodecasubstitution of the *meso*-carbon and β-pyrrole positions. In addition, core substitutions by either protonation of the two hydrogen-free pyrrole nitrogens (porphyrin dications)[3] or preparation of *N*-alkyl or *N*-aryl porphyrins[4] have been shown to lead to significantly distorted macrocycles, owing to steric congestion in the porphyrin core. We were interested in testing how far the macrocycle nonplanarity in dodeca-substituted porphyrins can be increased by a combination of both strategies, namely, core *and* peripheral substitution. Spectroscopic evidence already indicated that compounds such as 22,24-dihydrododecaphenylporphyrin dication are nonplanar in solution, but no detailed structural data were available.[2b] Additionally, only a few crystal structures of tetra-*meso*- or octa-β-substituted porphyrin dications were available for comparison with those of dodecasubstituted porphyrins. These included $[H_4tpp]^{2+}$ (H_2tpp = tetraphenylporphyrin, Scheme 1), which exhibits a nonplanar saddle conformation with pyrrole tilt angles of 33° and β-pyrrole displacements of 0.9–1.16 Å with respect to the mean plane.[3a] In contrast, the porphyrin skeleton in $[H_4oep][RhCl_2(CO)_2]_2$ (H_2oep = octaethylporphyrin) has a planar conformation.[3b]

Scheme 1. Structures of the investigated porphyrins.

The macrocycle of $[H_4tchp][CF_3COO]_2 \cdot 2CF_3COOH \cdot 2H_2O$ (H_2tchp = tetracyclohexa[*b*, *g*, *l*]porphyrin) is, surprisingly, almost planar (Fig. 1).[5, 6a] Two trifluoroacetate (TFA) anions are hydrogen-bonded to the pyrrole hydrogens in a monodentate fashion, with one carboxyl oxygen bonded to two neighboring N–H units on the same face of the porphyrin. In this unique structure, the neighboring pyrrole units are displaced pairwise above and below the mean plane. On the basis

[**] This work was supported by grants from the Deutsche Forschungsgemeinschaft and the National Science Foundation (CHE-93-05577).

of earlier structural data, alternating up-and-down displacement of the N–H units was predicted for all porphyrin dications; this conformation minimizes the steric interaction of the four core hydrogens.[3, 7] The 24 macrocycle atoms show an average deviation from the porphyrin mean plane of 0.129 Å, which is comparable to that found in some sterically unencumbered free-base porphyrins.[8]

In the related compound $[H_4tmtep][ClO_4]_2 \cdot CH_3OH$ (H_2tmtep = tetraethyltetramethylporphyrin), the average deviation from the porphyrin mean plane is 0.173 Å for the macrocycle atoms and 0.37 Å for the C_b atoms; this represents a rather moderate degree of distortion.[6b, 9] In contrast, $[H_4oep][CF_3COO]_2 \cdot 2CF_3COOH$ (Fig. 2)[6c] contains a significantly saddle-distorted macrocycle: the average deviation of the C_b atoms from the mean plane is 0.72 Å (0.333 Å for all 24 macrocycle atoms), which is about 30% smaller than that found in $[H_4tpp]^{2+}$.[3b] On each porphyrin face, a TFA ion acts as a monodentate ligand and binds through a carboxyl oxygen to two opposing N–H protons. The pyrrole rings are twisted with respect to each other by 30.7°; the corresponding value for $[H_4tchp]^{2+}$ is 17°. Thus, octa-β-alkyl-substituted porphyrin dications can have varying degrees of macrocycle distortion, depending on the geometry of the central N–H units. In contrast, all tetra-*meso*-arylporphyrin dications so far studied show similar nonplanar saddle conformations with C_b displacements of about 1–1.2 Å.[10]

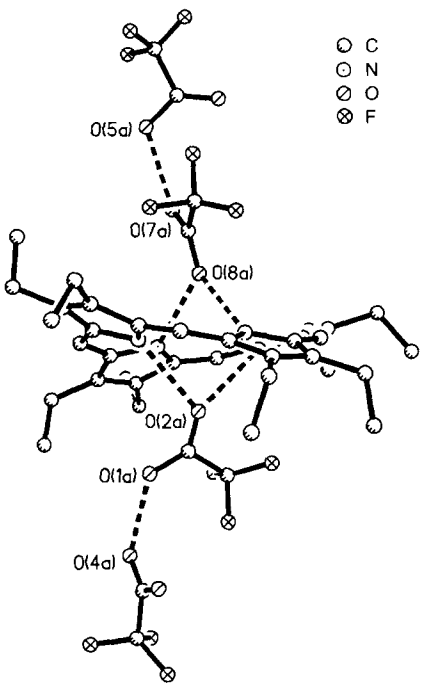

Fig. 2. Crystal structure of $[H_4oep][CF_3COO]_2 \cdot 2CF_3COOH$. Dashed lines indicate hydrogen bonds. Selected bond lengths [Å]: N(21)–O(8a) 2.871, N(23)–O(8a) 2.802, N(22)–O(2a) 2.798, N(24)–O(2a) 2.862, O(1a)–O(4a) 2.501, O(5a)–O(7a) 2.523.

The complex $[H_4oetpp][CH_3COO]_{3/2}[CF_3COO]_{1/2} \cdot 4CH_3COOH \cdot H_2O$ (H_2oetpp = octaethyltetraphenylporphyrin) is an example of a dodeca-substituted porphyrin dication combining both the structural characteristics of oep and tpp with core substitution (Fig. 3).[6d] The dication has a severely distorted macrocycle with C_b atom displacements of 1.357 Å from the porphyrin mean plane (0.612 Å for all macrocycle atoms). The pyrrole rings are tilted by 39.2° with respect to the macrocycle plane and by 53.1° with respect to each other. On each porphyrin face, an acetate ion acts as a bidentate ligand and binds through each carboxyl oxygen atom to an N–H proton. Initial studies on other oetpp dications indicate that the type of anion and the geometry of the hydrogen bonding to the core protons do not exert a major influence on the observed conformation in porphyrin dications.[10]

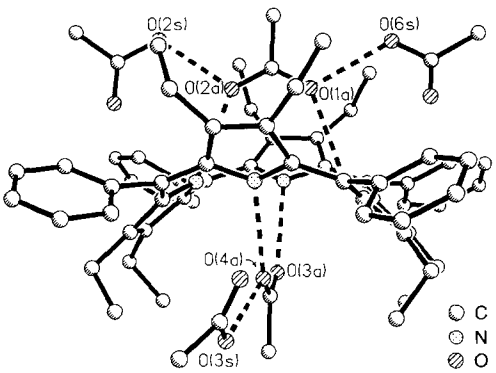

Fig. 3. Crystal structure of $[H_4oetpp][CH_3COO]_{3/2}[CF_3COO]_{1/2} \cdot 2CH_3COOH \cdot H_2O$. The minor TFA component, presumably due to contamination from a prior crystallization, is not shown. Dashed lines indicate hydrogen bonds. Selected bond lengths [Å]: N(21)–O(1a) 2.744, N(23)–O(2a) 2.759, N(22)–O(4a) 2.781, N(24)–O(3a) 2.758, O(4a)–O(3s) 2.596, O(1a)–O(6s) 2.592, O(2a)–O(2s) 2.559. The compound contains an additional acetic acid and water residue (not shown), which are hydrogen-bonded to each other: O(8')–O(9s) 2.288 Å.

The dodeca-substituted free bases and metalloporphyrins have conformations which are about as distorted as or slightly more distorted than the tpp dications. Thus, it might be expected that no further distortion is necessary to accomodate the four pyrrole hydrogens in the corresponding dications. Nevertheless, the $[H_4oetpp]^{2+}$ dication is about 30% more distorted than the corresponding free base, H_2oetpp.[11, 12] It is possible that porphyrins that are already nonplanar due to peripheral steric strain undergo further distortion more easily upon core protonation than do "normal" planar porphyrins. A special feature of *meso*-arylporphyrin dications is the large degree of in-plane rotation of the *meso*-aryl groups (e.g., 21° in $[H_4tpp]^{2+}$).[3a, 10] This feature has been used to account for the increased resonance interaction between the π electron system of the porphyrin macrocycle and the *meso*-aryl groups. This explains the bathochromic shifts of the absorption bands of the tpp dications vs. those of oep dications.[3a, 13] However, inspection of all the structures bearing *meso*-aryl groups[11] yields no evidence for shortening of the C_m–C_i bonds compared to those in the planar H_2tpp.[8c] Thus, the spectroscopic differences between the oep and tpp series reside solely in the electronic effects of the substituents and/or macrocycle conformations. Interestingly, the phenyl tilt angle in $[H_4oetpp]^{2+}$ (39.2°) is actually larger than that observed in $[H_4tpp]^{2+}$, which shows a smaller deviation from planarity. Similarily, compounds like [Cu(oetpp)] show tilt angles of approximately 46°.[2e] Thus, a linear correlation between *meso*-aryl tilt and porphyrin nonplanarity is not possible on the basis of the present data. In general terms, porphyrins that deviate strongly from planarity seem, however, to show a more coplanar arrangement of the aryl rings, which is significantly enhanced by core protonation.

The porphyrin conformation with the largest deviation from planarity observed so far is found in $[H_4obrtpp][CF_3COO]_2 \cdot 0.5CHCl_3$ ($H_2obrtpp$ = octabromotetraphenylporphyrin; Fig. 4).[6e] Overall, the structure is very similar to that of $[H_4oetpp]^{2+}$, with bidentate binding of the TFA carboxyl oxygens to opposing N–H hydrogens. The average deviation of the

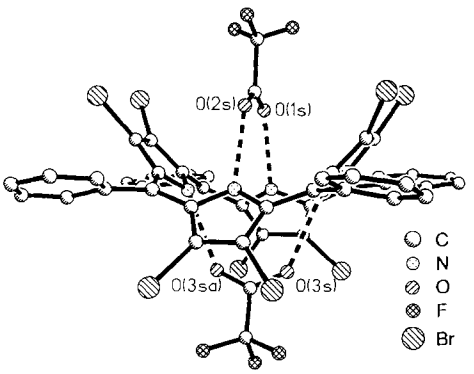

Fig. 4. Crystal structure of $[H_4obrtpp][CF_3COO]_2 \cdot 0.5CHCl_3$. Dashed lines indicate hydrogen bonds. Selected bond lengths [Å]: N(21)–O(2s) 2.744, N(23)–O(1s) 2.648, N(22)–O(3s) 2.685, N(22')–O(3s) 2.658. The compound contains two additional chloroform molecules (not shown) per unit cell.

24 macrocycle atoms from the mean plane is 0.689 Å; the corresponding figure for the C_b atoms is 1.521 Å. The distortion is about 63% greater than in the related octabromotetramesityl free base derivative.[2e] The increase upon protonation of H_2obrtpp is even larger than that observed upon going from H_2oetpp to $[H_4oetpp]^{2+}$. The extreme degree of nonplanarity is also reflected in the angles between the pyrrole rings of 62.1° and those between pyrrole rings and the macrocycle plane of 46.3°. Very surprising is the large in-plane rotation of the phenyl rings with tilt angles as small as 8.8° (average value 10.9°); the aryl rings are almost coplanar with the porphyrin plane. Even at this degree of coplanarity, no evidence for C_m–C_i bond shortening was found. Hence, the phenyl tilt observed in nonplanar porphyrins does not influence the spectroscopic characteristics of the nonplanar porphyrins. Disregarding electronic effects of different substituents or counterions, the bathochromic shifts of the absorption maxima are solely the result of increased macrocycle nonplanarity.

Correlations also exist between increasing macrocycle nonplanarity and selected geometrical characteristics: while most bond lengths and angles remain unaffected by comparison with those of planar porphyrins, increasing nonplanarity leads to a decrease in the N-C_a-C_m and C_a-C_m-C_a angles and an increase in the C_m-C_a-C_b and C_a-C_m-C_i angles. These structural correlations are independent of the way the macrocycle distortion is induced: the same trends are observed in the octa-β-substituted porphyrin dications, whose structure is determined solely by core strain, as in porphyrins with only peripheral steric strain.[2b, d, g–f, 11] These trends are no different in dodeca-substituted porphyrin dications possessing both peripheral and core strain. Since all nonplanar porphyrins described here have the same saddle-shaped distortion, the trends described are the result of the macrocycle distortion alone and not due to local effects of individual substituents, be they core hydrogen atoms or peripheral bulky substituents.

So far no structures of dodeca-substituted porphyrin dications have been found that are not more strongly distorted than the corresponding free base (unlike some oep derivatives). This indicates that sterically strained porphyrins with both β-alkyl and *meso*-aryl substituents behave conformationally like the sterically unencumbered tpp series upon protonation and not like the octaalkyl series. A detailed analysis of the exact geometry of the hydrogens in the core and their influence on the conformation will, especially in the case of the oep series, have to await neutron diffraction studies.

[5] Porphyrin dications are easily prepared by treatment of the respective free base porphyrins [2] with dilute acid in solution. All compounds gave satisfactory analytical data.

[6] Crystal data: a) $[H_4tchp][CF_3COO]_2 \cdot 2CF_3COOH \cdot 2H_2O$: $[C_{36}H_{40}N_4][C_2F_3O_2]_2 \cdot 2CF_3COOH \cdot 2H_2O$, red plate from $CHCl_3/CH_3OH$ + 1% TFA, triclinic, space group $P\bar{1}$, $a = 8.482(2)$, $b = 10.877(2)$, $c = 12.718(2)$ Å, $\alpha = 83.64(2)$, $\beta = 79.61(2)$, $\gamma = 78.43(2)°$, $V = 1127.2(4)$ Å^3, $Z = 2$, 2526 observed reflections with $F > 4.0\sigma(F)$, $\mu = 0.783$ mm^{-1}, $R = 0.059$, $R_w = 0.067$. b) $[H_4tmtep][ClO_4]_2 \cdot CH_3OH$: $[C_{32}H_{44}N_4][ClO_4]_2 \cdot CH_3OH$, red plate from CH_2Cl_2/CH_3OH + 3% $HClO_4$, triclinic, space group $P\bar{1}$, $a = 9.377(4)$, $b = 11.538(4)$, $c = 16.406(7)$ Å, $\alpha = 73.96(3)$, $\beta = 87.56(3)$, $\gamma = 80.97(3)°$, $V = 1684.8(12)$ Å^3, $Z = 2$, 3149 observed reflections with $F > 3.0\sigma(F)$, $\mu = 2.244$ mm^{-1}, $R = 0.093$, $R_w = 0.103$, disorder in one perchlorate anion. c) $[H_4oep][CF_3COO]_2 \cdot 2CF_3COOH$: $[C_{36}H_{40}N_4][C_2F_3O_2]_2 \cdot 2C_2F_3O_2H$, pink block from CH_2Cl_2/CH_3OH + 1% TFA, triclinic, space group $P\bar{1}$, $a = 11.647(4)$, $b = 12.167(5)$, $c = 17.954(7)$ Å, $\alpha = 82.39(3)$, $\beta = 72.61(3)$, $\gamma = 89.27(3)°$, $V = 2405.6(16)$ Å^3, $Z = 2$, 4700 observed reflections with $F > 4.0\sigma(F)$, $\mu = 1.088$ mm^{-1}, $R = 0.114$, $R_w = 0.122$, all TFA units severely disordered. d) $[H_4oetpp][CH_3COO]_{3/2}[CF_3COO]_{1/2} \cdot 4CH_3COOH \cdot H_2O$: $[C_{60}H_{64}N_4][C_2H_3O_2]_{3/2}$ $[C_2F_3O_2]_{1/2} \cdot 4CH_3CO_2H \cdot H_2O$, green block from CH_2Cl_2/CH_3OH + 5% acetic acid, triclinic, space group $P\bar{1}$, $a = 13.219(6)$, $b = 13.667(5)$, $c = 20.144(4)$ Å, $\alpha = 91.29(2)$, $\beta = 98.61(3)$, $\gamma = 108.11(3)°$, $V = 3411(2)$ Å^3, $Z = 2$, 6768 observed reflections with $F > 4.0\sigma(F)$, $\mu = 0.699$ mm^{-1}, $R = 0.081$, $R_w = 0.086$, 1 acetic acid residue disordered. e) $[H_4obrtpp][CF_3COO]_2 \cdot 0.5CHCl_3$: $[C_{44}H_{28}Br_8N_4][C_2F_3O_2]_2 \cdot 0.5CHCl_3$, green hexagon from $CHCl_3/CH_3OH$ + 1% TFA, orthorhombic, space group *Pmma*, $a = 16.358(2)$, $b = 19.437(3)$, $c = 17.629(3)$ Å, $V = 5604(2)$ Å^3, $Z = 4$, 2971 observed reflection with $F > 4.0\sigma(F)$, $\mu = 7.07$ mm^{-1}, $R = 0.063$, $R_w = 0.069$, 1 TFA and the solvent molecule disordered. Instruments used for data collections: a), b), c), and e): Siemens P4 diffractometer with attached rotating anode, 120 K, 2θ-θ-scans, $2\theta_{max} = 112°$, $Cu_{K\alpha}$ radiation (λ = 1.54178 Å); d) Syntex $P2_1$ diffractometer, 130 K, 2θ-θ scans, $2\theta_{max} = 115°$, $Cu_{K\alpha}$ radiation. Programs and refinement strategies used were as described in ref. [2g]. Further details on the crystal structure determinations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-58475.

[7] On the basis of structural data for porphyrin monocations partial sp^3 hybridization of the pyrrole nitrogens has also been suggested as a mechanism for relieving strain in the porphyrin core: N. Hirayama, A. Takenaka, Y. Sasada, E.-I. Watanabe, H. Ogoshi, Z.-I. Yoshida, *Bull. Chem. Soc. Jpn.* **1981**, *54*, 998; C. P. Hrung, M. Tsutsui, D. L. Cullen, E. F. Meyer, Jr., C. N. Morimoto, *J. Am. Chem. Soc.* **1978**, *100*, 6068. We found some evidence for this in the form of residual electron density at 0.8–1 Å from pyrrole nitrogens and outside the pyrrole plane. However, the limited resolution of core protons allows no direct conclusions to this effect.

Alternating Ferro- and Antiferromagnetic Interactions in a Mn^{II} Chain with Alternating End-On and End-to-End Bridging Azido Ligands**

Roberto Cortés, Luis Lezama, J. Luis Pizarro, M. Isabel Arriortua, Xavier Solans, and Teófilo Rojo*

In the last few years we have investigated the role played by pseudohalide ions, in particular the azido ion, in bridging different transition metals with the aim of studying their magnetostructural correlations. As a result, the first dinuclear Ni^{II} compound with bis(μ-end-on-azido) bridges[1] and the first metal compound having bis(μ-end-on-cyanato) bridges[2] were characterized.

Two possible bridging modes: end-to-end (EE) and end-on (EO) (Scheme 1) exist for the azido group. To date, dinuclear[3a, b] and tetranuclear complexes,[3c] and one-dimensional (1D) polymeric systems,[3b] have been synthesized with EO bridges, and dinuclear complexes[4a] and 1D polymeric systems[4b-d] with EE bridges. A complex with an infinite two-dimensional (2D) structure containing both EE and EO forms[5] has also been characterized. The EE bridges give rise to antiferromagnetic[4] and the EO bridges to ferromagnetic[3] interactions between the metal ions even for the Mn^{II} ion with $S = 5/2$.[6] The ferromagnetic behavior in the compounds with the EO bridges has been explained by the spin-polarization concept[7] for angles between 100–105°.

Scheme 1. Possible bridging modes for the azido ligand: Left: EO (ferromagnetic interactions); right: EE (antiferromagnetic interactions).

The different magnetic behavior caused by the two kinds of azido bridges, which is general for different metal ions,[6, 8-10] allows the possibility of obtaining very rare 1D systems with alternating ferro- (through EO bridges) and antiferromagnetic (through EE bridges) exchanges.[11] Such a compound must contain both types of bridging. With this aim in mind we developed a synthesis strategy in which metal and bidentate ligand are used in a 1:1 ratio. This should provide four vacant coordination sites around the metal ion, which should be filled by azide ions. Following this method, we successfully isolated a novel 1D Mn^{II} compound of the empirical formula $[Mn(N_3)_2(bpy)]_\infty$ (bpy = 2,2′-bipyridine) with alternating EO and EE bridges (Fig. 1).

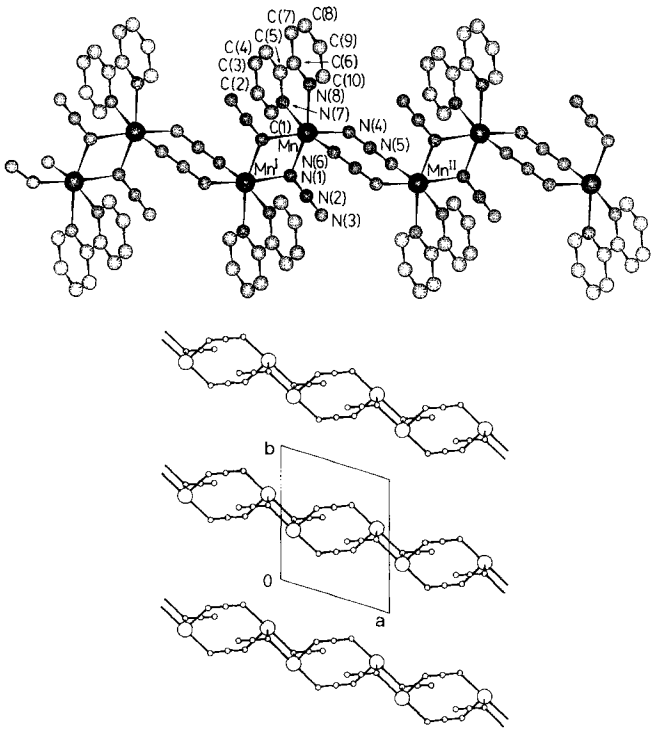

Fig. 1. Crystal structure of $[Mn(N_3)_2(bpy)]_\infty$. Top: View of the chain with alternating end-on and end-to-end coordination of the azido ligand. Bottom: Arrangement of the chains in the *ab* plane (only manganese and nitrogen atoms are shown). Selected distances [Å] and angles [°] (standard deviations in parentheses): Mn-N(1) 2.200(6), Mn-N(4) 2.244(6), Mn-N(6) 2.185(6), Mn-N(7) 2.237(5), Mn-N(8) 2.258(5), Mn-N(1)^{I} 2.276(6); N(1)-Mn-N(4) 92.3(2), N(1)-Mn-N(6) 98.8(2), N(1)-Mn-N(7) 94.3(2), N(1)-Mn-N(8) 162.2(2), N(4)-Mn-N(6) 90.5(2), N(4)-Mn-N(7) 89.5(2), N(4)-Mn-N(8) 98.4(2), N(6)-Mn-N(7) 166.9(2), N(6)-Mn-N(8) 95.3(2), N(7)-Mn-N(8) 71.8(2), Mn-N(1)-Mn^{I} 101.0(2), Mn-N(4)-N(5) 131.1(5), Mn-N(6)-N(5)^{II} 127.3(5); symmetry code: I = $-x, 1-y, 1-z$; II = $1-x, 1-y, 1-z$.

The crystal structure[12] consists of chains in which the Mn^{II} ions are alternatively linked by two EO and two EE azido bridges (Fig. 1). The two nitrogen atoms of the bpy ligand complete a distorted octahedral coordination sphere for each manganese ion. The EO and EE bridges are arranged *cis*, being perpendicular to each other. The Mn-N-Mn angle in the EO mode is 101.0° in good agreement with the results usually obtained for this kind of bridging. For the EE bridges the Mn-N-N angles are 131.1(5)° and 127.3(5)° for a chair conformation of the Mn-$(N_3)_2$-Mn unit and a torsion angle of 41.9°. The intrachain Mn···Mn distances are 3.455(6) Å (EO) and 5.343(5) Å (EE).

ESR measurements show an exchange-narrowed isotropic signal at $g = 2.0$ which is indicative of significant ferromagnetic interactions. A "half-field" signal is also observed. Variable-temperature magnetic susceptibility measurements have been performed on a powdered sample in the range 298 to 2 K with a SQUID SHE magnetometer. A global antiferromagnetic interaction is evident from the magnetic behavior as is shown in Figure 2. The χ_m value increases as the temperature decreases, reaching a rounded maximum at about 55 K and then decreases on cooling down to 2 K. The $\chi_m T$ value at room temperature is 4.0 $cm^3 K mol^{-1}$, smaller than the value expected for an uncoupled Mn^{II} ion. This value decreases with decreasing temperature tending to zero. This compound should exhibit alternating ferromagnetic and antiferromagnetic interactions, since *cis* EO bridges with a bridging angle as observed here are able to mediate a ferromagnetic interaction between the Mn^{II} magnetic cen-

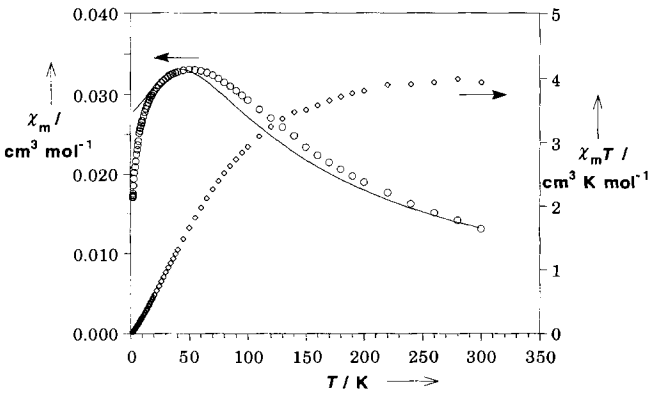

Fig. 2. Plot of $\chi_m T$ (○) and χ_m (○) of $[Mn(N_3)_2(bpy)]_x$ versus T. Solid line: best-fit curve according to Fisher [13a] for a classical or infinite spin linear chain, scaled to a real $S = 5/2$ value.

ters (as has recently been observed in the dinuclear complex $[Mn(N_3)_2(terpy)]_2 \cdot 2H_2O$[6] with an Mn-N-Mn angle of 104.6(2)° and $J/k = +3.5$ K), and the *cis* EE bridges with an M-N-N angle of ≈130° lead to antiferromagnetic coupling.[4a] Consequently, the magnetic behavior of this compound must be explained by assuming a positive J for EO and a negative J' for EE. A tentative fit of the experimental susceptibility to Fisher's equation[13a] for a classical or infinite spin linear chain, scaled to a real spin of 5/2[13b] (Fig. 2), shows a great discrepancy. No formula is available in the literature for an $S = 5/2$ ferro–antiferromagnetic alternating chain and we are now trying to elaborate an adequate model.

Experimental Procedure

A solution of 2,2'-bipyridine (0.15 g, 1 mmol) in methanol (10 mL) was added dropwise to a stirred aqueous solution (20 mL) of $Mn(ClO_4)_2 \cdot 6H_2O$ (0.35 g, 1 mmol). Excess NaN_3 dissolved in water was slowly added. This led to a yellow solution that was filtered and left to stand at room temperature. After several days prismatic, transparent, yellow, X-ray quality single crystals were obtained (yield 0.23 g; 77%).

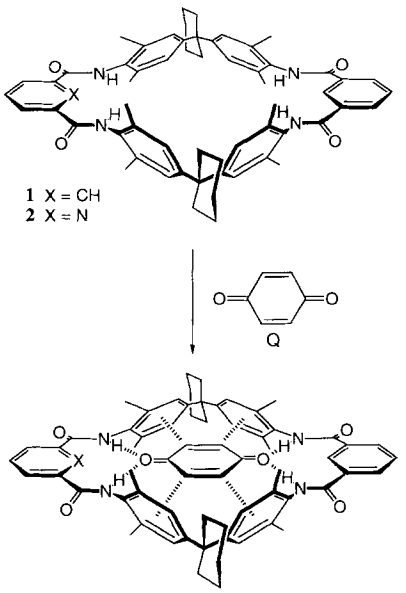
Supramolecular Activation of *para*-Benzoquinone



Paula A. Brooksby, Christopher A. Hunter,* A. James McQuillan,* Duncan H. Purvis, Alan E. Rowan, Richard J. Shannon, and Russell Walsh

A key feature of biochemical transformations is chemical activation of a bound substrate by noncovalent interactions with its protein environment. Although great progress has been made in the design of artificial enzymes, few of these systems use a specifically tailored molecular environment to enhance reactivity of the bound substrate,[1] but rather rely on positioning two reactive groups in close proximity.[2] In this paper, we demonstrate how a tailored environment can be used to polarize and activate a noncovalently bound substrate.

Quinones play an important role in photosynthesis. Photosynthetic reaction centers in plants and bacteria contain two closely spaced quinone cofactors, which are the ultimate electron acceptors on the electron transfer pathway and function as a two-electron gate.[3] The properties of the quinones change dramatically on complexation by the protein.[4] In particular, their reduction potentials are between 0.30 and 0.37 V more negative, depending on the particular organism. In an attempt to reproduce these properties, we have developed molecular receptors **1** and **2**, which complex *para*-benzoquinone (Q) through a combination of H-bonds and edge-to-face π–π interactions (Scheme 1).[5, 6] The intermolecular interactions were chosen not only for their molecular recognition properties, but also in the hope that they would cooperatively polarize the guest and modify its chemical properties.

The electrochemical properties of the complexes of Q with **1** and **2** were investigated by cyclic voltammetry. The properties of the two complexes were similar, but due to the low solubility of **1** most of the following discussion will focus on the complex **2** · Q. The experiments were carried out with 10^{-3} M solutions of Q in CH_2Cl_2, a platinum disk electrode, and 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. The electrolyte may reduce the affinity of Q for the

receptors through competition for the H-bonding sites. However, ^{1}H NMR studies showed that 10^{-2} M concentrations of TBAP had no effect on the binding.

The cyclic voltammogram of Q (Fig. 1a) showed a reversible one-electron reduction with an $E_{1/2}$ of -0.46 V. The reduction peak was at -0.53 V, and the corresponding oxidation peak

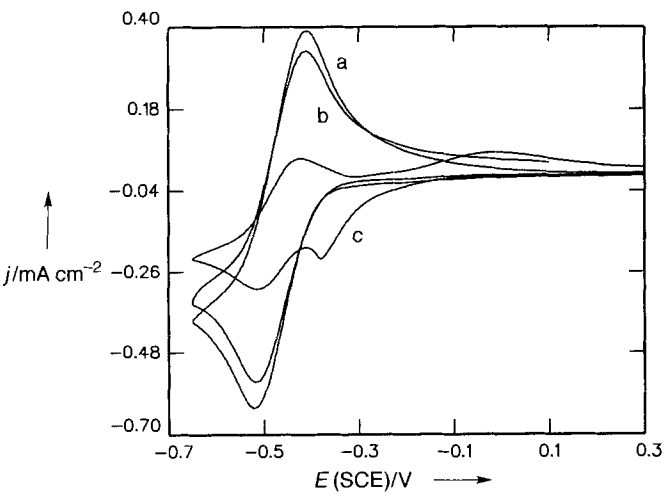

Fig. 1. Cyclic voltammograms of Q in 0.1 M solutions of TBAP in CH_2Cl_2. Platinum disk, 1.6 mm, working electrode. Saturated calomel reference electrode (SCE). Sweep rate 100 mV s^{-1}. a) 1.5×10^{-3} M Q. b) 1.1×10^{-3} M Q and 1.1×10^{-3} M benzanilide. c) 1.0×10^{-3} M Q and 1.0×10^{-3} M **2**.

appeared at -0.39 V. When the experiment was repeated in the presence of **1** or **2** (Fig. 1c), a reduction wave due to free Q was again observed, but a new subsidiary reductive wave appeared at -0.38 V, a shift of 150 mV relative to that of uncomplexed Q. A new oxidative wave also appeared at around 0.00 V, a shift of 390 mV relative to that of uncomplexed Q. The intensity of these new waves increased with increasing receptor concentration. The receptors are not electroactive over the potential range studied; this implies that the new waves are due to the quinone complexes. However, the separation between the reduction and corresponding oxidation peaks of these new waves is too large for the electron transfer to be a simple reversible process. The oxidative wave broadened and moved to higher potentials as the sweep rate was increased. This implies that there is a process which inhibits reoxidation of the quinone radical anion, but we have yet to discover the nature of this process. Protonation of the radical anion by acidic cosolvents leads to similar behavior, but the spectroscopic evidence presented below demonstrates clearly that protonation of the bound radical anion does not occur.

The nature of the species that give rise to the new waves at -0.38 V and 0.00 V was investigated by UV/Vis spectroelectrochemistry. Spectra were recorded as a function of electrode potential from a thin-layer cell.[7] The parent Q absorbs at 244 nm in the UV/Vis region but has no significant absorptions at longer wavelengths, while the semiquinone radical anion ($Q^{\bullet-}$) has very strong absorptions at 326 and 426 nm. This simplifies interpretation of the spectra in Figure 2. The reductive wave at

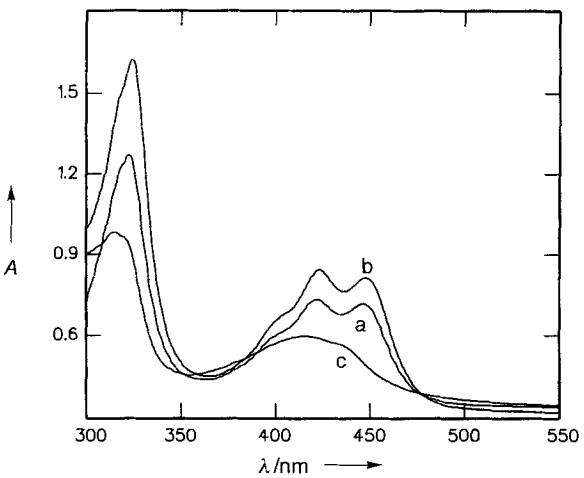

Fig. 2. UV/Vis absorption spectra of partially reduced Q in 0.1 M solutions of TBAP in CH_2Cl_2. The thin-layer electrochemical cell (Pt mesh electrode, 0.35 mm path length) has been described elsewhere [7]. Spectra were recorded at potentials corresponding to comparable stages of reduction. a) 1.5×10^{-3} M Q. b) 1.1×10^{-3} M Q and 1.0×10^{-3} M benzanilide. c) 1.4×10^{-3} M Q and 1.0×10^{-3} M **2**.

-0.38 V correlated with a decrease in the intensity of the Q absorption at 244 nm (not shown) and with the appearance of $Q^{\bullet-}$ absorptions at 324 and 412 nm (Fig. 2c). Similarly, the oxidative wave at $+0.00$ V correlated with the disappearance of the $Q^{\bullet-}$ absorptions. These results demonstrate clearly that the new subsidiary waves in the cyclic voltammogram (Fig. 1c) correspond to the reduction of Q and oxidation of $Q^{\bullet-}$ bound inside the receptor cavity. The spectra of the free and bound $Q^{\bullet-}$ differ significantly (Fig. 2a, c). The 426 nm absorption of $Q^{\bullet-}$ is shifted to shorter wavelength when it is bound inside the receptor, and the vibrational structure is less resolved. This reflects the different molecular environments of the two species.[8]

SNIFTIR experiments were used to probe changes in the hydrogen-bonding interactions that accompany reduction of the quinone complexes.[11] Figure 3 shows the SNIFTIR spectra, which are potential-induced difference spectra. Reduction of free Q is accompanied by a decrease in intensity of the 1669 and 1656 cm^{-1} bands (C=O stretch) and the appearance of $Q^{\bullet-}$ signals at 1505 and 1344 cm^{-1} (Fig. 3a). In the presence of **2**, two additional signals are observed in the difference spectrum (Fig. 3c). These signals are due to changes in the frequencies of the receptor amide stretches on reduction of the bound guest.

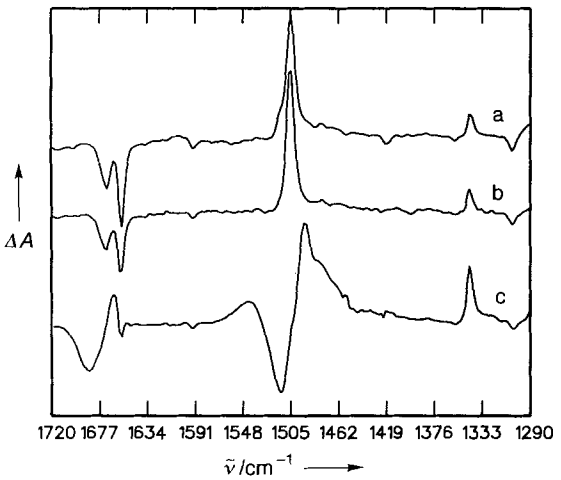

Fig. 3. SNIFTIR spectra of partially reduced Q in 0.1 M solutions of TBAP in CH_2Cl_2. Absorbance differences (ΔA) are due to a potential change from 0.0 to -0.5 V (SCE) in each case. a) 2.0×10^{-3} M Q. b) 1.5×10^{-3} M Q and 1.3×10^{-3} M benzanilide. c) 1.3×10^{-3} M Q and 1.0×10^{-3} M **2**.

The frequency of the amide I stretch shifts from 1686 to 1665 cm^{-1}; this indicates a decrease in the double bond character of the C=O bond. The amide II stretch also shifts from 1515 to 1543 cm^{-1}. It appears that the bound $Q^{\bullet-}$ carbonyl absorption is at 1492 cm^{-1} and that the free $Q^{\bullet-}$ absorption is subsumed in the negative amide II band. These changes imply that reduction of bound Q polarizes the amide bonds in the receptor so that the amide protons become more positive, hydrogen-bond more strongly to the guest, and stabilize the $Q^{\bullet-}$ negative charge.[12] Although such polarization effects are not accounted for by molecular mechanics force fields, calculations with the CHARMm force field also suggest that reduction of the complex is associated with an increase in the strength of the H-bonds, which stabilize the large negative charges on the $Q^{\bullet-}$ oxygen atoms.[9] The calculated H-bond lengths in the **1** · $Q^{\bullet-}$ complex (2.02, 2.04, 2.21, and 2.25 Å) are significantly shorter than in the **1** · Q complex (2.22, 2.31, 2.38, and 2.42 Å).

As a control, we repeated the experiments with benzanilide in place of the receptors. Even at 10^{-2} M concentrations of benzanilide (not shown), no significant changes were observed in the cyclic voltammogram of Q (Fig. 1b). Similarly, the UV/Vis spectroelectrochemical and SNIFTIR experiments gave spectra that were almost indistinguishable from those obtained for Q alone (Fig. 2b and 3b). ^{1}H NMR and FTIR spectra of Q in the presence of 10^{-2} M benzanilide show that there is no intermolecular hydrogen-bonding at these concentrations. Thus the changes in the electrochemical properties of the receptor · Q complexes can be attributed to the formation of a specific 1:1 complex rather than to the presence of amide groups that could interact with the radical anion.

This work demonstrates that if polarizing interactions such as H-bonds perturb the electronic structure of a noncovalently bound substrate in a cooperative manner, then the chemical properties of the substrate can be significantly modified.[10] The interactions that bind the quinone cofactors in photosynthetic reaction centers of purple bacteria involve an H-bond to each of the quinone oxygens, $\pi-\pi$ interactions, and hydrophobic contacts.[3] In addition, the quinones are linked to a non-heme iron(II) ion through a histidine bridge. The role of the iron ion has not been established, but it is thought to stabilize the buildup of negative charge on the semiquinone radical anions.[3] Although these results do not rule out this possibility, they show that H-bonding interactions alone are sufficient to produce a stabilization comparable to that observed in the natural systems. These interactions also appear to slow down reoxidation of the quinone radical anion, which would help prevent charge recombination in the photoinduced electron transfer reactions in the primary events in photosynthesis.

$(H_3N(CH_2)_6NH_3)_4[W_{18}P_2O_{62}]\cdot 3H_2O$, a Microporous Solid from Dawson Anions and 1,6-Diaminohexane**

Markus Hölscher, Ulli Englert, Bodo Zibrowius, and Wolfgang F. Hölderich*

The synthesis of solids with defined cavities is the main concern of many current research projects, with a special focus on the preparation of microporous materials containing transition metals. These metal atoms could serve as active sites for oxidation reactions and thus lead to shape-selective reactions due to the defined pore structure of the carrier—a principle that has been well established with zeolites.[1, 2]

For this reason the isomorphous substitution of silicon in zeolites by other elements has been intensively investigated. Taramasso et al., for instance, could report for the first time on titanium-containing ZSM-5 zeolites in 1983. This material showed catalytic activity in oxidation reactions with H_2O_2.[3] In the case of microporous aluminophosphates, which are closely related to zeolites (alternating AlO_4 and PO_4 tetrahedra form a three-dimensional network), it was shown that phosphorus as well as silicon could be substituted isomorphously by a variety of different metals.[4]

A different kind of approach was made by preparing three-dimensional microporous structures that consisted of the elements phosphorus, oxygen, and transition metal. Rather than using isomorphous substitution, completely new structures and groups of compounds were developed. Haushalter et al. reported on microporous molybdenum phosphates,[5] and Zubieta et al. were successful a short time ago in preparing a vanadium phosphate with elliptical cavities.[6] A microporous cobalt phosphate was prepared by Thomas et al. very recently.[7]

Heteropolyoxometallates of molybdenum and tungsten have been very thoroughly studied and are being used as technical catalysts.[8, 9] For that reason it might be very interesting to prepare these compounds in such a way that they become part of a microporous material. It was our aim to study this new alternative. The Keggin ion $M_{12}XO_{40}^{n-}$ or the Dawson ion $M_{18}X_2O_{62}^{m-}$ (X = P, Si, As, Ge; M = Mo, W; n = 3,4; m = 6) are classic examples. To our knowledge, these heteropolyoxometalates have been crystallized with a large variety of cations, but none of the reported structures showed defined micropores large enough to be useful for shape-selective catalysis.[10] During the course of our investigations to prepare such materials we were able to obtain the first example of that kind. Here we report on the synthesis and characterization of **1**, a reduced Dawson anion that is part of a microporous solid.

$(H_3N(CH_2)_6NH_3)_4[W_{18}P_2O_{62}] \cdot 3H_2O$ **1**

The hydrothermal reaction of tungsten, tungsten oxide, 1,6-diaminohexane, phosphoric acid, and water gave dark blue crystals of **1** in 90% yield.[11] The single-crystal structure analysis showed **1** to consist of discrete Dawson anions surrounded by 1,6-diaminohexane in such a way that the protonated amino groups of one molecule connect two Dawson units. A total of eight alkylammonium groups are in close contact with one anion (Fig. 1). The cavities constructed in this way along the crystallographic c axis have shortest O–O distances of 7.6 × 8.4 Å (internuclei distances). A view of the structure of **1** along the crystallographic b axis shows sheets of anions forming a zigzag chain parallel to the a axis in which every alternate anion lies at the same height (Fig. 2). Between these sheets the 1,6-diaminohexane molecules work as spacers, which likewise form channels. In this projection these openings have shortest O–O distances of 3.6 Å and C–C distances of 9.1 Å. They are too small for organic molecules and contain water molecules, which could be located in the structure analysis. The same is true for the cavities in the a direction, which have dimensions of approximately 3.6 × 8.7 Å.

The Dawson anion is built up from edge- and corner-sharing octahedra encapsulating two phosphorous atoms. In **1** the α-isomer of the anion has crystallized.[17] M–O distances were 1.69–1.71 for terminal oxygens, 1.91–2.08 for μ_2-bridging oxygens, and 2.34–2.38 for μ_3-bridging oxygens. P–O distances varied between 1.54 and 1.59 Å. Our structure determination is in good agreement both with the Dawson[18] and the d'Amour structures of Dawson anions.[19] The anions and the organic dications are connected through hydrogen bonds, and the fact that eight N atoms surround one anion suggests that the Dawson unit is the doubly reduced $[W_{18}P_2O_{62}]^{8-}$. Now we are trying to find evidence for this idea by means of cyclovoltametry. Bond valence calculations do not implicate further protonations.[20] FTIR as well as ^{13}C MAS-NMR and ^{31}P MAS-NMR spectra conformed to expectations.[21, 22, 23] Compound **1** crystallized as a single pure phase, as could be shown by comparing the experimental and the simulated X-ray powder diffraction pattern. Thermoanalyses in air showed that the compound became amorphous at about 200 °C. In the temperature range between 200 and 500 °C the diamine decomposed resulting in a weight loss of 11% (calculated for 1,6-diaminohexane and water of crystallization: 10.7%), and the anion was oxidized, which was observed as a change from dark blue to greenish yellow. To investigate whether the micropore volume is accessible, attempts were made to obtain adsorption isotherms both with

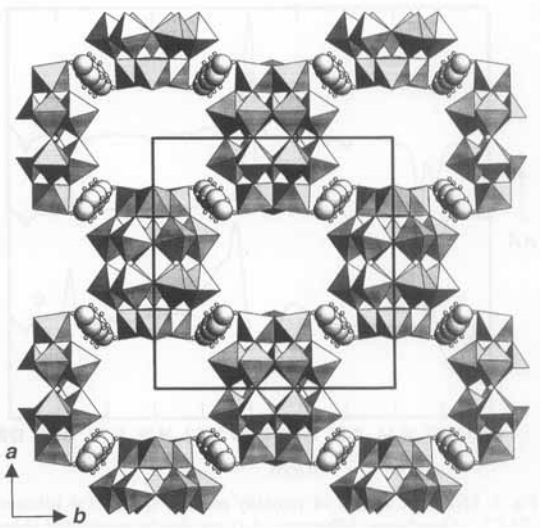

Fig. 1. View of the crystal structure of **1** along the crystallographic c axis. The arrangement of anions (polyhedral representation) and cations (radii arbitrary) forms rectangular openings.

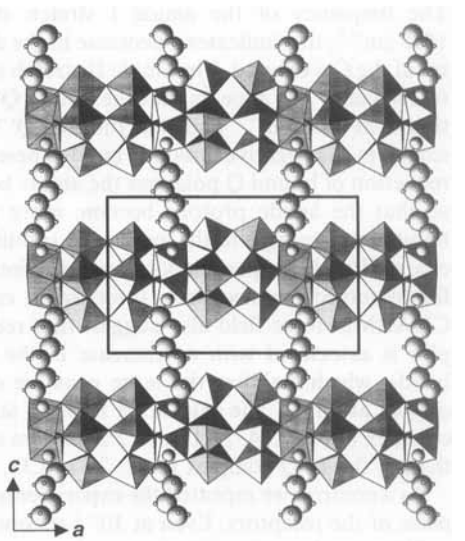

Fig. 2. View of the structure of **1** along the crystallographic b axis. The zigzag chain of polyanions runs parallel to the a axis. The $H_3N(CH_2)_6NH_3$ ions function as spacers in the c direction (carbon: large circles, hydrogen: small circles; nitrogen atoms without hydrogen atoms; radii arbitrary).

nitrogen and water as adsorbate. Finely powdered samples were degassed for 12 hours at temperatures between 100 and 200 °C in a vacuum of 10^{-5} Torr. Under these conditions none of the samples adsorbed nitrogen or water in substantial amounts. We are unable to explain this result at present.

We are also investigating whether the organic spacer influences the formation of the structure as a whole, or whether the choice of the diamine is critical enough to favor the formation of different heteropolyanions. Furthermore, we have started to perform experiments to explore the catalytic potential of **1** in oxidation reactions. We believe that a variety of new interesting compounds should be available, since the preparation of **1** is so surprisingly simple.

[21] IR (KBr disk, characteristic bands): ν[cm^{-1}] = 3449 (m, $\nu(H_2O)$), 3130 (m, $\nu(NH_3^+)$), 2930, 2860 (m, $\nu(CH_2)$), 1080 (m, $\nu(PO_4)$), 943, 912, 819 (vs, ν(W-O)).
[22] The ^{13}C and ^{31}P MAS-NMR spectra were measured on a MSL300 or MSL500 spectrometer using high-power proton decoupling at a resonance frequency of 75.5 MHz and 202.5 MHz, respectively. The contact time for ^{13}C CPNMR spectra was 1 ms. The signals in the ^{13}C NMR spectra at $\delta = 27.8$ and 41.8 (± 0.1 ppm) could be assigned to protonated 1,6-diaminohexane. The ^{31}P NMR spectrum shows three signals at $\delta = -1.2$, -7.2, and -13.0 (± 0.2 ppm) and a shoulder at $\delta = -14.2$. The strongest signal ($\geq 70\%$ of total intensity) at $\delta = -13.0$ can unambiguously be assigned to the phosphorus nuclei in the Dawson anion. The signal at $\delta = -1.2$ is caused by excess phosphoric acid and/or an adduct of phosphoric acid and 1,6-diaminohexane.

Environmental Sampling for Trace Analysis. By **B. Markert.** VCH, Weinheim, **1994.** 282 pp., hardcover, DM 248.00.—ISBN 3-527-30051-1

Enzymkinetik, 2nd Ed. By **S. Bisswanger.** VCH, Weinheim, **1994.** 321 pp., hardcover, DM 118.00.—ISBN 3-527-30032-5

The Chemistry of Metal CVD. Edited by **T. T. Kodas, M. J. Hampden-Smith.** VCH, Weinheim, **1994.** 530 pp., hardcover, DM 228.00/$ 135.00.—ISBN 3-527-29071-0

Deterministisches Chaos. By **H. G. Schuster.** VCH, Weinheim, **1994.** 288 pp., paperback, DM 78.00.—ISBN 3-527-29089-3

Research and Development of Vaccinees and Pharmaceuticals from Biotechnology. By **J.-P. Gregersen.** VCH. Weinheim, **1994.** 173 pp., paperback, DM 98.00/$ 60.00.—ISBN 3-527-30059-7

Biologische Bodensanierung. Edited by **K. Alef.** VCH, Weinheim, **1994.** 269 pp., paperback, DM 78.00.—ISBN 3-527-30058-9

Praktische Qualitätssicherung in der Analytik. By **V. Neitzel, K. Middeke.** VCH, Weinheim, **1994.** 190 pp., paperback, DM 85.00.—ISBN 3-527-28686-1

Umweltchemie. By **C. Bliefert.** VCH, Weinheim, **1994.** 453 pp., paperback, DM 68.00.—ISBN 3-527-28692-6

Molecular Ecology of Rhizosphere Microorganisms. Biotechnology and the Release of GMO's. Edited by **F. O'Gara, D. N. Dowling, B. Boesten.** VCH, Weinheim, **1994.** 177 pp., hardcover, DM 148.00/$ 90.00.—ISBN 3-527-30052-X

Organische Chemie, 2nd Ed. By **A. Streitwieser, C. H. Heathcock, E. M. Kosower.** VCH, Weinheim, **1994.** 1374 pp., hardcover, DM 128.00.—ISBN 3-527-29005-2

Nichtmetallchemie. By **T. M. Klapötke, I. C. Tornieporth-Oetting.** VCH, Weinheim **1994.** 493 pp., hardcover, DM 58.00.—ISBN 3-527-29257-8

Organic Reactions, Vol. 45. Edited by **P. Beak, E. Ciganek, D. Curran et al.** Wiley, Chichester, Great Britain, **1994.** 671 pp., hardcover, £ 79.00.—ISBN 0-471-03161-5

LIMS: Implementation and Management. By **A. S. Nakagawa.** Royal Society of Chemistry, Cambridge, **1994.** 180 pp., hardcover, £ 37.50.—ISBN 0-85186-824-X

Total Quality Management in the Chemical Industry - Strategies for Success. Edited by **G. R. Turner, R. P. Hadfield.** Royal Society of Chemistry, Cambridge, **1994.** 200 pp., hardcover, £ 37.50.—ISBN 0-85186-624-7

Current Topics in the Chemistry of Boron. Edited by **G. W. Kabalka.** Royal Society of Chemistry, Cambridge, **1994.** 406 pp., hardcover, £ 59.50.—ISBN 0-85186-535-6

Chemically Modified Surfaces. Edited by **J. J. Pesek, I. E. Leigh.** Royal Society of Chemistry, Cambridge, **1994.** 223 pp., hardcover, £ 49.50.—ISBN 0-85186-595-X

Chemical Instrumentation. By **R. P. Wayne.** Oxford University Press, Oxford, **1994.** 92 pp., paperback, £ 4.99.—ISBN 0-19-855796-5

Principles and Applications of Electrochemistry 4th Ed. By **D. R. Crow.** Blackie/Chapman & Hall, London, **1994.** 282 pp., paperback, £ 16.99.—ISBN 0-7514-0168-4

Container Molecules and Their Guests. (Monographs in Supramolecular Chemistry). By **D. J. Cram, J. M. Cram.** Royal Society of Chemistry, Cambridge. **1994.** 223 pp., hardcover, £ 49.50.—ISBN 0-85186-972-6

The Role of Oxygen in Improving Chemical Processes. 6th BOC Priestley Conference. Edited by **M. Fetizon, W. J. Thomas.** Royal Society of Chemistry, Cambridge, **1993.** 286 pp., hardcover, £ 57.50.—ISBN 0-85186-725-1

Experimental Toxicology, 2nd Ed. The Basic Issues. Edited by **D. Anderson, D. M. Conning.** Royal Society of Chemistry, Cambridge. **1993.** 566 pp., paperback, £ 25.00.—ISBN 0-85186-461-9

Further Advances in Chemical Information. Edited by **H. Collier.** Royal Society of Chemistry, Cambridge, **1994.** 193 pp., hardcover, £ 45.00.—ISBN 0-85186-545-3

Sugarless - Towards the Year 2000. Edited by **A. J. Rugg-Gunn.** Royal Society of Chemistry, Cambridge, **1994.** 197 pp., hardcover, £ 37.50.—ISBN 0-85186-495-3

The Development of Plastics. Edited by **S. T. I. Mossman, P. J. T. Morris.** Royal Society of Chemistry, Cambridge, **1994.** 120 pp., hardcover, £ 35.00.—ISBN 0-85186-575-5

Electrochemistry and Clean Energy. Edited by **J. A. G. Drake.** Royal Society of Chemistry, Cambridge, **1994.** 104 pp., hardcover, £ 32.50.—ISBN 0-85186-472-4

Biochemistry of Milk Products. Edited by **A. T. Andrews, J. Varley.** Royal Society of Chemistry, **1994.** 182 pp., hardcover, £ 39.50.—ISBN 0-85186-702-2

Waste Incineration and the Environment. Issues in Environmental Science and Technology, Vol. 2. Edited by **R. E. Hester, R. M. Harrison.** Royal Society of Chemistry, Cambridge, **1994.** 158 pp., paperback, £ 15.00.—ISBN 0-85404-205-9

Protecting Groups. By **P. J. Kociénski.** Thieme, Stuttgart, **1994.** 265 pp., paperback, DM 60.00.—ISBN 3-13-135601-4

Food. The Definite Guide. By **T. Coultate, J. Davies.** Royal Society of Chemistry, **1994.** 167 pp, paperback, £ 12.50.—ISBN 0-85186-431-7

Organometallics in Synthesis. A Manual. Edited by **M. Schlosser.** Wiley, Chichester, Great Britain, **1994.** 603 pp., hardcover, £ 60.00.—ISBN 0-471-93637-5

AUTHOR INDEX [*Angew. Chem. Int. Ed. Engl.* **1994**, *33*]

The page numbers in square brackets refer to the German edition [*Angew. Chem.* **1994**, *106*] of *Angewandte Chemie*. Page numbers in round brackets indicate errata.

INDEX OF AUTHORS AND REVIEWERS OF BOOKS

This index lists separately the names of Authors/Editors and Reviewers, respectively, of books reviewed in *Angew. Chem. Int. Ed. Engl.* **1994**, *33*.

Book Authors

Adloff, J.-P. 1198
Agosta, W. C. 236
Altmann, S. L. 482
Andrews, D. L. 1195
Baer, T. 1669
Baetzold, R. C. 586
Balogh, M. 1892
Barton, D. H. R. 1009
Bein, T. 1009
Bensaude-Vincent, B. 901
Billups, W. E. 2227
Blümich, B. 128
Bochmann, M. 2225
Bonn, G. 1401
Bonnell, D. A. 2226
Brett, A. M. O. 1989
Brett, C. M. A. 1989
Brock, W. H. 901
Bruce, D. W. 585
Brunner, H. 2225
Buerk, D. G. 791
Charsley, E. L. 586
Ciufolini, M. A. 2227
Clark, J. H. 239
Collison, D. 362
Cooper, S. R. 235
Cotton, F. A. 480
Cowan, J. A. 1196
Cox, D. E. 2227
Dehmlow, E. V. 1669
Dehmlow, S. S. 1669
Dvorák, J. 1989
Dwight, K. 1403
Eu, B. C. 481
Fischer, J. E. 2227
FIZ Chemie, 1305
Frank-Kamenetskii, M. D. 1303
Ganellin, C. R. 1783
Gaspar, P. P. 1198
Gasteiger, J. 1671
Georg, G. I. 480
Gileadi, E. 1304
Goldberg, Y. 1669
Golightly, D. W. 231
Göpel, W. 127
Guard, H. E. 1010
Halgas, J. 1012
Hamerloff, S. 2228
Hasegawa, A. 588
Hendra, P. 361
Hennel, J. W. 1670
Hitchman, M. L. 1403
Hoffmann, R. 1303 (1521)
Hoheisel, C. 697
Holtzhauer, M. 234
Homans, S. W. 360
Horváth, O. 483
Hunter, B. K. 1992

Ab initio calculations
- 1-Alkyl-2,5-(*ortho*-phenylene)-1-carbapentaborane(10) (C) 2296
- A Novel Hexamer of *t*BuC≡P: Synthesis, Structure, and Theoretical Studies (C) 2202
- Are Polar Organometallic Compounds "Carbanions"? The Gegenion Effect on Structure and Energies of Alkali-Metal Compounds (R) 1129
- Excited-State Carbon Acids: Theoretical Studies of Suberene and Cycloheptatriene (C) 2431
- 1(9)-Homocubene and 9-Homocubylidene: Theoretical Investigation of Structures, Energies, and Rearrangement Reactions (C) 668
- *s*-Indacene: A Delocalized, Formally Antiaromatic 12 π Electron System (C) 1192
- Magnetic Properties of Aromatic Transition States: The Diels–Alder Reactions (C) 1376
- New Sulfur- and Selenium-Bridged Copper Clusters; Ab Initio Calculations on $[Cu_{2n}Se_n(PH_3)_m]$ Clusters (C) 746
- Nonclassical 1,2-Diboretanes and 1,2-Diborolanes (C) 2303
- Octaplane: A Saturated Hydrocarbon with a Remarkably Low Ionization Energy Leading to a Cation with a Planar Tetracoordinate Carbon Atom (C) 1667
- Polymorphism and C=N–N=C Conformational Isomers of Azines: X-ray Crystal and Ab Initio Structures of Two Rotational Isomers of Methyl (*para*-Tolyl) Ketone Azine (C) 1081
- The Influence of Charge Distribution on Bond Lengths in the P_4O_6 Framework in Compounds of the Type P_4O_6X (C) 563
- The $S_{RN}2$ Pathway—A Mechanistic Alternative for Radicals in Polar Media? (C) 1985
- The Structures of Alkyl Derivatives of *arachno*-1-$C_3B_4H_{12}$ from Reactions of B_4H_{10} with Alkynes (C) 2298

Acrolein
- Kinetic Resolution of the Acrolein Dimer by Asymmetric Horner–Wadsworth–Emmons Reactions (C) 556

Activation of enzymes
- Activation of Glutathione Reductase by Light: A Novel Approach to Design Redox Photo-Enzymes (C) 581

Adamantylidene
- Matrix Spectroscopy of 2-Adamantylidene, a Dialkylcarbene with Singlet Ground State (C) 1964

Additions
- Conjugate Addition Reactions in Organic Synthesis (B) 1197

Adenosinephosphates
- New Cyclic Derivatives of 3′-Amino-3′-deoxyadenosine-5′-diphosphate, -triphosphate, and -methylenebis(phosphonate) (C) 1394

Agarose
- A Novel Reaction Sequence for the Coupling of Nucleophiles to Agarose with 2,2,2-Trifluoroethanesulfonyl Chloride (C) 120

AIDS
- Conocurvone—Prototype of a New Class of Anti-HIV Active Compounds? (H) 422 (1668)
- Vanadium(II)- and Niobium(III)-Induced, Diastereoselective Pinacol Coupling of Peptide Aldehydes to C_2-Symmetrical HIV-Protease Inhibitors (C) 685

Aldehydes
- On the Nature of Zinc Chloride–Aldehyde Interactions (C) 2089

Aldol reactions
- Catalytic Enantioselective C–C Coupling—Allyl Transfer and Mukaiyama Aldol Reaction (H) 417

Alkali metal compounds
- A New Method for the Synthesis of Heterometallic Complexes: Syntheses and Structures of $[(PhCH_2CH_2NLi)_3Sb(thf)]_2$ and $[Sb_3(cyN)_4(NMe_2)_2]Li$ (C) 1277
- 1,3-Dialkoxycalix[4]arenecrowns-6 in 1,3-Alternate Conformation: Cesium-Selective Ligands that Exploit Cation–Arene Interactions (C) 1506
- Doubly Lithiated Oligosilanes: Synthesis and Structure of the First Vicinal Dilithiodisilane (C) 2450
- Enantioselective Transformations and Racemization Studies of Heteroatom Substituted Organolithium Compounds (H) 175
- Ether-Solvated Sodium Ions in Salts Containing π-Hydrocarbon Anions: Crystallization, Structures, and Semiempirical Solvation Energies (C) 875
- Inversely Coordinating Silanide Ions in an Oligomeric Sodium Alcoholate (C) 216
- [(*N*-Lithio-*N*-mesitylsulfonyloxy-*tert*-butylcarbamate)$_2$ · (thf)$_3$]: Crystal Structure of a Nitrenoid (C) 115
- Metalation of Tris(trimethylsilyl)- and Tris(dimethylphenylsilyl)methane with Methylsodium: The First Dialkylsodate (C) 1268
- Phosphane Coordination to Magnesium: Synthesis and Structure of Bis[*ortho*, *ortho*′-bis{(dimethylphosphino)methyl}phenyl]magnesium (C) 2281
- $Rb_3[Nb_6SBr_{17}]$, the First Compound Containing an Isolated Trigonal-Prismatic Niobium Cluster (C) 1943
- Rearrangement and Selective Transmetalation of Bis(pyridyl)methyllithium (C) 693
- Tetralithiated Dibenzyl(methyl)phosphane (C) 2279
- The Lithocene Anion and "Open" Calcocene—New Impulses in the Chemistry of Alkali and Alkaline Earth Metallocenes (H) 2168
- The Simplest Metallocene Sandwich: the Lithocene Anion (C) 1744
- The Structures of Two Lithium Hydrazides: Is There Electron-Deficient Bonding? (C) 1746 (1988)
- Transannular Addition of Methyllithium to 5,12:6,11-Di[1,2]benzenodibenzo[*a*,*e*]cyclooctene and Its 5,6-Epoxy Derivative (C) 993

Alkaline earth metal compounds
- A Novel Organomagnesium Compound Consisting of Two Triple-Decker Cations $[LMg(\mu\text{-}Me)_3MgL]^+$ and an Octamethyltrimagnesate Anion: $[\{Me_2Mg(\mu\text{-}Me)_2\}_2Mg]^{2-}$ (C) 1257
- $[Be(dad)_2]$: Synthesis and Structure of a Diazabutadieneberyllium Complex (C) 1372
- Phosphane Coordination to Magnesium: Synthesis and Structure of Bis[*ortho*, *ortho*′-bis{(dimethylphosphino)methyl}phenyl]magnesium (C) 2281
- Sensitive and Selective Coloration of Cryptand-Type Crown Spirobenzopyrans for Alkaline-Earth Metal Compounds (C) 1163
- Solvent-Free Volatile Alkoxides of the Alkaline-Earth Elements (C) 105
- Synthesis and Crystal Structure of the "Open" Calcocene $[(tBu_2C_5H_5)Ca\cdot thf]$ (C) 2191
- Synthesis and Molecular Structure of Calcium Bis(trimethylstannanide) · 4 THF (C) 1493
- The Lithocene Anion and "Open" Calcocene—New Impulses in the Chemistry of Alkali and Alkaline Earth Metallocenes (H) 2168

Alkene complexes
- $[(Cp^{**}CoH)_2\text{-}\mu\text{-}\{\eta^2\text{:}\eta^2\text{-}cis\text{-}\mu\text{-}[(C_2H_5)_2Al\text{-}CH=CH\text{-}Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2\text{-}C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds (C) 2435
- Ligands as "Compass Needles": How Orientations of Alkene, Alkyne, and Alkylidene Ligands Reveal π-Bonding Features in Tetrahedral Transition Metal Complexes (R) 1565

Alkenes
- Houben-Weyl. Methoden der Organischen Chemie. Band E15, Teile 1–3. En-X- und In-X-Verbindungen (B) 1891
- Practical and Rapid Vicinal Hydroxylation of Alkenes by Catalytic Ruthenium Tetraoxide (C) 2312

Alkenols
- Intramolecular Photocyclization of ω,ω-Diphenyl-(ω−1)-alken-1-ols by an Exciplex Quenching Mechanism (C) 2113

Alkenyl sulfones
- Iron-Promoted, Regio- and Stereoselective Allylic Substitutions for the Synthesis of Alkenyl Sulfones Substituted at C-3 (C) 1949

Alkoxides
- Solvent-Free Volatile Alkoxides of the Alkaline-Earth Elements (C) 105

Alkylations
- Palladacycles as Intermediates for Selective Dialkylation of Arenes and Subsequent Fragmentation (C) 2421

Alkyne complexes
- $[Cp_2Ti(C\equiv CtBu)_2]$ as an Alkynyl Transfer Reagent: Synthesis and Characterization of the Asymmetrically Bridged Heterodimetallic Complex $[Cp_2Ti(C\equiv CtBu)_2Pt(PPh_3)]\cdot 0.5\,THF$ (C) 2083
- Bis(tetramethylbutynediol)nickel(0), the First Pure Monoalkyne Complex of Nickel and Its Chemistry (C) 1373
- Ligands as "Compass Needles": How Orientations of Alkene, Alkyne, and Alkylidene Ligands Reveal π-Bonding Features in Tetrahedral Transition Metal Complexes (R) 1565

- Towards One-Dimensional Carbon Wires Connecting Single Metal Centers: A Cumulenic C_5 Chain that Mediates Charge Transfer between Rhenium and Manganese Termini (C) 2199

Alkynes
- Complex-Stabilized Alkynyl and Cycloalkenyl Isocyanides (C) 330
- 1,4-Didehydrobutadiene: The Intermediate in a New Class of Thermally Induced Intramolecular Alkyne Couplings (C) 2470
- Electron Delocalization in Ethynyl-Bridged Binuclear Ruthenium(II) Polypyridine Complexes (C) 1884
- Fullerene–Acetylene Hybrids: On the Way to Synthetic Molecular Carbon Allotropes (C) 1366
- Houben-Weyl. Methoden der Organischen Chemie. Band E15, Teile 1–3. En-X- und In-X-Verbindungen (B) 1891
- Triple Bonds in Small Rings: Testing the Limits of Chemical Bonds (H) 1455
- Unexpected Reactions of Acetylenedicarboxylates with Zirconocene Complexes (C) 1850

Allenes
- Nonclassical Stabilization of Planar Allenes: Low Rotational Barriers for Allene Double Bonds (C) 2064

Allylacetates
- A Regioselective Palladium-Catalyzed Reduction of 3,3-Heterobimetalated Allylic Acetates–Synthesis and Reactivity of Allylic Bimetallic Compounds (C) 2448

Allyl cation
- Generation of the Parent Allyl Cation in a Superacid Cryogenic Matrix (C) 448

Allyl halides
- A New Synthesis of 1,3,4-Trideoxy-1,4-iminoglycitols of Varying Chain Length by $(C_3 + C_n)$-Coupling of Allyl Halides with Glyconitrile Oxides (C) 1295

Allylsilanes
- Lewis Acid Promoted [2+2] Cycloaddition of Allylsilanes and Unsaturated Esters: A Novel Method for Cyclobutane Construction (C) 1612
- Liquid Sulfur Dioxide as a Lewis-Acidic Solvent for the Alkylation and Alkoxyalkylation of Allylsilanes (C) 788

Aluminophosphates
- On the Nature of the Active Site in a Co-APO-18 Solid Acid Catalyst (C) 1871

Aluminum compounds
- Coordination Chemistry of Aluminum (B) 791
- $[(Cp^{**}CoH)_2$-μ-$\{\eta^2$:η^2-*cis*-μ-$[(C_2H_5)_2Al$-$CH=CH$-$Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2$-$C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds (C) 2435
- $[(CpNi)_2(Cp^*Al)_2]$: Cp*Al as a Bridging Two-Electron Ligand (C) 2482
- Donor-Stabilized Aluminum(I) Bromide (C) 1754
- Donor-Stabilized Aluminum(II) Bromide (C) 862
- Localization of Electrons in Intermetallic Phases Containing Aluminum (C) 2069
- Oxygen-Induced Structural Transformation of the Polynuclear Organoaluminum Complex $[Al_4(\mu_3$-8-quinolylimide$)_2(CH_3)_8]$ to $[Al_4(\mu_3$-8-quinolylimide$)_2(CH_3)_7(\mu$-$OCH_3)]$ (C) 1265
- $[P_4(Cp^*Al)_6]$: A Compound with an Unusual P_4Al_6 Cage Structure (C) 199
- Reactions of $[(C_5Me_5)ZrF_3]$ with $AlMe_3$—Synthesis and Structure of a Zirconium–Aluminum–Carbon Cluster (C) 967
- Soluble Organic Derivatives of Aluminosilicates with $Al_2Si_2O_4$ and $Al_4Si_2O_6$ Frameworks (C) 2103
- Subvalent Aluminum Halides as Examples of High-Temperature Species in Inorganic Syntheses (H) 1830
- Synthesis and Structure of the First Dimeric Iminoalane Containing an Al_2N_2 Heterocycle (C) 969
- Synthesis of the First Microporous Aluminum Phosphonate with Organic Groups Covalently Bonded to the Skeleton (C) 2335
- The First Carbon–Phosphorus–Aluminum Cage Compounds: Cyclooligomerization of Phosphaalkynes with Trialkylaluminum Compounds (C) 1491
- Unequivocal Partitioning of Crystal Structures, Exemplified by Intermetallic Phases Containing Aluminum (C) 2073

Amide cleavage
- Fast Amide Cleavage under Mild Conditions. An Evolutionary Approach to Bioorganic Catalysis (C) 346

Amidinium ions
- Axially Chiral Amidinium Ions with a Biaryl Skeleton: A New Class of Structure in Host–Guest Chemistry (C) 984

Amino acids
- Synthesis and Structure of the First Titanium(IV) α-Amino Acid Complexes (C) 1518
- Synthesis of a New Unnatural Amino Acid with a Benzodiazepine-Containing Side Chain and Incorporation into a Tripeptide (C) 1737
- Synthesis of Unsaturated Amino Acids by [3,3]-Sigmatropic Rearrangement of Chelate-Bridged Glycine Ester Enolates (C) 998

Amino alcohols
- Simple and Versatile Synthesis of Optically Active 1,2-Amino Alcohols by Grignard Addition to *N,O*-Dibenzylglyceraldimine and -lactaldimine (C) 1298

Aminomalonic acid
- Preparation and C-Alkylation of Peptides with Aminomalonate Building Blocks (C) 439

Aminopolyols
- Regio- and Stereoselective Electrophilic C-Substitution of 2-(*N,N*-Dibenzylamino)-1-,ω-alkanediols by Lithiation of Their Carbamates (C) 1734

Amorphous sulfides
- A Building Principle of Amorphous Chalcogenides of Transition Metals: The "Extrusion" of the Electron Rich Cluster $[Re_4S_2(SO_2)_4(CN)_{10}]^{8-}$ from a-Re_2S_7 (C) 770

Amphiphiles
- Bolaamphiphiles: From Golf Balls to Fibers (H) 1937
- Molecular Golf Balls: Vesicles from Bowl-Shaped Host Molecules (C) 1662
- Stable Flexible Fibers and Rigid Tubules Made from Single-Chain Perfluoroalkylated Amphiphiles (C) 1514

Analysis of proteins
- Ladder Sequencing of Peptides and Proteins—A Combination of Edman Degradation and Mass Spectrometry (H) 723

Analytical methods
- Analysis with Supercritical Fluids: Extraction and Chromatography (B) 1402
- An Anthracene-Based Fluorescent Sensor for Transition Metal Ions (C) 1975
- A Reagent for Determining Optical Purities of Diols by Formation of Diastereomeric Arylboronate Esters (C) 1182
- Chemical Analysis of Inorganic and Organic Surfaces and Thin Films by Static Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS) (R) 1023
- Thermal Analysis—Techniques and Applications (B) 586

Anhydroretinol
- Spectroscopic Studies of Anhydroretinol, an Endogenous Mammalian and Insect *retro*-Retinoid (C) 1837 (2348)

Annulenes
- Tetraaza[14]annulenezirconium(IV) Complexes with Butadiene Ligands and their Relationship with Bis(cyclopentadienyl)-zirconium(IV) Complexes (C) 2204

Anthracenes
- An Anthracene-Based Fluorescent Sensor for Transition Metal Ions (C) 1975

Antibiotics
- Antibiotics and Antiviral Compounds. Chemical Synthesis and Modification (B) 1119
- Biosynthetic Investigations on Pyridazomycin (C) 1648
- Incorporation of L-[Methyl-$^2H_3$]methionine and 2-[Hydroxy-^{18}O]hydroxyethylphosphonic Acid into Fosfomycin in *Streptomyces fradiae*—An Unusual Methyl Transfer (C) 341
- Synthesis of the Anthraquinone Framework of Dynemicin A (C) 781
- The Trehalase Inhibitor Salbostatin, a Novel Metabolite from *Streptomyces albus*, ATCC 21838 (C) 1844

Antibodies
- An Antibody-Catalyzed 1,2-Rearrangement of Carbon–Carbon Bonds (C) 1607
- Enantioselective, Multigram-Scale Synthesis with a Catalytic Antibody (C) 475
- Progress Toward An Antibody Glycosidase (C) 339
- Specific Binding of Antibodies to DNA through Combinatorial Antibody Libraries (H) 1827

Antimony compounds
- $[\{Sb_2(Ncy)_4\}_2Cu_4]$: A Mixed-Metal Antimony(III)/Copper(I) Complex Containing a Cu_4 Square Plane (C) 1875
- A New Method for the Synthesis of Heterometallic Complexes: Syntheses and Structures of $[(PhCH_2CH_2NLi)_3Sb(thf)]_2$ and $[Sb_3(cyN)_4(NMe_2)_2]Li$ (C) 1277
- $[SbN(SbCl)_3(NSbCl_2)(NSiMe_3)_2 \cdot SbCl_3]$, an Unusual Nitridoantimony Complex with a Heterocubane Structure (C) 569
- Trialkylstibanes as Bridging Ligands: Synthesis and Structure of the Dinuclear Complexes $[Rh_2Cl_2(\mu$-Sb*i*Pr$_3)(\mu$-$CR_2)_2]$ (C) 97

Antisense systems
- Amides as a New Type of Backbone Modification in Oligonucleotides (C) 226
- Stereocontrolled Synthesis of Oligo(nucleoside phosphorothioate)s (R) 709
- Synthesis of an Azathymidine and Its Incorporation into Oligonucleotides (C) 1654

Antitumor agents
- A New Application of Modified Peptides and Peptidomimetics: Potential Anticancer Agents (H) 305
- An Unusual Route to Potential Platinum Antitumor Compounds: Synthesis, Reactivity, and Spectroscopic Properties of the Pt^{IV} Complex *fac*-$[PtCl_3(NH_3)_2L]Cl$ (C) 1632
- A Water-Soluble Prodrug of Taxol with Self-Assembling Properties (C) 1583
- Chemistry and Biology of Taxol (R) 15
- Enediyne Quinone Imines: Truncated, Biologically Active Dynemicin Congeners (C) 2477

- Metal Complexes in Cancer Chemotherapy (B) 1672
- Platinum(II) Complexes with Porphyrin Ligands—Additive Cytotoxic and Photodynamic Effect (C) 2214
- Structure of an Antineoplastic Platinum Complex with a Bipyridyl-Crown Ether (C) 186
- Synthesis of C-2 Taxol Analogues (C) 1581
- Synthesis of the Anthraquinone Framework of Dynemicin A (C) 781

Antiviral agents
- Antibiotics and Antiviral Compounds. Chemical Synthesis and Modification (B) 1119
- A Short Route to [3-^{15}N]-3′-Azido-3′-deoxythymidine (N3-Labeled AZT) via 3-Nitro-AZT (C) 2454
- Regioselective Synthesis and Antiviral Activity of Purine Nucleoside Analogues with Acyclic Substituents at N7 (C) 562

Arene complexes
- Cyclotrimerization of Ethyne on the Complex Fragment [(η^1-tBu$_2$PCH$_2$PtBu$_2$)-Ni^0] with Formation of an η^6-Benzene–Nickel(0) Complex (C) 879
- Electron-Reservoir Complexes [Fe^{I}Cp-(arene)] as Selective Initiators for a Novel Electron Transfer Chain Catalyzed Reaction: General Synthesis of Fulvalene-Bridged Homo- and Heterodinuclear Zwitterions (C) 661
- Novel Rh^I Piano-Stool Complexes with New Hemilabile Ligands Ligating through Phosphane and Arene Groups: Synthesis, Characterization, and Reactivity (C) 2473
- [2,6-iPr$_2$C$_6$H$_3$(Me$_3$Si)NTl]$_4$—A Covalent Thallium(I)–Nitrogen Compound with Weak Arene–Thallium Interactions (C) 1351
- Tris(η^4-naphthalene)zirconate(2−) (C) 1973

Arenes
- 2,2′-Bipyrenyl and *para*-Terpyrenyl—A New Type of Electronically Decoupled Oligoarylene (C) 1957
- Homogeneous Catalytic Oxidation of Arenes and a New Synthesis of Vitamin K$_3$ (C) 2475
- Intramolecular [2+2] Cycloadditions of 2,2′-Bis(1-arylvinyl)-Substituted Biphenyls Induced by Photo Electron Transfer (C) 2300
- Ladder Polymers with a Heteroacene Skeleton (C) 2424
- Long-Lived *ipso*-Silylated *p*-Toluenium Ions: Evidence from a Kinetic Isotope Effect (C) 1094
- Palladacycles as Intermediates for Selective Dialkylation of Arenes and Subsequent Fragmentation (C) 2421

- Chromium Carbene Complexes in Organic Synthesis: Recent Developments and Perspectives (H) 303
- Cr^{III} and Fe^{III} Complexes with η^3-1,3,5-Triazacyclohexane Ligands (C) 1877
- Unusually Large Isotope Effects on NMR Chemical Shifts of Paramagnetic Organometallic Compounds (C) 2326

Clathrates
- A Clathrate Hydrate of Nitric Oxide (C) 691
- The First Water-Dependent Liquid Clathrate: X-Ray Evidence in the Solid for a $C-H\cdots\pi(Heteroarene)\cdots H-C$ Interaction (C) 566

Clays
- Organic Chemistry Using Clays (B) 1892
- Zeolite, Clay and Heteropoly Acid in Organic Reactions (B) 1893

Clusters
- $[\{Sb_2(Ncy)_4\}_2Cu_4]$: A Mixed-Metal Antimony(III)/Copper(I) Complex Containing a Cu_4 Square Plane (C) 1875
- A Cluster-Bound Triply-Bridging Phosphorus Atom Coordinated to Four $(Ph_3P)Au^+$ Units: $[Fe_3(CO)_9P\{Au(PPh_3)\}_4][BAr_4]$ (C) 75
- A Hexanuclear Gold(I) Complex: $[(Ph_3PAu)_2C(PPh_2AuPPh_2)\}_2](ClO_4)_2$ (C) 87
- A Triosmium Cluster Complex with a Carbene Ligand in an Unusual Coordination Mode (C) 1093
- Cluster Ions (B) 1669
- $[(Cp^{**}CoH)_2\text{-}\mu\text{-}\{\eta^2\text{:}\eta^2\text{-}cis\text{-}\mu\text{-}[(C_2H_5)_2Al\text{-}CH=CH\text{-}Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2\text{-}C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds (C) 2435
- $[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]$, a New Phosphorus-Bridged Copper Cluster (C) 1290
- $[Cu_{44}Se_{22}(PEt_2Ph)_{18}]$ and $[Cu_{44}Se_{22}(PnButBu_2)_{12}]$: Synthesis and Structure of Two Copper Clusters with Isomeric Cu–Se Frameworks (C) 2287
- Desulfurization of Benzo[*b*]thiophene by S/Ru Exchange: Formation and Structure of the Cluster $[Ru_3(CO)_8(C_8H_6)]$ (C) 1381
- Fullercages without Carbon—Fulleranes, Fullerenes, Space-filler-enes? (H) 843
- $[K([18]crown\text{-}6)]^+[Mo_4(\mu_4\text{-}H)(OCH_2tBu)_{12}]^-$, the First Alkoxidohydrido Cluster of Molybdenum. Evidence for a Rare, if not the First, Example of a μ_4-Hydride (C) 191
- Macropolyhedral Boron-Containing Cluster Chemistry: Isolation and Characterization of the First Macropolyhedral Thiaborane, the *arachno*-Type $[9,9'\text{-}S_2B_{17}H_{18}]^-$ Ion (C) 1599
- Metal Complexes of Marine Peptide Metabolites: A Novel Ag_4 Cluster (C) 1516
- $[Mn_4Te_4(SC_3H_7)_4]^{4-}$ and $[Mn_4Te_4(SeC_3H_7)_4]^{4-}$: Novel Heterocubane Clusters of Manganese (C) 2322
- $[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$: A Highly Symmetrical Giant Cluster with an Unusual Cavity and the Possibility of Positioning Paramagnetic Centers on Extremely Large Cluster Surfaces (C) 849
- New Sulfur- and Selenium-Bridged Copper Clusters; Ab Initio Calculations on $[Cu_{2n}Se_n(PH_3)_m]$ Clusters (C) 746
- $[(Ph_3PAu)_6(dppeAu_2)(AuCl)_4Pd]$, an Icosahedral Au_{12} Cluster with a Central Pd Atom (C) 207
- $Rb_3[Nb_6SBr_{17}]$, the First Compound Containing an Isolated Trigonal-Prismatic Niobium Cluster (C) 1943
- Reactions of $[(C_5Me_5)ZrF_3]$ with $AlMe_3$—Synthesis and Structure of a Zirconium–Aluminum–Carbon Cluster (C) 967
- Structural and Magnetic Characterization of a Novel Heptanuclear Hydroxo-Bridged Copper(II) Cluster of the Corner-Sharing Dicubane Type (C) 1184

Cobalt compounds
- A Novel Open-Framework Cobalt Phosphate Containing a Tetrahedrally Coordinated Cobalt(II) Center: $CoPO_4 \cdot 0.5\,C_2H_{10}N_2$ (C) 639
- $[(Cp^{**}CoH)_2\text{-}\mu\text{-}\{\eta^2\text{:}\eta^2\text{-}cis\text{-}\mu\text{-}[(C_2H_5)_2Al\text{-}CH=CH\text{-}Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2\text{-}C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds (C) 2435
- Functionalization of Aromatic Azo Compounds by the Cobalt-Catalyzed, Regioselective Double Addition of Tolane: 2,6-Distilbenylazobenzenes and 2,3-Dihydrocinnolines (C) 1603
- On the Nature of the Active Site in a Co-APO-18 Solid Acid Catalyst (C) 1871
- Porphyrins with Biconcave Frameworks (C) 889
- Schiff Base Complexes with Five-Coordinate Cobalt as Dioxygen Activating Sites in Zeolites (C) 431

Cofactors
- Isolation of RNA Aptamers for Biological Cofactors by In Vitro Selection (C) 1084

Complexes with carbon ligands
- A Novel Organomagnesium Compound Consisting of Two Triple-Decker Cations $[LMg(\mu\text{-}Me)_3MgL]^+$ and an Octamethyltrimagnesate Anion: $[\{Me_2Mg(\mu\text{-}Me)_2\}_2Mg]^{2-}$ (C) 1257
- $[Ru_3(CO)_6(\eta^5\text{:}\eta^1\text{-}C_5H_4)_3]$: The First Six-Membered Ru_3C_3 Ring Formed by Insertion of C_5H_4 Units into Metal–Metal Bonds of $[Ru_3(CO)_{12}]$ (C) 2193

- Bifunctional Compounds (B) 2225
- Chemical Bonding (B) 2225
- Equilibrium between Isocyanide and Carbene Complexes in Coordination Compounds of 2,6-Dihydroxyphenyl Isocyanide (C) 1356
- Fluorinated Isocyanides—More than Ligands with Unusual Properties (R) 1315
- Heterodimetal–Betaine Chemistry: Catalytic and Stoichiometric Coupling of Alkynyl Ligands under the Joint Influence of Zirconium and Boron Centers (C) 1480
- Monomer–Dimer Equilibria in Homo- and Heterodinuclear Cationic Alkylzirconium Complexes and Their Role in Polymerization Catalysis (C) 1634
- New Titanium – Boron Complexes with a Planar Tetracoordinate Carbon or a Planar Tricoordinate Phosphorus Center (C) 197
- Organometallics 1. Complexes with Transition Metal–Carbon σ-Bonds (B) 2225
- Organometallics 2. Complexes with Transition Metal–Carbon π-Bonds (B) 2225
- Towards One-Dimensional Carbon Wires Connecting Single Metal Centers: A Cumulenic C_5 Chain that Mediates Charge Transfer between Rhenium and Manganese Termini (C) 2199

Complexes with C_n bridges
- Novel Carbon Compounds with "Naked" C_n Units (H) 547

Complexes with hydrido ligands
- $[(Cp^{**}CoH)_2$-μ-$\{\eta^2:\eta^2$-*cis*-μ-$[(C_2H_5)_2Al$-$CH=CH$-$Al(C_2H_5)_2]\}]$ and $[\{Cp^*(\eta^2$-$C_2H_4)CoAl(C_2H_5)\}_2]$: Synthesis and Structure of Unusual Co–Al Cluster Compounds (C) 2435
- $[K([18]crown\text{-}6)]^+[Mo_4(\mu_4$-$H)(OCH_2tBu)_{12}]^-$, the First Alkoxidohydrido Cluster of Molybdenum, Evidence for a Rare, if not the First, Example of a μ_4-Hydride (C) 191
- Unusually Large Isotope Effects on NMR Chemical Shifts of Paramagnetic Organometallic Compounds (C) 2326

Complexes with nitrogen ligands
- Alternating Ferro- and Antiferromagnetic Interactions in a Mn^{II} Chain with Alternating End-On and End-to-End Bridging Azido Ligands (C) 2488
- A Model for α-Keto Acid Dependent Nonheme Iron Enzymes: Structure and Reactivity of $[Fe^{II}_2(Me_2hdp)_2(bf)](ClO_4)$ (C) 1886
- $[Be(dad)_2]$: Synthesis and Structure of a Diazabutadieneberyllium Complex (C) 1372
- Change of Orientation of Axial Imidazole Ligands in a Cytochrome b Model Complex in Response to a Change in the Oxidation State of the Metal Center (C) 1363
- Copper(II)-Mediated Oxidative Coupling of Bis(dimethylaminomethyl)arylruthenium Complexes to give $[(terpy)Ru^{III}$(pincer-pincer)$Ru^{III}(terpy)](CuCl_2)_4$ (C) 1282
- Cr^{III} and Fe^{III} Complexes with η^3-1,3,5-Triazacyclohexane Ligands (C) 1877
- Electron Delocalization in Ethynyl-Bridged Binuclear Ruthenium(II) Polypyridine Complexes (C) 1884
- Fairly Strong Ferromagnetic Interactions between Imino Nitroxide Ligands through a Diamagnetic Cu^I Ion in $[Cu^I(im\text{-}mepy)_2](PF_6)$ (C) 670
- Hydroxylamine, Hydrazine, and Diazene as Unidentate Ligands in Osmium and Ruthenium Complexes (C) 657
- Lanthanide(III) Tetraamide Macrocyclic Complexes as Synthetic Ribonucleases: Structure and Catalytic Properties of $[La(tcmc)(CF_3SO_3)(EtOH)](CF_3SO_3)_2$ (C) 773
- Luminescent Eu^{3+} and Tb^{3+} Complexes of a Branched Macrocyclic Ligand Incorporating 2,2′-Bipyridine in the Macrocycle and Phosphinate Esters in the Side Arms (C) 1501
- Nitrogen Donors in Organometallic Chemistry and Homogeneous Catalysis (R) 497
- Novel Copper Nitrosyl Complexes: Contributions to the Understanding of Dissimilatory, Copper-Containing Nitrite Reductases (H) 2057
- $[2,6\text{-}i Pr_2C_6H_3(Me_3Si)NTl]_4$—A Covalent Thallium(I)–Nitrogen Compound with Weak Arene–Thallium Interactions (C) 1351
- Pronounced Electronic Coupling in Rigidly Connected N,C,N-Coordinated Diruthenium Complexes over a Distance of Up to 20 Å (C) 1775
- $[SbN(SbCl)_3(NSbCl_2)(NSiMe_3)_2\cdot SbCl_3]$, an Unusual Nitridoantimony Complex with a Heterocubane Structure (C) 569
- Self-Assembly and Structure of a 3×3 Inorganic Grid from Nine Silver Ions and Six Ligand Components (C) 2284
- Structure of an Antineoplastic Platinum Complex with a Bipyridyl-Crown Ether (C) 186
- Synthesis and Structural Characterization of $[\{(Et_2O)Mg\}_6(NPh)_4Br_4]$: A Magnesium–Imide Cage Species Derived from a Dimagnesylamine Solution (C) 1000
- The Bonding Capability of Imido Complex Fragments of Groups 5–7 with Regard to the Isolobal Relationship (C) 1255
- The First Mononuclear Nitrosyl(oxo)-molybdenum Complex: Side-On Bonded and μ_3-Bridging NO Ligands in $[\{MoL(NO)(O)(OH)\}_2]NaPF_6\cdot H_2O$ (C) 1473
- The First Structurally Characterized Metal Complex Involving the Free Acid of a New Tris(pyrazolyl)borate as Ligand (C) 1983
- The Versatility of the Azido Ligand: Linkage of Ni^{II} Centers to Form a Chain with One End-to-End and Three End-On Bridges in Alternation (C) 2087
- Titanium Complexes with Tripodal Amido Ligands: Building Blocks for Stable Bimetallic Coordination Compounds Containing Highly Polar Metal–Metal Bonds (C) 676

Complexes with oxygen ligands
- A New Oxygen Tripod Ligand and Its First Complexes with p- and d-Block Elements (C) 991
- A Thermally Stable Peroxocopper(II) Complex with Unusual μ_4-Coordination of the Peroxo Ligand (C) 1969
- Carboxylatoiron(II) Aggregates: A Novel Fe^{II}_4 Complex with Threefold Symmetry (C) 1660
- Molecular Siloxane Complexes of Rare Earth Metals—Model Systems for Silicate-Supported Catalysts? (C) 1285
- Polar Superstructures Stabilized by Polymeric Oxometal Units: Columnar Liquid Crystals Based on Tapered Dioxomolybdenum Complexes (C) 2342
- Structural and Magnetic Characterization of a Novel Heptanuclear Hydroxo-Bridged Copper(II) Cluster of the Corner-Sharing Dicubane Type (C) 1184
- Synthesis and Structure of the First Organometallic Galloxane Hydroxide $Mes_6Ga_6O_4(OH)_4$ (C) 1244
- Synthesis and Structure of the First Titanium(IV) α-Amino Acid Complexes (C) 1518
- Two-Dimensional Sheets of Tetragonal Copper(II) Lattices: X-Ray Crystal Structure and Magnetic Properties of $[Cu(C_6O_4Cl_2)(C_4H_4N_2)]_n$ (C) 1759
- $[Zr_3Cp_2(O_2CN\text{-}iPr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}CCO)]$, the First Crystallographically Established Ketenylidene Complex; A Model for CO Reductive Cleavage on Metal Surfaces (C) 1188

Complexes with phosphorus ligands
- *trans*-Chelating Chiral Diphosphane Ligands Bearing Flexible *P*-Alkyl Substituents (AlkylTRAPs) and their Application to the Rhodium-Catalyzed Asymmetric Hydrosilylation of Simple Ketones (C) 111
- $[Cp^*Fe(\eta^5\text{-}P_5)]$, a Sandwich Complex with Diverse Ligand Properties (C) 1110
- $[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]$, a New Phosphorus-Bridged Copper Cluster (C) 1290
- $[Cu_{44}Se_{22}(PEt_2Ph)_{18}]$ and $[Cu_{44}Se_{22}$-$(PnButBu_2)_{12}]$: Synthesis and Structure of Two Copper Clusters with Isomeric Cu–Se Frameworks (C) 2287
- New Titanium – Boron Complexes with a Planar Tetracoordinate Carbon or a Planar Tricoordinate Phosphorus Center (C) 197
- Novel Rh^I Piano-Stool Complexes with New Hemilabile Ligands Ligating through Phosphane and Arene Groups: Synthesis, Characterization, and Reactivity (C) 2473
- Platinum-Iron Silylene Complexes and Metal-Promoted Substituent Exchange between $Si(NMe_2)_3$- and $P(OEt)_3$-Ligands (C) 2440
- Propeller Isomerism of the Triphenylphosphane Ligand in Half-Sandwich Ru^{II} Complexes (C) 866
- Thermally Induced Ring Cleavage of a 2*H*-1,2-Azaphosphirene Tungsten Complex (C) 2427

Complexes with silicon ligands
- Platinum-Iron Silylene Complexes and Metal-Promoted Substituent Exchange between $Si(NMe_2)_3$- and $P(OEt)_3$-Ligands (C) 2440

Complexes with sulfur ligands
- $[\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]^{2+}$: A Novel Tetranuclear Cationic Complex with a Rectangular S_4 Unit (C) 1882
- A Postulated Carrier of Gold in Hydrothermal Ore Solutions: Synthesis and Crystal Structure of $[(Ph_3P)_2N]$-$[Au(SH)_2]$, the First Homoleptic Hydrogensulfido Complex (C) 1852
- Homoleptic Thiolato Complexes: Di- and Trinuclear Ti^{IV} Complexes with Unexpected Metal–Sulfur Cores, $[NMe_2H_2]$-$[Ti_2(SMe)_9]$ and $[Ti_3(SMe)_{12}]$ (C) 1981
- Single-Crystal EPR Spectroscopy on $[^{57}Fe(NO)(S_2CNEt_2)_2]$: The "Triplet Signal" in the EPR Spectrum of $[Fe(S_2CNEt_2)_3]$ (C) 1497
- Synthesis and Characterization of Thiolato Complexes with Two-Coordinate Iron(II) (C) 1178
- Synthesis and Structure of $[Ni(SO_2)_6](AsF_6)_2$ and $[Fe(SO_2)_4(FAsF_5)_2]$ (C) 1663
- The First Metal Complexes with a Doubly S_3-Bridged Ferrocene Ligand (C) 1752
- Trigonal-Bipyramidal Technetium and Rhenium Complexes with Tetradentate NS_3 Tripod Ligands (C) 1354

Compound libraries
- A Novel Procedure for the Synthesis of Libraries Containing Small Organic Molecules (C) 2059

- A Solution-Phase Screening Procedure for the Isolation of Active Compounds from a Library of Molecules (C) 2061
- Binary Encoding of Compound libraries (H) 1573
- Expeditious Synthesis of a Novel C_3-Symmetric Receptor that Binds Peptides Sequence-Selectively (C) 2458
- Opportunities for New Chemical Libraries: Unnatural Biopolymers and Diversomers (H) 633
- Specific Binding of Antibodies to DNA through Combinatorial Antibody Libraries (H) 1827

Computer chemistry
- Neural Networks for Chemists. An Introduction (B) 1671
- The Determination of Maximum Common Substructures by a Genetic Algorithm: Application in Synthesis Design and for the Structural Analysis of Biological Activity (C) 1189

Computer simulations
- Theoretical Treatment of Liquids and Liquid Mixtures (B) 697

Conformation
- Conformational Requirements for Sweet-Tasting Peptides and Peptidomimetics (R) 1437
- On the Helicity of Oligomeric Formaldehyde (C) 1476
- Stable Tetrakis(trialkylsilyl)disilenes; Synthesis, X-Ray Structures, and UV/VIS Spectra (C) 1489
- Sterically Strained Porphyrins—Influence of Core Protonation and Peripheral Substitution on the Conformation of Tetra-*meso*-, Octa-β-, and Dodeca-Substituted Porphyrin Dications (C) 2485
- Trigonal Symmetry as a Host Design Element: Novel Conformation of Dodecakis(3,5-dimethylphenylthio)coronene in its 1,4-Dioxane Clathrate (C) 1587

Conjugation
- 2,2′-Bipyrenyl and *para*-Terpyrenyl—A New Type of Electronically Decoupled Oligoarylene (C) 1957
- Iterative Divergent/Convergent Approach to Linear Conjugated Oligomers by Successive Doubling of the Molecular Length: A Rapid Route to a 128Å-Long Potential Molecular Wire (C) 1360
- Nonclassical Stabilization of Planar Allenes: Low Rotational Barriers for Allene Double Bonds (C) 2064
- Stable Soluble Conjugated Carbon Rods with a Persilylethynylated Polytriacetylene Backbone (C) 763

Conocurvone
- Conocurvone—Prototype of a New Class of Anti-HIV Active Compounds? (H) 422 (1668)

Cooperative effects
- A Chiral Lewis Acid with Two "Metal" Centers: Cooperative Binding of Two Amine Molecules to a Chiral Diboronic Ester (C) 2452
- Sixteenfold Deprotonated γ-Cyclodextrin Tori as Anions in a Hexadecanuclear Lead(II) Alkoxide (C) 1863

Coordination
- $[(C_6H_5)_4P]^1_\infty[Cu_3I_4]$—The First Compound with a Helical Chain of Face-Sharing Tetrahedra as a Structural Element (C) 1841
- Alternating Ferro- and Antiferromagnetic Interactions in a Mn^{II} Chain with Alternating End-On and End-to-End Bridging Azido Ligands (C) 2488
- A Thermally Stable Peroxocopper(II) Complex with Unusual μ_4-Coordination of the Peroxo Ligand (C) 1969
- Base-Free Monomeric Organogallium Hydrides (C) 1253
- Bifunctional Compounds (B) 2225
- Bis(pentamethylcyclopentadienyl)(η^3-trimethylenemethane)zirconium: A New Mode of Bonding for the Trimethylenemethane Ligand (C) 2465
- Bis(tetramethylbutynediol)nickel(0), the First Pure Monoalkyne Complex of Nickel and Its Chemistry (C) 1373
- Carboxylatoiron(II) Aggregates: A Novel Fe^{II}_4 Complex with Threefold Symmetry (C) 1660
- Change of Orientation of Axial Imidazole Ligands in a Cytochrome b Model Complex in Response to a Change in the Oxidation State of the Metal Center (C) 1363
- Chemical Bonding (B) 2225
- Equilibrium between Isocyanide and Carbene Complexes in Coordination Compounds of 2,6-Dihydroxyphenyl Isocyanide (C) 1356
- "Free" $[Fe(tpp)]^+$ Cation: A New Concept in the Search for the Least Coordinating Anion (C) 2433
- Hexacoordinate Silicon in a Compound with an F_5SiC Unit (C) 1359
- Hydroxylamine, Hydrazine, and Diazene as Unidentate Ligands in Osmium and Ruthenium Complexes (C) 657
- Inversely Coordinating Silanide Ions in an Oligomeric Sodium Alcoholate (C) 216
- Ligands as "Compass Needles": How Orientations of Alkene, Alkyne, and Alkylidene Ligands Reveal π-Bonding Features in Tetrahedral Transition Metal Complexes (R) 1565
- Linear Coordination Polymers of Copper(II) and Fourfold Deprotonated Sugar Alcohols (C) 1742
- Molecules and Ions with Heptacoordinated Central Atoms (H) 1941
- New Titanium–Boron Complexes with a Planar Tetracoordinate Carbon or a Planar Tricoordinate Phosphorus Center (C) 197
- Novel Rh^I Piano-Stool Complexes with New Hemilabile Ligands Ligating through Phosphane and Arene Groups: Synthesis, Characterization, and Reactivity (C) 2473
- Organometallics 1. Complexes with Transition Metal–Carbon σ-Bonds (B) 2225
- Organometallics 2. Complexes with Transition Metal–Carbon π-Bonds (B) 2225
- Oxygen-Induced Structural Transformation of the Polynuclear Organoaluminum Complex $[Al_4(\mu_3\text{-8-quinolylimide})_2(CH_3)_8]$ to $[Al_4(\mu_3\text{-8-quinolylimide})_2(CH_3)_7(\mu\text{-}OCH_3)]$ (C) 1265
- Sixteenfold Deprotonated γ-Cyclodextrin Tori as Anions in a Hexadecanuclear Lead(II) Alkoxide (C) 1863
- Strategies for Nonmacrocyclic Polythioether Ligands: New Pentacoordinating Architectures (C) 319
- Structural Principles in Seven-Coordinate Subgroup Compounds: The Complex Anions MoF_7^-, WF_7^-, and $ReOF_6^-$ (C) 461
- Structure of a (4 + 4)-Coordinate Silicon Compound, a Precursor of Hypercoordinate Silyl Mono- and Dications (C) 1097
- Synthesis and Structure of $[Ni(SO_2)_6](AsF_6)_2$ and $[Fe(SO_2)_4(FAsF_5)_2]$ (C) 1663
- The First Mononuclear Nitrosyl(oxo)molybdenum Complex: Side-On Bonded and μ_3-Bridging NO Ligands in $[\{MoL(NO)(O)(OH)\}_2]NaPF_6\cdot H_2O$ (C) 1473
- The First Zwitterionic, Optically Active Disilicate with Pentacoordinate Silicon (C) 1186
- The Versatility of the Azido Ligand: Linkage of Ni^{II} Centers to Form a Chain with One End-to-End and Three End-On Bridges in Alternation (C) 2087
- Tris(η^4-naphthalene)zirconate(2−) (C) 1973

Copper compounds
- $[\{Sb_2(Ncy)_4\}_2Cu_4]$: A Mixed-Metal Antimony(III)/Copper(I) Complex Containing a Cu_4 Square Plane (C) 1875
- $[(C_6H_5)_4P]^1_\infty[Cu_3I_4]$—The First Compound with a Helical Chain of Face-Sharing Tetrahedra as a Structural Element (C) 1841
- A Thermally Stable Peroxocopper(II) Complex with Unusual μ_4-Coordination of the Peroxo Ligand (C) 1969
- Cellulose in Schweizer's Reagent: A Stable, Polymeric Metal Complex with High Chain Stiffness (C) 884
- $[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]$, a New Phosphorus-Bridged Copper Cluster (C) 1290
- $[Cu_{44}Se_{22}(PEt_2Ph)_{18}]$ and $[Cu_{44}Se_{22}(PnBurBu_2)_{12}]$: Synthesis and Structure of Two Copper Clusters with Isomeric Cu–Se Frameworks (C) 2287
- Fairly Strong Ferromagnetic Interactions between Imino Nitroxide Ligands through a Diamagnetic Cu^I Ion in $[Cu^I(im\text{-}mepy)_2](PF_6)$ (C) 670
- Linear Coordination Polymers of Copper(II) and Fourfold Deprotonated Sugar Alcohols (C) 1742
- Mesoscopic Sheets of a Cyano-Bridged Cu–Ni Coordination Complex: Template Synthesis at the Interlayers of Cast Multibilayer Films (C) 2483
- New Sulfur- and Selenium-Bridged Copper Clusters; Ab Initio Calculations on $[Cu_{2n}Se_n(PH_3)_m]$ Clusters (C) 746
- Novel Copper Nitrosyl Complexes: Contributions to the Understanding of Dissimilatory, Copper-Containing Nitrite Reductases (H) 2057
- Reductive Disproportionation of NO Mediated by Copper Complexes: Modeling N_2O Generation by Copper Proteins and Heterogeneous Catalysts (C) 895
- Spectroscopic and Reactivity Studies of a Copper-Containing Metallacrown (C) 195
- Structural and Magnetic Characterization of a Novel Heptanuclear Hydroxo-Bridged Copper(II) Cluster of the Corner-Sharing Dicubane Type (C) 1184
- Synthesis and Crystal Structure of a Monocarbene Complex of Copper (C) 672
- The Crystal Structures of Base-Free, Monomeric Arylcopper(I) and Arylsilver(I) Compounds; Two Cases of Mistaken Identity? (C) 2443
- The First Structurally Characterized Metal Complex Involving the Free Acid of a New Tris(pyrazolyl)borate as Ligand (C) 1983
- Two-Dimensional Sheets of Tetragonal Copper(II) Lattices: X-Ray Crystal Structure and Magnetic Properties of $[Cu(C_6O_4Cl_2)(C_4H_4N_2)]_n$ (C) 1759

Coronenes
- Trigonal Symmetry as a Host Design Element: Novel Conformation of Dodecakis(3,5-dimethylphenylthio)coronene in its 1,4-Dioxane Clathrate (C) 1587

Corrigenda 1521, 1668, 1988, 2348
- No Enantioselective Reactions in a Static Magnetic Field (C) 1461

Corroles
- Metallocorroles with Formally Tetravalent Iron (C) 731
Corrphycene
- Corrphycene: A New Porphyrin Isomer (C) 2308
Cross-conjugation
- Expanded Radialenes: A Novel Class of Cross-Conjugated Macrocycles (C) 468
Crown ethers
- A New Class of Novel Macrocyclic Mesogens (C) 1503 (1668)
- Biomimetic Model for a Photosynthetic Reaction Center: A Porphyrin with a Covalently Linked, Redox-Active Crown Ether (C) 2318
- Complexes of Partially Fluorinated Macrocycles with a Metal–Fluorine σ-Donor Bond and Their Suitability as Metal Ion Indicators (C) 2175
- Construction of a Multiwired Molecular Cable of Micrometer Length by a Self-Assembly Process (C) 2173
- Crown Compounds: Toward Future Applications (B) 235
Crystal growth
- Chemistry and Crystal Growth (R) 143
Cubanes
- 1(9)-Homocubene and 9-Homocubylidene: Theoretical Investigation of Structures, Energies, and Rearrangement Reactions (C) 668
Cumulenes
- Synthesis and Structure of the Smallest Cyclic Cumulene; Reaction of 1,3-Diynes with Zirconocene Complexes (C) 1605
Cyanide–isocyanide isomerism
- Cyanide–Isocyanide Isomerism in CN-Bridged Organometallic Complexes (C) 2090
Cyanines
- Phenothiazinyl-Substituted Cyanines: Model Compounds for Molecular Switches (C) 572
Cyanohydrins
- Synthesis and Reactions of Optically Active Cyanohydrins (R) 1555
Cyclizations
- A Novel Photosystem for Harvesting Visible Light to Drive Photoinduced Electron Transfer (PET) Reductions: β-Activation of α,β-Unsaturated Ketones for Radical Cyclizations (C) 1169
- 1,4-Didehydrobutadiene: The Intermediate in a New Class of Thermally Induced Intramolecular Alkyne Couplings (C) 2470
- Intramolecular [2+2] Cycloadditions of 2,2′-Bis(1-arylvinyl)-Substituted Biphenyls Induced by Photo Electron Transfer (C) 2300
- Intramolecular Photocyclization of ω,ω-Diphenyl-(ω−1)-alken-1-ols by an Exciplex Quenching Mechanism (C) 2113
- Novel Optically Active Hydrocarbons in Sediments: Evidence for an Extensive Biological Cyclization of Higher Regular Polyprenols (C) 1166
- Ring Closures on Polymeric Supports—Formation of Extremely Large Macrocycles by Intrapolymeric Cyclooligomerizations (C) 1960
Cycloadditions
- [2+2] Cycloaddition of Norbornenes with Alkynes Catalyzed by Ruthenium Complexes (C) 580
- Asymmetric Synthesis of Highly Substituted Pyrrolidines by 1,3-Dipolar Cycloadditions of Azomethine Ylides with *N*-Acryloylproline Benzyl Ester (C) 683
- Competing Reactions of Silenes: [2+2], [4+2], and [6+2] Cycloadditions with Cycloheptadiene and Cycloheptatriene (C) 77
- Construction of Carbon Frameworks with the Help of Ruthenium Complexes: 1,5-Cyclooctadiene as a Reagent in Transition Metal Catalyzed Reactions (H) 636
- Diastereoselective Reaction of a 1-Phosphaallyl Anion with an Alkyne: Structure of an Isolated Dihydrophospholyl Anion and Stereospecific Protonation to Give 2,3-Dihydrophosphole (C) 1953
- Intramolecular [2+2] Cycloadditions of 2,2′-Bis(1-arylvinyl)-Substituted Biphenyls Induced by Photo Electron Transfer (C) 2300
- Lewis Acid Promoted [2+2] Cycloaddition of Allylsilanes and Unsaturated Esters: A Novel Method for Cyclobutane Construction (C) 1612
- Nitrile Imines: From Matrix Characterization to Stable Compounds (R) 527
- The First Cycloaddition Reactions of Dimeric Arsenium Cations (C) 1267
- The Photochemical Synthesis of Fine Chemicals with Sunlight (R) 2009
Cyclobutaarenes
- A New Synthetic Route to 1,2-Dihydrocyclobutaarenes (C) 1757
Cyclobutabenzenes
- Palladium-Catalyzed C–H Activation of *tert*-Butyl Groups: A Simple Synthesis of 1,2-Dihydroxycyclobutabenzene Derivatives (C) 103
- The Effect of Fusion of Angular-Strained Rings on Benzene: Crystal Structures of 1,2-Dihydrocyclobuta[*a*]cyclopropa[*c*]-, 1,2,3,4-Tetrahydrodicyclobuta[*a,c*]-, 1,2,3,4-Tetrahydrodicyclobuta[*a,c*]-cyclopropa[*e*]-, and 1,2,3,4,5,6-Hexahydrotricyclobuta[*a,c,e*]benzene (C) 313
Cyclobutadienes
- New Types of Metal-Stabilized Cyclobutadiene Superphanes (C) 1272
Cyclobutanes
- Lewis Acid Promoted [2+2] Cycloaddition of Allylsilanes and Unsaturated Esters: A Novel Method for Cyclobutane Construction (C) 1612
Cyclodextrins
- Antenna Effect in Multichromophoric Cyclodextrins (C) 2438
- Cyclodextrins as Building Blocks for Supramolecular Structures and Functional Units (R) 803
- Molecular Recognition of C_{60} with γ-Cyclodextrin (C) 1597
- Sixteenfold Deprotonated γ-Cyclodextrin Tori as Anions in a Hexadecanuclear Lead(II) Alkoxide (C) 1863
- Toward Unified Enantioselective Chromatography with a Single Capillary Column Coated with Chirasil-Dex (C) 2222
- Wacker Oxidation of 1-Decene to 2-Decanone in the Presence of a Chemically Modified Cyclodextrin System: A Happy Union of Host–Guest Chemistry and Homogeneous Catalysis (C) 2100
Cycloheptatrienes
- Excited-State Carbon Acids: Theoretical Studies of Suberene and Cycloheptatriene (C) 2431
Cyclohexanols
- Regio- and Diastereoselective Photooxygenation of Chiral 2,5-Cyclohexadiene-1-carboxylic Acids (C) 1971
Cyclopentanols
- Syntheses of Cyclopentanols by a Silicon-Induced Cascade Reaction (C) 217
Cyclophanes
- 18-, 20-, and 22-Membered Dimetallaortho-, -meta-, and -para[7.7]cyclophanes—The First Typical Metallaphanes (C) 321
- *trans–cis* Isomerization upon One-Electron Oxidation of [12]- and [14]Tetrathiafulvalenophanes (C) 1379
- Porphyrin–Quinone Cyclophanes with Gradually Varied Donor–Acceptor Distances (C) 2428
- Scalemic 2-Formyl-3-hydroxy[2.2]paracyclophane: A New Auxiliary for Asymmetric Synthesis (C) 91
- Supramolecular Activation of *para*-Benzoquinone (C) 2489
- Synthesis and Properties of a Vertically Stacked Porphyrin(1)-Porphyrin(2)-Quinone Cyclophane (C) 1466
- Synthesis and Properties of a Vertically Stacked Porphyrin-Quinone(1)-Quinone(2) Cyclophane (C) 1463
Cyclopropanations
- Cyclopropanation by Methylene Transfer from (η^2-Formaldehyde)zirconocene Complexes (C) 1955
Cyclopropanes
- Cyclopropanes by Nucleophilic Attack of Mono- and Diaryl-Substituted (η^3-Allyl)palladium Complexes: Aryl Effect and Stereochemistry (C) 1280
- Ring Opening of Cyclopropane at 10 K (C) 558
Cyclosporin
- Cyclosporin: A Li- and Ca-Specific Ionophore! (C) 442
Cyclotheonamides
- Synthesis of Cyclotheonamide B and Its Derivatives (C) 1729
Cyclotrimerization
- Cyclotrimerization of Ethyne on the Complex Fragment [(η^1-*t*Bu$_2$PCH$_2$P*t*Bu$_2$)-Ni^0] with Formation of an η^6-Benzene–Nickel(0) Complex (C) 879
Cytochrome P-450
- Relationships between Structure and Function of Cytochrome P-450—Experiments, Calculations, Models (B) 359

Decaphenylferrocene
- Decaphenylferrocene and Decaphenylferrocenium Tetrafluoroborate (C) 1731
Dehydroamino acids
- Synthesis, Crystal and Molecular Structure of Boc-Pro-ΔPhe-Ala-ΔPhe-Ala-OMe; A Pentapeptide with a Novel β-Bend Ribbon Structure (C) 970
- Synthesis of Unsaturated Amino Acids by [3,3]-Sigmatropic Rearrangement of Chelate-Bridged Glycine Ester Enolates (C) 998
Dendrimers
- A "Branched-Monomer Approach" for the Rapid Synthesis of Dendrimers (C) 82
- A General Synthetic Strategy for Neutral Phosphorus-Containing Dendrimers (C) 1589
- Chemistry within a Unimolecular Micelle Precursor: Boron Superclusters by Site- and Depth-Specific Transformations of Dendrimers (C) 666
- Chiral Dendrimers from Tris(hydroxymethyl)methane Derivatives (C) 440
- Dendrimers: From Generations and Functional Groups to Functions (H) 2413
- Dendritic Macromolecules Incorporating Tetrathiafulvalene Units (C) 1761
- Dendritic Porphyrins: Modulating Redox Potentials of Electroactive Chromophores with Pendant Multifunctionality (C) 1739

- Organoplatinum Dendrimers Formed by Oxidative Addition (C) 847
- Single-Step Six-Electron Transfer in a Heptanuclear Complex: Isolation of Both Redox Forms (C) 2460

Denitrification
- Novel Copper Nitrosyl Complexes: Contributions to the Understanding of Dissimilatory, Copper-Containing Nitrite Reductases (H) 2057

Deoxynojirimycin
- An Enantioselective Synthesis of Deoxynojirimycin (C) 2320

Desulfurizations
- Desulfurization of Benzo[*b*]thiophene by S/Ru Exchange: Formation and Structure of the Cluster $[Ru_3(CO)_8(C_8H_6)]$ (C) 1381

Diarylcarbenes
- An Extremely Long-Lived Triplet Carbene; Reactivity, Optical Absorption, and Kinetics of Highly Congested Diarylcarbenes (C) 873

Diazabutadienes
- $[Be(dad)_2]$: Synthesis and Structure of a Diazabutadieneberyllium Complex (C) 1372

Diazaxanthylium salts
- 3,6-Diazaxanthylium Salts: Dyes with a New Chromophore (C) 863

Diazoanthrones
- Photodecomposition of 10-Diazo-2-hexadecylanthrone on Graphite Studied by Scanning Tunneling Microscopy (C) 2080

Diazo carbonyl compounds
- Ligand Effects on the Chemoselectivity of Transition Metal Catalyzed Reactions of α-Diazo Carbonyl Compounds (R) 1797

Diazo compounds
- α-Aryliodonio Diazo Compounds: S_N Reactions at the α-C Atom as a Novel Reaction Type for Diazo Compounds (C) 1952

Dibromine pentoxide
- Dibromine Pentoxide Br_2O_5 (C) 975

Dictionaries
- Comprehensive Dictionary of Physical Chemistry (B) 1785
- Dictionary of Trivial Names/Trivialnamen-Handbuch (B) 1305

Diels–Alder reactions
- A Concise Total Synthesis of (±)-Mamanuthaquinone by Using an *exo*-Diels–Alder Reaction (C) 853
- Asymmetric Diels–Alder Reactions Catalyzed by a Chiral Iron Lewis Acid (C) 1856
- Asymmetric 1,6-Induction in Hetero-Diels–Alder Reactions of Chiral Oxabutadienes for a De Novo Synthesis of Enantiomerically Pure Carbohydrates: Lewis Acid Dependent Reversal of Facial Selectivity (C) 980
- Magnetic Properties of Aromatic Transition States: The Diels–Alder Reactions (C) 1376
- Synthesis of Enediynes through Diels–Alder Addition (C) 1099

Dienone–phenol rearrangement
- An Antibody-Catalyzed 1,2-Rearrangement of Carbon–Carbon Bonds (C) 1607

Dihydroxyacetone phosphate
- Synthesis of Dihydroxyacetone Phosphate (and Isosteric Analogues) by Enzymatic Oxidation: Sugars from Glycerol (C) 209

Dihydroxydehydrocalamenene
- The Total Synthesis of *cis*-7,8-Dihydroxy-11,12-dehydrocalamenene by Regio- and Diastereoselective Alkylation of Chiral η^6-Arenetricarbonylchromium Complexes: An Unexpected Case of Nucleophilic Aromatic *tele*-Substitution with Methoxide as a Leaving Group (C) 109

Dihydroxylations
- Practical and Rapid Vicinal Hydroxylation of Alkenes by Catalytic Ruthenium Tetraoxide (C) 2312

Dimeric acids
- Assembly Properties of Bolaamphiphiles from Dimeric Acids (C) 2078

Diols
- A Reagent for Determining Optical Purities of Diols by Formation of Diastereomeric Arylboronate Esters (C) 1182
- Cyclohexane-1,2-diacetals (CDA): A New Protecting Group for Vicinal Diols in Carbohydrates (C) 2290
- Practical and Rapid Vicinal Hydroxylation of Alkenes by Catalytic Ruthenium Tetraoxide (C) 2312

Dioxiranes
- Dimesityldioxirane—A Dioxirane Stable in the Solid State (C) 2212

Dipeptide isosteres
- A Novel Route to Diastereomerically Pure (*E*)-Alkene Dipeptide Isosteres from β-Aziridinyl-α,β-enoates by Treatment with Organocopper Reagents (C) 652

Disilenes
- Stable Tetrakis(trialkylsilyl)disilenes; Synthesis, X-Ray Structures, and UV/VIS Spectra (C) 1489

Distance geometry calculations
- Determination of the Relative Configuration by Distance Geometry Calculations with Proton–Proton Distances from NOESY Spectra (C) 753

Dithiirane
- The First Isolable Dithiirane by Oxidation of a Dithietane (C) 777

Diversomers
- Opportunities for New Chemical Libraries: Unnatural Biopolymers and Diversomers (H) 633

Diynes
- Synthesis and Structure of the Smallest Cyclic Cumulene; Reaction of 1,3-Diynes with Zirconocene Complexes (C) 1605

DNA
- An Amazing Distortion in DNA Induced by a Methyltransferase (Nobel Lecture) (R) 1222
- Specific Binding of Antibodies to DNA through Combinatorial Antibody Libraries (H) 1827
- Strong, Specific Binding of Six Different DNA Sequences by a Single Conformation–Switching DNA Macrocycle (C) 1004
- Synthetic DNA and Biology (R) 1214
- The Polymerase Chain Reaction (Nobel Lecture) (R) 1209
- Unraveling DNA (B) 1303

DNA cleavage
- Calicheamicin θ_1^1: A Rationally Designed Molecule with Extremely Potent and Selective DNA Cleaving Properties and Apoptosis Inducing Activity (C) 183
- Enediyne Quinone Imines: Truncated, Biologically Active Dynemicin Congeners (C) 2477
- Fullerene–Oligonucleotide Conjugates: Photo-induced Sequence-Specific DNA Cleavage (C) 2472
- On the DNA Recognition Role of the Carbohydrate Sector in Calicheamicin: A Comparison of DNA Cleaving Capacity of Enantiomeric Calicheamicinones (C) 855
- Synthesis and Selective Radical Cleavage of C-4′-Modified Oligonucleotides (C) 1861

Dodecahedranes
- From an Insecticide to Plato's Universe – The Pagodane Route to Dodecahedranes: New Pathways and New Perspectives (R) 2239

Dötz reaction
- Chromium Carbene Complexes in Organic Synthesis: Recent Developments and Perspectives (H) 303

Genes
- Gene Regulation in Eukaryotes (B) 2349

Genetics
- Biotechnology. Vol. 2 Genetic Fundamentals and Genetic Engineering (B) 2349

Germanium compounds
- Stable Germirane Derivatives (C) 659
- Synthesis and Structure of the Disilagermirane $R_2Ge(SiR_2)_2$ and the Solvent-Separated Ion Pair $[Li([12]crown-4)_2][GeR_3]$; ($R = SiMe_3$) (C) 113
- Synthesis and Structure of the First Stable Germaneselone (C) 2316
- Synthesis, Structures, and Reactions of Two Bis(diaminostannylene)s and a Bis(diaminogermylene) Containing a Central C_6 Ring (C) 1156

Gluconamides
- Tunable Supramolecular Structures from a Gluconamide Containing Imidazole (C) 986
Glutathione reductase
- Activation of Glutathione Reductase by Light: A Novel Approach to Design Redox Photo-Enzymes (C) 581
Glycoconjugates
- A Highly Convergent Synthesis of the Lewis^y Blood Group Determinant in Conjugatable Form (C) 1468
- An Interactive Strategy for the Assembly of Complex, Branched Oligosaccharide Domains on a Solid Support: A Concise Synthesis of the Lewis^b Domain in Bioconjugatable Form (C) 1470
Glycopeptides
- Enzymatic Hydrolysis of Hydrophilic Diethyleneglycol and Polyethyleneglycol Esters of Peptides and Glycopeptides by Lipases (C) 336
- Recombinant Whole Cells as Catalysts for the Enzymatic Synthesis of Oligosaccharides and Glycopeptides (C) 1241
- Synthesis of *N*-Glycopeptide Clusters with Lewis^x Antigen Side Chains and Their Coupling to Carrier Proteins (C) 101
Glycoproteins
- *Aleuria aurantia* Agglutinin Recognizes Multiple Conformations of α-L-Fuc-(1→6)-β-D-GlcNAc-OMe (C) 88
Glycosidases
- Progress Toward An Antibody Glycosidase (C) 339
Glycosylations
- Sugar Calixarenes: Preparation of Calix[4]arenes Substituted at the Lower and Upper Rims with *O*-Glycosyl Groups (C) 2479
- Synthesis of a Biantennary Heptasaccharide by Regioselective Glycosylations (C) 1102
Glycosylimides
- Stereoselective Intramolecular Alkylation of Glycosylimides to Highly Functionalized Bicyclic 2,5-Azepanediones and Heterotricyclic [5.3.1.$0^{2,6}$] Undecanamides (C) 1979
Glycosylimines
- Conversion of Glycosyl Azides via *N*-Bromoglycosylimines to Aldononitriles (C) 751
Gold compounds
- A Cluster-Bound Triply-Bridging Phosphorus Atom Coordinated to Four $(Ph_3P)Au^+$ Units: $[Fe_3(CO)_9P\{Au(PPh_3)\}_4][BAr_4]$ (C) 75
- A Hexanuclear Gold(I) Complex: $[(Ph_3PAu)_2C(PPh_2AuPPh_2)\}_2](ClO_4)_2$ (C) 87
- A Postulated Carrier of Gold in Hydrothermal Ore Solutions: Synthesis and Crystal Structure of $[(Ph_3P)_2N]$-$[Au(SH)_2]$, the First Homoleptic Hydrogensulfido Complex (C) 1852
- Aurophilicity at Sulfur Centers: Synthesis and Structure of the Tetragold(I) Species $[(Ph_3PAu)_4S](CF_3SO_3)_2 \cdot 2CH_2Cl_2$ (C) 769
- Neutral Gold(I) Fluoride Does Indeed Exist (C) 212
- $[(Ph_3PAu)_6(dppeAu_2)(AuCl)_4Pd]$, an Icosahedral Au_{12} Cluster with a Central Pd Atom (C) 207
GPI anchor
- Synthesis of a GPI Anchor of Yeast (*Saccharomyces cerevisiae*) (C) 2177
Grignard reactions
- Enantioselective Reactions in a Static Magnetic Field (C) 454 (1461)
- Simple and Versatile Synthesis of Optically Active 1,2-Amino Alcohols by Grignard Addition to *N*,*O*-Dibenzylglyceraldimine and -lactaldimine (C) 1298
Group theory
- Icons and Symmetries (B) 482

Hafnium compounds

ICP atomic spectrometry
- Inductively Coupled Plasmas in Analytical Atomic Spectrometry (B) 231

Imides
- Synthesis and Structure of the Magnesium Imide $[(thf)MgNPh]_6$ (C) 356

Imines
- Diastereomerically Pure Mannich Bases from the Addition of Enamines to Ternary Iminium Salts (C) 2422

Iminoalanes
- Synthesis and Structure of the First Dimeric Iminoalane Containing an Al_2N_2 Heterocycle (C) 969

Iminophosphoranes
- Reactions of an Iminophosphoranylidene Carbenoid (C) 982

Immunoassays
- Luminescent Labels—More than Just an Alternative to Radioisotopes? (R) 1044

Immunosorption
- Immunosorption Techniques. Fundamentals and Applications (B) 234

Inclusion compounds
- Zigzag Channels in the Structure of Sebaconitrile/Urea (C) 649

Indacenes
- *s*-Indacene: A Delocalized, Formally Antiaromatic 12 π Electron System (C) 1192

Indigo derivatives
- Concerning the Questionable Existence of Thioxoindigoid Compounds (C) 739

Indoles
- 3*H*-Indole (C) 1153

Indolizidines
- Diastereoselective Synthesis of Amino-Substituted Indolizidines and Quinolizidines by the Intramolecular Hetero-Ene Reaction of Prolinal Imine and 2-Piperidine Carbaldimine (C) 458

Inorganic chemistry
- Inorganic Materials (B) 585

Inositols
- Synthesis of a GPI Anchor of Yeast (*Saccharomyces cerevisiae*) (C) 2177

Interfaces
- Structure of Electrified Interfaces (B) 2117

Intermediates
- Molecular Distortion in Reactive Chemical Intermediates (H) 962

Intermetallic phases
- Localization of Electrons in Intermetallic Phases Containing Aluminum (C) 2069
- Unequivocal Partitioning of Crystal Structures, Exemplified by Intermetallic Phases Containing Aluminum (C) 2073

In vitro selection
- Isolation of RNA Aptamers for Biological Cofactors by In Vitro Selection (C) 1084
Iodine compounds
- $[(C_6H_5)_4P]_\infty^1[Cu_3I_4]$ - The First Compound with a Helical Chain of Face-Sharing Tetrahedra as a Structural Element (C) 1841
- α-Aryliodonio Diazo Compounds: S_N Reactions at the α-C Atom as a Novel Reaction Type for Diazo Compounds (C) 1952
- Concerning the Mechanism of α-Elimination: Hypervalent Ion Pairing in an Iodocarbenium Iodide (C) 893
- Electrostatic Activation of Hypervalent Organo-Iodine Compounds: Bis(onio)-Substituted Aryliodine(III) Salts (C) 891
- Iodine Chains in $(Me_4Sb)_3I_8$ and Discrete Triiodide Ions in Me_4AsI_3 (C) 987
- Small Molecules Stabilized in Inorganic Frameworks: NbI_5 Monomers in the Novel Layered Compound $Nb_7S_2I_{19}$ (C) 334
Ion channels
- A Convergent Synthesis of 2,5-*trans*-Linked Oligo(tetrahydrofuran)s: Potential Building Blocks for a Polyether Helix with Ion Channel Activity (C) 1180
Ionophores
- Cyclosporin: A Li- and Ca-Specific Ionophore! (C) 442
Ions
- Gaseous Molecular Ions. An Introduction to Elementary Processes Induced by Ionization (B) 479
Iron compounds
- A Carbene–Iron Chelate Complex as a Source of a Ferraborane Derivative (C) 2218
- A Mixed-Valent, Unsymmetrical Fe^{II}-Fe^{III} Complex with a Terminal Phenola to Ligand as a Model for the Active Site of Purple Acid Phosphatases (C) 887
- A Model for α-Keto Acid Dependent Nonheme Iron Enzymes: Structure and Reactivity of $[Fe^{II}_2(Me_2hdp)_2(bf)](ClO_4)$ (C) 1886
- Asymmetric Diels–Alder Reactions Catalyzed by a Chiral Iron Lewis Acid (C) 1856
- Bond-Stretch Isomers: Fact not Fiction (C) 425
- Carboxylatoiron(II) Aggregates: A Novel Fe^{II}_4 Complex with Threefold Symmetry (C) 1660
- Change of Orientation of Axial Imidazole Ligands in a Cytochrome b Model Complex in Response to a Change in the Oxidation State of the Metal Center (C) 1363
- Chemistry of Iron (B) 1011
- $[Cp^*Fe(\eta^5\text{-}P_5)]$, a Sandwich Complex with Diverse Ligand Properties (C) 1110
- Cr^{III} and Fe^{III} Complexes with η^3-1,3,5-Triazacyclohexane Ligands (C) 1877
- Decaphenylferrocene and Decaphenylferrocenium Tetrafluoroborate (C) 1731
- "Frec" $[Fe(tpp)]^+$ Cation: A New Concept in the Search for the Least Coordinating Anion (C) 2433
- Iron–Carbene Complexes (B) 1894
- Iron-Promoted, Regio- and Stereoselective Allylic Substitutions for the Synthesis of Alkenyl Sulfones Substituted at C-3 (C) 1949
- Metallocorroles with Formally Tetravalent Iron (C) 731
- Mixed-Valence, Tetranuclear Iron Chelate Complexes as Endoreceptors: Charge Compensation Through Inclusion of Cations (C) 1621
- $[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$: A Highly Symmetrical Giant Cluster with an Unusual Cavity and the Possibility of Positioning Paramagnetic Centers on Extremely Large Cluster Surfaces (C) 849
- μ-Oxodiiron(III) Complexes of Porphycenes (C) 736
- (η^5-Pentamethylcyclopentadienyl)iron Complexes with η^5-2,3,5-Tricarbahexaboranyl and η^5-2,3-Dihydro-1,3-diborolyl Ligands (C) 203
- Platinum-Iron Silylene Complexes and Metal-Promoted Substituent Exchange between $Si(NMe_2)_3$- and $P(OEt)_3$-Ligands (C) 2440
- Single-Crystal EPR Spectroscopy on $[^{57}Fe(NO)(S_2CNEt_2)_2]$: The "Triplet Signal" in the EPR Spectrum of $[Fe(S_2CNEt_2)_3]$ (C) 1497
- Single-Step Six-Electron Transfer in a Heptanuclear Complex: Isolation of Both Redox Forms (C) 2460
- Synthesis and Characterization of Thiolato Complexes with Two-Coordinate Iron(II) (C) 1178
- Synthesis and Structure of the First [2$_2$]Metallocenophanes (C) 1479
- The First Metal Complexes with a Doubly S_3-Bridged Ferrocene Ligand (C) 1752
- Thermal and Optical Switching of Iron(II) Complexes (R) 2024
Isocyanides
- Complex-Stabilized Alkynyl and Cycloalkenyl Isocyanides (C) 330
- Equilibrium between Isocyanide and Carbene Complexes in Coordination Compounds of 2,6-Dihydroxyphenyl Isocyanide (C) 1356
- Fluorinated Isocyanides—More than Ligands with Unusual Properties (R) 1315
Isoelectronic analogues
- New Ionic, Isoelectronic Analogues of CO_2 and CS_2 (H) 1575
Isofagomine
- Isofagomine, a Potent, New Glycosidase Inhibitor (C) 1778
Isolobal relationship
- The Bonding Capability of Imido Complex Fragments of Groups 5–7 with Regard to the Isolobal Relationship (C) 1255
Isomerases
- Peptidyl-Prolyl *cis/trans* Isomerases and Their Effectors (R) 1415
Isomerization
- Cyanide–Isocyanide Isomerism in CN-Bridged Organometallic Complexes (C) 2090
- Photoisomerization of Highly Alkylated Butadienes (C) 204
- Propeller Isomerism of the Triphenylphosphane Ligand in Half-Sandwich Ru^{II} Complexes (C) 866
Isotope effects
- Unusually Large Isotope Effects on NMR Chemical Shifts of Paramagnetic Organometallic Compounds (C) 2326
Isotopic labeling
- A Short Route to [3-^{15}N]-3′-Azido-3′-deoxythymidine (N3-Labeled AZT) via 3-Nitro-AZT (C) 2454
Ivangulin
- A Short and Highly Stereoselective Synthesis of the 1,10-*seco*-Eudesmanolide Ivangulin (C) 2195

Keronopsins
- Keronopsins A and B, Chemical Defence Substances of the Marine Ciliate *Pseudokeronopsis rubra* (Protozoa): Identification by Ex Vivo HPLC (C) 1495
Ketenylidene complexes
- $[Zr_3Cp_2(O_2CN\mathit{i}Pr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}CCO)]$, the First Crystallographically Established Ketenylidene Complex; A Model for CO Reductive Cleavage on Metal Surfaces (C) 1188
Ketones
- Bridgehead Functionalization of Non-Enolizable Ketones: The First Preparatively Useful Methods (C) 2220
Kinetics

Molybdenum compounds
- Direct Metal–Metal Bonds Between High and Low Valent Complex Fragments: The Reaction of Metal Bases with the Metal Acids $[Re(NR)_3]^+$ and $[Mo(NR)_2]^{2+}$ (C) 678
- $[K([18]crown-6)]^+[Mo_4(\mu_4\text{-}H)(OCH_2tBu)_{12}]^-$, the First Alkoxidohydrido Cluster of Molybdenum, Evidence for a Rare, if not the First, Example of a μ_4-Hydride (C) 191
- $[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$: A Highly Symmetrical Giant Cluster with an Unusual Cavity and the Possibility of Positioning Paramagnetic Centers on Extremely Large Cluster Surfaces (C) 849
- Novel Conjugation of Hetero(macro)cycles and a Pentamolybdodiphosphonate Cage (C) 451
- Polar Superstructures Stabilized by Polymeric Oxometal Units: Columnar Liquid Crystals Based on Tapered Dioxomolybdenum Complexes (C) 2342
- The First Mononuclear Nitrosyl(oxo)molybdenum Complex: Side-On Bonded and μ_3-Bridging NO Ligands in $[\{MoL(NO)(O)(OH)\}_2]NaPF_6 \cdot H_2O$ (C) 1473

Monolayers
- Phase Transitions in Self-Assembled Monolayers Detected by Electrochemistry (C) 2332
Multiple bonds
- A Stannanediyl with a Tin–Carbon Multiple Bond (C) 456
- (Iminoboryl)borates $[(t\mathrm{Bu}N{\equiv}B)B t\mathrm{Bu}_2R]^-$ from the Azadiboriridine $NB_2t\mathrm{Bu}_3$ (R = Me, Bu) (C) 201
- Multiple Bonds Between Metal Atoms (B) 480

Nanostructures
- Nanostructures Based on Molecular Materials (B) 127
Naphtho[1.8-*bc*]boret
- Synthesis and Reactivity of a Naphtho[1,8-*bc*]boret (C) 1247
Natural products
- A Concise Total Synthesis of (±)-Mamanuthaquinone by Using an *exo*-Diels–Alder Reaction (C) 853
- A Convergent Total Synthesis of Calicheamicin γ_1^I (C) 858
- A Facile One-Pot Synthesis of a Trisaccharide Unit from the Common Polysaccharide Antigen of Group B *Streptococci* Using Cyclohexane-1,2-diacetal (CDA) Protected Rhamnosides (C) 2292
- A Short and Highly Stereoselective Synthesis of the 1,10-*seco*-Eudesmanolide Ivangulin (C) 2195
- Asymmetric Synthesis of Natural Products (B) 1891
- A Total Synthesis of (+)-2′*S*,3′*R*-Zoapatanol (C) 2182
- Biosynthetic Investigations on Pyridazomycin (C) 1648
- Chemistry and Biology of Taxol (R) 15
- Composition of Protocyanin, A Self-Assembled Supramolecular Pigment from the Blue Cornflower, *Centaurea cyanus* (C) 978
- First Total Synthesis of (±)-Rabelomycin (C) 99
- Keronopsins A and B, Chemical Defence Substances of the Marine Ciliate *Pseudokeronopsis rubra* (Protozoa): Identification by Ex Vivo HPLC (C) 1495
- New Total Syntheses of Strychnine (H) 1144
- Novel Optically Active Hydrocarbons in Sediments: Evidence for an Extensive Biological Cyclization of Higher Regular Polyprenols (C) 1166
- Spectroscopic Studies of Anhydroretinol, an Endogenous Mammalian and Insect *retro*-Retinoid (C) 1837 (2348)
- Synthesis of a GPI Anchor of Yeast (*Saccharomyces cerevisiae*) (C) 2177
- Synthesis of C-2 Taxol Analogues (C) 1581
- Synthesis of Cyclotheonamide B and Its Derivatives (C) 1729
- Synthesis of *N*-Glycopeptide Clusters with Lewis^x Antigen Side Chains and Their Coupling to Carrier Proteins (C) 101
- Synthesis of the First Fully Functionalized Core of the Zaragozic Acids/Squalestatins (C) 2187
- The First Total Syntheses of Taxol (H) 959
- The Sialyl Lewis^x Group and its Analogues as Ligands for Selectins: Chemoenzymatic Syntheses and Biological Functions (H) 178
- The Synthesis of Naturally Occurring (−)-Calyculin A (C) 673
- The Total Synthesis of *cis*-7,8-Dihydroxy-11,12-dehydrocalamenene by Regio- and Diastereoselective Alkylation of Chiral η^6-Arenetricarbonylchromium Complexes: An Unexpected Case of Nucleophilic Aromatic *tele*-Substitution with Methoxide as a Leaving Group (C) 109
- Total Synthesis of Soraphen $A_{1\alpha}$ (C) 2466
- Total Synthesis of Zaragozic Acid A/Squalestatin S1 (C) 2190
- Zaragozic Acid A/Squalestatin S1: Synthetic and Retrosynthetic Studies (C) 2184
Near-field microscopy
- Detection and Imaging of Single Molecules by Optical Near-Field Microscopy (H) 1723
- Mapping the Electrostatic Potential of Muscarinic and Nicotinic Agonists with Artificial Neural Networks (C) 643
Neural networks
- Neural Networks for Chemists. An Introduction (B) 1671
Neutron diffraction
- The Spin Density Distribution in the Tetracyanoethylene Radical Anion, $[TCNE]^-$, by Single-Crystal Polarized Neutron Diffraction (C) 1397
Nickel compounds
- Bis(tetramethylbutynediol)nickel(0), the First Pure Monoalkyne Complex of Nickel and Its Chemistry (C) 1373
- $[(CpNi)_2(Cp^*Al)_2]$: Cp*Al as a Bridging Two-Electron Ligand (C) 2482
- Cyclotrimerization of Ethyne on the Complex Fragment $[(\eta^1\text{-}t\mathrm{Bu}_2PCH_2Pt\mathrm{Bu}_2)Ni^0]$ with Formation of an η^6-Benzene–Nickel(0) Complex (C) 879
- Mesoscopic Sheets of a Cyano-Bridged Cu–Ni Coordination Complex: Template Synthesis at the Interlayers of Cast Multibilayer Films (C) 2483
- Synthesis and Characterization of the First Compounds Containing a Stable Phosphirenyl Cation: Crystal and Molecular Structure of $[Ni(\eta^3\text{-}PC_2t\mathrm{Bu}_2)(\eta^5\text{-}P_3C_2t\mathrm{Bu}_2)W(CO)_5]$ (C) 2330
- The Photochemical Activation of Carbon Dioxide Using a Nickel Complex (H) 173
- The Versatility of the Azido Ligand: Linkage of Ni^{II} Centers to Form a Chain with One End-to-End and Three End-On Bridges in Alternation (C) 2087
- Thianickelacycles by Ring-Opening Reactions of Cyclic Thioethers and Their Subsequent Carbonylation to Thioesters (C) 1748
Niobium compounds
- $Rb_3[Nb_6SBr_{17}]$, the First Compound Containing an Isolated Trigonal-Prismatic Niobium Cluster (C) 1943
- Small Molecules Stabilized in Inorganic Frameworks: NbI_5 Monomers in the Novel Layered Compound $Nb_7S_2I_{19}$ (C) 334
Nitrenoids
- [(*N*-Lithio-*N*-mesitylsulfonyloxy-*tert*-butylcarbamate)$_2$ · (thf)$_3$]: Crystal Structure of a Nitrenoid (C) 115
Nitric oxide
- A Clathrate Hydrate of Nitric Oxide (C) 691
- Reductive Disproportionation of NO Mediated by Copper Complexes: Modeling N_2O Generation by Copper Proteins and Heterogeneous Catalysts (C) 895
Nitrile imines
- Nitrile Imines: From Matrix Characterization to Stable Compounds (R) 527
Nitriles
- 1-Oxa-3,5,7,9-tetraazadecapentaene, a Model Oligonitrile with a Helical Structure in the Crystalline State (C) 2337
Nitrogen compounds
- Diastereomerically Pure Mannich Bases from the Addition of Enamines to Ternary Iminium Salts (C) 2422
- Monomeric Tris(imino)metaphosphates (C) 2111
- N-Heteroarene Dianions as Antiaromatic Ligands Bridging two Lanthanocene Moieties (C) 1171
- Polymorphism and C=N–N=C Conformational Isomers of Azines: X-ray Crystal and Ab Initio Structures of Two Rotational Isomers of Methyl (*para*-Tolyl) Ketone Azine (C) 1081
- The Biosynthesis of Nitro Compounds: The Enzymatic Oxidation to Pyrrolnitrin of its Amino-Substituted Precursor (C) 352
- The Structures of Two Lithium Hydrazides: Is There Electron-Deficient Bonding? (C) 1746 (1988)
Nitroxide radicals
- Preparation of Chiral Nitroxide Radicals and Spontaneous Optical Resolution by Recrystallization (C) 878
NMR spectroscopy
- A Dictionary of Concepts in NMR (B) 360
- *Aleuria aurantia* Agglutinin Recognizes Multiple Conformations of α-L-Fuc-(1→6)-β-D-GlcNAc-OMe (C) 88
- A Novel Type of Stereoisomerism in Calix[4]arene-Based Carceplexes (C) 2345
- Determination of the Relative Configuration by Distance Geometry Calculations with Proton–Proton Distances from NOESY Spectra (C) 753
- Difluoromethyl Compounds of Chalcogens: A NMR Study of the Reactions of $Cd(CF_3)_2 \cdot 2MeCN$ and $ZnBr(CF_3) \cdot 2MeCN$ with Dialkyl Chalcogenides and Boron Trifluoride (C) 323
- Effects of $^{35}Cl/^{37}Cl$,^{13}C Residual Dipolar Coupling on the Variable-Temperature ^{13}C CP/MAS NMR Spectra of Solid, Chlorinated Sodium Acetates (C) 1624
- FAST NOESY Experiments—An Approach for Fast Structure Determination (C) 332
- Fundamentals of Nuclear Magnetic Resonance (B) 1670
- In Situ NMR Investigations of Photocatalyzed Hydrogenations with Parahydrogen in the Presence of Metal Carbonyl Compounds of Group 6 (C) 755
- Magnetic Resonance Microscopy (B) 128
- Modern NMR Spectroscopy (B) 1992
- On the Mechanism of the Urocanase Reaction: Confirmation of the Structure of the NAD^+-Inhibitor Adduct by Direct ^{13}C-^{13}C Coupling (C) 1279
- Protein Structure Determination with Three- and Four-Dimensional NMR Spectroscopy (R) 277
- Selective Measurement of the Time-Dependence of Transient Overhauser Effects in Magnetic Resonance: Applications to Oligonucleotides (C) 343
- Unusually Large Isotope Effects on NMR Chemical Shifts of Paramagnetic Organometallic Compounds (C) 2326
- 2D NMR. Density Matrix and Product Operator Treatment (B) 1784
Nobel laureates
- Nobel Laureates in Chemistry, 1901–1992 (B) 2118
Nobel lecture
- An Amazing Distortion in DNA Induced by a Methyltransferase (Nobel Lecture) (R) 1222

- Split Genes and RNA Splicing (Nobel Lecture) (R) 1229
- Synthetic DNA and Biology (R) 1214
- The Polymerase Chain Reaction (Nobel Lecture) (R) 1209

Noble metals
- Homoleptic Noble Metal Carbonyl Cations (H) 1077

Nonacosan-10-ol
- The Effect of Chiral Bilayers: Wax Tubes made of (*S*)-Nonacosan-10-ol (C) 350

Nonlinear optics
- Synthesis and Third-Order Nonlinear Optical Properties of a Conjugated Porphyrin Polymer (C) 655

Norbornanes
- Electrostatic vs. Orbital Control of Facial Selectivities in π Systems: Experimental and Theoretical Study of Electrophilic Additions to 7-Isopropylidenenorbornanes (C) 1390

Norbornenes
- [2+2] Cycloaddition of Norbornenes with Alkynes Catalyzed by Ruthenium Complexes (C) 580

Nucleophilic aromatic *tele*-substitution
- The Total Synthesis of *cis*-7,8-Dihydroxy-11,12-dehydrocalamenene by Regio- and Diastereoselective Alkylation of Chiral η^6-Arenetricarbonylchromium Complexes: An Unexpected Case of Nucleophilic Aromatic *tele*-Substitution with Methoxide as a Leaving Group (C) 109

Nucleophilicity
- Scales of Nucleophilicity and Electrophilicity: A System for Ordering Polar Organic and Organometallic Reactions (R) 938

Nucleophilic substitutions
- A Novel Reaction Sequence for the Coupling of Nucleophiles to Agarose with 2,2,2-Trifluoroethanesulfonyl Chloride (C) 120

Nucleoside analogues
- Regioselective Synthesis and Antiviral Activity of Purine Nucleoside Analogues with Acyclic Substituents at N7 (C) 562

Nucleosides
- A Short Route to [3-^{15}N]-3′-Azido-3′-deoxythymidine (N3-Labeled AZT) via 3-Nitro-AZT (C) 2454
- Biomimetic Phosphonylation and Phosphorylation of Glycoses and Deoxynucleosides (C) 2302
- New Cyclic Derivatives of 3′-Amino-3′-deoxyadenosine-5′-diphosphate, -triphosphate, and -methylenebis(phosphonate) (C) 1394

Nucleotides
- Continuous Enzymatic Synthesis of 2′-Deoxythymidine-5′-(α-D-glucopyranosyl) diphosphate (C) 571

Octaplane
- Octaplane: A Saturated Hydrocarbon with a Remarkably Low Ionization Energy Leading to a Cation with a Planar Tetracoordinate Carbon Atom (C) 1667

Olefinations
- Acid-Catalyzed Olefination of Benzaldehyde (C) 1611

Oligoanthranilamides
- Novel Molecular Scaffolds: Formation of Helical Secondary Structure in a Family of Oligoanthranilamides (C) 446

Oligoarylenes
- 2,2′-Bipyrenyl and *para*-Terpyrenyl—A New Type of Electronically Decoupled Oligoarylene (C) 1957

Oligomers
- Iterative Divergent/Convergent Approach to Linear Conjugated Oligomers by Successive Doubling of the Molecular Length: A Rapid Route to a 128Å-Long Potential Molecular Wire (C) 1360

Oligonitriles
- 1-Oxa-3,5,7,9-tetraazadecapentaene, a Model Oligonitrile with a Helical Structure in the Crystalline State (C) 2337

Oligonucleotides
- Amides as a New Type of Backbone Modification in Oligonucleotides (C) 226
- Fullerene–Oligonucleotide Conjugates: Photo-induced Sequence-Specific DNA Cleavage (C) 2472
- Selective Measurement of the Time-Dependence of Transient Overhauser Effects in Magnetic Resonance: Applications to Oligonucleotides (C) 343
- Stereocontrolled Synthesis of Oligo(nucleoside phosphorothioate)s (R) 709
- Synthesis and Selective Radical Cleavage of C-4′-Modified Oligonucleotides (C) 1861
- Synthesis of an Azathymidine and Its Incorporation into Oligonucleotides (C) 1654
- Synthetic DNA and Biology (R) 1214

Oligosaccharides
- Recombinant Whole Cells as Catalysts for the Enzymatic Synthesis of Oligosaccharides and Glycopeptides (C) 1241

Oligosilanes
- Structures of 2-(Me_2NCH_2)C_6H_4-Substituted Oligosilanes (C) 1854

Oligo(tetrahydrofuran)s
- A Convergent Synthesis of 2,5-*trans*-Linked Oligo(tetrahydrofuran)s: Potential Building Blocks for a Polyether Helix with Ion Channel Activity (C) 1180
- A Multiple Five-Membered-Ring-Selective Williamson Reaction as a Key Step in the Stereoselective Construction of 2,5-Linked Oligo(tetrahydrofuran)s (C) 1873

Olympiadane (C) 1286

Organic chemistry
- Sourcebook of Advanced Organic Laboratory Preparations (B) 231

Organic conductors
- 61,61-Bis(trimethylsilylbutadiynyl)-1,2-dihydro-1,2-methanofullerene[60]: Crystal Structure at 100 K and Electrochemical Conversion to a Conducting Polymer (C) 1628

Organic synthesis
- Biocatalysts in Organic Synthesis (B) 1012
- Solid Supports and Catalysts in Organic Synthesis (B) 587

Organometallic compounds
- Are Polar Organometallic Compounds "Carbanions"? The Gegenion Effect on Structure and Energies of Alkali-Metal Compounds (R) 1129

Organometallic magnetic materials
- Organic and Organometallic Magnetic Materials—Designer Magnets (R) 385

Osmium compounds
- A Triosmium Cluster Complex with a Carbene Ligand in an Unusual Coordination Mode (C) 1093
- Hydroxylamine, Hydrazine, and Diazene as Unidentate Ligands in Osmium and Ruthenium Complexes (C) 657

Oxalate
- Human Oxalate—Really Just an End-Product of Metabolism? (C) 1780

Oxathietanes
- Synthesis, Structure, and Thermolysis of a Tetracoordinate 1,2λ^4-Oxathietane (C) 2094

Oxenoids
- The Oxenoid Character of Metalated Hydroperoxides O(M)OR: Oxidation of Organometallic Compounds R′M′ to R′OH under Mild Conditions (C) 1161

Oxidations
- Catalytic Pt^+-Mediated Oxidation of Methane by Molecular Oxygen in the Gas Phase (C) 1174
- Homogeneous Catalytic Oxidation of Arenes and a New Synthesis of Vitamin K_3 (C) 2475
- *trans*–*cis* Isomerization upon One-Electron Oxidation of [12]- and [14]Tetrathiafulvalenophanes (C) 1379
- Novel Bimetallic Model System for Cytochrome P_{450}: Effect of Membrane Environment on the Catalytic Oxidation (C) 2468
- Optically Active Lactones from a Baeyer–Villiger-Type Metal-Catalyzed Oxidation with Molecular Oxygen (C) 1848
- Oxidation of Metal-Coordinated Thioethers with Dimethyldioxirane—A New Stereoselective Synthesis of Chiral Sulfoxides (C) 1609
- Oxidation of Weakly Activated C–H Bonds (H) 69
- Oxygen Evolution by Oxidation of Water with Manganese Porphyrin Dimers (C) 1839
- Oxygen-Induced Structural Transformation of the Polynuclear Organoaluminum Complex [$Al_4(\mu_3$-8-quinolylimide$)_2$ $(CH_3)_8$] to [$Al_4(\mu_3$-8-quinolylimide$)_2$ $(CH_3)_7(\mu$-$OCH_3)$] (C) 1265
- The Oxenoid Character of Metalated Hydroperoxides O(M)OR: Oxidation of Organometallic Compounds R′M′ to R′OH under Mild Conditions (C) 1161
- Wacker Oxidation of 1-Decene to 2-Decanone in the Presence of a Chemically Modified Cyclodextrin System: A Happy Union of Host–Guest Chemistry and Homogeneous Catalysis (C) 2100
- X-Ray Structure Analysis of the Methane Monooxygenase: An Important Step toward Understanding the Oxidation of Methane in Biological Systems (H) 841

Oxygen activation
- Schiff Base Complexes with Five-Coordinate Cobalt as Dioxygen Activating Sites in Zeolites (C) 431

Oxygenations
- Regio- and Diastereoselective Photooxygenation of Chiral 2,5-Cyclohexadiene-1-carboxylic Acids (C) 1971

Ozone
- Ozone Formation through Decomposition of CFCs in the Stratosphere (C) 1108

Pagodanes
- From an Insecticide to Plato's Universe—The Pagodane Route to Dodecahedranes: New Pathways and New Perspectives (R) 2239
- Isopagodanes—Precursors of Unusual Cage Ions (C) 117

Palladium compounds
- Palladacycles as Intermediates for Selective Dialkylation of Arenes and Subsequent Fragmentation (C) 2421
- [$(Ph_3PAu)_6$(dppeAu_2)$(AuCl)_4Pd$], an Icosahedral Au_{12} Cluster with a Central Pd Atom (C) 207
- Synthesis of Oxa- and Azapalladacycles from Organostannanes (C) 2482
- The Reactivity of Phosphacymantrenes towards Palladium(II) and Palladium(0) Compounds: Synthesis, Structure, and Chemistry of Pd_2Mn_2 and Pd_3Mn_4 Arrays (C) 742

Parahydrogen
- In Situ NMR Investigations of Photocatalyzed Hydrogenations with Parahydrogen in the Presence of Metal Carbonyl Compounds of Group 6 (C) 755
Pentalenes
- Octahydro-1,2,3:4,5,6-dimethenopentalene-2-carbonitrile, the First Derivative of a Yet-Unknown $(CH)_{10}$ Hydrocarbon (C) 1639
Pentamethylbismuth
- Blue-Violet Pentamethylbismuth (H) 1726
Peptide hormones
- Peptide and Protein Hormones. Structure, Regulation, Activity. A Reference Manual (B) 1117
Peptide mimetics
- A New Application of Modified Peptides and Peptidomimetics: Potential Anticancer Agents (H) 305
- A Novel Route to Diastereomerically Pure (*E*)-Alkene Dipeptide Isosteres from β-Aziridinyl-α,β-enoates by Treatment with Organocopper Reagents (C) 652
- A Sugar Amino Acid as a Novel Peptidomimetic (C) 687
- Peptidomimetics–Tailored Enzyme Inhibitors (R) 1699
- Preparation and C-Alkylation of Peptides with Aminomalonate Building Blocks (C) 439
- Synthesis of Sulfonamido-Pseudopeptides: New Chiral Unnatural Oligomers (C) 2067
Peptides
- Conformational Requirements for Sweet-Tasting Peptides and Peptidomimetics (R) 1437
- Enzymatic Grooming of Organic Thin Films (C) 871
- Expeditious Synthesis of a Novel C_3-Symmetric Receptor that Binds Peptides Sequence-Selectively (C) 2458
- Life During a Golden Age of Peptide Chemistry: The Concept and Development of Solid-Phase Peptide Synthesis (B) 1990
- Metal Complexes of Marine Peptide Metabolites: A Novel Ag_4 Cluster (C) 1516
- Synthesis, Crystal and Molecular Structure of Boc-Pro-ΔPhe-Ala-ΔPhe-Ala-OMe; A Pentapeptide with a Novel β-Bend Ribbon Structure (C) 970
- Synthesis of a New Unnatural Amino Acid with a Benzodiazepine-Containing Side Chain and Incorporation into a Tripeptide (C) 1737
Pericyclic rearrangements
- The Pressure Effect in Pericyclic Rearrangements: the Cope Rearrangement, Electrocyclization, and the Intramolecular Diels–Alder Reaction (C) 1079
Peroxides
- Jacobson and Heintschel Peroxides (C) 775
Phanes
- New Types of Metal-Stabilized Cyclobutadiene Superphanes (C) 1272
Phase transfer catalysis
- Phase Transfer Catalysis (B) 1669
- Phase Transfer Catalysis. Selected Problems and Applications (B) 1669
Phase transitions
- Phase Transitions in Self-Assembled Monolayers Detected by Electrochemistry (C) 2332
Phenothiazin
- Phenothiazinyl-Substituted Cyanines: Model Compounds for Molecular Switches (C) 572
Phenylalkyne oligomers
- Iterative Divergent/Convergent Approach to Linear Conjugated Oligomers by Successive Doubling of the Molecular Length: A Rapid Route to a 128Å-Long Potential Molecular Wire (C) 1360
Pheromones
- Chemical Communication. The Language of Pheromones (B) 236
Phosgene
- A Kinetic Study of the Hydrolysis of Phosgene in Aqueous Solution by Pulse Radiolysis (C) 1259
Phosphaalkynes
- A Novel Hexamer of tBuC≡P: Synthesis, Structure, and Theoretical Studies (C) 2202
- Novel Trimerization of Phosphaalkynes in the Coordination Sphere of Ruthenium Complexes (C) 463
- Reactivity of a Phosphanylcarbene (λ^5-Phosphaacetylene) with Lewis Acids: X-Ray Crystal Structures of the First Carbene–Gallane Complex and *C*-Gallyl-Substituted Phosphorus Ylide (C) 578
- The First Carbon–Phosphorus–Aluminum Cage Compounds: Cyclooligomerization of Phosphaalkynes with Trialkylaluminum Compounds (C) 1491
Phosphacymantrenes
- The Reactivity of Phosphacymantrenes towards Palladium(II) and Palladium(0) Compounds: Synthesis, Structure, and Chemistry of Pd_2Mn_2 and Pd_3Mn_4 Arrays (C) 742
Phospholes
- Toward Polyphospholes: Synthesis and Structure of an α-Linked Quaterphosphole (C) 1158
Phosphonates
- Preparation and Preliminary Characterization of a Covalently Pillared Zirconium Phosphate–Diphosphonate with Interlayer Microporosity (C) 1594
Phosphorothioates
- Stereocontrolled Synthesis of Oligo(nucleoside phosphorothioate)s (R) 709
Phosphorus compounds
- A Cluster-Bound Triply-Bridging Phosphorus Atom Coordinated to Four $(Ph_3P)Au^+$ Units: $[Fe_3(CO)_9P\{Au(PPh_3)\}_4][BAr_4]$ (C) 75
- A General Synthetic Strategy for Neutral Phosphorus-Containing Dendrimers (C) 1589
- Borophosphates–A Neglected Class of Compounds: Crystal Structures of $Mn^{II}[BPO_5]$ (M^{II} = Ca, Sr) and $Ba_3[BP_3O_{12}]$ (C) 749
- $(t\text{BuSi})_2(PC_6H_{11})_3$: A Propellane-Like Cyclosilaphosphane with Remarkable Structure (C) 1484
- Diastereoselective Reaction of a 1-Phosphaallyl Anion with an Alkyne: Structure of an Isolated Dihydrophospholyl Anion and Stereospecific Protonation to Give 2,3-Dihydrophosphole (C) 1953
- First Resolution of a Free Fluorophosphane Chiral at Phosphorus (C) 1835
- Monomeric Tris(imino)metaphosphates (C) 2111
- Phosphane Coordination to Magnesium: Synthesis and Structure of Bis[*ortho*, *ortho*'-bis{(dimethylphosphino)methyl}phenyl]magnesium (C) 2281
- Phosphindolyl Anions by Elimination from 1-Phosphoallyllithium Complexes—η^5 and η^3 Coordination of a Phospholyl Fragment (C) 353
- Structure of a Mixed Phosphate/Phosphonate Layered Zirconium Compound from Synchrotron X-Ray Powder Diffraction Data (C) 2324
- Synthesis and Characterization of the First Compounds Containing a Stable Phosphirenyl Cation: Crystal and Molecular Structure of $[Ni(\eta^3\text{-}PC_2t\text{Bu}_2)(\eta^5\text{-}P_3C_2t\text{Bu}_2)W(CO)_5]$ (C) 2330
- Synthesis and Crystal Structure of the First Tetraaminophosphonium Salt $P(NH_2)_4I$ (C) 785
- Synthesis and Structure of the First Hybrid Borazine–Phosphazene Ring (C) 2277
- Synthesis of the First Microporous Aluminum Phosphonate with Organic Groups Covalently Bonded to the Skeleton (C) 2335
- Synthesis of the First 2*H*-1-Aza-2-phosphirene Complexes (C) 80
- Tetralithiated Dibenzyl(methyl)phosphane (C) 2279
- The First Carbon–Phosphorus–Aluminum Cage Compounds: Cyclooligomerization of Phosphaalkynes with Trialkylaluminum Compounds (C) 1491
- The Influence of Charge Distribution on Bond Lengths in the P_4O_6 Framework in Compounds of the Type P_4O_6X (C) 563
Phosphorus ylides
- 3-Phosphonio-1,2-diphosphaindenides and the Electrophilic Substitution of *C*-Phenyl-Substituted Ylides (C) 663
- Reactions of an Iminophosphoranylidene Carbenoid (C) 982
- Reactions of C_3O_2 with Stabilized Triphenylphosphoranes $Ph_3P{=}CHX$ (X = CN, COMe, COPh) (C) 576
Phosphorylations
- Biomimetic Phosphonylation and Phosphorylation of Glycoses and Deoxynucleosides (C) 2302
Photoacoustic calorimetry
- Time-Resolved Photoacoustic Calorimetry: From Carbenes to Proteins (R) 294
Photochemistry

- Structure of an Antineoplastic Platinum Complex with a Bipyridyl-Crown Ether (C) 186

Polyacrylic acid
- Synthesis of Very Highly Ordered Liquid Crystalline Phases by Complex Formation of Polyacrylic Acid with Cationic Surfactants (C) 1869

Polycycles
- Octahydro-1,2,3:4,5,6-dimethenopentalene-2-carbonitrile, the First Derivative of a Yet-Unknown $(CH)_{10}$ Hydrocarbon (C) 1639
- Synthesis of Centrohexacyclic Hydrocarbons by the Propellane Route: Centrohexaindan and Tribenzocentrohexaquinane (C) 1251

Polyenes
- 1,1-Di-, 1,2,3-Tri-, and 1,1,4,4-Tetra-*tert*-butyl-1,3-butadiene (C) 1369
- Keronopsins A and B, Chemical Defence Substances of the Marine Ciliate *Pseudokeronopsis rubra* (Protozoa): Identification by Ex Vivo HPLC (C) 1495

Polyethers
- A Convergent Synthesis of 2,5-*trans*-Linked Oligo(tetrahydrofuran)s: Potential Building Blocks for a Polyether Helix with Ion Channel Activity (C) 1180
- A Multiple Five-Membered-Ring-Selective Williamson Reaction as a Key Step in the Stereoselective Construction of 2,5-Linked Oligo(tetrahydrofuran)s (C) 1873

Polymerase chain reaction
- The Polymerase Chain Reaction (Nobel Lecture) (R) 1209

Polymerization
- Monomer–Dimer Equilibria in Homo- and Heterodinuclear Cationic Alkylzirconium Complexes and Their Role in Polymerization Catalysis (C) 1634
- Synthesis and Ring-Opening Polymerization of Highly Strained Ring-Tilted [2]Ruthenocenophanes (C) 989

Polymers
- Ladder Polymers and Oligomers Based on Hemiporphyrazine (C) 1646
- Liquid Crystal Polymers (B) 1013
- Synthesis and Third-Order Nonlinear Optical Properties of a Conjugated Porphyrin Polymer (C) 655
- Synthesis of a Fully Unsaturated "Molecular Board" (C) 2209

Polyoxometalates
- Coexistence of Mobile and Localized Electrons in Bis(ethylene)dithiotetrathiafulvalene (BEDT-TTF) Radical Salts with Paramagnetic Polyoxometalates: Synthesis and Physical Properties of $(BEDT\text{-}TTF)_8[CoW_{12}O_{40}]\cdot 5.5H_2O$ (C) 223
- $(H_3N(CH_2)_6NH_3)_4[W_{18}P_2O_{62}]\cdot 3H_2O$, a Microporous Solid from Dawson Anions and 1,6-Diaminohexane (C) 2491
- $[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$: A Highly Symmetrical Giant Cluster with an Unusual Cavity and the Possibility of Positioning Paramagnetic Centers on Extremely Large Cluster Surfaces (C) 849
- Novel Conjugation of Hetero(macro)cycles and a Pentamolybdodiphosphonate Cage (C) 451
- Synthesis and Structure of Oxovanadium(v)-Organophosphonate Cluster Encapsulating a Chloride Ion: $[ClV_7O_{12}(O_3PC_6H_5)_6]^{2-}$ (C) 325
- The Oxovanadium–Organoarsonate System: $[2\,CH_3OH \subset V_{12}O_{14}(OH)_4(PhAsO_3)_{10}]^{4-}$ and $[2\,H_2O \subset V_{12}O_{12}(OH)_2(H_2O)_2(PhAsO_3)_{10}(PhAsO_3H)_4]^{2-}$, Clusters with Nanometer Dimensions and Cavities for Neutral Molecules (C) 760
- The Oxovanadium–Organophosphonate System: Complex Cluster Structures $[(VO)_6(tBuPO_3)_8Cl]$, $[(VO)_4\{PhP(O)_2OP(O)_2Ph\}_4Cl]^-$, and $[V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}Cl_4]^{4-}$ with Encapsulated Chloride Anions Prepared from Simple Precursors (C) 757

Polythioethers
- Strategies for Nonmacrocyclic Polythioether Ligands: New Pentacoordinating Architectures (C) 319

Polyynes
- Hexaspiro[2.4.2.4.2.4.2.4.2.4.2.4]dotetraconta-4,6,11,13,18,20,25,27,32,34,39,41-dodecayne—An Exploding [6]Rotane (C) 869
- Polyynes—Fascinating Monomers for the Construction of Carbon Networks? (H) 1073
- Stable Soluble Conjugated Carbon Rods with a Persilylethynylated Polytriacetylene Backbone (C) 763

Porphycenes
- μ-Oxodiiron(III) Complexes of Porphycenes (C) 736

Porphyrazines
- Ladder Polymers and Oligomers Based on Hemiporphyrazine (C) 1646

Porphyrinoids
- Benziporphyrin, a Benzene-Containing, Nonaromatic Porphyrin Analogue (C) 1246
- Biomimetic Model for a Photosynthetic Reaction Center: A Porphyrin with a Covalently Linked, Redox-Active Crown Ether (C) 2318
- Chiroporphyrins: An Approach to Asymmetric Catalysts with Stereocenters Near the Plane of the Porphyrin Ring (C) 220
- Conformational Effects on the Redox Potentials of Tetraarylporphyrins Halogenated in the β-Pyrrole-Positions (C) 348
- Corrphycene: A New Porphyrin Isomer (C) 2308
- Crystal Structure of a Supramolecular Dimer Formed by π–π Interactions between Two Interlocked Cyclic Zinc Porphyrin Trimers (C) 429
- Dendritic Porphyrins: Modulating Redox Potentials of Electroactive Chromophores with Pendant Multifunctionality (C) 1739
- Enzyme Mimics (H) 551
- Facile Reduction of a Dialkyl Zirconium(IV) Octaethylporphyrin (OEP) Complex by H_2: Crystal Structure and Spectroscopic Characterization of $[(OEP)Zr\text{-}CH_2SiMe_3]$ (C) 95
- Free Acid Porphyrin and Its Conjugated Monoanion (C) 2215
- "Free" $[Fe(tpp)]^+$ Cation: A New Concept in the Search for the Least Coordinating Anion (C) 2433
- Metallocorroles with Formally Tetravalent Iron (C) 731
- Molecular Catalysts for Multielectron Redox Reactions of Small Molecules: The "Cofacial Metallodiporphyrin" Approach (R) 1537
- New Porphyrin Isomers (H) 1348
- New Porphyrinoid Macrocycles Containing Pyridine (C) 219
- μ-Oxodiiron(III) Complexes of Porphycenes (C) 736
- Platinum(II) Complexes with Porphyrin Ligands—Additive Cytotoxic and Photodynamic Effect (C) 2214
- Porphyrin–Quinone Cyclophanes with Gradually Varied Donor–Acceptor Distances (C) 2428
- Porphyrins with Biconcave Frameworks (C) 889
- Self-Assembly of a Dimeric Porphyrin Host (C) 2313

- Sterically Strained Porphyrins—Influence of Core Protonation and Peripheral Substitution on the Conformation of Tetra-*meso*-, Octa-β-, and Dodeca-Substituted Porphyrin Dications (C) 2485
- Synthesis and Properties of a Vertically Stacked Porphyrin(1)-Porphyrin(2)-Quinone Cyclophane (C) 1466
- Synthesis and Properties of a Vertically Stacked Porphyrin-Quinone(1)-Quinone(2) Cyclophane (C) 1463
- Synthesis and Third-Order Nonlinear Optical Properties of a Conjugated Porphyrin Polymer (C) 655
- 5,10,15,20-Tetra-*tert*-butylporphyrin and Its Remarkable Reactivity in the 5- and 15-Positions (C) 1879
- Tetraoxa[22]porphyrin(2.2.2.2) Dication and Tetraoxa[24]porphyrinogens(2.2.2.2) (C) 1151
- Tetra-*p*-tolylporphyrin with an Inverted Pyrrole Ring: A Novel Isomer of Porphyrin (C) 779
- Turcasarin, the Largest Expanded Porphyrin to Date (C) 1509

Propellanes
- Synthesis of Centrohexacyclic Hydrocarbons by the Propellane Route: Centrohexaindan and Tribenzocentrohexaquinane (C) 1251

Prostacyclin
- Prostacyclin and Thromboxane Synthase: New Aspects of Hemethiolate Catalysis (R) 1911

Protecting groups
- A Facile One-Pot Synthesis of a Trisaccharide Unit from the Common Polysaccharide Antigen of Group B *Streptococci* Using Cyclohexane-1,2-diacetal (CDA) Protected Rhamnosides (C) 2292
- Cyclohexane-1,2-diacetals (CDA): A New Protecting Group for Vicinal Diols in Carbohydrates (C) 2290
- The Selective Blocking of *trans*-Diequatorial, Vicinal Diols; Applications in the Synthesis of Chiral Building Blocks and Complex Sugars (H) 2272

Proteins
- Peptidyl-Prolyl *cis/trans* Isomerases and Their Effectors (R) 1415
- Protein Structure Determination with Three- and Four-Dimensional NMR Spectroscopy (R) 277

Protocyanin
- Composition of Protocyanin, A Self-Assembled Supramolecular Pigment from the Blue Cornflower, *Centaurea cyanus* (C) 978

Protonations
- Catalytic Enantioselective Protonation of Enolates (C) 1888
- Diastereoselective Reaction of a 1-Phosphaallyl Anion with an Alkyne: Structure of an Isolated Dihydrophospholyl Anion and Stereospecific Protonation to Give 2,3-Dihydrophosphole (C) 1953
- Enantioselective Protonation of Simple Enolates: Chiral Imide as a Chiral Proton Source (C) 107
- Substituent Effects and Complexation Phenomena in the Diastereoselective Protonation of Chiral Enolates (C) 1764

Proton transfer
- Proton-Transfer-Dependent Reversible Phase Changes in the 4,4'-Bipyridinium Salt of Squaric Acid (C) 181

Purple acid phosphatases
- A Mixed-Valent, Unsymmetrical Fe^{II}-Fe^{III} Complex with a Terminal Phenola to Ligand as a Model for the Active Site of Purple Acid Phosphatases (C) 887

Pyranoses
- Enol Triflate Pyranoses, Versatile Reagents for the Formation of Conjugated Systems on Pyranoses (C) 1499

Pyridazomycin
- Biosynthetic Investigations on Pyridazomycin (C) 1648

Pyrrolidines
- A New Synthesis of 1,3,4-Trideoxy-1,4-iminoglycitols of Varying Chain Length by $(C_3 + C_n)$-Coupling of Allyl Halides with Glyconontrile Oxides (C) 1295
- Asymmetric Synthesis of Highly Substituted Pyrrolidines by 1,3-Dipolar Cycloadditions of Azomethine Ylides with *N*-Acryloylproline Benzyl Ester (C) 683
- Remarkable Stereoselectivity in the Inhibition of α-Galactosidase from Coffee Bean by a New Polyhydroxypyrrolidine Inhibitor (C) 1242

Pyrrolnitrin
- The Biosynthesis of Nitro Compounds: The Enzymatic Oxidation to Pyrrolnitrin of its Amino-Substituted Precursor (C) 352

Quinodimethanes
- Buckminsterfullerene Adducts from *Ortho*-Quinodimethanes (C) 559

Quinones
- Enediyne Quinone Imines: Truncated, Biologically Active Dynemicin Congeners (C) 2477
- Porphyrin–Quinone Cyclophanes with Gradually Varied Donor–Acceptor Distances (C) 2428
- Synthesis and Properties of a Vertically Stacked Porphyrin(1)-Porphyrin(2)-Quinone Cyclophane (C) 1466
- Synthesis and Properties of a Vertically Stacked Porphyrin-Quinone(1)-Quinone(2) Cyclophane (C) 1463

Rabelomycin
- First Total Synthesis of (±)-Rabelomycin (C) 99

Radialenes
- Efficient Synthesis of Heteroradialenes by SN' Reaction (C) 1270
- Expanded Radialenes: A Novel Class of Cross-Conjugated Macrocycles (C) 468

Radical anions
- Purely Organic Mixed-Valence Molecules with Nanometric Dimensions Showing Long-Range Electron Transfer: Synthesis, and Optical and EPR Studies of a Radical Anion Derived from a Bis(triarylmethyl)Diradical (C) 2106
- The Spin Density Distribution in the Tetracyanoethylene Radical Anion, $[TCNE]^{\cdot -}$, by Single-Crystal Polarized Neutron Diffraction (C) 1397

Radical cations
- The First Spectroscopic Identification of an Enol Radical Cation in Solution: The Anisyldimesitylethenol Radical Cation (C) 1961

Radical ions
- Molecular Distortion in Reactive Chemical Intermediates (H) 962

Radicals
- A Kinetic Study of the Hydrolysis of Phosgene in Aqueous Solution by Pulse Radiolysis (C) 1259
- Calixarene-Based Macrocyclic Nonet ($S = 4$) Octaradical and its Acyclic Sextet ($S = 5/2$) Pentaradical Analogue (C) 2091
- Combination of Superexchange and Spin-Polarization Mechanisms Leads to a Novel Hydrocarbon Tetraradical with a High-Spin Ground State (C) 1104
- Determination of the Kinetics of Vinyl Radical Reactions by the Characteristic Visible Absorption Spectra of Vinylperoxyl Radicals (C) 1262
- Half a Century of Free Radical Chemistry (B) 1009
- Preparation of Chiral Nitroxide Radicals and Spontaneous Optical Resolution by Recrystallization (C) 878
- Prostacyclin and Thromboxane Synthase: New Aspects of Hemethiolate Catalysis (R) 1911
- Recycling in the Earth's Atmosphere: The OH Radical—Its Importance for the Chemistry of the Atmosphere and the Determination of Its Concentration (R) 1816
- Samarium Iodide Induced Intramolecular C-Glycoside Formation: Efficient Radical Formation in the Absence of an Additive (C) 1383
- Stereoselective Reactions of Sulfinylated Benzyl Radicals: Effects of Solvents and Lewis Acids (C) 1601
- Synthesis and Selective Radical Cleavage of C-4'-Modified Oligonucleotides (C) 1861
- The $S_{RN}2$ Pathway—A Mechanistic Alternative for Radicals in Polar Media? (C) 1985

Radiochemistry
- Handbook of Hot Atom Chemistry (B) 1198

Radiopharmaceuticals
- Technetium Radiopharmaceuticals—Fundamentals, Synthesis, Structure, and Development (R) 2258

Raman spectroscopy
- Fourier Transform Raman Spectroscopy. Instrumentation and Chemical Applications (B) 361
- Thermal Decomposition of Silver Oxide Monitored by Raman Spectroscopy: From AgO Units to Oxygen Atoms Chemisorbed on the Silver Surface (C) 85

Reaction mechanisms
- A Kinetic Study of the Hydrolysis of Phosgene in Aqueous Solution by Pulse Radiolysis (C) 1259
- An Extraordinarily Violent Molecular Dissociation: The Unprecedented Kinetic Energy Release in the Decomposition of $HONF^+$, a Singly Charged Metastable Ion (C) 123
- α-Aryliodonio Diazo Compounds: S_N Reactions at the α-C Atom as a Novel Reaction Type for Diazo Compounds (C) 1952
- Determination of Reaction Paths for Pentacoordinate Metal Complexes with the Structure Correlation Method (R) 823
- Determination of the Kinetics of Vinyl Radical Reactions by the Characteristic Visible Absorption Spectra of Vinylperoxyl Radicals (C) 1262
- Electrostatic vs. Orbital Control of Facial Selectivities in π Systems: Experimental and Theoretical Study of Electrophilic Additions to 7-Isopropylidenenorbornanes (C) 1390
- Free-Energy Relationship for Mesolytic Cleavage of C–C Bonds (C) 73
- Magnetic Properties of Aromatic Transition States: The Diels–Alder Reactions (C) 1376
- Nonreactive Interactions between Ethene and Halogens: Detection of a π-Donor Complex $C_2H_4 \cdots BrCl$ by Rotational Spectroscopy (C) 1512
- On the Mechanism of the Urocanase Reaction: Confirmation of the Structure of the NAD^+-Inhibitor Adduct by Direct ^{13}C-^{13}C Coupling (C) 1279

- Organizing Principle of Complex Reactions and Theory of Coarctate Transition States (R) 255
- Scales of Nucleophilicity and Electrophilicity: A System for Ordering Polar Organic and Organometallic Reactions (R) 938
- The $S_{RN}2$ Pathway—A Mechanistic Alternative for Radicals in Polar Media? (C) 1985

Reagents
- A Reagent for Determining Optical Purities of Diols by Formation of Diastereomeric Arylboronate Esters (C) 1182
- A Regioselective Palladium-Catalyzed Reduction of 3,3-Heterobimetalated Allylic Acetates–Synthesis and Reactivity of Allylic Bimetallic Compounds (C) 2448
- Enantiosclective Transformations and Racemization Studies of Heteroatom Substituted Organolithium Compounds (H) 175
- Enol Triflate Pyranoses, Versatile Reagents for the Formation of Conjugated Systems on Pyranoses (C) 1499
- O-Glycoside Syntheses under Neutral Conditions in Concentrated Solutions of $LiClO_4$ in Organic Solvents (C) 1944
- On the Nature of Zinc Chloride–Aldehyde Interactions (C) 2089
- Reactions in Supercritical Carbon Dioxide (H) 1452
- Sulphones in Organic Synthesis (B) 1404
- Supported Reagents. Preparation, Analysis and Applications (B) 239
- Synthesis and Properties of 2,4,6-Trimethylphenylborane (Mesitylborane), a Stable Alternative to Thexylborane (C) 851

Rearrangements
- An Antibody-Catalyzed 1,2-Rearrangement of Carbon–Carbon Bonds (C) 1607
- [2,3] Sigmatropic Wittig Rearrangement of Chiral Allyloxyacetaldehyde Hydrazones in the Diastereo- and Enantioselective Synthesis of Protected, γ,δ-Unsaturated α-Hydroxyaldehydes and Cyanohydrins (C) 2098
- Nitrile Imines: From Matrix Characterization to Stable Compounds (R) 527
- Synthesis of Unsaturated Amino Acids by [3,3]-Sigmatropic Rearrangement of Chelate-Bridged Glycine Ester Enolates (C) 998

Receptors
- Expeditious Synthesis of a Novel C_3-Symmetric Receptor that Binds Peptides Sequence-Selectively (C) 2458
- Mapping the Electrostatic Potential of Muscarinic and Nicotinic Agonists with Artificial Neural Networks (C) 643

Redox reactions
- Molecular Catalysts for Multielectron Redox Reactions of Small Molecules: The "Cofacial Metallodiporphyrin" Approach (R) 1537

Redox systems
- Dendritic Porphyrins: Modulating Redox Potentials of Electroactive Chromophores with Pendant Multifunctionality (C) 1739
- Redox Control for the Recognition of Ag^+ Ions in a Macrocycle Containing Two SH Groups or an S–S Bridge inside the Cavity (C) 1750

Reductions
- A Regioselective Palladium-Catalyzed Reduction of 3,3-Heterobimetalated Allylic Acetates–Synthesis and Reactivity of Allylic Bimetallic Compounds (C) 2448
- Enantioselective Reactions in a Static Magnetic Field (C) 454 (1461)
- Facile Reduction of a Dialkyl Zirconium(IV) Octaethylporphyrin (OEP) Complex by H_2: Crystal Structure and Spectroscopic Characterization of [(OEP)Zr-CH_2SiMe_3] (C) 95
- Novel Copper Nitrosyl Complexes: Contributions to the Understanding of Dissimilatory, Copper-Containing Nitrite Reductases (H) 2057
- Reductive Disproportionation of NO Mediated by Copper Complexes: Modeling N_2O Generation by Copper Proteins and Heterogeneous Catalysts (C) 895
- Supramolecular Activation of *para*-Benzoquinone (C) 2489

Rhenium compounds
- A Building Principle of Amorphous Chalcogenides of Transition Metals: The "Extrusion" of the Electron Rich Cluster $[Re_4S_2(SO_2)_4(CN)_{10}]^{8-}$ from a-Re_2S_7 (C) 770
- Direct Metal–Metal Bonds Between High and Low Valent Complex Fragments: The Reaction of Metal Bases with the Metal Acids $[Re(NR)_3]^+$ and $[Mo(NR)_2]^{2+}$ (C) 678
- Reactions at Both Ends of a Dimetalated Olefin: CS_2 Insertion into and Atom Transfer Reactions of $[Re(CO)_4\{trans\text{-}\mu\text{-}HC{=}C(CO_2Me)\}Re(CO)_4(NCMe)]$ (C) 568
- $[Re_2I_2(CO)_6(Se_7)]$, a Coordination Compound of Elemental Selenium with a Transition Metal: a Solution- and Solid-State Study (C) 193
- Towards One-Dimensional Carbon Wires Connecting Single Metal Centers: A Cumulenic C_5 Chain that Mediates Charge Transfer between Rhenium and Manganese Termini (C) 2199
- Trigonal-Bipyramidal Technetium and Rhenium Complexes with Tetradentate NS_3 Tripod Ligands (C) 1354

Rhodium compounds
- $[\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]^{2+}$: A Novel Tetranuclear Cationic Complex with a Rectangular S_4 Unit (C) 1882
- Cooperativity in Rh_2 Complexes: High Catalytic Activity and High Regioselectivity in the Hydroformylation of Olefins (H) 67
- Increase in the Enantioselectivity of Asymmetric Hydrogenation in Water Influenced by Surfactants or Polymerized Micelles (C) 2197
- Ligand Effects on the Chemoselectivity of Transition Metal Catalyzed Reactions of α-Diazo Carbonyl Compounds (R) 1797
- Novel Bimetallic Model System for Cytochrome P_{450}: Effect of Membrane Environment on the Catalytic Oxidation (C) 2468
- Novel Rh^I Piano-Stool Complexes with New Hemilabile Ligands Ligating through Phosphane and Arene Groups: Synthesis, Characterization, and Reactivity (C) 2473
- The First Decaisopropylmetallocene: One-Pot Synthesis of $[Rh(C_5iPr_5)_2]PF_6$ from $[Rh(C_5Me_5)_2]PF_6$ by Formation of 20 Carbon–Carbon Bonds (C) 1637
- Trialkylstibanes as Bridging Ligands: Synthesis and Structure of the Dinuclear Complexes $[Rh_2Cl_2(\mu\text{-}SbiPr_3)(\mu\text{-}CR_2)_2]$ (C) 97

Ring contractions
- Ring Contractions in Carbohydrates (H) 1345

RNA
- Split Genes and RNA Splicing (Nobel Lecture) (R) 1229

RNA aptamers
- Isolation of RNA Aptamers for Biological Cofactors by In Vitro Selection (C) 1084

RNA cleavage
- Lanthanide(III) Tetraamide Macrocyclic Complexes as Synthetic Ribonucleases: Structure and Catalytic Properties of $[La(tcmc)(CF_3SO_3)(EtOH)](CF_3SO_3)_2$ (C) 773

RNA polymerases
- Gene Regulation in Eukaryotes (B) 2349

Roelen, Otto
- Otto Roelen, Pioneer in Industrial Homogeneous Catalysis (R) 2144 (2348)

Rotanes
- Hexaspiro[2.4.2.4.2.4.2.4.2.4.2.4]dotetraconta-4,6,11,13,18,20,25,27,32,34,39,41-dodecayne–An Exploding [6]Rotane (C) 869

Ruthenium compounds
- $[Ru_3(CO)_6(\eta^5{:}\eta^1\text{-}C_5H_4)_3]$: The First Six-Membered Ru_3C_3 Ring Formed by Insertion of C_5H_4 Units into Metal–Metal Bonds of $[Ru_3(CO)_{12}]$ (C) 2193
- A Water-Soluble "Bear Trap" Exhibiting Strong Anion Complexation Properties (C) 2456
- Construction of Carbon Frameworks with the Help of Ruthenium Complexes: 1,5-Cyclooctadiene as a Reagent in Transition Metal Catalyzed Reactions (H) 636
- Copper(II)-Mediated Oxidative Coupling of Bis(dimethylaminomethyl)arylruthenium Complexes to give $[(terpy)Ru^{III}(pincer\text{-}pincer)Ru^{III}(terpy)](CuCl_2)_4$ (C) 1282
- Desulfurization of Benzo[*b*]thiophene by S/Ru Exchange: Formation and Structure of the Cluster $[Ru_3(CO)_8(C_8H_6)]$ (C) 1381
- Electron Delocalization in Ethynyl-Bridged Binuclear Ruthenium(II) Polypyridine Complexes (C) 1884
- From Triple-Decker to Metallabenzene: A New Generation of Sandwich Complexes (C) 1003
- Magnetic Spin Effects on Photooxidation Quantum Yields of Ru^{II}-tris(bipyridine) Type Complexes in Magnetic Fields up to 17.5 Tesla (C) 1772
- Novel Trimerization of Phosphaalkynes in the Coordination Sphere of Ruthenium Complexes (C) 463
- Pronounced Electronic Coupling in Rigidly Connected N,C,N-Coordinated Diruthenium Complexes over a Distance of Up to 20 Å (C) 1775
- Propeller Isomerism of the Triphenylphosphane Ligand in Half-Sandwich Ru^{II} Complexes (C) 866
- Synthesis and Ring-Opening Polymerization of Highly Strained Ring-Tilted [2]Ruthenocenophanes (C) 989

Salbostatin
- The Trehalase Inhibitor Salbostatin, a Novel Metabolite from *Streptomyces albus*, ATCC 21838 (C) 1844

Sandwich complexes
- An Efficient Access to Organocerium(IV) Complexes: Synthesis and Structure of Bis[1,3,6-tris(trimethylsilyl)cyclooctatetraene]cerium(IV) (C) 1618
- A Novel Organomagnesium Compound Consisting of Two Triple-Decker Cations $[LMg(\mu\text{-}Me)_3MgL]^+$ and an Octamethyltrimagnesate Anion: $[\{Me_2Mg(\mu\text{-}Me)_2\}_2Mg]^{2-}$ (C) 1257
- $[Cp^*Fe(\eta^5\text{-}P_5)]$, a Sandwich Complex with Diverse Ligand Properties (C) 1110

- Cyclopropanation by Methylene Transfer from (η^2-Formaldehyde)zirconocene Complexes (C) 1955
- Decaphenylferrocene and Decaphenylferrocenium Tetrafluoroborate (C) 1731
- Doubly Bridged *rac*-Metallocenes of Zirconium and Hafnium (C) 1946
- From Triple-Decker to Metallabenzene: A New Generation of Sandwich Complexes (C) 1003
- New Upswing of Organolanthanoid Research: A Very Promising Revival of Organocerium(IV) Chemistry and the First Stable Lanthanoid(II/III)–Carbene Complexes (H) 2165
- (η^5-Pentamethylcyclopentadienyl)iron Complexes with η^5-2,3,5-Tricarbahexaboranyl and η^5-2,3-Dihydro-1,3-diborolyl Ligands (C) 203
- Single-Step Six-Electron Transfer in a Heptanuclear Complex: Isolation of Both Redox Forms (C) 2460
- Synthesis and Characterization of the First Compounds Containing a Stable Phosphirenyl Cation: Crystal and Molecular Structure of $[Ni(\eta^3\text{-}PC_2tBu_2)(\eta^5\text{-}P_3C_2tBu_2)W(CO)_5]$ (C) 2330
- Synthesis and Crystal Structure of the "Open" Calcocene $[(tBu_2C_5H_5)Ca\cdot thf]$ (C) 2191
- Synthesis and Ligative Behavior of a Gallacyclopentadiene (C) 1370
- Synthesis and Ring-Opening Polymerization of Highly Strained Ring-Tilted [2]Ruthenocenophanes (C) 989
- Synthesis and Structure of the First [2_2]Metallocenophanes (C) 1479
- Synthesis and Structure of the First Titanium(IV) α-Amino Acid Complexes (C) 1518
- Tetraaza[14]annulenezirconium(IV) Complexes with Butadiene Ligands and their Relationship with Bis(cyclopentadienyl)-zirconium(IV) Complexes (C) 2204
- The First Decaisopropylmetallocene: One-Pot Synthesis of $[Rh(C_5iPr_5)_2]PF_6$ from $[Rh(C_5Me_5)_2]PF_6$ by Formation of 20 Carbon–Carbon Bonds (C) 1637
- The First Metal Complexes with a Doubly S_3-Bridged Ferrocene Ligand (C) 1752
- The Lithocene Anion and "Open" Calcocene– New Impulses in the Chemistry of Alkali and Alkaline Earth Metallocenes (H) 2168
- The Simplest Metallocene Sandwich: the Lithocene Anion (C) 1744

Scanning electron microscopy
- Scanning Electron Microscopy and X-Ray Analysis (B) 1306

Scanning tunneling microscopy
- Photodecomposition of 10-Diazo-2-hexadecylanthrone on Graphite Studied by Scanning Tunneling Microscopy (C) 2080
- Scanning Tunneling Microscopy and Spectroscopy. Theory, Techniques, and Applications (B) 2226

Schweizer's reagent
- Cellulose in Schweizer's Reagent: A Stable, Polymeric Metal Complex with High Chain Stiffness (C) 884

Selenium compounds
- $[Cu_{44}Se_{22}(PEt_2Ph)_{18}]$ and $[Cu_{44}Se_{22}(PnButBu_2)_{12}]$: Synthesis and Structure of Two Copper Clusters with Isomeric Cu–Se Frameworks (C) 2287
- New Sulfur- and Selenium-Bridged Copper Clusters; Ab Initio Calculations on $[Cu_{2n}Se_n(PH_3)_m]$ Clusters (C) 746
- Polynuclear Lanthanide Complexes: Formation of a Selenium-Centered Sm_6 Complex, $[\{(C_5Me_5)Sm\}_6Se_{11}]$, (C) 2110
- $[Re_2I_2(CO)_6(Se_7)]$, a Coordination Compound of Elemental Selenium with a Transition Metal: a Solution- and Solid-State Study (C) 193
- Synthesis and Characterization of the First Thiaselanes (C) 1770
- Synthesis and Selective Radical Cleavage of C-4′-Modified Oligonucleotides (C) 1861
- Synthesis and Structure of the First Stable Germaneselone (C) 2316

Self-assembly
- A Liquid-Crystalline Polymer Network Built by Molecular Self-Assembly through Intermolecular Hydrogen Bonding (C) 1644
- Assembly Properties of Bolaamphiphiles from Dimeric Acids (C) 2078
- A Water-Soluble Prodrug of Taxol with Self-Assembling Properties (C) 1583
- Construction of a Multiwired Molecular Cable of Micrometer Length by a Self-Assembly Process (C) 2173
- Designer Proteins: On the Art of Synthesizing De Novo Metalloproteins (H) 2055
- Micrometer-Scale Lateral Structuring of Organic Thiolate Layers through Self-Organization (C) 1274
- Phase Transitions in Self-Assembled Monolayers Detected by Electrochemistry (C) 2332

Trimethylenemethane
- Bis(pentamethylcyclopentadienyl)(η^3-trimethylenemethane)zirconium: A New Mode of Bonding for the Trimethylenemethane Ligand (C) 2465

Trimethylphenylborane
- Synthesis and Properties of 2,4,6-Trimethylphenylborane (Mesitylborane), a Stable Alternative to Thexylborane (C) 851

Triphenylmethyl radical
- Jacobson and Heintschel Peroxides (C) 775

Tris(imino)metaphosphates
- Monomeric Tris(imino)metaphosphates (C) 2111

Trivial names
- Dictionary of Trivial Names/Trivialnamen-Handbuch (B) 1305

Tungsten compounds
- $(H_3N(CH_2)_6NH_3)_4[W_{18}P_2O_{62}]\cdot 3\,H_2O$, a Microporous Solid from Dawson Anions and 1,6-Diaminohexane (C) 2491
- Synthesis and Characterization of the First Compounds Containing a Stable Phosphirenyl Cation: Crystal and Molecular Structure of $[Ni(\eta^3\text{-}PC_2tBu_2)(\eta^5\text{-}P_3C_2tBu_2)W(CO)_5]$ (C) 2330
- Synthesis and Structure of $[WOTe_3]^{2-}$ (C) 1859
- Thermally Induced Ring Cleavage of a 2*H*-1,2-Azaphosphirene Tungsten Complex (C) 2427

Turcasarin
- Turcasarin, the Largest Expanded Porphyrin to Date (C) 1509

Uranium compounds
- A Difunctional Receptor for the Simultaneous Complexation of Anions and Cations; Recognition of KH_2PO_4 (C) 467

Urea
- Zigzag Channels in the Structure of Sebaconitrile/Urea (C) 649

Urocanase
- On the Mechanism of the Urocanase Reaction: Confirmation of the Structure of the NAD^+-Inhibitor Adduct by Direct ^{13}C-^{13}C Coupling (C) 1279

Valence isomerization
- 3,3'-Bis(dicyanomethylene)-4,4,4',4'-tetramethyl-2,2'-bithiolanylidene, a Compound Containing the Fundamental Chromophore of Thioindigo: (*E*/*Z*) and Valence Isomers, Thermo- and Photochromism (C) 1966

Vanadium compounds
- Synthesis and Structure of Oxovanadium(v)-Organophosphonate Cluster Encapsulating a Chloride Ion: $[ClV_7O_{12}(O_3PC_6H_5)_6]^{2-}$ (C) 325
- The Oxovanadium–Organoarsonate System: $[2\,CH_3OH \subset V_{12}O_{14}(OH)_4(PhAsO_3)_{10}]^{4-}$ and $[2\,H_2O \subset V_{12}O_{12}(OH)_2(H_2O)_2(PhAsO_3)_{10}(PhAsO_3H)_4]^{2-}$, Clusters with Nanometer Dimensions and Cavities for Neutral Molecules (C) 760
- The Oxovanadium–Organophosphonate System: Complex Cluster Structures $[(VO)_6(tBuPO_3)_8Cl]$, $[(VO)_4\{PhP(O)_2OP(O)_2Ph\}_4Cl]^-$, and $[V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}Cl_4]^{4-}$ with Encapsulated Chloride Anions Prepared from Simple Precursors (C) 757

Vesicles
- Molecular Golf Balls: Vesicles from Bowl-Shaped Host Molecules (C) 1662
- Sterically Stabilized Vesicles (R) 1685
- Tunable Supramolecular Structures from a Gluconamide Containing Imidazole (C) 986

Vinyl radicals
- Determination of the Kinetics of Vinyl Radical Reactions by the Characteristic Visible Absorption Spectra of Vinylperoxyl Radicals (C) 1262

Vitamins
- Homogeneous Catalytic Oxidation of Arenes and a New Synthesis of Vitamin K_3 (C) 2475

Wacker oxidations
- Wacker Oxidation of 1-Decene to 2-Decanone in the Presence of a Chemically Modified Cyclodextrin System: A Happy Union of Host–Guest Chemistry and Homogeneous Catalysis (C) 2100

Water oxidation
- Oxygen Evolution by Oxidation of Water with Manganese Porphyrin Dimers (C) 1839

X-ray absorption spectroscopy
- X-Ray Absorption Spectroscopy of Amorphous Solids, Liquids, and Catalytic and Biochemical Systems—Capabilities and Limitations (R) 45

Zaragozic acids
- Synthesis of the First Fully Functionalized Core of the Zaragozic Acids/Squalestatins (C) 2187
- Total Synthesis of Zaragozic Acid A/Squalestatin S1 (C) 2190
- Zaragozic Acid A/Squalestatin S1: Synthetic and Retrosynthetic Studies (C) 2184

Zeolites
- A Novel Open-Framework Cobalt Phosphate Containing a Tetrahedrally Coordinated Cobalt(II) Center: $CoPO_4\cdot 0.5\,C_2H_{10}N_2$ (C) 639
- $(H_3N(CH_2)_6NH_3)_4[W_{18}P_2O_{62}]\cdot 3\,H_2O$, a Microporous Solid from Dawson Anions and 1,6-Diaminohexane (C) 2491
- Ionization and Delocalization in Potassium Zeolite L: A Combined Neutron Diffraction and Electron Spin Resonance Study (C) 641
- Schiff Base Complexes with Five-Coordinate Cobalt as Dioxygen Activating Sites in Zeolites (C) 431
- Stable Silanetriols as Building Blocks for the Synthesis of Titanasilasesquioxanes—Model Compounds for Titanium-Doped Zeolites (C) 1352
- Synthesis of the First Microporous Aluminum Phosphonate with Organic Groups Covalently Bonded to the Skeleton (C) 2335

- Zeolite, Clay and Heteropoly Acid in Organic Reactions (B) 1893

Zinc compounds
- Crystal Structure of a Supramolecular Dimer Formed by $\pi-\pi$ Interactions between Two Interlocked Cyclic Zinc Porphyrin Trimers (C) 429
- On the Nature of Zinc Chloride–Aldehyde Interactions (C) 2089

Zirconium compounds
- A Template Synthesis of Stable Conjugated Primary Enamines from Ketones, Nitriles, and Butadiene (C) 1114
- Bis(pentamethylcyclopentadienyl)(η^3-trimethylenemethane)zirconium: A New Mode of Bonding for the Trimethylenemethane Ligand (C) 2465
- Cyclopropanation by Methylene Transfer from (η^2-Formaldehyde)zirconocene Complexes (C) 1955
- Doubly Bridged *rac*-Metallocenes of Zirconium and Hafnium (C) 1946
- Facile Reduction of a Dialkyl Zirconium(IV) Octaethylporphyrin (OEP) Complex by H_2: Crystal Structure and Spectroscopic Characterization of [(OEP)Zr-CH_2SiMe_3] (C) 95
- Monomer–Dimer Equilibria in Homo- and Heterodinuclear Cationic Alkylzirconium Complexes and Their Role in Polymerization Catalysis (C) 1634
- Preparation and Preliminary Characterization of a Covalently Pillared Zirconium Phosphate–Diphosphonate with Interlayer Microporosity (C) 1594
- Reactions of [(C_5Me_5)ZrF_3] with $AlMe_3$—Synthesis and Structure of a Zirconium–Aluminum–Carbon Cluster (C) 967
- Structure of a Mixed Phosphate/Phosphonate Layered Zirconium Compound from Synchrotron X-Ray Powder Diffraction Data (C) 2324
- Synthesis and Structure of the Smallest Cyclic Cumulene; Reaction of 1,3-Diynes with Zirconocene Complexes (C) 1605
- Tetraaza[14]annulenezirconium(IV) Complexes with Butadiene Ligands and their Relationship with Bis(cyclopentadienyl)-zirconium(IV) Complexes (C) 2204
- Tris(η^4-naphthalene)zirconate(2−) (C) 1973
- Unexpected Reactions of Acetylenedicarboxylates with Zirconocene Complexes (C) 1850
- [$Zr_3Cp_2(O_2CNiPr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}CCO)$], the First Crystallographically Established Ketenylidene Complex; A Model for CO Reductive Cleavage on Metal Surfaces (C) 1188

Zoapatanol
- A Total Synthesis of (+)-2′*S*,3′*R*-Zoapatanol (C) 2182
