Two pairs of enantiomers [(Δ)-, (Λ)-*fac* and (Δ)-, (Λ)-*mer*] are principally possible for octahedral complexes of type MA_3B_3 [for bidentate ligands: $M(AB)_3$]. The chiral racemic complexes **2** and **3** crystallize in the cubic space group $Fd\bar{3}$. All four iron centers in **2** and **3** are identically coordinated, hence the complexes are present as either ($\Delta,\Delta,\Delta,\Delta$)-*fac* or as ($\Lambda,\Lambda$, Λ,Λ)-*fac* stereoisomers.[1] With an idealized representation, (the Fe–Fe distances differ from one another in both cases by less than 1.3%), **2** and **3** are shown to have approximately *T*-molecular symmetry (characterized by three C_2 and four C_3 axes).[5, 15] This contrasts with the spacer-complex $[Fe_4L_6^1]$ **1**, which is exactly S_4 symmetric and thus achiral (*meso*-form). In **1**, the ligands L^1 are arranged facially about the four iron centers; however, in this case two of the four iron centers have the same configuration [(Δ,Δ)- and (Λ,Λ)-*fac*].[14]

The mixed-valence character of **2** and **3** was established unambiguously from their Mössbauer spectra. Powder samples of complexes **2** and **3** each show, in a temperature range of 4.2–300 K, a virtually temperature independent triplet, arising from the overlap of two quadrupolar doublets [one high-spin Fe^{II} center: quadrupolar splittings $\Delta E_Q(4.2\ K) = 2.90$ (**2**), 2.79 (**3**) $mm\,s^{-1}$, isomeric shifts $\delta(4.2\ K) = 1.29$ (**2**), 1.29 (**3**) $mm\,s^{-1}$; three Fe^{III} centers: quadrupolar splittings $\Delta E_Q(4.2\ K) = 0.71$ (**2**), 0.84 (**3**) $mm\,s^{-1}$, isomeric shifts $\delta(4.2\ K) = 0.56$ (**2**), 0.55 (**3**) $mm\,s^{-1}$] (Fig. 2, left). The observation of distinct Mössbauer

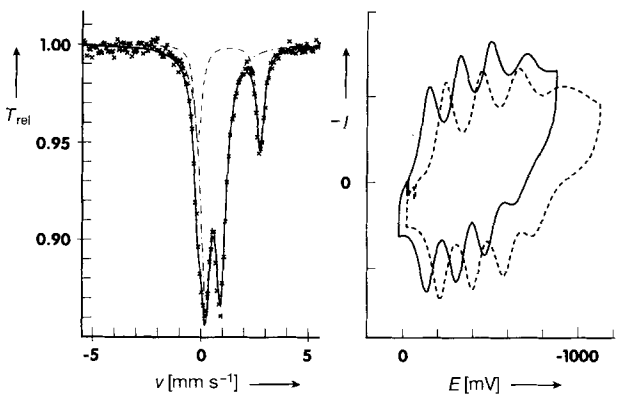

Fig. 2. Left: Mössbauer spectra of a powder sample of **2**, recorded at 4.2 K. The connecting line is the result of a two-doublet adjustment of the Lorentz line. Subspectra: Fe^{II} (- - -), $\Delta E_Q = 2.90\ mm\,s^{-1}$, $\delta = 1.29\ mm\,s^{-1}$, $\Gamma = 0.42\ mm\,s^{-1}$, 24% rel. intensity; Fe^{III} (- · - · -), $\Delta E_Q = 0.71\ mm\,s^{-1}$, $\delta = 0.56\ mm\,s^{-1}$, $\Gamma = 0.59\ mm\,s^{-1}$, 76% rel. intensity. Right: Pseudo-thin layer cyclic voltammogram of **2** (——) and **3** (····) in acetonitrile/0.1 M tetrabutylammonium hexafluorophosphate, scan rate $2\ mV\,s^{-1}$ (**2**), $5\ mV\,s^{-1}$ (**3**). Ordinate scale: one unit corresponds to 0.05 μA (**2**), 0.1 μA (**3**), negative current plotted upwards, potentials vs. ferrocene/ferrocenium (Fc/Fc^+).

subspectra for the Fe^{II} and Fe^{III} centers in complexes **2** and **3** indicates localized valences, at least on the Mössbauer timescale (ca. 10^{-7} s). Even at room temperature, no significant line-broadening occurs, which would point to a dynamic valence process. The seemingly contradictory results of the X-ray analyses of **2** and **3**, in which there were no apparent differences in the coordination spheres of the Fe^{II} and Fe^{III} centers are attributed to a statistical disordering of the Fe^{II} loci. For complexes **2** and **3**, no exchange interactions between the mixed-valence iron centers could be observed from temperature-dependent susceptibility measurements in the range 1.5–300 K. On the basis of the EPR spectroscopic results, it must, however, be assumed that a weak coupling ($J < 1\ cm^{-1}$) between these centers does exist, because only a single, very broad resonance signal at $g = 2$ is observed.

The redox-active iron centers of the mixed-valence complexes **2** and **3** are located in fairly inaccessible sites within these compounds, and possess very similar electrochemical properties. The cyclic voltammograms of these compounds under aprotic conditions[16] show an extreme dependency on the scan rate. Consequently, meaningful spectra of **2** and **3** could only be obtained under pseudo-thin-layer conditions[17] with a very slow scan rate. With these preconditions, cyclic voltammograms are observed which display four[18] quasi-reversible redox steps (Fig. 2, right). The recorded potentials are listed in Table 1. Notably, **3** is reduced at more negative potentials than **2**. As for

Table 1. Peak potentials for **2** and **3**, given in mV against Fc/Fc^+, derived from thin-layer cyclic voltammograms in acetonitrile/0.1 M tetrabutylammonium hexafluorophosphate with a scan rate of 2 mVs^{-1} (**2**) or 5 mVs^{-1} (**3**) (see Fig. 2, right).

		E^I	E^{II}	E^{III}	E^{IV}
2	E_{pc} [a]	−150	−330	−510	−700
	E_{pa} [b]	−130	−310	−470	−640
3	E_{pc} [a]	−240	−450	−660	−910
	E_{pa} [b]	−210	−390	−570	−720

[a] E_{pc}: cathodic peak potential. [b] E_{pa}: anodic peak potential.

the spacer complex **1**, only a very slight electronic interaction exists between the tetrahedrally arranged iron centers of compounds **2** and **3**. In contrast to complex **1**, which shows a one-potential four-electron transfer, a four-potential four-electron transfer is observed for **2** and **3**. These findings are probably due to the shorter iron–iron distances in **2** and **3** (compared to **1**); this gives rise to a stronger coulombic interaction between the metal centers, leading to a splitting of the redox potentials.

All in all, the compounds obtained, **2**[19] and **3**, may be viewed as neutral fragments. Species of this type are of considerable interest because of their analogies with the series metal atom $\{Na\}$, cryptatium $\{[Na^+ \subset (bpy)_3]e^-\}$, and electride $\{[K^+ \subset [2.2.2]cryptand],\ e^-\}$. Preliminary FAB mass spectrometric results confirm the assumption that inclusion complexes of type $[M \subset Fe_4L_6^3]$ (molecular zeolites, M = Na, K, Rb, Cs) may also be prepared by the method described above. A decisive advantage of the synthetic strategy utilized here is that complex structures with defined architecture and specific properties are accessible by spontaneous self-assembly and without the inconvenience associated with multistep synthesis.

Experimental Procedure

General procedure: Methyllithium solution (1.6 M in diethyl ether, 30 mmol) diluted with dry THF (10 mL) was added dropwise to a solution of the dialkyl malonate (30 mmol) in dry THF (50 mL) (N_2, −78 °C) over 30 min. The mixture was stirred for 1 h at −78 °C and then $FeCl_2 \cdot 4H_2O$ (5.96 g, 30 mmol) was added. After stirring for 1 h, a cooled (−78 °C) solution of oxalyl chloride (freshly distilled, 0.95 g, 0.65 mL, 7.5 mmol) in dry THF (20 mL) was added dropwise to the suspension, which was then warmed to 20 °C during 18 h and the resulting clear, deep red solution treated with saturated aqueous ammonium chloride solution (100 mL). The two phases were separated, the aqueous layer extracted three times with an alkyl halide (70 mL, trichloromethane for **2**, dichloromethane for **3**), and the combined organic phases dried over anhydrous sodium sulfate. After concentration to small volume (5 mL), the reaction product was crystallized by the addition of diethyl ether/hexane (1:1, 50 mL, 0 °C). Occasionally, black-red octahedra are formed (R = Me), which, on the basis of Mössbauer spectra (300 K), are shown to have a Fe^{II}/Fe^{III} ratio of 1:1 (Fe^{II}: $\Delta E_Q = 2.69\ mm\,s^{-1}$, $\delta = 1.20\ mm\,s^{-1}$, Fe^{III}: $\Delta E_Q = 0.55\ mm\,s^{-1}$, $\delta = 0.46\ mm\,s^{-1}$). Likewise, ruby-red octahedra (R = Et), which, on the basis of Mössbauer spectra (300 K), contain exclusively Fe^{III} ($\Delta E_Q = 0.77\ mm\,s^{-1}$, $\delta = 0.44\ mm\,s^{-1}$).

2: Ruby-red crystals from chloroform, by diffusion of diethyl ether. Yield: 1.47 g (55%); m.p. > 200 °C (decomp.); IR (KBr): $\tilde{\nu} = 1730\ cm^{-1}$ (C=O, broad); FAB MS (3-nitrobenzylalcohol matrix): *m/z* 2138 $[NH_4 \subset Fe_4L_6^2]$.

3: Ruby-red crystals from dichloromethane, by diffusion of diethyl ether. Yield: 1.23 g (40%); m.p. > 200 °C (decomp.); IR (KBr): $\tilde{\nu} = 1700\ cm^{-1}$ (C=O, broad). FAB-MS (3-nitrobenzylalcohol matrix): *m/z* 2475 $[NH_4 \subset Fe_4L_6^3]$.

Effects of $^{35}Cl/^{37}Cl$, ^{13}C Residual Dipolar Coupling on the Variable-Temperature ^{13}C CP/MAS NMR Spectra of Solid, Chlorinated Sodium Acetates**

Sergio H. Alarcón, Alejandro C. Olivieri,* Stephen A. Carss, and Robin K. Harris

The effects of combined residual dipolar and scalar coupling between spin 1/2 nuclei and a large variety of quadrupolar nuclei have been recently reviewed.[1] Interest from organic chemists in this phenomenon has been usually restricted to the (^{14}N, ^{13}C) case,[2] whose manifestation has almost disappeared from the literature due to the use of high-field NMR spectrometers.[1] Very recently, however, ^{13}C CP/MAS NMR spectra (CP = cross polarization, MAS = magic angle spinning) of solid chlorine-containing organic compounds have been shown to display splittings arising from residual coupling (mostly dipolar in nature) between the observed spin 1/2 ^{13}C nucleus and the $^{35,37}Cl$ isotopes ($S = 3/2$ in both cases) at bonding distances.[3] In all cases reported so far, carbon atoms bonded to a single chlorine atom were studied.[3] We report here on the effects of residual dipolar ($^{35}Cl/^{37}Cl$, ^{13}C) coupling at both bonding and nonbonding distances in compounds containing CH_2Cl, $CHCl_2$, and CCl_3 groups.

Detailed theory has been produced on this subject, including a fully computational solution of the (spin 1/2, spin 3/2) dipolar coupling under MAS conditions,[4, 5] first-order perturbation theory (valid when $|\chi/\nu_S| < 1$; χ is the quadrupole coupling constant and ν_S is the resonance frequency for the quadrupolar S nuclei),[2, 5, 6] and a polynomial fit to the exact solution (valid for $1 < |\chi/\nu_S| < 3$).[5] According to first-order perturbation theory,[6] the ^{13}C CP/MAS NMR signal of a carbon atom affected by a single chlorine nucleus at a distance r should give a symmetric doublet with a splitting $s = 6D_\chi(3\cos^2\beta^D - 1)/20\nu_S$ [$D = (\mu_0/4\pi)\gamma_I\gamma_S h/4\pi^2 r^3$; β^D is the angle between the vector $\boldsymbol{r}$ and the z_{EFG} axis of the quadrupole tensor at the $^{35,37}Cl$]. Since χ is substantial for the $^{35,37}Cl$ isotope bonded to the carbon nucleus, deviations are expected from the first-order regime even at high fields, in which case Equation (a) can be used (in the range $1 < |\chi/\nu_S| < 3$),[5] where s is still a symmetric splitting. It

$$s = D[(3\cos^2\beta^D - 1)/2](0.581|\chi/\nu_S| + 0.033|\chi/\nu_S|^2 - 0.021|\chi/\nu_S|^3) \quad \text{(a)}$$

should be noted that the ^{35}Cl and ^{37}Cl isotopes have similar nuclear properties, and their separate effects are thus difficult to detect. This means that the calculated effect on the observed carbon nucleus should be the weighted average of those corresponding to the individual isotopes.

Values of $\chi(^{35}Cl)$ for chlorinated organic compounds usually lie in the vicinity of -70 MHz,[7] so that $|\chi/\nu_S|$ is about 2.4 at 7.05 T [and thus Eq. (a) can be used] and 3.6 at 4.7 T. Therefore, in this latter case one has to resort to exact calculations, which predict a broad triplet with intensities in the ratio 1:1:2 (in the direction of increasing frequencies; the intrinsic asymmetry of these triplets depends on the sign of χ). [5] These results have been experimentally confirmed in organic compounds for carbon atoms directly bonded to a single chlorine.[3] The ^{13}C NMR signal resulting from coupling to two and three equivalent chlorine atoms is expected to be a 1:2:1 triplet and a 1:3:3:1 quartet, respectively, at high fields ($|\chi/\nu_S| < 3$), whereas more complex line shapes are predicted at lower fields. Figure 1 shows the experimental results obtained for sodium monochloro-(**1**), dichloro-(**2**), and trichloroacetate (**3**); the relevant chemical shift information is presented in Table 1. At ambient probe temperature, compound **1** gives, for both the carbon of the CH_2Cl group and for that of the carboxyl group, the expected 1:1 doublets at 7.05 T and 1:1:2 triplets at 4.7 T. Using

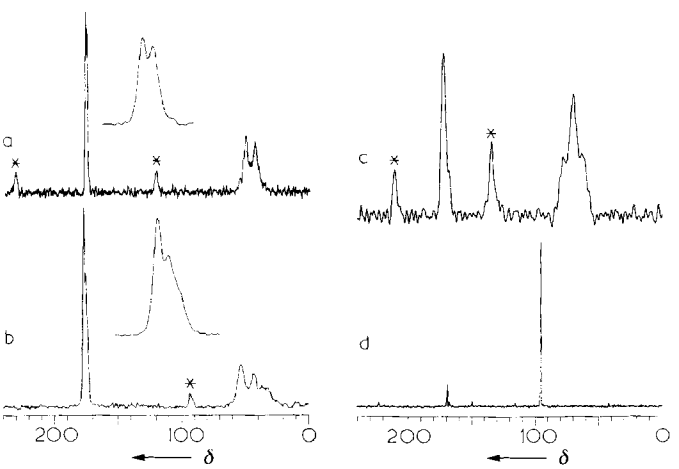

Fig. 1. ^{13}C CP/MAS NMR spectra for the compounds **1**–**3** in the solid state. a) Spectrum of **1** at ambient probe temperature, $B_0 = 7.05$ T, $\nu(^{13}C) = 75.4$ MHz. b) Spectrum of **1** at ambient probe temperature, $B_0 = 4.7$ T, $\nu(^{13}C) = 50.3$ MHz. c) Spectrum of **2** at 158 K (nominal temperature), $B_0 = 7.05$ T. d) Spectrum of **3** at ambient probe temperature, $B_0 = 7.05$ T. The low-temperature spectra (down to 163 K) of **3** were essentially identical to that shown in this figure. The inserts in spectra a) and b) show expansions of the carboxyl region. Asterisks denote spinning side bands.

$\chi(^{35}Cl) = -67.8$ MHz[8] [$\chi(^{37}Cl) = -53.4$ MHz; $Q(^{37}Cl)/Q(^{35}Cl) = 0.788$][9], $\nu_S(^{35}Cl) = 29.4$ MHz (24.5 MHz for ^{37}Cl), and a typical chloroacetate geometry ($r = 1.77$ Å, $\beta^D = 0$ for C2; $r = 2.74$ Å, $\beta^D = 30°$ for C1, see Fig. 2),[10] first-order per-

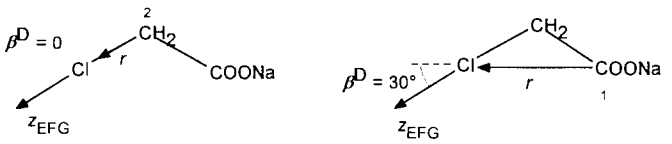

Fig. 2. Relative orientation of the internuclear vector r and the $^{35}Cl/^{37}Cl$ z_{EFG} axis for the carbon atoms C1 and C2 in **1**. EFG = electric field gradient

turbation theory in a magnetic field of 7.05 T gives symmetric splittings s of 9.2 ppm for the doublet of C2 and 1.6 ppm for the doublet of C1 (averaged in both cases according to the natural abundances of the Cl isotopes, ^{35}Cl, 75.5%; ^{37}Cl, 24.5%). On the other hand, if Equation(a) ($|\chi/\nu_S| = 2.31$ for ^{35}Cl; 2.18 for ^{37}Cl at 7.05 T) is used to calculate the splittings, one obtains values of s of 8.4 ppm and 1.4 ppm for the C2 and the C1 doublet, respectively, which are in better agreement with the experimental data (Table 1, $s = 7.8$ ppm for C2 and 1.0 ppm for C1 at 7.05 T). At 4.7 T neither first-order perturbation theory nor Equation (a) are appropriate. In this case a broad 1:1:2 triplet is expected on the basis of the exact calculations.[4, 5] Using the quadrupole data for **1**, $\nu_S = 19.6$ MHz for ^{35}Cl (16.3 MHz for ^{37}Cl) at 4.7 T, the exact calculation gives the following shifts of the signals relative to the isotropic ^{13}C frequency: -12.9; -2.8; $+7.8$ ppm for the C2 atom and -2.0; -0.4; $+1.2$ ppm for the C1 atom. These values are in excellent agreement with experimental ones: -12.2; -2.8; $+7.1$ ppm for the C2 triplet and -2.2; -0.5; $+1.1$ ppm for the C1 triplet (Fig. 1 and Table 1; values measured from the center of the 7.05 T doublets). In the case of compound **2**, the expected 1:2:1 triplet is only observed for the C2 signal in the low-temperature spectrum recorded at 7.05 T. The distance between adjacent peaks of this C2 triplet (8.0 ppm, Table 1) is very similar to that observed in the corresponding doublet for **1** at the same field. The expected long-range effect on C1 (a 1:2:1 triplet with interpeak distances of about 1 ppm) may be lost within the experimental line width (Table 1). Quadrupole data are not known for **2** but information is available on the corresponding acids;[8] this shows that all three compounds have similar $\chi(^{35}Cl)$ values. Thus, the ^{13}C NMR data for the C2 nucleus in compound **2** shown in Figure 1 and Table 1 are readily explained. Interestingly, the C2 triplet collapses into a broad singlet at room temperature, indicating that the reorientation of the $CHCl_2$ segment (or an overall molecular motion) may be able to induce an efficient $^{35}Cl/^{37}Cl$ longitudinal relaxation which causes the ^{13}C nucleus to be self-decoupled.[11] This effect has also been reported in other cases,[12] and is very pronounced in compound **3**; thus even at low temperatures (down to 163 K) two sharp ^{13}C singlets (Fig. 1 and Table 1) occur. The easier rotation of the threefold symmetric CCl_3 group in the solid is expected to lead to an even faster quadrupole relaxation than in the $CHCl_2$ case.

In summary, ^{13}C CP/MAS NMR spectra of chlorinated organic compounds recorded at high fields are expected to reveal complex line shapes, if the molecular motions are slow enough to prevent self-decoupling by fast quadrupole relaxation of the chlorine nuclei. However, the effects can be conveniently explained by the existing theory.

Experimental Procedure

^{13}C NMR spectra at 75.4 MHz were recorded with a Varian VXR 300 NMR spectrometer equipped with a Doty 7 mm probe; spectral width, 30 kHz; acquisition time, 39.4 ms (**1** and **2**), 59.7 ms (**3**); relaxation delay, 30 s (**1** and **3**), 300 s (**2**); contact time, 3 ms (**1**), 1 ms (**2**); memory, 8 K; number of acquisitions, 1840 (**1** and **2**), 84 (**3**); spinning speed, 4200 Hz (**1**), 2850 Hz (**2**), 4050 Hz (**3**). Spectra for compounds **1** and **2** were recorded in the CP mode, whereas compound **3** was studied by single-pulse acquisition. The CP spectrum for **2** was recorded at 50.3 MHz on a Chemagnetics CMX 200 NMR spectrometer equipped with a Bruker 7 mm probe; spectral width, 20 kHz; acquisition time, 20 ms; relaxation delay, 30 s; contact time, 3.5 ms; memory, 8 K; number of acquisitions, 2040; spinning speed, 4200 Hz. The temperature was lowered by cooling the driving gas in liquid N_2.

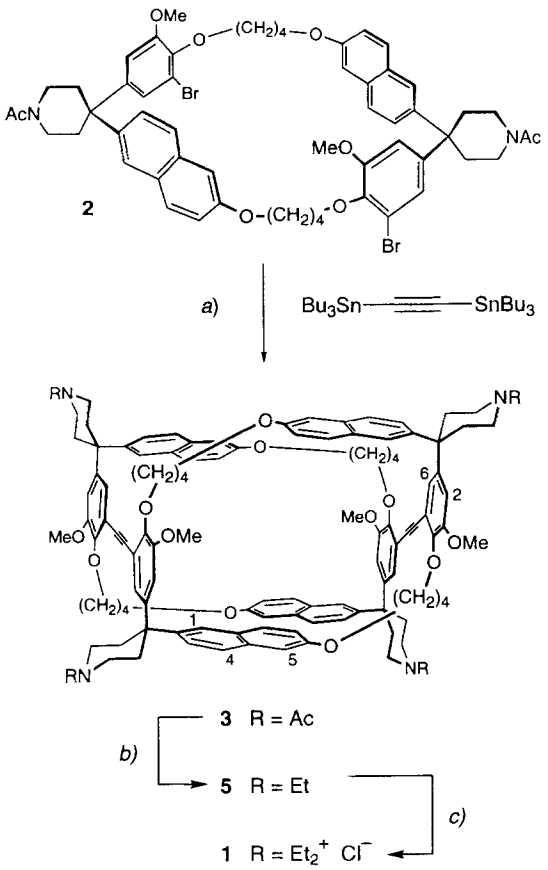
Dissolution of Cholesterol in Water by a Synthetic Receptor**

Blake R. Peterson and François Diederich*

Dedicated to Professor C. Rüchardt on the occasion of his 65th birthday



Cholesterol is an essential component of animal cells. This highly water-insoluble steroid serves as both a modulator of membrane fluidity and as a raw material for the production of steroid hormones and bile acids.[1] The hydrophobic properties of cholesterol, which make it an essential component of cell membranes, also make it lethal when deposited on arterial walls. The deposition of cholesterol-containing plaque in blood vessels, known as atherosclerosis,[2] is a leading cause of death in western industrialized societies. While current drug therapies focus on enzyme inhibition of endogenous cholesterol biosynthesis[3] or bile acid depletion[4] to reduce blood cholesterol

levels, the selective dissolution of cholesterol deposits by strongly binding synthetic receptors could provide a new alternative therapeutic strategy. Naturally occurring cyclodextrins[5, 6] could be used in such treatments, since they are known to form inclusion complexes with cholesterol in aqueous solution, but a lack of selectivity limits their scope as specific cholesterol-binding agents. Although a few synthetic cyclophane receptors have been used in studies of steroid recognition phenomena,[7-11] complexation of highly insoluble steroids such as cholesterol in aqueous solution has previously remained elusive. We describe herein the synthesis of a novel water-soluble tricyclic cyclophane receptor **1** which binds strongly and selectively to cholesterol in water.

The key step in the synthesis of **1** was the Pd^0-catalyzed Stille-type coupling[12] of equimolar amounts of bis(tributylstannyl)acetylene and dibromocyclophane **2** (Scheme 1), which can be prepared in multigram quantities in six steps starting from 2-bromo-6-ethoxynaphthalene.[11] This remarkable cyclization reaction produced the chiral D_2-symmetrical macrotricycle **3** selectively in 14% yield and none of the possible achiral isomer **4** with C_{2h} symmetry. Reduction of **3** with $LiAlH_4$ to tetramine **5** followed by quaternization with ethyl iodide and ion exchange chromatography (Cl^-) afforded the water-soluble receptor **1**.

Scheme 1. Synthesis and analytical data of receptor **1**. Reagents and yields: a) $[Pd(PPh_3)_4]$, 2,6-di-*tert*-butyl-*p*-cresol, dimethylformamide, 110 °C, pressure bottle, 2 d, 14%; b) $LiAlH_4$, Et_2O, 20 °C, 12 h, 59%; c) C_2H_5I, $CHCl_3$, 20 °C, 4 d, followed by ion exchange on Dowex resin (Cl^-) eluting with H_2O/CH_3OH 1:1, 78%. The formation of only one isomer in the Pd^0-mediated macrocyclization was evident from the one spot for the product in the thin-layer chromatogram ($R_f = 0.15$, SiO_2, CH_2Cl_2/CH_3OH 20:1) and the presence of only one set of corresponding resonances in the ^1H and ^{13}C NMR spectra. Two-dimensional NMR spectra of **5** demonstrated that the chiral D_2-symmetrical isomer **3** was formed exclusively. ROESY spectroscopy provided evidence of intramolecular aliphatic–aromatic $^1H\{^1H\}$ nuclear Overhauser effects (NOEs) which are only possible in the D_2-symmetrical compound (Fig. 1). In addition, molecular dynamics simulations with MacroModel[13] (Fig. 2) showed the D_2-symmetrical isomer **3** to be more stable than the C_{2h}-symmetrical isomer **4** by 6 kcal mol^{-1}, which would explain the exclusive formation of **3**.

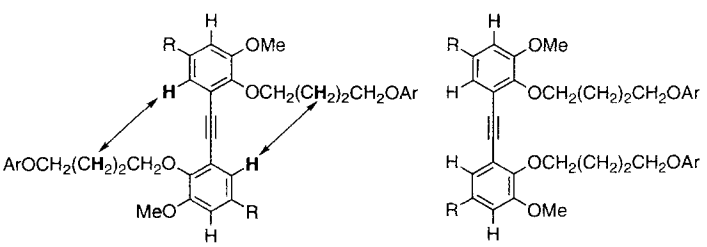

Fig. 1. Aromatic–aliphatic $^1H\{^1H\}$ nuclear Overhauser effects (NOEs) observed by ROESY spectroscopy of **5** support the D_2-symmetric structure. Irradiation at the frequency of the aromatic signal leads to approximately equal NOE enhancements for the two CH_2 groups shown. The alternative C_{2h}-symmetrical isomer cannot exhibit the observed NOE enhancements. Shown are only the fragments of the two isomers that are relevant to the NOE discussion. The D_2-symmetric isomer is represented on the left, the C_{2h}-symmetric on the right.

Receptor **1** is highly soluble in water (6 mg mL^{-1}, 3.0 mM) and does not aggregate appreciably at concentrations below 2.5 mM, as determined by ^1H NMR dilution experiments. This relatively high critical aggregation concentration (CAC) is due in part to the presence of the four peripheral CH_3O substituents, which have been shown to significantly increase the CAC values of other water-soluble cyclophanes.[14] When two cyclophanes **2** are connected by two acetylene bridges, the depth of the cavity increases from approximately 5 Å (in **2**) to roughly 11 Å (in **1**) (Fig. 2), which provides a nearly perfect environment, both in terms of space and hydrophobicity, for complete encapsulation

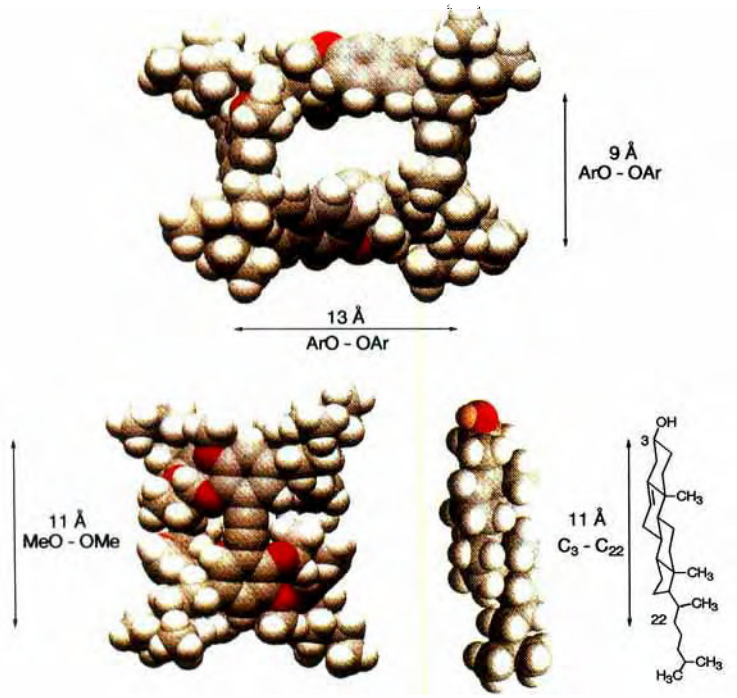

Fig. 2. Comparison of minimum-energy structures of **1** (top and bottom left) and cholesterol (bottom right) [13]. The top view shows the dimensions of the cavity entrance in **1** (9 × 13 Å). The bottom view of **1** shows the depth of the cavity (11 Å) which is sufficient to incorporate all four rings A–D of axially included cholesterol and parts of the hydrophobic side chain.

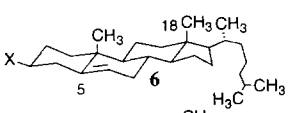
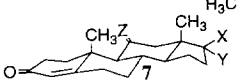
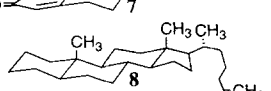
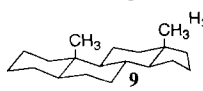
of a hydrophobic steroid like cholesterol in an axial orientation. Since the receptor has a cavity opening with dimensions of 9 × 13 Å, steroids can penetrate without significant steric hindrance.

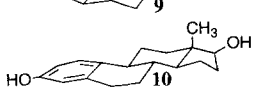
Table 1. Association constants K_a and binding free energies ΔG° for steroid complexes of **1** determined by solid–liquid extraction in H_2O at 295 K [a].

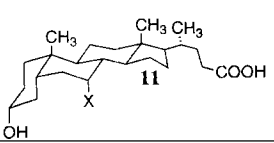












Steroid	K_a [L mol^{-1}]	$-\Delta G^\circ$ [b] [kcal mol^{-1}]	Solubility [M]
cholesterol	1.1×10^6	8.2	4.7×10^{-6} [c]
testosterone	6.8×10^4	6.5	8.3×10^{-5} [d]

[a] Solutions of **1** (1–2 mM) in H_2O were sonicated for 45 min in the presence of excess solid steroid and allowed to equilibrate at 295 K for 2 h. The suspension was centrifuged and the supernatant liquid filtered through a 0.45 μm cellulose acetate filter. Removal of water under reduced pressure was followed by addition of CD_3OD, which allowed determination of percent steroid extracted by integration of the ^{1}H NMR signals. For the calculation of K_a, see ref.[15]. The association constants given are average values for two diastereomeric complexes, which are of similar stability (see Table 2). [b] Data from triplicate runs. Reproducibility of ΔG° values: ±0.4 kcal. [c] Ref.[16]. [d] Ref.[17].

The complexation of two of the least water-soluble steroids, cholesterol and testosterone, by **1** in water was evaluated using the solid–liquid extraction method[15] (Table 1). The maximum solubility of cholesterol in pure water is 4.7×10^{-6} M.[16] Upon extraction of an excess of solid cholesterol with a 1.0 mM aqueous solution of **1**, a 8.5×10^{-4} M solution of cholesterol is obtained. This corresponds to a complexation-mediated increase in solubility by a factor of 190. The association constant for the **1**·cholesterol complex in pure water can then be calculated as $K_a = 1.1 \times 10^6$ L mol^{-1} (295 K). Solid testosterone is also extracted into water through complexation by **1**, although, at $K_a = 6.8 \times 10^4$ L mol^{-1}, its binding affinity is much lower. This can be readily explained by the higher affinity of the more polar testosterone to the aqueous phase, which is reflected in its higher solubility in water compared to that of cholesterol.[16, 17]

A more detailed analysis of the steroid-binding properties of **1** was obtained by ^{1}H NMR binding titrations in CD_3OD, in which all steroids and their complexes with **1** form homogenous

Table 2. Association constants K_a and binding free energies $-\Delta G^\circ$ from ^{1}H NMR binding titrations for 1:1 complexes of steroids and receptor **1** in CD_3OD at 298 K. Also shown are the complexation-induced changes in chemical shift of the protons of the CH_3 group at position 18 at saturation binding $\Delta\delta_{sat}$, which were evaluated in the titration [a].

		Steroid	X	Y	Z	K_a [L mol^{-1}]	$-\Delta G^\circ$ [kcal mol^{-1}]	$\Delta\delta_{sat}$ CH_3(18)
	**6a**	cholesteryl acetate	$OCOCH_3$			4800	5.0	1.95
	6b	5-cholestene	H			3200	4.8	1.19
	6c	cholesterol	OH			1500	4.3	1.70
	**7a**	testosterone	OH	H	H_2	2100	4.5	1.69
	7b	cortisone	$COCH_2OH$	OH	O	150	3.0	2.16
	7c	hydrocortisone	$COCH_2OH$	OH	α-H, β-OH	110	2.8	0.60
	**8**	5-α-cholestane				870	4.0	1.57
	**9**	5-α-androstane				500	3.7	1.74
	**10**	β-estradiol				390	3.5	2.04
	**11a**	lithocholic acid	H			310	3.4	0.57
	11b	chenodeoxycholic acid	OH			40	2.2 [b]	

[a] Association constants determined by nonlinear least squares curve fitting of 500 MHz ^{1}H NMR titrations. The resonances of the methyl groups at position 18 for the two diastereomeric complexes were not resolved, and the association constants given are an average value. This approximation is justified by the absence of significant differential complexation-induced shifts for the diastereomeric complexes. Reproducibility of K_a values: ±10%. [b] Estimated upper limit.

solutions in the desired concentration ranges. Similar highly accurate binding assays were not possible in D_2O owing to slow exchange kinetics and low steroid solubilities.

Although the hydrophobic driving force for complexation is much weaker in CD_3OD than in D_2O,[18] cholesterol and its derivatives **6a,b** and testosterone (**7a**) form stable complexes with **1** in the organic solvent (Table 2). The relatively high stability of the testosterone complex in CD_3OD may be explained by favorable electrostatic $\pi-\pi$ interactions between the electron-deficient α,β-unsaturated ketone moiety in ring A with the electron-rich aryl ether cavity walls of the receptor.[19] The complexes of other steroids studied are substantially less stable. The comparison between the binding of **6b** and **8** [$\Delta(\Delta G^\circ)_{\mathbf{6b}-\mathbf{8}} = 0.8$ kcal mol^{-1}] indicates that the unsaturation at C(5) of the steroid ring system contributes significantly to complex stability, although it is uncertain whether this effect is a result of favorable attractive interactions of the polarizable double bond with the receptor or due to differences in the steric fit inside the cavity. Unlike other cyclophanes that preferentially bind aromatic steroids,[9, 10] receptor **1** only forms a weak complex with **10**. Contributions of the aliphatic steroid side chain to complex stability are significant but small [$\Delta(\Delta G^\circ)_{\mathbf{8}-\mathbf{9}} = 0.3$ kcal mol^{-1}], which implies that this hydrophobic residue is only partially encapsulated. Increasing steroid polarity rapidly decreases binding affinity. Comparison of binding affinities of bile acids **11a** and **11b** indicates that a single highly solvated OH group on the steroid B ring substantially inhibits stable complex formation.

Steroid binding studies with **1** indicate that this receptor exhibits sufficient binding affinity and specificity to warrant further exploration as an agent for solubilizing solid cholesterol deposits under biological conditions. These studies may result in a new, receptor-based strategy for the dissolution of cholesterol deposits.

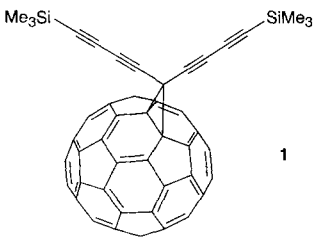
61,61-Bis(trimethylsilylbutadiynyl)-1,2-dihydro-1,2-methanofullerene[60]: Crystal Structure at 100 K and Electrochemical Conversion to a Conducting Polymer**

Harry L. Anderson, Corinne Boudon, François Diederich*, Jean-Paul Gisselbrecht, Maurice Gross*, and Paul Seiler*

Methanofullerenes are among the most thoroughly explored types of covalent fullerene derivatives.[1] Methano bridging may either occur at the junction between two six-membered rings (6-6 methano-bridged) or at the junction between a five- and a six-membered ring (6-5 methano-bridged). Further, by analogy with methanoannulenes,[2] methanofullerenes could occur as four possible valence isomers (closed 6-6, open 6-6, closed 6-5, and open 6-5 methano-bridged structures), depending on whether there is a transannular bond in the methanoannulene subunit (Scheme 1).

Scheme 1. The two possible isomeric methanofullerenes bridged at the 6-6 ring junction: the closed (left, observed) and open (right, not observed) 6-6 structures. The methanoannulene type substructures are highlighted.



Ever since the synthesis of the first methanofullerenes by Wudl et al.,[3] there has been controversy about their structure. Originally, the 6-6 methano-bridged derivatives were thought to have an open 6-6 structure. This conclusion was based on a low-quality and therefore not necessarily conclusive X-ray crystal structure analysis of 61,61-bis(4-bromophenyl)-1,2-dihydro-1,2-methanofullerene[60].[4] A transannular distance between the bridgehead atoms C(1) and C(2) of about 1.84 Å is observed, a value similar to that found for some partially open 1,6-methano[10]annulenes.[5] However, NMR evidence[6, 7] and theoretical calculations[8] strongly imply that 6-6 methano-bridged fullerenes have a closed 6-6 structure containing a cyclopropane ring. The preference for the closed over the open 6-6 structure, which seems to be independent of the nature of the substituents at the methano C atom,[8b] was explained in terms of the favorable [5]radialene-type bonding pattern observed in C_{60}. The shorter bonds with higher double bond character are located exocyclic to the pentagons.[6c, 8b]

We report here on the low-temperature (100 K) crystal structure analysis of 61,61-bis(trimethylsilylbutadiynyl)-1,2-dihydro-1,2-methanofullerene (**1**).[9] The first accurate X-ray data for

1

a 6-6 methano-bridged fullerene definitively confirm the preference for a closed 6-6 structure.[*] This paper also presents evidence that electrochemical polymerization of **1** yields an air-stable, electrically conducting film.

Two ordered crystal modifications of **1**, referred to as **1a** and **1b**, were obtained from CS_2 and toluene solutions, respectively.[10] Modification **1a** crystallized in the monoclinic space group $P2_1/c$ with four molecules of **1** and two CS_2 molecules in the unit cell; **1b** has a triclinic space group $P\bar{1}$, with two molecules of **1** and four toluene molecules. Here we mainly discuss the molecular geometry of the more accurate structure **1b**;[11] the geometry of **1a** is practically identical within the estimated standard deviations.

As expected, the butadiynyl substituents of **1b** (Fig. 1) are in a nearly symmetrical arrangement. Approximate C_{2v} symmetry

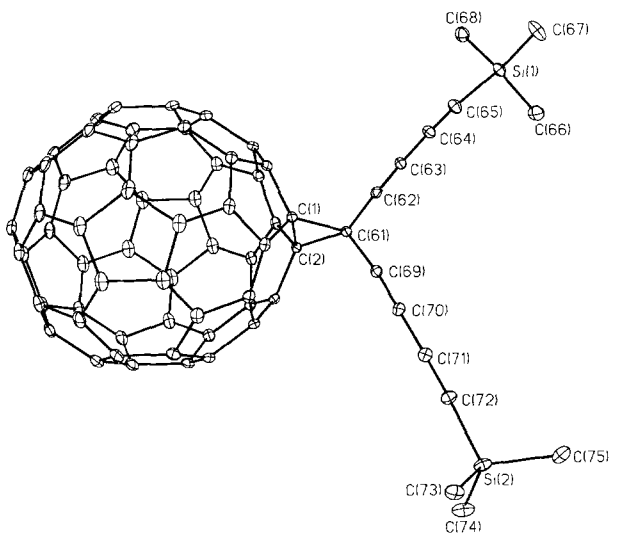

Fig. 1. Molecular structure of **1b**. Vibrational ellipsoids are shown at the 30% probability level. Selected bond lengths [Å] and angles [°] [11]: C(1)–C(61) 1.536, C(2)–C(61) 1.542, Si(1)–C(65) 1.849, C(65)–C(64) 1.210, C(64)–C(63) 1.372, C(63)–C(62) 1.201, C(62)–C(61) 1.440, C(61)–C(69) 1.440, C(69)–C(70) 1.207, C(70)–C(71) 1.372, C(71)–C(72) 1.212, C(72)–Si(2) 1.852; C(2)-C(1)-C(61) 59.4, C(1)-C(2)-C(61) 59.1, C(1)-C(61)-C(2) 61.5, C(62)-C(61)-C(69) 116.7.

is thus adopted. Bond lengths and angles are given in Figure 2.[4] The crucial 6-6 bond length C(1)–C(2) is 1.574(3) Å, which is close to the calculated value of 1.55(1) Å for a closed 6-6 structure.[8b] Except for the three-membered ring, the geometry of the bridged pyracylene (Fig. 2) is, on the whole, in good agreement with recent X-ray results obtained for dibenzohomopyracylene **2** (Fig. 3).[2c,12] The C–C bonds in the cyclopropane ring of **1b** are about 0.02–0.04 Å longer than those in the corresponding ring of **2**. The geometry of the three-membered ring in **1b** closely resembles that in some accurate structures of strained [n.1.1] propellanes,[13] which exhibit C–C bond lengths of about 1.58 Å for the central bond and 1.52 Å for the other cyclopropane bonds.

The strain at the bridgehead atoms C(1) and C(2) is evident from an analysis of the bond angles, which deviate significantly

[*] Addition in proof (August 9, 1994): Recently the X-ray structure analysis of another methanofullerene was reported: J. Osterodt, M. Nieger, F. Vögtle, *J. Chem. Soc. Chem. Commun.* **1994**, 1607.

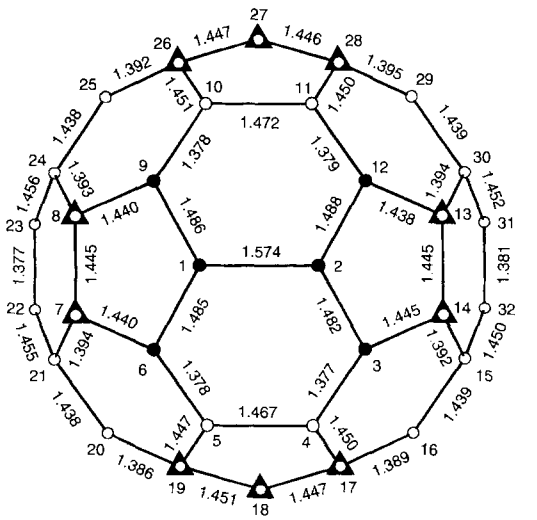

Fig. 2. Detail of structure **1b**; the methano bridge at C(1)–C(2) is omitted for clarity. Atoms nearest and furthest from the centroid Z_0 are marked with triangles and filled-in circles, respectively. Selected bond angles [°] [11]: C(2)-C(1)-C(6) 115.8, C(2)-C(1)-C(9) 116.4, C(6)-C(1)-C(9) 106.0, C(1)-C(2)-C(3) 116.6, C(1)-C(2)-C(12) 116.1, C(3)-C(2)-C(12) 105.9, C(2)-C(3)-C(4) 122.6, C(2)-C(3)-C(14) 108.0, C(4)-C(3)-C(14) 120.0, C(1)-C(6)-C(5) 122.6, C(1)-C(6)-C(7) 108.0, C(5)-C(6)-C(7) 119.9, C(1)-C(9)-C(8) 107.6, C(1)-C(9)-C(10) 122.6, C(8)-C(9)-C(10) 119.9, C(2)-C(12)-C(11) 122.6, C(2)-C(12)-C(13) 107.8, C(11)-C(12)-C(13) 119.7. Centroid–C distances [Å]: C(1) 3.726, C(2) 3.722, C(3) 3.557, C(4) 3.538, C(5) 3.532, C(6) 3.557, C(7) 3.519, C(8) 3.520, C(9) 3.567, C(10) 3.542, C(11) 3.541, C(12) 3.564, C(13) 3.515, C(14) 3.521, C(15) 3.532, C(16) 3.534, C(17) 3.523, C(18) 3.514, C(19) 3.519, C(20) 3.537, C(21) 3.536, C(22) 3.546, C(23) 3.539, C(24) 3.536, C(25) 3.540, C(26) 3.528, C(27) 3.520, C(28) 3.527, C(29) 3.536, C(30) 3.528, C(31) 3.541, C(32) 3.543.

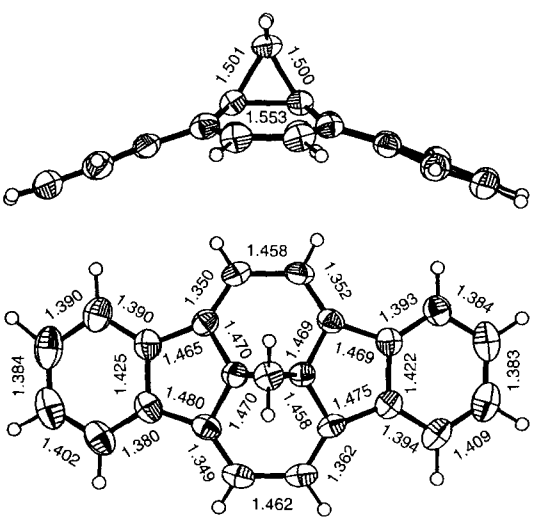

Fig. 3. Crystal structure of **2** [2c,12].

from ideal tetrahedral geometry. The three bond angles in the fullerene shell range from 105.9 to 116.6°, and the sums of these angles at C(1) and C(2) are 338.2 and 338.6°, respectively (about 10° larger than the ideal value of 328°). The bond angles at the other fullerene C atoms are 107.1–108.7° (mean 108.0°) in the pentagons and 119.3–120.9° (mean 120.0°) in the hexagons, values which are within the normal range.

The lengths of the 5-6 bonds within the C_{60} skeleton, excluding the bonds in rings containing C(1) or C(2), range from 1.438 to 1.457 Å (mean 1.449(5) Å);[11] the lengths of the 6-6 bonds range from 1.377 to 1.397 Å (mean 1.391(5) Å). This demonstrates that the [5]radialene-type bonding structure of C_{60} is preserved. The shortest 6-6 bonds are those on the edges of the bridged pyracylene moiety (mean 1.378 Å) and those in two of

the four equatorial positions (C(22)–C(23) and C(31)–C(32); mean 1.379 Å). These bonds have the highest double bond character and should have the highest reactivity towards nucleophiles.[14] The lengths of the 6-6 bonds in the rear hemisphere (not shown in Fig. 2) range from 1.383 to 1.395 Å.

Most of the five- and six-membered rings are planar with deviations from least-squares planes of less than 0.003 Å; the largest deviations (of up to about 0.06 Å) occur in the five-membered rings containing C(1) or C(2). The distances between the fullerene C atoms, excluding C(1) and C(2), and the centroid Z_o of the C_{60} ball range from 3.514 to 3.567 Å, the average being 3.539(11) Å. The C(1)–Z_o and C(2)–Z_o distances of 3.726 and 3.722 Å, respectively, are considerably longer than the average value; thus, as observed in other fullerene derivatives, C(1) and C(2) protrude from the C_{60} skeleton.[15] Atoms nearest to and furthest from the centroid Z_o are marked on Figure 2 by triangles and filled-in circles, respectively. The fullerene shell is slightly compressed along the axis perpendicular to the plane of the cyclopropane ring.

In the crystal packing of **1b** (Fig. 4), the fullerene molecules near the corners of the triclinic unit cell are related by a center of inversion. The shortest intermolecular C(60)···C(60) distance through the inversion center is 3.30 Å. There are two different types of toluene molecules in the unit cell. One ordered toluene molecule lies between two fullerenes with its molecular plane roughly perpendicular to the $Z_o \cdots Z_o$ axis (not indicated). Two short C···C distances (3.24 and 3.28 Å) separate this molecule from C(17) of one C_{60} sphere and one short distance (3.34 Å) from C(44) of another sphere. A slightly disordered toluene molecule lies parallel to the *b*,*c* plane between acetylenic substituents and does not have short contacts.

The more interesting crystal packing of **1a** is shown in Figure 5 as a projection onto the *b*,*c* plane of the monoclinic unit cell. Two fullerene molecules are related by a center of inversion occupied by the C atom of a CS_2 molecule. The shortest distances between solvent and C_{60} sphere are those between the central carbon atom of the CS_2 molecule and the atoms of the 5-6 bond C(44)–C(57) (3.24 and 3.36 Å, respectively). The intermolecular distances along the *c* axis between the electron-rich

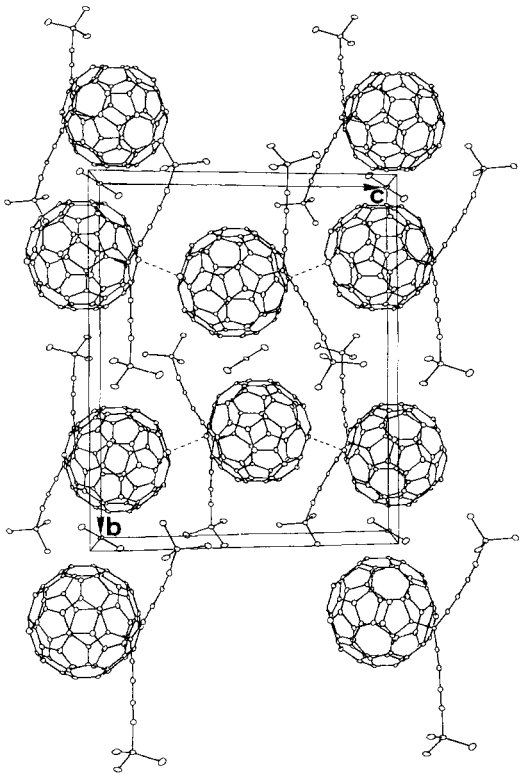

Fig. 5. Crystal packing in **1a** viewed along the *a* axis.

6-6 bonds C(8)–C(24) and the electron-deficient 5-6 bonds C(33)–C(34) of adjacent C_{60} spheres are remarkably short (four short C···C distances, 3.04–3.32 Å; only the shortest C(8)···C(33) distances are shown in Fig. 5).

Many butadiynes polymerize in the solid state to give polydiacetylenes.[16] In this case, the butadiyne moieties in the crystals **1a** and **1b** are too far apart to undergo this topochemical reaction. In solution, however, **1** does appear to undergo reductive electrochemical polymerization to give an insoluble, electrically conducting film on the surface of the platinum cathode.

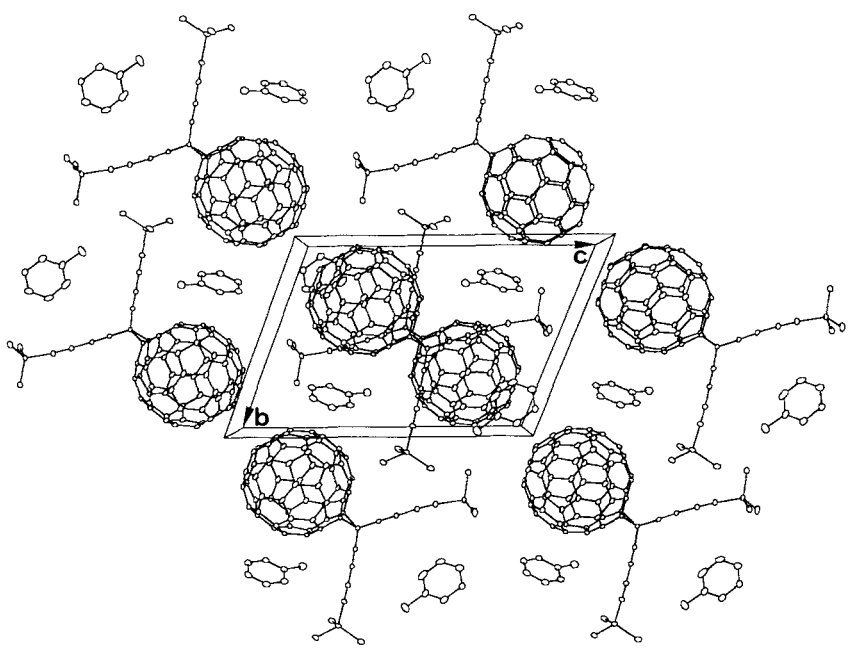

Fig. 4. Crystal packing in **1b** viewed along the *a* axis.

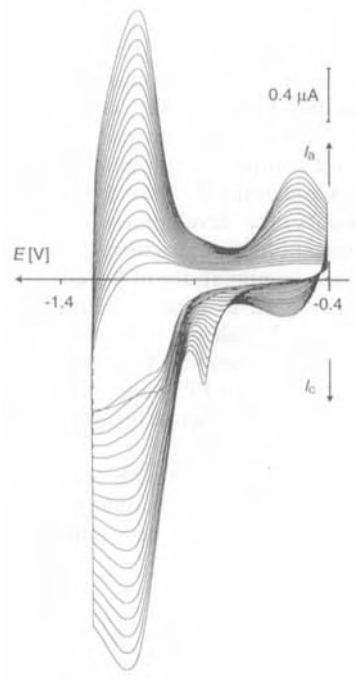

Fig. 6. Iterative cyclic voltammogram of **1** in $Bu_4N^+PF_6^-/CH_2Cl_2$ (0.1 M), Pt electrode, sweep rate 0.1 Vs^{-1} (19 cycles, vs. ferrocene).

Cyclic voltammograms of solutions of C_{60} in CH_2Cl_2 show three reversible one-electron reductions at −0.98, −1.37, and −1.83 V (vs. ferrocene). Only one well-defined reduction peak at −1.00 V (vs. ferrocene) is observed for **1** during the first scan.[17] Repeated potential cycling at 0.1 Vs^{-1} for this first reduction step (−0.40 to −1.30 V, vs. ferrocene) gives a voltammetric peak current which builds up with the number of scans (Fig. 6). During this reduction an insoluble, probably polymeric material accumulates on the platinum surface and forms a highly adhesive film, which is bright gold when thin (20–50 cycles) and orange when thicker (100–200 cycles). If the coated electrode is carefully rinsed and then reintroduced into a fresh solution containing only $Bu_4N^+PF_6^-$ in CH_2Cl_2 (0.1 M), the electrochemical response is still observed at the same potential and amplitude as for the last cycle in the original solution. This result confirms that an immobilized electroactive coating is formed on the electrode.

The morphology of the film was investigated with a scanning electron microscope (Fig. 7). The structure of the film appears to be homogeneous, with small ball-like features, resembling those previously observed in cathodic electropolymerized ruthenium bis(4-pyridyl)acetylene complexes.[18]

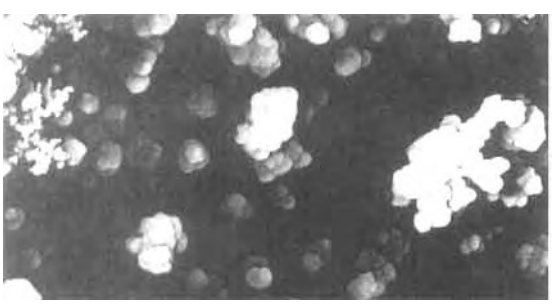

Fig. 7. Scanning electron micrograph of a film formed by polymerization of **1** on a Pt cathode (100 cycles), magnification: 3×10^3; 3 mm ≈ 1 μm.

The fact that the film continues to build up during electrolysis of **1**, even after it has covered the electrode, implies that it is electrically conducting. This conclusion is supported by the observation that film-covered electrodes give an essentially normal electrochemical response with known redox systems.[19] The C_{60} polymer is chemically stable in air and can be used as a material in electrodes with a reasonably wide electroactivity range (e.g., −0.8 to + 0.6 V, vs. ferrocene, 0.1 M solution of $Bu_4N^+PF_6^-$ in CH_2Cl_2).[20]

Reductive electrochemical polymerization has previously been reported for some simple alkynes,[21] as well as for a few metal complexes containing alkynyl pyridine ligands.[18,22] But in general, this type of electropolymerization has received little attention.[23]

[10] We first attempted an X-ray structure analysis of 61,61-bis(trimethylsilylethynyl)-1,2-dihydro-1,2-methanofullerene[60]. Large cubic single crystals were grown from cyclohexane, but these crystals were highly disordered and scattered to a resolution of only about 2.5 Å, so an accurate structure could not be obtained. Orientational disorder is common in such compounds. We sought to circumvent this problem by increasing the length of the acetylenic substituents, and suitable crystals of **1** were grown. Crystal data at 100 K for **1a** $[(C_{75}H_{18}Si_2)\cdot 1/2(CS_2), M_r = 1031.2]$: monoclinic, space group $P2_1/c$ (no. 14), $\rho_{calcd} = 1.57\ g\,cm^{-3}$, $Z = 4$, $a = 10.230(3)$, $b = 22.720(12)$, $c = 19.316(11)$ Å, $\beta = 103.37(4)°$, $V = 4368(4)$ Å^3. Enraf-Nonius CAD4 diffractometer, $Cu_{K\alpha}$ radiation, $\lambda = 1.5418$ Å. Crystal specimens of **1a** were obtained by slow evaporation of a CS_2 solution. At room temperature, the crystals lost their solvent very quickly in air, so they were cut and mounted at about 250 K. All investigated crystals were more or less twinned. To reduce the effect of this systematic error, all reflections were measured in at least two crystal orientations. Some of the strongly contaminated reflections were reexamined on the diffractometer after data collection. In most cases, the error could be reduced substantially. For 15 reflections no satisfactory correction could be made, and they were excluded from the analysis. The structure was solved by direct methods and refined by full-matrix least-squares analysis (SHELXTL PLUS), using an isotropic extinction correction and an exponentially modified weight factor $r = 4$ Å^2. $R(F) = 0.053$, $wR(F) = 0.068$ for 722 variables and 2872 observed reflections with $F > 4\sigma(F)$ and $\theta < 55°$ (heavy atoms, anisotropic; H atoms, isotropic; H positions based on stereochemical considerations). Crystal data at 100 K for **1b** $[(C_{75}H_{18}Si_2)\cdot 2(C_7H_8), M_r = 1159.3]$: triclinic, space group $P\bar{1}$ (no. 2), $\rho_{calcd} = 1.42\ g\,cm^{-3}$, $Z = 2$, $a = 12.580(1)$, $b = 13.547(2)$, $c = 17.984(2)$ Å, $\alpha = 109.08(1)$, $\beta = 90.37(1)$, $\gamma = 109.16(1)°$, $V = 2714(1)$ Å^3. Enraf-Nonius CAD4 diffractometer, $Cu_{K\alpha}$ radiation, $\lambda = 1.5418$ Å. Single crystals of **1b** were obtained by slow evaporation of a toluene solution. To avoid evaporation of the solvent molecules, a single crystal was cut and mounted at about 250 K. The structure was solved by direct methods and refined by full-matrix least-squares analysis (SHELXTL PLUS), using an isotropic extinction correction and an exponentially modified weight factor $r = 5$ Å^2. Final $R(F) = 0.049$, $wR(F) = 0.052$ for 857 variables and 8722 observed reflections with $F > 6\sigma(F)$ and $\theta < 75°$ (heavy atoms, anisotropic; H atoms, isotropic; H positions based on stereochemical considerations). Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.
[11] Estimated standard deviations are 0.002–0.004 Å for bond lengths and atom centroid distances, and 0.1–0.3° for bond angles in **1b**. The standard deviation s of the mean values (given in parentheses) was calculated according to the equation $s = [\Sigma_m(x_m - \langle x \rangle)^2/(m-1)]^{1/2}$.

[17] All electrochemical measurements were carried out with a 0.1 M solution of $Bu_4N^+PF_6^-$ in anhydrous dichloromethane as the supporting electrolyte. A potentiostat (Bruker EI30M) connected to an x-y plotter (Ifélec IF3802) was used. Electrolysis was performed in a classical three-electrode cell. The working electrode was a platinum disk electrode, the counter electrode a platinum wire, and the reference an aqueous Ag/AgCl electrode. Potentials were referenced to the internal ferrocene.

[18] J. M. Calvert, D. L. Peebles, R. J. Nowak, *Inorg. Chem.* **1985**, *24*, 3111–3119.

[19] For example, with a film-covered Pt electrode, the cyclic voltammograms of the ferrocene/ferricinium couple in $Bu_4N^+PF_6^-/CH_2Cl_2$ (0.1 M) exhibited peaks at + 0.44 V with respect to Ag/AgCl [$(E_{pa} + E_{pc})/2$], and a ΔE_p of 100 mV ($= E_p^{ox} - E_p^{red}$) at a sweep rate of 0.1 Vs^{-1}; with a bare Pt electrode, peaks were located at + 0.41 V with a ΔEp of 60 mV.

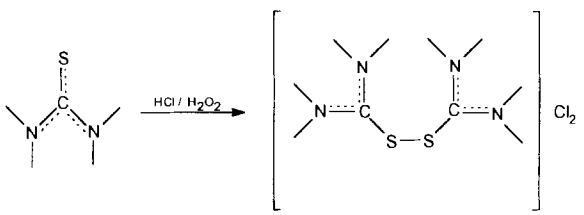
An Unusual Route to Potential Platinum Antitumor Compounds: Synthesis, Reactivity, and Spectroscopic Properties of the Pt^{IV} Complex *fac*-$[PtCl_3(NH_3)_2L]Cl$**

Ulrich Bierbach* and Jan Reedijk*

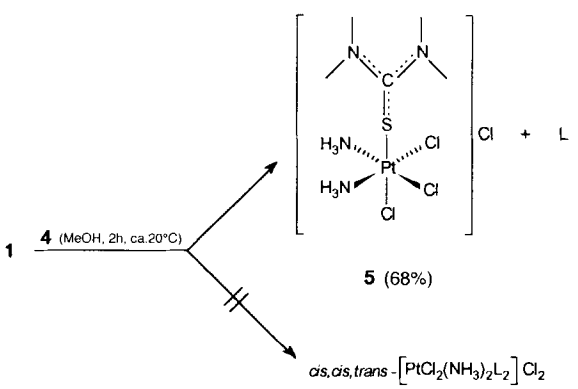
The clinical successes in the treatment of malignant tumors with cisplatin (*cis*-diamminedichloroplatinum(II) **1**, Scheme 1), particularly in the urogenital and gynecological areas,[1] are



1 **2**

Scheme 1. Cisplatin (**1**) and general formula **2** for potentially active, second-generation Pt^{II} and Pt^{IV} antitumor compounds: am = nonleaving groups (am(m)ine ligands). X = leaving groups (Cl^-, RCO_2^-), Y = axial ligands in Pt^{IV} complexes (Cl^-, OH^-).

counterposed by drastic side effects in the digestive tract and in the kidney region. In attempts to reduce the toxic side effects, coordinatively saturated, kinetically inert Pt^{IV} antitumor compounds have been prepared. Iproplatin, *cis,trans,cis*-$[PtCl_2(OH)_2(iPrNH_2)_2]$,[2] and tetraplatin, $[PtCl_4(dach)]$ (dach = *d,l-trans*-1,2-diaminocyclohexane),[3] are currently undergoing clinical trials. Acid-stable, lipophilic Pt^{IV} complexes with carboxylato ligands (in the *trans* positions, instead of OH^- or Cl^-) are possibly the first active antitumor compounds based on platinum that can be administered orally.[4] Apart from minimization of the undesired toxicity, the development of substances with different activity spectra (tumor specificity) is also important.[5] For this purpose new combinations of ligands are needed, which do not necessarily need to exactly follow the structure–activity relationship (see **2**, Scheme 1) for second-generation Pt^{II} and Pt^{IV} antitumor compounds. We have now expanded the spectrum of the ligands Y in Pt^{IV} compounds of type **2** by an S-donor ligand with the regioselective introduction of a thiourea derivative.



The oxidative dimerization of 1,1,3,3-tetramethylthiourea (**3**) leads to a doubly positively charged bis(formamidinium) ion with a central disulfide bridge (Scheme 2). Its synthetic potential

3 **4**

Scheme 2. Oxidative dimerization of **3** (L) to **4** ($[L-L]Cl_2$).

was first demonstrated by redox substitutions in Fe^{II} complexes, in which the thiolato ligands (under maintenance of the oxidation state of the central ion) were oxidized to the corresponding disulfide, which could be replaced by thiourea.[6] The 1:1 reaction of **4** with cisplatin yields **5**[7] (Scheme 3), the parent com-

Scheme 3. *fac*-$[PtCl_3(NH_3)_2L]Cl$ (**5**), the product of the oxidative addition of **4** to cisplatin (**1**). A chloride counterion from **4** becomes a ligand in **5**. The following mechanism seems plausible: 1. electrophilic attack of $[L-L]^{2+}$ on the Pt d_{z^2} orbital with 2e oxidation of the central ion; 2. square-pyramidal, positively charged Pt^{IV} transition state with thiourea coordination; 3. completion of the octahedral geometry and reduction of the charge by addition of Cl^- *trans* to sulfur.

pound of a new group of cationic, water-soluble Pt^{IV} complexes (the reaction with $[PtCl_2(en)]$ and other cisplatin derivatives leads to analogous complexes).[8] The overall reaction can be described as an oxidative *trans* addition of a thiourea ligand and

[**] L = 1,1,3,3-tetramethylthiourea. This research was supported by the Deutsche Forschungsgemeinschaft. We thank Johnson Matthey Ltd. (Reading, England) for the generous loan of platinum.

a chloro ligand. The desired *trans* addition of two thiourea ligands was not observed. Consequently the anions in **4** were exchanged by noncoordinating tetrafluoroborate (BF_4^-) to avoid an excess of anionic ligands in solution that compete with L. However, no reaction occurred, even after heating at reflux for several hours. Thus free chloride in solution must probably play a role in the mechanism of the oxidative addition (for details see the legend of Scheme 3).

Complex **5** is unusually acidic in aqueous solution: a 0.01 M solution has a pH value of 2, which is reached within 10 minutes after dissolution of the Pt^{IV} complex. A linear relationship was observed between the pH value and $\lg c_{Pt^{IV}}$, which indicates that independent of the degree of dilution one proton is released per complex cation, and **5** is thus a strong acid. This hypothesis can be explained as follows: hydrolysis occurs owing to the labilizing influence of the S donor on the Pt–Cl bond in *trans* position, and subsequently the aqua ligand is deprotonated to give a hydroxo ligand.

In the IR spectrum of **5** the broad stretching bands ν_{as}(NH) and ν_{sym}(NH) of the ammine ligands at $\tilde{\nu} = 3270$ and 3010 cm^{-1}, respectively, lie at unusually low wavenumbers. This observation indicates that hydrogen bonds of the NH–Cl type exist in the solid state. These have previously only been observed in antitumor complexes of Pt^{IV}, in which the N–H bond is strongly polarized, as confirmed by an X-ray structural analysis.[9] The band of the ν_{as}(CN) stretching vibration of the thiourea ligand (C = thiocarbonyl carbon) at $\tilde{\nu} = 1586$ cm^{-1} is shifted to higher wavenumbers by 80 cm^{-1} relative to the corresponding band of free **3**. This leads to the conclusion that the ligand coordinates through the sulfur atom, and consequently the bond order of the C–N bond in the thiourea ligand increases. Three intense vibrational bands in the far-IR spectrum are assigned as follows: $\tilde{\nu}_{as}$(PtCl) = 341 cm^{-1}, $\tilde{\nu}_{sym}$(PtCl) = 326 cm^{-1} for chloride *trans* to NH_3, corresponding to *a'* and *a''* assuming C_s symmetry for the complex, and $\tilde{\nu}$(PtCl) = 309 cm^{-1} for chloride *trans* to the S-donor ligand.

The ^{1}H NMR spectrum of **5** in [D_4]methanol shows, apart from a singlet for the methyl protons of the thiourea ligand at $\delta = 3.35$, an unusually well-resolved nine-line pattern for the ammine protons centered at $\delta = 5.82$ (Fig. 1). This is due to ^{195}Pt–^{1}H coupling, $^2J = 48$ Hz ("platinum satellites"), and ^{14}N–^{1}H coupling, $^1J = 53$ Hz. This latter quadrupole coupling is observed only in Pt^{IV} complexes.[10] Integration of the signals indicates that the ratio of NH_3 to CH_3 protons is 1:2 and consequently confirms the presence of only one thiourea ligand in **5**. Significant H,D exchange was not observed for the signal of the ammine protons, even after several hours in anhydrous [D_4]methanol. The ^{1}H-decoupled ^{195}Pt NMR spectrum of **5** in [D_4]methanol shows a quintet at $\delta = 910$ (ext. standard $K_2[PtCl_4]$), which corresponds to $\delta = -721$ when $[PtCl_6]^{2-}$ is used as a standard.[11] The splitting is due to the coupling of the two equivalent ^{14}N nuclei of the NH_3 ligands ($I = 1$) with the platinum isotope ^{195}Pt ($I = 1/2$, natural abundance 34%) (Fig. 2). The coupling constant $^1J(^{195}Pt,^{14}N) = 173$ Hz lies in a region characteristic for Pt^{IV} complexes with ammine ligands *trans* to chloro ligands. This value also points to the *cis* influence of the axial S donor on the ^{195}Pt–^{14}N coupling.[12] The introduction of a S-donor ligand, in other words the formal replacement of a chloro ligand in *cis*-$[(NH_3)_2PtCl_4]$ ($\delta_{Pt} = -145$ relative to $[PtCl_6]^{2-}$)[12] with a tetramethylthiourea ligand in **5**, leads, as expected, to a greater shielding of the Pt nucleus and thus to an upfield shift of the ^{195}Pt resonance.

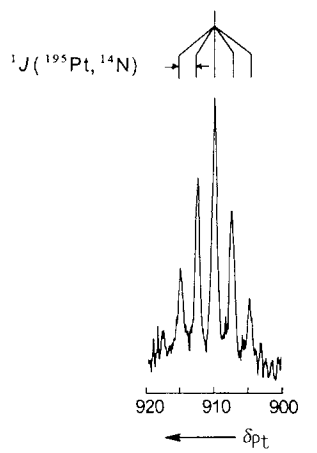

Fig. 2. ^{195}Pt{^{1}H} NMR spectrum of **5** (64 MHz, [D_4]methanol, $c = 10^{-2}$ M, 298 K, ext. standard $K_2[PtCl_4]$ (aq)) with a scheme of the heteronuclear coupling.

The primary target molecule in the mechanism of action of Pt antitumor compounds is chromosomal DNA.[13] In a model reaction we treated **5** with 5'-guanosine monophosphate (5'-GMP), a simple monomeric nucleic acid fragment, under physiological conditions. We will report on the preliminary results of these studies as well as on current in vivo investigations with **5** on P388 leukemia elsewhere.

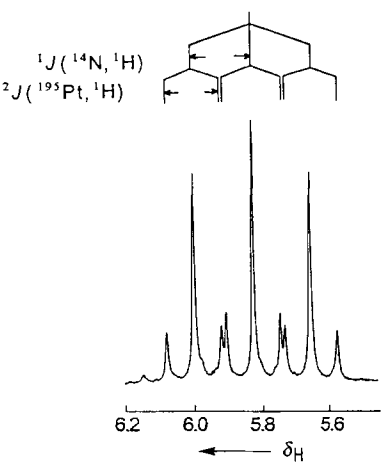

Fig. 1. ^{1}H NMR signal of the ammine ligands in **5** (300 MHz, [D_4]methanol, $c = 10^{-2}$ M, 298 K, TMS) with a scheme of the heteronuclear couplings.

Experimental Procedure

The ^{1}H and ^{195}Pt NMR measurements were conducted on a Bruker WM300 NMR spectrometer at 300 and 64 MHz respectively; the IR and far-IR spectra (KBr and polyethylene pellets, respectively) were recorded on a Bruker IFS 113v FT-IR spectrometer.

Synthesis of **5**: To a solution of 0.167 g (0.5 mmol) **4** [6] in 5 mL anhydrous methanol was added 0.15 g (0.5 mmol) cisplatin (**1**) [14]. The suspension was stirred at room temperature under exclusion of light for 2 h. Diethyl ether was added to the resultant orange-yellow solution until it became cloudy, and the mixture was stored for several days in a refrigerator. The resulting orange microcrystalline precipitate was filtered off and washed with diethyl ether to give 0.176 g (68%) of **5**. The complex crystallized as **5**·0.5CH_3OH, which was confirmed by C,H,N analysis.

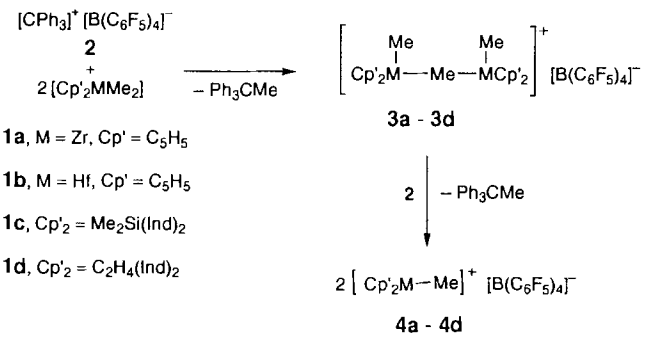
Monomer–Dimer Equilibria in Homo- and Heterodinuclear Cationic Alkylzirconium Complexes and Their Role in Polymerization Catalysis**

Manfred Bochmann* and Simon J. Lancaster

Base-free cationic Group 4 metal alkyl complexes of the general formula $[Cp_2M\text{-}R]^+$ (R = alkyl, M = Ti, Zr, Hf) are highly active catalysts for the polymerization of olefins.[1–3] In conventional homogeneous Ziegler catalyst systems cationic species of this kind are formed by the reaction of metallocenes with alkylaluminum activators such as methylaluminoxane.[1c, 4, 5] Aluminum-free complexes are best prepared by reacting dialkylated metallocenes $[Cp_2MR_2]$ with triphenylcarbenium salts of "noncoordinating" anions,[6] such as $[CPh_3][B(C_6F_5)_4]$ (**2** in Scheme 1). It is generally assumed that these reactions lead to monomeric cationic 14-electron complexes [Eq. (a)].[7] This reaction has found widespread application for the generation of cationic polymerization catalysts.[3, 8–11]



$$[Cp_2MR_2] + [CPh_3][B(C_6F_5)_4] \longrightarrow [Cp_2M\text{-}R][B(C_6F_5)_4] + Ph_3CR \qquad (a)$$

As part of our continuing interest in the characterization of homogeneous polymerization systems based on cationic alkyl metal complexes[2, 10, 12] we have shown recently that monomeric alkyl cations $[Cp_2ZrR]^+$ are indeed the only products if $R = CH_2Ph$, even in the presence of an excess of $[Cp_2ZrR_2]$, since the electron deficiency of the metal center is alleviated by the η^2-coordination of the benzyl ligand.[3, 13] However, we noted earlier in the case of methyltitanium complexes the appearance of a short-lived dimeric intermediate, $[(Ind_2TiMe)_2(\mu\text{-}Me)]^+$ (Ind = indenyl).[10, 14] Following the reaction of methylzirconium and -hafnium complexes with $[CPh_3][B(C_6F_5)_4]$ (**2**) at low temperature has now shown that the formulation of Equation (a) does not adequately describe the course of the reaction and that stable dimeric complexes may be the major products, depending on the reaction conditions.

The reaction of the methyl complexes $[Cp'_2MMe_2]$ (**1a–1d**) with **2** at −60 °C in CD_2Cl_2 led to the formation of dinuclear methyl-bridged complexes **3** (Scheme 1). The reaction is essentially quantitative. Evidently adduct formation with a neutral dialkylmetallocene stabilizes the 14-electron cation $[Cp'_2MMe]^+$ more effectively than a solvent molecule or anion coordination.

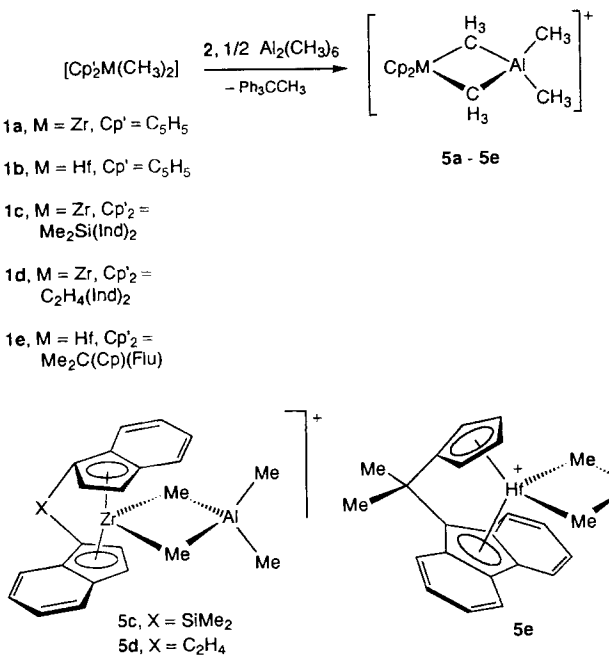
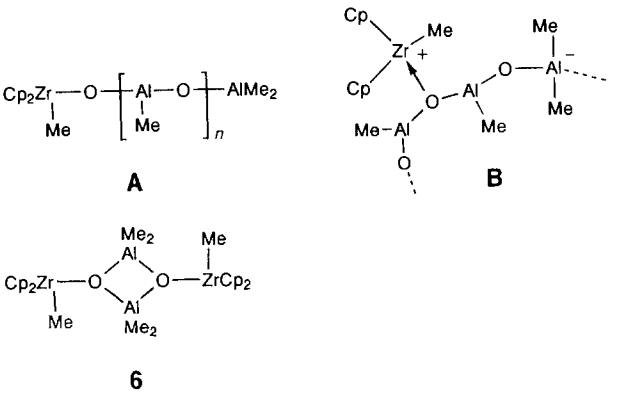
Scheme 1. Counterion of the complexes **3** and **4** is $[B(C_6F_5)_4]^-$.



Compounds **3a**-$[B(C_6F_5)_4]$ and **3b**-$[B(C_6F_5)_4]$ are obtained from dichloromethane/hexane mixtures as off-white, very hydrolysis-sensitive needlelike crystals, while the attempted isolation of **3c** led to the precipitation of a red oil which could not be crystallized. For spectroscopic examination the compounds are generated in situ in CD_2Cl_2. Since *rac*-**1c** consists of a mixture of (*R*) and (*S*) enantiomers, the formation of a cationic dimer results in two diastereomers in a ratio of 2:1 (Scheme 2). The cation **3d** forms a pair of diastereomers in a ratio of 1.7:1.

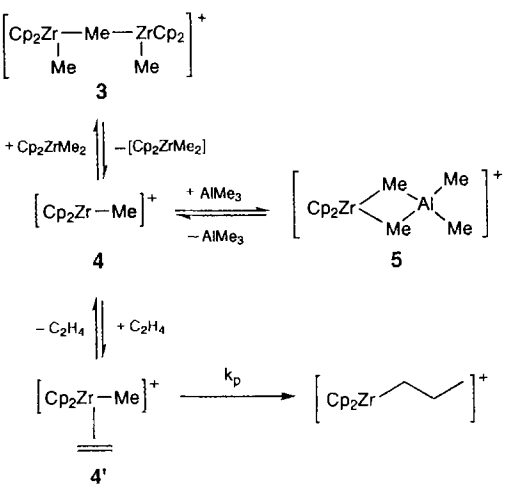


Scheme 2. Counterion is $[B(C_6F_5)_4]^-$.

The stability of the dimers and the rate of reaction with excess CPh_3^+ depends on the nature of the Cp ligands. The reaction of **3a** with **2** is essentially complete on warming a solution to −40 °C; this gives the monomeric cation **4a**.[15] By contrast, **3c** persists even in the presence of an excess of the triphenylcarbenium salt up to a temperature of about 20 °C. Although at that stage further reaction with **2** does take place, presumably with formation of **4c**, this is quickly followed by decomposition since **4c** is not stable in chlorinated solvents under these conditions. The cation **3d** is slightly less stable than **3c**, and conversion to **4d** begins already at 0 °C.[16] As in the case of **4c**, an unambiguous assignment of the Zr–Me ^{1}H NMR signal of **4d** was not possible.[17] The compounds are insufficiently soluble for NMR studies in toluene.

In the presence of trimethylaluminum the cations $[Cp'_2MMe]^+$ form preferentially the heterodinuclear complexes $[Cp'_2M(\mu\text{-}Me)_2AlMe_2]^+$ (**5a–5e**) (Scheme 3). The reaction of a

Scheme 3. Counterion of complex **5** is $[B(C_6F_5)_4]^-$. Flu = fluorenyl.



mixture of **1a**, Al_2Me_6, and **2** in CD_2Cl_2 at $-50\,^{\circ}C$ gave **5a**-$[B(C_6F_5)_4]$ as the main product, characterized in the ^1H NMR spectrum by two sharp singlets at $\delta = -0.48$ and $\delta = 0.68$, besides small quantities of **3a**-$[B(C_6F_5)_4]$ and residual Al_2Me_6. In the absence of **1a** there is no reaction between Al_2Me_6 and $[CPh_3]^+$ below $20\,^{\circ}C$. In contrast to Al_2Me_6, **5a** does not show fluctuating behavior in CD_2Cl_2 up to a temperature of $25\,^{\circ}C$. There is no evidence for an intramolecular exchange process between bridging and terminal methyl ligands of **5a**, or for an intermolecular exchange between **5a**, **3a**, and Al_2Me_6. The fluxional behavior of the latter is not influenced by the presence of the zirconium complexes. Whereas monomeric alkyl cations such as $[Cp_2Zr(\eta^2\text{-}CH_2Ph)]^+$ decompose slowly in CD_2Cl_2 above $-40\,^{\circ}C$ and more rapidly on warming to $20\,^{\circ}C$,[3] **5a** is stable in dichloromethane at $20\,^{\circ}C$ for several hours. The analogous hafnium complex **5b** shows similar behavior. Both complexes are isolated as colorless, pyrophoric needles in 90 and 74% yield, respectively. Once crystallized the complexes are only sparingly soluble in dichloromethane or toluene.

The *ansa*-metallocene complexes **5c**–**5e** were obtained similarly and have been characterized in CD_2Cl_2. They are stable in chlorinated solvents. On cooling to $-20\,^{\circ}C$ **5c**-$[B(C_6F_5)_4]$ precipitates as an oil which could not be crystallized.

The nature of the interaction between alkylaluminum compounds, such as methylaluminoxane (MAO), and metallocene catalysts has been the subject of much debate. While it could be shown that the reaction of $[Cp_2ZrMe_2]$ with solid MAO generated $[Cp_2ZrMe]^+$ on the surface,[5] the structure of the cationic species and the nature of the interaction between the catalyst and MAO under catalytic conditions, in other words in solution, remains uncertain. For example, coordination of an MAO oxygen atom to the metal center has been suggested, as in **A** or **B**,[18, 19] and Erker et al. were able to isolate complex **6**, formally an adduct between $[Cp_2ZrMe]^+$ and $[Al_2O_2Me_4]^{2-}$, which may be regarded as a model for such an interaction.[19] However, **6** does not possess any readily accessible coordination sites and is not catalytically active in the absence of excess MAO. Since MAO always contains significant amounts of $AlMe_3$ ($3.5 \pm 1\%$ have been estimated[20]) and is usually employed at Al/Zr ratios of 10^3 to 10^4,[21] it seems likely that the cationic zirconium species formed under these conditions is not $[Cp_2ZrMe]^+$ but the alkylaluminum adduct **5**. This assumption is supported by the finding that a large proportion of MAO can be replaced by $AlMe_3$ without loss of productivity.[22, 23] Catalysts generated from $[Cp'_2ZrX_2]$/**2** mixtures in the presence of excess AlR_3 have recently been reported (X = Cl, Me; R = Me, Et), although the resulting zirconium complexes have not been identified.[7g, 24]

According to the current mechanistic concept olefin polymerizations with the dimeric complexes **3** are only possible if **3** dissociates partially to **1** and the active species **4** (Scheme 4). The

Scheme 4.

catalytic activity should therefore decrease with increasing concentration of **1**, since the equilibrium is shifted towards **3** at the expense of the productive complex **4'**. However, ethylene polymerizations with 1:1 mixtures of **1a** and **2** in toluene produce only traces of polymer, whereas a ratio of 3:1 gives a productivity of 0.5×10^6 g PE(mol Zr +)$^{-1}$bar^{-1}h^{-1}. We explain this anomaly by the lack of stability of the unsubstituted cation **4a**. By contrast, complex **4c**, generated from a 1:1 mixture of *rac*-**1c** and **2**, polymerizes propene with excellent activities (Table 1) which decrease with increasing **1c**/**2** ratio, as expected (Fig. 1). Increasing the metallocene excess from 1:1 to 16:1 reduces the productivity at $20\,^{\circ}C$ by about one order of magnitude.[25] Since higher temperatures favor dissociation, this effect is less pronounced at $60\,^{\circ}C$ but still significant.

Similarly, alkylaluminum adducts **5** are coordinatively saturated and lack a vacant orbital suitable for binding the olefinic substrate. Initiation of chain growth requires therefore the dis-

[a] Polymerization conditions as given in Table 1. Polymerizations were terminated by methanol injection after 30 s. [b] Under the assumption that $[CPh_3^+]_0$ = maximum $[Zr^+]$ concentration.

for an Al/Zr ratio of only 1:1; at 20°C the addition of a 100-fold excess of $AlMe_3$ lowers the productivity by about a factor of 40. Higher aluminum concentrations also reduce the polymer molecular weight, probably as the result of chain-transfer reactions. Ethylene polymerizations with **5a** and **5b** show a similar trend. Large excesses of alkylaluminum are evidently not an essential requirement for high catalytic activity and may indeed be counterproductive.

Experimental Procedure

All manipulations were carried out under dry argon.

3a-$[B(C_6F_5)_4]$: **1a** (300 mg, 1.2 mmol) and **2** (400 mg, 0.43 mmol) were dissolved in CH_2Cl_2 (10 mL) at −78 °C. The pale yellow solution was layered with hexane (10 mL) and left to crystallize at −16 C. Off-white, very air-sensitive needles of **3a**-$[B(C_6F_5)_4]$ were obtained (150 mg, 0.13 mmol, 30%). The elemental analysis of the compond was low in C due to the sensitivity to hydrolysis ($C_{47}H_{29}BF_{20}Zr_2$, calcd. C, 48.4; H, 2.5; found C, 46.9; H, 2.3). The crystalline compound was only sparingly soluble in cold dichloromethane.

The procedure for generating solutions of **3**-$[B(C_6F_5)_4]$ in situ is exemplified below for **3a**-$[B(C_6F_5)_4]$. **1a** (100 mg, 0.39 mmol) and **2** (153 mg, 0.16 mmol) were each dissolved in CD_2Cl_2 (0.4 mL), cooled to −78 °C, and transferred to an NMR tube to give a yellow solution on mixing. The sample was inserted into a JEOL EX270 spectrometer at −60 °C. The triphenylcarbenium salt was consumed quantitatively under these conditions, and **3a**-$[B(C_6F_5)_4]$ was observed besides residual unconverted **1a**. **3c**-$[B(C_6F_5)_4]$ was obtained as a dark red oily precipitate. In all cases the assignment of the NMR signals was confirmed by 2D $^1H/^{13}C$ COSY experiments. **3a**-$[B(C_6F_5)_4]$: ^1H NMR (CD_2Cl_2, −60 °C): δ = −0.76 (s, 3 H, Zr-(CH_3)-Zr), 0.28 (s, 6 H, Zr-CH_3 terminal), 6.30 (s, 20 H, Cp); ^{13}C NMR (CD_2Cl_2, −60 °C): δ = 23.81 (q, ^1J(C,H) = 135.5 Hz, Zr-(CH_3)-Zr), 38.81 (q, ^1J(C,H) = 120.2 Hz, Zr-CH_3 terminal), 113.06 (Cp). **3b**-$[B(C_6F_5)_4]$: ^1H NMR (CD_2Cl_2, −20 °C): δ = −0.72 (s, 3 H, Hf-(CH_3)-Hf), 0.09 (s, 6 H, Hf-CH_3 terminal), 6.24 (s, 20 H, Cp); ^{13}C NMR (CD_2Cl_2, −20 °C): δ = 24.42 (q, ^1J(C,H) = 134 Hz, Hf-(CH_3)-Hf), 40.93 (q, ^1J(C,H) = 118 Hz, Hf-CH_3 terminal), 112.43 (Cp). **3c**-$[B(C_6F_5)_4]$: Only the Zr-CH_3 and Si-CH_3 signals were assigned. Signals in the indenyl region overlap because of the presence of two isomers as well as triphenylethane. ^1H NMR (CD_2Cl_2, −60 °C): isomer A: δ = −2.75 (s, 3 H, Zr-(CH_3)-Zr), −0.89 (s, 6 H, Zr-CH_3 terminal), 0.99 (s, 3 H, Si-CH_3), 1.11 (s, 3 H, Si-CH_3). Isomer B: δ = −2.93 (s, 3 H, Zr-(CH_3)-Zr), −0.88 (s, 6 H, Zr-CH_3 terminal), 0.98 (s, 3 H, Si-CH_3), 1.08 (s, 3 H, Si-CH_3). ^{13}C NMR (CD_2Cl_2, −60 °C) (isomer A): δ = −3.05 (Si-CH_3), −1.96 (Si-CH_3), 25.43 (q, ^1J(C,H) = 136.1 Hz, Zr-(CH_3)-Zr), 46.40 (q, ^1J(C,H) = 115.8 Hz, Zr-CH_3 terminal). **3d**: ^1H NMR (CD_2Cl_2, −60 °C): isomer A: δ = −2.99 (s, 3 H, Zr-(CH_3)-Zr), −0.87 (s, 6 H, Zr-CH_3 terminal). Isomer B: δ = −3.10 (s, 3 H, Zr-(CH_3)-Zr), −0.96 (s, 6 H, Zr-CH_3 terminal).

5a-$[B(C_6F_5)_4]$: Al_2Me_6 (0.7 mmol, 0.7 mL of a 1 mM solution in dichloromethane) was added to a solution of **1a** (0.18 g, 0.67 mmol) and **2** (0.8 g, 0.87 mmol) in dichloromethane (15 mL) at −70 °C. The resulting suspension was warmed to −20 °C with stirring until the yellow-orange color of **2** faded. Addition of cyclopentane (10 mL) produced a white precipitate which was filtered off, washed with cyclopentane, and dried in vacuo. Yield 0.6 g (0.60 mmol, 90%). The product contained traces of **3a**. Crystalline **5a** was only sparingly soluble in dichloromethane and could not be recrystallized without decomposition. ^1H NMR (270 MHz, CD_2Cl_2, −60 °C): δ = −0.48 (s, 6 H, terminal Al-CH_3), 0.68 (s, 6 H, μ-CH_3), 6.62 (s, 10 H, Cp). ^{13}C NMR (67.8 MHz, CD_2Cl_2, −60 °C): δ = −6.76 (q, ^1J(C,H) = 115.4 Hz, Al-CH_3), 38.51 (q, ^1J(C,H) = 113.5 Hz, μ-CH_3), 115.96 (Cp).

5b-$[B(C_6F_5)_4]$: **1b** (0.35 g, 1.0 mmol), **2** (0.92 g, 1.0 mmol), and Al_2Me_6 (1 mmol) were treated similarly in dichloromethane at −78 °C to −20 °C to give white, finely crystalline **5b** (0.80 g, 74%). Elemental analysis: calcd. $C_{38}H_{22}AlBF_{20}Hf$: C, 42.46; H, 1.75; found C, 43.46; H, 1.75. ^1H NMR (270 MHz, CD_2Cl_2, −20 °C): δ = −0.44 (s, 6 H, Al-CH_3), 0.98 (s, 6 H, μ-CH_3), 6.49 (s, 10 H, Cp). ^{13}C NMR (67.8 MHz, CD_2Cl_2, −60 °C): δ = −6.31 (q, ^1J(C,H) = 114 Hz, Al-CH_3), 38.20 (q, ^1J(C,H) = 114 Hz, μ-CH_3), 114.43 (Cp).

5c-$[B(C_6F_5)_4]$: **1c** (50 mg, 0.12 mmol) and **2** (120 mg, 0.13 mmol) were each dissolved in CD_2Cl_2 (0.4 mL). The solution of **1c** was transferred into an NMR tube, cooled to −78 °C, and treated with Al_2Me_6 (1 mL of a 0.05 mM solution), followed by the cold (−78 °C) solution of **2**. Spectra were recorded between −60 °C and 20 °C. ^1H NMR (270 MHz, CD_2Cl_2, −20 °C): δ = −0.81 (s, 6 H, μ-CH_3), −0.61 (s, 6 H, Al-CH_3), 1.29 (s, 6 H, Si-CH_3), 5.91 (d, 2 H, ^3J(H,H) = 3.3 Hz, Ind-C_5), 6.92 (d, 2 H, ^3J(H,H) = 3.3 Hz, Ind-C_5), 7.08–7.34 (m, 4 H, Ind-C_6, partially obscured by Ph_3CMe), 7.58 (d, 2 H, ^3J(H,H) = 8.6 Hz, Ind-C_6), 7.77 (d, 2 H, ^3J(H,H) = 8.6 Hz, Ind-C_6). ^{13}C NMR (67.8 MHz, CD_2Cl_2, −60 °C): δ = −7.12 (q, ^1J(C,H) = 115 Hz, Al-CH_3), −2.34 (Si-CH_3), 35.27 (q, ^1J(C,H) = 113.5 Hz, μ-CH_3), 85.16 (Si-C_5), 116.05 (C_5), 119.33 (C_5), 124.98, 125.84, 126.41, 128.91, 129.45, 132.65 (C_6).

5d-$[B(C_6F_5)_4]$: ^1H NMR (270 MHz, CD_2Cl_2, −20 °C): δ = −0.63 (s, 6 H, μ-CH_3), −0.58 (s, 6 H, Al-CH_3), 4.04 (s, 4 H, -C_2H_4-), 6.20 (d, 2 H, ^3J(H,H) = 3.3 Hz, Ind-C_5), 6.44 (dd, 2 H, J = 3.3 and 0.7 Hz, Ind-C_5), 7.07–7.35 (m, 4 H, Ind-C_6, partially obscured by Ph_3CMe), 7.58 (m, 2 H, Ind-C_6), 7.90 (dd, 2 H, J = 8.6 and 1.0 Hz, Ind-C_6). ^{13}C NMR (67.8 MHz, CD_2Cl_2, −60 °C): δ = −7.03 (q, ^1J(C,H) = 116.4 Hz, Al-CH_3), 30.93 (C_2H_4), 37.32 (q, ^1J(C,H) = 113.7 Hz, μ-CH_3), 108.30 (C_5), 117.05 (C_5), 122.68 (bridgehead-C of C_5) 124.49, 125.25, 127.44, 128.82, 129.00, 131.00 (C_6).

5e-$[B(C_6F_5)_4]$: ^{1}H NMR (270 MHz, CD_2Cl_2, 25°C): $\delta = -0.72$ (s, 3 H, Al-CH_3 terminal), -0.63 (s, 3 H, Al-CH_3 terminal), -0.57 (s, 6 H, μ-CH_3), 2.49 (s, 6 H, Me_2C), 5.58 (t, 2 H, ^3J(H,H) = 2.6 Hz, C_5), 6.32 (t, 2 H, ^3J (H,H) = 2.6 Hz, C_5); Flu: 7.75 (t, 2 H, ^3J (H,H) = 8.58 Hz), 7.34 (t, 2 H, ^3J(H,H) = 8.91 Hz), 7.96 (d, 2 H, ^3J(H,H) = 8.91 Hz), 8.22 (d, 2 H, ^3J(H,H) = 8.58 Hz). ^{13}C NMR (67.8 MHz, CD_2Cl_2, 25 °C): $\delta = -7.13$ (Al-CH_3 terminal), -7.01 (Al-CH_3 terminal), 28.55 (Me_2C), 28.63 (Me_2C), 29.02 (μ-CH_3); C_5H_4: 74.14, 102.75, 117.63; Flu: 111.95, 121.29, 121.94, 124.76, 125.12, 127.22, 131.41. The resonances of the anion are identical to those of noncoordinated $[B(C_6F_5)_4]^-$ and have not been listed.

Olefin polymerizations: low-sulfur toluene (20 mL) was equilibrated at the stated temperature with the olefin under 1 bar pressure. The appropriate amount of a standard solution of the dialkyl metallocene (and of Al_2Me_6 where applicable) was injected, followed by a solution of **2** in toluene. Immediate rapid polymerization was observed. The reactor was stirred magnetically at 1000 rpm. The reactions were terminated by the injection of methanol (2 mL). The polymer was precipitated with methanol/HCl, washed with methanol, and dried at 70 °C to a constant weight. The productivities given in the Tables are the averages of at least two independent experiments per data point and were calculated by using the propene solubilities in toluene given in [21b]. Melting points of polymers were determined with a DuPont DSC 10 differential scanning calorimeter. Polymers have not been fractionated. Molecular weights and polydispersities were determined by gel permeation chromatography (polystyrene standard, PLgel-column, 1,2-dichlorobenzene, 140 °C).

[13] Mixtures of $[Cp_2Zr(CH_2Ph)_2]$ and $[Cp_2Zr(CH_2Ph)]^+$ in ratios from 2:1 to 11:1 between -20 °C and -60 °C in CD_2Cl_2 fail to provide evidence for the formation of dimeric complexes: M. Bochmann, S. J. Lancaster, *Organometallics*, **1994**, *13*, 2235.
[14] A related dimeric thorium complex is known: X. Yang, C. L. Stern, T. J. Marks, *Organometallics* **1991**, *10*, 840.
[15] The Zr-CH_3 resonance signals of the monomeric complex **4a** could not be assigned with certainty. Singlets at $\delta = 0.76$ and 0.77 and a weaker signal at $\delta = 0.66$ are replaced on addition of $[D_5]$pyridine by a single signal at $\delta = 0.35$ (-50 °C). The signals at $\delta = 0.76$ and 0.77 remain unchanged on warming, whereas the signal at $\delta = 0.66$ broadens.
[16] The stability of dimeric methyl complexes of *ansa*-zirconocenes has consequences for the evaluation of the catalytic activity of these species at low temperatures. The stability of **3c** and **3d** at low temperature suggests that only half as many cationic centers are formed as are expected on the basis of Equation (a).
[17] The ^{1}H NMR spectrum of **4c** at -30 °C shows signals for Zr-Me at $\delta = -0.47$ and -0.61 which broaden on cooling. This finding may be consistent with the presence of solvent and anion adducts of **4c**, an unambiguous assignment was, however, not possible.

The First Decaisopropylmetallocene: One-Pot Synthesis of $[Rh(C_5iPr_5)_2]PF_6$ from $[Rh(C_5Me_5)_2]PF_6$ by Formation of 20 Carbon–Carbon Bonds**

Dirk Buchholz and Didier Astruc*

Dedicated to Dr. Françoise Moulines on the occasion of her 60th birthday

Decamethylmetallocenes $[MCp^*_2]$ ($Cp^* = C_5Me_5$)[1–3] have proven highly valuable as magnetic materials[1] and catalysts.[2] Transition metal complexes with pentaisopropylcyclopentadienyl ligands show a unique directionality,[4, 5] and form a new type of chiral metallocene.[6] The remarkable robustness of these metallocenes suggests their application in chemotherapy and catalysis. Sitzman et al.[4, 7] have shown that the reaction of pentaisopropylcyclopentadienylsodium with iron chloride does not lead to decaisopropyl ferrocene, but electron transfer takes place to give the C_5iPr_5 radical.[7] We now report the synthesis of the first decaisopropylmetallocene and compare the "built-from-inside" route starting from decamethylcobaltocenium and decamethylrhodocenium.

The homologation of permethylated ligands in cationic 18-electron complexes by using excess CH_3I and *t*BuOK has been shown to work with first-row transition metal sandwich complexes containing only one permethylated ring [Eqs. (1) and (2)].

$$[Fe(C_6Me_6)Cp]PF_6 \xrightarrow[\text{THF, 25 °C}]{\text{MeI + } t\text{BuOK}} [Fe(C_6Et_6)Cp]PF_6 \quad (1)$$

$$[CoCp^*Cp]PF_6 \xrightarrow[\text{THF, 60 °C}]{\text{MeI + } t\text{BuOK}} [Co(C_5iPr_5)Cp]PF_6 \quad (2)$$

Attempts to extend this route to first-row transition metal sandwich complexes in which both rings are permethylated

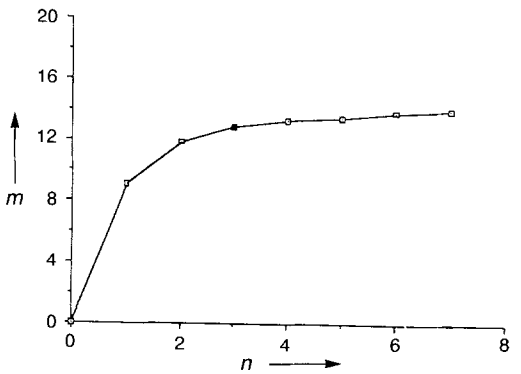
have not been successful. Starting from the complex $[FeCp^*(C_6Me_6)]PF_6$, a mixture of partially ethylated complexes is obtained, even under forcing conditions.[8] Similarly, $[CoCp^*_2]PF_6$[9] is incompletely permethylated on reaction with excess MeI and *t*BuOK in THF or with MeI and KOH in dimethoxyethane (DME) at 60 °C. The resulting mixture was treated again under similar conditions, and further methylation took place. After seven successive reactions, 69% permethylation was obtained, which appears to be the limit of steric saturation, and corresponds to roughly 14 added methyl groups per complex (Fig. 1).



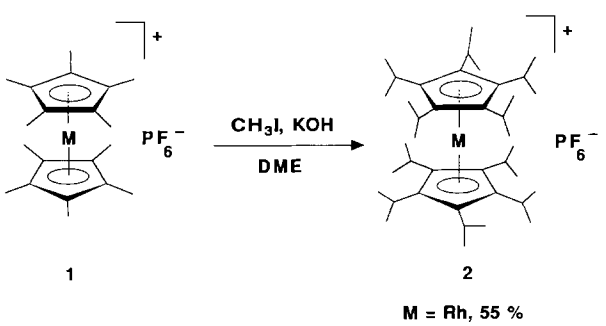


Fig. 1. Number of methyl groups *m* introduced in $[CoCp^*_2]PF_6$ as a function of the number of successive reactions *n* with excess KOH and MeI in DME at 60 °C.

We then reasoned that more space would be available between the two rings in decamethylrhodocenium since the atomic radius of Rh is greater than that of Co. Treatment of $[\{RhCp^*_2Cl_2\}_2]$ with Cp*Li in THF at −10 °C for 12 hours, followed by metathesis with aqueous HPF_6 and recrystallization from acetone/alcohol led to decamethylrhodocenium hexafluorophosphate **1** in 42% yield.[10, 11]. The reaction of $[RhCp^*_2]PF_6$ (**1**) with excess KOH and MeI in DME for two days at 60 °C afforded $[Rh(C_5iPr_5)_2]PF_6$ (**2**) in 55% yield after recrystallization from acetone/alcohol (Scheme 1).[12]

Scheme 1. Synthesis of **2**. An excess of CH_3I is used. For M = Co the reaction does not go to completion.

The ^1H NMR spectrum of **2** at 200 MHz in $C_6D_5NO_2$ shows a single septet for the ten equivalent methine protons at $\delta = 2.88$, and two doublets at $\delta = 1.17$ and 1.34 for the *endo* and *exo* methyl groups, as expected from the directionality of the *i*Pr groups in the C_5iPr_5 complexes. The signals of the methyl groups coalesce at 135 °C at which temperature no decomposition of the complex is observed. The rotation barrier of the ten *i*Pr groups in **2** is $\Delta G^{\neq} = 85.5 \pm 0.8$ kJ mol^{-1}.[13] If **3**[14] is allowed to react with excess KOH and MeI at 60 °C for three hours, **4** is obtained in 80% yield after recrystallization from acetone/alcohol.[15] In the ^1H NMR spectrum of **4** at 200 MHz in $C_6D_5NO_2$ the signals coalesce at 60 °C ($\Delta G^{\neq} = 70.3 \pm 0.8$ kJ mol^{-1}). Under these conditions, the signals for **5**[5] coalesce at 77 °C ($\Delta G^{\neq} = 71.3 \pm 0.8$ kJ mol^{-1}).

$[RhCp^*Cp]PF_6$ **3**

$[Rh(C_5iPr_5)Cp]PF_6$ **4**

$[Co(C_5iPr_5)Cp]PF_6$ **5**

The $\Delta G^{\neq}$ values for the coalescence of **4** and **5** thus differ very little from each other, which indicates that the interaction between the C_5iPr_5 ring and the Cp ring is not significant. On the other hand, the rotation barrier is higher in **2** than in **4** and **5**, as expected from the mutual steric hindrance of the two C_5iPr_5 rings. Note that, at low temperature, the single directionality of each C_5iPr_5 ring gives the possibility of obtaining two diastereoisomers of **2** (Fig. 2; **A**: clockwise/clockwise and **B**: clockwise/counterclockwise). Molecular models[15] of **2** show that **B** is considerably favored. Indeed, only the more favored diastereoisomer is detected by ^1H and ^{13}C NMR spectroscopy.[12]

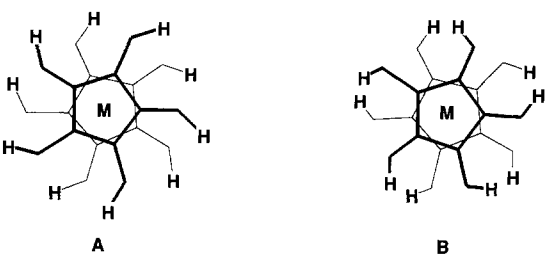

Fig. 2. The two possible conformations of decaisopropylmetallocenes. **A**: clockwise/clockwise, **B**: clockwise/counterclockwise. In the present case M = Rh^+.

In conclusion, in synthesizing the first decaisopropylmetallocene, we have shown that the permethylation of both rings in fully permethylated cationic 18-electron sandwich complexes is possible for complexes with second-row transition metals, but not for complexes of the first-row metals.

Experimental Procedure

2: **1** (518 mg, 1 mmol) and powdered KOH (5.6 g, 100 mmol) were dried in vacuo at 60 °C for 3 h, then CH_3I (14.2 g, 100 mmol) in degassed DME (20 mL) in was added by cannula. The reaction mixture was heated at 60 °C for 1 day. After the volatiles had been removed in vacuo, the solid residue was dissolved in CH_2Cl_2 and water. The aqueous phase was neutralized with HCl and washed with CH_2Cl_2. The combined aqueous extracts were shaken with an aqueous HPF_6 solution (5%), filtered over Na_2CO_3, and dried over Na_2SO_4. After removal of the solvent in vacuo, the residue was recrystallized from acetone/ethanol at −20 °C to give yellow crystals of **2** (440 mg, 55% yield). Correct C,H analysis; ^1H and ^{13}C NMR spectra see ref. [12].

4: Complex **4** was synthesized analogously from **3** (reaction time 3 h, 80% yield, see ref. [15]).

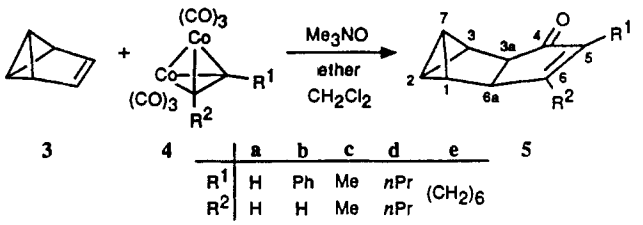
[14] B. L. Both, R. N. Haszeldine, M. Hill, *J. Chem. Soc. A* **1969**, 1299.
[15] **4**: ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.24 (d, 15H, ^3J(H,H) = 7.3 Hz), 1.30 (d, 15H, ^3J(H,H) = 7.3 Hz), 2.90 (sept, 1H, ^3J(H,H) = 7.3 Hz), 5.78 (s, 5H); ^{13}C NMR (62.38 MHz): δ = 20.3 (s), 24.5 (s), 27.0 (s), 87.8 (d, ^1J(Rh,C) = 6.7 Hz), 112.8 (d, ^1J(Rh,C) = 8.1 Hz). Correct C,H analysis. The X-ray crystal structure of **5** shows the single directionality of the five isopropyl groups: M. Cotrait, D. Buchholz, D. Astruc, unpublished results.



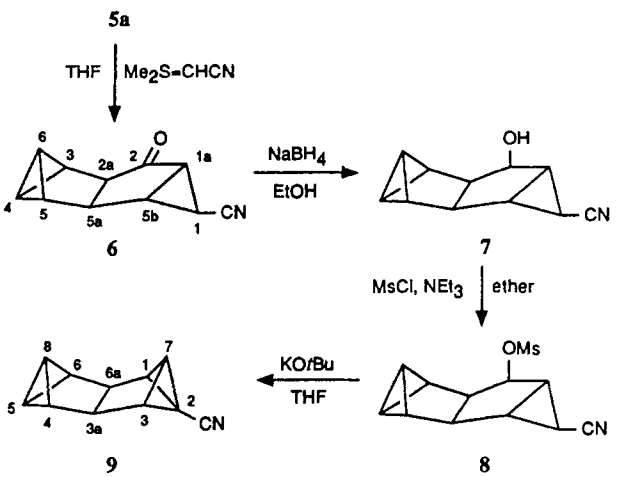
Octahydro-1,2,3:4,5,6-dimethenopentalene-2-carbonitrile, the First Derivative of a Yet-Unknown $(CH)_{10}$ Hydrocarbon**

Manfred Christl,* Michael Türk, Eva-Maria Peters, Karl Peters, and Hans Georg von Schnering

The "nonconjugated" bisbicyclobutane **1** has interesting reactivity. Owing to the proximity of the two bicyclobutane units, they interact either directly or after an external reagent has attacked either of the two.[1] In this context we have been interested in the synthesis of compounds in which two bicyclobutane units are next to one another but not linked directly. We report here on our first goal achieved in this area, the synthesis of the title compound **9**.

1  **2** 

In analogy to the synthesis of octabisvalenecarbonitrile (pentacyclo[5.1.0.0^{2,4}.0^{3,5}.0^{6,8}]octane-3-carbonitrile) by Prinzbach et al.,[2] the cyclopentenone derivative **5a** can be considered the key compound in the synthesis of **9**. We first contemplated a route starting with the allylic oxidation of hexahydro-1,2,3-methenopentalene **2**. In fact, compound **2** is known, but two preparations proceed in very low yields;[3,4] a third, a six-step sequence starting with benzvalene (**3**), has an overall yield of roughly 10% and is also quite time-consuming.[5]



3 **4**

R^1	H	Ph	Me	*n*Pr	$(CH_2)_6$
R^2	H	H	Me	*n*Pr	

5

The construction of cyclopentenones from olefins by the Pauson–Khand reaction[6] seemed to be ideal for the one-step conversion of **3** into **5a**. Thus we treated **3** with the dicobalt complex **4a**, but thereby only isomerized **3** into benzene. The intended reaction proceeded readily, however, when trimethylamine oxide, a reagent known for accelerating such reactions,[7] was added, and the desired product **5a** was isolated in 30–51% yield (see Experimental Procedure). Analogously, the derivatives **5b–e** were obtained in unoptimized yields of 33, 40, 43, and 35%, respectively.

By applying the reaction sequence recently used to transform tricyclo[4.1.0.0^{2,7}]hept-4-en-3-one into octabisvalenecarbonitrile,[2] we converted **5a** into the target compound **9** in four steps. Treatment of **5a** with dimethylsulfonium cyanomethanide provided oxonitrile **6** and its diastereomer with the opposite configuration at C1 in a 1:1 ratio (54% yield). After separation by flash chromatography (basic Al_2O_3, activity IV, diethyl ether), **6** was reduced with sodium borohydride to give hydroxynitrile **7** and its diastereomer (opposite configuration at C2) in a ratio of 4:1. Separation by flash chromatography (basic Al_2O_3, activity IV, dichloromethane) provided the pure compounds in yields of 48 and 16%, respectively. Treatment of

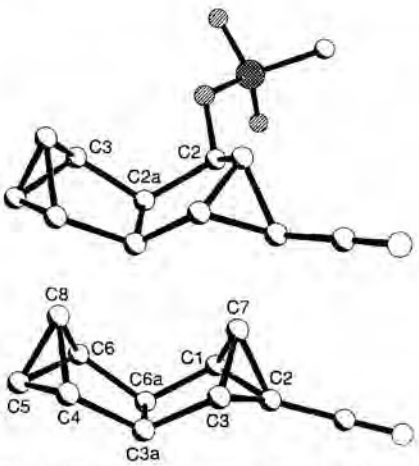
7 with methanesulfonyl chloride gave mesylate **8** (98%), which was converted into bisbicyclobutane **9** (83%) by reaction with potassium *tert*-butoxide in tetrahydrofuran. Compound **9** is the first derivative of the yet-unknown $(CH)_{10}$ hydrocarbon[8] octahydro-1,2,3:4,5,6-dimethenopentalene (hexacyclo[4.4.0.0^{2,4}.0^{3,5}.0^{7,9}.0^{8,10}]decane).

The structures of **8** and **9** were confirmed by X-ray structure analyses.[9] It is evident in Figure 1 that the cyclopropanecar-



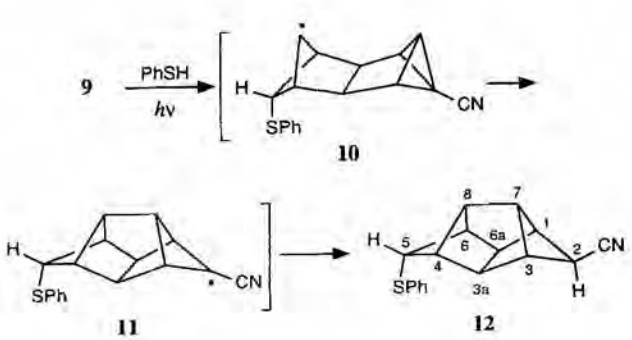


Fig. 1. X-ray crystal structures of **8** (top) and **9** (bottom) [9]. The central bonds in the bicyclobutane units have different lengths (143.6 (**8**), 145.6 (**9**, C5–C8), and 148.3 pm (**9**, C2–C7)), even though the flap angles of the bicyclobutane units are almost identical (111.1° (**8**), 110.5° (**9**, C4,5,6,8), and 111.7° (**9**, C1,2,3,7)). Thus the correlation between these bond lengths and flap angles [10] holds only for the unsubstituted bicyclobutane unit in **9**. The nitrile group in **9** causes the bonds of C2 within the three-membered rings [11] to be particularly long [C2–C1 (150.8 pm), C2–C3 (151.8 pm), and C2–C7]. The configuration of C2 is an inverted tetrahedron. The inversion parameter (angle between the bond vector C2–CN and the plane through C1,C2,C3) [12] is 174.6°. The *cis* annelation of the two five-membered rings in both **8** and **9** leads to relatively small distances between atoms that are not directly bonded [e.g. between C3 and the oxygen atom at C2 in **8** (280 pm) and between C7 and C8 in **9** (312 pm)], which results in large bond angles [C2-C2a-C3 (118.4°) in **8** and C1-C6a-C6 (116.4°) in **9**].

bonitrile unit and the mesylate group in **8** are *trans*. Thus the stereochemical prerequisite for the 1,3-elimination, in which the mesylate group is removed with inversion, is fulfilled. In **9** the distance between the bicyclobutane bridgehead atoms C7 and C8 is 312 pm.

This distance is small enough for a transannular reaction: irradiation of a solution of **9** and thiophenol in benzene furnished a 6:1 mixture of 1,3:4,6-ethane-1,2-diylidenepentalene (pentacyclo[5.3.0.0^{2,5}.0^{4,10}.0^{6,9}]decane) derivative **12** and its diastereomer (opposite configuration at C2) in 70% yield. This reaction is most likely a radical chain process analogous to the corresponding reaction of **1**.[11] The cyclobutyl radicals **10** and **11** are assumed to occur as intermediates.

The IR, NMR, and mass spectra, as well as elemental analyses, obtained for all new compounds are in agreement with the assigned structures. Selected physical data are given in Table 1.

Table 1. Selected physical data for **5a**, **6**–**9**, and **12**; 200 or 400 MHz ^{1}H NMR spectra, 50, 63, or 100 MHz ^{13}C NMR spectra, measured in $CDCl_3$; the assignments given in the NMR spectra are based on decoupling experiments, NOE effects, and ^{1}H,^{1}H COSY spectra.

Experimental Procedure

5a: A moderate stream of acetylene (passed through a trap at −78 °C to remove acetone) was bubbled through a stirred, ice-cooled solution of octacarbonyldicobalt (82.0 g, 240 mmol) in dichloromethane (700 mL) under nitrogen until release of CO could no longer be detected (ca. 5 h). The solution was transferred to an addition funnel and added dropwise under nitrogen within 45 min to a stirred suspension of anhydrous trimethylamine *N*-oxide (135 g, 1.80 mol) in a solution of benzvalene (**3**) [13] (19.0 g, 243 mmol) in diethyl ether (300–450 mL) cooled to −75 °C. The mixture was stirred and allowed to warm to 20 °C over 2 h. Then a gentle stream of oxygen was passed through the mixture for 4 h. Diethyl ether was added repeatedly to replace the solvent that evaporated, such that the original volume was maintained. The brown precipitate was filtered off, the filtrate extracted with water (4 × 100 mL), the organic phase dried with K_2CO_3, and the solvent removed by distillation. Distillation of the yellow-brown residue at 50–55 °C/0.15 mbar gave 9.5–16.1 g (30–51%) **5a**, which was pale blue in the cooled (−30 °C) receiving flask but turned yellow-brown upon warming to 20 °C. Trace amounts of volatile cobalt-containing compounds were probably the source of these colors. Impurities are not evident in the NMR spectra. Compound **5a** purified by preparative gas chromatography (1.5 m column, 20% EGA on Volaspher® A2, 90 °C) was colorless. Spectroscopic data are given in Table 1.

The Use of Heterometallic Bridging Moieties To Generate Tractable Lanthanide Complexes of Small Ligands**

William J. Evans,* Reiner Anwander, Robert J. Doedens, and Joseph W. Ziller

Dedicated to Professor M. Frederick Hawthorne on the occasion of his 65th birthday

Lanthanide chemistry is dominated by large, anionic ligands which meet the steric and electronic demands of these large electropositive metals. On the other hand, the chemistry of simple lanthanide complexes of general formula LnZ_3 in which Z is a small anionic ligand such as methanide, methanolate, ethanolate, or dimethylamido, is poorly developed since these complexes are either unstable or insoluble.[1, 2] The only homoleptic lanthanide complexes with small ligands which are tractable enough to be definitively characterized by X-ray crystallography are the hexamethyl "ate" complexes $[LnMe_6]^{3-}$ of the late lanthanides Ho, Er, and Lu.[2]

We describe here a method for the synthesis of isolable, soluble lanthanide complexes of small ligands Z (Z = NMe_2, Me) which also provides a convenient route to heterometallic complexes which have component combinations of interest with respect to polymerization catalysis[3] and the formation of materials from molecular precursors.[4] We also report details of the first structurally characterized molecular complexes containing a lanthanide metal and gallium.[5]

[**] We thank the Division of Chemical Sciences of the Office of Basic Energy Sciences of the Department of Energy for support for this research and the Deutsche Forschungsgemeinschaft for a Postdoctoral Fellowship (to R. A.).

For many years it has been known that trialkylaluminum complexes will add to lanthanide complexes containing bulky stabilizing co-ligands to form bridged heterometallic species such as those given in Scheme 1.

$[(C_5H_5)_2Yb(\mu\text{-}Me)_2Al(Me)_2]$[6]

$[Yb\{[\mu\text{-}N(SiMe_3)_2](\mu\text{-}Me)_2AlMe\}_2]$[7]

$[(C_5Me_5)_2Ln(\mu\text{-}Me)_2AlMe_2]_n$[5, 8b]

$[(C_5Me_5)_2Sm(\mu\text{-}C_2H_5)_2Al(C_2H_5)_2]$[8a]

Scheme 1. Examples of lanthanide heterometallic complexes.

Recently, we have shown that $AlMe_3$ will also bridge and stabilize metal ligand combinations such as $Y(OCMe_3)_3$ in $[Y\{(\mu\text{-}OCMe_3)(\mu\text{-}Me)AlMe_2\}_3]$[9] and $[(C_5H_4SiMe_3)Y(OCMe_3)_2]$ in $[(C_5H_4SiMe_3)Y\{(\mu\text{-}OCMe_3)(\mu\text{-}Me)AlMe_2\}_2]$.[10] We now report that $AlMe_3$ will not only react with soluble reagents containing bulky ligands, but that it will also react with and solubilize the insoluble materials formed from reactions of lanthanide halides with small anionic ligands.

The reaction of anhydrous $NdCl_3$ with three equivalents of $LiNMe_2$ (Z = NMe_2) in THF at room temperature formed a blue material which was identified as **1a** [Eq. (a)]. Reaction of $AlMe_3$ or $GaMe_3$ with a suspension of **1a** in hexane yielded the hexane-soluble products **2a** (violet-blue) and **2b** (blue), respectively.

$$NdCl_3 + 3\,LiNMe_2 \longrightarrow \underset{\mathbf{1a}}{[Nd(NMe_2)_3(LiCl)_3]} \xrightarrow{3\,MMe_3} [Nd(NMe_2)_3(MMe_3)_3] + 3\,LiCl \quad \text{(a)}$$

2a, M = Al; **2b**, M = Ga

The intensely colored solutions of **2** are stable at room temperature. Evaporation of the solvent results in oily residues which solidify at −35 °C. These solids slowly decompose at room temperature to form large colorless crystals of $[\{Me_2NMMe_2\}_2]$ (M = Al, Ga (**4**))[11] which sublime to the top of the container. Compounds **2a** and **2b** can be isolated in 80% yield by crystallization of the initially isolated solids from hexane at −35 °C; the molecular structure of **2b** is shown in Figure 1.[12]

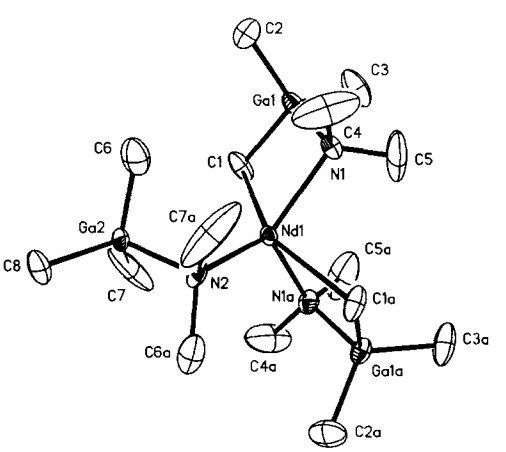

Fig. 1. Molecular structure of **2b**; the numbering is identical to that of isostructural **2a**. Thermal ellipsoids are drawn at the 50% probability level. Selected distances [Å] and angles [°] for **2b** are as follows (**2a** in brackets): Nd1-N1 2.395(5) [2.435(4)], Nd1-N2 2.362(10) [2.433(8)], Nd1-C1 2.749(7) [2.708(5)], Nd1-C6 3.28 [3.39], Nd1-C7 3.35 [3.21], Nd1-M1 3.276(1) [3.274(2)], Nd1-M2 3.242(1) [3.191(3)]; Nd1-N1-M1 94.7(2) [96.0(1)], Nd1-C1-M1 84.3(2) [85.7(1)], N1-Nd1-C1 77.3(2) [74.7(1)], N1-M1-C1 103.0(3) [102.5(2)], Nd1-N2-M2 94.5(4) [92.6(3)].

X-ray crystallography revealed that compounds **2a** and **2b** are isostructural, which is somewhat surprising considering the structural differences of the aluminum and gallium starting reagents and their different bonding patterns towards transition metal centers.[13] The overall structure shown in Figure 1 lacks the threefold symmetry found in $[Y\{(\mu\text{-}OCMe_3)(\mu\text{-}Me)AlMe_2\}_3]$.[9] Instead, there are only two symmetrically identical $[(\mu\text{-}NMe_2)(\mu\text{-}Me)MMe_2]$ chelating units (involving N1 and N1a) which have planar four-membered Nd-C-M-N metallacyclic rings. The third NMe_2MMe_3 unit involving N2 is disordered about the twofold symmetry axis and the methyl groups attached to aluminum or gallium in this unit are not as close to the Nd center as those in the other two units. A planar four-membered ring is not formed because neither of the two closest carbon atoms, C6 and C7, lie in a plane with Nd1, N2, and M.

The five ligands directly bound to Nd in **2** describe a distorted square pyramid in which N2 is slightly disordered. The Nd1–N1 distances of the bridges (**2a**, 2.435(4); **2b**, 2.395(5) Å) are longer than the terminal Nd–N(silylamido) distances in five-coordinate $[Nd\{N(SiHMe_2)_2\}_3(thf)_2]$ (2.343(5) Å)[14] and lie in the range found for terminal Nd–N(pyrazolato) bond lengths in the eight-coordinate complex $[Nd\{3,5\text{-di}(tert\text{-butyl})pyrazolato\}_3(thf)_2]$ (2.443(9) Å).[15] The Nd1–N2 distances are similar to the Nd1–N1 lengths (**2a**, 2.433(8); **2b**, 2.362(10) Å). The Nd1–C1 distances (**2a**, 2.708(5); **2b**, 2.749(7) Å) are similar to the Sm–C(μ-Me) distances in $[\{(C_5Me_5)_2Sm(\mu\text{-}Me)AlMe_2(\mu\text{-}Me)\}_2]$ (2.743(16) and 2.750(16) Å).[8b] In contrast, the Nd1–C6 and Nd1–C7 distances are more in the range of agostic interactions.[16] The bridging M1–C(methyl) distances (**2a**, 2.056(4); **2b** 2.073(6), Å) the M–N bond lengths (**2a**, 1.950(5) and 1.955(8) Å; **2b**, 2.048(6) and 2.043(11) Å), and the terminal M1–C(methyl) distances (average: **2a**, 1.958(9); **2b**, 1.984(11) Å) are not unusual.[7, 8, 13b]

Although solvent-free heterometallic peralkyl compounds like $NaBMe_4$ and $LiAlMe_4$ (Z = Me) have been very common reagents for a long time,[17] compounds of the type $M_xM'_yR_z$ containing a transition metal and a main group metal are very rare.[18] Furthermore, the above-mentioned "-ate" derivatives like $[Ln\{(\mu\text{-}Me)_2Li(tmeda)\}_3]$[2] are known only in the presence of coordinating donor solvents and are more stable for the late lanthanide elements.

$$\underset{\mathbf{1a}}{} \xrightarrow{GaMe_3} \underset{\mathbf{2b}}{[Nd(NMe_2)_3(GaMe_3)_3]} \longrightarrow [Nd\{(\mu\text{-}Me)_2GaMe_2\}_3] + [\{Me_2NGaMe_2\}_2] \quad \text{(b)}$$
$$\mathbf{3} \qquad \mathbf{4}$$

The reaction of **1a** with six equivalents or an excess of $GaMe_3$ under mild conditions (room temperature, hexane) afforded the heterometallic peralkyl complex **3** in 84% yield [Eq. (b)].

The formation of **3** is likely to occur through an intermediate **2b**, which can be seen clearly by the disappearance of M-NMe_2 vibrational modes in the IR spectra. The formation of the very stable **4**[11] undoubtedly helps drive the reaction to completion. Complex **3** is not sublimable and decomposes above 50 °C under high vacuum. Both **3** and **4** are very soluble in hexane and can be separated by fractional crystallization at −35 °C. Complex **3** crystallizes first as large blue pyramids (edge lengths ca. 5 mm), after which **4** crystallizes as colorless cubes. Complex **3** was characterized by IR spectroscopy, elemental analysis, and X-ray structural analysis (Fig. 2).[19]

The methyl groups in **3** are arranged in an octahedral geometry around Nd and a tetrahedral geometry around Ga. Each Nd-C-Ga-C ring is planar to within <0.07 Å. The fact that octahedral lanthanide complexes exist which contain larger bridging groups, for example **2a**, and smaller metals, for example $[Y\{(\mu\text{-}OCMe_3)_3(\mu\text{-}Me)AlMe_2\}_3]$,[9] suggests that the coordination environment around neodymium in **3** is sterically unsaturated. Complex **3** differs from the -ate complexes mentioned earlier in that the lanthanide metal is more electropositive than the other metallic component (electronegativities: Nd ≈ 1.1, Ga ≈ 1.8[20]). Therefore **3** is better described as a gallate ($[GaMe_4]^-$) rather than a neodymate ($[NdMe_6]^{3-}$) complex, although the most important aspect of this difference will be in the reactivity.

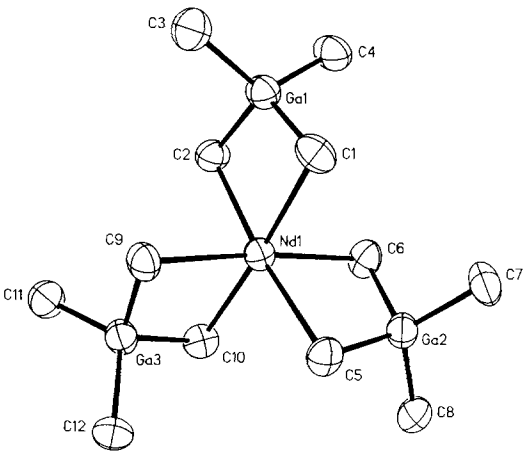

Fig. 2. Molecular structure of **3** with probability ellipsoids drawn at the 50% level. Selected distances [Å] and angles [°]: Nd1-C1 2.605(10), Nd1-C2 2.591(11), Nd1-C5 2.619(10), Nd1-C6 2.597(11), Nd1-C9 2.581(10), Nd1-C10 2.599(10), Ga-(μ-C) 2.115(11), Ga-(C_t) 1.989(13), Nd1-Ga1 3.129(1), Nd1-Ga2 3.136(1), Nd1-Ga3 3.117(1); Ga1-Nd1-Ga2 116.7(1), Ga2-Nd1-Ga3 121.1(1), Ga1-Nd1-Ga3 122.0(1), C1-Nd1-C2 84.5(3), Nd1-C1-Ga1 82.0(3), C1-Ga1-C2 110.7(4).

The Nd–C distances in **3** are close to that of the Nd–C bond length of 2.65 Å expected in the unknown $[Nd\{(\mu\text{-}Me)_2Li(tmeda)\}_3]$ on the basis of Shannon radii[21] and the known Ho and Er structures.[2a, b] Other relevant Nd–C distances are 2.53(2) and 2.70(2) Å in $[\{(C_5H_4CMe_3)_2Nd(\mu\text{-}Me)\}_2]$,[22] 2.517(7) Å in $[\{(C_5Me_5)_2Nd[CH(SiMe_3)_2]\}]$,[23a] and 2.506(7) Å in $[Me_2Si(C_5Me_4)_2Nd\{CH(SiMe_3)_2\}]$.[23b] The Ga–C distances in **3** are similar to those in **2b**.

The exchange of NMe_2 groups for methyl in reaction (b) is likely to occur in a stepwise fashion; examination of the analogous lanthanum system **1b** with four equivalents of $GaMe_3$ provided the partially exchanged complex **5** [Eq. (c)], which was characterized by elemental analysis, NMR spectroscopy, IR spectroscopy, and X-ray structural analysis (Fig. 3).[24]

$$\underset{\mathbf{1b}}{[La(NMe_2)_3(LiCl)_3]} + 4\,GaMe_3 \longrightarrow \underset{\mathbf{2c}}{[La(NMe_2)_3(GaMe_3)_3]} \longrightarrow [La\{(\mu\text{-}Me)_2GaMe_2\}\{(\mu\text{-}Me)(\mu\text{-}NMe_2)GaMe_2\}_2] + 0.5\,\mathbf{4} \quad \text{(c)}$$
$$\mathbf{5}$$

In complex **5**, the La–C distances in the two heteroleptic bridging units La(μ-Me)(μ-NMe_2) are rather long (2.891(5) and 2.992(5) Å) and are similar to those in $[La\{(Ph_2P)_2CH\}_3]$ (2.890(5), 2.790(4), 2.908(5) Å)[25] and even resemble the agostic La···C interactions in $[(C_5Me_5)La\{CH(SiMe_3)_2\}_2(thf)_x]$ (x = 0, 1; 2.978(6)–3.265(14) Å).[16] The La–C distances in the homoleptic bridging unit La(μ-$Me)_2$ are also relatively long in comparison to the Nd–C distances in **3**. In comparison, La–C (terminal alkyl) distances of 2.515(9) and 2.537(5)–2.651(8) Å are found in $[La\{CH(SiMe_3)_2\}_3]$[26] and $[(C_5Me_5)La\{CH(SiMe_3)_2\}_2(thf)_x]$,[16] respectively. The La–N bond lengths (2.451(4), 2.444(4) Å) are in the range of those found for terminal

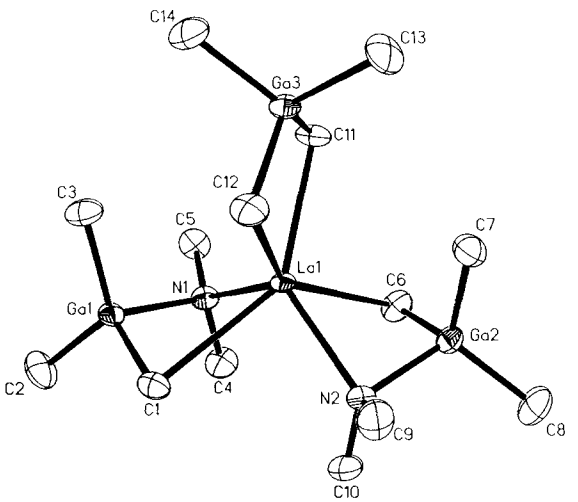

Fig. 3. Molecular structure of **5** with probability ellipsoids drawn at the 50% level. Selected distances [Å] and angles [°]: La1-C1 2.891(5), La1-C6 2.992(5), La1-C11 2.776(5), La1-C12 2.742(5), La1-N1 2.451(4), La1-N2 2.444(4), La1-Ga1 3.187(1), La1-Ga2 3.112(1), La1-Ga3 3.291(1), Ga1-C1 2.058(5), Ga2-C6 2.033(5), Ga3-C11 2.084(5), Ga3-C12 2.096(5), Ga-C, 1.978(7); C11-La1-C12 78.4(2), C1-La1-N1 71.2(1), C6-La1-N2 68.9(1).

La–N bonds in $[La\{N(SiMe_3)_2\}_3(PPh_3O)]$ (2.41(2) Å)[27a] and $[(C_5Me_5)_2La(NHMe)(H_2NMe)]$ (2.323(10) Å).[27b] A consequence of this irregular bonding pattern is that Ga1 and Ga2 lie closer to the La center than Ga3, and the La-C-Ga-N rings are nonplanar. The orientation of Ga1 and Ga2 toward the Ga3 unit and the arrangement of the methyl groups of the amido ligands with respect to the other methyl moieties appear to optimize the steric packing.

The isolation and characterization of complexes **2**, **3**, and **5** demonstrates that insoluble, oligomeric lanthanide complexes of small ligands can be "cracked" under very mild conditions (room temperature, hexane) by the attack of strong, soluble Lewis acids to form alkane-soluble, tractable compounds. This approach to developing the chemistry of lanthanide complexes of small ligands should be general; preliminary results show that species such as "$Ln(OMe)_3$" and InR_3 fit in this scheme.

Experimental Procedure

1: Addition of $LiNMe_2$ (2.22 g, 43.5 mmol) under nitrogen in a glovebox to a suspension of $NdCl_3$ (3.63 g, 14.5 mmol) in THF (50 mL) caused a spontaneous reaction indicated by a color change from pink to violet. After stirring the mixture at room temperature for two days, the solvent was removed to give a powder of composition **1a**. IR (Nujol): $\tilde{\nu}$ = 1205 m, 1126 s, 1113 s, 1052 m, 973 w, 893 vs, 459 m cm^{-1}. **1b** is prepared similarly.

2: Addition of MMe_3 (3 mmol) to a pink suspension of **1a** (0.40 g, 0.99 mmol) in hexane resulted in the extraction of soluble products into the hexane phase; this steadily darkened in color. After 12 h, the mixtures were centrifuged, concentrated, and crystallized. Analytical and spectroscopic data were collected on crystals grown from hexane solutions. **2a** (0.39 g, 80%): IR (Nujol): $\tilde{\nu}$ = 1220 sh, 1193 vs, 1145 w, 1113 s, 1091 w, 1043 s, 1024 w, 901 s, 695 vs, 580 vs, 537 m, 510 m, 480 m, 423 m, 311 m cm^{-1}. **2b** (0.51 g, 83%): IR (Nujol): $\tilde{\nu}$ = 1218 m, 1196 s, 1140 w, 1116 s, 1086 w, 1040 s, 971 w, 901 s, 724 s, 675 w, 650 w, 590 m, 556 s, 532 m, 495 w, 456 m, 411 s, 265 m cm^{-1}. Reaction of **1a** with one or two equivalents of MMe_3 also gave the homoleptic compounds **2**, but in lower yield.

3: To a suspension of **1a** (0.43 g, 1.05 mmol) in hexane (20 mL) was added $GaMe_3$ (0.63 mL, 6.30 mmol). After stirring this mixture for 36 h at room temperature, a white precipitate was separated from a blue hexane soluble product by centrifugation. After stirring for an additional 48 h, **3** can be separated from **4** by fractional crystallization at −35 °C as blue pyramidal crystals. **3** (0.47 g, 84%): IR (Nujol): $\tilde{\nu}$ = 1413 m, 1191 s, 736 s, 716 s, 582 s, 564 s, 527 s, 416 s, 289 s cm^{-1}.

5: A suspension of **1b** (0.75 g, 1.88 mmol) in hexane (20 mL) was extracted with $GaMe_3$ (0.75 mL, 7.52 mmol). The mixture was stirred overnight and centrifuged. Crystallization of the solution at −35 °C provided **5** as colorless crystals in 65% yield. IR (Nujol): $\tilde{\nu}$ = 1221 m, 1199 m, 1193 m, 1187 m, 1142 w, 1121 s, 1090 w, 1044 s, 904 s, 724 s, 664 m, 621 (sh) m, 598 m, 561 m, 530 m, 476 m, 408 s, 272 m cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 2.19 (s, 12H, NMe_2), 2.10 (s, 6H, μ-CH_3), 2.06 (s, 6H, μ-CH_3), −0.19 (s, 6H, $GaMe_2$), −0.23 (s, 12h, $GaMe_2$). $^{13}C\{^1H\}$ NMR (300 MHz, C_6D_6, 25 °C): δ = 42.7 (μ-CH_3), 41.8 (NMe_2), 41.3 (μ-CH_3), −3.1 ($GaMe_2$), −4.1 ($GaMe_2$).

Elemental analysis [%]: **1a**: Calcd for $NdLi_3Cl_3N_3C_6H_{18}$: C 17.85, H 4.49, N 10.41, Nd 35.73; found: C 16.42, H 4.26, N 10.96, Nd 35.0. – **2a**: Calcd for $NdAl_3N_3C_{15}H_{45}$: C 36.56, H 9.21, N 8.53; found: C 35.86, H 9.41, N 6.61. – **2b**: Calcd for $NdGa_3N_3C_{15}H_{45}$: C 29.01, H 7.30, N 6.77, Nd 23.23; found: C 27.50, H 7.25, N 5.44, Nd 22.3. – **3**: Calcd for $C_{12}H_{36}Ga_3Nd$: C 27.00, H 6.80, Nd 27.0; found: C 26.81, H 6.54, Nd 26.5. – **5**: Calcd for $C_{14}H_{42}Ga_3LaN_2$: C 28.67, H 7.22, N 4.78, La 23.7; found: C 27.16, H 7.00, N 4.82, La 21.8.

A Liquid-Crystalline Polymer Network Built by Molecular Self-Assembly through Intermolecular Hydrogen Bonding**

Takashi Kato,* Hideyuki Kihara, Uday Kumar, Toshiyuki Uryu, and Jean M. J. Fréchet*

The use of noncovalent interactions such as hydrogen bonds for materials design has attracted much attention.[1] Mesogenic structures can be obtained by self-assembly of two different components by means of selective hydrogen bond formation.[2-5] This concept has been extended to side-chain[3] and main-chain[4, 5] liquid-crystalline polymers.

We demonstrate here that a mesogenic three-dimensional network can be constructed by self-assembly through noncovalent interactions. Hydrogen-bonded cross-linked polymers were prepared by complexation of a polyacrylate (**1**) containing a benzoic acid moiety (H-bond donor) with various ratios of bifunctional 4,4′-bipyridine (**2**) and the monofunctional stilbazole **3** as

1

2

3

H-bond acceptors.[6] Compound **2** is capable of recognizing and binding carboxylic acid fragments of the polymer at each of its pyridyl ends and functions as a cross-linker. The hydrogen-bonded complexes were prepared by the evaporation method,[2, 3] and the stoichiometry of the H-bond donor and H-bond acceptors was maintained. For the ternary complex of **1**, **2**, and **3**, a mixture of H-bond acceptors (x/2 mol of **2** corresponding to x mol of the pyridyl unit, and y mol of **3**) was complexed with an amount of **1** containing $x + y$ mol of the H-bond donor moiety. The mol fraction of the pyridyl moiety of **2** relative to the all of the pyridyl units in the complex is represented as $\bar{x} = x/(x + y)$.

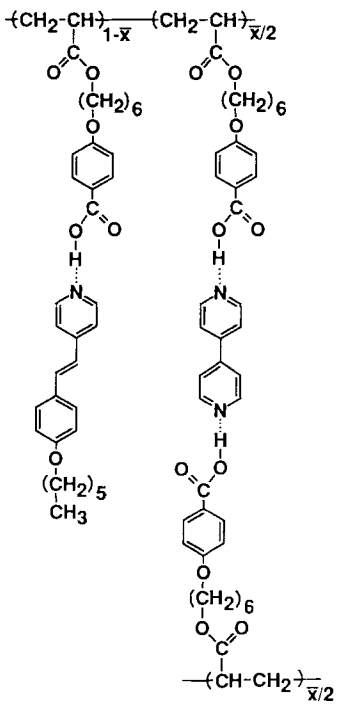

Fig. 1. Proposed molecular structure of the polymeric complex consisting of **1**, **2**, and **3**.

The proposed structure of the hydrogen-bonded 1:1 complex (containing an equimolar amount of H-bond donor and acceptor) prepared from H-bond donor polymer **1** and H-bond acceptors **2** and **3** is shown in Figure 1. The self-assembly of a cross-linked mesogen for the polymeric networks was expected.

Differential Scanning Calorimetry (DSC) thermograms of the polymeric complexes containing various ratios of **2** and **3** on heating scans are shown in Figure 2. Plots of transition temperatures of the polymeric complexes against $\bar{x}$, the mol fraction of pyridyl units of **2** in the mixture of **2** and **3**, are shown in Figure 3. The 1:1 complex of **1** and **3** behaves like a side-chain liquid-crystalline polymer[3d, 7] and exhibits

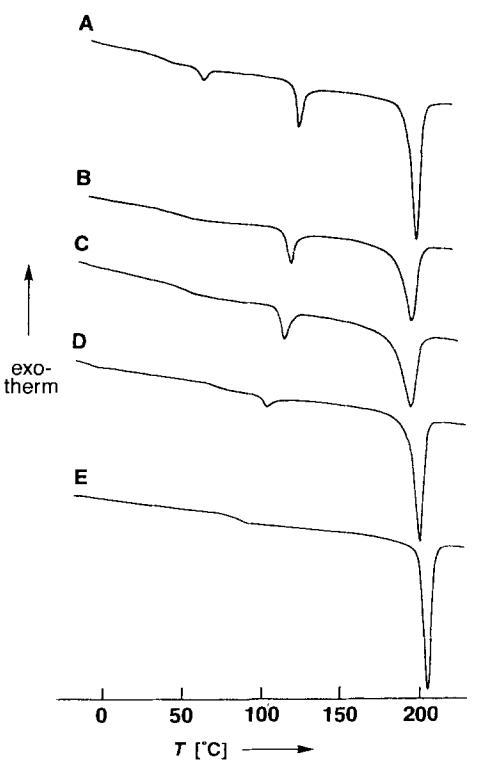

Fig. 2. DSC thermograms of polymeric complexes: A: $\bar{x} = 0$; B: $\bar{x} = 0.3$; C: $\bar{x} = 0.5$; D: $\bar{x} = 0.7$; E: $\bar{x} = 1.0$.

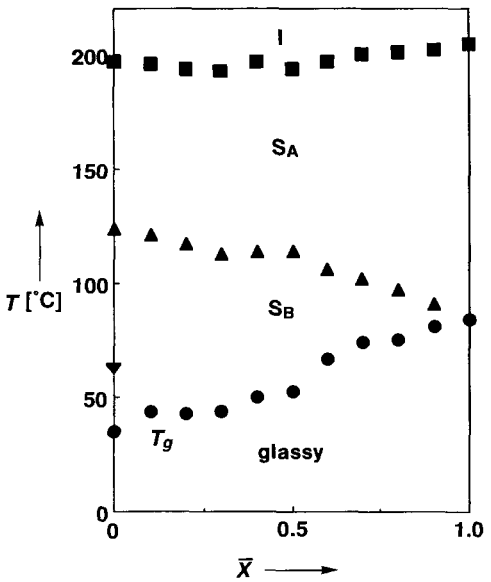

Fig. 3. Phase diagram of the polymeric complexes of **1** and mixtures of **2** and **3**.

and exhibits a smectic A phase from 124 to 197 °C (Fig. 2, curve A; Fig. 3, $\bar{x} = 0$). The enthalpy change of the smectic–isotropic transition is 20.2 $J\,g^{-1}$.

As the proportion of **2** in the polymeric complex increases, the glass transition temperature increases. Liquid-crystalline behavior is observed up to about 200 °C for the complexes in the whole composition range of the H-bond acceptor mixture. For example, the polymeric complex having a larger fraction of the cross-linking H-bond acceptor (Fig. 2, curve D; Fig. 3, $\bar{x} = 0.7$) shows smectic phases from 74 to 200 °C.

It is noteworthy that the binary 1:1 complex of **1** and **2** (Fig. 2, curve E; Fig. 3, $\bar{x} = 1.0$) exhibits a smectic phase up to 205 °C. The melt of the complex of **1** and **2** is viscous but shows shear flow between glass plates. The enthalpy change on transition to the isotropic phase on heating is 24.9 $J\,g^{-1}$. The smectic–isotropic transition occurs reversibly for these complexes. A focal conic fan texture develops when the complex is cooled from an isotropic phase. The X-ray diffraction pattern for the mesophase at 170 °C consists of one sharp inner peak at 39.8 Å and one diffused halo at 4.5 Å. The length of the fully stretched conformation between two polymer backbones that form the complex with **2** is estimated to be 41 Å by molecular modeling. These results indicate that the network complex retains a smectic A phase structure as shown in Figure 4. The phase transition curves change continuously as the proportion of the bifunctional moiety increases (Fig. 3). This phase diagram also supports the finding that the noncovalently cross-linked complex consisting of only **1** and **2** exhibits a smectic A phase. The X-ray diffraction pattern for the complex of $\bar{x} = 0.5$ at 70 °C above the glass transition temperature shows only two sharp reflections at 38.7 and 4.2 Å, which suggests the existence of a liquid-crystalline smectic B phase.[8] One sharp inner peak at 38.7 Å and one broad halo at 4.4 Å are observed when the sample forms a smectic A phase at 140 °C. The layer spacing is constant in the two mesophases for this sample.

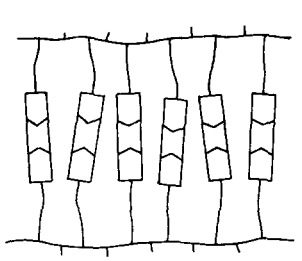

Fig. 4. Schematic illustration of the liquid-crystalline network structure formed by self-assembly of **1** and **2**. The rectangles in the middle made up of three components represent the hydrogen-bonded mesogenic unit.

In the self-assembled structure shown in Figure 4 liquid crystallinity is induced by the interaction between the pyridyl units of **2** and two benzoic acid moieties of **1**, which results in the formation of the hydrogen-bonded intermolecular mesogen. Moreover, the dynamic nature of the hydrogen bonding of the mesogen should contribute to the induction of a fluid mesomorphic phase and the reversibility of the cross-linking. When the sample is heated to the isotropic state, some of the hydrogen bonds between the carboxylic acid and bipyridyl moieties should break to form a disordered state. Upon cooling from the isotropic state, the intermolecular hydrogen bonds form again, which results in the smectic A phase.

Covalently cross-linked network based on liquid-crystalline polymers have been reported previously[9] for side-chain and main-chain polymers. In the case of the polymer containing a high density of covalent cross-links, molecular orientations were preserved in the solid state and no thermotropic liquid-crystalline behavior was observed for the polymers.[9]

The formation of a hydrogen-bonded mesogen in the polymer side-chain was first reported by Blumstein et al.[10] Solid-state mesomorphic order was observed for poly[(*p*-acryloyloxy)benzoic acid] and poly[(*p*-methacryloyloxy)benzoic acid] owing to the formation of a benzoic acid dimer. However, these H-bonded polymers did not show a liquid-crystalline state because of the lack of flexibility resulting from the absence of methylene spacers.

The system reported here is a novel polymeric network that exhibits liquid-crystalline behavior by self-assembly of polymers and small molecules by means of noncovalent interactions.

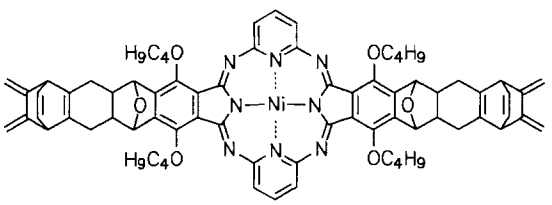
Ladder Polymers and Oligomers Based on Hemiporphyrazine**

Michael Rack and Michael Hanack*

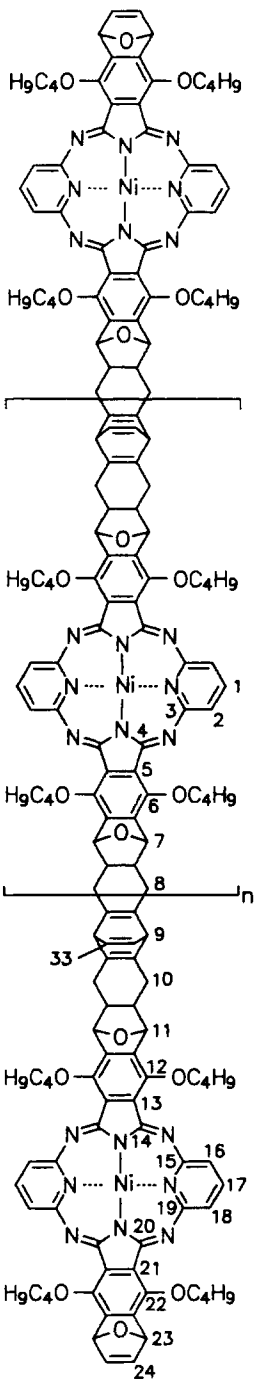


Conjugated polymers with ladder structure have received increasing attention over the last several years, as topics of both preparative and theoretical studies.[1] These structures are expected to have interesting electronic, optical, and magnetic properties. Repetitive Diels–Alder reactions have proved effective for synthesizing this type of polymer as well as its precursors.[2] The dienophilic and enophilic monomers used to date do not contain metallomacrocycles as structural fragments.[3]

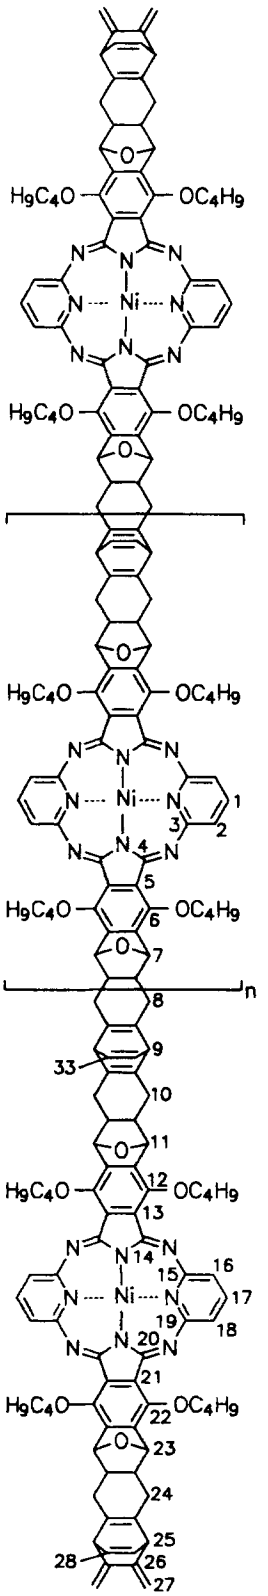
Ladder polymers that contain phthalocyanines as stabilizing units are not easily accessible, because an unsymmetrically substituted phthalocyanine is required for their preparation.[4] Hemiporphyrazinatometal(II) compounds[5] that have D_{2h} symmetry are easier to synthesize. With appropriate peripheral substitution one can obtain monomer precursors with good solubility, which can in turn be converted to ladder polymers.

We report on the synthesis of oligomers **5**–**9** (Scheme 1) using repetitive Diels–Alder reactions at standard pressure based on the hemiporphyrazinatonickel(II) compounds **1** and **2**[6] and pentaene **3**[7] (C_4H_9 = *n*-butyl).

1



2



3

We first heated the dienophilic hemiporphyrazine **1** (*syn, anti*) with an equimolar amount of the enophilic hemiporphyrazine **2** (*syn, anti*)[6] in refluxing toluene for seven days. (The notation *syn* and *anti* denotes the position of the oxygen bridges in **1** and **2**.) This reaction yielded a solid that is practically insoluble in typical organic solvents. The ^{13}C-CP/MAS NMR spectrum in Figure 1 shows characteristic signals consistent with the structure of polymer **4**.

The insolubility of **4** made it impossible to determine its molecular weight distribution. This fact, combined with the lack of spectroscopic data for the polymer, led us to conduct a systematic synthesis of model oligomers in order to characterize **4** by spectroscopy. In addition, the solubility limit of the oligomers was determined in stepwise fashion, in order to obtain

Waidelich, GSG Mess- und Analysengeräte Vertriebsgesellschaft mbH, Karlsruhe, for obtaining the laser desorption mass spectra.

information about the number of repeat units in **4**. To achieve these objectives, we used a two-step reaction starting with compounds **1**, **2**, and **3** to synthesize the trimers **5** and **6**, the pentamers **7** and **8**, and the heptamer **9** (Scheme 1). All oligomers were fully characterized by spectroscopic methods.[8]

2.5 **1** + **2** $\xrightarrow{73\%}$ **5** (n = 1)

2.5 **3** + **5** $\xrightarrow{80\%}$ **6** (n = 1)

2.5 **2** + **6** $\xrightarrow{65\%}$ **7** (n = 3)

2.5 **3** + **7** (n = 3) $\xrightarrow{81\%}$ **8** (n = 3)

2.5 **1** + **8** (n = 3) $\xrightarrow{36\%}$ **9** (n = 5)

Scheme 1. Synthesis scheme for oligomers **5**–**9**.

The trimer **5** was obtained by reaction of **1** (*syn, anti*) and **2** (*syn, anti*) (molar ratio 2.5:1) in refluxing toluene over seven days. The workup was accomplished by precipitation followed by chromatography on neutral alumina/5% H_2O (CH_2Cl_2/MeOH 20:1), to give **5** in 73% yield (see Scheme 1).[9] Trimer **6** was obtained by treating **5** with pentaene **3** (molar ratio 1:2.5) in refluxing toluene for 48 h. The crude product was purified by the same procedures as in the preparation of trimer **5**. Synthesis of the higher molecular weight oligomers **7**, **8**, and **9** was carried out analogously as for compounds **5** and **6** (see Scheme 1).[10] All oligomers are readily soluble in CH_2Cl_2 and $CHCl_3$ and exhibit nearly identical ^1H and ^{13}C NMR spectra. The ^{13}C NMR spectra of **5**, **7**, and **9** are depicted in Figure 1 (see the formulas for the numbering of the carbon atoms). Signals at $\delta = 80.7$ (C-23) and 142.5 (C-24) are attributed to the end groups, while the macrocyclic groups give rise to signals at $\delta = 158.5$ (C-4, 20), 155.7 (C-3, 19), 120.1 (C-2, 16, 18), and 139.7 (C-1, 17). The signals for the ladder-type structure fragments occur at $\delta = 31$ (C-8, 10), 42 (C-7a, 10a), 56.2 (C-9), and 82.7–83.8 (C-7, 11). The vinylene bridging atoms (C-33) yield the signal at $\delta = 139.8$.

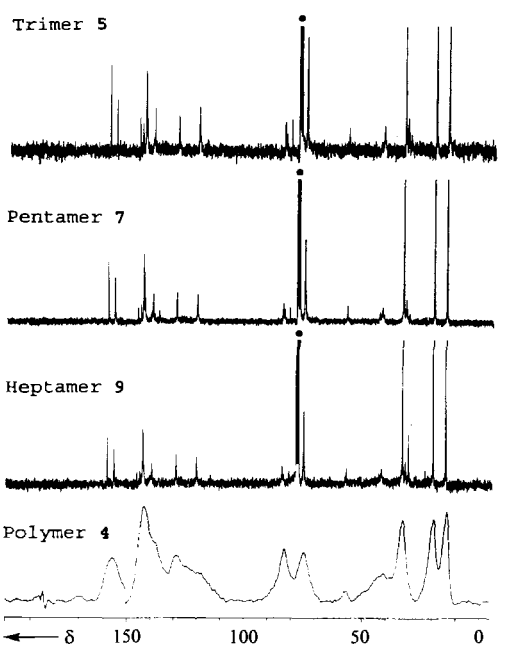

Fig. 1. ^{13}C NMR spectra of **5**, **7**, and **9**, 62.9 MHz, $CDCl_3$; •: signal from $CDCl_3$; ^{13}C CP/MAS NMR spectrum of polymer **4**.

The ^{13}C NMR spectra of **6** and **8** show characteristic peaks at $\delta = 41.9$–42.5 (C-23a), 53.3–53.5 (C-25), 101.4 (C-27), and 137.2 (C-24a) originating from the diene end groups. The positions of the signals for the carbon atoms of the macrocyclic moiety as well as the ladder-type structure fragments correspond to those observed for oligomers **5**, **7**, and **9**. The ^1H NMR spectra of oligomers **5**–**9** exhibit the expected signals.

The molecular weights of oligomers **5**–**9** were determined by ion spray and laser desorption mass spectrometry (LD-MS). For oligomers **5** and **6** molar masses of 3064.7 (calculated: 3065.3) and 3378.0 (calculated: 3377.8), respectively, were determined by the ion spray method.[11] The LD-MS method for determining the molecular weights of oligomers **7**–**9** yielded the following values: pentamer **7**: 5208.1 (calculated: 5213.1), pentamer **8**: 5526 (calculated: 5526), and heptamer **9**: 7393 (calculated 7361).

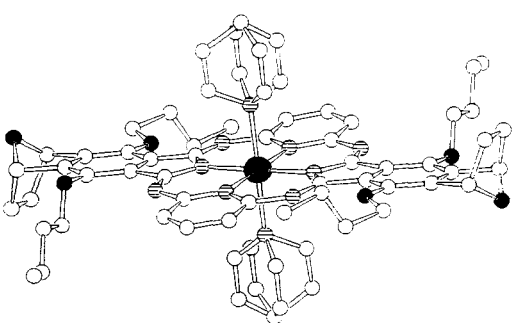
Oligomers **5**–**9** exhibit differences in their IR spectra only in the fingerprint region from 600 to 900 cm^{-1}. For oligomers **6** and **8** with diene end groups, a band at $\nu = 655$ cm^{-1} appears, whereas no absorption is observed in this region for oligomers **5**, **7**, and **9**. Oligomer **4** also shows no IR absorption at 655 cm^{-1}, which leads to the conclusion that its end groups are epoxynaphthalene fragments.

The ^{13}C CP/MAS NMR spectrum of polymer **4** is in agreement with the high-resolution ^{13}C NMR spectra of oligomers **5**, **7**, and **9** (Fig. 1), which provides additional support for the epoxynaphthalene end groups in **4**.

Oligomers **5**–**9** are formed as mixtures of isomers on account of the mixtures of *syn, anti* isomers of **1** and **2** employed, and the possible stereoisomers that form in Diels–Alder reactions. The NMR spectra of **5**–**9** therefore contain multiple peaks that are difficult to assign to the individual isomers. In order to obtain products with fewer isomers, **1** was treated with thin-layer chromatography on neutral alumina (eluting with CH_2Cl_2/MeOH 250:1), and **2** was subjected to column chromatography on alumina (eluting with ethyl acetate/hexane 1:3). Following separation of the *syn* and *anti* isomers, *anti*-**1** and *anti*-**2** were converted to trimer **5** (hereafter denoted as *anti*-**5**).[13]

The two configurational isomers of **1** cannot be distinguished by NMR spectroscopy. Therefore, an X-ray structure analysis of the bispyridine complex of *anti*-**1** was performed (Fig. 2).[14] Because the rings are rotating, only the average electron density distribution of the pyridine rings is shown in Figure 2.[15]

The two-configurational isomers of **2** could be distinguished by NMR spectroscopy.[16] As expected, the ^1H and ^{13}C NMR spectra of the *anti*-**5** trimer provides better resolution. Despite



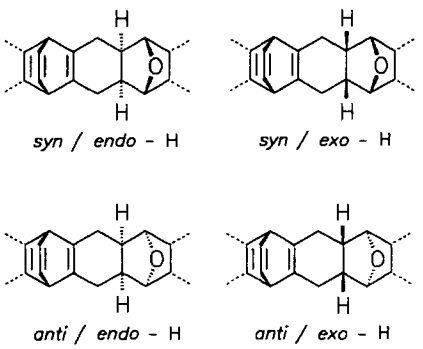


Fig. 2. Crystal structure of the bispyridine complex of *anti*-**1** [15].

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1515-1647 $ 10.00+.25/0

the use of the stereochemically pure compounds *anti*-**1** and *anti*-**2**, a large number of stereoisomers of *anti*-**5** are possible. These isomers are only in part due to the *exo*/*endo* attack that occurs in the Diels–Alder reaction. In our case, the adducts are solely bicyclic compounds, with possible formation of the isomers shown in Scheme 2. Here the *syn* and *anti* designations indicate the relative positions of the oxygen and vinylene bridges.

Scheme 2. Possible stereoisomers formed in the Diels–Alder reaction of bicyclic enophile **2** and dienophile **1**.

In comparable cycloaddition reactions the primary products obtained are solely the *syn*/*endo*-H isomers.[17] In our case, only a single isomer of *anti*-**5** should therefore be obtained; however, there are more peaks in the NMR spectra of *anti*-**5** than would be expected from a single isomer. Based on the signal doubling in the ^{13}C NMR spectrum of *anti*-**5**, we conclude that at least two isomers are formed. Determination of the exact structure of these isomers would require that they be separated, crystallized, and subjected to X-ray structure analysis. For the exact assignment of the ^{13}C NMR signals of *anti*-**5**, C/H-COSY and C/H-correlated long range coupled NMR spectra were obtained.[18]

We are presently working on aromatization procedures for the oligomers described here.

Experimental Procedure

5: 150 mg (0.16 mmol) of **1** and 80 mg (0.07 mmol) of **2** were dissolved in 20 mL of toluene and stirred 7 d under reflux. After the reaction mixture had cooled, the toluene was removed under vacuum. The green residue was taken up in a small amount of CH_2Cl_2, precipitated by addition of hexane, and centrifuged. This process was repeated twice in order to remove residual **1** and **2**. Further purification was accomplished by column chromatography on alumina (deactivated with 5% H_2O) eluting with $CHCl_3$. After chromatographic purification the compound was again precipitated in CH_2Cl_2/hexane and dried under vacuum at 75 °C. Compound **5** was obtained as an olive-green powder (145 mg, 73%).

6: 80 mg (0.26 μmol) of **5** and 12 mg (77 μmol) of **3** were dissolved in 10 mL of toluene and stirred 48 h under reflux. The workup proceeded analogously as in the preparation of **5**. Compound **6** was obtained as an olive-green powder (70 mg, 87%).

7–**9**: Reaction and workup were analogous to those described for **5** and **6**, with yields of 65, 81, and 36%, respectively.

4: Reaction procedure identical to that for **5**, except that equimolar amounts of **1** and **2** were used. Purification was possible by continuous extraction with CH_2Cl_2, after which the solvent was removed under vacuum.

[8] The measured UV/VIS spectra of oligomers **5**–**9** are equivalent to those of the starting monomers **1** and **2**. Aggregation of **5**–**9** was not observed.

[9] In all reactions only a single product was obtained. The decrease in the yield can be attributed to the formation of higher molecular weight oligomers, which remain on the column during chromatographic purification.

[10] Formation of ring structures was not observed in any of the conversions. The direct reaction of the *syn* isomers of **1** and **2** (equimolar) at ambient pressure also did not lead to the formation of ring structures.

[11] Determination of the molar masses was conducted using an API III TAGA 6000E mass spectrometer from the company Sciex. Samples in MeOH/CH_2Cl_2 (1:1) were injected with an injection pump at a continuous flow rate of 5 μL min^{-1}.

[12] Molecular weights were determined by matrix-supported laser desorption mass spectrometry using a VESTEC Laser-Tec focus (BenchTop II) instrument. Measurement conditions: positive ion mode, 26 KV acceleration current; matrix: sinapic acid and 2,5-dihydroxybenzoic acid.

[13] Assuming ideal stereochemistry in the Diels–Alder reaction for *anti*-**5** (*syn*-*endo*-H), the molecule would have a length of approximately 6.3 nm.

N–N bond and the amino acid side chain linked to a quaternary positively charged nitrogen atom. Structurally related compounds with partially or fully saturated pyridazine rings occur in biologically active cyclopeptides, for example the moiety **2** in luzopeptin A,[2] and piperazic acid (**3**) in citropeptin, himastatin, variapeptin, and others.[3] An N–N bond also appears in the pyrimidine nucleotide biosynthesis inhibitor pyrazofurin (**4**)[4] as well as in several noncyclic azoxy compounds, such as valanimycin (**5**).[5–9] Because of the N^+-bound side

chain, **1** exhibits chemical lability at a pH >6.5, limiting chemical derivatization approaches to improve the biological activity. Thus, we expected to gain information from the biosynthetic studies which allowed selective biological derivatization approaches, such as precursor-directed biosynthesis.[10] Here we present the results of our initial feeding experiments from which emerges an interesting novel biosynthetic pathway of general significance.

For the biogenetic origin of all carbon and heteroatoms in pyridazomycin **1** from building blocks of the primary metabolism, four principal working hypotheses were considered, in which I and II each require two, and III and IV, three building blocks, preferably amino acids (Scheme 1). A seemingly insurmountable microbiological problem, namely the low production of pyridazomycin by *Streptomyces violaceoniger* of 0.75 mg L^{-1}, was solved by strain selection experiments, extensive studies of the fermentation process (using a 1 L-fermentor), and, in particular, by avoiding an alkaline pH during the isolation procedure.[11] This finally enabled us to isolate pyridazomycin **1** in amounts of 20–30 mg L^{-1}.

The above-mentioned four hypotheses were examined by a series of feeding experiments with stable, isotopically labeled precursors in such a way that basic information was made available quickly (Table 1). Feeding experiments with ^{13}C-labeled acetate (universal precursor of the intermediates of the citric acid cycle and putative direct precursor of the C_2 building block in hypothesis III) and [1,3-$^{13}C_2$]glycerol (universal precursor of the carbohydrate metabolism and of amino acids deriving from pyruvate, such as alanine, valine, or leucine) provided "scrambling", in other words unspecific, indirect enrichments of several carbon atoms of **1**, in particular C-4′, C-5′, C-6′, and C-7′. Both precursors are definitely not immediately incorporated.

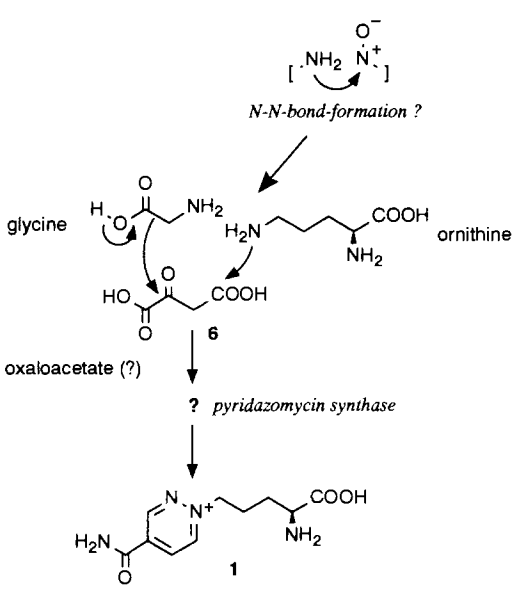
Scheme 1. Hypothetical precursors I–IV of pyridazomycin **1**. The numbers refer to the remaining carbon atoms of a precursor in **1**.

The C_5 amino acid glutamic acid serves as a metabolic precursor of the four amino acids ornithine, glutamine, proline, and arginine, in other words it has also the characteristic of a general precursor.

The feeding experiment with [5-^{13}C]glutamic acid showed a weak, but significant ^{13}C enrichment in the C-5 position of the pyridazomycin side chain. Since C-7′ of the carboxamide side chain was not enriched, and consecutive feeding experiments

Table 1. Incorporation experiments on pyridazomycin **1** with *Streptomyces violaceoniger* [a].

Precursor	Specific incorporation [%][12]	Enrichment in positions
[1,2-$^{13}C_2$]acetate [b]	0.7–3.7	C-4′, C-5′, C-6′, C-7′
[1,3-$^{13}C_2$]glycerol [c]	0.5–0.9	C-4′, C-5′, C-6′, C-7′
[5-^{13}C]glutamic acid [d]	0.6	C-5
[5-^{13}C]ornithine [e]	10.4	C-5
[5-^{15}N]ornithine [f]		N-1′
[2-^{13}C]glycine [g]	9.8	C-3′
[2-^{13}C,^{15}N]glycine [h]	11.5	C-3′, N-2′



[a] Additionally, feeding experiments with [3-^{13}C]-β-alanine, L-[2-^{13}C]leucine, [1-^{13}C]glycine, D,L-[4-^{13}C]aspartic acid, [^{13}C]urea, [*S*-$^{13}CH_3$]methionine, L-[5-^{15}N]glutamine, [2-^{15}N]glutamine, and [2,3-$^{2}H_4$]succinic acid, respectively, did not result in the enrichment of any of the atoms of **1**; [b] 12.2 mmol (99% ^{13}C); [c] 2.7 mmol (50% ^{13}C); [d] 3.4 mmol (99% ^{13}C); [e] 5.9 mmol (99% ^{13}C); [f] 3.0 mmol (99% ^{15}N); due to poor yield, the only signal observable in the ^{15}N NMR spectrum is N-1′; [g] 6.7 mmol (99% ^{13}C); [h] 3.3 mmol (99% ^{13}C, 99% ^{15}N); $^1J(C,N) = 2.6$ Hz.

with differently ^{15}N-labeled glutamine samples gave no incorporations, hypotheses I (or IV) for glutamine as one of the building blocks of the aromatic ring had to be rejected.

Feeding experiments with [5-^{13}C]- and [5-^{15}N]ornithine, however, confirmed the apparent idea that this amino acid serves directly as the immediate building block of the side chain. The former showed a significantly better incorporation than [5-^{13}C]glutamic acid. The ^{15}N NMR spectrum of **1** isolated after the experiment with [5-^{15}N]ornithine shows that the nitrogen atom N-1′ of the pyridazine ring derives directly from the 5-NH_2 group of this amino acid. These incorporation experiments along with several additional negative results (see Table 1, footnote [a]) finally ruled out the hypotheses I–III, thus, the [5C + 4C + 1C] hypothesis (IV) was favored and examined with regard to the C_1 pool. Within this phase of the studies a feeding experiment with [2-^{13}C]glycine (also useful as source of the tetrahydrofolic acid C_1-metabolism) gave a high specific incorporation (ca. 10%) into the expected position, namely C-3′ of **1**. Thus glycine is the second biosynthetic building block of pyridazomycin **1**. An additional feeding experiment with [2-^{13}C,^{15}N]glycine confirmed this conclusion and furthermore proved that N-2′ also derives from this amino acid (^{15}N NMR) and that the C–N bond of glycine remains intact, proven by the observed coupling ($^1J_{C,N}$ = 2.6 Hz) in the ^{13}C NMR spectrum of **1**. Since the feeding experiment with [1-^{13}C]glycine did not yield a ^{13}C-enriched sample of **1**, the origin of C-4′ from the carboxyl group of glycine was ruled out.

The results of the three feeding experiments with labeled glycine also allow a conclusion about the remaining building block of **1**: The incorporation of glycine is performed under decarboxylation, that is, under release of an electron pair. This requires an electrophilic carbon, preferably a carbonyl group, of the remaining building block to serve as an acceptor. Thus, we assume that oxaloacetate **6** is the most likely candidate for the remaining building block, because its functionalities permit both necessary bond formations, an aldol condensation of its carbonyl group with glycine (→ C-3′–C-4′ bond of **1**) and an amide bond formation of its (activated) γ-carboxyl group with the δ-NH_2 of ornithine (→ C-6′–N-1′ bond of **1**, Scheme 2). Even though an incorporation experiment with D,L-[4-^{13}C]-aspartate, which we expected to be transaminated into oxaloacetate **6**, failed, we still favor the [5C + 4C + 1C] hypothesis with **6** as the most likely third building block of pyridazomycin. The negative result may be caused by membrane permeability problems or the inability of the organism to transaminate aspartate into oxaloacetate. Thus, the formation of **6** in *Streptomyces violaceoniger* may be performed only by the citric acid cycle, whose metabolization into the uncertain carbon atoms of **1** is indicated by the feeding experiments with [1,2-$^{13}C_2$]acetate and [1,3-$^{13}C_2$]glycerol. Both compounds can serve as sources of the citric acid cycle, the former directly and thus more immediate than the latter, which has to be metabolized by glycolysis and the pyruvate decarboxylase complex. The specific incorporation rates[1,2] (Table 1) reflect these circumstances. Presently we are working on a synthesis of ^{13}C-labeled oxaloacetate parallel to the establishment of a cell-free system to examine **6** directly as a precursor. We are also looking for the stereochemical course of the glycine incorporation into **1**. Future aspects of our biosynthesis studies on **1** will focus on the N–N bond formation mechanism,[1,3] the order of the bond connection between the given biosynthetic building blocks as well as on the enzymes involved ("pyridazomycin synthase", see Scheme 2).

Scheme 2. Proposed mechanism of the biosynthesis of pyridazomycin **1**.

Experimental Procedure

Cultivation of the microorganism: *Streptomyces violaceoniger* (Tü 2557) was cultivated on slants (20% agar–agar, 10% malt extract, 4% glucose, 4% yeast extract, pH 7.0, adjusted before autoclaving) at 28 °C until sporulation occurred, then stored at 4 °C (for max. four months). The preculture for the fermentations was inoculated directly from the slants and shaken on a rotary shaker (type BS 4, B. Braun, Melsungen, FRG) in 250 mL Erlenmeyer flasks fitted with three baffles, filled with 100 mL medium (2.5% soybean meal, 2.5% mannitol, pH 6.8 before autoclaving) for 48 h at 28 °C and 250 rpm. 100 mL of the preculture was used to inoculate the 1 L fermentor (type ISF 100, Infors GmbH, Basel, Switzerland, filled with 1 L of the same medium as used for the preculture plus additional 30 mmol L^{-1} ornithine hydrochloride, except the feeding experiments with labeled ornithine and glutamic acid, respectively, 28 °C, aeration: 1.6 L min^{-1}, 700 rpm), harvesting about 64 h after inoculation.

Isolation of pyridazomycin **1**: The culture filtrate of the fermentations was exposed to an acidic ion exchange resin (Dowex 50) and washed with about 1.8 L demineralized water, elution with $NH_4^+HCOO^-$ (pH 5; gradient 0.3 M (1.5 L), 0.5 M (0.7 L), and 0.7 M (1 L). The fractions containing **1** were evaporated in vacuo at 40 °C and chromatographed on silica gel (column 60 × 3 cm, *n*BuOH:CH_3COOH:H_2O = 3:2:2), followed by chromatography on Sephadex G-10 (column 100 × 2.5 cm, MeOH:H_2O = 8:2, pH 4.0, adjusted with 0.1 M HCl) and lyophilization of the pyridazomycin-containing fractions.

Feeding experiments: The labeled compounds were dissolved in sterile water (100 mL) and added in four equal portions every six hours or continuously beginning at 25 h (after inoculation) to the growing 1 L-culture (1 L-fermentor) of *S. violaceoniger* (Tü 2557).

Labeled compounds: All the ^{2}H-, ^{13}C-, and/or ^{15}N-labeled compounds, if not synthesized (see below), were obtained from the Cambridge Isotope Laboratories, Cambridge, MA, USA. The variously labeled ornithine samples were synthesized according to Gould et al. [14] from 2-chloroethanol, K^{13}CN (99% ^{13}C) and K^{15}N (99% ^{15}N), respectively, and diethylacetamido malonate. The labeled glycerol was synthesized from bromoacetic acid and K^{13}CN (99% ^{13}C) via cyanoacetic acid, diethyl malonate, and diethyl 2-acetoxy malonate (oxidation with $PbOAc_4$). The [3-^{13}C]β-alanine was synthesized by hydrogenation (12 h, 25 °C, 90 mg Pt as catalyst, in ethanol (30 mL), acidified with concentrated HCl (0.2 mL)) of the previously mentioned labeled cyanoacetic acid (1.5 g) and purified by chromatography on silica gel (column, 30 × 2 cm, 1-propanol:H_2O = 4:1, yield: 0.3 g).

Preparation and Structure of $C_{76}(S_8)_6$: A First Step in the Crystallographic Investigation of Higher Fullerenes**

Rudi H. Michel, Manfred M. Kappes, Peter Adelmann, and Georg Roth*

"Higher fullerenes"—those molecular allotropes of carbon with more than 70 atoms per molecule—have recently become of great interest to preparative chemists and theoreticians. They are minor constituents of the "Krätschmer–Huffman soot"[1] which contains predominantly C_{60} and C_{70}. C_{76} is the smallest among the more abundant (C_{76}, C_{78}, C_{82}, C_{84}) "higher fullerenes" and small quantities of it have been separated chromatographically by a number of groups.[2–6] The topology and molecular structure of C_{76} has been studied theoretically by various methods.[7–10] A detailed prediction of C–C bond lengths in the C_{76} molecule based on ab initio SCF–Hartree–Fock calculations has been published by Colt and Scuseria.[9] There are two possible isolated pentagon ring isomers of C_{76}; these have D_2 and Jahn–Teller distorted T_d symmetry. The most stable isomer of C_{76} is predicted to be the D_2 form. Ettl et al.[5] confirmed this molecular symmetry by ^{13}C NMR measurements on C_{76} in solution. As a chiral species, C_{76} exists as a "right-handed" and a "left-handed" form. These are energetically degenerate and expected to occur in equal proportions (racemic mixture). Very recently, the kinetic resolution of the two chiral isomers has been demonstrated.[11] Effort has also been invested in the prediction of the electronic structure of the molecule.[12, 13]

Owing to the scarcity of the material—the total worldwide production of pure C_{76} is probably in the 10–100 mg range few computational predictions have ever been checked experimentally. In particular, very little information is currently available on solid-state and structural properties of C_{76} or C_{76}-containing compounds.[14] In a scanning tunneling microscopy (STM) study of various higher fullerenes, Li et al.[15] have shown that pure C_{76} appears to form closely packed layers. A crystal structure determination of either pure C_{76} or of any C_{76}-containing compound has, however, not yet been reported.

In this paper we describe the preparation and structure determination of the first C_{76}-containing van der Waals compound, $C_{76}(S_8)_6$. This material is a further representative of the family of fullerene–sulfur adducts, which have the general formula $C_{2n}(S_8)_m$,[16–19] and which are formed by a combination of fullerene molecules with S_8 rings. Its structure is closely related to that of the compound $C_{70}(S_8)_6$.[18] Just as in the C_{70} compound, which in the absence of a well-ordered C_{70} single crystal allowed the first molecular structure study of C_{70} in the solid state, $C_{76}(S_8)_6$ permits the determination of C–C bond lengths in an only weakly (van der Waals) matrix-perturbed fullerene molecule by diffraction methods. The material also offers, for the first time, the chance to perform macroscopic measurements on a structurally well-defined C_{76}-containing crystalline solid.

C_{76} was isolated from fullerene-containing soot prepared by the Krätschmer–Huffman method (electric arc evaporation of graphite in an inert gas atmosphere).[1] Toluene soot extract was coarsely separated by liquid chromatography on an activated alumina column with 5% and 15% toluene in hexane as eluent. Amount and composition of the resulting C_{76}-enriched starting material used for further purification by high-performance liquid chromatography (HPLC) has already been described elsewhere,[20] together with a more quantitative discussion of the whole procedure. Briefly, HPLC isolation of C_{76} was carried out with a Buckyclutcher column.[21] Three consecutive purification cycles were performed with a three-component eluent (50% toluene, 40% hexane, and 10% dichloromethane, 6 mL min^{-1}) in the first cycle and a different composition (28% toluene, 55% hexane, and 17% dichloromethane, 6 mL min^{-1}) optimized for C_{76}/C_{78} resolution in the second and third cycle. The resulting purity was better than 99% C_{76}.[22] Exposure to light was minimized during the whole separation process. Exposure to air was minimized in the third separation stage by purging with nitrogen. Third stage C_{76} solutions, once separated, were stored at below 0 °C prior to eluent removal during which heating above 40 °C was avoided. The solid material was recrystallized from CS_2, stored under nitrogen, and kept/transferred at low temperature prior to use.

Given the very small amount of material available—a few hundred μg in the present case—the growth of $C_{76}(S_8)_6$ single crystals of appreciable size and quality poses quite a challenge. The following procedure finally proved to be successful:

Crystals were grown by slow evaporation (under vacuum) of a solution of C_{76} and sulfur (in excess) in CS_2 at room temperature. A capillary (1 mm internal diameter, one end open) containing about 1 mm^3 of the solution was dipped with the closed end into a "CS_2-heat bath" and the total pressure adjusted such that the CS_2 bath was gently boiling. This stabilizes both the temperature and the CS_2 vapour pressure above the solution. The outer container was slightly heated from below to introduce a small temperature gradient. This helps to avoid unwanted

supersaturation of the solution at the surface and the container walls. The crystals obtained this way are isometric with linear dimensions of up to 0.5 mm. CCl_4 may be used to remove excess sulfur from the crystals. As an additional complication, the crystals are often twinned (rotation twin around the c axis).

Temperature-dependent X-ray diffraction measurements[23] show no evidence for a structural phase transformation between room temperature and 180 K. We concentrate on the low temperature data here, because they offer better $\sin\theta/\lambda$ resolution.

The structure (Fig. 1) was solved in space group Cm[24] by direct methods for the positions of the 26 symmetry independent

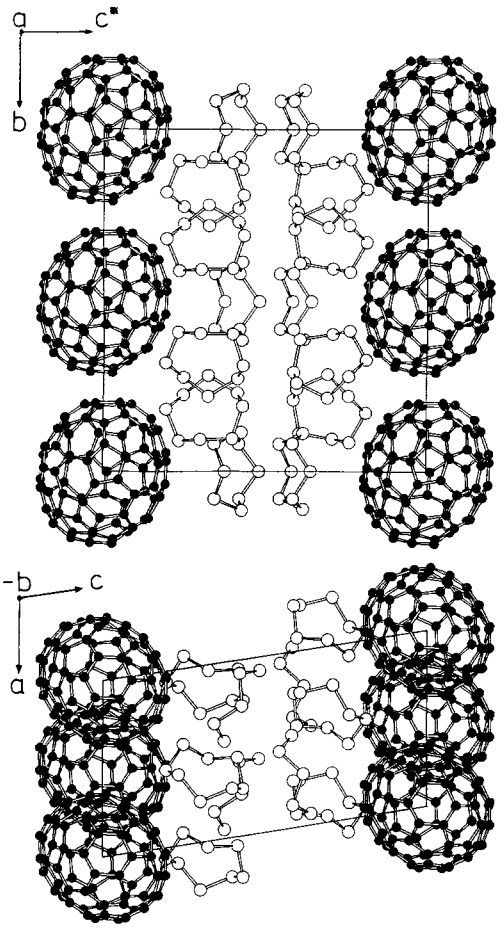

Fig. 1. The structure of $C_{76}(S_8)_6$ projected along the a (top) and b axis (bottom), black circles: carbon, open circles: sulfur atoms. For clarity, only one enantiomer in orientation I is drawn.

sulfur atoms. The arrangement of the sulfur atoms is similar to that in $C_{70}(S_8)_6$;[18] the sulfur atoms form layers (here: in the a-b plane) consisting of a rather complex array of four symmetrically distinct S_8 rings (in the usual "crown" configuration), two of them symmetry-restrained by the mirror plane of space group Cm. Sulfur–sulfur bond lengths range from 2.038 Å to 2.056 Å (average: 2.046(4) Å) and bond angles are close to 108°, in good agreement with the corresponding values observed in the various allotropes of elemental sulfur.[25] Also just as in $C_{70}(S_8)_6$, the fullerenes in $C_{76}(S_8)_6$ form planes between these sulfur sheets consisting of a pseudo-hexagonal arrangement of closely packed fullerene molecules. The center-to-center "packing distance" amounts to 10.4 Å along a and 11.5 Å along the diagonal in the a-b plane (at 180 K). The compound is a typical van der Waals solid with shortest carbon–sulfur distances on neighboring molecules ranging from 3.3 Å upwards. Also in analogy to $C_{70}(S_8)_6$, thin sections of $C_{76}(S_8)_6$ show a pronounced pleochroism (green/yellow) in the plane of closely packed fullerene molecules.

The optimum orientations of the C_{76} molecule were found by systematic, stepwise orientational search.[26] Figure 2 shows two one-dimensional sections through parameter space at the optimum orientations for the D_2 isomers along with a similar plot

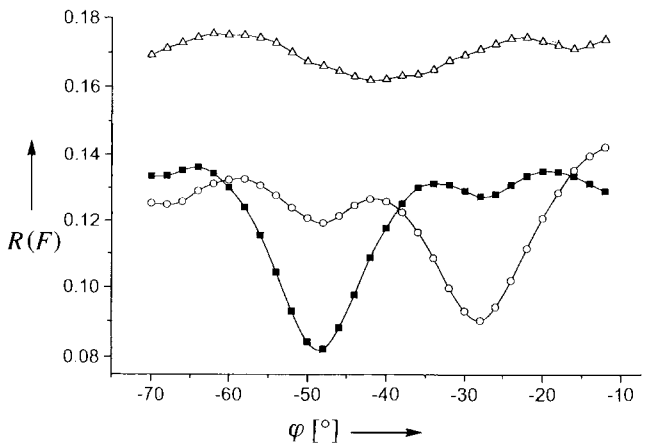

Fig. 2. $R(F)$ value ($|F| > 2\sigma(|F|)$) for C_{76} isomers plotted vs. rotation angle around the longest molecular axis. ■ D_2 isomer close to orientation I, ○ close to orientation II. All other angles and the center of gravity were fixed to their optimum values; △ representative plot for T_d isomer for comparison (rotation around a fivefold molecular axis oriented perpendicular to the mirror plane).

for the T_d isomer. The latter clearly does not fit the data nearly as well as the D_2 isomer and we take this as direct evidence for the overriding dominance of the D_2 isomer. We have found two differently oriented enantiomeric pairs of D_2-C_{76} molecules sharing the same site in $C_{76}(S_8)_6$. Their centers of gravity coincide and are situated on the mirror plane, but the three molecular twofold rotation axes of each of the four molecules are not aligned with any of the crystallographic axes. Starting from a reference orientation with the longest, second longest, and shortest molecular axis oriented along the b_f, a_f, and c_f axis of a fixed orthogonal coordinate system (with a_f, b_f, c_f parallel to the a, b, and c^* axis of the crystallographic unit cell), rotation angles of approximately $-48°$ around b_f, $+17°$ around a_f, and $-7°$ around c_f (in the sequence b_f, a_f, c_f) are necessary to arrive at the first optimum orientation (I). The second, slightly less favorable minimum of the R value occurs for rotation angles $-32°$, $-17°$, and $+6°$ (orientation II). The enantiomers are then generated by the mirror plane of the space group. Owing to the general orientation of the C_{76} molecules the "envelopes" of the two enantiomers do not coincide.[27] All four molecules appear to occupy the same site in a (spatially) random fashion. The occupancies are equal (by symmetry) for the two members of each enantiomeric pair but the first pair has a slightly higher occupation number. The resulting populations (2×0.28 and 2×0.22) and the rotation angles of the two enantiomeric pairs are temperature independent. Presumably, these orientations and their proportions are "frozen in" already during crystal growth and there appears to be no dynamic equilibrium between them at low temperature.

Despite the frequent overlap of many of the carbon atom positions, the resolution of the data[23] at 180 K is sufficient not only to identify the two pairs of orientations but also to extract

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1515-1652 $ 10.00+.25/0

some semiquantitative bond length data from it. For this purpose, a number of bond length restraints[28] were used during structure refinement.[29, 30] These restraints were chosen such that they do not put any bias onto the resulting *average* bond lengths of the "idealized" C_{76} molecule.[31] Figure 3 shows the C_{76} molecule in projections along the three molecular twofold axes.

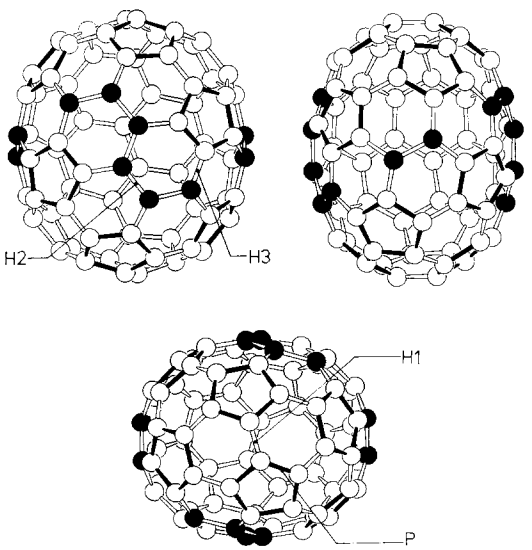

Fig. 3. D_2-C_{76} (one enantiomer) projected along the three principal axes of the molecule. Bonds of type "P" on the front of the molecule are drawn with solid lines, C atoms on "pyrene-type" sites as black spheres.

The overall dimensions of the C_{76} molecule[32] are 8.77(1), 7.77(1), and 6.92(1) Å, in fair agreement with the predicted ones (8.79, 7.64, 6.68 Å;[5] 8.82, 7.71, 6.83 Å[9]). Also, the "bond ordering" which has been predicted by SCF-HF[9] is confirmed experimentally: Bonds shared by a pentagon and a hexagon ("P") are long bonds (exp.: 1.436(4) Å, calcd: 1.453 Å,[9] solid lines in Fig. 3), those connecting the tips of two pentagons and joining two hexagons ("H1") are the shortest bonds in the molecule (exp.: 1.376(7) Å; calcd: 1.370 Å[9]). Near the "pole-caps" of C_{76} (viewed along the longest twofold molecular axis) this leads to the well-known "bond alternation" in the hexagons, most clearly seen in C_{60}[33] but also on the "pole-caps" of C_{70}.[18] Close to the equator this ordering is not possible for topological reasons both in C_{70} and C_{76}. In C_{76}, this leads (to a good approximation) to two additional groups of bonds, 12 bonds of type "H2" connecting the 16 atoms (per molecule) on "pyrene-type"[3] sites, which belong to three hexagons—these are the longest C–C bonds in the molecule (exp.: 1.485(8) Å, calcd: 1.482 Å[9])—and bond type "H3", (topologically similar to "H1") connecting the corners of the pentagons with the "pyrene-type" sites (exp.: 1.409(6) Å, calcd: 1.404 Å[9]). Due to the pronounced disorder[34] of the C_{76} molecule in $C_{76}(S_8)_6$, a more detailed comparison of calculated and individual experimental bond lengths cannot be performed.[28]

A note on the principal limitations of this work seems appropriate at this stage: The structure has been "solved" (in the classical crystallographic sense) only for the sulfur atoms. The orientational disorder of the C_{76} molecule prohibits such an approach (with no reference to the expected molecular shape) for the fullerene molecule. Even more important, crystal chemical knowledge, usually very helpful—if not decisive—in judging the correctness of a structure solution, is of very little help in this case. The superposition of more than one C_{76} molecule on the same site inevitably leads to "unreasonably short" apparent *intramolecular* C–C distances. Previous knowledge about *intermolecular* distances (of the van der Waals type), on the other hand, is not sufficient to favor (a priori) any orientation over the other. We are therefore left with the problem that neither the correctness nor the uniqueness of the present structural model can be proven rigorously.[35] This problem is intrinsic to cases where a major part of the structure is partially disordered and it gets worse with increasing size and decreasing symmetry of the disordered group. In this sense, such structural models with pronounced molecular disorder—among them the present one—should not be taken as "the final word" on the respective structures.

We have been able to show that the diffraction data measured for $C_{76}(S_8)_6$ are compatible with the postulated chiral D_2 structure of C_{76} and also to establish some basic semiquantitative aspects of its bond ordering by diffraction methods. Under crystal chemical aspects it is interesting to note that, just as in the case of $C_{70}(S_8)_6$, the combination of the larger fullerene C_{76} with the "bulky" S_8 rings leads to a structurally very similar and also comparatively well-defined heteromolecular van der Waals solid which, although intrinsically disordered, again offers atomic resolution of the fullerene molecule even at room temperature. The reason why most of the fullerene–sulfur adducts show no cage rotation at room temperature presumably lies in the specific interaction of fullerenes with the S_8 rings (possibly due to the nucleophilicity of sulfur as proposed in ref. [36]), a point which is, however, not sufficiently understood as yet.

A really substantial improvement of the quality of the bond length data for C_{76} can be expected from diffraction experiments on corresponding compounds with only one enantiomer. The kinetic resolution of the two chiral isomers of C_{76} by asymmetric osmylation, which has recently been demonstrated by Hawkins and Meyer,[11] has now opened a possible synthetic path to such compounds.

[21] Regis Chemical Company, 5μm particle size, 10 mm × 250 mm.

[22] The purity was estimated by mass spectrometry. HPLC analysis showed 5% impurities at longer retention times. Since the mass spectra did not show any evidence for fullerenes higher than C_{76}, the impurity might be due to C_{76} oxide.

[23] Untwinned single crystal, dimensions 0.08 × 0.09 × 0.36 mm^3, four-circle diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, N_2-cryostat, lattice parameters: 295 K: $a = 10.506(2)$, $b = 20.624(4)$, $c = 19.563(3)$ Å, $\beta = 98.8(1)^\circ$, 180 K: $a = 10.410(3)$, $b = 20.500(6)$, $c = 19.480(5)$ Å, $\beta = 98.8(1)^\circ$, thermal expansion coefficients $(-1/\Delta T)\Delta d/d$ just below room temperature: 9.3×10^{-5}, 6.1×10^{-5}, and 4.4×10^{-5} K^{-1} along a, b, and c respectively. Data collection at 180 K: Full sphere 0–20°, half sphere 20–40°, asymmetric unit 40–55° 2θ, $\sin\theta/\lambda = 0$–0.65 Å^{-1}, 4830 symmetry independent reflections, 3487 with $|F|^2 > 2\sigma_{|F|}^2$, $\mu = 12.9$ cm^{-1}, $R_{int} = 0.03$, $R_{sigma} = 0.048$.

[24] Among the three possible space groups consistent with the systematic extinctions, $C2$ and $C2/m$ could be ruled out because the final arrangement of the sulfur atoms does not comply with these symmetries. Atomic displacement ellipsoids of some of the sulfur atoms are elongated along b. Comparison of the 295 K with the 180 K data suggests that these displacements are dominated by static positional disorder, probably reflecting the fact that the C_{76} part of the structure obeys the mirror symmetry only in a statistical sense but not locally. Efforts to refine the structure in space group $C1$ (including pseudomeroedric and racemic twinning) failed. Also, there is no indication (from line splitting or intensity symmetry) for a deviation from the average monoclinic symmetry over the whole temperature range studied.

[26] A single C_{76} molecule (D_2 as well as T_d isomer) was used as a "probe". Approximate atomic coordinates for the free molecule were kindly provided by the authors of ref. [8]. The parameter space is six-dimensional, with three orientational variables (Euler angles) plus three translational variables specifying the center of gravity which is, however, approximately known, once the sulfur arrangement has been determined. $R(F)$ values (4197 reflections) for rigid group refinement of C_{76}: Sulfur only: 0.20, with orientation I: 0.078, orientation I + II: 0.06. The fact that these R values are already not too far from the internal consistency R value of 0.03 suggests that the experimental molecular shape is quite close to the predicted one. It was also tried to directly build up the molecule by collecting the individual carbon atoms from successive Fourier syntheses. The resulting list of peaks contained most of the actual atom positions generated by the orientational search. Due to the superposition of four molecules on the same site, it is, however, almost impossible to unambiguously assign the Fourier peaks to the four individual (two symmetry independent) C_{76} molecules without a reference to the molecular shape.

[27] In the second orientation, the superposition of the enantiomeric pair results in almost the same "envelope" as for the first orientation, but the local arrangement of the carbon atoms is different and it is clearly not just the arrangement that would have been obtained by applying a local twofold axis to the C_{76} molecule or by interchanging the two enantiomers. This "correct orientation but wrong isomer" case is responsible for the shallow side minima in Figure 2. Besides these, there is a large number of additional, shallow local minima.

[28] The ideal symmetry of the "free" molecule was imposed by restraining distances equivalent under the idealized symmetry of tbe free molecule to be equal to each other within an estimated standard deviation of 0.01 Å. These restraints make groups of four atoms (related by the three twofold molecular axes) equivalent to each other, thus reducing the number of independent carbon atoms on the C_{76} molecule from 76 to 19 and the number of different C C bonds from 114 to 30. Equivalent bonds on the two differently oriented molecules were also tied together. If all variables were refined freely under these restraints, the resulting 30 C–C bond lengths ranged from 1.25 to 1.55 Å. This broad range reflects the high overlap of atoms on different molecules sharing the same site. Therefore, the 30 independent bonds on the idealized molecule were further grouped into four classes of topologically equivalent bonds (see text) which were restrained to have equal lengths within an estimated standard deviation of 0.03 Å. These average distances themselves were refined freely. The restraints are treated by the refinement program [30] as additional "soft data". This also helps to avoid singularities in the least squares calculations. The relative weighting of the diffraction data and the restraints, however, is quite a delicate problem. In detail, the bond lengths actually depend on this weighting (as well as on the type of restraints chosen), the estimated standard deviations probably underestimate the actual errors and the figures we give should therefore be considered approximate.

[29] Full matrix least squares [30], anisotropic displacement parameters for sulfur, one common isotropic displacement factor ($u = 0.044(1)$ Å^2) for all carbons, 692 variables, $R(F) = 0.0395$ for 3487 observed, $R(F) = 0.0634$ for all data, see [30] for definitions; goodness of fit (GOF) for all data: 1.055, restrained GOF: 0.941. Largest peak in a final Fourier synthesis below 0.49 electrons per Å^3, located on the envelope of the C_{76} molecule. Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe Gesellschaft für wissenschaftliche Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-380024.

[30] G. M. Sheldrick, Program system Shelxl-93, unpublished.

[31] They do imply, however, that the influence of the van der Waals bonding on individual bond lengths of the C_{76} molecule can be neglected, a fair assumption for the present purpose, because the experimental accuracy for individual bond lengths is far from being sufficient to identify the expected small distortions on the order of 0.01 Å, see Q. M. Zhang, J. Y. Yi, J. Bernholc, *Phys. Rev. Lett.* **1991**, *66*, 2633–2636.

[32] Defined here as twice the average distance from the center of gravity of the molecule to the atom pairs close to the three twofold molecular axes; it is not quite clear, which definitions are used in refs. [5] and [9].

Ed. Engl.* **1992**, *31*, 640–643.

[34] Presumably, this disorder is intrinsic to this compound: A second, much smaller crystal from a different batch, studied at room temperature, showed qualitatively similar disorder phenomena.

[35] Once the existence of a second pair of enantiomers has been established, the dimensionality of the relevant parameter space more than doubles (six rotations, six translations, one additional occupancy). A "verified solution" of this disorder problem would require the evaluation of the R value on a sufficiently closely spaced grid in this 13-dimensional space—given the size of the structure, this is nearly impossibly. What we have actually done is to seek the solution in a six-dimensional section through the 13-dimensional space. Nothing guarantees that the solution in this subspace is also the global optimum in the true 13-dimensional parameter space.

Synthesis of an Azathymidine and Its Incorporation into Oligonucleotides**

Karl-Heinz Altmann,* Susan M. Freier, Uwe Pieles, and Tammo Winkler

The inhibition of protein synthesis by antisense oligonucleotides is a fundamentally new approach in medicinal chemistry research.[1] The concept is based on the very specific rules that govern the mutual recognition of nucleic acids (Watson–Crick base pairing) and aims to exploit the selective hybridization of an (antisense) oligonucleotide to a complementary base sequence on the appropriate messenger RNA in order to block the expression of a disease-related protein. The general viability of this strategy has been proven in a large number of in vitro experiments; however, these experiments have also demonstrated that the antisense oligonucleotide should be sufficiently stable towards enzymatic degradation in order to achieve significant inhibitory effects on protein synthesis.[1] Since natural oligonucleotides are rapidly degraded under physiological conditions, the quest for metabolically more stable compounds has led to the design and investigation of various types of sugar-, base-, and backbone-modified oligonucleotides or oligonucleotide analogues.[1, 2] These include oligonucleotides containing carbocyclic nucleosides **1** (Fig. 1)[3, 4] and thia analogues of

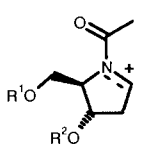
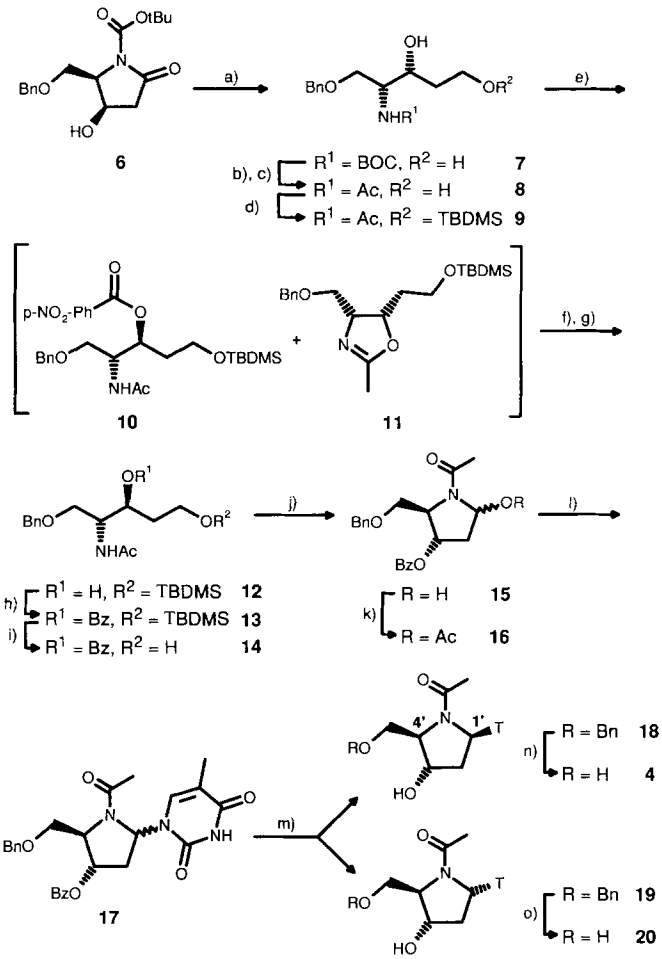
base = thymine



thymidine[6] and ribothymidine **2**[7] (base = thymine). In contrast, no oligonucleotides are known so far that incorporate pyrrolidine-based nucleoside analogues **3**.

Compounds of type **3** with R' = H can be expected to be chemically too unstable to be incorporated into antisense oligonucleotides,[8] but the corresponding acetylated derivatives (R' = Ac) could be interesting building blocks for antisense molecules. While the exact hybridization properties of these modified oligomers for complementary RNA are difficult to predict, molecular models indicate that acetylated building blocks of type **3** can be accomodated within standard nucleic acid duplex structures without major distortions. Moreover, it appears likely that the increased steric bulk of the acetamido group (as compared to the furanose oxygen atom) may impede recognition of the corresponding oligonucleotides by nucleolytic enzymes and therefore lead to improved metabolic stability.



These considerations led us to investigate the properties of modified oligonucleotides containing nucleoside analogues of type **3** with R' = Ac. We first focused our attention on azathymidine **4**, an analogue in which the oxygen atom of the ribofuranosyl unit is replaced by an *N*-acetyl group. A 13-step synthesis of compound **4** starting from 2-deoxyribose has recently been reported.[9] In this paper we now describe a different approach to the synthesis of **4**, the incorporation of this building block into selected oligonucleotide sequences, and the hybridization properties and nuclease resistance of these oligomers.

Our strategy for the synthesis of **4** relies on the Lewis acid catalyzed generation of a suitably protected *N*-acyliminium ion **5** as the key reactive intermediate.[10] In situ trapping of **5** with silylated thymine as a nucleophile and subsequent protecting group manipulations should then lead to the target compound **4**.

As shown in Scheme 1 the synthesis started from optically active pyrrolidine **6**, which can be prepared in three steps from BOC-D-Ser(OBn)-OH (BOC = *tert*-butoxycarbonyl) according to literature procedures.[11] Treatment of **6** with $NaBH_4$/EtOH in the presence of catalytic amounts of HCl gave partially protected amino triol **7** in practically quantitative yield. Compound **7** was directly converted into the crystalline *N*-acetylated compound **8** by acid-catalyzed removal of the BOC protecting group and subsequent acylation with *N*-acetoxysuccinimide (AcONSu). Selective silylation of the primary hydroxyl group of **8** with *tert*-butyldimethylsilyl chloride (TBDMS-Cl)[12] furnished **9**, whose elaboration into **4** required inversion of the configuration at the secondary hydroxyl group. Mitsunobu reaction of **9** with *p*-nitrobenzoic acid as the external nucleophile[13] produced a roughly 1:1 mixture of the desired *p*-nitrobenzoate **10** and oxazoline **11**. No reaction occurred under standard Mitsunobu conditions[14] with either benzoic or formic acid as external nucleophiles. The mixture of **10** and **11** was converted to the desired amino triol **12** by saponification with NaOH/THF and subsequent opening of the oxazoline ring with NaOAc/dimethoxyethane (DME)/H_2O at 125 °C in 60% overall yield (based on **9**). Benzoylation followed by TBDMS removal with NH_4F/MeOH[15] then gave **14** as the immediate precursor of acetal **15**. In contrast, TBDMS cleavage from *rac*-**13** with tetrabutylammonium fluoride (TBAF) resulted in quantitative migration of

NaOMe (1.1 equiv), MeOH, RT, 1.5 h, 86%; 2. flash-chromatography in CH_2Cl_2/MeOH 12.5/1: **18**: 33%, **19**: 48%; n) H_2, 10% Pd-C, MeOH, RT, 1.25 h, quant.; o) H_2, 10% Pd-C, MeOH, RT, 1.25 h, quant.

the benzoyl group to the primary hydroxyl group. Oxidation of **14** with tetra-*n*-propylammonium perruthenate (TPAP)/*N*-methylmorpholine *N*-oxide (NMMO)[16] furnished acetal **15** in 41% yield. The moderate yield is mainly caused by rapid further oxidation of **15** to the corresponding lactam. For this reason the reaction mixture was worked up after 1.5 h, the product was isolated, and recovered **14** was resubjected to oxidation. Compound **15** was converted into acetate **16**, the immediate precursor of *N*-acyliminium ion **5**. Treatment of **16** with $SnCl_4$ in the presence of $(TMS)_2$-thymine at −15 °C for 1 h gave a 93% yield of **17** as a mixture of diastereomers which could not be separated at this stage. Transesterification with NaOMe/MeOH and subsequent chromatographic separation then gave **18** and **19** in 33% and 48% yield, respectively. The identity of **18** and **19** was determined by NOE difference spectroscopy (NOE = nuclear Overhauser enhancement). While a strong NOE was observed between H-4' and H-6 of the base in **19**, no such NOE was detectable in **18**. Instead, an NOE between H-1' and H-4' in **18**

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1515-1655 $ 10.00+.25/0

clearly indicated a *cis* relationship for these two protons. The synthesis of **4** as well as its diastereomer **20** were completed by benzyl ether cleavage by catalytic hydrogenation in essentially quantitative yield.[17] According to their ^{1}H NMR spectra each of these compounds exists in MeOH solution as an approximately 1:1 mixture of rotamers.

For the oligonucleotide synthesis **4** was converted into the protected phosphoramidite **21** according to standard methodology[18a] (Scheme 2). Compound **21** was used for the preparation

Scheme 2. a) 4,4'-Dimethoxytrityl chloride (DMTr-Cl), Et_3N, DMAP, RT, 27 h, 70%; b) $NCCH_2CH_2OP[N(i\text{-}C_3H_7)_2]_2$, diisopropylammonium tetrazolide, CH_2Cl_2, RT, 23 h, 70%.

of four oligonucleotides containing between one and four azathymidine residues (vide infra). The oligonucleotides were synthesized according to standard solid-phase procedures,[18b] and no special problems were encountered in the coupling of **21**.[19] The 5'-4,4'-dimethoxytrityl (DMTr) protected oligonucleotides were purified by reversed-phase high-performance liquid chromatography (RP-HPLC), and the DMTr group was subsequently removed by treatment with 80% AcOH for 20 min at room temperature. Capillary electrophoresis (CE) indicated that the fully deprotected compounds were at least 95% pure.[20]

The data for the hybridization of three of these four oligonucleotides with complementary RNA (as the target of antisense oligonucleotides) are summarized in Table 1. It is evident that

Table 1. Hybridization of oligodeoxynucleotides containing azathymidine **4** with complementary RNA sequences (oligoribonucleotides).

Oligonucleotide [a]	T_m [b, e]	T_m(WT) [c, e]	ΔT_m/mod. [d]
d(**t**CC AGG **t**G**t** CCG CA**t** C)	57.4	62.3	−1.2
d(CTC GTA CC**t** TTC CGG TCC)	62.8	63.3	−0.5
d(CTC GTA C**tt** **tt**C CGG TCC)	55.8	61.8	−1.5

[a] **t** = azathymidine **4**. [b] Melting temperature of the duplex between the modified oligodeoxynucleotide and the corresponding complementary oligoribonucleotide (RNA) in °C. [c] Melting temperature of the unmodified wild-type (WT) duplex in °C. [d] $T_m - T_m$(WT) per modified building block. [e] Determined in 10 mM phosphate buffer, pH 7, containing 100 mM Na^+ and 0.1 mM ethylenediaminetetraacetic acid (EDTA) [22].

the incorporation of azathymidine causes a modest destabilization of the DNA/RNA heteroduplex (as compared to the unmodified wild-type duplex), which is reflected in an average decrease of the T_m-value of 1.3 °C per modification. The destabilizing effect may arise from distortions of the normal duplex structure caused by the acetyl substituent on nitrogen, although this is not obvious from molecular models (vide supra). In addition, different rotamers about the tertiary amide bond may affect binding in a different manner.

In contrast to the destabilizing effect of **4** on overall binding affinity incorporation of **4** into an oligonucleotide does not lead to any adverse effects on the specificity of hybridization with complementary RNA. As shown in Table 2 the differences in

Table 2. Hybridization of d(CTC GTA CCt TTC CGG TCC) with r(GGA CCG GAA **Y**GG UAC GAG) [a].

Y	T_m [b, e]	ΔT_m [c, e]	ΔT_m(WT) [d, e]
rA	62.8	–	–
rC	53.1	−9.7	−8.9
rG	54.9	−7.9	−1.7
rU	51.1	−11.7	−7.5
average	–	−9.7	−6.0

[a] **t** = **4**. [b] Melting temperature of the modified DNA/RNA heteroduplex in °C. [c] Difference in melting temperature between the fully matched (**Y** = rA) and the respective mismatched duplex in °C. [d] Difference in melting temperature between the fully matched (**Y** = rA) and the respective mismatched wild-type (WT) duplex (i.e. all hybrids contain natural thymidine in place of **4**). [e] Determined in 10 mM phosphate buffer, pH 7, containing 100 mM Na^+ and 0.1 mM EDTA [22].

melting temperature between the fully matched DNA/RNA duplex containing a single azathymidine residue ("**t**") as part of the DNA strand (**t**:A base pair) and the various mismatched hybrids (containing **t**:C, **t**:G, and **t**:U base pairs, respectively) in all three cases even exceed the corresponding temperature differences for the parent duplexes containing natural thymidine in place of **4**. In view of the very limited data base this apparent enhancement of hybridization specificity by the incorporation of **4** should not be overinterpreted, but the data presented in Table 2 certainly indicate that oligodeoxynucleotides containing **4** should hybridize to complementary RNA with similar specificity as the corresponding wild-type oligodeoxynucleotides.

To evaluate the nuclease resistance of oligonucleotides containing azathymidine **4** we investigated the stability of TCC AGG TGT CCG **ttt** C to degradation by 3'-exonucleases in 10% heat-inactivated fetal calf serum (FCS).[1] Not considering loss of the natural 2'-deoxycytidine residue at the 3'-end, the half-life of this oligonucleotide in FCS has been determined to be $\gg$48 h.[23] Under the same experimental conditions the unmodified wild-type oligonucleotide has a half-life of only 2 h. Thus, the modified oligonucleotide displays a >20-fold increase in nuclease resistance.

In view of these results pyrrolidino nucleosides of type **3** with R' = Ac should be excellent tools for the stabilization of antisense oligonucleotides against degradation by 3'-exonucleases. However, additional experiments are required to determine whether the hybridization affinity of fully modified sequences (containing only building blocks of type **3** with R' = Ac) would still suffice for biological applications.

[23] The natural nucleotide building block at the 3′-end of the oligonucleotide is present only for synthetic convenience, as it allows solid-phase oligonucleotide synthesis to be conducted starting from a commercially available support. This residue is removed from the oligonucleotide by the action of 3′-exonucleases rather rapidly, independent of the nature of the adjacent building blocks. The degree of protection against degradation by 3′-exonucleases conferred by the modified building blocks **4** in TCC AGG TGT CCG **ttt** C is therefore determined by the half-life of the $(n-1)$ species generated by removal of the 3′-terminal cytidine residue.

Active Surface Carbon—A Reactive Intermediate in the Production of Synthesis Gas from Methane and Carbon Dioxide

Michael F. Mark and Wilhelm F. Maier*

An efficient use of the climatically relevant gases CH_4 and CO_2 (greenhouse effect) as a source of carbon is a central issue in heterogeneous catalysis.[1] The reaction (a) of CO_2 with CH_4 to give a mixture of CO and H_2 (synthesis gas), so-called dry or CO_2 reforming, is a particularly elegant way to utilize both gases directly.[2, 3] The synthesis gas resulting from reaction (a) has a

$$CH_4 + CO_2 \rightleftharpoons 2\,CO + 2\,H_2 \quad \Delta H_{R298} = 261\ kJ\ mol^{-1} \qquad (a)$$

lower H_2/CO ratio than that produced by the cleavage of CH_4 with steam (steam reforming[4]), which is advantageous for hydroformylations and Fischer–Tropsch processes. CO_2 reforming was exploited[5] industrially in the USA already in 1948 and is still used today in the Calcor process, mainly for the manufacture of CO.[6] Renewed interest has been shown in this conversion because of its potential use as an effective reaction for energy storage,[7, 8] and because it allows a carbonization (coking)-free utilization of CO_2.[2]

Rh, Ir, and Ru support catalysts have proved particularly useful in the case of the extremely endothermic equilibrium reaction (a). A coking-free conversion on Rh, Ru,[2, 3, 8] and Ir[2, 3] catalysts has been reported. In contrast Ni, Pt, and Pd catalysts are less suited for CO_2 reforming, since they are not as active as Rh, Ru, or Ir catalysts. Furthermore, Ni and Pd catalysts are prone to deactivation caused by carbonization.[2, 3, 9] At the expense of a loss in activity Ni catalysts can be used after passivation with H_2S.

Although Fischer and Tropsch[11] reported the reaction of natural gas with carbon dioxide already in 1928, even today the reaction mechanism has not been completely clarified. On account of kinetic investigations Bodrov and Apel'baum postulated the formation of water as an important intermediate.[12] The basis of the presently accepted mechanism[3] is the dissociative adsorption of CO_2 and the stepwise dissociation of CH_4 at active metal centers (Scheme 1). In 1991 the observed activity order of the catalyst metals was correlated with the CO_2 dissociation activity.[9]

$$CH_4 + s \rightleftharpoons [CH_{xs} + (4-x)H_s] \rightleftarrows C_s + 2\,H_2$$
$$CO_2 + 2\,s \rightleftharpoons CO_s + O_s$$
$$C_s + O_s \rightleftharpoons CO_s + s$$
$$CO_s \rightleftharpoons CO + s$$

Scheme 1. Currently accepted mechanism for the formation of synthesis gas [3]. The support is indicated by 's' (surface); thus C_s corresponds to a carbon atom adsorbed on the surface (surface carbon).

The detection of small amounts of ethane in the decomposition of methane on Rh/SiO_2 catalysts at 250 °C was interpreted as evidence for the formation of CH_x units on the surface.[13, 14] Solymosi et al.[14] observed the formation of C species of differing reactivity on Rh catalysts; the most reactive form of these C species reacts with H_2 to give methane even at 80 °C. The same

authors discussed an alternative mechanism for the conversion of active surface carbon C_s with CO_2[14] for the first time in 1993 (Scheme 2).

$$CH_4 + Rh_s \cdots\rightarrow C_s{-}Rh_s + 2H_2\uparrow$$

$$C_s - Rh_s + CO_2 \longrightarrow 2\,CO\uparrow + Rh_s$$

Scheme 2. Alternative mechanism for the formation of synthesis gas [14].

The mechanism of this reaction was of particular interest to us because of the effective utilization of CO_2. In the preceeding investigations under gas phase flow conditions we were able to confirm the exceptional activity and selectivity of Rh and Ir on Al_2O_3. Since an almost linear relationship exists between conversion and the size of the active metal surface for both support catalysts, the influence of particular surface structures on the mechanism can be excluded. The reaction of CH_4 with CO_2 is not limited by diffusion under the chosen reaction conditions (35 mL min^{-1}, CH_4:CO_2 = 1:1) up to 800 °C, and is first order in CO_2 and CH_4, confirming the participation of both reactants in the rate-determining step.

The interaction of the starting materials CH_4 and CO_2 with a Rh(5%)/Al_2O_3 catalyst was investigated in detail by pulse chemisorption under the reaction conditions used in CO_2 reforming (700 °C). An exclusively mesoporous γ-Al_2O_3 (CONDEA pural, S_{BET} = 78 m^{2}g^{-1}, pore diameter ca. 20 nm) was used as the support. After just a few experiments at 700 °C this catalyst displayed a constant activity over many weeks, as well as a stable dispersion (CO chemisorption) of 3.25% (active metal surface 0.8 m^{2}g^{-1}). The sizes of the Rh crystallites range from 10–30 nm; TEM studies confirm the stable, relatively low dispersion (Fig. 1). Under steady state conditions at 700 °C, 150 mg catalyst, and a volume flow of 35 mL min^{-1} CH_4/CO_2, more than 90% of the equilibrium conversion [conversion (CH_4) = 70%; conversion (CO_2) = 88.5%] can be achieved. In control experiments the pure Al_2O_3 support proved to be completely inactive for CO_2 reforming.

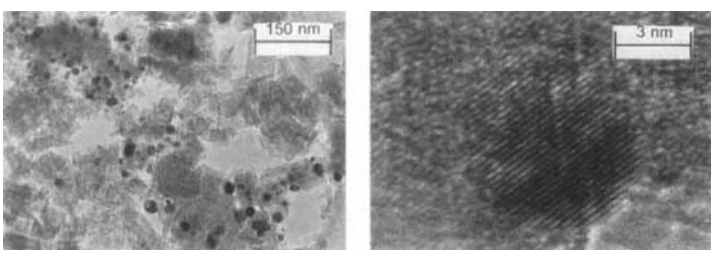

Fig. 1. A transmission electron micrograph (TEM) of the used Rh/Al_2O_3 catalyst; Overview showing Rh particles (left), and a high resolution picture of a small Rh particle with atomic resolution of the crystal lattice (right). The identity of rhodium was confirmed by X-ray scattering (EDX) analysis using an electron beam of 2 nm diameter.

In CO_2-pulsed chemisorption studies on a Rh/Al_2O_3 catalyst at 200–400 °C Solymosi et al.[13] were only able to detect the formation of less than 0.1% CO. When CO_2 pulses (0.33 monolayers C_s/Rh_s) are applied to a pre-reduced and flushed Rh catalyst (reduction: 1 h, 30 mL min^{-1} H_2 at 600 °C; flushing: 30 min 30 mL min^{-1} He at reaction temperature) there is no detectable amount of CO produced [error < 3%, Eq. (b)]. This confirms the results of Solymosi et al. and indicates an extremely small interaction between CO_2 and the reduced Rh.

$$CO_2 + Rh_s \longrightarrow CO + O{-}Rh_s \qquad (b)$$

When the first CH_4 pulse (0.33 monolayers C_s/Rh_s) is applied to the pre-reduced and flushed Rh catalyst sample at 700 °C, a quantitative decomposition of CH_4 is observed. The detection of CO_2 and CO in the product pulse in addition to H_2 is due to unavoidable residual oxygen on the catalyst surface. After the second pulse the formation of hydrogen dominates clearly, and a total amount of carbon remains which corresponds to a third of a monolayer. When the catalyst is now subjected to CO_2 pulses at the same temperature, 72% and 18% of the CO_2 will be converted exclusively into two equivalents of CO after the first and second pulses, respectively. This corresponds to a 90% conversion of the surface carbon. During additional CO_2 pulses no further CO formation is detectable. The residual carbon (approximately 0.03 monolayers) is obviously not reactive and could be detected as CO_2 released above 400 °C during a temperature-programmed oxidation. This shows that 90% of the surface carbon arising from the decomposition of methane on a Rh catalyst reacts extremely fast with CO_2 to give CO, and must therefore be highly reactive.

The question can then be asked whether this reactive surface carbon C_s is present in some form in a stoichiometric relationship at the Rh surface, for instance as a sort of surface carbide. Thus, the decomposition of methane was carried out repeatedly on a pre-reduced catalyst with up to 80 methane pulses (about 25 carbon monolayers).

The degree of CH_4 dissociation decreases with increasing coverage of the catalyst surface (encapsulating carbon), presumably since the catalytically active centers become inaccessible or deactivated.[13, 14] Methane is decomposed many times over in relation to the Rh surface. Even with a coverage of more than 15 monolayers it is still possible to observe a dissociation of about 50% of the pulsed methane. In contrast to the results of Solymosi et al., who studied the CH_4 decomposition on a Rh catalyst at lower temperatures (200–400 °C),[13, 14] we were able to detect H_2 in the product gas but no ethane. After exposure of the carbon coated Rh catalyst to CO_2 pulses, an almost quantitative conversion of a limited number of CO_2 pulses into 2 CO can be detected depending on the amount of CH_4 previously dissociated (Figs. 2 and 3). Figure 2 shows the mass-spectrometric response signal at *m/z* values of 28 and 44 from identical CO_2 pulses on a catalyst previously coated with carbon, and from the empty catalysis tube (calibration pulse). The calibration pulse documents the CO formation through fragmentation in the mass spectrometer.

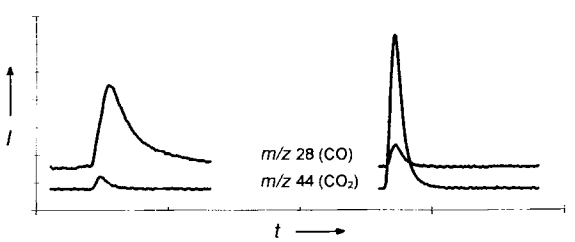

Fig. 2. Signal intensities at *m/z* = 44 and 28 of the product after identical CO_2 pulses in an empty tube (calibration pulse, right) and over the Rh(5%)/Al_2O_3 catalyst coated with 2.5 monolayers of preadsorbed carbon by prior decomposition of methane. One division on the time axis represents 50 s.

Figure 3 shows the typical rapid decay of the CO_2 conversion after seven CO_2 pulses on a Rh catalyst coated with 2.5 monolayers of carbon by CH_4 decomposition. The amount of surface carbon which is transformed by CO_2 into CO is determined by the amount of CH_4 dissociated and the CO produced. From the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1515-1658 $ 10.00+.25/0

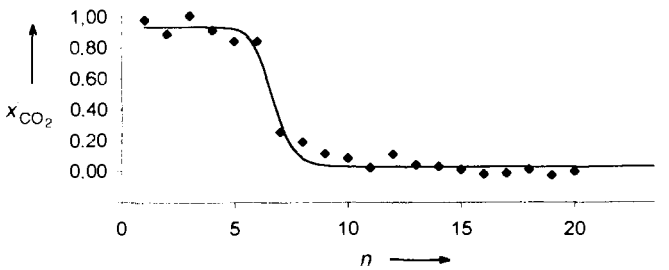

Fig. 3. CO_2 conversion x (entirely to 2 equivalents CO) as a function of increasing CO_2 pulse count n over a Rh(5%)/Al_2O_3 catalyst coated with about 2.5 monolayers of carbon (determined from the peak areas at mass 44).

plot of preadsorbed monolayers of carbon against monolayers of CO_2 released (with 2 CO as the only product) (see Fig. 4) it is evident that at lower carbon coverages the surface carbon reacts almost quantitatively. However, as the coverage increases, an increasingly large proportion of unreactive carbon remains on the surface of the catalyst. Even with a coating of 13 monolayers there are still 9 monolayers of active carbon present, which are transformed spontaneously and quantitatively by CO_2 to CO. This is inconsistent with the formation of defined surface species, and suggests the formation of highly reactive carbon as the active center for the CO_2 transformation. Possibly rhodium does not participate in the conversion of CO_2 and is soley responsible for the activation of methane and the formation of active surface carbon.

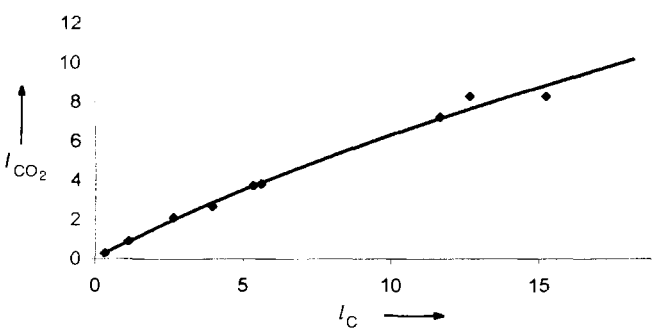

Fig. 4. Dependence of the amount of CO_2 (I_{CO_2}) converted (to 2 equivalents CO) in monolayers CO_2/Rh_s on the amount of preadsorbed carbon I_c in monolayers C_s/Rh_s.

Even though hydrogen is the only detectable product from methane decomposition in the stepwise CO_2 reforming, the question remains whether this reactive surface carbon contains any hydrogen-containing CH_x species. Since the release of hydrogen proceeds stoichiometrically within experimental error—two equivalents of H_2 are released per equivalent of CH_4 converted the concentration of partially dissociated methane (CH_x) species must be lower than the experimental error of about 5%. This was confirmed by deuteration experiments. At 700 °C the surface carbon can be effectively hydrogenated to methane by using pulses of hydrogen. If a catalyst previously coated with carbon is flushed at 700 °C with D_2 (30 mL min^{-1}), the deposited carbon is deuterated exclusively to CD_4. A significant amount to the partly deuterated methane was not detectable. This confirmed the investigations of Solymosi et al.,[14] who could not find any CH_x intermediates in in situ IR studies of the CH_4 decomposition on a Rh/Al_2O_3 catalyst.

After it was shown that the stepwise catalytic conversion of CH_4 with CO_2 in the presence of rhodium proceeds nearly quantitatively, it can be assumed that the same reaction mechanism as in Scheme 2 is operative in the continuous reaction process at identical reaction conditions.

Decisive for carbonization-free CO_2 reforming is a rapid reaction of the active carbon with CO_2, which avoids a high surface coverage of carbon. Such conditions can, of course, only be achieved when both reactants are added simultaneously, which corresponds to the well-known reaction conditions of the CO_2 reforming process. That this is the case with Rh/Al_2O_3 catalysts is shown by our results as well as those of Richardson et al.,[8] who were able to carry out the reaction under steady-state conditions (CH_4:CO_2 = 1:1, 500–800 °C) without deactivation, and who failed to observe any C deposition on the Rh catalyst even after longer reaction times.

The mechanism of the related reaction for production of syngas from methane and oxygen on Rh and Pt catalysts also appears to proceed via a reactive surface carbon intermediate. On account of the high selectivity of hydrogen in this reaction, Hickman and Schmidt[15] postulated that the complete decomposition of CH_4 with associated desorption of H_2 occurs as a preliminary step, prior to the selective oxidation of the resulting surface carbon with O_2 to give CO. Similar behavior in the CO_2 and steam reforming processes suggests that the reaction of CH_4 with H_2O proceeds by the same mechanism. The same stepwise mechanism may possibly form the basis of all these reactions of methane for the production of syngas. The exact characterization of the reactive carbon and its structural difference to unreactive carbon still remains to be clarified.

Experimental Procedure

The pulse experiments were carried out by using a catalyst characterization unit AMI 1 (Altamira Instruments). Gas pulses with a volume of 50 μL (ca. 2 μmol) were passed over the catalyst sample using helium carrier gas (30 mL min^{-1}). The interval between consecutive pulses was about 4 min. The gas flow containing products was monitored on-line with a thermal conductivity detector and a mass spectrometer (Ametek M200 M). The sampling for the mass spectrum was achieved by a quartz capillary located directly behind the catalyst sample, which was positioned in a heated, U-shaped quartz tube (internal diameter 4 mm). The temperature of the catalyst bed was monitored by a thermocouple attached to the outside—calibration experiments confirmed the outside to be at the same temperature as the catalyst bed. Rh(5%)/Al_2O_3 (390 mg) was used as catalyst. This was produced by an impregnation process from $RhCl_3 \cdot H_2O$ and Al_2O_3 Condea Pural 200 (S_{BET} = 78 m^2 g^{-1}). In order to ensure the reproducibility of the CH_4 and CO_2 chemisorption studies, the catalyst was subjected to an oxidation–reduction cycle between individual CH_4 and CO_2 chemisorption measurements (in each case 30 mL min^{-1}, O_2/30 min/600 °C, H_2/2 h/600 °C). The metal dispersion, that is the ratio of Rh atoms at the surface (Rh_s) to the total number of Rh atoms, was determined by CO-pulsed chemisorption, with an adsorption stoichiometry CO:Rh_s = 1:1, and yielded 3.25%. This dispersion remained constant throughout the studies. Before starting the pulse sequences the catalyst was reduced at 600 °C for 1 h in a flow of H_2 (30 mL min^{-1}) and then brought up to the desired reaction temperature of 700 °C by using a ramp rate of 10 K min^{-1} and a flow of He (30 mL min^{-1}). Finally the pulses of reactant gases CH_4 or CO_2 were applied. The TEM studies were obtained at 200 KeV on a field emission electron microscope (Hitachi HF2000).

Carboxylatoiron(II) Aggregates: A Novel Fe^{II}_4 Complex with Threefold Symmetry**

Stéphane Ménage, Hiroshi Fujii, Michael P. Hendrich, and Lawrence Que, Jr.*

Studies on the coordination chemistry of carboxylatoiron(II) complexes have recently been stimulated by the emergence of a new subclass of metalloproteins with nonheme diiron sites,[1] including hemerythrin (Hr),[2] the R 2 protein of ribonucleotide reductase (RNR),[3] and methane monooxygenase (MMO).[4] The diiron oxidation state is strongly implicated in the dioxygen binding and activation chemistry found for these proteins, and crystallographic studies show that carboxylato ligands bridge the divalent metal centers in hemerythrin and ribonucleotide reductase.[2a, 3b] As a result of efforts to model such protein sites, a number of bis(μ-carboxylato-*O*,*O'*)diiron complexes have been characterized, including $[Fe_2(\mu\text{-}O_2CCH_3)_2(tpa)_2](BPh_4)_2$[5, 6] $[Fe_2(\mu\text{-}OH)(\mu\text{-}O_2CCH_3)_2(Me_3tacn)_2]X$,[7] and $[Fe_2(\mu\text{-}H_2O)(O_2CCH_3)_4(tmen)_2]$;[8] the latter two complexes have additional μ-hydroxo and μ-aqua bridges. Furthermore, a new bridging motif, the monodentate carboxylate bridge supported by two other bidentate carboxylate bridges, has been found in $[Fe_2(biPhMe)_2(O_2CH)_4]$[9] and $[Fe_3(biPhMe)_2(O_2CCH_3)_6]$.[10] Using the carboxylate-containing tetradentate tripodal ligand bpg, we have synthesized a novel Fe^{II}_4 aggregate with crystallographic threefold symmetry; this is the largest carboxylatoiron(II) aggregate structurally characterized to date.

The combination of $Fe(ClO_4)_2\cdot 6H_2O$, Hbpg, $C_6H_5CO_2H$, and Et_3N in a molar ratio 1:1:1:2 in MeOH under argon engenders a light yellow precipitate which affords hexagonal crystals of **1** upon crystallization from CH_3CN/Et_2O. X-ray diffraction studies[11] show a tetrairon aggregate (Fig. 1), which consists of three crystallographically identical $Fe(bpg)(O_2CC_6H_5)$ units coordinated to a central Fe^{II} ion. The central iron ion (Fe 1) has a slightly distorted octahedral coordination environment formed by three benzoate oxygen atoms and three bpg carboxylate oxygen atoms; the Fe–O distances are 2.026(7) and 2.182(6) Å, respectively. The face consisting of the benzoate oxygen atoms spans a larger area than the corresponding face consisting of the bpg oxygen atoms, as indicated by respective O-Fe-O angles of 93.7 (4)° and 83.9(2)° within each face.

$[Fe_4(bpg)_3(O_2CC_6H_5)_3](ClO_4)_2$ **1**

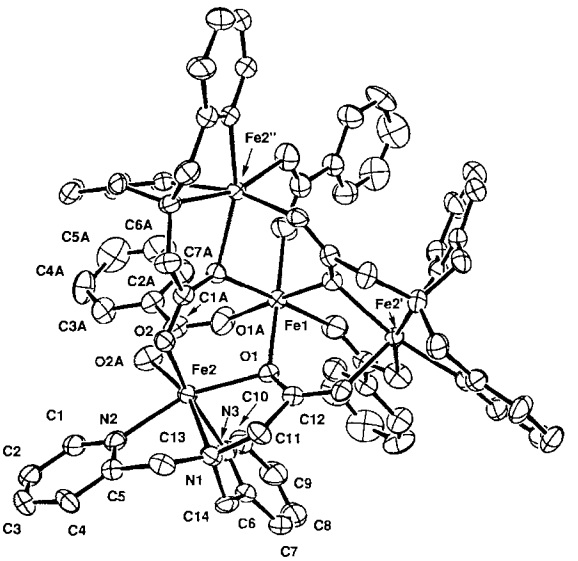

Fig. 1. Crystal structure of the $[Fe_4(bpg)_3(O_2CC_6H_5)_3]^{2+}$ cation in **1** (ORTEP plot, view down the threefold axis; 50% probability ellipsoids). Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe1-O1 2.182(6), Fe1-O1A 2.026(7), Fe2-O1 2.168(6), Fe2-O2 2.143(6), Fe2-O2A 1.999(7), Fe2-N1 2.278(8), Fe2-N2 2.177(9), Fe2-N3 2.128(8), Fe1-Fe2 3.393(7), Fe2-Fe2' 5.484(7); Fe1-O1-Fe2 102.5(3), O1-Fe2-O2A 122.2(3), O1-Fe2-N1 75.4(2), O1-Fe2-N2 148.3(3), O1-Fe2-N3 82.8(2).

The aggregate is assembled as a trio of (μ-carboxylato-*O*)bis(μ-carboxylato-*O*,*O'*)diiron(II) pairs. Benzoate bridges between Fe 1 and the peripheral Fe 2 ions in a bidentate manner using the O1A *anti* lone pair for Fe 1 and the O2A *syn* lone pair for Fe 2. One bpg carboxylate oxygen atom acts as an monodentate bridge between Fe 1 and one Fe 2 ion and at the same time serves as part of a bidentate bridge between Fe 1 and a second Fe 2 center. Thus, the bpg carboxylate groups serve to hold three metal ions together, and the long Fe–O distances reflect this trinuclear bridging mode. Such a trinuclear arrangement with a monodentate bridge between one pair of metal centers and a bidentate bridge for another pair has been previously observed in $[Mn(O_2CCH_3)_2(H_2O)_4]$[12] and demonstrates the versatility of lone pairs on carboxylate oxygen atoms in bridging metal centers.[13] The Fe 1–Fe 2 distance of 3.393(7) Å compares favorably with the corresponding Fe–Fe distance of 3.325(1) Å found for $[Fe_3(biPhMe)_2(O_2CCH_3)_6]$, which also consists of a central iron ion connected to the terminal iron centers by this triply bridging motif.

The peripheral iron centers have N_3O_3 coordination environments derived from the nitrogen atoms of bpg and oxygen atoms from one benzoate and carboxylates of two different bpg ligands. The O1-Fe2-O2A angle of 122.2(3)° deviates most strongly from an ideal octahedral arrangement, no doubt a result of the *syn*, *anti* bridging mode of the benzoate ligand. The Fe 2–O 2A bond is the shortest (1.999(7) Å) of the complex and is *trans* to the expectedly long $Fe-N_{amine}$ bond (2.278(8) Å). The $Fe-N_{py}$ distances (2.177(9) and 2.138(8) Å) are typical of $Fe^{II}-N_{py}$ bonds. The peripheral Fe 2 centers are separated from each other by a distance of 5.484(7) Å.

The NMR spectrum of **1** exhibits a number of well-resolved isotropically shifted resonances that indicate an intact tetranuclear aggregate in solution (Fig. 2). The signals have been assigned on the basis of their relative intensities, T_1 values, COSY

[**] This work was supported by a grant from the National Institutes of Health (GM-38767).

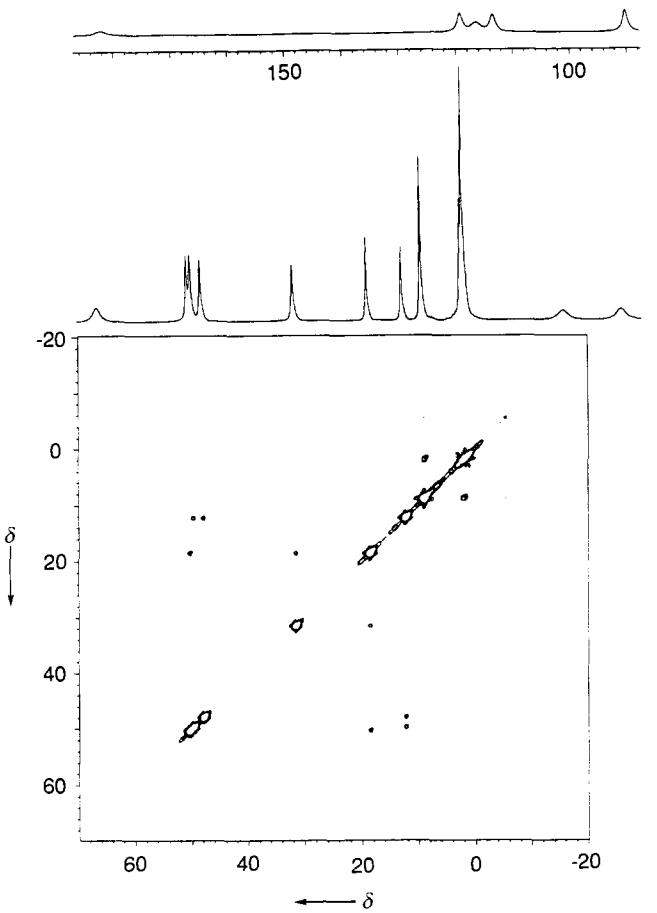

Fig. 2. 1D- and 2D (COSY) ^{1}H NMR spectra of **1** obtained at 300 MHz in CD_3CN.

connectivities, and comparisons with other high-spin iron(II) pyridine complexes.[14] Two sets of pyridine resonances are observed, each resonance corresponding to a proton per bpg unit, consistent with the distinct environments found for each of the pyridine units on the individual bpg ligands. The benzoate protons are also paramagnetically shifted (*m*: $\delta = 9.9$; *p*: $\delta = 4.2$), demonstrating that the carboxylato ligands remain coordinated in solution.

The EPR spectrum of **1** as a solid and dissolved in acetonitrile exhibits a signal at $g = 21$ which is enhanced in parallel mode ($H_1 \parallel H$) and increases in intensity as the temperature is lowered to 2 K (Fig. 3). These properties indicate that the signal arises from the ground doublet of an integer spin system.[15] Uncoupled Fe^{II} centers ($S = 2$) are expected to exhibit signals near $g = 8$, while a tetrairon(II) cluster with strong ferromagnetic coupling ($S = 8$) would result in a signal near $g = 32$. Thus, the position of the EPR signal of **1** indicates the presence of weak ferromagnetic interactions within the tetrairon aggregate. However, the complexity of the energy levels associated with a tetrairon species with weak ferromagnetic coupling does not allow us at present to pinpoint the origin of this signal without further investigation.

The temperature dependence of the magnetic moment of **1** at 0.31 T applied field is consistent with the EPR data. From 300 to 150 K its μ_{eff} value remains relatively constant at 10.4 μ_B (or 5.2 μ_B per Fe center), increases to a maximum of 10.8 μ_B (or 5.4 μ_B per Fe center) at 10 K, and then decreases dramatically below 10 K. The high temperature value suggests that the four iron centers are effectively uncoupled at high temperature, since it is

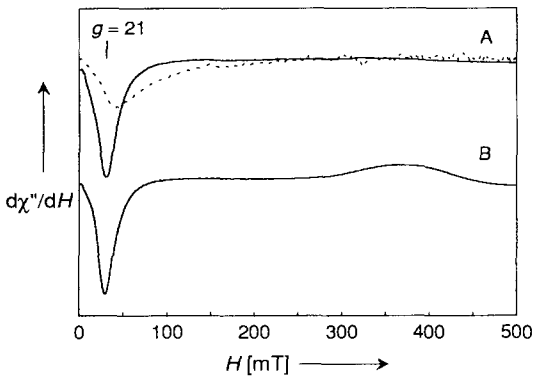

Fig. 3. EPR spectra of **1** in acetonitrile (A), $H_1 \parallel H$ (——), $H_1 \perp H$ (· · ·), and (B) 9 mg solid, $H_1 \parallel H$. The feature at $H = 375$ mT in (B) is not observed in solution and is of uncertain origin. Instrumental parameters: microwaves, 0.2 mW at 9.1 GHz, modulation, 0.1 mTpp at 100 kHz; gain for (A), 5000; gain for (B), 350.

only slightly higher than the spin-only value calculated for the uncoupled aggregate (9.8 μ_B per Fe_4 unit or 4.9 per Fe center). The value observed would be consistent with an uncoupled aggregate, when the spin-orbit coupling effects of high spin Fe^{II} centers are considered. The increase in magnetic moment at lower temperatures suggests the presence of weakly ferromagnetic coupling interactions, while the dramatic decrease of μ_{eff} below 10 K is attributed to zero-field splitting effects. A more detailed description of the magnetic properties of **1** is unavailable due to the complexity of the tetranuclear spin system. Given the large differences in the Fe1–Fe2 and the Fe2–Fe2 distances, the dominant magnetic interaction likely occurs between the central ion and the peripheral ions.

We have reported the structure and properties of a novel carboxylatotetrairon(II) aggregate. As carboxylato ligands are proposed as the initial binding loci for iron(II) ions in the threefold symmetric channels of the iron storage protein ferritin,[16] it is possible that aggregates similar to **1** may form in such channels.[17] If weak ferromagnetic interactions occur among these iron(II) centers, their presence in ferritin may be discerned by integer spin EPR spectroscopy.

Experimental Procedure

1: Treatment of $Fe(ClO_4)_2 \cdot 6H_2O$ (180 mg, 0.5 mmol) in MeOH (5 mL) with Hbpg (130 mg, 0.5 mmol), $HO_2CC_6H_5$ (61 mg, 0.5 mmol), and Et_3N (0.14 mL, 1 mmol) in MeOH (10 mL) under argon afforded a light yellow precipitate after stirring for 10 min. Recrystallization with CH_3CN/Et_2O afforded hexagonally shaped crystals suitable for X-ray diffraction. Correct C,H,N analysis.

Caution! Metal complexes with organic ligands and perchlorate anions are potentially explosive. Care should be exercised in handling these complexes, and they should be prepared in small amounts.

[17] Interestingly, when exposed to O_2, **1** converts to a (μ-oxo)diiron species with an NMR spectrum identical to that of the previously reported $[Fe_2O(O_2CC_6H_5)(bpg)_2](ClO_4)$ (S. Ménage, L. Que, Jr., *New. J. Chem.* **1991**, *15*, 431–438).

Molecular Golf Balls: Vesicles from Bowl-Shaped Host Molecules**

Albertus P. H. J. Schenning, Bas de Bruin, Martinus C. Feiters,* and Roeland J. M. Nolte*

Synthetic molecules containing a hydrophilic head group and one or two hydrophobic tails are known to form a great variety of supramolecular structures such as micelles, multilayers, rods, and vesicles.[1] It has been proposed that the type of aggregate structure depends on the shape of the amphiphile, as characterized by the so-called "packing parameter".[2] Recent studies, however, indicate that other factors are important. For example, single-tail surfactants with a large rigid segment[3, 4] or surfactants with a hyperextended chain[5] form vesicles instead of micelles, as predicted by the shape–structure concept. Vesicular structures are also formed by two-headed single-chain surfactants, for instance the lariat ether bolaamphiphiles.[6] We report here that bowl-shaped host **2**, which has two tails, two head groups, and a rigid cleft, forms vesicles upon dispersal in water.

Amphiphile **2**[7] was synthesized in two steps (Scheme 1): first **1a**[8] was treated with hexadecylamine in acetonitrile under Finkelstein conditions[9] (60%) and subsequently the product was methylated with methyl tosylate in toluene (80%).

Scheme 1.

When **2** (10 mmol) was dissolved in methanol (50 µL) and injected in water (3 mL) vesicles were formed, as could be deduced from electron microscopy.

As can be seen in Figure 1, the application of both the freeze-fracture and the negative staining technique show the presence of spherical vesicles with a diameter of approximately 4000 Å. These aggregates have a closed structure, as deduced from subsequent encapsulation experiments[1] with the fluorescent dye ethidium bromide.[10] Conductivity measurements revealed that the critical aggregation concentration (CAC) of **2** is 2×10^{-5} M. A vesicle dispersion of the amphiphile was dried on a glass plate in vacuo to give a cast film which was examined by X-ray diffraction. The diffraction patterns displayed a clear periodicity of 53 Å up to the 10th order reflection.

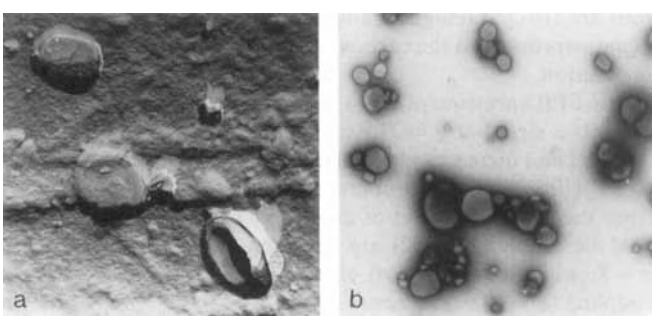

Fig. 1. Electron micrographs of a 0.02 M dispersion of **2**. Freeze-fracture (magnification 28000 ×) (a) and negative staining technique (magnification 9000 ×) (b).

[**] This work was supported by Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for Scientific Research (NWO).

Based on these data, we propose that the vesicles have a structure similar to that of a golf ball (Fig. 2). The thickness of the bilayer is 53 Å, which corresponds to two fully extended hexadecylamine chains. The host amphiphiles are aligned with their concave binding moieties facing the aqueous phases.

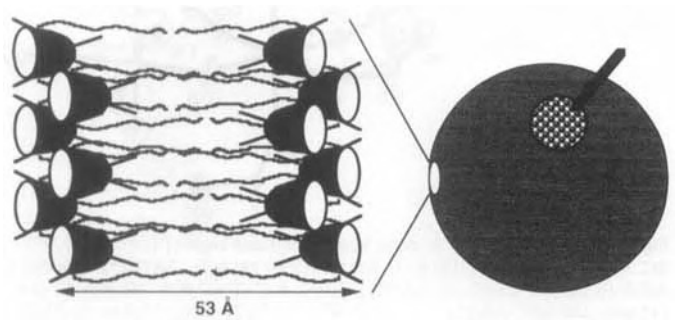

Fig. 2. Schematic representation of a vesicle formed by **2**.

We previously showed[11] that molecular clips such as **1b** can bind aromatic substrates in chloroform, for example resorcinol and its derivative **3**. Binding occurs by π-π stacking interactions with the two aromatic "walls" of **1b** and by hydrogen bonding with the urea carbonyl groups, as determined by IR and ^{1}H NMR spectroscopy.

The binding properties of **2** were determined in chloroform and water by NMR and UV/Vis titration experiments.[12] In chloroform, resorcinol and resorcinol derivative **3** form 1:1 inclusion complexes with **2**; the corresponding association constants are $K_a = 3400$ and 500 M^{-1}, respectively. These values are similar to those measured for these guests with **1b** ($K_a = 2600$ and 700 M^{-1}, respectively). In water, under the CAC of **2**, compound **3** is bound in a 1:1 host–guest ratio with an association constant of $K_a = 3 \times 10^5$ M^{-1}. This value is very high when compared to that in chloroform, but is of the same order of magnitude as that found for amphiphilic cyclophanes[13] with nonionic guests. Titration experiments with **2** in concentrations above the CAC indicated that only 50% of the molecular bowls are capable of binding a guest molecule. In a separate experiment we checked with electron microscopy that the vesicle structure is not destroyed by guest binding. The titration curve could only be fitted by assuming that half of the host molecules are involved in the binding process. In this case, we obtained a good correlation for a 1:1 complex with a binding constant of $K_a = 4 \times 10^5$ M^{-1}. This result suggests that only the dimples on the outer surface of the molecular golf balls are accessible to guest molecules and that the inner part of the aggregates cannot be reached.

In summary, we have shown that molecular objects with high binding affinities can be formed from rigid host molecules that have two tails and two ammonium groups. Further studies are aimed at stabilizing the aggregates by polymerization. Application of the polymerized structures can be conceived in the field of chromatographic separation of organic molecules. To this end the synthesis of chiral derivatives of **2** is currently in progress.

[12] Binding constants in chloroform were determined by ^{1}H NMR by following the chemical shift of appropriate host and guest protons and by UV/Vis by following the absorption of the guest **3** at 438 nm as a function of its concentration ($0-2 \times 10^{-4}$ M). For both types of experiments the same constant host concentration was used (5×10^{-4} M). In water, NMR measurements could not be applied for this purpose because of the occurrence of broad lines due to aggregation of **2**. Under the CAC of **2** the absorbance of **3** was monitored at 450 nm as a function of the guest concentration ($0-1.8 \times 10^{-5}$ M) with a constant host concentration of 2.5×10^{-6} M. At a concentration above the CAC of **2** the absorbance of **3** was monitored at 534 nm as a function of the guest concentration ($0-5 \times 10^{-4}$ M), with a constant host concentration of 2.5×10^{-6} M. The errors in the binding constants are approximately 10% and 50% for the experiments in chloroform and water, respectively.

Synthesis and Structure of $[Ni(SO_2)_6](AsF_6)_2$ and $[Fe(SO_2)_4(FAsF_5)_2]$**

Enno Lork, Jan Petersen, and Rüdiger Mews*

The chemistry of SO_2 as a ligand[1] and solvent[2] has been studied in great detail. The coordination behavior of this three-atom molecule is remarkably versatile: Six different bonding modes are known;[1] this figure does not take into account insertion products obtained from organometallic reactions.[3] Vibrational spectra and/or stability criteria allow predictions to be made on the nature of the metal–ligand linkage;[1] these predictions are often, but not always, correct.

The most common modes of coordination for SO_2 ligands in transition metal chemistry are η^1-S and side-on η^2-SO; however, examples of S- or SO-bound bridging ligands are also known. Only three complexes (Ni^{II} and Mn^{II} chemistry[4–7]) in which the SO_2 ligands are exclusively O-bound, as determined by X-ray structure analysis, have been reported to date. In these complexes a maximum of two SO_2 ligands in a *trans* arrangement are attached to a six-coordinate metal center.

The oxidation of Ni powder with AsF_5 in liquid SO_2 yields $[Ni(SO_2)_n](AsF_6)_2$.[8] Accounts in the literature regarding the nature of the Ni–ligand bond and the number *n* of coordinated SO_2 molecules differ. Passmore and Desjardins[8] have suggest-

[**] This work was supported by the Fonds der Chemischen Industrie.

ed that $n = 2$. From the IR spectrum they concluded that SO_2 is O-coordinated; the tetrahedral environment of the central Ni atom followed from magnetic measurements. However, the similarity of the IR spectrum to that obtained for $[Mg(OSO)_2(\mu\text{-}F_2AsF_4)_2]_n$,[9] which was unambiguously characterized by X-ray structure analysis, is indicative of a six-coordinate environment.

We report here on the observation that the bis(sulfur dioxide) complex **2**, isolated as a yellow powder, is a degradation product of the green, crystalline six-coordinate complex **1**, the first characterized homoleptic SO_2 complex. Complex **1** is only stable in

$$Ni + 3\,AsF_5 \xrightarrow{SO_2} \underset{\mathbf{1}}{[Ni(SO_2)_6](AsF_6)_2} + AsF_3$$

$$\xrightarrow{-4\,SO_2} \underset{\mathbf{2}}{[Ni(SO_2)_2](AsF_6)_2}$$

the presence of an excess pressure of SO_2 or in contact with liquid SO_2; rapid decomposition even occurs under an SO_2 atmosphere. The X-ray structure analysis of **1** at $-100\,^{\circ}C$ shows that the Ni^{II} center is octahedrally coordinated with O-bound SO_2 ligands (Fig. 1).[10] The Ni–O bond lengths are 203.3(3)–204.3(4) pm, and the Ni–O–S angles range from 139.8(2) to 145.6(2)°. The distance between S and the coordinating oxygen atom ($d(O_\mu\text{–}S)$, 144.3(4)–145.0(4) pm) is slightly greater than that in free SO_2 ($d(SO) = 143.1$ pm[13]); the bond between S and the noncoordinated oxygen atom is, on the other hand, markedly shortened ($d(S\text{–}O_t)$, 140.5(4)–141.8(4) pm). These results are consistent with previously established bonding models.[14]

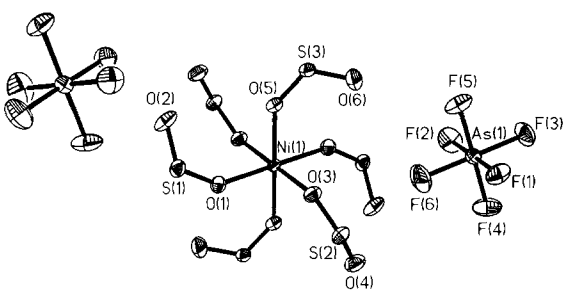

Fig. 1. Crystal structure of **1**; bond lengths [pm] and angles [°]: Ni-O 203.3(3)–204.4(3), O_μ-S144.3(4)–145.0(4), S-O_t 140.5(4)–141.8(4), As-F 169.6(4)–173.3(3); Ni-O-S 139.8(2)–145.6(2), O-S-O 116.2(2)–117.5(2), F-As-F 89.2(2)–90.7(2).

From these studies we conclude that O-coordination of SO_2 in transition metal chemistry is not as uncommon as previously thought and that it occurs for metal centers with oxidation states $\geq$ II. The lability of these complexes has prevented their characterization by X-ray structure analysis. The number of isolable, homoleptic SO_2 complexes is expected to be very limited, but this structural type is certainly quite common for compounds of the general formula $[ML_m(SO_2)_n]^{2+}$ with $n = 1, 2$, in which SO_2 is present as coligand.

In his report on the oxidation of iron with AsF_5 in liquid SO_2, P. A. W. Dean did not explicitly state how many SO_2 ligands were present in the product.[15] An X-ray structure analysis of the product **3** shows that four SO_2 ligands are attached to the

$$Fe + 3\,AsF_5 \xrightarrow{SO_2} \underset{\mathbf{3}}{[Fe(SO_2)_4(AsF_6)_2]}$$

central Fe atom; two $FAsF_5$ ligands in a *cis* relationship complete the octahedral coordination geometry (Fig. 2).[16] At

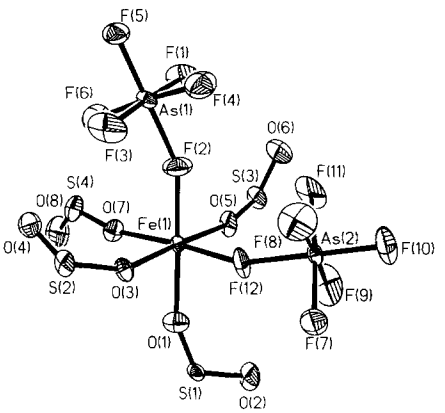

Fig. 2. Crystal structure of **3**; bond lengths [pm] and angles [°]: Fe-O 207.5(7)–212.3(6), O_μ-S 141.4(7)–144.4(7), S-O_t 137.3(9)–141.8(7), As(1)-F(2) 180.2(6), As1-F 167.6(6)–171.6(6), As(2)-F(12) 176.3(5), As(2)-F 167.9(7)–169.9(6); Fe-O-S 142.6(4)–164.5(5), O-S-O 117.2(5)–119.4(5), Fe-Fe(2)-As(1) 155.7(4), Fe-F(12)-As(2) 148.2(3).

room temperature complex **3** rapidly loses some of the SO_2 ligands.

Experimental Procedure

Complex **1** was prepared according to the literature [8] by oxidation of Ni powder with AsF_5 in liquid SO_2 at room temperature. The reaction was carried out in a high-pressure Schlenk vessel [17], which was equipped with a porcelain frit. After filtration of the reaction solution, the solvent was transfered into the ice-cooled side arm of the reaction vessel. Green crystals of **1** were formed. The solvent SO_2 was removed by evaporation under normal pressure at 0 °C.

The synthesis [14], isolation, and preparation of single crystals of **3** was achieved in an analogous fashion [18].

Three-Dimensional Interpenetrating Double and Triple Framework Structures in $[Cd(bpy)_2\{Ag(CN)_2\}_2]$ and $[Cd(pyrz)\{Ag_2(CN)_3\}\{Ag(CN)_2\}]$

Takayoshi Soma, Hidetaka Yuge, and Toschitake Iwamoto*

By replacing CN bridges in multidimensional CN-linked metal complexes by NC-Ag-CN or NC-Ag-(CN)-Ag-CN units, we have obtained **1** (bpy = 4,4′-bipyridine) and **2** (pyrz = pyrazine), which are composed of double and triple interpenetrating frameworks, respectively. In both compounds the three-dimensional frameworks are constructed entirely by coordinative linkages. The interpenetrating triple framework of **2** is unprecedented.

$[Cd(bpy)_2\{Ag(CN)_2\}_2]$ **1** $[Cd(pyrz)\{Ag_2(CN)_3\}\{Ag(CN)_2\}]$ **2**

A number of the topologically different multidimensional structures with M-CN-Cd links have been developed using $[M(CN)_4]^{2-}$ moieties (M = Ni, Pd, Pt: square planar; M = Cd, Hg, Zn: tetrahedral) as building blocks.[1–5] We have recently replaced the CN group in the M-CN-Cd link (5.5 Å long) with the bidentate linear NC-Ag-CN and NC-Ag-(CN)-Ag-CN groups to extend the bridge to 10.5 Å and 16 Å, respectively. In this way we obtained in the first case, [Cd(4-methylpyridine)$_2\{Ag(CN)_2\}_2$] · 4-methylpyridine, a compound with an interwoven double network, and in the second case, the polymeric complex $[Cd(4\text{-methylpyridine})_4\{Ag_2(CN)_3\}][Ag(CN)_2]$, which is composed of linear chains,[6] in which only the unidentate 4-methylpyridine completes the octahedral coordination of the Cd atoms. Novel supramolecular structures may be generated by using extended linear bridging ligands as spacers between the Cd atoms.

Colorless crystals of **1** formed in the reaction of $CdCl_2$ and $K[Ag(CN)_2]$ (1:2 molar ratio) and a small excess of bipyridine in aqueous solution; the pH of the solution was adjusted to 10 with $NH_2CH_2CH_2OH$ and $CH(OH)CO_2H(CH_2CO_2H)_2$. Crystals of **2** were obtained from an aqueous solution of $K_2[Cd(CN)_4]$, $AgNO_3$, and pyrazine (1:2:1 molar ratio) under the same basic conditions. The postulated compositions were confirmed by elemental analysis, and the structures were determined by single-crystal X-ray diffraction.[7]

In the structure of **1** the Cd atoms are located at the origin and equivalent positions in the $P2_1/c$ space group and are each linked by four *catena*-μ-$[Ag(CN)_2]^-$ ligands to four further Cd atoms (Fig. 1 top). A two-dimensional network along the *bc* plane results with an approximately rhombic mesh (edge length

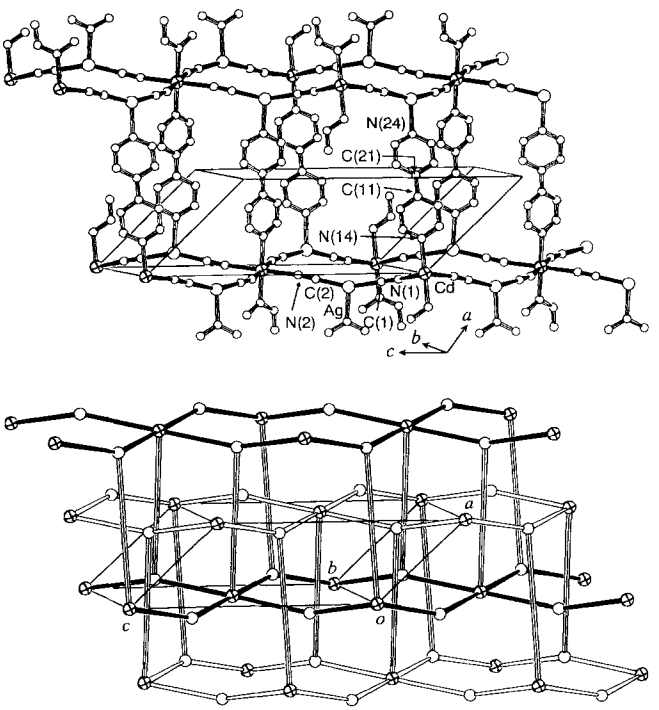

Fig. 1. Top: One of the 3D frameworks observed in **1**; view along the *b* axis; the unit cell is sketched in with the thin lines. Bottom: View of the interpenetrating double framework structure of **1**. Cd: balls with crosses; Ag: white balls; CN: white sticks; bpy: lined sticks.

of $(b + c)/2 \approx 10.5$ Å, acute angle of roughly 66°). The Cd-NC-Ag-CN-Cd bridge in **1** is about twice the length of the Hofmann-type Cd-NC-Ni bridge.[1] The Cd atoms in the network coordinate to two bpy ligands in a *trans* arrangement to attain octahedral coordination. The Cd-NC-Ag units deviate from linearity (Cd-N(2)-C(2) 157.9(4)°). The network puckers such that the $Ag(CN)_2$ moieties shift alternately upwards and downwards out of the *bc* plane. The bpy ligands are "threaded" through the meshes of the immediately adjacent networks and bound to the Ag atoms in subsequent network (Fig. 1 bottom). The Ag atoms are three-coordinate, the Ag–N(24) distance is 2.463(3) Å, and the C-Ag-C units are bent out of the *bc* plane (C(1)-Ag-C(2) 153.6(2)°). The threaded network generated by translation along the *a* axis is thus completely independent; no direct covalent bonds link the interpenetrating networks. Owing to the puckering of the network, the Cd-(bpy)-Ag distance of 11.93(2) Å is shorter than $2a \sin\beta = 12.85(1)$ Å. The dihedral angle between the pyridine rings of the bpy ligands is 27.5°.

The hexacoordinate Cd atoms in **2** are located on the twofold axes of the $P2/c$ space group and are interconnected to form a three-dimensional framework (Fig. 2). The Cd···Cd distance in the Cd(*catena*-μ-pyrz)-Cd unit along the C_2 axis parallel to the *b* axis is 7.560(3) Å, in the Cd-(*catena*-μ-NC-Ag(CN)Ag-

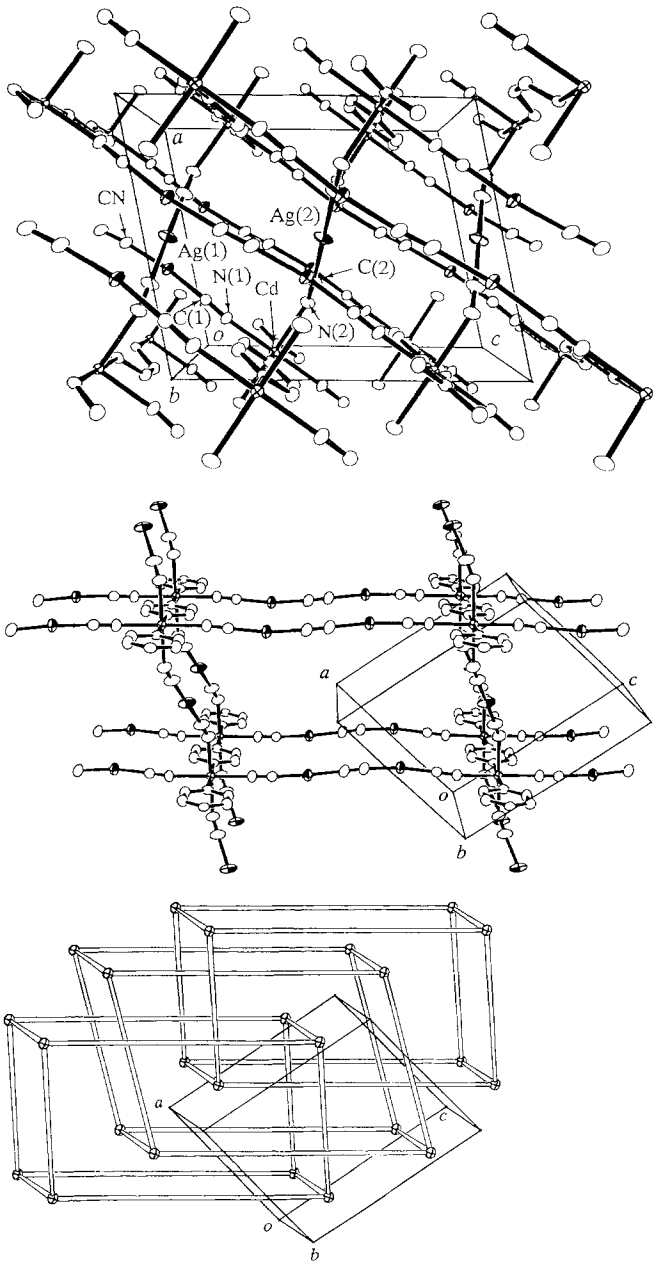

Fig. 2. Top: Unit cell structure of **2** viewed along the *b* axis; the unit cell is sketched in with thin lines. Middle: View of one of the three frameworks. Bottom: Representation of the interpenetrating triple framework structure along with a sketch of the unit cell; Cd atoms: balls with crosses; pyrz, $Ag(CN)_2$, and $Ag_2(CN)_3$ units: sticks.

CN)-Cd unit parallel to the [101] roughly 16 Å, and in the Cd-(*catena*-μ-NC-Ag-CN)-Cd unit parallel to [121] or [1$\bar{2}$1] approximately 9.6 Å. Because of the C_2 symmetry, crystallographic discrimination between the C and N atoms of the central CN group in the NC-Ag-(CN)-Ag-CN unit is impossible. The two-dimensional networks formed by the Cd-pyrz-Cd and Cd-NC-Ag-(CN)-Ag-CN-Cd links (horizontal layers in Fig. 2 middle) are stacked along [101] with a separation of roughly 3.2 Å. Two such layers are connected by perpendicular Cd-NC-Ag-CN-Cd bridges to form a three-dimensional framework structure. These links "thread" the meshes of adjacent networks such that the first and fourth are coordinatively connected. In this way three sets of interpenetrating frameworks are formed which give an unprecedented triple framework structure without any direct chemical bonds. The layers (horizontal in Fig. 2 middle and bottom) have a zigzag arrangement since the direction of the Cd-NC-Ag-CN-Cd bridge changes alternately from [121] to [1$\bar{2}$2] in a set of the framework. The Ag–Ag distance between the NC-Ag-CN and NC-Ag-(CN)-Ag-CN linkages is 3.144(1) Å, only slightly longer than that in Ag metal (2.89 Å).

Extended linear structures with $Ag(CN)_2$ bridges have been observed in $[Zn(en)_2][\{Ag(CN)_2\}_2]$ (en = ethylenediamine)[8a] and in $[Cu(2,2'\text{-bpy})_2][\{Ag(CN)_2\}_2]$.[8b] Compounds with multiple, three-dimensional, interpenetrated structures are also known: two interpenetrated 3D frameworks linked by coordinative bonds occur in the anticuprite-type $M(CN)_2$ (M = Cd, Zn)[2d, 4a] and in $[Zn(H_2O)_2(bpy)_2] \cdot SiF_6$.[9] in the latter the monodentate aqua ligands do not participate in bridging. Six three-dimensional interpenetrated diamondlike frameworks exist in $[Cu\{NC(CH_2)_4CN\}_2]_n \cdot nNO_3^-$.[10] The adiponitrile bridge between the Cu^I atoms is about 12 Å long, and the NO_3^- ions do not participate in the bridging. Five interpenetrated framework structures were found in the diamondlike 3D framework formed by the hydrogen bonds between adamantane-1,3,5,7-tetracarboxylic acid molecules.[11]

The individual frameworks in **1** and **2** may be considered 2D networks supported by bpy or NC-Ag-CN pillars. Crystal structures with such large cavities are stabilized either by inclusion of suitable guests or by interpenetrating lattices. The difference in the span length of the bridging moieties (bpy, pyrz, NC-Ag-CN, and -NC-Ag-(CN)-Ag-CN) is an important factor in determining the multiplicity of the framework.

Octaplane: A Saturated Hydrocarbon with a Remarkably Low Ionization Energy Leading to a Cation with a Planar Tetracoordinate Carbon Atom**

Jennifer E. Lyons, Danne R. Rasmussen, Mark P. McGrath, Ross H. Nobes, and Leo Radom*

We have recently suggested the *alkaplane* family of molecules as a new class of saturated hydrocarbons containing a potentially planar tetracoordinate carbon atom.[1] The alkaplanes consist essentially of a $C^q(CH)_4$ unit containing the target quaternary carbon atom (C^q), capped above and below by cycloalkane moieties. Examples characterized in detail through ab initio calculations include octaplane (**1**), hexaplane (**2**), and biheptaplane (**3**).[1, 2] Our calculations for octaplane show a structure

1 **2** **3**

with S_4 symmetry (Fig. 1) and the closest approach to planarity reported to date for a tetracoordinate carbon atom in a neutral saturated hydrocarbon.[3] The $C^1C^qC^2$ angle that would be 180° in an exactly planar arrangement is found to be 168.8° in octaplane (**1**).

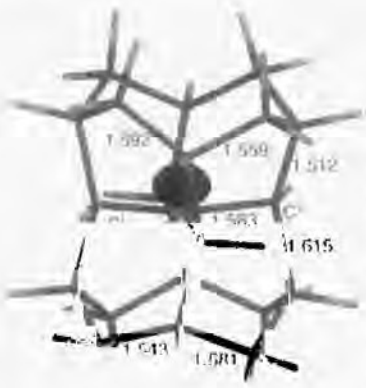

Fig. 1. Selected C–C bond lengths [Å] calculated at the HF/6-31G* level and highest occupied molecular orbital (HOMO) for **1** (symmetry S_4). The $C^1C^qC^2$ bond angle is 168.8°. The HOMO is largely a p-type lone pair orbital localized on the central carbon atom. Some distortion from radial symmetry can be seen. The orbital surface was drawn at a value corresponding to a density of 0.15 eÅ^{-3}.

One striking feature of the electronic structure of the alkaplanes is the highest occupied molecular orbital (HOMO) which is basically a p-type lone pair orbital localized on the quaternary carbon atom, as shown in Figure 1 for octaplane. This is likely to lead to interesting chemical and physical properties. In particular, one might expect ionization energies for alkaplanes to be substantially lower than for other saturated hydrocarbons. In the present paper, we explore this point for the octaplane molecule (**1**) and examine the effect of ionization on the structure.

The structures and energies of octaplane (**1**) and the octaplane radical cation (**1**$^{\bullet+}$) were determined by standard ab initio calculations,[4–6] carried out with the TURBOMOLE,[7] GAUSSIAN 92,[8] and CADPAC 5[9] programs. The structures of **1** and **1**$^{\bullet+}$ shown in Figures 1 and 2 were characterized as equilibrium structures through HF/6-31G* geometry optimizations and HF/3-21G frequency calculations.[10]

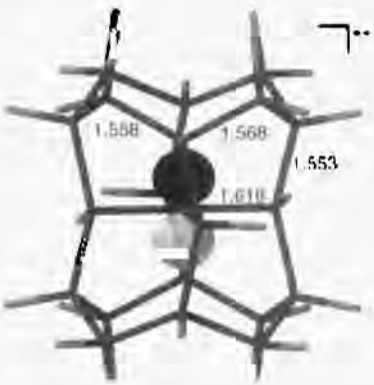

Fig. 2. Selected C–C bond lengths [Å] calculated at the HF/6-31G* level and singly occupied molecular orbital (SOMO) for **1**$^{\bullet+}$ (symmetry C_{4h}). The SOMO is a half-filled p-type orbital localized on the central carbon atom. The orbital surface was drawn at a value corresponding to a density of 0.15 eÅ^{-3}.

All C–C bonds in the structures of **1** and **1**$^{\bullet+}$ calculated at the HF/6-31G* level are in the range 1.51–1.62 Å. Some of these bonds are long but they are not unusual for strained hydrocarbons (cf. bond lengths of 1.53–1.61 Å in the diterpene lauren-1-ene).[3g] The C–C bond lengths in the cyclooctane rings appear to be relatively unaffected by ionization of octaplane (all are about 1.56–1.59 Å) although they are somewhat longer than those in free crown cyclooctane (1.535 Å at HF/6-31G*). The four central C–C bonds, on the other hand, are lengthened on ionization from 1.583 Å in neutral octaplane to 1.618 Å in the radical cation. The most striking effect of ionization of octaplane, however, is a significant reduction in the out-of-plane distortion forces present in the central five-carbon moiety of neutral octaplane. This results in a singly charged octaplane radical cation (**1**$^{\bullet+}$) with C_{4h} symmetry and a *planar tetracoordinate carbon atom* (see Fig. 2). Although planar tetracoordinate carbon has been found in hydrocarbon dications (e.g. CH_4^{2+}),[11] octaplane cation is the first reported *singly charged* saturated hydrocarbon containing a planar quaternary carbon atom.

The adiabatic ionization energy for octaplane was calculated at the MP2/6-31G*//HF/6-31G* level and is found to be 4.63 eV (Table 1). Test calculations for a selection of molecules for which experimental data are available[12] and/or for which accurate (G2) calculations[13] can be performed (e.g. NH_3, CH_2, CH_4) show that the ionization energies at the MP2/6-31G* level are generally too low by about 0.3–0.7 eV. On this basis, we estimate that the ionization energy for octaplane is approximately 5 eV. This is strikingly low, comparable in fact to the experimental values for the alkali metals lithium and sodium (5.39 and 5.14 eV, respectively)! In comparison, the lowest experimental value[12] for a neutral saturated hydrocarbon is 7.1 eV for tetra-*tert*-butyltetrahedrane.[14]

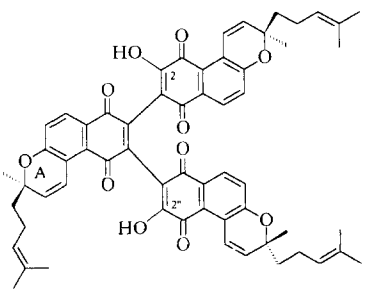
[**] The award of an Australian National University Vacation Scholarship to J. E. L. and a generous allocation of time on the Fujitsu VP2200 of the Australian National University Supercomputer Facility are gratefully acknowledged.

The orbital depicted in Figure 2 is the singly occupied molecular orbital (SOMO) of the octaplane radical cation $\mathbf{1}^{\bullet+}$, corresponding to the removal of one electron from the HOMO of octaplane (**1**). Whereas the SOMO in $\mathbf{1}^{\bullet+}$ has almost radial symmetry, the HOMO in **1** shows some distortion towards the neighboring C–C bonds (see Fig. 1). It is thus not a pure p-type lone pair orbital but includes some bonding contributions between the central carbon atom and its four neighboring carbon atoms. This is allowed because of the lower (S_4) symmetry. The weakening of the four central C–C bonds and the reduction in the out-of-plane distortion forces following ionization can be rationalized in terms of this small degree of participation in bonding, seen in the HOMO of octaplane but not in the SOMO of octaplane cation.



The remarkably low ionization energy predicted for octaplane (**1**) is likely to result in properties quite distinct from those of other neutral saturated hydrocarbons. We believe that the octaplane radical cation, a singly charged saturated hydrocarbon containing a planar tetracoordinate carbon atom, may be isolable as a salt[15] and formed from the oxidation of octaplane.[16] These and other intriguing features may provide added impetus to attempts at its challenging synthesis.

[10] Evidence that the structures calculated at the HF/6-31G* level are indeed equilibrium structures was gained from geometry optimizations performed on distorted structures of **1** and $\mathbf{1}^{\bullet+}$. These were all found to collapse back to higher symmetry. Further evidence comes from HF/3-21G frequency calculations on the S_4 and C_{4h} structures of **1** and $\mathbf{1}^{\bullet+}$, respectively, which give all real frequencies. For related systems in which it has been possible to carry out both HF/6-31G* and HF/3-21G vibrational analyses, we have found that the results are in very close agreement with one another.

Corrigenda

In the Highlight "Conocurvone – Prototype of a New Class of Anti-HIV Active Compounds?" by H. Laatsch (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 422), some of the structural formulas have been incorrectly depicted. The following are correct:

1a
1b: H instead of ring

2a: R^1 = H, R^2 = OH
2b: $R^1 = R^2$ = H
2c: R^1 = H, R^2 = *p*-$OCOC_6H_4Br$
2d: $R^1 = R^2 = SC_6H_5$

The title of the communication by C. Balzereit, C. Kybart, H.-J. Winkler, W. Massa, A. Berndt (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1487) should read "A Highly Distorted and an Undistorted Borirane, C–B Hyperconjugation induced by C–Si Hyperconjugation".

In the communication "A New Class of Novel Macrocyclic Mesogens" by P. R. Ashton, D. Joachimi, N. Spencer, J. F. Stoddart, C. Tschierske, A. J. P. White, D. J. Williams, and K. Zab (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1503), the phase S_p for compounds **9**, **10**, and **12** in Table 1 should be replaced by S_A.

A Broad Base from Theory to Applications

Cluster Ions. (Wiley Series in Ion Chemistry and Physics.) Edited by *C-Y. Ng, T. Baer* and *I. Powis*. Wiley, Chichester, 1993. 479 pp., hardcover £ 80.00—ISBN 0-471-93830-0

This book contains a survey of recent developments in fundamental research on cluster ions. It consists of seven chapters, mostly concerned with van der Waals clusters, although carbon and silicon clusters are also included. The title is in fact too broad, suggesting to the reader that metal clusters are also covered.

First W. Kamke describes cluster studies using the photoelectron–photoion coincidence (PEPICO) technique, dealing both with the experimental aspects and with applications to van der Waals systems. This method is very effective for recording photoelectron spectra of size-selected neutral clusters, especially when applied with electrons of zero kinetic energy (threshold photoelectrons, TPE). The use of the technique is illustrated by examples, such as studies of the unimolecular decay of noble gas clusters, charge transfer in mixed clusters, and ion–molecule reactions in ammonia clusters. The next chapter by C. Lifshitz is concerned with the unimolecular and collision-induced decomposition of proton-bound clusters and carbon cluster ions. For the first of these ion types, with the general formula $H^+(M_n)$, excitation typically results in a solvent molecule M being "evaporated" off within a few microseconds. By measuring the kinetic energies of the ejected molecules one can determine bond energies, and collision-induced dissociation reveals isomeric structures. The section on carbon clusters deals particularly with the currently fashionable fullerenes C_{60}^+, C_{70}^+, and C_{84}^+ and their novel chemistry. In Chapter 3 M. F. Jarrold describes the many unique features of the physics and chemistry of positive and negative silicon cluster ions. The author has worked intensively in this field, using a variety of experimental methods to obtain the fullest possible information. Some of his results from drift-tube measurements are in striking disagreement with those obtained by Smalley's group using Fourier transform ion cyclotron resonance; the reason for this discrepancy is not yet known.

The fourth chapter by J. M. Lisy describes vibrational spectroscopic studies of solvated proton and metal ion clusters which serve as models for dilute electrolyte solutions. An interesting result is that proton clusters generated in a corona discharge are relatively cold, and consequently more than one infrared photon is needed for dissociation, whereas the metal ion clusters, which are produced by association and are relatively warm, are dissociated by only one CO_2 laser photon. Next (Ch. 5) J. M. Farrar reports on the electronic photodissociation of mass-selected van der Waals clusters, mainly with regard to the influence of solvation on this process. The closer one approaches to the condensed phase, i.e. the greater the number of solvent molecules attached to the central ion, the further the absorption is shifted towards the infrared. Measurements of this effect are reported for several systems; for example, the addition of up to six ammonia molecules to Sr^+ shifts the absorption maximum from about 400 nm to about 1400 nm. However, the number of ligands is still insufficient to simulate the transition from gas phase clusters to the liquid phase. Noble gas clusters are the subject of Chapter 6, by I. Last and T. F. George, then in the final chapter B. G. Brunetti and F. Vecchiocattivi report on autoionization dynamics of collision complexes. In a typical experiment noble gas atoms are excited into metastable states by electron impact, then atoms of a single metastable species are selected by optical excitation and are allowed to collide with a reaction partner under thermal conditions. Whereas the average time needed for a collision is about 10^{-12} s, autoionization takes place in about 10^{-15} s. After describing the experimental technique the authors discuss applications involving hydrogen, mercury, alkali metal, and noble gas atoms, and molecules such as N_2, CO, Cl_2, H_2O, and even CF_3Cl.

The individual chapters are carefully written, and the authors are acknowledged experts in the areas covered. I greatly enjoyed reading the book and can recommend it unreservedly to other physical chemists in the field.

Phase Transfer Catalysis. 3rd Revised and Enlarged Edition. By *E. V. Dehmlow* and *S. S. Dehmlow*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 499 pp., hardcover DM 188.00, $ 125.00—ISBN 3-527-28408-7/1-56081-206-0

Phase Transfer Catalysis. Selected Problems and Applications. By *Y. Goldberg*. Gordon and Breach, Longhorne, PA, 1993. 456 pp., hardcover $ 170.00 ($ 95.00 if ordered from the publishers by private individuals).—ISBN 2-88124-870-5

Phase transfer catalysis (PTC) has nowadays become an indispensable tool for organic synthesis. Many reactions can be carried out more efficiently and selectively by this method, and others for which it has been used were not even possible previously.

The above book by Dehmlow and Dehmlow replaces the second edition published ten years ago, having been updated and, where necessary, revised. It includes many new developments in PTC.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/1515-1669 $ 10.00+.25/0*

The literature coverage now extends to mid-1990, while at the same time some outdated references have been dropped. There are 1700 new literature citations, bringing the total to over 3600, now listed (unlike the earlier editions) in alphabetical order. The subject index too is a valuable aid when working with this book.

Goldberg's book on the same subject is based on one originally published in Russian in 1989, which has been revised and updated for this English version. It contains about 1300 literature references extending up to 1991. The subject index, which is mainly substance-orientated, is a useful working aid.

The book by Dehmlow and Dehmlow begins with two chapters of more than 60 pages altogether on the theoretical basis of PTC. The first chapter is mainly concerned with the principles underlying the effectiveness of the most important types of catalysts, while the second deals with the mechanistic aspects of the different variants of the PTC method. Chapter 3 (over 300 pages long) is concerned with synthetic applications of PTC. It begins with a section on the choice of reaction conditions, such as the type and quantity of catalyst, the solvent, and the stirring rate. Particular attention is given to enantioselective PTC, describing its applications, problems, and the many potential sources of error. Next the authors describe various practical applications of PTC, arranged so far as possible according to reaction types. These include substitutions leading to alkyl halides, nitriles, esters, thiols, sulfides, and ethers, *N*- and *C*-alkylations, alkylations and acylations of ambidentate anions, isomerizations, H/D exchange reactions, and additions at C=O and C=N bonds. Also treated in detail are α-, β-, and γ-elimination reactions, the preparation of phosphonium and sulfonium ylides, nucleophilic aromatic substitutions, applications of PTC to organometallic compounds, and reductions and oxidations. It is pleasing to find that as well as giving well-proven synthetic recipes the authors include general principles that have been derived for carrying out various types of transformations under phase transfer conditions. The large amount of factual information is very clearly presented, often in the form of tables, enabling the reader not only to quickly find specific details but also to get an overview of a chosen area.

Goldberg's book differs considerably from that of Dehmlow and Dehmlow, both in emphasis and in structure. A first chapter (24 pp.) dealing with the theoretical fundamentals is followed by several chapters describing some selected areas of application of PTC. Chapter 2, the longest in the book with about 100 pages, is concerned with PTC in the chemistry of N-heterocycles. Alkylations and acylations of compounds of this class are described, as also are reactions of halogenated N-heterocycles with nucleophiles. Reactions of N-heterocycles with carbenes are treated next, followed by oxidations and reductions, as well as the use of PTC in the preparation of such compounds. In Chapter 3 (about 50 pp.), on PTC in organometallic chemistry, much attention is devoted to reactions involving organosilicon compounds; other reactions discussed include those of mercury, molybdenum, tungsten, iron, cobalt, and platinum compounds. Chapter 4 (about 70 pp.) is devoted to catalysis by metal complexes under phase transfer conditions, including reductions, oxidations, dehydrogenations, and carbonylations. Chapter 5, on three-phase catalytic reactions (about 30 pp.), discusses the advantages and disadvantages of using quaternary onium salts, crown ethers, or open-chain polyethers immobilized on polymers or other substrates for a variety of reactions. In Chapter 6, on asymmetric phase transfer catalysis (about 50 pp.), Goldberg discusses in great detail a number of types of reactions for which PTC has proved more or less successful. He also analyzes a number of experiments that failed completely and were thus of no interest for synthetic purposes, and identifies the factors that previously led to wrong interpretations. These latter discussions are extremely valuable for any chemist intending to apply PTC to asymmetric syntheses for the first time. However, reactions giving optical purities of 15–19% should not be regarded as satisfactory, as is implied on page 299. Chapter 7 (about 40 pp.) is concerned with less common variants of PTC; here the author discusses cationic reactions, reactions at phase boundaries between neutral species, inverse PTC, electron phase transfer, and reactions under the influence of ultrasonic excitation at phase boundaries.

The book by Dehmlow and Dehmlow is a standard work on PTC, affording the reader a comprehensive overview ranging from the theoretical fundamentals to the diverse wealth of practical applications of this useful method in synthetic chemistry. It is an indispensable monograph for every chemist, being suitable not only for organic chemists with experience of PTC but also for those about to use this method of synthesis for the first time. Goldberg's book does not give such a comprehensive picture, nor was that the author's aim. Instead it is intended for specialists. Because of this quite different approach it may be regarded as complementary to the Dehmlow and Dehmlow monograph, extending the subject and treating it in greater depth, with detailed discussions of many applications of PTC. At some points one might say that it gives too much information—for example, the details given beside the reaction arrows of the synthesis schemes. In both books the subject matter is clearly arranged, in a readable style, and in a sturdy binding. No library should be without them.

Fundamentals of Nuclear Magnetic Resonance. By *J. W. Hennel* and *J. Klinowski*. Longman, Harlow (UK), 1993. 288 pp., paperback £ 22.50.—ISBN 0-582-06703-0

In their preface the authors formulate their aim: it is to explain the physical and mathematical basis of NMR *simply* but *exactly*. In a certain sense they succeed. However, the question is: what *are* the fundamentals of nuclear magnetic resonance? In the opinion of the authors they are the magnetic dipole moment (of a compass needle, a current loop, an orbiting electron, or a nucleus with a spin), the magnetization of a macroscopic sample in thermodynamic equilibrium, the Larmor precession of an isolated spin, Bloch's equations, the Fourier transformation, the Zeeman and dipolar parts of the Hamiltonian, the method of (second) moments, and the spin-echo and COSY experiments.

Sure, all these topics *are* fundamentals of NMR, and I would regard it as almost a moral obligation of all those who practise NMR to be thoroughly familiar with fundamentals of this kind. It may well be the experience of Jacek Hennel and Jacek Klinowski that only too many are not. And I must admit that the authors' overview and judgement are very likely quite correct. Therefore, let us admit that there is a need to explain such fundamentals simply and exactly. Does the book fulfill the promise?

It starts with a chapter of 42 pages on the "Elements of Quantum Mechanics". It is supplemented by five appendices explaining topics from "Complex Numbers" to "Sinusoidal Operators." This is now the third recent book on NMR which I have read in which the authors assume, on the one hand, that they must provide an introduction to complex numbers and,

on the other, that their readers should master quantum mechanics up to the (spin) density matrix, the Hilbert space and the like. In my opinion it is a complete illusion to hope that someone who needs an introduction to complex numbers is able to appreciate any exposition of quantum mechanics. I am afraid, therefore, that Hennel's and Klinowski's book is of little help to those who have *not* previously followed a course in quantum mechanics. For those who have done so (and have worked through their homework problems) the book may be a useful revision, and they may like to see how quantum mechanics is applied *exactly* and *simply* and at great length to practical cases. However, a major problem is that the book does not lead the reader far enough. Almost all the fundamentals remain on an educational, a cultural level. They do not open the door to practical modern NMR. On the whole the book breathes the air of the fifties, maybe sixties. Pake's ingenious but hopelessly obsolete "high frequency bridge" is described to illustrate how NMR is detected. Pulse and FT NMR are discussed but no modern probehead or related instrumentation is shown. Of the total of 54 references no less than 37 appeared in or before 1967, and 19 of these are from the fifties. All those from after 1980 are monographs and textbooks. Abragam appears under 1983, whereas I bought my copy of his book in 1961.

The final chapter is on "Nuclear Magnetic Relaxation". It brought me an almost nostalgic re-encounter with Gierer and Wirtz (1953) and their microviscosity coefficients. I had hoped for a more up-to-date climax. I recommend the book for introductory NMR teaching, either in a class or in a laboratory course, and to all those who do practical NMR work and desperately feel that they do not really understand the fundamentals of their experimental tool. But they should not expect a link between these fundamentals and their own work.

Neural Networks for Chemists. An Introduction. By *J. Zupan* and *J. Gasteiger*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 305 pp., hardcover DM 138.00, paperback DM 68.00. —ISBN 3-527-28592-X/1-56081-791-7 (hardcover), 3-527-28603-9/1-56081-793-3 (paperback)

To explain precisely the basic concepts of a new interdisciplinary area of research and communicate them to a wide readership is a difficult task. Jure Zapan and Johann Gasteiger have managed to do this very successfully. This book offers a sound introduction to artificial neural networks, with insights into their architecture, functioning, and applications, which is intended not only for chemists but also for scientists from other disciplines. The capabilities and limitations of different systems are compared and evaluated. The authors have sensibly limited their treatment to a few carefully chosen and clearly distinguished types of networks, explaining how they are used for classifying, modeling, and analyzing molecules and their properties, for evaluating visual images (e.g., to interpret spectra or to analyze structure–activity relationships), and for controlling chemical reactions. The book is written in a readable style and is well structured. The reader's task is made easier by providing a short summary of the main learning objectives at the start of each chapter, and by the use of easily remembered mnemonics. The treatment is divided into two parts, one concerned with theory and the other with describing different types of applications. This arrangement means that, after studying the clear and very informative introduction to the topic, the reader can look at the examples of applications and assess the suitability of the chosen method in each case, possibly even suggesting an alternative solution. The chapters on Kohonen networks and counterpropagation systems are especially good. The examples of applications, such as the representation of the three-dimensional electrostatic potential of a molecule in the form of a two-dimensional map using the Kohonen approach, surprise one at first by the simplicity of the concepts, but this is in itself an illustration of one of the strengths of artificial neural networks. The authors explain clearly and concisely how these principles can be applied in order to make an appropriate selection of representative data for an analysis using neural networks. The reader is not distracted from the core issues by too many literature references in the text; instead the authors give a useful selection at the end of each chapter.

In our view there are only a few aspects of neural networks that have not been fully covered in the book. The authors have not discussed effective algorithms for the systematic optimization of network architectures—for example, genetic algorithms. Also, in restricting the discussion to the back-propagation algorithm for multipositional networks the authors have covered only a part (admittedly by far the largest) of the range of reliable strategies for supervised learning. A similar criticism applies to the choice of applications. In particular, the analysis of biological macromolecules receives only marginal treatment, being limited to predicting the three-dimensional structures of proteins from their amino acid sequences. Here it would have been desirable to include some more examples—e.g., the use of neural networks to analyze data banks—as these methods have already advanced considerably and much effort is being put into further developments. However, additional topics such as these can no doubt be included in a second edition. This is a very well-written guide for anyone who wants to make greater use of information theories in chemistry. The excellent quality of the contents and the presentation should ensure that it reaches a wide international readership.

Homogeneous Transition Metal Catalyzed Reactions. Edited by *W. R. Moser* and *D. W. Slocum*. (Series: Advances in Chemistry, Vol. 230.) American Chemical Society, Washington, DC, 1992. 625 pp., hardcover $ 139.95.—ISBN 0-8412-2007-7

This book contains a substantial number of the presentations from the symposium on "New Science in Homogeneous Transition Metal Catalyzed Reactions", held during the 199th National Meeting of the American Chemical Society, in Boston, Massachusetts, April 22–27, 1990.

About one third of the chapters have been written by chemists working in industrial laboratories. The authors are in general very well known for their contributions to the field. The fact that the papers are subjected to the editorial standards of the ACS is a further warranty for the high quality of the book.

The book has been organized in six chapters: Spectroscopy and Mechanism, 7 papers; Asymmetric Induction and Shape Selectivity, 4 papers; C–H Activation, 4 papers; Carbonylation and Synthesis Gas Conversion, 13 papers; General Functionalization, 9 papers; Oligomerization and Polymerization, 4 papers. Some of the contributions are written in the style of a review article, while others report original research.

The first chapter concerns the application of spectroscopic techniques (such as IR, NMR, flash photolysis) to the identification and study of catalytic intermediates. Chaos in catalytic oxidations and a theoretical study related to intermediates in the cobalt catalyzed hydroformylation are also discussed.

In the second chapter enantioselective hydrogenation (mainly by ruthenium systems), homo-Diels–Alder reactions, and hydroboration are discussed. One paper describes a remarkable substrate selectivity in the epoxidation of olefins by manganese porphyrin catalysts.

In the third chapter a review article describes various catalytic functionalizations of hydrocarbons under irradiation. Examples related to the mercury photosensitized activation of C–H bonds and to the conversion of ethanol to ethylene glycol are then presented. Model stoichiometric reactions using rhodium and iridium complexes are also included.

In the chapter involving the chemistry of carbon monoxide six papers are dedicated to hydroformylation (or related chemistry) with different metal catalysts (rhodium, ruthenium, platinum, and cobalt). Carbonylations of olefinic substrates to amino acid precursors and to azacyclic compounds are also described. Three papers deal with the carbonylation of oxygenated compounds and one with the water-gas shift reaction. The activation of carbon monoxide by 17-electron porphyrin complexes of cobalt, rhodium, and iridium(II) is also discussed.

In the chapter on general functionalization, reactions leading to cyclic and macrocyclic compounds through intermolecular insertion reactions of diazo compounds or through palladium catalyzed allylic alkylation are discussed. Palladium catalysis, as well as model nickel chemistry, is also described in some examples of conjugated addition reactions. One paper relates to new applications of so-called "classic process chemistry" (such as hydrocyanation or cyclopropanation) to the manufacture of commodity chemicals. Evidence of the heterogeneous nature of the catalysis in the hydrosilylation of olefin substrates promoted by the "Karstedt" catalyst [i.e. platinum bis(divinyltetramethyldisiloxane)] is presented. The catalytic and noncatalytic hydrosilylation of acetyl metal complexes is also described. Other papers report on the amination of ethylene glycol, the deoxygenation of platinum allyl oxides and aryl oxides by carbon monoxide as a model for the catalytic deoxygenation of phenols, and the reduction of methanol by the tetracarbonylcobalt anion assisted by carbon dioxide and cobalt cation.

The polymer chemistry chapter contains papers on the catalytic synthesis of polymethylsilsesquioxanes, on the ionic nature of Ziegler–Natta catalysts derived from titanocene halides and organoaluminum Lewis acids ($RAlCl_2$), and on catalysis by half-sandwich chromium compounds (model for Phillips catalysts) in ethylene polymerization and in the ring-opening metathesis polymerization of norbornene. A proposal for a new mechanism of the Fischer–Tropsch synthesis based on model organometallic chemistry is also presented here.

Although the arrangement of the subject matter seems a little arbitrary, the book presents an overview of different aspects of homogeneous catalysis by transition metal complexes which is comprehensive enough to give a rough idea of the scope of applications of this type of catalysis. Moreover, the book is mainly directed to specialists in the field. However, some of its interest has perhaps been "diluted" due to the very long editorial time. For this reason, and due to the rather high price of the volume, I do not think that many people or institutions will acquire it. This is really a pity since I find it a very good, useful, and stimulating "pot-pourri" of themes related to homogeneous catalysis by transition metal complexes.

Metal Complexes in Cancer Chemotherapy. Edited by *B. K. Keppler*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 436 pp., hardcover DM 196.00, $ 125.00.—ISBN 3-527-28425-7/1-56081-216-8

This book contains 17 articles reporting on the present state of knowledge in the area of metal complexes with cytostatic activity. The metallic elements concerned range through the alphabet from A (e.g., Au) to V (vanadium). Although clinical success has so far been convincingly demonstrated only for platinum compounds (cisplatin, carboplatin), it is now recognized that a wide variety of other metal complexes offer promising possibilities, even though it is not yet possible to fully evaluate their real effectiveness, nor have they been proved in clinical use. Nevertheless, we know that even during the development of cisplatin there was a stage when its usefulness was seriously questioned. As the editor points out in the introduction to this book, one of the main driving forces for research in this field is the hope of discovering metal complexes with modes of action different from those of the platinum cytostatic agents.

The elements platinum, ruthenium, and tin each occupy three chapters of the book. Another four chapters are devoted to complexes of gold, gallium, and titanium and to cyclopentadienyl complexes of various metals. A further four are concerned with general aspects, namely the present clinical status of metal compounds (M. E. Heim), the stages in the development of an antitumor agent from initial testing to final release (F. T. Saur), the current situation in the treatment of colon and rectal tumors with special reference to metal complexes (M. R. Berger, M. H. Seelig, A. Galeano), and a possible novel therapeutic approach based on reactions of metal complexes with serum proteins (F. Kratz).

The most comprehensive articles are those on platinum compounds. E. von Angerer reports on the state of development of platinum complexes for the treatment of hormone-dependent tumors, T. Klenner and coworkers on the activity of various platinum phosphonate complexes in the treatment of bone tumors, and E. Holler on the mode of action of carcinostatic platinum complexes. The articles on ruthenium are concerned with the basic features of the interaction of ruthenium with biomolecules (M. J. Clarke), and with new developments in cytostatic ruthenium complexes with DMSO or N-heterocycles as ligands (G. Mestroni et al. and B. K. Keppler et al., respectively). Two chapters, by F. Huber and R. Barbieri and by M. Gielen et al., respectively, describe organotin compounds with various ligands (dipeptides, mercapto amino acids, salicylic acid). J. Crowe then attempts to define the extent and limitations of the analogy between tin compounds and cisplatin. The remaining four articles are concerned with tumor-inhibiting gold and gallium compounds (by O. M. Di Dhubhghaill and P. J. Sadler,

and by P. Collery and C. Pechery, respectively), the current state of development of budotitan (B. K. Keppler et al.), and progress on cytostatic metallocene compounds (P. Köpf-Maier).

The editor's attempt to provide an up-to-date standard work on the rapidly growing subject of cytostatic metal complexes is to be welcomed. The most recent previous monograph of this kind (*Platinum, Gold, and Other Metal Chemotherapeutic Agents*, edited by S. J. Lippard) is already ten years old. The more recent book *Transition Metal Complexes as Drugs and Chemotherapeutic Agents*, by N. Farrell, is not directly comparable as its aims are different. However, the rapid pace of developments has already made Keppler's book out of date in a few places. For example, in the field of platinum cytostatic agents such important developments as the work on bis-platinum complexes and the orally effective platinum(IV) compounds have not been included. This could be a consequence of the selection of authors: apart from one exception all the contributions are from European laboratories and medical institutes. This latter fact is in itself a positive sign, as it reflects the increased interest in this field in Europe, but the two new developments mentioned above have both come from the USA.

Most of the articles, though unfortunately not all, are of a quality and comprehensiveness that one expects in a standard work. I did not like the fact that too many of the contributions contain a mini-review of the history of tumor-inhibiting metal complexes, as this leads to a good deal of repetition. The standard of production is on the whole good. There are few errors and faults of presentation, and the fact that in the last article Figures 18 and 24 are not in color, as they were claimed to be, is not a disaster.

Specialists in the field, whether they are bioinorganic chemists with medical interests or medical scientists interested in chemical aspects, will probably buy the book without even examining its contents beforehand. Every library concerned with this area of science should have the book in its collection.

Fluorescence Spectroscopy. New Methods and Applications. Edited by *O. S. Wolfbeis*. Springer, Heidelberg, 1993. XX, 310 pp., hardcover DM 168.00.—ISBN 3-540-55281-2

Fluorescence is increasingly an "in" topic! Anyone who takes up this little book edited by Wolfbeis will certainly agree that much progress is being made in the application of fluorescence spectroscopy.

In this book of 21 chapters Wolfbeis, an analytical chemist, has succeeded in putting together a thoroughly up-to-date picture of the wide variety of ways in which fluorescence processes can be used in qualitative and quantitative analysis. The authors, well-known experts in the field, each present their own view of the situation. Schulman leads off with a critical overview of the subject. Rigles and coworkers then describe a relatively unfamiliar application of fluorescence correlation spectroscopy which allows one to observe individual fluorophore molecules. MacKay describes the application of a digitalized two-dimensional detector array utilizing luminescence phenomena for rapid imaging of processes that emit fluorescence.

Rettig reports on kinetic studies using fluorescence probes that are excited using synchrotron radiation. Bastiaens and Visser describe the use of fluorescence relaxation spectroscopy to observe rapid conformational changes in dimeric flavoproteins. Oelkrug and coworkers have carried out surface microstructure studies into the interaction of adsorbed fluorophore molecules with the substrate. Trettnak then reports on a purely analytical topic, namely the application of fluorescence quenching in optical sensor technology.

Beginning the next topic area, "Applications of Fluorimetry", Schneckenburger and Schmidt describe how pollution damage to forests has been studied by in situ measurements of the laser-induced time-resolved fluorescence of NADH and photopigments on leaves and branches. Riegler and Möhwald have used fluorescence microscopy to study the formation of structures and domains in Langmuir–Blodgett films, by incorporating fluorescence probes into the film. Applications of time-resolved fluorescence to the imaging of concentration distributions in cell biology studies are reported by Lakowicz and coworkers. Hermetter et al. use phase-modulated fluorescence spectroscopy to obtain insights into the structures of cell membranes, in particular the arrangement of ether phospholipid molecules. Pyrene labeling is a very useful way of introducing a fluorescence probe, and Kinnunen et al. describe the use of this method to study biomembranes. Slavik shows how suitable fluorescence labels can be used to observe intracellular processes.

In the area of the more conventional analytical applications of fluorescence, the current trend is towards the use of near infrared fluorescence. Miller et al. discuss the choice of suitable fluorophores for such work. Valcárcel and Lúque de Castro describe the use of flow injection analysis with coupled detection of a fluorescent product. The use of fluorescent tracer compounds in environmental analysis and hydrogeology is already a well established method. Goldberg and Weiner report on further extensions of fluorescent tracer techniques based on multidimensional analysis of spectra.

The fourth topic area is the application of fluorescence methods to immunological analysis. Klein and coworkers describe the wide variety of ways in which fluorescence can be used in immunoassay as a very sensitive labeling method. By labeling with rare earth complexes in conjunction with time-resolved luminescence measurements Hemmilä has achieved extremely low levels of detectability. Jansen reports on the use of similar techniques to analyze environmental samples. The monograph ends with contributions on the use of time-resolved fluorescence measurements in physiology, to reveal discontinuities in the potential and in the concentrations of sodium and calcium ions in nerve fibers (by Ross and by Kamino et al., respectively).

Altogether this is a worthwhile excursion into the world of fluorescence applications, which Wolfbeis has selected and presented very successfully. Despite the rather high price, it is well worth buying!

Sterically Stabilized Vesicles

Danilo D. Lasic*

After significant developments in liquid crystal and polymer research, scientists became interested in lyotropic systems containing polymers. These studies investigated, for instance, phase behavior and stability characteristics of suspensions of colloidal particles containing water-soluble or surface-adsorbed polymers or block copolymers. The most frequently studied were micelles, latex particles, and lipid vesicles (liposomes). Liposomes aggregate and fuse in the presence of hydrophilic polymers but their properties were difficult to explain when block copolymers were adsorbed or surfactants with larger polymeric polar heads were inserted into the liposome membrane, because such systems are inherently ill defined. Liposomes containing diacyl surfactants with covalently linked, longer polymer chains display many new properties with very important consequences for both basic and applied research. They stimulate fundamental studies on phase behavior and polymer conformation, scaling laws, colloidal and surface properties, and cell function; applications deal predominantly with liposomes as drug delivery systems. While in basic research theory is currently more advanced than experiment, in medical applications theoretical understanding lags behind experimental achievements. It was discovered only relatively late that liposomes with an appropriate polymer coating are significantly more stable in a biological milieu, a necessary condition for their utility as drug carriers. In particular in medical applications, this practice has rejuvenated the field of anticancer therapy and targeted drug delivery. All these advances were made possible by an effective and synergistic overlap of many different disciplines.

1. Introduction

Matter in nature occurs, in general, in three states. Certain substances, however, behave under special conditions neither as a gas, nor as a liquid, nor as a solid. Liquid crystals, for instance, simultaneously exhibit some properties of liquids (including low viscosity and tendency to form droplets) as well as of solids (anisotropy of optical, mechanical, electrical, and magnetic properties).[1,1] The liquid-crystalline state of matter has several important properties which enable, and may be necessary for, biological processes and life: at relatively high diffusion and permeability rates it offers certain organizational ordering and barrier properties, and serves to store information.[2] In the lipid bilayer, the most common mesophase found in living cells, lipid molecules self-organize into large sheets which close to form membranes. They can be either in the fluid or solid state. The temperature of the phase transition from crystal to liquid crystal, that is, at which the two dimensional solid fluidizes (T_c), is an important parameter in liposome as well as biomembrane behavior.

In addition to thermotropic liquid crystals in which properties depend on temperature, some molecules form ordered structures by interactions with various solvents. In most cases, these molecules are amphiphiles, containing a hydrophilic and hydrophobic group in the same molecule. They can form various lyotropic liquid crystalline phases whose structures are determined by polar and nonpolar interactions of molecules that contain both groups. Examples of these amphiphilic molecules include some proteins, polypeptides, and predominantly, polar lipids in mixtures with water.[3-5]

Polar lipids aggregate in aqueous solutions into ordered structures in a variety of liquid crystalline phases (Fig. 1). Although phase diagrams can be calculated in some cases on the basis of molecular geometry and intermolecular interactions, we shall simply state that self-organization of these systems is due to the tendency of hydrophilic parts of the molecules to be in contact with water while the nonpolar parts prefer an apolar environment. The topology of various liquid crystalline phases and colloid aggregates offer exactly this molecular organization.[1-5]

Liquid crystals are characterized by long-range order and, depending on the temperature, short-range order or disorder. With respect to the symmetry of a particular phase, the order may include zero-, one-, or two-dimensional positional periodicity and some degree of orientational order. The phases, with the exception of some nonequilibrium cubic phases,[6] are thermodynamically stable, and molecules can reversibly self-organize into various structures upon appropriate changes in concentration(s), temperature, pressure, ionic strength, or pH.

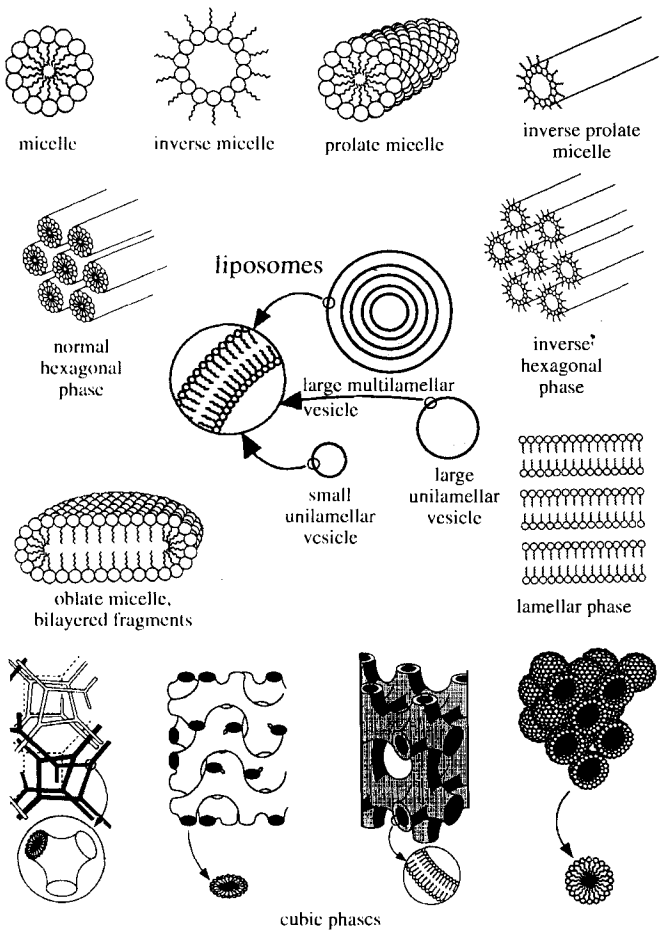

Fig. 1. Schematic representation of aggregates and phases formed by different amphiphiles at different concentrations in mixtures with water. Under these conditions spherical inverse micelles occur only with some charged single-chain surfactants at higher temperatures; they are, however, found frequently in ternary mixtures with a nonpolar phase. In aqueous suspensions the inverse hexagonal phase is coated with a lipid monolayer. The sphere represents the hydrophilic part of the molecule, while the hydrophobic tail is shown as a wavy line.

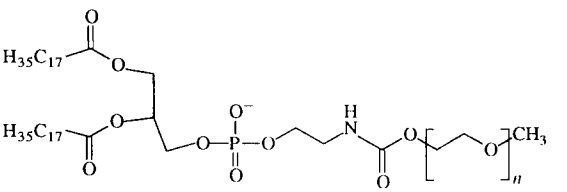
Upon the dilution of lyotropic liquid crystalline phases, the periodic lipid water structure can disintegrate into colloidal particles, especially if the dilution is accompanied by an input of (mechanical) energy, such as agitation or shaking. The molecular assembly and local molecular symmetry is retained in the small and intermediate range, while the long-range order is lost. Another possibility is that the homogeneous, lyotropic, liquid crystalline phase disproportionates upon dilution into a heterogeneous system comprising a fully swollen liquid crystalline phase in excess water.[4] An example of the former process is the disintegration of large micelles of normal hexagonal phase of single-chain polar lipids into small micelles;[4] the breakdown of lamellar phases of diacyl lipids normally results in the formation of liposomes.[7] With the exception of simple micelles, the loss of long-range order in systems after dispersing the liquid crystalline phases into colloidal particles normally results in the loss of thermodynamic stability.[8]

Liposomes are spherical, self-closed vesicles of colloidal dimensions with phospholipid bilayers that sequester part of the solvent in which they are suspended in their interior.[9, 10] According to size and number of lamellae, small or large unilamellar vesicles or, in the case of many concentric bilayers, large multilamellar vesicles may be defined (Fig. 1).[11]

Because of their structure, chemical composition, and colloidal size, which can be well controlled during preparation, liposomes possess several useful properties. The most important features are small size, for instance, rather uniform particle size distributions in the range from 20 nm to 500 nm (some methods allow formation of larger liposomes with diameters up to 50 μm), and special membrane and surface characteristics, which include bilayer phase behavior, its mechanical properties and permeability, charge density, presence of surface-bound or grafted polymers, or attachment of special ligands. Additionally, due to their amphiphilic character and very large surface-to-volume ratio, liposomes form powerful solubilizing or dispersing systems for a wide range of compounds. Apart from these physico-chemical properties, liposomes from natural lipids exhibit many special biological characteristics, including biocompatibility, biodegradability, and (specific) interactions with biological membranes and cells.[2]

Based on these properties, liposomes are used in several applications, for example, as solubilizers or dispersants for sparingly soluble substances, as sustained release and delivery systems for the micro-encapsulated substances, and as stabilizers, protective agents, and microreactors. All living cells on the planet are surrounded by a membrane in which various proteins are embedded into the lipid bilayer. This bilayer is analogous to the liposome bilayer and similarly represents a mechanical, chemical, and electrical barrier between exterior and interior. There-

Danilo D. Lasic was born in Ljubljana, Slovenia in 1952, where he studied Chemistry and completed his PhD on lyotropic liquid crystals at the Department of Solid State Physics at Institute J. Stefan in Ljubljana in 1979. He was a post-doctoral research fellow with Charles Tanford at Duke University and Helmut Hauser at the ETH Zurich, and visiting scientist at the Physics Department of the University of Waterloo, Ontario, Canada. From 1988 to 1993 he worked at Liposome Technology, Inc. (LTI) in the San Francisco Bay Area. Since the beginning of this year he has been employed by MegaBios, where he is studying cationic liposomes for gene therapy. His academic research on thermodynamics and mechanism of vesicle formation was an excellent preparation for his active participation in the development of Stealth liposomes at LTI. His book on this subject, Liposomes: from Physics to Applications, was published in 1993.



fore, in addition to the above-mentioned applications, which have had significant impact in several industries, the unique properties of liposomes offer a very useful model system in many fundamental studies on topology, membrane biophysics, photophysics and photochemistry, colloidal interactions, cell function, signal transduction (including traffic of synaptic vesicles with encapsulated neurotransmitters), secretion and many others.[2, 5, 11-16]

Bilayers can be made entirely from naturally occurring substances and are therefore nontoxic, biodegradable, and practically nonimmunogenic. This makes them ideal candidates for drug delivery systems. Apart from these well-known endeavors, liposomes are also employed in industry as adjuvants in vaccination, signal enhancers or carriers in medical diagnostics and analytical biochemistry, and transfection vectors in genetic engineering. Currently, however, the largest marked is in cosmetics, in which liposomes serve as dispersants or support matrices for various ingredients and, according to some reports, as penetration enhancers. Although some of the claims of cosmetics producers are not supported by rigorous scientific tests, liposomes, at the very least, represent an improvement simply because hydrophobic substances are suspended in an aqueous and biocompatible matrix as opposed to creams and gels that use skin-irritating oils, alcohols, and surfactants.[2]

2. Liposomes in Drug Delivery

The optimistic expectations for liposomes as drug delivery systems have not been met, mostly because of stability problems. Although the problems with shelf-life were successfully solved in most cases, the stability of liposomes in liposomicidal environments of biological systems presented a greater challenge that was only recently solved.[17, 18]

Intravenously administered liposomes quickly release the encapsulated or membrane-bound molecules. The leakage can be greatly reduced by the inclusion of cholesterol into their membranes,[19] but this did not help much in the fast sequestration and clearance of liposomes by the mononuclear phagocytic (MP) cells of the immune system located mostly in liver and spleen, which is the major drawback in most applications. First attempts to alter their biodistribution by either surface ligands or membrane composition were undertaken in the late seventies. The results showed that liposome disposition can be changed, but predominantly within the mononuclear phagocytic system itself. To prolong the circulation time of liposomes in the blood without recourse to undesired methods such as presaturation, suppression, or impairment of the MP system, small, neutral liposomes composed of rigid lipids and cholesterol were used. The first substantial improvements, however, were achieved by the incorporation of ganglioside G_{M1} or phosphatidylinositol at between 5 and 10 mol% into the bilayer.[20] The best results were obtained by substituting a synthetic polymer-containing lipid for these two lipids. The longest circulation times were achieved with polyethylene glycol covalently bound to the phospholipid (Fig. 2). Intermediate molecular weights (1500–5000 Da) at a concentration of about 5 mol% in the bilayer gives rise to the longest liposome circulation times.[18] Figure 3 shows blood clearance profiles of several different formulations.

DSPE, $n \approx 16, 45, 113$

Fig. 2. Structural formula of the poly(ethylene glycol)-lipid mPEG-DSPE. They are normally applied as the sodium salt. Usually molecular weights of poly(ethylene glycol) (PEG) are 750, 1000, 2000, 3000, 5000, and 12000. Commercial grade PEG has a polydispersity index p of 1.1, while that of BioTech grade is 1.05; p does not change after linkage.

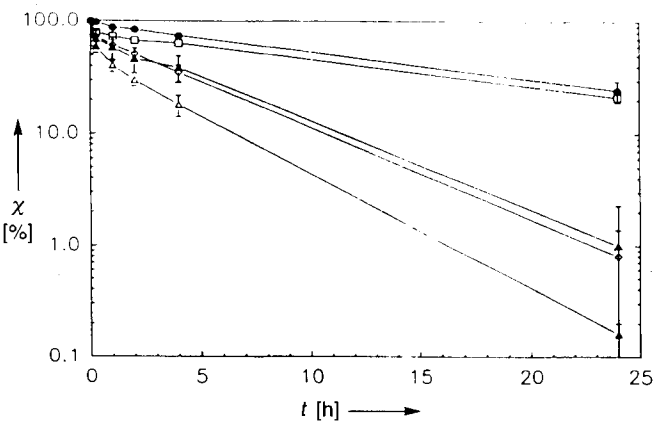


Fig. 3. Blood clearance profiles of several liposome formulations as percentage of the injected dose χ as a function of time t. From top to bottom: ^{2000}mPEG-DSPE/EPC/Chol (●), ^{5000}mPEG-DSPE/EPC/Chol (□), ^{120}mPEG-DSPE/EPC/Chol (▲), EPC/Chol (2/1) (○), and EPG/EPC/Chol (△); formulations with molar ratio 0.15/1.85/1. Abbreviations: mPEG = methoxy poly(ethylene glycol), DSPE = distearoyl phosphatidylethanolamine, EPC = partially hydrogenated egg phosphatidylcholine (iodine value 40), Chol = cholesterol, EPG = egg phosphatidylglycerol. The 100-nm liposomes were labeled with ^{67}Ga-desferal (from ref. [67]).

Similar approaches have been tried with other colloidal particles, from micelle-forming block copolymers[11] to latex particles.[22] Whereas latex particles with adsorbed block copolymers such as PEG–PPO (polyethyleneglycol–polypropyleneoxide) showed changes in pharmacokinetics similar to those of PEG-grafted liposomes;[2] the block copolymer micelles containing PEG chains were taken up rapidly by macrophages by pinocytosis.[21]

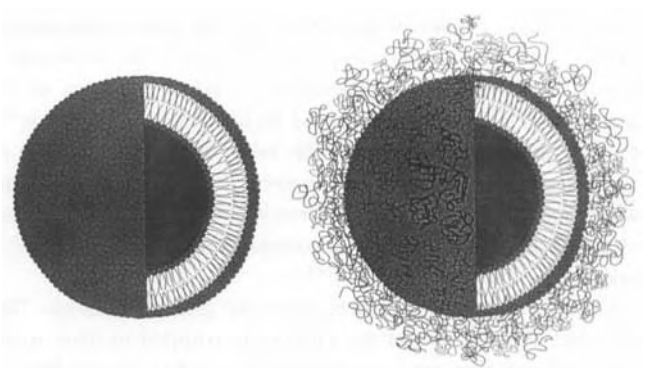

Fig. 4. Schematic representation of conventional (left) and Stealth liposomes (right). Polymer chains can be attached to one or both sides of the vesicle. By courtesy of Phillip Le Roy Carter, Liposome Technology, Inc. (LTI).

In general, however, surface grafting of polymers offers much better control over the colloidal properties. Furthermore, surface adsorption of polymers onto liposomes normally leads to leakage of the encapsulated molecules,[23] and liposomes can often aggregate.

In our opinion the enhanced liposome stability in the biological milieu is due to the steric barrier that the surface-attached polymer presents to the interacting macromolecules. For this reason they are often called sterically stabilized liposomes;[24] commercially they are often referred to as Stealth* liposomes because of their invisibility to the body's immune system (Fig. 4).

3. Stability of Liposomes

In liposome research and applications the term stability is used rather vaguely and is often not properly defined. In the broadest sense it refers to the stability of the particle and its constituents, including the entrapped molecules, in any, including liposomicidal, environment. This general definition of stability contains various aspects which can be defined separately but often act synergistically.

I shall arbitrarily define stability as a sum and product of physical, chemical, and colloidal stability. In addition to these inherent stability components, the definition must also include the stability of liposomes under the conditions of the application, which is often in liposomicidal environment. Since most of them are of pharmaceutical nature, one can define biological and shelf-life stabilities, which are each a cumulative property of several of these stabilities.

3.1. Physical Stability

This aspect mostly involves preservation of the liposome structure and entrapment, that is, the stability of liposome size and shape (size distribution of the sample), and of the barrier properties of the bilayers for the encapsulated or membrane-bound molecule.

Both the preservation of the size as well as encapsulation depends on the mechanical properties of the bilayers and the thermodynamics of the systems.

Vesicles are thermodynamically unstable because the symmetric membrane is curved, and the low energy conformation of membranes is, in general, planar (that is, the spontaneous curvature $C'_0 = 0$). The excess energy of each vesicle due to its curvature is $8\pi K$, where K is the elastic bending modulus of the membrane.[12, 25, 26] Vesicles could be formed spontaneously[27] only in the case of bilayers with very low values of K[28] or asymmetric bilayers with nonzero spontaneous curvature, which may originate from differences in internal and external phase, from nonbalanced lipid compositions, or from the use of asymmetric bipolar lipids.[29–35]

Once the liposome is formed, however, it is rather stable. This indicates that liposomes are kinetically trapped in their structures, because they are formed in an irreversible nonequilibrium process during which excesses of energy are high;[2, 8, 26, 36] the energy needed to open or break them can be 50 kT.[2, 37] The above analysis shows that part of the energy input during liposome formation becomes stored in the conformational energy of the bilayer–bilayer curvature[38] and is responsible for their metastability.

A simple Gedanken (thought) experiment shows the advantage of kinetically trapped systems over systems in thermodynamic equilibrium for applications such as microencapsulation. A system at equilibrium quickly adjusts to the external change (for instance, dilution, change in concentration(s), temperature, pressure, presence of other substances, or injection into body fluids) by changing phase. For instance, micelles or microemulsion droplets quickly disintegrate upon dilution (that is, move into a different region of the phase diagram), while liposomes made from phospholipids with very low values of critical micelle concentration (cmc) are stable against dilution. This simple analysis can explain many of the unexpected findings on drug delivery with colloidal carriers.

It is also interesting to note that liposomes can be stabilized against some phase transitions, such as freeze-thawing and freeze-drying by the addition of water-soluble cryoprotectants like sucrose. This enables manufacturing of freeze-dried (lyophilized) liposome formulations with improved shelf-life stabilities.[39]

Liposome integrity also depends strongly on the mechanical properties of the bilayer. Mechanically stronger (more cohesive) bilayers are expected to resist external perturbations better. Measurements with micropipette manipulations allow the determination of stretching moduli of a particular membrane [isotropic dilatation modulus ($K_{d/c}$) and critical areal strain (τ) of various bilayers],[40, 41] and these values correlate with the stability of liposomes. Table 1 shows the values of $K_{d/c}$ and τ for various bilayers. A general observation is that cholesterol makes bilayers more cohesive by inducing the ordered fluid phase.[41, 42]

Bilayers can also be mechanically stabilized by polymerization[43–48] or by using lipids with fluorocarbon chains.[49–51] Despite reduced van der Waals attraction between the carbon chains, these lipids form stronger and less permeable bilayers due to stronger hydrophobic interaction.[2]

Table 1. Mechanical properties of bilayers as measured by the micropipette manipulation technique. The compressibility modulus $K_{d/c}$ and tensile strength τ of various liposome bilayers are shown. 3.2. Chemical Stability

Most biomolecules are degraded in a variety of ways, and lipids are one of the most sensitive naturally occurring substances. The most common degradation pathways are oxidation and hydrolysis (Fig. 5). In general, the polar heads are much more stable than the hydrocarbon chains. Hydrocarbon chains, especially unsaturated ones, are subject to oxidation, whereas hydrolysis pinches off one or both hydrocarbon chains from the backbone of lipid molecule. Because the reaction is acid- and base-catalyzed, it exhibits a strong pH dependence (Fig. 5, top left).[52, 53] The protective measures therefore include optimization of pH, normally around 6.5, and, preferentially, freezing or drying the sample in the presence of cryoprotectants.

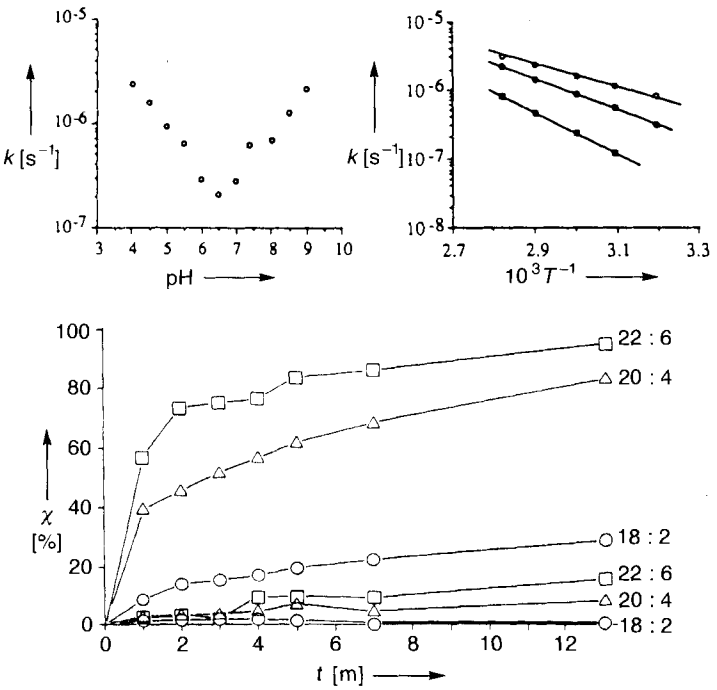

Fig. 5. The chemical stability of liposomes. Top: hydrolysis rate of soybean lecithin in liposomes as a function of pH (left) and temperature (right); the temperature dependence was performed at pH 4.0 (○), 6.5 (□), and 8.0 (●) (by courtesy of M. Grit and D. Crommelin, Utrecht University). Bottom: oxidation of polyunsaturated fatty acids in egg lecithin liposome at 38 °C in vented vials as a function of time (in months). The lower three curves show the reduction in oxidation rate due to the presence of 1 mol% antioxidant 2,6-di-*tert*-butyl-4-methylphenol (BHT). The information to the right of each curve gives the chain length and degree of unsaturation. For example, 22:6 indicates a C_{22} chain with 6 double bonds (by courtesy of Frank Martin, LTI).

Oxidation is a radical reaction that ultimately results in the breakage of chains or, in the case of two adjacent double bonds, formation of cyclic peroxides. Protective measures, which include the use of saturated lipids and addition of antioxidants such as vitamin E (α-tocopherol) or BHT (butylated hydroxytoluene), reduce the oxidation rate substantially, and samples can be stable, within tight specifications (normally the maximum allowable change in chemical composition is 2%), for years.[54]

Several synthetic lipids, including those with fatty acids linked to the glycerol backbone through an ether linkage, are chemically more stable;[35] they are, however, not biodegradable by mammalian enzymes. That limits their use in parenteral drug delivery, although they are often used in chemical or cosmetic applications.

3.3. Colloidal Stability

In phospholipid liposome preparations the particle size increases mainly as a result of particle aggregation, because size growth due to Ostwald ripening is negligible.[2, 55] Aggregation is the first step in vesicle–vesicle fusion[56] and depends on the thermodynamic stability of the sample, crystal defects, and the presence of intrinsic or exogeneous, fusogenic substances or vectors. Fusion is practically an irreversible process (liposome fission is rarely spontaneous) while aggregation can be reversible.

There are several attractive and repulsive forces which act between colloidal particles. Ubiquitous is the van der Waals attraction that acts between all particles separated by a medium with different polarizing properties. Particles bearing the same charge experience an electrostatic repulsion. These two forces are the basis of the DLVO theory (DLVO = Derjaguin, Landau, Verwey, Overbeek) of the stability of colloidal particles in which a colloidal system is defined as stable if a minimum (with a depth of approximately $\Delta E < 10$ kT) exists on the graph of potential energy vs distance.[57] In many cases, however, this theory could not predict the stability of liposomes against aggregation. To elucidate why colloidal suspensions have a lower stability than expected, additional attractive forces between colloidal particles, such as hydrophobic attraction or ion–ion correlation attraction were introduced,[58–60] while the stability of uncharged liposomes and liposomes in media of high ionic strength, could only be explained after other repulsive forces between two liposomes such hydration[61] and undulation[62] were recognized.

The origin of some of these forces is not known yet, and they are still controversial. For instance, recently hydration as source of a repulsive force was questioned, and the protrusion repulsive force, a steric repulsion caused by the vertical motion of polar heads, was proposed.[63] The situation is even less clear with respect to the attractive long-range hydrophobic force between two liposomes.[55, 58, 64] Qualitatively, however, this attraction can be explained as a consequence of the perturbation of the water structure. Bulk water molecules have directed hydrogen bonds; this three-dimensional network of hydrogen bonds is highly perturbed near molecules with a hydrophobic surface.[65, 66] The formation of additional H-bonds between water molecules which form the cage around the hydrophobic surface may not compensate the entropy loss and/or the loss of electrostatic contribution in this two-dimensional surface of water molecules relative to that in the three-dimensional arrangement of bulk water molecules. A tension is created, which results in a location that has an unfavorable free energy. Because water molecules tend to leave these positions an attractive force is created. However, their long-range character still cannot be satisfactorily explained.

These forces provide a basis to explain the stability of liposomes. Predominantly, surface charge density, zeta potential,

size distribution and homogeneity, as well as ionic strength and pH of the medium determine colloidal stability in vitro. In biological systems, however, the behavior is completely different because of the presence of active liposomicidal substances.

Additional repulsive interactions emanate from molecules attached to the surface (see Section 4.1). Since Egyptian times it has been known that lyophobic colloids, such as pigments in inks, can be stabilized by natural polymers such as arabic gum, starch, or cellulose. This gives rise to the so-called steric repulsion, which will be discussed in Section 4.

3.4. Biological Stability

Even the most stable conventional liposomes are rather unstable in a biological milieu. In addition to interactions with various plasma components and enzymes, they are actively taken up by the body's immune system (Fig. 6). Mechanical stability can help to reduce the interactions in vitro and reduce leakage in vivo but cannot slow down appreciably the uptake of liposomes by phagocytic cells upon parenteral administration.

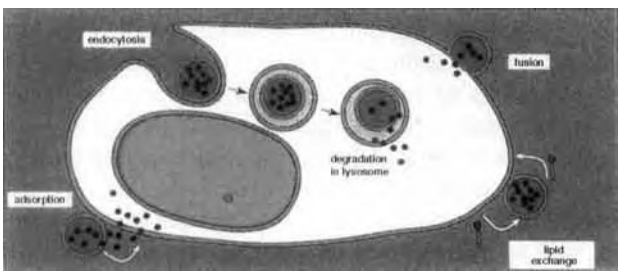

Fig. 6. Interactions of liposomes with cells. The four most important interactions are adsorption, lipid exchange, fusion, and endocytosis (from ref. [82]).

The predominant mechanisms of liposome clearance from blood[2, 24] are 1) opsonization (= preparation for phagocytosis) by immune and nonimmune components in blood such as immunoglobulins, complement factors, and fibronectin, which trigger subsequent macrophage uptake and 2) reaction with plasma (lipo)proteins.

In order for effective opsonization to take place it was hypothesized that a macromolecule has to bind to the liposome surface.[24] This absorption can be either chemi- or physisorption; the total adsorption energy W_{tot} contains contributions from electrostatic W_{est}, hydrophobic W_{hfo}, van der Waals W_{vdW}, hydrogen bonding W_{Hbond}, and specific interactions W_{spec} [Eq. (a)]. Specific interactions occur mostly when antibodies, antigens, or haptens are attached. Obviously, an ideal targeting system for drugs would eliminate all contributions to W_{tot} with exception of W_{spec}. In addition, the adsorption or adhesion probably requires conformational change in some proteins to trigger subsequent macrophage uptake.

$$W_{tot} = -W_{est} - W_{hfo} - W_{vdW} - W_{Hbond} - W_{spec} \quad (a)$$

Similar conclusions may be drawn for interaction with plasma proteins. More cohesive bilayers interact with plasma components less avidly and exchange lipid molecules with the surroundings more slowly. Very cohesive bilayers in the gel state, however, contain too many hydrophobic defects to be stable.[2]

Uncharged liposomes should be more stable, because any strong ionic binding is absent ($W_{est} = 0$). For mechanically stronger (that is, more cohesive) bilayers, hydrophobic binding, for example, the penetration of a segment of the macromolecule into the bilayer, should also be reduced (reduction of W_{hfo}). Physisorption, however, is not prevented (that is, W_{vdW} and W_{Hbond} are negative, and this may explain the lower stability of such bilayers in vivo and their macrophage uptake. Physisorption can be greatly reduced by the presence of a steric shield of an inert, nonimmunogenic ($W_{spec} = 0$), nonionic ($W_{est} = 0$) polymer (see Fig. 4 right). Surface-grafted polymers can prolong blood circulation times for fluid and less cohesive or charged liposomes.[66] This property is important for designing cholesterol-free liposomes with well-defined leakage characteristics as well as for improving their encapsulation efficiency for hydrophobic molecules.

In contrast to electrostatic stabilization, which was effective in many in vitro applications, steric stabilization is a suitable way of stabilizing particles in biological systems and in media with high or variable salinity.

4. Theoretical Understanding of Steric Stabilization of Liposomes

4.1. Two Specific Models for Steric Stabilization

The repulsive forces between two particles can be greatly increased by coating the surface of the particle with appropriate molecules.[68] Natural and synthetic polymers are the most common materials used. They must be inert, well solvated, compatible with the solvent, and have a polarizability close to that of water. Steric stabilization can be induced by attaching polymers to the surface, either by adsorption, hydrophobic insertion, electrostatic binding, or, preferentially, by grafting through covalent bonding. Nonionic, water-compatible, flexible, and well-hydrated polymers are preferred. The repulsion between surfaces with attached polymers was shown to be dependent on the density of grafting and degree of polymerization. For low grafting densities, that is, in the region where the polymer chains cannot interact among themselves, the so-called mushroom model was defined. Conformational entropy of the mushroom is reduced upon approach of other surfaces, and steric repulsion in this model at a distance h[69] is defined according to Equations (b) and (c). D is the average distance between adjacent grafting points, a the size of the segment, and N the degree of polymerization. At higher densities where the interaction of the polymers causes their extension, the so-called brush model can be applied [Eq. (d)].[68]

$$F_{st}^{m} = \frac{kT}{D^2 h_c}\left(\frac{h_c}{h}\right)^{8/3} \quad (b)$$

$$h_c = Na\left(\frac{a}{D}\right)^{2/3} \quad (c)$$

$$F_{st}^{br} = \frac{kT}{D^3}\left[\left(\frac{h_c}{h}\right)^{9/4} - \left(\frac{h}{h_c}\right)^{3/4}\right] \quad (d)$$

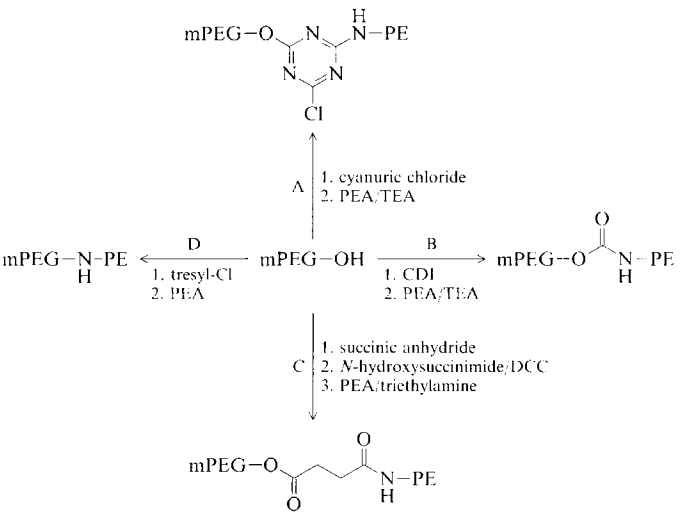
The repulsion in the brush regime is determined by the competition between an elastic force associated with the conformational entropy of the chains and an osmotic force related to the monomer-monomer interactions. These equations describe the repulsion between liposomes when the polymers on their surface form a depletion or an adsorption layer.[70] In the case of polymers forming depletion layers, the polymer conformation in the mushroom regime probably looks more like an inverse droplet or pear (rather than a hemisphere of polymers forming the adsorption layer). This conformation alters the density profile on the surface, but leaves the scaling laws unchanged.[71] Theoretical analysis of this case predicted that the chains will be 40% longer than in the case of a mushroom of an adsorption-layer-forming polymer,[72] that is, the polymer extension is larger than the Flory radius (defined as $R_F = aN^{3/5}$), namely 7/5 R_F.

4.2. An Extended DLVO Interparticle Potential

For the most general case the total potential between the particles should include all the above-mentioned forces, including the steric factor (st) [Eq. (e)]. A treatment analogous to the

$$V_{tot} = -V_{vdW} - V_{hfo} + V_{est} + V_{hyd} + V_{und} + V_{st} \qquad (e)$$

DLVO model for two potentials[57] should be performed to find the stability of the system. In a first approximation potentials could be treated as additive. For rigorous treatment, however, possible interdependence of various terms should be taken into account. It is reasonable to expect that the electrostatic, hydration, and steric interactions are interrelated when surfaces are charged or polymers are covalently bound, because of different water structure at the surface.[73]



In the case of grafted polyelectrolyte chains, however, the conformation of chains themselves is a function of electrostatic interactions and surface charge. Obviously detailed analyses should be performed.[73, 74]

5. Coupling of Poly(ethylene glycol) to Lipids

PEG polymer chains of various lengths can be covalently coupled to lipids by means of several different coupling agents. Although shorter oligoethyleneoxide spacers have been coupled to many different lipids,[75] the only lipid used for the attachment of longer PEG chains was phosphatidylethanolamine (PE) with different chain lengths and degrees of saturation, because of the reactivity of the amino group. The reactivity of this group is further enhanced by deprotonation by triethylamine. Several researchers also attached PEG chains on cholesterol, but results in general do not show prolonged blood circulation times.[76] Since molecules like cholesterol-O-$(CH_2$-CH_2-$O)_{24}$-H are commercially available surfactants, this is not unexpected, because due to their high cmc values, PEG–lipid molecules can be quickly lost, especially after dilution, from the bilayer. For instance, in the amphotropic cholesterol derivative tetraoxycholesteryl hemisuccinate, a cmc of 1.6 mM was measured.[77]

Synthesis with other phospho- or sphingolipids has either not yet been performed or yielded products with rather unstable and hydrolyzable ester bonds. PEGs of different chain lengths, for instance, with a degree of polymerization $n = 3$, 8, 17, 45, 115, and 270, and polydispersities have been attached. The polydispersity of the polymer depends on the polydispersity index p (defined as the weight average molecular weight divided by the number average molecular weight) of the starting material and virtually does not change during the synthesis (see also legend to Fig. 2).

All coupling strategies are adopted from protein-chemistry.[78] They start with methoxy-PEG (mPEG) and use phosphatidylethanolamine as lipid. Three different synthetic routes (Scheme 1) were employed yielding ester (route C), secondary amine (routes A and D), and uretane (route B) linkages.[18] Although the hydrolysis of the ester linkage formed in route C is probably too slow to contribute significantly to the liposome uptake (e.g. in cells), this linkage is less stable than the urethane bond.[79] The coupling in route A, however, uses a toxic reagent, which is undesirable for in vivo applications.

Scheme 1. Four different synthetic routes to link the polymer PEG to the lipid PE. Most frequently used is route B. Abbreviations: mPEG methoxy poly(ethylene glycol), PE phosphatidylethanolamine, TEA triethylamine, CDI carbonyldiimidazole, DCC dicyclohexylcarbodiimide. By courtesy of Samuel Zalipsky, LTI.

From the above considerations the following synthetic route was developed: The reaction of mPEG (1) and carbonyl diimidazole (CDI) in a molar ratio of 1:1.1 in dried benzene under a nitrogen atmosphere at 75 °C for 16 hours yielded the carbamate of mPEG ether. Coupling of this carbamate to phosphatidylethanolamine was achieved by heating with triethylamine in a 1:2:2 molar ratio at reflux in benzene at 95 °C for 6 hours. The resulting PEG-PE was purified by reverse-phase silica gel chromatography by eluting with chloroform/methanol or water/ethanol mixtures. Because PEG-PE forms micelles in aqueous solutions, it can be purified simply by dialyzing the micellar solution against water or, preferably, against saline. PEG-lipids behave as ionic surfactants in aqueous solutions, and addition of electrolytes appreciably reduces their cmc values; according to preliminary measurements, the cmc of ^{2000}PEG-DSPE decreases from mM to 30 μM upon addition to salt.

Recently the synthesis was further improved. The coupling reaction can be performed at 45 °C in 10 minutes if succinimidyl carbonate of PEG is used rather than PEG activated by car-

bonyl diimidazole. The high rate of this reaction allows polymer to be coupled to the preformed liposomes in aqueous phase[80] and probably makes this method more advantageous than the use of PEG activated by tresyl chloride.

With heterobifunctional PEG chains antibodies can be subsequently attached to the far end of the grafted polymer chain.[80] Because all the above syntheses use unreactive mPEG on one side, a heterobifunctional polymer derivative was prepared that carried the reactive succinimidyl carbonate for the attachment to the amino group of phosphatidylethanolamine on one side and a tertbutyloxycarbonyl(Boc)-protected hydrazine group on the other. The chemical versatility of the hydrazide group[80] enables various ligands including monoclonal or polyclonal antibodies to be linked to preformed functionalized liposomes containing this conjugate.

Preliminary results with several other polymers did not match the prolongation of blood circulation as achieved by PEG-modified liposomes. It seems that poly(acrylamide) and poly(vinylpyrrolidone) do not combine the hydrophilicity and flexibility of PEG. The same was true for oligo- and polysaccharides such as glucuronic acid, dextrans, cellulose derivatives, and copolymers of glucuronic acid with simple sugars. These polymers can form stronger and denser steric shields (possibly with more hydrogen bonding sites), but mobility of the chains is reduced. Furthermore, there are many specific receptors for various sugars in the body. I am sure, however, that there are other polymers that can impose the same effect.

Liposomes containing PEG-lipid can be prepared by using virtually all the standard preparation methods. Hydration of thin films improves the dispersal, and liposomes have fewer lamellae. Unilamellar liposomes are generally characterized by enhanced stability. During formation the PEG-lipid is possibly unevenly distributed in the two monolayers. In addition to steric (colloidal) stabilization, this could enhance thermodynamic stability by generating nonzero spontaneous curvature. Additionally, as suggested by a referee, PEG-lipid can be distributed unevenly with respect to the chain length: lower degrees of polymerization may tend to accumulate in the inner monolayer. The argument of nonzero spontaneous curvature is definitely true for the liposomes with polymers attached only on the outer surface. In fact, at an appropriate grafting density a condition $C_0 = 1/R$, meaning that the spontaneous curvature is inversely proportional to the liposome radius, can be achieved.

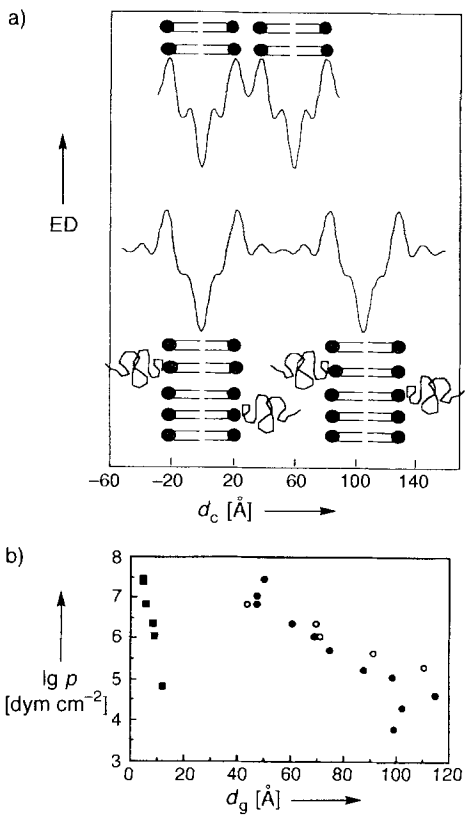


Fig. 7. a) Electron density (E.D.) in arbitrary units as a function of distance from bilayer center (d_c) of bilayers with (bottom) and without (top) ^{2000}PEG-lipid, as determined by small-angle X-ray scattering (SAXS) measurements on multilamellar vesicles. Two bilayers are shown, and it can be clearly seen that the presence of polymer increases the gap between the bilayers. Furthermore, increased electron density in the aqueous gap may indicate that the polymer, which is known to form the depletion layer, is stretched away from the bilayer. b) Dependence of the gap (distance between bilayer surfaces, d_g) between adjacent lamellae on pressure. ■: stearoyloleoyl phosphatidylcholine/cholesterol (2/1) bilayers, ● and ○: same bilayers with 4 mol% of ^{2000}PEG-lipid in 100 mM and 1 mM NaCl, respectively. At all pressures the presence of polymer-bearing lipid markedly increases the aqueous gap between the bilayers (from ref. [80]).

6. Discussion of Some Experimental Results

The effect of increased repulsive pressure above the membrane and reduced adsorption of macromolecules recognized by the immune system on the blood circulation lifetimes was tested by measuring the repulsive pressure between membranes with and without incorporated polymer-bearing lipid. Figure 7a shows that in multilamellar vesicles bilayers containing PEG-lipid the interbilayer spacings are much larger, and even upon strong compression (Fig. 7b) the bilayers are still 4 nm apart, whereas surface-unmodified bilayers show practical collapse to the hard wall repulsion.[80, 81]

The interbilayer repulsion was calculated from the repulsive pressure exerted by the surface-attached polymer in the mushroom model [dotted line, Eq. (f)]. When $N = 44$, $a = 0.35$ nm, $D = 3.57$ nm, the calculated value agrees with experimental data.[82] For distances smaller than h_c, the repulsive pressure is zero.

$$P = \frac{5\,kTNa}{2(D^2/a)}\left(\frac{a}{(h/2)}\right)^{8/3} \qquad \text{(f)}$$

Similar results were obtained by measurement of the surface force.[83] Incorporation of PEG-lipids gives rise to a repulsive force between the two bilayers at all separations. Equilibrium force profiles were reversible and practically insensitive to changes in temperature and ionic strength. The thickness of the steric barrier could be controlled by adjusting the concentration of PEG-lipids and was found to be in agreement with theoretical predictions.[83] These results show increased repulsion with increasing amount of PEG polymer, though biological data give optimal circulation times at lower surface coverages or a saturation-like behavior at grafting densities that ensure complete coating of the surface. Whether this is due to the dynamics of the system, phase transition, phase segregation, increased lateral

pressure, induction of defects, or simply to the oversimplified model will be discussed later.

The presence of surface-attached polymers was confirmed by the measurements of zeta potential.[84] Decreased mobility of PEG-coated liposomes relative to the conventional sample with the same surface charge was attributed to the hydrodynamic drag exhibited by the polymer. The estimated thickness of 5 nm was in agreement with the extension obtained both by measurement of the osmotic stress and the surface force[83] and by theoretically predicted values.[82]

More direct evidence for the hypothesis that reduced interactions lead to increased stability comes from protein adsorption studies on the PEG-coated surfaces. The preliminary investigations demonstrated that on the PEG-lipid containing BLM (black lipid membranes) less protein was adsorbed, and interactions with lipoproteins were reduced.[85] To elucidate the importance of the chain density and flexibility on the uptake of liposomes in the bloodstream, similar studies are being performed at higher grafting densities.

Similarly, reduced protein adsorption and a concomitant 40-fold increase in blood circulation times were seen in the case of polystyrene latex particles (75 nm) coated with polyethylene oxide (>5000 Da)–polypropylene oxide (>3000 Da) block copolymers.[86] Here too, the protein adsorption rate decreased, and the circulation times increased only up to a certain critical density,[87] and as for liposomes (see Table 2 and Fig. 8), optimal stability was found near the mushroom–brush transition.[87]

The simple theory presented above states that higher grafting densities of longer chains result in stronger repulsion and, presumably, better stabilization and longer circulation times. Accordingly, in vitro studies have shown increased repulsion with increasing grafting density and chain length.[83, 88] In vivo experiments, however, do not exhibit this behavior. The longest circulation times were obtained when the PEG contained about 5–10 mol% of relatively short chains ($N = 40–130$); the optimum seems to lie at 5% of PEG-lipids with chains of length $N = 40–70$.

Table 2 shows the stability of liposomes in blood circulation. These studies are very difficult to compare because researchers use different labels, lipid compositions and concentrations, liposomes of different size distributions, and different animals. They also do not report the plasma-induced leakage from the sample (that is, the fraction of the label released through leakage during circulation and not on liposome uptake). This may result in underestimates as high as 30–40%. Nevertheless I have compiled data of comparable studies. If not indicated otherwise in Table 2, small vesicles at unsaturated lipid doses were used. Researchers report mostly the percentage of the dose remaining in circulation at a particular time, or the ratio of the remaining label and the amount taken up by liver and spleen (B/RES). More confusion arises because researchers normalize this either to the starting dose or dose recovered at particular time point. High ratios therefore do not necessarily mean long circulation times but could be an artifact of label losses, for instance. Being aware of these pitfalls I tried to define a single quantity to correlate and unify these numbers. For qualitative discussion we shall rely on the "stealthiness factor" arbitrarily defined at time t after injection [Eq. (g)].

$$SF = \{t_{1/2}[h] - 3\} + (B/RES)[t] \times F[t] \qquad (g)$$

Table 2. Stability of 100-nm liposomes in the blood circulatory system as a function of grafting density and polymer chain length. Various physico-chemical parameters of the systems are also shown. M_{PEG} = molecular weight of poly(ethylene glycol). Mol% = percentage of PEG-lipid in the bilayer. $t_{1/2}$ = half-life of the liposomes in the blood. B/RES ratio of the amount of liposome label present in blood to that in the reticuloendothelial system (liver and spleen) 24 hours after injection. SF = stealth factor. n = degree of polymerization. R_F = Flory radius, R_g = radius of gyration. D = average distance between grafting points as based on the square lattice. ρ = density of monomers per lipid area in the bilayer. Conf: conformation of the polymer as mushroom (m) or brush (br). Δ = the difference between the size of the polymer and their separation. Negative values of Δ infer overlap and zero indicates the transition to the brush conformation.

Mostly I will use $t = 24$ hours and numerical factor $F[t = 24\ \text{h}] = 5$. Because the blood/RES ratio is less characteristic than blood levels its weighting is, empirically, smaller than that of the blood circulation halflife $t_{1/2}$ (normally 2/3 of the value); the halflife is not used as a sole parameter because the value of $t_{1/2}$ can be too low as a result of leaky liposomes, not well purified samples, and anatomical disorders than can cause liposomes to be lost by leakage into extravascular space and not by endocytosis. Furthermore, the background noise and secondary clearance (the so-called β clearance) of the label can contribute $<1\%$ to the fractions in the blood a day after injection; this corresponds to a halflife of 3 h, and therefore 3 h are empirically subtracted. SF values below 5 characterize conventional liposomes, while for Stealth liposomes SF $>10-15$. These numbers are also sensitive to the type of the label. In the experiments whose results are listed in Table 2, predominantly water-soluble liposome markers were employed.

The best results, as judged from $t_{1/2}$, B/RES, and SF values, are associated with Δ values around 0, where Δ is defined as the difference between the average distance between attachment points of the polymer chains and the size of polymer as defined by Flory radius. At large Δ values the coverage is incomplete. Separate mushrooms start to interact and overlap at $\Delta = 0$, while for $\Delta < 0$ a polymer brush is formed. There is not much correlation between SF and n, the monomer density per site above the bilayer. At shorter chain lengths and very high grafting densities there is no effect, probably because the too thin surface barrier cannot prevent van der Waals binding.[18] When the chains are longer, the correlation may follow the Δ dependence, that is, SF is sensitive to the mushroom–brush transition of the polymer conformation.

Qualitatively, three reasons why SF does not increase with Δ and n above a certain optimal level, as expected from Equation (g) are possible: 1) flexibility of the polymer chains, 2) phase segregation and/or collapse of a polyoxyethylene brush, and 3) reduced solubility of the PEG-lipid in the bilayer due to the increased lateral pressure of the polymer above the surface of the bilayer or additional surface tension. Or in other words, our assumption that blood circulation times are inversely proportional to the protein adsorption, which is again inversely proportional to the repulsive pressure above the membrane, must be refined.

Flexibility of the surface-attached polymer chains is important in reducing the adsorption of blood components on biocompatible surfaces.[89] It was speculated that correlation times of chain motion (that is, the inverse of the frequency of conformational changes in the chains) should be greater than the contact times of molecules for bonding to occur. Although NMR relaxation studies of the polymer chains grafted to liposomes have not been performed yet, similar work in PEG polymers showed the correlation between molecular motion and adsorption rates.[90] The importance of chain mobility, that is, ever changing molecular conformation, and its effect on adsorption[18] was recently termed mobile steric hindrance.[91] It is reasonable to expect that the mobility and flexibility of polymer chains decrease with grafting density. Increased polymer concentration at the surface may have, however, two other effects as well. At higher local PEG concentration the polymer chains may undergo intra- and intermolecular reactions, which may lead to condensation of the chains and thereby the collapse of the brush.[92] The process is analogous to the phase segregation of aqueous PEG polymer solutions at higher concentrations and ionic strengths[93] (above the ϑ temperature). The incorporation of PEG-lipid into the bilayer at higher mol fractions may be reduced, and polymer molecules form a separate mixed micellar phase which may be difficult to detect in the presence of liposomes.[94] Even higher PEG-lipid concentrations lead to the dissolution of liposomes.[94] Alternatively, high lateral pressure between polymer chains may affect the stability of the bilayer, and the formation of various defects within the bilayer surface may lead to the exposure of hydrophobic groups and protein adsorption.[83] Various studies, including measurements of protein adsorption, blood circulation times, liposome stability and leakage in vitro, as well as spectroscopic and scattering studies of polymer conformation and dynamics may resolve this question. It seems that both mushroom and brush arrangements of polymer have advantages and disadvantages: both reduce protein adsorption, but the mushroom shape cannot protect the surface from smaller macromolecules, while the brush form either causes bilayer defects and phase changes, or allows weak protein adsorption. This may be tested experimentally: liposome covered simultaneously with a brush of shorter polymer and a mushroom of a longer one (for example 4–6 mol% of PEG 2000 and 2 mol% of PEG 5000) should exhibit the highest biological stability.

All these models assume complete inertness of the PEG chains. The assumption that the adsorption enthaply ΔH for protein binding onto PEG can be (slightly) negative can, however, explain qualitatively the difference between in vitro measured repulsive pressure and biological stability. A simple model of adsorption rate in the absence of PEG (K) and on the PEG chains (k), in which ϑ is the fraction of the surface coated by polymer, yields adsorption rate according to Equation (h).

$$A = K(1 - \vartheta) + k\vartheta \qquad \text{(h)}$$

The postulate that biological stability is the reciprocal of the protein adsorption rate gives maximum stability if the first term becomes zero at complete coverage, and in the brush regime, A is proportional to $k\vartheta'$, where ϑ' is proportional to PEG concentration on the surface. In other words, simultaneous binding to two or more chains may be implied.[95] Figure 8 shows data from Table 2 and theoretical curve from Equation (h), assuming that biological stability is inversely proportional to A, that is, stability $= A^{-1}$, for $K = 0.033$ and $k = K/10$. Of course, this simple picture gives no insights on the molecular level.

Yet another unanswered question is why the blood circulation times decrease with increasing liposome size. The liver hardly takes up liposomes larger than 200 nm, but uptake by the spleen increases, which suggests a different mechanism and/or mediator for these two organs. It is possible that small proteins of the complement system still bind to the liposome surface but that their interactions with the receptors in the spleen are compromised by the steric barrier, and that this interaction is size dependent. Alternatively, the binding of the protein may simply depend on the curvature of the liposome (which also defines the interactions between polymer chains and their mobility) or on

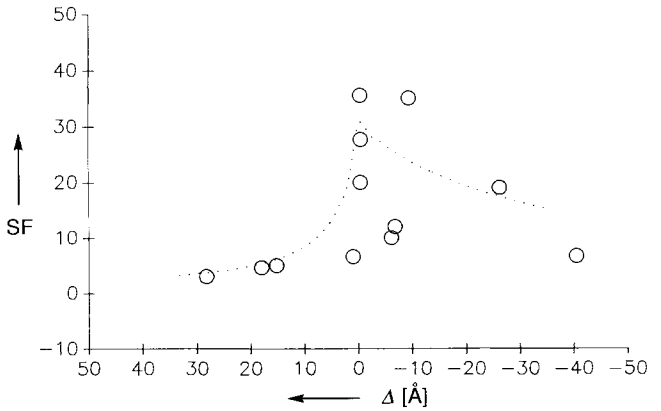

Fig. 8. Stealth factor SF as a function of the difference between the average separation of polymer grafting points D and the Flory radius R_F. Data points are from Table 2 and unpublished data from M. Newman and M. C. Woodle. The dotted line is a fit from the simple empirical equation, Equation (h).

rotational diffusion rate of the particle, and is therefore size-dependent.

This brings us to the final question: can we make an artificial colloidal particle comparable to erythrocytes, which circulate for 100 days and have SF values larger than 2000. Specific interactions, including those with molecules such as dysopsonins or histocompatibility complexes, must play a role, because, despite their sophisticated steric stabilization by glycocalyx, erythrocytes from one person cannot circulate in a person with a different blood group. A thick brush of 7.5 kDa polysaccharides on the red blood cell seems to be much more rigid and dense than the artificial polymer coatings.

7. Applications of Sterically Stabilized Liposomes

Sterically stabilized vesicles are suitable models for studies of polymers and scaling laws, colloid stability, and cell biology. Apparently in cells specific attraction and nonspecific repulsion play an important function, as in these vesicles. Therefore, sterically stabilized liposomes offer a much better model for the study of cell function and interactions than conventional liposomes, which can exhibit many nonspecific attractive interactions. In addition, the nonspecific repulsion of sterically stabilized liposomes offers several useful applications, mostly in diagnostics and drug delivery.

In addition to liposomes and other lyotropic colloidal particles, PEG-lipid molecules can stabilize other lipid structures as well. A typical example are foams. Due to the bulky polar heads, PEG-lipids in pure form do not form very stable foams. However, foams made from lecithins containing 5–10 mol% of PEG-lipids are extremely stable and refractory to the addition of the defoaming agent ethanol. While typical lecithin foams collapse within minutes, these foams can be stable for months. The stability is probably due to the reduced drainage of water because of the presence of well-swollen and immobilized polymer in the aqueous layer. At present, however, it is still too early to speculate on potential applications, such as coating of various surfaces with PEG-lipid-containing monolayers.

7.1. Medical Applications of Sterically Stabilized Liposomes

Stealth liposomes provide an entirely new and unique drug delivery vehicle because of their ability to evade quick clearance by the immune system. With such liposomes Ehrlich's idea (now almost one century old) of a magic bullet—a drug delivery system that would target only diseased cells—became practically possible. Indeed, early studies have shown increased delivery of antibody-labeled stealth liposomes to the target tissue in accessible sites. The accessible sites upon system administration are in vascular compartments,[96] at sites of increased vascular permeability (which occurs naturally at the sites of infections, inflammations, tumors, and other traumatic conditions, or can be induced artificially)[97–100] and upon localized administration in the peritoneal cavity and in the central nervous system compartment.[101] This is also the case in nontargeted stealth liposomes, which represent the majority of applications and will be discussed below. An unresolved problem is the delivery of the encapsulated drug into the cell, because most cells are not phagocytic, and fusion of liposomes and cells is a very rare phenomenon. One approach to overcome this difficulty is to promote fusion by surface-attached fusogenic proteins. Simpler ways include attempts to induce leakage of liposomes by changes in temperature or pH, or the preparation of liposomes with compromised stability.

Although this is one of the current hot issues in liposome research, several applications are not affected by lack of drug bioavailability.[2] For instance, the anthracycline anticancer drugs can be loaded at very high concentrations (normally 1 g drug per 7.5 g lipid, see Figure 9) and have elicited great improvements in therapeutic efficacy upon encapsulation into stealth liposomes. According to current understanding,[117] the prolonged presence of liposomes in blood allows them to extravasate into sites where the vasculature is leaky. This is often

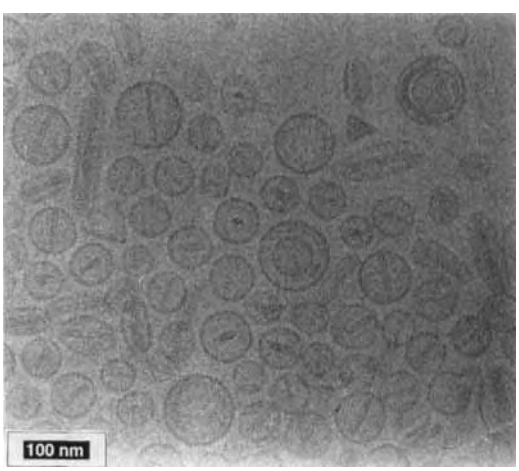

Fig. 9. Cryoelectron micrograph image of unilamellar vesicles with encapsulated drug. Doxorubicin can be encapsulated at very high lipid concentrations by using various gradients. We used an ammonium sulfate gradient in which weak base NH_3 (pK = 9.3) exchanges with weak base doxorubicin · HCl (pK = 8.3). When doxorubicin enters the liposome, its charged form precipitates with sulfate as counterion, and this molecular sink keeps the chemical potential gradient of doxorubicin unchanged until most of the drug is precipitated. This results in very high concentrations in the liposome interior. Solidification of the drug gives rise to peculiar changes in liposome shapes. I thank P. Frederik, University of Limburg, Maastricht for this picture.

the case in tumors,[97-99] and indeed, experiments with animals and humans have shown that the drug concentration in tumors on delivery with liposomes is ten times higher than on administration of the free drug.[102-105] In these cases, it seems that liposomes are trapped in the tissue, where they slowly release their contents either by leakage or upon degradation by enzymes such as phospholipases. This agrees with the observation that peak drug levels in tumors are observed three to four days after liposome administration as compared to a few hours for the free drug.[98] The peak concentration of the drug can be 10–30 times higher when the drug is encapsulated in stealth liposomes.[106]

Figure 10 shows the effect of various treatments on the tumor size in a C26 solid tumor mouse model, which is virtually insensitive to treatment with free adriamycin (= doxorubicin, "S-Dox") or with conventional liposomes containing the drug.[107] Animals treated with placebo liposomes and their mixture with free drug as controls did not show any significant effect over the untreated (that is, saline injected) animals. The administration of stealth liposomes containing adriamycin, however, resulted in complete remission of tumors on early treatment and in significant improvements on delayed treatment. Virtually identical results were obtained with the very similar drug epirubicin.[108]

Improvements were also achieved in other resistant tumor models, such as mammary carcinoma (Fig. 11). Adriamycin formulation was substantially more effective not only in curing mice with recent implants from various tumors but also in reducing the incidence of metastases originating from these intramammary implants.[109] The growth of human lung tumor xenografts in scid (scid = severe combined immunodeficient) mice was completely arrested by adriamycin formulation, while free drug and drug encapsulated in conventional liposomes were ineffective.[110]

The same extravasation mechanism of small liposomes at sites of leaky vasculature can be used in the treatment of inflammations and infections, which are also characterized by enhanced vascular permeability.[111]

While many new drugs are currently being monitored and tested for encapsulation into sterically stabilized liposomes, phase I and II clinical trials of doxorubicin encapsulated into stealth liposomes in humans have yielded very encouraging results. It was found that blood circulation times in humans, as measured by the plasma concentration of the drug, are around 45 hours. This results in reduced bone marrow suppression, neutropenia, and leucopenia, as well as shifted biodistribution of doxorubicin from the body into tumors, as in AIDS patients with Kaposi sarcoma.[103, 112] The measured concentrations of doxorubicin in these lesions were 11.4-, 5.2-, and 9.9-fold higher for injected doses of 10, 20, and 40 mg m^{-2}, respectively.[103] In contrast to the free drug for which the dose-limiting factors are acute myelosuppression (reduction of white blood cell count) and cumulative cardiotoxicity, the dose-limiting factor of the stealth liposome encapsulated drug is stomatitis, a skin disease—in this case lesions—inside the mouth.

As mentioned above, the property of sterically stabilized vesicles to avoid rapid uptake by liver and spleen made the concept of targeted liposomes feasible for in vivo applications. Currently much effort is devoted to this area in order that these vesicles containing drugs or markers and labeled with appropriate anti-

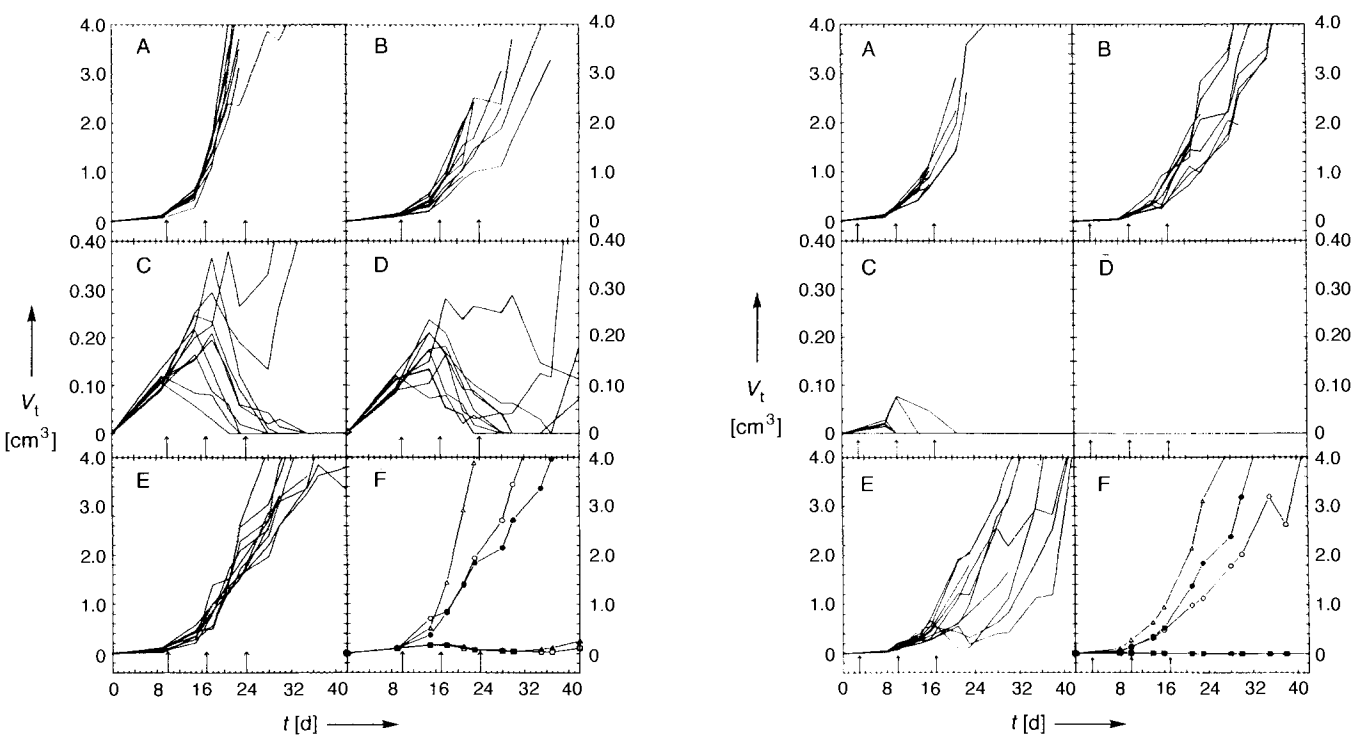

Fig. 10. The effect of the anticancer drug epirubicin on the growth of solid C26 tumor, which is practically resistant to conventional therapies: the graph shows the tumor volume (V_t) as a funtion of time t. Mice were injected with 10^6 C26 cells on day zero. Treatments were conducted (arrows) on days 3, 10, and 17 (left), or 10, 17, and 24 (right). Panels A–E show the tumor growth of ten animals for different treatments. A: saline (control); B: free epirubicin at 6 mg per kilogram body weight; C and D: epirubicin in Stealth liposomes at 6 mg kg^{-1} and 9 mg kg^{-1}, respectively; E: control (mixture of Placebo liposomes and free drug); F: averages of all these treatments—from left to right: saline, free drug, mixture, and overlapping the two liposome encapsulated drugs. (Note the different scale for C and D.) From ref. [102]. Virtually identical results were obtained with doxorubicin-containing Stealth liposomes [103].

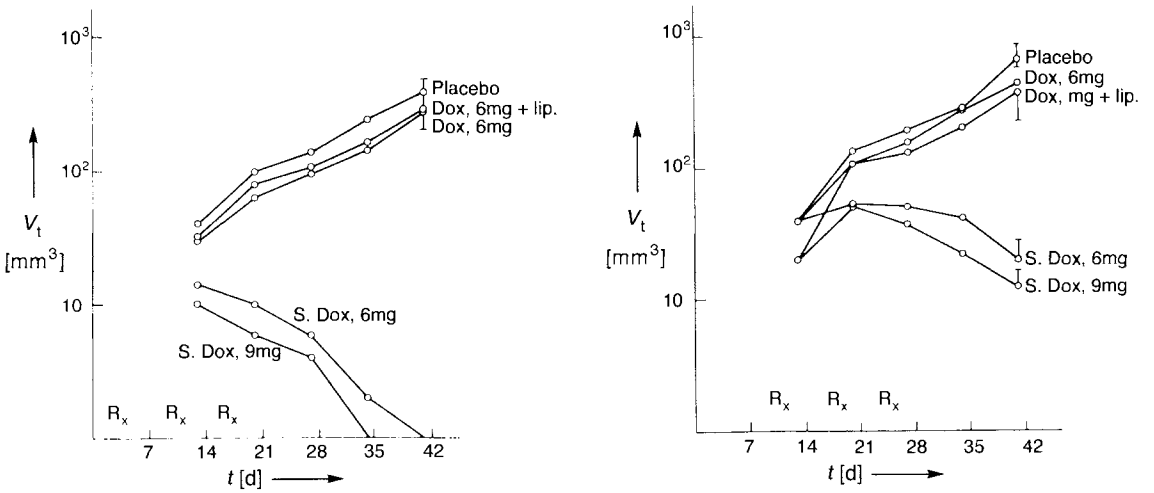

Fig. 11. Dependence of the tumor sizes (V_t) on time in mice with implanted mammary MC2B tumors (1 mm^3). The treatment (R_x) in the left-hand graph was on days 3, 10, and 17. For the right-hand graph treatment was delayed by one week (days 10, 17, and 24). The treatment included (from top to bottom) saline, mixture of free doxorubicin and placebo liposomes (6 mg kg^{-1}), free drug at 6 mg kg^{-1}, and doxorubicin encapsulated in Stealth liposomes at 6 and 9 mg kg^{-1} (from ref. [104]).

bodies and other ligands target cancer cells, atherosclerotic lesions and plaques, sites of ischemia, and some other traumatic areas.

8. Concluding Remarks

In conclusion, polymer-grafted liposomes and their applications show an interplay of various sciences, from theoretical polymer physics, colloid and interface science, organic chemistry, to biology, immunology, pharmacology, medicine, anatomy, and oncology. As a result very stable liposomes in biological environments were designed and showed remarkable therapeutic potential. The next goals are now to improve spatial and temporal control of the release of the encapsulated drug. Targeting can be improved in physically accessible sites by the attachment of antibodies to the far end of polymer chains. Better control of the temporal release of the drug will be tackled mostly by three routes: physical approaches use temperature, pH, or (target) binding-sensitive induced phase change, chemical approaches try to destabilize liposomes at a particular location by a chemical change of membrane-forming lipid and the formation of bilayers with fusogenic ability, and biological approaches employ surface-attached fusogenic molecules or stimulate internalization. For such a rational liposome design, of course, liposomes must be made from an appropriate bilayer matrix. We dare to conclude that sterically stabilized vesicles are an example of how complex and elusive problems can be solved by a multidisciplinary approach. For the continuation of this development even broader interdisciplinary work will be required.

Peptidomimetics—Tailored Enzyme Inhibitors

Joachim Gante*

Dedicated to Professor Hans Joachim Langmann on the occasion of his 70th birthday

Peptides and proteins (there is no clear boundary between the two classes of compounds) are absolutely essential components of organisms in many ways. While proteins have biocatalytic functions and are important components of tissues, peptides play an important role in the organism as hormones, neurotransmitters, and neuromodulators. Peptides and their analogues have long been used in medicinal chemistry as therapeutic agents for pathological conditions generally characterized by a disruption of the interplay between messenger molecules or enzyme substrates and their targets, the receptors and enzymes. For various biochemical and biophysical reasons there is an increasing tendency towards the use of chemical "Trojan horses" known as peptidomimetics. The chances that such agents are active generally increase with the magnitude of the "deceptive effect", in other words in proportion to the degree of conversion of a peptide into a non-peptide. Rational design has become a catchphrase which is at present applied frequently to the development of peptidomimetics. New computer programs are invaluable tools in such design processes. However, in spite of the many advances already made, we are still far from the final goal, the de novo design of peptidomimetics. Rational design is nonetheless advancing rapidly, and it is already clear that developments in the area of peptidomimetics have given a great boost to peptide chemistry as a whole. This can be expected to continue, so that in future peptide chemistry may be characterized by a type of symbiotic alliance between peptides and non-peptides.

1. Introduction

Over the years peptidomimetics[1] have become immensely important for both organic and medicinal chemists. In the biological, chemical, and pharmaceutical areas they offer interesting advantages over physiologically active peptides, which as active substances are crucial for the organism. Apart from increasing the effectivity and selectivity of peptides, which may decrease side effects, improving oral bioavailability and prolonging the activity by hindering enzymatic degradation within the organism are of particular importance.[2]

It is possible by combining computer graphics, modern NMR techniques, and X-ray structural analysis to design drugs by constructing and synthesizing tailor-made molecules, the structural spectrum of which lies between slightly modified peptides on the one side and pure non-peptides on the other. "Browsing" in peptide libraries[3] and the discovery of completely new non-peptidic structures in the course of empirical mass screening often provide new lead structures, which can in turn be subjected to structural variation in order to optimize the required properties of the active substance.

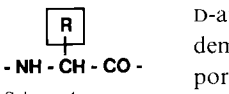
The synthesis of such compounds can require the use of the complete arsenal of synthetic organic chemistry. Thus modern peptide chemistry (which includes that of the mimetics) cannot rely only on traditional synthetic methods.

The generation of peptidomimetics is based primarily on the knowledge of the conformational, topochemical, and electronic properties of the native peptide and that of its address, in other words, the receptor or the active site of the enzyme with which it interacts. The design of peptidomimetics as potential bioactive substances must take particular account of two structural factors: 1) a favorable fit (total conformation) with respect to the corresponding complementary spatial situation at the active site; if necessary the conformation can be stabilized by the introduction of elements conferring rigidity; 2) the placement of certain structural elements (e.g. functional groups, polar and hydrophobic regions) in defined positions so that the required interactions (e.g. hydrogen bonds, electrostatic or hydrophobic interactions) can occur.

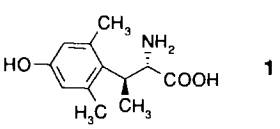
Thus for example in the case of enzyme inhibition both prerequisites require knowledge of the corresponding steric features of the enzyme–substrate complex and the mechanism of enzyme catalysis, that is, its modus operandi. The latter is a precondition for a specific course of action, since it may indicate which reactants are involved at which sites in the complex in a certain reaction. In addition the knowledge of the bioactive

conformation of an active substance is essential in drug design. Apart from spectroscopic methods (NMR) and X-ray structural analysis, computer modeling is an important tool in such studies.



This review has been written with the goal of further clarifying the basic features of drug design. The immense amount of material available makes it necessary to limit the discussion to a few characteristic and important examples. After discussing general structural and synthetic aspects, we will examine some current examples of the application of peptidomimetics in the area of therapeutically relevant enzyme inhibition. The effect of such active substances (e.g. CCK antagonists, angiotensin II receptor antagonists) on receptors has been described very recently in a review in this journal.[2b]

2. Structural Possibilities

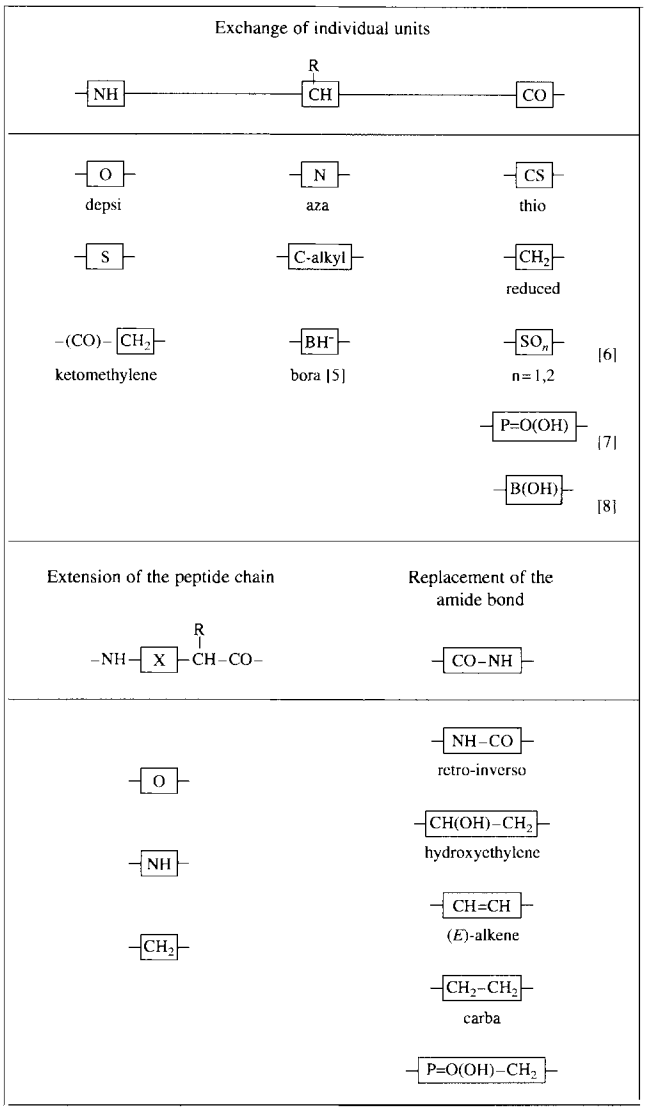


From a structural point of view peptidomimetics can be prepared by approaches ranging from the slight modification of the initial structure to the generation of a pure nonpeptide.

2.1. Modification of the Side Chains of Amino Acid Residues

One possible strategy for modifying the side chains of amino acids is the well-known practice of replacing natural by unnatural side chains and the exchange of L- for D-amino acids (Scheme 1). A recent example demonstrates that this procedure is still important today: modification of the tyrosine side chain by introducing methyl groups in the 2′-, 6′-, and β-positions hinders free rotation about the $C^{\beta}-C^{\gamma}$ bond and can thus favor the formation of bioactive conformations (**1**).[4]

Scheme 1.

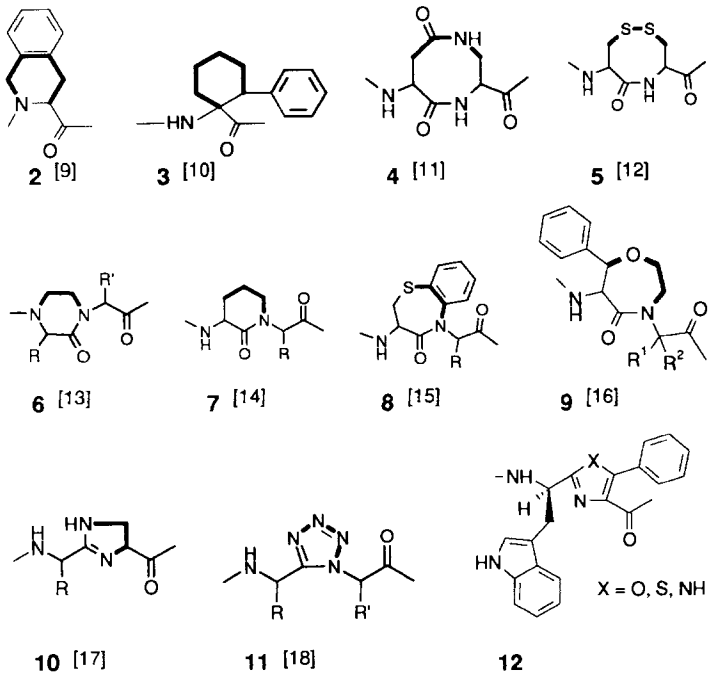


1

2.2. Modification of the Peptide Backbone

Modification of the peptide backbone refers to the generally isosteric or isoelectronic exchange of units in the peptide chain and the introduction of additional fragments.[2c] The most general modifications are listed in Table 1.

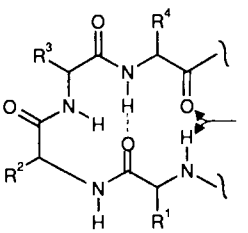
Table 1. The most frequent modifications to the peptide backbone.



Joachim Gante was born in 1933 in Berlin and studied chemistry at the Freie Universität in Berlin. He received his Ph.D. and "Habilitation" for his research on peptide-analogous azapeptides. In 1968 he joined E. Merck in Darmstadt, where he has directed research on peptidomimetics as potential pharmaceuticals and developed fundamental methods of peptide synthesis. He also has a professorship at the Technische Hochschule in Darmstadt, where he lectures on peptide chemistry.

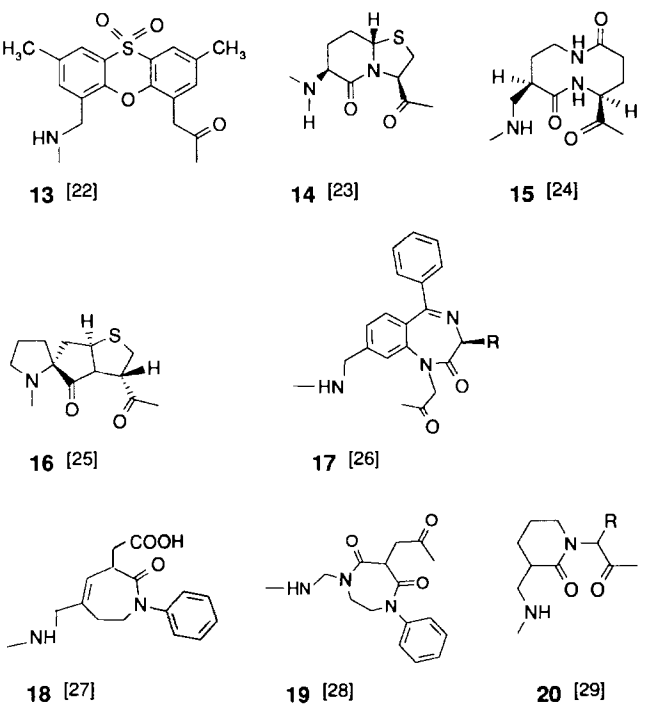
2.3. Conformation-Stabilizing Rings (Bridging)

The conformation of a peptide can be stabilized or fixed by the introduction of bridges of various lengths between different parts of the molecule; such elements make the molecule more rigid (Scheme 2). The bridging can either occur within a single amino acid residue as in **2** and **3**, or may involve several amino acid residues; in general two amino acid residues take part (dipeptide analogues). Bridges can be introduced at various sites and involve various backbone regions. The bridge can be a link between two side chains (as in **4** and **5**), between two backbone units (**6**), or between a side chain and backbone unit (**7**–**9**). In addition the peptide bond can be completely or exclusively incorporated into the ring (**10** and **11**).



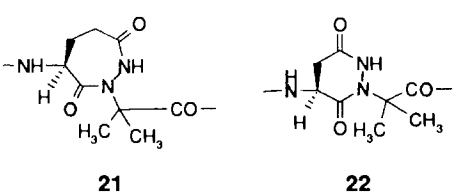
Scheme 2. Bridging in peptidomimetics.

Mimetics in which the peptide bond is involved also include peptide azoles like **12**, which have recently been the subject of an interesting article.[19] Hexapeptide analogues containing such units show a substance P antagonistic activity up to ten times higher than that of the original peptide.



2.4. Induction and Stabilization of Secondary Structures (β Turns, γ Turns, α Helices)

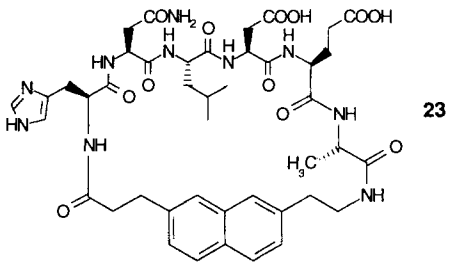
The retention of peptide secondary structures by mimetism is an important tool in drug research which is applied with the goal of fixing those bioactive conformations characterized to a high degree by such structural elements. In addition to α-helix and β-sheet structures, turns and loops are essential conformational components for peptides and proteins.[20] The apparently most important "turning point", the β turn, is formed from four amino acids and is stabilized by a hydrogen bond between the carbonyl group of the first amino acid and the NH group of the fourth (Scheme 3). A second hydrogen bond can further stabilize the β turn. A γ turn is formed in a similar manner from three amino acids.



Scheme 3. Structure of a typical β turn.

A few examples from the tremendous amount of available material (which has been surveyed in recent reviews[2a, 2b, 21]) demonstrate that the structural motifs range from still recognizable peptide chains to completely non-peptidic components (**13**–**20** in Scheme 4).

Scheme 4. Characteristic β- (**13**–**17**) and γ-turn mimetics (**18**–**20**).



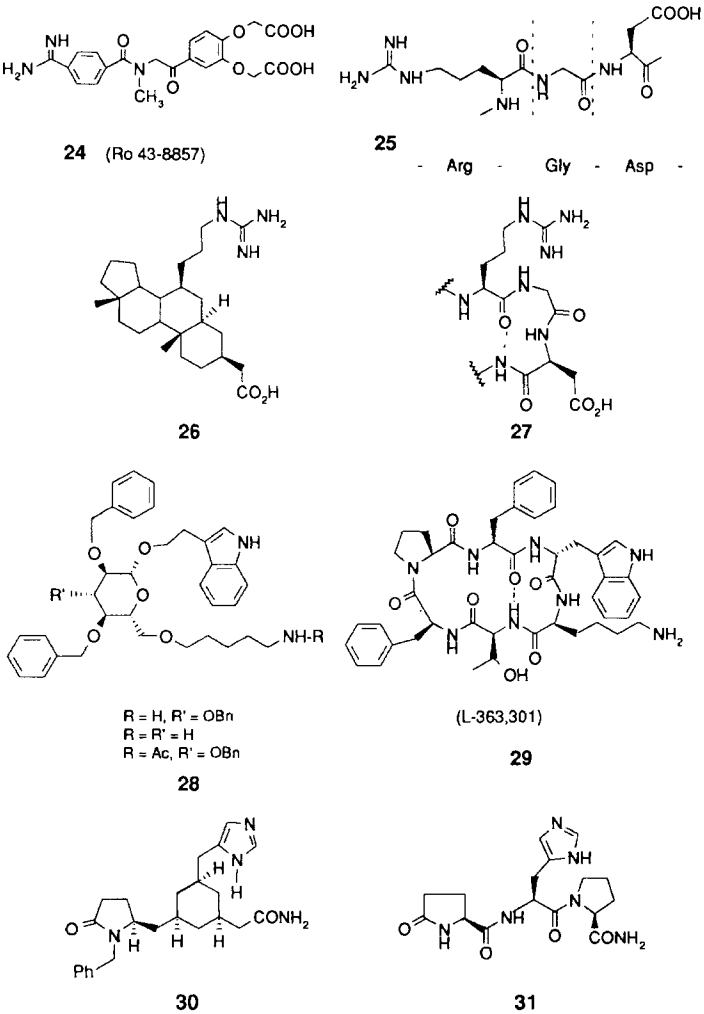
Whereas structure **13** can be used to produce two antiparallel peptide chains,[22a] the same tricyclic system has also recently been employed in the construction of β-sheet mimetics with corresponding parallel chains simply by changing the anchor groups.[22b] α-Helix initiators of the cyclic hydrazide type (**21** and **22**, Scheme 5) have recently been described.[30]

Scheme 5. α-Helix initiators.

A new Ω-loop mimetic has also been described recently.[31] Ω loops are larger, conformationally stabilized curves in a peptide chain which involve 6–16 amino acid residues. The Ω-loop

mimetic **23** mimics the sequence 41–48 in interleukin-1α, an important mediator in immunological and inflammatory processes.[32] Ω Loops are found in many proteins, where they can for example link β strands, and are generally anchored securely to the protein surface. They are considered to play an important role in biological recognition. It has been demonstrated that Ω loops are also involved (by complexation) in trypsin inhibition.[33]

23



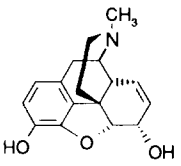
2.5. Scaffold Peptidomimetics

In scaffold mimetics a completely unnatural framework is used to support those side-chain elements of the original peptide which are responsible for its effectiveness. Compounds of this type appear particularly interesting with regard to their potential oral bioavailability, which is a serious general problem for peptides. It is therefore only logical to use frameworks or structural elements based on natural products or drugs whose oral resorption is established. The relative conformational rigidity of such systems is also important, as it often prevents the hydrophobic collapse[34] of a partial structure to afford an inactive conformation (see Section 6).

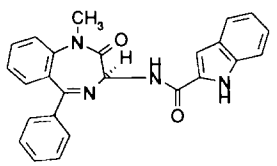
A number of important scaffold mimetics are shown in Scheme 6. Compound **24**, a mimetic of the partial sequence Arg-Gly-Asp (RGD) (**25**) in fibrinogen, is a potent adhesion receptor (GpIIb/IIIa) antagonist (it prevents thrombocyte aggregation), and carries the end groups vital for its activity (amidine, carboxyl substituents) in the correct positions.[35] While in **24** the framework still shows peptidic features, compound **26** is a typical scaffold mimetic, whose steroid skeleton bears the appropriate groups. Interestingly, it does indeed show GpIIb/IIIa-antagonistic activity, albeit weak.[36] As is evident in Scheme 6, this mimetic is able to imitate an β turn in the area of the RGD sequence of **27** apparently relevant for activity.

β-D-Glucose serves as the scaffold for mimetics such as **28** of the cyclic hexapeptide **29**, which has been known for some time to bind to the somatostatin receptor.[37] A remarkable feature of these β-turn mimetics is that changes in their concentration cause them to function as either agonists or antagonists towards the relevant receptor. Amazingly, acetylation leads to an umpolung, giving a selective substance P (SP) antagonist, which is the very first neutral effector of this type to be described.[38]

Compound **30**[39] is an effective analogue of the tripeptide thyreotropin releasing hormone (TRH) **31**.

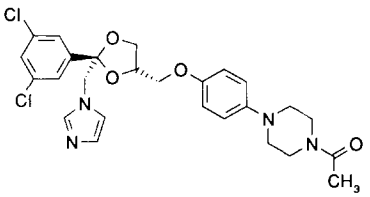


Scheme 6. Characteristic scaffold mimetics (left) and the original peptides (right).



2.6. Non-Peptide Mimetics

Non-peptide mimetics have generally been discovered in the course of random screening of large numbers of substances, which include culture filtrates of microorganisms and fungus metabolites. These mimetics belong to various classes of organic compounds and have no apparent structural relationship with the natural peptide ligands. The term limetics (from ligand mimetics) has been coined for this group of peptidomimetics.[40] The wide variety of structures is demonstrated by compounds **32**–**36** (Scheme 7).



Extremely successful drug design was carried out with the help of computer modeling for the series of angiotensin II antagonists of the type DuP 753 (**36**).[45] The highly active structure **37** was optimized systematically from a series of similar compounds by superposition on the presumed bioactive conformation of angiotensin II (AII, **38**) (Scheme 8). For example, the suggested superposition of the structures indicated that the butyl group in **37** corresponds spatially to the Ile^5 side chain of **38**. The N-C-N unit of the imidazole and the acrylate double bond in **37** both mimic peptide bonds, while the thienyl group takes the place of the Phe^8 phenyl ring. Compared with the corresponding mimetic containing a phenyl ring, this hetero-

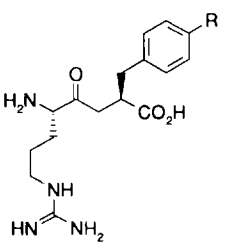
Scheme 8. Superposition of the calculated conformation of **37** and that of angiotensin II (**38**).

cyclic compound leads to an increase in the binding strength by a factor of 5 and to an increase in the activity subsequent to oral administration. More recently it has been possible on the basis of the data referred to above to develop a refined angiotensin II model with a greater congruence of structurally more diverse A II antagonists.[46]

The further development of the oxytocin antagonists related to compound **35** (cf. Scheme 7) has led to a number of compounds including **39**, which has an IC_{50}-value of less than 10 nM.[47]

39

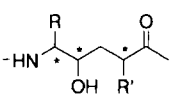


3. Synthesis of Peptidomimetics

The synthesis of peptidomimetics is often much more complicated than peptide synthesis especially as the degree of mimetism increases. On the one hand, it is not generally as simple to increase the chain length of the mimetics as that of peptides, and on the other, it is no longer possible to take advantage of the chiral pool of optically active amino acids. Instead the defined stereochemistry corresponding to the endogenous peptide must be set. The complete arsenal of methods provided by organic chemistry is required for the variety of structures of peptidomimetics. The synthetic possibilities will be demonstrated below with some examples from the area of backbone-modified peptides.

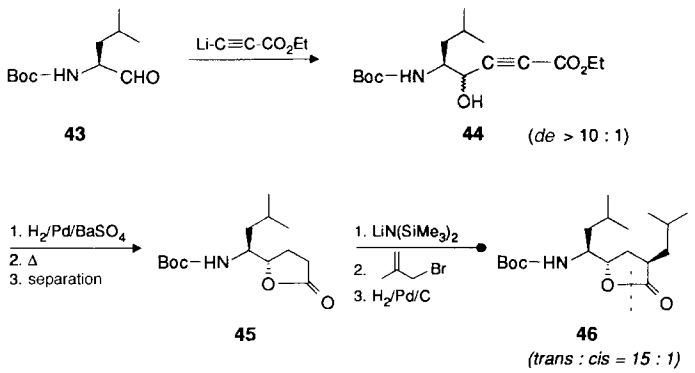
3.1. Carbapeptides

One of the classes of backbone-modified peptides most often studied is the carbapeptides. Strictly speaking carbapeptides are those in which the NH unit of the amide bond is replaced by a CH_2 group (ketomethylene, (Ψ(CO-CH_2)). According to a broader definition this class also includes hydroxyethylene (Ψ(CHOH-CH_2)) and carba (Ψ(CH_2-CH_2)) modifications (see Table 1). Ketomethylene[48] and hydroxyethylene[49] peptide analogues play a role particularly in the chemistry of enzyme inhibitors;[50] compounds containing dipeptide-analoguous hydroxyethylene groups are among the most active inhibitors of renin[51] and HIV-1 protease[52] (see Sections 5.2.1 and 5.5).



Ketomethylene analogues have in fact even been found to occur naturally! Umezawa et al. have isolated the arphenamines A (**40**) and B (**41**), potent inhibitors of arginyl aminopeptidase, from *Chromobacterium violaceum*, determined their structures, and recently synthesized them.[53] These compounds are of considerable therapeutic interest, for example as immunomodulators, opioid peptide degradation inhibitors, and carcinostatics.[54]

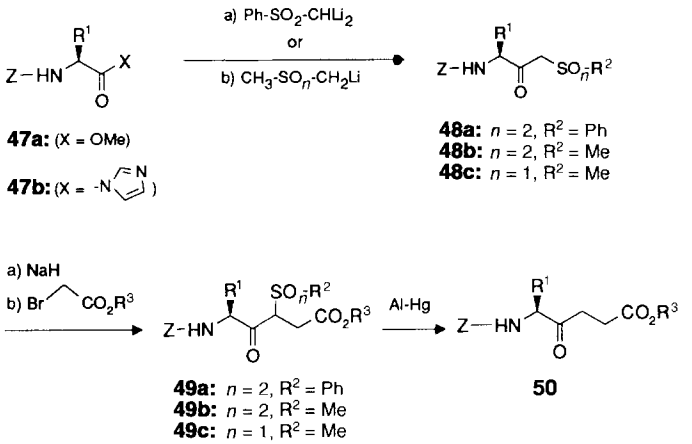
40 (R = H)



41 (R = OH)

Synthetic approaches for Ψ(CHOH-CH_2) dipeptide analogues have been described in a recent review.[49] In the construction of the the α-substituted hydroxyethylene unit **42**, controlled stereochemistry at all three stereocenters is of particular importance. The starting material is an enantiomerically pure amino acid derivative (from the chiral pool), so that stereoselectivity is preprogrammed.[49, 55]

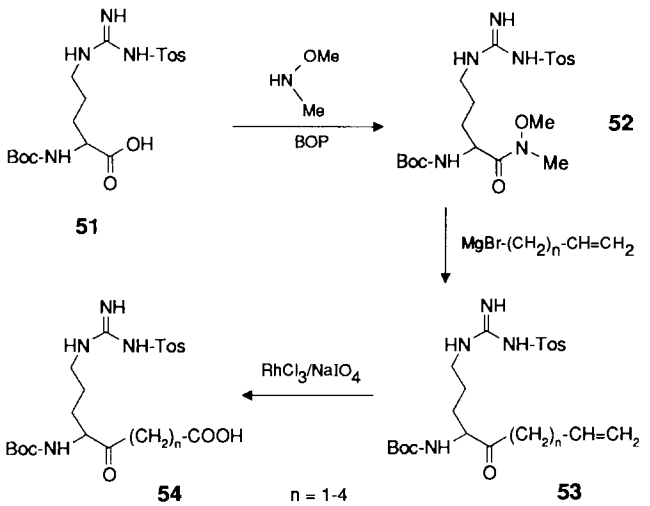
42



A relatively elegant synthesis (Scheme 9) starts from the Boc-protected amino aldehyde **43**, which is treated with the lithium derivative of ethyl propynoate to give **44**. Hydrogenation gives lactone **45**, which in turn is metalated and treated with methallyl bromide. Final hydrogenation affords the α-substituted lactone **46**,[56] which can undergo ring-opening with nucleophiles (OH^-, NHR) to give the linear peptide analogues. In a more

Scheme 9. Synthesis of hydroxyethylene dipeptide units according to Fray et al. [56]. Boc = *tert*-butoxycarbonyl.

recent synthesis, which also starts with aldehydes but leads only to the α-unsubstituted products, titanated propionates are used as homoenolate components.[57]

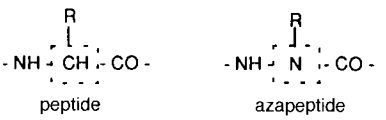


Interesting new aspects of the synthesis of ketomethylene peptide analogues have resulted from the use of β-ketosulfones **48a,b** and -sulfoxides **48c**, which can be obtained from the respective reactions of protected amino acid esters and imidazolides **47** with lithiated phenyl methyl sulfone[58] or with lithiated dimethyl sulfone and dimethyl sulfoxide[59] (Scheme 10). Metalation of **48** and reaction with bromoacetates yields **49**, and subsequent reductive desulfurization affords the corresponding carba-Gly dipeptide analogues **50**.

Scheme 10. Synthesis of ketomethylene dipeptide units according to Lygo [58] and Gante et al. [59]. Benzyloxycarbonyl (Z) or Boc groups are used as protecting groups.

It has been shown[59] that an α substituent can be introduced by using a branched α-bromocarboxylate. With enantiomerically pure halogen compounds, which are readily available from the chiral pool of amino acids, it should be possible to obtain stereoisomerically pure analogues of almost all the natural amino acids. This approach has also been shown to be suitable for the preparation of $\Psi(CH_2\text{-}CH_2)$ and $\Psi(CH{=}CH)$ dipeptide analogues.[58]

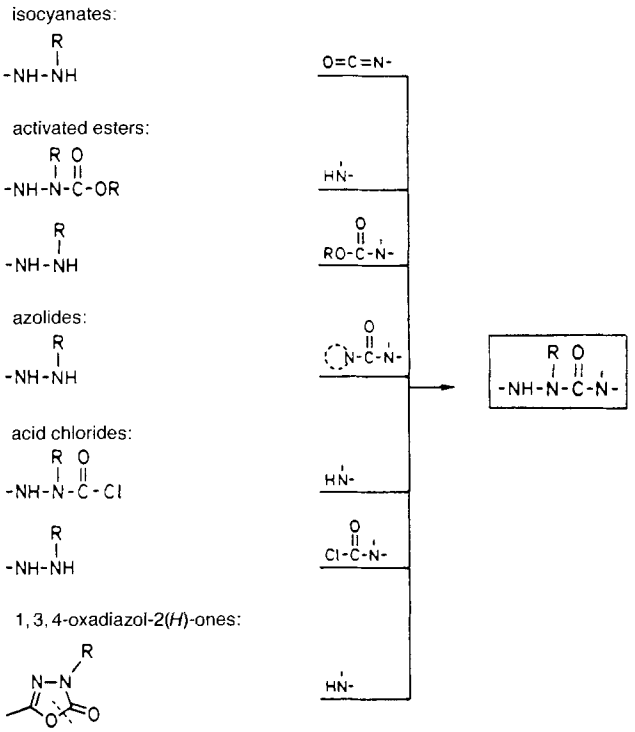
A different procedure is employed for the synthesis of ketomethylene analogues of arginyl dipeptide derivatives, which have been shown to be extremely efficient and protease-resistant thrombin inhibitors (see Section 5.3)[60] (Scheme 11). The *N,O*-



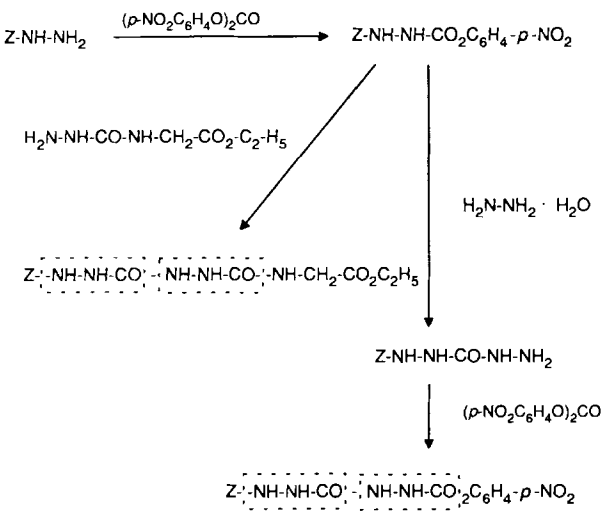
Scheme 11. Synthesis of ketomethylene analogues of arginyl dipeptide derivatives according to DiMaio et al. [60]. Tos = tosyl.

dimethylhydroxamic acid derivative **52**[61] prepared from the protected amino acid **51** was converted by a Grignard reaction into **53**, and subsequent Sharpless oxidation[62] provided the required carboxylic acid **54**. An improved synthesis of the precursors for arginyl dipeptidomimetics using N-α-Boc-Arg-Z_2 has recently been reported.[63]

3.2. Azapeptides

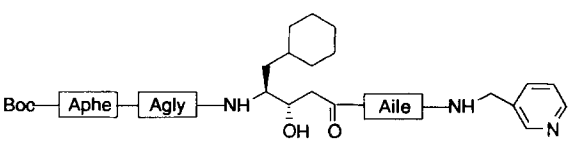


Another class of backbone-modified peptides that has become important in pharmaceutical chemistry is the azapeptides.[64] In these peptide analogues the α-CH group of one or more amino acid residues in a peptide chain is replaced isoelectronically by a nitrogen atom with retention of the original side chain (Scheme 12).



Scheme 12. Azapeptides formed by the isoelectronic exchange of an α-CH group in a peptide chain by an N atom.

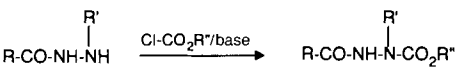
Since N-N(R)CO units are generally components of substituted semicarbazides (C-terminal azaamino acid esters are exceptions), the construction of azapeptides from substituted hydrazines or hydrazides by the formal introduction of a carbonyl group between two nitrogen atoms can be carried out very simply. The various possibilities for the synthesis of these azaamino acid residues[64] are shown schematically in Scheme 13. Azapeptides can also be prepared by the direct linkage of azaamino acids in any particular order, such that in principle any "pure" azapeptide should be available by repetitive synthetic sequences, as shown in Scheme 14 for C-terminal activated esters.[65]



The first analogue of this type of a biologically active compound (**55**, Scheme 15) has recently been described; here all the

Scheme 13. Synthetic strategies for azapeptides.

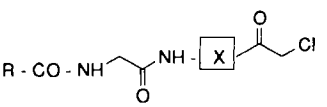
Scheme 14. Direct linkage of azaamino acid residues.



55

Scheme 15. The three-letter code for the amino acid is preceded by an A to denote the corresponding azaamino acid [67].

aza groups were connected by use of the nitrophenyl ester method.[66] In contrast to the native peptide, which is a highly active renin inhibitor,[68] and the previously synthesized compounds with only one azaamino acid residue (Aphe,[69] Agly,[70] or Aile[71]), this all-azapeptide **55** has no inhibitory effect on renin, probably for conformational reasons.

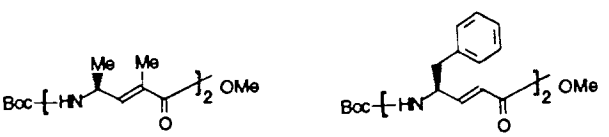


Gray et al. recently showed that longer chain azapeptides can also be obtained by solid-phase synthesis by incorporation of azaglutamine residues into poliovirus and adenovirus polyprotein sequences.[72] C-terminal azaamino acid esters **57** can be readily obtained by reaction of the corresponding hydrazides **56** with chloroformates[64b, 65, 67, 73] (Scheme 16). Aza-

56 **57**

Scheme 16. Synthesis of C-terminal azaamino acid residues. R = amino acid or peptide residue, R′ = H, alkyl, benzyl, R″ = alkyl, aryl.

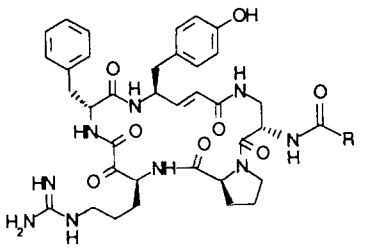
peptides of this type are extremely interesting and therapeutically relevant inhibitors of serine and cysteine proteases.[67] The same is true for the aza analogues **58** of the amino acid chloromethyl ketones **59**, which in analogy with the aza esters **57** can be prepared by simple hydrazine acylation.[74]



58: X = NH
59: X = CH_2

4. Recent Modification Principles

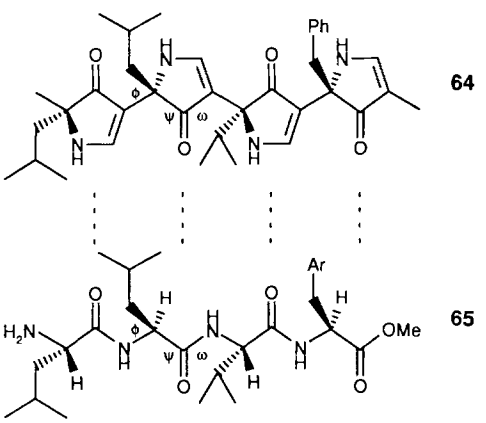
In the study of peptidomimetics three newer directions of development are worthy of mention because of their interesting application possibilities, in particular for backbone-modified peptides; these are the use of vinylogous amino acids as building blocks, special oligopyrrolinones, and the novel peptoid principle.



4.1. Vinylogous Peptides

Vinylogous peptides, which are not true peptide isosteres and are conceptionally related to hexose-DNA, can form secondary structures similar to those of peptides. This makes them interesting as potential receptor and enzyme ligands. Thus the X-ray crystal structure of **60**, which contains α-methyl groups, exhibits an antiparallel β-sheet structure, whereas **61** has a corresponding parallel structure.[75]

60 **61**

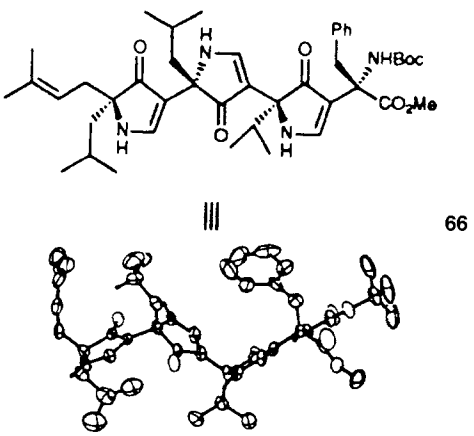


Such peptide analogues do indeed occur naturally: the marine sponge *Theonella* was found to have the cyclic peptidic structures cyclotheonamides A (**62**) and B (**63**), which contain vinylogous tyrosine, and a further unusual amino acid, α-ketoarginine.[76] These natural products inhibit thrombin, an important enzyme in the blood coagulation cascade, and are thus of interest in medicinal chemistry as potential antithrombotics (see Section 5.3).

62 R = H
63 R = Me

4.2. Oligopyrrolinones

Observations on the relevance of β-strand conformations for the binding of inhibitors to proteolytic enzymes and molecular modeling studies have led recently to the concept of a new type of peptidomimetic system in which a greatly modified backbone is integrated into cyclic structures (which are again vinylogous amino acids) to produce oligopyrrolinones.[77] Scheme 17



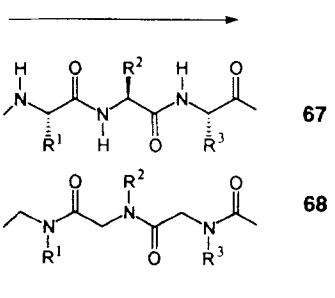
Scheme 17. Comparison of the structures of oligopyrrolinone **64** and peptide **65**. Ar = aryl.

shows a section (**64**) of the chain of such a compound and a corresponding tetrapeptide fragment from equine angiotensinogen (**65**), which has been demonstrated to have a parallel β-sheet structure in the crystalline state. The mimetic contains all the features necessary for the formation of an analogous secondary structure: not only the dihedral angles ϕ, ψ, and ω, and the orientation of the side chains are completely appropriate, the structural preconditions for the formation of the hydrogen bonds necessary for the construction of β-strand conformations are also present.

Although the chain is completely atypical and the various amino acid residues are arranged orthogonal to the chain, the orientation of the amine and carbonyl groups in the vinylogous peptide corresponds almost exactly to that in the peptide. In addition, even though the vinylogous pyrrolinone NH groups do not form part of the backbone, they are about as basic as the amide group, and are thus able to stabilize β conformations by intra- and intermolecular hydrogen bonds.

The results of model studies were confirmed to a large extent by the synthesis of compound **66** (Scheme 18). The X-ray structures of **65** and **66** confirm the spatial overlap between the side chains and the carbonyl groups. It is also evident that **66** forms an antiparallel β-sheet structure, which demonstrates clearly that the pyrrolinone N atoms act as H-bond donors between the strands of the desired β conformations.

66



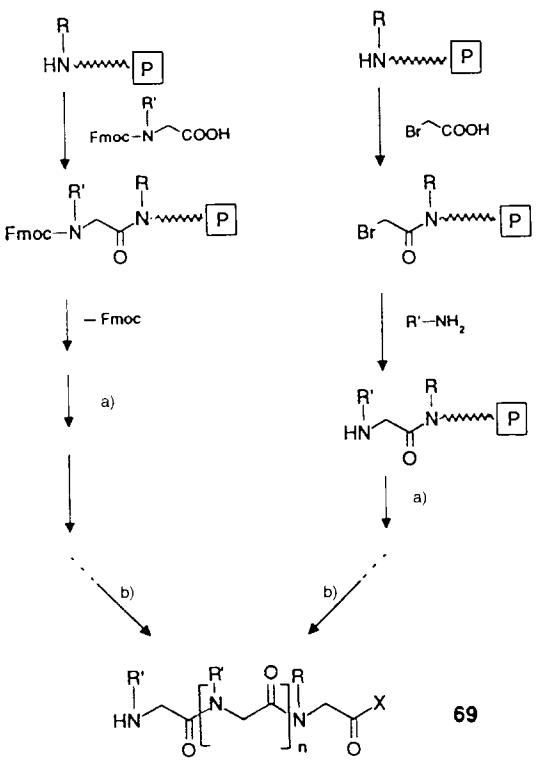
Scheme 18. Structural formula and X-ray crystal structure of **66**, an oligopyrrolinone unit.

The synthesis of these peptidomimetics is particularly relevant, because the iterative construction of the chain by a repetitive reaction sequence is thus possible.

4.3. Peptoids

The recently described oligomeric peptide analogues called peptoids are extremely interesting.[78] These compounds contain *N*-alkylated glycines joined together in a peptide-like manner, in which the α-CHR groups have been replaced by NR units (the aza principle), and conversely, the NH groups (of the peptide bond) by CH_2 units (the carba principle). The positions of the side chains and carbonyl groups of the original peptide chain **67** remains unchanged, as can be seen from the comparison with the peptoid chain **68** (Scheme 19).

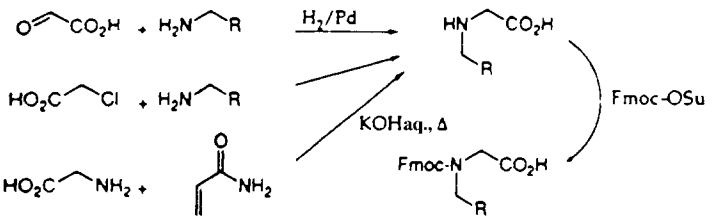
The amino acid sequence in the peptoids is opposite to that in the peptides. This aspect of the peptoids is reminiscent of the retro-inverso peptidomimetics, which have been known for some time and which have recently been reviewed in detail.[79] Peptoids are not chiral, since the side chains corresponding to the normal amino acids are attached



67

68

Scheme 19. Comparison of segments of peptide (**67**) and peptoid chains (**68**).



to the N atoms and only achiral CH_2 groups are present instead of NH groups. Most of the peptoid amino acids have been prepared; the oligomers can be obtained from the corresponding monomers in any required chain length by using the solid-phase method with Rink amide resin.[80] Two procedures are used: *N*-alkyl glycines protected at the amino group and side chain functionalities (e.g. by 2-fluorenylmethoxycarbonyl (Fmoc) or *t*Bu) are coupled, either automatically or manually, to the NH_2 groups at the end of the polymer by using the coupling reagents benzotriazol-1-yloxy-tris-(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) or bromo-tris(pyrrolidino)phosphonium hexafluorophosphate (pyBrOP);[78a] alternatively, the corresponding polymeric bromoacetyl compounds undergo repetitive reactions with the necessary amines (submonomer solid-phase synthesis) to give **69**[78b] (Scheme 20).

Scheme 20. Solid-phase synthesis of peptoids. R = R′ = H or protected side chain; X = NH_2, OH; $n \leq 23$; P = polymer resin. a) The reaction sequence is repeated n times; b) the peptoid is deprotected and cleaved from the resin.

With the newer procedure protecting groups for the NH_2 functions are not required and the monomer does not have to be prepared in advance, since the subunits are generated directly on the resin. The protected monomeric glycines can be obtained readily (Scheme 21).

Conformational studies (Ramachandran plot,[81] molecular modeling) show that peptoids have much greater conformational flexibility than the peptides. The absence of CO–HN hydrogen bonds (no NH groups are present in the peptoid chain!) naturally affects secondary structures. As experiments have demonstrated, peptoids are not degraded by important proteolytic enzymes such as papain, chymotrypsin, and thermolysin. This has important implications for the development of orally active drugs.

Scheme 21. Synthesis of peptoid monomers [78a]. The residue R is protected.

Initial studies showed that peptoid analogues of biologically active peptides can be as effective enzyme inhibitors as the original peptides. Thus the activity of analogues of Ac-Trp-Arg-Tyr-OMe (inhibition constant $K_i = 100$ μM), an α-amylase inhibitor, is comparable with that of the native compound, but the retro sequence Ac-Nhtyr-Narg-Nhtrp-NH_2 ($K_i = 200$ μM) shows a higher activity than the "forward" sequence Ac-Nhtry-Narg-Nhtyr-NH_2 ($K_i = 350$ μM).[*]

As another example, the peptoid sequence analogous to the peptide Ac-Glu-Leu-Ala-Thr-Gln-Ser-Phe-Ser-NH_2, which inhibits the 3C-protease of hepatitis A virus, shows inhibition only if the retro sequence is used; the magnitude of the inhibition is approximately the same as that of the original peptide. The observation that peptoid analogues of peptide sequences from the HIV tat protein also bind to TAR-RNA may have ramifications for AIDS research.

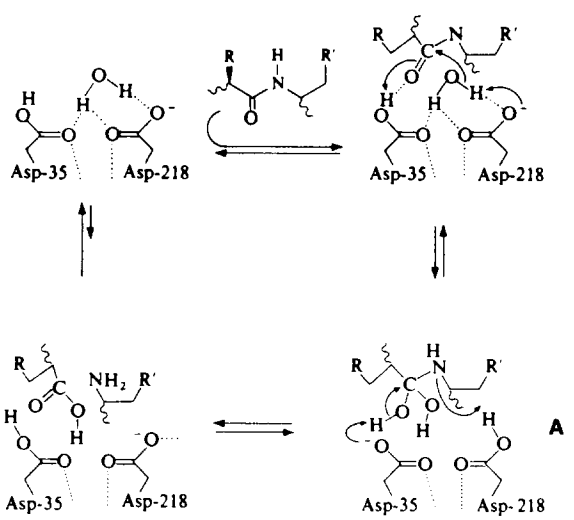
The greatest potential of the peptoids may however lie in peptoid libraries, analogous to peptide libraries, which may be prepared by automated multiple syntheses. These libraries should facilitate the discovery of new non-peptidic lead structures by simultaneous screening.

5. Enzyme Inhibition by Peptidomimetics

5.1. Introduction

As already mentioned, enzyme inhibition[82] is another highly topical area of application for peptidomimetics in addition to interactions with receptors.[2b] Proteases[83] naturally offer an attractive field of study for peptide analogues because of the sequential structure of their substrates. Proteases are essential to numerous biological processes and have a wide variety of functions. Thus certain proteases can liberate peptide hormones and neuromodulators from inactive precursor molecules (e.g. renin, angiotensin converting enzyme (ACE)), others activate other enzymes (e.g. blood clotting factors), and still other peptidases (e.g. enkephalinase) repress biological response by degrading the corresponding messenger peptide.

It is not surprising that such enzymes are regulated by endogeneous protease inhibitors to ensure optimal performance.[84] It is clear that it may be possible with the aid of exogeneous inhibitors of such enzymes to intervene when the biological equilibrium of this kind is pathologically disturbed. The goal is to construct inhibitors that exhibit a strong (reversible or irreversible) binding to the enzyme and thus compete with the nat-



[*] Peptoid nomenclature: the three-letter code for the relevant amino acid is preceded by N or Nh for the (side-chain) homologue.

ural substrate. The activity of an inhibitor is due to the degree of the displacement of the substrate from the active site.

Since detailed knowledge of the way the enzyme works is often extremely important for the design of effective peptidomimetics of this type, we will briefly give a classification of the proteases according to their mechanism of action. Proteases can be divided into four groups; in Table 2 several examples are given for each case.[82b] In serine proteases the hydroxyl group in the side chain of a serine residue acts as a nucleophile in the active site.[85] Cysteine proteases contain a cysteine SH group near a histidine imidazole ring as a mechanistically essential element of the active site.[86] Aspartyl proteases use the β-carboxyl groups of two aspartic acid residues at the catalytic center to stabilize the tetrahedral transition state for the hydrolytic cleavage of a peptide bond[87] (Scheme 22). A tetrahedral transition state is also involved in the mechanism of action of certain metalloproteases that have a Zn ion at the binding site. The Zn ion complexes a molecule of water and and also acts as a Lewis acid in the activation of the NH–CO bond to be cleaved.[88]

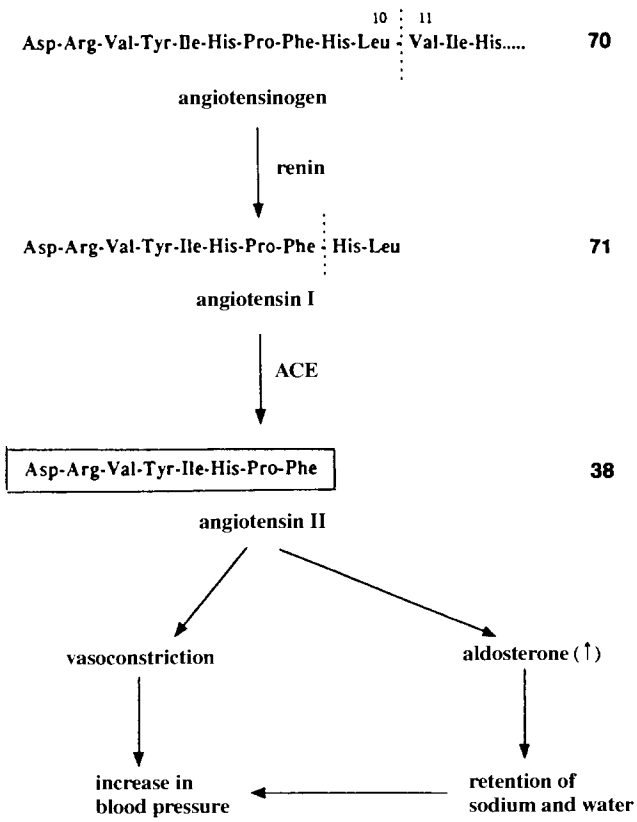
Scheme 22. Mechanism of catalysis for aspartyl proteases. A denotes the tetrahedral transition state.

Proteases are also classified according to their substrate specificity, in other words, their ability to recognize and cleave peptide bonds either adjacent to certain amino acids or within certain characteristic amino acid sequences.[82b] For this purpose recognition sites exist within the enzyme which correspond to certain positions in the substrate or inhibitor.

To characterize the cleavage site of a substrate, the amino acid sequences are numbered starting from this site in the direction of both the N-terminus and the C-terminus, according to a scheme proposed by Schechter and Berger.[89] The cleavage site is denoted as the P_1-P'_1 position and corresponds to the S_1-S'_1 position of the enzyme (Scheme 23).

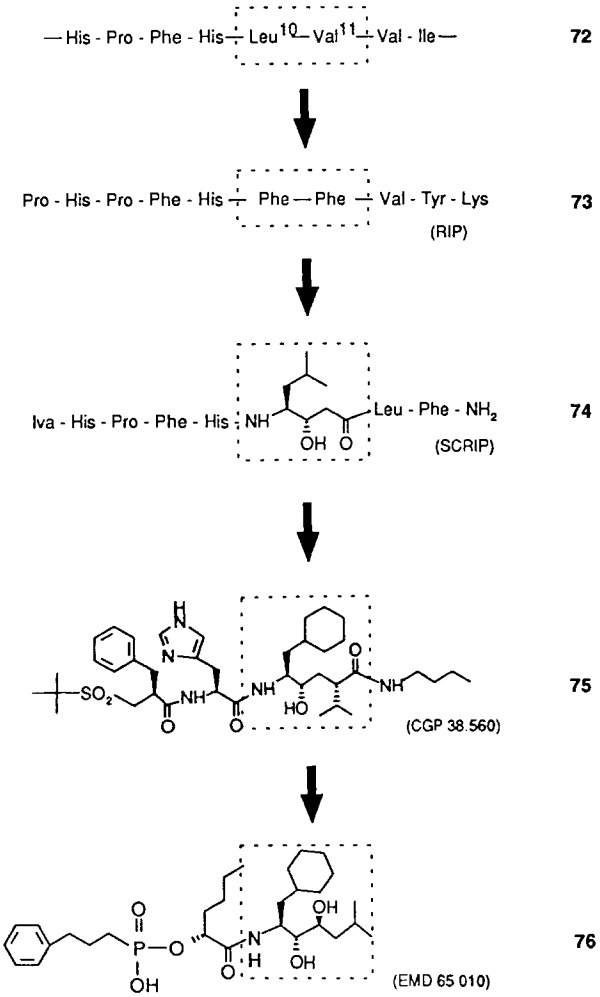
Scheme 23. Definition of the nomenclature used to describe the specificity of a protease according to Schechter and Berger [89]. The amino acid residues of the substrate are designated P or P', the corresponding residues in the enzyme S or S'. In the structural formula the cleavage site is marked by an arrow and is the starting point for the numbering of the sequence. The N-terminus of the substrate is labeled with an N, the C-terminus with a C.



5.2. Influencing the Renin–Angiotensin System

One of the most important therapeutic applications for enzyme inhibitors is influencing the renin–angiotensin system (RAS). This complex includes both the renin inhibitors[90] and the inhibitors of the angiotensin converting enzyme (ACE).[91]

The RAS is characterized by a sequence of enzymatic reactions, the last of which releases the octapeptide angiotensin II (A II, **38**)), which has strongly hypertensive properties. Therapeutic efforts are targeted towards lowering the A II level in order to reduce an A II-dependent, pathologically increased blood pressure to a normal value. As can be seen from Scheme 24, this goal can be achieved by intervention at various positions.



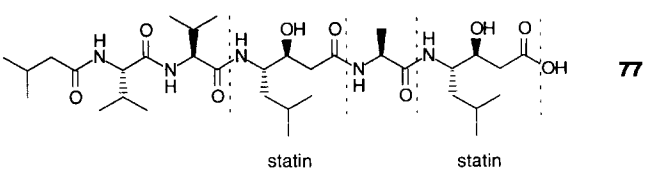
First the globular protein angiotensinogen (**70**) is cleaved by renin, an aspartyl protease that occurs mainly in the kidneys, between the amino acid residues Leu^{10} and Val^{11} to give the biologically inactive decapeptide angiotensin I (A I, **71**). Thus inhibition of this enzyme makes it possible to influence the formation of A II as early as this point in the cascade.

In a second step A I (**71**) is cleaved by the metalloprotease ACE; a dipeptide unit is split off to give the octapeptide angiotensin II (**38**). This is the stage at which the ACE inhibitors intervene to lower the A II level.

Scheme 24. RAS cascade: release and physiological effects of angiotensin II (**38**).

A completely different method of influencing A II is blockage of the A II receptor by A II antagonists; the formation of A II is not influenced here (see Section 2.6).

Scheme 25. The development of renin inhibitors.



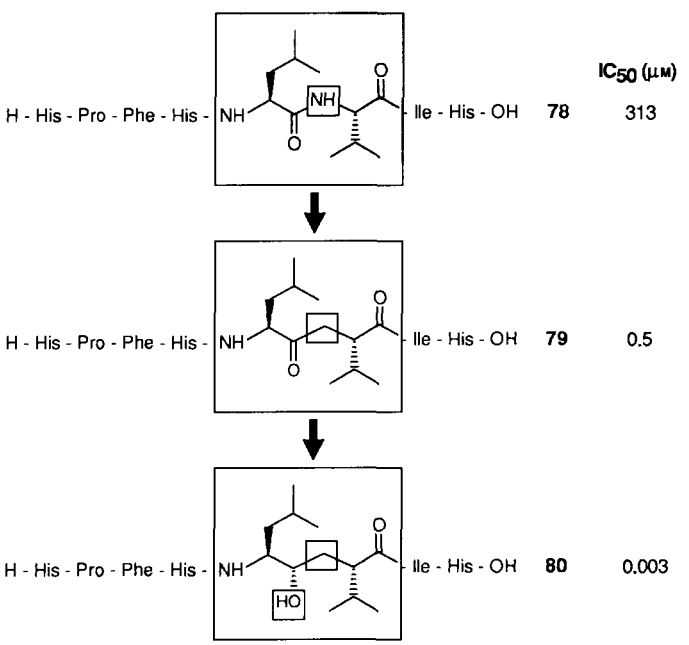
5.2.1. Renin Inhibitors

The continuous development of renin inhibitors based on the natural substrate angiotensinogen (**72**) starting from a pure peptide and progressing to true peptidomimetics is demonstrated by the compounds shown in Scheme 25. This sequence of structures shows the course of development starting from an analogue of the substrate angiotensinogen, **73** (RIP = renin inhibiting peptide),[92] to the transition state analogue **76**,[93] which has almost nothing in common with the original peptide structure.

The inhibitor properties of compound **73** are caused by the exchange of the Leu-Val fragment in the P_1-P'_1 position of the human angiotensinogen fragment **72** by Phe-Phe, which renders the octapeptide no longer cleavable by renin.

A considerable increase in the activity of the renin inhibitors was made possible by the application of the transition state analogy principle.[94] In such analogues the P_1-P'_1 position is modified by replacing the two amino acids by a dipeptide-analogous unit containing an sp^3 hydroxymethylene group in place of the carbonyl group of the amide bond in the center (**74**, SCRIP = statin containing renin inhibiting peptide).[95] This group thus mimics the tetrahedral transition state for the hydrolysis of the natural substrate (see Scheme 22).

The idea of using such residues arose from the observation made by Umezawa et al.[96] that the peptidic aspartyl protease inhibitor pepstatin (**77**) isolated from microorganism culture filtrates can interfere in the RAS mechanistically because of the γ-amino-β-hydroxycarboxylic acid statin it contains. The transition state analogue binds much more effectively to the enzyme, and the persistence of the inhibitor at the binding site is increased by its enzymatic inertness.



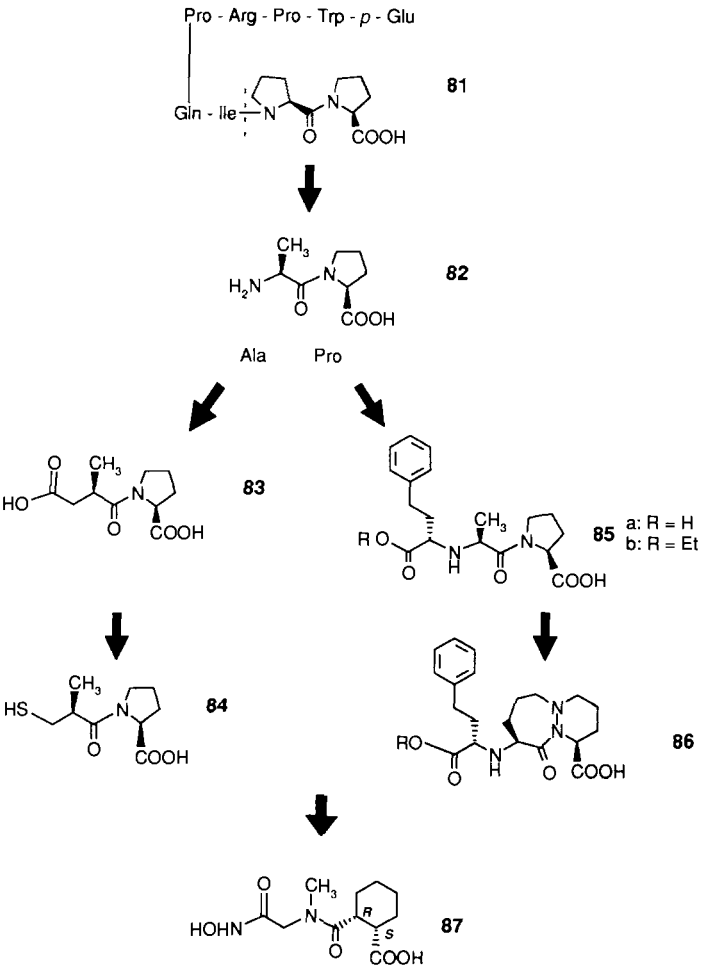
Like **75**, such dipeptide-analogous units can contain an additional carbon atom in the peptide backbone (hydroxyethylene modification, see Section 3.1), in which case they have a chain length corresponding to that of a dipeptide.[97]

It can also be seen from structures in Scheme 25 that the number of amino acid residues in the molecule can be considerably reduced without any negative effect on the high inhibitory activity of these compounds (the IC_{50} values all lie in the nanomolar range). It is hoped that renin inhibitors with reduced

peptide character and molecular weight will have an increased oral bioavailability, which has been unsatisfactory so far.

A further development in this direction is the use of C-terminal dihydroxyl components, as found in compound **76**, as a mimetic surrogate for the normal peptide bond in this section of the molecule.[93] As is evident from Scheme 25, it is also possible to use components at the N-terminus which resemble the original amino acid only in terms of their backbone length and side chain (**75**) or are totally different (**76**). Apart from the structures shown, a large variety of similar compounds has been developed,[98] some of which exhibit marked oral bioavailability.

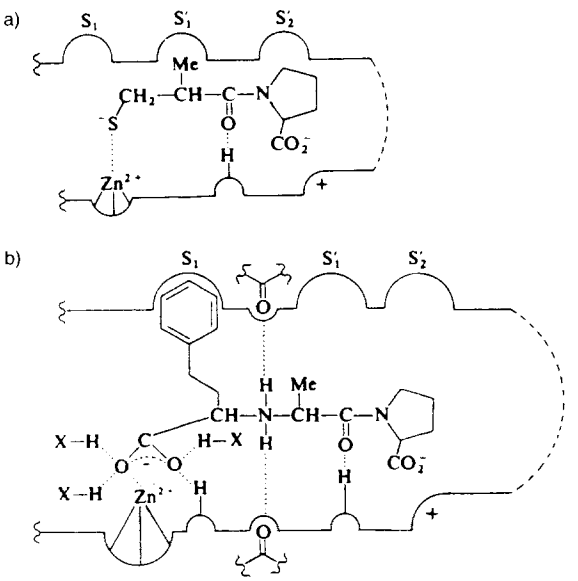
The increase in activity brought about by mimetism at only a single position in the backbone can be demonstrated very well by a renin inhibitor of the carba type[94] (Scheme 26). The transition from a purely peptidic inhibitor (**78**) to the carbapeptide **79** leads to an increase in the activity by a factor of about 600, while further modification to give the dihydrocarbapeptide **80** affords a further increase by a factor of about 170.



Scheme 26. Results of carba-type mimetism on the activity of a renin inhibitor.

In both modifications the site of biochemical attack can be demonstrated very clearly. In **79** the resistance of the isosteric peptide bond surrogate to cleavage prevents the subsequent liberation from the active site which normally occurs when the cleavage products diffuse. The change to compound **80** additionally introduces the transition state effect, in which further interactions lead to an even stronger binding to the enzyme.

5.2.2. *ACE Inhibitors*

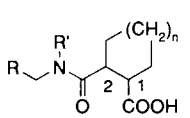


The starting point for the synthesis of mimetics of inhibitors of the angiotensin converting enzyme (ACE), a metalloprotease with a Zn ion at the active site, is the nonapeptide teprotide (**81**) (Scheme 27). It has been shown that the observed bradykinin-potentiating property of this substance, which was originally isolated from snake venom, is due to the inhibition of ACE.[99]

Scheme 27. Development of ACE inhibitors.

It was later observed that even the modified C-terminal fragment Ala-Pro (**82**) inhibits ACE, if only very weakly. At that time it was known[100] that benzylsuccinic acid has a blocking effect on carboxypeptidase A (CPA), which is mechanistically closely related to ACE; thus α-methylsuccinylproline **83** was synthesized.[101] It was expected that the carboxyl group would coordinate with the Zn ion and thus strengthen the enzyme binding, and indeed **83** was found to be more effective than **82** by a factor of 100. The replacement of the carboxyl group by the more strongly Zn-coordinating mercapto group led finally to captopril (**84**), the activity of which is yet 1000 times greater. This ACE inhibitor has been on the market for years as a very successful orally active drug for reducing high blood pressure and is also effective against heart failure.[101]

Another approach, in which the alanine residue of **82** was retained, led to enapril (**85**), another extremely successful blood pressure reducing drug.[102] In this case the strength of the enzyme binding is apparently due not only to the extra carboxyl group but in particular to the phenylethyl side chain; in comparison with captopril (**84**), **85** is able to undergo an additional hydrophobic interaction with the S_1 subsite of the enzyme (Scheme 28). It is evident in Scheme 28b that, as in the case of captopril, a cationic group of the enzyme forms an ionic bond with the proline carboxyl group of **85**, while a hydrogen bond donor from the enzyme interacts with the carbonyl group of



Scheme 28. Binding interactions between the active site of ACE and captopril (**84**) (a) [103] and enapril (**85**) (b) [102a,104].

alanine and the *N*-carboxyalkyl group binds to the Zn ion of the enzyme.

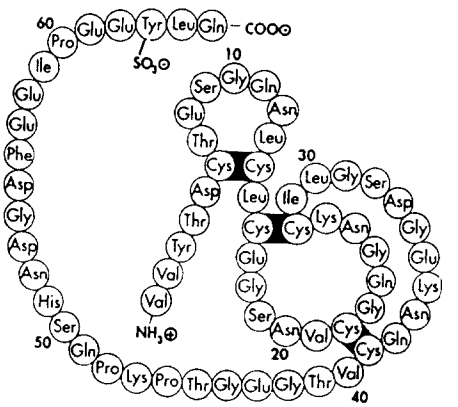
In fact only the ethyl ester derivative **85b** is suitable for oral application, since the free acid **85a** is not resorbed.[82b] In the organism the ester is cleaved enzymatically to give the active acid, such that it can be considered as a prodrug. The further development of this principle led eventually to cilazapril (**86**),[105] a compound with a high degree of mimetism.

A completely new class of ACE inhibitors, in which the peptoid principle was applied for the first time (inadvertently?) to a group of known drugs, has recently been described.[106] These structures contain 1,2-cycloalkane dicarboxylic acid residues as proline equivalents; one carboxyl group is linked by an amide bond to an aminoalkyl group, which in turn bears the Zn-coordinating substituent in the form of a mercapto, carboxyl, or hydroxamic acid group (**88**). Although the 2*R* configuration is

88

R = -CH_2-CH_2-SH, -CH_2-COOH, -CH_2-CONHOH
R' = H, alkyl
n = 1, 2

essential for the activity of such compounds, position 1 can have either *S* or *R* configuration. In contrast, in the classical ACE inhibitors an *S* configuration at the C-terminal carboxyl group is absolutely necessary.



The most active compound, with an IC_{50} of 7 nM (comparable to that of captopril), is hydroxamic acid **87** (1*S*,2*R* *cis* form, see Scheme 27).[106] It is described as showing in vitro and in vivo activity in various animal species and has a very low toxicity; it is at present undergoing clinical trials. Many other highly potent analogues of both captopril and enapril have also been synthesized by variations at many different sites in the molecules.[107]

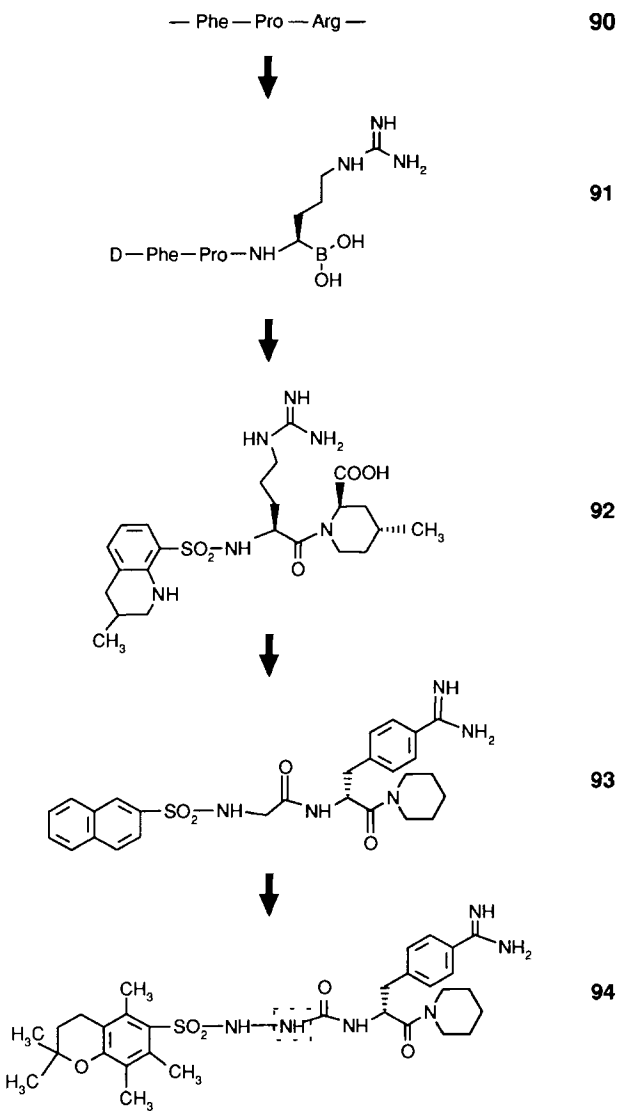
5.3. Thrombin Inhibitors

Thrombin, a serine protease similar to trypsin, is a key enzyme in the blood clotting system.[108] It promotes coagulation in many ways, mainly by cleaving fibrinogen to give fibrin, but also by activating factors V, VIII, and XIII, and by activating protein C at the surface of endothelial cells with the help of thrombomodulin.[109] Thrombin also induces platelet aggregation and promotes the proliferation of endothelial cells, the liberation of the plasminogen activator, and contraction and dilation of the blood vessels.[110] Because of these properties, selective inhibition of thrombin may result in efficient control of various pathophysiological states such as thrombosis and arteriosclerosis, and prevention of myocardial infarction.

The possibilities for thrombin inhibition, including that by non-peptidic compounds, are many. For example, thrombin is inhibited by heparin, a mixture of sulfated polysaccharides. Heparin functions indirectly on the enzyme by influencing various activity-regulating factors.[111] Thrombin is also inhibited indirectly by vitamin K antagonists such as warfarin.[112]

Since such drugs have serious side effects, mainly because of a lack of specificity, there has long been interest in the development of more specific thrombin inhibitors that work directly. One of these is hirudin (**89**), a polypeptide isolated from the leech (*Hirudo medicinalis*) containing 65 amino acid residues (Scheme 29), from which various analogues have been developed.[113]

89

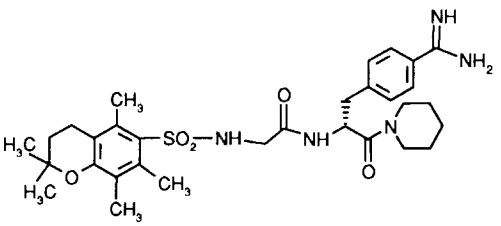


Scheme 29. Structure of hirudin (**89**).

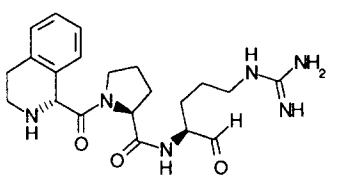
Hirudin forms a noncovalent, high-affinity complex with thrombin and hinders the approach of substrate molecules sterically by binding to various fixation points of the enzyme.[114] Hirudin, with an inhibition constant K_i of 20 fM, is the strongest known thrombin inhibitor.[115] For a long time it was available only with difficulty and in small amounts, but hirudin can now be obtained in large amounts and with a high degree of purity by expression in yeast or *E. coli*. The rec-hirudin obtained in this way lacks the sulfate group at Tyr^{63}, but the reduction in activity is small. The Ciba-Geigy product CGP 39393 with a K_i value of 230 fM is highly active and is at an advanced stage of clinical evaluation.[116]

Hirudin fragments, for example deca- and dodecapeptides from the C-terminus, have also been shown to be active.[117]

Thrombin inhibition by the natural products cyclotheonamide A and B (**62** and **63**)[76] has already been mentioned (see Section 4.1).



The development of an extremely interesting series of peptidomimetics for influencing thrombin activity was based on substrate analogues. These inhibitors occupy the active site rather than fibrinogen and thus block the normal function of the enzyme. This class of substances is based on the sequence Phe-Pro-Arg (**90**) in fibrinogen (Scheme 30), which is adjacent to the peptide bond to be cleaved.[118] The development from the peptide to the "complete" peptidomimetic, which contains no natural amino acids, can be demonstrated clearly by the compounds shown in Scheme 30.

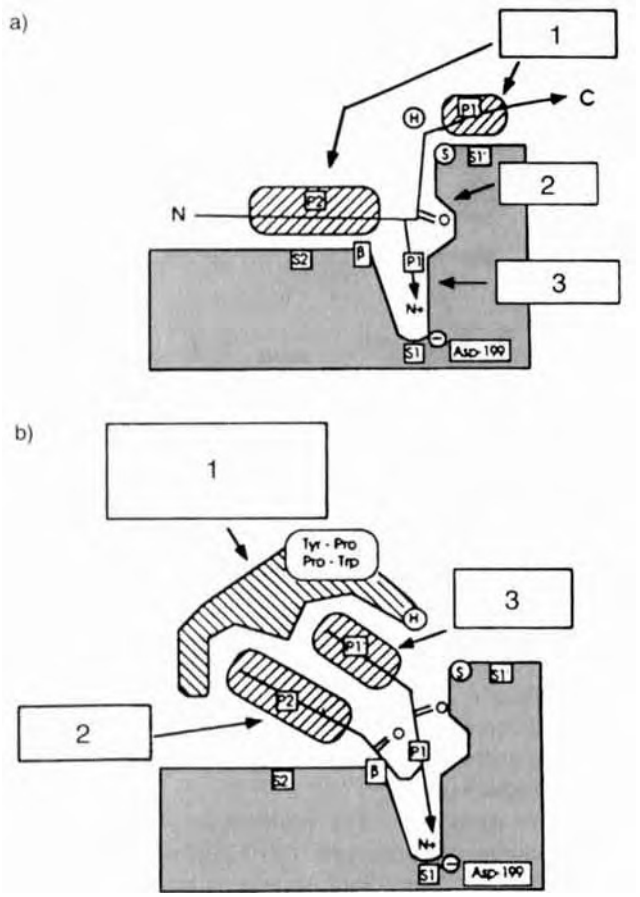


Scheme 30. Development of thrombin inhibitors.

The exchange of D-Phe for Phe and the additional replacement of the carboxyl group in Arg by various residues gave the corresponding chloromethyl ketone,[119] aldehyde,[120] and nitrile;[121] however, the most effective analogue was the boroarginine derivative **91** which has an extremely high activity (K_i = 3.6 pM!).[122] This compound has been found to mimic the tetrahedral transition state of the catalyzed reaction.[123] Recently the *N*-acetyl derivative of **91** was shown to be active in vivo and to influence both venous and arterial thrombosis.[124]

The next step in mimetism, which was based on the observation that even the simple methyl ester of tosylarginine is a thrombin inhibitor, led to the highly active sulfonamide derivative **92** (argatroban, MD 805).[125] Replacement of the arginine by the unnatural amino acid *p*-amidinophenylalanine and introduction of a glycine residue into the molecule led among others to compound **93** (NAPAP);[126] the derivative having the modified phenylalanine residue with the unnatural D configuration is 1000 times more active than that with the L isomer.[127] The final molecule in this series is compound **94**,[128] the azaglycine analogue of the highly active compound **95**,[129] a further development of the NAPAP principle. A considerable increase in activity has been reported for compound **94**. Since such azapeptides also show resistance to enzymatic degradation, they should have improved stability within the organism as well as increased activity.

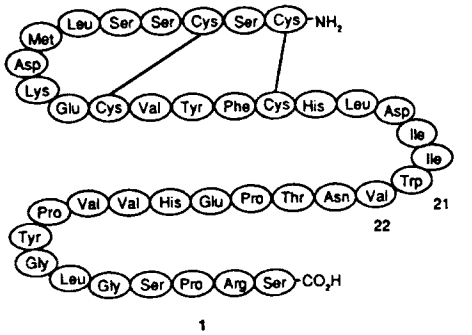
Further developments of the principles discussed above which have led to compounds with improved properties include the replacement of D-Phe by the corresponding rigidified amino acid D-Tic (tetrahydroisoquinolinecarboxylic acid) in the tripeptidealdehyde **96**.[130] and combinations with the hirudin motif



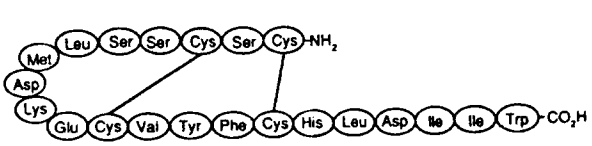
(hirulog 1 and hirulog 4), in which D-Phe-Pro-Arg is attached to the hirudin sequence 53–64 by means of spacers of different lengths composed of glycine residues.[131] The replacement of the spacer by a variable number of ω-aminopentenoyl residues in this series leads to products with improved activity.[132] Other newer variations make use of ketomethylene arginyl dipeptide residues[133] and diphenylmethyl residues instead of the Phe side chain.[134]

The nature of the binding of the thrombin inhibitors to the enzyme has been the subject of many detailed studies. It has recently been observed that intramolecular hydrophobic interactions which had previously been neglected may be essential in the binding of argatroban- and NAPAP-type inhibitors.

Although it had been supposed earlier that thrombin inhibitors generally bind in the the same manner as the substrate (substrate-like binding),[135] X-ray structural studies have



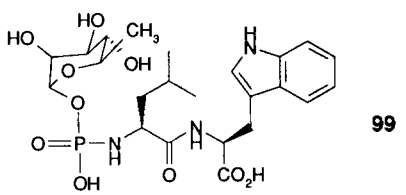
shown a different type of binding (inhibitor-like) for inhibitors of the types mentioned.[127,136] Hydrophobic interactions are found in the bioactive conformations of argatroban (**92**) (between the tetrahydroquinolyl and piperidine groups) and of NAPAP (**93**) (between the naphthyl and piperidine groups; Scheme 31), and the conformations are thus subject to so-called hydrophobic collapse (for an explanation see Section 6). As shown in Scheme 31, the hydrophobic residues interact solely with hydrophobic pockets formed by the amino acid residues 47–50 (Tyr-Pro-Pro-Trp) of the enzyme.



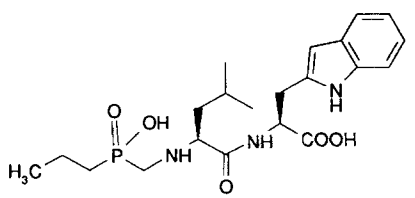
Scheme 31. a) Binding of a substrate to a trypsin-like serine protease. 1: hydrophobic groups, 2: pocket for an oxy group, 3: recognition pocket, C: C-terminus, N: N-terminus, H: His^{43}, S: Ser^{205}, β: β-autocatalytic site. b) Hydrophobic collapse during the binding of the inhibitor to thrombin. 1: extra loop, residues 47–50 containing two pockets, the P pocket (proximal to Ser^{205}) and the D pocket (distal to Ser^{205}). This loop is not present in trypsin. 2: hydrophobic group in the D pocket, 3: hydrophobic group in the P pocket.

5.4. ECE Inhibitors

The use of inhibitors of the endothelin converting enzyme (ECE) in the treatment of cardiovascular disorders has recently become a subject of great interest. Endothelin-1 (ET-1, **98**), a peptide containing 21 amino acids with two disulfide bridges, can be isolated from endothelial cells and shows a strongly vasoconstricting and hypertensive activity. This peptide is liberated from a precursor peptide, the big ET-1 (**97**) with 38 amino acids, by an ECE-mediated hydrolytic cleavage of the Trp^{21}-Val^{22} bond (Scheme 32).[137]

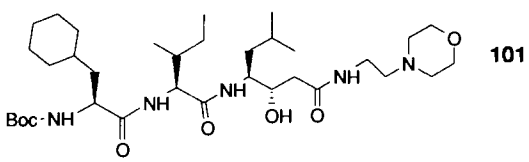


97

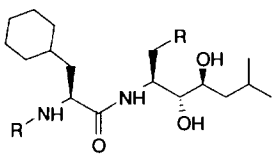


98

Scheme 32. Big endothelin-1 (**97**) and endothelin-1 (**98**).



Endothelin exists in several forms, ET-1 (**98**), ET-2, and ET-3. Since ET-1 seems to play the dominant role in humans, all the pharmacological studies so far have been concerned with this particular isoform. A high ET level seems to play an important role in pathophysiological conditions such as high blood pressure,[138] acute kidney failure,[139] and coronary and cerebral vasospasm.[140] Accordingly, lowering an extreme ET level by inhibiting the enzymatic release of ET appears to be an attractive therapeutic goal. Other attempts to reach this goal have



99

100

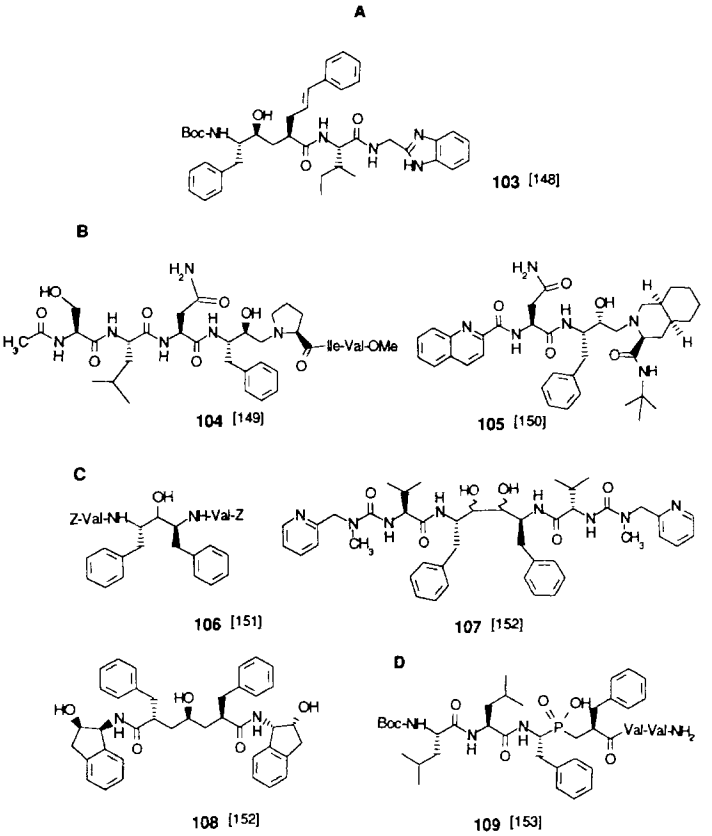
101

102

Scheme 33. ECE inhibitors. **102**: R = 1-naphthyl, $K_i = 2.3 \times 10^{-8}$ M; R = 2-naphthyl, $K_i = 3.1 \times 10^{-9}$ M.

involved the blockage of the endothelin receptor by corresponding antagonists.[2b]

Since the structure of the ECE is still relatively unclear, the conception and synthesis of antagonists is presently still in its initial stages. On the one hand ECE is inhibited by inhibitors of the metalloprotease neutral endopeptidase (NEP) such as phosphoramidon (**99**)[141] and more simple analogues such as **100**[142a] as well as by the chelating agents EDTA and *o*-phenanthroline. This suggests that ECE is a metalloprotease[142b] (Scheme 33). On the other hand there is evidence that ECE activity is possibly due to the aspartyl proteases cathepsin D and/or cathepsin E.[143] Further evidence for an aspartyl protease comes from the recent discovery that an enzyme activity isolated from rat lung is very effectively inhibited by pepstatin (**77**), a potent pepsin inhibitor.[144] This provided the stimulus for optimizing certain structural principles known from transition state analogues of renin inhibitors (see Section 5.2.1) for ECE inhibition. The result was two groups of inhibitors of the statin (**101**) and diol (**102**) types,[144] which in some cases show high specificity for ECE over renin and cathepsin D.

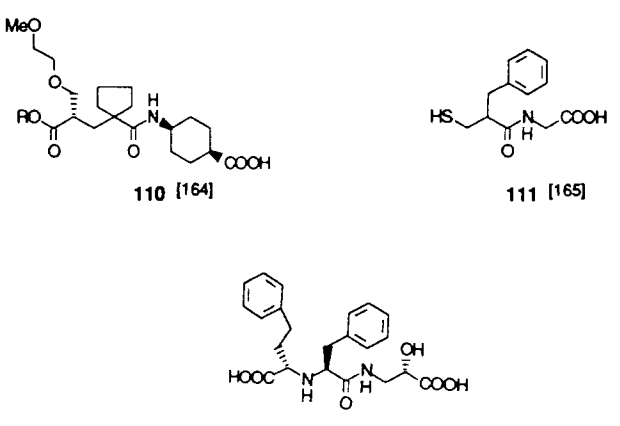


5.5. Inhibitors of Other Proteases

The detailed discussion of inhibitors of therapeutically relevant enzymes will now be followed by a short treatment of some other recent developments in this area.

In addition to some completely different approaches[145] the development of inhibitors of the HIV-1 protease has become an interesting target in AIDS therapy.[2c,146] This aspartyl protease, which is vital for the replication of the virus, is responsible for the proteolytic processing of the gag and gag-pol polyproteins to give infectious virions.[147] As an aspartyl protease, the HIV-1 protease can in principle be influenced by substances of the renin-inhibitor type containing statin or hydroxyethylene units (**103**, Scheme 34).[148] Other highly active inhibitors are of the hydroxyethylamine type (**104** and **105**).[149,150] More recent developments are based on the observation that the HIV-1 protease crystallizes as a C_2-symmetric homodimer, in which each chain provides one aspartate residue which plays an important role in the catalysis.[151] On the basis of this result various types of inhibitors have been synthesized in which the peptide bond is replaced by C_2-symmetric and C_2-pseudosymmetric units (**106**–**108**).[151a,152]

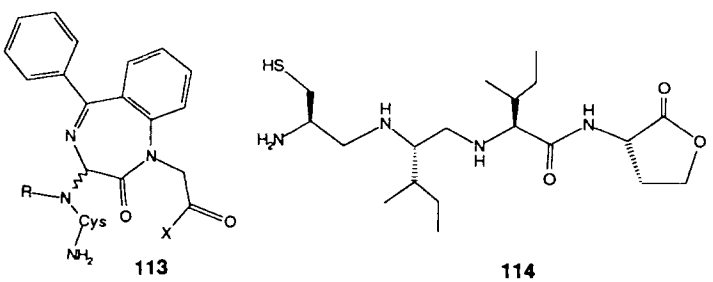
Phosphinic acid derivatives such as **109**, in which the central CHOH group has been replaced isosterically, have also proved to be highly active.[153] Further developments of the principles discussed here are described in the recent literature.[154–161]



Inhibitors of the neutral endopeptidase (NEP), a Zn metalloprotease, have been the subject of increasing interest. NEP has two physiological functions: in the central nervous system it inactivates the enkephalins, endogeneous opioid peptides,[162] and it also mediates the proteolytic degradation of the atrial natriuretic peptide (ANP), a peptidic vasodilator secreted by atrial tissue which has a blood pressure regulating function.[163] The inhibition of this enzyme can thus have both pain-relieving and blood pressure reducing effects. It is not surprising that the inhibitors of this metalloprotease developed so far are structurally similar to ACE inhibitors, as ACE belongs to the same

Scheme 34. Inhibitors of HIV-1 protease. **A**: renin inhibitor type (**103**); **B**: hydroxyethylamine type (**104**, **105**); **C**: C_2-(pseudo)symmetric type (**106**–**108**); **D**: phosphinic acid type (**109**).

class of proteases. Characteristic compounds that have been developed as ANP degradation inhibitors primarily for cardiovascular indication are candoxatril (**110**),[164] thiorphan (**111**),[165] and Sch 39370 (**112**)[166] (Scheme 35). New developments, mainly analogues of these compounds, can be found in the more recent literature.[167–170]



Inhibitors of elastase, a serine protease, are of interest for combating pulmonary emphysema.[2c,171] It is hoped that inhibition of collagenase, a metalloprotease, may lead in particular

Scheme 35. ANP degradation inhibitors. Candoxatril: **110**, R = 5-indanyl; candoxatrilat: **110**, R = H.

to drugs for combating rheumatoid arthritis, a pathological condition in which this enzyme is involved by excessive proteolysis.[82b,172] Inhibitors of peptidyl-prolyl *cis/trans* isomerases (PPIases), a group of enzymes involved in protein folding which can influence the immune system, are also of current interest.[2c,173] Inhibitors of cysteine proteases, which include papain, can influence pathological conditions caused by defective functions of such proteases in processing biologically active peptides.[82b,174] Inhibitors of enzymes that degrade the neuropeptides neurotensin and neuromedin could lead to effective treatment of pain.[175]

The efficiency of different forms of peptidomimetism cannot be more clearly demonstrated than by the example of two compounds recently described independently, which as inhibitors of the enzyme farnesyl protein transferase (FPT) may lead to highly interesting possibilities for cancer therapy. Both **113**, which has a novel cyclic dipeptide-analogous unit of the benzodiazepine type,[176] and the tetrapeptide-analogous lactone **114**,[177] characterized by two reduced amide bonds at the N-terminus, can inhibit the growth of certain types of tumor cells very effectively (Scheme 36).

113 **114**

Scheme 36. X = Met-COOH, Ser-COOH, Leu-COOH, Met-COOMe, Met-$CONH_2$.

These substances are directed against oncogenic ras proteins, which play a decisive role in the formation of most human pancreas and colon tumors. These oncogenic ras proteins, which are formed by point mutations, require the linkage of a farnesyl group to a cysteine SH group of the C-terminal tetrapeptide group of the protein so that they can adhere to the inner side of the cell membrane. Only in this state are they able to induce uninhibited cell division. The goal of this protein deactivation approach is preventing the transfer of the farnesyl residue by inhibiting the farnesyl protein transferase that catalyzes this process.[178]

In contrast to other approaches of this type[178,179] (in some cases with appropriate tetrapeptides analogous to the C-terminus[179,180]), the mimetics of the peptides described above are able to penetrate the cell membrane and are also much more resistant towards degrading enzymes.

It has been shown that these compounds are able to inhibit the coupling of the farnesyl group to the mutated ras protein (and thus its adherence to the cell membrane) even at a very low concentration, thus leading to cell growth inhibition. In cell cultures these substances show high selectivity and extremely low toxicity.

6. Conclusions and Future Prospects: Hydrophobic Collapse, De Novo Design

New impulses for the rational design of new drugs may come from the information available on the apparently quite general phenomenon known as hydrophobic collapse. Because of its potential importance in the planning of new peptidomimetics, we shall present a short description of this phenomenon and its consequences.

When the whole spectrum of presently known peptidomimetics is considered, it becomes clear that they have one structural feature in common with many pharmacophores of known drugs: they contain hydrophobic groups that are either conformatively rigid or at least limited in their flexibility. This reduction in conformational mobility hinders intramolecular hydrophobic interactions, which in aqueous media (i.e. also at the receptor and the active site) would lead to a collapse of a bioactive conformation with concomitant loss of activity. This phenomenon is referred to as hydrophobic collapse.[181]

The basis for this phenomenon is the hydrophobic effect,[182] which plays an important role in all biological processes. This effect is used to explain the observation that when complicated molecules are dissolved in water the interactions between hydrophobic groups and the solvent are reduced to a minimum. Thus because of this effect proteins have, for example, developed develop structures that make use of hydrophobic interactions for binding ligands to receptors. In enzymes such hydrophobic pockets are important in binding substrates and inhibitors. The "construction blueprint" of proteins seems ideal for the stabilization of such hydrophobic pockets, for example at active sites of enzymes, and the hydrophobic collapse in the absence of the ligand is thus prevented.

For the ligands, too, this type of conformational stabilization often appears to be necessary for the effective presentation of the hydrophobic groups required for an interaction with the active site of the enzyme. Without this stabilization, which can for example be achieved by rigidifying scaffolds, the active substance would undergo hydrophobic collapse to give an inactive conformation. On the other hand, the hydrophobic collapse of a ligand can also be advantageous, since in some cases only the collapsed conformation is bioactive. This can be shown, for example, for cyclosporin A[183] and for thrombin inhibitors (see Section 5.3).

The design of peptidomimetics must always take into account whether a hydrophobic collapse is to be prevented or induced. Thus in the future it will generally continue to be important for the discovery of new lead peptidomimetic structures to look for scaffolds, whose rigidity would prevent the hydrophobic collapse of essential groups in an aqueous medium. The scaffolds previously identified, such as the sugar or steroid scaffolds (see Section 2.5) appear to fulfill these conditions.

A goal that has not yet been achieved is the de novo design of peptidomimetics. At present, natural substrates, inhibitors, or a lead structure identified by screening (plant or animal extracts, substances isolated from microorganisms, compound libraries) are required as the starting point for a development sequence. In contrast, de novo design implies development without such a starting point. Thus for example the structure of an inhibitor

would be developed based only on the known amino acid sequence of an enzyme or the natural interaction partner.

Attaining the final goal of de novo design would have immense practical value in medicinal chemistry. Consider the extremely labor-intensive research in drug development, in which the conventional approach still relies primarily on empirical findings. This investment of time and effort is the obvious result of the statistical fact that thousands of compounds must be synthesized and tested before one of them is deemed marketable; the other compounds are weeded out in stringent pharmacological, toxicological, and clinical tests. Certainly with the help of de novo development this rejection rate could be drastically reduced.

A step in the direction of de novo design has been taken by various computer programs such as CAVEAT[184] which have the goal of calculating new active structures based only on the active site of the enzyme. The program DESIGN has recently been introduced[185] and used for designing a template for mimicking the enzyme thioredoxin.

The rational design of peptidomimetics is, however, already possible to a certain extent even today, as we hope to have shown in this review. Highly refined methods of conformational analysis (e.g. NMR, X-ray structural analysis) and the new computer programs have made an important contribution to the current state of the art. Rational design has already proved to be very useful in translating peptide structures with their biological information content into low molecular weight non-peptidic molecules.

Synthetic chemistry has also made great progress. Without the modern methods developed by organic chemists the construction of complex, stereochemically defined molecules with particular functional groups and hydrophobic elements attached to a non-peptidic scaffold would hardly have been possible.

Further progress in this area depends on the combined efforts of organic and medicinal chemists, as well as contributions from other disciplines concerned with the chemistry of biological systems. The goal of this effort is the design of compounds that are compatible with living systems, as well as the development of synthetic methods producing compounds that satisfy specific chemical, structural, conformational, topographical, and dynamic requirements on the one hand and are biologically active on the other. Research on peptidomimetics illustrates this trend, and on the basis of what has been achieved so far and the justified hope of further progress, the realization of the goal of tailor-made peptidomimetic enzyme inhibitors certainly appears within reach.

[1] A peptidomimetic is defined as a substance having a secondary structure as well as other structural features analogous to that of the original peptide, which allows it to displace the original peptide from receptors or enzymes. As a result the effects of the original peptide are inhibited (antagonist, inhibitor) or duplicated (agonist).

[186] **Addendum**: Many publications on the topics in this review have appeared since the submission of this manuscript. A selection (up to April 1994) are listed here.

Structure: a) M. Quibell, W. G. Turnell, T. Johnson, *J. Chem. Soc. Perkin Trans. 1* **1993**, 2843; b) J. A. Robl, M. P. Cimarusti, *Tetrahedron Lett.* **1994**, *35*, 1393; c) N. K. Harn, S. J. Cripps, G. M. Rishton, *ibid.* **1994**, *35*, 1389; d) E. Graf von Roedern, H. Kessler, *Angew. Chem.* **1994**, *106*, 684; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 687; e) J. A. Robl, M. P. Cimarusti, L. M. Simpkins, H. N. Weller, Y. Y. Pan, M. Malley, J. D. DiMarco, *J. Am. Chem. Soc.* **1994**, *116*, 2348; f) K. Burgess, K.-K. Ho, *ibid.* **1994**, *116*, 799; g) P. P. Mager, *Med. Res. Rev.* **1994**, *14*, 75 (review); h) C. Aleman, J. J. Perez, *Int. J. Pept. Protein Res.* **1994**, *43*, 258; i) M. Marraud, V. Dupont, V. Grand, S. Zerkout, A. Lecoq, G. Boussard, J. Vidal, A. Collet, A. Aubry, *Biopolymers* **1993**, *33*, 1135.

ACE/NEP inhibition: a) J. L. Stanton, D. M. Sperbeck, A. J. Trapani, D. Cote, Y. Sakane, C. J. Berry, R. D. Ghai, *J. Med. Chem.* **1993**, *36*, 3829; b) G. A. Flynn, D. W. Beight, S. Mehdi, J. R. Koehl, E. L. Giroux, J. F. F. French, P. W. Hake, R. C. Dage, *ibid.* **1993**, *36*, 2420; c) A. Patel, H. J. Smith, R. D. E. Sewell, *Prog. Med. Chem.* **1993**, *30*, 328; d) S. DeLombaert, M. D. Erion, J. Tan, L. Blanchard, L. El-Chehabi, R. D. Ghai, Y. Sakane, C. Berry, A. J. Trapani, *J. Med. Chem.* **1994**, *37*, 498; e) J. L. Stanton, G. M. Ksander, R. deJesus, D. M. Sperbeck, *Bioorg. Med. Chem. Lett.* **1994**, *4*, 539; f) J. French, G. A. Flynn, E. L. Giroux, S. Mehdi, B. Anderson, D. C. Beach, J. R. Koehl, R. C. Dage, *J. Pharmacol. Exp. Ther.* **1994**, *268*, 180; g) M.-C. Fournié-Zaluski, P. Coric, S. Tucaud, N. Rousselet, W. Gonzalez, B. Barbe, I. Pham, N. Jullian, J.-B. Michel, B. P. Roques, *J. Med. Chem.* **1994**, *37*, 1070.

Inhibition of aspartyl proteases: a) S. S. Abdel-Meguid, *Med. Res. Rev.* **1993**, *13*, 731 (review).

Inhibition of HIV-1 protease: a) H. L. Sham, D. A. Betebenner, C. Zhao, N. E. Wideburg, A. Saldivar, D. J. Kempf, J. J. Plattner, D. W. Norbeck, *J. Chem. Soc. Chem. Commun.* **1993**, *13*, 1052; b) D. S. Holmes, I. R. Clemens, K. N. Cobley, D. C. Humber, J. Kitchin, D. C. Orr, P. Binakumari, I. L. Paternoster, R. Storer, *Bioorg. Med. Chem. Lett.* **1993**, *3*, 503; c) K. T. Chong, M. J. Ruwart, R. R. Hinshaw, K. F. Wilkinson, B. D. Rush, M. F. Yancey, J. W. Strohbach, S. Thaisrivongs, *J. Med. Chem.* **1993**, *36*, 2575; d) D. S. Holmes, R. C. Bethell, N. Cammack, I. R. Clemens, J. Kitchin, P. McMeekin, C. L. Mo, D. C. Orr, B. Patel, *ibid.* **1993**, *36*, 3129; e) A. Wonacott, R. Cooke, F. R. Hayes, M. M. Hann, H. Jhoti, P. McMeekin, A. Mistry, P. Murray-Rust, O. M. P. Singh, M. P. Weir, *ibid.* **1993**, *36*, 3113; f) M. Vaillancourt, B. Vanasse, E. Cohen, G. Sauve, *Bioorg. Med. Chem. Lett.* **1993**, *3*, 1169; g) K. A. Newlander, J. F. Callahan, M. L. Moore, T. A. Tomaszek, Jr., W. F. Huffman, *J. Med. Chem.* **1993**, *36*, 2321; h) H. L. Sham, D. A. Betebenner, N. Wideburg, A. C. Saldivar, W. E. Kohlbrenner, A. Craig-Kennard, S. Vasavanonda, D. J. Kempf, J. J. Clement, *FEBS Lett.* **1993**, *329* (1, 2), 144; i) A. K. Ghosh, W. J. Thompson, M. K. Holloway, S. P. McKee, T. T. Duong,

Mills–Nixon Effect: Wherefore Art Thou?

Jay S. Siegel*

The structural chemistry conundrum known as the Mills–Nixon effect is a progeny of the empirical successes of van't Hoff and Kekulé. The proposed effect states that small ring annelation onto benzene would induce significant bond length alternation within the benzene nucleus;[1] a reasonable postulate if benzene existed as an equilibrium mixture of Kekulean valence tautomers. Indeed, at the time of the conception of the Mills–Nixon hypothesis, the details of benzene's structure as resonance hybrid or tautomeric equilibrium were still in debate. Although the debate has been essentially resolved in favor of a single D_{6h} benzene,[2] the remnants of predictions based on the antiquated equilibrating model linger as a provocative postulate without structural experimental backing. Recent advances in organic structural chemistry are bringing the geometric aspects of this problem to a close. It is instructive, however, to follow this "garden path" from its beginnings.

The work of the Palermo school in general and Koerner's study of the isomers of halogenated benzenes in particular spawned a dichotomy in the conceptualization of molecular structure that discriminated between static and dynamic (permutation) symmetry.[3] In order to account for Koerner's observations, a high symmetry structure for benzene appeared to be necessary, and many chemist's searched for this in the form of a single ideal valence structure.[4] Kekulé's original structure failed Koerner's test in that two *ortho*-chlorobenzenes were predicted.[5] however, its salvation materialized in the idea of a time-averaged structural equilibration which Kekulé called the oscillation theory.[6] In this proposal, the structure of benzene had alternate double and single bonds in a D_{3h} structure that was in equilibrium with another equivalent structure, where the double and single bonds had traded places. Kekulé demonstrated that the oscillation of the bonds exchanged the identity of the two *ortho*-dichlorobenzene isomers and thus created a dynamic permutational symmetry. This idea of a dynamic structure for benzene was considered ludicrous by the community and was heartily ridiculed by "Findig" in 1886.[7] Nonetheless, Kekulé's proposal marks the beginning of the problem of single versus double energy minima in structural chemistry.[8]

In 1887, van't Hoff's "Dix Années dans l'Histoire d'une Theorie" expanded upon and generalized his 1874 observations that carbon should have four valences radiating toward the corners of a regular tetrahedron.[9] From this spatial imperative, he formulated a tetrahedral theory for carbon–carbon bonding where the number of juxtaposed vertices represented the order of the bond: point–point (single); edge–edge (double); face–face (triple). Due to the great success of the model in predicting the isomers of saturated and unsaturated compounds, van't Hoff's tetrahedra were applied to gauge the structural details of the Kekulé forms of benzene. Each valence structure was viewed as three (van't Hoff) double bonds grouped to form a six-atom ring. Each double bond comprised two regular tetrahedra connected edge to edge; the terminal angle having a magnitude of 109.5° as dictated by the tetrahedral elements. Thus, the Kekulé forms possessed alternating bond lengths and external angles α and β of about 110 and 125°, respectively (Fig. 1).

Even with the backing of the highly successful tetrahedral theory, Kekulé's proposal was considered to have received "a death-blow" in 1888.[10] Despite this premature epitaph, the germ of Kekulé's oscillating benzene structure remained fertile, and the advent of the concept of tautomerism gave his idea new life.[11] It reappeared in the work of Reddelien in 1915, when he suggested that it should be experimentally possible to test for the two forms, and indicated that the action of ozone on benzene might serve this purpose.[12] Indeed, in 1932, Levine and Cole ozonolyzed *o*-xylene and found glyoxal, methylglyoxal, and dimethylglyoxal as products.[13] No single Kekulé form could give rise to this mixture and therefore they concluded that the single isomer of *o*-xylene was actually a rapidly equilibrating mixture of the two Kekulé forms, each susceptible to attack by ozone.

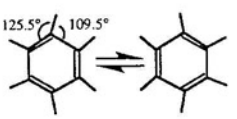

Fig. 1. Kekulé's view of the oscillating structure of benzene; quantitative structural aspects were derived from the tetrahedral construction of van't Hoff. This is the model accepted by chemists circa 1930 and upon which Mills and Nixon made their postulate.

The concept of the rapidly equilibrating Kekulé forms also captured the imagination of Mills and Nixon in 1930.[1] They proposed a structure perturbation approach to test for the oscillation hypothesis. Given that there really were two distinct forms of benzene and two distinct external angles α and β, then controlled annelation should favor either α or β as the angle within the annelation and therefore "freeze-out" one Kekulé form. The "ideal" angle α of 109.5° matched well with that of the 108° angle of a five-membered ring; therefore, indan and tetralin became the chosen test structures. Lacking the necessary structural tools to observe the actual bond alternation in the isomer, they pursued the regioselective reactivity of hydroxyindan and tetralin.

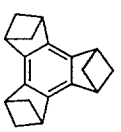
During the years immediately following Mills and Nixon's article, Pauling published his seminal works on the Nature of the Chemical Bond and the concept of resonance.[14] Shortly after his work on resonance, Pauling and L. E. Sutton addressed the possible structural ramifications of ring annelations a la Mills and Nixon.[15] Unlike Mills and Nixon's view of benzene as a tautomeric equilibrium, Pauling's resonance hybrid ideas depicted benzene as a single symmetrical form, not a time average between two Kekulé forms.[16] Sutton and Pauling concluded that the stabilization due to resonance was so great as to be only slightly perturbed by any annelations. Nonetheless, they admitted that the energy differences necessary to account for the observed selectivity would not mandate experimentally detectable changes in goemetrical structure. Coulson and Longuet-Higgins also investigated the Mills–Nixon effect and concluded that it would be at best small, but in the opposite direction (a "reversed" Mills–Nixon effect).[25]

The ensuing 60-year period has been replete with computational and experimental investigations of the Mills–Nixon proposal, however, none of these studies has been conclusive and often they arrive at divergent conclusions.[17] Recently, tricyclobutabenzene (**1**) has emerged as the "touchstone" for evaluating the structural aspects of the Mills–Nixon effect, and finally the result of ab initio HF/6-31G(D) calculations and density functional theory (DFT) and experiment (low-temperature high-accuracy X-ray crystallography) have converged harmoniously.

Three groups collaborating among Berkeley, Essen, and Rice[18] have crystallographically confirmed computational predictions first made specifically by Stanger (3-21G)[19] and later more generally by Baldridge and Siegel (6-31G(D))[20] that **1** adheres more closely to the Pauling model than the Longuet-Higgins model, or more importantly that "benzene, even if distorted in the σ-plane, simply wants to remain 'aromatic'." The Berkeley and Rice groups (W. E. Billups, M. M. Haley, D. L. Mohler, and K. P. C. Vollhardt) prepared four highly strained annelated benzenes and determined their structures crystallographically in a collaboration with R. Boese, D. Bläser, and A. H. Maulitz in Essen, Germany. The crystals of **1** were grown, using Boese's exceptionally elegant sublimation technique, from material prepared by the method of Randy P. Thummel (University of Houston).[21]

All four of the structures determined by Boese's team (**1**–**4**) show characteristic features of small strained rings, such as elec-



1 **2** **3** **4**

tron density deformations consistent with "bent bonds."[22] *In no case is any appreciable bond alternation observed*; specifically, the bond lengths in the central ring of **1** are 1.40 and 1.38 Å as compared to 1.50 and 1.33 Å for a standard C_{sp^2}–C_{sp^2} single and double bond, respectively.[23] Additional ab initio computations by these researchers corroborated the crystallographic findings.

The elegant work of these three research groups conclusively brings to a close an important chapter of the Mills–Nixon story, with Pauling's predictions surfacing as quite general among simple annelated benzenes. Questions still remain, however, about the feasibility of inducing bond alternation purely through sigma strain.

In contrast to the present experimental data, Stanger demonstrated that computations on an artificially constrained benzene structure with the C-C-H angles crimped to 90° yield a central ring with a bond length alternant geometry (1.52 and 1.33 Å).[19] Empirically, strain induced by bicyclic annelations gives rise to anomalous effects (e.g. the bicyclic effect proposed by Lehn for pyramidal inversion at nitrogen). Structural predictions by ab initio calculations (HF/6-31G(D) and DFT) on bicyclic annelated benzenes point to a new class of strained benzenoids, for example **5**, with significant bond length alternation (0.06–0.1 Å).[20] Experimental investigations on this series of structures related to **5** will either finally uncover a Mills–Nixon distorted benzene or identify a serious shortcoming of split-valence level HF theory for the prediction of strained hydrocarbon structure.

5

In hindsight, one can discuss the Mills–Nixon effect from the point of view of how a given perturbation will alter the average structure of a species described by a double-well versus, a single-well potential. The isotopic perturbation work of Saunders et al. most clearly illustrates this principle.[24] The average position in a double-well structure is defined by the relative population of the two wells. A small energy change in either well leads to a large change in population and therefore a large shift in the average structure, in other words double-well equilibria should be quite sensitive to small perturbations. The average position in a single-well potential, however, is related to the anharmonicity of the well, which is normally less sensitive to such perturbations. This simple hindsight can not fully explain why such draconian perturbations lead to such minor effects on the delocalized structure of benzene, but it definitely illuminates to the modern chemist the origins of this anachronistic structural proposal called the Mills–Nixon effect.

[15] L. E. Sutton, L. Pauling, *Trans. Faraday Soc.* **1935**, *31*, 939.
[16] This distinction of single versus double minima is clearly stated by Sutton and Pauling. "It appears very definitely that benzene is a single molecular species and ... we can say that it is a hybrid of the two Kekulé structures ... and that the angles between pairs of external valencies are all 60°. ... Our procedure here is different from that of Mills and Nixon, for they assumed that the molecule had either structure I or structure II, whereas we consider that initially it has the symmetrical resonating structure and then calculate how much it is distorted when a ring is attached."

Detection and Imaging of Single Molecules by Optical Near-Field Microscopy

Thomas Basché

„... we never experiment with just one electron or atom or molecule. In thought experiments we sometimes assume we do; this invariably entails ridiculous consequences."
Erwin Schrödinger, 1952

The successful storage and spectroscopic characterization of individual atoms in electromagnetic traps and the development of microscopic techniques with atomic resolution such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM) are two examples that make us realize that Schrödinger's notion has been outpaced by reality. One should, however, bear in mind that the observation of single particles, as commonplace as it may seem today, has only become possible within the past 10–15 years, regardless of the technique. This Highlight deals with new developments in the field of optical detection of single molecules; other methods of detection are not covered.

The first optical detection of a single molecule in the condensed phase was achieved in 1989 with the spectroscopic characterization of an individual pentacene molecule in an organic mixed crystal at low temperatures (T = 1.5 K).[1] Not much later, and independent of the research on solids, efforts to detect individual dye molecules in a liquid were successful.[2]

A single molecule in a solid at low temperature is a very sensitive spectroscopic probe for the properties of its local environment, owing to its extremely narrow optical linewidth. In contrast, for single-molecule detection (SMD) in liquids or, more general, for all techniques that can be performed at room temperature, analytical aspects are as important as the measurement of spectroscopic details. SMD represents the ultimate limit in chemical trace analysis and has been proposed as a realistic method for sequencing the DNA of the human genome within a reasonable period of time. In molecular biology the detection of single fluorescence-labeled species (proteins, viruses) is a foreseeable and increasingly important development.

Optical spectroscopy of single molecules has already given rise to a host of new experimental results, including the development of techniques for the optical characterization of individual molecules with ever increasing sensitivity. Ultrasensitive fluorescence detection is ideally suited for the optical observation of single molecules. The experimental challenge here lies in the discrimination of the weak fluorescence of a single molecule from the matrix background light (Rayleigh and Raman scattering, matrix luminescence). Since the signal of the molecule is proportional to the intensity of the incident radiation (power/area), and since the background light and the concomitant background noise level increase with the power, enhanced sensitivity is achieved by decreasing the area of illumination. Consequently, tight focusing of the exciting laser light is essential. Focusing with lenses, however, invariably involves the fundamental Abbe diffraction limit to resolution, which states that foci of dimensions less than the wavelength of the light used are not possible. Fortunately, the method of near-field scanning optical microscopy (NSOM) developed during the last few years

circumvents this limit and is therefore ideally suited for fluorescence detection of single molecules. Recently, using this new microscopic technique, Betzig et al.[3] and Ambrose et al.[4] independently succeeded in imaging individual dye molecules on the surface of a substrate at room temperature. Before these experiments are described, let us first look at the principles and potential applications of near-field optical microscopy.

Conventional optical microscopy has a limited resolution of about $\lambda/2$ of the optical wavelength employed. This theoretical resolution limit is a consequence of diffraction effects due to the wave characteristics of light; for green light under ideal conditions this limit is roughly 0.3 μm, and with good optical microscopes it can in fact be reached. (However, even in confocal microscopy resolution better than $\lambda/2$ can be achieved using special "tricks".) When light is passed through a small aperture, whose diameter is less than the wavelength, the dimensions of the light beam at a distance close to the aperture are nearly unchanged. This area is called the optical near field. Such an aperture can be scanned raster fashion across the surface of a close-lying object. Many recorded points can then be combined to reconstruct an image of the surface. The resolution of this microscopy is not limited by the wavelength of light, but only by the size of the aperture and its distance from the object.

Near-field microscopy in the visible regime was first demonstrated independently by Pohl et al.[5] and Lewis et al.[6] Since then, several optical near-field probes have been developed. In most cases the light is directed from the light source to the aperture by a some sort of wave guide. To collect images quickly and with a good signal-to-noise ratio, it is of special importance to pass as much light as possible through the miniscule aperture. To this end, the tips of tapered optical fibers and micropipettes with dimensions on the order of 10 nanometers turned out to be ideal apertures. Other aperture geometries have also been proposed and were recently successfully employed, for example, a partially metal-coated tetrahedral tip.[7] The aperture can also be used to collect light from the object and to scatter evanescent waves from the near field into propagating modes of the optical wave-guide.

We will next describe a schematic setup of a near-field microscope in the so-called illumination (or transmission) mode (Fig. 1). Here the tip of a tapered optical fiber is used as an aperture and scanned raster fashion across the object of interest. The light is coupled into the fiber through an objective. The fiber tapers from the original fiber diameter to a tip having a flat face perpendicular to the fiber axis. The tip is produced by simultaneously heating the fiber with a CO_2 laser and pulling the ends apart. This process leads to apertures from 20 to 500 nm with high reproducibility. Finally, the tip is vapor-coated with a metal film (Al) to prevent the light from leaking out at the sides. The sample is placed within about 10 nm of the fiber tip and is moved in the x,y direction with a piezoelectric transducer. The signal is detected at each point, and the image is generated pixel by pixel. During the scan the distance between the fiber tip and the object must be kept constant by using an active feedback mechanism. An elegant approach to this is shear force feedback detection (not included in Fig. 1), in which the fiber tip is excited at one of its a high-quality mechanical resonance frequencies. The damping of the vibration as the object approaches the tip is then recorded as a distance-dependent

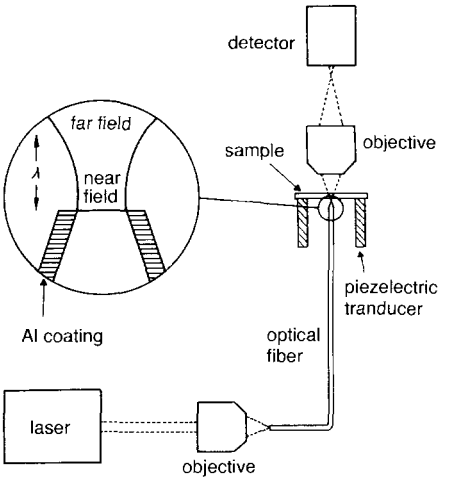

Fig. 1. Schematic setup of a scanning near-field microscope. The inset (middle left) shows the fiber tip with the near-field and far-field regions. For details see text.

signal. A lateral resolution (x,y) of about 12 nm (or $\lambda/43$) could be demonstrated with a setup similar to that shown in Figure 1.[8]

The best resolution currently possible in NSOM is roughly two to three orders of magnitude less than that of other scanning microscopic techniques like STM and AFM. Yet NSOM offers some highly interesting possibilites: 1) All contrast mechanisms known in conventional optical (far-field) microscopy can be employed, e.g. polarization, refractive index, and fluorescence. 2) NSOM is possible under ambient conditions, and light has only a weak disturbing effect on samples – an important prerequisite for the study of biomolecules. 3) Specific interactions in the optical near field (evanescent modes) can, for example, lead to local amplifications of the fluorescence. 4) NSOM can be combined with other optical spectroscopies without loss of its high local resolution. A good review of the latest, in part spectacular research in near-field microscopy, frequently conducted on biological systems, is presented in the conference proceedings[9] of the Second Near-Field Optics Conference, Raleigh, NC, USA, 1993. In addition to NSOM images of blood cells or DNA, images of, for example, quantum layers are shown. First investigations on magnetooptical data storage with NSOM have yielded storage densities of 7 Gbit cm^{-2} at a local resolution of 30–60 nm.[10]

Figure 2 shows an NSOM image (Betzig et al.) of lipophilic carbocyanine molecules spread with high dilution (about 23 molecules per μm^2) over a thin poly(methyl methacrylate) (PMMA) film.[3] High dilution ensures a mean distance between the dye molecules which is larger than the diameter of the aperture – this condition is necessary for the distinction of individual molecules. The setup of the near-field microscope was as shown in Figure 1. The excited, fluorescing single molecules, which appeared as microscopic points of light, were detected with a lateral resolution of 50 nm and a vertical resolution of 5 nm. The view that the emissions indeed arise from individual molecules is supported by a number of arguments. Most convincing is the fact that photoinduced bleaching, which happens to some of the molecules after longer illumination, does not lead to the gradual decrease of the signals, but to the discrete and total extinction of individual emissions. The very good signal-to-

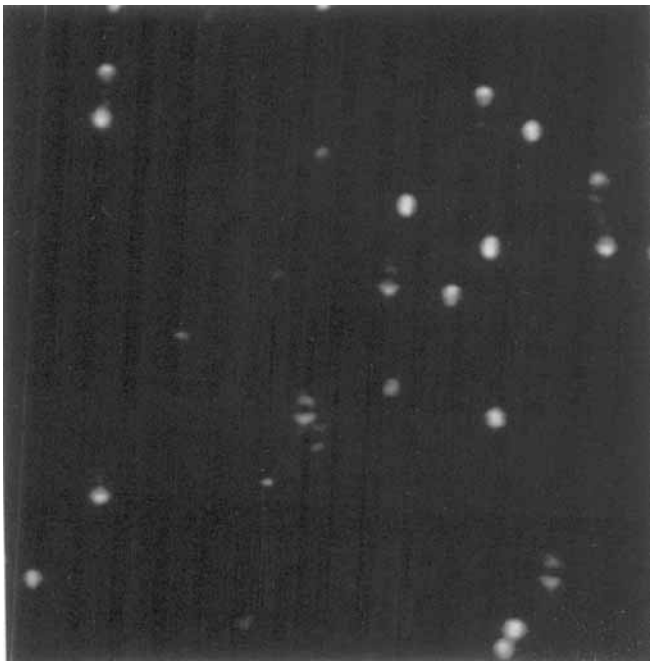

Fig. 2. Near-field microscopic picture of fluorescent single carbocyanine dye molecules on the surface of a PMMA substrate (from ref. [3]).

noise ratio in Figure 2 is attributed to the low background signal in the NSOM technique; as already discussed, only a very small sample volume is illuminated with high intensity. It is not yet clear if fluorescence amplification by evanescent fields in the optical near field contributes to the signal. At closer inspection, different geometric shapes of the structures in Figure 2 are apparent. They result from different orientations of the molecular transition dipoles. From an analysis of these shapes, the authors could determine the arrangement of the individual molecular transition dipoles, in other words of the individual molecules, on the surface. Moreover, by reverse reasoning, Betzig et al. were also able to use the molecular point dipole to map the optical near field of their fiber tip.

Ambrose et al. succeeded in imaging the fluorescence of single rhodamine 6G molecules on a silica surface using basically the same NSOM setup.[4] An interesting result of their investigation is the observation of reversible photobleaching of individual molecular chromophores. The authors attribute this effect to hopping motions that change the molecular orientation and consequently the excitation probability of the molecules. In a sense, this implies that a photoinduced reaction of a single molecule at room temperature has been observed.

We can expect that near-field microscopy will lead to many fascinating experiments with individual molecules in the near future. These include investigations on the conditions for light-induced photobleaching of individual chromophores, an unwanted effect that limits all sensitive fluorescence measurements at room temperature. Time-resolved measurements after excitation with picosecond pulses or by analysis of the fluorescence autocorrelation function are also just being tackled.[11] New perspectives of special interest are offered by investigations of single molecules at low temperatures with a combination of NSOM and optical spectroscopy. Here, an extremely high spectral resolution can be used additional to the high local resolution in NSOM.

Blue-Violet Pentamethylbismuth

Bernhard Neumüller and Kurt Dehnicke*

Pentavalent bismuth has such a high oxidation potential in acidic solution that manganese metal can be oxidized to manganate(VII) and water to oxygen. Thus, for a long time only bismuth(V) compounds with highly electronegative partners, such as fluorine and oxygen, were considered as isolable solids. Examples include BiF_5, which forms linear chains of edge-linked octahedra,[1] and hexafluorobismutates such as $NaBiF_6$ derived from it.[2] The synthesis of defined oxo compounds of pentavalent bismuth is already far more difficult. The well-known "Bi_2O_5" has still not been prepared in a pure form. In contrast, several mixed-valent bismutates(III)/(V), such as $(Ba,K)BiO_3$[3] or the high-temperature superconductors of the copper–bismuth family $Bi_2Sr_2CaCu_2O_{8+x}$,[4] have been obtained as stoichiometric compounds; however, the positions of Bi^{III} and Bi^{V} could not be identified either by spectroscopy or by crystallography. The locations of Bi^{3+} and Bi^{5+} in the crystal lattice were clearly assigned for the first time recently, based on the Bi–O distances, in the mixed-valent silver bismutate $Ag_{25}Bi_3O_{18}$ obtained by high-pressure synthesis from Ag_2O, "Bi_2O_5", and oxygen.[5]

Under these circumstances it was very surprising that pentaphenylbismuth (**1**)[6] and the complex ions tetraphenylbismutonium[6] and hexaphenylbismutate[7, 8] derived from it were prepared readily. Hexaphenylbismutate was recently structurally characterized in $[Li(thf)_4][BiPh_6]\cdot 2THF$.[9] Because of the relatively large group electronegativities of phenyl groups and their substituted derivatives,[10] these appear, among organic ligands, to be particularly suitable for the stabilization of Bi^{V}. In the meantime, several more pentaarylbismuth(V) compounds have been prepared and structurally characterized (Table 1). All

Table 1. Structurally characterized pentaorganobismuth compounds.

Compound	No.	Color solution	Color solid	Local symmetry in the solid	Ref.
$BiPh_5$	**1**	violet	violet	C_{4v}	[11]
$(4\text{-}MeC_6H_4)_3Bi(C_6F_5)_2$	**2**	yellow	yellow	C_{4v}	[12]
$(4\text{-}FC_6H_4)_3Bi(C_6F_5)_2$	**3**	yellow	yellow	C_{4v}	[12]
$Ph_3Bi(2,6\text{-}F_2C_6H_3)_2$	**4**	orange-red	orange-red	C_{4v}	[12]
$Bi(4\text{-}MeC_6H_4)_5\cdot Li(THF)_2Cl$	**5**	violet-red	violet-red	D_{3h}/C_{4v}	[13]
$(4\text{-}MeC_6H_4)_3Bi(2,6\text{-}F_2C_6H_3)_2$	**6**	orange-red	orange-red	C_{4v}	[13]
$Ph_3Bi(C_{12}H_8)$	**7**	orange-red	orange-red	C_{4v}	[13]
$Ph_3Bi(2\text{-}FC_6H_4)_2$	**8**	red	violett	C_{4v}	[14]
$(4\text{-}MeC_6H_4)_3Bi(2\text{-}FC_6H_4)_2$	**9**	red	orange	D_{3h}	[14]
$BiMe_5$	**10**	blue-violet	violet	D_{3h}	[15]

of these compounds have monomeric molecular structures, in which the square-pyramidal arrangement (local symmetry C_{4v}) predominates. Exceptions are **9**, in which the Bi atom is trigonal-bipyramidally surrounded (local symmetry D_{3h}), and **5**, which possesses a local symmetry between C_{4v} and D_{3h}.

Taking all these findings into consideration the possibility of preparing methylbismuth(V) compounds had to be regarded as highly unlikely, since the CH_3 group with 2.472 has the lowest group electronegativity of all organic groups (cf. phenyl: 2.717).[10] However, Seppelt et al. have recently successfully synthesized pentamethylbismuth (**10**) by treatment of dichlorotrimethylbismuth, which in turn was accessible from trimethylbismuth and sulfuryl chloride, with methyllithium in diethyl ether at −95 °C according to Equation (a):[15]

$$Bi(CH_3)_3Cl_2 + 2\,LiCH_3 \xrightarrow[-95\,^\circ C]{Et_2O} \underset{\mathbf{10}}{Bi(CH_3)_5} + 2\,LiCl \qquad (a)$$

Violet crystals of **10**, which were suitable for an X-ray structure analysis at −163 °C, were isolated from the blue-violet solution at −110 °C. According to this structure analysis **10** is trigonal bipyramidal; its Bi–C distances are equal within the standard deviations (227 and 230(2) pm). This finding is in accordance with the large atomic radius of the Bi atom, which leads to only small ligand–ligand interactions; thus, there are no measureable differences between the axial and the equatorial position.[16]

Compound **10** is very unstable, in solution it decomposes, probably with evolution of ethane, to give trimethylbismuth; in the crystalline state it explodes on rapid warming to room temperature. All the methyl groups are equivalent in the ^1H NMR spectrum even at −90 °C. This suggests that the CH_3 groups change places by way of a Berry mechanism, during which the tetragonal pyramid is an intermediate state.[17]

In contrast, the salt containing the tetramethylbismutonium cation, prepared by a quaternization reaction from trimethylbismuth and methyl trifluoromethanesulfonate [Eq. (b)], is thermally stable up to 150 °C.

$$Bi(CH_3)_3 + CH_3OSO_2CF_3 \longrightarrow [Bi(CH_3)_4]^+SO_3CF_3^- \qquad (b)$$

The structure of the cation fits perfectly into the series of tetramethylelement compounds of N to Sb, which are also tetrahedral. There were indications of the existence of the $[Bi(CH_3)_4]^+$ ion previously, however, in the β decay of $^{210}Pb(CH_3)_4$.[18]

When reaction (a) was carried out with excess methyllithium and in the presence of tetrahydrofuran at −78 °C, hexamethylbismutate, which is isoelectronic with hexamethyltellurium,[19] can be isolated as yellow crystals [Eq. (c)].[15]

$$Bi(CH_3)_3Cl_2 + 3\,LiMe \xrightarrow{THF} [Li(THF)_4]^+[Bi(CH_3)_6]^- \qquad (c)$$

As expected, the octahedral hexamethylbismutate is only stable at low temperatures. Its Bi–C bonds of 230 to 236(2) pm are slightly longer than those in **10**.

A fascinating, but still not fully answered question is the relationship between the color and the structure of pentaorganobismuth compounds. Ab initio calculations on the hypothetical BiH_5 reveal that the HOMO–LUMO separation is only about half as large for tetragonal symmetry as it is for trigonal-bipyramidal symmetry, when relativistic effects are taken into consideration.[14] A charge transfer transition explaining the blue color of pentaphenylbismuth could thus be easily deduced from its tetragonal-pyramidal structure. A look at Table 1 shows, however, that this is only valid for **5**, whereas all other arylbismuth(v) derivatives are yellow to orange-red despite having tetragonal-pyramidal structures. The packing effects[14] and electron-withdrawing effects of substituents, above all for those derivatives with fluoro-substituted phenyl groups, were put forward to explain this behavior.[12] In contrast, the + I effect of the methyl groups is used to explain the blue color of **10**. This effect should ease the charge transfer transition despite the trigonal-bipyramidal structure.[15]

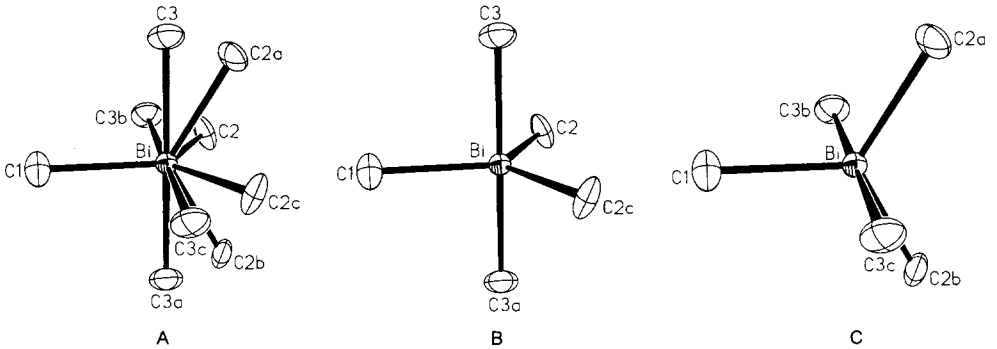

Fig. 2. Structure of the molecule of **10** with **A** as the resultant of the two disordered units B and C. Only the C atoms 2 and 3 participate in the disorder (50% probability for the thermal ellipsoids; in the original publication [15] two thermal ellipsoids, ((3a) or (3b), (2a) or (2b)) were drawn with the wrong spatial orientation).

To assess the possible influence of special features of the packing effects on the blue-violet color of pentamethylbismuth, we drew the unit cell using the atomic coordinates that were made available to us.[20] The view along the crystallographic *b* axis is shown in Figure 1. The atoms Bi and C1 lie on the section line

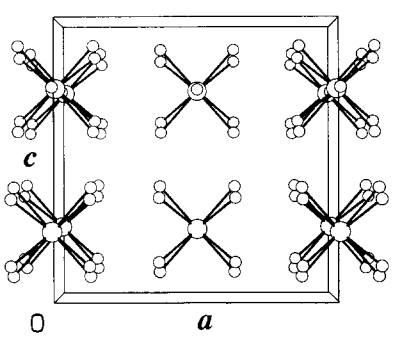

Fig. 1. Illustration of the unit cell of **10** showing the disorder. View along the crystallographic *b* axis.

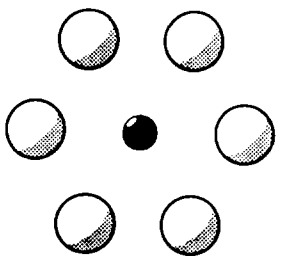
intersecting mirror planes (cf. also Fig. 2). The chosen view of the unit cell of **10** gives the impression of tetragonal symmetry for the individual molecules, as is the case in the structure of BiF_5 along the needle axis.[1] Unlike the latter example, in **10** this impression is simulated by a disorder of the $Bi(CH_3)_5$ molecules, as it results (form **A**) from the superposition of two trigonal-bipyramidal units (**B** and **C** in Fig. 2). In the solid-state structure of **10** at −163 °C there are no indications of a conceivable dynamic process involving a Berry pseudorotation, contrary to what was detected for **10** in solution even at −90 °C.[15] Such indications would be expressed by special features of the thermal ellipsoids of C2 and C3. Thus, there is no doubt about the trigonal-bipyramidal structure of **10**.



However, on the otherhand, the unit cell would allow installation of single $Bi(CH_3)_5$ molecules with tetragonal symmetry along the *b* axis, which as "coloring centers" might then be responsible for the blue-violet color. The occasional occurrence of such tetragonal units, which are intermediates in the pseudorotation process, cannot be ruled out without further investigation because pseudorotation is still to be expected at the melting point of **10** at −110 °C .[21] An ab initio calculation at a very high level of theory will be required before a definitive explanation of the correlation between the color and the structure of pentamethylbismuth can be made.

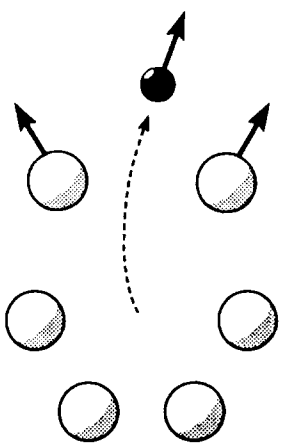
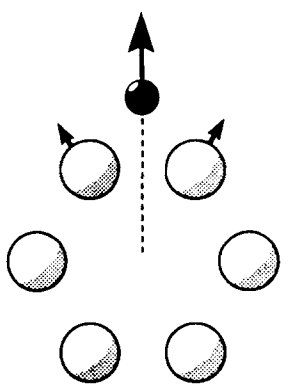
[20] We thank Prof. Dr. K. Seppelt for providing us with the structure data. The structure of **10** was solved in the non-conventional setting *Ccnm* by the authors [15]. Our Figures are based on the conventional setting *Cmcm*.
[21] Based on the structure data available to us a twinning of the crystals for **10** is difficult to imagine. Unlike in the case of a superstructure, which, for example, would lead to the doubling of one of the lattice constants. However, this would mainly affect the positions of the C atoms. As a result of the high scattering factor of the bismuth atoms, superstructure reflections, which might occur, could only be detected with low-temperature measurements.

Handbook of Hot Atom Chemistry

Edited by J.-P. Adloff et al.





1992. XIII, 702 pages.
Hardcover. DM 345.00.
ISBN 3-527-29001-X

Hot atom chemistry is an increasingly important field, which has contributed significantly to our understanding of many fundamental processes and reactions. Its techniques have become firmly entrenched in numerous disciplines, such as applied physics, biomedical research, and all fields of chemistry.

Written by leading experts, this comprehensive handbook encompasses a broad range of topics. Each chapter comprises a collection of stimulating essays, giving an in-depth account of the state-of-the-art of the field, and stressing opportunities for future work.

An extensive introduction to the whole area, this book provides unique insight into a vast subject, and a clear delineation of its goals, techniques, and recent findings. It also contains detailed discussions of applications in fields as diverse as nuclear medicine, geochemistry, reactor technology, and the chemistry of comets and interstellar grains.

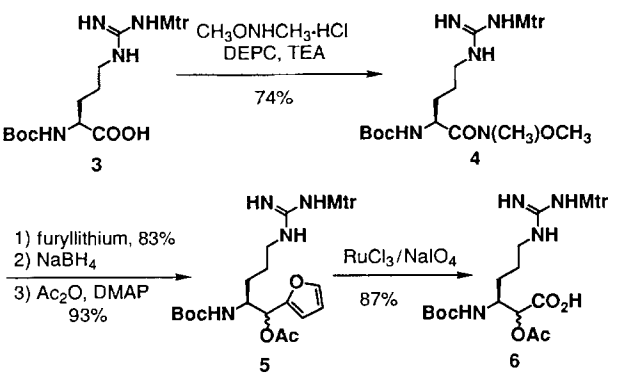
Synthesis of Cyclotheonamide B and Its Derivatives**

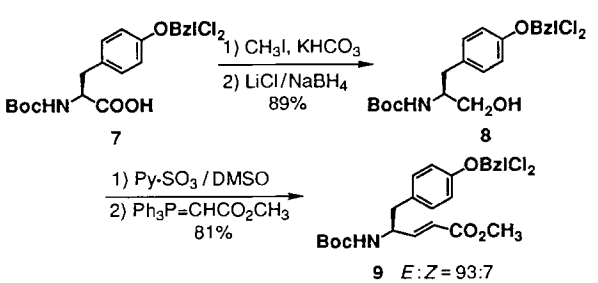
Jingen Deng, Yasumasa Hamada, Takayuki Shioiri,* Shigeki Matsunaga, and Nobuhiro Fusetani

Cyclotheonamides A (**1**: R = CHO; X, Y = O) and B (**2a**: R = Ac; X, Y = O) have been isolated from a marine sponge of the genus *Theonella* collected off Hachijo-jima Island, Japan.[1] These macrocyclic pentapeptides strongly inhibit various proteinases, particularly thrombin, and are the first macrocyclic thrombin inhibitors having two novel amino acid residues: a vinylogous tyrosine and an arginine extended by a carbonyl group in the α-position (α-carbonyl homologue of arginine) (Scheme 1). Their structural uniqueness as well as intriguing biological activities motivated their total synthesis[2–5] and determination of their mechanism of serine protease inhibition.[4, 6]



cyclotheonamide A **1**, R = CHO, X, Y = O
cyclotheonamide B **2a**, R = Ac, X, Y = O
2b, R = Ac, X = H, Y = OH
2c, R = Ac, X = OH, Y = H

Scheme 1. The macrocyclic pentapeptides **1** and **2** and the disconnections crucial for the convergent synthesis.



Herein, we report on an effective total synthesis of cyclotheonamide B (**2a**) and its derivatives **2b** and **2c**, in which the α-carbonyl group of the arginine homologue is reduced. In our strategy, the organophosphorus reagents diethylphosphonocyanidate ($(C_2H_5O)_2P(O)CN$, DEPC)[7] and pentafluorophenyldiphenylphosphinate ($Ph_2P(O)OC_6F_5$, FDPP),[8] were used for formation of the peptide bond with satisfactory efficiency. A convergent strategy was adopted (Scheme 1), and coupling of the two fragments was accomplished at the position at which no epimerization can occur. The noteworthy features are the high-yielding (>80%) final macrolactamization with FDPP and the utilization of the 2-furyl group as the synthetic equivalent of the carbonyl group.[9]

Since the α-carbonylamide function was reported to form tetrahedral hemiketals with serine proteases[4, 6] and play a main role in the enzyme affinity of cyclotheonamide A (**1**), we expected to use the two dihydro analogues **2b** and **2c** to confirm the biological importance of the α-carbonylamide moiety.

Synthesis of the western part started from N^{α}-*tert*-butoxycarbonyl-N^{ω}-(4-methoxy-2,3,6-trimethylbenzenesulfonyl)-(*S*)-arginine (**3**, Boc-(*S*)-Arg(Mtr)-OH), which was coupled with *N*,*O*-dimethylhydroxylamine (DEPC, triethylamine (TEA), dimethylformamide (DMF), room temperature (RT), 4 h). The resultant Weinreb amide **4** was condensed with 2-furyllithium, generated from furan (*t*BuLi, THF, −78 °C, 1 h; 0 °C, 4 h), followed by reduction ($NaBH_4$, MeOH, −10 °C, 0.5 h) and then acetylation (Ac_2O, DMAP, CH_2Cl_2, RT, 12 h) to give the furan derivative **5** as a mixture of the *syn* and *anti* isomers in a ratio of 61:39).[10] The ruthenium-catalyzed oxidation ($RuCl_3$/$NaIO_4$, $CH_3CN/CCl_4/H_2O$, 1.5 h)[9, 11] smoothly afforded the α-acetoxycarboxylic acid **6**, a precursor of the α-carbonyl homologue of arginine.

Synthesis of the (*E*)-vinylogous (*S*)-tyrosine derivative **9** was achieved stereoselectively and in good yield from the amino alcohol **8** in a one-pot reaction.[12] *N*-*tert*-Butoxycarbonyl-*O*-2,6-dichlorobenzyl-(*S*)-tyrosine (**7**, Boc-(*S*)-Tyr(Cl_2Bzl)-OH) was converted into **8** by synthesis of the methyl ester (CH_3I, $KHCO_3$, DMF, RT, 4 h) and subsequent reduction (LiCl/$NaBH_4$, THF/EtOH, RT, 12 h) according to our method.[13] Oxidation of **8**

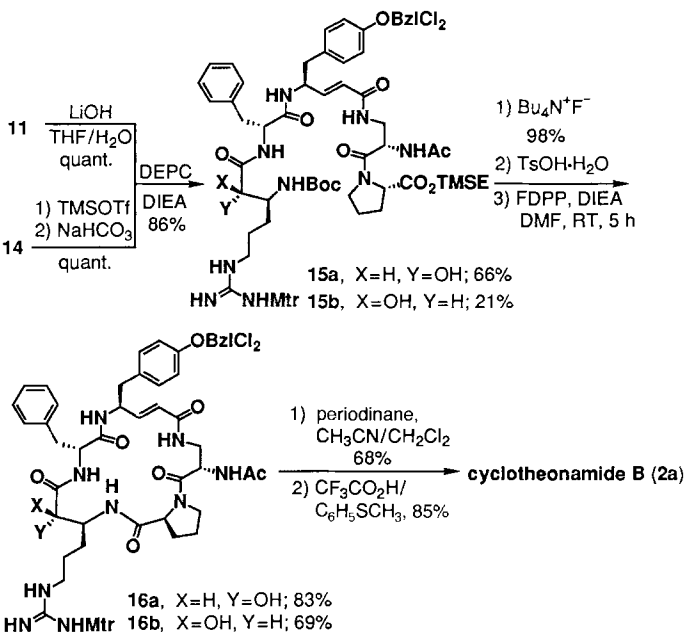
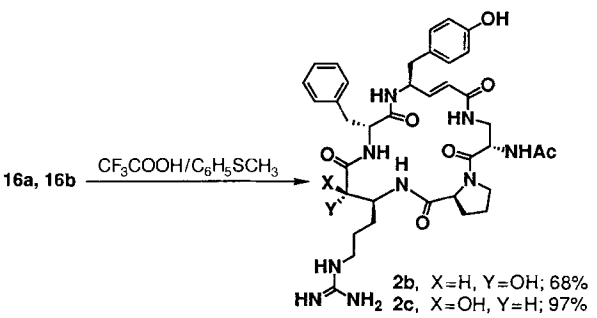
(dimethyl sulfoxide (DMSO), sulfur trioxide/pyridine complex, TEA, 0.5 h) followed by Wittig reaction with methoxycarbonylmethylenetriphenylphosphorane afforded the (*E*)-vinylogous tyrosine derivative **9** (m.p. 125–126 °C, $[\alpha]_D^{25} = +4.3$ ($c = 1.03$ in MeOH) as the major product together with a small amount of the corresponding (*Z*) isomer (*E*:*Z* = 93:7).



The required western fragment **11** was prepared from **9** by attachment of Boc-(*R*)-phenylalanine (**10**, Boc-(*R*)-Phe-OH) and then the arginine derivative **6** through acidic deprotection of the N-terminal Boc group (4N HCl/dioxane, 0 °C, 2 h then RT, 0.5 h) and coupling by use of DEPC (TEA, DMF, 0 °C, 12 h). Compound **11** was obtained as a mixture of the *syn* and *anti* isomers, **11a** and **11b**, in a ratio of 69:31.



The eastern fragment **14** (m.p. 88–89 °C, $[\alpha]_D^{22} = -42.3$ ($c = 1.05$ in $CHCl_3$) was synthesized by condensation of N^{α}-Cbz-N^{β}-Boc-(*S*)-2,3-diaminopropionic acid (**12**)[14] (Cbz = carbobenzoxy) with the salt of (*S*)-proline trimethylsilylethyl (TMSE) ester and toluenesulfonic acid (**13**) in the presence of of DEPC (TEA, DMF, 0 °C, 12 h), subsequent hydrogenolytic removal of the Cbz group (H_2, $PdCl_2$, MeOH, 0.5 h), and acetylation of the free amino group (Ac_2O, TEA, CH_2Cl_2, RT, 12 h).

Before the convergent construction of the whole carbon skeleton of cyclotheonamide B (**2a**), the protecting group at the C-terminus of **11** was removed under alkaline conditions (LiOH, THF/H_2O, 0 °C, 3.5 h then RT, 3.5 h), and the protecting group at the N^{β}-terminus of **14** was cleaved by treatment with trimethylsilyl triflate (TMSOTf) in CH_2Cl_2 and then saturated aqueous $NaHCO_3$. TMSOTf was more effective than CF_3CO_2H or *p*-TsOH. Coupling of the two deprotected fragments (DEPC, diisopropylethylamine (DIEA), DMF, 0 °C, 12 h) afforded the linear pentapeptides **15a** and **15b**, which were easily separated by column chromatography on silica gel[15] in yields of 66 and 21%, respectively. After removal of the protecting group at the C-terminus ($Bu_4NF \cdot 3H_2O$, THF, 0 °C, 3.5 h then RT, 1.5 h) and then at the N-terminus (*p*-TsOH·H_2O, CH_2Cl_2, RT, 12 h), the macrolactamization was efficiently achieved by use of FDPP in the presence of DIEA in DMF to give **16a** and **16b** in 83 and 69% yield, respectively. The major isomer **16a** was oxidized with the Dess–Martin periodinane[16] (CH_3CN/CH_2Cl_2 (1:2), 50 °C, 6 h) to give the oxo compound. Subsequent removal of both the 2,6-dichlorobenzyl and the 4-methoxy-2,3,6-trimethyl-

benzenesulfonyl groups with trifluoroacetic acid/thioanisole (RT, 20 h) followed by purification with preparative HPLC afforded cyclotheonamide B (**2a**) ($[\alpha]_D^{24} = -13.1$ ($c = 0.2$ in MeOH), which was identified by comparison of its spectra with those of the natural product. Analogously, deprotection of **16a** and **16b** and then purification by HPLC afforded the hydroxy derivatives of cyclotheonamide B, **2b** and **2c**, in 68 and 97% yield, respectively (**2b**: $[\alpha]_D^{25} = -7.9$ ($c = 0.21$ in MeOH); **2c**: $[\alpha]_D^{25} = -4.2$ ($c = 0.22$ in MeOH)).

The enzyme inhibiting activities of the synthetic cyclotheonamide B (**2a**) and its hydroxy derivatives **2b** and **2c** were evaluated against thrombin and trypsin in comparison with natural cyclotheonamide A (**1**). Although **2a** showed full activity against thrombin and trypsin,[17] **2b** and **2c** exhibited little or no activity. These results clearly indicate that the α-carbonylamide portion dominates the enzyme inhibiting action of cyclotheonamides. A more detailed investigation of the inhibiting action and the synthesis of analogues of cyclotheonamide B are in progress.

[17] The IC_{50} values for our synthetic cyclotheonamide B (**2a**) against thrombin and trypsin are 7.2 and 17 ng mL^{-1}, respectively, while those for natural cyclotheonamide A (**1**) are 7.2 and 10 ng mL^{-1} under the same conditions. Since cyclotheonamide B was not available, the comparative study of the enzyme inhibition was not possible.

Decaphenylferrocene and Decaphenylferrocenium Tetrafluoroborate**

Herbert Schumann,* Alexander Lentz, Roman Weimann, and Joachim Pickardt

In memory of J. J. Zuckerman

Although decaphenylferrocene (**1**) was first described in 1983 by Slocum et al.,[1] a symmetrical sandwich structure has not to date been established for this metallocene. The NMR spectra of **1**, obtained from $[Fe(CO)_5]$ and C_5Ph_5Br, were interpreted by Masters et al. in terms of a zwitterionic complex $[(\eta^5\text{-}C_5Ph_5)Fe]^+[(\eta^6\text{-}C_6H_5\text{-}C_5Ph_4]^-$.[2] The proposed structure could not however be confirmed by X-ray structure analysis. One argument in favor of this zwitterionic structure arises from the considerable spatial requirements of the five phenyl groups, whose coplanar arrangement about the cyclopentadienyl anion is therefore hindered. A propeller-like structure, analogous to that observed for decaphenylstannocene,[3] is adopted. It is argued that the short Fe–Cp_z distance of 170 pm (Cp_z = center of cyclopentadienyl ligand),[4] which has been shown to be necessary for additional π-bond stabilization of ligand–iron bonding in symmetric sandwich compounds, can no longer be achieved. However, in octaphenylferrocene,[5] which has only two fewer phenyl groups, an Fe–Cp_z distance well within that required for stabilization is observed. The same holds for the recently described pentaphenylferrocene[6] and for decabenzylferrocene,[7, 8] in which all the benzyl groups point away from the metal, in contrast to all other previously known pentabenzylcyclopentadienyl complexes.[9]

At first our investigations confirmed the argument based on bond-length criterion presented above. Thus, reaction of $[(C_5Ph_5)Fe(CO)_2Br]$[10] in xylene at 80 °C yielded, after hydrolysis with conc. HCl, only the orange-red salt **2**. In the complex

$[Fe(\eta^6\text{-}C_6H_4Me_2)(\eta^5\text{-}C_5Ph_5)]^+[FeCl_4]^-$ **2**

cation of **2**, a sterically less demanding xylene molecule was found to replace the second C_5Ph_5 ligand.[11] Also, the metathesis and metal-vapor methods successfully employed in the synthesis of decaphenylstannocene could not be applied to decaphenylferrocene. However, when $[(C_5Ph_5)Fe(CO)_2Br]$ was heated for two days in boiling xylene [Eq. (a)], **1** was isolated in 30% yield as a pink, microcrystalline powder, insoluble in all common solvents. Complex **1**, which is inert to 0.1 N HCl and is stable up to 400 °C, was also formed when **2** was heated to 350 °C [Eq. (b)].

$$2[(C_5Ph_5)Fe(CO)_2Br] \xrightarrow{130\,^\circ C} \underset{\mathbf{1}}{[Fe(C_5Ph_5)_2]} + FeBr_2 + 4\,CO \qquad (a)$$

The single crystal X-ray structure analysis of **1** (Fig. 1)[12] performed on the microcrystals obtained could only be refined to R = 0.159. An in-depth discussion of the bonding in **1** is therefore not possible. However, like the ^{13}C solid-state NMR, IR, and Raman spectra,[13] the structure analysis also confirms the presence of a symmetric sandwich complex, isostructural with decaphenylstannocene.[14] Oxidation of **1** with $NOBF_4$ yielded

$$\underset{\mathbf{2}}{[Fe(\eta^6\text{-}C_6H_4Me_2)(\eta^5\text{-}C_5Ph_5)]^+[FeCl_4]^-} \xrightarrow{350\,^\circ C} \underset{\mathbf{1}}{[Fe(C_5Ph_5)_2]} \qquad (b)$$

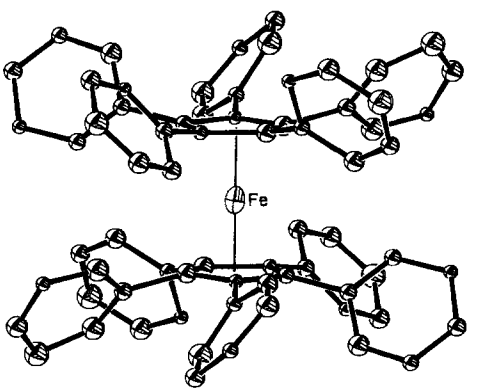

Fig. 1. ORTEP diagram of a molecule of **1** (ellipsoids at the 50% probability level). The average distance between the Fe atom and the C atoms of the Cp ligand is 211 pm.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB "Anisotropic Fluids") and the Bundesministerium für Bildung und Wissenschaft through the Graduiertenkolleg "Synthese und Strukturaufklärung niedermolekularer Verbindungen".

decaphenylferrocenium tetrafluoroborate **3** [Eq. (c)] in 81% yield as dark, reddish brown crystals, which were extremely soluble in polar solvents.

$$\underset{\mathbf{1}}{[Fe(C_5Ph_5)_2]} + [NO]^+[BF_4]^- \longrightarrow \underset{\mathbf{3}}{[Fe(C_5Ph_5)_2]^+[BF_4]^-} + NO \qquad (c)$$

Cyclic voltammetric investigations (Fig. 2) show that **3** is reversibly reduced to **1** in CH_3CN. Precipitation of **1**, which is

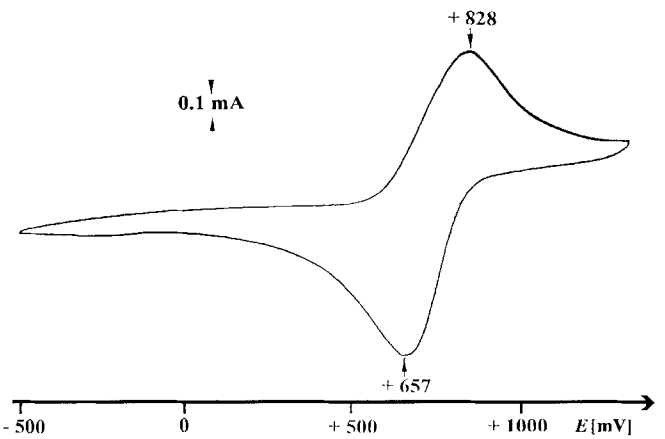

Fig. 2. Cyclic voltammogram of $[Fe(C_5Ph_5)_2]$ / $[Fe(C_5Ph_5)_2]^+[BF_4]^-$ [4.4 mg of **3** per mL of CH_3CN solvent; supporting electrolyte Bu_4NBF_4 (0.1 M); Pt/Pt electrodes (0.56 cm^2); Ag/AgCl reference electrode (Metrohm); salt bridge agar-agar/sat. KCl solution; potential scanned at 200 mVs^{-1}; room temperature; E_0 = +743 mV (Ag/AgCl)]. We thank Dr. Miklautz, Schering AG, Berlin, for the cyclic voltammetric measurements.

only sparingly soluble in CH_3CN, is observed. The redox potential [mV] for the one-electron oxidation of **1** is +743 (Ag/AgCl) and is therefore of the same order of magnitude as the values obtained for the parent compound ferrocene (+493[15] and +433[16] in CH_3CN, +593 in THF[16]), decabenzylferrocene (+333 in CH_3CN, +563 in THF),[16] pentabenzylferrocene (+443 in CH_2Cl_2),[16] and benzylferrocene (+403 in CH_3CN)[17] (all vs. Ag/AgCl).

The salt **3** crystallizes from CH_2Cl_2 with two molecules of solvent in the crystal lattice.[18] Two independent $[Fe(C_5Ph_5)_2]^+$

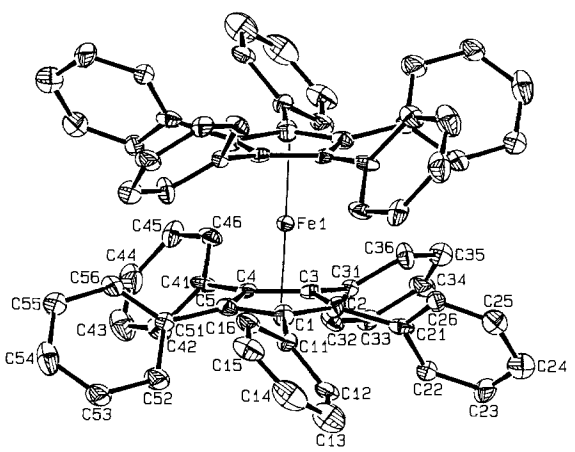

Fig. 3. ORTEP diagram of one of the two cations of **3** (ellipsoids at the 50% probability level). Selected bond lengths, deviations [pm] and interplanar angles [°]. Fe-C1 217(1), Fe-C2 215(1), Fe-C3 213(1), Fe-C4 216(1), Fe-C5 221(1), Cp-C11 18(6), Cp-C21 34(6), Cp-C31 23(6), Cp-C41 19(6), Cp-C51 24(6); Cp-Ph1 43.7(7), Cp-Ph2 57.6(6), Cp-Ph3 47.2(7), Cp-Ph4 50.9(7), Cp-Ph5 48.8(7).

ions are located within the unit cell. The positions occupied by the Fe atoms are related by a crystallographic center of inversion. One of the two cations is shown in Figure 3. The sandwich structure of the symmetrically disposed cyclopentadienyl ligands can be clearly seen. The cyclopentadienyl ligands are separated by distances of 358.6 (Fe1) and 358.0 pm (Fe2). The Fe^{3+} ions are shifted by 6.7 (Fe1) and 4.7 pm (Fe2) from the Cp_z-Cp_z line. The phenyl substituents bound to the planar cyclopentadienyl ligands are not only twisted out of the plane of the cyclopentadienyl ligands in a propeller-like arrangement, but also point away from the metal center. The two cyclopentadienyl ligands are therefore able to approach the Fe^{3+} ion more easily. Although the interplanar distance is 27 pm greater than that observed for decabenzylferrocene (331.3 pm[7]), it is, nonetheless, clearly shorter than that for decaphenylstannocene (480.2 pm[3]). In the latter, molecular stabilization through π interactions between the central tin atom and the cyclopentadienyl ligands is not possible, but also not necessary.

Experimental Procedure

1: A blue solution of $[(C_5Ph_5)Fe(CO)_2Br]$ (2.5 g, 3.9 mmol) in xylene (100 mL) was heated under reflux for 48 h. The mixture was acidified to pH 1 with conc. HCl and ice water. A reddish brown precipitate was collected and combined with the organic phase from the filtrate. The mixture was concentrated and the solid obtained extracted for 24 h with toluene, 2 d with THF, and then 5 h with CH_2Cl_2. The product **1** was obtained from the residue and dried at 10^{-3} Torr. Correct C,H analysis; MS (70 eV, 370 °C): *m/z* (%): 948 (32) $[M^+ + H]$, 947 (56) $[M^+]$, 946 (100) $[M^+ - H]$, 501 (23) $[M^+ - C_5Ph_5]$, 446 (2) $[C_5Ph_5^+]$.

3: To a suspension of **1** (0.60 g, 0.63 mmol) in CH_2Cl_2 (20 mL) was added rapidly $NOBF_4$ (0.12 g, 1.00 mmol). After it had been stirred for 12 h at room temperature, the mixture was filtered. The solution was treated with ether (20 mL) and cooled to −30 °C. Reddish brown crystals of **3** were obtained (0.53 g, 81%). M.p. 315 °C (dec.); correct C,H analysis; ^1H NMR (270 MHz, CD_2Cl_2, TMS): δ = 5.9–6.6 (Ph-H); MS (70 eV, 360 °C): *m/z* (%): 948 (15) $[M^+ + H]$, 947 (33) $[M^+]$, 946 (44) $[M^+ - H]$, 502 (13) $[M^+ - C_5Ph_5 + H]$, 501 (25) $[M^+ - C_5Ph_5]$, 446 (13) $[C_5Ph_5^+]$.

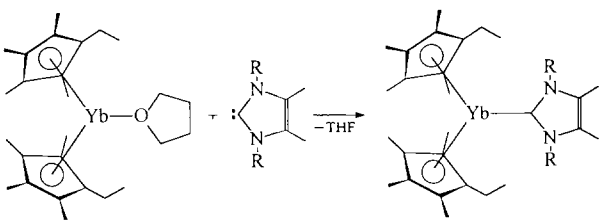
Organolanthanoid–Carbene-Adducts**

Herbert Schumann*, Mario Glanz, Jörn Winterfeld, Holger Hemling, Norbert Kuhn,* und Thomas Kratz



Dedicated to Professor Ekkehardt Lindner on the occasion of his 60th birthday

Carbenes usually exhibit acceptor properties as ligands and are most often dependent on classic backbonding for the formation of stable metal complexes. For this reason lanthanoid metals with their 4f electrons, which lie deep in the inside of the electron shell and thus hardly participate in bonding, are considered to be very poor coordination partners for carbenes. The reports that have recently appeared on stable derivatives of imidazol-2-ylidene[1] open up new possibilities due to the nucleophilic character of these compounds. The successful synthesis of stable adducts with iodine,[2] tellurium,[3] selenium,[4] and, in particular, the bond formation to electron-deficient centers such as GeI_2,[5] AlH_3,[6] and BH_3[7] gave the impression that it should also be possible to prepare lanthanoid carbene complexes.[8] Particularly suitable for this should be oligomethylated bis(cyclopentadienyl)samarium(II), -europium(II), and -ytterbium(II) derivatives, which can not only alter the oxidation state,[9–11] but also have enough space for a sterically demanding third ligand because of their bent structure.

[**] Organometallic Compounds of Lanthanoids, Part 86. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Bundesministerium für Bildung und Wissenschaft (Graduiertenkolleg „Synthese und Strukturaufklärung niedermolekularer Verbindungen"). Part 85: H. Schumann, J. Winterfeld, M. Glanz, R. D. Köhn, H. Hemling, *J. Organomet. Chem.*, in press.

Thus, treatment of the bis(ethyltetramethylcyclopentadienyl)ytterbium complex **1** with the imidazol-2-ylidenes **2** leads to the corresponding organolanthanoid–carbene adducts **3** in good yields. Compounds **3** are thermally very stable (decomposition temperature at 0.1 mbar for **3a** is 229 °C and 155 °C for **3b**) and can be isolated as black crystals. They are soluble in relatively polar and aromatic solvents such as tetrahydrofuran, diethyl ether, toluene, and benzene. In contrast, they are only sparingly soluble in hexane or pentane. Both products **3** are considerably more stable to air and moisture than **1**.

1 **2a**: R = Me **3a**: R = Me
2b: R = *i*Pr **3b**: R = *i*Pr

The chemical shifts in the ^1H and ^{13}C NMR spectra of **3a** and **3b** are as expected and are not significantly different from the data of complex **1** and those of the carbenes **2**. These results and the intense dark color of the isolated adducts clearly show that quasi-coordinative Yb^{II}–C bonds are present in **3** and that **3a** and **3b** are not paramagnetic Yb^{III} compounds. The ^{13}C NMR spectrum also indicates a new quality of the metal carbene interactions, since in **3**, in contrast to the ylidene complexes of I_2, Se, Te, GeI_2, BH_3, and AlH_3,[2–7] the carbene carbon atom is slightly shifted for the first time to higher field by about 8 ppm.

The electron impact (70 eV) mass spectra of **3a** and **3b** show no peak for the molecular ion; only several peaks for metal–carbene fragments occur in addition to the expected signals for $[(C_5Me_4Et)Yb]^+$ and $[(C_5Me_4Et)_2Yb]^+$.

In the crystal the ylidene forms a planar five-membered ring, the plane of which to a good approximation also contains all the atoms bound to the heterocycle (Fig. 1). Alternating bond lengths, which are also observed in other complexes, occur within the carbene ring; however, here they are not so pronounced.[7] Whereas the C13–N (1.387(5) Å) distance indicates

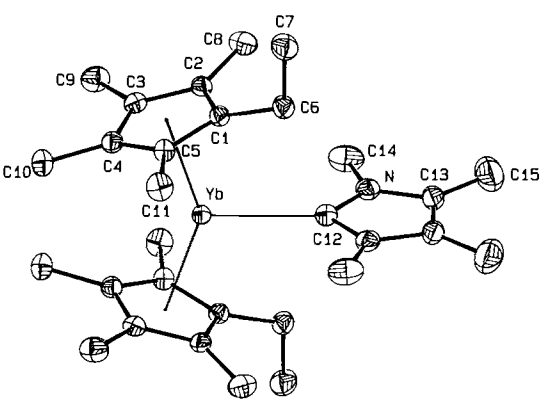

Fig. 1. Crystal structure of **3a** (ORTEP [12], thermal ellipsoids drawn at 50% probability level (the atom positions produced by symmetry operations [−x, y, 1.5−z] are not shown). Selected distances [Å] and angles [°] (standard deviations are given in parentheses) [13]: Yb–C1 2.669(4), Yb–C2 2.692(4), Yb–C3 2.688(4), Yb–C4 2.671(4), Yb–C5 2.648(3), Yb–C12 2.552(4); Cp-Yb-Cp 144.0(4), Cp-Yb-C12 107.5(4).

a formal single bond, the distances C13–C13′ (1.358(11) Å) and C12–N (1.362(4) Å) are shorter and lie in the range expected for double bonds. The exocyclic C–C (1.489(6) Å) and N–C bonds (1.453(6) Å) of the ylidene,[7] and the Yb–C distances to the cyclopentadienyl ligand[9] (average 2.674(4) Å) as well as the Cp-Yb-Cp and Cp-Yb-C12 angles[9] correspond to the expected values. The Yb–C12 bond length is appropriate for an extended single bond and is slightly longer than the corresponding distances in $[\{Cp_2Yb(\mu\text{-Me})\}_2]$ (2.49 Å, 2.54 Å);[16] however, it is significantly shorter than the corresponding bonds in $[Cp^*_2Yb(\mu\text{-Me})BeCp^*]$ (2.77 Å)[17] or $[Cp^*_2Yb(\mu\text{-Et})AlEt_2(thf)]$ (2.85 Å).[18] This illustrates the problems associated with the discussion of the structure in comparison to classic carbene complexes. Whereas the nearly trigonal-planar configuration of the C12 atom, which almost corresponds to sp^2 hybridization, and the p_π-p_π interactions in the bonds C12–N can be interpreted as characteristic features of a carbene complex, the Yb–C12 distance does not fit into the range expected for a double bond. As a consequence of the lack of Yb–C backbonding, **3a** and **3b** can be considered as Fischer-type carbene adducts of organolanthanoid(II) compounds.

Experimental Procedure

Compound **1** was obtained analogously to Cp^*_2Yb [9], and **2a, b** were prepared according to literature [1]. The NMR spectra were recorded with a Bruker AMX 200 spectrometer at 200 MHz (^1H) or 50.32 MHz (^{13}C).

3a: **2a** (0.16 g, 1.3 mmol) in THF (5 mL) was added dropwise to a solution of **1** (0.68 g, 1.2 mmol) in THF (40 mL) at −30 °C and stirred for 12 h at 25 °C. The solvent was removed under vacuum, the residue washed with hexane (15 mL) and suspended in toluene (40 mL). The clear solution was concentrated to 20 mL from which black crystals of **3a** were obtained at −25 °C.

Yield 0.63 g (80%); m.p. (0.1 mbar) 229 °C. ^1H NMR ([D$_8$]THF): δ = 3.37 (s, 6H, NCH_3), 2.48 (q, 4H, $C_5CH_2CH_3$), 2.08 (s, 6H, CCH_3), 1.84 (s, 12H, C_5CH_3), 1.82 (s, 12H, C_5CH_3), 0.86 (t, 6H, $C_5CH_2CH_3$); ^{13}C NMR ([D$_8$]THF): δ = 205.0 (:C), 125.8 (CCH_3), 119.0 ($C_5CH_2CH_3$), 111.8 (C_5CH_3), 111.1 (C_5CH_3), 35.9 (NCH_3), 19.8 ($C_5CH_2CH_3$), 16.7 ($C_5CH_2CH_3$), 10.9 (C_5CH_3), 10.8 (C_5CH_3), 8.6 (CCH_3). Correct elemental analysis for $C_{20}H_{46}N_2Yb$ (595.74).

3b: Analogously to **3a**, **1** (0.31 g, 0.6 mmol) was treated with **2b** (0.10 g, 0.6 mmol) and black crystals of **3b** were obtained at −25 °C. Yield 0.29 g (78%); m.p. (0.1 mbar) 155 °C. ^1H NMR (C_6D_6): δ = 3.67 (sept, 2H, $NCHCH_3$), 2.57 (q, 4H, $C_5CH_2CH_3$), 2.18 (s, 12H, C_5CH_3), 2.12 (s, 12H, C_5CH_3), 1.55 (s, 6H, CCH_3), 1.22 (t, 6H, $C_5CH_2CH_3$), 1.17 (d, 12H, $NCHCH_3$); ^{13}C NMR (C_6D_6): δ = 198.1 (:C), 124.8 (CCH_3), 118.9 ($C_5CH_2CH_3$), 111.9 (C_5CH_3), 111.0 (C_5CH_3), 49.7 ($NCHCH_3$), 21.0 ($NCHCH_3$), 20.5 ($C_5CH_2CH_3$), 16.8 ($C_5CH_2CH_3$), 12.0 (C_5CH_3), 11.7 (C_5CH_3), 8.9 (CCH_3). Correct elemental analysis for $C_{33}H_{54}N_2Yb$ (651.85).

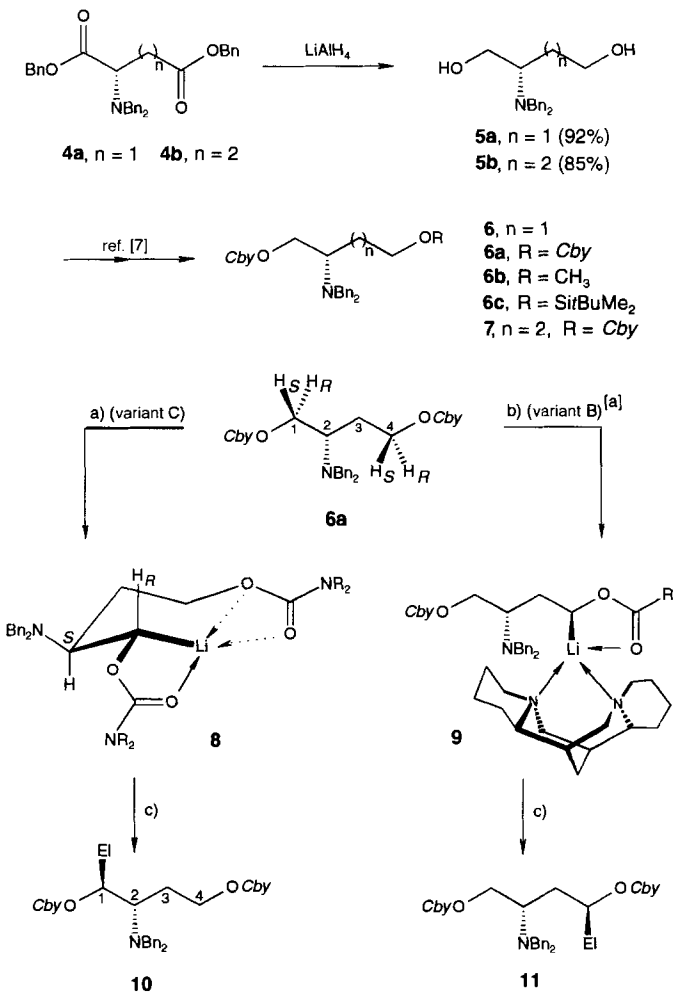
Regio- and Stereoselective Electrophilic C-Substitution of 2-(*N*,*N*-Dibenzylamino)-1,ω-alkanediols by Lithiation of Their Carbamates**

Walter Guarnieri, Matthias Grehl, and Dieter Hoppe*

Dedicated to Professor Werner Tochtermann on the occasion of his 60th birthday

Enantiomerically pure β-amino-α-hydroxy acids and aminopolyols are becoming increasingly important for the synthesis of enzyme inhibitors.[1] We report here on a simple and very flexible approach to these classes of compounds. The carbamate derivatives **1** of (*S*)-2-(*N*,*N*-dibenzylamino)-1-alkanols can be deprotonated at C-1 by *sec*-butyllithium to give the configurationally stable ion pairs **2** (El = Li) or **3** (El = Li), which react with electrophiles stereospecifically with retention of configuration (Scheme 1).[2] Deprotonation in the presence of the achiral additive *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA, variant A) is directed by the stereogenic center at C-2 and favors the removal of the (*pro-R*) proton H_R; in contrast, in the presence of (−)-sparteine (variant B) H_S is abstracted.[3, 4]



Scheme 1. Variant A: a) *s*BuLi, TMEDA, Et_2O, −78 °C; Variant B: b) *s*BuLi, (−)-sparteine, Et_2O, −78 °; c) electrophile ElX.

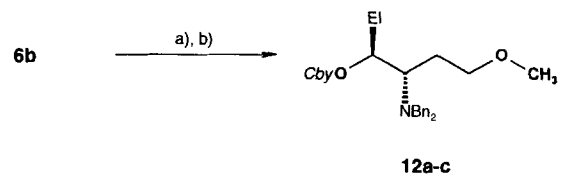
[+] X-ray structure analysis

[**] This research was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Pharma Research Center of Bayer AG, Wuppertal.

When we applied this method to dicarbamate **6a**,[7, 8] which was prepared from (*S*)-aspartic acid via diol **5a**,[5, 6] we observed that the reaction following variant A was completely unselective: the four possible products **10**, 1-*epi*-**10**, **11**, and 4-*epi*-**11** formed in roughly equal amounts (Scheme 2). Variant

Scheme 2. a) 1.5 equiv *s*BuLi, Et_2O, 5 h at −78 °C. b) 1.5 equiv *s*BuLi, 1.5 equiv (−)-sparteine, Et_2O, 5 h at −78 °C. c) Electrophile EIX (see Table 1). −78 → 20 °C. [a] Side reaction.

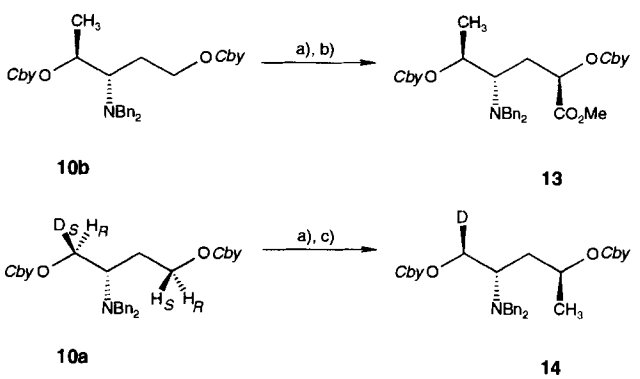
B with sparteine provided the diastereomerically pure substitution products **10** and **11** in varying proportions.[9] Since exclusive formation of regioisomers **10** occurred only with especially reactive electrophiles like CH_3OD and CO_2, we suspected that the 4-carbamoyloxy group is involved in the rapid formation of a bicyclic chelate[10, 11] such as **8**, which is in a slow equilibrium with the sparteine complex[12] **9**. This hypothesis was confirmed convincingly when we conducted the lithiation in the absence of an external complexing agent (variant C).[3] Trapping the intermediate lithium compound with diverse electrophiles gave exclusively the diastereomerically pure regioisomers **10** (Table 1).[8, 14] The proposed intermediate **8** is characterized by high reactivity and low basicity; even the bulky electrophile diisopropyl ketone added readily to give **10k**. Acylation of **10f–h** with acid chlorides also proceeded smoothly without epimerization.[15]



The following control experiments underline the importance of a second complexing group in the 4-position in determining the course of the reaction.[16] The 4-silyl ether[4, 6] **6c** is inert

Table 1. Aminoalkanediol derivatives **10** and **12–16**.

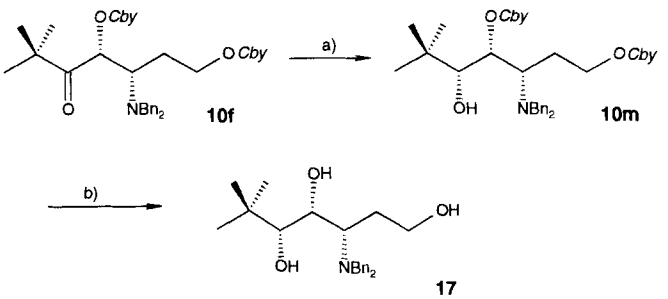
Starting Material	Variant	EIX	Product [a]	El	Yield [%]	$[\alpha]_D^{20}$ [b]
6a	C	MeOD	**10a**	D	95	−29.2
6a	C	CH_3I	**10b**	CH_3	93	+14.3
6a	C	CO_2	**10c**	CO_2Me [c]	92	−20.2
6a	C	Me_3SiCl	**10d**	Me_3Si	73	+17.3
6a	C	Me_3SnCl	**10e**	Me_3Sn	75	+19.4
6a	C	*t*BuC(=O)Cl	**10f**	*t*BuC(=O)	81	−40.2
6a	C	[d]	**10g**	[f]	83	−51.8
6a	C	EtC(=O)Cl	**10h**	EtC(=O)	80	−33.0
6a	C	$Me_2C=O$	**10i**	$Me_2C(OH)$	85	+11.3
6a	C	$iPr_2C=O$	**10k**	$iPr_2C(OH)$	75	+14.6
6a	C	EtCH=O	**10l**	EtCH(OH) [e]	80	–
6b	C	CH_3I	**12a**	CH_3	69	+18.4
6b	C	CO_2	**12b**	CO_2Me [c]	74	−27.3
6b	C	[d]	**12c**	[f]	71	−64.6
10b	B	CO_2	**13**	CH_3	90	−12.5
10a	B	CH_3I	**14**	CO_2Me [c]	88	+4.7
7	B	CO_2	**15**	CO_2Me [c]	78	−1.3
7	C	CO_2	**16**	CO_2Me [c]	61	−21.4



[a] All products were obtained in diastereomeric and regioisomeric purity of ≥97 %. [b] $c = 0.8–1.2$ in $CHCl_3$. [c] After esterification of the acid with diazomethane. [d] (*E*)-$CH_3CH=CHC(=O)Cl$. [e] Mixture of epimers, (1*R*):(1*S*) = 85:15. [f] (*E*)-$CH_3CH=CHC(=O)$.

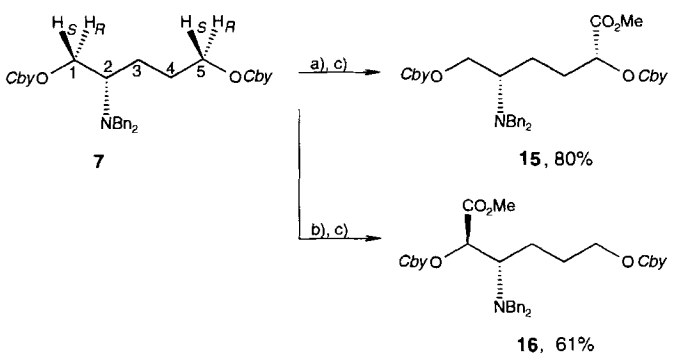
even at −40 °C under the conditions for variant C (and also B); however, the 4-methyl ether[6, 8] **6b** was deprotonated readily at −78 °C and yielded the diastereomerically pure substitution products **12a–c** (Scheme 3, Table 1).

Scheme 3. a) 1.5 equiv *s*BuLi, Et_2O, 5 h at −78 °C. b) EIX, −78 → 0 °C. **12a**: El = CH_3; **12b**: El = CO_2Me; **12c**: El = (*E*)-$CH_3CH=CHC(=O)$.



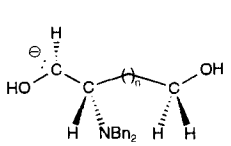
Directed substitution at C-4 is possible by a second deprotonation step following variant B; this was demonstrated by the conversion of the 1-methyl derivative **10b** into ester **13** (Scheme 4).[8, 19] The 1-H_S atom can also be protected against deprotonation by deuteriation, owing to the extraordinarily large H/D kinetic isotope effect.[20] When the (1*S*) deuterio derivative

Scheme 4. a) 1.5 equiv (−)-sparteine, 1.5 equiv *s*BuLi, Et_2O, 5 h at −78 °C. b) 1. CO_2, 2. CH_2N_2; 90 %. c) CH_3I, −78 → 0 °C; 86 %.



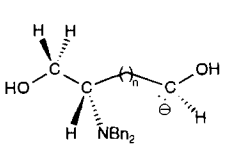
10a was deprotonated in the presence of (−)-sparteine (variant B), exclusively 4-H_S was abstracted. Subsequent methylation led to pure diol **14**[8, 19] with an extended carbon chain.

The configuration of adducts **10** was established by the X-ray structure analysis[17] of triol **17**,[18] which was obtained from ketone **10f** (Scheme 5).



Scheme 5. a) $NaBH_4$, Et_2O, 0 °C, 2 h; *ds* = 5:1; separation by chromatography (diethyl ether/pentane (1:5) on silica gel), 70% **10m**. b) $LiAlH_4$, Et_2O, 12 h reflux, 65%.

In contrast, (*S*)-2-(*N*,*N*-dibenzylamino)-1,5-pentanediyl dicarbamate (**7**),[7, 8] which was prepared in three steps from (*S*)-glutamic acid, was lithiated selectively at C-5 when variant B was employed. The analogous reaction according to variant C, though sluggish, proceeded at C-1. Carboxylation and esterification provided the pure isomers **15** and **16**,[8] respectively (Scheme 6, Table 1). This result indicates that a sterically less favorable homologue of the bicyclic chelate of type **8** is involved.



Scheme 6. a) 1.5 equiv (−)-sparteine, 1.5 equiv *s*BuLi, Et_2O, 5 h at −78 °C. b) 1.5 equiv *s*BuLi, Et_2O, 5 h at −78 °C. c) 1. CO_2, 2. CH_2N_2, −78 → 0 °C.

The procedure described here offers a simple, direct approach to synthetic equivalents of essentially stereohomogeneous aminodihydroxyalkanides like **18** and **19**. As demonstrated,

18 (n = 1,2)

19 (n = 1,2)

the cleavage of the carbamate group is possible reductively or hydrolytically under acid catalysis.[3b, 11a]

Experimental Procedure

Variant C: A solution of dicarbamate **6a** (595 mg, 1.00 mmol) in diethyl ether (6 mL) was cooled in a dry ice/acetone bath while 1.5 mmol of a ca. 1.4 M solution of *sec*-butyllithium in isopentane/cyclohexane was added dropwise. The reaction mixture was stirred for 5 h at −78 °C. Then 1.70 mmol of the electrophile was added, and the reaction mixture was allowed to warm slowly (14 h) to room temperature. The reaction mixture was worked up by the addition of 6 mL of water. The aqueous phase was extracted with diethyl ether, and the combined organic phases were dried and concentrated under vacuum. The crude products were purified by column chromatography on silica gel eluting with diethyl ether/pentane. In variants A and B TMEDA (174 mg, 1.50 mmol) and (−)-sparteine (351 mg, 1.5 mmol), respectively, were added to the solution of dicarbamate **6a**.

Chem. Int. Ed. Engl.* **1992**, *31*, 1459.
[5] Diols **5a** [6d] and **5b** were obtained by $LiAlH_4$ reduction of dibenzyl esters **4a** and **4b**, respectively, which were prepared from (*S*)-aspartic and (*S*)-glutamic acid, respectively, in analogy to the procedure of L. Velluz et al. [6c]. **5a**: $[\alpha]_D^{20} = +17.4$ (*c* = 1.9 in $CHCl_3$); **5b**: $[\alpha]_D^{20} = +69.5$ (*c* = 1.2 in $CHCl_3$).
[6] a) M. T. Reetz, M. T. Drewes, A. Schmitz, *Angew. Chem.* **1987**, *99*, 1186; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1141; b) Review: M. T. Reetz, *ibid.* **1991**, *103*, 1559 bzw. **1991**, *30*, 1531; c) L. Velluz, G. Amiard, R. Heymes, *Bull. Soc. Chim. Fr.* **1954**, 1012; d) P. Gmeiner, A. Kärtner, D. Junge, *Tetrahedron Lett.* **1993**, *34*, 4325.
[7] Dicarbamates **6a** (75%) and **7** (79%) were obtained from the reactions of **5a** and **5b**, respectively, with 2,2,4,4,-tetramethyl-1,3-oxazolidin-3-carbonyl chloride and NaH [3b]. For the synthesis of silyl ether **6c**, **5a** was silylated selectively at the 4-OH group with *tert*-butyldimethylsilyl chloride and then carbamoylated according to [3b]. Methyl ether **6c** was obtained by desilylation of **6c** (with tetrabutylammonium fluoride) and subsequent O-methylation (methyl iodide, sodium hydride). $[\alpha]_D^{20}$ (*c* = 1.0–1.3 in $CHCl_3$): **6a** = −40.9; **6b** = −28.5; **6c** = −14.4; **7** = −11.8.
[7] Dicarbamates **6a** (75%) and **7** (79%) were prepared by reaction of **5a** and **5b**, respectively, with 2,2,4,4,-tetramethyl-1,3-oxazolidine-3-carbonyl chloride according to the sodium hydride method. The silyl ether **6c** was obtained by selective silylation of **5a** (4-OH group) with *tert*-butyldimethylsilyl chloride and subsequent carbamoylation [3b]. For the preparation of the methyl ether **6b**, compound **6c** was desilylated with tetrabutylammonium fluoride and then *O*-methylated (methyl iodide, sodium hydride). $[\alpha]_D^{20}$ (*c* = 1.0–1.3 in $CHCl_3$): **6a** = −40.9; **6b** = −28.5; **6c** = −14.4; **7** = −11.8.
[8] Satisfactory C,H analyses (C ± 0.3, H ± 0.3) were obtained for all new compounds.
[9] Reaction of **6a** with CO_2 under the conditions of variant B gave only regioisomer **10c**; reaction with $(CH_3)_3SnCl$ yielded products **10e** and **11e** in a 7:3 ratio; **11e**: $[\alpha]_D^{20} = -37.8$ (*c* = 2.0 in $CHCl_3$).
[10] The structure of the bicyclic chelate is not yet known; formula **8** offers only a plausible explanation of its role in the reaction. It is not known whether the lithium cation is complexed by the more basic oxo group, the ester oxygen atom, or both [11–13].
[11] References to related bicyclic chelates of 1,3- and 1,4-dicarbamates: a) M. Paetow, H. Ahrens, D. Hoppe, *Tetrahedron Lett.* **1992**, *33*, 5327; b) *ibid.* **1992**, *33*, 5323.
[12] X-ray structure analysis of a lithiated carbamate, see: M. Marsch, K. Harms, O. Zschage, D. Hoppe, G. Boche, *Angew. Chem.* **1991**, *103*, 338; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 321.
[13] The *N*,*N*-dibenzylamino group is a poor coordinating function for Li^+, see: P. Sommerfeld, D. Hoppe, *Synlett* **1992**, 764.
[14] The ratios of isomers were determined by ^1H NMR spectroscopy. The detection limit for the minor diastereomers and regioisomers was roughly 3%. The enantiomeric purity of the substitution products was > 98% *ee*. Diol **5a** served as the standard in the purity determinations: *ent*-**5a** was not found as an impurity [GC analysis of alcohol **6c** in the form of *N*-(*S*)-(1-phenylethyl)urethane]. Racemization during the lithiation can be excluded, since the very improbable deprotonation at the stereogenic center C-2 of **6** or **7** would lead to degradation or elimination.

[15] In general the acylation of primary and secondary alkyllithium compounds is problematic because of the deprotonation and addition reactions of the ketone formed.

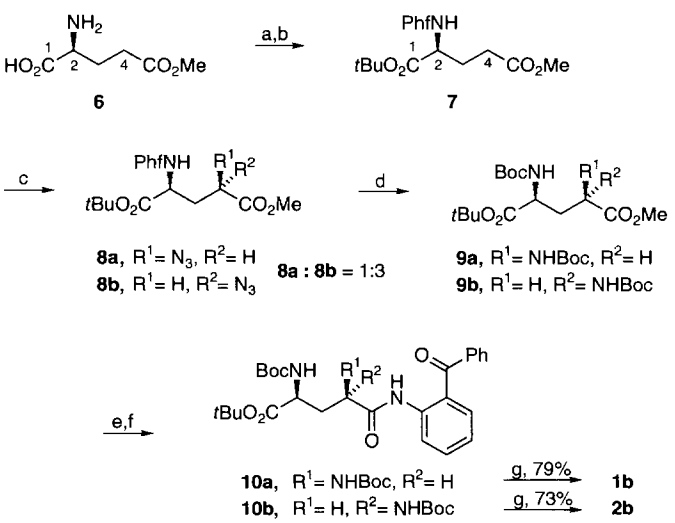
Synthesis of a New Unnatural Amino Acid with a Benzodiazepine-Containing Side Chain and Incorporation into a Tripeptide

Johann Mulzer,* Fridtjof Schröder, Alessandro Lobbia, Jürgen Buschmann, and Peter Luger

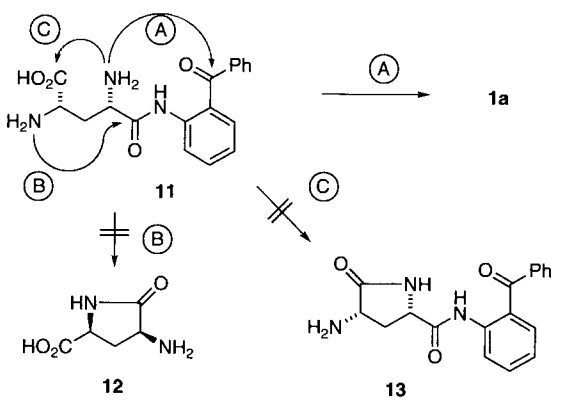


Owing to the constantly growing therapeutic importance of new physiologically active peptidomimetics,[1] the pool of available unnatural amino acids must be continually increased.[2] Of particular interest are the α-amino acids, which have side chains with a functional group that can act as a receptor ligand. In this case the peptidomimetic formed from these amino acids can behave as both a peptide and non-peptide receptor ligand.

Various hydrogenated forms of benzodiazepine have proved themselves to be good receptor ligands.[3] The amino acids **1a** and **2a** appear to be particularly attractive building blocks for peptidomimetics. Owing to the 1,3-substitution of the amino functions on the peptide, the benzodiazepine and peptide chain should be sufficiently far apart; however, a certain degree of mutual interaction is still maintained. The form of functionalization in **1a** and **2a** is analogous to that in the arylalanines histidine and trytophan. Little is known about the synthesis of 2,4-diaminoglutaric acids: Belokon et al. successfully synthesized the *anti*-(2*S*,4*S*)-diaminoglutaric acid via a stabilized asymmetric nickel complex;[4] the corresponding *syn* compound is unknown. The synthesis of the target compounds **1a** and **2a** is essentially a question of differentiating between the two amino acid groups. This is especially so for the *syn*-diaminoglutaric acid because of its *meso* symmetry.

Our retrosynthetic analysis showed that **1** and **2** could be made by a half-side Sternbach cyclization[5] of the *syn*- (**3**) and *anti*-2,4-diaminoglutaric acid derivatives (**4**), respectively. These in turn could be formed from the regioselective amination of N-protected (*S*)-glutamate (**5**).

The synthesis is shown in Scheme 1. Use of Rapoport's 9-phenylfluoren-9-yl (Phf) protecting group[6] and the C-1 *tert*-butyl ester completely blocked the 2-position in glutamate **7**, leading to selective formation of the 4-enolate upon treatment



Scheme 1. Synthesis of **1b** and **2b**. a) Trimethylsilyl chloride, 9-phenylfluoren-9-yl bromide, $Pb(NO_3)_2$, 80%. b) *N*,*N*′-Dicyclohexyl-*O*-*tert*-butylisourea, CH_2Cl_2, 25 °C, 2 d, 76%. c) 1. KHDMS, THF, −60 °C; 2. 2,4,6-Triisopropylbenzenesulfonyl azide, −78 °C, 50 min, 54%. d) Boc_2O, 10% Pd/C, H_2 (4 bar), MeOH, 91%. e) LiOH, THF, 91%. f) *N*-Methylpiperidine, isobutyl chloroformate, CH_2Cl_2, −10 °C, 30 min, then 2-aminobenzophenone, 25 °C, 72 h, 78%. g) 1. EtOAc, HCl (pH = 4.5), 25 °C, 90 min; 2. H_2O, Na_2CO_3 (pH = 8.5), 3 h, then acetone, Fmoc-*O*-succinimide, 25 °C, 20 h.

with potassium hexamethyldisilazide (KHDMS). Quenching this enolate with 2,4,6-triisopropylbenzenesulfonyl azide (trisyl-azide)[7] gave a 1:3 mixture of diastereomeric azides, **8a** and **8b**. Use of a chiral auxiliary on the neighboring carboxyl group would certainly have led to a better selectivity, but, as the diastereomers could be easily separated at a later stage, this complication was avoided. Catalytic hydrogenation of **8** in the presence of *tert*-butoxycarbonyl(Boc) anhydride led, in one step, to removal of the Phf protecting group, hydrogenation of the azide to the amine, and protection of both amine groups with Boc groups. The two ester groups in **9** are easily differentiable: the methyl ester can be selectively hydrolyzed with lithium hydroxide and subsequently transformed into the amide **10** with aminobenzophenone. The diastereomers **10a** and **10b** were easily separated at this stage by column chromatography.

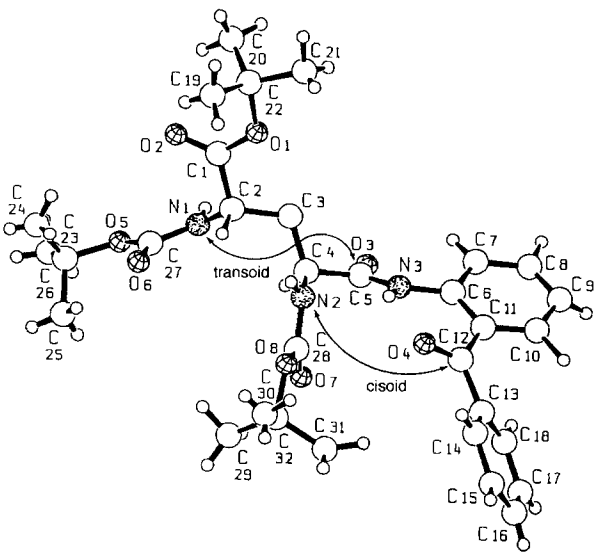
Cyclization of **10a** and **10b** gave, after removal of the Boc groups with gaseous HCl in ethyl acetate, the benzodiazepines **1a** and **2a**, respectively. The solvent and the isobutene produced were removed under vacuum. The reaction was completed by addition of aqueous sodium carbonate until the pH value reached 8.5. Because of the instability of the free amino acids, they were immediately converted into their crystalline fluoren-9-ylmethoxycarbonyl (Fmoc) derivatives **1b** and **2b**.[9]

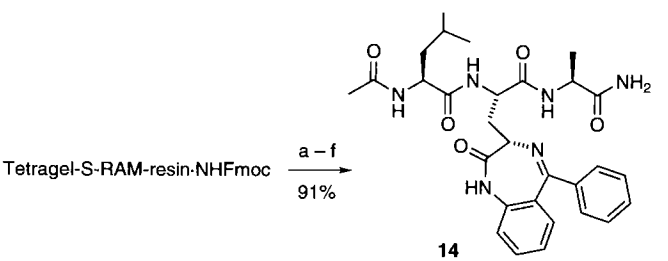
Cyclization of the aminoketones to the seven-membered ring compound **1** (Scheme 2, pathway A) proceeded smoothly, which

Scheme 2. Cyclization of **11**.

is surprising as two competing cyclizations to γ-lactams **12** (pathway B) and **13** (pathway C) are conceivable. Since the reaction takes place also in the solid phase, the crystal structure of the cyclization substrate **10b** (Fig. 1) may indicate the reasons for the conformational preference of one pathway over another. If the conformation in the section C-2 to C-5 determines the reaction pathway (numbering as in Fig. 1) and the NH-Boc and CO_2t-Bu groups are less important, then N-2 and C-12 are brought sufficiently close for a nucleophilic attack by their cisoid conformation. The 12-CO group is twisted in the benzophenone unit, thus allowing attack of N-2 on the π* CO orbital; in contrast, N-1 and C-5 (pathway B) are transoid, as are N-2 and C-1 (pathway C), which makes the reaction impossible. The structures of **10a**, **10b**, and the products of their reactions were established on the basis of the crystal structure of **10b**.

To prove that the new amino acids can be incorporated into peptides, **2b** was coupled in a stepwise fashion with (*S*)-Fmoc-alanine and (*S*)-Fmoc-leucine using the Merrifield solid-phase method to give the tripeptide, whose free NH_2 group was subse-





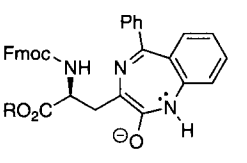


Fig. 1. Crystal structure of **10b** [11].

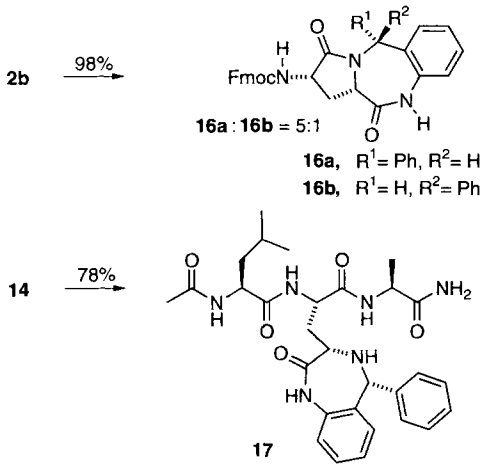
quently acetylated (Scheme 3). After separation from the resin, amide **14** was obtained in diastereomerically pure form (HPLC, 500 MHz ^{1}H NMR, 125 MHz ^{13}C NMR), indicating the enan-

Scheme 3. a) Piperidine (20% in DMF), 4 min. b) L-Fmoc-Ala-OH, TBTU [10], iPr$_2$EtN, CH_2Cl_2, 15 min. c) **2b**, TBTU, iPr$_2$EtN, CH_2Cl_2, 15 min. d) L-Fmoc-Leu-OH, iPr$_2$EtN, CH_2Cl_2, 15 min. e) 10% Ac_2O in DMF, 30 min. f) 96% CF_3CO_2H, 35 °C, 2.5 h.



tiomeric and diastereomeric purity of the amino acid **2b**. Despite the activation from the C=N bond **2** cannot racemize, as deprotonation to **15** would lead to an antiaromatic 8π electron system.

15

To study the question of how much the diastereofacial shielding of functional groups is affected by their incorporation into peptide chains, the C=N bonds in **2b** and in **14** were hydrogenated under identical conditions (Scheme 4). In the first case a diastereomeric mixture of **16a** and **16b** (5:1) was formed; in the second case the tripeptide **17** was obtained diastereomerically pure (500 MHz ^{1}H NMR). Higher selectivities are therefore obtainable in peptide chains than with isolated amino acids. The configuration of the newly formed stereocenters in **16** and **17** was determined by difference NOE (nuclear Overhauser enhancement) experiments.

In conclusion α-amino acids with benzodiazepine-containing side chains have been prepared for the first time and their suitability for peptide coupling has been demonstrated. The synthe-

sis is applicable to all stereoisomers of the 1,3-diamino system and can probably be extended to other 1,*n*-diamino systems. The physiological properties of **1a** and **2a** and their incorporation into peptidomimetics is currently under investigation.

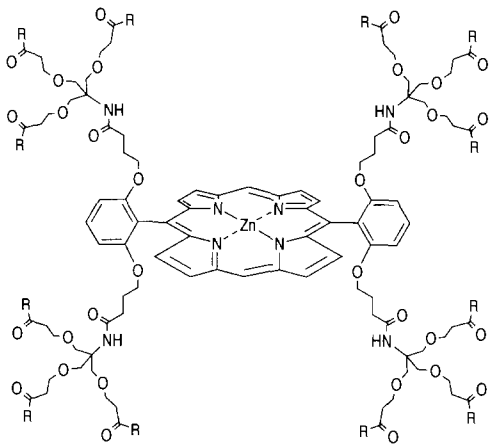
Dendritic Porphyrins: Modulating Redox Potentials of Electroactive Chromophores with Pendant Multifunctionality**

Peter J. Dandliker, François Diederich,* Maurice Gross,* Carolyn B. Knobler, Alain Louati, and Elizabeth M. Sanford



Dedicated to Professor Helmut Ringsdorf on the occasion of his 65th birthday

The synthesis[1] of cascade polymers has recently sparked much interest.[2] Efficient nonlinear growth schemes quickly provide high molecular weight, monodisperse globular structures with unique properties. A considerable body of work has focused on changing functional groups on the outer surface of dendrimers;[3] however, the idea of incorporating initiator cores with well-defined functional properties is less well explored.[4] Recent work has shown that the polarity in the interior of dendrimers changes markedly with increasing cascade generation.[4b] Constructing a dendrimer around a porphyrin core could alter the polarity of the surroundings of the electrophore and modify its electrochemical behavior. Dendritic porphyrins could therefore be regarded as models for electron-transfer proteins like cytochrome c, which exhibits oxidation potentials in aqueous solution 300–400 mV more positive than those of similarly ligated heme model systems that lack the hydrophobic peptide shell.[5, 6] We report here on the synthesis of the porphyrin compounds **1**–**3** using cascade polymer methodology. Preliminary electrochemical studies on **1**–**3** suggest that the environment of redox-active chromophores can be controlled through encapsulation in dendrimers; this opens up a method for the selective synthesis of redox catalysts.

The starting point for the synthesis of the cascade molecules **1a**–**3** through to the third generation was the tetraacid **7** pre-

pared from ester **6** (Scheme 1). The X-ray crystal structure of **6** shows that the four linkers for dendritic arm attachment have the desired spatial arrangement above and below the zinc porphyrin plane.[7]

The polyether–amide cascade described by Newkome et al.[8] was chosen to generate the cascade polymers **1a**/**b**, **2a**/**b**, and **3** (Scheme 1). Thus, the first generation dendritic zinc porphyrin **1a** (Table 1) was obtained in 75% yield from **7** and **8** by using the peptide coupling methodology, followed by purification by preparative gel permeation chromatography (GPC, Biorad Biobeads SX-3, toluene). Subsequent hydrolysis of **1a** with LiOH in $MeOH/H_2O$ smoothly afforded the first generation dodecacarboxylic acid **1b**.

A repeat of this reaction sequence gave the second generation compounds **2a** and **2b** bearing 36 methyl esters and 36 carboxylic acids, respectively. The structures of these compounds were confirmed by ^1H and ^{13}C NMR spectroscopy and mass spectrometric (MS) analysis. The fast atom bombardment (FAB) mass spectrum of **2a** shows the protonated molecular ion peak as the base peak at $m/z = 6547$ (calcd 6547) in addition to a peak at $m/z = 6167$ assigned to a fragment formed by loss of a single

[a] The matrices for FAB- and MALDI-TOF-MS determinations were 3-nitrobenzyl alcohol and 2,4,6-trihydroxyacetophenone, respectively.

monomeric fragment $NHC(CH_2OCH_2CH_2CO_2CH_3)_3$. The matrix-assisted laser desorption ionization time-of-flight (MALDI TOF) mass spectrum of **2b** shows the molecular ion peak as base peak at $m/z = 6043$ (calcd 6041) and peaks corresponding to fragment ions resulting from successive loss of $NHC(CH_2OCH_2CH_2COOH)_3$ moieties.

Finally, coupling of **2b** with **8** gave the third generation dendrimer **3** bearing 108 methyl esters (51% yield). The integrity of the zinc porphyrin core in **3** was confirmed by the ^1H NMR and UV VIS spectroscopic studies (Table 1). As expected, the ^{13}C NMR spectrum shows only a single set of peaks for the outer cascade layer. The MALDI-TOF mass spectrum shows the molecular ion peak as the base peak at m/z 18900 (calcd 19044) together with minor peaks at around m/z 37000 and m/z 54000 corresponding to ionic, gas-phase complexes of two and three molecules of **3**, respectively. The dendritic zinc porphyrins **1a**, **2a**, and **3** are red, viscous oils; the polycarboxylic acids **1b** and **2b** are red, low-melting solids (Table 1).

The GPC chromatograms of esters **1a**, **2a**, and **3** show a single sharp peak for each compound and thus provide further confirmation that the cascade molecules are monodisperse. The results of detailed GPC and light-scattering studies will be published in due course.

Computer-generated models of **3** predict a globular molecule, approximately 4 nm in diameter (Fig. 1).[12] The densely packed structure of **3** resembles in size and shape the electron-transfer protein cytochrome c, which also has an encapsulated porphyrin core, (Fig. 1).[13, 14]

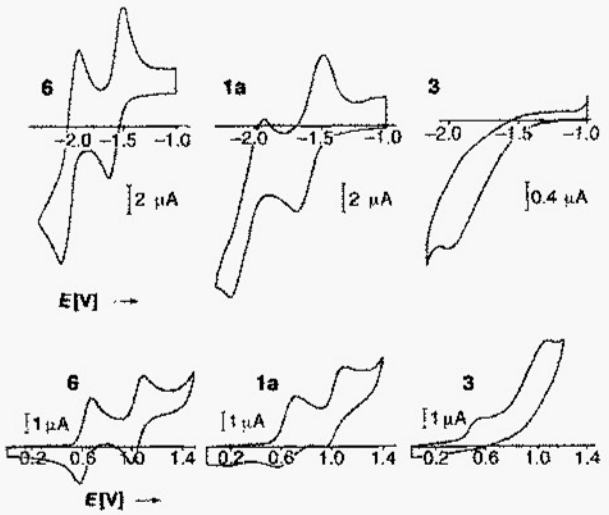
The influence of the close-packed dendritic branches on the redox properties of the central zinc porphyrin unit was studied by cyclic voltammetry in THF and CH_2Cl_2 with $Bu_4N^+PF_6^-$ (0.1 M) as the supporting electrolyte (Table 2).

Esters **1a** and **2a** exhibit two reversible one-electron reduction processes at the Hg electrode in the explored potential range (from -1 to -2.5 V vs. SCE) (Fig. 2, top). The absolute potential difference between the first and second reduction potentials is 0.49 and 0.46 V, respectively. These values agree well with the range of 0.35 to 0.40 V typically observed for ring-centered reductions of metalloporphyrin complexes.[15] The third generation compound **3** shows a less well defined wave for a single irreversible reduction process, which is located at approximately -1.9 V in dilute solutions (Fig. 2 top). Control experiments with **9** suggest that signals for the electrochemical reduction of the zinc porphyrin in **3** overlap with signals produced by irreversible multielectron transfers involving the dendritic branches. The region of overlap is between -1.6 V and the accessible potential limit of the solvent.

Table 2. Redox potentials for the zinc porphyrins [a]

Porphyrin	$E^{1,2}_{red}$(I) [b]	$E^{1,2}_{red}$(II) [b]	$E^{1,2}_{ox}$(I) [b]	$E^{1,2}_{ox}$(I) [c]	$E^{1,2}_{ox}$(II) [c]
ZnTPP [d]	−1.50	−1.94	+1.08		
6	−1.60	−2.01	+0.85	+0.63	+1.04
1a	−1.69	−2.18	+0.87	+0.71	+1.09
2a	−1.72	−2.18	+0.65	+0.63	+1.07
3	−1.90 [e, g]		+0.55 [f, g]	+0.54 [g]	+1.00 [g]

[a] Redox potentials as determined by cyclic voltammetry: $E^{1,2}$ (approximated by $(E^c_p + E^a_p)/2$) in V vs. SCE; supporting electrolyte $Bu_4N^+PF_6^-$ (0.1 M), reductions performed at the Hg electrode (dropping mercury electrode), scan rate 5 Vs^{-1}; oxidations performed at the Pt electrode, scan rate 50 mV s^{-1}; $T = 298$ K. [b] Solvent THF. [c] Solvent CH_2Cl_2, scan rate 100 mV s^{-1}. [d] Zinc *meso*-tetraphenylporphyrin (ZnTPP). [e] Poorly resolved signal. [f] Broad signal. [g] Irreversible transfer, peak potential from CV measurements.



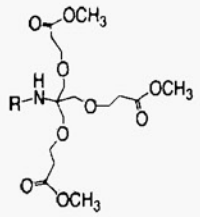


Fig. 2. Top: Reduction cyclic voltammograms in THF (0.1 M $Bu_4N^+PF_6^-$). Working electrode: Hg drop. Scan rate = 5 V s^{-1}, $T = 298$ K. Bottom: Oxidation cyclic voltammograms in CH_2Cl_2 (0.1 M $Bu_4N^+PF_6^-$). Working electrode: Pt. Scan rate = 0.10 Vs^{-1}, $T = 298$ K.

The first reduction potential of the zinc porphyrin unit becomes more negative with increasing dendrimer generation. The values obtained obtained are more negative than the potential for the reduction of the central unit **6** by 90 to 300 mV. This trend can be explained by the increasingly electron-rich microenvironment created by the dendritic branches around the porphyrin core. Because the microenvironment of the porphyrin core becomes increasingly electron rich on moving from **1a** to **3**, electron addition becomes energetically more difficult.

8 R = H
9 R = CH_3CO

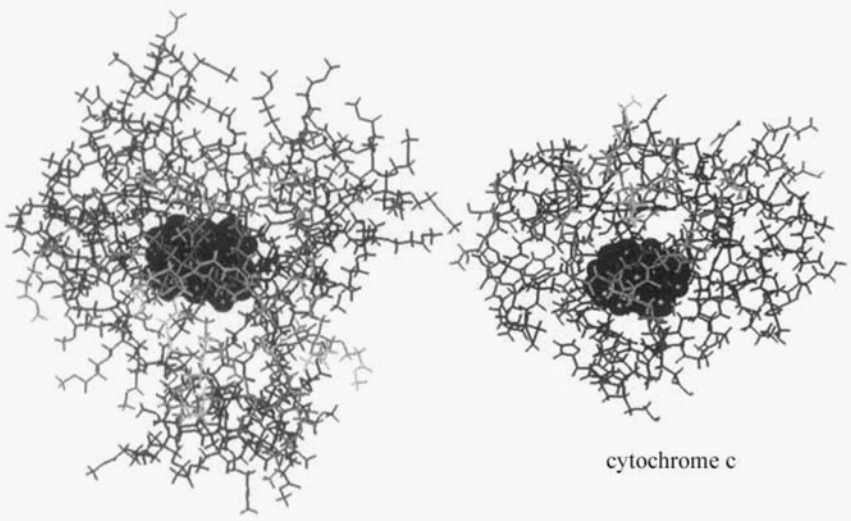

Fig. 1. Computer-generated model of the dendritic zinc porphyrin **3** [12]. For comparison, the X-ray crystal structure of cytochrome c (bonita) at 2.3 Å resolution [14].

A similarly strong microenvironmental effect on the electrochemical properties was observed when the oxidation of **1a**, **2a**, and **3** was compared to that of **6**. Between 0 and 1.2 V, the complexes **1a** and **2a** display two reversible oxidation steps at the platinum electrode in CH_2Cl_2 (Fig. 2 bottom). In THF, on the other hand, only one oxidation step is observed before reaching the anodic solvent-accessible potential limit. For compound **3**, the two oxidation processes that are observed in THF become completely irreversible in CH_2Cl_2 (Fig. 2 bottom). Control compound **9** does not show any sign of oxidation in THF or CH_2Cl_2 up to the anodic potential limit. In all the dendritic systems described above, electrochemical oxidation is expected to generate a monocation by removal of an electron from the porphyrin π system. Evidence for this comes from the potential difference between the first reduction and the first oxidation, which ranges from 2.37 to 2.56 V. These values are comparable to the separation of 2.25 ± 0.15 V reported for other metalloporphyrin complexes.[15] In the dendritic complexes, the first oxidation potentials are up to 300 mV (THF) less positive than the value for zinc porphyrin **6**. This can again be explained by the increasingly electron-rich microenvironment provided by the dendritic branches, which favors the generation of the porphyrin radical cation.

Rather than using traditional through-bond substituent effects to influence the electrochemical behavior of metalloporphyrins, we have modulated the redox characteristics of **1a**, **2a**, and **3** with a through-space mechanism, namely, the control of the electrophore's environment.[16] Electrochemical studies into the potential of water-soluble iron porphyrin analogues of **1a**–**3** as mimics of cytochrome c are currently in progress.

Linear Coordination Polymers of Copper(II) and Fourfold Deprotonated Sugar Alcohols**

Peter Klüfers* and Jörg Schuhmacher

In the presence of Cu^{II} or Pd^{II} ions, polyols are multiply deprotonated, even in aqueous solution, and bind as chelate ligands to the metal ion.[1] Because of the structural variety of polyols—diols, triols, and sugar alcohols, but also low molecular weight carbohydrates, oligo- and polysaccharides—they are versatile building blocks for the systematic synthesis of complex structures. Metal-containing polymers are, for example, obtained by using polysaccharides as ligands. Simple polyols should be suitable as building blocks for coordination polymers in which metal ions combine with polyolato ligands to form extended structures. Polymer chains are expected when difunctional metal building blocks are used. This principle is illustrated on the left side of Scheme 1 for a deprotonated bisdiol and Cu^{II} ions, which are generally difunctional towards diolato(2−) ligands.

Scheme 1. The polymeric cuprate ions (without charges) in **1** (left) and **2** (right).

We report here on the successful crystallization from aqueous solution and the structure determination[2] of two linear polyolato cuprates containing one-dimensional polymeric anions based on two different sugar alcohols, the simplest bisdiol, erythritol (Eryt), and the trisdiol, dulcitol = galactitol (Dulc).

Eryt Dulc

Crystals of $Na_2[Cu(ErytH_{-4})]\cdot Eryt\cdot 12H_2O$ **1** contain the fully deprotonated form of erythritol as the building block of the coordination polymer (Scheme 1 left and Fig. 1 bottom). The structure analysis shows that both the complexed tetraanion and the free, nondeprotonated erythritol exist side by side in the crystal. We had not expected to obtain this structure. Our original aim was the synthesis of a mononuclear complex of the same stoichiometry but with two dianionic ligands per copper ion. When the reaction is expressed as equilibrium (a), it becomes clear that the acidity constants for the four protolysis steps of the polyol must be very similar in order

$$[Cu(ErytH_{-2})_2]^{2-} \rightleftharpoons [Cu(ErytH_{-4})]^{2-} + Eryt \qquad (a)$$

to achieve a bias towards the right-hand side. The nondeprotonated erythritol molecules in the crystal are an essential component in the structure; they form short (but asymmetric), chelate-like hydrogen bonds with the cuprate chains, which thus leads to extensive crosslinking of the polymer chains (Fig. 1 bottom: $d(O\cdots O^-) = 258.0(5)$ and 252.8(6) pm).

In basic solutions of the trisdiol dulcitol and an excess of copper did not yield a complex containing $DulcH_{-6}$ ligands. Instead, a tetraanionic ligand is found in $Li_2[Cu(DulcH_{-4})]\cdot 10H_2O$ (**2**)—the primary OH groups are not deprotonated. The coordination polymer formed has the same topology as **1**, but is more rigid (Scheme 1 right). Despite the large stability constants of polyolato–copper complexes,[1a] the hexaol is not completely deprotonated. A structural feature, which we first observed when using β-cyclodextrin as the polyol component[3] and then with the polysaccharide cellulose,[1a] competes with complexation: whenever possible, the polyolate adopts a conformation which allows formation of short intramolecular hydrogen bonds of the type $O-H\cdots O^-$. Dulcitol is no exception to this rule; the C_6 chain adopts a centrosymmetric S-shaped conformation in which the two terminal O-H groups act as intramolecular hydrogen-bond donors to the third nearest oxygen atom in the chain. The donor–acceptor distance of 248.2(5) pm is unusually short for a polyolate. The hydrogen bond is "compressed" because, with its formation, angular strain builds up in the C_6 chain, and all C–C–C angles are greater than 120° (Fig. 2). This explains why intramolecular hydrogen bonds are not observed in the crystal structures of dulcitol itself and all other sugar alcohols, since these contain only hydroxy groups and no strongly binding alkoxide functions, which could act as acceptors.[4]

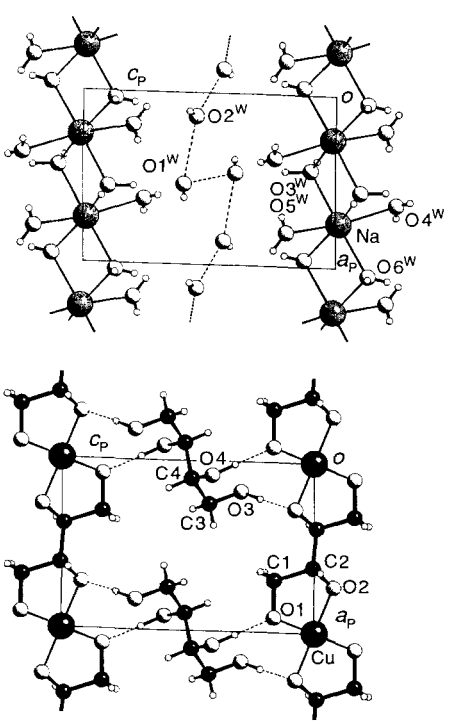

Fig. 1. Projection along [0$\bar{1}$0]. Top: Section at $y = 0$; $[Na(H_2O)_4]_2\cdot 4H_2O$ with disordered hydrogen bonds [2]; water O atoms are indicated with O^w. Bottom: Section around $y = 1/2$; $[Cu(ErytH_{-4})]\cdot$ Eryt, selected distances [pm] and angles [°]: Cu–O1 191.2(4), Cu–O2 192.2(4); O1-Cu-O2 87.2(2), O1-C1-C2-O2 47.6(5), O3-C3-C4-O4 −69.5(5).

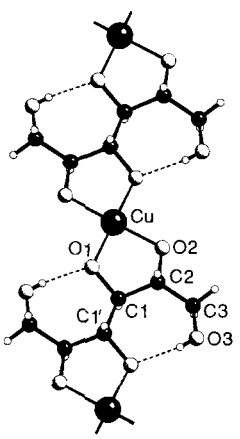

Fig. 2. Cuprate ion in **2**, selected distances [pm] and angles [°]: Cu–O1 195.2(3), Cu–O2 193.8(3); O1-Cu-O2 84.52(12), C2-C1-C1' 120.3(4), C1-C2-C3 122.0(4), O3-C3-C2 116.1(4), O1-C1-C2-O2 47.7(5).

In the crystals of both **1** and **2**, further structural fragments are responsible for the lateral arrangement of the anionic rods in a three-dimensional structure. Fragments of this type also lead to formation of extended structures in other crystals, even in the absence of a polymeric motif. In **1**, chains of edge-sharing hexaaquasodium octahedra[5a] and cooperative associations of water molecules[5b] serve this purpose (Fig. 1 top). In **2**, a homodromic[4] helix of water molecules winds round the 2_1 axis along [010]. The water molecules organize the three-dimensional crystalline structure by binding directly to both the lithium cations and the cuprate ions, which are arranged parallel to the water helices. The significance of this endless, one-dimensional cooperative system in the structure is emphasized by the fact that further cooperative sequences run in and out of the helix; the characteristic intramolecular $O-H\cdots O^-$ bond also does not exist in isolation, but is embedded in this system (Fig. 3).

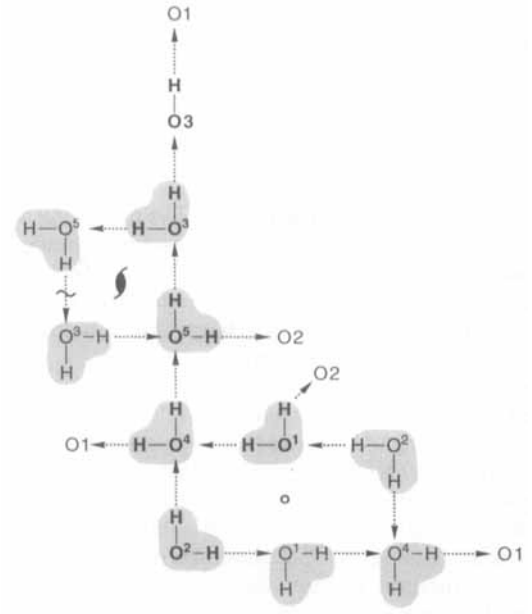

Fig. 3. Section of the cooperative hydrogen bonding system in **2**. The O atoms of water molecules are designated by O^n; the hydrogen bonding surrounding the atoms in bold print is given in full: O3, O^1, O^2, and O^3 are also ligands at Li. The crystallographic symmetry elements 2_1 and $\bar{1}$ are denoted by the appropriate symbols. The start of a new turn in the homodrome helix around 2_1 is marked by a wavy line.

Both of the coordination polymers introduced here belong to a class of materials, the metal-containing polymers, that are of interest because of their (potential) properties as materials (e.g., special magnetic effects, formation of nematic phases).[6] The polyolato complexes are, in addition, made from alkoxides which are readily accessible from inexpensive starting materials and are stable towards protolysis in alkaline aqueous media. In the design of a target complex, it should be taken into account that the sequence of the acidity constants is not comparable with that found for mineral acids. The acidity constants for the individual steps seem to differ only slightly. *Multiple* deprotonation to form polyolato ligands, even in aqueous solution is typical for the complex chemistry of polyols. Only the protons embedded in the intramolecular $O-H\cdots O^-$ structural fragments are not easily accessible.

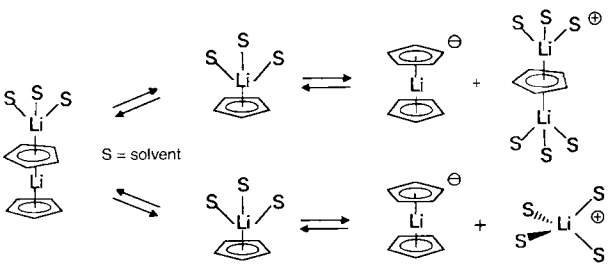
The Simplest Metallocene Sandwich: the Lithocene Anion**

Sjoerd Harder* and Marc Heinrich Prosenc

Metallocenes of alkali metals were the first known organometallic cyclopentadienyl compounds.[1] Their versatility in the syntheses of cyclopentadienyl transition metal complexes led to a widespread interest in their structures.[2–4] A structural form commonly observed is a polymeric chain of bridging η^5-cyclopentadienyl rings alternating with alkali metal cations, with or without solvation (**1**).[2] Additional solvation of the metal cation may break the polymer chain into smaller oligomers or monomeric units (**2**).[3]



1 **2** **3**

The possible existence of alkali metal cyclopentadienides (**3**) with a sandwich structure in solution has been discussed previously,[5] and recently new evidence for such sandwich complexes was obtained.[6] Results of a cryoscopic molecular weight determination for cyclopentadienyllithium ([CpLi]) in liquid ammonia, suggested an equilibrium between the monomer and a higher species.[6a] This could be either a stacked dimer or a combination of an anionic $[Cp_2Li]$ sandwich complex with an inverse sandwich cation (Scheme 1, top).[7]

A recent extensive NMR study shows that, at low temperature, monomeric [CpLi] dissolved in THF is in equilibrium with a metallocene anion with a sandwich structure and a THF-solvated Li cation (Scheme 1, bottom).[6b] Though some crystal structures of Li^+ sandwiched between π-electron systems are known,[8] definite structural proof of the simplest metallocene, the lithocene anion, was still lacking. We here describe the syn-

Scheme 1.

thesis and solid-state structure of the dicyclopentadienyllithium anion (**3**, M = Li).

Mixing [CpLi] and Ph_4PCl (molar ratio 2/1) in THF results in the formation of large yellow-brown crystals of $[Ph_4P]^+[Cp_2Li]^-$, suitable for an X-ray structure determination.[9] Figure 1 shows a plot of the monoclinic unit cell with

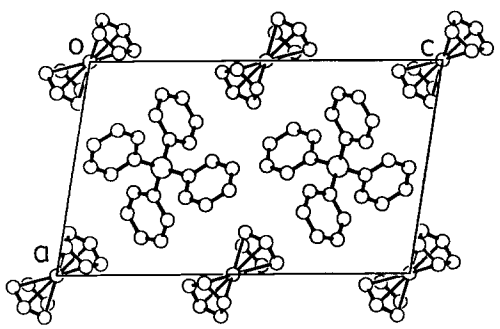

Fig. 1. Crystal structure of $[Ph_4P]^+[Cp_2Li]^-$: view of the monoclinic unit cell along the *b* axis (space group: $P2/c$).

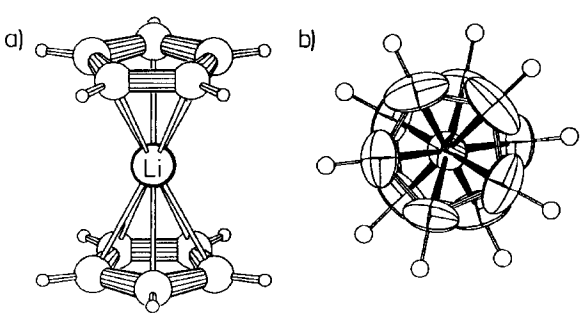
$P2/c$ symmetry. The Ph_4P cations show C_2 symmetry; the phosphorus atoms are located on crystallographic two fold axes. The $[Cp_2Li]$ anions are positioned on crystallographic inversion centers. In this respect, the crystal structure of the $[Cp_2Li]$ anion is comparable to those of magnesocene, chromocene, ferrocene, cobaltocene and nickelocene.[10] All these compounds crystallize in centrosymmetric monoclinic spacegroups in which metals are located on inversion centres.

The structure of the $[Cp_2Li]$ anion is shown in Figure 2. The Cp rings are perfectly planar (max. deviation from least-squares plane: 0.001 Å). The coplanarity of the Cp rings is inherent to



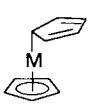


Fig. 2. a) Molecular structure of the $[Cp_2Li]$ anion. C–Li-bond distances [Å]: C1-Li 2.362(3), C2-Li 2.366(4), C3-Li 2.303(3), C4-Li 2.262(3), C5-Li 2.298(4), average (2.318(4)). C C-bond distances vary from 1.340(5) to 1.387(5), average 1.362(5) Å. b) ORTEP plot showing disorder within the planes of the cyclopentadienyl rings (top view; ellipsoids represent 50% probability).

the centrosymmetric nature of this metallocene anion. The $Cp_{centroid}$–Li distance of 2.008(4)Å is at the high end of the 1.79–2.06 Å range previously observed in [CpLi] compounds like **2**, and also slightly longer than the comparable distance of 1.967 Å in polymeric unsolvated $[Me_3SiCpLi]$ (type **1** wihout solvation).[2c] In the $[Cp_2Li]$ anion the C–Li bond distances vary only slightly 2.262(3) to 2.366(4) Å, average 2.318(4) Å),[21] and the angle between the $Cp_{centroid}$–Li axis and the Cp plane is 87.1(3)°. Therefore, the Cp–Li interaction can be regarded as η^5-coordination of a ring that has hardly slipped. η^5-Coordination has been calculated to be the most stable interaction for Cp–Li bonding[11] and is commonly observed in structures of [CpLi] compounds.[2c, 3] Bonding in [CpLi] is regarded to be highly ionic,[12] similarly, the bonding in the $[Cp_2Li]$ anion should be considered ionic.

The Cp rings in the $[Cp_2Li]$ anion are almost perfectly staggered. However, high anisotropy in the ring thermal parameters indicates substantial disorder in the positions of the Cp carbon atoms (see Fig. 2b).[13] This is most likely due to small energy differences between staggered and eclipsed conformations. Recent MNDO calculations on the $[Cp_2Li]$ anion do indeed indicate essentially free rotation of the Cp rings around the longitudinal axis.[6b]

In the context of the theoretical discussion on out-of-plane bending of the hydrogen atoms in cyclopentadienyl–metal species, that is, bending away from or toward the metal,[6b, 11, 14, 15] it would be interesting to determine the Cp-hydrogen positions. Unfortunately, the Cp hydrogens in the crystal structure of the $[Cp_2Li]$ anion could not be exactly located. Attempts to localize and refine hydrogen atoms were severely hindered by the large thermal parameters of atoms in the Cp ring (Fig. 2b).

The $[Cp_2Li]$ anion is isoelectronic with its first-row relatives $[Cp_2Be]$[16] and the $[Cp^*_2B]$ cation ($Cp^* = \eta^5$-C_5Me_5).[17] However, the latter compounds are not isostructural with the $[Cp_2Li]$ anion but are of the slipped sandwich type with one η^1- and one η^5-coordinated Cp ligand (**4**). Preference for this geometry has been discussed in terms of three-dimensional aromaticity,[14, 18] but can also be explained by simple size arguments. The very short (η^5-Cp_{plane})–Be distance of 1.505(6) Å does not favor a symmetrical D_{5d} sandwich complex in which the Cp···Cp distance (3.01 Å) would be shorter than the interlayer distance in graphite,[19] the Cp···Cp distance in a D_{5d} $[(\eta^5\text{-}Cp^*)_2B]$ complex would be even shorter. The D_{5d} sandwich structures observed for the isovalent second-row relatives $[Cp_2Mg]$ and the $[Cp^*_2Al]$ cation,[20] on the other hand, exhibit relatively long Cp···Cp distances of 3.96(1) and 3.67(1) Å, respectively. As in these compounds, the long Cp···Cp distance of 4.012(8) Å in the Cp_2Li-anion apparently does not induce substantial ring slippage.

4

In summary, the $[Cp_2Li]$ anion has a staggered sandwich structure with D_{5d} symmetry (average C–Li bond distance of 2.318(4) Å) and shows a striking similarity with the structure of $[Cp_2Mg]$ (staggered D_{5d} conformation, average C–Mg bond distance of 2.304(8) Å).

Experimental Procedure

$[Ph_4P]^+$ $[Cp_2Li]^-$: (the synthesis was carried out under argon with normal Schlenk techniques and predried solvents). Addition of CpLi (0.30 g, 4.16 mmol) dissolved in 15 mL of THF to a suspension of anhydrous Ph_4PCl (0.78 g, 2.08 mmol) in 15 mL of THF results in immediate formation of a slightly turbid orange-red solution. The reaction mixture was centrifuged, and the clear solution decanted. After 12 h at room temperature, large yellow-brown crystals of $[Ph_4P]^+$ $[Cp_2Li]^-$ were isolated and washed with THF (yield 0.76 g, 76%). The crystals are very slightly soluble in THF. ^{1}H NMR (250 MHz, [D$_8$]THF, 25 °C, TMS): δ = 5.37 (s, 10 H,

CpH), 7.50–7.80 (m, 20 H, Ph_4P). ^{13}C NMR: δ = 104.1 (Cp), 118.7 (d, ^1J(C,P) = 353 Hz, Ph_{ipso}), 131.1 (d, ^2J(C,P) = 50 Hz, Ph_{ortho}), 135.7 (Ph_{para}), 135.8 (Ph_{meta}).

The Structures of Two Lithium Hydrazides: Is There Electron-Deficient Bonding?

Nils Metzler, Heinrich Nöth,* and Hermann Sachdev

Dedicated to Professor Michael F. Lappert on the occasion of his 65th birthday

N-Lithiohydrazides are useful synthetic reagents.[1] However, their structures have not been investigated until very recently,[2] in contrast to the well-developed chemistry and structural chemistry of alkali metal amides, aldimides, and ketimides.[3] Also, our knowledge of the state of lithium hydrazides in solution is negligible,[4] although anionic rearrangements of several lithium bis(organosilyl)hydrazides have been investigated thoroughly by NMR methods.[5]

In the course of our studies related to the synthesis of borylated hydrazines from lithium hydrazides and diorganylboron halides we obtained the compounds **1** and **2**[6] as single crystals, which we studied by X-ray structure analysis.

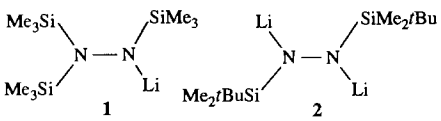

Figure 1 depicts an ORTEP diagram of one of the two crystallographically independent molecules of **1**.[7] Both show very similar bonding parameters. The most noticeable feature of **1** is

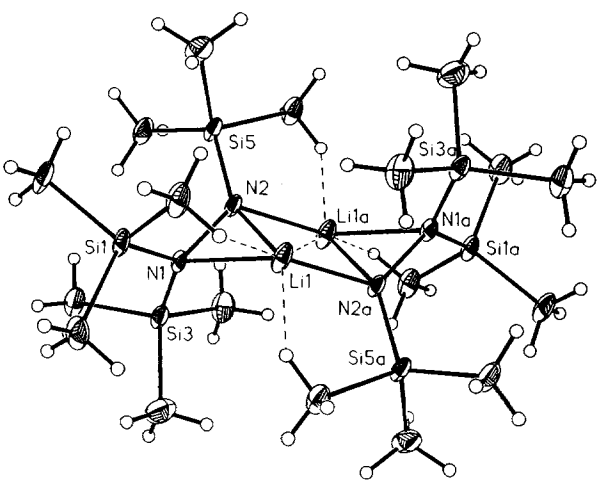

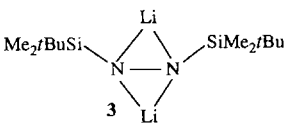

Fig. 1. ORTEP representation of the molecular structure of one of the two crystallographically independent $(\mathbf{1})_2$ molecules. Thermal ellipsoids represent 25% probability. Selected bond lengths [Å]: N1–Si1 1.744(4), N1–Si3 1.767(5), N2–Si5 1.712(4), N1–Li1 2.15(1), N1–N2 1.509(6), N2–Li1 1.925(9), Li1–Li1a 2.28(2). Selected bond angles [°]: Si1-N1-Si3 125.3(2), Li1-N1-N2 60.5(3), Si1-N1-Li1 96.6(3), Si3-N1-Li1 125.1(3), Si1-N1-N2 116.8(3), Si3-N1-N2 114.3(3), Si5-N2-N1 124.7(3), Si5-N2-Li1 147.6(4), Si5-N2-Li1a 108.2(3), N2-Li1-N2a 108.2(4), N1-Li1-N2 43.1(2), Li1-N2-Li1a 71.8(4).

its centrosymmetric *dimeric* nature which can be perceived as being formed from two three-membered LiN_2 rings. The Li···Li distances (2.28, 2.32 Å) are short. The skeleton is composed of tricoordinated Li and tetracoordinated N atoms. The

Li–N distances fall into two groups: two are short (1.93(1) Å) and one is longer (2.15(1) Å). This corresponds with the structural features of lithium amides.[3] The angles N-Li-N′ range from 43.1(2)° to 129.7(5)° and those at N2 from 71.8(4) to 147.6(4)°. In contrast, bond angles subtended at atom N1 are closer to a tetrahedral angle. The Si–N2 bond length is significantly shorter (1.712(4) Å) than Si–N1 bond lengths (1.744 and 1.767(5) Å); the latter compare well with those observed for $(t\mathrm{BuMe_2SiNH-NHLi})_6$.[2] More important, however, is the rather long N1–N2 bond. Although the Li atoms in $(\mathbf{1})_2$ are tricoordinated (by N atoms) the two short Li···H contacts (2.27 Å and 2.31 Å) suggest agostic interactions, which contribute to the steric shielding of the Li centers.

Compound **2** proved to be a *trimer* in the solid state and cocrystallizes with one molecule of hexane.[8] Figure 2 presents a view of the molecular structure at the top and the architecture of the skeletal atoms in more detail at the bottom. The molecule possesses a crystallographically imposed C_2 symmetry. The monomeric unit in **2** is represented by **3**; this Li_2N_2 bicyclic skeleton is also the energy minimum on the potential energy surface according to HF/6-31G** calculations for the model compound $Li_2N_2H_2$.[9] The side-on coordination of Li atoms has also been predicted by ab initio calculations for $H_2N-NHLi$[10] as well as for the isoelectronic species $ONHLi_2$ and $ONLi_3$.[11] Three monomeric $Li_2N_2R_2$ units associate as shown at the bottom of Figure 2, and the resulting Li_6N_6 skeleton is composed of pentacoordinated N atoms and tetracoordinated Li centers, which also feature two agostic Li···H contacts.

The Li–N bond lengths in $(\mathbf{2})_3$ fall within a much narrower range than those in $(\mathbf{1})_2$. There are three different sizes of Li-N-Li′ bond angles: close to 70°, close to 95° and close to 108°. Moreover, the structure reveals two types of N′-N-Li bond angles: two are close to 66.5° and the third at 123°. Si-N-Li bond angles can be as large as 135°.

The N–N bonds in $(\mathbf{2})_3$ (1.556(3), 1.563(4) Å) are longer than in $(\mathbf{1})_2$ which are in turn longer than in $(\mathrm{LiHN-NHSiMe_2}t\mathrm{Bu})_6$ (1.49 Å).[2] All exceed those found for hydrazine itself or organylhydrazines (1.45–1.48 Å). This points to an increasing charge transfer from Li to N as one moves from neutral hydrazines to (formal) hydrazide(2−) units.

The pentacoordinated nitrogen atoms in $(\mathbf{2})_3$ as well as electron-counting according to Wade's rules suggest that it is a bicapped distorted hexagonal antiprism in which two vertices are missing, resulting in an *arachno* type of compound.[12] As shown at the bottom of Figure 2, the skeleton is indeed built from deltohedra, as is typical for electron-deficient compounds. A molecule with a geometriy similar to $(\mathbf{2})_3$ is Bürger's $[\mathrm{PhSi(NLi}\cdot t\mathrm{Bu})_3]_2$,[13] which has also been considered an electron-deficient cluster.

Wiberg et al.[4] have pointed out that **1** is dimeric in solution. This has now been verified for the solid state as well as in solution (C_6D_6) which also contains monomeric **1**, as multinuclear NMR spectra show.[14] Moreover, the NMR data of **2** are consistent with its trimeric nature in deuterobenzene solution. There is only one signal for the Li atoms, and all silyl groups are equivalent as demonstrated by four ^{13}C NMR signals for $SiMe_2CMe_3$ substituent. Therefore, the structure of $(\mathbf{2})_3$ is obviously more symmetrical in the solution than in the solid state.

Present evidence suggests that the degree of association of metalated silyl and organyl hydrazines[5] will not only depend on the ratio of the number of N atoms to the number of metal centers, but also on the steric demand of the substituents as well as on the absence or presence of donor molecules that interact with the metal centers.[3, 15] It appears that lithium and other metal hydrazides may be an exceptionally interesting and suitable class of compounds with which to study the degree of association and bonding along the series of oligomeric species from R_3N_2M through $R_2N_2M_2$ and RN_2M_3 to N_2M_4.

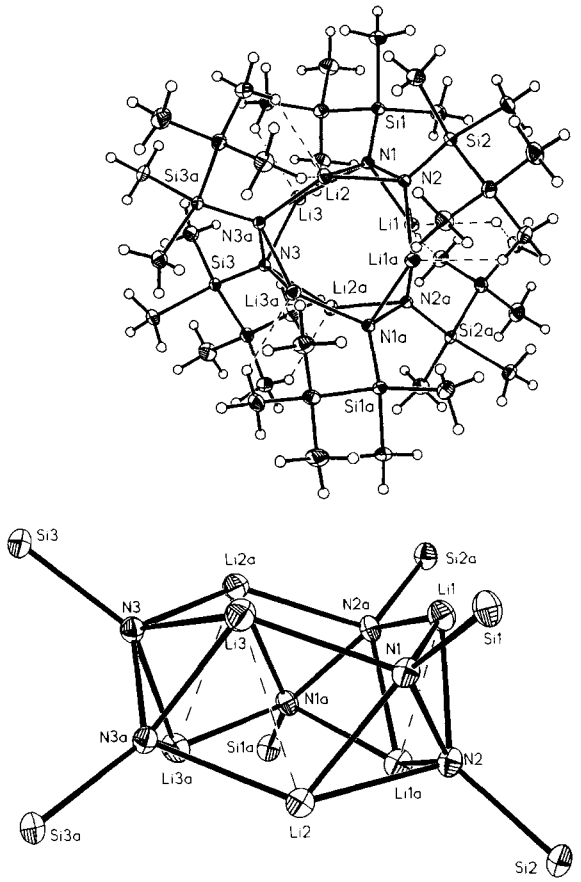

Fig. 2. Top: ORTEP representation of $(\mathbf{2})_3$. Thermal ellipsoids represent 25% probability. Note the two agostic Li···H interactions for each Li atom (represented by dotted lines). Selected bond lengths [Å]: N2–Si2 1.715(2), N1–Si1 1.716(2), N3–Si3 1.715(2), Li1–N1 1.939(5), Li1–N1a 2.000(5), Li2–N2 1.948(5), Li2–N1 1.940(5), Li3–N3a 1.950(5), Li3–N3 1.954(5), Li2–Li3 2.279(6), Li1–Li2a 2.908(6), Li2-Li3 2.279(6), Li2–Li3a 2.904(6), Li1–Li1a 2.277(9), Li1–Li3 2.906(7), N1–N2 1.556(3), N3–N3a 1.563(4). Selected bond angles [°] (standard deviations are 0.1 to 0.2°): N2-N1-Li1 65.9, N2-N1-Li2 66.7, N2-N1-Li3 123.0, Li3-N1-Li1 94.8, Si1-N1-Li1 116.2, Si1-N1-Li2 135.0, N1-N2-Li2 66.2, N1-N2-Li1a 123.1, Li1-N2-Li1a 70.6, Si3-N3-Li2a 110.5, N3a-N3-Si3 126.54, Si3-N3-Li3a 134.6, N3a-N3-Li3 66.3. Bottom: "Side" view on the core of $(\mathbf{2})_3$ to demonstrate the deltohedral array of the skeleton.

[6] $(\mathbf{1})_2$: $(\mathrm{Me_3Si})_3N_2H$ (8.00 g, 32.2 mol) was dissolved with stirring in 100 mL of *n*-hexane. A solution of LiBu in hexane (20.6 mL, 1.56 M) was added. After heating at reflux for 2 h, crystals of $(\mathbf{1})_2$ separated on cooling. Yield 93%, m.p.

183–185 °. Correct elemental analysis. ^{1}H NMR (270.17 MHz, C_6D_6, 28 °C): $\delta = 0.24$ (broad, dimer, 85% intensity), 0.13 (broad, $NLiSiMe_3$), 0.11 (s, $N(SiMe_3)_2$). The last two signals are assigned to monomeric **1**. Their intensity ratio is 2:1 and their total intensity is 15%; ^{6}Li NMR (39.76 MHz, C_6D_6): $\delta = 1.10$ (s, sharp); ^{7}Li NMR (105.01 MHz, C_6D_6): $\delta = 1.76$ (s, sharp); ^{13}C NMR (67.94 MHz, C_6D_6): a) of $(\mathbf{1})_2$: $\delta = 3.80$ (broad, $N(Li)SiMe_3$), 2.84 ($NSiMe_3$); b) of **1**: $\delta = 1.98$ (s, $N(Li)SiMe_3$), 1.29 (s, $N(SiMe_3)_2$), 0.91 (s, $N(SiMe_3)_2$. ^{29}Si NMR (53.67 MHz, C_6D_6): a) of $(\mathbf{1})_2$: $\delta = 6.76$ (broad); b) of **1**: $\delta = 6.93$ (broad), 6.52 (broad).

$(\mathbf{2})_3 \cdot C_6H_{14}$: $(t\mathrm{BuMe_2Si})_2N_2H_2$ (7.82 g) dissolved in *n*-hexane (100 mL) was allowed to react with a 1.56 M solution of LiBu in hexane at ambient temperature and with stirring. After heating the mixture for 1 h at reflux, followed by cooling, to −20 °C, crystals including single crystals of $(\mathbf{2})_3$ separated. Yield: 86%, m.p. 73–76 °C, correct elemental analysis. All NMR data were recorded in C_6D_6. ^{1}H NMR (270 MHz): $\delta = 0.98$ (s, $SiMe_2CMe_3$), 0.93 (s, $SiMe_2CMe_3$), 0.23 (s, $SiMe_2CMe_3$); ^{6}Li NMR (39.76 MHz): $\delta = 1.10$ (sharp); ^{7}Li NMR (105.01 MHz): $\delta = 1.44$ (s, sharp); ^{13}C NMR (67.94 MHz): $\delta = 0.55$ ($SiMe_2CMe_3$), 1.84 ($SiMe_2CMe_3$), 18.59 ($SiMe_2CMe_3$), 28.88 ($SiMe_2CMe_3$), 14.25 (CH_2), 22.67 (CH_2), 38.78 (CH_3). The latter three signals result from hexane. ^{29}Si NMR (53.67 MHz): $\delta = -0.47$.

[7] a) X-ray structure determination of $(\mathbf{1})_2$. Crystal size = 0.3 × 0.4 × 0.5 mm, $(C_9H_{27}LiN_2Si_3)_2$, $M_r = 254.54$ g mol^{-1}, colorless prism, $a = 8.85(1)$, $b = 9.598(9)$, $c = 21.98(2)$ Å, $\alpha = 100.62(7)$, $\beta = 91.9(1)$, $\gamma = 115.90(8)$°, $V = 1636$ Å^3, triclinic, space group = $P\bar{1}$, $Z = 2$, $\rho_{calcd} = 1.033$ g cm^{-3}, $F(000) = 560$. Data collection: Nicolet R3m four-circle diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, $T = 173$ K, 2θ-range = 3.8–48° in h, $-/+k$, $-/+l$, scan speed = 1.8 to 29.3° min^{-1}, ω scans, scan width = 1.4°, 5489 data collected, 5110 independent reflections, 3708 considered observed ($F > 3\sigma(F)$). Structure solution: SHELXTL PLUS (VMS), non-hydrogen atoms anisotropic, H atoms in calculated positions, riding model, 271 refined parameters, ratio of observed data to no. of variables = 13.6:1, $R = 0.095$, $R_w = 0.11$, $1/w = \sigma^2(F) + 0.0004\,F^2$, wR_2 (on F^2) = 0.2466, GOF = 2.21, largest diff. peak/hole = 0.79/−1.09 e Å^{-3}. The crystal of $(\mathbf{1})_2$ was only weakly diffracting, which may account for the fairly high R values. b) Further details of the structure determination are deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftliche Information, D-76344 Eggenstein-Leopoldshafen and may be obtained by quoting the depository number CSD-58392 and the literature citation.

[8] X-ray structure determination of $(\mathbf{2})_3$. Crystal size: 0.4 × 0.45 × 0.55 mm, colorless prism, $a = 21.782(5)$, $b = 12.465(3)$, $c = 21.839(4)$ Å, $\beta = 101.71(1)$°, $V = 5806(2)$ Å^3, $Z = 4$, monoclinic, space group $C2/c$, $\rho_{calcd} = 1.034$ g cm^{-3}, $\mu = 1.75$ cm^{-1}, $F(000) = 2000$. Data collection: Siemens P4 diffractometer, $Mo_{K\alpha}$ radiation, $T = 173$ K, 2θ-range = 3.8–48° in h: −1 to 23, k: 0 to 13, l: −24 to 24, ω scans, scan speed = 3° min^{-1}, scan range = 1.2°, 4634 reflection collected, 4137 independent reflections ($R_{int.} = 0.035$), 2317 observed ($4\sigma(F)$). Structure solution: Siemens SHELXTL PLUS PC. Refinement: SHELX93 PC, direct methods, non-hydrogen atoms refined anisotropically, H atoms freely refined except the hydrogen atoms of the CH_2 groups of hexane, $R = 0.0448$ (with data $I > 4\sigma(I)$), $R = 0.0625$ (all data), $wR_2 = 0.1154$ (F^2!). Data to parameter ratio = 10:1. $1/w = \sigma^2(F_0)^2 + (0.0486P)^2 + 12.0653P$ where $P = (F_o^2 + 2F_c^2)/3$, GOF = 1.029 on F^2, largest difference peak/hole = 0.59/−0.58 e Å^{-3}. See also [7b].

[9] Ab initio HF/6-31G** calculations on $Li_2N_2H_2$ showed that a bicyclic structure like **3** with C_2, symmetry is the most stable one. Calculated bond lengths [Å]: N–N = 1.529, N–Li = 1.828, Li···Li′ = 3.030; calculated bond angles [°]: Li-N-Li′ = 111.94, Li-N-N′ = 63.87, N-Li-N′ = 52.26, N-Li-Li′ = 34.03. The population analysis according to Mulliken resulted in the following partial charges [e]: H = 0.233, N = −0.726, Li = 0.492 and indicates electron density between Li and N atoms. However, it is known for any population analysis that the charges are likely to be overestimated. In addition, the calculation suggests (very) weak Li···Li′ interaction ($p_{\mu\nu} = 0.045$). This lies on the borderline for a meaningful interpretation. The long Li···Li′ distance corresponds with the long Li···Li distances in $(\mathbf{2})_3$. However, it should been noted that the Li···Li′ distances between the two sets of six membered rings in $(\mathbf{2})_3$ are much shorter than in the monomeric model.

[14] ^{1}H NMR spectra for $(\mathbf{1})_2$ show three broad signals due to the presence of dimer and monomer in an approximate 89:11 ratio. There is only one signal for the dimer, but the expected three signals were observed in the ^{13}C NMR spectra, and only two rather broad signals for the monomer. We could not resolve the broad signals by changing the resonance frequencies, solvent, and temperature.

Thianickelacycles by Ring-Opening Reactions of Cyclic Thioethers and Their Subsequent Carbonylation to Thioesters**

Phillip T. Matsunaga and Gregory L. Hillhouse*

In the pathway of CO_2 fixation in anaerobic bacteria, nickel is believed to play a key role in the synthesis of acetyl coenzyme A (acetyl-CoA) by the metalloenzyme carbon monoxide dehydrogenase. Although the majority of studies on CO-dehydrogenase have been performed on the acetogenic bacteria *Clostridium thermoaceticum* and *Autobacterium woodii*, this enzyme is also found in some methanogenic, sulfate-reducing, and photosynthetic bacteria.[1] EPR data indicate that Ni is involved in the binding of CO, which is incorporated as the C-1 carbon of acetyl-CoA, and EXAFS data suggest that the Ni atom is four-coordinate with N- and S-donor ligands in the coordination sphere. Although the biosynthesis of acetyl-CoA is probably effected at multiple sites and not at a single Ni center in the native enzyme, we report herein the preparation of simple Ni complexes containing N-donor ligands (bipyridine (bpy)) as well as alkyl and thiolate ligands. One such complex reacts with CO to give a thioester in a transformation analogous to that involved in acetyl-CoA biosynthesis. Holm and co-workers have reported a series of Ni complexes that model the Ni site in CO-dehydrogenase and demonstrate an alternate route to the synthesis of thioesters.[2]

We recently showed that the O atom of N_2O can be abstracted by Ni alkyl complexes, which enabled us to prepare stable examples of otherwise inaccessible Ni alkoxides containing β-H atoms.[3] The unavailability of N_2S as an S-atom source led us to investigate the use of cyclic thioethers as precursors to thiolatenickel complexes. This strategy seemed attractive since reactions involving sulfur-atom abstraction from ethylene sulfide and ring-opening of thietane and tetrahydrothiophene by transition-metal cluster complexes have been described.[4, 5]

The Ni^{II} complex **1** [6] reacts with ethylene sulfide (THF solution, 20 °C) to effect reductive elimination of butane and

addition of the ring-opened episulfide to give the monomeric thiametallacycle **2** in 30% yield as the only soluble complex; the remainder of the Ni precipites as NiS (see Table 1 for spectroscopic data).[7] Although a number of Ni thiolates are known,[8] cyclic derivatives like **2** have not been previously reported.

Since the conversion **1** → **2** probably requires rate-limiting reductive elimination of butane from **1**, we investigated the reaction of the Ni^0 complex **3** (cod = 1,5-cyclooctadiene)[9] with ethylene sulfide. The conversion **3** → **2** proceeds under much milder conditions (0 °C, 30 min) to give **2** in 21% isolated yield.

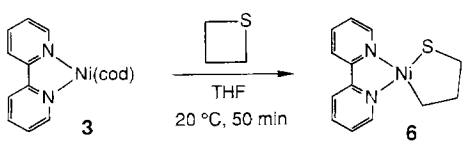
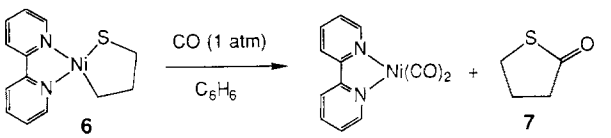
6: Blue crystals. ^{1}H NMR: δ = 2.29-2.36 (m, 4 H, CH_2), 3.10 (t, 2 H, SCH_2), 6.31 (t, 1 H, bpy), 6.34 (t, 1 H, bpy), 6.63 (d, 2 H, bpy), 6.72 (t, 1 H, bpy), 6.84 (t, 1 H, bpy), 8.42 (d, 1 H, bpy), 9.40 (d, 1 H, bpy). ^{13}C{^{1}H} NMR: δ = 29.4, 32.2, 42.3, 119.5, 120.5, 125.0, 125.7, 133.5, 135.4, 147.6, 150.6. Correct elemental analysis for $C_{13}H_{14}N_2SNi$. Molecular weight: M_{calcd} = 289. M_{found} = 313.

[a] ^{1}H NMR spectra recorded at 500 MHz, ^{13}C{^{1}H} NMR spectra recorded at 125.8 MHz, C_6D_6 solutions, 20 °C. Molecular weights were determined in THF solution by the Signer method [14].



Here again, most of the Ni precipitates as NiS (with ethylene as a by-product), consistent with other studies in which **3** has been shown to extract sulfur from dibenzothiophene to give NiS as the metal-containing product.[10]

Propylene sulfide reacts with **3** to give a 6:1 mixture of **4** and **5** in an overall yield of 22%. Steric factors appear to



dictate the product distribution in this reaction in which insertion occurs preferentially at the least substituted S–C bond to give **4** as the major product.

The four-membered cyclic thioether, thiethane, reacts with **3** to produce the thiametallacyclopentane complex **6** in 47% yield. Tetrahydrothiophene, however, is unreactive toward **3**.

The five-membered ring thus seems not to possess sufficient ring strain to promote C–S bond cleavage. Moreover, **3** is unreactive toward oxygen analogues such as propylene oxide, oxetane, and tetrahydrofuran. These observations probably reflect the greater C–O bond strengths in cyclic ethers relative to the C–S bonds in cyclic thioethers. More reactive cyclic substrates (for example, cyclic anhydrides), however, do give rise to C–O bond cleavage.[11]

The [(bpy)Ni(R)(OR)] complexes undergo carbonylation reactions to give [(bpy)Ni(CO)$_2$] and esters.[3, 12] In an analogous reaction, carbon monoxide (1 atm, 20 °C) reacts with **6** to give [(bpy)Ni(CO)$_2$] and γ-thiobutyrolactone (**7**).[13] No intermediates were detected by spectroscopy in this transformation, and we have no mechanistic basis for differentiating between initial CO insertion into the Ni–S or the Ni–C bond of **6** prior to reductive elimination of the thiolactone. The 28% isolated yield of **7** is relatively low, possibly a consequence of the tendency

of thiolactones, particularly those of small ring size, to polymerize. Under similar conditions, the reaction of **2** with CO does not give a clean product, possibly because of excessive ring strain in the expected thioester.

We are continuing to investigate the chemistry of these thiametallacyclic complexes, and are examining other cyclic substrates to evaluate the extent of substrate compatibility with this ring-opening methodology.

Experimental Procedure

All reactions were carried out under argon with standard Schlenk and high-vacuum techniques and dry, air-free solvents.

2: (Method A) To a solution of **1** (0.250 g, 0.916 mmol) in THF (10 mL) was added, dropwise, ethylene sulfide (54.5 µL, 0.916 mmol) by syringe. The solution was stirred at ambient temperature for 7 h, during which time the color changed from green to blue. The solution was filtered, and the residue was washed with THF (3 × 5 mL). The filtrate was concentrated to 5 mL, and pentane (5 mL) was added to precipitate the product. The solid was filtered and washed with pentane (3 × 5 mL). The residual solvent was removed under reduced pressure to yield 0.076 g (0.28 mmol, 30%) of **2** as dark blue microcrystals.
Method B: **2** was synthesized in 21% yield from **3** with a modified procedure described above—the reaction was carried out at 0 °C over a 30 min period.

4, **5**, **6**: Analogous procedures to that described for **2** were used for all compounds. Reaction conditions are given in the reaction equations, yields in the text.

7: A solution of **6** (0.050 g, 0.17 mmol) in C_6D_6 (1 mL) was exposed to carbon monoxide (1 atm). After 30 min, the excess CO was removed and the volatiles were separated from [(bpy)Ni(CO)$_2$] by vacuum transfer. Analysis by ^{1}H NMR spectroscopy (internal standard: ferrocene) gave a yield of 0.047 mmol (28%) for **7**. The product was identified by spectral comparison with an authentic sample.

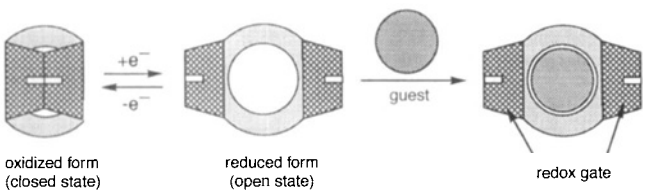
Redox Control for the Recognition of Ag^+ Ions in a Macrocycle Containing Two SH Groups or an S–S Bridge inside the Cavity**

Tatsuya Nabeshima,* Hiroyuki Furusawa, and Yumihiko Yano

An advanced and challenging target in host–guest chemistry is the construction of a host molecule having the ability of specific recognition regulated in a similar fashion to that observed, for example, in allostery or in cooperative effects.[1] The external stimulus or effector may be a molecule, ion, electron, etc.[2] We have been interested in an electron as an effector, because the redox reaction between thiols and disulfides controls perfectly the enzymatic activity of ribonuclease.[3] However, perfect and facile regulation using the reaction has been extremely difficult because of some drawbacks in the artificial systems:[4] quantitative interconversion between redox forms could not be performed,[5] or the reduced form is somewhat difficult to treat without oxidation owing to its high sensitivity to molecular oxygen.[6] Additionally, a more critical problem is that a recognition site could not be made to vanish completely despite a large conformational change induced by the redox reactions.

In this paper we provide a new concept of gating, the interconversion of an open and a closed state of a recognition site (Fig. 1) that uses the redox reactions between thiols and disulfides for regulation, and report novel artificial ionophores **1** (**1**(red), the reduced form for the open state; **1**(ox), the oxidized form for the closed state) designed on the basis of this concept. Host molecules **1** are novel macrocyclic polyethers with a redox gate containing sulfur atoms inside the binding cavity. This system solved all problems mentioned above and regulates remarkably high Ag^+ affinity. To the best of our knowledge, this is the first example of gating to control ion recognition.



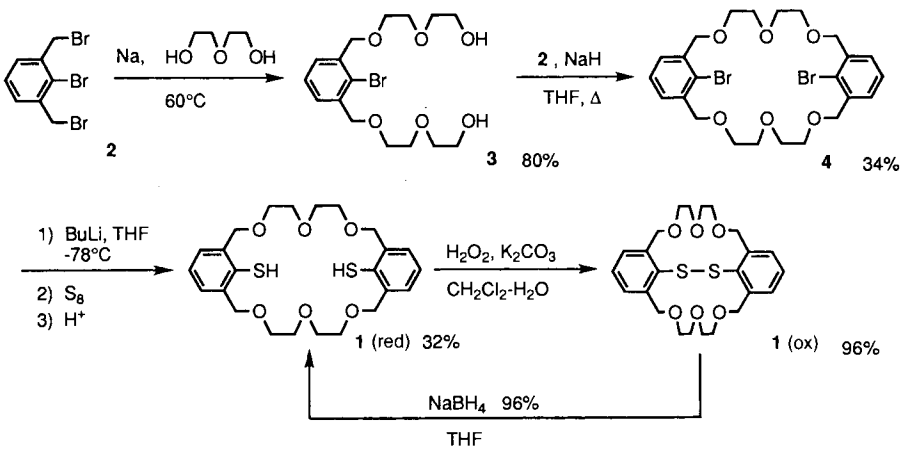


Fig. 1. Principle of molecular recognition controlled by a redox gate.

Tribromide **2**[7] was treated with an excess of diethylene glycol to give diol **3** (Scheme 1). Cyclic dibromide **4** was obtained in 34% yield by the reaction of **2** and **3**. Lithiation of **4**, followed by treatment with elemental sulfur, afforded **1**(red) bearing two thiol groups, in 32% yield as colorless crystals after recrystallization from EtOAc. The form **1**(red) was oxidized by iodine or peroxide such as hydrogen peroxide to yield **1**(ox) quantitatively. The proximate and inward arrangement of the thiol groups in the **1**(red) ring should prevent generation of polymeric compounds. Importantly, **1**(red) is very stable under aerobic conditions: no detectable amount of **1**(ox) was observed by ^1H NMR spectroscopy after bubbling oxygen through a solution of **1**(red) in chloroform for several hours. The oxidized form **1**(ox) was

Scheme 1. Synthesis of **1**.

reverted by $NaBH_4$ to **1**(red) in 96% yield, thus confirming the quantitative interconversion.

Solvent extraction (3×10^{-5} M metal picrate and 0.1 M metal chloride in H_2O; 3×10^{-4} M **1** in 1,2-dichloroethane) showed that both **1**(red) and **1**(ox) exhibit almost no affinity toward alkali metals.[8] Inspection of CPK models suggests that the sulfur atoms permit coordination of only two oxygen atoms in the ring, which is not sufficient for the recognition of alkali metals. On the other hand, **1**(red) extracts several soft heavy metals (0.01 M metal nitrate and 3×10^{-5} M picric acid in H_2O; 3×10^{-4} M **1** in 1,2-dichloroethane): 44, 36, and 13% of the initial amount of the picrate were extracted for Pb^{2+}, Cu^{2+}, and Cd^{2+}, respectively. The best recognition was for Ag^+ (ca. 100%). However, very little, if any, Cr^{3+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, and Zn^{2+} was extracted (0, 1, 0, 3, 0, and 3%, respectively). Without picric acid (3.0 mM metal nitrate solutions), remarkably high Ag^+ selectivity was observed by atomic absorption spectroscopy (extractability:[9] 216, 8, and 8% for Ag^+, Cu^{2+}, and Pb^{2+}, respectively). Furthermore, Ag^+ was specifically extracted (extractability: 175, 0, and 0% for Ag^+, Cu^{2+}, and Pb^{2+}, respectively) from a mixture of Ag^+, Cu^{2+}, and Pb^{2+} (3.0 mM each). The extractability for Ag^+ suggests that **1**(red) can capture at least two Ag^+ ions. A 1:2 complexation between **1**(red) and Ag^+ was also implied by UV/VIS titration by monitoring at 295 nm.[10]

Specific Ag^+ binding by **1**(red) was also observed in a transport experiment through a liquid membrane of 1,2-dichloroethane in a dual cylindrical apparatus.[2d] As seen in Figure 2, Ag^+ was exclusively transported by **1**(red). In contrast, Cu^{2+}, Pb^{2+}, Zn^{2+}, Cd^{2+}, Na^+, and K^+ were not transported at all within experimental error, although **1**(red) exhibits a low affinity for some of the metals. In the case of **1**(ox), Ag^+, Pb^{2+}, and Cu^{2+} were not detected in the receiving phase. These facts reveal that Ag^+ is bound only when the gate is open, as also seen in the extraction. In competitive transport ($[Ag^+] = [Pb^{2+}] = [Cu^{2+}] = 0.01$ M in the source phase), the high Ag^+ selectivity

of **1**(red) was not changed. Addition of *m*-chloroperbenzoic acid (*m*-CPBA) to the transport system 8 h after the start caused an abrupt increase of Ag^+ transported and subsequent termination of the transport (Fig. 2). This phenomenon can be rationalized by the closing of the gate to release Ag^+ bound to the **1**(red) and by the lack of Ag^+ binding of **1**(ox). Although the structure of **1**(red)-Ag^+ is unclear,[11] these results explicitly show that the sulfur atoms of **1** function very efficiently as a redox gate to regulate selectivity as well as binding strength to metal ions.

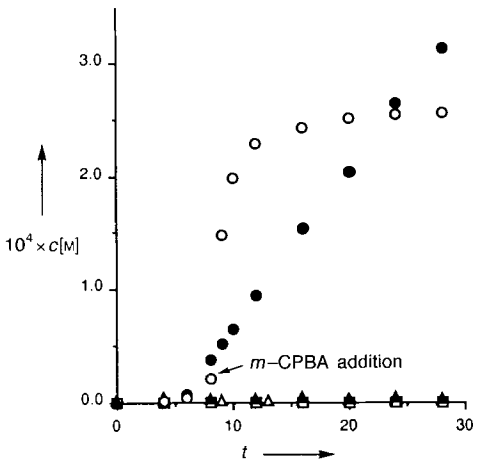

Fig. 2. Transport of Ag^+ (●), Cu^{2+} (□), and Pb^{2+} (▲) by **1**(red) and Ag^+ by **1**(ox) (△) through a liquid membrane, and the effect of *m*-CPBA on the transport (○). The concentration of **1** in the organic phase (1,2-dichloroethane) was 2×10^{-4} M. The initial concentration of metal nitrate in the aqueous source phase was 0.01 M, the receiving phase was deionized water. The concentrations of the metal ion in the receiving phase were determined by atomic absorption spectroscopy.

Many artificial systems for regulation of ion and molecular recognition reported so far could not achieve complete elimination of the recognition site; all-or-nothing regulation was extremely difficult. Without doubt the gating reported here is one of the most convenient and capable methodologies for such regulation and, therefore, will be useful and important for the construction of various sophisticated recognition systems (artificial systems for transport and modulation of molecular information [2d, 12] such as systems combining molecular recognition and other molecular functions, and regulated by some external conditions.

Experimental Procedure

3: Under N_2 **2** (9.06 g, 26.4 mmol) was added in several portions to a solution of Na (2.80 g, 0.122 mol) dissolved in diethylene gylcol (84 g). The mixture was heated at 60 °C for 2 days. After cooling, 3 N HCl (50 mL) was added, followed by extraction with CH_2Cl_2 (2×100 mL). The organic layer was washed with H_2O (2×150 mL), then dried over $MgSO_4$, and concentrated in vacuo. The residue was purified on a silica gel column, by elution with EtOAc/*n*-hexane/ethanol (5:4:1, v/v) to give a pale yellow oil **3** (8.35 g, 80% yield). ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 2.17$ (br. s, 2H; OH), 3.55–3.85 (m, 16H), 4.66 (s, 4H; $ArCH_2$), 7.25–7.50 (m, 3H, ArH); HRMS (EI): *m/z* 392.08548 (calcd 392.08345) $[M^+]$.

4: Under N_2 a solution of **2** (5.31 g, 15.5 mmol) and **3** (6.08 g, 15.5 mmol) in THF (40 mL) was added very slowly to a refluxed suspension of NaH (1.51 g, 55% in oil, 34.6 mmol) in THF (900 mL). The mixture was then heated at reflux for three days. After the reaction had been quenched by the addition of H_2O, the solvent was removed in vacuo. The residue was diluted with CH_2Cl_2 (150 mL), washed with 3 N HCl (100 mL), H_2O (100 mL), and brine (100 mL), and subsequently dried with $MgSO_4$. The residue obtained after concentration of the solvent was extracted with hot *n*-hexane to give crude **4**, which was purified by recrystallization from EtOAc. Yield: 3.00 g, 34%. M.p. 108–110 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.74$ (s, 16H), 4.61 (s, 8H; $ArCH_2$), 6.90–7.45 (m, 6H; ArH); MS(EI): *m/z* 576 ($[M+4]$, 2.4%), 574 ($[M+2]$, 4.7%), 572 ($[M^+]$, 2.5%).

1(red): A solution of *n*BuLi (1.54 M) in *n*-hexane (1.30 mL, 2.00 mmol) under N_2 was added at −78 °C to a solution of **4** (401 mg, 0.698 mmol) in THF (100 mL). The mixture was stirred for 4.5 h at −78 °C, and then S_8 (69 mg, 2.15 mmol) was added. After further stirring at −78 °C for 1 h, the mixture was gradually warmed to about 5 °C, and then 3 N HCl (1 mL) was added. The solvent was removed in vacuo, and the residue thus obtained was diluted with CH_2Cl_2 (50 mL), washed with H_2O (30 mL), dried over $MgSO_4$, and concentrated in vacuo. Recrystallization from EtOAc gave **1**(red). Yield: 108 mg, 32%. M.p. 160–163 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.60$–3.85 (m, 16H), 4.61 (s, 8H, $ArCH_2$), 4.82 (s, 2H; ArSH), 7.00–7.35 (m, 6H; ArH); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 69.89$, 70.62, 73.16, 124.86, 129.45, 134.30, 136.06; IR (KBr) 2532(SH) cm^{-1}; HRMS (FAB): *m/z* 503.1553 (calcd 503.1538) $[M+Na]^+$.

1(ox): A solution of **1**(red) (24. mg, 0.050 mmol) in CH_2Cl_2 (30 mL) was mixed with 30% H_2O_2 (5 mL) and K_2CO_3 (50 mg) in H_2O (25 mL) for 15 min at room temperature. The organic layer was washed with H_2O (20 mL) and brine (20 mL), dried over $MgSO_4$, and then concentrated in vacuo to afford **1**(ox) (23 mg, 96%). No by-product was detected by ^{1}H NMR (200 MHz) and TLC analysis. M.p. 139–142 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.60$–3.85 (m, 16H), 4.71 (s, 8H; $ArCH_2$), 7.30–7.45 (m, 6H; ArH); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 70.55$, 71.85, 72.21, 127.79, 129.74, 130.62, 143.69; HRMS (FAB) *m/z* 479.1576 (calcd 479.1562) $[M+H]^+$.

Reduction of **1**(ox) to **1**(red) with $NaBH_4$: To a solution of **1**(ox) (140 mg, 0.29 mmol) in THF (40 mL) at room temperature was added $NaBH_4$ (25 mg, 0.66 mmol). The mixture was stirred for 30 min. After addition of 3 N HCl (5 mL), concentration in vacuo, and dilution with CH_2Cl_2 (30 mL), the residue was washed with H_2O (25 mL), dried over $MgSO_4$, and then concentrated in vacuo to afford crude product, which was recrystallized from EtOAc to give **1**(red) (134 mg, 96%).

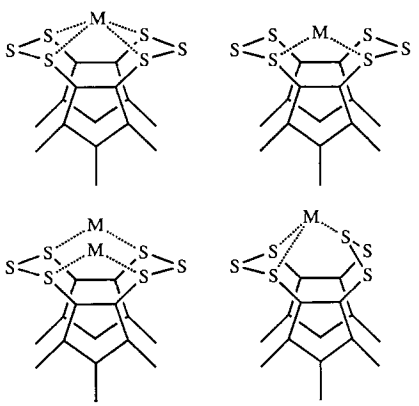
The First Metal Complexes with a Doubly S_3-Bridged Ferrocene Ligand**

Scott L. Ingham and Nicholas J. Long*

During the past two decades, polythioether macrocycles have been extensively studied because of their potential as ligands for the coordination of heavy metals in unusual oxidation states and geometries.[1-8] The flexibility of the macrocycles and the stability of the complexes formed has resulted in their use in nuclear medicine,[9] organometallic chemistry,[6] and the design of ion-selective receptors.[8, 10, 11] These macrocyclic compounds have also been modified in order to develop new functionalities. One such modification is the incorporation of a metallocene unit into a crown ether ring.[12, 1] This system contains both a redox function and a fragment able to bind a metal cation, and has been shown to possess useful electrochemical and chromogenic properties.[14] The compounds can be designed to recognize electrochemically the binding of a charged guest and, as such, are thought to have immense potential as chemical sensors, redox-switchable ligands, and catalytic systems.[15, 6]

We recently synthesized and characterized the first doubly chalcogen-bridged metallocenophane, 1,1′,2,2′-bis(1,2,3-trithia-1,3-propanediyl)ferrocene (**1**).[17] This molecule possesses the aforementioned, potentially useful attributes of a redox-active center and a metal binding site. We now report on the first metal (copper) complexes of this doubly S_3-bridged ferrocene **1**.

The 1,2-arrangement of the S_3 chains on the cyclopentadienyl rings results in the formation of a "basket-shaped" ligand, which potentially offers different modes of coordination (Fig. 1). Binding of the four central sulfur atoms results in tetradentate arrangement, linking of one atom from each S_3 bridge in a bidentate structure. Depending on the size of the metal species, bidentate coordination could occur on each side of the ligand system or involve more than one ferrocenophane **1** (see later). Although the chair–chair form is most favored and is adopted in the solid state,[17] the chair–boat conformer is also observed in solution.[18] Because of the orientation of the sulfur lone pairs, the sulfur bridges in the latter conformer would be expected to act as a tridentate ligand. It should be noted that Rauchfuss et al. have utilized **1** and analogous systems to form disulfide-bridged ferrocene polymers.[19]



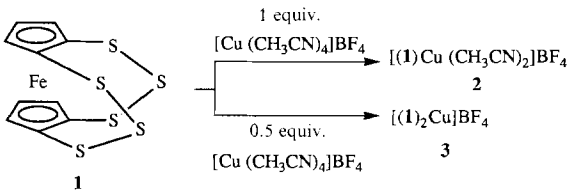


Fig. 1. A representation of the possible metal complexes formed by the ferrocenophane **1**.

Because soft metals preferentially bind to sulfur, we chose to use the copper complex $[Cu(CH_3CN)_4]^+$ in our initial investigations into the coordination properties of **1**. Depending on how many of the weakly bound acetonitrile molecules it displaces, **1** could potentially act as mono-, bi-, tri-, or tetradentate ligand. A solution of **1** in CH_2Cl_2 was treated with $[Cu(CH_3CN)_4]BF_4$ (1 equiv), and almost immediately an orange solution of **2** was formed (Scheme 1). From the experimental data, it was clear

Scheme 1. Reactions of **1** with $[Cu(CH_3CN)_4]BF_4$.

that two acetonitrile molecules had been displaced. Apparently, the copper-to-ligand bonding is not as strong in **2** as in other copper–thioether complexes, since filtration through silica or alumina resulted in decomposition and regeneration of **1**. Heating or prolonged stirring of the reaction mixture resulted in formation of an insoluble, presumably polymeric, species.

Treatment of **1** with 0.5 equivalents of $[Cu(CH_3CN)_4]BF_4$ (Scheme 1) led to instantaneous formation of a reasonably air-stable, orange-red complex **3**, which analyzed as $[(\mathbf{1})_2Cu]BF_4$, formed with loss of all acetonitrile ligands from copper (yield = 0.030 g, 62%; FAB$^+$-MS: m/z 813 $[M^+ - BF_4]$). Again, filtration of the solution led to decomposition, but dilution with diethyl ether resulted in the formation of orange-red crystals, which were then subjected to an X-ray structure analysis.[20]

It is interesting to note that there is very little difference between the ^{1}H NMR spectra of the ligand **1** and the complexes **2** and **3** (chair–chair and chair–boat conformations are again observed). This is presumably due to the very similar geometry of these compounds and, less importantly, to the weak coordination of the copper ion, which is thus distant from the cyclopentadienyl rings. Sato et al.[13] also found only small changes in IR, NMR, and electronic spectral data on going from analogous free ligands to the corresponding metal complexes. They suggested that the ferrocene moiety of the complexes is little influenced by coordination of a metal to the sulfur atoms of the crown ether. These conclusions were backed up by preliminary electrochemical data.[21]

The Cu complex **3** crystallized in the space group $I2(1)/a$ with 1.5 molecules per asymmetric unit. The structure of the cation is illustrated in Figure 2. The two ferrocenophane ligands form a distorted tetrahedral arrangement around the copper(I) ion. Distortion is manifested in a large angle for S(4a)-Cu(1)-S(4) (145.4(2)°); however, all Cu–S distances are around 2.35 Å, a value comparable to those in analogous Cu complexes with thioether macrocycles.[22, 23] As expected from models showing the orientation of the lone pairs on the sulfur atoms, each ferrocenophane acts as a bidentate ligand; one sulfur from each S_3 bridge is involved in coordination. Generally, there is not much change in the structure of the ferrocenophane when it is trans-

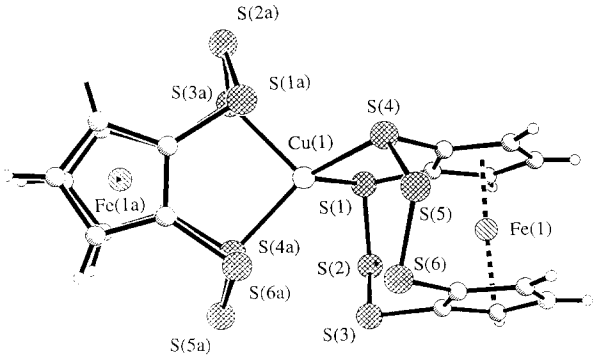

Fig. 2. Molecular structure of the cation in **3**. Selected bond lengths [Å] and angles [°]: Cu(1)–S(1) 2.358(3), Cu(1)–S(4) 2.347(3), S(1)–S(2) 2.088(4), S(4)–S(5) 2.088(4), S(2)–S(3) 2.037(4), S(5)–S(6) 2.038(4); S(1)-S(2)-S(3) 105.3(2), S(4)-S(5)-S(6) 103.9(2), C(12)-S(4)-S(5) 101.8(4), C(11)-S(1)-S(2) 103.0(4), C(22)-S(6)-S(5) 104.5(4), C(21)-S(3)-S(2) 103.7(4), S(4a)-Cu(1)-S(4) 145.4(2), S(4a)-Cu(1)-S(1) 106.64(10), S(1)-Cu(1)-S(4) 92.46(11).

formed from the free state[17] to being part of a complex. However, it is worth noting that the S–S bond lengths involving the copper-coordinated sulfur atoms (e.g., S(1)–S(2) 2.088(4) and S(4)–S(5) 2.088(4) Å) are noticeably greater than those involving uncoordinated sulfur atoms (S(2)–S(3) 2.037(4) and S(5)–S(6) 2.038(4) Å) (cf., the average S–S bond length in S_3-bridged ferrocenes[17, 24] and osmocenes[25] of 2.054(4) Å). The increase in bond length is presumably due to a removal of electron density from the sulfur to the copper atom.

The cyclopentadienyl rings are virtually parallel and eclipsed (which is to be expected, since all reported structures for trichalcogen-bridges metallocenes show this eclipsed conformation[17, 24, 25–28]). The fact that sulfur atoms are only slightly displaced from the ring planes indicates that there is virtually no strain within the structure. There is also very little difference between the bond angles around the bridgehead and the analogous angles in the free ferrocenophane. The bridges are, as expected, in the chair–chair conformation, which is the most populous form of **1** in solution.

We are currently investigating the coordination of various transition metals with differing geometries and oxidation states to the ligand system **1**.

Experimental Procedure

2: To a yellow solution of **1** (0.050 g, 0.13 mmol) in dichloromethane (25 mL) was added $[Cu(CH_3CN)_4]BF_4$ (0.042 g, 0.13 mmol). The solution immediately turned orange and was stirred at room temperature for 30 min. Dilution of the solution with diethyl ether (25 mL) resulted in formation of two layers and crystallization of orange crystals of **2** (0.037 g, 47%, m.p. 120–122 °C). Satisfactory elemental analysis. FAB$^+$-MS: *m/z* $[M^+ - (CH_3CN)_2]$; ^{1}H NMR ($CDCl_3$): δ = 2.00 (s, 6H; CH_3CN), 4.09 (dd, 1H; C_5H_3), 4.14 (d, 2H; C_5H_3), 4.62 (t, 1H; C_5H_3), 4.69 (m, 2H; C_5H_3).

3: A solution of **1** (0.040 g, 0.107 mmol) in dichloromethane (25 mL) was treated with $[Cu(CH_3CN)_4]BF_4$ (0.017 g, 0.053 mmol). The resultant red solution was stirred for 1 h or heated to 50 °C for 5 min. Dilution of the solution with diethyl ether (20 mL) and crystallization of 0 °C overnight gave orange-red crystals of **3** (0.030 g, 62%, m.p. 135–137 C). Satisfactory elemental analysis. FAB$^+$-MS: *m/z* 813 $[M^+ - BF_4]$; ^{1}H NMR ($CDCl_3$), δ = 4.09 (m, 1H; C_5H_3), 4.14 (d, 2H; C_5H_3), 4.62 (t, 1H; C_5H_3), 4.69 (m, 2H; C_5H_3).

[20] Crystal data for **3**: $CuFe_2S_{12}F_4BC_{20}H_{12}$; M = 899.07; monoclinic space group $I2_1a$, a = 24.816(5), b = 12.634(1), c = 27.250(4) Å, β = 90.95(2)°, V = 8542(2) Å^3, Z = 12, ρ_{calcd} = 2.097 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 2.688 mm^{-1}, T = 293 K. Data were collected on a Rigaku AFC7R diffractometer ($Mo_{K\alpha}$, graphite monochromator, θ_{max} = 22.5°) with an orange, lamellar single crystal. The structure was solved by a combination of Patterson and Fourier techniques. The positions of hydrogen atoms were calculated. Absorption corrections with semiempirical ψ scans (minimum and maxium transmission coefficients 0.8465 and 0.9989, respectively). Full matrix least-squares refinement on F_o^2 for 5584 reflections, 520 parameters, and 10 restraints converged to $wR2$ = 0.1947 (all data), conventional $R1$ = 0.0591 (observed data, 3911 reflections with $F_o^2 > 2\sigma(F_o^2)$), $(\Delta/\sigma)_{max}$ = −0.015, GOF (all data) = 1.109. Residual electron density = 1.917, −0.656 e Å^{-3}. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ, on quoting the full journal citation.

[21] The electrode potentials of **1** and **3** differ by only 0.02 V for the ferrocene redox center, indicating that copper coordination has little influence on the electrochemical properties. Complex **3** also decomposes over a short period of time during the electrochemical experiment. Full electrochemical discussion on doubly trichalcogen-bridged ferrocenes will be included in a forthcoming publication: N. J. Long, P. R. Raithby, P. Zanello, *J. Chem. Soc. Dalton Trans.*, in press.

Donor-Stabilized Aluminum(I) Bromide**

Mario Mocker, Christian Robl, and Hansgeorg Schnöckel*

Dedicated to Professor Nils Wiberg on the occasion of his 60th birthday

The structures of gaseous monohalides of the monovalent elements of Group 3 have been extensively studied as high-temperature species by spectroscopy.[1] The information available about the structures of these compounds in the solid state varies considerably: for the heavy homologues In and Tl, monohalides can be stabilized as ionic compounds. For the lightest homologue, BX compounds are found with interesting polyhedral structures and B–B bonds;[2] however, these are metastable towards disproportionation to elemental boron and boron trihalide. We are not aware of any structurally characterized solid monohalides of aluminum and gallium.[3] Recently, however, we obtained a metastable solution of AlCl[6] by condensing the high-temperature species AlCl with toluene/ether.[7] However, to date the structure of AlCl in these solutions still remains unclear. From solutions prepared analogously by cocondensation of AlBr with triethylamine we have isolated an aluminum(I) halide as a solid for the first time; we report here on its preparation and structure.

The cocondensation of AlBr (35 mmol, prepared from aluminum and HBr at about 1000 °C) and a mixture of NEt_3 (0.25 mol) and toluene (0.5 mol) afforded a dark red solution on thawing of the condensate at about −100 °C, from which a yellow solid slowly precipitated (yield ca. 50%). The ^{27}Al NMR spectrum of the red solution shows a broad signal at $\delta = 120$.[8] When the solution is warmed to 110 °C, the solid formed originally decomposes completely in about a week, and an aluminum mirror is deposited.[9] Only one sharp signal for $AlBr_3 \cdot NEt_3$ at $\delta = 102$ can still be recognized in the ^{27}Al NMR spectrum of the solution that has been heated for a week.

The yellow solid obtained directly after the cocondensation precipitates as fine needles after washing with toluene/pentane.[10] These needles decompose above about 95 °C under disproportionation to give metallic Al and $AlBr_3 \cdot NEt_3$.[11] The analysis of the solid (Al, Br content) and the determination of the oxidation number of aluminum ($Al^+ + 2H^+ \rightarrow H_2 + Al^{3+}$) support the composition **1**. The Raman spectrum of the solid,

$(AlBr \cdot NEt_3)_n$ **1**

which contains very few bands, indicates that the compound obtained is highly symmetrical.[12] No details about the structure of the compound can be deemed from the IR spectroscopic results, since traces of hydrolysis products ($NEt_3 \cdot HBr$) always occur even if the most extreme care is taken during the preparation of the compound in a glove box (under argon).

Crystals suitable for the structure analysis are obtained by recrystallization of the yellow precipitate in benzene. The result of the X-ray structure analysis is illustrated in Figure 1.[13] The four bromine atoms bound to a square Al_4 ring alternate above and below the plane of the ring. The vacant fourth coordination site at each of the aluminum atoms is occupied by a triethylamine ligand, resulting in an approximate D_{2d}-symmetric structure. The Al–Al distance (264 pm) lies in the range expected for single bonds. This is also confirmed by quantum chemical calculations on a model compound for **1**, $Al_4Br_4 \cdot 4NH_3$:[14] The calculated Al–Al distance here is 264 pm, and the SEN (shared electron number)[18] is 1.3. A value of 380 kJ mol^{-1} was calculated for the tetramerization energy [$4(AlBr \cdot NH_3) \rightarrow Al_4Br_4 \cdot 4NH_3$]. Thus, as expected, the Al–Al interaction is stronger than that in the donor-free electron-deficient compound Al_4Cl_4 with T_d symmetry ($\Delta E_{SCF} = E_{SCF}(Al_4Cl_4) - 4E_{SCF}(AlCl) = 145$ kJ mol^{-1}), although the Al–Al bond (263 pm) in this case is not shortened significantly. However, the tetramerization energy increases drastically to 363 kJ mol^{-1}, when the electron correlation (here MP2) is taken into consideration and by the use of larger basis sets.[19]

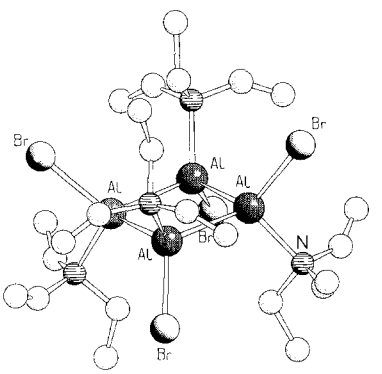

Fig. 1. Crystal structure of **1** (hydrogen atoms not shown). Selected bond lengths [pm] and angles [°] (standard deviations in parentheses): Al–Al 264.3(3), Al–Br 241.7(2), Al–N 209.5(6); Al-Al-Al 90.0(1), Br-Al-N 101.7(2), N-Al-Al 114.8(2), Br-Al-Al 118.4(1).

Significantly shorter Al–Al bonds occur in $Al_2Br_4 \cdot 2D$.[20] This shortening of the bonds is plausible also as a result of a simple estimation: $d(Al^{2+}) < d(Al^+)$.[21] The dissociation energy for the corresponding donor-free chloride Al_2Cl_4 to give two molecules of $AlCl_2$ of 100 kJ mol^{-1} is additional evidence for the notable strength of such Al–Al bonds.[22]

In comparison to the Al–Br distances in $AlBr_3$ (220 pm)[24] and $Al_2Br_4 \cdot 2$anisole (230 pm),[20] that in **1** (242 pm) is particularly long. This stepwise increase in the Al–Br distances is plausible because of the increasing size of the relevant ions $Al^{3+} < Al^{2+} < Al^+$. In agreement with this argumentation, the Al–N distance (209 pm) in **1** is particularly long: in comparison, for the NH_3 adduct of $AlCl_3$ and $AlBr_3$ an Al–N distance of 200 pm[27] was measured and for $NMe_3 \cdot AlCl_3$ even a distance of 196 pm.[28]

Subsequently a Raman spectrum was recorded of the single-crystal studied by X-ray crystallography. According to this spectrum the fine crystalline yellow precipitate, which occurs directly after the cocondensation, is the same compound as that on which the X-ray structure analysis was also carried out. Thus, sufficient solid is available for further reactions of **1** ($n = 4$), for example for the preparation of new organoaluminum(I) compounds.

[8] NMR spectra (C_6D_6, 25 C): Jeol GSX-270 or Bruker EX-400 spectrometer, TMS or external $[Al(H_2O)_6]^{3+}$ as standard. ^{27}Al NMR: $\delta = 120$. After dissolution of the yellow crystals: ^1H NMR: $\delta = 0.93$ (t), 1.18 (t), 2.40 (g), 3.08 (g); ^{13}C NMR: $\delta = 9.80$, 12.46, 46.82, 49.05.

[9] At approximately 50 C, a slow decomposition can be observed first after one week.

[10] If attempts are made to dissolve the yellow solid in C_6D_6 the majority of the solid remains undissolved. The ^{27}Al NMR spectrum of the remaining solution shows only a weak broad signal at $\delta = 120$, which is difficult to differentiate from the background noise. Signals for two (on raising the temperature to 60 C also for more than two) different ethyl groups are observed in the ^1H and ^{13}C NMR spectra [8]. The elucidation of the structure present in solution is a focus of current investigations.

[11] On warming, $AlBr_3 \cdot NEt_3$ can be detected in the mass spectrometer.

[12] Raman spectrum: Bruker FRA-106 spectrometer; Nd: YAG, 1064 nm, $\tilde{\nu}$ [cm^{-1}] (rel. int.) = 2936 (10), 2884 (5), 1452 (3), 1297 (1.5), 1044 (1), 895 (0.5), 734 (0.5), 571 (0.5), 442 (1.5), 410 (1.5), 315 (1), 152 (6). We assign the band at 410 or 442 cm^{-1} to the totally symmetric stretch (a_1). As a consequence of the strong couplings between some of these stretches, the reliable assignment of the remaining a_1 stretches is only possible with the help of extensive quantum chemical calculations, which are the subject of current investigations.

[21] With anisole as donor, the distance determined experimentally (253 pm) corresponds to that from quantum chemical calculations, from which a SEN of 1.4 was calculated for the Al–Al bond, which can be interpreted as a π contribution resulting from Br → Al back bonds.

[22] This energy value is based on a combination of quantum chemical calculations (in order to prevent open-shell systems) with experimental thermodynamic values: $2AlCl_3 \rightarrow 2AlCl_2 + Cl_2$; $\Delta H_R = 608$ kJ mol^{-1} [23]. Since ab initio calculations for the reaction $2AlCl_3 \rightarrow Cl_2Al-AlCl_2 + Cl_2$ give a value of $\Delta H_R = 510$ kJ mol^{-1}, the dissociation energy for $Cl_2Al-AlCl_2 \rightarrow 2AlCl_2$ is about 100 kJ mol^{-1}.

[24] The structure of $AlBr_3$ in the gas phase has still not been studied. The Al–Br distance is expected, however, correspond to that of the terminal Al–Br bond of Al_2Br_6 (222 pm [25]): also the terminal Al–Cl distance of Al_2Cl_6 corresponds to that of $AlCl_3$ [26].

Crystal Structure of 2,5-Di-*tert*-butylhydroquinone: Polar Stacking of Nonpolar Hydrogen-Bonded Sheets with Trigonal Symmetry**

Otto Ermer* and Christof Röbke

While the title compound **1** is a rather trivial and cheap substance, its crystal structure[1] involves unusual features worth reporting. In the crystal, **1** forms trigonal, puckered sheets held together by hydrogen bonds. The topology of the sheets is analogous to that of elemental (gray) arsenic with chair conformations of *trans*-fused six-membered rings (α-As). It may be developed from α-As through replacement of the As atoms by H-bonded three-membered rings of oxygen atoms, and the As–As bonds by covalent 2,5-di-*tert*-butyl-*p*-phenylene links (Figs. 1, 2). We are not aware of another published example of H-bonded sheet architecture with this super-arsenic connectivity pattern. The H bonds (O···O distances: 2.832(3) and 2.878(3) Å) are bent outward (Fig. 1), because of the small size of the O_3 ring and probably also because of electrostatic repulsions between the bridging H atoms. Three-membered rings of H-bonded oxygen atoms are rare and only a few other examples could be retrieved from the literature.[2] Like **1**, these cases are bulky (tertiary) alcohols, which is not surprising since the small intraannular angles of the H-bonded O_3 rings lead to large extraannular space. Interestingly, the best structure of the water trimer $(H_2O)_3$ also involves a H-bonded O_3 ring,[4] the geometry of which is very similar to that in the crystals of **1**.

1

Centrosymmetric molecules usually crystallize in centrosymmetric space groups, and in many cases even retain the molecular center of symmetry in the crystal.[4] The hydroquinone **1** is a rare example of a centrosymmetric, nonpolar molecule with a noncentrosymmetric, polar crystal structure.[5, 7] The space group of **1**, $P31c$, is trigonal with six molecules in the cell.[1] The

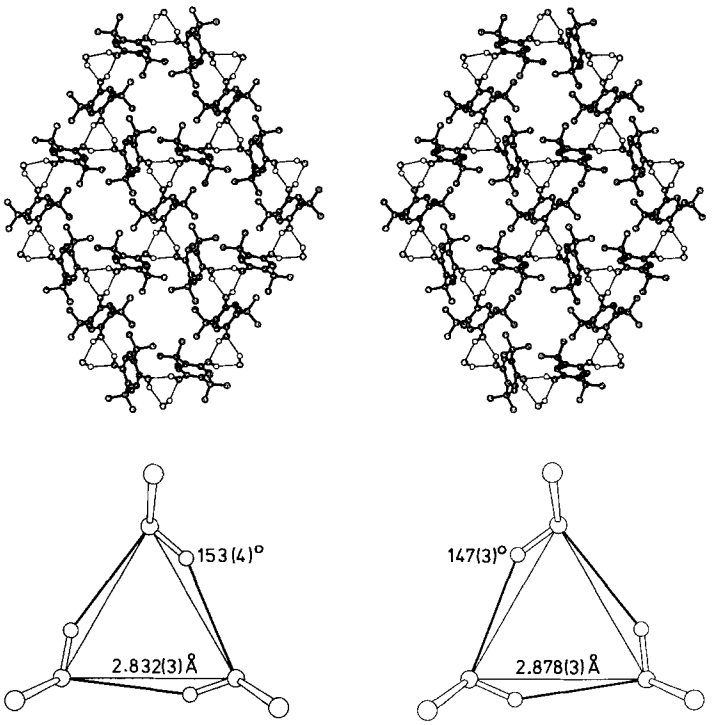

Fig. 1. Top: Stereoview (approximately along the c axis) of a section of a trigonal H-bonded sheet of **1**; H atoms omitted, except alcoholic ones; thin lines represent H bonds. Note the effective centrosymmetry and nonpolarity of the sheet. Bottom: The two independent H-bonded O_3 rings with O···O distances and O–H···O angles; standard deviations in parentheses; crystallographic C_3 symmetry.

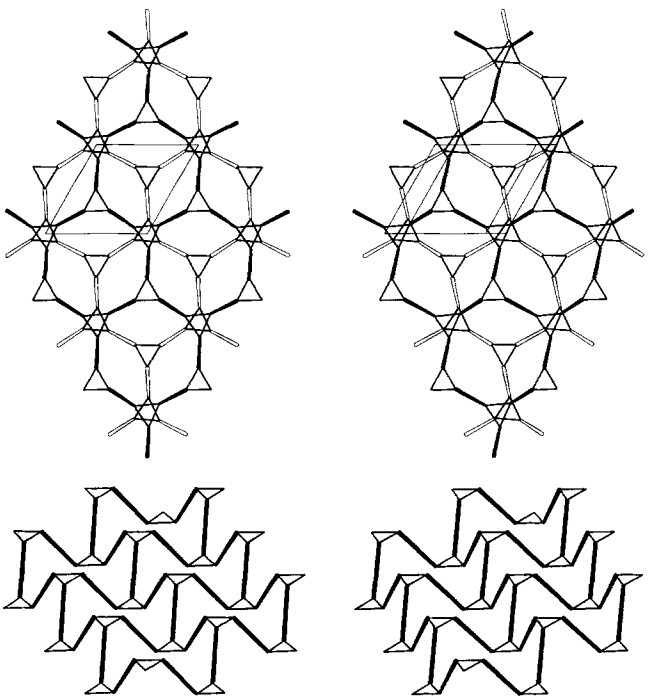

Fig. 2. Top: Diagrammatic stereoview (along c axis for left member of the pair) of two adjacent H-bonded sheets of **1**. The unit cell edges are indicated. Only the oxygen positions are drawn. The equilateral triangles (C_3 symmetry) represent the H-bonded O_3 rings, and the interconnecting rods (solid in the upper, outlined in the lower sheet) symbolize the di-*tert*-butyl-*p*-phenylene links. Note the polarity of the stacking pattern (layer sequence ABAB...) despite the virtually centrosymmetric and nonpolar individual sheets. Bottom: Oblique diagrammatic stereoview of a single sheet to highlight its super-arsenic topology.

molecules of **1** thus have no crystallographic symmetry although their conformation in the crystal is centrosymmetric to a very good approximation (see structural formula and Fig. 1; even the higher symmetry C_{2h} is still well approximated). Moreover, this non-crystallographic local center of symmetry is maintained throughout the puckered H-bonded trigonal sheets. The entire sheets are thus centrosymmetric and consequently nonpolar. The polarity of the overall three-dimensional crystal structure of **1** arises from the polar stacking of the nonpolar sheets along the trigonal crystal axis c (layer sequence ABAB...). Figure 2 shows a diagrammatic representation of this remarkable stacking pattern. Its polarity is immediately evident since one-third of the H-bonded O_3 rings are stacked at a distance of $c/2$ with their emanating *p*-phenylene links oriented pyramidally in one direction, while the other two-thirds of the O_3 rings are stacked at a distance c with the pyramidal orientation of their links in the opposite direction (c, trigonal cell edge length).[8] It would be interesting, at least from a theoretical point of view, to measure nonlinear optical properties of **1**. Such phenomena should be rather weak as a result of the large, almost perfectly centrosymmetric substructures, that is, the individual H-bonded sheets.

Remarkably, the crystal structure of **1** appears to be completely ordered, probably because steric congestion pretty much locks the conformation of **1** (see structural formula and Fig. 1). This follows simply from the repulsion between the *ortho*-positioned hydroxyl and *tert*-butyl groups, which prevents orientational disorder by rotation around the C–O and C(sp^2)–C(sp^3) bonds. (Note that the preferred orientation of a phenolic OH group is coplanar with the aromatic ring;[10] the alternative coplanar orientation of OH in **1** would be rather unfavorable because of the bulky *ortho*-positioned *tert*-butyl group.) Evidence for the steric hindrance of **1** is seen in the compressed angles of the six-membered ring shown in the structural formula (114.6(2), 114.8(2)°).

[1] Large crystals shaped like truncated hexagonal pyramids were obtained from a 2:1 acetone/toluene mixture. Polar trigonal space group $P31c$ (No. 159), $Z = 6$, $a = 11.430(3)$, $c = 18.198(3)$ Å; $\rho_{calcd} = 1.076$, $\rho_{exp.} = 1.081$ g cm^{-3}; intensity measurements at room temperature on a four-circle diffractometer ($\lambda_{Mo} = 0.71069$ Å, $\theta_{Mo}(max) = 30°$); structure solution with direct methods; C, O refined (on F^2) anisotropically, H isotropically, including 2090 reflections (88 reflections with very negative F^2 not considered); $R(F) = 0.041$, $wR(F^2) = 0.114$ (1737 reflections with $F > 4\sigma(F)$); $w = 1/[\sigma(F_o^2)^2 + 0.01p^2]$, where $p = [\max f(F_o^2, 0) + 2F_c^2]/3$; maximum residual electron density, 0.20 e Å^{-3}. The centrosymmetric space group $P\bar{3}1c$, which is also compatible with diffraction symmetry and systematic extinctions, was discarded: Attempts to solve the structure in this space group by direct methods did not lead to a refinable model that makes sense structurally. Trial refinements in $P\bar{3}1c$ with a structural model derived by translating the trigonal H-bonded layers so that the molecules of **1** occupy inversion centers gave R values of about 0.40. Moreover, this model in $P\bar{3}1c$ involves unacceptably short atomic contacts between neighboring layers. It is noted that statistical indicators of the intensity distribution lie about midway between the expectation values for centrosymmetric and noncentrosymmetric structures. Finally, it is noteworthy that in the full-matrix refinements in the correct polar space group $P31c$ no serious correlations related to the pseudo centrosymmetry occurred (program SHELXL93; G. M. Sheldrick, University of Göttingen, 1993). Further details of the crystal structure analysis may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting th depository number CSD-58130 and the journal citation.

[5] In a wider sense, all noncentrosymmetric crystal structures are polar; in a more restricted sense, this applies only to those permitting a permanent dipole moment. The latter comprise the 10 crystal classes C_1, C_s, C_2, C_{2v}, C_3, C_{3v}, C_4, C_{4v}, C_6 and C_{6v} [6]. The crystal structure of **1** is thus polar also in the restricted sense (crystal class C_{3v}, crystallographic three-fold axis is the polar axis).

[6] *International Tables for Crystallography, Vol. A, Space Group Symmetry* (Ed.: T. Hahn), Reidel, Dordrecht, **1987**, p. 788.

[7] Quantitative information about the frequency of centrosymmetric molecules crystallizing in noncentrosymmetric space groups would require the tedious inspection of all known noncentrosymmetric crystal structures. To get a preliminary lead, we selected the noncentrosymmetric space group $Pna2_1$ (No. 33) and with the help of the *Cambridge Structural Database*, CSD (F. H. Allen, O. Kennard, R. Taylor, *Acc. Chem. Res.* **1983**, *16*, 146), inspected all published crystal structures of this symmetry. This space group was chosen since it occurs fairly frequently (1834 entries in the CSD up to January 4, 1994), and is achiral (avoidance of chiral natural products). With some reliability, eleven virtually centrosymmetric molecular structures in $Pna2_1$ could be identified (frequency 0.6%; CSD codes: DIBXIV, DMXPCR10, DMXPMO10, FAHNOR05, FETCOW, FUYMIV, IMZNCU, KILWOR, SIKRIN, SIWDEH01, THUPDC01). A purely organic example is the β form of 9,9'-anthril (H.-D. Becker, B. W. Skelton, A. H. White, *Austr. J. Chem.* **1991**, *44*, 181). Interestingly, in addition to these cases, 35 noncentrosymmetric, polar molecular structures that form almost ideally centrosymmetric, weakly bound dimers (H-bonds, dipole and van der Waals forces) could be retrieved in $Pna2_1$ (frequency 1.9%; CSD codes: BAAANL10, BDMGCO10, BEPPUH, BOTYUE, BZCBAP, DAFPUV, DUMTAG, FAWTAY10, FAYGAN01, FOPMOM, GAXJIY, GESCAI, GIKDIN, HXMHCH10, JOXDAB, JUJXUH, JUJYAO, JUNFUT, KACDOH, KEDDIG, KEVFUM, KOCYIK, KOYHEL, KUFHIC, MAMBRF, SEPPIM, SLFNMA02, SUCHED, TMPSUL10, TOLDIN, TORDAZ, VAVKEI, VOVRED, VOVTEF, VOYJUO); the unit cells contain eight molecules, that is, one centrosymmetric dimer per asymmetric unit. An example of such a H-bonded, centrosymmetric dimer in $Pna2_1$ is a diphenyltriazolone (A. D. Rae, C. G. Ramsay, P. J. Steel, *Austr. J. Chem.* **1988**, *41*, 419). Caution is required when analysing and evaluating crystal structures of this nature: Often the noncentrosymmetric space groups concerned may not be derived unambiguously through the systematic absences of reflections, and the centrosymmetric choice then has to be reliably excluded by other means (cf. R. E. Marsh, *Acta Crystallogr. Sect. B* **1986**, *42*, 193). In the present example of space group $Pna2_1$ the centrosymmetric alternative with the same systematic extinctions is *Pnam* (or *Pnma*, No. 62). Furthermore, the influence of crystal twinning, disorder effects, and poor data quality must be considered, as well as the possibility of not clearly recognizable solvent molecules built into the crystal lattice. About 85% of all commonly used solvents consist of noncentrosymmetric, polar molecules! Finally, when pseudosymmetry is present, strong parameter correlations usually ensue from pseudosymmetry in the structure refinements; see, however, ref. [1].

[8] The stacking pattern of hexagonal graphite (layer sequence ABAB...) is comparable to that of **1**. However, since the carbon sheets are planar, the space group symmetry of hexagonal graphite, $P6_3/mmc$, is much higher, but nonpolar, and centrosymmetric. The space group of **1**, $P31c$, is a subgroup of $P6_3/mmc$. The stacking pattern of (gray) α-arsenic is different from **1** and is nonpolar and centrosymmetric (layer sequence ABCABC..., rhombohedral space group $R\bar{3}m$); this holds similarly for rhombohedral graphite (again space group $R\bar{3}m$) [9].

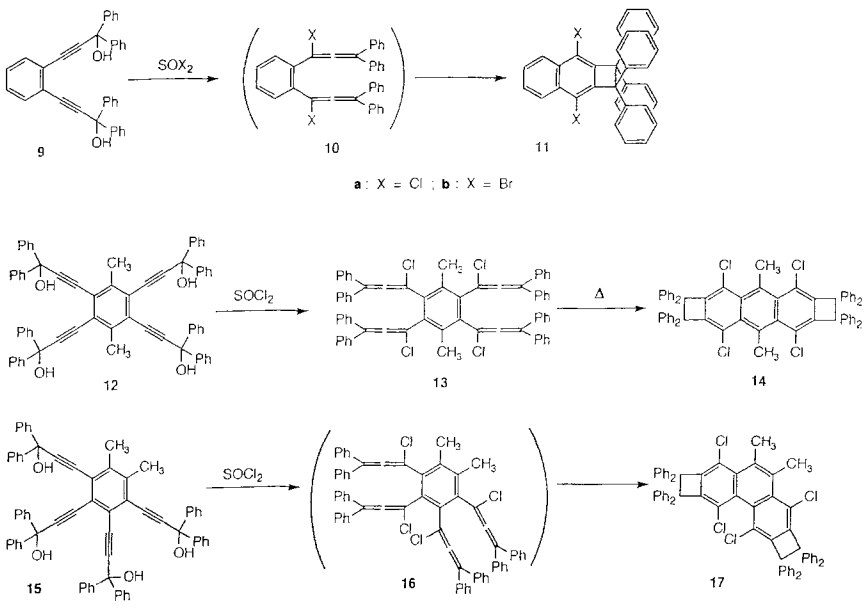
A New Synthetic Route to 1,2-Dihydrocyclobutaarenes**

Fumio Toda,* Koichi Tanaka, Isao Sano, and Toru Isozaki

Highly strained aromatic compounds such as benzocyclobutene, naphthocyclobutene, and anthrodicyclobutene[***] have long been considered interesting from the point of view of structural[1] and synthetic organic chemistry.[2] For example, 1,2-dimethylenecyclohexa-3,5-diene, which is easily derived from benzocyclobutene by thermolysis, is a useful intermediate for the synthesis of various organic compounds in Diels–Alder reactions.[2] However, in many cases, preparation of benzocyclobutenes is not easy. For example, the synthesis of naphthodicyclobutene from 1,2-dimethylenecyclobutane and dimethyl cyclobutene-1,2-dicarboxylate requires six reaction steps.[3]

We now report on a very simple synthetic route to benzocyclobutene derivatives **5** starting from enediynediols **3**, which can easily be prepared by Pd-catalyzed condensation of 1,2-dihalogenocycloalkenes **1** with 1,1,-diphenyl-2-propyn-1-ol (**2**),[4] by thermal cyclization of the diallene intermediates octa-1,2,4,6,7-pentaenes **4** derived from **3** by a propargyl rearrangement (Scheme 1). The idea for this synthesis came from the well-known thermal cyclization of diallene derivatives to 3,4-dimethylene-1,2-cyclobutenes.[5, 6] For example, 3,4-dibromo-1,1,6,6-tetraphenyl-1,2,4,5-hexatetraene (**7**), which can easily be derived by reaction of 1,1,6,6,-tetraphenyl-2,4-hexadiyne-1,6-diol (**6**) with hydrobromic acid, cyclizes to 1,2-dibromo-3,4-bis-(diphenylmethylene)cyclobutene (**8**) (Scheme 1 bottom).[6, 7] Applying the same principle, compounds **11**, **14**, and **17** (Scheme 2) as well as **20** and **23** (Scheme 3) were synthesized.



Scheme 1.

The acetylenic alcohols substituted with a bulky *tert*-butyl group instead of Ph reacted only as far as the thermally stable diallene intermediate. For example, treatment of 1,2-bis(3,3-di-*tert*-butyl-3-hydroxy-1-propynyl)benzene (**24**), prepared from *o*-dibromobenzene and 1,1-di-*tert*-butyl-2-propynol (colorless prisms, 48% yield, m.p. 167–169 °C), with $SOCl_2$ in THF gave 1,2-bis(3,3-di-*tert*-butyl-1-chloro-1,2-propadienyl)benzene (**25**) as colorless prisms (53% yield, m.p. 158–159 °C); IR: $\tilde{\nu}$ = 1950,

[***] According to IUPAC nomenclature, these compounds should be referred to as 1,2-dihydrocyclobutaarenes. The names used here are however more common.

Scheme 2.

Scheme 3.

1920 cm^{-1} (C=C=C); ^1H NMR: δ= 1.3 (*t*Bu, 36H) 7.3 (Ph, 4H); UV: λ_{max} (ε) = 240 (22000), 288 nm (11000). After it had been heated in toluene under reflux for 4 h, **25** was recovered unchanged.

Experimental Procedure

3,8-Dichloro-1,1,2,2,-tetraphenylnaphthocyclobutene (**11a**): A mixture of *o*-dibromobenzene (10 g, 42 mmol), **2** (36 g, 170 mmol), CuI (0.1 g), $[(Ph_3P)_2PdCl_2]$ (0.1 g), PPh_3 (0.52 g), and NEt_3 (200 mL) was heated under reflux for 44 h. After filtration, the organic layer was evaporated to give, after recrystallization from EtOAc/hexane, 1,2-bis(3-hydroxy-3,3-diphenyl-1-propynyl)benzene (**9**) as colorless prisms (16.3 g, 79% yield, m.p. 152–154 °C); IR [8]: $\tilde{\nu}$ = 3270 cm^{-1} (OH). After a solution of **9** (0.5 g), pyridine (0.2 mL), and $SOCl_2$ (0.2 g, 2.7 mmol) in THF (50 mL) had been stirred at room temperature for 5 h, the solution was extracted with toluene. The toluene solution was worked up by the usual method to give **11a** as colorless prisms (0.26 g, 40% yield, m.p. 200–201 °C). The ^1H NMR spectrum [8] shows a sharp singlet at δ = 7.0 corresponding to 20 shielded aromatic protons in addition to the normal aromatic proton signal at δ = 7.7 corresponding to four protons. Treatment of **9** with $SOBr_2$ gave the dibromo analogue **11b** as colorless prisms in 47% yield (m.p. 229–231 °C); ^1H NMR: δ = 7.0 (20H), 7.7 (4H). In both cases, the diallene intermediate **10** was too labile to be isolated.

Anthrodicyclobutene (**14**): Tetrakis(3-hydroxy-3,3-diphenyl-1-propynyl)-*p*-xylene (**12**) was prepared from tetrabromo-*p*-xylene and **2** as colorless prisms (85% yield, m.p. 281–283 °C); IR: $\tilde{\nu}$ = 3350, 3480 cm^{-1} (OH); ^1H NMR: δ = 2.6 (Me, 6H), 5.9 (OH, 4H), 7.6–7.2 (Ph, 40H). Compound **12** was treated with $SOCl_2$ in THF as described above to give the tetraallene derivative **13** as colorless prisms (95% yield); IR: $\tilde{\nu}$ = 1940 cm^{-1} (C=C=C); ^1H NMR: δ = 2.5 (Me, 6H), 7.3 (Ph, 40H). (200 °C, 10 min). However, the crystal of **13** did not have a sharp melting point and transformed to **14** on heating (200 °C, 10 min). Heating of **13** (0.2 g) in toluene (20 mL) under reflux for 1 h gave **14** as yellow prisms (0.19 g, 95% yield, m.p. >300 °C): ^1H NMR: δ = 3.3 (Me, 6H), 7.0 (Ph, 40H); UV [8]: λ_{max} (ε) = 237 (81000), 297 (53000), 398 (2200), 425 (2900), 451 nm (3100).

Phenanthrodicyclobutene **17**: Tetrakis(3-hydroxy-3,3-diphenyl-1-propynyl)-*o*-xylene (**15**) was prepared from tetrabromo-*o*-xylene and **2** as colorless prisms (69% yield, m.p. 215–218 °C); IR: $\tilde{\nu}$ = 3320 cm^{-1} (OH); ^1H NMR: δ = 2.4 (Me, 6H), 3.1 (OH, 4H), 7.5–7.2 (Ph, 40H). Compound **15** was treated with $SOCl_2$ in THF. The tetraallene derivative **16** was obtained as an oil (IR: $\tilde{\nu}$ = 1940 cm^{-1} (C=C=C)), which gradually cyclized to 4,5,8,11-tetrachloro-9,10-dimethyl-1,1,2,2,6,6,7,7,-octaphenyl-phenanthrodicyclobutene (**17**). Recrystallization from toluene yielded **17** as pale yellow prisms (59% yield based on **15**, m.p. >300 °C); ^1H NMR: δ = 3.0 (Me, 6H), 7.0 (Ph, 40H); UV: λ_{max} (ε) 232 (64000), 269 (22000), 297 (47000), 345 nm (19000).

3,6-Dichloro-4,5-bis(diphenylmethylene)-1,1,2,2,-tetraphenylbenzodicyclobutene **20a**: 3,4-Bis(diphenylmethylene)-1,2-bis(3-hydroxy-3,3-diphenyl-1-propynyl)cyclobutene (**18**) was prepared from **8** [6,7] and **2** as colorless needles (94% yield, m.p. 195 °C). Reaction of **18** with $SOCl_2$ gave 1,2-bis(1-chloro-3,3-diphenyl-1,2-propadienyl)-3,4-bis(diphenylmethylene)cyclobutene (**19a**) as red prisms (65% yield, m.p. not sharp); IR: $\tilde{\nu}$ = 2000, 1930 cm^{-1} (C=C=C); UV: λ_{max} (ε) = 279 (25000), 365 (14000), 468 nm (8100). After it had been heated in toluene under reflux for 1 h, **19a** gave **20a** as yellow prisms (70% yield, m.p. 259–260 °C); ^1H NMR: δ = 6.9 (Ph, 30H), 7.3 (Ph, 10H); UV: λ_{max} (ε) = 236 (44000), 261 (34000), 312 (50000), 373 nm (15000). Bromo analogue **20b** was prepared with $SOBr_2$ (54% yield, m.p. >300 °C).

3,7-Dichloro-1,1,2,2,-tetraphenylbenzothiophenocyclobutene (**23**): 2,3-Bis(3-hydroxy-3,3-diphenyl-1-propynyl)thiophene (**21**) was obtained from 2,3-dibromothiophene and **2** as colorless prisms (45% yield, m.p. 166–168 °C) and treated with $SOCl_2$ in THF to give **23** via the diallene intermediate **22**. After recrystallization from EtOAc, colorless prisms were obtained (97% yield, m.p. 214–216 °C): ^1H NMR: δ = 6.8 (Ph, 20H), 7.6 (thiophene, 2H); UV: λ_{max} (ε) = 239 (20800), 269 (3700), 308 nm (1200).

Two-Dimensional Sheets of Tetragonal Copper(II) Lattices: X-Ray Crystal Structure and Magnetic Properties of $[Cu(C_6O_4Cl_2)(C_4H_4N_2)]_n$

Satoshi Kawata, Susumu Kitagawa,* Mitsuru Kondo, Isamu Furuchi, and Megumu Munakata

Transition metal coordination polymers have been the subject of intensive research in the last few decades, and major advances have been made in both their theoretical description and their applications as new materials.[1] The most remarkable developments are perhaps the preparation and characterization of molecular-based magnets and oxide superconductors.[2] Some of these compounds are considered as two-dimensional (2D) systems having interesting cooperative effects. We were thus interested in novel 2D compounds based on transition metal complexes.

Transition metal complexes can form various kinds of assemblies. Two-dimensional coordination polymers having coupled localized metal d electrons and delocalized ligand π electrons are of substantial interest owing to their anticipated cooperative magnetic behavior and conductive properties. In particular, 2D copper polymers are the preferred systems for the realization of a new conductive and magnetic phase as an extreme case of the Hubbard model, in which a single electron spin is arranged on each corner of a square lattice.[3] Many inorganic metal halides, calcogenides, and hydroxides have layered structures.[2c] But molecular-based layer compounds, in which spins on metals are coupled over a sheet, are still rare, on account of the lack of methods for linking monomer units. Fortunately, there are many 1D coordination polymers,[2c, 4] and cooperative phenomena have been observed in several 1D polymers containing bridging organic ligands such as oxalate,[5] squarate,[6] and 3,6-substituted 2,5-dihydroxy-*p*-benzoquinones ($H_2(R_2$-DHBQ)).[7] A useful approach to 2D coordination polymers is to fabricate "woven" 2D coordination polymers from 1D polymers as the warp and additional ligands as the woof, which bridge the linear chains. A key point here is the choice of bridging ligands, which should link the 1D polymers without breaking the chain structures.

Chloranilic acid (H_2CA, which corresponds to $H_2(R_2$-DHBQ) with R = Cl) forms 1D chains with Ca^{II}, Sr^{II}, and Y^{III} ions, which are interlinked by CA^{2-} or another bridging ligands such as water molecules.[7h, i] These results encouraged us to utilize CA chains of transition metals as the warp in a 2D polymer. We have succeeded in synthesizing and characterizing a 2D polymer **1** (pz = pyrazine), where pz is used as the woof in the

$[Cu(CA)(pz)]_n$ **1**

woven coordination polymer. The structure and magnetic properties of the corresponding 1D polymer, $[Cu(CA)]_n$, were first reported in 1962.[7b, g] Although the X-ray structure has not been published, EXAFS studies and the magnetic properties imply one-dimensional ribbon structures for $[Cu(CA)]_n$ and $[Cu(CA)L_2]_n$, where L is a nitrogen-containing ligand such as pyridine.[7k]

The crystal structure of **1** shows parallel sheets, which consist of square arrays of Cu^{II} ions bridged by CA^{2-} ions and pyrazine ligands (Fig. 1).[8] The repeating unit Cu(CA)(pz) develops along the *bc* plane. All copper atoms of **1** are linked by coordination bonds giving a 2D structure essential to a 2D band structure. The sheets are well separated from each other: the shortest interlayer metal–metal distance is 9.785(2) Å, while within the layer the distances between the nearest neighbors Cu-CA-Cu and Cu-pz-Cu are 7.993(1) and 6.977(2) Å, respectively. In contrast, zigzag chains are found in $\{[Y_2(CA)_3(H_2O)_6] \cdot 6.6H_2O\}_n$,[7i] and $\{Na_2[M(H_2\text{-DHBQ})_3] \cdot (H_2O)_{24}\}_n$ (M = Mn^{II}, Cd^{II}),[9a] and additional H_2-$DHBQ^{2-}$ ions link these chains to afford large cavities available for building zeolite- or clathrate-like structures.[9]

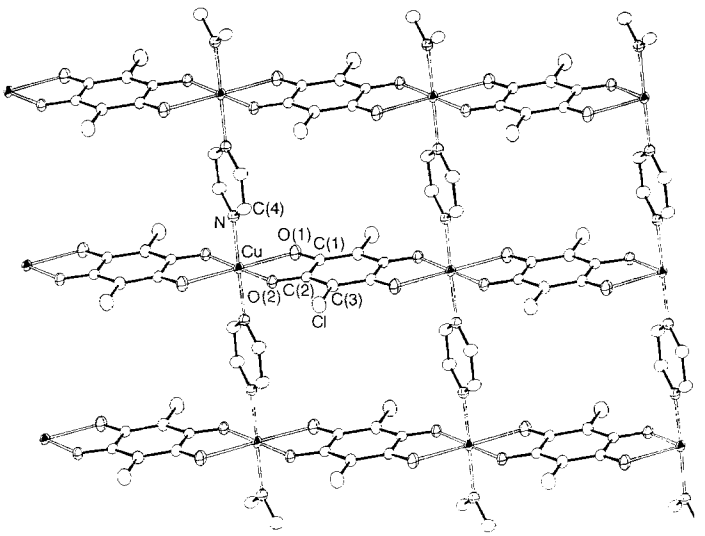

Fig. 1. Crystal structure of **1**; view onto the *bc* plane. Important bond lengths [Å] and angles [°]: Cu-O(1) 2.290(2), Cu-O(2) 1.955(2), Cu-N 2.091(2), Cl-C(3) 1.729(3), O(1)-C(1) 1.233(3), O(2)-C(2) 1.281(3), N-C(4) 1.338(2), C(1)-C(2) 1.537(4), C(2)-C(3) 1.369(3); O(1)-Cu-O(2) 77.23(7), Cu-O(1)-C(1) 109.9(2), Cu-O(2)-C(2) 119.7(2), C(1)-C(2)-C(3) 119.5(2), Cu-N-C(4), 121.7(2).

The geometry around the copper atom is a distorted elongated octahedron. All of the CA^{2-} ligands and the copper atoms sit on the crystallographic mirror plane, and the line connecting the copper and nitrogen atoms of the pz ligands coincides with the crystallographic twofold axis perpendicular to the mirror plane, which indicates that the Cu–N bonds are perpendicular to the CA^{2-} plane. The Cu–N distance (2.091(2) Å) is slightly longer than those for usual bridging pz ligands in Cu^{II} complexes.[10] The pz ligand is also planar, and the Cu-pz-Cu distance falls within the range reported for pz-bridged complexes.[10] The twist angle ($\theta = 14.7°$) of the pz ring out of the plane CuN_2O_2 is small compared with that in other pz-bridged polymers. Interestingly, the Cu–O distances are not identical: one (1.955(2) Å) is similar to that found in the corresponding linear chains (EXAFS study),[7k] whereas the other (2.290(2) Å) is longer than the C–O separations reported for typical Cu^{II} complexes.[11] The effect of the asymmetrical coordination is also found in the different C–O distances in the CA^{2-} ion, 1.233(3) and 1.281(3) Å. One of the distances is shorter than those reported for the free chloranilate ion (1.243(7), 1.253(7) Å),[12] and the other is longer, which indicates that the ligand has a *p*-quinone form[7, 9, 13] like that in $[Cu_2(terpy)_2(CA)]^{2+}$

(terpy = 2,2′:6′,2″-terpyridine),[13a] but is dissimilar to the ligands in $\{[Y_2(CA)_3(H_2O)_6]\cdot 6.6H_2O\}_n$[7i] and $\{[Pr_2(CA)_3(C_2H_5OH)_6]\cdot 2C_2H_5OH\}_n$,[9b] in which CA^{2-} has a delocalized electron system. Therefore the environment of the Cu^{II} ion consists of four short in-plane bonds and two longer out-of-plane bonds, giving rise to a distorted tetragonal "4 + 2" configuration.

The ESR spectrum consists of three signals (g values 2.304, 2.082, and 2.068) indicating that magnetic orbital is formed mainly by the $d_{x^2-y^2}$ orbital. No hyperfine structure was observed; however, the linewidth appeared to be extremely narrow, which suggests significant exchange coupling. The magnetic susceptibilities χ_M were measured over temperatures of 2–300 K. $\chi_M T$ decreases at lower temperatures, indicative of weak antiferromagnetic exchange coupling leading to a singlet ground state. The data were analyzed by using the Heisenberg linear chain theory with a mean field approximation[14] to give $J = -2.86\ cm^{-1}$, $zJ' = -1.05\ cm^{-1}$, $g = 2.09$, and $\rho = 7.12\%$.[15] The absolute values of the exchange coupling constants are smaller than that for $[Cu(CA)]_n$, which has a planar ribbon structure ($-24.5\ cm^{-1}$), and are comparable to that for $[Cu(CA)L_2]$,[7k] which suggests that the magnetic orbital $d_{x^2-y^2}$ of **1** is no longer simply parallel to chloranilate plane but a plane formed by Cu–N(pz) and Cu–O(CA) vectors. The absolute values of J and zJ' are also smaller than those for pz-bridged coordination polymers.[10] These differences in the exchange parameters are attributed to the interaction of the magnetic orbital and pyrazine π orbital, which is greatly associated with the twist angle θ of the pz ring. The θ angles for $[Cu(pz)_2(ClO_4)_2]_n$ and $[Cu(pz)_2(CH_3SO_3)_2]_n$ are 66.1° ($J = -5.3\ cm^{-1}$), and 28.5° ($J = -3.82\ cm^{-1}$), respectively,[10e,f] while in **1** the pz ring is tilted by 14.7°. Thus the smaller twist angle of **1** makes antiferromagnetic interaction smaller.

The hydrogen-bond donor CH_3OH also served as the woof in the synthesis of a woven polymer.[7l,m,16] Single crystals of **2** also afford the 2D layers in which the straight 1D $[Cu(CA)(CH_3OH)_2]$ chains are linked by two hydrogen bonds

$[Cu(CA)(CH_3OH)_2]_n$ **2**

(O···O distance: 2.845(3) Å) between the apically coordinated CH_3OH ligand and the oxygen atom of CA^{2-} in the nearest neighbor chain (Fig. 2).[17] A similar hydrogen bond is also found between oxygen atoms of aqua ligands and Et_2DHBQ^{2-} in $\{[Ca(Et_2DHBQ)_2]\cdot 3H_2O\}_n$, where the corrugated chains are linked by hydrogen bonds (3.094(7) Å) longer than those in **2**.[7l] The repeating unit of $Cu(CA)(CH_3OH)_2$ develops along the *ac* plane. The geometry around the copper atom is a distorted elongated octahedron. The four chloranilate oxygen and the copper atoms form a basal plane, because the Cu–O distances are shorter than the two apical $Cu-O(CH_3OH)$ distances, which results in the Cu-CA-Cu distance (7.672(1) Å) being shorter than that of **1** by about 0.3 Å. Therefore the magnetic orbital in **2** lies on the basal plane, in contrast to **1**. The interchain hydrogen bonds lead to short nearest neighbor Cu–Cu distances (5.108(1) Å), and the geometry of the 2D sheet can be regarded as a rectangular array of copper atoms.

Complexes **1** and **2** are good examples of lattice structures formed by coordination and/or hydrogen bonds. The fabrication of 2D polymers from warp and woof components has been shown to be quite useful in the construction of tetragonal copper lattices. This concept can also be applied to a wide variety of compounds having square lattices.

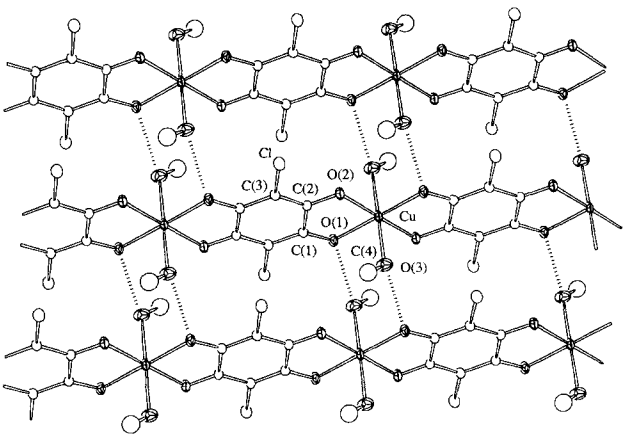

Fig. 2. Crystal structure of **2**: view onto the *ac* plane. Important bond lengths [Å] and angles [°]: Cu-O(1) 2.006(2), Cu-O(2) 1.963(2), Cu-O(3) 2.278(3), Cl-C(3) 1.727(3), O(1)-C(1) 1.262(3), O(2)-C(2) 1.258(3), O(3)-C(4) 1.392(5), C(1)-C(2) 1.530(4), C(2)-C(3) 1.394(3); O(1)-Cu-O(2) 82.41(8), Cu-O(1)-C(1) 112.7(2), Cu-O(2)-C(2) 113.7(2), C(1)-C(2)-C(3) 119.6(2), Cu-O(3)-C(4) 132.8(3). The dashed lines denote the hydrogen bonds; O(1)---O(3′), 2.845(3).

Experimental Procedure

Syntheses of the Complexes: **1**: An aqueous solution (10 mL) of $Cu(NO_3)_2$ (6×10^{-5} mol), CH_3COOH (25×10^{-5} mol), and CH_3COONa (50×10^{-5} mol) was transferred to a test tube, then an aqueous solution (10 mL) of pz (6×10^{-5} mol) and H_2CA (6×10^{-5} mol) was poured into the tube without mixing the two solutions. Dark green platelets began to form within a week. One of these crystals was used for X-ray crystallography. Correct C,H,N analysis. IR (KBr pellet): $\tilde{\nu}[cm^{-1}] = 3117m$, 1634m, 1534s, 1416m, 1373m, 1277m, 1161w, 1119m, 1090w, 1065m, 997w, 851m, 615w, 575w, 473w.

2: The very slow growth of the crystals is essential to obtaining single crystals for X-ray structure determination. Oxidation of copper(I) complexes was used. A methanol solution (20 mL) of chloranil (6×10^{-5} mol) and $[Cu(CH_3CN)_4]PF_6$ (6×10^{-5} mol) was added to a methanol solution (10 mL) of thiochrome (6×10^{-5} mol). The clear yellow solution was transferred to a test tube and kept at room temperature. A small amount of black platelets formed over two months. One of these crystals was used for X-ray crystallography.

Physical Measurements: IR spectra were measured on a Jasco FT/IR-8000 or Hitachi I-5040FT-IR spectrophotometer. KBr discs were prepared for measurements. ESR spectra were recorded at X-band frequency with a JEOL RE-3X spectrometer operating at 9.1–9.5 GHz. Resonance frequencies were measured on an Anritsu MF76A microwave frequency counter. Magnetic fields were calibrated with an Echo Electronics EFM-2000AX NMR field meter. The magnetic susceptibility data were recorded over the temperature range from 2 to 300 K at 1 T with a SQUID susceptometer (Quantum Design, San Diego, CA) interfaced with an HP Vectra computer system. All data were corrected for diamagnetism which was calculated from Pascal's table. The temperature-independent paramagnetism was assumed to be $60\times10^{-6}\ cm^3 mol^{-1}$. Least-squares fittings of the magnetic susceptibility to approximate equations for the antiferromagnetic chain were performed with the least-squares program NGRAPH on a NEC PC9801 computer.

[8] X-ray analysis: A suitable crystal was chosen and mounted on a glass fiber with epoxy resin. Cell constants and the orientation matrix for collection of intensity data for each crystal were based on the setting angles of 21 carefully centered reflections with 2θ values in the range of $48.10^\circ < 2\theta < 49.90^\circ$. The structures were solved by direct methods (Rigaku TEXSAN crystallographic software package of Molecular Structure Corporation). Full-matrix least-squares refinement was carried out with anisotropic thermal parameters for all non-hydrogen atoms. After anisotropic least-squares refinement for non-hydrogen atoms, all hydrogen atoms were located in the difference Fourier map, but their parameters were not refined. The final cycle of full-matrix least-squares refinement was based on N_o and n variable parameters and converged with unweighted R-factors of $R = \sum||F_o| - |F_c||/\sum|F_o|$, $Rw = [\sum|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2}$ where $w = 4F_o^2/\sigma^2(F_o^2)$. Crystal data: $CuCl_2O_4N_2C_{10}H_4$, $M = 350.60$, monoclinic, space group $C2/m$, $a = 9.785(2)$, $b = 6.977(2)$, $c = 7.993(1)$ Å, $\beta = 97.26(1)^\circ$, $V = 541.3(2)$ Å^3, $Z = 2$, $\varrho_{calcd} = 2.151$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, $F(000) = 346$, $\mu(Mo_{K\alpha}) = 25.26$ cm^{-1}, $T = 23^\circ$C. Dendritic Macromolecules Incorporating Tetrathiafulvalene Units**

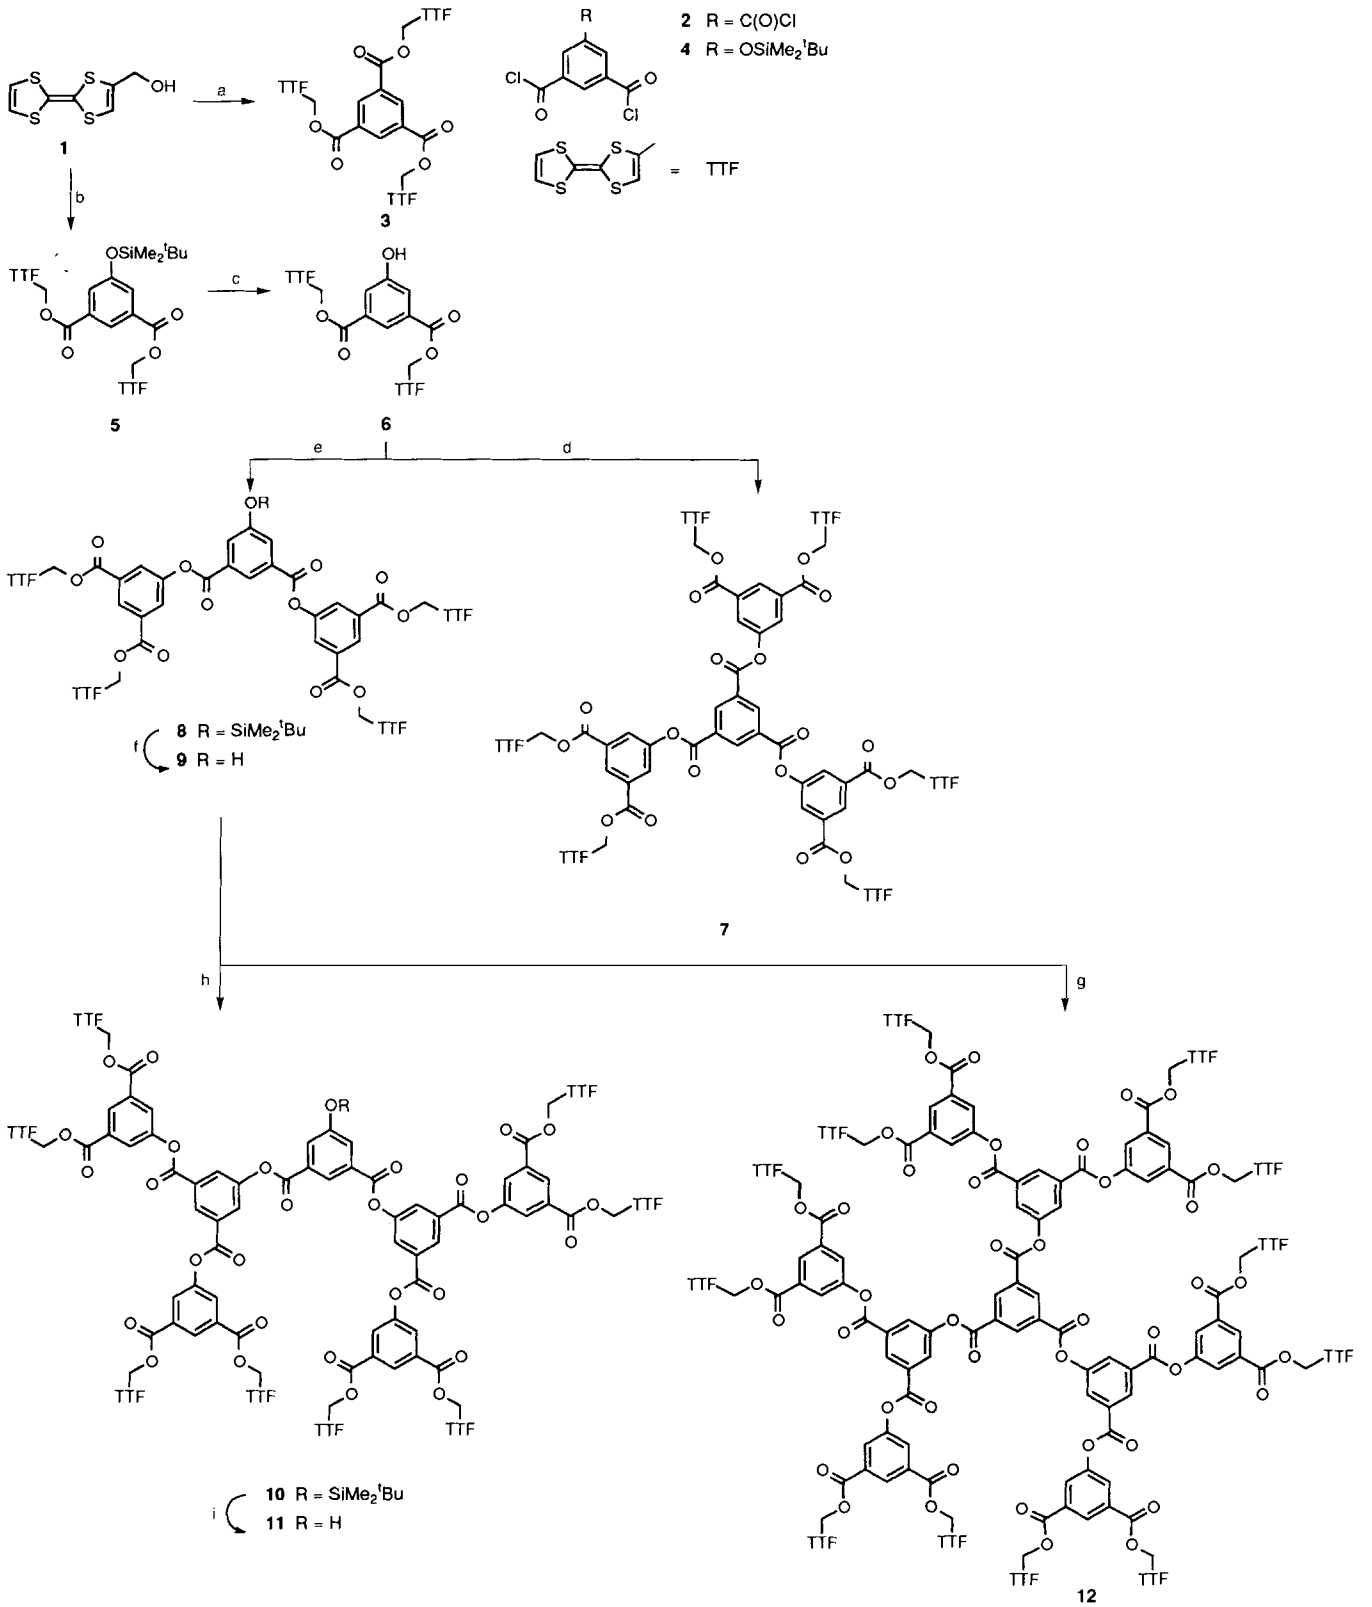
Martin R. Bryce,* Wayne Devonport, and Adrian J. Moore

A burgeoning topic at the interface of supramolecular and polymer chemistry is the synthesis and characterization of dendritic macromolecules (also termed "starburst polymers" or "cascade molecules").[1-12] These macromolecules comprise a polyfunctional core surrounded by covalently linked layers of monomers, with a branch occurring at each monomer unit. This structure gives rise to a hyperbranched polymer possessing a high level of three-dimensional order; control over molecular weight, topology, interior cavity size, and surface functionality can be achieved. Current interest in these materials stems from the fundamental synthetic challenges they pose and the range of properties they may display, such as, self-assembly, molecular recognition, and catalysis, and their potential applications in molecular electronic devices. The incorporation of redox-active molecular units into a dendrimer structure is essentially unexplored. In this context, organometallic systems with arene–iron[10] and ruthenium–terpyridine monomers[11] elaborated into dendrimer structures have recently been reported, and dendritic polyradicals have been prepared.[12]



We now describe the first examples of dendritic macromolecules that contain redox-active tetrathiafulvalene (TTF) units. The incorporation of TTF into hyperbranched structures presents a fascinating prospect for the following reasons:[13] 1) oxidation of TTF to the cation radical and dication species occurs sequentially and reversibly at relatively low potentials (for unsubstituted TTF, $E^{1/2} = +0.34$ and $+0.74$ V, vs. Ag/AgCl); 2) the oxidation potentials can be finely tuned by the attachment of appropriate substituents; 3) the TTF cation radical is thermodynamically very stable; and 4) oxidized TTF units are key components of molecular conductors, because of their propensity to form highly-ordered stacks.

The starting TTF monomer unit for the present synthesis is 4-(hydroxymethyl)tetrathiafulvalene (**1**).[14] By a convergent synthetic strategy based on a repetitive coupling/deprotection sequence, we have assembled the symmetrical dendrimer **12** which contains 12 TTF units at the periphery of the macromolecule. The key functionalized reagent for the esterification reactions that build up successive generations is 5-(*tert*-butyldimethylsiloxy)isophthaloyl chloride (**4**).[15] In an initial model experiment we established that TTF derivative **1** could be readily esterified by reaction with 1,3,5-benzenetricarbonyl chloride (**2**) to yield the tris(TTF) derivative **3** in 83% yield. The analogous reaction of **1** with the silyl-protected diacid dichloride **4** gave compound **5** (92% yield), deprotection of which gave the dendrimer arm **6** (85% yield) (Scheme 1).

Reaction of compound **6** with triacid trichloride **2** in the presence of 4-dimethylaminopyridine (DMAP) as base gave the hexakis(TTF) dendrimer **7** (75% yield). No reaction occurred when triethylamine was used instead of DMAP. Following the same procedure, reaction of **6** with reagent **4** yielded compound **8** (85% yield), which was desilylated to give the phenol derivative **9** (95% yield). Compounds **9** and **4** reacted in the presence of a

Scheme 1. a) **2**, CH_2Cl_2, Et_3N, 18 h, 20 °C, 83%; b) **4**, CH_2Cl_2, Et_3N, 18 h, 20 °C, 92%; c) Bu_4NF, THF, 12 h, 20 °C, 85%; d) **2**, CH_2Cl_2, DMAP, 18 h, 20 °C, 75%; e) **4**, CH_2Cl_2, DMAP, 18 h, 20 °C, 85%; f) Bu_4NF, THF, 12 h, 20 °C, 95%; g) **2**, CH_2Cl_2, *N*,*N*-dimethylaniline, 56 h, 20 °C, 48%; h) **4**, CH_2Cl_2, *N*,*N*-dimethylaniline, DMAP, 56 h, 20 °C, 76%; i) Bu_4NF, THF, 56 h, 20 °C, 50%.

mixture of *N*,*N*-dimethylaniline and DMAP (optimum ratio 1/1 v/v) to yield octakis(TTF) derivative **10** (76% yield, no product was obtained when either triethylamine, *N*,*N*-dimethylaniline, or DMAP were used as the sole base). Desilylation of **10** yielded phenol derivative **11** (50% yield). Compound **9** reacted, as expected, with **2** to give the dendrimer **12** decorated with twelve peripheral TTF units (48% yield). A notable feature of the above iterative esterification reactions is the need to select care-

fully the correct base for the reaction; this is in accord with previous observations of Miller et al.[15] Dendrimers **3**, **7**, and **12** are stable when stored below 0 °C; after seven days at room temperature in the dark and under an argon atmosphere, notable decomposition is observed (Table 1).

Table 1. Selected characteristic data for compounds **3** and **5**–**12** [a].

3: Orange solid; m.p. 37–38 °C; PDMS: *m/z*: 859.3 (M^+, calcd: 859.24 for $C_{30}H_{18}O_6S_{12}$); ^{1}H NMR ($CDCl_3$): δ = 8.85 (s, 3H), 6.45 (s, 3H), 6.29 (s, 6H), 5.10 (s, 6H); UV (CH_2Cl_2): λ_{max} = 220, 307, 365 nm (after addition of an excess of I_2: 225, 363, 439, 590 nm).

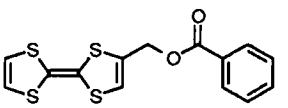
9: Yellow oil; ^{1}H NMR [$(CD_3)_2CO$]: δ = 9.30 (br. s, 1H), 8.15 (t, J = 1.5 Hz, 3H), 7.73 (d, J = 1.5 Hz, 6H), 6.86 (s, 4H), 6.63 (s, 8H), 5.20 (s, 8H).

10: Orange oil; PDMS: *m/z*: 1505.0 (M^{2+}/2, calcd: 3011.9 for $C_{118}H_{76}O_{24}S_{32}Si$); ^{1}H NMR [$(CD_3)_2CO$]: δ = 8.62 (t, J = 1.5 Hz, 1H), 8.56 (t, J = 1.5 Hz, 2H), 8.25 (d, J = 1.5 Hz, 12H), 7.94 (d, J = 1.5 Hz, 6H), 6.81 (s, 8H), 6.58 (s, 16H), 5.18 (s, 16H), 1.03 (s, 9H), 0.32 (s, 6H).

11: Orange oil; ^{1}H NMR [$(CD_3)_2CO$]: δ = 9.30 (br. s, 1H), 8.14 (t, J = 1.5 Hz, 7H), 7.78 (d, J = 1.5 Hz, 14H), 6.83 (s, 8H), 6.58 (s, 16H), 5.15 (s, 16H).

12: Orange oil; ^{1}H NMR [$(CD_3)_2CO$]: δ = 8.54 (s, 3H), 8.17 (t, J = 1.5 Hz, 9H), 7.73 (d, J = 1.5 Hz, 18H), 6.84 (s, 12H), 6.61 (s, 24H), 5.19 (s, 24H); UV (CH_2Cl_2): λ_{max} = 220, 296, 363 nm (after addition of an excess of I_2: 223, 262, 291, 363, 590 nm).

[a] All the new compounds were isolated pure (as judged either by C,H combustion analysis or analysis by gel permeation chromatography) after column chromatography on silica; PDMS = plasma desorption mass spectroscopy.



The redox behavior of the dendrimers **3**, **7**, and **12** was investigated by cyclic voltammetry (CV) (Table 2). The dendrimers **3**, **7**, and **12** exhibit the characteristic redox behavior typical of the TTF system: they show two quasi-reversible redox couples at

Table 2. Cyclic voltammetry data (in volts). Experimental conditions: sweep rate 100 mVs^{-1}, 0.1 M Bu_4NPF_6, Ag/AgCl reference electrode, platinum working and counter electrodes, 20 °C.

	$E_1^{1/2}$	$E_2^{1/2}$
TTF [a]	0.34	0.74
3 [a]	0.42	0.84
7 [b]	0.45	0.86
12 [a]	0.43	0.81
13 [a]	0.48	0.86

[a] Solvent: MeCN. [b] Solvent: MeCN/CH_2Cl_2 (1/1 v/v).

approximately $E_1^{1/2} \approx +0.45$ and $E_2^{1/2} \approx +0.85$ V. The results of classical CV, chronoamperometry, and CV with ultramicroelectrodes clearly show that for the dendrimers **3**, **7**, and **12** each couple involves a simultaneous multielectron transfer; at least five electrons are transferred for compound **12** in each redox couple. Formation of these species bearing a multiple positive charge produces no significant perturbation from the redox behavior of the parent TTF phenyl ester **13**. It can thus be concluded that there is no significant interaction between the charged TTF units in the dendrimer derivatives **3**, **7**, and **12**.[16] Oxidation of the TTF units in dendrimers **3**, **7**, and **12** has also been achieved by reaction with an excess of iodine in dichloromethane solution. After addition of iodine, the UV spectra show the presence of a new broad absorption band centered at λ_{max} 590 nm, which is consistent with the formation of the TTF cation radical.[17]

13

In summary, we have established an efficient methodology for the assembly of the first TTF dendrimers; these materials provide unprecedented scope for the study of charge-transfer interactions involving functionalized dendrimers.

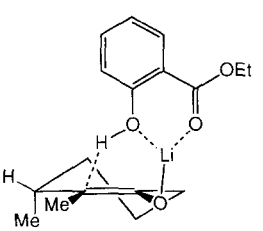
Substituent Effects and Complexation Phenomena in the Diastereoselective Protonation of Chiral Enolates**

Norbert Krause*

In contrast to alkylation and acylation, protonation at carbanionic carbon centers in stereoselective syntheses has received little attention. Some successes with enantioselective protonation of prochiral enolates have been achieved in recent years.[1, 2] However, little is still known about diastereoselective protonation of chiral enolates,[3] despite the fact that it is a frequently used reaction in areas such as the synthesis of natural products.[4] Up until now, it has not been possible to systematically develop methods for *reagent-controlled diastereoselective or enantioselective protonation* which could be applied to a range of compounds. In other words, suitable proton sources for particular compounds have had to be found only by trial and error.[1-4] Only in two cases[2b, f] could the observed stereoselectivity be explained (assumed chelate-type interactions between "carbanion" and protonating agent). There is therefore a need for a systematic study into the steric and electronic influence of the starting material and the proton source on the stereoselectivity of protonation reactions. We now report on the diastereoselective protonation of chiral lithium enolates of type **2**.



Cyclic enolates of this type are, depending on their ring size, conformationally more or less strongly fixed and can only exist as (*E*) isomers. They are obtained by 1,4-addition of organocuprates[5] to readily available 2-methyl-2-cycloalkenones **1**.[6] The

use of a range of cuprates allows various residues R to be introduced at C-3 of the enolate. However, by analogy with the enolization of carbonyl compounds with lithium diisopropylamide (LDA),[7] it must be assumed that the organocopper compound formed in the Michael addition is bound to the lithium enolate[8] and influences its protonation.

A prerequisite for high stereoselectivity in protonation reactions is that the acidity of the proton source is markedly higher than that of the protonated product, so that complete protonation is achieved.[9] The reaction must also proceed with C-protonation and not O-protonation, since the stereochemistry of the tautomerization of the enol formed in the latter case is probably beyond the influence of the protonating agent. Conditions favorable to C-protonation are achieved in kinetically controlled protonations with weak organic acids.[10] In addition, the rate of protonation of the enolate by the proton source must be considerably higher than the rate of proton exchange between the enolate and the protonation product, since the latter can lead to epimerization of the chiral product. It is therefore essential that the proton source be available in large excess *at all times during reaction* (addition of the enolate to the proton source and not vice versa). To avoid epimerization of the protonation product, basic metallic salts present in the reaction mixture must be trapped during workup (e.g., with acetic acid).

In the case of the chiral enolate **2a**, prepared by 1,4-addition of lithium dimethylcuprate to **1** ($n = 1$), the kinetically controlled diastereoselective protonation to give *cis*-**3a** was of interest, since thermodynamic control favored the *trans* product (equilibrium ratio 81:19,[11] see Table 1). In the protonation with phenols a marked substituent effect was observed: phenols substituted with donor groups preferentially yielded *trans*-**3a**, whereas phenols substituted with acceptor groups largely yielded *cis*-**3a**.[12, 13] This substituent effect, observed for the first time in stereoselective protonation, implies that charge separation in the transition state leading to *trans*-**3a** is greater than in that leading to *cis*-**3a**. The substituent effects were particularly marked in *ortho*-substituted phenols, which possess the structural prerequisites for the formation of chelate complexes (*cis* protonation was favored with salicyl alcohol, 2-hydroxyacetophenone, and salicylaldehyde[12]). By far the highest selectivity towards *cis*-**3a** (96:4) resulted from protonation with ethyl salicylate. Here, a comparatively rigid chelate complex (e.g., **4**) is probably formed as a result of interactions between the lithium ion of the enolate and the carbonyl and hydroxyl oxygen atoms of the salicylate (the fourth coordination point of the lithium ion is assumed to be occupied by the copper species formed by cuprate addition[8]). Clearly, this type of chelation reduces the degrees of freedom of the system to such an extent that the difference in the activation barriers for the transition states leading to *cis*- and *trans*-**3a** reaches a preparatively useful magnitude (a product ratio of 96:4 corresponds to a difference in the Gibbs activation energy of about 5 kJ mol^{-1}).

4

Table 1. Equilibrium ratios for ketones **3** [a] and product ratios for their syntheses by protonation of enolate **2** with ethyl salicylate (X = 2-CO_2Et).

Product	*n*	R	Equilibrium ratio *trans*:*cis*	Product ratio *trans*:*cis*
3a	1	Me	81:19	4:96
3b	1	*n*Bu	76:24	3:97
3c	1	$(CH_2)_3CH=CH_2$	78:22	3:97
3d	0	Me	87:13	17:83
3e	2	Me	55:45	1:99

[a] By base-catalyzed equilibration.

Such high stereoselectivities could only be achieved by the addition of the enolate to an excess of the salicylate. With reverse addition, proton exchange between the enolate and the protonation product clearly occurs, which leads to a drastic reduction in the diastereoselectivity (a *cis*:*trans* ratio of 69:31 was observed). The influence of temperature was, on the other hand, small

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. I thank Markus Oberthür for carrying out some of the experiments.

(protonation at $-20\,^{\circ}C$ instead of $-80\,^{\circ}C$: *cis*:*trans* = 92:8). Similarly, changes in the ester function of the salicylate hardly affected the selectivity.[12] The introduction of a methyl group at C-3 of the salicylate, on the other hand, led to the loss of *cis* selectivity (*cis*:*trans* = 53:47). Clearly, a type **4** chelate cannot be formed here because of the steric interactions between the additional methyl group and the enolate. Finally, in order to investigate the effect on the stereoselectivity of protonation exerted by the copper cluster coordinated to the lithium enolate **2a**,[8a] the copper-free enolate was prepared by transmetalation of the corresponding silyl enol ether with MeLi. Protonation with ethyl salicylate resulted in a *cis*/*trans* ratio of 86:14 in diethyl ether and 92:8 in THF. The formation of complex **4** therefore also occurs in the absence of copper; in this case, the fourth coordination site of the lithium ion is probably occupied by solvent, which hardly influences the diastereoselectivity of the proton transfer.

The *cis*-selective protonation with salicylates can be extended to numerous chiral five-, six-, and seven-membered ring enolates with various substituents (see Table 1).[14] Thus, with six-membered ring enolates having *n*-butyl or 4-penten-1-yl residues at C-3, the protonation products **3b** and **3c** were formed with a *cis* selectivity of 97:3. Protonation of the methyl-substituted, five-membered ring enolate yielded a product ratio of 83:17 and that of the corresponding seven-membered ring enolate **3e** a ratio of 99:1. Thus, *cis* selectivity increases with increasing ring size. Interestingly, the same trend is also observed for the equilibrium ratios[11] (see Table 1). The kinetically controlled protonation with ethyl salicylate therefore "works against" the increasing thermodynamic preference for the *trans* product with decreasing ring size.

In summary, marked substituent effects and complexation phenomena have been observed for the first time in the diastereoselective protonation of type **2** chiral enolates with phenols. High *cis* selectivities were obtained by protonation with ethyl salicylate. The application of this concept to the diastereoselective protonation of other cyclic and acyclic enolates with chiral centers or axes is the subject of current investigations.

Experimental Procedure

MeLi (20.0 mL, 30.0 mmol, 1.5 M in diethyl ether) was added, dropwise at $-10\,^{\circ}C$ to a suspension of CuI (2.86 g, 15.0 mmol) in diethyl ether (100 mL). The clear cuprate solution was cooled to $-80\,^{\circ}C$ and treated with 2-methyl-2-cyclohexenone (1.10 g, 10.0 mmol) in diethyl ether (20 mL). After the mixture had been stirred for 30 min at $-80\,^{\circ}C$, a yellow suspension was formed. This was transferred through a Teflon tube under nitrogen pressure and added dropwise to a solution of ethyl salicylate (6.65 g, 40.0 mmol) in diethyl ether (50 mL) also cooled to $-80\,^{\circ}C$. The mixture was warmed to room temperature and treated with acetic acid (2.3 mL, 40.0 mmol). After filtration through celite the filtrate was washed once with saturated $NaHCO_3$ solution and three times with water. After the solvent had been removed, the crude product was purified by column chromatography (silica gel, diethyl ether/hexane 1:20). Ethyl salicylate (6.02 g) and *cis*-2,3-dimethylcyclohexanone (*cis*-**3a**) (0.96 g, 76%, colorless liquid, d.s. = 96:4) were obtained. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 0.76$ (d, $J = 7.1$ Hz, 3H; 3-Me), 0.91 (d, $J = 6.9$ Hz, 3H; 2-Me), 1.53–1.66 (m, 1H), 1.72–1.89 (m, 3H), 2.10–2.33 (m, 3H), 2.47–2.56 (m, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta = 11.9$ (3-Me), 14.6 (2-Me), 23.4 (C-5), 31.2 (C-4), 37.4 (C-3), 40.7 (C-6), 49.3 (C-2), 214.3 (C-1)

[12] Ratio *trans*-**3a** : *cis*-**3a** (determined by GC; OV-1701, H_2) in the protonation with substituted phenols: X = 2-CN: 78:22; 2-CONHPh: 72:28; 4-COMe: 67:33; 4-NH_2: 65:35; 4-OH: 62:38; 3-CO_2Et: 53:47; 3-NO_2: 53:47; 2-NO_2: 52:48; 4-OMe: 52:48; 3-Cl: 51:49; 4-CO_2Et: 50:50; 4-NO_2: 50:50; 4-Me: 48:52; 4-F: 48:52; H: 47:53; 4-Br: 44:56; 3-CF_3: 42:58; 4-Cl: 41:59; 4-I: 41:59; 4-CN: 40:60; 2-Cl: 39:61; 2-CH_2OH: 30:70; 2-COMe: 16:84; 2-CHO: 13:87; 2-CO_2Ph: 11:89; 2-CO_2tBu: 6:94; 2-CO_2Me: 4:96; 2-CO_2Et: 4:96.

[13] The use of the Hammett equation on the values obtained for the *meta*- and *para*-substituted phenols bearing donors and weak acceptors yields an approximately straight line plot ($\rho = +0.46$, $r = 0.94$). This means that the reactions with these proton sources probably have a common mechanism. Large deviations occur with nitrophenols and carbonyl-substituted phenols; this indicates that a different mechanistic pathway is followed.

[14] Collidinium trifluoroacetate, recently used for the *cis*-selective protonation of a cyclic titanium enolate [4f], is not suitable for *cis*-selective protonation of lithium enolate **2a** (product ratio: *trans*-**3a** : *cis*-**3a** = 73:27)

A Novel Approach to the Stereoselective Synthesis of β-Mannosides

Yukishige Ito and Tomoya Ogawa*

Among several problems in oligosaccharide synthesis, the formation of β-mannoside has been considered to be one of the most challenging. Since a β-mannose residue linked to the C-4 position of *N*-acetylglucosamine (GlcNAc) represents the "core" structure of asparagine (Asn)-linked oligosaccharides,[1]

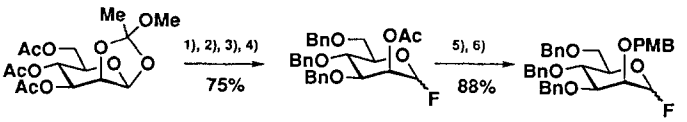
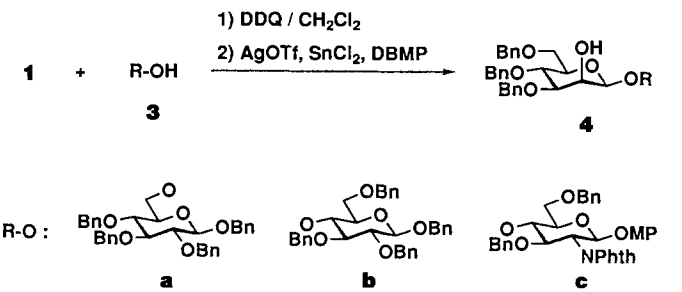
the formation of this type of glycosidic linkage is of general significance in the field of glycoconjugate synthesis. Due to its 1,2-*cis*-arrangement, and the stereoelectronically disfavored anomeric equatorial C–O linkage, construction of β-mannosides based on conventional technology is difficult to achieve.[2] Although the "insoluble silver catalyst" (i.e. Ag silicate or zeolite) method serves as the practical approach,[3] the degree of β-selectivity is highly dependent on the reactivity of substrates. As a consequence, the proper choice of protecting groups both on the glycosyl donor and the acceptor (aglycon) is critical for substantial selectivity.[4] In addition, this method requires a highly unstable bromide as a donor. Thus, the use of modern glycosylation technologies,[5] which are now considered to be more well-adapted to complex oligosaccharide synthesis than the halide-based conventional approach, has been essentially eliminated.



A new concept, the so-called "aglycon delivery" method has been reported by Barresi and Hindsgaul,[6] and later by Stork and Kim.[7, 8] Although complete stereochemical control could be realized, both of these approaches seem to require the manipulation of rather sensitive intermediates (isopropenyl ether or alkoxychlorosilane). Furthermore, the whole sequence is quite probably compatible only with severely limited range of protecting groups.

Taking these results into consideration, we turned our attention to *p*-methoxybenzyl (PMB) ether as a stereocontrolling element. The PMB group is frequently employed as a protecting group for an alcohol group in organic synthesis. It can be deprotected oxidatively by using 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ)[9] or cerium(IV) ammonium nitrate (CAN),[10] presumably via the intermediacy of oxocarbenium species **I** (Scheme 1). Thus, starting from the mannosyl donor **II**, which



Scheme 1. Use of 2-*O*-PMB derivative for β-mannosidation. a: activation; b: workup. A = aglycon; Ac = acetyl; Bn = benzyl.

carries a PMB group at the C-2 position, we expected that treatment with alcohol in the presence of DDQ and under anhydrous conditions would give the mixed acetal **III**.[11] After subsequent activation at the anomeric position, β-mannoside (**IV**) should be formed. To examine such a possibility, mannosyl fluoride **1**[12] was synthesized in six steps from the known orthoester **2** (Scheme 2) in 65% overall yield.

Scheme 2. Preparation of mannosyl fluoride **1**. 1) NaOMe/MeOH, room temperature; 2) benzyl chloride, NaH/DMF, 0 °C → room temperature; 3) 70% AcOH, room temperature; 4) Et_2NSF_3/toluene, 0 °C; 5) iBu_2AlH/THF, −40 °C; 6) PMBCl, NaH/DMF, 0 °C → room temperature.

Compound **1** served as glycosyl donor in the β-mannosidation; its reaction with alcohols **3a–c** in CH_2Cl_2 in the presence of DDQ and molecular sieves (4 Å) proceeded smoothly to give the corresponding mixed acetal, which was treated, without purification, with $AgOSO_2CF_3$ (AgOTf) and $SnCl_2$ in the presence of 2,6-di-*tert*-butyl-4-methylpyridine (DBMP) and molecular sieves (4 Å) (Scheme 3). The disaccharides **4a–c** were obtained stereoselectively (Table 1).[13]

Scheme 3. Stereoselective mannosidation. Step 2) was performed in a solvent specified in Table 1. Phth = phthaloyl.

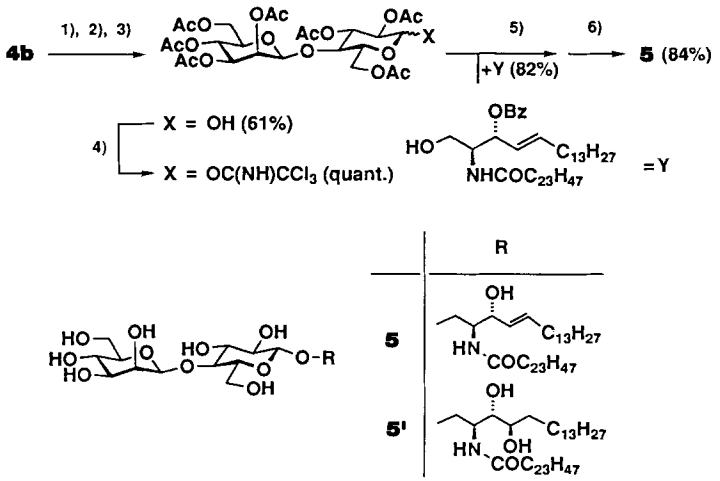


Table 1. Results of stereoselective mannosidation.

Entry	ROH	Solvent [a]	Product	Yield [%]	$[\alpha]_D$ [b]
1	**3a** [c]	Et_2O	**4a**	74	
2	**3a**	CH_2Cl_2	**4a**	65	−4.7 ($c = 1.1$)
3	**3a**	MeCN	**4a**	67	
4	**3b** [c]	CH_2Cl_2	**4b**	52	
5	**3b**	Et_2O	**4b**	45	+3.0 ($c = 0.8$)
6	**3c** [d]	CH_2Cl_2	**4c**	40	+45.2 ($c = 1.4$)

[a] Indicates the solvent used for the treatment with AgOTf/$SnCl_2$/DBMP. [b] Measured in $CHCl_3$ at 20 ± 3 °C. [c] See ref. [19a]. [d] See ref. [19b].

Although the effect of solvent seems to be minimal (entries 1–3, 4 and 5 in Table 1), the reaction in toluene was quite sluggish and resulted in an intractable mixture, presumably due to poor stabilization of the cationic intermediate. Also to be noted is that the GlcNAc derivative **3c**, which contains a *p*-methoxyphenyl (MP) group known to be sensitive under oxidative conditions,[14] could be used as a substrate.

To confirm the stereoselectivity of this transformation unambiguously, disaccharide **4b** was converted into the mannose-containing glycosphingolipid **5**[15] (Scheme 4). Synthetic **5** was compared with **5′** derived from wheat flour. The synthesis of the latter as well as that of the α-Man isomer **5′α** was reported by

Scheme 4. Synthesis of glycosphingolipid **5**. 1) H_2, $Pd(OH)_2$/C/MeOH, 45 °C; 2) Ac_2O/pyridine/DMAP, room temperature; 3) NH_2NH_2/AcOH/DMF, 50 °C; 4) CCl_3CN, 1,8-diazabicyclo[5.4.0]undec-7-ene./CH_2Cl_2, 0 C → room temperature; 5) Me_3Si-OTf, molecular sieves 4 Å/$CHCl_3$, 0 C; 6) NaOMe/THF/MeOH.

Koike et al.[16] The chemical shifts of carbohydrate portions of **5** and **5′** in the ^1H NMR spectrum were essentially identical[17] and clearly distinguishable from those of **5′α**.[18]

The method described here can be carried out simply and, more importantly, it is expected to be compatible with a variety of manipulations encountered in oligosaccharide synthesis. We are currently trying to use this approach to stereoselectively synthesize Asn-linked oligosaccharides.

Experimental Procedure

Synthesis of **4a**: To an ice-water cold mixture of DDQ (42 mg, 0.19 mmol) and powdered molecular sieves (4 Å, 0.3 g) in CH_2Cl_2 (0.5 mL) was added with stirring a solution of **1** (102.7 mg, 0.179 mmol) and **3a** (65.9 mg, 0.121 mmol) in CH_2Cl_2 (2.5 mL). After being stirred at room temperature for 3 h, the mixture was quenched by stirring with a solution of ascorbic acid (0.7%), citric acid, (1.3%), and NaOH (0.9%) in water (3 mL), diluted with ethyl acetate, and filtered through Celite. The filtrate was washed with water, aqueous $NaHCO_3$, and brine, successively, dried (Na_2SO_4), and evaporated in vacuo. After evacuation at high vacuum for 1 h the crude acetal was obtained.

The solution of the acetal in ether (8 mL) was added dropwise to an ice-water cold mixture of AgOTf (62 mg, 0.24 mmol), $SnCl_2$ (46 mg, 0.24 mmol), DBMP (59 mg, 0.24 mmol), and powdered molecular sieves (4 Å, 0.3 g) in ether (2 mL), and the mixture was stirred at room temperature for 2.5 h. After being stirred with aqueous $NaHCO_3$, the mixture was diluted with ethyl acetate, filtered through Celite, and the filtrate was washed with brine, dried ($MgSO_4$), and evaporated in vacuo. The residue was purified by silica gel column chromatography (hexane/ethyl acetate 2:1) to afford **4a** (87.1 mg, 74%): m.p. 115–117 °C (from ether/hexane); ^1H NMR (CD-Cl_3) δ = 4.50 (d, ^3J(H,H) = 8 Hz, 1H, H-1′), 4.32 (s, 1H, H-1²); ^{13}C NMR (CD-Cl_3) δ = 102.3 (^1J(C,H) = 160 Hz, C-1′), 100.2 (^1J(C,H) = 156 Hz, C-1²).

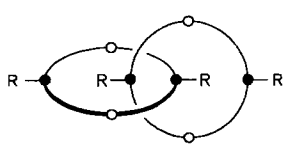
Isomeric Lactam Catenanes and the Mechanism of their Formation



Stephan Ottens-Hildebrandt, Stephan Meier, Wolfgang Schmidt, and Fritz Vögtle*

The increasing interest in catenanes during the last years is documented by a rising number of publications.[1] Through the outstanding work of Sauvage et al.[2] and Stoddart et al.,[3] certain catenane types have been made accessible. High yields were obtained by skillful use of supramolecular template effects.[4] Likewise, the one-[5] and two-step[6] syntheses of neutral catenanes of type **1**, **2** described in 1992 were achieved with

1: R = OCH_3
2: R = H

≙

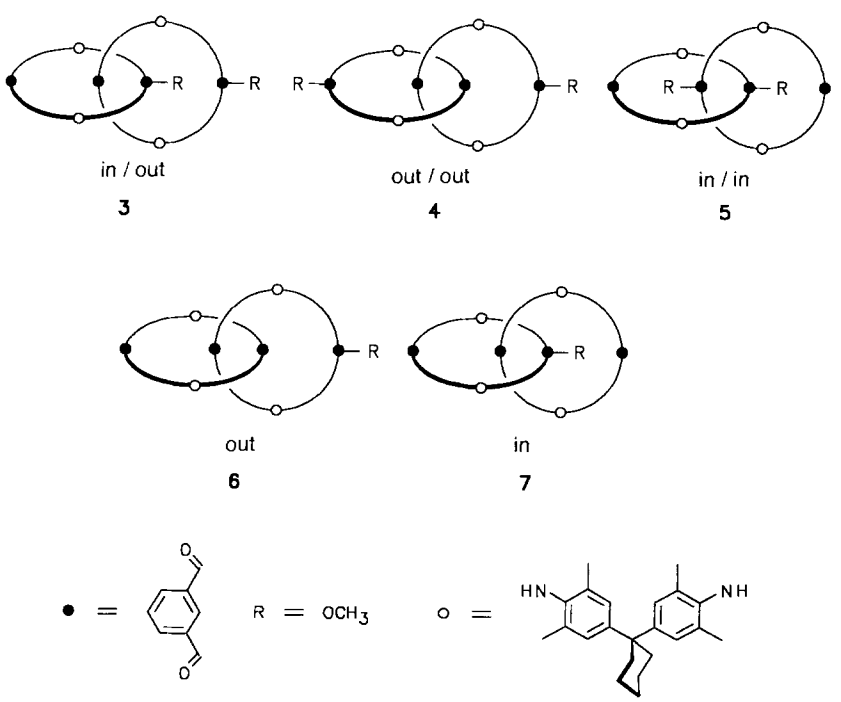
Telefax: Int. code + (228)73-5662

amazingly simple building blocks and remarkably high yields. The question concerning the mechanism of formation of these octalactam catenanes and, in particular, the underlying template interaction has not, however, been adequately addressed. Until now it has been assumed that "orthogonalization", the perpendicular preorganization of the catenane building blocks, is based on three effects: steric complementarity, hydrogen bonding between carbonyl oxygen atoms and amide protons, and $\pi-\pi$ interactions[7] between the benzene rings of host and guest subunits.[5, 6]

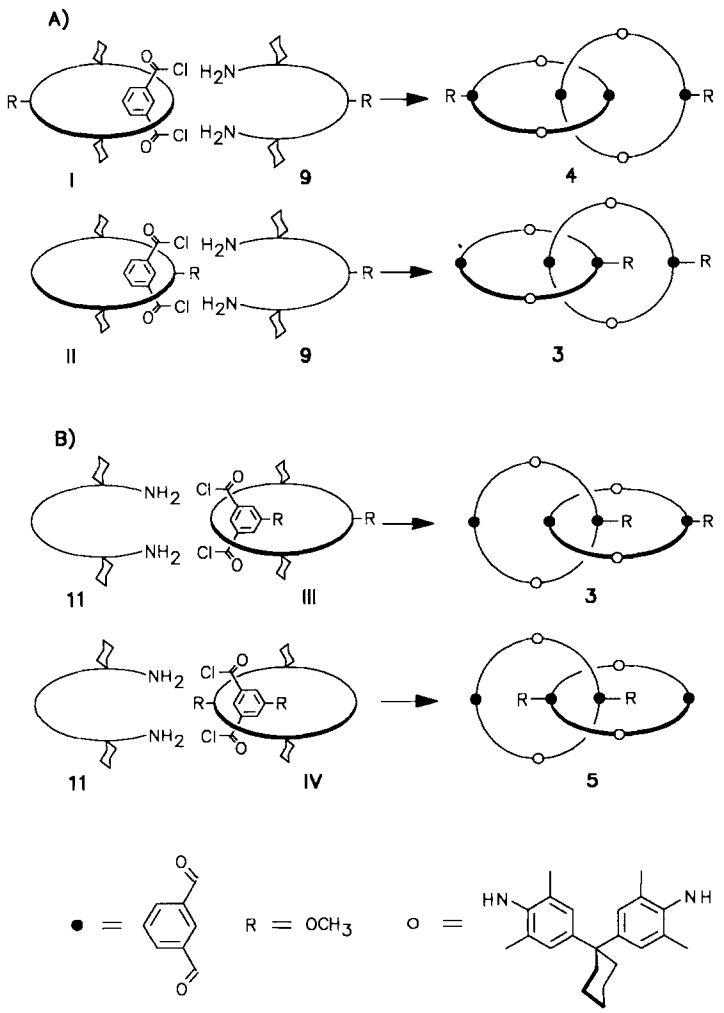
Herein we report on the syntheses of the isomeric [2]catenanes **3**–**5** and of **6** (Scheme 1), and on our conclusions concerning their mechanism of formation. The synthetic strategy which leads to the monomethoxy-substituted catenane **6** makes it possible, for the first time, to obtain lactam catenanes with two different interlocking macrocycles. In this synthesis, formation of the catenanes can be detected by mass spectrometry.[8]

The isomeric [2]catenanes **3**–**5** and **6** were synthesized by three different routes (Scheme 2, A and B; Scheme 4, C). The isomers **3** and **4** were prepared by a method developed by Hunter (route A);[6] instead of the unsubstituted diamine **11**, the methoxy-substituted diamine **9** was used in the reaction with isophthaloyl dichloride (**8**). The resulting mixture contained the substituted macromonocycles **12** and **13** (Scheme 4), and the isomeric dimethoxy catenanes **3** and **4** (17 and 23% yield, respectively).[9] The products were separated by column chromatography and show characteristic differences in their NMR spectra.[10]

In an attempt to synthesize the third dimethoxy-substituted catenane isomer **5**, we performed the reaction with starting materials having a reversed substitution pattern: 5-methoxyisophthaloyl dichloride (**10**) and the diamine **11** were employed (route B). Besides the monocycles **12** and **13**, the isomers **3** and **5** were formed exclusively (2.7 and 1.4% yield, respectively). Isomer **5** was isolated by column chromatography. As expected, important portions of its NMR spectra resemble that of catenane **1**.

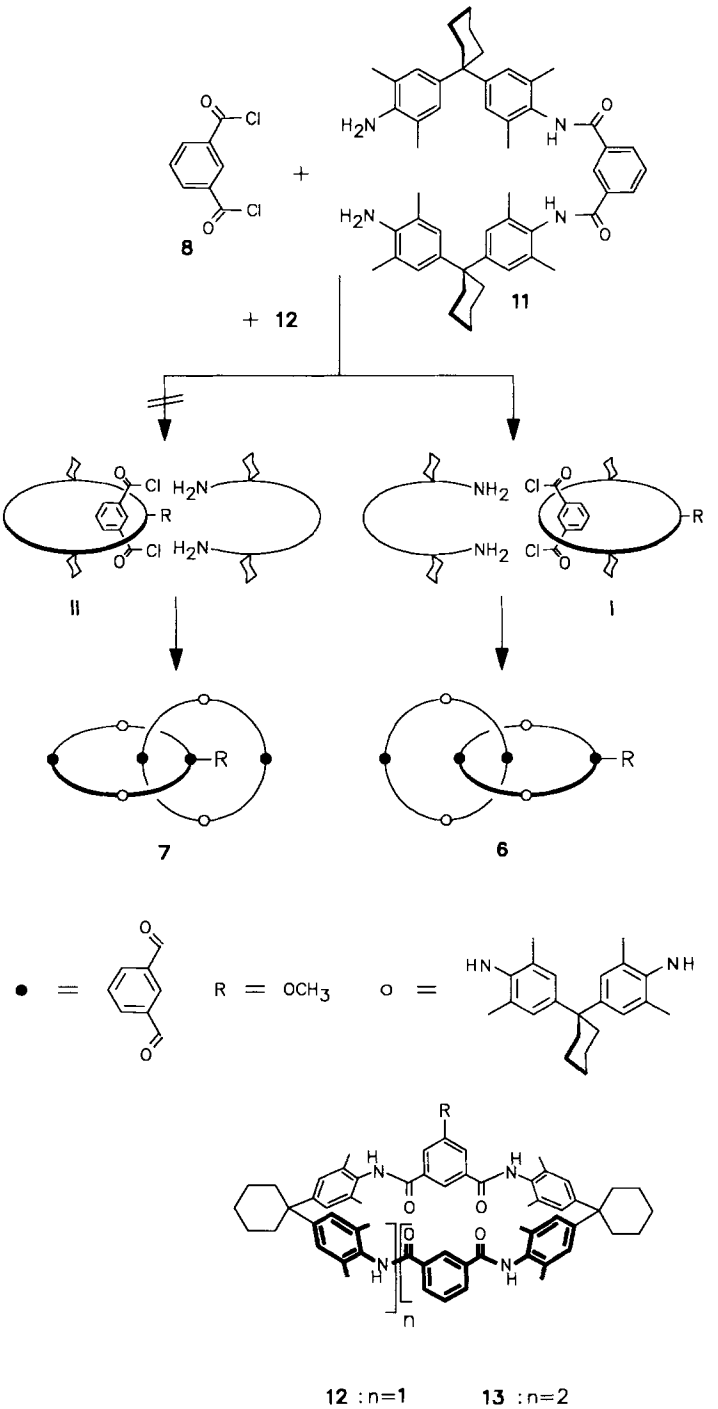


Scheme 2. Route A leads to a different set of dimethoxy-substituted catenanes (**3**, **4**) than route B (→ **3**, **5**).



The route-dependent, selective formation of the stable isomers **4** and **5**[11] allows conclusions to be drawn about the mechanism of ring interlocking. We assume that the supramolecular template effect, which is responsible for catenation, results from the respective diacid dichlorides (**8**, **10**) "lodging" as guests in the host, the intermediate macromonocycle **12**, in such a way that the metaphenylene ring of the guest is orthogonal to the ring plane of the host (Scheme 3).[12] Because of the two isophthaloyl binding sites in the host cycle, there are two possible orientations (I, II and III, IV, respectively) for each acid chloride (**8** and **10**). Routes A and B thus lead to selective formation of isomers **4** and **5**, respectively, in addition to **3**.

This mechanism provides an explanation for the significantly different yields obtained in routes A and B: In the case of route B, the methoxy substituent on the diacid dichloride may cause steric hindrance in the host–guest complexes. Catenanes **3** and **5** in route B should thus be formed in lower yields than **3** and **4** in route A.



To provide further evidence for the hypothesis that the reaction proceeds via an intermediate monocycle of type **12**, we carried out a synthesis following route C (Scheme 4). Building blocks **8** and **11**, which have already been used by Hunter et al. for other targets,[6] were mixed in the presence of macrocycle **12**, obtained as a byproduct in routes A and B. Of the two possible monomethoxy-substituted isomers **6** and **7**, only **6** was formed in 3%

Scheme 1. The three isomeric disubstituted catenanes **3**–**5** and the isomeric monosubstituted catenanes **6** and **7**.

Scheme 3. The proposed template and orthogonalization mechanism (cf. I–IV) provides an explanation for the formation of different catenane isomers (**3**, **4** and **3**, **5**) in routes A and B.

12 : n=1 **13** : n=2

Scheme 4. Route C. The "catenation" of the macromonocycle **12** with **8** and **11** leads to formation of catenane **6**. The guest diacid dichloride **8** and the host **12** are locked in an orthogonal arrangement (**I**). The functional groups are fixed and thus preorganized for reaction with the diamine **11**.

yield. The combination of the three reaction components **8**, **11**, and **12** to form a single product is consistent with our proposed orthogonalization and interlocking mechanism shown in Schemes 3 and 4. Other mechanisms, in particular the interlocking of two open-chain fragments such as **8** with **9** or **9** with **9**, do not appear to be significant.

An advantage of route C lies in the fact that the catenane **6** formed from the monocycle **12** can be identified unambiguously from the molecular peak in the mass spectrum, because the isomeric macromonocycle (identical molecular mass) cannot be formed in route C.

The orthogonalization and interlocking mechanism has far-reaching consequences: In future more reagents of types I–IV will become available, in which a host cavity (e.g., **12**) and a (di)functionalized guest (e.g., **8**, **10**) are bound together by macromolecular interactions in an orthogonalized precatenane (prerotaxane, cf. I–IV) bearing two reactive groups. The synthesis of a variety of other catenanes by reaction with other partners and the formation of rotaxanes have now become feasible.

Experimental Procedure

Route A: 1.04 g (1.29 mmol) **9** mixed with 0.4 mL triethylamine and 0.26 g (1.29 mmol) **8**, each dissolved in 250 mL anhydrous dichloromethane, were added simultaneously over 24 h under argon to 1 L of stirred anhydrous dichloromethane. The solvent was evaporated in vacuo and the residue dissolved in 300 mL chloroform. The organic layer was washed with 50 mL water, dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by column chromatography (SiO_2, 40–60 μm; dichloromethane/ethyl acetate 7:1). Four fractions were isolated: First fraction (catenane isomer **4**): Yield 300 mg (23%); thin-layer chromatography (TLC): $R_f = 0.58$ (SiO_2, dichloromethane/ethyl acetate 7/1); m.p. >300 °C (decomp.); ^{1}H NMR (400 MHz, $CDCl_3/CD_3OD$ 95/5): $\delta = 0.37$ (s, 6H; Ar-CH_3), 0.72 (s, 6H; Ar-CH_3), 1.00–2.40 (m, 76H; Ar-CH_3 and aliphatic CH_2), 3.64 (s, 6H; OCH_3), 6.02, 6.06 (broad, 4H; arom. H), 6.45–6.60 (broad, 4H; arom. H), 6.78, 6.84 (broad, 4H; arom. H), 7.00–7.10 (broad, 4H; arom. H), 7.13 (dt, $^3J = 8$, $^4J = 1.5$ Hz, 2H; arom. H), 7.17 (t, $^3J = 8$ Hz, 2H; arom. H), 7.31 (pseudo-t;

$^4J = 1.5$, $^4J = 1.5$ Hz, 2H; arom. H), 7.60 (pseudo-t, $^4J = 1.5$, $^4J = 1.5$ Hz, 2H; arom. H), 7.78 (dt, $^3J = 8$, $^4J = 1.5$ Hz, 2H; arom. H), 7.88 (t, $^4J = 1.6$ Hz, 2H; arom. H), 8.26 (t, $^4J = 1.5$ Hz, 2H; arom. H); ^{13}C NMR (62.9 MHz, $CDCl_3$/CD_3OD 95/5): δ = 16.71, 17.90, 18.20, 18.32, (Ar-CH_3), 22.81, 26.18, 34.24, 34.52, 35.93, 36.23 (CH_2), 44.62, 45.11 (C_q), 55.42 (OCH_3), 116.85, 117.37, 122.85, 125.03, 127.42, 127.68, 128.37, 129.52, 130.75 (CH), 125.50, 130.08, 130.21, 130.83, 130.88, 130.95, 132.62, 133.70, 134.15, 134.29, 134.72, 134.79, 135.70, 135.81, 136.06, 146.15, 146.36, 148.56, 149.44, 160.48, 163.20, 163.98, 164.04, 166.27, 166.34, 168.75 (C_q); FAB-MS: *m/z*: 1871.0 [$(M + H)^+$] ($C_{122}H_{132}N_8O_{10}$: 1870.43).

Second fraction (catenane isomer **3**): Yield 220 mg (17%); TLC (SiO_2): R_f = 0.32 (dichloromethane:ethyl acetate 7:1); m.p. > 300 °C (decomp.); ^{1}H NMR (250 MHz, CD_2Cl_2/CD_3OD 95/5): δ = 0.61 (s, 6H; Ar-CH_3), 0.90–2.70 (m, 82H; Ar-CH_3 and aliphatic CH_2), 3.85, 3.90 (s, 6H; OCH_3), 6.29, 6.32 (broad, 4H; arom. [8] Reported partly at GDCh lectures in Constance (December 8, 1993), Cologne, Münster, Tübingen, and Krefeld as well as at lectures in Ravello and Stockholm.

[9] The remaining products from routes A–C consisted of mixtures of open-chain and monocyclic higher oligomers, which were not separated chromatographically.

[10] The structures of the various isomers were confirmed by the ^{1}H NMR, ^{13}C NMR (see *Experimental Procedure*), and, in particular, NOESY spectra. Using electrospray mass spectrometry, Prof. Dr. M. Przybylski, Universität Konstanz, is attempting to distinguish between catenane isomers **3**–**5**.

[11] No interconversion or equilibration of the isomeric catenanes could be observed even at higher temperature (300 °C). The translation of the rings seems to be hindered by the cyclohexyl residues, as proposed in earlier publications [6, 7].

[12] We do not exclude the possibility that the isopthaloyl dichloride (**8** or **10**) already forms *one* amide bond with the corresponding diamine (**9** or **11**) before "lodging" in the host.

Synthesis and Characterization of the First Thiaselanes**

Josef Hahn* and René Klünsch

Until now selanes H_2Se_x and the thiaselanes $H_2S_ySe_{x-y}$ derived from them by selenium–sulfur exchange were only known in the form of organo[1] and chloro derivatives.[2] We report here on the synthesis and NMR spectroscopic characterization of thiaselanes with the general formula $H_2S_mSe_n$, as well as on the isolation of

1,3-dithiatriselane H-S-Se-S-H (**1**), a solid which melts at −40 °C. It is surprising that attempts to synthesize thiaselanes have been unsuccessful so far, since binary sulfur–hydrogen compounds H_2S_x with chain lengths of up to $x = 35$ are known.[3] The conversion of sulfanes into thiaselanes according to the general reaction (a)

$$-S-S- + Se-Se- \longrightarrow 2\,S-Se- \quad (a)$$

should, on the basis of calculations,[4] be exothermic. Furthermore, on the basis of these calculations, as well as from a simple comparison of the stability of thiols and selenols, it is expected that isomers containing SH groups are favored over those with SeH groups. Therefore, our first efforts concentrated on the synthesis of α,ω-dithiaselanes.

Initial attempts to produce thiaselanes using a method based on a gentle synthesis of sulfanes[5] by protolysis of silylated selenium–sulfur chains of the general formula $(MePh_2Si)_2S_2Se_n$ and $(Ph_3Si)_2S_2Se_n$ failed owing to the instability of the starting materials.[6] However, the desired products were obtained by condensing hydrogen sulfide and dichlorodiselane [Eq. (b)].

$$2\,H_2S + Se_2Cl_2 \longrightarrow \underset{\mathbf{2}}{H-S-Se\ Se-S-H} + 2\,HCl \quad (b)$$

Because the starting materials as pure substances react very vigorously with each other even at low temperatures, liquid hydrogen sulfide (in excess) was treated at −78 °C with a very dilute solution of dichlorodiselane (ca. 6 wt% in CS_2). Under these conditions an orange-yellow solution and a small amount of an orange-red solid is formed. In the orange-red solution remaining after evaporation of the hydrogen sulfide at −40 °C only thiaselanes of differing composition could be detected by NMR spectroscopy (Table 1).

Table 1. ^1H and ^{77}Se NMR parameters (δ(Se) relative to Me_2Se) of the thiaselanes from reaction (b); saturated solution in CS_2/[D_6]-benzene 6/1 at 295 K.

	δ(H) [a]	δ(Se) [a]	^2J	^3J(Se,H)[Hz] [b]	^4J
H–S, Se, H–S **1**	3.43	527	3.53	–	–
H–S–Se, H–S–Se **2**	3.52	729	3.65	2.60	–
$H-S^1-Se^2$, $H-S^5-Se^4$, Se^3 **3**	3.59	685 (2, 4) 918 (3)	3.49	2.10	1.10
$H-S^1-Se^2$, $H-S^6-Se^5$, Se^3, Se^4 **4**	3.66	682 (2, 5) 887 (3, 4)	3.53	2.54	1.66
H–S–Se, S, H–S–Se **5**	3.62	750	3.65	–	1.32
$H^a-S^1-Se^2-S^3$, $H^b-S^6-Se^5-Se^4$ **6**	3.69 (a) 3.68 (b)	749 (2) 954 (4) 690 (5)	3.65 (a, 2) 3.60 (b, 5)	– 2.32 (b, 4)	1.94 (a, 4) –

[a] The atoms which correspond to the δ-values are given in brackets. [b] The coupling atoms are given in brackets.

1,4-Dithiatetraselane **2**, the expected product according to Equation (b), was not the major product even under optimum reaction conditions. Due to a disproportionation reaction it was obtained along with 1,3-dithiatriselane **1** in the molar ratio 1:1.7 to 1:3. Further disproportionation products were disulfane and dithiaselanes with more than four chalcogen atoms. Disproportionation is fast during the condensation reaction; afterwards it is notably slower. Disproportionation of the product mixture was almost halted at −78 °C, and could be forced back into the above range during the reaction by a high concentration of HCl (saturation of the liquid hydrogen sulfide with HCl prior to the start of the reaction). At room temperature (Ar atmosphere) the half-life of dithiatetraselane **2** in dilute CS_2 solution is about 20 h, whereas that of the more stable dithiatriselane **1** is roughly 5 d. From changes in concentration in the CS_2 solution it is concluded that there is a stepwise disproportionation in which one selenium atom is transferred at a time [Eq. (c)]. Because of their low solubility, the higher thiaselanes precipitated and could no longer be detected by NMR spectroscopy.

$$H-S-Se_o-S-H + H-S-Se_p-S-H \longrightarrow H-S-Se_{o-1}-S-H + H-S-Se_{p+1}-S-H \quad (c)$$

1,3,5-Trithiapentaselane **5** and 1,3,6-trithiahexaselane **6** are derived formally from 1,4,7-trithiaheptaselane (not detected) by the cleavage of two and one selenium atoms, respectively. In spite of the large excess of H_2S, compounds of this type can arise directly from the secondary reaction (d), or by subsequent disproportionation (for $n = 2$).

$$H_2S_2Se_n + Se_2Cl_2 + H_2S \longrightarrow H-S-Se_n-S-Se_2-S-H + 2\,HCl \quad (n = 1.2) \quad (d)$$

After removal of the solvent at −50 °C a mixture of thiaselanes was obtained as an orange-red solid which turns into a dark red oil above −40 °C. The solid was no longer completely soluble in CS_2; however, the soluble fraction contained approximately the original distribution of thiaselanes. 1,3-Dithiatriselane **1** could be sublimed in vacuo (10^{-5} mbar) at −45 °C from the orange-red solid. It could be trapped at −78 °C without other more volatile disproportionation reaction products, and could be isolated as a pale yellow solid which melts at −40 °C with decomposition. The only impurity was the less volatile 1,4-dithiatetraselane **2** (3–5 mol%).

Mixtures of thiaselanes containing more sulfur could also be obtained in a synthesis analogous to that above. The tetrathiaselanes **7**–**9** (Table 2) arise in the synthesis of 1,2,5,6-tetrathiahexaselane **8** by dropwise addition of a solution of Se_2Cl_2 (ca. 4 wt% in CS_2) into solvent-free disulfane saturated with HCl (molar ratio 1:100) at −78 °C [Eq. (e)]. This condensation reaction is also accompanied by disproportionation, and the tetrathiaselanes with one, two, and three Se atoms **7**, **8**, and **9**, respectively, were present in the molar ratio 1.5:1:0.5.

$$2\,H_2S_2 + Se_2Cl_2 \longrightarrow H-S-S-Se-Se-S-S-H + 2\,HCl \quad (e)$$

[a] See Table 1. [b] Not determined.

The conclusive identification of the thiaselanes in the mixtures was achieved by ^1H and ^{77}Se NMR spectroscopy. The most impor-

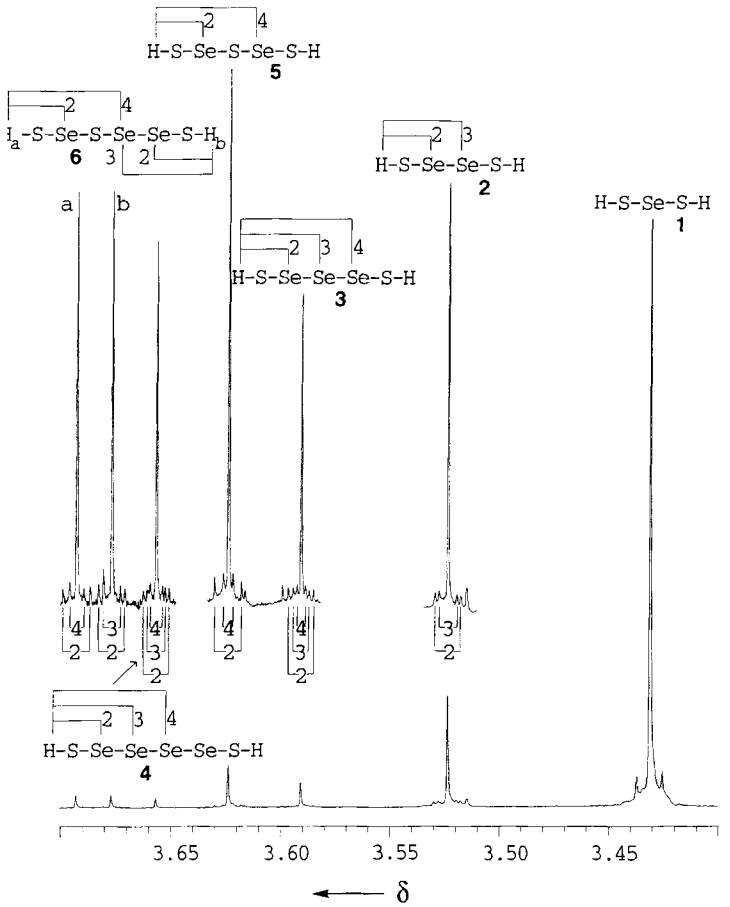

Fig. 1. ^{1}H NMR spectrum of the thiaselanes from reaction (b). The labels on the signals indicate the satellites due to ^{77}Se,^{1}H coupling. Additionally, the number of bonds is given through which the nuclei are coupled; this number is repeated in the structural formulae; frequency 300.13 MHz; temperature 295 K.

tant relationships between the structure and NMR parameters are summarized here.

1. The number of Se atoms in a molecule can be derived from the number of ^{77}Se satellite pairs[7] in the ^{1}H NMR spectrum (Fig. 1). Within a molecule, the value of the coupling constant decreases with the number of bonds separating the coupling nuclei.

2. The δ(H) values[8] increase with increasing chain length (**1** → **2** → **3** → **4**, **5** → **6**, Table 1; **7** → **8** → **9**, Table 2). A downfield shift also results, to a lesser extent, when one selenium atom is exchanged for one sulfur atom while the chain length remains constant (**3** → **5**, **4** → **6**, Table 1).

3. The environment of the ^{77}Se nuclei has, as expected, a very strong influence on their magnetic shielding. According to the equation in Scheme 1, δ(Se) of a given Se atom is dependant on the number of Se and S atoms in the α-, β-, and γ-positions. As is found for alkanes[9] and phosphanes,[10] the neighboring atoms in the α- and β-positions cause a downfield shift and those in γ-positions an upfield shift. Consistent with the greater electronegativity, the constants for sulfur are always more positive (stronger downfield shifts).

The constitution of the thiaselanes **1**–**9** follows unequivocally from the structural dependence of the NMR parameters (points 1–3). This means that in addition to the known interchalcogen–hydrogen compounds of oxygen and sulfur, H-S-O-H[11] and H-O-S-S-O-H,[12] those of sulfur and selenium have now been synthesized. In contrast to the former compounds, the oxasulfanes, which have only been detected by matrix or neutralization–reionization mass spectrometry, the thiaselanes can be obtained on a preparative scale. Thus, in addition to the isolation of H-S-Se-S-H **1**, the separation of the higher homologues as pure compounds and the investigation of their chemical reactions looks promising.

$\delta(\mathrm{Se}) = -227 + i\,\alpha_X + j\,\beta_X + k\,\gamma_X \pm 5$; X = S, Se

i, j, k = number of S or Se atoms in α, β, and γ positions, respectively

$\alpha_S = 377$, $\beta_S = 264$, $\gamma_S = -34$, $\alpha_{Se} = 311$, $\beta_{Se} = 254$, $\gamma_{Se} = -36$

Scheme 1. Calculation of δ(Se) with chemical shift increments.

Experimental Procedure

The thiaselanes were synthesized under inert conditions (argon atmosphere). All glassware used must be completely free of grease, and acidified by boiling in concentrated hydrochloric acid.

$H_2S_2Se_n$: Hydrogen sulfide (300 mL, 280 g, 4.2 mol), dried over P_4O_{10}, was condensed into a reaction flask at −78 °C, and dried (P_4O_{10}) HCl gas was added until saturation. With continued cooling and vigorous stirring, a solution of Se_2Cl_2 (5 g, 22 mmol) in CS_2 (70 mL) was added from a dropping funnel cooled to −78 °C. The mixture was stirred for 1 h and subsequently excess H_2S condensed off. For complete removal of H_2S, the mixture was warmed to −50 °C in vacuo (1 mbar).

$H_2S_4Se_n$: H_2S_2 and Se_2Cl_2 were reacted analogously to the synthesis given above. A solution of Se_2Cl_2 (0.92 g, 4 mmol) in CS_2 (20 mL) was added dropwise to H_2S_2 (20 mL, 27 g, 0.4 mol) saturated with HCl gas. H_2S_2, which is less volatile than H_2S, could not be completely removed by the low temperatures required.

Magnetic Spin Effects on Photooxidation Quantum Yields of Ru^{II}-tris(bipyridine) Type Complexes in Magnetic Fields up to 17.5 Tesla**

Dieter Bürßner, Hans-Joachim Wolff, and Ulrich E. Steiner*

Today a large number of magnetic field and magnetic isotope effects on the rates and yields of chemical reactions are known.[1] Their mechanisms are closely related to electronic- and nuclear-spin polarization effects arising from chemical reac-

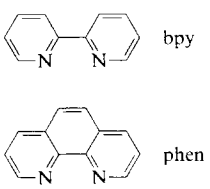
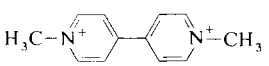
Klaschka for their help in organizing the experiment at Grenoble.

tions. The acronyms CIDEP and CIDNP have become established for these effects. The systematic study of all these effects is the object of *spin chemistry*.[2] For magnetic field effects to influence chemical reaction rates, processes of electron spin must be kinetically coupled to processes of chemical change. In a magnetic field, the Larmor precession of the unpaired electron spins will modify the spin processes and thereby possibly alter the overall reaction kinetics. As a general rule, the magnetic field dependence of the observed kinetic effect reflects the ratio between the rates of inherent processes (spin processes and connected chemical processes) and the frequency of Larmor precession. Typically, the magnetic field effect has its strongest dependence on the relative change of the field at the point where both spin precession and internal processes occur at about the same rate (note that at a field of 1 Gauss (0.1 mT) the Larmor precession period is 0.36 μs). The effect approaches a saturation value at field strengths several times higher. Most spin chemical experiments reported so far have been conducted in fairly weak magnetic fields (several 100 Gauss) for the obvious reason that this is sufficient if the internal spin processes are governed by hyperfine coupling. The field strength has, at least, been limited by the usual laboratory equipment for generating variable magnetic fields, that is, electromagnets which can only provide several Tesla of magnetic induction. Few investigations have utilized the fields of superconducting solenoids[3] or have applied pulsed magnetic fields.[4, 5] In one paper[6] magnetic field effects at one high-field value of 14.5 T, produced by a Bitter type magnet, have been compared to effects at low fields; however, rather small effects were seen. In this communication we report the first investigations[7] where the field is gradually varied from zero field to the highest field of 17.5 Tesla. Magnetic field dependent reaction kinetics could be measured for a system exhibiting the highest saturation fields observed so far and allowing determination of the fastest chemical and spin processes investigated so far by spin chemical methods.

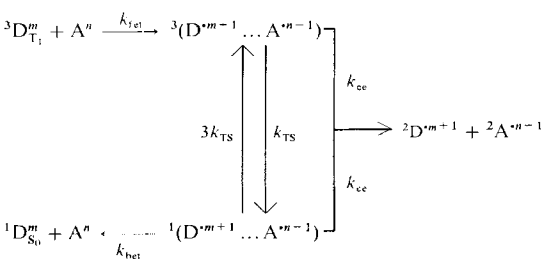


The reaction we studied is the photooxidation of Ru^{II}-tris-(bipyridine) type complexes **1a**–**1d** by methylviologen (MV^{2+}).



$[Ru^{II}(bpy_3)]^{2+}$ **1a**

$[Ru^{II}(bpy)_2(phen)]^{2+}$ **1b**



$[Ru^{II}(bpy)(phen)_2]^{2+}$ **1c**

$[Ru^{II}(phen)_3]^{2+}$ **1d**

The relevant reaction steps (Scheme 1) apply in general to electron transfer reactions with photoexcited triplet states. A triplet excited electron donor $^3D^m$ ($^3[Ru^{II}L_3]^{2+}$) undergoes electron *forward* transfer in a diffusion-controlled reaction (rate constant k_{fet}) with a singlet ground state electron acceptor $A^n(MV^{2+})$ to generate a radical-ion pair $D^{\bullet m+1}\ldots A^{\bullet n-1}$ ($[Ru^{III}L_3]^{3+}\ldots MV^{\bullet+}$), which may dissociate (with rate constant k_{ce} of cage escape) to form the free radical ions, or else can undergo a *backward* electron transfer in the solvent cage to regenerate the ground-state reactants. The reaction scheme assumes conservation of spin multiplicity during the electron transfer steps. Thus the primary radical-ion pair (RIP) forms as a triplet spin state, and backward electron transfer (with rate constant k_{bet}) is only possible after a spin-flip transition to the corresponding singlet RIP state, occurring with a rate constant of k_{TS} and, for spin statistical reasons, of $3k_{TS}$ for the reverse process. An external magnetic field modifies the *rate* of spin equilibration in the RIP (for details see below) and thereby affects the overall efficiency of backward electron transfer and, indirectly, of cage escape (η_{ce}). The latter quantity is measured in our experiments.

Scheme 1.

The sources, preparation, and purification of the compounds employed in this investigation are described in Refs. [8,9]. The experiments were carried out with a Bitter magnet at the High Magnetic Field Laboratory of MPI/CNRS at Grenoble. The magnetic field effect on the formation of free radicals was investigated by photostationary illumination in a continuous flow system.[10, 11] The $MV^{\bullet+}$ radicals produced in the photoreaction were protected against reoxidation through Ru^{III} complexes in the bulk by adding 2×10^{-2} M EDTA as a sacrificial donor to reduce Ru^{III} to Ru^{II}. The experiments were carried out in aqueous solutions with concentrations of 2×10^{-5} M for the complexes and 3×10^{-3} M for MV^{2+}. Further experimental details can be found in ref. [9].

The observed magnetic field dependence of the cage escape efficiency η_{ce} (which corresponds to the measured magnetic field effect on the quantum yield of photoinduced $MV^{\bullet+}$ radical production) with the four complexes **1a**–**1d** is depicted in Figure 1.

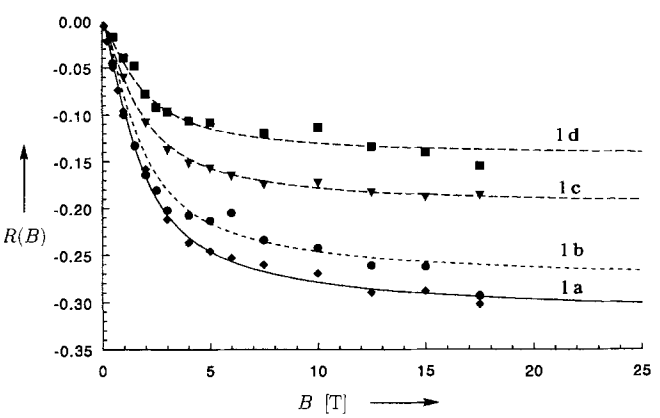


Fig. 1. Relative magnetic field effect $R(B) = (\eta_{ce}(B) - \eta_{ce}(0))\eta_{ce}(0)^{-1}$ on the quantum yield of $MV^{\bullet+}$ radical production in the photoreaction with complexes **1a**–**1d**. The curves are results of theoretical simulations of the magnetic field dependence of η_{ce} using the parameters given in Table 1.

There is a pronounced ligand effect on the magnetic field sensitivity, which decreases regularly for every replacement of a bipyridine ligand by a phenanthroline ligand. In the low-field region the values measured with the Bitter magnet are in very good agreement with the results previously obtained up to 3.3 Tesla with the electromagnet in our laboratory.[9] However, the new experiments with the fivefold extended field range clearly exhibit saturation behavior of the field effect above fields of about 5 Tesla.

The observed magnetic field dependence can be excellently reproduced by theoretical simulations based on our recently reported theoretical model,[9, 12] which may be briefly summarized as follows: In the description of the spin state of the primary RIP ($[Ru^{III}L_3]^{3+} \cdots MV^{\bullet+}$) we make use of the concept of *effective spin* in order to account for the strongly spin-orbit-coupled nature of the Ru^{III} ground state in its low-spin d^5 electron configuration. The changes of the RIP spin state are governed by the fast relaxation of the effective spin at Ru^{III} described by a magnetic field independent relaxation time $\tau_S = T_1 = T_2$ (at zero field, k_{TS} in Scheme 1 is equal to $(4\tau_s)^{-1}$) and by the Zeeman interaction which, due to the strongly anisotropic g-tensor of Ru^{III}, enforces a fast loss of spin correlation between the effective spin at the complex and the spin at $MV^{\bullet+}$. Cage escape of the RIP and backward electron transfer are treated as first-order chemical rate processes with rate constants k_{ce} and $k_{bet,i}$, respectively; individual rate constants of backward electron transfer are employed for the four spin substates (denoted by index i) of the pair. These individual rate constants correspond to the products of the rate constant k_{bet} of the hypothetically spin-allowed process with the individual singlet characters $p_{S,i}$ of the respective spin states, one of them being essentially of singlet, three of them essentially of triplet nature. The efficiency of cage escape and its magnetic field dependence are calculated by numerically solving the pertinent stochastic Liouville equation and averaging the result over all orientations of the Ru^{III} complex.

In the simulation of the observed magnetic field effect, the values of the g-tensor components of the Ru^{III} complexes were taken from ESR spectra measured at low temperature in a solid matrix of acetonitrile/sulfuric acid,[13] whereas the rate constants τ_S^{-1}, k_{ce}, and k_{bet} were treated as empirical fit parameters. As it turned out, in order to reproduce the absolute values of η_{ce} (0) (the cage escape efficiency at zero field) and the full magnetic field effect curves within the bounds of experimental error, all three parameters of the set could be fixed with certainty within a margin of $\pm 20\%$ for each of the complexes. Thus a fairly precise, *absolute* determination of τ_S^{-1}, k_{ce}, and k_{bet} is possible with our method. No supplementary information on these parameters is needed beforehand. The values determined for the four complexes are listed in Table 1.

Since the four spin substates of the primary RIP exhibit kinetic differences the overall kinetics of the RIP decay is not truly monoexponential. An effective overall decay time may be defined, however, as in Equation (a). As can be seen from Table 1,

$$\tau_{eff} = \frac{\eta_{ce}}{k_{ce}} \qquad (a)$$

τ_{eff} lies around 100 ps. Under conditions of diffusion-controlled formation of the RIPs in a homogeneous reaction, as in our experiment, it would be impossible to observe the RIPs directly with ps time-resolution, since even with the highest acceptor concentration the time of formation of the RIP cannot be decreased below several ns. Direct observation of the RIP is, however, feasible and has been reported for a number of chemically linked systems of electrons donor and acceptor (dyads) where the forward electron transfer step is not limited by diffusion (cf. Ref. [14]). In a ps time-resolved study of dyads composed of a Ru^{II}-tris(bipyridine) type electron donor and a methylviologen type electron acceptor connected by a covalent spacer of one or two CH_2 links, Yonemoto et al.[15] observed RIP lifetimes between 8.5 and 70 ps, depending on the number n of links and the thermodynamic driving force of backward electron transfer ΔG^0_{bet}. For $n = 2$ and $\Delta G^0_{bet} = -1.65$ eV, a situation that can be considered as corresponding closely to the case of the RIPs formed in our free diffusion reaction, the observed value is 70 ps, which indeed comes rather close to the values determined by our spin chemical approach. Thus, while the ps time-resolved studies of the dyads corroborate the conclusions from our spin chemical investigations, the spin chemical approach yields additional, highly relevant information on the nature of the process that, in fact, determines the *observable* effective decay time of the RIP, not only in our freely diffusing systems but, of course, also in the dyads. The magnetic field effects described here give unequivocal evidence that the overall backward electron transfer is a two-step process involving spin conversion followed by spin-conserving electron transfer. Using relation (b) we can predict from our results the lifetimes $\tau_{bet,eff}$ (cf. Table 1) that would

$$\tau_{bet,eff} = \frac{\eta_{ce}}{(1-\eta_{ce})}\frac{1}{k_{ce}} \qquad (b)$$

be observed for our RIPs if cage escape could be excluded. On comparison of these values with $\tau_{bet} = k_{bet}^{-1}$, the time constant of the spin-allowed backward transfer, it becomes clear that the $\tau_{bet,eff}$ values are significantly longer which implies that the observed lifetime must be strongly controlled by the spin relaxation process. This conclusion suggests that before discussing lifetimes of the RIP derived from the ps experiment in terms of electron transfer theory, the observed time constants must be decomposed into a spin conversion part and an electron transfer part. The spin chemical approach, as applied here, seems the only way to achieve such a kinetic separation. Hence, it should be a great experimental challenge to verify our conclusions by *directly* observing the magnetic field effect on the decay time of dyadic RIPs in ps time-resolved experiments.

For k_{ce} a value of 5×10^9 s^{-1} based on an estimation using the Eigen–Debye equation is usually referred to in the literature.[16] The k_{ce} values resulting from our analysis are of the same order of magnitude. A deviation by a factor of 2–3 seems acceptable in view of the assumptions in the diffusional model. Further-

Table 1. Characteristic reaction parameters for the primary Ru^{III} complex/$MV^{\bullet+}$ radical pair.

Ligands	Parameters									
	ΔG^0_{bet} [eV] [a]	η_{ce} [a]	$g_\perp$ [b]	$g_\parallel$ [b]	k_{ce} [ns^{-1}] [c]	k_{bet} [ns^{-1}] [c]	τ_S [ps] [c]	τ_{eff} [ps] [d]	τ_{bet} [ps] [e]	$\tau_{bet,eff}$ [ps] [f]

[a] Data from ref. [9]. [b] Data for ref. [13]. [c] From a simulation of the magnetic field dependence of η_{ce}. [d] Equation (a). [e] $\tau_{bet} = k_{bet}^{-1}$. [f] Equation (b). [g] Minor deviations from our preliminary values in [7] are due to more precise values of the g-tensor components employed in the present calculations. Here we use individual experimental values for each complex, whereas in [7] for both the $(bpy)_3$ and the $(phen)_3$ complex only a common, approximate set of values for the g-tensor components was used.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1717-1774 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 17

more, we note that the slight decrease of k_{ce} observed as bipyridine ligands are replaced by the somewhat larger phenanthroline ones is in agreement with the prediction of diffusion theory, according to which the rate constant of dissociation of a pair of reactants should decrease with increasing reaction distance. Taking into account that the backward electron transfer is a nonadiabatic process that depends on the value of the electronic coupling matrix element, the fact that k_{bet}, too decreases by such a type of ligand substitution seems to support an assumption of increasing reaction distance because a concomitant decrease of the electronic coupling matrix element is expected for increasing separation. Since ΔG^0_{bet} is constant, only a change in the coupling matrix element or in the internal reorganization energy associated with electron backward transfer or in both may account for a change of k_{bet}. Which of these two possibilities applies on substituting bipyridine by phenanthroline ligands cannot be decided at present.

The parameter τ_S is the paramagnetic relaxation time of the Ru^{III} complex in the RIP. It seems unlikely that the presence of the $MV^{\bullet+}$ radical near the Ru^{III} complex has a significant effect on τ_S, and thus it may be conveniently compared to the corresponding value in the free Ru^{III} complex. Because of the short relaxation time and the large g-tensor anisotropy, an ESR signal of the present type of Ru^{III} complexes is not detectable in liquid solutions. However, indirect experimental access to τ_S is possible through the linewidth of ^1H resonances in NMR spectra.[17, 18] Actually a value of $\tau_S \approx 20$ ps was evaluated by Doddrell et al.[19] for $[Ru(acac)_3]$ in a field range from 0.2 to 6 T. We have measured the ^1H-T_1 times for $[Ru(bpy)_3]^{3+}$, from which the electronic relaxation times 25 ps and 9 ps, respectively, have been determined.[20] These values are in rather good agreement with the spin chemical τ_S values. In particular these data confirm that our spin chemical inference of a decrease of τ_S on replacing bipyridine by phenthroline ligands is correct.

In conclusion, we have shown that the spin chemical modeling of the magnetic field effects observed over a large range of magnetic fields allows an excellent simulation of the experimental data with a minimum of parameters. There is a substantial amount of evidence that the determined parameters represent reliable physical information that is not easily, if at all, available otherwise. This renders the method most valuable for a deep look into the details of fast backward electron transfer kinetics and paramagnetic relaxation occuring on a time scale of several tens of ps, with strongly spin–orbit coupled paramagnetic intermediates.

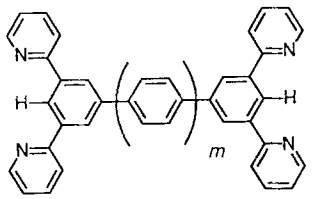
Pronounced Electronic Coupling in Rigidly Connected N,C,N-Coordinated Diruthenium Complexes over a Distance of Up to 20 Å**



Marc Beley, Sandrine Chodorowski-Kimmes, Jean-Paul Collin, Philippe Lainé, Jean-Pierre Launay,* and Jean-Pierre Sauvage*

Molecular systems able to ensure fast long-range electron transfer are an essential requirement for the application of thermal or photoinduced charge separation in artificial photosynthesis[1] and in molecular electronics.[2] Mixed-valence complexes are the prototypes of molecules able to undergo fast electron transfer usually between two metals and through a bridging ligand.[3–11] We recently reported that a bridging ligand consisting of two cyclometalating bipyridylbenzenes connected back-to-back (**1**) affords diruthenium ($\mathbf{5}^{3+}$)[12, 13] and diosmium[13] complexes displaying intense communication between both metal centers at a M–M distance of roughly 11 Å. (Strong intervalence coupling over this distance has also been recently observed in the "[Ru(pincer–pincer)Ru]" systems[14]). In the present paper, we describe extended systems with two N,C,N coordination sites connected by various aromatic spacers, and show that strong communication can occur in diruthenium compounds with much longer bridging ligands. These ligands contain up to four phenyl rings and thus lead to a Ru–Ru distance of around 20 Å.

The synthesis of the ligand precursors **2**-H_2 and **3**-H_2, as well as their diruthenium(II) complexes $\mathbf{6}^{2+}$ and $\mathbf{7}^{2+}$, was described recently.[15] In these complexes the metals are connected by a 4,4″-terphenyldiyl and 4,4‴-quaterphenyldiyl ligand, respec-

tively, and the whole edifice is stabilized by the four additional pyridine units bonded to the metal centers.

The UV/VIS data for the diruthenium(II) complexes and some of their most significant electrochemical parameters are given in Table 1. All three compounds show an intense absorption band in the visible region (500–550 nm), which corresponds to a metal-to-ligand charge transfer transition. As expected, UV bands originating from ligand-centered transitions are also present. The reduction potentials of the compounds are much lower (< -1.5 V) than those of classical ruthenium complexes with six coordinating N atoms such as $[Ru(terpy)]^{2+}$ [16] (terpy = 2,2′,6′,2″-terpyridine, $E = -1.25$ V). It should be stressed that the reduction is very likely to be ligand localized. As already observed,[12, 13] the N_5C coordination polyhedron makes the complexes much weaker electron acceptors than their N_6 congeners because of the strong donating character of the σC–Ru bond. Accordingly, oxidation of Ru^{II} to Ru^{III} is very easy, occurring at potentials from +0.34 to +0.52 V, that is, about 0.8 V less anodic than for noncyclometalated complexes of the $[RuN_6]^{2+}$ family. The electron-rich character of the cyclometalating N,C,N fragment is so pronounced that the Ru^{III}/Ru^{IV} couple can even be clearly detected.

Table 1. UV/VIS data, electrochemical parameters, and comproportionation constants K_c for the diruthenium complexes $\mathbf{5}^{2+}$, $\mathbf{6}^{2+}$, and $\mathbf{7}^{2+}$.

Complex	Absorption [a] λ_{max} [nm] ($\varepsilon \times 10^{-4}$ [M^{-1} cm^{-1}])	$E_{1/2}$ [b] Oxidation	Reduction	K_c [d]
$\mathbf{5}^{2+}$	543 (3.06), 516 (3.06) 287 (11.29), 220 (6.75)	0.505, 0.340	−1.55	690
$\mathbf{6}^{2+}$	513 (3.53), 369 (5.65), 287 (12.7), 243 (7.12), 223 (7.13)	1.39 [c], 0.510	< −1.5	16
$\mathbf{7}^{2+}$	511 (3.50), 374 (5.77), 288 (13.23), 243 (8.11), 228 (8.44)	1.39 [c], 0.515	< −1.5	6

The comproportionation constant K_c corresponding to equilibrium (a) can be obtained by analyzing the cyclic voltammetry

$$Ru^{II}, Ru^{II} + Ru^{III}, Ru^{III} \rightleftharpoons 2Ru^{II}, Ru^{III} \quad (a)$$

data for the two electrochemical processes in Scheme 1 or by equilibrium studies.[6] In the case of $\mathbf{5}^{n+}$, both potentials are

$$Ru^{II}, Ru^{II} \rightleftharpoons Ru^{II}, Ru^{III} + e$$

$$Ru^{II}, Ru^{III} \rightleftharpoons Ru^{III}, Ru^{III} + e$$

Scheme 1.

sufficiently different to allow a direct determination of K_c.[12] However in the case of $\mathbf{6}^{n+}$ and $\mathbf{7}^{n+}$, a single electrochemical wave is observed, which precludes a similar determination of K_c. Nevertheless, this is possible by using a redox titration, in which the optical density ($\log I_o/I$) is plotted as a function of the amount of oxidant or the quantity of electricity in an electrolysis. This is basically the procedure described by Taube et al. some years ago[6] but with a least squares refinement of the comproportionation constant, as described elsewhere.[17] The values obtained in this way are collected in Table 1. As could be anticipated, for the longer system $\mathbf{7}^{2+}$ the K_c value approaches the statistical value of 4.

The spectra of the mixed-valence complexes are depicted in Figure 1. In the case of $\mathbf{5}^{3+}$, the directly recorded spectrum is shown, because the comproportionation constant is large enough; the corrected spectra given for $\mathbf{6}^{3+}$ and $\mathbf{7}^{3+}$ were obtained by subtracting the contribution of the homovalent species. All complexes display an intense intervalence transfer (IVT) band in the near-infrared (NIR) region (Table 2). This band is exceptionally intense for $\mathbf{5}^{3+}$. It decreases with intermetallic distance but remains strong even for $\mathbf{7}^{3+}$.

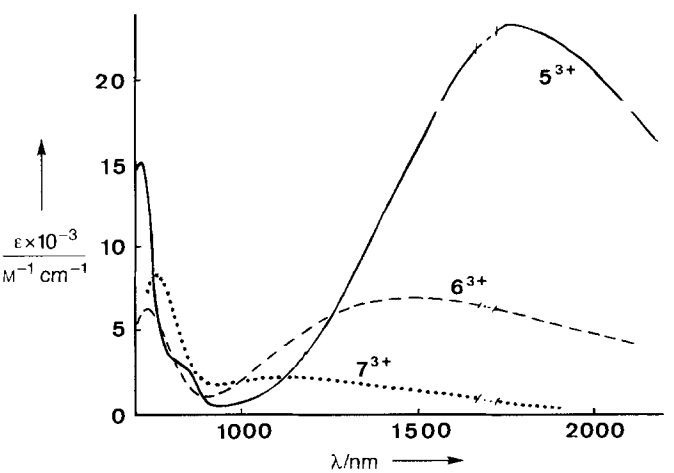

Fig. 1. Corrected spectra of the mixed-valence dinuclear complexes $\mathbf{5}^{3+}$, $\mathbf{6}^{3+}$, and $\mathbf{7}^{3+}$ showing the intervalence transitions.

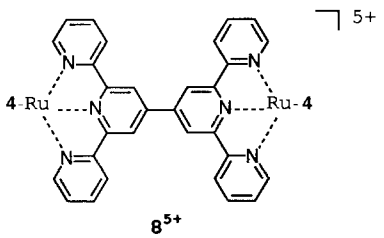
There is some overlap of the intervalence band with the nearby charge transfer band in the case of $\mathbf{6}^{3+}$ and especially of $\mathbf{7}^{3+}$. Nevertheless, this does not preclude a quantitative evaluation of

Table 2. IVT bands in the NIR region [a] and calculated matrix elements V_{ab} for the diruthenium complexes 5^{3+}, 6^{3+}, 7^{3+} and 8^{5+}.

Complex	Ru–Ru [b] [Å]	λ_{max} [nm]	$\Delta\tilde{\nu}_{1/2}$ [cm^{-1}]	ε_{max} [M^{-1} cm^{-1}]	V_{ab} [eV]
5^{3+}	11	1936	2660	22000	0.127
6^{3+}	15.5	1650	5112	6600	0.074
7^{3+}	20	1214	5714	2200	0.041
8^{5+} [c]	11	1580	4008	1620	0.047



[a] In CH_3CN. [b] Approximate distances. [c] Ref. [11].

the data. We have deconvoluted the spectra into a sum of Gaussian components using a method already proposed by Reimers and Hush[9] and described elsewhere.[17]

The intervalence band parameters allow the determination of the metal–metal coupling parameter V_{ab}, according to the Hush formula [Eq. (b)], where V_{ab} is the coupling in cm^{-1}, ε_{max} the

$$V_{ab} = 2.05 \times 10^{-2} (\varepsilon_{max} \tilde{\nu}_{max} \Delta\tilde{\nu}_{1/2})^{1/2} / R_{MM} \quad \text{(b)}$$

maximum extinction coefficient, $\tilde{\nu}_{max}$ the band position in cm^{-1}, $\Delta\tilde{\nu}_{1/2}$ the full-width at half-maximum in cm^{-1}, and R_{MM} the metal–metal distance in Å. For comparison, the same set of data for the dinuclear complex 8^{5+} containing two RuN_6 moieties is also included in Table 2.

8^{5+}

From the V_{ab} values of Table 2 it is obvious that the biscyclometalated complexes 5^{3+}, 6^{3+}, and 7^{3+} are very strongly coupled, considering the large metal–metal separations, (11–20 Å). Noteworthy is the dramatic difference between the isoelectronic complexes 5^{3+} and 8^{5+}, which have a very similar Ru–Ru distance. In fact, the electronic coupling in the noncyclometalated system 8^{5+} is similar to that in compound 7^{3+} (comparable V_{ab} values), despite the much longer bridge in 7^{3+} (four aromatic rings as opposed to two in the connecting rod).

It is interesting to search for the theoretical reasons for these differences. We have thus determined the V_{ab} couplings by Extended Hückel calculations.[19] First we compared the bis(N_6) complex 8^{5+} with the bis(N_5C) complex 5^{3+}. Even though the crystal structure of 5^{3+} (with PF_6^- as counterion) shows a small dihedral angle (22°) between the two halves of the molecule,[12] the calculation was made for a planar conformation, which greatly simplifies the discussion. (An investigation of the angle influence shows a decrease of only 7% of the coupling between 0 and 20°). The values thus obtained are reasonably close to the experimental ones (Table 3) and confirm the higher coupling of the cyclometalated species. Analysis of the energy levels and eigenvectors shows that on passing from 8^{5+} to 5^{3+} there is a general increase in the energy of the ligand levels, which induces a stronger mixing with the metal orbitals. (This effect is also apparent in a theoretical comparison of N,N and C,N donors using the Fenske–Hall method.[20]) Since furthermore the Ru–C bond is shorter than the Ru–N bond by 0.1 Å,[12] it is not surprising that stronger coupling results.

Table 3. Experimental and calculated values (from Extended Hückel calculations with planar conformation of the bridging ligand) of the metal–metal couplings (in eV) for complexes of the type [(terpy)Ru–bridging ligand–Ru(terpy)]$^{n+}$; comparison of 5^{3+} and 8^{5+}.

Bridging ligand	Complex	V_{ab}, expt.	V_{ab}, calcd.
bis(terpy)	8^{5+}	0.047	0.047
1^{2-}	5^{3+}	0.127	0.090

Thus the higher coupling through bis(N,C,N) ligands can be mainly explained by their strong electron-donating character. Clearly, the charge transfer from the bridging ligand to Ru^{III} is much more favorable for 5^{3+}, 6^{3+}, and 7^{3+} than for 8^{5+}, in agreement with orbitals with matching energies. This energy matching principle has recently been applied to diruthenium compounds with terminal cyclometalating ligands and a normal bis(terpy) bridge and also leads to high coupling.[21] However, in the present study the influence of the N/C exchange is not correctly reproduced by the Extended Hückel method. Calculational work with more advanced methods is in progress to improve our description of these systems. Another open problem is the more rapid decrease of the metal–metal coupling with distance in the case of the bis(N,C,N) complexes (see Fig. 2). This seems to confirm an earlier prediction that it is difficult to obtain simultaneously both strong coupling and a low decay rate.[22]

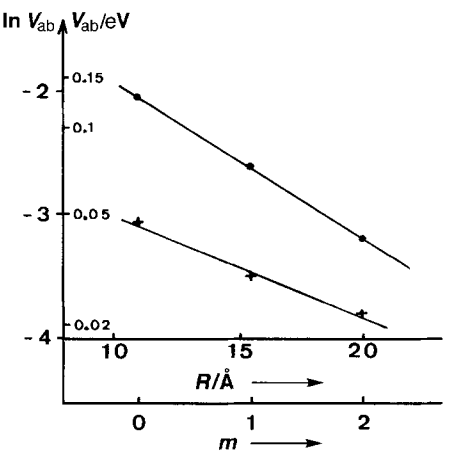


Fig. 2. Decrease in the metal–metal coupling for the isoelectronic series: bis(terpyridyl) (+) and biscyclometalated complexes (●).

In conclusion, the present series of dinuclear complexes displays intense electronic coupling over up to 20 Å in their mixed-valence forms. This reflects a favorable ligand-to-metal charge transfer interaction owing to the strong reducing character of the bis(cyclometalated) bridging systems.

Experimental Procedure

The synthesis of 5^{2+}, 6^{2+}, and 7^{2+} has been reported elsewhere [12,13,15]. The complexes were electrolyzed in acetonitrile containing 0.1 M NBu_4PF_6. The complex concentration was in the range 5×10^{-5} to 1×10^{-4} M, and the progress of the oxidation was followed coulometrically. UV/VIS/NIR spectra were recorded during the electrolysis with 1 cm cells and a Shimadzu UVPC 3101 spectrophotometer. The determination of comproportionation constant and the deconvolution of intervalence and charge transfer bands have been described elsewhere [17].

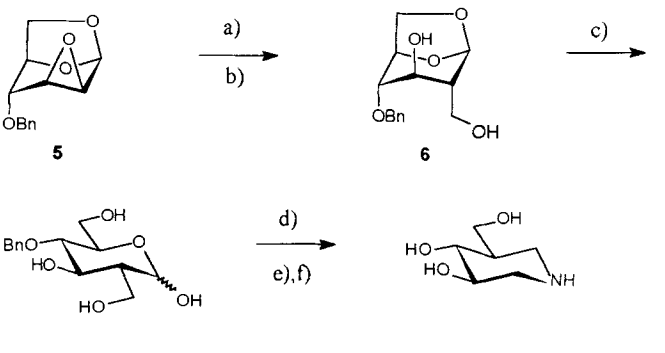
Isofagomine, a Potent, New Glycosidase Inhibitor**

Tina M. Jespersen, Wenling Dong, Michael R. Sierks,* Troels Skrydstrup, Inge Lundt, and Mikael Bols*



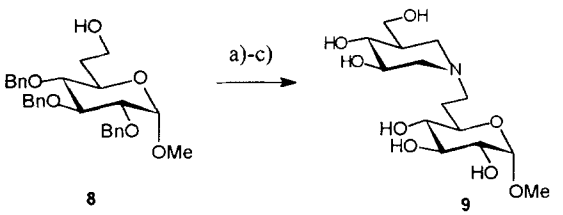
Glycosidases are an important group of enzymes that have been the subject of intense research.[1] The strong interest in the development of glycosidase inhibitors in the last decade was stimulated by the isolation of potent, naturally occurring inhibitors.[2] However, there is still much debate about the exact steric and electronic nature of the transition state for enzymatic glycoside cleavage.[3] We rationalized that since the enzymatic glycoside cleavage would result in formation of carbocation **1**, a good mimic of the transition state would be a compound able to accept a positive charge at the anomeric position. In this paper we report the synthesis of such a compound, isofagomine (**2**) and a disaccharide analogue of **2**. These compounds appear to be good transition state mimics, as both compounds are strong inhibitors of several glucosidases; indeed, isofagomine is the most potent β-glucosidase inhibitor reported so far.

1 **2** **3**, R=H **4**, R=OH

A large number of sugar analogues having a nitrogen atom in place of the oxygen atom in the ring, such as fagomine (**3**)[4] and deoxynojirimycin (**4**)[5], have been reported to be glycosidase inhibitors.[6] Surprisingly no sugar analogues with a nitrogen in place of the anomeric carbon have ever been prepared. In an attempt to design a good transition state mimic, we chose glucose analogue **2**, in which the oxygen atom in the ring has been replaced by carbon, the anomeric carbon replaced with nitrogen, and the 2-hydroxyl group removed. Compound **2** should have the general structure of glucose, be stable, and be able to accept a positive charge at the anomeric position.

The synthesis of **2** started from known epoxide **5**,[7] a compound that can be prepared in four steps from levoglucosane (Scheme 1). Opening of the epoxide by reaction with ten equiv-

Scheme 1. a) CH_2=CHMgBr, THF, 87%; b) 1. O_3; 2. $NaBH_4$, 96%; c) 1 M H_2SO_4, reflux, 1 h, 97%; d) $NaIO_4$, MeOH/H_2O 1:1, 45 °C, 5 h, 72–87%; e) NH_3/H_2O, H_2 (5000 kPa), Pd/C, 86%; f) H_2 (101 kPa), Pd/C, HCl, 71%.



alents of vinyl magnesium bromide in refluxing THF[8] gave the corresponding 2-*C*-vinyl compound in 87% yield, which upon ozonolysis[9] in ethanol at 0 °C and subsequent reduction with $NaBH_4$ was converted into the 2-*C*-hydroxymethyl derivative **6** in 63% yield. Hydrolysis of this 1,6-anhydride in refluxing 1 M sulfuric acid gave 4-*O*-benzyl-2-deoxy-2-*C*-hydroxymethyl-D-glucose (**7**) in 97% yield. Treatment of **7** with five equivalents of $NaIO_4$ at 45 °C resulted in slow cleavage of the bond between C-5 and C-6 to give the resulting dialdehyde, which was isolated in yields from 72 to 87%. This reaction is sluggish compared to other similar cleavages with periodate, because only the open-chain form of the compound reacts. Hydrogenation[10] of the dialdehyde in 0.23 M ammonia in EtOH gave the piperidine in 86% yield, surprisingly with the 4-*O*-benzyl group intact. It was important to have a low concentration of ammonia during the

[**] This work was supported by NATO (grant CRG 930718).

ring closure to avoid formation of a 1,5-diamino compound. The benzyl group was removed by hydrogenation in the presence of hydrochloric acid to give the hydrochloride of isofagomine (**2**) in 71% yield.[11] Isofagomine is clearly in the $^4C_1$ conformation, as apparent from the large coupling constants (11–13 Hz) of the axial protons adjacent to the nitrogen atom, H-2ax and H-6ax, with H-3 and H-5, respectively. The hydrochloride salt could be converted to the free amine **2** by chromatography on silica gel (EtOH/25% NH_4OH, 10:1).

We also prepared a transition state analogue for enzymatic cleavage of the 1,6-linked disaccharide isomaltose. The sugar derivative **8**,[12] which has a hydroxyl group at C-7, was subjected to Swern oxidation[13] to give the corresponding aldehyde in 85% yield (Scheme 2). Reductive coupling[10] of the aldehyde

8 **9**

Scheme 2. a) $(COCl)_2$, DMSO, Et_3N, $-70 \rightarrow 20$ °C, 85%; b) **2**, H_2 (5000 kPa), Pd/C, 84%; c) H_2 (101 kPa), Pd/C, HCl, 94%.

with **2** in the ratio 1:1 by hydrogenation with palladium on carbon gave the tertiary amine in 84% yield, again with the benzyl groups intact. The benzyl groups were removed by hydrogenation in the presence of hydrochloric acid to give the isomaltose analogue **9** in 94% yield.[14]

To evaluate how well **2** and **9** mimic the transition state for glycoside hydrolysis, the inhibition constants of these compounds were determined for a number of glycosidases, α-glucosidase (yeast), β-glucosidase (almonds), and isomaltase (baker's yeast), with *p*-nitrophenylglycosides as substrates; the inhibition constants are listed with those of the known inhibitor deoxynojirimycin (**4**) in Table 1. Enzyme assays were performed at 37 °C in phosphate buffer (0.05 M, pH 6.8) as described in the literature.[15, 16] The constant K_m was calculated with the program Grafit;[17] the K_i values were calculated by plotting the apparent K_m values versus inhibitor concentration.

Table 1. K_i values for glycosidase inhibition [μM].

Enzyme [a]	**4**	**2**	**9**
α-glucosidase (yeast)	25.4	85.9	58.8
β-glucosidase (almonds)	47.5	0.11	2.32
isomaltase (baker's yeast)	11.2	7.23	103

[a] The enzymes were purchased from Sigma Chemical Co., St. Louis, MO (USA).

Isofagomine (**2**) is a better inhibitor than **4** against two of the three glucosidases, but shows the strongest inhibition against β-glucosidase; in this case its K_i value is 440 times lower than that obtained for **4**. In fact **2** is the most potent inhibitor of β-glucosidase from sweet almond known. The disaccharide analogue **9** has generally weaker inhibition, but is still a very potent inhibitor. It is not surprising that the K_i values for **9** are lower than those of isofagomine for the α- and β-glucosidase, because these enzymes are fairly nonspecific. Thus mimicking the aglycon group should not provide any additional binding. The poorer inhibition constant obtained with isomaltase is more surprising, but is probably because the glucoside substituent on nitrogen is equatorial for steric reasons and thus mimics a β-1,6 linkage more closely than an α-1,6 linkage. We are currently investigating this hypothesis.

In view of the many piperidine and pyrrolidine sugar analogues that have been prepared and tested for glucosidase inhibition, the strong inhibition of isofagomine is quite surprising, especially considering the high K_i values previously observed for fagomine (**3**). With all the recent work on glycoside inhibitors the structural features for a good azasugar inhibitor were considered to be well defined;[18, 19] one group even derived an equation to predict inhibition constants of compounds against β-glucosidases.[15] This equation implies that the K_i of isofagomine should be approximately 1 mM. Since the experimental value is 0.1 μM, this represents an error of 10^4. Apparently sugar analogues with a nitrogen atom in place of the anomeric carbon have not been accounted for in the structural analysis of glycoside inhibitors. The strong inhibition of compound **2** may arise from a specific interaction between the positively charged NH group in the anomeric position and a negatively charged carboxylate group. Apparently the structure for electrostatic interaction in the active site is more favorable in the β-glucosidase than in the α-glucosidase, which thus accounts for the large difference in inhibition contants beteen the two enzymes. Our findings imply that azasugars such as **4** may inhibit by the same mechanism. Apparently the geometric features do not favor this interaction, since **4** is a poorer inhibitor than **2**.

Human Oxalate—Really Just an End-Product of Metabolism?

Steffen Albrecht,* Herbert Brandl, and Christoph Schönfels

Oxalate is a product of human metabolism which is not currently considered to have any physiological importance. Gall stone and kidney stone complaints and calcification of organs are, of course, often caused by crystallization of calcium oxalate. Only plant cells[1] and certain bacteria (*Oxalobacter formigenes, Pseudomonas oxalaticus*) are known to metabolize oxalate [Eqs. (a), (b)].

$$HOOCCOOH + O_2 \xrightarrow{\text{oxalate oxidase}} 2CO_2 + H_2O_2 \quad (a)$$

$$HOOCCOOH \xrightarrow{\text{oxalate decarboxylase}} HCOOH + CO_2 \quad (b)$$

A highly sensitive and specific chemiluminometric method was developed to determine oxalate in body fluids.[2] It is based on the rapid oxidation of oxalate by H_2O_2 in the presence of carbodiimide and a suitable fluorophore at a low pH. The resulting intermediate, monoperoxyoxalic acid, breaks down into CO_2 and O_2 by exciting the fluorophore. The overall reaction is described by Equation (c) and the light emission by Equation (d). The emitted light can be measured with sensitive luminometers to detect very small oxalate concentrations to 200 nmol L^{-1}. Since interference from other organic molecules does not occur, the method is suitable for oxalate determination in biological samples.

$$(HOOC)_2 + H_2O_2 + R\text{-}N{=}C{=}N\text{-}R + F \xrightarrow{H^+} H_2O + 2CO_2 + R\text{-}NH\text{-}C(O)\text{-}NH\text{-}R + F^* \quad (c)$$

$$F^* \longrightarrow F + h\nu \quad (d)$$

(R = cyclohexyl; F = 9,10-diphenylanthracene; F* = fluorophore in first excited singlet state)

The determination of the oxalate content of human serum and plasma samples gave reproducible values which were different for the two media[3] and confirmed by data in recent literature.[4] Our experiments gave average values of 4.0 μmol L^{-1} for oxalate in plasma and 12.3 μmol L^{-1} for oxalate in serum—a result which was difficult to interpret at first.

During the examination of hemodialysis patients another noteworthy result appeared: The total amount of oxalic acid precipitated in the dialyzate significantly exceeded the amount that was calculated from the difference in oxalate concentration in the plasma before and after dialysis, taking the total blood volume into account. Possibly high intracellular oxalate concentrations are the cause of this discrepancy. It is known that partial lesion of human blood cells occurs, both during the coagulation process and high-speed centrifugation, and during the blood flow in the capillary tubes of the dialysis capsules. Hence intracellular oxalate concentrations were determined in erythrocytes, thrombocytes, granulocytes, and monocytes, since no reliable data was available.

These blood cells were obtained from 60 adults aged 20 to 40 years and separated using known methods (see Experimental Procedure). After a final washing step with physiological NaCl solution, the cell suspensions, which contained 10^5 to 10^6 cells per mL, were quick-frozen three times in liquid nitrogen, and 100 μL 15% HCl was added per mL cell suspension, which resulted in complete lesion of the cells. Next the oxalate concentration in the supernatant was determined by chemiluminometric measurements. Values between 0.1 and 10 mg L^{-1} were obtained. The average erythrocyte and thrombocyte volumes were determined using differential blood cell counting devices. Average volumes of 1100 and 3100 fL were assumed for granulocytes and monocytes, respectively, based on literature values.[5]

The oxalate concentrations summarized in Table 1 were calculated taking into account the relevant cell counts and volumes. The intracellular oxalate concentration exceeds that in the plasma by at least two orders of magnitude, independent of the cell type. The question of whether the oxalate is produced extra- or intracellularly cannot be answered at present. There is no evidence of active ATP-dependent transport processes for oxalate, as are known for alkaline and alkaline earth metal ions. It is likely that intracellular formation of oxalate is enzyme catalyzed from the precursors serine, L-hydroxyproline, tyrosine, phenylalanine, tryptophan, and L-ascorbic acid.[4] The intracellular oxalate concentrations are similar to the known concentrations of other substances in human cells. For example, the concentration of 2,3-diphosphoglycerate in erythrocytes is 4720 μmol L^{-1}.[5] Of course, the oxalate concentrations given in Table 1 have to be taken as total oxalate. It is not possible to state how the oxalate is present in vivo. Because oxalate is a small mono- or dianion, most of it should be bound, that is, complexed with transition metal cations. Since with our method the oxalate concentrations are measured at pH 1, the majority of the oxalate is present as the free monoanion or as the neutral acid; even calcium oxalate microcrystallites would dissolve under these conditions. The following questions thus arise: Is oxalate really just an end-product of human metabolism? If it is, what purpose do the high intracellular oxalate concentrations have?

Table 1. Average intracellular oxalate concentration in human blood cells and extracellular oxalate concentration in heparin plasma.

Cell type	No. of samples	Oxalate conc. [μmol L^{-1}]	2 SD [μmol L^{-1}] [a]
erythrocytes	60	615	±183
thrombocytes	36	890	±223
granulocytes	60	1830	±411
monocytes	26	2910	±638
heparin plasma	60	3.98	±1.68

[a] Standard deviation.

The enzyme-catalyzed oxalate metabolism known in the plant kingdom [Eq. (a)] could indicate that an oxalate oxidase pathway may also be important in human metabolism. A human enzyme with oxalate oxidase activity and the genetic determination of this enzyme would be prerequisite; we are currently conducting preliminary investigatious is this direction. The reaction products H_2O_2 and CO_2 have important biochemical functions: H_2O_2 forms a substantial component of the "respira-

tory burst" of cells capable of phagocytosis and is generated mainly from O_2 during inflammatory processes [Eq. (e)].

$$2H^+ + 2O_2^{\cdot-} \xrightarrow{\text{superoxide dismutase}} H_2O_2 + O_2 \qquad \text{(e)}$$

The oxalate oxidase pathway may be an alternative to Equation (e). It was recently confirmed experimentally that mechanisms should exist by which oxalate can be enzymatically converted in human blood cells. When separated human neutrophilic granulocytes are stimulated with endogenic noxious substances such as zymosan or endotoxin, the intracellular oxalate concentration, in comparison to unstimulated cells, is only 60 to 65% of the values given in Table 1. If investigations using molecular biology demonstrate the existence and genetic determination of one or more enzymes with oxalate oxidase activity, this would be the first time that it was shown that oxalate is not just a useless end-product of human metabolism. From our results it is not possible to state how oxalate exists in human blood cells, only that it is present in considerable amounts.

Experimental Procedure

Cell separation: The separation of the erythrocytes was performed by dextran sulfate sedimentation. Granulocytes were isolated from the supernatant by density gradient centrifugation, according to the method of Eckert [6]. Thrombocytes were separated by centrifugation, according to the method of Kazemi et al. [7]. Monocytes were isolated according to Hamid [8]. All cell counts were performed on a differential blood cell counting device from Coulter (Krefeld).

Chemiluminometric measurements: After centrifugation the cell-lysate superantants were measured with a luminometer LB 9503 from Berthold, Wildbad (100 µL sample volume, measuring time 4 s). Further details are given in ref. [2]. Duplicate measurements were performed, and the standard deviation was always less than 4%.

An Overall Picture of Biomembranes from the Mosaic of Data

Biomembranes. Physical Aspects. Edited by *M. Shimitzky*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 371 pp., hardcover DM 198.00, $ 135.00.—ISBN 3-527-30021-X/1-56081-771-2

This book is the first volume in a series that aims to provide a structure for the many-faceted subject of biological membranes; it is concerned with the physical phenomena that result from the integrity and fluidity of lipid double layers. This is a well-chosen topic to begin the series, as it introduces the basic principles for later discussions of membrane functions.

Although the present picture of lipid membrane structures is fairly clear, it is a mosaic made up of many thousands of publications. Does this book fulfill its claim to provide the picture with a structure? In my view it mainly does; three of the chapters achieve this especially well, and these will be described first. In Chapter 4 on "Fluidity, Dynamics, Order", B. Wieb van der Meer defines in a brief and simple way six types of dynamic processes in lipid membranes, then treats these in a textbook style, comparing and evaluating their importance. Molecular alignment, domain formation, and asymmetry in membranes are thoroughly discussed, as also are basic concepts, methods, and current problems. The bibliography to this chapter is systematically arranged and includes full titles, enabling the reader to quickly find material on topics of particular interest. Chapter 7 on the electrical properties of membranes (L. M. Loew) is much shorter, but this too strikes me as perfect in its way. Here again one finds an easily readable text, with illustrations that are precisely in harmony with it, and the titles of the most important publications are given. Also very pleasing is Chapter 6, in which Y. I. Henis gives a detailed description, with up-to-date illustrations, of the interesting method of "fluorescence photobleaching recovery".

On the other hand, the remaining four chapters are competently written surveys of particular topic areas, rather than attempts at providing a structure. In Chapter 1 D. Marsh summarizes the thermodynamic equations from the more extensive treatment in his book *Phospholipid Bilayers*, but a clear physical model fails to emerge from the illustrations or from the qualitative descriptions of the forces that are at work. Chapter 2, by D. Chapman, is concerned with phase transformations in lamellar, hexagonal, and cubic phases. In my view this does not really fit into the subject of biomembranes, despite the inclusion of a section entitled "Biological Relevance" which introduces comparisons with cell partitioning, domain formation, etc. The same comment applies to the topic of micelles in Chapter 3 by D. Lichtenberg, since to my knowledge micelles in the usual sense do not occur in biological systems. In contrast liposomes are not treated in sufficient detail. There are no electron micrographs of these, nor is there anything on fusion models or undulations. Most of the figures are more likely to mislead than to elucidate the text (examples: Figs. 8 and 9 show micelles that are not curved, which is very untypical; Fig. 4 shows turbidity occurring as a result of micelle formation, despite the fact that micellar solutions are nearly always quite clear; Fig. 2 shows molecular models that are cone-shaped, even though there are no examples of these). That leaves only Chapter 5 on lipid–protein interactions, by A. H. Parola, which is by far the longest in the book. I feel that the content of this chapter is well summarized by the author's comment on page 221 that "...work on membrane protein purification and reconstitution leaves very limited evidence of specific lipid requirements for membrane protein reactivation...". The listing of the many proteins whose interactions with liposomes have been investigated makes boring reading for the nonspecialist, and the discussion of the results yields few surprises. On the other hand, a novel idea that could be important is the model of malignant plasma membranes with intercalated domains of electroneutral lipids (also containing DNA?—this point is not made clear). The comprehensive survey of protein–lipid interactions is, of course, of central interest to the specialist reader.

The book is undoubtedly an important addition to the literature for the reader envisaged in the preface, who is engaged in research in this field. He or she will find here comprehensive information on membrane fluidity, membrane proteins, and electrical properties. However, this thorough coverage extends only up to 1988; beyond that it becomes thin. For the students also envisaged as potential users, I recommend Chapters 4, 6, and 7 as readable introductions; they will also find Chapter 5 useful, although much of it can be skipped over. With regard to the introductory Chapters 1–3, the student would be better served by other books, such as *Phospholipid Bilayers*, by G. Cevc and D. Marsh, *Membrane Mimetic Chemistry*, by J. H. Fendler, and *Intermolecular and Surface Forces*, by J. N. Israelachvili. It is not until Chapter 4 when the focus turns to biological aspects that the book begins to fulfill its special objective. One must therefore hope for the best in the volumes that are to follow.

Medicinal Chemistry. The Role of Organic Chemistry in Drug Research. Edited by *C. R. Ganellin* and *S. M. Roberts*. Academic Press, London, 1993. 302 pp., hardcover £ 29.00.—ISBN 0-12-274120-X

Eight years after the publication of the first edition of this book, this new edition has appeared. It consists of 14 chapters with 17 authors, offering the reader an excellent survey of the pharmacological aspects and the synthesis, development, and medical importance of new pharmaceutical products. The descriptions of pharmacologically active compounds and their meth-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ods of preparation are illustrated throughout by structural formula diagrams.

Seven of the chapters are revised and updated treatments of topics that were included in the first edition, and these appear at the beginning and end of the new version, as follows: Chapter 1, "Introduction to Receptors and the Action of Drugs"; Chapter 2, "Structure and Catalytic Properties of Enzymes"; Chapter 3, "Receptor Pharmacology"; Chapter 10, "Beta Blockers"; Chapter 11, "Salbutamol: A Selective β_2-Stimulant Bronchodilator"; Chapter 12, "Discovery of Cimetidine, Ranitidine and other H_2-Receptor Histamine Antagonists"; Chapter 14, "Clavulanic Acid and Related Compounds: Inhibitors of β-Lactamase Enzymes". The new chapters that have been added are: Chapter 4, "Drug Access and Prodrugs"; Chapter 5, "QSAR and the Role of Computers in Drug Design"; Chapter 6, "The Current Status and Future Impact of Molecular Biology in Drug Discovery"; Chapter 7, "General Approaches to Discovering New Drugs: A Historical Perspective"; Chapter 8, "Discovery and Development of Cromakalim and Related Potassium Channel Activators"; Chapter 9, "Angiotensin-Converting Enzyme (ACE) Inhibitors and the Design of Cilazapril"; Chapter 13, "Fluconazol, an Orally Active Antifungal Agent".

Following the introduction to the general principles of pharmacology in the first half of the book, the emphasis in the second half is on the practical importance of pharmaceutical compounds in areas where there is likely to be impressive progress in the age of our modern industrial society. Chapter 8 describes a new therapeutic principle for the treatment of cardiac and circulatory disorders and bronchial asthma, which is becoming increasingly important with the discovery of the mechanism whereby cromakalim acts as a potassium channel activator. Chapter 9 is concerned with ACE inhibitors, which are now the most favored agents for the treatment of hypertension and cardiac degeneration. The development of ACE inhibitors such as captopril, enalapril, and cilazapril is described, together with their biological properties. Chapter 10 discusses the chemistry, pharmacology, and clinical effects of beta blockers, which competitively and reversibly inhibit the positive inotropic and chronotropic effects of catecholamines on the heart (by blocking the β_1 receptors), and also inhibit bronchospasmolysis by blocking the β_2 receptors. Chapter 11 is concerned with salbutamol and analogous compounds derived from adrenalin and isoprenalin, which are used in the treatment of bronchial asthma. Chapter 12 is devoted to cimetidine and ranitidine, two compounds that rank as milestones in the development of H_2-receptor histamine antagonists and are used in the treatment of gastritis and ulcers; their preparation is described in detail and structure–activity relationships are discussed. Chapters 13 and 14 are concerned with antiinfectives, in particular with the widely used orally active antifungal agent fluconazol and with clavulanic acid which is used as an inhibitor of β-lactamase enzymes. A combination of clavulanic acid with amoxicillin has proved successful as a further development in the penicillins field.

This altogether excellent book, an enlarged revision of the edition published in 1985, is a valuable addition to other recently published books on medicinal chemistry (R. B. Silverman, *The Organic Chemistry of Drug Design and Drug Action*; B. Testa, W. Fuhrer, E. Kyburz, and R. Giger, *Perspectives in Medicinal Chemistry*; both published in 1992). *Medicinal Chemistry* contains many valuable articles which help the reader to understand important concepts of pharmacology and molecular biology, and describe new developments in pharmacological agents.

2D NMR. Density Matrix and Product Operator Treatment. By *G. D. Mateescu* and *A. Valeriu*. PTR Prentice Hall, Englewood Cliffs, 1993. 200 pp., hardcover $ 50.00.—ISBN 0-13-013368-X

This book aims to provide the reader with a detailed guide to analyzing multiple-pulse NMR experiments, using the density matrix and product operator approaches. The text is deliberately and unashamedly didactic in its approach, and the calculations are set out step-by-step without leaving out any intermediate results. In addition, the manipulations by which a result is simplified and interpreted are also set out in some detail.

The first section of the book is devoted to examples of the use of the density matrix approach, the first such example being an analysis of the HETCOR experiment whereby one observes ^{13}C and obtains a two-dimensional $^{13}C-^{1}H$ shift correlation spectrum. The authors introduce the concept of the density matrix, explaining how to set up the equilibrium conditions, the effect of pulses, how to calculate evolution, and finally how to calculate observables. Each of these ideas is introduced as it is needed in deducing the effect of the pulse sequence, and so there is a natural flow to the discussion, with the concepts appearing in context. Having completed the analysis, the authors then compare this with an attempt at a vector analysis of the sequence, showing that the vector method is at best cumbersome, and at its worst extremely confusing. The reader is left with the impression that multiplying matrices together is preferable to trying to understand the apparently random rules that govern these vectors.

The main criticism of this opening section is that it rather fudges the important issue of the connection between the terms one sees at the end of a calculation and the appearance of a two-dimensional spectrum. The authors do not make a clear distinction between terms which simply affect the amplitude or phase of a peak and those which contain the information about the frequencies present in the F_1 spectrum. Further, the connection between the form of these terms and the phase (or even sign) of the peaks in the spectrum is not well described.

The density matrix section goes on to cover the INADEQUATE and COSY procedures. As before, the issues of phase and lineshapes are somewhat lost, and the difference between the phase properties of the cross and diagonal peaks in COSY spectra receives scant attention. The section closes with a discussion of "phase cycling" in the COSY experiment; in fact the topic covered is frequency discrimination, which is rather a different matter.

The second section of the book goes on to introduce the product operator formalism, again using the approach of showing how a calculation is done and highlighting the rules by which these operators are manipulated. Some time is spend on establishing the relationship between the operators, their matrix representations, and observable signals; this is a welcome discussion. Once again HETCOR is used as the first example but, incredibly, this is the only *two-dimensional* experiment analyzed using product operators. The remainder of the examples are all one-dimensional experiments, such as DEPT; in these cases the analysis is extended to include magnetic equivalence. It is very unfortunate that the authors did not include COSY and double-quantum-filtered COSY as examples, as these both provide excellent vehicles for explaining the usefulness and properties of product operators. Generally speaking, this section on product operators does not read well; the overall impression is one of confusion, and a lack of structure and authority.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1717-1784 $ 10.00+.25/0

The book closes with a series of appendices which bring together the concepts used in the rest of the book, i.e., listings of matrix representations of rotation operators, properties of operators, rotations, etc. In addition some of the quantum-mechanical background is given in more detail, together with discussions of the more formal aspects of the theory.

This book has a thoroughly laudable aim — to show the reader exactly how to do density matrix and product operator calculations. There are few texts available which seek to do this and so, despite its less than ideal presentation of the subject, some will no doubt find this book a helpful guide.

Comprehensive Dictionary of Physical Chemistry. Edited by *L. Ulický* and *T. J. Kemp*. Ellis Horwood/PTR Prentice Hall, New York, 1992. 472 pp., hardcover $ 45.00.—ISBN 0-13-151747-3

Physical chemistry has grown by leaps and bounds in recent years. In the past dozen years alone, dramatic progress has been witnessed in areas as diverse as the imaging of atoms and molecules by scanning tunneling microscopy, the discovery and characterization of a host of new cluster molecules such as the fullerenes, the imaginative practical applications that have been found for theoretical concepts such as chirality or similarity, the breakthroughs in molecular recognition studies with the mapping of biological receptors and other species, the realization of the role played by chaos in chemical systems, and the rapidly developing uses of fuzzy logic and neural networks in the solution of a wide range of chemical problems. It has certainly been an exciting time and there can be little doubt that physical chemistry today is one of the most vibrant and dynamic areas of chemistry. Keeping pace with this exciting whirl of activity has not been easy, and so there is ample scope for review works such as dictionaries and encyclopedias to expound and elucidate what has been going on. Indeed, one turns to such works with a certain sense of relief to guide one through the intricate maze of development that is current physical chemistry.

Thus it was with eager anticipation that I embarked on reading the *Comprehensive Dictionary of Physical Chemistry*. My expectations were further heightened as I read on the opening pages that this work is to form part of a series that will "encompass outstanding works by world-class chemists" and moreover that the series as a whole is intended to "become a by-word for quality". Imagine then my disappointment when I discovered that not one of the research areas enumerated above had even been mentioned in this "comprehensive" dictionary! As I delved deeper into this work, my sense of frustration was compounded when it became apparent that this work not only failed to reflect the dynamism and energy of modern physical chemistry but that it also succeeded in making the physical chemistry of yesteryear uninspiring and boring. This double whammy set me to wondering how a book that was announced with so much fanfare could make an exciting subject seem so insipid. I eventually came to the conclusion that this work fails for three major reasons.

First, this dictionary was not originally written in English but is a translation from the Slovak. A team of eight translators were involved in this project, and differences in approach and style are all too evident. In some parts of the dictionary British English is used whereas American English is used in other parts. Worse yet, the language is often stilted and in some instances just plain wrong. Thus, we read on page 343 that radioactive elements are "chemical elements whose all isotopes are radioactive", and on page 193 that "although it is impossible to materialize a model of an ideal crystal, it represents an abstraction which is very useful mainly to explain laws governing crystal forms"; again on page 262 a molecule is defined as "the smallest stable particle constituting matter which is composed of atomic nuclei and electrons bound by chemical bonds and which exhibits its specific chemical properties". On occasion, the English thoroughly confuses the reader, as in the definition of the point group of a molecule on page 317: "a symmetry group that characterizes the symmetric properties of molecules", or when we are told that "the Schrödinger equation, just as the other postulates of quantum mechanics, cannot be derived" (p. 323).

Secondly, the dictionary contains more than a fair share of factually inaccurate or, at the very least, highly misleading statements. For instance, on page 27 the planetary model of the atom is ascribed to Rutherford, whereas this model was first put forward by the Japanese physicist Nagaoka. In the discussion on quantum chemistry on page 174, we are informed that the Hamiltonian of a molecule is "an operator of the total energy Born–Oppenheimer approximation". In fact, the Hamiltonian of a molecule and the Born–Oppenheimer approximation are two quite separate matters that should not be mixed up with one another. The treatment of symmetry (p. 412) becomes almost hilarious when it is stated that the human body consists of two halves, one being the mirror image of the other. One can only wonder where the authors imagine the human heart to be located! In spite of statements in the preface to this work that "entries were required to be factual" and that all entries were "scrutinized by readers, discussed by the specialist commission and approved by the editorial board" such errors are to be found in many entries in this dictionary.

Thirdly, the entire work is seriously out of date and is written in a style very reminiscent of the 1970s. This impression is reinforced by the 6-page bibliography at the end of the book; this lists references dating mainly from the 1960s and 1970s and earlier. Moreover, the presentation of the material is dry and unimaginative. The figures and diagrams are particularly poor, and when one thinks of some of the highly imaginative uses made of illustrations in many modern American technical books it is surprising that the publisher would want to put something so dreary on the market. Particularly when the work is billed as "a very direct source of contemporary physical chemistry"! All of which is most unfortunate, for there is presently a very real need for good guides to the current physical chemistry landscape. Whereas there are many encyclopedias and dictionaries of chemistry as a whole, there is precious little devoted specifically to physical chemistry. The work under review will not be able to fulfill the need, and so for the time being the gap will remain. Those on the cutting edge of physical chemistry who fancy themselves as budding lexicographers should please take note!

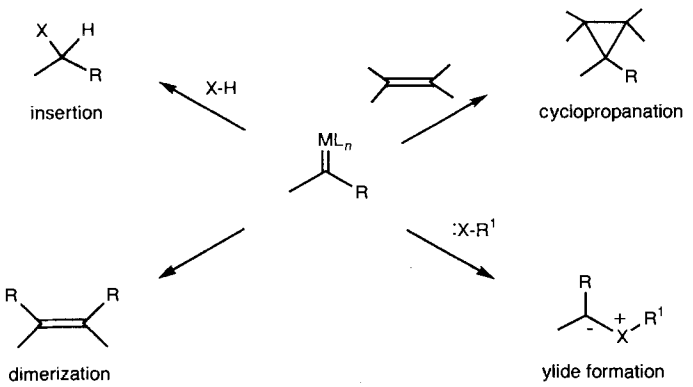
Ligand Effects on the Chemoselectivity of Transition Metal Catalyzed Reactions of α-Diazo Carbonyl Compounds**

Albert Padwa* and David J. Austin

The transition metal catalyzed reaction of α-diazo carbonyl compounds has found numerous applications in organic synthesis, and its use in either heterocyclic or carbocyclic ring formation is well precedented. Early work in this area made use of insoluble copper catalysts. Although these catalysts are still employed today, their use has decreased significantly with the advent of homogeneous copper catalysts and catalysts based on other metals. The discovery that Rh^{II} carboxylates facilitate nitrogen loss from diazo compounds rekindled significant interest in the field of diazo/carbenoid chemistry. Since the realization that Rh^{II} carboxylates are superior catalysts for the generation of transient electrophilic metal carbenoids from α-diazo carbonyl compounds, intramolecular carbenoid addition and insertion reactions have assumed strategic importance in C–C bond-forming reactions in organic synthesis. In contrast to other catalysts that are suitable for carbenoid reactions of diazo compounds, those constructed with the dirhodium(II) framework are most amenable to ligand modifications that, in turn, can influence reaction selectivity. This article will emphasize the chemical behavior of transition metal carbenoid complexes that are greatly affected by the nature of the ligand groups attached to the metal center. Much of the discussion will center on the ability of the dirhodium(II) ligands to determine reaction preference toward different functional groups on the same molecule.

1. Introduction

Catalytic methods for the generation of metallocarbenes have attracted a great deal of attention in recent years.[1–6] The early investigations of diazo compounds revealed that the problems of selectivity and reactivity could be significantly reduced by using transition metals for their decomposition.[7] The first example of a metal-mediated reaction of an α-diazo carbonyl compound was described by Silberrad and Roy in 1906.[8] Copper dust was added to accelerate the decomposition of ethyl diazoacetate yielding triethyl 4,5-dihydropyrazole-3,4,5-tricarboxylate and was described as follows: "When the diazoacetate is added to copper dust, no reaction appears to take place below 80°, but above that temperature the addition of the first drop of ester is accompanied by an explosion of sufficient violence to shatter the flask". From that time forward, a wide range of transition metal complexes have been used for α-diazo carbonyl decomposition. The most common transition metals include complexes of Cu^{II},[2] Rh^{II},[3] Mn^{II},[9] Fe^{II},[9] Co^{II},[9] Ni^{0},[10] Ni^{II},[11] Zn^{II},[12] Mo^{II},[13, 14] Ru^{II},[13, 15] Ru^{III},[13, 15] and Pd^{II}.[16] Many carbonyl[14, 15] and porphyrin[17] complexes, and to a lesser extent, Brønsted and Lewis acids have also been utilized.[18]



The metal-catalyzed reactions of α-diazo carbonyl compounds is not limited to cyclopropanation, even though the focus of many studies has centered on this transformation.[19] Metallocarbenoid reactions involving either X–H insertions (X = C, O, N)[20] or ylide generation[21] have also been used to prepare complex synthetic targets. Copper and rhodium complexes are particularly effective catalysts for reactions of diazo compounds, and an increasing number of chemical syntheses are based on this catalytic methodology.[3, 4] Some of the common reactions of metallocarbenes are given in Scheme 1.

Although many recent reports deal with the control of stereoselectivity[1–4] and—in particular with chiral catalysts—enantioselectivity[22] of metal-catalyzed α-diazo carbonyl reactions, a growing number of examples also addresses the question of chemoselectivity. Regioselectivity not only depends on the type of α-diazo carbonyl compound used, but is also governed by steric, conformational, and electronic factors. In certain cases, the nature of the solvent and the oxidation state of the metal can also play an important role. This review broadly defines the boundaries of our present knowledge in this field. Such an

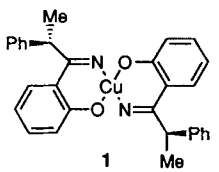
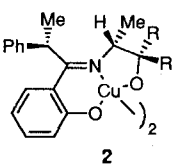


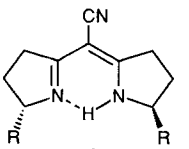
Scheme 1. Typical reactions of metallocarbenes. R = alkyl, aryl, or carbonyl.



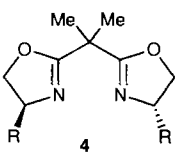
overview will put in perspective what has been accomplished. We hope it will provide impetus for further investigation of metal-catalyzed reactions of diazo carbonyl compounds.

2. Enantioselectivity in Carbenoid-Mediated Reactions

The ability of transition metal catalysts to induce asymmetry in catalytic cyclopropanation has attracted a great deal of attention recently.[22] The first report of cyclopropanation involving a chiral transition metal catalyst was described by Nozaki et al., who used the Cu^{II} complex **1**.[23] The enantiomeric excess (*ee*) obtained with this catalyst for the reaction of styrene with ethyl diazoacetate was only 10%. Aratani et al.[24] were able to increase the enantioselectivity of the cyclopropanation reaction greatly by using a different Cu^{II} complex (**2**) as the catalyst.



1



2

Further improvement in the enantioselectivity of cyclopropanation by using a copper catalyst containing the chiral semicorrin ligand **3**, R = alkyl, was reported by Pfaltz et al.[25] who later changed the ligand to the bis(oxazoline) ligands **4** and **5**;[26] these catalysts were studied independently by Evans et al.,[27] and Masamune et al.[28] The same catalysts also proved to be quite effective for aziridination[29, 30] and Diels–Alder[31] cycloadditions. Complexes containing other metals such as Fe^{III} and Mg^{II} with the same ligands are also effective catalysts for Diels–Alder reactions.[32] Other catalysts that show good

enantioselectivity for cyclopropanation include Nakamura's bis(1,2-dioximato)cobalt(II) (**6**),[33] Doyle's dirhodium(II) tetrakis(methyl 2-pyrrolidone-5-carboxylate) complex (**7**),[34] as well as (tribornylphosphito)copper(I) chloride,[35] copper(II) tartrate,[36] a trifluoroacetylcamphor complex of copper(II),[37] chiral iodoporphyrinrhodium(III) complexes,[38] and a variety of other rhodium(II) carboxylates,[39] carboxamides,[40] and binaphthylphosphonates.[41] Enantiomeric excesses are generally moderate to excellent, and this represents an area of intense current research and the subject of several timely reviews.[1, 22]

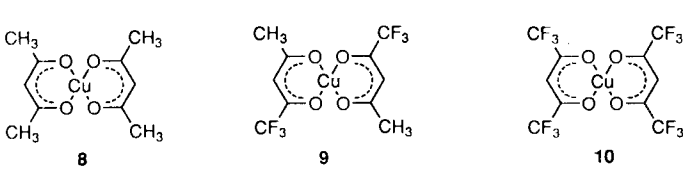
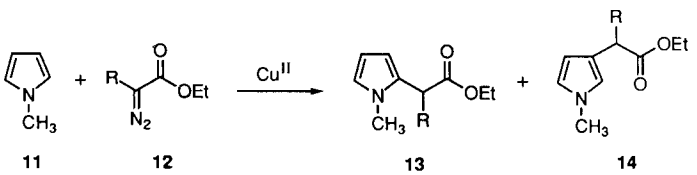
Albert Padwa was born in 1937 in New York City. He studied chemistry at Columbia University and received his Ph.D. in 1962 for his work with Cheves Walling on reactions of organic hypohalites. He spent a year (1962–1963) as a NSF postdoctoral research associate at the University of Wisconsin working with Howard E. Zimmerman on cyclohexenone photochemistry. In 1963 he was appointed Assistant Professor of chemistry at the Ohio State University. After three years he moved to the State University of New York, Buffalo, as an Associate Professor and was promoted to full professor in 1969. Since 1979 he has been the William P. Timmie Professor of Chemistry at Emory University in Atlanta. His research interest centers on heterocyclic chemistry, synthetic methodology using cycloadditions, the chemistry of small rings, photochemistry, and the utilization of transition metal carbene complexes for organic synthesis.

3. Copper Catalysts for Carbenoid Generation



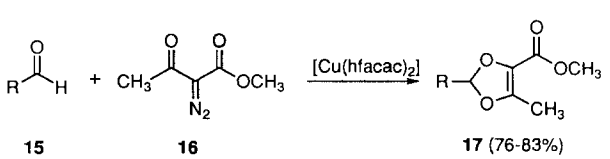
Copper is a group IB (Group 11) element in the first transition series with atomic number 29, a relative atomic mass of 63.546, and an electron configuration of $1s^2 2s^2 2p^6 3s^2\ 3p^6 3d^{10} 4s^1$ for its neutral metal Cu^0. The more common oxidation states of copper include 0, I, II, III, and IV. Copper(I) is a d^{10} transition metal that shares formal stoichiometry with the alkali metals, but retains its transition metal character. Two-coordinate copper forms linear complexes, while three-coordinate copper has a planar geometry. Complexes of four-coordinate copper are most often tetrahedral, but can also be square-planar. Six-coordinate copper complexes are octahedrally disposed. An example of some transition metal geometries and their respective d-orbital hydridizations are given in Scheme 2.

Scheme 2. Geometries of the complexes, the hybridization of the central metal atom, and the orbitals of the metal participating in hybridization.



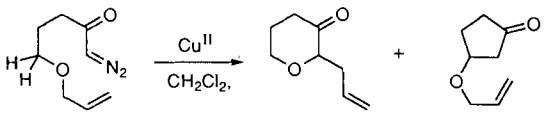
Copper(II) is a d^9 transition metal with a trigonal-planar geometry in three-coordinate complexes, while four-coordinate species have been found in both distorted tetrahedral and square-planar geometries. Five-coordinate systems are trigonal-bipyramidal, and six-coordinate complexes are commonly octahedral. In addition to copper metal, both Cu^I and Cu^{II} complexes can decompose α-diazo ketones. Copper catalysts for α-diazo ketone decomposition are traditionally classified as either heterogeneous or homogeneous. Some examples of heterogeneous copper catalysts are Cu powder,[42] Cu_2O,[43] $CuSO_4$,[44] and CuX (X = Cl, Br).[45] Homogeneous copper catalysts such as trifluoromethanesulfonatocopper(I) (copper(I) triflate)[46] and $Cu^I(PR_3)$[47] were developed later and have since played a major role.[48] Because Cu^{II} is reduced to Cu^I by the diazo functionality,[46, 49] Cu^I is probably the active catalytic species. Since copper(II) triflate is much easier to handle, it is often employed in place of copper(I) triflate.[50] Another homogeneous catalyst, $[Cu(acac)_2]$ (**8**), has also been used for cyclopropanation,[39] heteroatom insertions into X–H (X = N, O) bonds,[40] and ylide formation.[41] Products derived from carbon–hydrogen insertions are less prevalent, but have been reported as side products in moderate yield.[51, 52] Of all the copper catalysts, $[Cu(acac)_2]$ has the unique ability to be altered electronically without changing the overall geometry. The complexes [Cu(tfacac)$_2$] (**9**) and [Cu(hfacac)$_2$] (**10**) are conveniently prepared reagents that are useful for exploring the effect of electronically different ligands on the reactivity of copper carbenoids.

X-ray crystallographic data shows that the $[Cu(acac)_2]$ complex **8** has a Cu–O bond length of 1.90 Å,[53] while that of the hexafluoroacetylacetonate complex **10** is slightly longer (1.96 Å).[54] The complexes are both square planar, but [Cu(hfacac)$_2$] is often isolated in an octahedral geometry with axially disposed dative ligands.[55] Many perfluorinated copper(II) acetylacetonate complexes have been synthesized,[56] and the effects of the electron-withdrawing groups on their Lewis acidity and thermodynamic behavior have been reported.[57] The fluorinated copper compounds **9** and **10** are commercially available, as is the $[Cu(acac)_2]$ complex **8**.



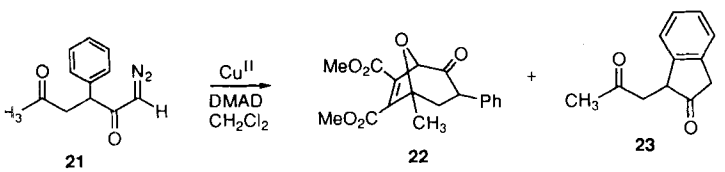
4. Chemoselectivity of Copper Carbenoid Mediated Reactions

One of the first studies on the effect of ligands on the reactivity of Cu^{II} catalysts was reported by Maryanoff,[58] who examined the insertion of the carbenoid derived from diazoester **12** into an aromatic *N*-methyl pyrrole. Thus, treatment of pyrrole **11** with either ethyl diazoacetate or ethyl diazomalonate in the presence of catalytic $[Cu(acac)_2]$ gave mainly the 2-substituted pyrrole **13** and a minor amount of the 3-substituted isomer **14**. When treated under identical conditions with [Cu(hfacac)$_2$], an overall increase in the yield of **13** was noted.



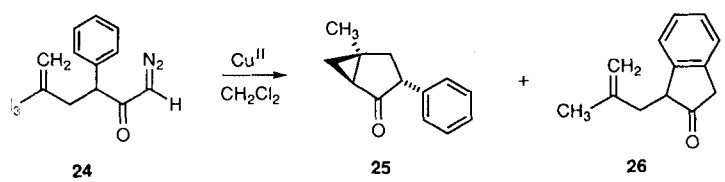
R = H	[Cu(acac)$_2$]	33%	3%
	[Cu(hfacac)$_2$]	45%	12%
R = CO_2Me	[Cu(acac)$_2$]	58%	7%
	[Cu(hfacac)$_2$]	73%	10%

Alonso and Garcia[59] reported on the efficient use of [Cu(hfacac)$_2$] in the reaction of 2-diazo-3-oxobutyrate (**16**) with aldehydes (**15**, R = alkyl, alkenyl, aryl) to give substituted 1,3-dioxole carboxylates (**17**). The reaction is high-yielding and free of the side products encountered with $[Cu(acac)_2]$, such as epoxidation, insertion, dimerization, and Wolff rearrangement. This



transformation was also adapted to electron-rich alkenes and alkynes with much success.[60]

An interesting example of the influence of the ligand of the copper catalyst on chemoselectivity was recently reported by Clark et al.,[52] who examined the use of several copper catalysts for the formation of oxonium ylides. When α-diazo ketone **18** was treated with a catalytic amount of $[Cu(acac)_2]$ in dichloromethane under reflux, the oxonium ylide rearranges to form pyran **19** and a small amount of insertion product **20**. $[Cu(hfacac)_2]$ as catalyst increases the yield of **19**, and no pentanone **20** was detected. Oxonium ylides with seven- and eight-membered rings were also synthesized selectively.

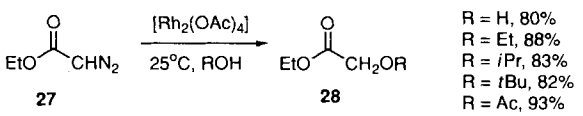


$[Cu(acac)_2]$	61%	12%
$[Cu(hfacac)_2]$	83%	0%

We encountered another example of an interesting chemoselectivity effect using Cu(II) catalysts in a study of the reaction of α-diazo ketone **21** in which carbonyl ylide formation (**22**) competed with aromatic C–H insertion (**23**).[61] In general,

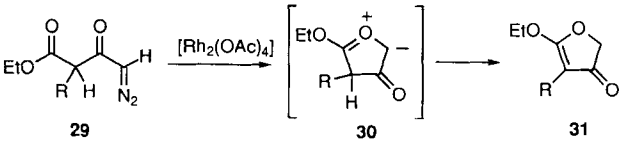
$[Cu(acac)_2]$	71%	19%
$[Cu(tfacac)_2]$	77%	0%
$[Cu(hfacac)_2]$	29%	0%

copper catalysts show a preference for cyclopropanation and ylide formation over C–H insertion. In the competitive copper-mediated reaction of α-diazo ketone **24**, all of the copper catalysts showed a preference for intramolecular cyclopropanation (**25**) to the total exclusion of aromatic C–H insertion (**26**).[61]



$[Cu(acac)_2]$	86%	0%
$[Cu(tfacac)_2]$	75%	0%
$[Cu(hfacac)_2]$	50%	0%

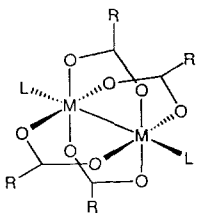
$[Cu^{II}(hfacac)_2]$ has also been used for the formation of arsonium, stibonium, bismuthonium, selenonium, and telluronium ylides.[62] These ylides could not be obtained by thermal or $[Cu(acac)_2]$ decomposition of the starting diazo compounds because the ylides were unstable under the harsh reaction conditions. The fluorinated catalyst exhibited much greater reactivity and allowed the generation of the ylides at significantly lower temperatures.



5. Rhodium Catalysts for Carbenoid Generation

The enormous utility of rhodium(II) carboxylates in the catalytic decomposition of diazo compounds has become apparent over the last decade.[1–6] Rhodium-mediated carbenoid reactions generally proceed under much milder conditions than is common for classical synthetic methodology with copper or its complexes.[7] In 1973 Teyssié et al. described the decomposition of ethyl diazoacetate (**27**) with $[Rh_2(OAc)_4]$[63] via a rhodium carbenoid intermediate and subsequent intermolecular O–H insertion with alcohols to produce ethers (**28**). Later they reported

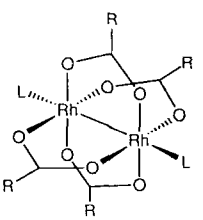
the ability of the rhodium catalyst to induce insertion of the diazo compound into N–H and S–H bonds. Insertion into C–H bonds was originally reported to occur only with $[Rh_2(tfa)_4]$,[64] but it is now widely accepted that all of the rhodium(II) carboxylates can induce this insertion reaction.[3]



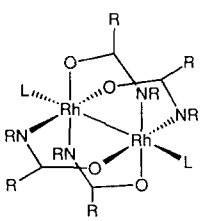
In the same year that Teyssié et al. described the first example of cyclopropanation using a rhodium catalyst (1976),[65] Bien et al. reported on the decomposition of an α-diazo ketone (**29**, R = alkyl) with formation of a carbonyl ylide intermediate (**30**) using $[Rh_2(OAc)_4]$.[66] Although the 1,3-dipole ultimately underwent a hydrogen shift to produce furanone **31**, the system was later modified to allow for intramolecular cycloaddition.[67] Since this early report, rhodium(II) has become the premier catalyst for α-diazo carbonyl decomposition.[1–4] Consequently, interest in the synthesis and chemical behavior of new Rh^{II} dimers has significantly increased in recent years.[68–70]

Rhodium is a Group VII (Group 9) element in the second transition series with atomic number 45, a relative atomic mass of 102.9055, and an electron configuration of $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^8 5s^1$ for its neutral metal Rh(0). Known oxidation states of rhodium include −I, 0, I, II, III, IV, V, and VI, but much of the chemistry of rhodium centers about the oxidation states I, II, and III. Rhodium(I), a d^8 transition metal, forms planar complexes when its coordination number is 3 or 4, although some four-coordinate rhodium complexes

are tetrahedral. Five-coordinate rhodium species are in trigonal bipyramidal environments. The most common Rh^{I} complexes in organic chemistry are Wilkinson's catalyst[71] $[Rh(PPh_3)_3]Cl$ and $[Rh(diphos)(thf)_2]^+$[72], both having been widely used in catalytic hydrogenation. Instead of diphos, chiral phosphane ligands have been employed with some success.[73] Monsanto's carbonylation of methanol to acetic acid[74] is an extremely successful commercial process involving homogeneous catalysis that proceeds through an anionic Rh^{I} complex, $[Rh(CO)_2I_2]^-$.



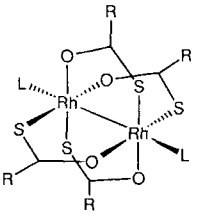
Rhodium(III) is a d^6 transition metal whose five-coordinate complexes can be either trigonal-bipyramidal or square-pyramidal. Six-coordinate Rh^{III} complexes such as the very useful $RhCl_3 \cdot 3H_2O$ are octahedral. Both Rh^{I} and Rh^{III} complexes have been shown to decompose diazo compounds,[63] but neither proved as efficient as Rh^{II}.



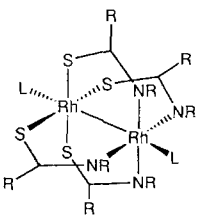
32

Rhodium(II) is a d^7 transition metal that has a propensity to form Rh–Rh metal bonds. The first reported rhodium dimer, the acetate **32** (M = Rh, $R = CH_3$) was initially described by Chernyaev et al.[75] as a rhodium(I) formate, but later its structure was corrected on the basis of single crystal X-ray diffraction studies.[76] $[Rh_2(OAc)_4]$ is the most common and best studied Rh^{II} catalyst.[68, 69]

Other transition metals that form metal–metal bonds centered within carboxylate bridging ligands include Re,[77] Tc,[78] Mo,[79] W,[80] Cr,[81] Ru,[82] Os,[83] Pt,[84] Cu,[85] and mixed Cr–Mo complexes.[86] $[Mo_2(OAc)_4]$[87] decomposes α-diazo ketones with limited success, but less is known about the other catalysts. The ligands associated with rhodium(II) dimers can be categorized as bridging (RCO_2 in **32**) or axial (L in **32**). The bridging ligands, by convention, are used to categorize the rhodium dimers into seven different types. Dimers like **33**, with bridging carboxylic acid ligands, are known as rhodium(II) carboxylates. Amides and 2-oxypyridines are commonly used to form rhodium(II) carboxamides such as **34**. The analogous thio-



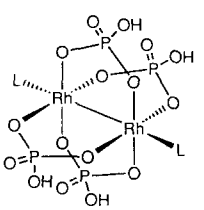
33



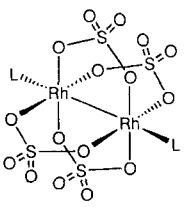
34

carboxylate (**35**) and thioamidate (**36**) complexes are much less common, but have also been prepared. Some additional species include the rhodium(II) phosphonates **37**, sulphonates **38**, and dirhodium complexes without bridging ligands (**39**).

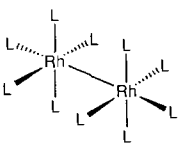
Axial ligands (L in **33**–**39**) form a much weaker bond to rhodium than bridging ligands,[88] and are easily removed by photolysis or by heating the complex under vacuum.[89] Some of the axial ligands found in complexes of rhodium(II) acetate are



35

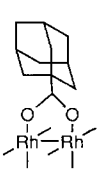


36

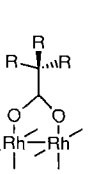


water,[90] thiol,[91] tetrahydrothiophene,[92] phosphane,[93] acetonitrile,[94] amine,[95] pyridine,[96] carbonyl,[97] formate,[98] thioformate,[99] halogen (X = Cl[100] and Br[101]), arsenic,[102] and antimony.[102] Since the axial position is believed to be the site of binding with the carbene center, these ligands are usually absent when the dimers are used for catalytic processes. Nevertheless, these ligands do influence the Rh–Rh distance, which in turn may be partially responsible for the reactivity of the carbenoid.

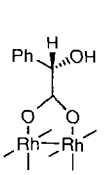
37



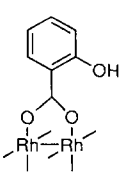
38



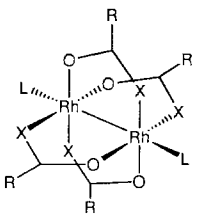
39



Rhodium(II) carboxylates containing a large variety of alkyl or aryl substituents have been prepared. Rhodium(II) acetate is readily made by heating $[Rh^{III}Cl_3 \cdot 3H_2O]$ with sodium acetate and glacial acetic acid in ethanol under reflux.[103] Complexes containing carboxylate ligands with lower pK_a values can be formed simply by treating rhodium trichloride with the appropriate carboxylate salt in ethanol.[104] Ligand exchange is another method of synthesis: Rhodium(II) acetate or octanoate is heated with a carboxylate salt in chlorobenzene. For acetate exchange, the solution is heated at reflux in a Soxhlet extraction apparatus which contains a 1:1 mixture of Na_2CO_3 and sand. This serves to remove acetic acid and drives the equilibrium toward completion. The types of complexes with bridging carboxylates that have been used include the adamantane-1-carboxylate (**40**),[105] the pivalate (**41**),[92] the triphenyl acetate (**42**),[105] the mandelate (**43**),[106] and the salicylate (**44**).[107] (Only one of the four bridging ligands has been depicted in the structural formulas in each case.)



40



41, R = CH_3
42, R = Ph

43

44

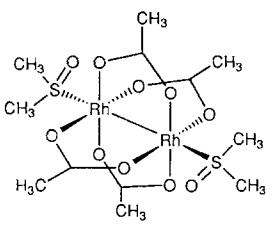
45

Rhodium(II) carboxylate complexes with ligands that have different electronic properties to acetate are most commonly those with perfluorinated substituents, for example, the trifluoroacetate complex $[Rh_2(tfa)_4]$ (**45**, R = CF_3; X = O) or the perfluorobutyrate complex $[Rh_2(pfb)_4]$ (**45**, R = C_3F_7; X = O). Although formally considered carboxylates, both the geometry and reactivity of these catalysts differ greatly from that of the rhodium alkyl carboxylates.

All of the rhodium(II) carboxylates that have been structurally investigated exist in the lantern arrangement, both with and without axially bound ligands (L). Changes in the length of the Rh–Rh bond of the dimer are directly related to its reactivity.[68] The Rh–Rh bond length for $[Rh_2(OAc)_4 \cdot 2H_2O]$ (**46**) was initially reported to be 2.45 Å,[76] but later corrected to 2.38 Å.[82, 90] The distance anticipated for a normal Rh–Rh single bond is on the order of 2.7–2.8 Å. This shorter distance originally led to the postulate of a Rh–Rh triple bond, which became the subject of much controversy, since the spectral evidence pointed to a single Rh–Rh bond. Theoretical calculations,[108] spectral measurements,[109] and ESR studies[88] have subsequently demonstrated that the Rh–Rh bond of the dimer is best described as a single bond. The Rh–Rh lengths of some typical complexes of type **45** are given in Table 1.

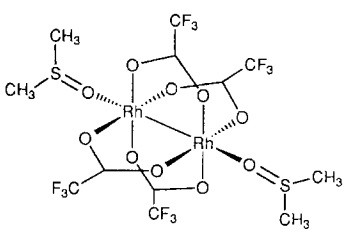
Table 1. Bond lengths for some typical Rh^{II} catalysts

Complex	X	R	L	Rh–Rh bond length [Å]
46	O	CH_3	H_2O	2.38
47	O	$C(CH_3)_3$	H_2O	2.37
48	O	CF_3	H_2O	2.41
49	S	CH_3	$CH_3C(S)OH$	2.55
50	S	$C(CH_3)_3$	PPh_3	2.58
51	O	C_3H_7	none	2.36
52	O	CH_3	MeOH	2.37
53	O	CH_3	$PhCH_2SH$	2.40
54	O	CH_3	pyridine	2.39
55	O	CH_3	PPh_3	2.45
62	NH	CH_3	none	—
63	NH	CH_3	DMSO	2.44
64	NH	CF_3	pyridine	2.47



The Rh–Rh bond of the carboxylates generally falls within the range of 2.37 to 2.49 Å. Standard alkyl and aryl carboxylates have the shorter bond lengths, while those of the perfluorinated type are longer. The electronic effect of the bridging ligand on the Rh–Rh bond is easily noted by a comparison of the pivalate $[Rh_2(piv)_4 \cdot 2H_2O]$ (**47**) with the trifluoroacetate $[Rh_2(tfa)_4 \cdot 2H_2O]$ (**48**). The effect of the electron-donating trimethylacetate ligand is to shorten the Rh–Rh bond (2.37 Å),[92] while the electron-withdrawing trifluoroacetate ligand has the opposite effect (length: 2.41 Å).[110]

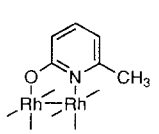
Rhodium(II) thiocarboxylates are much less common and characteristically less stable.[111] $[Rh_2(SAc)_4]$ (**49**)[112] and rhodium(II) thiopivalate $[Rh_2(tpiv)_4]$ (**50**)[113] possess long Rh–Rh bond lengths of 2.55 and 2.58 Å, respectively.



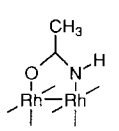
Axial ligands can significantly influence the length of the Rh–Rh bond.[88, 92] X-ray crystal structure analysis of rhodium(II) dimers without axially bound ligands are rare. Rhodium(II) butyrate (**51**) has no axial substituents and a Rh–Rh bond length of 2.36 Å.[114] As described earlier, the Rh–Rh bond of $[Rh_2(OAc)_4 \cdot 2H_2O]$ (**46**) is 2.38 Å long.[82, 90] When the water ligands are replaced with methanol (**52**), this distance shortens slightly to 2.37 Å.[114] The effect of the two benzylthiol groups in **53** is a lengthening of the Rh–Rh bond to 2.40 Å.[115]

Nitrogen ligands are common in Rh^{II} complexes and tend to lengthen the Rh–Rh distance to essentially the same value as in the thiol complexes. The Rh–Rh bond length in compound **54** (with pyridine ligands) was determined to be 2.39 Å.[116] A more dramatic bond lengthening is seen by the addition of triphenylphosphane at the axial position, giving rise to complex **55** which contains a Rh–Rh bond of 2.45 Å.[93]

Perhaps the most interesting axial ligand effect noted involves dimethyl sulfoxide (DMSO). As axial ligand in $[Rh_2(OAc)_4 \cdot 2dmso]$ (**56**),[92] DMSO bonds to rhodium through the sulfur atom. However, in $[Rh_2(tfa)_4 \cdot 2dmso]$ (**57**),[117, 118] the oxygen atom of the sulfoxide moiety is attached to the rhodium center.

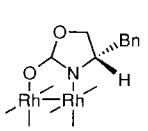


56

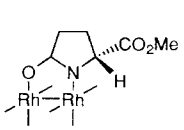


57

Sulfur is also the preferred ligating atom in rhodium(II) propionate[117] and rhodium(II) benzoate.[119] The ambidentate character of DMSO is well known, but a different site of attachment on the same metal within the same oxidation state is unusual.[120] This effect is not completely understood but is believed to be related to the greater Lewis acidity of $[Rh_2(tfa)_4]$ (caused by its electron-withdrawing ligands) than $[Rh_2(OAc)_4]$ (containing the more electron-donating alkyl ligands). In addition to influencing the distance between the Rh atoms, both the bridging and axial ligands can also alter the spectral properties of the rhodium dimers.[68] The clearest evidence is seen in the colors of complexes: $[Rh_2(OAc)_4(H_2O)_2]$ (**46**) and $[Rh_2(tfa)_4(H_2O)_2]$ (**48**) are emerald green and $[Rh_2(OAc)_4(PPh_3)_2]$ (**55**) deep red;[121] $[Rh_2(OAc)_4(dmso)_2]$ (**56**) exists as orange prisms, and $[Rh_2(tfa)_4(dmso)_2]$ (**57**) as dark blue needles.[117]



Another important class of rhodium(II) dimers are those in which one oxygen and one nitrogen atom are the ligating atoms of the bridging ligand instead of two oxygen atoms. A typical example of such a dimer is the 2-oxypyridine system (**58**).[122]

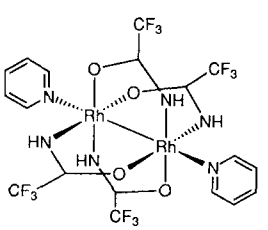


58

59

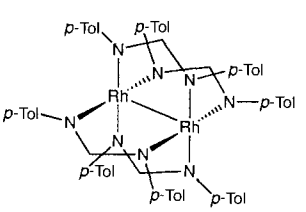
60

61



(For compounds **58**–**61** only one of the ligands are depicted). Other rhodium(II) carboxamides that have been prepared incorporate, for instance, acetamide (**59**),[123] or the chiral oxazolidinone (**60**)[124] and pyrrolidinone (**61**) ligands.[125] Catalysts **60** and **61** have become extremely important in enantioselective cyclopropanations.[22]

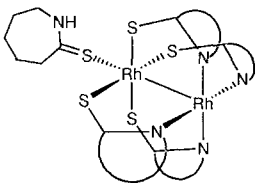
The oxypyridine rhodium(II) complexes, like the carboxamides, are structurally related to the carboxylates in that they both adopt the lantern structure. The Rh–Rh bond length for the oxypyridine system ranges from 2.35 to 2.36 Å and for the carboxamides from 2.39 to 2.45 Å. The absence of axial ligands has been proposed to account for the shorter Rh–Rh distance in the oxypyridine complexes. The substituent on the 6-position of the pyridine ring is located directly over the axial position, thus preventing coordination.[122]



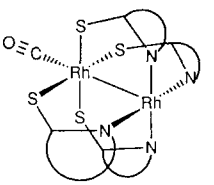
The effect of axial ligands on the carboxamide systems is not so clear, since fewer X-ray crystal structures have been performed on these complexes. The acetamidate $[Rh_2(acm)_4]$ (**62**, of type **59**) without axial ligands has been characterized, but no atomic parameters are available.[123] In the complex with DMSO in the axial position, $[Rh_2(acm)_4(dmso)_2]$ (**63**), the interrhodium distance is 2.44 Å.[126] The DMSO ligands bind to the Rh atom through sulfur, as in the alkyl carboxylates. This is consistent with a relatively electron-rich rhodium atom and is undoubtedly related to the electron-donating character of the nitrogen atom.

The trifluoroacetamide $[Rh_2(tfm)_4]$ is the only example of a perfluorinated carboxamide that has been reported to date. The complex containing axial pyridine ligands (**64**) has a Rh–Rh bond length of 2.47 Å,[127] which is slightly longer than that of a nonfluorinated carboxamide. The binding mode of DMSO with this complex would be worth investigating, since the bridging ligands contain both an electron-donating nitrogen atom and an inductively withdrawing trifluoromethyl group.

Only one example of a rhodium dimer with ligands bridging through two nitrogen atoms has been described: the Rh–Rh bond length in this *p*-tolylformamidinate $[Rh_2(fmd)_4]$ (**65**) is 2.43 Å.[128]

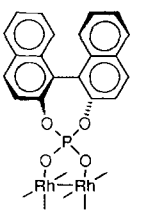


64

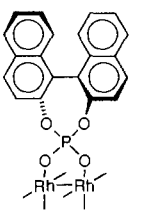


65

Structural studies on rhodium(II) thiocarboxamides indicate that these complexes exhibit some interesting geometric features. Unlike the thiocarboxylate and carboxamides, the thiocarboxamide ligands do not coordinate to the rhodium metal with a *trans* arrangement of S and N ligating atoms. Two thiocaprolactam complexes have been examined: each contain only one axial ligand, namely monodentate thiocaprolactam ($[Rh_2(tcap)_4(Htcap)]$ **66**) or carbonyl ($[Rh_2(tcap)_4CO]$ **67**).[129] In addition to the unique orientation of the bridging ligands, the single axial ligand coordinates to the Rh atom bearing only sulfur as ligating atom. The Rh–Rh bond in these complexes is rather long (2.49 Å).

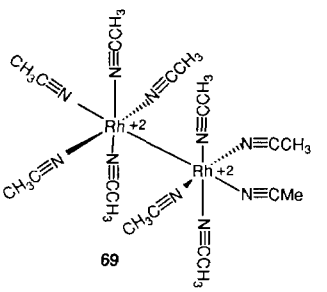


66



67

Sulfonate[130] and phosphonate[131] complexes were among the first noncarboxylate Rh^{II} catalysts to be prepared. The sulfonate complex was never structurally investigated, but rhodium(II) phosphonate $[Rh_2(HPO_3)_4(H_2O)_2]$ displays a 2.48 Å Rh–Rh bond.[132] These bridging ligands have not been extensively utilized, but the unusually long Rh–Rh bond of the phosphonate prompted the synthesis rhodium(II) complexes of (*S*)-(+)-1,1′-binaphthyl-2,2′-diylphosphate ($[Rh_2\{(S)\text{-bnp}\}_4]$[133] (**68a**)) from $Na_4[Rh_2(CO_3)_4]\cdot 2.5H_2O$ and of the (*R*)-(−) isomer ($[Rh_2\{(R)\text{bnp}\}_4]$[134] (**68b**)) by ligand substitution of $[Rh_2(OAc)_4]$. (In the structural formulas only one of the four ligands is depicted.)

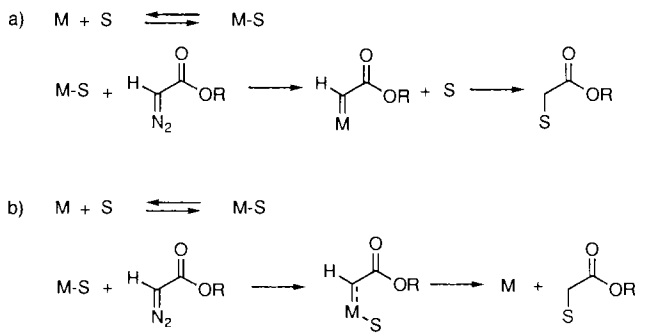


68a

68b

Two types of substituent commonly encountered in nonbridged rhodium(II) dimers are alkyl- or aryl-substituted cyano or isocyano ligands. An example of such a complex is the acetonitrile $[Rh_2(CH_3CN)_{10}(BF_4)_4]$ (**69**).[135] This field is a relatively new and growing area of research. Bond lengths in the nonbridged systems are the longest encountered: 2.62 Å for compound **69**,[135] and values ranging from 2.78 to 2.83 Å for the isocyanides.[136] Interestingly, these bonds more closely approximate a Rh–Rh single bond length of 2.7–2.8 Å.

69

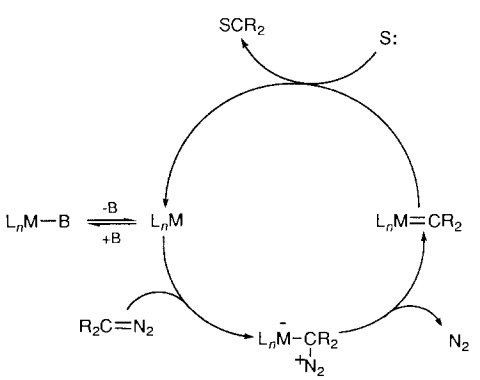


6. Chemoselectivity of Rhodium(II)-Mediated Reactions

6.1. Mechanism

Structural studies of the rhodium(II) dimers with their characteristic axial binding may ultimately provide insight into the structure of the carbenoid intermediate. A particularly interesting example reported by Doyle et al.[137] indicated that

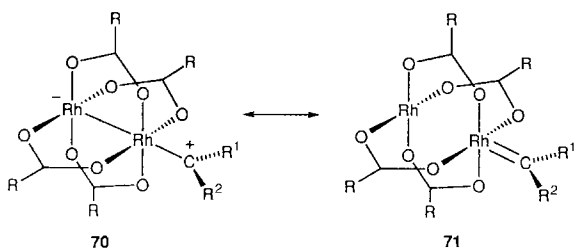
$[Rh_2(pfb)_4]$ can form π complexes with olefins, while none of the unactivated carboxylates or carboxamides exhibit this type of behavior. Unfortunately, no spectroscopic or crystallographic data is available for these π-bonded carbenoids. Proof of their existence and insight into the nature of the intermediate is obtained through reactivity–selectivity correlations with known, stable Fischer carbenes.[138]



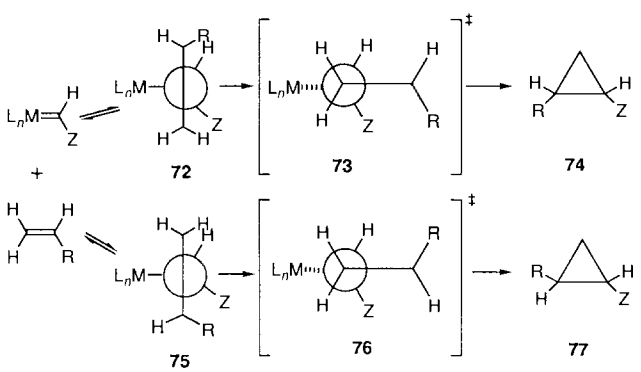
The first detailed description of a mechanism for the rhodium(II)-mediated decomposition of an α-diazo ketone was postulated by Teyssié et al. (Scheme 3).[63] In the first step a metal–

Scheme 3. Mechanism of the transition metal catalyzed reaction of α-diazocarbonyl compounds according to Teyssié et al. a) Carbenoid mechanism. b) Coordination mechanism.

substrate complex (M–S) is formed, which subsequently dissociates when the metal is attacked by the α-diazo ester. Extrusion of nitrogen results in formation of the metal–carbene complex. This complex then reacts with the substrate in what has been described as an attack from outside the coordination sphere of the metal (carbenoid mechanism). Teyssié proposed a mechanism, in which the metal–substrate complex remained intact during the formation of the metallocarbenoid (coordination mechanism). The substrate and carbene then react within the coordination sphere of the metal. Rhodium carbenoids are believed to react by the carbenoid mechanism and palladium carbenoids by the coordination mechanism.



Somewhat later Doyle proposed the catalytic cycle of Scheme 4 to explain the course of the reaction between an α-diazo carbonyl compound and a transition metal such as rhodium.[1] The first step of the sequence is decomplexation of the

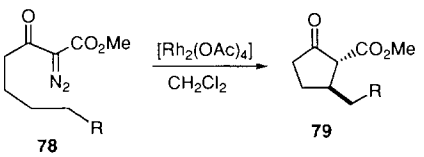


Scheme 4. Mechanism of the transition metal catalyzed reaction of α-diazocarbonyl compounds according to Doyle et al. S = substrate; M = metal; R = alkyl, aryl; B = Lewis base

metal from the Lewis base (that is, the solvent). This is followed by attack of the diazo functionality at the metal to form a zwitterionic metallo intermediate. At this point nitrogen is extruded, presumably through some sort of π backbonding, to form the metal carbenoid. The carbenoid can then react with the various substrates present (alkene, C–H bond, etc.), ultimately producing the observed product. The initial catalyst is regenerated to complete the catalytic cycle.

The resonance structures **70** and **71** have been proposed to describe the rhodium(II) carbenoid species.[1, 22] It should be noted, however, that no rhodium carbenoid has ever actually been isolated or observed by spectroscopy.

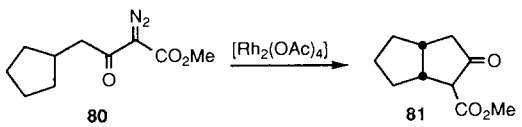
As the resonance structures **70** and **71** suggest, the carbenoid intermediate should behave as a metal-stabilized carbocation. Doyle has used this representation of the rhodium carbenoid in his proposed mechanism of cyclopropanation (Scheme 5).[1]



Scheme 5. Mechanism of cyclopropanation according to Doyle et al. Z = CO_2Et; R = alkyl.

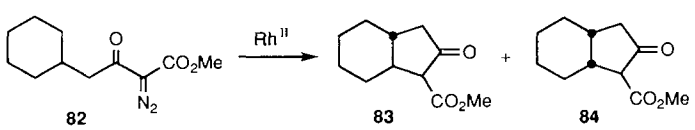
First, coordination of the rhodium carbenoid with the alkene leads to complexes **72** or **75**. The orientation of the alkene substituent R can be either *syn* or *anti* to the carbene substituent Z; the initial relationship is expressed in the cyclopropane products **74** and **77**, respectively. The σ bond forms at the least substituted C atom of the alkene, which enables better stabilization of the positive charge developed in the transition state (**73** and **76**) at the more highly substituted C atom. Backside displacement of the metal results in collapse of the complex with concomitant cyclopropane formation (**74** and **77**). Interaction of the R and Z groups in both the π complex and transition state were thought to be important in determining the relative amounts of the diastereomeric cyclopropanes produced.[139]

6.2. C–H Insertion Reactions



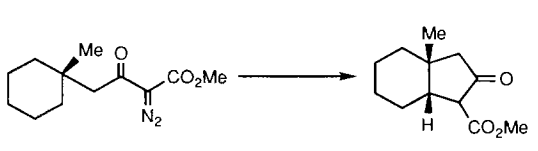
6.2.1. Steric Factors

Much of what is known today about intramolecular insertions into C–H bonds of carbenoids has come from independent studies by Taber et al.[140] and Doyle et al.[141] Initial reports involved the reaction of α-diazo-β-ketoester **78** with rhodium(II) acetate as the catalyst.[140] The major product isolated from this reaction was the 2-carboalkoxy-substituted cyclopentanone system **79**. This seminal report clearly demonstrated that with freely rotating acyclic systems C–H insertion can be an efficient process.[140]



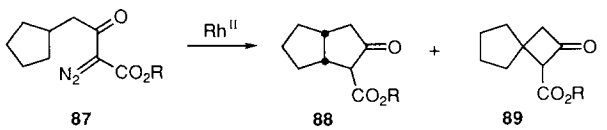
78 **79**

Steric factors may play an important role in determining the ratio of potential insertion products. Thus, insertion into C–H bonds of cyclopentane[142] gives only the *cis*-substituted products (example: **80** → **81**). However, when this insertion occurs



80 **81**

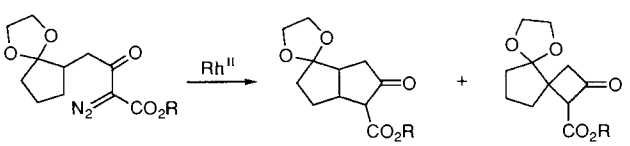
with a cyclohexane, the observed *cis* to *trans* ratio depends on the nature of the catalyst. For example, treatment of the diazo ketone **82** with $[Rh_2(OAc)_4]$ acetate led to a 3:1 mixture of the *trans* and *cis* insertion products **83** and **84**, respectively. Changing the catalyst to the octanoate $[Rh_2(oct)_4]$ increased the ratio to 5:1. With the even larger tetraphenylporphyrin rhodium chloride ([Rh(tpp)]Cl), the ratio increased to 15:1 in favor of the *trans* product. In contrast, when the methylcyclohexyl compound **85** was used as substrate, only *cis*-octahydro-1*H*-indole **86** was obtained. In this case, the methyl group blocks the approach of the rhodium carbenoid to the equatorial hydrogen that is responsible for the formation of the *trans* product.



82 **83** **84**

$[Rh_2(OAc)_4]$	3:1
$[Rh_2(oct)_4]$	5:1
$[Rh_2(tpp)]$ Cl	15:1

85 **86**

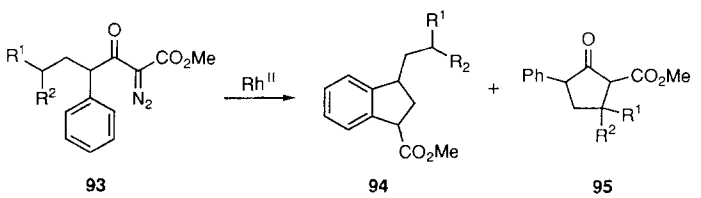


Cyclization of electrophilic rhodium–carbene complexes of conformationally mobile acyclic compounds results in the preferential formation of five-membered rings.[140] The order of reactivity of the target C–H site is methine > methylene > methyl.[140] Recently, Ikegami et al. have reported that triphenylacetate $[Rh_2(tpa)_4]$, which features a bulky bridging ligand on the rhodium metal, exhibits an exceptionally high order of selectivity for insertion into a methylene C–H bond rather than into a methine C–H bond in the catalytic decomposition of α-diazo-β-keto esters appended to cyclic systems.[143] The original papers by Taber et al.[140] and Cane and Thomas[142] reported that the reaction of diazo ester **87** (R = alkyl) with $[Rh_2(OAc)_4]$ yielded a 2:1 mixture of **88** and **89**. In contrast, the reaction of **87** with $[Rh_2(tpa)_4]$ led to the smooth formation of **88** (R = alkyl) with no detectable amounts of **89**. The virtually complete selectivity for insertion into the

87 **88** **89**

$[Rh_2(OAc)_4]$	2:1
$[Rh_2(tpa)_4]$	>30:1

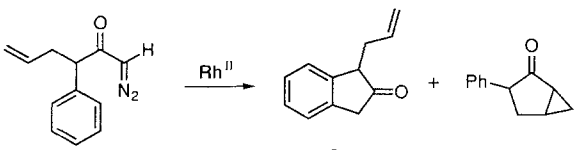
methylene C–H bond was ascribed to the steric bulk of the bridging ligand on the rhodium. This catalyst is superior to $[Rh_2(OAc)_4]$ for C–H insertion in a cyclic system. Also worthy of mention is the tetraacetamidate[144] $[Rh_2(acm)_4]$, which resulted predominantly in insertion into the methine C–H bond rather than into the methylene C–H bond because this catalyst discriminates on the grounds of electronic factors[145, 146] (see the reaction **90** → **91** + **92**). Hence, $[Rh_2(tpa)_4]$, for which steric factors control the regioselectivity, can be complementary to $[Rh_2(NHAc)_4]$ for site-selective C–H insertion reactions.



90 **91** **92**

$[Rh_2(OAc)_4]$	37:63
$[Rh_2(tfa)_4]$	56:44
$[Rh_2(acm)_4]$	14:86
$[Rh_2(piv)_4]$	37:63
$[Rh_2(OBz)_4]$	54:46
$[Rh_2(OCOCHPh_2)_4]$	64:36
$[Rh_2(OCOCMePh_2)_4]$	82:18
$[Rh_2(tpa)_4]$	96: 4

Rhodium(II) triphenylacetate, which features a bulky bridging ligand, has also been shown by the Ikegami group to be very much more selective for insertion into aryl C–H bonds than for insertion into aliphatic C–H bonds or for cyclopropanation in Rh^{II}-catalytic reactions with α-diazo carbonyl compounds.[147]



Taber and Ruckle had initially demonstrated that the energy requirements for aryl insertion were approximately the same as those for methylene insertion in the $[Rh_2(OAc)_4]$-induced reaction of α-diazo ketone **93**.[140] When $[Rh_2(tpa)_4]$ or the diphenylmethylpropionate $[Rh_2(O_2CCMePh_2)]$ was used, insertion into the aryl C–H bond (formation of **94**) predominated over methylene C–H insertion (formation of **95**). It was suggested that the larger steric bulk of the bridging ligand on the rhodium retards the methylene C–H insertion process.

93 **94** **95**

R^1, R^2 = H, CH_3		
	$[Rh_2(OAc)_4]$	85:15
	$[Rh_2(OCOCHPh_2)_4]$	54:46
	$[Rh_2(tpa)_4]$	96: 4

$[Rh_2(tpa)_4]$ catalysis also favors aryl insertion over cyclopropanation. Thus, the $[Rh_2(tpa)_4]$-catalyzed cyclization of **96** led to the formation of indan-2-one **97** in 83% yield, with no trace of the cyclopropane **98**, whereas $[Rh_2(OAc)_4]$ catalysis of **96** gave **97** and **98** in 26 and 63% yield, respectively.[147] It would seem that the steric bulk of the triphenylacetate ligand does not interfere at all with the insertion into aryl C–H bonds.

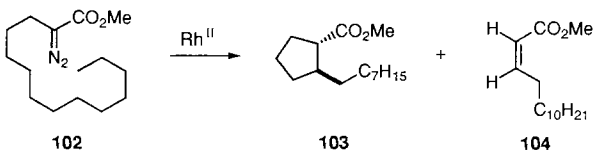
$[Rh_2(tpa)_4]$	83%	0%



6.2.2. *Electronic Factors*

The Taber group recently noted that the ligand on the rhodium(II) carboxylate catalyst plays an important role in the cyclization of α-diazo ketone **99**.[148] Strong electron-withdrawing ligands favor β-hydride elimination (to form **101**), while the 1,5-insertion reaction (→ **100**) is favored by electron-donating ligands. The more reactive rhodium carbenoid derived from the trifluoroacetate catalyst favors the entropically less demanding pathway (β-hydride elimination). A similar trend was noted with α-diazo ester **102**, which forms **103** and **104**.

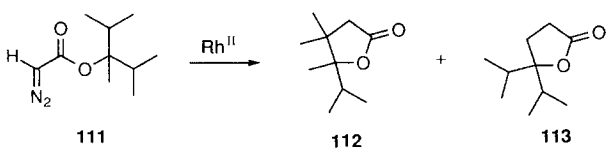
A detailed mechanism describing the role of the metal in the C–H insertion reaction was proposed by Taber et al. (Scheme 6):[140] Initial attack of the α-diazo carbonyl at the axial position of the rhodium dimer **105** gives intermediate **106**. This is followed by cleavage of the Rh–Rh bond with concomitant loss of nitrogen to generate **107**. At this point the rhodium metal needs to be electrophilic enough to coordinate with a C–H sigma bond in a three-centered arrangement (**108**). Electronic reorganization ultimately results in carbon–carbon bond formation **109**. A subsequent elimination of the rhodium hydride produces the C–H insertion product **110** and recovered catalyst. This highly speculative mechanism raises a number of

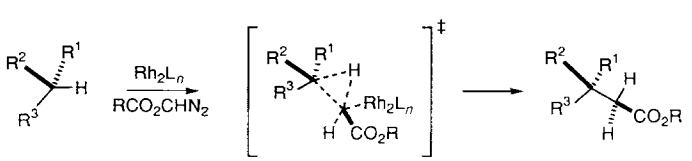


105 **106** **107** **108** **109** **110**

Scheme 6. Mechanism of C–H insertion according to Taber et al. R = alkyl, aryl; E = CO_2R'; R' = alkyl, aryl.

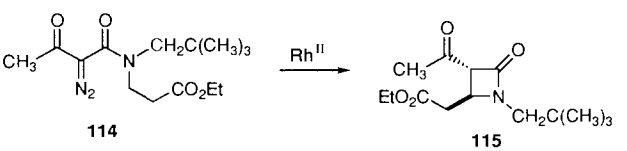
interesting issues. Cleavage of the Rh–Rh single bond is most unusual considering the high degree of stereoselectivity generally encountered in these reactions. According to the above suggestion, the electronic nature of the bridging ligand should have an effect on lability of the Rh–Rh bond and thereby influence the mechanism of the insertion reaction.

Carbenoid formation with α-diazo esters provides a convenient method for synthesizing highly substituted γ-lactones. Doyle's group has shown that treatment of 2,3,4-trimethyl-3-pentyl diazoacetate (**111**) with $[Rh_2(OAc)_4]$ in dichloromethane at 25 °C resulted in the formation of nearly equal amounts of the γ-lactones **112** and **113**.[141, 146] In the $[Rh_2(OAc)_4]$-catalyzed



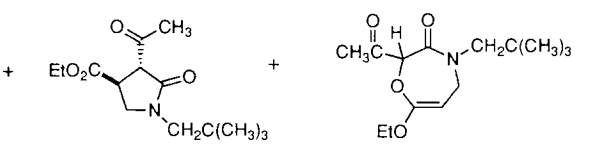
111 **112** **113**

$[Rh_2(OAc)_4]$	53:47
$[Rh_2(pfb)_4]$	32:68
$[Rh_2(acm)_4]$	99: 1



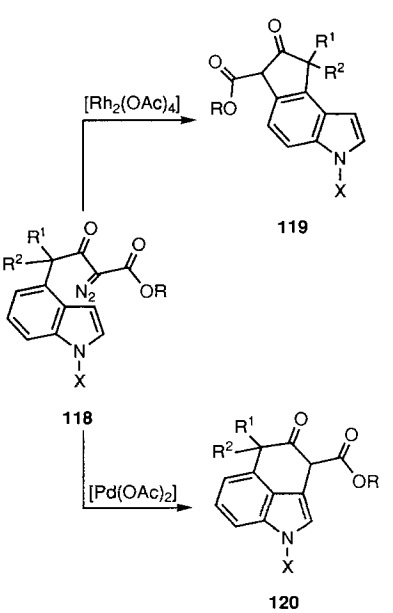
reaction, an approximately statistical distribution of C–H insertion products results. By changing the ligand on the catalyst, significant manipulation of the product ratio was achieved. While $[Rh_2(pfb)_4]$ afforded a mixture of lactones, use of the catalyst $[Rh_2(acm)_4]$ led to the exclusive formation of lactone **112**. Thus, regiocontrol in these reactions can clearly be achieved by ligand variation. The results also emphasize that the C–H insertion reaction occurs from a metal–carbene rather than a free carbene intermediate. The enhanced regioselectivity with donor ligands implies a tighter transition state for insertion reactions catalyzed by $[Rh_2(acm)_4]$.

Metal–carbene reactions catalyzed by dirhodium(II) carboxylates and carboxamides are electrophilic in character, resembling those of a metal-stabilized carbocation more than those of a metal–carbene.[1] Furthermore, the C–H insertion occurs with retention of configuration at the carbon–hydrogen bond undergoing reaction, and the high degree of enantioselectivity that is achieved with chiral dirhodium(II) carboxamides suggests that the ligands remain intact on the dirhodium framework during the insertion process. To account for these observations Doyle et al. suggested a mechanism for C–H insertion (Scheme 7)[141] that is fundamentally different from Taber's proposal.[140] The Doyle mechanism involves overlap of the p orbital of the carbene carbon with the σ orbital of the reacting C–H bond. C–C and C–H bond formation takes place concertedly as the metal–carbene dissociates. Electron-withdrawing ligands will increase the electrophilicity of the carbene thereby causing bond formation to take place at a greater distance from the reacting C–H bond (earlier transition state) with a resulting decrease in selectivity. Ligands with decreased electron-withdrawing ability, such as carboxamides, will result in a later transition state and greater selectivity.



Scheme 7. Mechanism of C–H insertion according to Doyle et al. R, R^1, R^2, R^3 = alkyl, aryl.

The importance of conformational factors in the intramolecular carbenoid reactions of α-diazoacetoacetamides has also been established by the Doyle group.[149] A series of diazoacetoacetamides, when treated with a catalytic quantity of a rhodium(II) carboxylate, afforded a product derived from a carbonyl ylide intermediate as well as those derived from intramolecular C–H insertion. Decomposition of **114** in refluxing benzene gave rise to a mixture of β- and γ-lactams (**115** and **116**) and, in addition, **117** arising from a carbonyl ylide. Changing the catalyst from $[Rh_2(pfb)_4]$ through $[Rh_2(OAc)_4]$ to $[Rh_2(acm)_4]$ yielded significant differences in the product distribution. The major

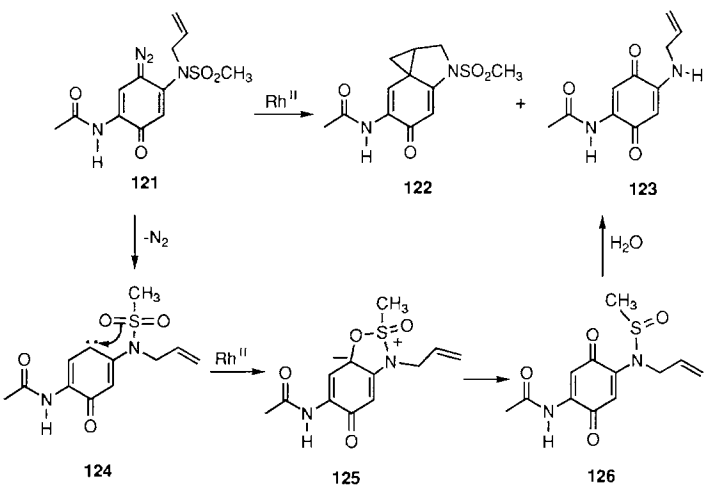


114 **115**

116 **117**

$[Rh_2(pfb)_4]$	22 : 17 : 61
$[Rh_2(OAc)_4]$	59 : 10 : 30
$[Rh_2(acm)_4]$	64 : 26 : 10

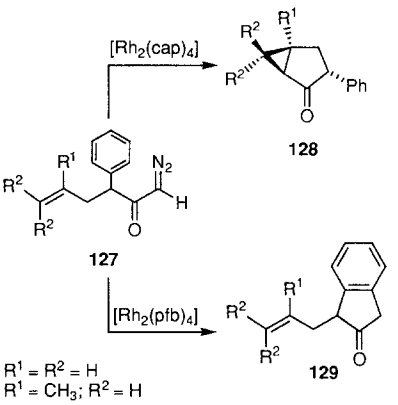
product from the $[Rh_2(pfb)_4]$-catalyzed reaction of **114** is **117**, which arises from ester carbonyl entrapment of the intermediate metal–carbene. This is undoubtedly related to the fact that this Rh^{II} complex possesses the highest oxophilicity of the three catalysts. Dominant formation of the β-lactam ring was attributed to a conformational preference that juxtaposes the carbenoid center and the less sterically encumbered amide substituent, which activates the C–H bond adjacent to the amide nitrogen atom.



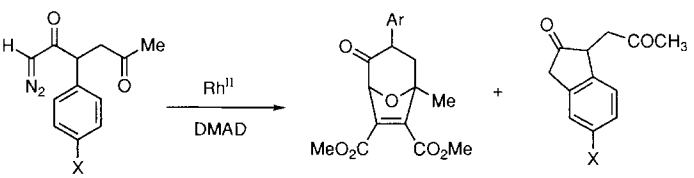
118 **119** **120**

The hapalindole family of alkaloids was prepared in high yield through an intramolecular indole C–H insertion reaction.[150]

When $[Cu(acac)_2]$ was used as the catalyst, only the tricyclic structure **119** was formed in 20% yield. This compound resulted from insertion of the carbenoid into the 5-position of the indole ring in **118**. Switching the catalyst to rhodium(II) acetate still afforded the undesired adduct **119**, but in much higher yield (89%). On the other hand, palladium(II) acetate catalysis in methanol gave the desired compound **120** in 71% yield. The postulated mechanism of the palladium-catalyzed reaction proceeds through a zwitterionic intermediate which is favored in polar solvents and results in cyclization at the 3-position of the indole. The rhodium-catalyzed reaction takes place preferentially through a five-membered transition state.



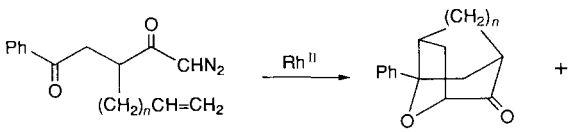
The synthesis of spirocyclopropyl quinone **122**, which serves as the precursor to the A-ring of the antitumor antibiotic CC-1065, by an intramolecular carbenoid addition was investigated by Sundberg et al.[151] Catalytic decomposition of diazo ketone **121** with $[Rh_2(piv)_4]$ at 40 °C for 2 h proved to be the most effective conditions for cyclopropanation. The desulfonylated quinone **123** was also formed in varying yields depending on the particular catalyst and conditions used. Whereas reaction with



$[Rh_2(OAc)_4]$ was rather slow, the more soluble $[Rh_2(oct)_4]$ and $[Rh_2(piv)_4]$ led to a faster reaction and improved the cyclopropane to quinone ratio. The origin of the desulfonylated quinone **123** was traced to an intramolecular oxygen transfer to the carbenoid carbon producing **126**, which was hydrolyzed to **123** under the reaction conditions.

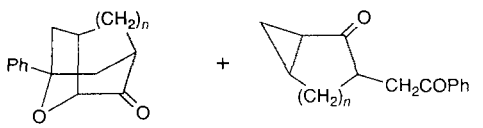
6.3. Competition Experiments

Carboxylate and carboxamide ligands of dirhodium(II) catalysts were also found to influence chemoselectivity in metal-mediated transformations of α-diazo carbonyl compounds.[152] The choice of catalyst exerted effective control on competitive intramolecular cyclopropanation and intramolecular aromatic substitution with 1-diazo-3-aryl-5-hexen-2-ones **127**. Use of $[Rh_2(OAc)_4]$ yielded products from both transformations (**128** and **129**) in nearly equal amounts, but $[Rh_2(pfb)_4]$ catalyzed only the aromatic substitution, and $[Rh_2(cap)_4]$ only the cyclopropanation. Similar results were obtained from dirhodium(II) catalysts in competition between intramolecular cyclopropanation and insertion into tertiary C–H bonds, aromatic cycloaddition and C–H insertion, cyclopropanation and aromatic cycloaddition, and C–H insertion and aromatic substitution. What is so remarkable is the degree to which chemoselectivity can be achieved over such a broad spectrum of carbene reactions by simply changing the ligands on the catalyst from perfluorobutyrate to carboxamide. The significant difference in chemical behavior between $[Rh_2(tfa)_4]$ and $[Rh_2(cap)_4]$ has been attributed to the large differences in charge and in frontier orbital properties. With certain substrates conformational effects may also play a dominant role in product formation.[152]



The choice of catalyst also exerted a dramatic effect on the product distribution in reactions with diazo compounds **130** and **133**, substrates in which intramolecular aromatic substitution competes with carbonyl ylide formation.[153] Thus, the $[Rh_2(OAc)_4]$-catalyzed decomposition of **130** in the presence of dimethyl acetylenedicarboxylate (DMAD) gave rise to a mixture of oxabicyclooctanone **131** (60%) and the 2-indanone **132** (20%); carbonyl ylide formation predominated over attack on the aromatic ring. However, on changing the catalyst to $[Rh_2(cap)_4]$, only the carbonyl ylide cycloadduct **131** was formed (90%). In contrast, use of the more electrophilic $[Rh_2(pfb)_4]$ resulted in exclusive formation of the aromatic substitution product **132** (85%). Diazo compound **133** showed a similar pattern of reactivity (formation of **134** and **135**).

$[Rh_2(OAc)_4]$	60%	20%
$[Rh_2(cap)_4]$	90%	0%
$[Rh_2(pfb)_4]$	0%	85%



The reactions of 3-allyl-1-diazopentane-2,5-dione (**136**) and 3-butenyl-1-diazopentane-2,5-dione (**140**) with a Rh^{II} catalyst

were also studied.[154] The three major products corresponded to the intramolecular reaction of a carbonyl ylide intermediate (products **137** + **138** and **141** + **142**, respectively) and intramolecular cyclopropanation (products **139** and **143**, respectively). Changing the catalyst from $[Rh_2(OAc)_4]$ to $[Rh_2(tfa)_4]$ caused a rather startling and unexpected alteration in product distribution with diazo dione **136**: cycloadduct **137** was the major product isolated when $[Rh_2(tfa)_4]$ was used, whereas cycloadduct **138** was the major regioisomer formed with the other two catalysts. No such regiochemical crossover was observed with the three catalysts for the butenyl-substituted **140**. Intramolecular cyclopropanation occurs to a considerable extent with all catalysts in systems where a bicyclo[3.1.0] ring system is produced (**139**; $n = 1$). The importance of this pathway diminishes when a bicyclo[4.1.0] ring system (**143**; $n = 2$) is formed, presumably as a result of conformational and entropic factors.

136, $n = 1$ **140**, $n = 2$

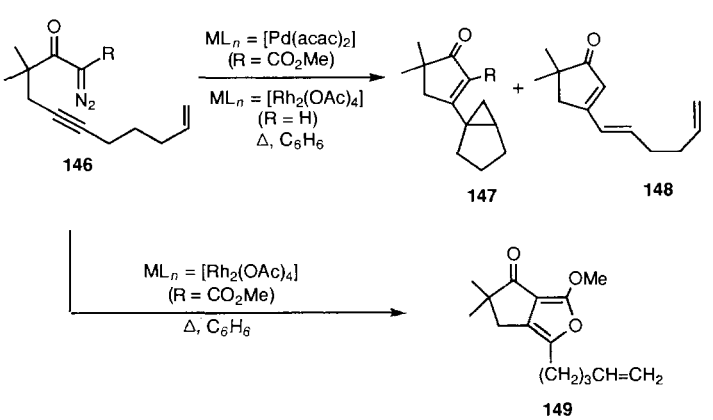
$[Rh_2(cap)_4]$	52%	11%	32%	17%

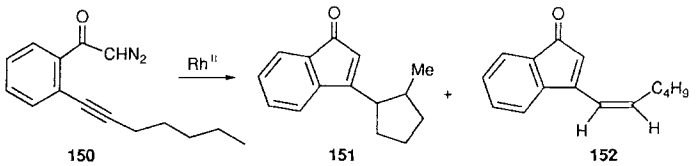
The regiochemical differentiation for diazo dione **136** by the rhodium catalyst is most remarkable. Regiochemical control in [3 + 2] dipolar cycloaddition reactions has generally been rationalized on the basis of FMO considerations (FMO = frontier molecular orbital).[155] Cyclization by overlap of the lone pair of electrons of the more remote carbonyl group and an orbital of the reactive α-keto metallocarbene intermediate is believed to be followed by dissociation of the catalyst and generation of a dipole not complexed to the metal.[21] However, to explain the results with diazo dione **136**, the mechanism needs to be modified. One possibility is that immediately after dipole generation, the $[Rh_2(tfa)_4]$ catalyst coordinates to the nearby olefinic π bond.[156] This complexation may very well lower the LUMO energy of the tethered alkene and consequently shift the cycloaddition from a LUMO- to a HOMO-controlled process. Alternatively, the $[Rh_2(tfa)_4]$ catalyst may still be coordinated (η^2 or η^3) to the dipole, and this complex could undergo a subsequent intramolecular cycloaddition with a different regiochemical profile. Further work is necessary before one can distinguish between these two possibilities.



Recently Pirrung and Zhang explored the asymmetric dipolar cycloaddition reactions of diazo compounds mediated by tetrakis(binaphthyldiylphosphate)dirhodium ($[Rh_2(bnp)_4]$).[134] The interrhodium distance in this catalyst is 0.1 Å longer than in the corresponding carboxylates,[157] which should have an effect on its catalytic properties. Interestingly, the cycloaddition of diazo dimedone (**144**) to furan catalyzed by $[Rh_2(bnp)_4]$ provided **145** in 50% yield and with 49% *ee*. The working hypothesis for the above cycloaddition reaction involves an initial cyclopropanation,[158] and this model was used to rationalize the asymmetric induction observed. However, this hypothesis was difficult to reconcile with all of the experimental observations.

144 **145**

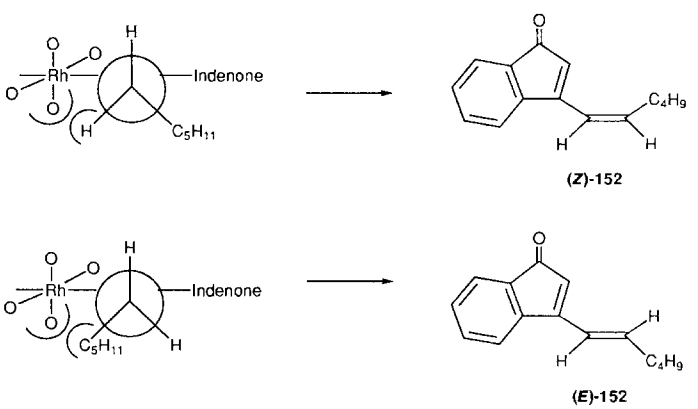
6.4. Alkyne Metathesis Reaction



The insertion of alkynes into transition metal–carbon bonds is a well-documented reaction and has been observed in nearly all of the triads of transition metals.[159] The Rh^{II}-catalyzed reaction of α-diazo ketones bearing tethered alkyne units has recently been used for the construction of polycyclic skeletons. Hoye and Dinsmore et al. examined the intramolecular carbenoid additions to acetylenes.[160] Their results indicated that the product distribution was markedly dependent upon the nature of the catalyst. For example, treatment of α-diazo ketone **146** with catalytic $[Pd(acac)_2]$ produced cyclopropane **147** (R = CO_2Me) in 78% yield. However, when $[Rh_2(OAc)_4]$ was used as the catalyst, **147** was not formed. Instead, furan **149** was isolated in 65% yield. This compound arose by a 1,5-electrocyclization reaction of the initially produced vinyl carbenoid. Removal of the stabilizing ester carbonyl gave both **147** (R = H) and the 1,2-hydrogen shift product **148**. The ratio of products also varied on changing the ligands on the rhodium atom.

146 **147** **148** **149**

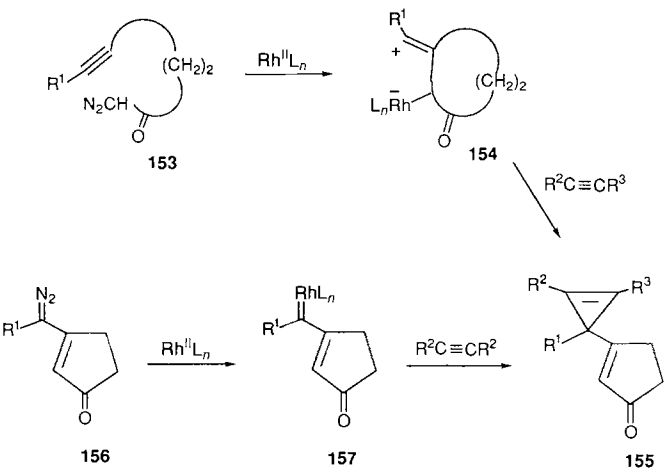
An analogous set of results were encountered in a study of the Rh^{II}-catalyzed reaction of *o*-alkynyl-substituted α-diazo-



acetophenone derivatives.[161] Several structural influences were observed by varying the nature of the substituent group attached to the alkyne carbon atom. In the cyclization reaction a rhodium-stabilized carbenoid added to the acetylenic π bond to generate a vinyl carbenoid. The vinyl carbenoid underwent both CH and CC migration (**151**), as well as δ-CH insertion into the alkyl backbone (**152**). The α-diazo alkyne insertion reactions

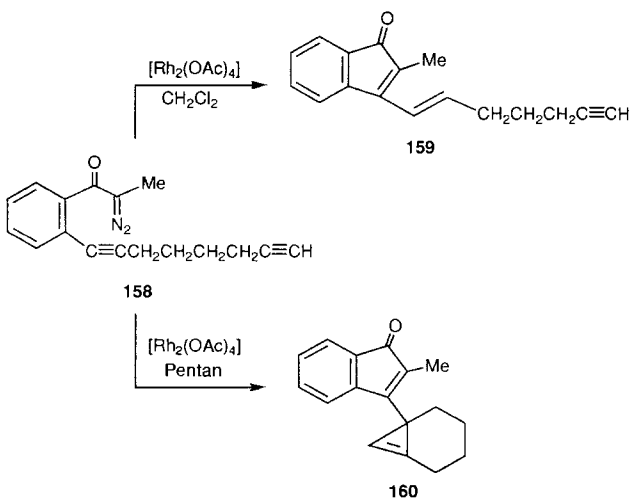
150 151 152

$[Rh_2(man)_4]$	50:50
$[Rh_2(OAc)_4]$	66:33
$[Rh_2(oct)_4]$	80:20
$[Rh_2(pfb)_4]$	10:90



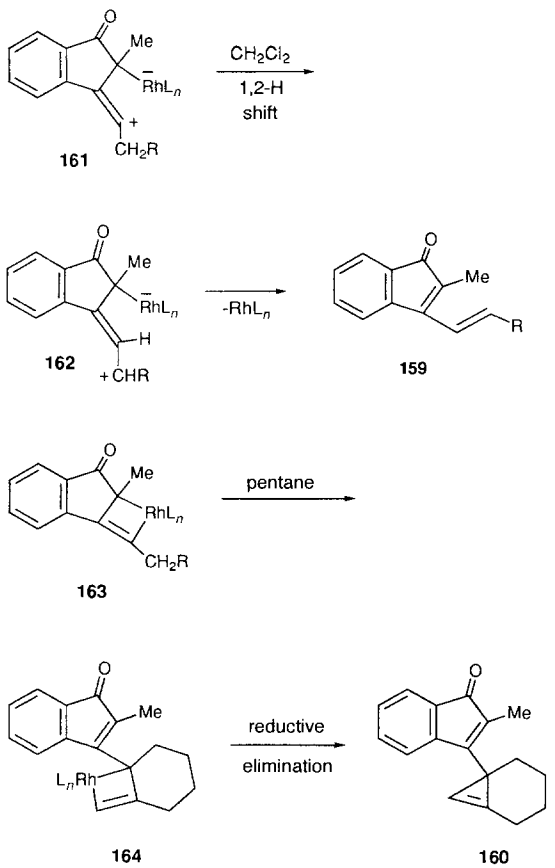
in this system were ligand dependent, which implies that a metalated species is involved in the product-determining step. By choice of the catalyst, the product distribution could be manipulated. The more electron-withdrawing perfluorobutyrate ligand favors β-hydride elimination, while 1,5-insertion is favored by the more electron-donating ligands. The rhodium carbenoid intermediate is highly electron-deficient at the carbon center and is further destabilized by an electron-withdrawing ligand. With this more reactive intermediate, the entropically less demanding β-hydride elimination pathway is favored as noted earlier. Another point worth noting is the preferential formation of the thermodynamically less stable *Z* isomer **152** as product of the 1,2-hydrogen shift. The rhodium carboxylate restricts the orientation of the alkyl chain in the metal carbene intermediate (Scheme 8), and thus directs the hydrogen migration.[162–164]

Scheme 8. Stereochemical considerations in the preferred formation of (*Z*)-**152**.



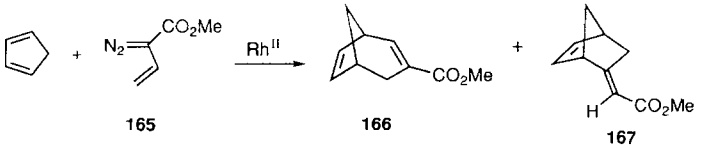
An added complication is the marked influence of the solvent on the mechanism as well as on the chemoselectivity of the reactions (see Section 6.5). Many intermediates may be envisioned along the pathway from **150** to **152**, and it is not an easy task to identify the mechanistic differences.

In another study of the rhodium(II)-catalyzed alkyne insertion reaction, Hoye and Dinsmore reported on the Rh^{II}-catalyzed double *internal–external* alkyne insertion reaction of an acetylenic α-diazo ketone.[165] The initially formed rhodium carbenoid intermediate apparently underwent internal insertion into the tethered alkyne unit followed by a second external addition to produce a cyclopropenyl-substituted cyclopentenone derivative (**155**). Migration of the rhodium metal to the remote alkyne carbon by a [2 + 2] cycloaddition/cycloreversion path (**153**–**157**) was discounted on the basis that the distribution of products derived from **153** differed significantly from that obtained from the rhodium carbenoid species **157** generated from the vinylogous diazo ketone precursor **156**. Instead, the results were rationalized by proposing the intermediacy of zwitterion **154**.

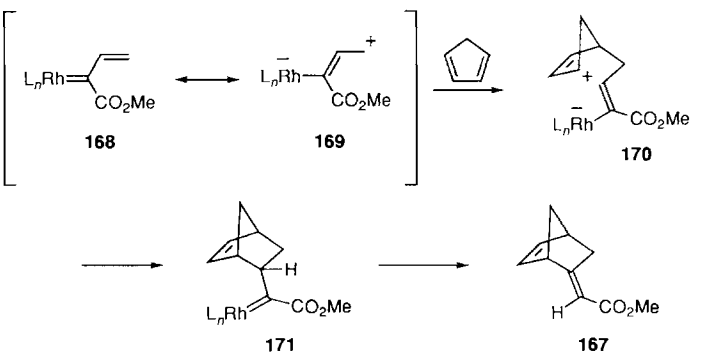


153 154 156 157 155

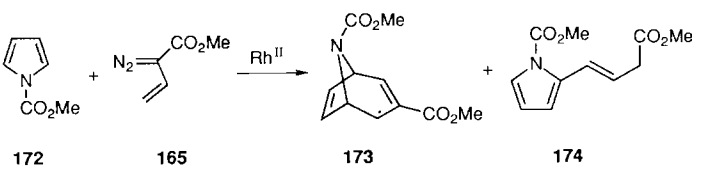
Our subsequent work[166] showed that the reaction mechanism was markedly dependent on the solvent employed in the Rh^{II}-catalyzed insertion reactions. The treatment of α-diazo ketone **158** with a catalytic quantity of $[Rh_2(OAc)_4]$ at 25°C in CH_2Cl_2 afforded a 2:1 mixture of the *cis* and *trans* alkenyl-substituted indenones **159** (R = $(CH_2)_3C{\equiv}H$) in 85% combined yield, whereas $[Rh_2(oct)_4]$ as catalyst in this solvent furnished a 2:3 mixture of cyclopropene **160** and indenone **159**. Use of pentane instead of CH_2Cl_2 with $[Rh_2(OAc)_4]$ resulted in the exclusive formation of cyclopropene **160** (80%). The degree



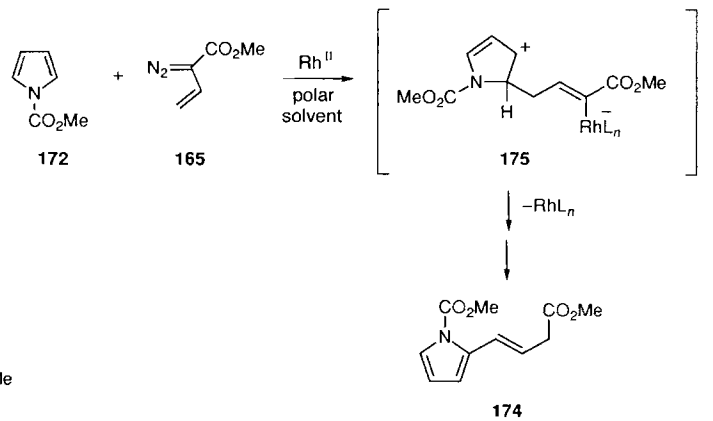
to which chemoselectivity can be achieved by simply changing the solvent from CH_2Cl_2 to pentane is extremely unusual.



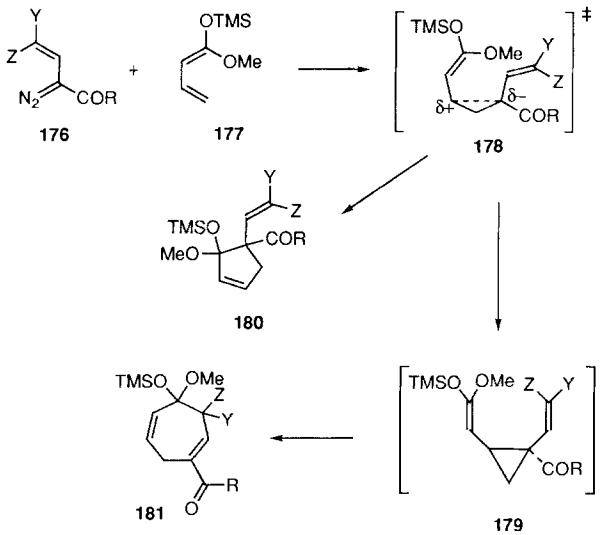
In the mechanism proposed to account for the formation of indenone **159**, the initially formed carbenoid cyclizes stepwise in accord with the Hoye–Dinsmore proposal.[165] A 1,2-hydrogen shift from **161** (R = $(CH_2)_3C{\equiv}H$) yielding **162** is followed by dissociation to **159** and regeneration of the rhodium catalyst. The intermediates en route to **159** are dipolar, which would explain why the generation of **159** is strongly inhibited in pentane. Metal migration occurs via the metallocyclobutene intermediates **163** (R = $(CH_2)_3C{\equiv}H$) and **164** in pentane so as to avoid charge buildup.



6.5. Solvent Effects on Chemoselectivity

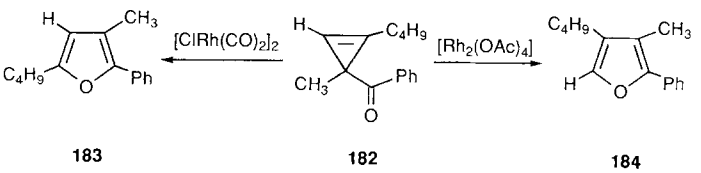


Davies et al. showed that the rhodium(II)-catalyzed decomposition of vinyldiazomethanes in the presence of dienes represents a direct and stereoselective method for the construction of seven-membered rings.[167] For example, the rhodium(II)-catalyzed reaction of vinyldiazomethane **165** with cyclopentadiene resulted in a mixture of **166** and **167**.[168] Both the solvent and the ligands on the catalyst had a major effect on the product distribution. The formation of **166** through a tandem cyclopropanation/Cope rearrangement[167] was greatly enhanced in less polar solvents. Electron-withdrawing ligands (such as trifluoroacetate) on the rhodium facilitated formation of **167**, by stabilizing the dipolar resonance structure **169** of the metal–vinylcarbenoid **168**; thus the vinyl terminus acts as a competing electrophilic center generating the dipolar structure **170** which then undergoes ring closure followed by a 1,2-hydrogen shift. Nonpolar solvents as well as electron-releasing ligands severely retard this reaction, which accounts for the variation in product ratio.

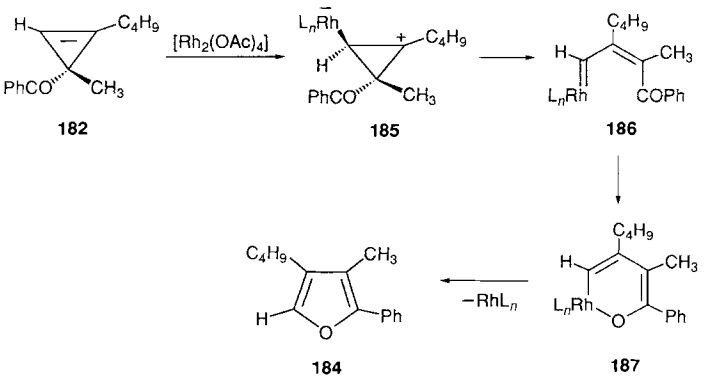


The reaction of **165** with *N*-methoxycarbonyl-substituted pyrrole (**172**) also gave a mixture of two products, **173** and **174**.[168, 169] Once again, the distribution of products could be controlled through the use of an appropriate solvent and catalyst. Electron-withdrawing ligands on the rhodium such as trifluoroacetate strongly enhanced the formation of the alkylated product **174**. On changing to nonpolar solvents, the formation of **174** was totally suppressed, since polar intermediates are involved in its production. The results encountered with pyrrole

172 are very similar to those found in the reaction of **165** with cyclopentadiene.[166] More than likely the formation of **174** proceeds through intermediate **175** by pyrrole attack at the vinyl terminus of the resulting carbenoid derived from **165**. Rearomatization of **175** is facilitated intramolecularly with the generation of a rhodium hydride species which undergoes reductive elimination and double-bond isomerization producing pyrrole **174**.

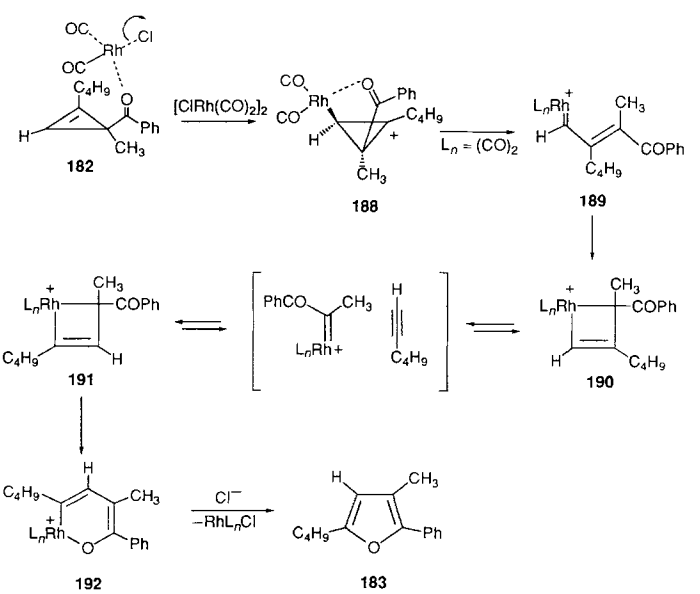


Still another example of a catalyst/solvent effect on the product distribution in this [3 + 4] annulation reaction was described by Davies et al. in the context of their approach to the tropane ring skeleton.[170] The Rh^{II}-catalyzed reaction of vinyldiazo methanes (**176**, Y = CO_2Et, Ph; Z = H, OMe) in the presence of diene **177** afforded both five- and seven-membered rings (**180** and **181**) depending on the choice of catalyst and solvent.



The occurrence of a partially dipolar transition state caused by a nonsynchronous cyclopropanation step explained the results: if the cyclopropanation step were not completed, side products from the dipolar structure **178** would be observed. Nonpolar solvents did destabilize the polar transition state, and formation of the five-membered ring **180** was totally suppressed. Under these conditions the normal cyclopropanation/Cope rearrangement product (**181**) was isolated in high yield.

6.6. Effect of the Oxidation State of the Metal on the Chemoselectivity



The interaction of transition metal complexes with strained carbocyclic compounds has been a subject of considerable interest in recent years.[171] These metals catalyze a variety of rearrangements, the course of which depends on the nature of both the substrate and the metal complex.[172] Due to both synthetic and theoretical aspects, the rhodium(II)-catalyzed ring opening of cyclopropene derivatives is particularly important.[173, 174] Our research has demonstrated an unusual effect on the regioselectivity of ring opening of the cyclopropene by the oxidation state of the metal:[175] catalysis by the Rh^{II} compound $[Rh_2(OAc)_4]$ of the reaction of an unsymmetrically substituted cyclopropene such as **182** gave a substituted furan (**184**) derived from cleavage of the less substituted σ bond. In contrast, Rh^{I} catalysis with $[ClRh(CO)_2]_2$ resulted in cleavage of the more substituted σ bond producing the regioisomeric furan **183**.

The model of Doyle, Müller et al.[176] readily accounts for the Rh^{II} results: a preferential electrophilic attack by the Rh^{II} catalyst *trans* to the ketone moiety produces the more substituted cyclopropyl cation **185**. Disrotatory ring opening of **185** leads to the carbene complex **186**. Electrocyclization of the vinyl carbenoid to **187** followed by reductive elimination eventually affords furan **184**.

The mechanistic rationale for the formation of the other regioisomeric furan **183** with a Rh^{I} catalyst proposes electrophilic attack of $[ClRh(CO)_2]_2$ on the less substituted carbon

of the cyclopropene π bond to give the tertiary cyclopropyl carbocation **188**. Ring opening followed by a rapid electrocyclization reaction produces the metallocyclobutene **190**. Equilibration of **190** with the thermodynamically more stable 1,3-disubstituted isomer **191** proceeds by a cycloreversion–cycloaddition pathway.[177, 178] Rhodium migration from carbon to oxygen followed by reductive elimination produces the observed furan. The different reactivity of the catalysts can be explained by the fact that the formal increase in oxidation state from Rh^{I} to Rh^{III} which accompanies the conversion **189** → **190** is a much more facile process than the comparable $Rh^{II} \rightarrow Rh^{IV}$ formal oxidation.[171]

7. Summary and Outlook

Dirhodium(II) acetate and related carboxylates react with α-diazo carbonyl compounds to form metal carbenes, which undergo a broad spectrum of chemical transformations, including cyclopropanation, carbon–hydrogen insertion, ylide generation, and aromatic cycloaddition. The carboxylate and carboxamide ligands of dirhodium(II) catalysts can cause chemoselectivity in competitive metal carbene transformations of diazo compounds to switch between competitive transformation. Although $[Rh_2(OAc)_4]$ is most often used to test the feasibility of metal carbene transformations, chemoselectivity with this catalyst generally falls between those of $[Rh_2(pfb)_4]$ and $[Rh_2(cap)_4]$. Either charge control or HOMO/LUMO control or both may be operating in these transformations, and with certain substrates, conformational effects play a dominant role in product formation.

In the future, ligands with different backbones containing chiral groups will be developed. Many different Rh^{II} complexes containing a wide assortment of bidendate ligands can be envisaged. The investigation of the catalytic behavior of transition metal complexes for organic synthesis is at its very beginning. Consequently, our understanding of the role that ligands play in influencing diastereo- and chemoselectivity with transition metal complexes is still in a primitive state. As is the case in all new areas of research using catalysts, investigation of the chemistry of these transition metal complexes in the near future will be dominated by the search for asymmetric synthesis.

We are indebted to our excellent co-workers for their commitment and considerable contributions in the form of ideas and experiments. Their names can be found in the references. We are particularly grateful to the National Institutes of Health and the National Science Foundation for generous support. Some aspects of the research were only possible through the cooperation of other groups, in particular those of Professors Michael P. Doyle at Trinity University and Chris Moody at Loughborough University.

Recycling in the Earth's Atmosphere: The OH Radical—Its Importance for the Chemistry of the Atmosphere and the Determination of Its Concentration

Franz Josef Comes*

The troposphere, the part of the earth's atmosphere which is closest to the surface, harbors important life processes. This important part of our environment contains primarily nitrogen and oxygen. In addition, it comprises a number of other substances, which are generally present in low concentrations. The primary reason for the low content of these trace components is the activity of a diatomic radical, namely the hydroxyl radical. OH is the main constituent of the oxidizing potential of the troposphere and causes the transformation of many trace components into water-soluble forms, which can then rain out and be removed from the troposphere. OH has therefore acquired the title "detergent of the atmosphere". The knowledge of local hydroxyl radical concentrations is therefore an important piece of information, especially with respect to model calculations for atmospheric chemistry. The OH concentration is very low and its determination represents a significant analytical challenge. It is controlled in a delicate manner by chemical formation and decomposition reactions, which interact to create a recycling process in the troposphere.

1. Introduction

When talking about the earth's atmosphere and its chemistry, one thinks primarily of the gas envelope covering the globe. This is an incomplete view, a fact which is demonstrated nearly daily by the presence of clouds. Hence, there are also liquid components of the atmosphere, but in addition, there also exist solid ones (e.g., aerosols). These additional components play a role in the chemistry of the atmosphere which must not be neglected. In spite of the fact, that the earth's atmosphere is not a single phase, this article will primarily focus on the gaseous phase, as the processes to be discussed here are basically pure gas-phase processes. On the other hand, our knowledge of processes in the other phases of the atmosphere is still very fragmentary.

The atmosphere is bound to the earth by gravity, which leads to an atmospheric density distribution that can be described well by the barometric equation. According to this equation, density decreases roughly exponentially with increasing altitude. If the entire mass of the atmosphere were condensed to the pressure found at the earth's surface, we obtain the so-called scale height, about 8 km. In a liquefied state, the same quantity would only be a few meters. Compared to the diameter of our planet of about 13000 km, these values indicate the comparatively small total mass of the atmosphere.

The atmosphere has a characteristic temperature profile. Beginning at the surface, there is a nearly linear decrease in temperature with increasing altitude up to the tropopause, at an average altitude of 10–15 km. The tropopause is the region where the temperature ceases to decrease; in the beginning of the stratosphere the temperature begins to increase again. The part of the atmosphere from the surface to the tropopause is called the troposphere. Due to the physically unstable layering of the air in the troposphere, turbulent mixing of the gases takes place. About 80% of the total mass of the atmosphere is present in the troposphere. Even though the troposphere can be considered as quasi-closed due to the temperature inversion in the tropopause, there are several important possible exchange processes, such as the transport of ozone from the stratosphere into the troposphere.[1] The transport in the reverse direction is also possible; a fact illustrated by many reports about the transport of chlorofluorocarbons (CFCs) into the stratosphere.

Our interest in the atmosphere and especially the troposphere stems from the fact that it is the region in which human life on earth is taking place. It therefore represents an important aspect of our environment. The impact on this environment caused by human activity is increasing considerably. The world's population is increasing rapidly, and encroachments on nature, caused by industrial and agricultural developments, are becoming more numerous. These interventions also have effects on the upper layers of the atmosphere. The reports on the Antarctic ozone hole have demonstrated how vulnerable this part of our environment turns out to be. It is therefore of vital interest to understand precisely those processes that primarily determine the behavior of the atmosphere. This includes above all the processes connected with the hydroxyl radical. The cleansing action of the OH radical controls the content of trace components in our

atmosphere. These trace species include, for example, poisonous carbon monoxide, the greenhouse gas methane, sulfur dioxide, and the nitrogen oxides.[2]

1.1. Fundamental Photochemical Processes

The atmosphere can be viewed as a chemical reactor filled to a large extent with gaseous substances and "heated" by the sun. The solar spectrum is that of a black body at nearly 6000 K. The incident solar power on the earth is described by the solar constant, which gives the incident energy on the outer edge of the atmosphere at vertical irradiation per m^2 per second, $S = 1.368\ Wm^{-2}$. Absorption in the atmosphere changes this radiation, especially in the UV region.

The most important components of the atmosphere, such as nitrogen and oxygen, completely absorb the short wavelength UV radiation ($\lambda < 200$ nm) at high altitudes, so that this radiation cannot reach the surface. The penetration of lower wavelength radiation, between about 200–300 nm, to the ground would, however, be fatal for organic life. Nature has provided an additional shield against this, resulting from the photochemical decomposition of the oxygen molecule. In the lower, and hence more dense, layers of the stratosphere the decomposition of O_2, which here only occurs partially, leads to the formation of a new oxygen species, namely ozone. Newly formed oxygen atoms can react with the oxygen molecules still present in a ternary collision to form O_3 [Eq. (1) where M = third collision partner e.g. O_2, N_2].[3]

$$O + O_2 \xrightarrow{M} O_3 \qquad (1)$$

This reaction leads to the stratospheric ozone layer, or just ozone layer for short, which is often discussed in the media.[4] This layer contains about 90–95% of the total ozone and is centered at around 25 to 30 km in altitude, depending on season and geographic location. The remaining 5–10% of the ozone are located in the troposphere and there fulfill an important function.[5]

The stratospheric ozone layer is of interest to us primarily due to its absorption of UV radiation. Ozone absorbs very strongly between 200 and 300 nm, leading, with a quantum yield of about 0.9–1.0, to a molecular fragmentation into metastable products [Eq. (2a)]. The other process leads to products in their ground states [Eq. (2b)].[6]

$$O_3 + h\nu \longrightarrow \begin{cases} O(^1D) + O_2(^1\Delta_g) & (2a) \\ O(^3P) + O_2(^3\Sigma_\sigma^-) & (2b) \end{cases}$$

The stated quantum yields are correct as long as the wavelengths in question are below 306 nm. For longer wavelengths the quantum yield for the formation of singlet species [Eq. (2a)] decreases and, in the troposphere, vanishes completely above 330 nm.[7] The presence of ozone as a very effective absorber of UV radiation leads to the fact that solar radiation reaching the earth's surface has a lower wavelength limit of about 300 nm. This assures sufficient protection for organic life on earth. Radiation above this limit is increasingly less absorbed and, hence, reaches the surface in increasing proportions.

The problems connected with the shielding effect of ozone and anthropogenic influences thereupon are well known[8] and will not be further discussed here. The photochemical limit for reaction (2a), which is of great importance for the following discussion, lies at 310 nm. This value can be modified by the internal energy content, that is the thermal energy of the ozone molecule. Measurements at this limit and the determination of the quantum yield for the process (2a) are very important and have shown that above about 330 nm, there is no more photochemical production of singlet oxygen species by the sun in the troposphere.[7]

Until now, only the processes themselves, but not their relevance, have been discussed; this will be done now. Both dissociation products, $O(^1D)$ and $O_2(^1\Delta_g)$, from reaction (2a) are metastable because of their electronic states. They have large radiative lifetimes of 148 s and 65 min,[9] respectively, and have a significant energy content of 189 and 94 $kJ\,mol^{-1}$, respectively. Since ozone does exist in the troposphere, and solar radiation below 330 nm can penetrate into the troposphere, singlet oxygen is produced in the troposphere. Of the two particles, primarily the $O(^1D)$ atom is photochemically active as it is extraordinarily reactive. The rate constants of $O(^1D)$ for many of its relevant

Franz Josef Comes, born in 1928, obtained his Diplom in Physics in Mainz, and his doctorate at the Max-Planck-Institut für Chemie (Otto-Hahn-Institut) in Mainz working with Paneth on the study of meteorites by mass spectrometry. After this excursion into geophysics and cosmochemistry, he worked on problems of molecular spectroscopy and reaction kinetics at the University of Bonn with Groth where he obtained his habilitation in 1964 and became Professor in 1969. In 1970 he was awarded the Fritz-Haber prize of the Deutsche Bunsengesellschaft for fundamental work on photodissociation, photoionization, and molecular and photoelectron spectroscopy. After a guest professorship at the University of Southern Carolina, Los Angeles, followed by a period as guest in the synchrotron group of Desy in Hamburg, he accepted the chair of Physical Chemistry at Frankfurt University in 1972. His interests include the application of lasers in chemistry, in particular in studies on reaction dynamics. Other fields of research are atmospheric chemistry and applications of the photovoltaic effect, in particular for the development of solar cells from amorphous silicon and germanium.

reactions are nearly equal and frequently gas kinetic, so that its further reactions in the atmosphere are essentially controlled by the concentration of the reaction partners.[10] In our geographic latitudes, water vapor is the third most common atmospheric component, after N_2 and O_2. $O(^1D)$ reacts exceptionally well with H_2O, with a temperature-independent rate constant of 2.02×10^{-10} molecules $cm^{-3}s^{-1}$, leading to the formation of hydroxyl radicals [Eq. (3)].[11]

$$O(^1D) + H_2O \longrightarrow 2OH \quad (3)$$

This indicates that water vapor is the most important reaction partner of $O(^1D)$ and reaction (3) is the most significant process for the initial formation of OH in the troposphere.

The reaction dynamics of reaction (3) is very interesting because the energy is distributed unequally between the two OH products; thus, one of the two OH radicals can be identified as stemming from the water molecule and the other one as coming from the reaction with $O(^1D)$. This indicates that a very fast chemical process without a longer lived transition complex is occurring.[12]

The production of $O(^1D)$ during the UV photolysis of ozone leads to the formation of hydroxyl radicals. The chemical activity of these OH radicals leads to their role as the "detergent of the atmosphere".[13] The process of OH formation itself, however, possesses a certain dramatic element as well. In general, it would be expected that the absorption by stratospheric ozone removes all solar radiation that can act in the photolysis of tropospheric ozone, as is the case for the absorption by N_2 and O_2. This is, however, not the full story. On the long wavelength side of the O_3 UV absorption, in other words, in a region with decreasing absorptivity, a certain fraction of the solar radiation can penetrate to the ground. On the other hand, the intensity of the solar radiation increases with increasing wavelength. The result of these dueling effects is depicted in Figure 1, which shows the course of the O_3 absorption cross section (dotted line) and the transmission of sunlight to the surface (heavy dashed line).[14] Of special interest is the region around 310 nm, the photochemical limit for the $O(^1D)$ formation (this limit refers to O_3 at 0 K!). Ozone also absorbs at longer wavelengths, but this leads primarily to the formation of $O(^3P)$ atoms [Eq. (2b)], which cannot initiate the relevant reaction (3). The third curve in Figure 1 (thinly dashed) shows the portion of the absorption cross section which can induce process (2a). This leads to the dotted area in Figure 1, which indicates the overlap crucial to $O(^1D)$ formation. Only in this region is tropospheric $O(^1D)$ formation, and subsequent OH production possible. The initial photochemical step of OH formation by ozone photolysis through sunlight turns out to be a very selective overall process, which is only active in a very narrow window.

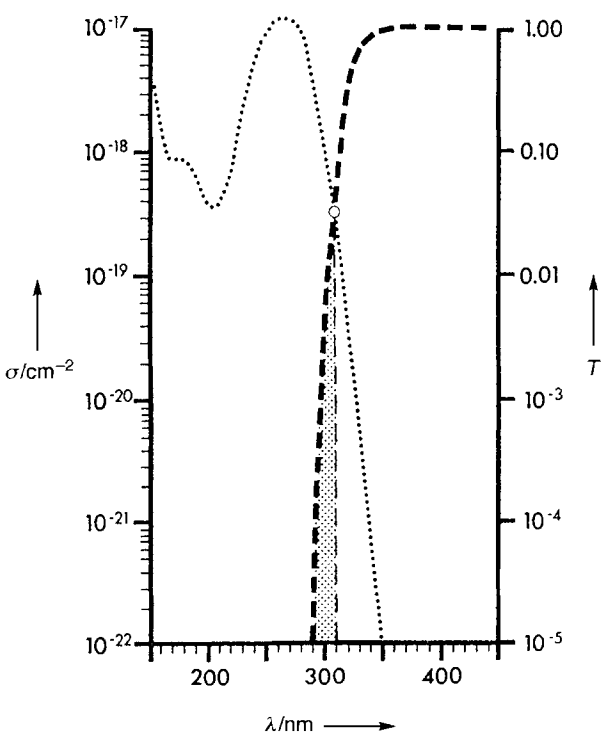

Fig. 1. ·····: UV absorption cross section σ of ozone; - - - - - -: transmitted sunlight after passage through the upper atmosphere; – – – – –: $O(^1D)$-producing absorption cross section of ozone. Dotted area: region where tropospheric $O(^1D)$ formation is possible.

1.2. Atmospheric Recycling Processes

Radicals are known throughout chemistry primarily as short-lived intermediates in complex chemical processes. Due to their high reactivity, their chemical lifetime is usually short and their stationary concentration is low. This is particularly true for tropospheric OH radicals, for which, according to recent model calculations, the stationary concentration in our latitudes on summer middays is about 10^6 particles per cubic centimeter (3×10^6 particles $cm^{-3} \triangleq 0.1$ pptv (parts per trillion (10^{12})in volume units).[15] As their existence is directly linked with the UV activity of the sun, they should be tied to a daily cycle which approximately reflects the solar incidence. In Section 1.1 the cleansing function of OH radicals was mentioned. What is the nature of this function?

OH radicals are reactive. Many of their reactions with atmospheric gases have been examined and measured. The first notable result of these investigations is that hydroxyl radicals do *not* react with the most common components of the troposphere. In decreasing order of abundance, these are nitrogen, oxygen, water vapor, argon, and carbon dioxide. OH radicals only react readily with so-called tropospheric trace components, which have abundances of 1 ppmv or even significantly below that. As an oxidizing agent, OH frequently transforms these trace gases into water-soluble chemical species. Subsequent raining out removes these trace components from the atmosphere, a process we have described as the cleansing effect. It causes the atmospheric content of trace components to be low, even though these components are continuously released into the atmosphere even by non-anthropogenic, that is, natural, sources. Hydroxyl radicals are therefore important reaction partners in many processes in atmospheric chemistry and, hence, their concentration is a crucial parameter for the chemistry of the atmosphere.

The thus far described aspect of tropospheric photochemistry is therefore an extremely selective overall process: the upper atmosphere only permits the penetration of a small fraction of

high-energy UV radiation into the troposphere, which leads to the release of excited, hence reactive, oxygen atoms from the ozone present in trace quantities. These oxygen atoms then react almost exclusively with water vapor to give OH radicals, which in turn selectively choose trace components as reaction partners, which establishes the prerequisites for the cleansing process.

The discussion thus far has dealt with the initial formation of hydroxyl radicals by ozone photolysis and their further chemical actions. The ozone content of the troposphere played a significant role in this context. A question now arises: why does the troposphere contain ozone at all? There are two possible sources for this ozone. For one, there is the possibility that stratospheric ozone is transported into the lower layers of the atmosphere. A second potential source is chemical events in the troposphere, which are closely linked to the OH radical.

In terms of quantity, the most important reaction partner for the OH radical is carbon monoxide, CO. It is present in the troposphere with nearly 0.1 ppmv. Even though methane, another important reaction partner for the OH radical, is about tenfold more abundant than CO, it reacts slower with OH, putting it in second place. These two species contribute about 90% of the entire OH removal. Their reactions with OH determine its atmospheric lifetime of about one second. Even though OH radicals react with many other trace components, such as SO_2 and other hydrocarbons, these do not significantly influence the total OH budget. On the other hand, however, OH has an often crucial role in the atmospheric balance of these trace species.

The reaction of OH with CO leads to a very interesting result [Eq. (4)]. CO is oxidized to CO_2, and a hydrogen atom is formed. The reaction proceeds via an intermediate that yields a temperature dependence different from the typical Arrhenius behavior.[16] The H atoms thus formed can now initiate an important event in the atmosphere, since they react with atmospheric oxygen. This reaction (5) exhibits another characteristic of

$$OH + CO \longrightarrow CO_2 + H \quad (4)$$

$$H + O_2 \xrightarrow{M} HO_2 \quad (5)$$

of tropospheric reactions. In order for an HO_2 molecule to form from the reactants H and O_2, the excess energy, which is the binding energy, must be carried off by a third collision partner (M). Ternary collisions are notably less frequent than bimolecular reactions and become more probable only in denser media, such as the troposphere. Reaction (5) re-establishes the oxidizing potential which was temporarily lost by the reaction of OH in (4). In clean air above continents, the main reaction partner of HO_2 is the nitrous oxide molecule NO, which is oxidized to NO_2 [Eq. (6)]. This oxidation has two remarkable products.

$$HO_2 + NO \longrightarrow NO_2 + OH \quad (6)$$

NO_2 is formed, a member of the NO_x family, which, at higher NO_x concentrations, reacts primarily with OH according to Equation (7) to yield HNO_3, and thus represents a significant sink for the OH radical. On the other hand, (6) also regenerates OH. Hence OH has completed a cycle in the reactions (4)–(6), which corresponds to the formal reaction $CO + NO + O_2 \rightarrow CO_2 + NO_2$, and one can talk about OH recycling. Cycles such as this one are typical for atmospheric chemistry and determine the equilibria which result from the interaction of sources and sinks.

$$OH + NO_2 \xrightarrow{M} HNO_3 \quad (7)$$

Connected with NO_2 is a further characteristic phenomenon of atmospheric chemistry, namely the fact that the chemical processes occur in a radiation field. In this field, many compounds, for example, ozone, are not stable, because they can decompose by photodissociation. This is also the case for the NO_2 molecule due to its reaction (8).[17]

$$NO_2 + h\nu(\lambda \leq 430\ nm) \longrightarrow NO + O \quad (8)$$

Solar irradiation in this wavelength region reaches the troposphere in sufficient intensity, therefore a photochemical equilibrium between NO and NO_2 is rapidly established. The oxygen atoms created in this way react, owing to the high O_2 content of the troposphere, to directly yield O_3. This represents an important source of ozone in the troposphere.

Reactions (4)–(8) are important steps in the recycling mechanisms for the OH radical. Their individual importance in this recycling process is determined by atmospheric conditions governing their chemistry. This means simply that their contribution to the total process varies with the concentrations of the reactants involved. This principle will be demonstrated by using the photochemical formation of ozone as an example. If, for instance, there is sufficient NO present in the atmosphere, it is transformed to NO_2, and subsequent photolysis yields O_3. The sequence of reactions (4)–(6), (8), and (1) adds up to the following stoichiometry:

$$CO + 2O_2 \longrightarrow CO_2 + O_3.$$

One ozone molecule is formed for each oxidized CO molecule. If, on the other hand, the NO concentration is very small, reaction (6) becomes correspondingly slower, and two other processes begin to become more important [Eqs. (α) and (β)]:

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2 \quad (\alpha)$$

$$HO_2 + O_3 \longrightarrow OH + 2O_2 \quad (\beta)$$

$$H_2O_2 + h\nu \longrightarrow 2OH \quad (\gamma)$$

As H_2O_2 is cleaved by UV light [Eq. (γ)],[18] the reaction sequence (4), (5), (α), and (γ) leads to

$$2CO + O_2 \longrightarrow 2CO_2,$$

which does not cause a change in the O_3 content by CO oxidation. HO_2 can also react with O_3, which gives, according to (4), (5), and (β), and an overall loss of ozone.

$$CO + O_3 \longrightarrow CO_2 + O_2,$$

The reactions (4)–(8) describe only the subsequent reactions of OH radicals initiated by CO. Methane is a second important

reaction partner for OH. During this reaction [Eq. (9)], OH is

$$CH_4 + OH \longrightarrow CH_3 + H_2O \quad (9)$$

converted to H_2O, and a methyl radical is formed. The further reactions in the oxidation mechanism of CH_4 are heavily influenced by a ternary collision process [Eq. (10)], which becomes rather likely under troposphere conditions.

$$CH_3 + O_2 \xrightarrow{M} CH_3O_2 \quad (10)$$

Reaction (10) leads to the peroxy radical, which upon contact with NO converts it into NO_2 [Eq. (11)]. This in turn can yield

$$NO + CH_3O_2 \longrightarrow NO_2 + CH_3O \quad (11)$$

O atoms by photolysis [Eq. (8)] and hence is a precursor for O_3. The methoxy radical CH_3O reacts rapidly with O_2 to yield formaldehyde and one molecule of HO_2 [Eq. (12)]. The HO_2

$$CH_3O + O_2 \longrightarrow HCHO + HO_2 \quad (12)$$

from (12) can yield OH by reaction (6), which means that methane oxidation can also lead to OH recycling.

The intermediates in reactions (9)–(11) are short-lived, while formaldehyde is a longer lived species, which, however, also decomposes upon solar irradiation. Its atmospheric lifetime of several hours leads to concentrations of the order of 1 ppbv, even in non-polluted air. The most important further reaction of HCHO is its photodissociation [Eq. (13)], which can proceed by two pathways. The onset of cleavage into H and HCO, however, is below 335 nm.[19]

$$HCHO + h\nu(\lambda \leq 370\ nm) \longrightarrow H_2 + CO \quad (13a)$$

$$HCHO + h\nu(\lambda \leq 335\ nm) \longrightarrow H + HCO \quad (13b)$$

Pathway (13b) is important, because H and HCO react rapidly with O_2 [Eqs. (5) and (14)] to yield HO_2, which in turn is converted into OH by NO.

$$HCO + O_2 \longrightarrow HO_2 + CO \quad (14)$$

The quantum yields for reactions 13a and 13b are strongly wavelength dependent, in addition, above 330 nm the quantum yields are also dependent on pressure.[1]

Apart from methane, there is a multitude of other hydrocarbons in the troposphere. Their concentrations, however, are very much lower under normal circumstances. These hydrocarbons are classified in the literature as NMHC (non-methane hydrocarbons). The majority of them react readily with OH, which generally makes them an initial OH sink. In combination with the chemistry of NO_x, however, many of them are potential sources for HO_2 by subsequent peroxide formation [see Eq. (10)]. This couples them with the OH recycling mechanism. For one group of hydrocarbons, there are, apart from the man-made sources, significant natural sources, stemming from biogenic processes. For isoprene and monoterpenes, the important sources come from the tree and bush vegetation, with isoprene stemming primarily from deciduous and monoterpenes from coniferous trees. The oceans are also significant sources of hydrocarbons formed by biogenic processes.

In a recent study on the mountain station of Izana on Tenerife, there were indications that more consideration has to be given to these biogenic substances in future field measurements of OH.[20] Even though these substances can play special roles in local situations, their influence on the OH content in the normal troposphere is generally small.

The two examples of CO and CH_4, which are the most important reaction partners for OH in the "normal", in other words, nonpolluted troposphere, allowed the demonstration of a recycling process for OH. The extent of OH regeneration is dependent on the actual concentrations of the reactants. The measured stationary OH concentration in the troposphere is therefore the result of a sensitive equilibrium, which is controlled to a significant extent by these recycling mechanisms.

2. Results of Model Calculations and Conditions for their Verification

Models are an abstraction of reality. Results of model calculations can lead to important predictions. However, models always require experimental verification. In order to test models for the chemistry of the troposphere, an identification of all significant reaction partners, including the OH radical itself, is necessary, which must be as complete as possible. The comparison of measured and calculated concentrations can then serve to verify or falsify existing models. The fact that such a fundamental question like testing models for atmospheric chemistry is brought up in connection with measurements on the OH radical stems from the chemical properties of this molecule. It reacts with all relevant trace components, and does so rapidly. The latter implies that the formation and further reaction of individual OH radicals occur in a fairly small space. This has important consequences for the development of models, as it can be used to reduce the complexity of models in a reasonable way.

The rate at which substances in a reactive system appear and/or disappear is determined by the reactive properties of those substances and their concentration. The concentrations are given at the beginning of the reaction and after that are determined by the reactions themselves. Atmospheric reactions, however, occur in open systems. Air movements, that is transport, can also effect concentration changes. This transport is both turbulent and directional, which on one hand leads to good mixing, on the other to a certain wind velocity. It would therefore be very helpful if the quantities governing the transport could be neglected in the model calculations, as the main interest during model testing lies in the chemical aspect. This aspect consists of comparisons of measurement results from a single determination. If the transport term is to be neglected, it is necessary that the measurements satisfy certain conditions. As the measurements are performed in a system which is fixed in space, these conditions must include the maximum measurement volume and the time interval for the measurement. The conditions are always satisfied as long as the volumes are small and the time intervals short. But what is "small" and "short" in this context?

In order to estimate these quantities, a value for the air velocity is required. A moderate wind of 10–30 km h^{-1} (classified as a weak to moderate breeze) implies that the air moves about 3–9 m per second. A time interval of one second corresponds to the characteristic time for the chemical turnover of OH radicals in the atmosphere. Through transport, individual OH radicals would on average not exceed a volume extending over a few meters in diameter. A complete determination of all quantities relevant to the model calculations in a measurement volume that is restricted to a spatial extent of a few meters will therefore not lead to an incorrect spatial and temporal averaging of the desired measurement values. The mixing caused by the turbulence always present in air streams leads to an unavoidable natural averaging, which has the effect of making measurement conditions less stringent. This leads to air pockets with a certain spatial extent in which the approximation holds that the contained mass of air is homogeneously mixed. As long as the UV irradiation by the sun does not change over the course of a few seconds –which is unlikely even for a rapidly changing cloud cover—the measurement interval can be increased, with all other conditions remaining unchanged. For a wind velocity of 20 km h^{-1}, an air pocket of about 100 m, and a measurement cell size of 6 m, the time interval would be 20 seconds.

To determine the "local" concentrations of the relevant trace components in order to test models of the atmospheric chemistry, measurement intervals from a few seconds to one minute are permissible for measurement cells extending over a few meters. Measurements that do not fulfill these criteria, namely those which are not local and fast, lead to unacceptable averaging. Its extent depends on the lifetime of the components involved. Furthermore, the nonlinearity of the occurring processes significantly increases the error caused by this averaging.[21] This nonlinearity is especially noteworthy for the effect of the NO_x concentration on the stationary concentration of the OH radical. For low values of the NO_x concentration, the recycling of OH by reaction (6) dominates. If the NO_x concentration increases, however, process (7) becomes more significant and overall OH is lost. This creates a maximum in the OH concentration for the range of 1 to several ppbv NO_x, as long as other factors are held essentially constant.

The conclusions reached above are especially significant for techniques that require extended measurement pathlengths of several kilometers for the determination of tropospheric OH.[22] Another remark must be made here, which is based on the results of three studies by us in 1991, 1992, and 1993. In all cases, during the day there were severe variations in the measured OH concentrations. These occurred in a time frame from a few to tens of minutes.[20] Because the OH radical reacts with all relevant trace components and has a short lifetime (1 s), it simultaneously acts as a tracer which rapidly reacts to variations in the chemical composition of the atmosphere as well as the homogeneity of physical parameters (e.g., temperature, humidity). These brief variations can also be found in the results of another group of researchers, who also used a locally measuring detection method.[23] This indicates that homogeneity can only be assumed for smaller volumes of air. Absorption measurements that are done over extended pathlengths can lead to erroneous interpretations.

Since the hydroxyl radical is a key component in the chemistry of the troposphere, the determination of its local concentration therefore yields important information. The high reactivity, however, limits the measurement interval of the detection method. In combination with the movement of the air this determines the maximum size of the critical volume that can be used for the measurement. Together, both conditions define the quality of a local measurement. This determination yields a value $c_i(x,t)$, that is the concentration c of a atmospheric component i in location x at time t. The value of $c_i(x,t)$ is assumed to be representative for the given choice of x and t. Model calculations make use of continuity equations, which describe the temporal change of a component's concentration at a given location by the processes which effect these changes. Limited to gas-phase components, these are the sources Q, sinks S, and the effect of transport T. The equation can then be written as (15).

$$\frac{dc_i(x,t)}{dt} = Q_i(x,t) - S_i(x,t) + T_i(x,t) \tag{15}$$

There is such an equation for every component i. Since the terms Q, S, and T are also affected by other components j, (15) represents a system of coupled differential equations. The preceding discussion has shown that for a single measurement the T term can be neglected as long as a fast and local determination is performed. For this case, which is only valid for a time interval corresponding to the measurement interval, Equation (15) simplifies to include only the source and sink terms, which describe chemical events.

Even though many gas-phase reactions relevant to atmospheric processes have been quantitatively studied in the laboratory and the search for atmospheric trace components has yielded a considerable list of them, the total picture is still incomplete. It can therefore not be expected that there will be good agreement between the measured and calculated values for the OH concentration. The first goal will be to determine the discrepancy between these values and to show how it behaves over time. The time interval in question could be an hour or even a whole day. In this case, the studies of the temporal behavior are subject to the complete continuity equation, because for time intervals longer than minutes the transport term has to be taken into account. Fast local measurements of the above-mentioned quality within certain time intervals Δt will allow conclusions about the transport during Δt. Two important pieces of information can be expected from these efforts, namely the quality and completeness of the model calculations as well as the effect of transport. Only when these data have either led to a confirmation of the previous assumptions or to an improved new set of assumptions, will it be possible to address more fundamental questions of atmospheric chemistry. These could include the question whether the currently observable increase in the methane concentration is due to increased output by its sources or decreased activity by its sinks. A worldwide decrease in the OH concentration could be a reason for the latter effect.

Figure 2a shows the results of model calculations for clean continental air, which describe an atmospheric situation which is valid for the point in time that is characterized by the parameter set.[15] The picture shows the important steps in the OH budget and the percentage of the given particles which partici-

pate in that step. Therefore 70% of OH radicals react with CO to give CO_2 and H. For the selected situation, CH_4 contributes another 18% to the removal of OH. The OH recycling process contributes 54% of the OH formed, while 46% stem from $O(^1D)$ from the primary ozone photolysis. For Figure 2b the initial concentration of NO_x was increased to 2 ppbv. As expected, there is a definite increase in the contribution to OH recycling by the reaction of HO_2 with NO. This leads to a decrease of the percentage for the primary OH formation by ozone photolysis to now only 16%. The role of NO_2 as OH sink is indicated by its 13% share in the total OH removal process.

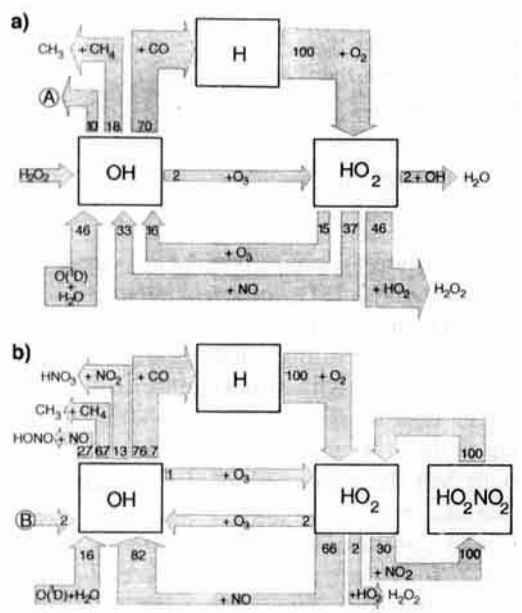

Fig. 2. Recycling mechanisms and circulation of OH. a) pure air conditions [CO]: 0.15 ppmv, $[NO_x]$: 0.01 ppbv, $[O_3]$: 20 ppbv, $[H_2O]$: 1.2%, $[CH_4]$: 1.64 ppmv, $T = 293$ K, [OH]: 9×10^5 cm^{-3}. Ⓐ stands for reactions with NO_2, H_2O, H_2O_2, and decomposition products of CH_4. b) Moderately polluted air [CO]: 0.37 ppmv, $[NO_x]$: 2 ppbv, $[O_3]$: 52 ppbv, $[H_2O]$: 1.2%, $[CH_4]$: 1.64 ppmv, $T = 293$ K. [OH]: 5×10^6 cm^{-3}. Ⓑ stands for other sources.

This example indicates that the OH lifecycle is very sensitive to the presence of NO_x. While Figure 2 shows the relative shifts in significance for the individual channels, it does not provide absolute values for the involved quantities. In connection with the NO_x contribution, these data would show that the OH concentration calculated by the model is not only dependent on the NO_x content in a nonlinear fashion, but also that the OH concentration as a function of the NO_x content, exhibits a definite maximum.[21] This leads to the interesting situation that "a little bit" of pollution is quite beneficial for the OH radical. Nitrogen oxides can therefore be both beneficial as well as detrimental to the OH concentration. For locations close to cities, which is the case for many areas in Western Germany, NO_x values are found that are usually beyond the maximum and therefore lead to a negative correlation between OH and NO_x (cf. Section 3).

3. Measurements in the Troposphere

It is necessary to find an appropriate technique to measure the OH radical concentration in order to do justice to its importance as a test substance for tropospheric models. The measurement volume and time interval must satisfy the criteria laid out above if a critical examination of the model is to be possible. The volume should not exceed a few cubic meters, and the interval should not be longer than a minute. Apart from the determination of the OH concentration, ancillary measurements are necessary to describe the conditions in the atmosphere which are relevant to the OH chemistry. As the OH concentration is directly related to ozone photolysis, the ozone concentration as well as the photolytically active solar irradiation are to be determined initially. In atmospheric chemistry, this active solar irradiation is described by the rate of ozone photolysis, $J(O_3)$. This quantity is defined by Equation (16),[5] where $\sigma(\lambda)$ is the absorp-

$$J(O_3) = \int_{\lambda_{min}}^{\lambda_{max}} \sigma(\lambda)\phi(\lambda)J(\lambda)\,d\lambda \qquad (16)$$

tion cross section of ozone, $\Phi(\lambda)$ the quantum yield of $O(^1D)$, and $J(\lambda)$ the photon flux. λ_{min} and λ_{max} are the lower and upper wavelength boundaries, respectively, between which tropospheric production of $O(^1D)$ from O_3 is possible. The wavelength interval for the measurement from λ_{min} to λ_{max} is given by the dotted region in Figure 1. The product of the ozone photolysis rate and the ozone concentration yields the $O(^1D)$ concentration. The measurement of the ozone photolysis rate places strict demands on the instrumentation. It is necessary to quantitatively detect the effective radiation, which is incident from all directions, at one point in space at all relevant wavelengths.

Other ancillary data required include the concentration of water vapor and NO_x (NO, NO_2), as well as another photolysis rate, namely that of NO_2, $J(NO_2)$, which is critical to the chemistry of the atmosphere due to the photodecomposition of NO_2 [Eq. (8)]. Together with the determination of the CO and CH_4 concentrations, this means that all significant components for the OH lifecycle are being recorded. The restriction of all concentration measurements to the same space and time conditions required for the OH determination is not necessary in all cases. This restriction helps, however, to minimize problems due to transport. A measurement setup capable of determining the concentration of all mentioned species simultaneously in the same volume would be ideal. The determination of the photolysis rates do not create any new problems with respect to spatial considerations, as they have to be performed as point measurements.

The most difficult aspect of the described measurement regime for testing tropospheric models is the determination of the OH concentration. It turns out that the technique employed here is capable of determining not only the OH concentration, but also that of other components, all in the same measurement step. The apparatus presented here is so far the only one with the necessary sensitivity and measurement speed capable of yielding absolute values for the local tropospheric OH concentration.[*] It should be noted that until recently there have been no known reports regarding measurements that satisfy these requirements for the verification of tropospheric models, even though this has been attempted for the last 25 years.[24]

[*] Recently, two reports were published (Mount [22b], Eisele et al. [23]) describing two methods which rely on UV long path absorption and chemical detection, respectively. The latter methods are local, but not absolute, and require subsequent calibration.

The basic idea for this instrument, which was developed in Frankfurt, is the absolute determination of concentrations of gases by the absorption of light. As the most intense absorption of the OH radical stems from the transition $A^2\Pi \leftarrow X^2\Sigma$ at 308 nm, the measurement has to be done in the UV. At surface temperatures, the molecule is present in the vibrational ground state, and here the lowest rotational states are excited. Figure 3 shows the most suitable portion of the absorption spectrum together with the spectroscopic terms for the transitions.[25] The

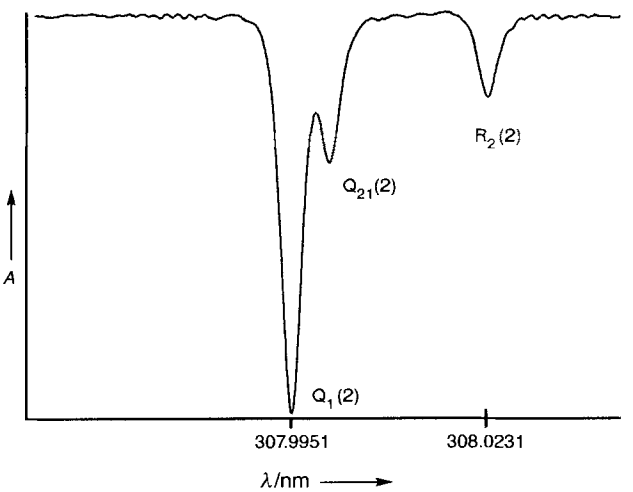

Fig. 3. OH spectrum at 308 nm under atmospheric conditions (1013 mbar, 293 K). A = OH absorption in arbitrary units.

transition probabilities for these line absorptions are known well enough to enable the calculation of the corresponding absorption cross sections for the transitions.[26] To determine the concentration from the absorption it is necessary to know the line width caused by the atmospheric pressure and the temperature, as well as the line width of the light source employed for the absorption measurement.[27] The intensity ratio of the three absorption lines shown in Figure 3 is determined by the surrounding temperature. The transitions $Q_1(2)$ and $Q_{21}(2)$ originate from the same spin system starting from the same ground state, which makes their intensity ratio temperature independent. This means that the same population can be assumed, with good accuracy, for the initial state. The $R_2(2)$ transition stems from a different spin system.[28] Its initial state differs energetically from that of the other two transitions, so that the line intensity ratio of $R_2(2)$ to $Q_1(2)$ and $Q_{21}(2)$ is temperature dependent. The expected atmospheric absorption spectrum can therefore vary with the external temperature. In order to obtain a measurable absorption ($\Delta I/I_0 = 1 \times 10^{-5}$) for the strongest line $Q_1(2)$ at an OH concentration of 5×10^5 cm^{-3}, a pathlength of 1.2 km is required.

Apart from this technique developed in Frankfurt, which relies on the measurement of the three mentioned absorption lines, another method has recently become known. It depends on a long-path absorption with a pathlength of 20.6 km and utilizes the three OH absorption lines above 308 nm, namely $P_1(1)$, $Q_{21}(3)$, and $Q_1(3)$. The method exploits the coincidence of these line positions with the emission of the XeCl eximer laser. Even though the averaging over long absorption pathlengths is expected to lead to some inaccuracies, there are additional errors in the corresponding publications, which question the value of this method. These errors stem mainly from the use of incorrect absorption cross sections, which were too large.[2b]

Absorption measurements are characterized by the fact that the total absorption is determined. If several species absorb in the same wavelength range, a further determination of their respective contributions to the total absorption is necessary. For this spectral data are required. In general, different species have different spectra, so that their contribution to the total can be determined by properly constructing the total spectrum from its constituent spectra. This is done by a fitting procedure. This basically simple procedure cannot be directly applied to atmospheric measurements as every attenuation of the light can be a priori interpreted as a molecular absorption. In the atmosphere, however, the intensity of a light beam can be changed not only by the desired molecular absorptions, but scattering processes (Rayleigh, Mie, etc.) also contribute to the attenuation. Since these processes are independent of each other, the well-known Lambert–Beer law can be used in the form described by Equation (17), which gives the light intensity I_L for a given wave-

$$I_L(\lambda) = I_0(\lambda) \exp(-L \sum_i N_i \sigma_i) \tag{17}$$

length after passage through a distance L in a medium with the absorption or scattering cross section σ_i for a gas mixture with the partial densities N_i. The scattering effects can be factored out using a factor A and one obtains Equation (18), in which σ_j

$$I_L(\lambda) = I_0(\lambda) A \exp(-L \sum_j N_j \sigma_j) \tag{18}$$

are now only the cross sections for the molecular absorptions. The factor A must be ≤ 1, because only the fraction A of the original light intensity I_0 can contribute to the molecular absorptions. The new baseline to which the atmospheric absorption is referred is now $A \times I_0$, where A is generally unknown. A can be assumed to be constant for the observed wavelength region. If a measurement is performed on an absorber that is characterized by an isolated absorption line, $A \times I_0$ can, in principle, be determined at two wavelengths, namely right at the position of the line and right next to it. This situation is generally not found for molecular gases under atmospheric conditions. The spectra are usually not fully resolved and there is a continuous baseline absorption. Therefore a spectral region should be recorded that allows the identification of the absorbing substance or substances. If the whole spectral region is recorded the determination of $A \times I_0$ can be avoided. For example, if the ratio of the measured light intensities at two different wavelength positions λ_1 and λ_2, $I(\lambda_1)$ and $I(\lambda_2)$, is formed, one obtains an expression which no longer contains $A \times I_0$, if I_0 is independent of wavelength for the respective interval [Eq. (19)]. The method

$$I(\lambda_1)/I(\lambda_2) = \exp\left\{-L \sum_j N_j [\sigma_j(\lambda_1) - \sigma_j(\lambda_2)]\right\} = \exp\left(-L \sum_j N_j \Delta\sigma_j\right) \tag{19}$$

is therefore a procedure that utilizes the differential absorption, that is, the structural component of the total absorption, to

determine the absolute quantities of the absorbing species. To fit the component spectra, it is necessary to measure them first in the laboratory, using the pure components. It is essential that these comparison spectra are recorded under atmospheric conditions, which means that the spectra are obtained in air at atmospheric pressure. This allows all of the effects caused by Doppler and pressure broadening, which change the spectra in characteristic ways, to be taken into account.

In atmospheric chemistry, OH concentrations of 5×10^5 cm^{-3} must be measured, therefore the detection limit for the absorption must be at around 1×10^{-5}–2×10^{-5}, as it is unrealistic to assume pathlengths of more than 2 km. This pathlength is currently the upper limit when the discussed measurement requirement for locality is to be satisfied. This pathlength of 2 km must be obtained by multiple reflections between mirrors of a suitable cell (e.g., according to White[29]). This cell has a small volume, and the distance between the mirrors, which determines the dimensions of the cell, is only a few meters. The Frankfurt setup has a mirror distance of 6 meters and hence requires about 300 reflections.[30]

The atmosphere is not optically homogeneous; the glimmering of air is well known. The intensity fluctuations in the light beam caused by this are big enough to make measurements impossible which attempt to quantify effects on the order of 10^{-5}. Studies of the temporal behavior of these effects, which are caused by density fluctuations in the air, have shown that they occur in a time frame that is longer than 100 μs.[31] If it were possible to obtain the entire desired spectral information in a time interval of less than 100 μs, the atmosphere could be considered as sufficiently stable. The spectrum obtained in this way would have a baseline that remains unchanged over this time period.

This baseline characterizes the continuous background underlying the structured absorption (given by $\Delta\sigma$). It is not a straight line over the entire spectral region of the absorption, but exhibits a structure with statistical fluctuations. The summation of many single spectra during the course of a measurement yields a total spectrum that is characteristic for the corresponding atmospheric situation, exhibiting an as yet unknown characteristic baseline. The spectrum is worked up, as was discussed above, by fitting the spectra of its components. After the contributions of all component spectra are removed, a residual spectrum remains, which, together with the continuous background, represents the baseline. Once the baseline is known, Equation (19) can be used to determine the absolute concentration of each absorber.

The basic principles for the determination of the local tropospheric OH concentration, as performed in Frankfurt, have now been described. Our field measurements in the Black Forest (1991)[32] and in the Taunus (1992)[33] have shown that the concentration of three additional gases could be measured in the wavelength range of the selected OH absorption, namely SO_2, $C_{10}H_8$ (naphthalene), and HCHO (formaldehyde). This transforms the absorption method into a multicomponent method in which the individual components are all measured under the same conditions, which is an ideal prerequisite for the testing of models.[34]

The measurements on SO_2 have another use as well. There are other, very sensitive nonoptical analytical methods available for this gas. These "conventional" methods must be calibrated before use. The optical method described herein can then be used for this calibration. The SO_2 measurements therefore act as a secondary standard, as SO_2 is nearly always present in measurable quantities.

The schematic setup of the apparatus in Frankfurt is shown in Figure 4.[35] A laser functions as primary light source; the beam quality is improved by an additional modulator which stabilizes the beam intensity. The beam passes through a 6m-long multireflection cell and reaches a total pathlength of 1.2 km before arriving at the detector. A newer version of the apparatus utilizes not only the UV light at 308 nm, which is obtained by frequency doubling, for the measurements, but also its first harmonic radiation at 616 nm. For this 616 nm beam, a second multireflection cell, identical to the first one except for a different mirror coating, is placed parallel to the UV cell. NO_2, which is so important for the chemistry of the atmosphere, absorbs in this wavelength region. The multicomponent system is hereby expanded by another interesting component.[36] As NO_2 is directly involved in OH recycling, and the measurements obtained in this apparatus are absolute, this expansion is especially valuable for the measurements on OH. As for SO_2, there are conventional techniques available for NO_2, which require additional calibration.

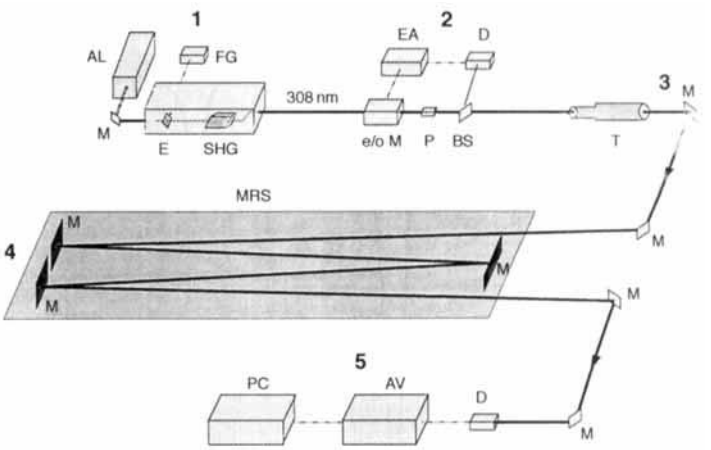

Fig. 4. Schematic representation of the measurement setup. 1) Components of the UV laser; AL: argon ion laser, M: mirror, E: etalon, SHG: frequency doubler (second harmonic generator), FG: function generator. 2) Components of the control and stabilizing unit; e/o M: electrooptic modulator, P: polarizer, BS: beam splitter, EA: error amplifier, D: photodiode. 3) T: telescope, M: mirror. 4) Shaded area: 6m-long multireflection cell (MRS) allowing a path length of 1.2 km in the free troposphere. 5) Components of the detection unit; D: photodiode, AV: averager, PC: computer.

Figure 5 shows the results of a measurement which was performed on September 7, 1992, on the Kleiner Feldberg in the Taunus mountains in Germany. The complete UV absorption spectrum is shown in Figure 5a. The contributing component spectra were sequentially subtracted from the total spectrum. For the sake of illustration, this was done in different orders. On that particular day, the concentration of formaldehyde was below the detection limit, therefore the spectrum contains "only" three components.

The success of this analysis of the atmospheric absorption spectrum is also a confirmation of the quality of the technique.

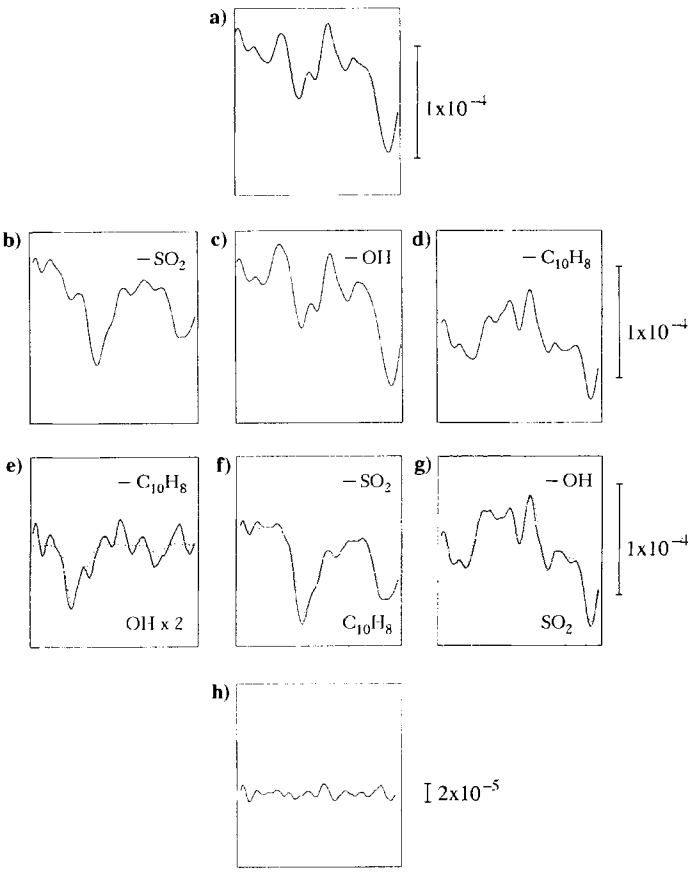

Fig. 5. Single measurement at 1:00 pm CET on September 7, 1992 at the Taunus Observatory of the University Frankfurt/Main, located on the Kleiner Feldberg (FRG) (800 m above sea level). a): Total tropospheric spectrum in the region of OH absorption; b)–d): Total spectrum corrected for the presence of SO_2, OH, and naphthalene, respectively; e)–g): Remaining spectrum after subtraction of SO_2/naphthalene, OH/SO_2, and naphthalene/OH, respectively. h): Residual spectrum. ·····: Reference, ——: Troposphere. The spectra shown correspond to the following concentrations of OH, naphthalene, and SO_2: [OH] = 0.05 pptv, [$C_{10}H_8$] = 40 pptv, [SO_2] = 3 ppbv.

In addition, the results were verified by further independent experiments, which can only be mentioned here.[33] This should satisfy the demand of analytical chemists that any single technique must be verified by independent procedures in order to receive a high degree of confidence. It remains to be noted that it is now finally possible to begin with the long-desired testing of models of the chemistry of the atmosphere.

4. Conclusion and Outlook

Atmospheric chemistry is the chemistry of atmospheric trace components. Hydroxyl radicals play a central role in this chemistry. Their reactions have a crucial influence on the chemistry of the trace species and thereby initiate the self-cleansing process of the atmosphere. That is why the OH radical is also called the detergent of the atmosphere. These molecules therefore also play an important role as a test substance for the verification of existing models.

The above discussion has shown that OH radicals in the troposphere are subjected to a recycling process. This recycling process is a very sensitive instrument in the maintenance of the balance between OH sources and sinks and thereby has a decisive influence on the oxidative potential of the troposphere. In the course of these cycles, the hydroperoxy radical HO_2 also occupies an important position, therefore the determination of its concentration is also an important goal. Due to its comparatively lower reactivity it is present in higher stationary concentrations than OH, but its spectroscopic properties have so far not allowed suitable in situ measurements. The transfer of the fast detection technique presented here to a spectral region suitable for HO_2 appears feasible, however. A new laser system would have to be developed for this application.

Due to the low tropospheric OH concentration, experimental tests of atmospheric models by field measurements are a significant challenge for analytical chemistry. The work summarized here is supposed to show that it is now possible to carry out this test and that a critical verification of atmospheric models can now be performed, something atmospheric chemists have waited a long time for. The developments in Frankfurt further permit measurements in which the absolute concentrations of other atmospheric components, which are used in the verification of the models as well, can be determined simultaneously with and at the same location as OH. The analytical technique described here is therefore a local multicomponent technique which has the required sensitivity as well as the necessary temporal and spatial resolution to enable the realization of such an important endeavor as the verification of models for the chemistry of the atmosphere.[37]

The experimental results described in this article were taken from several Ph.D. and Master's (Diplom) theses. My special gratitude goes to W. Armerding, A. Herbert, M. Spiekermann, J. Walter, and C. Rüger. This work was supported by the Bundesministerium für Forschung und Technologie and the Deutsche Forschungsgemeinschaft.

[37] Note added in proof (August 5, 1994): In the time which has elapsed between the submission and the publication of this review two extensive series of measurements have been carried out at the mountain station of Izana on Tenerife, by the German Sun Observatory and by the Spanish Weather Service with international collaboration. These studies reveal strong correlations between OH concentrations measured with short wave solar radiation and important trace components such as O_3, H_2O, NO_x, hydrocarbons. In certain cases the OH concentrations measured exceeded 1×10^7 cm^{-3}.

F. Cramer
Chaos and Order
The Complex Structure of Living Systems
With a foreword by I. Prigogine

1993. 250 pages with 89 figures. Hardcover.
DM 48.00.
ISBN 3-527-29067-2

What is life? How do ideas arise in our brain? Is there a vital force?
Recent progress in biological research has had a profound effect on our perception of nature. A deeper understanding of nonlinear systems far from equilibrium and of self-organization are no longer outside the scope of science. Professor F. Cramer, who is well known for his contributions in the field of molecular biology, uses his own insights as a starting point for developing an overall picture of the great questions that have always fascinated mankind.

'[Chaos and Order] is the work of a man who rejects a fragmented view of the universe, who refuses to be a prisoner of preconceived doctrines. There is a feeling of excitement, a feeling that we are living at a unique moment in the history of science. The world appears to us at the same time as more strange, but also as more connected and more harmonious, than to any of the generations which have preceded us. I can only hope that Cramer's book will inspire many readers and will receive the international acclaim that it fully deserves.'

Specific Binding of Antibodies to DNA through Combinatorial Antibody Libraries

Michael Famulok* and Dirk Faulhammer

The immune system of a higher developed organism is probably the most potent system in nature for the highly specific recognition of all different kinds of molecular species. The antibody repertoire in man or mouse has a diversity between 10^7 and 10^{11}. The enormous number of antibody specificities is achieved by the combination of a relatively small number of incomplete genes (see e.g. immunoglobulin G1, Scheme 1). For

Scheme 1. Immunoglobulin G1. The regions shown in gray represent the Fabs. They consist of the variable (V_H) and the constant (C_H1) regions of the heavy chain, as well as the variable (V_L) and constant (C_L) regions of the light chain. The antigen is bound mainly in the complementarity-determining regions (CDR regions) within the V_H and V_L.

the variable region V_H of the heavy chain around 100 V_H genes combine with 30 diversity genes (D genes) and 6 joining genes (J genes) to yield about 18000 different complete V_H chains. Because of inaccuracies in connecting the genes and enzymatic treatment, this number can increase by three orders of magnitude. The variable region V_L of the light chain results from the combination of 100 V_L genes with 5 J genes. An antigen binding site consists of a V_L and a V_H chain; their random fusion increases the number of possible combinations to 10^{11}. Finally, somatic mutations in these gene regions can raise the number of different antibody specificities even further by several orders of magnitude. This diversity, however, is far from fully utilized by the organism. The actually existing repertoire is sufficient for the development of antibodies against an incredible number of possible antigens, and as a result it effectively protects an organism against pathogenic or otherwise harmful agents.

This natural process, however, has certain limitations. Overcoming them would be of great importance for the more extensive technical, therapeutic, and diagnostic application of antibody technology. For example, the generation of antibodies specific for nucleic acids, such as double-stranded DNA (dsDNA) or RNA, by classical immunization of animals is quite often difficult, because nucleic acids typically lead to an extremely weak immune response. Likewise, the generation of catalytic antibodies by immunization with transition state analogues (TSAs) does not always lead to results desirable for an effective catalyst. In addition, only a fraction of the antibodies isolated from TSA-immunized animals bind the immunogen. On the other hand, only a few binders obtained are catalytically active.

For these and other reasons, extensive effort has been devoted for some time to the generation of synthetic antibodies, whereby the natural process is not only copied, but even improved.[1] The goal is to use an antibody library with a huge number of binding specificities without relying on the immunization of animals or the employment of eukaryotic cells. A recent publication by Barbas et al. on the specific recognition of double-stranded DNA (dsDNA) by semisynthetic antibodies shows that these efforts are very promising.[2]

How is it possible to copy nature's combinatorial process of antibody formation in the laboratory? How can it be used successfully for the selection of antibodies with novel functionalities? More importantly, how can the selected functional molecules be traced back genetically and amplified?

Among the most decisive steps for the generation of antibody diversity in vitro is the expression of single antigen-binding fragments (Fabs) in the bacterium *Escherichia coli*.[3] The antigen-binding fragment is a heterodimer which consists of a light chain and a fragment of the heavy chain. Another crucial aspect is the amplification of V_H and V_L genes by the polymerase chain reaction (PCR).[4] This was employed in the straightforward construction of libraries from the genomic cDNA of antibody-producing cells (spleen, bone marrow, peripheric blood cells). Furthermore, in this step semisynthetic antibody genes can be used, in which a part of the complementarity-determining region (CDR) is substituted by a randomized oligonucleotide. Finally, a gene vehicle, a vector, is required which is suitable for cloning the largest possible number of antibody genes and for

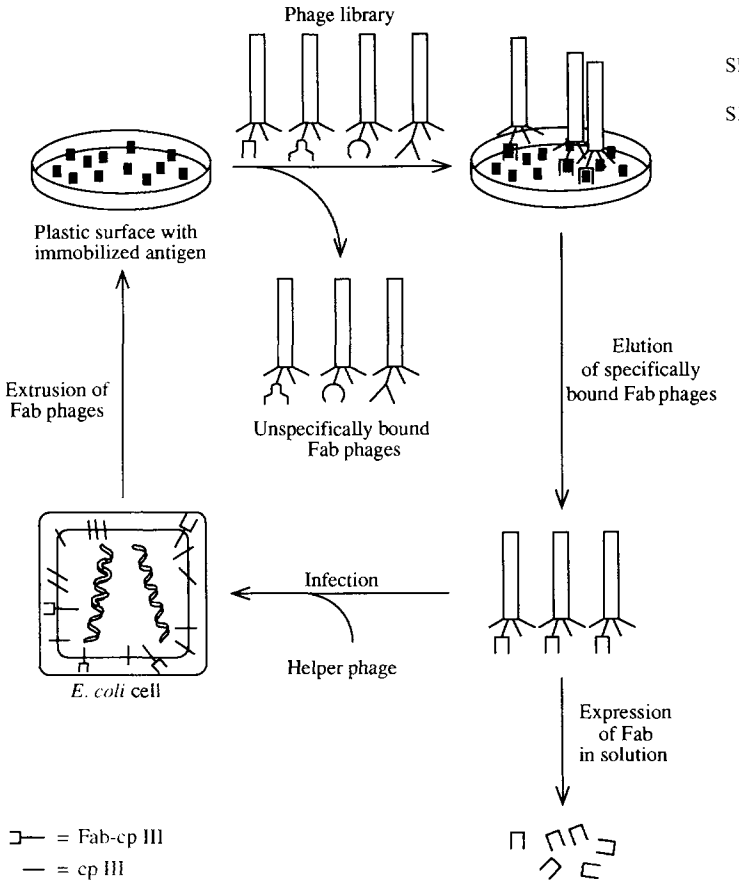
multiplying the corresponding proteins in the foreign cells. For this purpose, a bacterial virus (phage) is used, which contains the genes for the heavy and light chain and which is able to specifically infect bacteria with high efficiency.[5] Another crucial advantage of phage was shown by G. P. Smith in 1985: any peptide can be exprimed on the phage surface.[6] This was achieved by cloning the peptide-encoding DNA into the phage in such a way that the resulting peptide is fused with either its N- or C-terminus to a phage protein called coat protein III (cpIII). The cpIII is responsible for the binding of the phage to the bacterium. For that purpose it is exprimed at the phage surface at about four copies per virion. Exactly the same fusion principle could be applied to the antibody genes.[7] For the construction of the antibody library a specially designed vector (fdCAT1) is used. This vector is constructed in such a way that owing to its fusion with cpIII the heavy chain can be anchored to the inner membrane of the bacterium, whereas the light chain is excreted into the periplasm, the space between the inner and outer bacterial membrane. Hence, the two chains assemble on the membrane to give the complete antibody. By this design it is possible to combine the genetic and the structural information: the interior of the phage contains the antibody genes which are expressed on the outside such that the antibody can interact with its antigen in solution. In addition, it is thus possible to select the phage by binding them to immobilized antigens, for example, by means of affinity chromatography. The phage selected in this way can then be used again to infect bacteria. This selection process can be repeated until a maximal enrichment of functional antigen-binding fragments (Fabs) is achieved.

However, this method still had two disadvantages: the phage requires cpIII on its surface to enter the bacterium. But after the direct cloning of the antibody genes into the phage, all four cpIII molecules on the "tip" of the phage contain a Fab, which leads to a dramatic reduction of infectivity. Futhermore, the four Fabs on the phage tip lead to an increase in binding capacity; in this way, weak binders can simulate low dissociation constants by chelatization effects.

This problem was circumvented by using a special cloning vector, the phagemid pComb3, in combination with a helper phage for the cloning of the antibody library (Scheme 2). A phagemid is a hybrid of phage and plasmid, which consists of parts of the genome of a single-stranded DNA phage and of double-stranded components of plasmid DNA. Phagemids can reproduce within a host cell just like double-stranded plasmids. The simultaneous infection of the cells by the helper phage (M13) results in the synthesis of the gene products required for the packaging of phage particles, including the phagemids. In this case the phagemids can reproduce just like single-stranded DNA phages. In addition to the coat proteins, both intact cpIII and the Fab–cpIII fusion protein are produced; their genetic information is contained in the DNA of the helper phage and phagmid, respectively. If the DNA of the helper phage is mutated in a special way, the phagemid DNA is packaged preferentially. When the assembled phage is excreted from the cell, its surface is usually supplied with three cpIIIs and one Fab–cpIII fusion protein. The excreted phage thus contains the genetic information for the antibody genes in the form of a single-stranded copy of the phagemid DNA, together with a Fab molecule at its surface as well as the cpIII molecules required for



Scheme 2. Phagemid rescue of phagemid DNA by helper phages. The phagemid contains the genes for the light chain (Lc) and for the fusion protein, which consists of the cpIII and the heavy chain (Hc) of the Fab. Transformation into *E. coli* cells leads to the expression of the Fab–cpIII fusion protein in the periplasm (see text for details). The helper phage exprimes all the proteins required in the construction of the virus particle, including cpIII. Since the phagemid carries signals required for phage packaging, the phagemid DNA is packaged into the phage particle in single-stranded form.

efficient infection. In this way about 10^5 copies of each phage and of each set of antibody genes are produced.

The selection step, in technical terminology referred to as "panning", is represented in Scheme 3. The whole pool consisting of roughly 10^{12} Fab-containing phage (10^5 copies $\times$ 10^7 different phages in the library) is incubated with the antigen, which is immobilized on a plastic surface. Nonbinding phages are eluted with binding buffer, and the binding phages are thus enriched by about 100-fold. Specifically binding phages are then eluted, for example by affinity elution with the antigen or by lowering the pH. The isolated phages are used again to infect bacteria and amplify the phagemid DNA during cell growth. This DNA can then be packaged after addition of the helper phage, and the Fab can be exprimed at the surface, as described above. These steps are repeated until most of the phage of the enriched phage–Fabs of the pool bind to the antigen. The DNA is then isolated from the specifically binding phage–Fabs, the cpIII gene is removed by treatment with restriction enzymes, and the phagemid is regenerated by ligation. The phagemid can now be used to infect bacteria that do not exprime the Fab at their surface, because the cpIII part at the surface is missing. The unfused Fab is produced in soluble form, and the free antibody can be isolated from the bacterial cell extract. The antibodies can now be tested individually for their binding affinity to the antigen.

Barbas et al. used three antibody libraries each consisting of 10^9 different molecules,[2] in which certain regions in the V_H chain were randomized, to isolate specific DNA-binding anti-

Scheme 3. The panning process for selection of antigen-specific Fabs (see text for details).

bodies. In one library 10 amino acids in the CDR-3 of the heavy chain were randomized, in the other two libraries 16 amino acids. In general the CDR-3 of the antibody contributes most significantly to antigen recognition, because this region is characterized by the highest diversity. For the first two libraries the V_L region was held constant; in the third library the V_L chain contained a short randomized portion. For the panning, dsDNA from human placenta was used, which was immobilized on a plastic surface. After four cycles of panning, individual Fabs were tested for their binding behavior by enzyme linked immunosorbent assay (ELISA). Two Fabs (SD1 and SD2) gave a strongly positive signal. Both Fabs, which were bound to the immobilized DNA, could be eluted with a DNA solution that was only 10^{-9} M, which indicates a dissociation constant between 10 and 100 nM. The antibody SD1 clearly binds preferentially to G-C-rich regions; increasing concentrations of poly(dG) · poly(dC) and poly(dG-dC) · poly(dG-dC) inhibit its binding to DNA, whereas poly(dA) · poly(dT) or poly(dA-dT) · poly(dA-dT) do not show such an effect.

The antibodies selected by Barbas et al. do not fulfil the demands for an immediate technical or therapeutic application. In order to do so, they would have to bind with much better sequence specificity. With their preference for G-C-rich regions, however, the selected Fabs provide the basis for a novel class of sequence-specific DNA-binding molecules. This becomes evident when the 16-mer V_H region of SD1 is compared to the 10-mer V_H region of SD2. The amino acid sequence of both initially randomized regions show considerable homologies:

SD1: Gly-Arg-Ala-Tyr-Gly-Gly-Asn-Gly-Leu-Lys-Met-Met-Ser-Leu-Asp-Asn

SD2: Gly-Arg-Gly-Trp-Ser-Gly——————————Ser-Leu-Asp-Ile

However, SD1 contains six additional amino acids. Since this is the most significant difference between the two Fabs, it is thought that this insertion of six amino acids might be responsible for the G-C preference of SD1. The effect of changes in this region on the sequence specificity of the antibody is being tested.

Antibodies tailored for the recognition of specific DNA sequences could be used in many different ways. In genome mapping, for example, specific DNA sequences could be blocked making them inaccessible to other enzymes. Synthetic DNA-binding Fabs could be used to interfere with the control of the expression of specific genes, which could be employed in a range of therapeutic applications. Sequence-specific antibodies might help to identify certain DNA sequences in gene diagnostics. But these are only a few of the potential applications. It is important to note that in principle the range of applications is unlimited whether for the generation of synthetic biocatalysts or for the neutralization of viruses or toxins. One of the most important prospects might be the selection and improvement of catalytic antibodies. The first promising results have already been reported.[8, 9] For example, Chen et al. showed that an antibody library from mice immunized with a TSA hapten could be transferred to phage.[8] From this phage library, hapten-binding clones were isolated, some of which were catalytically active. This result was the proof for the principal applicability of combinatorial Fab libraries for the generation of catalytic antibodies.

It can be expected that a broad spectrum of antibody chains with various binding motifs will soon be available. The corresponding genes could be used as building blocks for the construction of designer antibodies. Another emerging possibility is the selection of antibodies that function even under exotic conditions, for example in the presence of organic solvents or toxic compounds.

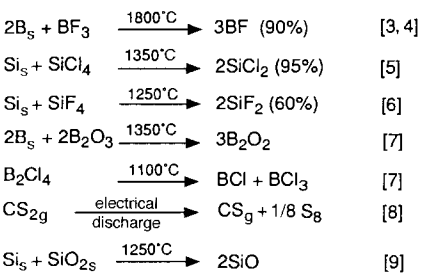
Subvalent Aluminum Halides as Examples of High-Temperature Species in Inorganic Syntheses

Jörg J. Schneider*

It is now 20 years since the pioneering work of P. L. Timms in the field of chemical synthesis with subvalent compounds EX_n of the third and fourth main group elements (especially with E = B and Si) (Scheme 1).[11] Subvalent in this context means

Scheme 1. Selected cocondensation reactions of the subvalent HT species BF (A) and $SiCl_2$ (B) with organic and inorganic compounds at −196 °C.

that the valence of the element E in these compounds is lower than the maximum valence allowed in the group. A variety of special handling techniques were developed to produce these compounds and to allow them to react with suitable partners, and, in particular, to have these high-temperature (HT) species available in preparative quantities on a laboratory scale.[1, 2] In the meantime, a large number of these molecules is experimentally accessible (Table 1).



Disproportionation and comproportionation reactions are the most common synthesis routes (Scheme 2). In every case, as a second step after their actual synthesis (mostly at high temperatures), trapping of these species at low temperatures (e.g. at −196 °C) is essential to bridle their extraordinary reactivity.

[*] Priv.-Doz. Dr. J. J. Schneider

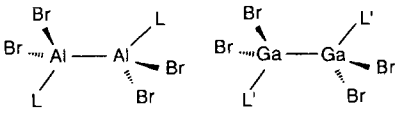
Table 1. Selected examples of preparatively accessible subvalent HT species of main group elements [2b].

BF	CS	
BCl	CF_2	
BC_2	CBr_2	
B_2O_2		
AlCl	SiO	P_2
AlF	SiS	PF
	SiC	PN
	SiF_2	PF_2
	$SiCl_2$	

All HT molecules presented in Table 1 have coordination numbers far below the maximum possible numbers, which explains this high reactivity. Careful treatment of these molecules with suitable reactants between −196 °C and room temperature enables largely selective reactions. Once the researcher has mastered the hurdles associated with the challenging experimental conditions during the synthesis of such compounds, he is rewarded with attractive yields and the above-mentioned extraordinarily high reactivity of these molecules. This allows a rich synthetic chemistry even at very low temperatures. Recently, the potential of subvalent HT species, especially those of the aluminum species, has been rediscovered.

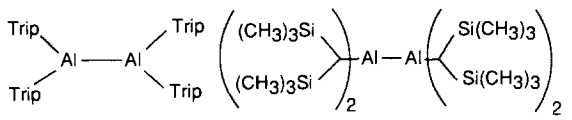
Scheme 2. Disproportionation and comproportionation reactions for the synthesis of subvalent HT compounds of the group 13 and group 14 elements with references. The pressure is less than 10^{-1} Torr for all reactions.



For some time, H. Schnöckel's research group has specialized in the preparation and investigation of the reaction behavior of subvalent EX (E = Al, Ga; X = Cl, Br) species. They have obtained AlX and GaX by cocondensation of atomic Al or Ga and gaseous HX in very good yields [Eq. (a)].[10]

$$E_s \xrightarrow[10^{-2}\ \text{Torr}]{\text{ca. } 1000\,^\circ\text{C}} E_g \xrightarrow[10^{-2}\ \text{Torr (90\%)}]{\text{HX, } -196\,^\circ\text{C}} EX + \tfrac{1}{2}H_2 \qquad \text{(a)}$$

E = Al, Ga; X = Cl, Br



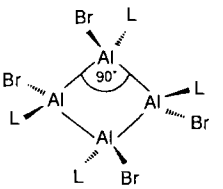
Initially, work centered on the actual synthesis, matrix isolation, and spectroscopic characterization of these HT species. Lately, more preparatively oriented work, especially on

alanediyl AlCl, has spawned important contributions to the chemistry of Al^{I} and, more recently, also to that of Al^{II}. Crucial to the preparative breakthrough in this sector of high-temperature chemistry was the observation that AlCl as well as its heavier homologue GaCl could be prepared as metastable molecules and stored in a mixture of toluene and diethyl ether at low temperature for quite some time. A spectacular result of these studies, for instance, was the synthesis of $[(\eta^5\text{-Cp*})Al]_4$,[11] the first homoleptic $(\eta^5\text{-Cp*})Al$ cluster, subject of an earlier Highlight.[12] Recently, again from H. Schnöckel's research group, the synthesis and characterization of donor-stabilized $AlBr_2$ (**1**) (Scheme 3) was reported.[13a] It is a subvalent aluminum(II)

2.527(6) 2.395(6)

1 [13a] **2** [14]

2.647(3) 2.660(1)



3 [15] **4** [16a]

Scheme 3. E–E distances [Å] in the subvalent compounds **1**–**4**. L = anisole, L' = 1,4-dioxane, Trip = 2,4,6-tri-isopropylphenyl.

halide stable at room temperature. The corresponding halide of the heavier homologue gallium (compound **2**) has been known for some time and its structure has been characterized.[14] Donor-stabilized $AlBr_2$ forms by comproportionation from a cocondensation solution of AlBr and anisole, in which $AlBr_3$ (10%) is also present. The actual primary product of the reaction $AlBr_2$ is trapped at $-30\,^{\circ}C$ by the donor solvent anisole (L) in the form of a stable complex $Al_2Br_4 \cdot L_2$ (**1**). The presence of $AlBr_3$ in the cocondensate as an "impurity" is thus essential for the in-situ formation of the new $Al^{II}Br_2$ species. The extended synthesis route to **1** via AlBr is necessary, since $AlBr_2$ cannot be made directly from Al atoms and HBr on a preparative scale.[13b] In the solid, **1** does not disproportionate into Al^{I} and Al^{III} compounds.

The Al–Al bond in **1** is noticeably shorter than that in other organoalanes such as **3** and **4**, and similar to the one found for the radical anion $\mathbf{3}^{\bullet -}$. One-electron reduction of **3** and **4** to $\mathbf{3}^{\bullet -}$ and $\mathbf{4}^{\bullet -}$, respectively, entails a significant shortening of the central Al–Al bond (Δd(Al–Al) = 0.17[15] and 0.13 Å, respectively).[16] Additional π bonding contributions in the radical anions are supposed to be responsible for this. If a—purely hypothetical—shortening of the Al–Al bond of the same order as upon reduction of **3** and **4** occurs on going from **1** to $\mathbf{1}^{\bullet -}$, an Al_2 system with an E–E bond even shorter than that found so far in $\mathbf{3}^{\bullet -}$ and $\mathbf{4}^{\bullet -}$ would result. H. Schnöckel et al. now have also succeeded in preparing Et_3N-donor-stabilized AlBr (**5**) and have characterized this species spectroscopically as well as structurally. This has just recently been reported in *Angewandte Chemie*.[17]

Unlike the donor-stabilized $AlBr_2$ **1**, **5** is tetrameric in the crystal ($[BrAl{\leftarrow}NEt_3]_4$) and features a square Al_4 unit. The Al–Al distances in **5** (2.643(3) Å) lie within the range of Al–Al single bonds.[11, 15, 16a] Similarly, in contrast to **1**, **5** already forms around $-100\,^{\circ}C$ from the cocondensate mixture of (AlBr/toluene and Et_3N). Accordingly, no efficient formation of $AlBr_2$ from AlBr and $AlBr_3$, as is supposed to happen during the synthesis of **1**, occurs under these reaction conditions, and consequently no formation of an aluminum(II) system is observed. Not until $-30\,^{\circ}C$ does the actual comproportionation reaction between AlBr and $AlBr_3$ set in leading to the formation of $AlBr_2$.[13] The trapping of the HT species AlBr with the appropriate donor solvent in the right temperature range is thus of prime importance for the formation of AlX or AlX_2 molecules in these syntheses. This has certainly to be taken into account during further studies of AlX and possibly GaX. The rather elongated Al–Br bonds (as compared to those in **1**[13] and $AlBr_3$[18]) in **5** support its formulation as an aluminum(I) bromide. The same holds for the Al–N bonds if one compares them to those found for the NH_3 and Me_3N adducts of $AlBr_3$.[19] These observations are in accord with an increasing ionic radius in the series $Al^{3+} < Al^{2+} < Al^{+}$.

5, L = Et_3N

The formation of **5** constitutes the second synthesis of a homonuclear Al_4 cluster from monomeric AlX. It remains to be seen if a conventional preparative route to these unusual Al^{I} and Al^{II} compounds (**5** and possibly **1**) can be found, as has already been the case for $[(\eta^5\text{-Cp*})Al]_4$.[20] Since the E–E bond is already present in **1**, and since halide substitution should be easy, **1** suggests itself as a starting material for the synthesis of other dialanes like **4**. For the heavier element homologues Ga and In this has already been illustrated by type **2** compounds.[21] This opens an alternative route to new dialane type molecules, a class of compounds which so far has only been accessible by reduction of dialkyl element halides.[22]

Preparative synthetic chemistry under extreme conditions, be it in the form of free-atom syntheses, or in the application of highly reactive subvalent molecules as shown in this Highlight, has once again proven its merits among other preparative methods. It continues to offer surprising results such as unexpected molecules like **1** and **5**.

In this context, a speculative glance at the neighbor of aluminum in group 14 should be permitted. Maybe for SiX_2[23] or even SiO (both preparatively quite accessible subvalent HT species) there exist unexpected ways of stabilizing them analogously to AlX or GaX. Then a complex-bound SiO, whether at a main group metallic center or at a transition metal center (analgous to CO?) could in this way become a reality in the future.

The Search for Selective, Neutral Anion Receptors

Dieter E. Kaufmann* and A. Otten

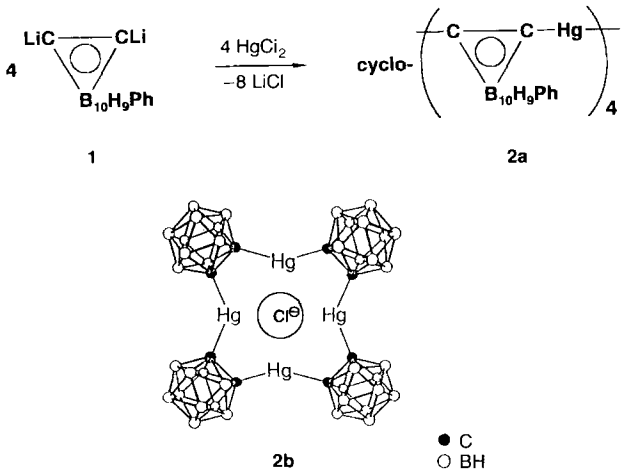
The binding of guest to host molecule for selective activation for a subsequent reaction is an extremely successful principle in biological processes and in organic synthesis. Thus the synthesis of organic mono- or bicyclic host macrocycles has become established over the last 25 years for the selective complexation of cationic guests and opened diverse possibilities for applications.[1]

The synthesis of molecules for the selective recognition of anions is, in contrast, more difficult from the outset, because

- the anions are coordinatively saturated and therefore bind only sluggishly
- their size requires that the macrocycles that must be developed are significantly larger than those for cations, and
- the solvent-dependent formation of ion pairs or their very efficient solvation impede a selective complexation.

The rapid development—also stimulated by the huge significance of biological anion receptors –of supramolecular chemistry in the past decade has contributed to the increased efforts to synthesize molecules for the recognition of anions.[2] Interesting fields of application are molecular recognition, development of synthetic enzyme analogues, transport of anions, and homogeneous catalysis. In medical diagnosis the concentration of anions is already routinely determined with very ion-selective electrodes.[3]

Different structure and binding concepts have been investigated with the aim of recognizing anions selectively. At first it made sense to use the experience gained from the chemistry of cation receptors and to prepare, by addition of electrophiles, the electronic inverse and thus polyammonium macro- and oligocycles as well as guanidinium compounds fundamentally suitable for anion complexation. These macrocycles with protonated or quaternary nitrogen functions display high positive charge densities and a strong ability for complexation, and consequently also an often very small selectivity for the guest anions. Uncharged host molecules for anions should, in principle, provide a better chance for selectivity.



Very recently interesting syntheses of charged and neutral host molecules have been developed. In 1993 Stang and Zhdankin[4] reported a simple synthesis of macrocyclic tetrabiphenyldiyltetraiodium compounds that are unusual cationic molecular cages. Presently the selective complexation of anions and/or basic neutral molecules by these molecules is being investigated.

Covalently bound Lewis acid centers are suitable binding sites for coordinative complexation of anion and basic molecules according to another bonding concept: they invariably have lone electron pairs. The work of Jung et al.[5] on a macrocyclic

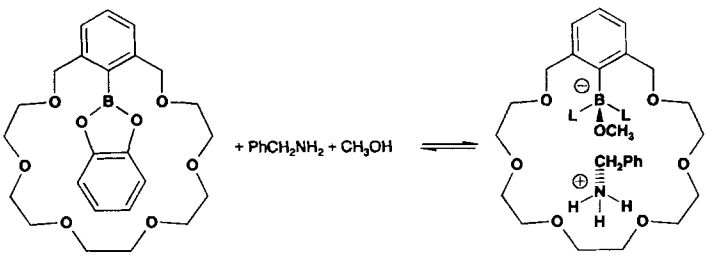
trisilane as well as that of Newcomb et al.[6] and Kuivila et al.[7] on stanna-coronands and -cryptands fit into this concept. Ion transport studies gave strong evidence for the selective and reversible inclusion of a halide ion; this was proven by solid-state ^{119}Sn NMR spectroscopy and crystal structure analyses.

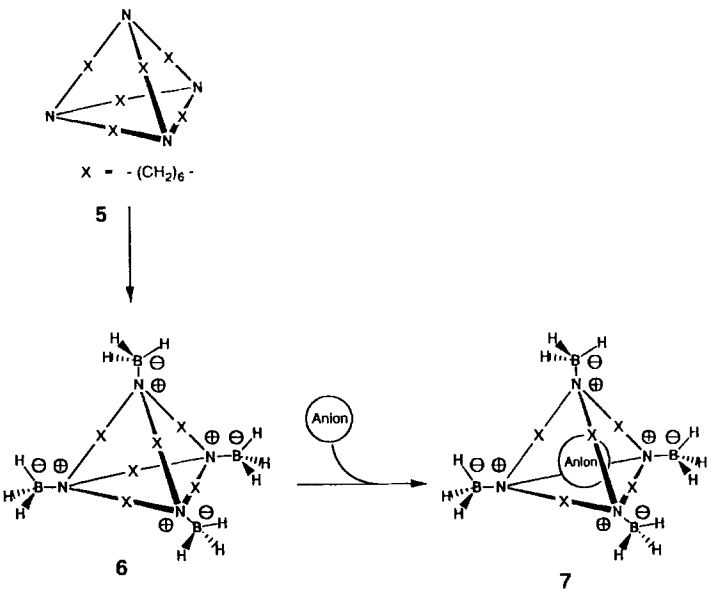
Hawthorne et al.[8] postulated that a kinetic template effect resulted in the exclusive formation of the tetradentate [12]mercuracarborand-4 on treatment of 1,2-dilithio-3-phenyl-*ortho*-carborane (**1**) with mercury halides, although on energetic considerations the trimeric [9]mercuracarborand-3 was the preferred product. These "anti-crown" complexes are accessible in good yields, soluble in polar organic solvents, and can bind halide guest anions reversibly (structure **2b** shows the results of the crystal structure analysis).



1 2a 2b

Simon et al.[9] developed electrodes with membranes incorporating the organomercury compounds and displaying a pronounced selectivity for chloride ions.

As early as 1985 Katz[10] reported on the cooperative binding of a hydride and a chloride ion by 1,8-diborylated naphthalene (hydride sponges). Oligoboron anticoronands or -cryptands are, on the other hand, as yet unknown. After a theoretical study by Jacobson and Pizer was published in 1993,[11] macrotricyclic host molecules with boron atoms in the four bridgehead positions are considered particularly promising synthetic targets because of their predicted strong binding to, and selectivity for, anions.



With the synthesis of the crown ethers **3** containing *one* Lewis acidic boryl substituent, Reetz et al.[12] opened the way to a new class of neutral host molecule that, depending on the anion, can bind either the anion or the cation of potassium salts monotopically, or both ions heterotopically. These host molecules can also recognize and incorporate two different organic guest molecules: an alcohol/amine mixture has indeed been shown to be bound heterotopically as in **4**. Steric factors are particularly important for the molecular recognition, so the host **3** can distinguish between methanol and ethanol.

Recently Schmidtchen et al.[13] were the first to report the synthesis and properties of an uncharged artificial anion host without Lewis acid character, thus demonstrating a third possibility for anion recognition: the borane/amine adduct **6**, which

3 4

is readily accessible by treatment of the known macrotricyclic amine **5** with BH_3·THF, can form a complex with anions through anion–dipole interaction with the strong B–N dipoles. For optimal stabilization of the anion, the orientation of the dipoles by a macrotricyclic framework like that of **6** is important.

5 6 7

This precise preorganization for the fixation of the negatively charged guest species brings both advantages and disadvantages. Problems lie in the often difficult syntheses of preorganized hosts, the subsequent changes in their structure that are always laborious to perform, and the often strong binding of the anion to the host that results in poor decomplexation and regenerability. Favorable aspects are the ability to fix the binding site of the guest quite precisely, the exact positioning of the anchor groups, and the choice of guest according to size. The crystal structure analysis shows that the cavity in **6** is smaller than that in the fourfold positively charged macrocyclic ammonium salt as a result of the distorted tetrahedral N atoms in the adduct. The α-CH_2 protons in the host molecule may be used as a ^{1}H NMR probe for conformational changes caused by anion complexation during the titration of **6** with ammonium or phosphonium salts. This experiment shows that large iodide and phosphorus hexafluoride anions are complexed only to a slight extent, and whereas the small chloride and cyanide anions are readily incorporated, binding to the bromide ion is virtually optimal. The exchange of the guest in a 1:1 host–guest complex

can also be achieved. Both the 1:1 host–chloride complex and the displacement of the chloride ion by a bromide or iodide ion was detected by electrospray mass spectrometry.

Interesting applications should be possible through the controlled change of the dipole strength by selection of the borane entity and through variation of the framework of the host molecule.

A long road lies ahead before the anion host molecules are as versatile as their cationic counterparts. Chemists wait in eager anticipation for these new approaches to lead to a breakthrough in the use of neutral anion receptors.

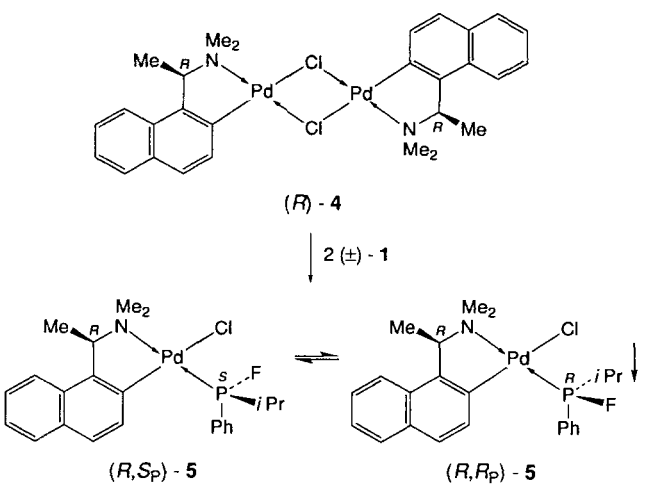
First Resolution of a Free Fluorophosphane Chiral at Phosphorus

Michael Pabel, Anthony C. Willis, and S. Bruce Wild*

Dedicated to Professor Ekkehard Lindner on the occasion of his 60th birthday

Following the first resolution of a simple acyclic tertiary phosphane in 1961,[1] the question arose as to the suitability for resolution of other simple trivalent phosphorus compounds, especially halophosphanes of the type PXR^1R^2, which in optically active form would be valuable intermediates for subsequent syntheses. Calculations of the energy barrier for the pyramidal inversion of compounds of this type indicated that configurational stability at phosphorus increased with attachment of electronegative substituents, for example chlorine or especially fluorine atoms.[2] Nevertheless the first reported attempts at synthesizing optically active fluoro- and chlorophosphanes from optically active compounds of the type $P(NR_2)R^1R^2$ by cleavage of the amino group with acyl halides, hydrogen chloride, or phosphorus trichloride were unsuccessful.[3] In 1992, however, it was reported that (*S*)-(−)-[P(SMe)Cl*t*BuPh]CF_3SO_3 of 63% optical purity could be desulfurized with tris(dimethylamino)phosphane at −70 °C to give (*S*)-(+)-PCl*t*BuPh of 49.4% optical purity before purification.[4] The chlorophosphane lost its optical activity over 20 h in the polarimeter cell. In other work it has been shown that (±)-PClMePh and (±)-AsFMePh can be resolved as ligands in certain iron(II) complexes, but these halogen-containing ligands cannot be liberated from the metal.[5] Here we report that (±)-**1** can be readily resolved by the separation of diastereomers of certain optically active palladium(II) complexes containing the phosphane, and that free (S_P)-(−)-**1** can be liberated in optically pure form from the less soluble diastereomer.



(±) - **1**

Based on the literature procedure for the synthesis of $PFtBu_2$,[6] (±)-**1** was isolated in 55% yield by heating a mixture of (±)-PClPh*i*Pr[7] and sodium fluoride in sulfolane and distilling with collection at −196 °C. The $^{31}P\{^1H\}$ NMR spectrum of the freshly thawed distillate in benzene at 25 °C indicated 86% of (±)-**1**, along with a number of minor impurities including the disproportionation product **2** [Eq. (a)]. A neat sample of (±)-**1**, after 16 h at 25 °C, had disproportionated into **2** and (*R**,*R**)/(*R**,*S**)-**3**. Thus, (±)-**1** is considerably less stable than $PFtBu_2$, which showed no evidence of decomposition when heated at 150 °C for 100 h, even in the presence of a trace of sodium fluoride.[6] It is noteworthy, however, that the disproportionation of (±)-**1** is slowed down dramatically in benzene.[8]

$$\underset{(\pm)\text{-}\mathbf{1}}{3\ \mathrm{PFPh}i\mathrm{Pr}} \longrightarrow \underset{\mathbf{2}}{\mathrm{PF_3Ph}i\mathrm{Pr}} + \underset{(R^*,R^*)/(R^*,S^*)\text{-}\mathbf{3}}{\mathrm{Ph}i\mathrm{PrP{-}PPh}i\mathrm{Pr}} \qquad \text{(a)}$$

The reaction of two equivalents of (±)-**1** with (*R*)-**4** in dichloromethane produced the pair of diastereomeric complexes (*R*,R_P)- and (*R*,S_P)-**5** in almost equal amounts (Scheme 1).

Scheme 1.

This was evidenced by a sharp doublet at $\delta = 185.14$ ($^1J(P,F) = 927.8$ Hz) and a broad doublet at $\delta = 181.36$ ($^1J(P,F) = 937.5$ Hz) in the $^{31}P\{^1H\}$ NMR spectrum. Interestingly, the relative intensity of the resonance at $\delta = 185.14$ increased to 75% over 18 h and then remained constant at this equilibrium value. Consistent with this observation, removal of solvent, followed by dissolution of the residue in diethyl ether, and subsequent filtration to remove a small quantity of solid impurity gave a colorless solution, which on concentration afforded the diastereomer having $\delta = 185.14$ in 64% combined yield in a typical second-order asymmetric transformation.[9] The final mother liquor was found to contain both diastereomers in the equilibrium 75:25 ratio. In pure form, (*R*,R_P)-**5** is kinetically stable in CD_2Cl_2.[10] The configurationally homogeneous product having $\delta = 185.14$, colorless prisms readily soluble in dichloromethane and benzene, and moderately soluble in diethyl ether, was identified as (*R*,R_P)-**5** by X-ray crystallography.[11]

The molecular structure of (*R*,R_P)-**5** is shown in Figure 1, together with selected bond lengths and angles. Compound (*R*,R_P)-**5** is the first alkylarylfluorophosphane complex to be isolated, and the structure determination performed is the first to our knowledge on an organofluorophosphane palladium

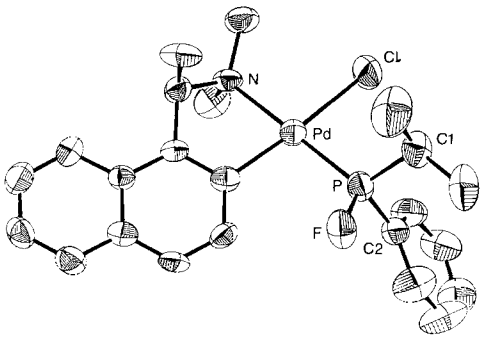

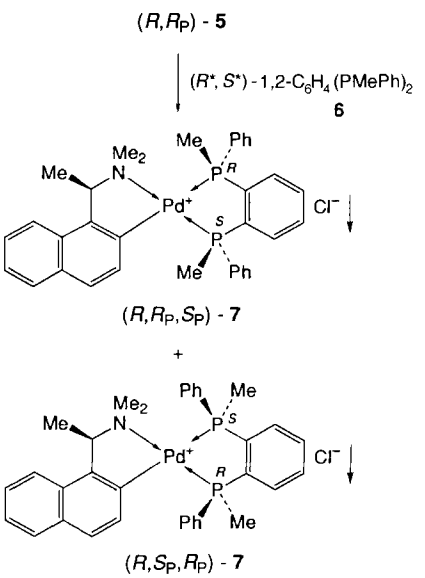

Fig. 1. Crystal structure of (R,R_P)-**5** (ORTEP diagram, thermal ellpsoids enclose 50% probability levels). Selected distances [Å] and angles [°]: P–F 1.589(5), P–Pd 2.215(3), P–C1 1.819(10), P–C2 1.786(9), Pd-P-F 117.1(2), Pd-P-C1 115.0(3), Pd-P-C2 115.3(3), F-P-C1 99.4(4), C1-P-C2 107.0(5), C2-P-F 100.9(4).

complex. The P–F distance in (R,R_P)-**5** is slightly longer than the P–F bonds in similar diarylfluorophosphane complexes,[12] but very similar to the corresponding distance in *trans*-[Ni-$Br_2(PF/Bu_2)_2$],[13] where the P–F bond was shortened by 4 pm upon complexation.[14] The coordination geometry around the palladium in the complex is slightly distorted from square-planar; the fluorophosphane is situated *trans* to the dimethylamino group, which is typical for such complexes.[15] The liberation of optically pure (S_P)-(−)-**1** from (R,R_P)-**5** was effected by treatment of the complex with achiral **6**[16] in benzene (Scheme 2).

Scheme 2.

The displacement proceeds with retention of configuration at phosphorus to give homochiral (S_P)-(−)-**1** as verified by the quantitative regeneration of the starting complex (R,R_P)-**5** from the free ligand and (*R*)-**4** (Scheme 1) in a rapid quenching experiment. A solution of (S_P)-(−)-**1** having $[\alpha]_D^{20} = -210$ ($c = 0.59$ in C_6H_6) was obtained within 30 min of liberation, the minimum period required to remove (R,R_P,S_P)- and (R,S_P,R_P)-**7** and prepare an accurate sample of the phosphane for measurement. Significantly, however, although the rotation of the solution increased to zero within 6 h (presumably by intermolecular fluorine exchange[3, 4]), the $^{31}P\{^1H\}$ NMR spectrum of a sample taken from the same solution showed no discernible disproportionation into **2** and $(R^*,R^*)/(R^*,S^*)$-**3** over 6 h.

Presently we are examining the stereochemistry of reactions of (S_P)-(−)-**1** in coordinated and free form.

Experimental Procedure

(±)-**1**: A mixture of chlorophenylisopropylphosphane (11.75 g, 63.0 mmol) and sodium fluoride (14.36 g, 342.0 mmol) in sulfolane (120 mL) was heated with stirring at 140 °C for 80 min. The product (b.p. 93 °C, 14 mmHg) was collected at −196 °C. Yield 6.09 g (55%). $^{31}P\{^1H\}$ NMR (121.42 MHz, CD_2Cl_2, 25 °C, H_3PO_4): $\delta = 183.10$ (d, $^1J(P,F) = 855.3$ Hz) (ca. 86%); ^1H NMR (299.95 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 0.91$ (ddd, $^3J(H,P) = 15.6$ Hz, $^3J(H,H) = 6.9$ Hz, $^4J(H,F) = 1.2$ Hz, 3 H; CH_3), 1.21 (ddd, $^3J(H,P) = 13.5$ Hz, $^3J(H,H) = 6.9$ Hz, $^4J(H,F) = 1.2$ Hz, 3 H; CH_3), 1.94–2.14 (m, 1 H; CH), 7.44–7.62 (m, 5 H; C_6H_5); $^{13}C\{^1H\}$ NMR (75.43 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 15.30$ (dd, $^2J(C,P) = 19.2$ Hz, $^3J(C,F) = 5.5$ Hz; CH_3), 16.85 (dd, $^2J(C,P) = 15.3$ Hz, $^3J(C,F) = 2.7$ Hz; CH_3), 34.09 (dd, $^1J(C,P) = 21.4$ Hz, $^2J(C,F) = 12.1$ Hz; CH), 128.71 (dd, $^3J(C,P) = 7.7$ Hz, $^4J(C,F) = 1.7$ Hz; *meta*-CH), 129.64 (dd, $^2J(C,P) = 23.1$ Hz, $^3J(C,F) = 8.2$ Hz; *ortho*-CH), 130.66 (s; *para*-CH), 140.66 (dd, $^1J(C,P) = 29.1$ Hz, $^2J(C,F) = 10.5$ Hz; *ipso*-C); ^{19}F NMR (282.20 MHz, $CDCl_3$, 25 °C, $CFCl_3$): $\delta = -208.44$ (dd, $^1J(F,P) = 857.5$ Hz, $^3J(F,H) = 13.7$ Hz). A sample of (±)-**1** after 16 h at 25 °C had the following $^{31}P\{^1H\}$ NMR spectrum in CD_2Cl_2: $\delta = -13.18$ (td, $^1J(P,F_{ax}) = 849.8$ Hz, $^1J(P,F_{eq}) = 979.6$ Hz) (**2**): −8.98 (s) and −15.30 (s), [$(R^*,R^*)/(R^*,S^*)$-**3**].

(R,R_P)-**5**: A solution of (*R*)-**4** (7.67 g, 10.0 mmol) in dichloromethane (200 mL) was added over 5 min to a solution of (±)-**1** (4.07 g of 86% purity, 20.3 mmol) in the same solvent (100 mL). After stirring for 18 h the solvent was removed from the reaction mixture in vacuo, and the residue was dissolved in diethyl ether (400 mL). The solution was filtered and concentrated to ca. 60 mL, whereupon a colorless microcrystalline solid precipitated. The crude product was washed with 25 mL of cold diethyl ether and dried in vacuo. Concentration of the mother liquor yielded additional product. Three recrystallizations of the combined crude material from diethyl ether gave the pure product. Yield 6.65 g (64%). M.p. 182 °C. $[\alpha]_D^{20} = +35.2$ ($c = 0.88$ in CH_2Cl_2). $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$, 25 °C, H_3PO_4): $\delta = 185.14$ (d, $^1J(P,F) = 927.8$ Hz); ^1H NMR (299.95 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 1.00$ (dd, $^3J(H,P) = 14.3$ Hz, $^3J(H,H) = 7.1$ Hz, 3 H; *i*Pr-CH_3), 1.68 (dd, $^3J(H,P) = 20.3$ Hz, $^3J(H,H) = 7.4$ Hz, 3 H; *i*Pr-CH_3), 1.97 (d, $^3J(H,H) = 6.3$ Hz, 3 H; benzyl-CH_3), 2.58 (d, $^4J(H,P) = 1.8$ Hz, 3 H; N-CH_3), 2.90 (d, $^4J(H,P) = 3.9$ Hz, 3 H; N-CH_3), 2.92–3.06 (m, 1 H; *i*Pr-CH), 4.31 (d of quart., $^4J(H,P) = 6.8$ Hz, $^3J(H,H) = 6.3$ Hz 1 H; benzyl-CH), 7.20–8.20 (m, 11 H; aromatics); $^{13}C\{^1H\}$ NMR (50.31 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 14.95$ (dd, $^2J(C,P) = 6.0$ Hz, $^3J(C,F) = 3.1$ Hz; *i*Pr-CH_3), 18.27 (d, $^2J(C,P) = 4.2$ Hz; *i*Pr-CH_3), 23.64 (s; benzyl-CH_3), 34.28 (dd, $^1J(C,P) = 28.5$ Hz, $^2J(C,F) = 12.5$ Hz; *i*Pr-CH), 47.66 (d, $^3J(C,P) = 2.7$ Hz; N-CH_3), 50.93 (d, $^3J(C,P) = 3.3$ Hz; N-CH_3), 72.60 (d, $^3J(C,P) = 3.5$ Hz; benzyl-CH), 123.09–148.94 (aromatics); ^{19}F NMR (282.20 MHz, $CDCl_3$, 25 °C, $CFCl_3$): $\delta = -185.08$ (dd, $^1J(F,P) = 927.8$ Hz, $^3J(F,H) = 24.4$ Hz); MS (70 eV: 511.1 [M^+]; correct elemental analyses were obtained.

(S_P)-(−)-**1**: A solution of **6** (67.5 mg, 209.4 μmol) in benzene (1 mL) was added to a stirred solution of (R,R_P)-**5** (106.8 mg, 209.3 μmol) in the same solvent (1 mL). The mixture was diluted immediately with benzene (4 mL) and centrifuged to give a colorless solution of (S_P)-(−)-**1**, $[\alpha]_D^{20} = -210$ ($c = 0.59$ in C_6H_6), and a sediment of (R,R_P,S_P)- and (R,S_P,R_P)-**7**. Treatment of this solution with (*R*)-**4** regenerated quantitatively (R,R_P)-**5** as shown by spectral comparisons.

Spectroscopic Studies of Anhydroretinol, an Endogenous Mammalian and Insect *retro*-Retinoid**

Fadila Derguini,* Koji Nakanishi, Jochen Buck, Ulrich Hämmerling, and Felix Grün

Carotenoids obtained through diet have been adapted for a wide variety of essential roles in animal physiology. The most commonly used primary metabolite, retinol (vitamin A1, **1a**), acts as the prohormone in at least three distinct effector pathways in mammals. The visual pigment rhodopsin uses *11-cis*-retinal (**2**) as its chromophore;[1] retinoic acid (**1b**) performs functions during cellular differentiation and morphogenesis[2] through the control of gene expression by ligand-dependent nuclear receptors. Retinol itself, or metabolites distinct from the retinoic acid series, is essential for regulation of spermatogenesis[3] and the immune system.[4] 14-Hydroxy-4,14-*retro*-retinol (14-HRR, **3**), the first bioactive *retro*-retinoid reported, functions as a potent intracellular agonist of retinol-dependent events in immune cells.[5] First isolated from mammalian cells, 14-HRR has also been identified in *Drosophila* and other insect cells. In addition, we found another naturally occurring *retro*-retinoid, anhydroretinol (AR, **4**), which reversibly inhibits retinol and 14-HRR dependent effects and blocks B lymphocyte proliferation as well as activation of resting T lymphocytes.[6] 14-HRR and AR constitute the first agonist/antagonist pair of lipid signaling molecules to be reported. Anhydroretinol, a physiological retinol derivative, was originally isolated from fish liver oils;[7] however, its biological role remained obscure, and until recently it was referred to as the "inactive retinoid".[8] More recently AR was characterized in a variety of mammalian cells, for example in liver and lung cells,[9a] in transformed mouse fibroblasts,[9b] and in insect cell lines such as *Drosophila* S2M3 cells and *Spodoptera frugiperda* SF 21 cells, where it is the predominent retinol metabolite. In contrast, a subclone of this latter line, SF 9, did not produce a detectable amount of AR.[6] Addition of [^{3}H]retinol to cell preparations followed by immediate extraction and analysis by high-pressure liquid chromatography (HPLC) does not lead to spontaneous formation of anhydroretinol. Moreover, AR is not detected when cells are kept at 4 °C, fixed with glutaraldehyde, or treated with sodium azide. Thus its synthesis is dependent on an active metabolic state. The newly discovered biological role of AR, as a naturally occurring 14-HRR antagonist, makes the study of anhydroretinol of special interest. We describe here the purification of AR from *Drosophila* Schneider S2M3 cells and the characterization of its synthetic isomers.

Insect S2M3 cells were grown in Schneider's medium. HPLC analysis of the lipid fraction (Fig. 1a) indicated the ability of the cells to metabolize retinol to various retinoids common both to mammalian and insects, as well as to insect-specific retinoids. On the basis of UV absorption spectra, retention times, and/or coelution studies with standards, the peak at 25 min was identified as 14-HRR ($\lambda_{max} = 324$, 348, 365 nm), and that at 18 min as a mixture of 3- and 4-hydroxyretinol (3/4-OH-Rol; $\lambda_{max} =$

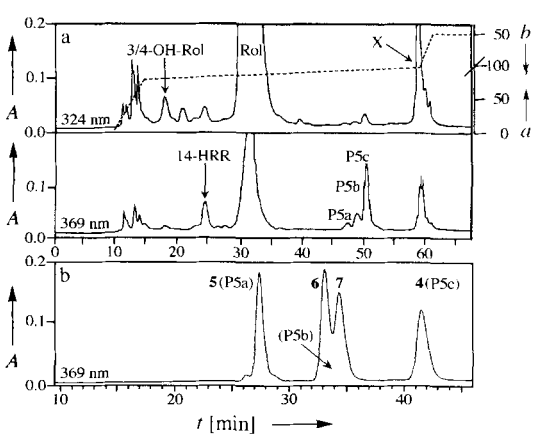

Fig. 1. HPLC profile of a) retinoid metabolites from a 4 g Schneider S2M3 cell pellet (X = retinyl ester; gradient elution: a = percentage of MeOH in MeOH/H_2O, b = percentage of MeOH in MeOH/$CHCl_3$; detection at 324 and 369 nm), and b) synthetic anhydroretinol isomers (isocratic elution H_2O/CH_3OH 14/86; detection at 369 nm).

325 nm).[10] Fractions eluting between 48 and 52 min (P5a, b, c) exhibit UV/VIS spectra with vibronic fine structure and maxima around 270, 348, 368, and 390 nm, characteristic of a *retro*-retinoid skeleton comprising six double bonds.[11] These fractions were shown by photoisomerization experiments to be isomers of the same chromophore.

The major isomer P5c was purified from bulk cultures of S2M3 by reversed-phase HPLC; a 180 g cell pellet yielded 60 absorbance units at 369 nm, which corresponds to 128 μg of pure P5c. The high-resolution electron ionization mass spectrum (EI-MS) gave *m/z* 268.2186 (calculated for $C_{20}H_{28}$: *m/z* 268.2191) indicative of loss of one molecule of water from the parent compound retinol (*m/z* 286 [M^+]). From these data and the characteristic UV/VIS spectrum P5c can be identified as anhydroretinol.[7, 12] This was confirmed by analysis of the ^{1}H NMR spectrum (Table 1), which was identical to that reported for synthetic all-*trans*-anhydroretinol.[13] In order to confirm these data and provide direct physical proof for the configurations of the anhydroretinol isomers, we measured the ^{1}H NMR and UV spectra of the four major anhydroretinol isomers obtained upon acid-catalyzed dehydration of retinol.

Table 1. Spectroscopic data of anhydroretinol isomers **4**–**7**.

all-*trans*-AR **4**: ^{1}H NMR ($CDCl_3$): δ = 1.3 (s, 6H; 1-Me_2), 1.51 (t, J = 1.5 Hz, 2H; 2-H_2), 1.92, 1.93, 1.96 (3 × s, each 3H; 5-, 9-, 13-Me), 2.13 (m, 2H; 3-H_2), 5.04 (d, J = 10.4 Hz, 1H; 15-H-*E*), 5.22 (d, J = 17 Hz, 1H; 15-H-*Z*), 5.79 (t, J = 3 Hz, 1H; 4-H), 6.20 (d, J = 11 Hz, 1H; 12-H), 6.39 (d, J = 12.5 Hz, 1H; 7-H), 6.46 (dd, J = 17, 10.4 Hz, 1H; 14-H), 6.45 (d, J = 15 Hz, 1H; 10-H), 6.60 (dd, J = 15, 11 Hz, 1H; 11-H), 6.78 (d, J = 12.5 Hz, 1H; 8-H); UV-VIS (MeOH): λ_{max} (ε) = 270, 348, 369 (125000), 390 nm; CI-MS: *m/z*: 269 [(M + H)$^+$].

(8*Z*)-AR **5**: ^{1}H NMR (CD_3OD): δ = 1.28 (s, 6H; 1-Me_2), 1.50 (t, J = 6 Hz, 2H; 2-H_2), 1.90, 1.92, 2.0 (3 × s, each 3H; 5-, 9-, 13-Me), 2.12 (m, 2H; 3-H_2), 5.04 (d, J = 11 Hz, 1H; 15-H-*E*), 5.24 (d, J = 17 Hz, 1H; 15-H-*Z*), 5.77 (t, J = 4 Hz, 1H; 4-H), 6.24 (d, J = 11 Hz; 12-H), 6.47, (dd, J = 17, 11 Hz, 1H; 14-H), 6.54 (d, J = 12.4 Hz, 1H; 7-H), 6.64 (d, J = 12.4 Hz, 1H; 8-H), 6.68 (dd, J = 15, 11 Hz, 1H; 11-H), 6.90 (d, J = 15 Hz, 1H; 10-H); UV-VIS (MeOH): λ_{max} (ε) = 273, 348, 365 (50000), 385 nm; CI-MS: *m/z*: 269 [(M + H)$^+$].

(12*Z*)-AR **6**: ^{1}H NMR (CD_3OD): δ = 1.30 (s, 6H; 1-Me_2), 1.52 (t, J = 6 Hz, 2H; 2-H_2), 1.89, 1.91, 1.93 (3 × s, each 3H; 5-, 9-, 13-Me), 2.13 (m, 2H; 3-H_2), 5.15 (d, J = 11 Hz, 1H; 15-H-*E*), 5.26 (d, J = 17 Hz, 1H; 15-H-*Z*), 5.78 (t, J = 4 Hz, 1H; 4-H), 6.12 (d, J = 11 Hz, 1H; 12-H), 6.36 (d, J = 15 Hz, 1H; 10-H), 6.40 (d, J = 12 Hz, 1H; 7-H), 6.78 (d, J = 12 Hz, 1H; 8-H), 6.80 (dd, J = 15, 11 Hz, 1H; 11-H), 7.07 (dd, J = 17, 11 Hz, 1H; 14-H); UV-VIS (MeOH): λ_{max} (ε) = 270, 348, 364 (50000), 383 nm; CI-MS: *m/z*: 269 [(M + H)$^+$].

(6*Z*)-AR **7**: ^{1}H NMR (CD_3OD): δ = 1.14 (s, 6H; 1-Me_2), 1.52 (t, J = 6 Hz, 2H; 2-H_2), 1.92, 1.95 (2 × s, each 3H; 9-, 13-Me), 2.08 (s, 3H; 5-Me), 2.21 (m, 2H; 3-H_2), 5.03 (d, J = 11 Hz, 1H; 15-H-*E*), 5.23 (d, J = 17 Hz, 1H; 15-H-*Z*), 5.67 (m, 1H; 4-H), 6.19 (d, J = 11 Hz, 1H; 12-H), 6.39 (d, J = 12 Hz, 1H; 7-H), 6.46 (d, J = 15 Hz, 1H; 10-H), 6.47 (dd, J = 17, 11 Hz, 1H; 14-H), 6.64 (dd, J = 15, 11 Hz, 1H; 11-H), 6.69 (d, J = 12 Hz, 1H; 8-H); UV-VIS (MeOH): λ_{max} (ε) = 270, 347, 364 (75000), 385 nm; CI-MS: *m/z*: 269 [(M + H)$^+$].

Various methods for the dehydration of vitamin A leading to anhydroretinol (10 to 30% yield) are described in the literature.[7, 12, 14] Figure 1 b shows the HPLC profile of synthetic AR isomers. Indeed, the fourth and major peak eluting at 41.2 min, which corresponds to P5c, was identified as all-*trans*-anhydroretinol **4**. The (6*E*) configuration was confirmed by the 10% nuclear Overhauser effect (NOE) observed between 1-Me_2 and 8-H. The chemical shifts of 4-H (δ = 5.79) and 1-Me_2 (δ = 1.3), both downfield compared to the analogous signals of (6*Z*)-*retro*-retinoids (δ = 5.63 and 1.11),[13, 15] provided corroboration.

The first peak eluting at 27.2 min (P5a) was shown to correspond to the (8*Z*) isomer **5** (Table 1). The (8*Z*), (10*E*), and (12*E*) configurations were deduced from the NOEs of –7, 14, and 11% observed for 7-H, 10-H, and 14-H respectively, upon irradiation of 12-H. The (10*E*) configuration was also supported by the observed coupling constant J(10,11) = 15 Hz.

The second compound eluting at 33 min exhibits a ^{1}H NMR spectrum characteristic of the (12*Z*) isomer **6** (Table 1). The (6*E*) configuration derives from the chemical shifts of 1-Me_2 (δ = 1.30) and 4-H (δ = 5.78). The *E* configuration of the C-8 C-9 double bond is evident from the upfield shift of 10-H (δ = 6.36) as compared the analogous signal of the (8*Z*) isomer (δ = 6.90). The (10*E*) configuration derives from the coupling constant J(10,11) = 15 Hz, and the (12*Z*) configuration from the chemical shifts of 12-H (δ = 6.12) and 14-H (δ = 7.07), which are upfield and downfield, respectively, of the corresponding signals (δ = 6.2, 6.46) of the all-*trans* isomer.

The compound eluting at 34.4 min has been characterized as the (6*Z*) isomer **7** based on the upfield chemical shifts of 1-Me_2 and 4-H, and the downfield chemical shift of 5-Me reported for (6*Z*)-*retro*-retinoids.[13, 15] Thus fraction P5b (cf. Fig. 1 a) contains both (12*Z*)- and (6*Z*)-anhydroretinol (**6** and **7**, respectively). (10*Z*)-AR and other possible di-*cis* isomers were not formed in sufficent amounts to be isolated and characterized.

Figure 2 shows the UV/VIS absorption spectra of (8*Z*)-, (12*Z*)-, and (6*Z*)-AR isomers as compared to that of all-*trans*-AR. Their absorption maxima and extinction coefficients are listed in Table 1. Because the compounds decompose slowly when kept dry, the extinction coefficient of each isomer was determined by directly computing the ratios of the integrated peaks from UV absorption and the ratios of the specific radioactivity of [^{3}H]retinol and [^{3}H]AR isomers prepared from [^{3}H]retinol.

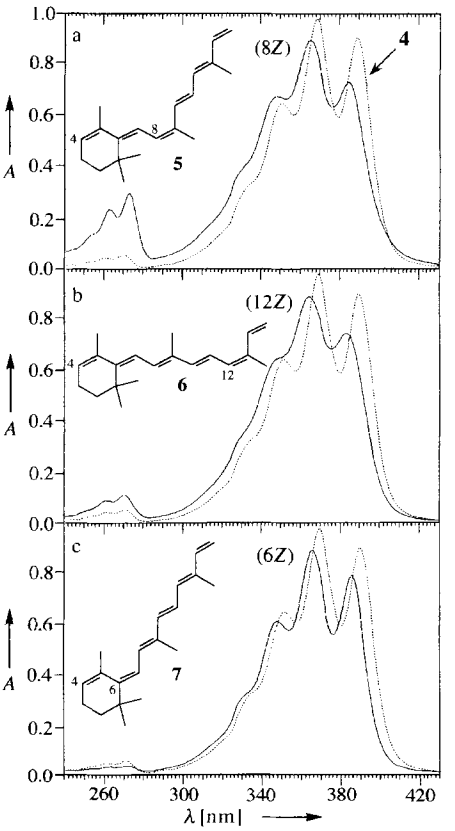

Fig. 2. UV/VIS absorption spectra (photodiode array detector) of (8*Z*)- **5** (a), (12*Z*)- **6** (b), (6*Z*)- **7** (c), and all-*trans*-anhydroretinol **4** (dotted line) in H_2O/CH_3OH 14/86.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1818-1838 $ 10.00+.25/0

all-*trans*-Anhydroretinol exhibits a weak band for *cis* double bonds at 262 nm ("*cis* band"), a strong band at 369 nm ($\varepsilon = 125000$), and a well-resolved vibronic structure. Isomerization of a double bond is accompanied by a slight blue shift in the λ_{max}, an increase in the intensity of the *cis* band, and a more diffuse vibronic structure. Thus, the (8*Z*) isomer, in which the *cis* double bond is central, exhibits the strongest *cis* band.

Anhydroretinol, a good model for the study of polyenes by absorption spectroscopy,[11, 14] has received increasing attention because of its newly discovered biological role. Its antagonism to 14-HRR suggests that these *retro*-retinoids might function as ligands for cytoplasmic or nuclear receptors.[6] In the insect cell line SF21, AR is synthesized by a cytosolic enzyme with a molecular weight of 41 kDa.[16] Characterization of this enzyme and isolation of 14-HRR and AR binding proteins are currently being pursued.

Experimental Procedure

^{1}H NMR spectra were recorded on a Varian VXR-400 spectrometer in $CDCl_3$ or CD_3OD. The chemical shifts δ are relative to $\delta(CHCl_3) = 7.24$ or $\delta(CH_3OH) = 3.30$. High-resolution EI mass spectra were measured on a JEOL DX-303 HF spectrometer (matrix: perfluorokerosine, PFK). Chemical ionization mass spectra (CIMS) were measured on a NERMAG R1010 spectrometer (carrier gas: methane).

Isolation of anhydroretinol from insect cell culture: Schneider S2M3 cells were grown in Schneider's insect medium supplemented with 10% fetal bovine serum (FBS) or 10% horse serum (Gibco, Life Technologies Inc., Grand Island, NY, USA) in the exponential growth phase at a density of $2-4 \times 10^6$ cells per mL. Cells were treated with 10^{-5} M retinol 12 h prior to harvesting by centrifugation, and the pellets were worked up according to McClean's method [17]. Retinoids present in the acetonitrile/butanol phase were separated with a preparative C_{18} reversed-phase column (Vydac 218 TP, 22 mm × 30 cm; Vydac, Hesperia, CA, USA) with a water/methanol/chloroform gradient (cf. Fig. 1a, 100% H_2O → 100% MeOH → MeOH/$CHCl_3$ 1:1; flow rate 8 mL min); photodiode array detector (Waters 991).

Preparation of anhydroretinol isomers by acid dehydration [7a]: A solution of all-*trans*-retinol (20 mg, Sigma) in absolute ethanol (10 mL) was treated with anhydrous HCl to a final concentration of 0.3 M. After 15 min at room temperature the solution was neutralized by titration with a 10 M sodium hydroxide solution, and diluted with about 5 mL of water. The solution was extracted with hexane, the organic layer was washed with water and concentrated, and the residue was dissolved in methanol. The mixture of anhydroretinol isomers was isolated by preparative HPLC as described above. Further separation was achieved on an analytical C_{18} reversed-phase column by isocratic elution (Vydac 201 TP, 5.4 mm × 30 cm; H_2O/CH_3OH 14:86, flow rate 1 mL min^{-1}).

Oxygen Evolution by Oxidation of Water with Manganese Porphyrin Dimers**

Yoshinori Naruta,* Masa-aki Sasayama, and Takao Sasaki

A tetranuclear manganese cluster in the photosystem II (PS II) of higher plants and cyanobacteria catalyzes evolution of oxygen by four-electron oxidation of water.[1, 2] Owing to the instability of preparations of PS II, only a limited amount of information on this cluster is available.[2, 3] Extensive efforts have been made to synthesize *structural* models of water oxidation complex (WOC),[1a, 4–6] but evolution of oxygen by catalytic oxidation of water has never been attained with them.[7] We report herein the catalytic oxidation of water to molecular oxygen with rigidly linked manganese porphyrin dimers.

As a functional model complex, we used the dimanganese complexes **1**–**3** of dimers of triphenylporphyrin (TPP)[8] linked by an *o*-phenylene bridge. Cyclic voltammetry of dimers **1** and **2** in dry acetonitrile showed reversible waves.[10] In an aqueous

acetonitrile solution (5% v/v H_2O in CH_3CN) containing nBu_4NOH, all these Mn complexes showed a similar irreversible discharge current at ≥ 1.2 V (vs. Ag/Ag^+).[11] The anodic oxidation of the aqueous acetonitrile solution without the manganese porphyrin dimers did not evolve oxygen in the potential range up to + 2.3 V (vs. Ag/Ag^+). However, the electrochemical oxidation of a solution containing **2** (1.0 mM) showed oxygen evolution at the potential range + 1.2 – + 2.0 V with a faradaic efficiency of 5–17% (Fig. 1). The other dimanganese complex-

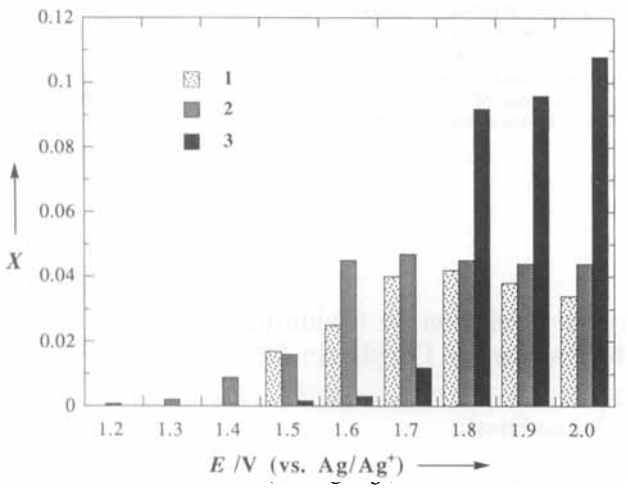

Fig. 1. Evolution of oxygen by catalytic oxidation of water at different anodic potentials [11]. X = mol O_2 per mol catalyst per min.

es, **1** and **3**, also produced O_2 at similar potentials, whereas the corresponding monomeric manganese porphyrin complexes[9] (2.0 mM) did not show O_2 evolution. Of the three dimers **3** showed the highest activity at rather high potential range, and its maximum turnover number (mol O_2/mol catalyst) was 9.2 in the presence of nBu_4NOH. The observed rate of oxygen evolution was proportional to the concentration of the applied complex. These results also indicate that the manganese porphyrin dimers are involved in the rate-determining step of O_2 evolution.

The evolved O_2 was analyzed during the reaction by a mass spectrometer with direct gas introduction through a Teflon membrane.[12] When a solution containing $H_2{}^{16}O$ and $H_2{}^{18}O$ (1:1) and the catalyst **3** underwent reaction at an anodic potential of + 1.8 V (vs. Ag/Ag^+), the isomeric ratio of the evolved O_2 was $^{16}O_2{:}^{16}O,^{18}O{:}^{18}O_2 = 1:2:1$, the same as the expected statistical distribution.[13]

According to the mechanism of this oxygen evolution, two possible electrochemical pathways can be considered. If the reaction proceeds through a two-electron pathway, although this has a higher oxidation potential ($E^0(H_2O/H_2O_2) = 1.78$ V vs. normal hydrogen electrode) than the four-electron oxidation process ($E^0(H_2O/O_2) = 1.23$ V),[14] H_2O_2 is produced. Oxygen could evolve even through this two-electron oxidation, because of the high catalase activity of the applied manganese dimers.[15, 16] To differentiate between these two pathways, we performed the anodic oxidation of the solvent at + 1.8 V for 8 min without any manganese complex, and then added the dimer **3** in the absence of current. Oxygen formation was not detected, and thus the oxygen evolved does not arise from H_2O_2. Independently, we confirmed the absence of H_2O_2 in the reaction mixture by means of a H_2O_2-sensitive electrode after the anodic oxidation of the solvent.

The number of electrons n involved in this reaction was determined by means of a rotating disk electrode. From the Levich plot of the dimer **3**, we obtained $n = 3.7$,[17] which is exactly twice that of the corresponding monomer [MnPFPP].[18] Thus, we can conclude that the O_2 evolution in the present case is based on a *four-electron* oxidation. Clarification of the detailed reaction mechanism is now under way, but since the two-electron oxidation of a $Mn^{III}(OH)$ complex can give the corresponding $Mn^{V}(=O)$,[19] the following mechanism is plausible for the present example: If HO^- ions coordinate to each Mn ion of the dimer inside the cavity, the resultant $Mn^{V}(=O)$ dimer could form a $Mn^{IV}-O-O-Mn^{IV}$ complex,[20] because of the proximity of the Mn ions. The peroxy bridge could be replaced by HO^- ions, and simultaneous decomposition would give O_2 and the Mn^{III} complex.

This is the first demonstration of oxygen evolution by the four-electron oxidation of water with structurally well-defined binuclear manganese complexes. These results are also very interesting in light of theoretical predictions.[21]

[17] From the Levich equation, $i_l = \Gamma n \omega^{1/2}$, $\Gamma = 0.62 FA D^{2/3} \nu^{-1/6} C^*$, where i_l and ω denote the limiting current and the angular velocity of the electrode, respectively. Γ is the constant term under the fixed conditions. F is the Faraday constant, A is the surface area (0.0314 cm^2) of the electrode, D is the diffusion

constant, ν is the kinematic viscosity, and C^* is the catalyst concentration (1.0×10^{-3} M). n was determined from the slope of Levich plot $I/n = 1.7 \times 10^{-5}$ A. The kinetic viscosity n was found to be 4.8×10^{-3} cm^{2}s^{-1}, and the diffusion constant $D = 2.4 \times 10^{-5}$ cms^{-1} for the observed solvent system with ferrocene as a standard compound. In consideration of the higher molecular weight of **3**, n and D for **3** should be smaller than those of ferrocene and the actual n should be larger than that estimated.

[18] Under the same conditions the Levich plot of the corresponding monomer [MnPFPP] gave $n = 1.8$.

[19] Similar oxidation of [MnTMP] through a one-electron oxidation process gives the corresponding stable $Mn^{IV}(=O)$ complex, see J. T. Groves, M. K. Stern, *J. Am. Chem. Soc.* **1987**, *109*, 3812–3814; R. S. Czernuszewicz, Y. Oliver Su, M. K. Stern, K. A. Macor, D. Kim, J. T. Groves, T. G. Spiro, *J. Am. Chem. Soc.* **1988**, *110*, 4158–4165.

$[(C_6H_5)_4P]\,{}^1_\infty[Cu_3I_4]$—The First Compound with a Helical Chain of Face-Sharing Tetrahedra as a Structural Element**

Hans Hartl* and Farbod Mahdjour-Hassan-Abadi

The tremendous structural diversity of iodocuprates(I) $[Cu_xI_y]^{(y-x)-}$ can be explained firstly by the fact that Cu^I can have trigonal-planar as well as tetrahedral coordination in these compounds, and secondly, since in addition to the corner- and edge-sharing of CuI_4 tetrahedra, the unusual face-sharing of tetrahedra is also possible. It was long considered unlikely that MX_4 tetrahedra could be linked through common faces, since the centers of the tetrahedra would be quite close.[1] In undistorted CuI_4 tetrahedra with an average edge length of 4.4 Å the Cu–Cu distance would be only 1.81 Å. In the previously reported face-sharing iodocuprates(I) the Cu atoms are far enough from the centers of the tetrahedra that Cu–Cu distances of 2.45–2.53 Å are found (Cu–Cu distance in metallic copper: 2.56 Å). The first iodocuprates(I) with face-sharing tetrahedra may have been considered exotic exceptions,[2] but now it is apparent that this linkage mode is a special, though not uncommon feature of the structural chemistry of iodocuprates(I). Two, three, and five face-sharing CuI_4 tetrahedra[3] are known, as well as endless chains of face-sharing tetrahedra. In $[(C_2H_5)_4N]\,{}^1_\infty[Cu_2I_3]$ and $[(C_3H_7)_4N]\,{}^1_\infty[Cu_3I_4]$ units of two and three face-sharing CuI_4 tetrahedra, respectively, are linked through common edges to form chains.[3, 4] Besides the examples among the iodocuprates(I) only two anions with face-sharing MX_4 tetrahedra are known: heptabromopentacuprate(I) $[Cu_5Br_7]^{2-}$[5] and the dinuclear pentathiolatodicobaltate $[Co_2(SC_3H_7)_5]^-$.[6]

Scientists in various fields and even artists have puzzled over the linkage of tetrahedra through common faces. For example, a helical chain of face-sharing tetrahedra was described by A. H. Boerkijk[7] and by Buckminster-Fuller,[8] who named it a "tetrahelix" (see Fig. 1). In accordance with quasi-periodic structures this chain was called a "Bernal spiral", since it has an irrational twist angle (vide infra) and thus an infinite translation period in the direction of the chain. A few years ago band structure calculations for hypothetical compounds, including CuI, with this helical structure were conducted.[9] But an actual compound with this kind of tetrahedron chain was not known at that time. We were thus even more surprised when we found that the CuI_4 tetrahedra of the anion in $[(C_6H_5)_4P]\,{}^1_\infty[Cu_3I_4]$ occur in the form of a helix of face-sharing tetrahedra.

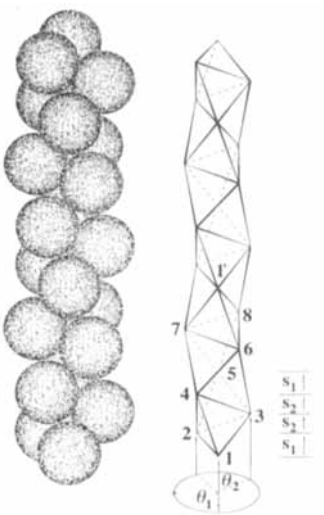

Fig. 1. Helix of iodine tetrahedra in $[(C_6H_5)_4P]\,{}^1_\infty[Cu_3I_4]$. Left: Sphere model. Right: Polyhedra representation; the twist angles θ_1 and θ_2 are 138.2 and 131.8°, respectively; the pitch parameters s_1 and s_2 have values of 0.348 and 0.309, respectively (for details see text).

The construction of the helix of tetrahedra can be described as follows (Fig. 1): If a vertex of a tetrahedron (in this case an iodine atom) is designated as the helical unit, then the other vertices are found by rotation about the axis of the chain by the twist angle θ and subsequent translation in the direction of the chain axis by $s \times$ edge length of the tetrahedron. In the ideal helix of tetrahedra the pitch parameter s has the value 0.3162. The twist angle θ, 131.81....°, is irrational, in other words, the helix does not repeat itself upon translation in the direction of the chain.[9]

In crystalline $[(C_6H_5)_4P]\,{}^1_\infty[Cu_3I_4]$ the chain achieves the translationally identical arrangement after eight turns (eight tetrahedra). This periodicity is possible owing to two different twist angles $\theta_1 = 138.2$ and $\theta_2 = 131.8°$ (average: 135°). The corresponding pitches of 1.533 and 1.359 Å and the average I–I edge length of 4.40 Å imply pitch parameters $s_1 = 0.348$ and $s_2 = 0.309$, respectively. The arrangement in the chain has the order $\ldots\theta_1,\theta_2,\theta_2,\theta_1$ with $\ldots s_1,s_2,s_2,s_1\ldots$.

Complete occupancy of the centers of the iodine tetrahedra with Cu^I would result in unrealistically short Cu–Cu distances. Thus in the COOP calculations (COOP = crystal overlap orbital population) for the hypothetical helix of CuI tetrahedra the Cu–I distances were set arbitrarily at 3.30 Å, and as a result the Cu–Cu distances increased to 2.20 Å, which is still short.[9] In the $\,{}^1_\infty[Cu_3I_4^-]$ helix this distance problem is solved by the occupancy of four centers of the iodine tetrahedra by only three Cu^I ions. The three copper atoms are distributed over the four centers of the tetrahedra and the centers of the face-sharing triangles such that realistic Cu–Cu distances of roughly 2.30 Å result.

X-ray structural investigations of $[(C_6H_5)_4P]\,{}^1_\infty[Cu_3I_4]$ at 22 and −145 °C (crystal 1) and at −140 °C (crystal 2)[10] showed that the occupancy parameters for the individual split atom positions are temperature dependent. At room temperature the Cu atoms Cu1, Cu2 had occupancies at the centers of the tetrahedra of 0.71(2) and 0.44(2), respectively, and the Cu atoms Cu3, Cu4, Cu5 occupancies at the centers of the triangles of 0.17(2), 0.19(2), and 0.06(1), respectively. When the crystal was cooled slowly to −145 °C, the occupancy parameters changed: Cu1, Cu2, and Cu3 were 0.50(2), 0.53(2), and 0.39(2), respec-

[**] Synthesis and Structural Investigations of Iodocuprates(I), Part 16. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. Roald Hoffmann for a valuable tip and Dipl.-Chem. F. Schröder for conducting the DSC measurements. Part 15: M. Hoyer, H. Hartl, *Z. Anorg. Allg. Chem.* **1992**, *612*, 45–50.

tively, and positions Cu4 and Cu5 were no longer occupied. When crystal 2 was cooled rapidly to $-140\,^{\circ}C$, occupancy parameters for Cu1, Cu2, Cu3, and Cu4 of 0.60(1), 0.45(1), 0.36(1), and 0.06(1), respectively, were found. In this case position Cu5 remained unoccupied. The distribution of Cu^{I} in crystal 2 can be considered as a frozen intermediate of the high- and low-temperature structures of crystal 1.

The arrangement of the Cu^{I} ions (Fig. 2) and their temperature factors at room temperature are indicative of great mobility within the chain. The Cu^{I} ions change positions by moving through the shared faces of the coordination tetrahedra to the unoccupied center of a neighboring tetrahedron. This hypothesis is supported by the specific conductivity in the chain direction of roughly $10^{-7}\,S\,cm^{-1}$, which is greater than that perpendicular by a factor of 10^{3}.[11] On cooling, the conductivity decreases continuously and jumps at $-100\,^{\circ}C$. Differential thermal analysis and differential scanning calorimetry both show a reversible thermal process at $-100(\pm 2)\,^{\circ}C$, which can be interpreted as the freezing/thawing of the Cu^{I} motion ($\Delta H = \pm 0.21\,kJ\,mol^{-1}$; exothermic on cooling).

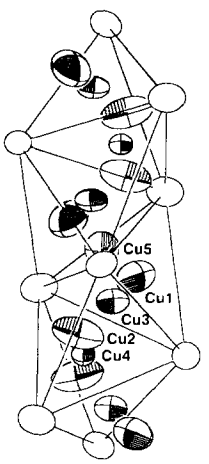

Fig. 2. Section of the helix of tetrahedra $^{1}_{\infty}[Cu_3I_4^-]$ at room temperature. (ORTEP plot at the 50% probability level; Cu atoms: hatched vibrational ellipsoids; I atoms: outlines of the vibrational ellipsoids.) On slow cooling to $-145\,^{\circ}C$ (crystal 1) only positions Cu1, Cu2, and Cu3 are occupied; on rapid cooling to $-140\,^{\circ}C$ (crystal 2) positions Cu1, Cu2, Cu3, and Cu4 are occupied. The Cu–I distances range from 2.417(2) to 3.09(1) Å at room temperature and from 2.525(6) to 3.216(8) Å at lower temperatures.

The individual $^{1}_{\infty}[Cu_3I_4^-]$ chains are chiral. In the crystal the chains are separated by the tetraphenylphosphonium ions and arranged in a rod packing parallel to the [100] direction. A racemic mixture of chains is required by symmetry (space group *Ccca*).

A definite answer to the question of why certain cations lead to specific types of iodocuprates(I) has not yet been possible. We can also not explain why tetraphenylphosphonium ions are accompanied by the formation of the unusual helical tetrahedron chains, whereas anions having the same composition form $[Cu_3I_4^-]$ chains with other linkage modes when the cation is methyltriphenylphosphonium, tetrapropylammonium, or bis(formamidium).[12]

Experimental Procedure

A mixture of tetraphenylphosphonium iodide (1.16 g, 2.5 mmol), iodine (1.27 g, 2.5 mmol), and Cu powder (1.27 g, 5 mmol) was heated in anhydrous acetone (50 mL) under a nitrogen atmosphere until the solution turned pale yellow and was filtered while hot. The cooled solution provided white, needle-shaped crystals with the composition $[(C_6H_5)_4P][Cu_3I_4]$. M.p. 254–256 °C. When the filtrate was allowed to stand for an extended time or petroleum ether was added, white flakes or prismatic crystals formed with the composition $[(C_6H_5)_4P][CuI_2]$-A and -B, respectively [13]. M.p. 210 °C.

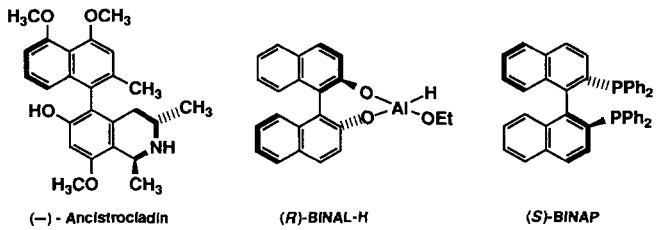
Asymmetric Synthesis of Biaryls by Intramolecular Oxidative Couplings of Cyanocuprate Intermediates**

Bruce H. Lipshutz,* Frank Kayser, and Zi-Ping Liu



Dedicated to Professor Manfred Schlosser on the occasion of his 60th birthday

The biaryl nucleus is a key subunit associated with many natural products[1] (e.g., steganone, ancistrocladin, etc.) and forms the basis of several nonracemic reagents (e.g., BINAL-H, BINAP, etc.) of extraordinary value in synthetic chemistry (Scheme 1).[2] Owing to the substitution pattern on the ring(s) or other restraints, hindered rotation about the adjoining C–C bond gives rise to the stereochemical feature known as atropisomerism. Given the importance of this structural type, there are

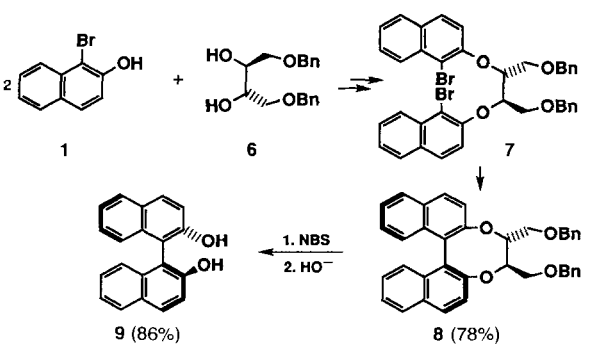
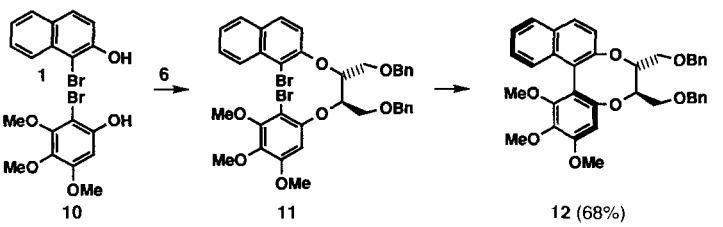
[**] This research was supported by the National Science Foundation (CHE-93-03883) and the Deutsche Forschungsgemeinschaft (fellowship to F. K.). We warmly thank Prof. K. B. Sharpless for a generous gift of nonracemic **14b** used in this study.

relatively few chemical methods that directly yield nonracemic biaryls.[3] Some rely on intermolecular coupling of organometallic compounds,[4] while others are based on intramolecular bond formation by the traditional Ullmann coupling.[5] Varying levels of generality and stereocontrol are observed. We now describe an experimentally straightforward, general method, which affords nonracemic biaryls with virtually complete stereoinduction.



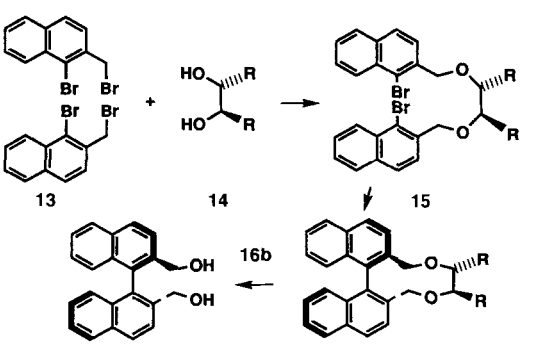
Scheme 1. Examples of binaphthyl derivatives.

In our approach to the well-known 2,2′-binaphthol system,[6] inexpensive 1-bromo-2-naphthol (**1**) was converted to dibromide **3a** with lactic acid ester **2a** (R′ = Me). Treatment of **3a** with *t*BuLi[7] followed by addition of solubilized CuCN[8] presumably led to formation in situ of a higher order cyanocuprate **4a**,[9] which produced the binaphthyl **5a** upon exposure to oxygen.[10] A ^{1}H NMR analysis (500 MHz) revealed an 83:17 ratio



2-**5** : **a**, R = Me; **b**, R = Ph

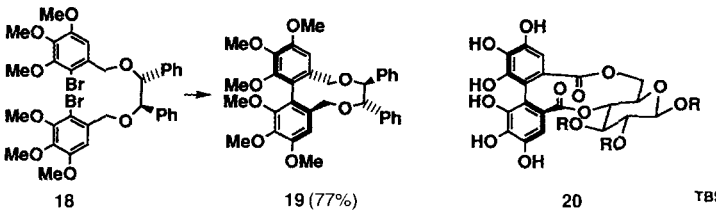
of diastereomers (66% *de*). With the mandelic acid derivative **3b**, **5b** was obtained with 80–90% *de*. To increase the *gauche* interaction(s) assumed to be responsible for the induction,[11]



tartaric acid was converted to diol **6**. Consecutive Mitsunobu reactions of **6** with **1** yielded **7**.[12] Treatment of **7** in an analogous procedure to that used for **3** resulted in formation of a single binaphthyl derivative **8**. Removal of the tether could be accomplished in a one-pot process, by double benzylic oxidation with *N*-bromosuccinimide (NBS) followed by addition of aqueous KOH. (*S*)-2,2′-Binaphthol (**9**) was thus obtained directly. The identity of the product was confirmed by comparison with authentic material.[13]

In an identical procedure, linkage of **1** and **10** with tether **6** provided the mixed dibromide **11**. Dilithiation,[7] cyanocuprate formation, and oxidation of **11** at 0 °C afforded the nonracemic unsymmetrical biaryl **12**, again, as a single product (by NMR spectroscopy).

The method applies equally well to 2,2′-C-substituted binaphthyls such as **17**. In these cases, the simpler, more readily available nonracemic vicinal diols **14** served as tethers[14] in the formation of dibromodiethers **15** from **13** (2 equiv). Intramolecular biaryl coupling led in each case to a single diastereomer **16**, even though a ten- rather than an eight-membered ring was formed (cf. **16** vs. **8**).[15]



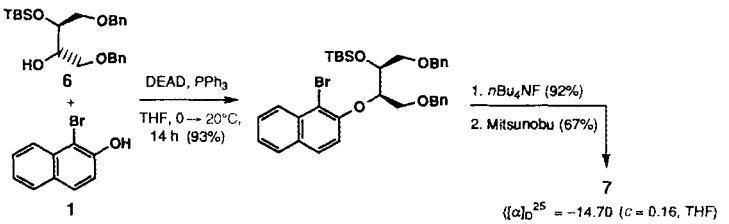
14-**16** : **a**, R = Me; **b**, R = Ph

Removal of the tether in **16b** was best effected by catalytic hydrogenation in HOAc over Pd on charcoal at room temperature. The resulting diol **17** was thus obtained in 90% yield. The specific rotation of the product compared quite favorably with the reported value.[16]

Finally, this method appears well-suited for use in the synthesis of the biaryl portion in several natural products of current interest, such as vancomycin,[17a] the michellamines,[17b] and the ellagitannins (e.g., tellimagrandin II (**20**), R = 3,4,5-trihydroxybenzoyl).[17c] A step towards target **20**[18] was achieved by subjecting dibromodiether **18** to cuprate-induced coupling. Biaryl **19** was obtained in 77% yield as the only observable isomer.[19]

In summary, a powerful new method for controlling axial chirality in numerous biaryl systems has been developed. This

18 19 (77%) 20



proceeds with oxidation of intramolecularly constructed cyanocuprates. The aryl bromide precursors are readily available; the nonracemic tethers are derived from inexpensive members of the "chiral pool"; and the couplings take place, unlike their intermolecular counterparts,[20] at practical temperatures and are thus expected to be more amenable to scale-up.

Experimental Procedure

16b: Copper cyanide (180 mg, 2.0 mmol) was placed in an oven- and flame-dried three-necked round-bottom flask (100 mL) equipped with a T-top (for argon/vacuum), a thermometer adapter fitted with a gas dispersion tube, and a rubber septum. The flask was once again gently dried with a heat gun under vacuum and allowed to cool to room temperature under argon. THF (35 mL) was added, and the resulting suspension cooled to $-78\,^{\circ}C$. In a round-bottom flask (50 mL), dibromodiether **15b** (1.31 g, 2.0 mmol) was dissolved in THF (35 mL). The flask was cooled to $-78\,^{\circ}C$, and 4.2 equiv of *tert*-butyllithium (4.98 mL, 8.4 mmol, 1.7 M in pentane) added dropwise to give a clear yellow solution. The reaction mixture was stirred at this temperature for 0.5 h. The dilithium compound was transferred with a cannula to the flask containing the CuCN suspension. The mixture was warmed to $-40\,^{\circ}C$ with gentle stirring. A clear yellow solution of the higher order cuprate was obtained. This was recooled to $-78\,^{\circ}C$. The argon flow was then stopped and dry oxygen (passed through a trap at $-78\,^{\circ}C$) was bubbled through the reaction mixture for 30 min, whereupon the solution turned dark. The mixture was allowed to warm to $0\,^{\circ}C$, and the oxygen flow was continued for 1.5 h. The reaction was then quenched with a solution of methanol and concentrated aqueous $NaHSO_3$ (2 mL). The mixture was allowed to warm to room temperature and poured into a solution of 10% NH_3 in concentrated NH_4Cl (100 mL). After it had been stirred for 0.5 h, the organic layer was separated. The aqueous phase was extracted three times with ether, and the combined extracts were subsequently washed with 5% HCl, saturated $NaHCO_3$, and brine. The organic phase was dried over $MgSO_4$ and filtered. The solvent was removed under reduced pressure. Chromatography of the crude mixture on silica gel (hexane/ethyl acetate 90/10) gave **16b** as a white crystalline product (720 mg, 73%). 0.48; IR (KBr): $\tilde{\nu}$ = 3030, 3020, 2835, 1455, 1340, 1090, 1070, 1030, 820, 750, 695 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$): δ = 4.35 (s, 2H, 2 × CH), 4.58 und 4.69 (AB, 4H, J = 10.7 Hz, 2 × CH_2), 6.88–7.03 (m, 12H, Ar-H), 7.17 (t, 2H, J = 7.6 Hz, Ar-H), 7.42 (t, 2H, J = 7.3 Hz, Ar-H), 7.90 (d, 2H, J = 8.4 Hz, Ar-H), 7.94 (d, 2H, J 8.4 Hz, Ar-H), 8.07 (d, 2H, J = 8.5 Hz, Ar-H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 70.5, 87.3, 125.8, 126.3, 126.9, 127.2, 127.3, 127.8, 127.9, 128.4, 133.0, 133.5, 134.3, 136.6, 139.3; EI-MS: *m/z* (%): 386 (6), 281 (23), 280 (100), 279(73), 276 (15), 265 (11); CI-MS (CH_4): *m/z* (%): 493 (1.5), 387 (10), 325 (15), 298 (22), 297 (90), 296 (19), 295 (31), 281 (56), 280 (44), 267 (99), 197 (100), 107 (71); high-resolution EI-MS: $C_{36}H_{29}O_2$ (M +1): calcd: 493.21674, found: 493.21676.

[10] All new compounds gave satisfactory IR, NMR, MS, and HRMS data.
[11] Further discussion is deferred to the full account of this work.
[12] The tether was attached as follows (TBS = *tert*-butyldimethylsilyl, Bn = benzyl, DEAD = diethyl azodicarboxylate):

[13] The isolated binaphthol **9** showed an $[\alpha]_D^{25}$ of -31 (c = 0.0125, THF). This confirms the sense of chiral induction in the cyclization (i.e., that the (*S*) isomer was formed). A scale-up of this reaction has not yet been attempted.
[14] Diol **14a** is commercially available, and **14b** can be obtained by Sharpless asymmetric dihydroxylation; cf. G. A. Crispino, K.-S. Jeong, H. C. Kolb, Z.-M. Wang, D. Xu, K. B. Sharpless, *J. Org. Chem.* **1993**, *58*, 3785.
[15] It should be noted that the sense of the asymmetric induction in the synthesis of **16** is opposite to that observed in that of **8**. This observation is in accord with the conformational requirements of an eight- versus a ten-membered ring [11].
[16] a) Observed $[\alpha]_{546}^{23}$ = + 82 (c = 0.056, THF); ref. [16b] $[\alpha]_{546}^{23}$ = + 86 (c = 1.0, acetone); b) S. Miyano, M. Tobita, H. Hashimoto, *Bull. Chem. Soc. Jpn.* **1981**, *54*, 3522.

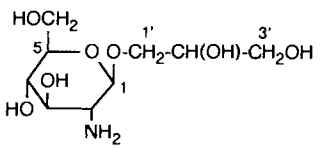
The Trehalase Inhibitor Salbostatin, a Novel Metabolite from *Streptomyces albus*, ATCC 21838

László Vértesy,* Hans-Wolfram Fehlhaber, and Arno Schulz



Although microbial cultures constitute an enormously rich source of the most varied secondary metabolites, there have till now been very few systematic studies of the metabolic products of any given organism. Usually, only those compounds that respond to specific biological or biochemical screening tests are isolated and characterized. So-called chemical screening has recently also come into use,[1] but this, too, yields only a random selection of metabolites.

High performance mutants of *Streptomyces albus*, ATCC 21838, are used for production of the polyether antibiotic salinomycin,[2] which is a coccidiostatic. Industrially, feed antibiotics are often not applied in a pure form, but as a dried

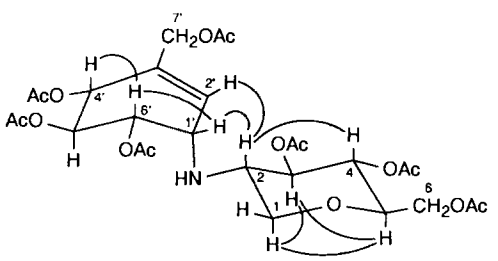
fermentation material—after digestibility has been checked—because of the good specific yields thus attained. In order to investigate the compounds produced by this strain, and to obtain a better understanding of its secondary metabolism, we studied the culture filtrate from a long-term fermentation (twelve days) of a salinomycin overproducer. The strain was grown in submerged culture, on a nutrient-rich, complex medium. Salinomycin and its by-products[2] were identified in a butanol extract of this medium, along with small amounts of $\Delta^{22(29)}$-hopene and several other hopanoids. The antibiotic elaiophylin,[3] which is produced by the wildtype strain ATCC 21838 at levels of up to 3%, was also detected at a concentration of less than 0.01% of the dry product.

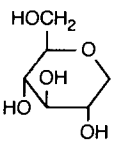
The non-extractable residue was separated on an ion exchanger: the neutral fraction contained primarily α,α'-trehalose; nucleotide bases, mainly cytidine, and two novel natural products were isolated from the basic fraction. One of these was identified as 2',3'-dihydroxypropyl-(2-amino-2-deoxy)-β-D-*gluco*pyranoside (**1**) from its NMR data and from the mass spectrometric fragmentation of its peracetyl derivative. The physiological significance of **1** is unclear. A capsule biopolymer of *Actinobacillus pleuropneumoniae* that contains the phosphorylated *N*-acetyl derivative of **1** was recently described;[4] synthetically produced fatty acid esters of **1** displayed immunological activity.[4b]



1

2

The main component of the basic fraction, which was present at a concentration of 1 mg L^{-1} in the culture supernatant, was assigned the structure **2**: The NMR spectra of **2** and of its peracetyl derivative **2'** (Scheme 1) were completely analyzed by H,H-correlation NMR spectroscopy (Table 1); selective NOE measurements (see Scheme 1) and high resolution mass spectrometry were also performed. We have named this unusual



Scheme 1. Structure of the peracetyl derivative **2'**. The curved lines indicate the protons which gave rise to positive NOEs.

pseudodisaccharide salbostatin;[5] it consists of valienamine linked to 2-amino-1,5-anhydro-2-deoxyglucitol, which till now had not been reported as a natural product. Salbostatin has a specific rotation of $[\alpha]_D = +115$ and therefore, given the rotation values of valienamine (+ 48.6)[6a] and of 1,5-anhydroglucitol **3** (+ 42.3),[6b] which is isosteric to the second part of the molecule, presumably has the D-configuration shown in **2**.

Table 1. ^{1}H NMR data for salbostatin **2** and the peracetyl derivative **2'**.

Although the 1,5-anhydroglucitol **3** has been found in several organisms,[7] nothing is known about the function of this class of compounds. Valienamine is known as a component of the validamycin-type aminoglycoside antibiotics,[8a] and of α-glucosidase inhibitors. The latter are of pharmaceutical interest, because of their inhibitory action on intestinal enzymes.[8b]

3

Salbostatin (**2**) shows no antibiotic activity; it does not inhibit the enzymes saccharase and maltase (EC 3.2.1.26, EC 3.2.1.20, from the mucus of porcine small intestine), and it inhibits aldose reductase (EC 1.1.1.21, from murine liver) only weakly ($IC_{50} = 0.68$ mM L^{-1}).[9] However, it is an effective inhibitor of trehalase (EC 3.2.1.28, from porcine kidneys), with an inhibition constant $K_i = 1.8 \times 10^{-7}$ M. The inhibition is competitive with respect to trehalose. Since trehalose is the most important storage and transport form of glucose in many insects and fungi, and in several pollen bodies, trehalase inhibitors are sought-after compounds in the plant protection industry. Apart from the validamycins, known trehalase inhibitors include trehalostatin,[10] trehazolin,[10] and suidatrestin.[11] Salbostatin **2** could serve as a new lead structure for the design and production of novel active compounds.

Salbostatin is considered to play a role in the abundant trehalose production of the organism *Streptomyces albus*, ATCC 21838. The importance of trehalose metabolism in the sporulation of *Streptomyces griseus* and in the hydrobiosis and anhydrobiosis of yeast has been reported.[12]

We have not yet investigated the acidic fraction from *Streptomyces albus*. Amphoteric fructos-1-yl-dipeptides with strong inhibitory activity towards the endopeptidase EC 3.4.24.11 have been isolated; they are however present only at extremely low concentrations.[13] Salbostatin (**2**) is therefore quantitatively the most important metabolite of *Streptomyces albus*, ATCC 21838, after salinomycin.

Experimental Procedure

Instruments used: HR-EI mass spectrometer, Kratos MS-902S (70 eV, R. P. 10000); CI mass spectrometer, Kratos MS-80RFA (isobutane); ^{1}H NMR spectrometer, Brucker AX-270 and AM-400WB.

Isolation of **1** and **2**: The culture filtrate (1800 L) from a 12 day fermentation of a salinomycin-overproducing mutant of *Streptomyces albus*, ATCC 21838, was extracted with *n*-butanol (600 L). The nonpolar components of this extract were isolated by chromatography on silica gel. The aqueous phase was concentrated under vacuum (to 150 L), and diluted with CH_3OH (600 L). After separating the high molecular weight precipitate, the basic components were adsorbed on a cation

exchanger (Dowex 50WX2, acid form), and subsequently eluted with 0.5 M aqueous NH_3. The resulting product mixture was separated by chromatography on S-Sepharose and on Fractogel TSK HW-40 (monitored with iodine, Rydon–Smith, and α-naphthol/sulfuric acid staining, and by UV detection at 210 nm). Total yield of **1** and **2** was 0.9 g and 1.5 g, respectively.

Hexaacetyl derivative of **1**: Compound **1** (10 mg) was dissolved in anhydrous pyridine (3 mL) and acetic anhydride (1 mL). The solution was maintained at room temperature for 15 h. Ice was then added, and the reaction was extracted with $CHCl_3$. After chromatographic purification on silica gel with $CHCl_3/CH_3OH$ (99:1), 5 mg of hexaacetyl-**1** was isolated. HR-EI MS: *m/z* 506.1865 (0.2%), [$M + H^+$, calcd 506.1874 for $C_{21}H_{32}NO_{13}$], 446.1437 (3%), [$M - AcNH_2$, calcd 446.1425], 330.1193 (4%), [$M - OCH_2CH(OAc)CH_2OAc$, calcd 330.1188], 159.0662 (100%), [$^+CH_2CH(OAc)CH_2OAc$, ber. 159.0657], 143.0584 (40%), [$AcOCH{=}CHNHAc^+$; ber. 143.0582]; ^1H NMR ($CDCl_3$, 270 MHz): δ = 5.15, 5.10 (2 t, 9 Hz, 3α-H, 4β-H), 5.0 (d, 3.5 Hz, 1α-H), 4.1–4.4 (m, 7H), 3.65 (m, OCH_2), 2.0–2.1 (6 OAc).

Salbostatin **2**: $[\alpha]_D^{20} = +115$ ($c = 1$, H_2O); $C_{13}H_{23}NO_8$ (321); CI MS: *m/z* 322 (100%), [$M + H^+$], 304 (11%), [$MH^+ - H_2O$], 286 (9%), [$MH^+ - 2H_2O$], 164 (33%), [$^+H_3NC_6H_{11}O_4$]; ^1H NMR ([D$_6$]DMSO/D_2O, 400 MHz; see Table 1); ^{13}C NMR ([D$_6$]DMSO, 68 MHz): δ = 52.8 (d, C-1'), 57.6 (d, C-2), 61.4 (t, C-6, C-7'), 69.1 (t, C-1), 70.2, 70.5, 70.9, 72.9, 76.6, 81.7 (6 d, C-3, C-4, C-5, C-4', C-5', C-6'), 120.4 (d, C-2'), 140.5 (s, C-3').

Heptaacetyl derivative of **2**: salbostatin (50 mg) was dissolved in anhydrous pyridine (3 mL) and acetic anhydride (1 mL). The solution was maintained at room temperature for 15 h, treated with ice, and extracted with $CHCl_3$. Chromatographic purification on silica gel with $CHCl_3/CH_3OH$ (99:1) afforded 16.6 mg heptaacetyl salbostatin **2'**. HR-EI MS: *m/z* 615.2108 (4%), [M^+; calcd 615.2164 for $C_{27}H_{37}NO_{15}$], 555.1911 (25%), [M – AcOH, calcd 555.1952], 495.1698 (17%), [M – 2AcOH, calcd 495.1741], 471.1743 (22%), [M – AcOCH=CHOAc, calcd 471.1740], 231.0865 (100%), [$AcOCH_2CH_2CH(OAc)CH(OAc)^+$, calcd 231.0868]; ^1H NMR ($CDCl_3$, 400 MHz) see Table 1. NOE difference spectroscopy and Fig. 1.

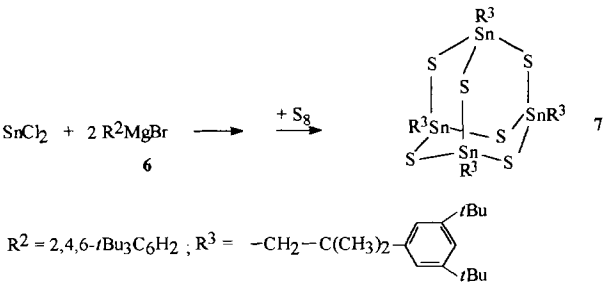
Bis(2,4,6-tri-*tert*-butylphenyl)stannanediyl: A Diarylstannylene without Donor Stabilization**

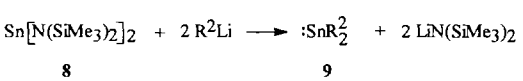
Manfred Weidenbruch,* Josephin Schlaefke, Annemarie Schäfer, Karl Peters, Hans Georg von Schnering, and Heinrich Marsmann

The nature of the tin–tin bonding in distannenes (distannaethenes) has not yet been completely rationalized. Thus, the distannene **1** of Lappert et al. is the sole structurally characterized compound of this type, and in the solid state is best described as a double donor–acceptor adduct of two stannylenes (stannanediyls) **2** (Scheme 1). Evidence for this includes the tin–tin interatomic distance,[1, 2] which is hardly shorter than that of tin–tin single bonds,[3] the results of quantum mechanical calculations,[2, 4] ^{119}Sn solid-state NMR data,[5] and the dissociation of **1** in solution into two stannylene molecules **2**.[6]



Scheme 1. R = $(Me_3Si)_2CH$; R^1 = 2,4,6-*i*$Pr_3C_6H_2$.

Different behavior is observed for the tetraaryldistannene **5**,[7] which, according to ^{119}Sn NMR data,[7, 8] retains its structural integrity even in solution. Moreover, trapping reactions with chalcogens[9] or phenylacetylene[8] indicate the likely presence of a double bond in **5**. The distannene **5** is formed together with the stannylene **4** upon photolysis or thermolysis of the cyclotristannane **3**, with which it exists in thermal equilibrium over a wide temperature range.[7] In the solid-state, however, only the three-membered ring **3** is present at room temperature;[10] hence no X-ray structure analysis on **5** has been possible.



The replacement of the 2,4,6-triisopropylphenyl groups R^1 in **4** and **5** with the significantly bulkier 2,4,6-tri-*tert*-butylphenyl groups R^2, in order to suppress the formation of the analogous cyclotristannane, proved not possible at first. This was due not only to the aryl/alkyl isomerization ($R^2 \rightarrow R^3$) previously known for R^2 groups,[11, 12] but also to disproportionation reactions of the presumed tin(II) intermediate species. Thus, reaction of the Grignard reagent **6** with tin(II) chloride—which in the case of the corresponding 2,4,6-triisopropylphenyl compound had led smoothly to **3**[8, 9]—gave rise to a dark red solution, from which, upon addition of sulfur, the tin sesquisulfide **7** with rearranged alkyl groups was isolated, as well as tin(IV) compounds.

[**] Compounds of Germanium and Tin. Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. Part 12: M. Weidenbruch, A. Ritschl, K. Peters, H. G. von Schnering, *J. Organomet. Chem.* **1992**, *437*, C25.

Success was finally achieved by the reaction of the tin(II) amide **8**[13] with 2,4,6-tri-*tert*-butylphenyllithium,[14] from which highly air-sensitive, dark red crystals of **9** were obtained. The ^{1}H and ^{13}C NMR spectra clearly show that insertion of the unsaturated tin atom into one of the methyl C–H bonds of the *ortho-tert*-butyl substituents had not occurred. Furthermore, molecular mass determinations (cryoscopic in benzene) and the absence of $^1J(^{119}Sn,^{117}Sn)$ coupling in the ^{119}Sn NMR spectrum indicate the presence of monomeric stannylene molecules in solution.

A crystal structure analysis[15] (Fig. 1) established the composition of **9** and confirmed that this stannylene also exists in monomeric form in the crystal, since the shortest tin–tin distance (884 pm) lies outside of any bonding interaction. Whereas

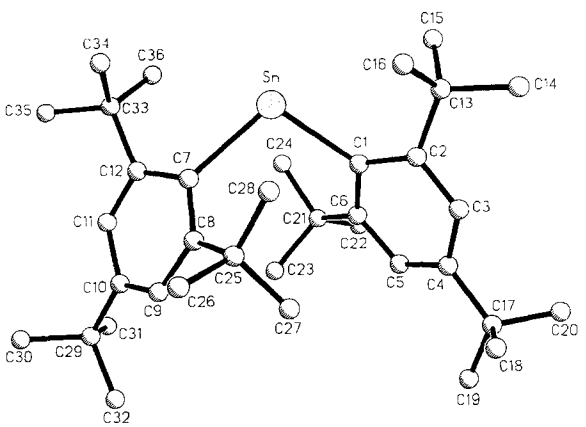

Fig. 1. Molecular Structure of **9** in crystal (without H atoms). Selected bond lengths [pm] and angles [ ]: Sn–C1 225.5(4), Sn–C7 226.7(4); C1-Sn-C7 103.6(1), C1-C2-C13 122.7(4), C1-C6-C21 124.2(4), C7-C8-C25 123.9(4), C7-C12-C33 122.7(3).

the tin–carbon interatomic distances correspond to those in **2**,[6] the C-Sn-C angle is widened by about 8°, presumably on account of the greater steric demands of the R^2 groups. The two phenyl rings are each twisted by 54° from the C1-Sn-C7 plane, forming an angle of 30° with respect to one another, thereby permitting optimal orientation for the bulky *ortho-tert*-butyl groups. Agostic interactions between the tin atom and the neighboring methyl C–H bonds were not observed, since all four *ortho-tert*-butyl groups point away from the tin atom. The carbon atom C24 does approach the tin atom at a distance of 312 pm, though this distance is still probably too great for an interaction between the C–H bond and the unsaturated tin atom.

Compound **9** is the first diarylstannylene which exists without intramolecular donor-stabilization.[16] The only other structurally characterized diarylstannylene $[2,4,6\text{-}(CF_3)_3C_6H_2]_2Sn$: (**10**) probably owes its stability to the close contact between the fluorine atoms of the *ortho*-CF_3 groups and the low-valent tin atom.[17] A recent report describes R^1R^4Sn: (**11**, $R^4 = 2,4,6\text{-}[(Me_3Si)_2CH]_3C_6H_2$), whose substituents show similar steric demands to **9**.[18] Isolation of **11** has not yet been accomplished.

Evidently, the bulky *ortho-tert*-butyl groups in **9** not only hinder cyclotristannane formation, but also destabilize a possible distannene. The ^{119}Sn NMR spectrum of **9** is unusual and shows, instead of the expected singlet, two signals at $\delta = 961$ and 1105 in an intensity ratio of about 4:1 at room temperature. These coalesce upon heating to 50 °C into a single signal at $\delta = 980$, which persists even after cooling. The obvious supposition is that a partial isomerization of **9** into the sterically less encumbered stanylene R^2R^3Sn: (**12**) takes place in solution; this is supported not only by the ^{13}C NMR spectrum, in which a CH_2 group at $\delta = 62.5$ is detected unambiguously, but also through trapping reactions, from which thus far only products with one aryl/alkyl isomerized R^3 group were isolable.

The positions of both signals is of interest since they are clearly distinct from that of molecule **2**,[5] as well as that of a structurally related compound in which both C-H hydrogen atoms of **2** are replaced with an ethylene bridge,[19] and that of **11**,[18] which display drastically deshielded tin nuclei ($\delta > 2200$). Rather, the chemical shifts observed for **9** and **12** lie in the region typical for hetero-substituted stannylenes,[20] for example **8**,[21] and also for **10**.[17] Whereas these stannylenes minimize their electron deficiency through interaction between free electron pairs and an unoccupied 5pπ-orbital at the tin center, the reason for the similar shielding of the tin nuclei in **9** and **12** is currently still obscure.

Experimental Procedure

A solution of 2,4,6-tri-*tert*-butylphenyllithium (14.7 g, 46 mmol) in toluene (70 mL) was added slowly dropwise, with the exclusion of air and moisture, to a solution of **8** (10.0 g, 23 mmol) in toluene (40 mL), and the dark red mixture stirred for about 3 h. After concentration of the solution to 80 mL, cooling to −30 °C afforded **9** (9.0 g, 64%) as dark red rectangular crystals. M.p. 125–130 °C. ^{1}H NMR (300 MHz, C_6D_6): $\delta = 1.16, 1.26, 1.33, 1.34, 1.38$ (each s, 9H), 1.68 (s, 6H), 7.41 (s, 1H), 7.44 (s, 1H), 7.46 (s, 1H), 7.57, 7.576; $^{13}C\{^1H\}$ NMR (75.44 MHz, C_6D_6): $\delta = 31.54, 31.64, 31.77, 31.86, 32.90, 33.23, 34.75, 35.09, 35.14, 38.80, 40.09, 62.50, 119.68, 120.02, 122.20, 125.65, 128.87, 129.28, 148.13, 150.34, 150.47, 150.93, 156.70$; $^{119}Sn\{^1H\}$ NMR (112.22 MHz, [D$_8$]toluene, Me_4Sn): $\delta = 950.6$, 1120.1 (270 K); 960.8, 1105.0 (293 K); 980.4 (323 K); UV/VIS (*n*-pentane): $\lambda_{max} = 476$ nm.

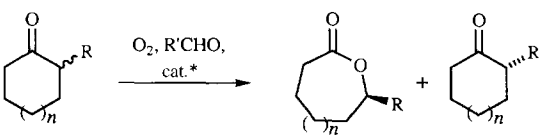
Optically Active Lactones from a Baeyer–Villiger-Type Metal-Catalyzed Oxidation with Molecular Oxygen**



Carsten Bolm,* Gunther Schlingloff, and Konrad Weickhardt

Catalyzed asymmetric oxidations are of paramount importance for the synthesis of chiral building blocks. Enantioselectivities of over 90% have been achieved in the dihydroxylation of olefins[1] and in the epoxidation of allyl alcohols[2] and nonfunctionalized *cis* alkenes.[3] In general, highly oxidized reagents, such as peracids or other peroxy compounds, are employed as the source of oxygen. *Mukaiyama* et al. reported that molecular oxygen could also be used as a simple oxidizing agent in the asymmetric oxidation of olefins provided that an oxygen acceptor, such as an aldehyde, were present in stoichiometric quantities.[4] As part of our investigations into the activation and transfer of oxygen,[5] we have now developed an enantioselective, metal-catalyzed variant of the Baeyer–Villiger oxidation, a reaction which had previously only been achieved with the help of enzymes.[6]

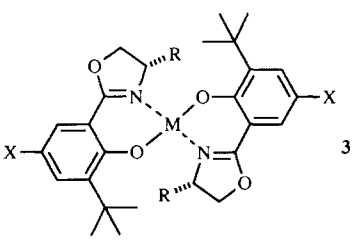
[**] This research was supported by the Schweizerischer Nationalfonds and the Deutsche Forschungsgemeinschaft (project: oxygen transfer / peroxide chemistry). We thank Professors Pfaltz and Schiess, Universität Basel, for samples.

In the presence of an aldehyde and a metal catalyst, cyclic ketones are oxidized to lactones with molecular oxygen.[5, 7] We chose 2-phenylcyclohexanone (**1a**) as the model compound for our investigations into the asymmetric oxidation reaction, because **1a** is converted into lactone **2a** in high yields and with good regioselectivities in the reaction catalyzed by achiral nickel and copper complexes.[5] The enantiomeric excesses (*ee*) ob-



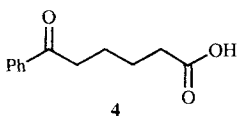
rac-**1** **a**: $n = 1$, R = Ph; **b**: $n = 1$, R = 4-Cl-Ph; **c**: $n = 1$, R = 4-MeO-Ph; **d**: $n = 0$, R = Ph; **e**: $n = 2$, R = Ph

(*R*)-**2** (*S*)-**1**

cat.* = Ni or Cu complex with chiral ligands

tained for lactone **2a** and ketone **1a** can be determined reliably and unambiguously by HPLC on a chiral column. With the optically active nickel(II) complex **3a**, *rac*-**1a** was converted to *rac*-**2a**, regardless of the reaction conditions employed; with the corresponding copper complex, **2a** was obtained with enantioselectivities of up to 69% *ee*.

3a: M = Ni, R = Alkyl, X = H
b: M = Cu, R = *t*Bu, X = NO_2
c: M = Cu, R = *t*Bu, X = H
d: M = Cu, R = *i*Pr, X = NO_2
e: M = Cu, R = *i*Pr, X = H



In order to achieve good reactivity and high asymmetric induction, several reaction parameters had to be optimized. The best results were obtained with *p*-nitro-substituted copper complex **3b** in water-saturated benzene and with pivalaldehyde as the oxygen acceptor (= coreducing agent) (Table 1). Use of 1 mol% of (*S,S*)-**3b** as catalyst at room temperature and under an oxygen atmosphere resulted in formation of lactone (*R*)-**2a** in 41% yield and 65% *ee* after 16 hours; at 6 °C, an increase in

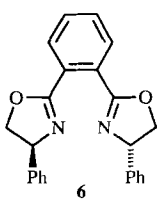
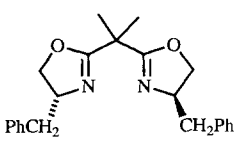
[a] Determined by HPLC on a chiral phase. [b] 6 d at 6 °C. [c] Reaction time 5 d. [d] The absolute configuration was not determined. [e] No base-line separation.

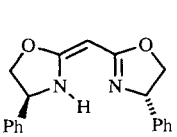
enantioselectivity was observed (69% *ee*). Since the unreacted ketone was enriched in enantiomer (*S*)-**1a**,[8] the lactone formation formally corresponds to a kinetic resolution. The "overoxidation" product, 6-oxo-6-phenylhexanoic acid (**4**), was isolated as a byproduct. In the absence of an aldehyde, copper-catalyzed oxidations with molecular oxygen also result in formation of **4**.[9–11] Lactone **2a** was found to be stable under the reaction conditions and was not oxidized to **4**. The reaction was suppressed when 5 mol% of catalyst, 2,6-di-*tert*-butylcresol as a radical trap, or an excess of the free ligand **5** were used.[12] Racemic lactone was obtained in the presence of molecular sieves (4 Å) or solid $NaHCO_3$. Only small or negligible quantities of lactone were formed in other solvents, such as, ethyl acetate, acetone, *tert*-butyl methyl ether, acetonitrile, cyclohexane, toluene, or 1,2-dichloroethane, which was the solvent used in the Ni-catalyzed reaction.[5] Aromatic aldehydes did not give satisfactory results as coreducing agents in the Cu-catalyzed reaction; even with longer reaction times, poorer yields and enantioselectivities were obtained (Table 1, entries 3 and 4).



4



The 1:1 complexes obtained from copper(II) trifluoromethanesulfonate and the C_2-symmetric bisoxazolines **6**–**8**[13, 14a] also catalyzed the formation of optically active **2a**; the yields and enantioselectivities were however poor: with **6**, 39% yield (12% *ee*); with **7**, 39% yield (25% *ee*); and with **8**, 25% yield (12% *ee*).



5a: R = *t*Bu, R' = *i*Pr
b: R = H, R' = *t*Bu
c: R = NO_2, R' = *t*Bu

6

7

8

The steric and electronic properties of the ligand influence the activity and enantioselectivity of the catalyst. Higher yields were obtained with the *p*-nitro-substituted complexes **3b** and **3d** than with the corresponding unsubstituted compounds **3c** and **3e**; the enantiomeric excesses obtained were not always higher: with **3b**, 41% yield (65% *ee*); with **3c**, 29% yield (57% *ee*); with **3d**, 57% yield (32% *ee*); and with **3e**, 34% yield (36% *ee*).

Without the *tert*-butyl substituent on the arene (**5b** and **5c**),[14] the ligand formed copper complexes which were only weakly active (yield < 10%). In the substrates, electronic effects play a secondary role. The *p*-chlorophenyl- and *p*-methoxyphenyl-substituted ketones **1b** and **1c** were transformed into lactones **2b** and **2c** with very similar enantioselectivities (Table 1, entries 7 and 8). The dependency of reactivity on ring size corresponds to that observed for peracids:[15, 16] **1a** was oxidized fastest, **1d** slower (Table 1, entry 9), and **1e** not at all. The alkyl-substituted cyclic ketone 2-cyclohexylcyclohexanone and the positional isomer 4-phenylcyclohexanone did not react.

We are currently working on elucidating the course of reaction and on other oxidation reactions with the new catalysts.[17]

Experimental Procedure

The ketone (1 mmol) and the catalyst (10 μmol) were dissolved in water-saturated benzene (2.5 mL) and treated with the aldehyde (0.5 mmol) and water (100 μL). The mixture was stirred under an oxygen atmosphere for 16–20 h, diluted with diethyl ether (150 mL), and washed with saturated aqueous $NaHCO_3$ solution (50 mL). The organic phase was dried over Na_2SO_4. After removal of the solvent, the crude product was chromatographed on silica gel. The enantiomeric excesses for **1** and **2** were determined by HPLC, when necessary, after bulb-to-bulb distillation under high vacuum [Chiracel ODH (Daicel); flow rate 0.5 mL min^{-1}; for **2a**: UV detector (254 nm), 2-propanol/hexane 1/3, retention times: (*S*)-**2a**: 12.4 min, (*R*)-**2a**: 16.0 min; for **1a**: UV detector (220 nm), 2-propanol/hexane 1/9, retention times: (*S*)-**1a**: 14.5 min, (*R*)-**1a**: 15.7 min].

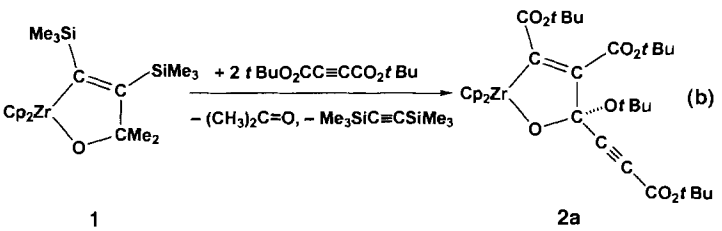
Unexpected Reactions of Acetylenedicarboxylates with Zirconocene Complexes

Uwe Rosenthal,* Andreas Ohff, Wolfgang Baumann, Rhett Kempe, Annegret Tillack, and Vladimir V. Burlakov

In cyclizations of unsaturated compounds using the metallocene fragments "Cp_2M" (M = Ti or Zr), which are frequently employed preparatively, relatively little is known about competing reactions between double and triple bonds and other functional groups. For substrates in which a triple bond is present, coordination at the metal center leads to the initial formation of a metallacyclopropene complex.[1] This is normally followed by reaction with a further triple bond and the formation of metallacyclopentadiene complexes.[2] Alternatively, reaction of the metallocene alkyne complex with a carbonyl group, in place of the second triple bond, gives rise to a metalladihydrofuran.[2] We have recently reported a special example, in which the zirconocene alkyne complex $[Cp_2Zr(L)(Me_3SiC{\equiv}CSiMe_3)]$, L = THF (**I**),[3] pyridine (**II**),[4] reacts with acetone to give the zirconadihydrofuran $[Cp_2Zr{-}O{-}C(Me_2){-}C(SiMe_3){=}C(SiMe_3)]$ **1**.[5] Thus, whether the carbonyl group is tolerated by the metallocene unit, or instead becomes involved in the cyclization is of decisive importance for the use of unsaturated carboxylic esters in this synthesis.[6] Herein, we report on model reactions of metallocenes with acetylenedicarboxylates and their unexpected outcome.



In the case of the titanocene complex, the reaction with dimethyl acetylenedicarboxylate is already known;[7] the expected metallacyclopentadiene is formed [Eq. (a)]. In contrast, analogous reactions with zirconocene are unknown.

(a)

With the recently synthesized and structurally characterized zirconocene alkyne complexes **I**[3] and **II**,[4] as well as the reactive zirconadihydrofuran **1**,[5] suitable precursors are available for the generation of the unstable zirconocene "Cp_2Zr" (c.f. ref. [2d]). This reacts under mild conditions with selected acetylenedicarboxylates to give unexpected products. For the reactions with the dicarboxylate diesters, the dihydrofuran **1** proved the most appropriate.

With dimethyl acetylenedicarboxylate, no defined products could be isolated from these reactions. Upon exposure of **1**, in *n*-hexane, to di-*tert*-butyl acetylenedicarboxylate, bis(trimethylsilyl)acetylene and acetone are cleaved, and the "Cp_2Zr" moiety reacts with two equivalents of acetylenedicarboxylate. This does not give rise to the substituted metallacyclopentadiene expected, as is the case, for example, with diphenylacetylene.[5] Instead, insertion of an ester carbonyl group from the second molecule of alkyne leads to the zirconadihydrofuran **2a** [Eq. (b)]. Complex **2a** crystallizes from *n*-hexane as colorless prisms, sensitive towards air and moisture, and melting with decomposition above 130 °C.

(b)

1 2a

Characterization of **2a** by IR and NMR spectroscopy confirms the unusual reaction depicted in Equation (b), in which zirconocene "Cp_2Zr" reacts with the acetylenedicarboxylate in a molar ratio of 1:2. For the crystal structure analysis of **2a**, suitable crystals could only be obtained from a THF/*n*-hexane mixture.[8] These crystals contain an additional molecule of solvent coordinated to **2a**, and are therefore present as the THF-adduct **2b**. The structure of **2b** in the crystal is shown in Figure 1.

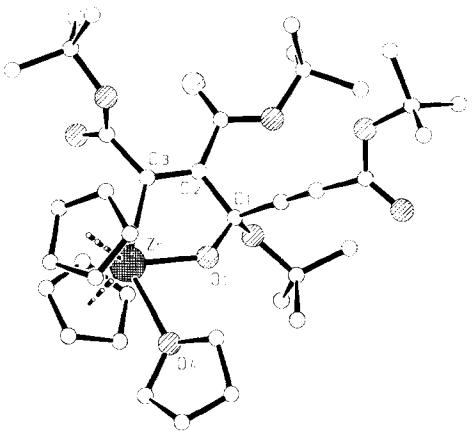


Fig. 1. Structure of **2b** in crystal, selected distances [Å] and angles[°]: Zr-O1 2.002(6), Zr-C3 2.391(8), Zr-O4 2.451(7), O1-C1 1.374(10), C1-C2 1.502(12), C2-C3 1.304(12); O1-Zr-C3 70.9(3), C1-O1-Zr 128.4(5), O1-C1-C2 109.5(7), C1-C2-C3 117.4(8), Zr-C3-C2 112.9(6).

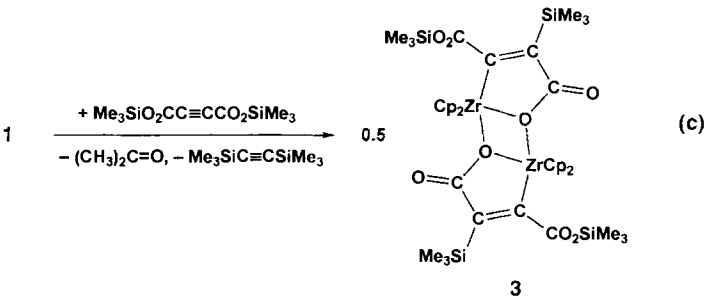

The central structural element is a nearly planar zirconadihydrofuran ring. Two Cp ligands are attached to the central metal atom, and in complex **2b**, unlike other metalladihydrofurans,[5] a THF molecule is coordinated in addition. The THF ligand (Zr–O 2.451(7) Å) is more weakly bound than in complex **1** or comparable compounds (Zr–O 2.122–2.390 Å[3]).

A completely different product was formed upon reaction of **1** with bis(trimethylsilyl) acetylenedicarboxylate. Here, the zirconocene unit reacts with only one alkyne molecule, which leads to the dimeric zirconadihydrofuranone complex **3**, following an unusual 1,3-migration of a trimethylsilyl group from an oxygen atom to a carbon atom [Eq. (c)]. Complex **3** crystallizes as colorless prisms, which are not sensitive towards oxygen and moisture, and melt with decomposition above 175 °C.

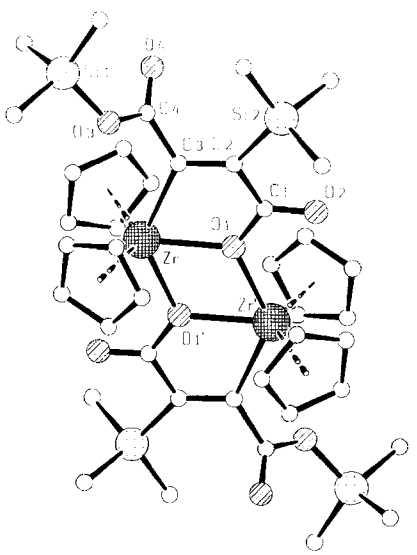
(c)

A reaction of the zirconocene **1** with bis(trimethylsilyl) acetylenedicarboxylate in a 1:1 molar ratio and the formation of a symmetrical complex are confirmed by the spectroscopic data. In the ^{13}C NMR spectrum of **3**, signals arising from the alkyne C atoms occur at $\delta = 222.6$ (C_α) and 138.2 (C_β); the latter shows a $^1J_{(C-Si)}$ coupling of 64 Hz. Further proof of the unexpected location of the silyl group is the coupling of the $SiMe_3$ protons with C_β ($J \approx 1.5$ Hz) in the CH-coupled NMR spectrum. The ^{29}Si chemical shifts of the two differently bonded silyl groups are clearly distinguished ($\delta = 21.7$, -6.6); hence, the low-field signal of the CO_2SiMe_3 unit (free ester: $\delta = 29.1$) and the high-field signal of the sp^2-C-$SiMe_3$ group can be assigned.

The X-ray structure analysis of **3**[8] yielded a dimeric structure which is depicted in Figure 2. Molecule **3** is C_i-symmetric with the center of symmetry at the center of the four-membered Zr–O–Zr–O ring. This ring is planar; the O atoms simultaneously form part of a five-membered zirconafuranone. Each Zr center is coordinated as a distorted trigonal bipyramid; the Cp ring centroids and O1 are in equatorial positions, O1′ and C3 in axial positions. The structure of **3** is comparable to that of a dimeric zirconafuranone, which is formed by a completely different reaction from **1** and CO_2.[9]



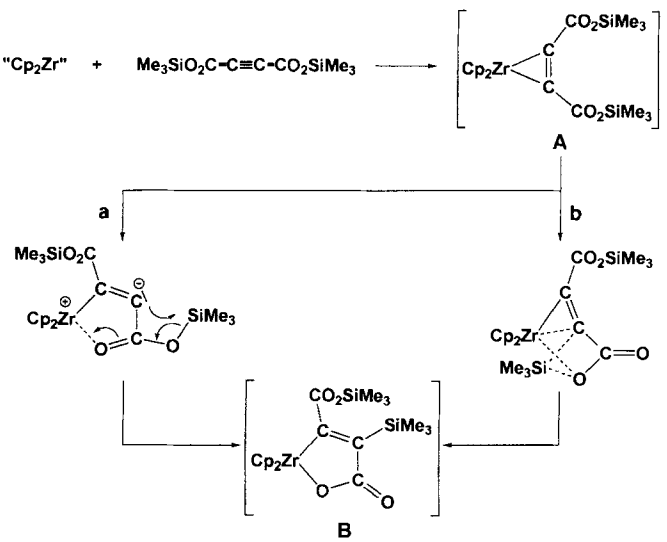


Fig. 2. Structure of **3** in crystal, selected distances [Å] and angles[ ]: Zr-O1 2.2213(14), Zr-O1′ 2.3073(14), Zr-C3 2.371(2), O1-C1 1.349(2), O2-C1 1.217(3), C1-C2 1.482(3), C2-C3 1.348(3), C3-C4 1.494(3); O1-Zr-O1′ 63.83(6), O1-Zr-C3 70.45(6), Zr-O1-Zr′ 116.17(6), C1-C2-C3 115.1(2), C3-C2-Si2 132.6(2), C2-C3-C4 118.1(2).

As the key step in the formation of **3**, the transition metal-induced 1,3-migration of the silyl group in bis(trimethylsilyl) acetylenedicarboxylate, from an oxygen atom to carbon, is surprising in view of the oxophilicity of silicon. Such O → C silyl migrations are very rare and were previously observed only in the rearrangement of silyl ketene acetals[10] and carbanion–oxyanion isomerizations.[11] Due to the high Si–O bond energy, trialkylsilyl groups in uncharged molecules normally only migrate from atoms other than oxygen. Thus, in the generation of **3**, the similarly high oxophilicity of zirconium and the simultaneous formation of the Zr–O bond and the Zr–O–Zr–O four-membered ring must play an important role.

The nature of the intermediate species in this reaction is not clear. As such, we would like to propose two possible mechanisms (Scheme 1), starting with coordination of the alkyne at the metal center and the formation of the metallacyclopropene **A**. The subsequent course of the reaction depends upon which

Scheme 1. Possible (unverified experimentally) reaction pathways for the intramolecular migration of a trimethylsilyl group from an oxygen atom to a carbon atom upon reaction of "Cp_2Zr" with bis(trimethylsilyl) acetylenedicarboxylate.

oxygen atom of the ester functionality interacts with the zirconium center. Rearrangement to **B** may be rationalized both as a 1,3 silyl group migration with an ionic transition state structure (path a, similar to a silyl-Wittig or retro-Brook rearrangement[12]) as well as in terms of a concerted mechanism (path b, formally comparable with a dyotropic rearrangement[13]). Both pathways are illustrated here in greatly simplified form, since **B**, of course, exists as a dimeric metallacycle, thus an intermolecular migration of the silyl group in the formation of **3** is likewise feasible. Experimental proof in favor of either mechanism is not yet at hand.

Overall, the varying course of the reaction of acetylenedicarboxylates with metallocenes "Cp_2M" is influenced both by the metal and by the alcohol component of the ester. Thus, in comparison to titanium, zirconium displays a pronounced tendency towards varied and unusual reactions of the ester group due to its greater oxophilicity and larger atomic radius.

Experimental Procedure

All manipulations were carried out with the exclusion of oxygen and moisture. Despite the relatively low yields for **2a** and **3**, no side-products could be isolated.

2a: A solution of di-*tert*-butyl acetylenedicarboxylate (492 mg, 2.18 mmol) in *n*-hexane (10 mL) was added to an orange solution of **1** [5] (0.49 g, 1.09 mmol) in *n*-hexane

(20 mL). The solution was filtered and allowed to stand at room temperature for 8 h without stirring. A yellow solid crystallized and was separated from the mother liquor and washed with *n*-hexane. Recrystallization from *n*-hexane gave **2a** (198 mg, 27%) as a colorless solid (m.p. > 130 °C (decomp), correct elemental analysis). $C_{34}H_{46}O_8Zr$, M_r = 674 g mol^{-1}; IR (Nujol): $\tilde{\nu}$ = 2216 cm^{-1} (ν(C≡C)), 1700, 1640, 1570 cm^{-1} (ν(C=O), ν(C=C)); NMR (C_6D_6, Bruker ARX 300, 30 °C): δ (^{1}H) = 1.29, 1.54, 1.57, 1.61 (s, 9H, CMe_3), 6.26, 6.27 (s, 5H, Cp); δ ($^{13}C\{^1H\}$) = 27.9, 28.5, 28.7, 30.8 (CCH_3), 76.2, 79.0, 79.7, 83.1 (CCH_3), 113.8, 114.1 (Cp), 77.8, 91.2, 99.6, 146.2, 155.0, 161.0, 172.9, 196.7 ($C_{quart.}$).

2b: The zirconocene complex **2a** was recrystallized from a THF/*n*-hexane mixture affording **2b** in the form of colorless needles (m.p. > 105 °C (decomp)). $C_{38}H_{54}O_9Zr$, M_r = 746.03 g mol^{-1}; IR (Nujol): $\tilde{\nu}$ = 2235, 2213 cm^{-1} (ν(C≡C)), 1697, 1669, 1574 cm^{-1} (ν(C=O), ν(C=C)); NMR ([D$_8$]THF, Bruker ARX 300, 30 °C): δ (^{1}H) = 1.35, 1.45, 1.48, 1.56 (s, 9H, CMe_3), 6.14, 6.30 (s, 5H, Cp), 1.78, 3.62 (m, 4H, THF); δ ($^{13}C\{^1H\}$): = 28.1, 28.5, 28.8, 31.0 (CCH_3), 75.6, 78.8, 79.1, 82.1 (CCH_3), 112.1, 112.8, (Cp), 76.6, 90.0, 102.9, 143.9, 153.8, 162.0, 175.0, 196.6 ($C_{quart.}$), 26.3, 68.1 (THF).

3: Complex **1** (586 mg, 1.3 mmol) was dissolved in *n*-hexane (25 mL). An equimolar quantity of bis(trimethylsilyl) acetylenedicarboxylate (0.34 mL, 1.3 mmol) was added at room temperature, and the orange solution was allowed to stand without stirring. After some time, the reaction mixture became orange-brown and a light yellow solid crystallized. After 12 h, the mother liquor was decanted and the residue washed with cold *n*-hexane and then recrystallized from THF/*n*-hexane (1/5). This yielded **3** (237 mg, 38%) as a colorless solid (m.p. > 175 °C (decomp), correct elemental analysis). $C_{40}H_{56}O_8Si_4Zr_2$, M_r = 959.64 g mol^{-1}; IR (Nujol): $\tilde{\nu}$ = 1660, 1651, 1528 cm^{-1} (ν(C=O), ν(C=C)); NMR (C_6D_6, Bruker ARX 300, 30 °C): δ (^{1}H) = 0.39, 0.55 (s, 9H, $SiMe_3$), 6.10 (s, 10H, Cp); δ($^{13}C\{^1H\}$) = 0.5, 0.7 (CH_3), 113.0 (Cp), 138.2 (ZrC=C), 176.7, 180.2 (C(O)O), 222.6 (ZrC=C); δ(^{29}Si) = − 6.6 ($CSiMe_3$), 21.7 ($OSiMe_3$).

A Postulated Carrier of Gold in Hydrothermal Ore Solutions: Synthesis and Crystal Structure of $[(Ph_3P)_2N][Au(SH)_2]$, the First Homoleptic Hydrogensulfido Complex**

José Vicente,* María-Teresa Chicote,* Pablo González-Herrero, Peter G. Jones, and Birte Ahrens

It has been suggested that considerable quantities of gold may be transported in hydrothermal ore solutions as $[Au(SH)_2]^-$. Although solubility measurements of gold and Au_2S in aqueous sulfide or H_2S solutions indicate formation of this complex, it has never been isolated.[1] Interest in hydrogensulfido metal complexes stems from the reactivity they exhibit toward organic substrates,[2] their proposed role as intermediates in important industrial (hydrodesulfuration)[3] and biological catalytic processes,[4] and their use as models in theoretical studies.[5] However, although approximately one hundred such complexes have been reported, few have been fully characterized.[4, 6, 7] The majority of hydrogensulfido complexes involve the transition elements (we are aware of two exceptions, $[\{Ga(tBu)_2(\mu\text{-}SH)\}_2]$[7] and $[Mg\{\eta^3\text{-}HB(3\text{-}tBupyz)_3\}(SH)]$,[8] pyz = pyrazolyl), most commonly Mo[9] and Ru.[10] All these complexes are stabilized by auxiliary ligands (e.g., cyclopentadienyl,[11] carbonyl,[9b, 12] or phosphane[13]). We report here the synthesis and crystal structure of the first homoleptic hydrogensulfido metal complex.

Slow addition of a solution of $[(Ph_3P)_2N][Au(acac)_2]$[14] (Hacac = acetylacetone) to a saturated solution of H_2S (both in dichloromethane) gave the salt $[(Ph_3P)_2N]$-**1** in 91% yield [Eq. (a)]. Alternatively, **1** was obtained more directly by bubbling H_2S through a solution of $[(Ph_3P)_2N][AuCl_2]$ in Et_2NH

[**] Complexes with S-donor Ligands, Part 1. This work was supported by Dirección General de Investigación Cientifica y Técnica (PB-92-0982-C) and the Fonds der Chemischen Industrie. P. G.-H. is grateful to Fundacion Cultural CAM for a grant.

(65% yield). Hydrogensulfido complexes have been prepared 1) by reaction of H_2S or HS^- with chloro,[15] hydroxo,[16] oxo,[17] hydrido,[18] or carbonyl[19] complexes; 2) by oxidative addition of H_2S to low-valent metal complexes;[20] 3) by insertion of sulfur into an M–H bond;[21] and 4) by reaction of sulfido complexes with H_2[22] or protic acids;[6d, 23] our method is a new example of the synthetic utility of acetylacetonatogold complexes.[14, 24]

The solid-state IR spectrum of $[(Ph_3P)_2N]$-**1** is almost identical to that of $[(Ph_3P)_2N][AuCl_2]$, except for the absence of the band at 350 cm^{-1} assigned to ν(AuCl) and the presence of a new band at 340 cm^{-1} that can reasonably be assigned to ν(AuS). The two IR-active bands in the 2300–2600 cm^{-1} region corresponding to ν(SH) vibration modes cannot be clearly assigned; however, these bands are generally not observed or are, at best, weak.[4, 6–23] The ^1H NMR spectrum of $[(Ph_3P)_2N]$-**1** in $CDCl_3$ shows the resonance from the SH protons at $\delta = -1.22$. In most hydrogensulfido complexes, this signal appears between $\delta = +4$ and $\delta = -4$.[4, 6–23]

The salt $[(Ph_3P)_2N]$-**1** crystallizes with two formula units in the asymmetric unit.[25] In the anion **1**, the gold atom shows essentially linear coordination (S-Au-S 176.7, 178.2(1)°) with Au–S bond lengths of 227.7(4), 227.8(4), 228.8(4), and 229.7(3) pm (cf. 226.2, 227.1(8) pm in the anion $[Au(S\text{-}Ph)_2]^-$).[26] There are no short Au···Au contacts.

The hydrogen atoms of the SH^- ligands could not be located in the X-ray analysis, despite the otherwise acceptable precision; use of a different counterion might prove more successful. There are no short S···N contacts that might indicate hydrogen bonds. Crystallographically, the $[Au(SH)_2]^-$ anion is thus essentially indistinguishable from $[AuCl_2]^-$. Nonetheless, we are confident that we have measured $[Au(SH)_2]^-$ for the following reasons: 1) $[AuCl_2]^-$ is not stable in the presence of H_2S, yet $[(Ph_3P)_2N]$-**1** was synthesized in and single crystals were grown from dichloromethane saturated with H_2S; 2) complex $[(Ph_3P)_2N]$-**1** and $[(Ph_3P)_2N][AuCl_2]$ react to give a brown precipitate, which has not yet been characterized; and 3) we have determined the unit cell of an authentic sample of $[(Ph_3P)_2N][AuCl_2]$: it is tetragonal, primitive, but with marked I-pseudocentering, and with cell constants of $a = 2947.1(3)$, $c = 1570.0(2)$ pm at -130 °C.[27]

Experimental Procedure

A solution of $[(Ph_3P)_2N][Au(acac)_2]$ (181 mg, 0.19 mmol) in dichloromethane (8 mL) was added dropwise to a saturated solution of H_2S in dichloromethane (4 mL). The resulting solution was stirred under an H_2S atmosphere for 15 min, filtered through celite, and concentrated (3 mL). Addition of diethyl ether (15 mL) gave a white precipitate that was filtered off and dried under vacuum to give $[(Ph_3P)_2N]$-**1**. Elemental analysis for $C_{36}H_{32}AuNP_2S_2$: calcd C 53.93, H 4.02, N 1.75, S 8.00, Au 24.57; found C 53.96, H 4.03, N 1.79, S 7.61, Au 25.04. M.p. 141 °C, $\Lambda_M = 111\ \Omega^{-1}\,cm^2\,mol^{-1}$ (4.4×10^{-4} M in acetone)].

[25] Crystal data for $[(Ph_3P)_2N]$-**1**: $C_{36}H_{32}AuNP_2S_2$, monoclinic, $P2_1/n$, $a = 2511.9(9)$, $b = 992.9(4)$, $c = 2679.2(9)$ pm, $\beta = 94.42(3)°$, $V = 6.662(4)$ nm^3, $Z = 8$, $\mu = 4.7$ mm^{-1}, $T = -100$ °C. A colorless needle (ca. $0.8 \times 0.15 \times 0.1$ mm) was mounted in inert oil (type RS3000, Riedel de Haën). A total of 11994 intensities, of which 11489 were independent, were registered on a Siemens R3 diffractometer fitted with an LT-2 low-temperature attachment ($Mo_{K\alpha}$ radiation, $2\theta_{max}$ 50°, absorption correction based on ψ-scans). The structure was solved by the heavy-atom method and refined anisotropically on F^2 (program SHELXL-93, G. M. Sheldrick, University of Göttingen). H atoms were included using a riding model; however, H atoms of the anion could not be located even with high-angle refinement. The final $wR(F^2)$ value was 0.117, with conventional $R(F)$ 0.057, for 757 parameters and 762 restraints. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the deposition number CSD-401041.

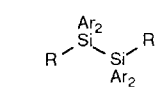
[27] Note added in proof (3.8.1994): By chance we recently obtained the salt $[(Ph_3P)_2N][AuCl_2] \cdot CH_2Cl_2$ as a byproduct in another reaction; the compound crystallizes in the $P2_1/c$ space group with $a = 921.89(10)$, $b = 2381.5(2)$, $c = 1654.35(14)$ pm, $\beta = 102.551(8)°$ at -100 °C (P. G. Jones, *Z. Kristallogr.*, submitted).

Structures of 2-(Me_2NCH_2)C_6H_4-Substituted Oligosilanes**



Johannes Belzner,* Nicola Detomi, Heiko Ihmels, and Matthias Noltemeyer

Isolable cyclotrisilanes[1] owe their existence to the stabilization of the strained three-membered ring by bulky substituents. Not only their stability, however, but also their formation through metal-mediated coupling of dihalosilanes is founded on the steric demands of the substituents at the silicon centers:[1,2] bulky groups force a conformation on the intermediate 3-halo-1-metallatrisilane in which the proximity of the termini of the acyclic trisilane favors an intramolecular ring closure (Thorpe–Ingold effect). Previously, bulky alkyl or aryl groups whose silyl substituents are blocked by alkyl groups in the *ortho* positions were used as suitable substituents for the synthesis of stable cyclotrisilanes. Against this background, the stability and the ready formation of the cyclotrisilane **1a**[3] by transformation of the appropriate diaryldihalosilane with magnesium is astounding; the 2-(dimethylaminomethyl)phenyl substituent introduced by Corriu et al.[4] into the chemistry of highly coordinated silicon compounds has only a relatively moderate steric effect and should actually favor the formation of larger rings. Also unusual is the reactivity of **1a**, which transfers all three diarylsilanediyl constituents of the ring to several substrates.[3,5]

1a: R = 2-(Me_2NCH_2)C_6H_4
1b: R = 2,6-$Me_2C_6H_3$
1c: R = H

Both the unexpected stability and the reactivity of **1a** made it desirable to investigate its structure in the crystal. An added goal was to gain more insight into the structural principles of 2-(dimethylaminomethyl)phenyl-substituted oligosilanes. We report here on the structures of the cyclotrisilane **1a** and the di- and tetrasilanes **2b** and **2c**, accessible from it.

Ar = 2-(Me_2NCH_2)C_6H_4

2a: R = Li
2b: R = H
2c: R = $SiMe_3$
2d: R = Cl

Cyclotrisilane **1a** crystallizes with two independent molecules in the asymmetric unit.[6] Neither in **1a** (**A**) (Fig. 1) nor in **1a** (**B**) is there a coordinative interaction between the amino and the silicon centers; moreover, the ^{29}Si NMR chemical shift of **1a**, which at $\delta = -64.7$ lies in the expected range for perarylated cyclotrisilanes, also precludes the formation of highly coordinated structures in solution. Though in the three-membered ring

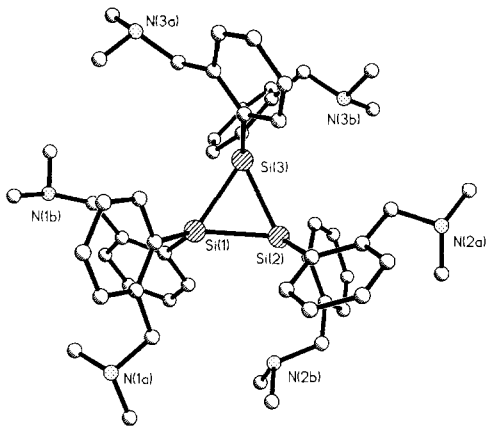


Fig. 1. Structure of the cyclotrisilane **1a** in the crystal (molecule **A**). Selected distances [pm] (the values in square brackets refer to molecule **B**): Si(1)–Si(2) 235.2(2) [236.4(2)], Si(2)–Si(3) 236.8(2) [235.7(2)], Si(3)–Si(1) 237.2(2) [235.6(2)], Si–C (averaged) 189.2(5) [189.2(5)].

of molecule **1a** (**A**) small deviations from the ideal geometry of an equilateral triangle are present, in **1a** (**B**) the Si–Si distances are identical, within experimental error. The endocyclic bonds (between 235 and 237 pm) are distinctly shorter than most experimentally determined bonds in other cyclotrisilanes.[7] The average Si–Si bond length in **1b**,[8] which was the only perarylated cyclotrisilane whose structure in the crystal had been studied previously, is 240.7 pm. In contrast, the average Si–Si bond length of 236.2 pm in **1a** approaches the value calculated for the parent compound (233–234 pm).[9] These observations show clearly that the 2-(dimethylaminomethyl)phenyl substituent does indeed have a relatively low steric demand, and class cyclotrisilane **1a** as a structurally hardly distorted member of this type of compound. The unusually facile cleavage of all three Si–Si bonds of **1a** cannot be predicted from its solid-state structure. Intramolecular stabilization of an intermediate silanediyl by the amino group of the aryl substituents cannot be excluded as reason for this reactivity.[10]

Cyclic trisilane **1a** can be converted by treatment with lithium into the vicinal dilithiodisilane,[11] whose reactions with electrophiles make many other disilanes accessible. Thus the protonation of **2a** with cyclopentadiene[12] yields the disilane **2b**,[13] which is moderately sensitive to hydrolysis. Figure 2 depicts one of the two independent molecules in the asymmetric unit

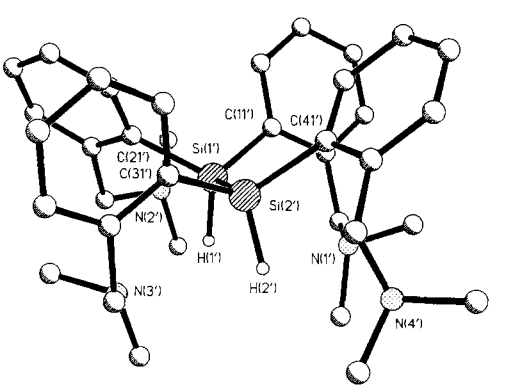

Fig. 2. Structure of the disilane **2b** in the crystal (molecule **A**). [**2b** (**A**)].[6] The inter-silicon distance of 238.4 pm in this compound is larger than that in **1a**.[14] Remarkable is the synperiplanar conformation about the Si–Si bond, since for tetraaryl-[15] and 2,2-dialkyl-1,1-diaryldisilanes,[16] antiperiplanar arrangements of the substituents were found. The eclipsed, sterically unfavorable conformation of **2b** is apparently adopted because of a coordinative interaction—which is, however, weak—between amino and silicon centers: the distances from the amino nitrogen atoms N(1′) and N(2′) to the silicon center Si(1′) and from N(3′) to Si(2′) are significantly smaller than the sum of the van der Waals radii of these elements (365 pm).[17, 18]

A completely different situation arises for tetrasilane **2c**, which is prepared by the reaction of **2a** with Me_3SiCl (Fig. 3):[6] Coordination between the amino and the silicon center no longer occurs. The additional steric congestion caused

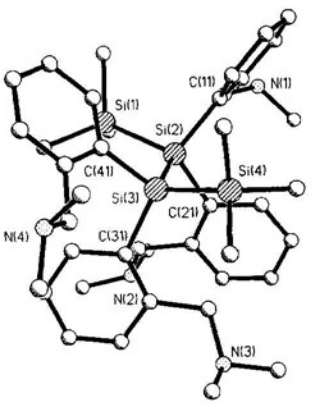

Fig. 3. Structure of the tetrasilane **2c** in the crystal. Selected distances [pm] and dihedral angles [°]: Si(1)-Si(2) 241.05(13), Si(2)-Si(3) 241.3(2), Si(3)-Si(4) 240.12(13), Si(2)-C(11) 191.2(3), Si(2)-C(21) 191.6(3), Si(3)-C(31) 192.0(3), Si(3)-C(41) 191.7(3); C(41)-Si(3)-Si(2)-Si(1) 35.3(2), Si(1)-Si(2)-Si(3)-C(31) 77.2(3), C(31)-Si(3)-Si(2)-C(21) 52.3(3), C(21)-Si(2)-Si(3)-Si(4) 77.3(2), Si(4)-Si(3)-Si(2)-C(11) 35.7(3), C(11)-Si(2)-Si(3)-C(41) 82.2(2).

by two trimethylsilyl groups results in an approximately antiperiplanar arrangement of the substituents about the central Si(2)–Si(3) bond. Despite this staggered conformation the system additionally relieves the steric pressure by a significant stretching of the Si(2)–Si(3) bond to 241.3 pm. The average C_{aryl}–Si bond length of 191.7 pm is also distinctly longer than that in **1a** ($\bar{d}_{Si-C} = 189.2$ pm) and **2b** ($\bar{d}_{Si-C} = 189.3$ pm) and reflects the steric strain in **2c**.

Apart from the diversity of their structures whose variety is certainly not exhausted by the three compounds described here, the 2-(dimethylaminomethyl)phenyl-substituted di- to tetrasilanes have large potential for application in synthesis. For instance, **2b** can be transformed quantitatively under mild conditions with *N*-chlorosuccinimide into the dichloro compound **2d**.[19] At present we are investigating whether **2d** and **2a** open preparative paths to the previously unknown class of base-coordinated disilenes.[10a]

Experimental Procedure

2b: Lithium turnings (30 mg, 4.36 mmol) were added to a solution of **1a** (647 mg, 0.73 mmol) in THF (11 mL). The mixture was stirred for 14 h at 20 °C, and the resulting deep red solution was filtered and treated at 0 °C with cyclopentadiene (290 mg, 4.39 mmol). THF was exchanged for 15 mL hexane. The suspension was filtered and concentrated. On cooling to −6 °C, 401 mg (92%) of **2b** crystallized as colorless crystals (m.p. 91–92 °C).

2c: To a solution of **2a**, prepared from **1a** (1.366 g, 1.54 mmol) and lithium (64 mg, 9.21 mmol) in THF (20 mL) and cooled at −10 °C, was added a solution of Me_3SiCl (1.17 mL, 9.21 mmol) in THF (5 mL). After stirring for two hours at 20 °C, the solvent was exchanged for 30 mL hexane, the resulting suspension filtered, and the filtrate evaporated to half its volume. On cooling to −6 °C 609 mg (54%) of **2c** precipitated as colorless crystals (m.p. 183–185 °C). ^{1}H NMR (C_6D_6, 72 °C, 300 MHz): $\delta = 0.35$ (s; 18 H, $SiMe_3$), 2.09 (s; 24 H, Me), 2.88, 3.31 (AB system, $J = 15$ Hz; 8 H, CH_2), 7.01, 7.26, 7.84 (3 mc (1:1:2); 16 arom. H); ^{13}C NMR ($CDCl_3$, 27 °C, 75.47 MHz): $\delta = 3.16$ ($SiMe_3$), 45.19 (NMe_2), 63.1 (CH_2), 125.24, 127.24, 129.22, 135.2, 139.18, 145.62 (arom. C); ^{29}Si NMR ($CDCl_3$, 27 °C; 59.63 MHz): $\delta = -13.6$ ($SiSiMe_3$), −26.8 ($SiSiMe_3$); MS (70 eV): *m/z* (%): 738 (3) [M^+], 369 (100) [$(M/2)^+$], 134 (15) [$Ar^+ - H$]; correct C,H,N analysis.

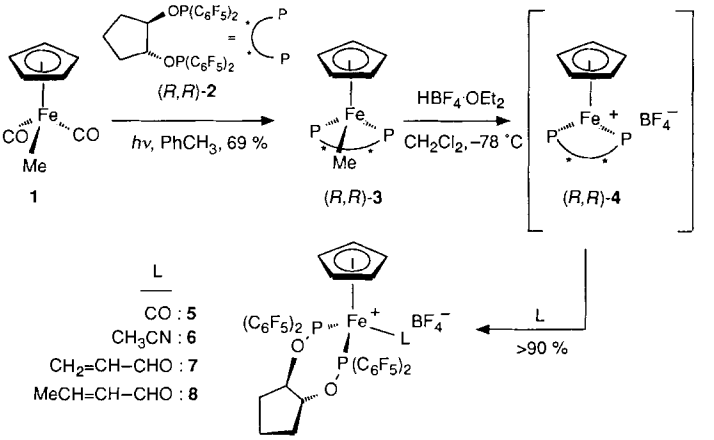
[18] The distances between N(3′) and Si(1′) as well as between N(1′) and Si(2′) are also smaller than 365 pm; nevertheless, an additional coordinative interaction is not indicated, mainly because the lone pairs of the amino nitrogen atoms do not point towards the silicon centers.
[19] **2d** is also obtained by treatment of **1a** with $CHCl_3$.

Asymmetric Diels–Alder Reactions Catalyzed by a Chiral Iron Lewis Acid**

Ernst Peter Kündig,* Bernadette Bourdin, and Gérald Bernardinelli

Very impressive results have recently been reported for enantioselective Diels–Alder reactions catalyzed by chiral Lewis acids.[1, 2] Main group elements dominate in this chemistry, and aluminum- and boron-based catalysts with chiral ligands have produced the best results to date. We report here on a highly enantioselective Diels–Alder reaction catalyzed by a Lewis acid derived from an easily prepared and well-defined transition metal complex.



Titanium[2o] and copper[2k, l] complexes apart, only three examples of asymmetric transition-metal catalysts for the Diels–Alder reaction have been reported. An Fe^{III}-based Lewis acid, containing a C_2-chiral bis(oxazoline) ligand and generated in situ, catalyzed the reaction between cyclopentadiene and 3-acryloyl-1,3-oxazolidin-2-one to give the cycloadduct with 86% ee and 99:1 *endo/exo* selectivity.[3] Lower enantioselectivities (<60%) were observed for the same reaction with another Fe^{III} system with bis(sulfoxide) ligands,[4] which had also been generated in situ. The reactions between cyclopentadiene and the dienophiles acrolein, methacrolein, and methyl methacrylate, catalyzed by a chiral Lewis acid based on zirconium, also gave only modest enantioselectivities.[5]

Achiral transition-metal catalysts for the Diels–Alder reaction were investigated by several groups.[6–8] The complex $[CpFe(CO)_2(thf)]BF_4$ was one of a series of catalysts studied by Hersh et al. They found that the Diels–Alder reaction between acroleins and cyclopentadiene was accelerated in the presence of the iron(II) complex. The catalytic activity, however, was significantly greater than expected on the basis of stoichiometrically determined rate constants.[6a] This suggested that another catalyst, a Brønsted or Lewis acid impurity, was present and cast some doubt on the role of the iron complex in this process. According to these authors, the best evidence for involvement of the iron center would be to demonstrate that a chiral analogue is capable of asymmetric induction in this reaction. We here provide this evidence.

The Lewis acidity of the d^6 iron(II) center in the complex described above arises as a result of the overall positive charge of the complex and the presence of the two CO acceptor ligands. This effect is, however, attenuated by the donor ligand Cp, and $[CpFe(CO)]^{2+}$ is a weak Lewis acid as a result. The most direct way to asymmetrically modify this complex is by substituting one or both carbonyl ligands by a chiral ligand. It is readily apparent that Lewis acidity will only be preserved if the electronic characteristics of the new ligand resemble those of CO. In the search for a catalyst with chirality at the metal center, Hossain et al. found that substitution of one of the two CO ligands by PPh_3 completely suppressed activity in the Diels–Alder reaction. Some activity remained, however, with the less electron-rich complex $[CpFe(CO)\{P(OMe)_3\}(thf)]BF_4$.[8b]

We recently reported the synthesis of both enantiomers of several new C_2-chiral phosphorus ligands that, to a degree, emulate the bonding characteristics of CO.[9] We envisaged replacing the two *cis* carbonyl ligands of various transition-metal catalysts with these new ligands and using the resulting complexes in asymmetric reactions. For the investigations reported here, we chose to modify the Lewis acid $[CpFe(CO)_2]^+$ with the fluorophenyl ligand (*R,R*)-**2**.

Complex [CpFe(L)Me] (**3**) was readily prepared by photolytic ligand substitution in **1** (Scheme 1). Treatment of a CH_2Cl_2

Scheme 1. Synthesis of the chiral Lewis acid **4** and its complexes with CO, acetonitrile, acrolein, and crotonaldehyde.

solution of **3** with HBF_4 at −78 °C presumably generated the coordinatively unsaturated cationic intermediate **4**. Reaction of **4** with CO in situ afforded the carbonyl complex **5**, and reaction with MeCN gave complex **6**. The X-ray structure analysis of **6** shows the spatial arrangement of the four bulky pentafluorophenyl groups in the complex (Fig. 1).[10]

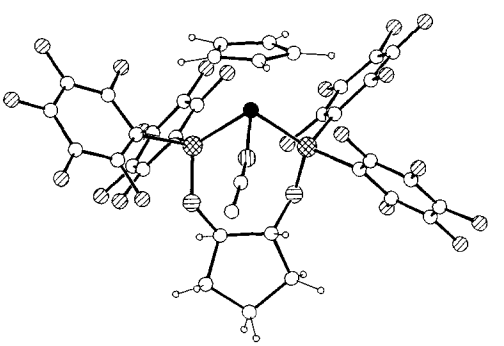


Fig. 1. Crystal structure of rac-**6**. The (*R,R*) enantiomer is shown. ● = Fe, ○ = N, ⊜ = O, ⊕ = P, ◎ = F.

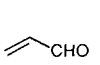

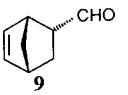

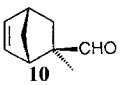

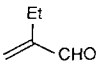

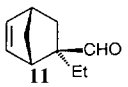

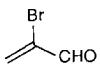

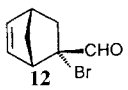

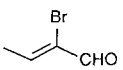

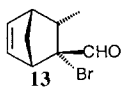

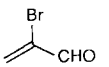

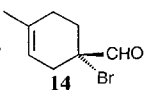

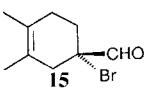

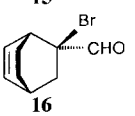

The deep green solution of **4** in CH_2Cl_2 turned dark red when acrolein was added. Addition of hexane resulted in precipitation of a brown solid **7**, which was found to be the acrolein complex with an η^1 M–O=C interaction.[11] Full characterization proved difficult because of the instability of **7** in solution and its high reactivity towards Lewis bases.

In the presence of 5 mol% of (*R,R*)-**7** and 2.5 mol% of 2,6-di-*tert*-butylpyridine, methacrolein reacted with cyclopentadiene to give (1*S*,2*R*,4*S*)-2-methylbicyclo[2.2.1]hept-5-ene-2-carbaldehyde (**10**) in 62% yield, 90% *ee*, and with an *exo/endo* formyl selectivity of 97/3. This and further examples of asymmetric

8			−20/28	 **16**	10/90 [m]	88 [l]	>99 [h]

[a] The reactions were carried out in freshly distilled CH_2Cl_2 (1 M solution) with 5 mol% of catalyst, 2.5 mol% of 2,6-di-*tert*-butylpyridine, and equimolar portions of diene and dienophile (unless otherwise noted). [b] The structure shown is the major product. [c] The terms *exo* and *endo* refer to the position of the formyl group. [d] Isolated yield after flash chromatography. [e] Determined by GC analysis after conversion to the acetal derivative of (2*R*,4*R*)-pentanediol [14]. [f] The configuration was assigned by comparing the sign of $[\alpha]_D$ with that in the literature: (*R*)-**9** [1a], (*R*)-**10** [1a,14]. [g] Determined from the ^{1}H NMR spectrum after conversion to the acetal derivative of (2*R*,4*R*)-pentanediol. [h] Determined from the ^{1}H NMR spectrum in the presence of the chiral shift reagent Eu(hfc)$_3$. [i] Assignment after conversion to norbornen-2-one and comparison of the sign of $[\alpha]_D$ with that in the literature [13a,21]. [j] Determined by GC analysis on a chiral column (MN FS-Lipodex E). [k] A single regioisomer was observed. [l] 5 equiv of diene was used; yield with 1 equiv was 28%. [m] *endo*-Formyl assignment is based on ^{1}H NMR and GC comparison.

Diels–Alder reactions between α,β-enals and dienes are listed in Table 1. 2,6-Di-*tert*-butylpyridine was added to scavenge residual acid impurities. In the absence of a scavenger, the rate of reaction was found to vary; this is consistent with Hersh's findings.[6a] More importantly, enantioselectivities were lower (20–60% *ee*) and not reproducible. This behavior is expected if a competing achiral catalyst is present.[12]

The best results were obtained with the very reactive dienophile α-bromoacrolein. Corey et al. used this compound for the synthesis of versatile cycloaddition products.[2i, 13] As was observed with other Lewis acid catalysts, high *exo* selectivity was found for α-substituted enals. Yields were lower with other dienophiles, but enantioselectivities remained quite high. Thus, while the *ee* of the *endo* product **9** from the reaction with acrolein matched the best literature result,[14] yield and *exo*/*endo* selectivity were low. (*E*)-Crotonaldehyde did not react. Higher reaction temperatures proved impracticable because of slow decomposition of the catalyst above −20 °C. The yield for the reaction of α-bromoacrolein (entry 8) with cyclohexadiene was improved from 28 to 88% by increasing the proportion of diene from one equivalent to five. It is noteworthy that a single enantiomer of the *endo*-formyl diastereomer was formed in this reaction is and that diastereoselectivity is good.

A transition state, based on the solid state structure of **6**, that accounts for the observed stereoselectivity is shown in Figure 2. The diene approaches the olefin *si* face of the s-*trans* conformer

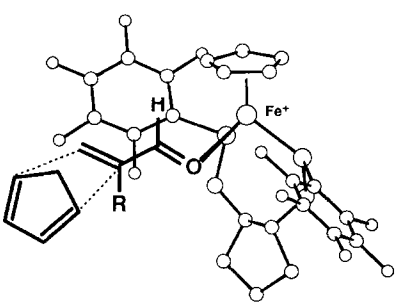

Fig. 2. Model of the transition state for the Diels–Alder reaction catalyzed by **7**. A partial structure of complex **6**, the coordinated α-substituted enal, and the cyclopentadiene are shown.

of the coordinated enal. The *re* face is shielded by a pentafluorophenyl ring of the ligand (*R*,*R*)-**2**.

In conclusion, despite the limitations that can be attributed to the weak Lewis acidity[15] and low thermal stability of **7**, these first results are highly encouraging. They confirm the hypothesis that chiral ligands that model the bonding properties of CO are attractive for asymmetric catalysis. Further studies will focus on understanding the transition state in these reactions and on improving the catalytic system for the Diels–Alder reaction and other Lewis acid catalyzed processes.[15]

Experimental Procedure

(*R,R*)-**3**: A N_2-saturated solution of **1** [16] (0.291 g, 1.5 mmol) and (*R,R*)-**2** (1.249 g, 1.5 mmol) [9] in toluene (90 mL) was irradiated at 15 °C with a 125 W high-pressure mercury lamp equipped with a pyrex filter. A slow stream of N_2 was maintained throughout the reaction, and progress was monitored by *IR* analysis (νCO) of samples taken from the reaction. When all starting material had been consumed, the mixture was filtered through Celite, and volatiles were removed under vacuum. Recrystallization from hexane at −20 °C afforded (*R,R*)-**3** (1.004 g, 69%). Enantiomeric purity was >99% as measured by HPLC (Daicel OD, eluent: hexane/*i*PrOH 400/1). M.p. 141 °C (decomp.); $[\alpha]_D^{20} = +1.83$ ($c = 0.2$ in $CHCl_3$); ^{1}H NMR (400 MHz, C_6D_6, 21 °C): $\delta = 0.37$ (br. t, ^3J(H,P) = 6.5 Hz, 3H; Me), 1.12–1.76 (m, 6H; CH_2), 3.87–4.02 (m, 1H; OCH), 3.97 (s, 5H; C_5H_5), 4.21–4.35 (m, 1H; OCH); ^{31}P NMR (162 MHz, C_6D_6, 21 °C, H_3PO_4): $\delta = 156.81$ (AB(bd), ^2J(P,P) = 82 Hz; P_1), 158.13 (AB(bd), ^2J(P,P) = 82 Hz; P_2); ^{13}C NMR (100 MHz, CD_2Cl_2, 21 °C): $\delta = -25.3$ (br. t, ^2J(C,P) = 28 Hz; CH_3), 18.8 (CH_2), 28.8 (d, J(C,P) = 7 Hz; CH_2), 29.2 (d, J(C,P) = 4 Hz; CH_2), 80.0 (OCH), 81.8 (d, J(C:P) = 5 Hz; OCH), 84.9 (C_5H_5), 136.4–137.5 (m, C_{arom}), 138.9–140.0 (m, C_{arom}), 140.4–145.2 (m, C_{arom}), 146.0–147.0 (m, C_{arom}), 148.7–149.5 (m, C_{arom}). Anal.: calcd for $C_{35}H_{16}F_{20}FeO_2P_2$ (966.28): C 43.50, H 1.67; found: C 43.36, H 1.81.

(*R,R*)-**7**: To a stirred solution of (*R,R*)-**3** (0.581 g, 0.6 mmol) in CH_2Cl_2 (60 mL) at −78 °C was added HBF_4 (90 µL of a 54% solution in ether, 1 equiv). After 15 min at −75 °C, the green solution was treated with acrolein (210 µL, 5 equiv) and an immediate color change to red was observed. The reaction mixture was allowed to warm up to −20 °C over a period of 3.5 h, and then concentrated to about 10 mL. The product was precipitated by addition of hexane (20 mL), isolated, and then washed several times with the same solvent. A red-brown powder (*R,R*)-**7** was obtained in 90% yield (0.591 g). ^{1}H NMR (400 MHz, CD_2Cl_2, −20 °C): $\delta = 9.79$ (br. s, 1H), 7.09–6.83 (br. d, 1H, $J = 15$ Hz), 6.82–6.60 (m, 1H), 6.35–6.10 (m, 1H), 4.47 (s, 5H), 4.23–4.02 (m, 1H), 3.90–3.70 (m, 1H), 2.15–1.25 (m, 6H); ^{31}P NMR (162 MHz, CD_2Cl_2, −20 °C, H_3PO_4): $\delta = 156.15$ (AB(bd), $J = 79$ Hz, P_1), 159.55 (AB(bd), $J = 79$ Hz, P_2).

Cycloaddition reactions: To freshly distilled CH_2Cl_2 (2 mL) was added at −40 °C (*R,R*)-**7** (110 mg, 0.1 mmol) and 2,6-di-*tert*-butylpyridine (12 µL, 0.05 mmol). The resulting dark red solution was then treated with methacrolein (170 µL, 2.0 mmol). After the mixture had been stirred for 15 min, freshly distilled cyclopentadiene (170 µL, 2.0 mmol) was slowly added (5 min). The reaction mixture was stirred at −20 °C for 20 h. The catalyst was precipitated by addition of hexane, and washed three times with the same solvent. The combined organic phase was exposed to air to remove traces of residual catalyst by oxidation. Filtration through Celite, solvent removal, and flash chromatography on silica gel (eluent hexane/ether 10/1) gave **10** in 62% (174 mg) with an *endo*/*exo* ratio of 3/97 (determined by GC before chromatography). The *ee* of *exo*-**10** was 90%.

[10] Crystallographic data for *rac*-**6**: Red crystals were grown from a CH_2Cl_2/hexane solution. $(C_{36}H_{16}NO_2P_2F_{20}Fe)(C_6H_{14})(PF_6)$, $M_r = 1223.4$; $\mu = 0.582$ mm^{-1}, $F(000) = 2440$, $\rho_{calcd} = 1.80$ g cm^{-3}, monoclinic, $P2_1/n$, $Z = 4$, $a = 11.893(5)$, $b = 16.213(8)$, $c = 23.402(8)$ Å, $\beta = 91.09(1)°$, $V = 4512(3)$ Å^3, from 25 reflections ($14 < 2\theta < 26°$). Cell parameters and intensities were measured at room temperature on a Nonius CAD4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), ω–2θ scans, scan width $1.2° + 0.25 \tan\theta$, and scan speed 0.02–0.14° per s. Two reference reflections measured every 100 reflections showed variation less than $3.2\sigma(I)$. $-11 < h < 11$, $0 < k < 16$, $0 < l < 23$; 4978 measured reflections, 4838 unique reflections of which 2862 were observable ($|F_o| > 4\sigma(F_o)$). Data were corrected for Lorentz and polarization effects but not for absorption. The structure was solved by direct methods (MULTAN 87 [17]), all other calculations used XTAL [18] system and ORTEP [19] programs. Atomic scattering factors and anomalous dispersion terms were taken from ref. [20]. Full-matrix least-squares refinement based on F with weighting 1 gave final values $R = wR = 0.010$ for 656 variables. Hydrogen atoms were placed in calculated positions. Both the PF_6^- and hexane molecules are disordered. The fluorine atoms of PF_6^- were found at 13 sites with population parameters ranging between 0.25 and 1; the hexane molecules were entirely disordered. The disorder results in rather high residual R factors. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[11] Complex **7** is stable in the solid state and can be handled in air. It reacts with CH_3CN to give **6** quantitatively. In CH_2Cl_2, **7** decomposes gradually above −20 °C. The ^{1}H NMR spectrum showed **7** to be a 1:1 complex of acrolein with **4**. Although signals were broad, the pattern is consistent with an M–O=C σ-bound acrolein. The IR spectrum of the more stable crotonaldehyde complex **8** showed an absorption at 1604 cm^{-1} (in KBr). Compared to free (*E*)-crotonaldehyde, the carbonyl band in the complex is shifted by 88 cm^{-1} to lower wavenumbers. This is consistent with the proposed mode of coordination of the Lewis acid. Synthesis and Structure of $[WOTe_3]^{2-}$

Donna R. Gardner, James C. Fettinger, and Bryan W. Eichhorn*

In contrast to the large number of compounds containing terminal oxido,[1] sulfido,[2] and selenido[3] ligands, compounds containing terminal tellurido ligands are rare.[4] For example, the $[MQ_4]^{2-}$ ions are known for M = Mo, W; Q = O, S, and Se but not for Te.[5] The first compound with a terminal tellurido ligand, $[W(PMe_3)_4(Te)_2]$, was isolated only a few years ago.[6] Subsequently, several tellurido complexes of the early transition metals (Zr, Hf, Nb, Ta, W) have been prepared and characterized.[7-11] The methods for preparing tellurido species vary from direct oxidative additions of elemental Te to disilyltelluride elimination reactions. It is somewhat surprising that reactions between polytelluride anions and precursors of transition metal complexes have thus far not led to compounds containing terminal tellurido ligands; similar reactions involving the lighter polychalcogenides have been successful.[3, 12, 13]

We have been investigating the chemistry of the polychalcogenides with dinuclear Mo and W carboxylato complexes having metal–metal quadruple bonds. The reaction between $[Mo_2(O_2CMe)_4]$ and K_2Te_4 in ethylenediamine (en) that gave the unusual $\{[Mo_2(\mu\text{-}Te_2)_2(en)_2]_2(\mu\text{-}Te_3)_2(\mu\text{-}Te_2)\}^{2-}$ ion was described previously.[14] In an attempt to extend this chemistry to the dinuclear tungsten systems, we conducted similar experiments with $[W_2(O_2CC_3H_7)_4]$ and K_2Te_2. Herein we report the synthesis and characterization of a novel product from these reactions, $[WOTe_3]^{2-}$, which contains three terminal tellurido ligands. The existence of this compound suggests that homoleptic $[MTe_4]^{n-}$ ions may indeed be isolable in contrast to previous beliefs.[12]

The reaction of $[W_2(O_2CC_3H_7)_4]$ and K_2Te_2 in en gave low yields of the $[WOTe_3]^{2-}$ ion as the PPh_4^+ salt. The dark red-brown crystals have been characterized by single-crystal X-ray diffraction, IR spectroscopy, and energy dispersive X-ray analysis (EDX). The same crystalline compound[15] was also isolated in low yields from the reaction of WCl_4 and K_2Te_2 in en. The source of the oxygen atom in the product is not known for either reaction. The more reasonable reaction of $WOCl_4$ and K_2Te in en is complicated by the extensive aminolysis of $WOCl_4$, and $[WOTe_3]^{2-}$ is not detected. The same reaction conducted in *N*,*N*-dimethyformamide (DMF) gives the $[OW(Te_4)_2]^{2-}$ ion as originally reported by Kolis and Flomer.[16] The majority of the reactions between transition metal complexes and polytellurides reported thus far involve DMF solvent and give polytellurido complexes. For example, Kolis and Flomer have shown that reactions of WCl_6 and WCl_4 and solutions of polytelluride anions (Te_x^{2-}, where $x = 2-5$) in DMF lead to the W^{IV} compound $(PPh_4)_2[WO(Te_4)_2]$.[16] In contrast, numerous compounds containing terminal sulfido and selenido ligands have been prepared from polychalcogenide precursors in DMF (e.g. $[WSe_4]^{2-}$, $[Mo_2(S)_2(\mu\text{-}S)_2(\eta^2\text{-}S_2)_2]^{2-}$, and $[W_2Se_6]^{2-}$).[17-19]

The single-crystal X-ray structure[20] of $(PPh_4)_2[WOTe_3]\cdot 0.5en$ reveals that the C_{3v}-symmetrical $[WOTe_3]^{2-}$ ion is isostructural to $[WOS_3]^{2-}$ (Fig. 1).[22] The distortions from idealized tetrahedral symmetry arise from the differences in size between the Te^{2-} and O^{2-} ligands. The W–Te bond lengths (2.54(1) Å average) in $[WOTe_3]^{2-}$ are among the shortest M–Te contacts reported to date[6, 7, 9-11] but are best described as

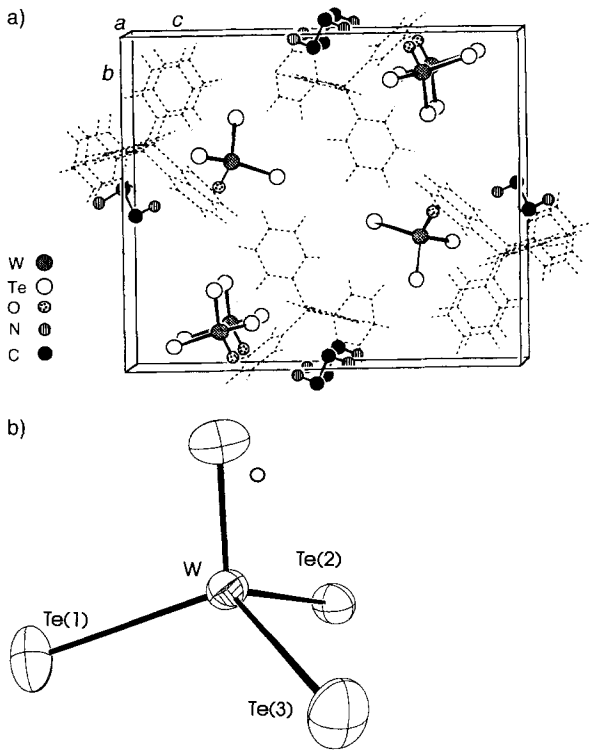

Fig. 1. a) Unit cell of $(PPh_4)_2[WOTe_3]\cdot 0.5en$ and b) ORTEP drawing of the $[WOTe_3]^{2-}$ anion. Selected interatomic distances [Å] and angles [°]: W–O 1.716(6), W–Te(1) 2.544(2), W–Te(2) 2.542(2), W–Te(3) 2.530(1); Te(1)-W-Te(2) 110.29(6), Te(1)-W-Te(3) 111.68(3), Te(1)-W-O 109.2(2), Te(2)-W-Te(3) 110.20(4), Te(2)-W-O 107.3(2), Te(3)-W-O 108.1(2).

double bonds (see below). The short bonds are consistent with the high oxidation state of W and the low coordination number of the metal ion relative to other known W compounds. The W–O bond length (1.716(6) Å) is within the range reported for other W^{VI} complexes (1.89–1.57 Å)[11b] and is shorter than the W–O contacts in the $[WO_4]^{2-}$ and $[WOS_3]^{2-}$ ions at 1.79 and 1.760 Å, respectively.[22] This apparent trend of decreasing W–O distance for the $[WOQ_3]^{2-}$ ions (where Q = O, S, and Te) is attributed to the decreasing π-donor ability of the heavier chalcogenides.[22] The ethylenediamine solvate molecule and the two PPh_4^+ ions are well separated from the anion and are crystallographically well behaved.

The IR spectrum of the $[WOTe_3]^{2-}$ ion (KBr pellet) shows bands associated with the PPh_4^+ ions, the en solvate molecule, and a strong ν_{W-O} band at 904 cm^{-1}. A summary of the structural and IR spectroscopic data for the $[WOQ_3]^{2-}$ ions is given in Table 1. The increase in W–O force constants (f_{W-O}) for the $[WOQ_3]^{2-}$ ions where Q = O, S, Se, and Te parallels the trend in decreasing W–O distances and W–Q π-bond orders (see below). In addition, the colors of the $[WOQ_3]^{2-}$ ions change

Table 1. Structural and IR spectroscopic data for the $[WOQ_3]^{2-}$ ions where Q = O, S, Se, Te.

Cmpd.	W–O [Å][a]	W–Q [Å][a]	$\tilde{\nu}_{W-O}$ [cm^{-1}]	f_{W-O} [mdyn $Å^{-1}$]	Ref.
$[WO_4]^{2-}$	1.79	1.79	931[b], 829	6.38	[23]
$[WOS_3]^{2-}$	1.76	2.20	878	6.66	[23]

from colorless (Q = O) to yellow (Q = S) to orange-red (Q = Se) to dark red-brown (Q = Te) as expected from the decrease in energy of the $^1A \rightarrow {}^1E$ ligand-to-metal charge transfer transition (see below).

The maximum M–Q bond order in a tetrahedral $[MQ_4]^{2-}$ ion is 2.25, which gives a total of nine M–Q bonds ($4\sigma + 5\pi$).[25] When all four Q ligands are of equal π-donor ability (e.g. $[WO_4]^{2-}$) the π interactions transform under $e + t_2$ symmetry and are of course distributed equally among the four Q atoms (Fig. 2). When the Q ligands are of differing π-donor

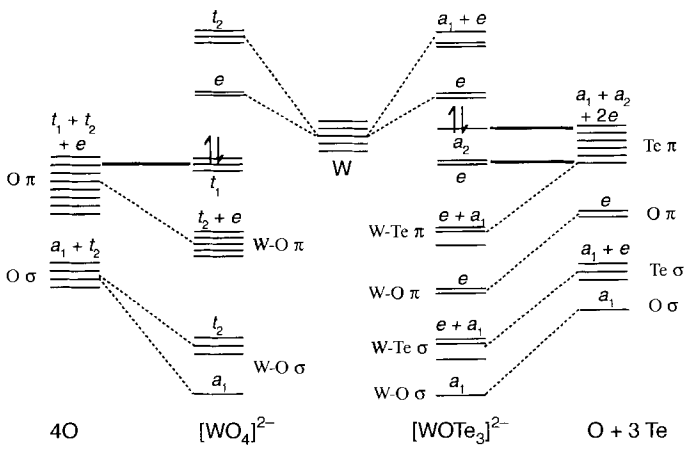

Fig. 2. Qualitative orbital interaction diagrams for $[WO_4]^{2-}$ and $[WOTe_3]^{2-}$. The latter illustrates the limiting valence description comprising $W^-{\equiv}O^+$ and W=Te interactions. The d orbitals for W are given in the middle.

ability, the individual bond orders may vary in order to attain the five strongest possible π bonds. For example, one could obtain a W–O bond order of three with W–Te bond orders of two for the $[WOTe_3]^{2-}$ ion in the limiting case (Fig. 2).[26] Due to the trends in bond lengths and f_{W-O} values in the $[WOQ_3]^{2-}$ series, it appears that $[WOTe_3]^{2-}$ is approaching this limit. One may therefore assign formal W–Te bond orders of two in this complex. The only reported metal–tellurido complexes that could potentially have W–Te bond orders of more than two are the *cis*-$[WTe_2(PMe_3)_2(\eta^2\text{-}OCR_2)]$ compounds where R = H, Ph.[11] The $[WOTe_3]^{2-}$ ion represents the limit of Te incorporation in the tetrahedral $[WQ_4]^{2-}$ ion that does not require a W–Q bond order of more than two. Attempts to prepare $[WTe_4]^{2-}$ are in progress.

Experimental Procedure

Method 1: With Schlenk techniques $[W_2(O_2CC_3H_7)_4]$ (100 mg, 0.14 mmol) and K_2Te_2 (54 mg, 0.16 mmol) were dissolved in approximately 8 mL of en. After the solution was stirred for 8 h at room temperature, $K(O_2CC_3H_7)$ was removed by filtration and solid PPh_4Br was added to induce crystallization. Red-brown needles of $(PPh_4)_2[WOTe_3]\cdot 0.5en$ were obtained after 6 d in low yield (ca. 8 mg, 6% yield based on Te).

Method 2: In a dry box, en (3 mL) was added to a vial containing WCl_4 (32.6 mg, 0.10 mmol). The green suspension was stirred for 30 min before K_2Te_x (20 mg, ≈0.10 mmol) and K_2Te_2 (20 mg, 0.06 mmol) were added as solids. The resulting red-brown solution was stirred for an additional 4.5 h. After the solution was filtered, solid PPh_4Br (84 mg, 0.20mmol) was added to induce crystallization. Red-brown needles of $(PPh_4)_2[WOTe_3]\cdot 0.5en$ were isolated after 8 d (ca. 6 mg, 5% based on W). Crystals were characterized by EDX, single-crystal X-ray diffraction (indexed cell) and IR ($\nu_{W-O} = 904\ cm^{-1}$).

$[W_2(O_2CC_3H_7)_4]$ was prepared according to published procedures [26] except $Na(O_2CC_3H_7)$ was used instead of $Na(O_2CtBu)$. ^1H NMR (400 MHz, [D$_6$]benzene): $\delta = 0.92$ (t, 12H), 1.80 (sextet, 8H), 3.12 (t, 8H). $^{13}C\{^1H\}$ NMR (100 MHz, [D$_6$]benzene): $\delta = 13.7, 21.6, 38.2, 183.6$. K_2Te_2 and K_2Te_x ($x \approx 1$) were prepared from stoichiometric amounts of K and Te in refluxing DMF.

[20] Crystal Data: Monoclinic, $P2_1/n$, $a = 14.290(5)$, $b = 16.693(4)$, $c = 19.75(2)$ Å; $\beta = 99.73(6)°$; $V = 4644(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.855\ g\,cm^{-3}$. Data were collected at 20 °C [4491, $I > 2\sigma(I)$] on an Enraf-Nonius CAD4F diffractometer using $Mo_{K\alpha}$ radiation ($\lambda = 0.70930$ Å) and a $\theta/2\theta$ scan mode; $2\theta_{max} = 44.9°$; $\mu = 0.143\ mm^{-1}$; min./max. transmission = 0.723/1.00. Lorentz and polarization corrections were applied. A secondary extinction correction was also applied in the final stages of refinement. The structure was solved by direct methods and successive Fourier syntheses and refined against $|F^2|$ to $R(F) = 0.033$ and $R_w(F^2) = 0.077$ (unit weights) with the SHELXS solution package [21]. An empirical correction for absorption was made by using psi-scans. Maximum $\Delta/\sigma = 0.005$ for the last cycle with 509 parameters. Residual electron density ca. 2.4 Å from the W center (near the O atom) was observed in the later difference maps. The residual electron density could be refined as a Te atom with a partial occupancy of ca. 5% or a Br atom with a partial occupancy of ca. 7%. EDX analysis showed W, Te, and P in all samples and small amounts of Br in two of the crystals analyzed. For the final refinement, we assumed the chemical composition of $WTe_{3.05}O_{0.95}NP_2C_{49}H_{44}$ showing a 5% occupancy of Te near the O position. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-58291.

[26] Formally, the W–O interaction must be described as either a single bond ($W^+\text{–}O^-$) or a triple bond ($W^-{\equiv}O^+$), because the W–O p interactions in the $[WOTe_3]^{2-}$ ion (C_{3v}) transform under *e* symmetry. However, linear combinations of the 3 Te π orbitals possess two π-type *e* combinations and can compete with O for the W-based *e* acceptor orbitals. For a bonding analysis of $[WOSe_3]^{2-}$, see A. Müller, E. Diemann, *Chem. Ber.* **1969**, *102*, 2044.

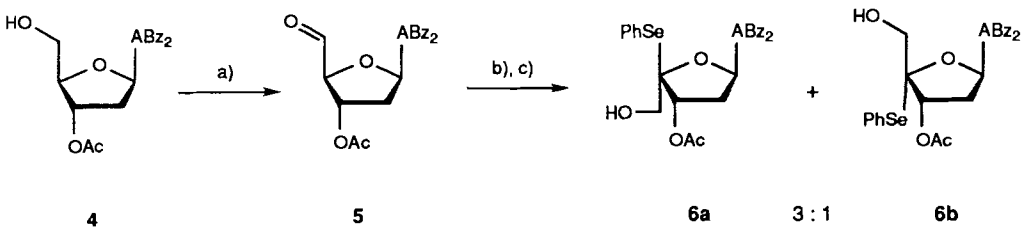
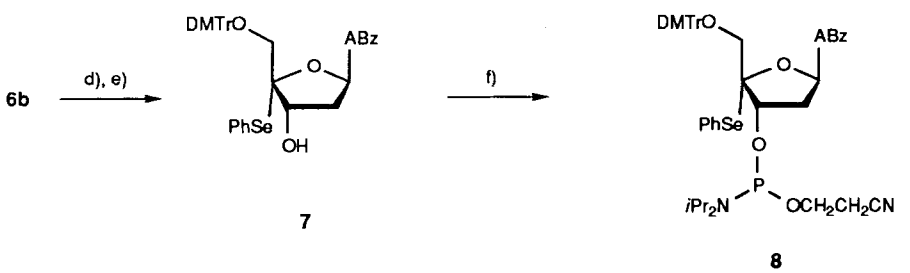
Synthesis and Selective Radical Cleavage of C-4′-Modified Oligonucleotides**

Bernd Giese,* Adrian Dussy, Cornelius Elie, Peter Erdmann, and Urs Schwitter

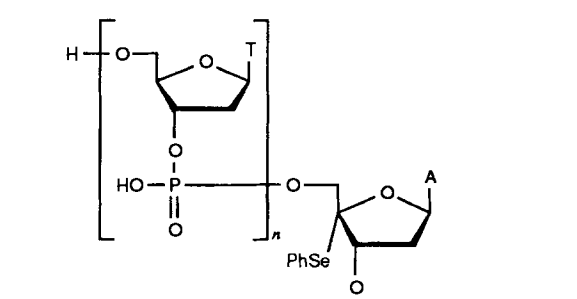


Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday



The chemotherapeutic action of the antibiotics bleomycin and neocarzinostatin is initiated by the abstraction of H atoms from the 4′- and/or 5′-position of the deoxyribose of DNA.[1] In studies with mononucleotides we recently found evidence for the Schulte-Frohlinde mechanism[2] for the anaerobic cleavage of the DNA strand.[3] Selenide **1** was photolyzed to generate the 4′-nucleotide radical **2**, which decays heterolytically to the radical cation **3**. Its occurrence was proven by chemical trapping experiments[3a] and by conductivity measurements.[3b]

However, since these experiments were conducted in nonaqueous solution on mononucleotides bearing phosphoric ester groups, conclusions regarding the radical reactions of oligonucleotides in water are problematic. We report here on the synthesis of 4′-deoxyribonucleotide radicals and studies of the strand scission of oligonucleotide radicals in aqueous solution.



It was necessary to test whether selenide **8** could tolerate the oxidative, acidic, and basic conditions of the steps in oligonucleotide synthesis with the DNA synthesizer. Thus, we prepared dimer **9** as the triethylammonium salt both from **7** according to

Scheme 1. a) $(COCl)_2$, dimethyl sulfoxide (DMSO), NEt_3, CH_2Cl_2, −78 °C; b) PhSeCl, NEt_3, CH_2Cl_2, −78 to 0 °C, 87% (steps a + b); c) $Bu_4NBH_3(CN)$, THF, −78 to 0 °C, H^+/H_2O, 88%; d) *p*-dimethoxytrityl chloride (DMTrCl), pyridine, 20 °C, 85%; e) NaOMe, MeOH, 10 min, NH_3, MeOH, 50 min, 0 °C, 93%; f) $NC(CH_2)_2O(iPr_2N)PCl$, $NEtiPr_2$, CH_2Cl_2, CH_3CN, 20 °C, 90%. Bz = benzoyl, A = adenosyl.

The deoxythymidine derivative **1** has the wrong L-*lyxo* configuration at C-4′ for incorporation in oligonucleotides. However, selenation of deoxyadenosine **4** and subsequent reduction to the alcohol provides both the *lyxo* compound **6a** analogous to **1** and the *ribo* isomer **6b**, which were separated by flash chromatography (silica gel, ether:CH_2Cl_2 = 3:2).[4] Following appropriate protecting group manipulations (**6b** → **7**), the deoxyadenosyl derivative was converted into **8**,[5] the building block for the oligonucleotide synthesis (Scheme 1).

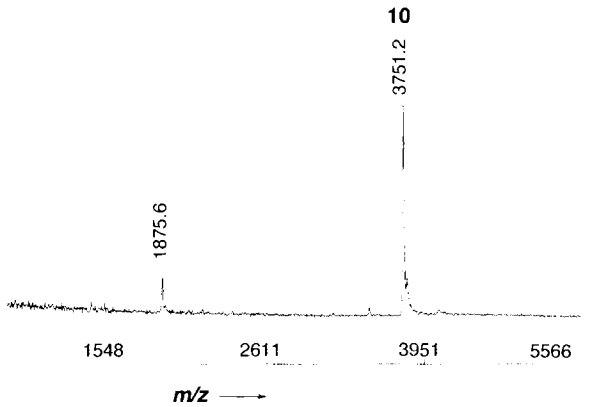

Fig. 1. MALDI-TOF mass spectrum (negative-ion mode) of the modified dodecamer **10**. The signal at *m/z* 1875.6 corresponds to the doubly deprotonated molecular ion of **10**.

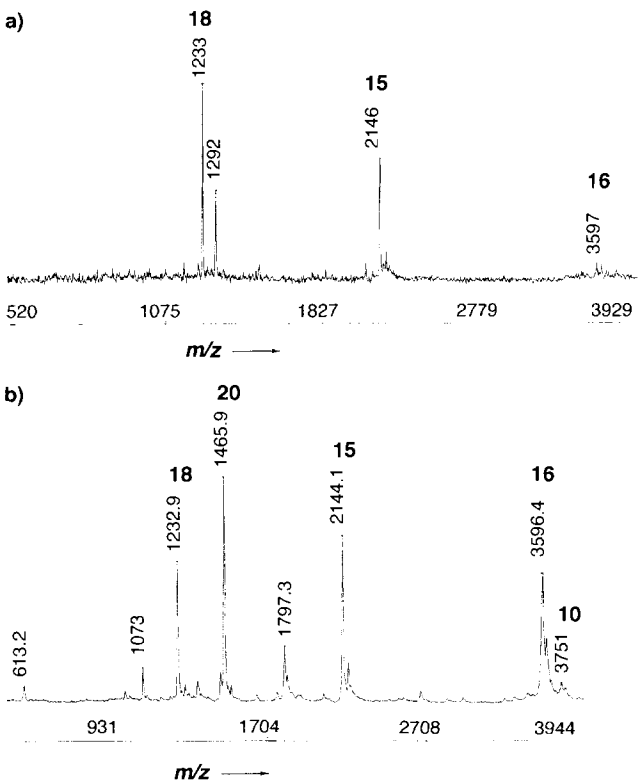
the phosphotriester method,[6] and from phosphoramidite **8** with the DNA synthesizer.[7, 8] Thus deoxyadenosine derivative **8** is a nucleotide derivative that can be incorporated into oligonucleotides prepared with a synthesizer. Oligomers **10**–**12** were synthesized analogously; in each, the eighth nucleotide in the deoxythymidine chain is the precursor for the 4′-deoxyadenosyl radical.[9] Oligomers **10**–**12** were characterized by analytical gel electrophoresis and MALDI-TOF mass spectrometry[10] (Fig. 1).

An aqueous solution of the modified oligonucleotide **10** was irradiated with light having a wavelength >320 nm.[11] Within 60 min 90% of starting material **10** had reacted and given rise to predominantly the cleavage products **15** and **18** (Fig. 2a). When the photolysis experiment was conducted in the presence of an excess of glutathione,[11] then the H-trapping products **16** and **20** were formed in addition to **15** and **18** (Fig. 2b). The products were analyzed and assigned based on their MALDI-TOF mass spectra and by comparison of their HPLC retention times with those of the independently prepared compounds **15**, **16**, and **20**.



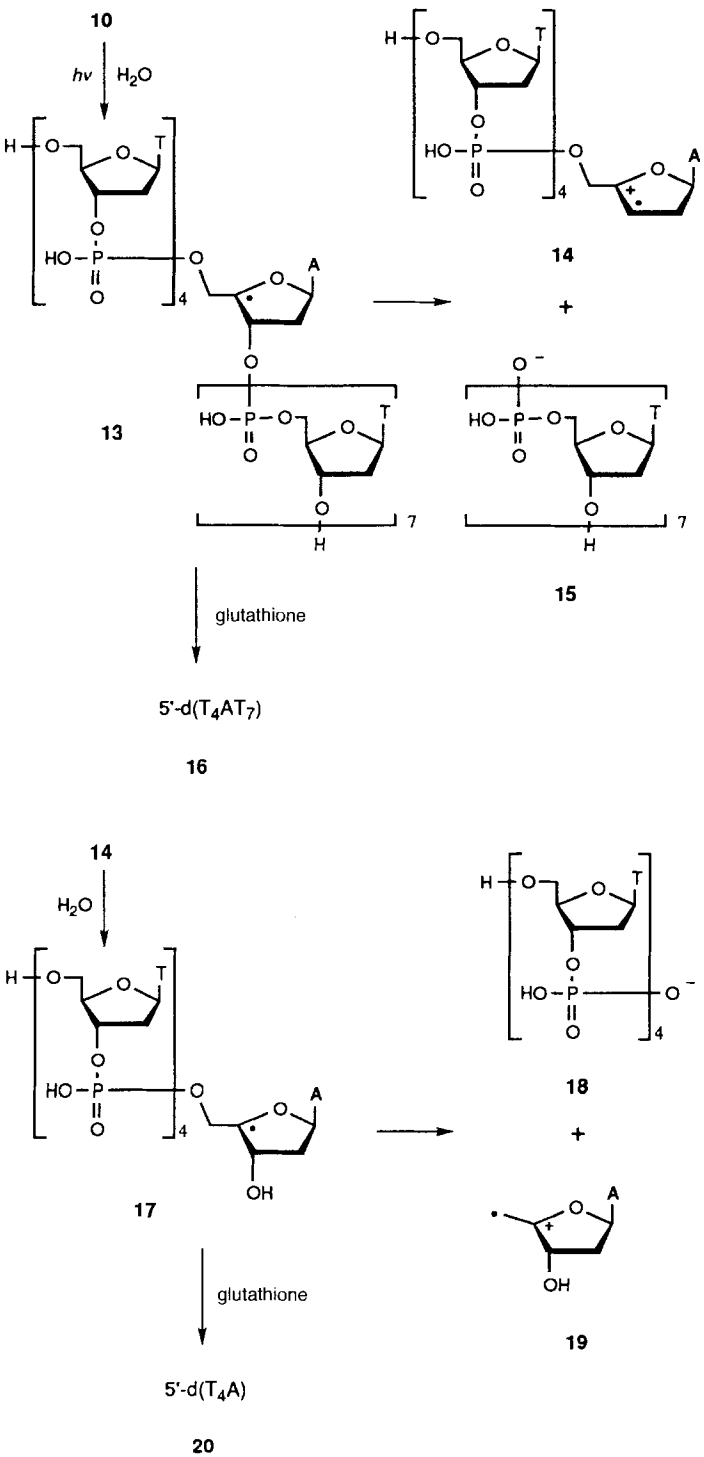


Fig. 2. MALDI-TOF mass spectrum (negative-ion mode) of the reaction mixture after irradiation (60 min) of a) an aqueous solution of **10** and b) an aqueous solution of **10** in the presence of glutathione. The signal at *m/z* 1292 is not yet assigned, but is thought to correspond to the glycolate of cleavage product **18**. The signals at *m/z* 1797.3 and 1073 correspond to the doubly deprotonated molecular ions of **16** and **15**, respectively. The dimer of glutathione gives rise to the peak at *m/z* 613.2.

The results of these experiments with oligodeoxyribonucleotides in water agreed remarkably well with the results of our

model studies.[3] The oligomeric 4′-deoxynucleotide radical **13** generated selectively from the radical precursor **10** is trapped as dodecamer **16** by H abstraction, or it decays heterolytically to the phosphorylated heptamer **15** and the radical cation **14**. Reaction of **14** with H_2O provides the pentanucleotide radical **17**, which is either converted into pentanucleotide **20** with glutathione, or cleaves off the phosphorylated tetramer **18**. The subsequent reactions of the reactive monomeric fragment **19** cannot be described in detail yet; however, the HPLC trace shows that adenine is released.

The reaction of the oligomeric 4′-deoxyribonucleotide radical **13** proceeds quite uniformly. The H-trapping products **16** and **20**, and the cleavage products **15** and **18** were formed in the presence of glutathione in a total yield of 80% (HPLC analysis). These experiments prove that under anaerobic conditions and in water 4′-oligonucleotide radicals cleave off the oligomeric phosphates at the 3′- and 5′-positions. The incorporation of radical precursors thus opens up new possibilities for the selective cleavage of DNA.

[7] J. Stollwerk, in *Gentechnische Methoden* (Eds.: S. Bertram, H. G. Gassen), Fischer, Stuttgart, **1991**, p. 201. The coupling efficiency for the synthesis of **9** from amidite **8** was 98% (measured according to the trityl method).

[8] Characteristic NMR data (300 MHz instrument) for the triethylammonium salt of **9**: ^1H NMR (CD_3OD): $\delta = 4.51$ (m, 1H, H-3′(thymidine)), 5.35 (m, 1H, H-3′(adenosine)), 6.28 (t, 1H, H-1′, $J(1',2') = 7.5$ Hz, thymidine), 6.57 (dd, 1H, H-1′, $J(1',2a') = 4.4$, $J(1',2b') = 7.5$ Hz, adenosine), 7.73 (s, 1H, H-6(thymidine)), 8.13 (s, 1H, H-2(Adenin)), 8.29 (s, 1H, H-8(Adenin)); ^{13}C NMR (CD_3OD): $\delta = 66.86$ ($J(C,P) = 4.3$ Hz, C-5′(thymidine)), 76.39 ($J(C,P) = 4.7$ Hz, C-4′(thymidine)), 87.33 ($J(C,P) = 8.6$ Hz, C-3′(adenosine)), 98.62 ($J(C,P) = 11.2$ Hz, C-4′(adenosine)); ^{31}P NMR (CD_3OD, standard H_3PO_4): $\delta = 0.184$.

[9] The synthesis of the oligonucleotides was conducted with an ABI 392 DNA synthesizer in batch sizes of 0.2 μmol. After seven thymidine units, building block **8** was introduced; the reaction time allowed for the coupling was 30 min. The coupling efficiency for this step was 98% (measured according to the trityl method). Then four, eight, or twelve thymidine units were added on, during which the coupling efficiency decreased to 92–95%. The samples were deprotected with ammonia, purified by passage through an OPC cartridge (MWG-Biotech), concentrated, purified by HPLC (Merck Lichrospher 10 RP-18,5 μm, eluent: linear gradient of 5–40% CH_3CN in aqueous 0.1 M triethylammonium acetate buffer over 20 min, pH 7), and then lyophilized.

[10] M. Karas, F. Hillenkamp, *Anal. Chem.* **1988**, *60*, 2299; E. Nordhoff, A. Ingendoh, R. Cramer, A. Overberg, B. Stahl, M. Karas, F. Hillenkamp, P. F. Crain, *Rapid Commun. Mass Spectrom.* **1992**, *6*, 771; U. Pieles, W. Zürcher, M. Schär, H. E. Moser, *Nucleic Acids Res.* **1993**, *14*, 3191. The experiments were conducted with a Vestec Benchtop II instrument in the negative-ion mode. Matrix solution: 2,4,6-trihydroxyacetophenone (0.3 M) in $CH_3CN:H_2O:EtOH = 50:45:5$; additional solution: ammonium tartrate (0.1 M) in H_2O. The aqueous solution of the sample (1 μL) was mixed with the matrix solution (1 μL) and the additional solution (0.5 μL). After the sample had dried the measurements were conducted with a laser intensity of 0.2 μJ per pulse (accumulation of 30–50 pulses per individual measurement; pulse length 3 ns). When the laser intensity was increased, fragmentation reactions of the starting compound **10** were evident in the MALDI spectrum. We are examining the effect of the matrix and the wavelength of the laser on this fragmentation.

[11] A degassed aqueous solution (pH 7) of **10** (100–200 μL; $A_{260} = 0.1$–0.2 optical density) was irradiated (Oriel Hg high-pressure lamp, 500 W, 320nm filter) at 20 °C. For the photolysis experiments in the presence of a H donor 2 mg of glutathione was added (pH 3). Samples were taken at 5, 10, 20, 40, and 60 min and analyzed by HPLC [9] and MALDI-TOF MS [10]. The peaks in the HPLC trace were assigned by comparison with those of the independently synthesized compounds **15**, **16**, and **20** and by HPLC enrichment and MALDI-TOF MS. The mass spectrum shown in Fig. 2 was recorded for the product mixture obtained by radiation for 60 min in the presence of glutathione. In the HPLC trace each of the H-trapping products **16** and **20** appear as two peaks, which indicates that as in the model experiments [3] the H trapping is not stereoselective.

Sixteenfold Deprotonated γ-Cyclodextrin Tori as Anions in a Hexadecanuclear Lead(II) Alkoxide**

Peter Klüfers* and Jörg Schuhmacher

Polyols (including carbohydrates) can, in the presence of suitable metal salts, be multideprotonated to polyolato ligands even in aqueous solution. Due to the large variety of available polyols, metal complexes having very differing structural characteristics can be obtained. For instance, polysaccharides can serve as a backbone for polymers containing metals,[1] and coordination polymers can be synthesized with sugar alcohols.[2] Multinuclear complexes which are similarly spatially extended, but of nonpolymeric character, can be conceived with oligosaccharides. Cyclodextrins are especially suitable for this purpose. However, the number of the metal ions that can be incorporated into a double torus at higher pH values is limited due to the high tendency of such systems to form intramolecular hydrogen bonds of the type $O-H\cdots O^-$. Four Cu^{2+} ions were thus incorporated between two multideprotonated β-cyclodextrin tori to form a polyolatometalate.[3] In contrast, in a simple metal polyolate, a metal polyolatometalate, which bears the same relationship to a polyolatometalate as a higher aggregated hydroxide to a hydroxometalate, it should be possible to obtain a greater metal-to-ligand ratio.

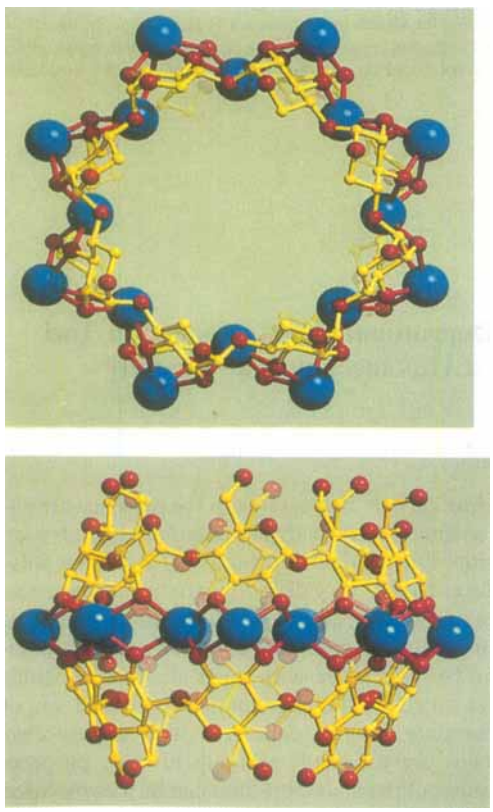
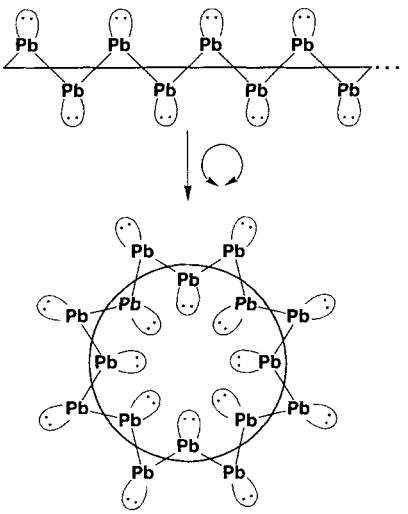
[**] Polyol–Metal Complexes, Part 11. This work was supported by the Bundesministerium für Forschung und Technologie (grant no. 0319368A), Akzo AG, Wuppertal, and Wacker-Chemie, Munich (cyclodextrin donation). Part 10: [5].

Experiments based on this principle have now led to the first structurally characterized lead(II)–carbohydrate complex. These investigations have helped to answer several questions of current interest: The ability of polyols to undergo multiple deprotonation to give polyolato ligands in aqueous solution has been demonstrated. Equally impressively, it has been shown that new and unusual structures can be synthesized from polyols. The complex also appears to be an example of a multinuclear complex formed by a cooperative mechanism.

We used γ-cyclodextrin (cyclomaltooctaose, γ-CD) as the polyol component in the experiments described below. Highly refractive, colorless crystals of $[Pb_{16}(\gamma\text{-}CDH_{-16})_2]\cdot$ ca. $20\,H_2O$ (**1**) precipitate from hot aqueous solutions of the cyclodextrin containing substoichiometric quantities of lead(II) nitrate and NaOH in a ratio of 1:2. The X-ray structure analysis confirms the formation of a hexadecanuclear lead complex,[4] whose structure is shown in Figure 1. Both cyclodextrin tori in the complex are deprotonated sixteenfold, and each of the alkoxide O atoms is coordinated in a bridging fashion to two lead atoms. The unusual arrangement of the lead atoms in the form of an eight-point star can be understood by comparison with the structure of the coordination polymer $[Pb(C_4H_6O_3)]\cdot H_2O$ (**2**), in which the dianion of the simple diol anhydroerythritol (*meso*-oxolane-3,4-diol) is incorporated in a structure with an analogous topography.[5] Scheme 1 (top) shows a strip made from lead(II) cations and diolate dianions in **2**. If a strip of suitable length is closed to form a ring, the principle behind the construction of **1** (middle) can be recognized. The analogy is not perfect, however, since the metal-bonding diolate ligands are displaced with respect to one another in **2** (Scheme 1, bottom),





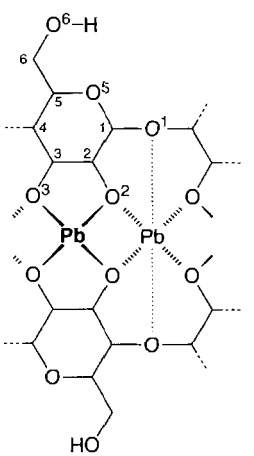


Fig. 1. Crystal structure of **1** (top: without C-6 and O^6 atoms of the anhydroglucose fragments, O^6 = O atom at C-6); blue: Pb, red: O, yellow: C. See Scheme 2 for the numbering of atoms. The distances to the nearest atoms of the given type (min/max/middle, in Å; the values in parentheses are the standard deviations of the last decimal place): Pb–O^2, O^3 2.212(15)/2.502(15)/2.37; Pb_{inner}–O^1 3.100(13)/3.273(13)/3.19; Pb···Pb (intramolecular) 3.7631(12)/3.9364(12)/3.829. Bottom: Projection of the structure perpendicular to the that in the upper picture.

Scheme 1. The relationship between the structure of the simple polymeric lead(II) diolate **2** [5] and that of **1**.

but are exactly opposite one another in the double torus in **1** (Scheme 2). The outer lead atoms (left in Scheme 2) are thus part of two five-membered chelate rings; they have the same environment as the copper atoms in the β-cyclodextrin salt. The inner Pb atoms are, on the other hand, in a more unusual environment: four alkoxide O atoms from four different anhydroglucose units and two additional O^1 atoms approximately 0.8 Å further away, which function as ligating atoms, combine to form a (4 + 2) coordination sphere (Scheme 2, right). The shape of the CD tori in **1** is different than usual; the cyclodextrin truncated cones are widened at the base by the large Pb_{16} ring (Fig. 1, bottom). The distance between opposing inner Pb atoms is 12.5 Å. The space within the double torus is therefore not constricted at the middle. For the purpose of its use as a host compound, it can be assumed that a channel with an almost constant diameter of approximately 8 Å runs through the double torus (assuming the van der Waals' radius of a Pb^{2+} ion including the lone pair to be 2 Å). Hydrogen bonds are less important in **1** than in polyolatocuprates. This can be understood in terms of the weaker acceptor

Scheme 2. The numbering of the C and O atoms of an anhydroglucose unit and the environment of the inner (right) and the outer lead atoms (left) in **1**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1818-1864 $ 10.00+.25/0

properties of μ_2-alkoxido O atoms compared to terminal O^- functions. The lead atoms also bind water molecules only very loosely, because the latter have to approach from the side of the stereochemically active lone pair. There are, therefore, only weak contacts between lead atoms and water molecules, mostly with a Pb–O distance >3.4 Å. The majority of the bonding intermolecular distances between lead and cyclodextrin O atoms are also found in this range.

Remarkably, **1** crystallizes from solutions with an excess of cyclodextrin. It is not, therefore, high lead concentrations which are the driving force for the incorporation of the 16 Pb atoms in the double torus. The behavior of this system rather indicates a cooperative mechanism which leads to the formation of **1** alongside lead-free tori.

It may at first seem surprising that all the protons in **1** from the α,β-diol groups are cleaved, although, in the aforementioned cuprates, protons remain tightly bound in hydrogen bonds, even at higher pH values. It should however be noted that a similar situation is observed with the aqua ligand, which can also undergo multideprotonation. In weakly acidic solution, double deprotonation to give a bridging oxo ligand can be observed, whereas in alkaline solution a terminal hydroxide ligand is formed after a single deprotonation.[6]

We then asked ourselves whether polyols can be deprotonated in aqueous solutions around pH = 7, or whether the competing reactions in the aqueous system determine the distribution of the products formed. Given the surprisingly high formation constants of polyolatometalates,[1a] it appears conceivable that metal polyolates could be formed in neutral solution. A counterargument, on the other hand, is the claim, also found in more recent overviews, that carbohydrates can only form complexes of weak stability in neutral solution;[7] here, the possibility of deprotonation was not considered. It should however be noted that dissolution of saccharides and numerous metal salts in water—and the comment refers to this typical experimental procedure—does not yield neutral, but distinctly acidic solutions. Adjustment of the pH to about 7 results in formation of precipitates from these metal salt–saccharide solutions, which, at first glance, could be taken for the corresponding metal hydroxides; however, in the case of Cu^{II}, for example, the color of the precipitate is turquoise and not the pure blue of the expected hydroxide. Subject to the determination of the formation constants, the conditions for the precipitation of **1** contribute to the clarification of the extent to which carbohydrates can be deprotonated in neutral aqueous solution: A solution of 0.107 M $Pb(NO_3)_2$ and 0.0154 (= 0.123/8) M γ-CD was found to have a pH of 3.4 at room temperature. On addition of NaOH, the colorless, gelatinous precipitate described above formed at around pH 5.7. After the addition of two molar equivalents of NaOH with respect to lead, the solution itself had a pH of 9.2; the neutral point was first crossed after the addition of nine tenths of this amount. A solution that was adjusted to the neutral point also formed crystals of **1** on heating. The homologous β-CD compound remained in solution under similar conditions, so that all protolysis equilibria were represented; after addition of two equivalents of NaOH, the pH of this system was also found to be 9.2.

These findings show that carbohydrates, ubiquitous in organisms, can form stable complexes in the form of deprotonated ligands in this pH range, which is of special interest in biochemistry. Their hydroxide-like, voluminous, gelatinous appearance seems to have detracted attention from these complexes until now. At lower temperatures, **1** also behaves in a typical fashion: The crystals obtained at 75 °C swell at room temperature in the then opalescent mother liquor within the course of an hour, without dissolving to any large extent; the X-ray reflections then disappear in the background noise. If the gelatinous precipitate is warmed to 75 °C, it recrystallizes in about the same time.

The structures of **1**, **2**, and a lead 1,2-glycerolate[8] with a structure analogous to that of **2** emphasize the possibility of manipulating building blocks based on oxide structures—here the PbO modifications—through the polyolato ligands. In the coordination polymer **2**, PbO layers are broken down into strips. In contrast, in **1** the building motif of the solid undergoes an ordering to form a ring, a variation which goes beyond the mere removal of a given linkage pattern present in the solid.[9]

Experimental Procedure

Lead(II) nitrate (3.31 g, 10.0 mmol) and γ-CD (2.00 g, 1.54 (= 12.3/8) mmol) were dissolved in water (15 mL). The addition of NaOH (20 mL, 1 M) led to the formation of a colorless gelatinous mass. On warming to 75 °C, a clear solution resulted, from which highly refractive colorless crystals of **1** precipitated. A dehydrated sample decomposed above 210 °C without melting.

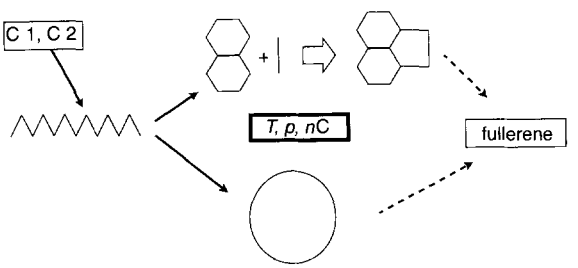
On the Mechanism of Fullerene Formation**

Thilo Belz, Harald Werner, Friedrich Zemlin, Ursula Klengler, Michael Wesemann, Bernd Tesche, Elmar Zeitler, Armin Reller, and Robert Schlögl*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday



Fullerenes[1] differ in their molecular character from the currently known forms of elemental carbon such as graphite (including derived turbostratic variations) and diamond. They do not form extended two- or three-dimensional structures, but closed molecular systems based on sp^2-carbon atoms as the common building block. Fullerenes can currently be prepared by thermal treatment of graphite[2] and pyrolysis of arenes in flames.[3] Separation and purification techniques are also available.[4] Graphitic tubules[5] and onionlike spheres,[6] which are related to the fullerenes, have been structurally characterized and produced in microscopic quantities, but are not yet available in pure form and preparative amounts.[7] Given both the diversity of products and methods of production, and the necessity to develop generally applicable syntheses for novel carbon forms, the question arises as to the mechanism of formation of these compounds. Methods involving the thermal treatment of carbon in an electric arc, with fluxes of highly energetic electrons, or with a laser beam have the disadvantage that only limited control over the selectivity of formation of particular products has been possible up to now; the exact production parameters do, however, have a crucial influence on the product distribution.[8] We chose to investigate the formation of fullerenes in an electric arc despite the low degree of control over the course of the reaction, since this is now the most important method for the production of significant amounts of fullerenes. When more is known about the formation processes, this technique should also have considerable potential in the preparation of molecular forms of carbon other than soluble fullerenes.

The initial formation of C_x fragments containing no heteroatoms is the common step in all synthetic routes to fullerenes. According to numerous growth theories,[9] these fragments form small rings that combine with C_1 and C_2 units to give additional five- or six-membered rings and eventually fullerenes (Scheme 1). A second growth theory postulates that the first step is the formation of large monocyclic compounds. Shock annealing under certain conditions then results in the formation of numerous linkages between the carbon atoms in these monocycles to give carbon clusters. These then isomerize to fullerenes, which are thermodynamically stable under the reaction conditions. Evidence for this sequence was provided by mass-spectrometric experiments in the vapor phase under model conditions used for the synthesis of fullerenes.[10] The suggested mechanisms[11] differ on the question whether many small rings condense together and oligomerize via polycyclic arenes to form fullerenes, or whether a large carbon ring isomerizes to produce a fullerene molecule.

All reaction pathways leading to fullerene molecules require an atmosphere that is as inert as possible. This ensures that the lower chemical stability of five- compared to that of six-membered rings does not result in a decrease in concentration of the five-membered ring structures below a critical level. Furthermore, reactants which form stable carbon–heteroatom bonds under the reaction conditions should not be present, since they would prevent the formation of an all-carbon compound.

Previous investigations into the mechanism of formation relied on experiments carried out in the vapor phase with mass-selected sections of the primary product spectrum obtained from carbon vaporization. Due to a microstructure that is X-ray amorphous, fullerene black, which is the main product formed in the synthesis of fullerenes, has hardly been investigated structurally.[12] Studies in this area could provide significant clues on the mechanism of formation. Assuming that fullerene black arises from all the failed self-organization processes which lead to fullerenes, we would expect a microstructure consisting of platelets if the reaction proceeds by polycondensation of small rings and a three-dimensional, random microstructure if the isomerization process dominates.

The experiments were performed with an arc-discharge carbon vaporization apparatus,[13] which produces soluble fullerenes with a 10% selectivity. Using emission spectroscopy,[14] we were only able to observe the bands corresponding to C_1 and C_2 units. Figure 1 shows the low-resolution spectra with band assignments.[15] The substantial change in the partial pressure of helium, which causes an increase in yield from 0.025 to 10%, is clearly not accompanied by a change in the nature of the species in the plasma. The reactions in the graphite vaporization experiments leading to the formation of the C_x clusters and to fuller-

Scheme 1. Postulated mechanisms for the formation of fullerenes.

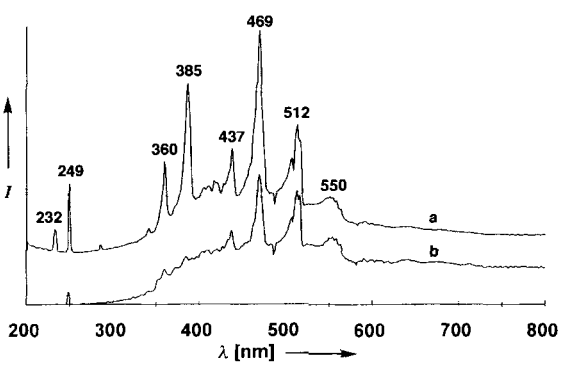


Fig. 1. Emission spectrum of an electric arc during fullerene synthesis. Discharge conditions: graphite rods for spectroscopy (Ringsdorf RW 4), diameter 6.15 mm, current 150 A, alternating current, distance between electrodes (regulated) 3.0 mm. The helium pressure during the measurement of spectra a and b (×4) was 10 and 2×10^4 Pa, respectively. The band at 249 nm is assigned to the C_1 fragment; all other bands belong to the transitions of singlet and triplet C_2 molecules (232: Mulliken system; 360, 385: Deslandres–d'Azambuja system; 437, 469, 512, 550: Swan system). Refer to the text for a discussion of those signals overlapping with bands of the CN molecule.

enes obviously proceed in the cool part of the carbon cloud outside the range accessible to emission spectroscopy (diffuse background in the visible region). The spectra thus give an insight into the initial precursors of fullerenes, but not into the formation of larger carbon frameworks. Even the small C_3 fragment with an expected principal band at 405 nm cannot be detected. This is consistent with earlier observations in laser vaporization experiments that C_3 fragments were detected by mass spectrometry in the cold region of the apparatus, but not in the plasma emission spectrum.[16] This evidence emphasizes the significance of the colder zones within the reaction chamber for the construction of larger frameworks. The hot zone is, in contrast, the source of building blocks.[17] The rate at which the building blocks are supplied is, however, fundamental to the whole process and is determined by the parameters in the hot zone, as can be seen from the spectra in Figure 1.

The different intensity ratios of the bands corresponding to the C_2 fragments in the spectra of Figure 1 arise because of overlap in the 360 and 385 nm regions with bands assigned to CN molecules, which dominate when traces of nitrogen are added to the quench gas. Their appearance at low partial pressures of helium (spectrum a) is explained by the fact that the carbon fragments react with residual air components in the absence of the inert quench gas. This has consequences for the growth mechanism.

A systematic investigation into the structural and chemical properties of conventional carbon black and fullerene black indicates that the two nanocrystalline carbon forms differ markedly. This can be deduced from the differing microstructure, which has been investigated by means of high-resolution transmission electron microscopy (TEM).[18] In the mesoscopic region both materials consist of spherical aggregates of many primary building blocks.[19]

Figure 2 clearly reveals that the spherical aggregates in conventional carbon black are formed from many planar basic structural units (BSU),[20] which are stacked in a parallel

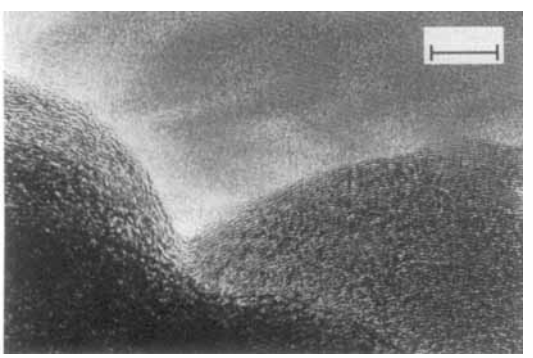

Fig. 2. High-resolution TEM image of carbon black (industrial sample FW-1 from Degussa). The spacing between the planar carbon platelets agrees with that between the layers in graphite (approximately 340 pm). The length of the bar represents 10 nm.

arrangement.[21] Stacking errors caused by platelets being tilted with respect to the stacking axis and by nonplanar objects (BSU of differing ring size) result in formation of the bent secondary structure in the carbon black particles. No in-plane correlation exists between the BSU (turbostratic arrangement).[20]

The microstructure of fullerene black is far more complex and depends to a large extent on the reaction conditions. Under conditions that give rise to high yields of C_{60}, the structures shown in Figure 3 have been observed. A network of continuously curved multilayers of carbon can be recognized inside the particle. The spacing of parallel layers is similar to that observed in conventional carbon black or graphite. The carbon layers are far more extended[22] than those in BSU of conventional carbon black. Large parts of the particles are composed of amorphous carbon that is not arranged in two-dimensional layers, but rather as a tangle of threadlike polymers.

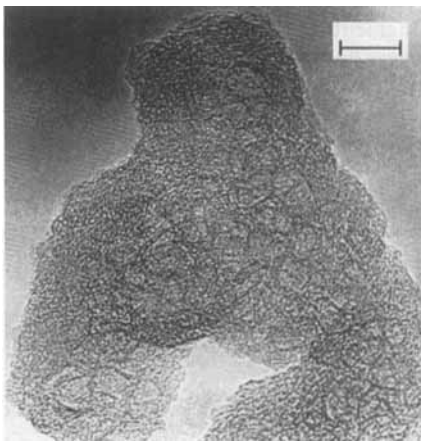

Fig. 3. High-resolution TEM image of fullerene black. The experimental conditions were adjusted to optimize the C_{60} yield. One can see the empty cavities inside the continuous carbon loops. The enhanced contrast of the loops suggests a two-dimensional structure of layered aggregates which are not quite parallel to one another. The length of the bar represents 10 nm.

If energy input and quench-gas pressure in the plasma chamber are reduced, the threadlike molecules can be observed directly on the periphery of the fullerene black particles. Figure 4 shows a single tangled cluster of these carbon threads. The fact that continuous curves of different radii are present both in and perpendicular to the plane of projection of the microscope explains the "interrupted contrast" (cf. "regular contrast" of the BSU in Fig. 2). A platelike primary structure can thus be ruled out. Figure 4 provides clear evidence for the formation of large (possibly irregularly) crosslinked rings of carbon atoms, which are required for fullerene formation. It also becomes clear why fullerene black is considerably more susceptible to oxidation and chlorination reactions than conventional carbon black.[12]

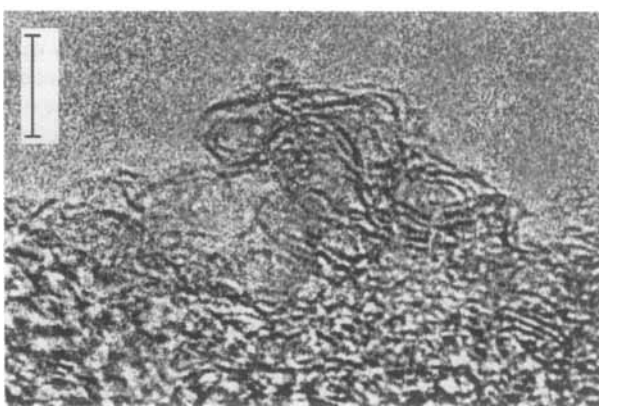

Fig. 4. Section of a high-resolution TEM image of fullerene black. The reaction conditions were chosen to maximize the ratio of higher fullerenes relative to C_{60}; this reduced the overall yield markedly. The length of the bar represents 5 nm.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1818-1867 $ 10.00+.25/0

The growth of the carbon threads is largely suppressed if the plasma apparatus is operated without a quench gas at a residual pressure of about 10^{-4} bar.[23] In this case, the few remaining collision partners are no longer inert, and chain termination reactions by incorporation of a heteroatom from the residual gas occur very frequently (see also text to Fig. 1). This is also reflected in the extremely low rate of fullerene formation. A highly resolved TEM image of this product is shown in Figure 5. Color coding is used to depict a section through the projection plane of the microscope. The objects with a red border are short fragments of carbon threads. Their orientation is irregular, and a very hard but not very dense form of carbon that is completely amorphous to X-rays results.[24] The mechanical hardness of this material suggests that the units in Figure 5 are covalently bonded.

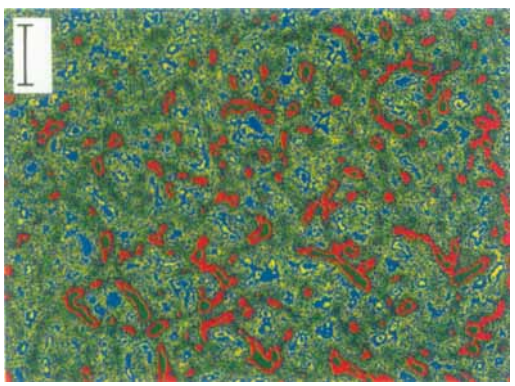

Fig. 5. Artificial color-coded representation of a highly resolved section of a TEM image of hard fullerene black. Under the conditions chosen, the yield of soluble fullerenes was less than 0.4%. The length of the bar represents 2 nm.

In summary, the microstructural analysis of different fullerene black samples clearly indicates that a significant proportion of the vaporized carbon atoms condenses to form threadlike molecules. These combine to ring systems, which either form intramolecular links, or fall apart if their energy content is too high. Intermolecular bonds are then formed when the density is sufficiently high. The proportion of ring growth and shock annealing determines the yield of soluble fullerenes. The majority of rings are apparently not able to react to form stable fullerenes, since either the ring size cannot be suitably adjusted, or bond formation releases too much energy and dissociation and polymerization results.

A portion of the vaporized carbon apparently reacts to form more or less planar layers. This can be explained by early ring closure and formation of C_x rings ($x = 5, 6, 7$). The conclusion that a range of ring sizes are formed follows from the observed continuous curvature of the resulting layers. This reaction pathway, which proceeds parallel to the linking up of larger monocycles, may be the mechanism for the formation of graphitic tubules and onionlike spheres. It is unlikely that such structures are formed by linking of monocycles; a condensation mechanism is much more probable.

The detrimental effect of heteroatoms acting as chain-terminating reagents was also clearly shown and is consistent with evidence from the synthesis of fullerenes.[25] It is known that linear or cyclic intermediates in the formation of complex carbon species can be trapped and thus detected by addition of heteroatoms to the quench gas. Our observations indicate that these products do not arise as a result of disruption of the main process, but rather from the increased frequency of side reactions.

Our findings complement those obtained in vapor phase experiments[26] and show that in the "caldron" of the plasma reactor both condensation and crosslinking reactions of macrocycles proceed side by side. At the same time, cyclic compounds are formed and fall apart, depending on the energy content of the molecule and its immediate environment. The "recipe" for the synthesis of fullerenes, fullerene black, and planar, layered structures is determined by the local properties of the vapor phase outside the plasma. These observations and the fundamentally different structures of the condensation products point to kinetic control of the overall reaction. The selectivity of the condensation of the small primary fragments produced in the plasma is determined by their concentration, by the efficiency of energy exchange,[27] and by heteroatoms disrupting growth and rearrangement of the carbon fragments.

[8] The yield of soluble fullerenes is a sensitive and complex function of the helium vapor pressure (used for quenching), the electrode diameter, and the distance between the electrodes, which also influences the selectivity of formation of the various fullerenes: hot plasmas with a small electrode separation give increased quantities of higher fullerenes at lower overall yields. Graphitic tubules can be found within the carbon slag formed on the negative electrode used in the arc discharge with direct current. Graphitic onionlike spheres apparently arise only when fullerene black is intensively bombarded with electrons; however, the desired structure is not obtained in every batch, even when conditions are identical. It has not been proved beyond doubt whether graphitic onionlike spheres can be produced by other thermal processes, since transmission electron microscopy has, up to now, been the only possible means of identification.

[17] In plasmas, a large number of charged particles are also formed. The electrical charge can influence the formation of fullerenes, and this source of building blocks could give rise to additional selectivity. However, the fact that fullerenes are also produced under conditions in which charged species are absent suggests that electrically charged building blocks are helpful but not essential.
[18] All samples were investigated supported on amorphous carbon films after deagglomeration in an ultrasonic bath of acetone. Siemens (Elmiskop 102,

120 kV, double tilt, side entry), Jeol (CX 200, 200 kV, double tilt, top entry), and Phillips (CM 20, modified with a cryoprojection lens, ultrahigh vacuum in the sample chamber, single tilt, side entry) instruments were used.

[22] The layered character of the objects, shown with continuous contrast, also follows from powder X-ray diffraction data, which show a clear peak corresponding to the interlayer separation of 341 pm and a complex, modulated background [13]. This material can be distinguished from the electrode graphite, which may contaminate the product, by its much lower combustion temperature [12].
[23] Since the apparatus was designed for the manufacture of large amounts of fullerenes, we operated with a regulated electrode separation and continuous external adjustment of the graphite rods, which led to a leak rate of the same order as the residual pressure. This factor could only be eliminated if the whole apparatus was placed in a glove box with an inert atmosphere.
[24] Presumably, this material is always formed when the apparatus is in operation and acts as a "getter" to the vapor-phase contaminants (helium 5.0). Moreover, such particles may well act as nuclei for the condensation of large fullerenes. A. Goeres, E. Sedelmayer, *Chem. Phys. Lett.* **1991**, *184*, 310; H. W. Kroto, K. McKay, *Nature* **1988**, *331*, 328.

[27] This is determined by the thermal conductivity and partial pressure of the quench gas, as well as by a steep temperature gradient in the gas chamber, which was achieved by placing a metal plate around the plasma chamber to provide efficient cooling of the quench gas.

Synthesis of Very Highly Ordered Liquid Crystalline Phases by Complex Formation of Polyacrylic Acid with Cationic Surfactants

Markus Antonietti* and J. Conrad

Ionic surfactants and oppositely charged polyelectrolytes spontaneously form addition complexes that precipitate from aqueous solution. Neighboring group effects, which begin to operate at very low concentrations, are important for the formation of such complexes. A highly cooperative zipper mechanism is observed, and the stoichiometry of the complexes (with respect to charge) is usually 1:1.[1-3]

The properties of such complexes in nonaqueous solvents and in the solid state have, however, only recently been investigated. The poly(*n*-alkyltrimethylammonium styrene sulfonate) system shows highly ordered lamellar structures, which clearly adopts different phase modifications when the chain length of the alkyl groups is varied.[4] The driving force for the formation of these phases is the incompatibility between the ionic backbone and alkyl side chains, otherwise known as the amphotropy of the system.

We now propose a system in which complex formation occurs at the polyacrylic acid backbone and in which steric effects prevent a parallel orientation of the *n*-alkyl chains and formation of the resulting layered structures. For the first time, yet more diverse phase structures can be achieved in this polymer system.

The polyelectrolyte–surfactant complex PAA–C_{12}, obtained by simple mixing of polyacrylic acid and dodecyltrimethylammonium chloride, is a highly elastic, deformable material. Even in an unextended cast film, strongly doubly refracting domains of only a few micrometers in size can be seen with a polarizing microscope. Extension results in necking and hardening of the material; at the same time, the size of the doubly refracting domains increases to the millimeter range. The observed effects are not temperature dependent; that is, the structure remains unchanged up to decomposition of the material. Figure 1 shows the photograph under a polarizing microscope of a slightly stretched sample; Figures 2 and 3 show the wide-angle and small-angle X-ray diffractograms of the unextended sample.

Fig. 1. Photograph under a polarizing microscope of PAA–C_{12} at an extension of $\lambda = 1.5$ nm.

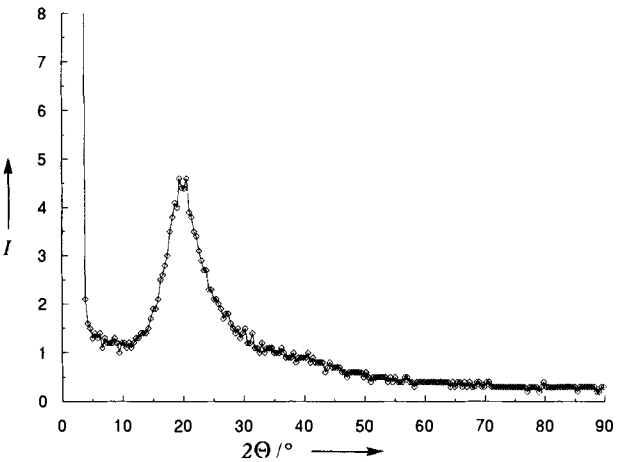

Fig. 2. Wide-angle diffractogram of PAA–C_{12}, $\lambda = 0.154$ nm, I = intensity (in counts per second).

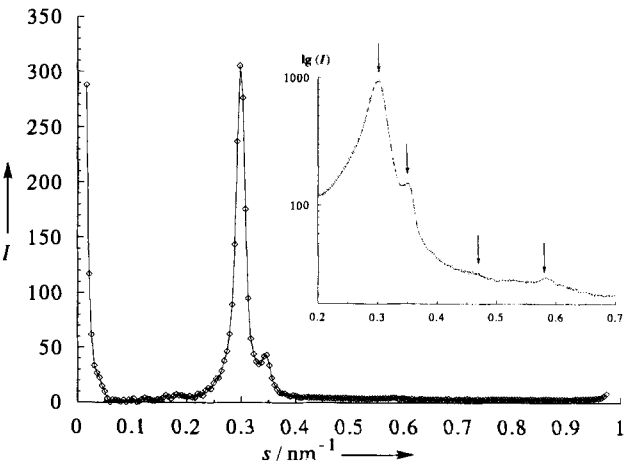

Fig. 3. Small-angle diffractogram of PAA–C_{12}, the scattering vector is defined as $s = 2\sin\theta/\lambda$. For clarity at higher orders of diffraction, the logarithmic plot of the filtered spectrum is included. I = intensity (in counts per second).

The wide-angle X-ray data show that PAA–C_{12} is locally an amorphous unstructured material. The observed peak is clearly broader than for the analogous polystyrene sulfonate derivative; this indicates a higher disorder or a nonlamellar arrangement of the alkyl side chains.

The small-angle diffractogram shows a number of unusually narrow scattering peaks, which indicates the existence of a highly ordered liquid crystalline structure. A peak sequence of 1:1.16:1.63:2 can be identified from a logarithmic plot and the scattering at the extended sample. These results are indicative of a face-centered cubic lattice. A cell size of 5.80 nm can be deduced from the absolute position of the peak.

Clearly, the simple polyelectrolyte–surfactant complex poly(dodecyltrimethylammonium acrylate) PAA–C_{12} also spontaneously forms highly ordered, amphotropic liquid crystalline structures. In contrast to the analogous polystyrene sulfonate derivatives, which essentially exist in lamellar layers, PAA–C_{12} can be classified, based on its optical and mechanical behavior, as having a cylindrical morphology in which the ionic backbone chains are embedded in a continuous alkyl matrix. The symmetry type (face-centered cubic, FCC) determined by small-angle X-ray diffraction does not appear to agree with the cylindrical symmetry. This discrepancy might be explained by periodic fluctuations in thickness of the cylinder, which couple strongly because of the incompressibility; an FCC symmetry would thus result (Fig. 4). However, without extensive modeling of the electron density profile for this particular system, this remains speculation.

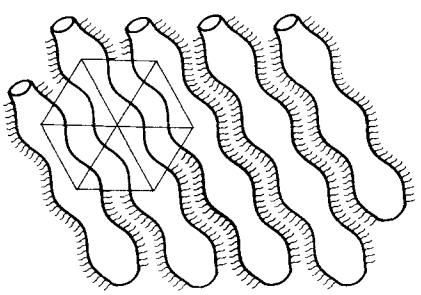

Fig. 4. Model for the structure of the amphotropic phase of PAA–C_{12}.

Such highly correlated fluctuations in thickness are not unusual, especially in lamellar structures, and are observed in lyotropic surfactant phases[5, 6] and, on a different scale, in block copolymers in the solid state.[7, 8] The phenomenon originates from the different packing of the alkyl chains and backbone and is also referred to as "frustration".[9]

In contrast to a simple FCC lattice, the structural model described above is also consistent with the polymeric nature of the backbone, which results from the presence of an extensive ionic phase. For PAA–C_{12}, the relative phase volumes of the disperse ionic phase and alkyl matrix range from about 0.3 to 0.7. These values are exactly in the region in which cylindrical morphology is also be observed for block copolymers. With this model, the size of the unit cell is 5.8 nm; the distance between the fluctuations along the chain is 4.10 nm.

In the complexes described, the average diameter of a cylinder can be estimated at about 2.1 nm from the lattice parameters and the relative phase volumes (obtained from the stoichiometry). From this value, the number of polymer chains per cylinder cross section can then be calculated. For an extended chain conformation, the maximum number is 5. Because of fluctuations in thickness and chain folding, a smaller number of around two or three is likely for steric reasons. Interestingly, this means that the chains would then act as a sort of "spun thread" of almost extended polymer chains (Fig. 5), a morphology which, until now, only had its parallel in nature,[10] but no synthetic analogues.

Fig. 5. Arrangement of the polymer chains in the cylindrical phase.

Electron microscopy and structure-sensitive solid-state NMR spectroscopy will now be used for further investigations into the structure of PAA–C_{12} to PAA–C_{18} complexes. It should be possible to extend the construction principle presented here to other polyelectrolyte complexes. Thus, by altering the polyelectrolyte (charge separation, molar volumes, hydrophobicity, glass-transition temperature) or the soap molecule (length, number of tails, functionality, platelet-like or disc-like structure), a wide spectrum of morphologies could be generated. Our simple approach to this system, based on self-organization, uses cheap starting materials which are available in large quantities. The further development of this class of materials may therefore be eagerly awaited.

Experimental Procedure

Polyacrylic acid (5.0 g, Aldrich, $M_w \approx 250000\ g\,mol^{-1}$) was dissolved in water (200 mL) and converted into the sodium salt with NaOH. Dodecyltrimethylammonium chloride (24 g, Aldrich) was added dropwise to water (200 mL) with stirring. The precipitated crude complex still contained large amounts of excess surfactant, salt, and water. The complex was purified by dissolving it in 2-butanol and carefully adding water until phase separation into a gelatinous phase rich in complex and a water phase occurred. The water phase was rich in salt and unconverted surfactant. The aqueous layer was discarded and the sol–gel separation repeated until no more chloride could be detected with silver nitrate. The solvent can be evaporated directly from thin layers of the gelatinous phase under vacuum. The elemental analysis of the complexes showed minimal residual quantities of sodium and chloride ions (<0.01%). The presence of salt and free surfactant (by Cl^- determination) and of unchanged acrylic acid units (by $Na^{\oplus}$ determination) in the product could thus be ruled out; the pure 1:1 complex was obtained. The film was dried under vacuum (24 h, 60 °C); high-resolution solid-state NMR spectroscopy was used to show that all butanol and water had been eliminated. Water is reabsorbed in low concentrations into the film under environmental conditions, this does not however influence the described effects.

On the Nature of the Active Site in a CoAPO-18 Solid Acid Catalyst**

John Meurig Thomas,* G. Neville Greaves,* Gopinathan Sankar, Paul A. Wright, Jiesheng Chen, Andrew J. Dent, and Leonardo Marchese

Just as with crystalline enzymes, crystalline microporous inorganic catalysts, typified by zeolites, are amenable to direct, in situ X-ray (or neutron) study,[1, 2] a quantitative description of the local environment of the active site being obtainable from the diffraction pattern. The situation is not so straightforward with crystalline aluminophosphate-based catalysts, represented by MAPOs, where M is a divalent cation (Co, Ni, Zn, Mn, Mg etc) that isomorphously substitutes for some of the aluminum in the framework. Framework-substitution of trialent aluminum ions by divalent ones such as Co^{II} not only confers Brønsted acidity upon the resulting solid—a proton, loosely attached to one of the framework oxygen atoms, is required to maintain electroneutrality—it also introduces redox behavior.[3, 4] When the Co^{II} ion is oxidized to the Co^{III} state the Brønsted acidity necessarily disappears. Here, the concentration of M (in this case Co) is generally so low—seldom exceeding a few percent and often much less—that X-ray diffraction (XRD) cannot yield the desired (local) structural information. Under these circumstances, X-ray absorption spectroscopy (X-ray absorption near edge structure, XANES and extended X-ray absorption fine structure, EXAFS) is the preferred method of probing the environment of the active site, especially when it is used in combination[5] with X-ray diffraction, the principal purpose of the latter being to monitor the long-range integrity of the catalyst during the various processes of activation, deactivation and regeneration.

We recently described[6, 7] a family of molecular sieve catalysts in which minute amounts of cobalt ions are framework-substituted in place of aluminum ions in the open structure of a synthetic aluminum phosphate known as ALPO-18.[8] These solid acid catalysts $H_x(Co_xAl_{(1-x)}PO_4)$, $x \leq 0.04$, efficiently convert[7] methanol to light olefins (predominantly ethylene and propylene), a process well-known[9-11] to require more than modest Brønsted acidity. Typically, at 400 °C and a weight hourly space velocity (WHSV) of 1.5, methanol is completely converted to ethylene (22.4 percent), propylene (51.2), and C_4 olefins, chiefly butenes, (25.6) and a trace of methane.

The CoAPO-18 catalysts are synthesized hydrothermally in the presence of an organic template, *N,N*-diisopropylethylamine at 150 to 180 °C for three to ten days—full details are given elsewhere[6, 7]—the template-free samples being obtained by calcining the as-synthesized ones in gaseous oxygen at 550 °C for about one hour. Prior to use they were reduced in hydrogen at 400 °C.

ALPO-18 has a framework structure[12] closely related to that of the aluminosilicate (zeolitic) mineral chabazite. In the as-prepared, template-incarcerated state, samples of the CoAPO-18 catalyst (framework composition $Co_{0.04}Al_{0.96}PO_4$) are colored bright blue, consistent with Co^{II} in tetrahedral coordination. Upon calcination the color changes to green; IR and other spectroscopic measurements (to be reported fully elsewhere[13]) show that Co^{III} is then the predominant valence state. Idealized positions of cobalt in each valence state are shown in Figure 1. The spectroscopic changes shown in Figure 2 are consistent with local structures A and B of Scheme 1 for the redox Brønsted acid states exhibited by the catalyst.

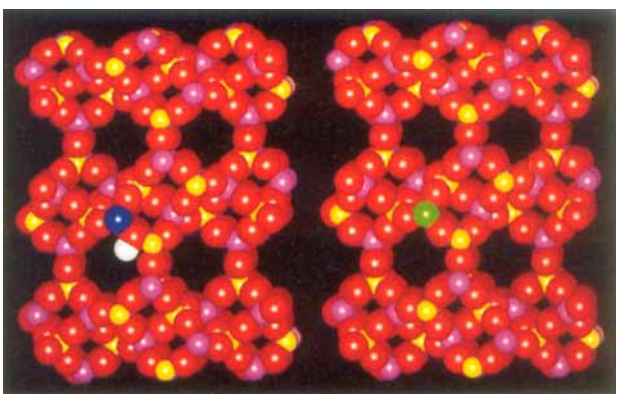

Fig. 1. Computer graphic representation of the cobalt-containing ALPO-18 structure. The framework is very similar to that of the aluminosilicate mineral chabazite. The actual colors of the calcined and reduced forms of the catalyst are green and blue, respectively. Color code: red, oxygen; blue, Co^{II}; green, Co^{III}; white, hydrogen; purple, phosphorus; yellow, aluminum.

To make headway in the understanding of the catalytic behavior of CoAPO-18 it is important to define in quantitative terms the environment of the cobalt ion in the calcined and reduced states (the structures A and B of Scheme 1, respectively). This may be achieved from a series of in situ measurements using synchrotron radiation in which a combination of EXAFS spectra and XRD patterns are recorded. Details of two distinct kinds of combined EXAFS-XRD procedures that we have developed have been published previously.[14] In this study, because of the considerable dilution of the catalytically active transition metal ion, the EXAFS of cobalt was detected in fluorescence geometry, exploiting a multielement solid-state detector system.[15] By employing a rapidly scanning encoded monochromator[16] in QuEXAFS/XRD (QuEXAFS is the acronym for quick EXAFS mode[17, 18]), the recording of in situ cobalt EXAFS spectra were interpolated by those of XRD patterns, measured below the cobalt K-edge at 7430 eV ($\lambda = 1.6635(4)$ Å). Exposure times for EXAFS and XRD were 600 s and 258 s, respectively, so that with a deadtime of 42 s there is a total cycle time of 15 min. Specimens were mounted in a specially designed furnace with windows optimized for detecting X-ray fluorescent and transmitted beams, as well as a large range of diffraction angles.

Combined QuEXAFS/XRD results charting the in situ calcination and reduction of CoAPO-18 are given in Figure 3. In the course of these treatments there are no significant changes in the diffraction patterns demonstrating that the framework remains intact through the burn-out of the template and the subsequent activation of the catalyst. In contrast, the detailed environment of the Co ions, which amounts to a small fraction of the total structure, (by X-ray absorption) alters substantially, first through calcination and then on reduction. The oxidation of Co^{II} to Co^{III} that accompanies calcination results (Fig. 3 middle) in a 1.2 eV shift in the K-edge, in an increase in the pre-edge feature at 7710 eV, and in a decrease in frequency of the EXAFS oscillations. The latter reflects what amounts to a massive reduction in the oxygen nearest neighbor distance from 1.95 Å for Co^{II}–O to 1.83 Å for Co^{III}–O. Both these distances correspond to cobalt in high-spin states; the shorter bond length of Co^{III}–O lying comparatively close to the framework tetrahedral Al–O separations of 1.73 Å. Variations in the position of the absorption edge and of the cobalt–oxygen bond length with temperature are given in Figure 4. Note in particular that, in the temperature interval 300–500 °C, the Co^{II}–O distance falls prior to oxidation; this probably results from the collapse of the template. The final Co^{III}–O distance of 1.83 Å is reached by 500 °C and corresponds to state A in Scheme 1 and to the IR spectrum in Figure 2a.

The emergence of the new stretching bands at 3573 cm^{-1} (Fig. 2) on heating the calcinated CoAPO-18 in hydrogen, is attributable to Brønsted acid states.[7] This directly ties in with the structural changes upon reduction, in the cobalt EXAFS (Fig. 3 bottom and 4). We identify the restoration of the oxidation state from Co^{III} to Co^{II}, by the movement to lower energies in the K-edge position and diminution in the pre-edge feature (see Fig. 3 bottom). The EXAFS oscillation frequency is also enhanced corresponding to an increase in the primary cobalt–oxygen bond length from 1.83 Å to 1.90 Å—still significantly shorter than the 1.95 Å bond length of the starting material prior to calcination but now significantly longer than the 1.73 Å of the Al–O framework tetrahedral bonds. These changes are manifest between 300 °C and 400 °C, the working temperature of the CoAPO-18 catalyst.[7]

Detailed EXAFS analysis of CoAPO-18 in state B (Scheme 1) shows that the cobalt site in the activated material is not perfectly tetrahedral symmetrical, but that there is one longer cobalt–oxygen distance, close to 2.04 Å. This we tentatively ascribe to a protonated bridging oxygen between cobalt and a neighboring phosphorus.

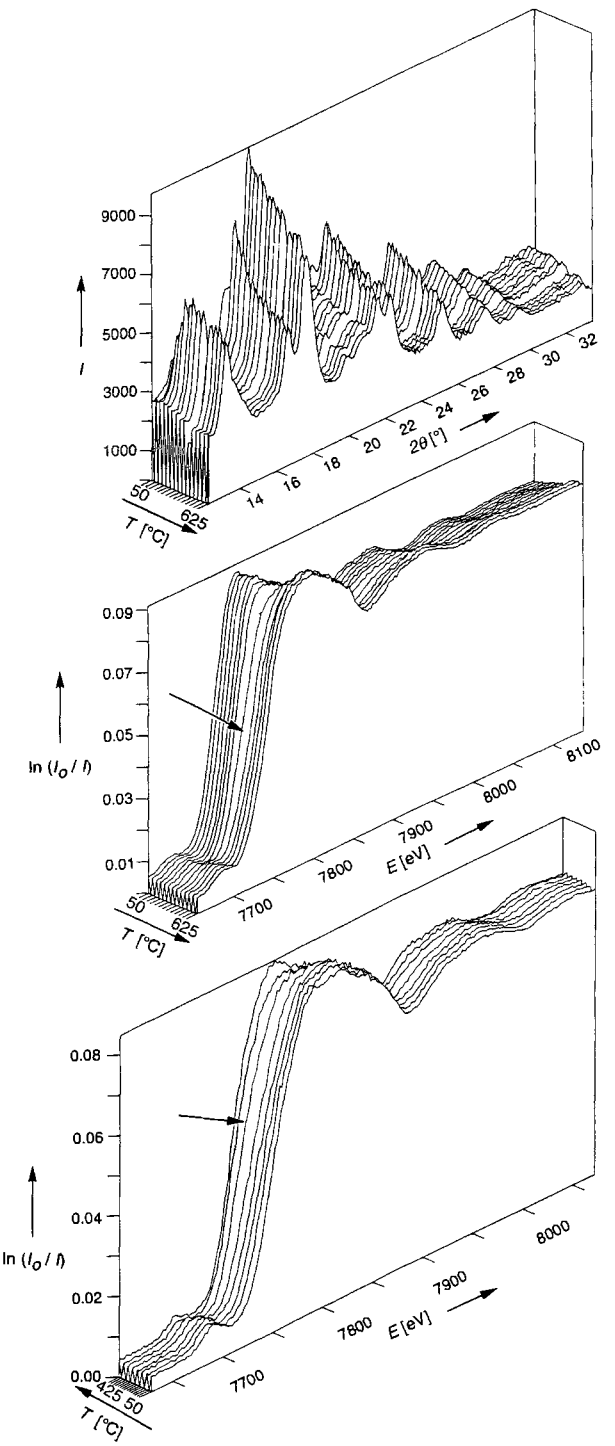

Fig. 3. Combined in situ XRD (top) and cobalt K-edge EXAFS (middle) recorded during the calcination of CoAPO-18. The shift in the K-edge on oxidation of Co^{II} to Co^{III} is indicated by the arrow. Bottom: In situ cobalt K-edge EXAFS measured during the course of the reduction of CoAPO-18, with the shift in the K-edge of Co indicated.

To our knowledge this is the first report describing the simultaneous changes in bond length and oxidation state of the active center of a solid inorganic catalyst, during calcination and reduction. All the redox changes that occur around cobalt in this

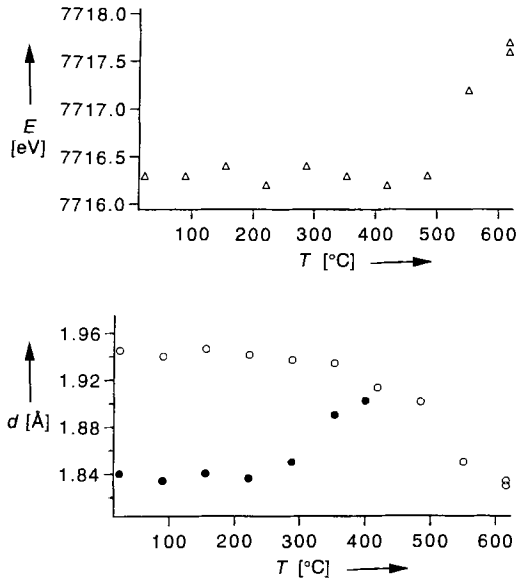

Fig. 4. Temperature variation of the position of Co K-edge, represented as E (top) and cobalt oxygen average bond lengths (d) measured from in situ EXAFS (bottom) during calcination (open circles) and reduction (filled circles) of CoAPO-18. Data were analyzed by using the EXCURVE suite of programs [19].

dilute metal catalyst CoAPO-18 when it is calcined in O_2 and then reduced in H_2 to generate Brønsted acidity take place around 350 °C, which is the temperature for the onset of catalysis. Quantum mechanical and other studies of the kind recently initiated[20, 21] are needed before the mechanistic details of the overall catalytic reaction can be elucidated.

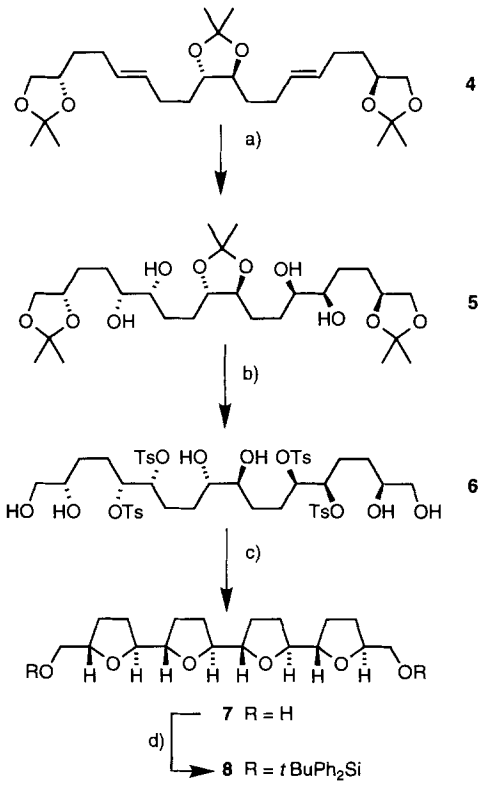
A Multiple Five-Membered-Ring-Selective Williamson Reaction as a Key Step in the Stereoselective Construction of 2,5-Linked Oligo(tetrahydrofuran)s**

Holger Wagner and Ulrich Koert*

2,5-Linked oligo(tetrahydrofuran)s are important components of naturally and unnaturally occurring polyethers. Dimeric tetrahydrofurans of type **12** and **15** (see Scheme 3) form part of the structures of naturally occurring annonin compounds.[1] Unnatural oligo(tetrahydrofuran)s of type **8** (see Scheme 2) are of interest as potential elements of an ion channel active polyether helix.[2]

To date the acid-catalyzed, intramolecular ring opening of an epoxide **1** with the formation of the tetrahydrofuran **2** has been widely used (Scheme 1) for the stereoselective synthesis of 2,5-linked tetrahydrofurans.[3] A possible alternative is a five-membered-ring-selective intramolecular Williamson reaction of the dihydroxy-tosylate **3**.[4] The diol unit of **3** should be readily available with good stereocontrol by means of a Sharpless dihydroxylation.[5] We report here on the successful application of a multiple five-membered-ring-selective Williamson reaction for the synthesis of enantiomerically pure oligo(tetrahydrofuran)s.



1 2 3

Scheme 1. Alternative synthetic routes to 2,5-disubstituted tetrahydrofurans; a) intramolecular epoxide opening; b) intramolecular five-membered-ring-selective Williamson reaction.

Sharpless dihydroxylation of the enantiomerically pure diene **4** yielded the tetraol **5** with a selectivity of 9:1 per double bond (determined by NMR spectroscopy) (Scheme 2). The quadruple tosylation and the subsequent triple, acidic acetonide cleavage led to the hexahydroxytetratosylate **6**. All four tetrahydrofuran rings were formed in a single step, in a stereocontrolled manner, by means of a quadruple Williamson reaction. The resulting water-soluble diol **7** could be converted to the di(*tert*-butyldiphenylsilyl) ether **8** which is soluble in organic solvents. The C_2 symmetry of the oligo(tetrahydrofuran) **8** was shown by the half set of signals in the ^1H and ^{13}C NMR spectra (Table 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Wacker AG and BASF AG for donatations of chemicals.

Scheme 2. Synthesis of the tetrameric tetrahydrofuran **8**; a) 1 equiv AD-mix-β, tBuOH/H_2O 1:1, 0 → 20 °C, 12 h (98%); b) 1. 16 equiv p-tosyl chloride, pyridine, 2. AcOH/H_2O 10:1, 40 °C, 8 h (89%, two steps); c) 12 equiv NaH, THF, 3 h, 40 °C (55%); d) tBuPh$_2$SiCl, imidazole, DMF (95%).

The strict five-membered-ring selectivity in the multiple Williamson reaction is remarkable. In terms of the extended Baldwin rules[6] the 5-*exo-tet* ring closure is clearly favored over the 6-*exo-tet* reaction and the reactions leading to other possible larger rings. No intermediates with only one, two, or three closed tetrahydrofuran rings were observed when the multiple reaction was followed by thin layer chromatography. This finding indicates a cooperative process and requires further study.

In order to investigate the extent of reagent control in the diastereoselective dihydroxylation step more closely we turned to compounds with only two tetrahydrofuran rings (Scheme 3) which are easier to analyze. Olefin **9** could be converted with the AD-mix-β[7] to diol **10** and, with the corresponding AD-mix-α, to diol **13**. The same stereoselectivity of 9:1 was observed for both reactions. In a control experiment compound **9** was dihy-

droxylated with OsO_4/*N*-methylmorpholine-*N*-oxide which resulted in two diols **10** and **13** in a ratio of 1:1. The chiral centers of olefin **9**, therefore, have no controlling influence on the dihydroxylation. The observed stereocontrol is due solely to the Sharpless dihydroxylation reagent. Diols **10** and **13** can be converted by a multiple five-membered-ring-selective Williamson reaction analogous to the reaction in Scheme 2 into the dimeric tetrahydrofuranols **11** and **14**, respectively, and subsequently to the corresponding disilyl ethers **12** and **15**.

The enantiomerically pure alkenes **4** and **9** were prepared by standard methods (Scheme 4). The double alkylation of acetylene with bromide **16**[9] and the subsequent (*E*)-selective reduction to the olefin yielded compound **9**. Reaction of two equivalents of alkyne **19** with one equivalent of dibromide **18**[10] and subsequent (*E*)-selective reduction to the olefin yielded diene **4**.

The synthetic sequence of reagent-controlled, diastereoselective dihydroxylation and multiple five-membered-ring-selective Williamson reaction presented here opens up an efficient, bidirectional route to the enantiomerically pure oligo(tetrahydrofuran)s.

$[\{Sb_2(Ncy)_4\}_2Cu_4]$: A Mixed-Metal Antimony(III)/Copper(I) Complex Containing a Cu_4 Square Plane**

Donald Barr, Andrew J. Edwards, Samantha Pullen, Michael A. Paver, Paul R. Raithby, Moira-Ann Rennie, Christopher A. Russell, and Dominic S. Wright*

We recently demonstrated that stepwise metalation of primary amines (RNH_2) employing $[(Me_2N)_3Sb]$ as a reagent is an effective and versatile method of synthesizing Sb/Li heterometallic complexes which contain a range of polyamido Sb anions.[1–3] The "mixed-metalation" reaction of $[(Me_2N)_3Sb]$ with the anionic antimony complex $[(cyNH)_4Sb]^-Li^+$ produces $[(cyN)_4Sb_3(NMe_2)_2Li]$, containing the polynuclear amidoantimony anion $[(cyN)_4Sb_3(NMe_2)_2]^-$. The cage complex $[(PhCH_2CH_2NLi)_3Sb(thf)]_2$, containing the first structurally characterized $[Sb(NR)_3]^{3-}$ trianion, is the product of the reaction between $[(Me_2N)_3Sb]$ and the neutral amidolithium complex $[PhCH_2CH_2NHLi]_n$.[1] In addition to $[(Me_2N)_3Sb]$, the dimeric complexes $[(Me_2N)Sb(\mu\text{-}NR)]_2$, which have two reactive Me_2N groups,[2] can themselves be employed as metalating reagents. Thus, the reaction of $[(Me_2N)Sb(\mu\text{-}Ncy)]_2$ with $[cyNHLi]_n$ results in the rational assembly of $[\{Sb_2(Ncy)_4\}_2Li_4]$, which contains an $Sb_4N_8Li_4$ cage of two interlocked "broken" cubes and which is a potential source of the $[Sb_2(Ncy)_4]^{2-}$ dianion.[3] Currently, we are interested in using polyamidoantimony anions (Scheme 1) as novel ligands to a range of transition and main group metals. We report here the synthesis of **1** by the

Scheme 1. Polyamidoantimony anions.

transmetalation reaction between $[\{Sb_2(Ncy)_4\}_2Li_4]$ and CuCl (see Experimental Procedure) [Eq. (a)].

$$[\{Sb_2(Ncy)_4\}_2Li_4] + 4\,CuCl \xrightarrow{C_6H_5CH_3} \underset{\mathbf{1}}{[\{Sb_2(Ncy)_4\}_2Cu_4]} + 4\,LiCl \quad (a)$$

The X-ray crystallographic study of **1**[4] shows it to be a polyhedral cage complex, in which two terminal $[Sb_2(Ncy)_4]^{2-}$ ligands stabilize a central Cu_4 core (Fig. 1). The structure of **1** is very different to that of the analogous lithium compound

$[\{Sb_2(Ncy)_4\}_2Li_4]$ in which there is a tetrahedral arrangement of the four Li centers.[3] Although a number of mixed-metal Cu/Sb and Cu/As complexes has been structurally characterized,[5] the structure of **1** has a unique Cu/Sb framework. The structure illustrates for the first time that such polyamidoantimony anions can be employed as effective and robust ligands to other metals.

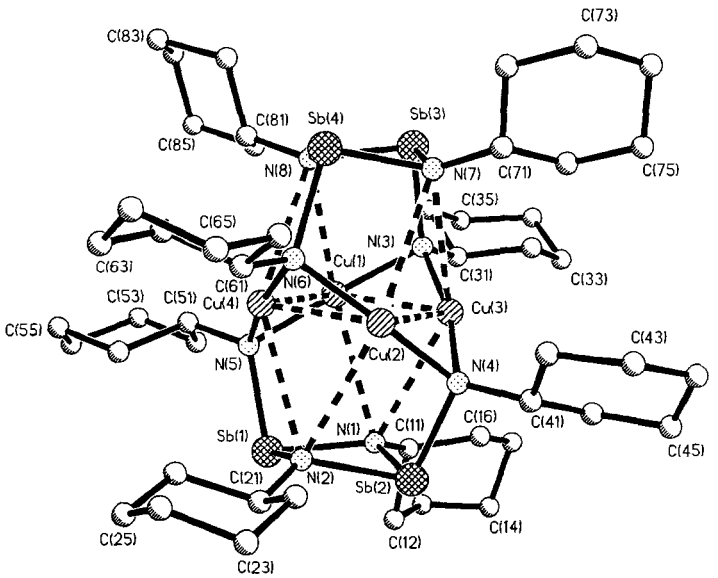

Fig. 1. The molecular structure of **1**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Sb(1)-N(1) 2.07(1), Sb(1)-N(2) 2.09(1), Sb(2)-N(1) 2.05(1), Sb(2)-N(2) 2.07(1), Sb(3)-N(7) 2.09(1), Sb(3)-N(8) 2.08(1), Sb(4)-N(7) 2.09(1), Sb(4)-N(8) 2.07(1), Sb(3)-N(3) 2.06(1), Sb(4)-N(6) 2.07(1), Sb(2)-N(4) 2.06(1), Sb(1)-N(5) 2.05(1), mean Cu···Cu 2.57, range (μ-cyN)···Cu 2.92–3.04, mean Cu-N to pendant Ncy 1.93; mean N-Sb-N 78.2, mean Sb-N-Sb 99.6; Cu···Cu···Cu 90.0, mean Cu-N-Cu 83.2.

The Cu_4 core of **1** is essentially square planar (range Cu···Cu···Cu 88.3(9)–91.1(9)°, sum of angles 360°) (Fig. 1). The pendant CyN arms of each terminal $[Sb(Ncy)_4]^{2-}$ ligand form Cu-(μ-N)-Cu bridges at opposite edges of the central Cu_4 unit (mean Cu–N 1.93 Å). Presumably, the Cu_4 fragment is largely held together by these Cu-(μ-N)-Cu bridges which result in a roughly linear coordination of the Cu centers of the core (mean N-Cu-N 168.7°). However, longer range Cu···(μ-N)···Cu interactions also occur with the Sb-bridging cyN centers of the $[Sb_2(Ncy)_4]^{2-}$ ligands (range 2.92–3.04 Å). As a result of these weak interactions, the $[Sb(\mu\text{-}Ncy)]_2$ rings are forced into a distinctly puckered conformation so as to bring the μ-N centers of each into closer contact with opposite Cu···Cu edges of the Cu_4 core. The possibility of Cu···Cu bonding in the Cu_4 unit of **1** cannot be discounted. The Cu···Cu distances in the core (mean 2.57 Å), although somewhat longer than those observed in $[CuCH_2SiMe_3]_4$ (2.42 Å),[6] are almost identical to those present in Cu metal (2.56 Å[7]). Within the $[Sb_2(Ncy)_4]^{2-}$ dianions the Sb–N distances are typical of those found in other amidoantimony complexes.[8]

A similar structural motif to that in **1** has been observed recently in $[\{(C_6H_4)_2O_2(Me_2SiNtBu)_2\}_2Cu_4]$,[9] in which two essentially organic dianions stabilize a Cu_4 square planar core (mean Cu···Cu 2.67 Å). However, whereas in **1** the four N donor centers of each $[Sb_2(Ncy)_4]^{2-}$ dianion (two pendant cyN, two μ-Ncy) bridge all four sides of the Cu_4 core, in $[\{(C_6H_4)_2O_2(Me_2SiNtBu)_2\}_2Cu_4]$ the four donor centers of each ligand (two pendant *t*BuN, two O) bridge only two adjacent sides of the Cu_4 fragment.

Experimental Procedure

A slurry of $[\{Sb_2(Ncy)_4\}_2Li_4]$ [3] (1.28 g, 1 mmol) in $C_6H_5CH_3$ (30 mL) was treated at 0 °C with CuCl (0.2 g, 4 mmol). Heating to reflux followed by stirring for 5 min yielded an intense yellow solution with precipitation of lithium chloride. Filtration through Celite with subsequent reduction to about 7 mL led to the precipitation of a yellow solid which redissolved by upon gentle warming. Storage at room temperature for 24 h yielded yellow crystalline blocks of **1**. First batch yield 0.55 g (36%). The relatively low yield is due to the high solubility of the complex; m.p. ca. 200 °C (decomp); ^{1}H NMR (C_6D_6, +25 °C, 250 MHz): δ = 3.8 (m), 2.5 (m), 1.5 (m) (cy groups). Satisfactory elemental analyses (C,H,N) were obtained.

Cr^{III} and Fe^{III} Complexes with η^3-1,3,5-Triazacyclohexane Ligands**

Randolf D. Köhn* and Gabriele Kociok-Köhn

Many complexes having triazacyclononane and larger macrocyclic amines as ligands are known.[1] They are used as bioinorganic model systems and as catalysts for olefin polymerization.[2] Therefore, it is surprising that hardly any complexes with the smaller triazacyclohexane ligands **1** are known (see Scheme 1). Many N-alkylated triazacyclohexanes are commerically available, while the larger macrocyclic amines are much more expensive or can be obtained only by time-consuming syntheses.

Some poorly characterized Cr and Mo tricarbonyl complexes with **1**[3] are described. Only a few other complexes of this type have been characterized by X-ray crystallography,[4] and here the metal is mostly coordinated by only one nitrogen atom of **1**. The only case of η^3 coordination was found in a complex of **1b** with $InMe_3$;[4d] however, this structure could not be well refined owing to the highly disordered *i*Pr groups.

We have found that addition of **1** to solutions of $[CrCl_3(thf)_3]$ in THF or $FeCl_3$ in Et_2O results in the precipitation of the 1:1 complexes **2** and **3**, respectively (Scheme 1; for physical data of these and other new compounds see Table 1). These complexes

Scheme 1. Reactions of **1a** (R = Me) and **1b** (R = *i*Pr) with $[CrCl_3(thf)_3]$ in THF to give **2a** and **2b** (M = Cr), respectively, and with $FeCl_3$ in Et_2O to give **3a** and **3b** (M = Fe), respectively.

Table 1. Selected spectroscopic data of **2**–**4** [a].

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Graduierten Kolleg of the Bundesministerium für Bildung und Wissenschaft. R. D. K. thanks the Deutsche Forschungsgemeinschaft for a Habilitation fellowship and Prof. Dr. H. Schumann for the support of this work.

remain unchanged over several days when exposed to air, and the most inert complex **2b** was not even attacked by aqua regia. They are soluble in strongly polar solvents such as dimethylsulfoxide (DMSO); the iron complexes **3a**, **b** are also soluble in CH_2Cl_2 and $CHCl_3$.

Suitable crystals for X-ray crystallography were obtained by slow evaporation of a solution of **3a**[5] in CH_2Cl_2. Figure 1 shows the structure of **3a**. The triazacyclohexane ligand is coordinated through all three nitrogen atoms to the iron center. Although there is only one crystallographic mirror plane, the molecule has nearly C_{3v} symmetry. The Fe–N and Fe–Cl bond lengths are all 225 pm. These comparatively long Fe–N distances are similar to those in Fe^{III} trimethyltriazacyclononane complexes.[7] Since the bond lengths and angles in the ligand of **3a** show no unusual distortions, the nitrogen lone pair is assumed to form a 24° angle with the Fe–N axis (see Scheme 3). The resulting poor overlap can explain the long Fe–N bond length.

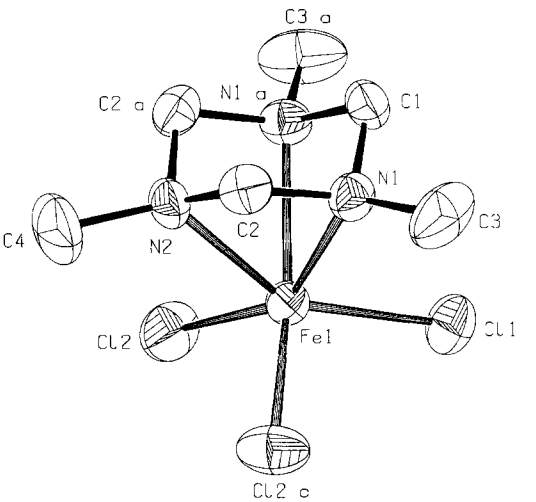

Fig. 1. Crystal structure of **3a** (ORTEP plot, ellipsoids for 50% probability, hydrogen atoms are omitted). Selected distances [pm] and angles [°]: Fe-Cl1 224.96(14), Fe-N1 225.3(2), N1-C1 146.0(3), N1-C3 147.0(4), Cl1-Fe-Cl2 103.37(4), Cl1-Fe-N1 94.36(7), Cl1-Fe-N2 150.79(9), N1-Fe-N2 60.98(9), Fe-N1-C3 129.8(2), C1-N1-C2 109.8(2), C1-N1-C3 114.4(3), N1-C2-N2 102.8(2).

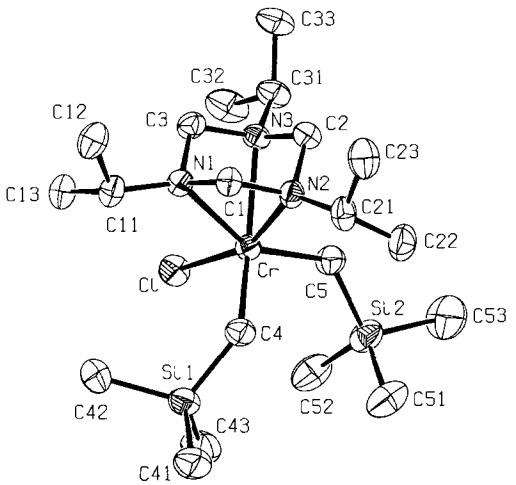
Complex **2b** reacted slowly with $LiCH_2SiMe_3$ in toluene to form the brown dialkylated complex **4** (Scheme 2), a toluene soluble, but petroleum ether insoluble solid, in 42% yield. In the

Scheme 2.

workup the crude product soluble in petroleum ether includes a deep purple chromium-containing oil; the toluene-insoluble residue contains a brown chromium compound. No pure compounds were isolated from these fractions. No trialkylated com-

pound was isolated when **4** was treated with an excess of $LiCH_2SiMe_3$ or MeLi.

Complex **4** can be recrystallized from toluene; its crystal structure[6] shows a η^3-bound triazacyclohexane ligand. The Cr–N bonds *trans* to the alkyl groups are much longer (229.2 and 229.8 pm) than the bonds *trans* to the chloro ligand (218.1 pm). The average Cr–N bond length of 225.7 pm is nearly identical to the Fe–N distances in **3a**. The Cr–C distances (208.6 and 208.0 pm) and the Cr–Cl distance (231.6 pm) are in the normal range.



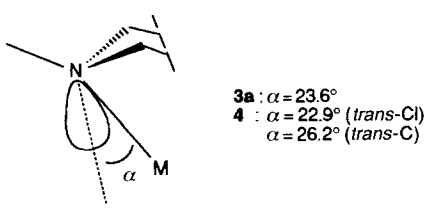


Fig. 2. Crystal structure of **4** (ORTEP plot, ellipsoids for 50% probability, hydrogen atoms are omitted). Selected distances [pm] and angles [°]: Cr-Cl 231.6(1), Cr-C4 208.6(5), Cr-N1 229.2(4), Cr-N2 218.1(4), N1-C1 147.7(6), N1-C11 149.3(6), Cl-Cr-C4 101.1(2), Cl-Cr-C5 94.4(2), C4-Cr-C5 105.7(2), Cl-Cr-N1 97.2(1), Cl-Cr-N2 157.8(1), C4-Cr-N3 151.5(1), N1-Cr-N2 62.7(1), Cr-N1-C11 133.0(3), Cr-N1-C1 90.0(3), Cr-N2-C21 130.6(3).

The bond lengths in **3a** and **4** are similar despite the sterically more demanding ligands in **4**. Elongated metal–N bonds were also found in the only other known complex with a η^3-triazacyclohexane ligand.[4d] As in **3a**, the C-N-C angles in **4** indicate that the nitrogen lone pair forms an angle of 23–26° with the Cr–N bond (Scheme 3).

Scheme 3. Angles between the N–M bonds and the position of the nitrogen lone pairs estimated from the C–N bonds.

Despite the ring strain in complexes with η^3-triazacyclohexane ligands, Cr^{III} and Fe^{III} complexes can be prepared easily and are stable in air and at temperatures well over 100 °C. Derivatization by reaction with $LiCH_2SiMe_3$ showed that the corresponding organometallic complexes can be obtained. Two crystal structures showed that the distances between the metal center and the cyclic amine are similar to those in complexes with *N,N',N''*-trimethyltriazacyclononane ligands despite the ring strain.

Experimental Procedure

All reactions were performed with standard Schlenk techniques, under dry argon, and in dry solvents when not stated otherwise. All compounds provided satisfactory elemental analyses (C,H,N,Cr,Fe).

2a: Triamine **1a** (0.10 mL, 0.71 mmol) (dried over 3 Å molecular sieves) was added to $[CrCl_3(thf)_3]$ (117 mg, 0.47 mmol) in 20 mL of THF at room temperature. After 30 min of stirring, the purple precipitate was isolated by filtration in the air and washed with Et_2O. After drying in vacuo, 122 mg of purple **2a** (90%) was obtained. M.p. 270 °C (decomp).

Complex **2b** was prepared analogously to **2a** from **1b** and $[CrCl_3(thf)_3]$ in THF, and was obtained as a purple powder (90% yield). M.p. 300 °C (decomp). **3a** (m.p. 170 °C (decomp)), and **3b** (m.p. 130 °C (decomp)) were prepared analogously to **2a** and **2b** from $FeCl_3$ in Et_2O, and were obtained as orange-yellow powders (90% yield).

4: Complex **2b** (543 mg, 1.46 mmol) and $LiCH_2SiMe_3$ (290 mg, 3.08 mmol) in 20 mL of toluene were stirred at room temperature for 4 d. The solvent was removed in vacuo and the purple residue washed with petroleum ether. The remaining brown solid was extracted with toluene. Concentration and drying in vacuo left 295 mg (42%) of brown **4**. The compound can be recrystallized from toluene at −20 °C, m.p. 150 °C (decomp).

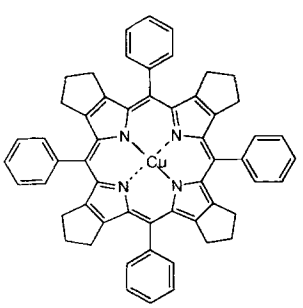
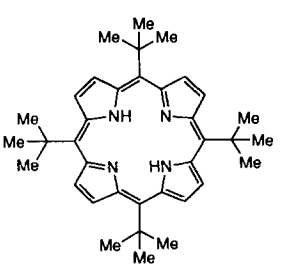
5,10,15,20-Tetra-*tert*-butylporphyrin and Its Remarkable Reactivity in the 5- and 15-Positions**

Tadashi Ema, Mathias O. Senge, Nora Y. Nelson, Hisanobu Ogoshi, and Kevin M. Smith*

Both 2,3,7,8,12,13,17,18-octaethylporphyrin H_2(OEP) and 5,10,15,20-tetraphenylporphyrin H_2(TPP) have been used extensively as models for natural porphyrin systems.[1] We recently showed that the hybrid of these two systems, 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetraphenylporphyrin (H_2(OETPP) **1**), displays quite remarkable physical and spectroscopic properties,[2] along with analogues such as dodecaphenylporphyrin (H_2(DPP) **2**),[3] 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetranitroporphyrin,[4] and various 2:3,7:8,12:13,17:18-tetraalkano-5,10,15,20-tetraphenylporphyrins.[2b, 5] In particular, for example, we showed that

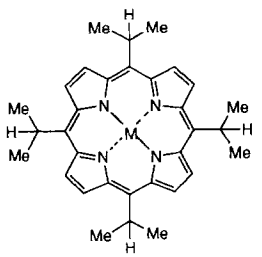


1 M = 2H
9 M = Zn



2

H_2(OETPP) and other highly congested dodecasubstituted porphyrins possess highly nonplanar conformations in the solid state and in solution,[2a, b] whereas the core macrocycle in the dodecasubstituted porphyrin copper(II) complex **3** is perfectly planar.[6] We suspected that nonplanar conformations approaching or similar to those in **1** and **2** might be achieved simply by attaching one or more *tert*-butyl groups to the porphyrin periphery. In the present paper we show that the prototype, 5,10,15,20-tetra-*tert*-butylporphyrin (H_2(TTBP) **4**), is so distorted that its fundamental reactivity no longer parallels that of regular porphyrins, or for that matter of any known nonplanar porphyrin.



3

4

Treatment of equimolar amounts of pyrrole and pivalaldehyde at high dilution (26 mM) with BF_3 catalysis[7] provided minimal quantities of H_2(TTBP) detectable only by spectrophotometry. When the reaction was repeated with significantly higher concentrations of the reagents (150 mM), H_2(TTBP) (λ_{max} ($CHCl_3$) 446, 552, 596, 628, and 692 nm; Fig. 1) was isolated in 8.8% yield. Under similar conditions reaction of 2-methylpropanal with pyrrole gave a 5.1% yield of 5,10,15,20-tetraisopropylporphyrin (H_2(TIPP) **5**) (λ_{max} (CH_2Cl_2) 420, 524, 560, 602, and 656 nm; Fig. 1). Figure 1 shows the optical spectra of **4** and **5**. The significantly greater red shift of the bands of **4** indicate that it has presumably a greater deformation from planarity than **5**. A direct correlation between significant red shifts in the optical spectra with nonplanarity of the porphyrin core has been shown already.[2]

5 M = 2H
6 M = Ni
7 M = $4H^{2+}$

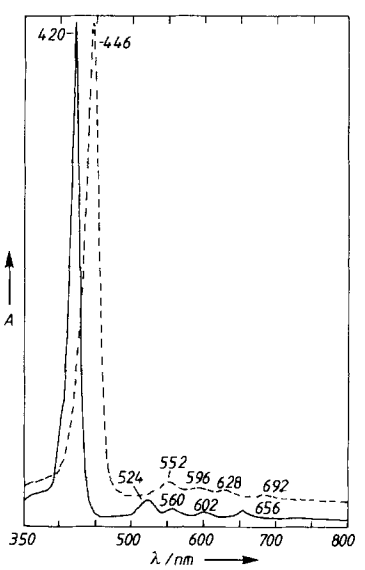


Fig. 1. Optical spectra of **4** (---) and **5** (—) in CH_2Cl_2.

Thus far we have been unable to obtain a satisfactory crystal structure for **4** or for any of its "normal" porphyrin derivatives. However, the single-crystal X-ray structure analysis of the nickel(II) complex of H_2(TIPP), [Ni(TIPP)] **6**, showed a nonplanar macrocycle conformation (λ_{max} (CH_2Cl_2) 422, 548, and 590 nm), indicated by an average deviation of the 24 macrocycle atoms from their least-squares plane by 0.36 Å; the largest out-of-plane displacements are observed for the *meso* carbon atoms (0.74 Å). These displacements are larger than those observed in, for example, [Ni(OEP)],[9] which proves that the steric interaction of the *meso*-isopropyl groups with neighboring β-pyrrole hydrogens leads to some distortion in the macrocycle (Fig. 2).[8a, 10] On the basis of the further bathochromic absorp-

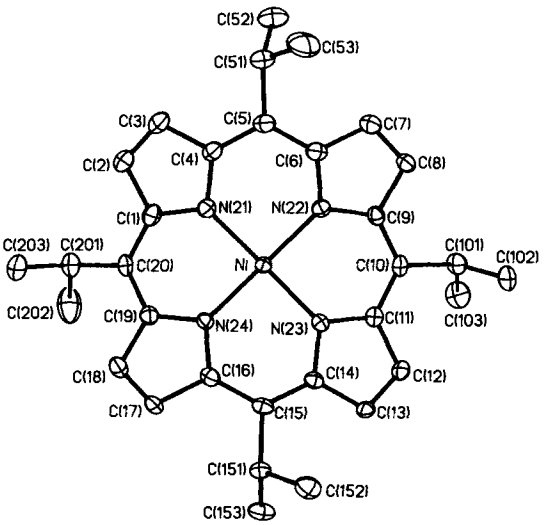
tion shifts observed for both the free base H_2(TTBP) and its nickel(II) complex (λ_{max} (CH_2Cl_2) 451, 582, 622 nm) relative to the corresponding TIPP derivatives, we conclude that TTBP has to be considerably more distorted than TIPP.



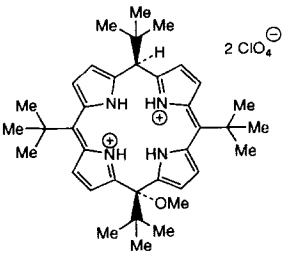


Fig. 2. Molecular structure of **6**. Ellipsoids are drawn at the 50% probability level; hydrogen atoms have been omitted for clarity. Selected structural features: Average Ni–N_p bond length: 1.896(3) Å; average angle of individual pyrrole rings with N_4 plane: 22.8°.

Although nonplanar porphyrins have significant atypical physical and electrochemical properties,[2–6] these substances (**3** and **4** as prototypes) have shown expected reactivity with regard to metal insertion and even protonation (though nonplanar porphyrins have been shown to be very strong bases compared with H_2(OEP) and H_2(TPP)). Treatment of H_2(OETPP), for example, with $HClO_4$/MeOH gave the corresponding dication diperchlorate (λ_{max} 464, 624, 678 nm). Similarly, treatment of H_2(TIPP) under the same conditions led to formation of **7** with absorption maxima at 424, 586, and 634 nm in CH_2Cl_2 (Fig. 3). However, when H_2(TTBP) **4** was treated under the same conditions, quite remarkably, protonation took place on a *meso* carbon atom (instead of on nitrogen) to yield **8** after nucleophilic addition of methanol. Figure 3 shows the optical spectrum of this diprotonated "porphodimethene" (5,15-dihydroporphyrin); Figure 4 shows its structure in the crystal.[8b] It is clear that protonation on carbon enables the eventual formation of the pophodimethene **8**, which dramatically relieves the steric congestion present in the nonplanar porphyrin **4**. Compound **8** has a roof-type structure, in which the two sp^3-hybridized *meso* carbon atoms facilitate significant out-of-plane rotations of the pyrrole rings to minimize steric interactions of the bulky *meso* substituents with β-pyrrole groups.

8

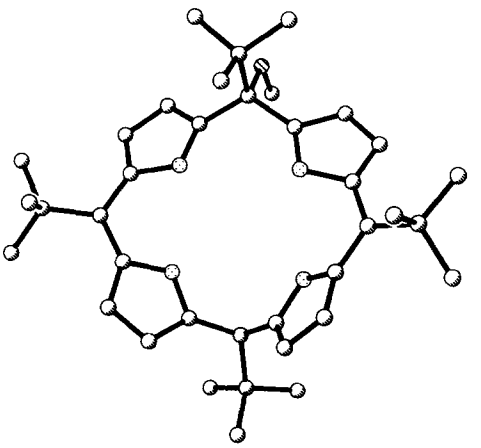

Fig. 4. Molecular structure of the porphyrin dication of **8**. Hydrogen atoms have been omitted for clarity. Selected structural features: Average C_a-N-C_a bond angle: 111.4(6)°; average C_m–C(*t*Bu) bond length: 1.547(10) Å; mean deviation of 24 core atoms from their least-squares plane: 0.47 Å.

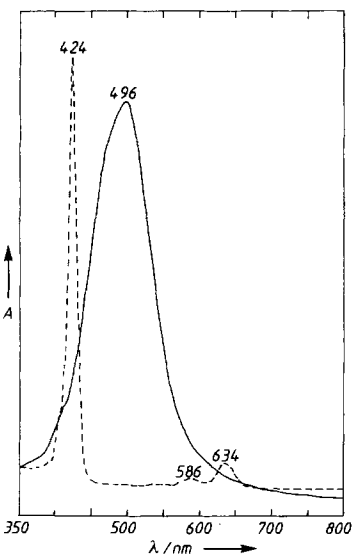

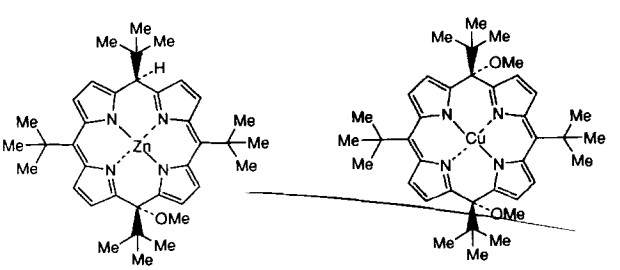

Fig. 3. Optical spectra of **7** (---) and **8** (—) in CH_2Cl_2 (containing $HClO_4$).

Treatment of H_2(OETPP) **1** with zinc(II) acetate in methanol/chloroform gave the "normal" zinc(II) chelate **9**, which exhibits absorption maxima in CH_2Cl_2 at 442, 574, and 630 nm, typical for a metalloporphyrin. In stark contrast, *prolonged* treatment of H_2(TTBP) **4** with the same reagents gave the zinc(II) porphodimethene **10**, in a reaction analogous with the formation of the dication **8**.[10] The reaction product has an absorption spectrum in CH_2Cl_2 with a single band at 456 cm and a shoulder at 570 nm. Figure 5 displays the molecular structure of **10**.[8c] Prolonged treatment of **4** with copper(II) acetate (an oxidant) in methanol/chloroform gave the copper(II) bismethoxypor-

10 **11**

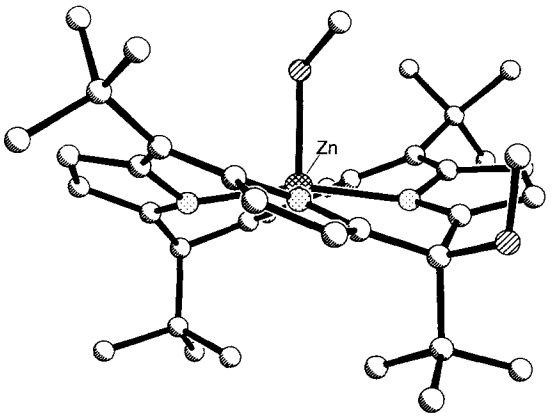

Fig. 5. Molecular structure of **10**. Hydrogen atoms have been omitted for clarity. Selected structural features: Average $Zn-N_p$ bond length: 2.023(4) Å; average $C_m-C(t\mathrm{Bu})$ bond length: 1.573(8) Å; average $C_m-O(CH_3)$ bond length: 1.446(7) Å; average deviations of the 24 core atoms from their least-squares plane: 0.414 Å.

phodimethene **11**. This is a product of metalation like the zinc(II) complex **10**, but here metalation is followed or preceded by oxidation to the π cation radical or π dication, followed by attack by methanol as a nucleophile.[10] The absorption spectrum of this compound in CH_2Cl_2 consists of two overlapping bands at 454 and 496 nm. Figure 6 shows the molecular structure of **11**.[8d] In the structures of both **10** and **11** the *tert*-butyl groups at the sp^3-hybridized *meso* carbons have a synaxial orientation. These compounds exhibit a roof-type macrocycle conformation, similar to the porphodimethenes prepared earlier by Buchler et al. through total synthesis.[11]

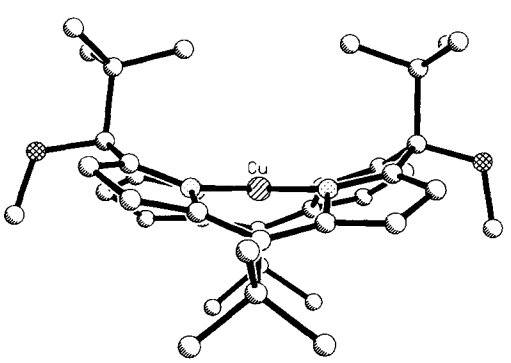

Fig. 6. Molecular structure of **11**. Hydrogen atoms have been omitted for clarity. Selected structural features: Average $Cu-N_p$ bond length: 1.950(8) Å; average $C_m-C(t\mathrm{Bu})$ bond length: 1.577(14) Å; average $C_m-O(CH_3)$ bond length: 1.426(12) Å; average deviations of the 24 core atoms from their least-squares plane: 0.437 Å.

It seems clear that H_2(TTBP) **4** must have an extremely distorted porphyrin macrocycle, possibly more distorted than any previously reported in our series on nonplanar porphyrins.[2-5] The degree of distortion appears to be so dramatic that normal protonation and metalation reactions are diverted to yield atypical products which no longer possess the pseudoplanar, fully conjugated porphyrin macrocycle.

[10] Note that treatment of H_2(TIPP) or H_2(OETPP) with zinc(II) acetate or copper(II) acetate under these conditions gave the "normal" porphyrin-type chelates. Very brief treatment of H_2(TTBP) with nickel, copper, or zinc acetate gave metal chelates possessing optical spectra characteristic of normal nonplanar metalloporphrins; in the case of the zinc and copper chelates these were transformed with time into the porphodimethenes.

$[\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]^{2+}$: A Novel Tetranuclear Cationic Complex with a Rectangular S_4 Unit**

Kiyoshi Isobe,* Yoshiki Ozawa, Amelio Vázquez de Miguel,* Tian-Wei Zhu, Kui-Ming Zhao, Takanori Nishioka, Takashi Ogura, and Teizo Kitagawa

The oxidation of M–SH to M–S–S–M functionalities (M = metal) has been intensively studied in several metal complexes in connection with its significance in biological, mineralogical, and industrial processes.[1] There have, however, been few reports of the oxidation of the $M(\mu\text{-}SH)M$ functionality in metal complexes.[2] Since this functionality occurs commonly in many such processes, we felt that this chemistry warranted further investigation. Thus, we synthesized μ-methylene rhodium complexes **1** ($Cp^* = \eta\text{-}C_5Me_5$) containing the μ-SH ligand.[3] The oxidation of the μ-SH complexes afforded the novel tetranuclear complexes **2** by a unique intermolecular oxidative coupling. The D_{2h} symmetric S_4 unit in the complex has been of interest for both experimental and theoretical chemistry for a long time.[4]

Treatment of **1a** with O_2 in the presence of an excess of H_2S led to the formation of the tetranuclear rhodium complex **2a** · $3H_2O$ in 81% yield. This complex is amphiphilic, and is

$[\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]XY$ **2**
2a: X = Cl, Y = OH; **2b**: X = Y = BF_4

soluble in water and in organic solvents such as CH_2Cl_2 and $(CH_3)_2CO$. The BF_4 complex **2b** was precipitated from an aqueous solution of **2a** · $3H_2O$ with $NaBF_4$. Both complexes **2** are diamagnetic and recrystallization from CH_2Cl_2/Et_2O yielded black crystals of **2a** · CH_2Cl_2 · $4H_2O$ and **2b**, respectively.

The structures of **2a** · CH_2Cl_2 · $4H_2O$ and **2b** (Fig. 1) were confirmed by single-crystal X-ray diffraction;[5] the structures of the cations of **2** are isostructural and have approximately $2/m$ symmetry. The complex cations consist of two $Cp^*_2Rh_2(\mu\text{-}CH_2)_2$ groups with a Rh–Rh single bond (2.6618(4) Å) and four S atoms lying in the same plane. The rectangular planar S_4 unit bridges two $Rh_2(\mu\text{-}CH_2)_2$ groups to form a Rh_4S_4 eight-membered ring with a new centrosymmetric chairlike core. Two of the four S–S distances (S1–S2* and S1*–S2 1.979(1) Å) in the S_4 unit are very short; their bond lengths lie between S–S distances observed for free S_2 (1.89 Å)[6] and H_2S_2 (2.055 Å).[7] Short S–S distances in S_2 ligands (1.962(1) Å), indicative of appreciable double-bond character,[8a] have also been found in many disulfido complexes,[8b] for example, $[\{CpRu(PMe_3)_2\}_2(\mu\text{-}S_2)](SbF_6)_2$. The other two distances in the S_4 unit (S1–S2 and S1*–S2*), however, are quite long (2.702(1) Å), but nonetheless are significantly shorter than the sum of the van der Waals radii of these atoms (3.60 Å). Similar S–S distances have been found in transannular S–S bonds in S_8^{2+} (2.86 Å)[9] and [1,5-{$(MeC_5H_4)Ru(PPh_3)$}$_2S_6$] (2.772(3) Å).[10]

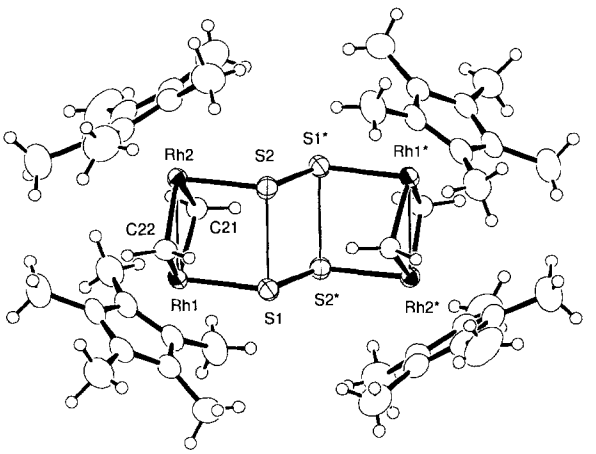

Fig. 1. Structure of the cation of **2b**. Selected bond lengths [Å] and angles [°]: Rh1–Rh2 2.6618(4), Rh1–S1 2.353(1), Rh2–S2 2.346(1), S1–S2* 1.979(1), S1–S2 2.702(1), Rh1–C21 2.034(3), Rh1–C22 2.054(3), Rh2–C21 2.038(3), Rh2–C22 2.062(3); Rh1-Rh2-S2 90.08(2), Rh2-Rh1-S1 90.90(2), Rh1-S1-S2* 112.15(4), Rh2-S2-S1* 111.16(4), Rh1-C21-Rh2 81.6(1), Rh1-C22-Rh2 80.6(1). The deviations of Rh1, Rh2, S1, and S2 from the least squares plane are 0.0009(5), −0.0008(5), −0.011(1), and 0.010(1) Å, respectively. (Atoms with * have equivalent coordinates $-x, -y, -z$.)

The Rh-Rh-S units form angles that are close to right angles (Rh1-Rh2-S2: 90.08(2), Rh2-Rh1-S1: 90.90(2)°). The Rh1, Rh2, S1, and S2 atoms form a plane: their deviations from the least squares plane are very small (Fig. 1). There is no torsional angle between the two Rh–Rh bonds; thus, the four S atoms lie in the same plane. This provides further evidence for bonding interactions within the S_4 unit. The Rh–S distances (2.353(1) and 2.346(1) Å) in **2** are in good agreement with the sum of the covalent radii, which can be taken to be 2.35 Å using $[Cp^*_2Rh_2(\mu\text{-}CH_2)_2(CH_3)_2]$ (1.32 Å for Rh)[11] and S_8 (1.03 Å for S) as reference compounds. The above data strongly support the proposed structure with an S_4 unit. The structure of the S_4 ligand in **2** resembles that of cyclobutadiene (Fig. 2). The different cyclobutadiene framework of Se_4 has been found in $[W_2(CO)_{10}Se_4]^{2+}$ in which the two $[W(CO)_5(\eta^2\text{-}Se_2)]^+$ groups are linked by long Se–Se bonds (3.015(2) Å); each set of two selenium atoms, which forms a short Se–Se bond (2.213(2) Å), is coordinated to a W atom.[12] Complexes **2** contain the first example of a D_{2h} symmetric S_4 unit which has been determined by X-ray analysis. Interestingly, the geometry of the S_4 unit in **2** is similar to those of the neutral S_4 molecule calculated by both Raghavachari et al.[4a] and Morokuma et al.[13]

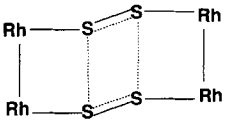

Fig. 2. The Rh_4S_4 framework of complexes **2**.

The character of the S–S bonds was further investigated by resonance Raman spectroscopy. The ν(S–S) and ν(Rh–S) stretching Raman bands were observed at 579 and 260 cm^{-1}, respectively, for an aqueous solution of **2a** · $3H_2O$. These modes are selectively resonance-enhanced with the excitations at 363.8 and 514.5 nm, respectively. Figure 3 shows resonance Raman spectra of **2a** · $3H_2O$ and of a sample enriched in ^{34}S in H_2O (excited at 363.8 nm). Since the band of [^{32}S] **2a** at

[**] We gladly acknowledge the award of a Japan Society for the Promotion of Science fellowship (A. V. de M.) and the World Bank for supporting this research.

579 cm^{-1} shows a down field shift of 15 cm^{-1} upon ^{34}S substitution (in close agreement with the expected shift ($\Delta\tilde{\nu}$ = 17 cm^{-1}) for the oscillator) we assign the band at 579 cm^{-1} to the ν(S–S) mode. Thus the $\tilde{\nu}$ value of **2a** is larger than those observed for disulfido complexes such as $[\{(CpRu(PMe_3)_2\}_2(\mu\text{-}S_2)](SbF_6)_2$, which has S–S double-bond character (530 cm^{-1}).[8a] The other ν(S–S) mode attributed to the weak S–S bond was not observed in the spectrum. This is in agreement with the calculations.[13] The band at 260 cm^{-1} of **2a** shows a slight ($\Delta\nu$ = 1–3 cm^{-1}) down field shift upon substitution with ^{34}S. This suggests the assignment of this band to the ν(Rh–S) stretch.

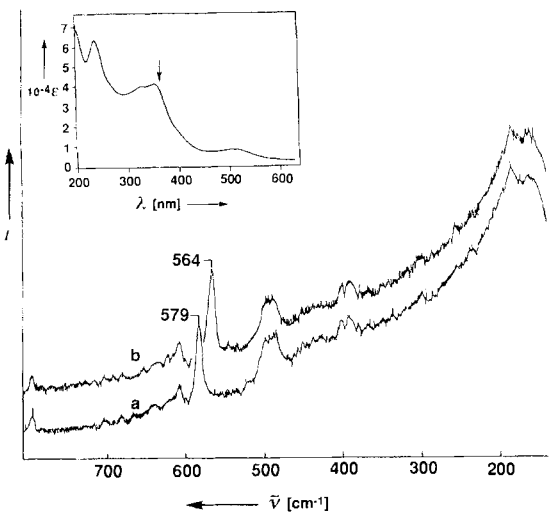

Fig. 3. Resonance Raman spectrum of **2a** · 3 H_2O at 25 °C in H_2O, excited at 363.8 nm: a) spectrum of $[^{32}S]$**2a** · 3 H_2O. b) spectrum of $[^{34}S]$**2a** · 3 H_2O. Inset: Electronic spectrum of **2a** · 3 H_2O at 25 °C in H_2O.

A simple formal charge comparison of **2** with that of the similar tetranuclear complex $[\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}CN)_2](PF_6)_2$[14] suggests that the S_4 unit has the charge of −2. Ab initio MO calculation, however, has revealed that the structure of the S_4 unit in **2** resembles that of the free neutral S_4 molecule.[13] This indicates that the rectangular isomer of neutral S_4 is stabilized in **2** by the appropriate arrangement of the Rh atoms. For instance, the length of the Rh–Rh bond (2.6618(4) Å) in the complex is almost as long as that of the long S–S bonds in the neutral S_4 rectangle.[4a, 13] Furthermore, the planar Rh_2S_2 framework and the lack of the torsional angle between two Rh–Rh bonds are requirements for the formation of the plane of the four S atoms.

Although the structure of the S_4 unit may change somewhat in the coordination sphere of a transition metal as compared to that of the free S_4 molecule,[13] our proposed structure should also be valid for other S_4 compounds[13] since our experimental results are consistent with calculations.

Compounds **1** are not oxidized in air in the absence of free H_2S. The use of excess H_2S may play an important role in formation of the $Rh(SH_2)$ species containing a framework such as $[Rh(SH)-Rh(SH_2)]^+$, in which the H_2S ligand attached to the cationic complex is most likely oxidized at first.[15] Although further experiments are needed to establish the mechanism for the oxidation, the reaction probably involves a three-electron process in which **1** is oxidized to **2**, and the oxygen is reduced to water [Eq. (a)].

$$2[Rh_2Cp^*_2(\mu\text{-}CH_2)_2(\mu\text{-}SH)]^+ + 2H_2S + 3/2\,O_2 \longrightarrow [\{Rh_2Cp^*_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]^{2-} + 3H_2O \quad \text{(a)}$$

Experimental Procedure

Preparation of **2a** · 3 H_2O and **2b**: To a suspension of $[Rh_2Cp^*_2(\mu\text{-}CH_2)_2Cl_2]$ (0.50 g, 8.7×10^{-4} mol) in CH_3OH (40 cm^3) was bubbled H_2S for 30 min at 23 °C. The resulting red-brown solution of **1a** was exposed to O_2 gas with stirring for 48 h (the first 24 h at −47 °C and then at room temperature) using a balloon of O_2. The resulting deep brown mixture was filtered to remove the white solid of S_8 and evaporated to dryness in vacuo. The residue was extracted with H_2O/CH_2Cl_2 (150/30 cm^3). The product of **2a** · 3 H_2O was isolated from the water phase after removal of the water under a reduced pressure at 40 °C (0.44 g, 3.5×10^{-4} mol, 81%). The addition of $NaBF_4$ (1.0 g, 9.1×10^{-3} mol) in water (30 cm^3) to the water phase quickly gave a crystalline precipitate of **2b** (0.48 g, 3.9×10^{-4} mol, 89%). Recrystallization of **2a** · 3 H_2O and **2b** from CH_2Cl_2/Et_2O yielded black crystals of **2a** · CH_2Cl_2 · 4 H_2O and **2b**, respectively.

The preparation of a sample of **2a** · 3 H_2O enriched in ^{34}S was carried out similarly by use of $[^{34}S]H_2S$ (93.7 atom%, 50 cm^3) in a closed system. Satisfactory analyses have been obtained for **2a** · 3 H_2O, **2a** · CH_2Cl_2 · 4 H_2O, and **2b**. NMR data of **2a** · CH_2Cl_2 · 4 H_2O: ^1H NMR (400 MHz, CD_2Cl_2, 23 °C, TMS): δ = 9.80 (s, 2H; μ-CH_2), 9.05 (s, 2H; μ-CH_2), 8.87 (s, 2H; μ-CH_2), 7.65 (s, 2H; μ-CH_2), 1.71 (s, 60H; Cp*); ^{13}C NMR (100 MHz, CD_2Cl_2, 23 °C, TMS): δ = 185.90 (t, ^1J(Rh,C) = 27 Hz; μ-CH_2), 176.54 (t, ^1J(Rh,C) = 26 Hz; μ-CH_2), 104.45 (s; C_5Me_5), 10.26 (s; $C_5\mathit{Me}_5$); ^{103}Rh NMR (12.6 MHz, CD_2Cl_2, 23 °C, Rh metal): δ = +1345.

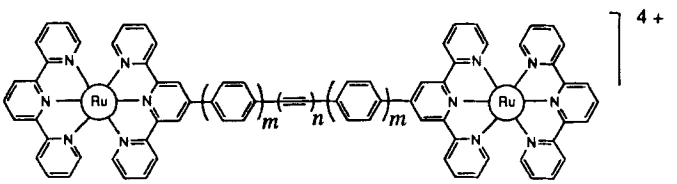
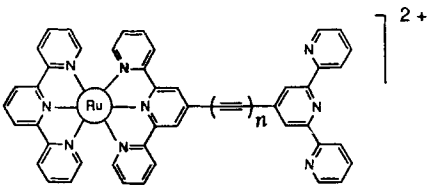
Electron Delocalization in Ethynyl-Bridged Binuclear Ruthenium(II) Polypyridine Complexes**

Andrew C. Benniston, Vincent Grosshenny, Anthony Harriman,* and Raymond Ziessel*



Photoactive transition metal chelate complexes figure prominently as chromophores in supramolecular systems where they are intended to promote long-range energy and/or electron transfers.[1] In order to ensure directionality it is necessary to construct rigid systems and, to increase the separation between components, it is desirable that the excited state is long lived.[2] The lifetimes of most luminescent metal chelates decrease with decreasing energy of the excited state.[3] However, for closely coupled binuclear complexes the triplet excited state lifetime may exceed the value expected simply on the basis of its energy level due to electron delocalization over an extended π^* system.[4-6] This can be a non-trivial effect and, for example, Meyer et al.[4] observed a 20-fold increase in triplet lifetime for a binuclear ruthenium(II) complex with respect to a corresponding mononuclear complex of comparable triplet energy. We have now observed even more pronounced temporal extension for certain ethynyl-substituted bis(terpy)-ruthenium(II) complexes (terpy = 2,2′:6′,2″-terpyridyl) in acetonitrile solution at 25 °C. Our strategy converts a poor sensitizer (i.e., the triplet lifetime is too short to facilitate long-range energy or electron transfer between weakly coupled reagents) into a potentially viable sensitizer. This finding is especially important because terpy is an ideal building block for construction of rigid supramolecular wires.

The ethynyl-bridged ruthenium(II) complexes (see Fig. 1) were synthesized by reacting, under mild conditions, the ditopic bis(terpy) ligands[7] with [Ru(terpy)(dmso)Cl_2] (dmso = dimethylsulfoxide).



Complex **1** has a distorted octahedral structure[8] and, relative to tris(bpy)ruthenium(II) **2** (bpy = 2,2′-bipyridyl), a short-lived triplet state,[9] due to mixing between charge-transfer and

[Ru(terpy)$_2$] **1** [Ru(bpy)$_3$]$^{2+}$ **2**

(higher energy) metal-centered states. Thus, in deoxygenated acetonitrile solution at 25 °C, **1** exhibits extremely weak luminescence with a maximum (λ_p) at 650 nm for which the quantum yield (Φ_p) is <0.0002 and the lifetime (τ_p) is (565 ± 35) ps. In contrast, luminescence from **2** is centered at 621 nm and is characterized by $\Phi_p = 0.06$ and τ_p = (980 ± 20) ns. Both triplets are readily observed by laser flash photolysis techniques, with lifetimes (τ_t) of (610 ± 40) ps and (960 ± 30) ns, respectively, for **1** and **2**. Covalent attachment of two bis(terpy)ruthenium(II) complexes through one or two ethynyl groups attached to the 4′-position, giving **3a** and **3b**, respectively (Fig. 1), causes a

3a : $n = 1$ $m = 0$
3b : $n = 2$ $m = 0$
5a : $n = 1$ $m = 1$
5b : $n = 2$ $m = 1$

4a : $n = 1$
4b : $n = 2$

Fig. 1. Structures of the discussed ethynyl-substituted Ru^{II} complexes (counterion: PF_6^-)

dramatic increase in triplet lifetime, phosphorescence yield, and emission maximum (Table 1). There is an almost 1000-fold increase in triplet lifetime for a single ethynyl bridge, despite the decrease in triplet energy that occurs, and an additional increase in lifetime for a double ethynyl bridge. The corresponding mononuclear complexes, **4a** and **4b**, also show increased lifetimes and luminescence yields and decreased triplet energies but the changes are less pronounced than observed with the binuclear complexes (Table 1). Interestingly, insertion of a phenyl ring

between terpy and ethynyl groups, giving **5a** and **5b**, causes the triplet lifetimes and luminescence yields to approach those recorded for **1** but, in particular, the lifetimes still remain significantly longer than that of the unsubstituted compound (Table 1).

The decreased rates of nonradiative deactivation observed for **3** and **4** relative to **1** are attributed to selective population of ligands possessing extended π^* orbitals.[4-6] Thus, upon excitation the electron is promoted to the ethynyl-substituted terpy ligand where it is delocalized over the extended π-electron system that includes both terpy subunits. This hypothesis is sup-

[**] This work was supported by the National Science Foundation (CHE 9102657) and the Centre National de la Recherche Scientifique.

ported by examination of the relevant absorption spectra: Thus, metal-to-ligand charge-transfer absorption maxima (λ_{max}) are apparent at 515 nm ($\varepsilon = 32800\ M^{-1}cm^{-1}$) and 457 nm ($\varepsilon = 15400\ M^{-1}cm^{-1}$) for **3a** and at 512 nm ($\varepsilon = 39300\ M^{-1}cm^{-1}$) and 453 nm ($\varepsilon = 20200\ M^{-1}cm^{-1}$) for **3b**, while a single maximum is observed for **1** at 470 nm ($\varepsilon = 16100\ M^{-1}cm^{-1}$). Comparison of the photophysical properties observed for **3** and **4**[10] suggests more pronounced electron delocalization in the binuclear complexes. Indeed, absorption and luminescence maxima are more red-shifted and triplet lifetimes are significantly longer for **3** than for **4**.

There is significant electronic coupling between terpy and ethynyl groups and among adjacent ethynyl groups. However, insertion of a phenyl ring into the π-electron system causes a substantial decrease in the magnitude of electronic coupling. This is evident from the less pronounced red-shifted absorption[11] and luminescence spectra, and from the shorter triplet lifetimes observed for **5** relative to **3**. Since it is known that electronic coupling between terpy and phenyl groups is significant in the ground state,[12] the decreased electronic communication found for **5** relative to **3** must arise from poor orbital overlap at the ethynyl–phenyl connection and not at the terpy–phenyl link. This may be due to poor spatial overlap of π* orbitals on the reactants or to an electronic factor.

Electron delocalization is also manifest in the triplet absorption spectra recorded after laser excitation at 532 nm. The triplet differential absorption spectrum recorded for **1** shows bleaching of the ground-state chromophore at 470 nm, a weak ligand-centered transition at higher energy, and very weak absorption stretching across the near infra-red region (Fig. 2a). In addition, **3a** and **3b** exhibit intense Gaussian-shaped absorption bands centered at 850 and 860 nm, respectively (Fig. 2b). These

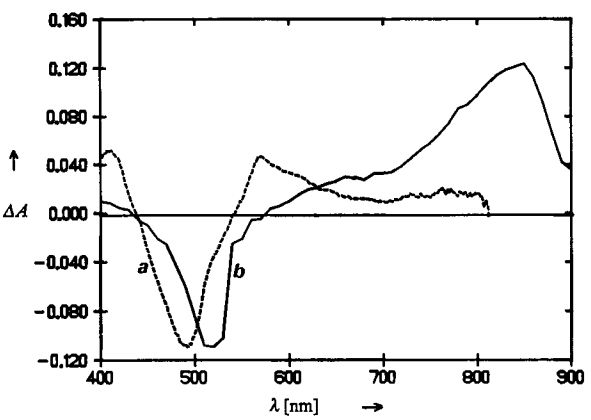

Fig. 2. Transient differential absorption spectra recorded (a) 50 ps after laser excitation of **1** and (b) 20 ns after laser excitation of **3a** in deoxygenated acetonitrile solution. Laser excitation was at 532 nm with a 30 ps pulse.

new bands arise from monophotonic excitation, and decay at a rate identical to that measured in the bleaching region or by emission. They are attributed to electron delocalization between the ethynyl-bridged terpy subunits. Comparable intervalence charge-transfer bands are observed for **4a** and **4b** at 595 and 630 nm, respectively, but not for the phenyl-bridged compounds **5a** and **5b**.

The enhanced triplet lifetimes observed for the ethynyl-substituted complexes can be attributed to selective population of the substituted ligand. Because of its lower energy, there will be less pronounced mixing of the charge-transfer state with the (higher energy) metal-centered state. Delocalization of the electron over an extended π*-orbital causes a reduction in the magnitude of electron–electron repulsion and a smaller nuclear displacement, which result in weakened overlap between vibronic levels in triplet and ground state manifolds.[13, 14] It is also noteworthy that addition of a second ethynyl group causes a further enhancement in triplet lifetime. This means that linear supramolecular systems might be constructed that could span a lipid bilayer but still retain a relatively long excited state lifetime.

Experimental Procedure

General procedure for preparation of the PF_6^- salts of **3a**, **3b**, **4a**, **4b**, **5a**, and **5b**. A stirred solution of $[Ru(terpy)(dmso)Cl_2]$ (2 equiv) and $AgBF_4$ (2.2 equiv) in Ar-purged CH_3OH (50 mL) was heated at 80 °C for 10 h. After cooling to room temperature, the deep red solution was filtered over cotton-wool and transferred via cannula to a CH_3OH (10 mL) suspension of the corresponding ditopic ligand [7] (100 mg scale, 1 equiv). During heating at 100 °C, complexation was evidenced by development of an orange coloration. After a few hours, the solution was filtered over Celite and NH_4PF_6 (10 equiv) in water (2 mL) was added. Slow evaporation of CH_3OH led to the precipitation of a deep red solid, which was filtered, washed with water and diethyl ether, and chromatographed (alumina, 3–10% CH_3OH/CH_2Cl_2). The resultant complexes were recrystallized from CH_3OH/toluene: **3a**, 25% yield, FAB-MS (*meta*-nitrobenzylalcohol (*m*-NBA)): *m/z* 1593 $[M^+ - PF_6]$. A Model for α-Keto Acid Dependent Nonheme Iron Enzymes: Structure and Reactivity of $[Fe^{II}_2(Me_2hdp)_2(bf)](ClO_4)$**

Yu-Min Chiou and Lawrence Que, Jr.*

α-Keto acid dependent nonheme iron enzymes[1] catalyze a variety of metabolic reactions involving the functionalization of an unactivated C–H bond, concomitant with the oxidative decarboxylation of the cofactor α-keto acid. A general reaction with substrate (A) proceeds according to Equation (a).

$$A + O_2 + RCOCOOH \longrightarrow AO + RCOOH + CO_2 \qquad (a)$$

Of the various enzymes in this category, only for the *Pseudo monas* 4-hydroxyphenylpyruvate (HPP) dioxygenase[2, 3] has an iron ligand been identified. The isolated enzyme is blue (λ_{max} = 595 nm, ε = 2600 $M^{-1}cm^{-1}$)[4] arising from a tyrosine-to-Fe^{III} charge-transfer transition on the basis of resonance Raman evidence;[5] the low energy of the transition further suggests that only *one* tyrosine is present in the iron coordination environment. Histidine residues are also proposed as ligands to the iron atom from the comparison of the amino acid sequences of enzymes in this class.[6]

In our first effort to model such enzymes, we have reported the properties of two benzoylformate complexes, **1** and **2**, which

$[Fe^{II}(6tla)(bf)](ClO_4)$ **1** $[Fe^{II}(tpa)(bf)](ClO_4)$ **2**

have pyridine-rich ligand environments.[7] These compounds react with dioxygen and undergo quantitative oxidative decarboxylation of the bound α-keto acid, but their reactions take place over a period of two days to a week. In light of the established coordination of the tyrosine residue in HPP dioxygenase, we have explored the effect of introducing a phenolato ligand on this chemistry and report our results in this communication.

The combination of the phenolate-containing tripodal ligand H-Me_2hdp,[8] NEt_3, Na(bf), and $Fe(ClO_4)_2 \cdot 6H_2O$ in MeOH affords complex **3**, from which orange prismatic crystals are obtained upon recrystallization from CH_3OH/Et_2O. Its X-ray structure[9] (Fig. 1) shows **3** to be $[Fe^{II}_2(Me_2hdp)_2(bf)](ClO_4)$, in which the two Fe^{II} centers are bridged by two phenolato ligands and the carboxylato group of the bf ligand. There is a pseudo twofold symmetry axis located at the center of the $[Fe_2(OR)_2]$ core. The Me_2hdp and bf ligands provide a six-coordinate, roughly octahedral ligand array about each iron atom. The Fe···Fe distance (3.049(2) Å) and Fe-O-Fe angles (93.2(2) and 91.6(2)°) are the *smallest* thus far reported for complexes with the generalized $[Fe^{II}_2(OR)_2]$ core,[10] most likely due to the presence of a third bridge, the bidentate carboxylato group of the bf ligand, between the iron(II) centers. This is the first example of such a triply bridged diiron(II) core, but related core structures are found among diiron(III)[11] and $Mn^{III}Mn^{(IV)}$[12] complexes.

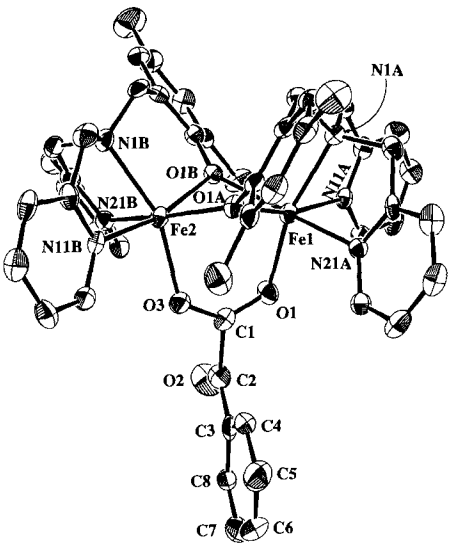

Fig. 1. ORTEP plot of the $[Fe^{II}_2(Me_2hdp)_2(bf)]^+$ ion of **3** (50% probability ellipsoids). Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe1-O1 2.104(6), Fe1-O1A 2.055(5), Fe1-O1B 2.205(5), Fe1-N1A 2.208(7), Fe1-N11A 2.163(7), Fe1-N21A 2.189(7), Fe2-O3 2.098(6), Fe2-O1A 2.140(5), Fe2-O1B 2.045(5), Fe2-N1B 2.211(6), Fe2-N11B 2.174(7), Fe2-N21B 2.200(7), Fe1···Fe2 3.049(2); Fe1-O1A-Fe2 93.2(2), Fe1-O1B-Fe2 91.6(2), O1A-Fe1-O1B 76.3(2), O1A-Fe2-O1B 78.0(2), O1-C1-C2-O2 83(1).

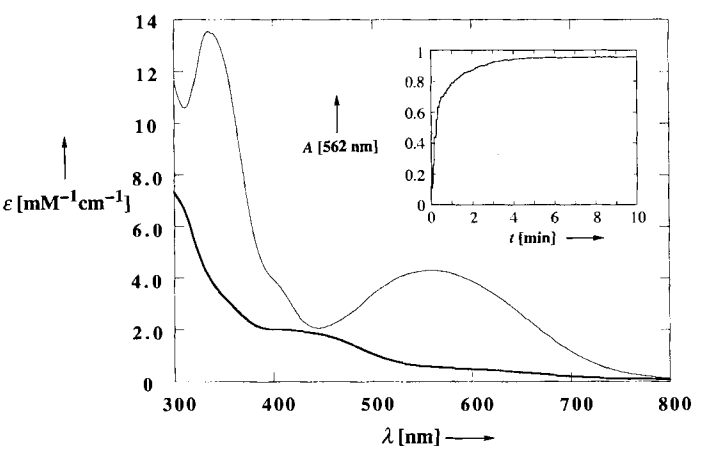
Exposure of the yellow-orange solution of **3** to air in CH_3CN *immediately* turns it purple-blue (Fig. 2); the UV/VIS features are similar to those of the previously reported $[Fe^{III}_2O(hdp)_2(O_2CC_6H_5)](BPh_4)$.[13] The low-energy absorption band (562 nm) is associated with a Ph-O^--to-Fe^{III} charge-transfer transition, which is red-shifted from that of its hdp-analogue (522 nm) due to the electron-donating methyl substituents. The positive-ion FAB mass spectrum of the oxygenated products shows signals at *m/z* at 913 and 941, corresponding to parent ions of $[Fe^{III}_2(O)(Me_2hdp)_2(O_2CC_6H_5)]^+$ (**4**) and $[Fe^{III}_2(O)(Me_2hdp)_2(bf)]^+$ (**5**), respectively. The presence of two distinct complexes was also confirmed by HPLC analysis of the isolated organic products which shows approximately equimolar amounts of benzoic acid and benzoylformic acid. Thus, about half of **3** undergoes oxidative decarboxylation upon exposure to dioxygen, while the remaining half simply autoxidizes.



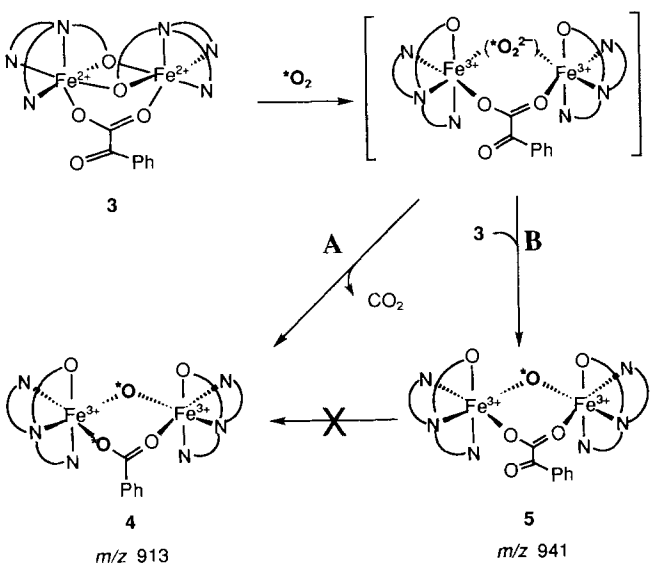


Fig. 2. UV/VIS spectra of **3** (bold line; λ_{max} = 450 nm (ε = 1800 $M^{-1}cm^{-1}$)) and its oxygenation products in CH_3CN (plain line) with features at 336 (ε = 13500), 410 (sh, ε = 3600), and 562 nm (ε = 4300 $M^{-1}cm^{-1}$). The inset shows the time-dependent change of the absorbance at λ = 562 nm at 20 °C upon exposure to O_2.

[**] This work was supported by the National Institutes of Health (GM-33162). We thank Professor Doyle Britton for his expertise in the X-ray diffraction experiments.—Abbreviations used: CI-MS = chemical ionization mass spectrometry; FAB-MS = fast atom bombardment mass spectrometry; bf = benzoylformate; hdp = 2-[(bis(2-pyridylmethyl)amino)methyl]phenolate; HPP = 4-hydroxyphenylpyruvate; Me_2hdp = 2-[(bis(2-pyridylmethyl)amino)methyl]-4,6-dimethylphenolate; 6tla = tris(6-methyl-2-pyridylmethyl)amine; tpa, tris(2-pyridylmethyl)amine.

To gain further insight into the mechanism, the reaction of **3** with dioxygen has also been carried out in $^{18}O_2$. FAB-MS results establish that both oxygen atoms from $^{18}O_2$ can be incorporated into **4**, as indicated in the isotope distribution of parent-ion envelope: *m/z* (%): 913 (2) $[[^{16}O_2]M^+]$; 915 (78) $[[^{16}O, ^{18}O]M^+]$; 917 (20) $[[^{18}O_2]M^+]$. The CI-MS of the isolated benzoic acid shows the incorporation of *one* ^{18}O atom in 84% yield, so the second ^{18}O is likely to be found on the μ-oxo bridge. The FAB mass spectrum shows only one ^{18}O atom is incorporated into complex **5**: *m/z* (%): 941 (68) $[[^{16}O]M^+]$; 943 (32) $[[^{18}O]M^+]$. Since the CI-MS data on the isolated benzoylformic acid shows no ^{18}O incorporation, the label incorporated in **5** must be on the μ-oxo bridge. The low level of isotope incorporation at the oxo bridges in **4** and **5** is probably due to the facile exchange with solvent water, as indicated in a parallel experiment carried out in $^{16}O_2$ with the addition of trace amounts of $H_2{}^{18}O$.[14]

Based on these results, we propose the mechanism shown in Scheme 1. Upon exposure to dioxygen, the iron(II) complex **3** is stoichiometrically converted to a (μ-peroxo)diiron(III) complex. Intramolecular nucleophilic attack of the bound peroxide at the α-carbon of the bf ligand results in the oxidative decarboxylation of this α-keto acid and the reduction of the peroxide to yield **4** (pathway A). In this pathway, complex **3** serves both as the reaction center and the substrate. Alternatively, this O_2 adduct can be reduced by a second molecule of **3** to afford the autoxidation product (**5**) (pathway B), as has been well documented for iron(II) porphyrins[15] and several nonheme iron(II) compounds.[16] The possibility that complex **5** converts to **4** upon exposure to O_2 can be excluded, since an acetonitrile solution of **5**, obtained by direct synthesis, remains unchanged in air for days (as monitored by ^{1}H NMR) without any formation of complex **4**. Therefore, iron(II) is required for the oxidative decarboxylation of the bf ligand.

Scheme 1. Proposed mechanism for the reaction of **3** with dioxygen in CH_3CN. The ligands are shown schematically. * = Isotopic labeling.

Complex **3** reacts with O_2 approximately three to four orders of magnitude faster than **1** and **2**. The inset in Figure 2 shows a pseudo-first-order increase of the absorbance at 562 nm at 20 °C, with k_{obs} of 2.8 min^{-1}. The facile oxygenation reaction of **3** may be due to two factors: the presence of the electron-rich phenolate which lowers the Fe^{III}/Fe^{II} redox potential and promotes the attack of dioxygen at the iron centers[17] and the presence of the dinuclear unit which facilitates reduction of O_2 to the peroxide state. However both factors also make the iron(II) centers much more susceptible to autoxidation, so the oxidizing equivalents generated in the reaction are used for the conversion of Fe^{II} to Fe^{III}, rather than substrate oxidation as in the cases of **1** and **2**. So the detailed mechanisms for the oxidative decarboxylation of the bound α-keto acid may differ for the mononuclear complexes **1** and **2** and the dinuclear complex **3**.

In HPP dioxygenase, the tyrosine ligand presumably facilitates the electrophilic attack of dioxygen as well, but the active site prevents formation of dinuclear complexes such as **4** and **5** to maintain its catalytic viability. Perhaps a sterically more hindered hdp-like ligand may prevent oxo-bridged dimer formation and form a mononuclear $[Fe^{II}(bf)]$ complex that reacts readily with O_2 to afford oxidative decarboxylation of α-keto acid and substrate oxidation. Further work in modeling α-keto acid dependent nonheme iron enzymes is in progress.

Experimental Procedure

Caution! Metal complexes with organic ligands and perchlorate ions are potentially explosive.

3: In an argon atmosphere, a solution of H-Me_2hdp (0.34 g, 1.0 mmol) and NEt_3 (0.10 g, 1.0 mmol) in MeOH was treated with $Fe(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1.0 mmol) to produce a light yellow solution. Addition of a solution of Na(bf) (0.09 g, 0.5 mmol) in MeOH afforded an orange solid upon stirring (75% yield). Recrystallization was accomplished by vapor diffusion of CH_3OH/Et_2O to yield diffraction quality crystals with the composition $3 \cdot CH_3OH$. Correct C,H,N analysis for $C_{51}H_{53}ClFe_2N_6O_{10}$.

5: H-Me_2hdp (0.34 g, 1.0 mmol) and NEt_3 (0.20 g, 2.0 mmol) were dissolved in MeOH (20 mL) and treated with $Fe(ClO_4)_3 \cdot 10H_2O$ (0.54 g, 1.0 mmol) in MeOH (1–2 mL) to afford a purple-blue solution. To this solution was added Na(bf) (0.09 g, 0.5 mmol). A purple-blue precipitate was obtained upon stirring (60% yield). Correct C,H,N analysis for $5 \cdot MeOH \cdot 3H_2O$: $C_{51}H_{59}ClFe_2N_6O_{14}$; positive-ion FAB-MS: *m/z*: 941 $[M^+]$.

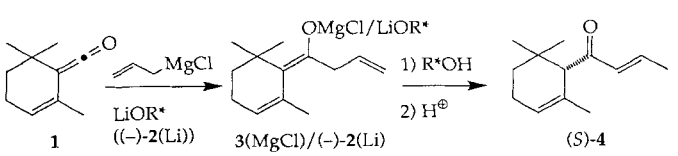
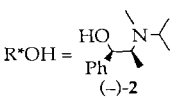
(and enolate-rich) at low conversion, as one equivalent of (−)-**2**(Li) is generated during this process. In order to test whether the enolate protonation is more enantioselective at low conversion, **3**(Li) was treated with 0.5 equivalents of (−)-**2** (−60 °C, 2 min) and the reaction mixture quenched with Me_3SiCl (2 equiv) (−60 → 20 °C, 30 min). Much to our surprise, no trace of **5** was detected; this indicated complete consumption of **3**(Li). Instead, approximately equal amounts of ketone (*S*)-**6** (94% *ee*) and the unexpected enol silyl ether (*S*)-**7** were formed.



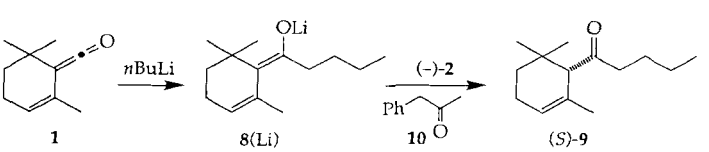


Scheme 1. "Autocatalytic" enantioselective protonation of **3**(Li).

Catalytic Enantioselective Protonation of Enolates

Charles Fehr* and José Galindo

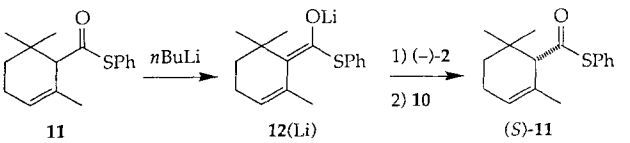
In 1988, we reported the efficient synthesis of enantiomerically pure (*S*)-α-damascone ((*S*)-**4**) by the Grignard reaction with ketene **1** followed by enantioselective protonation[1–7] of the mixed Li/Mg enolate complex **3**(MgCl)/(−)-**2**(Li) ($E/Z \approx 9:1$[8a]) with (−)-*N*-isopropylephedrine ((−)-**2**) (80–84% *ee*, 84% yield; 99% *ee* after crystallization, 55% yield).[1] Conversely, the analogous magnesium-free lithium complex **3**(Li)/(−)-**2**(Li) showed lower enantiofacial discrimination (65% *ee*), and the lithium-free magnesium enolates **3**(MgCl) and **3**(MgCl)/(−)-**2**(MgCl) gave less than 20% *ee*.



During further investigation of this reaction, we have found that protonation of the ligand-free enolate **3**(Li) ($E/Z \approx 98:2$[8a]), prepared from silyl enol ether **5**,[8b] with (−)-**2** affords (*S*)-**4** with excellent enantioselectivity (95% *ee*) (Scheme 1).[9, 10] Evidently, this protonation is only ligand-free

After purification by chromatography on silica (cyclohexane/ethyl acetate 99/1), (*S*)-**7** of high enantiomeric purity was isolated ($[\alpha]_D^{20} = -339$ ($c = 0.04$ in $CHCl_3$), 94% *ee*).[9] This enantioselective protonation is thus catalytic: the protonated intermediate (*S*)-**6** makes available an acidic proton (at C(2)) for the protonation of the chiral lithium alkoxide (−)-**2**(Li) ("autocatalytic system")[11] (Scheme 1). In a second experiment, **3**(Li) was protonated with 0.3 equivalents of (−)-**2** (−60 °C, 10 min), and the intermediate enolate (*S*)-**6**(Li) quenched with 5% aqueous HCl. Ketones (*S*)-**6** and (*S*)-**4** were obtained in 86% yield and 93% *ee* (from **5**).[12] This procedure certainly represents the most elegant access to the precious fragrance (*S*)-α-damascone ((*S*)-**4**).[13]

We then examined the enantioselective protonation of enolate **8**(Li), which was generated in situ from ketene **1** and *n*BuLi (1 equiv; THF, −100 → −70 °C) ($E/Z \geq 97.3$).[8a] With 1.1 equivalents of (−)-**2** (−70 °C, 2 min; −70 → −5 °C, 10 min), (*S*)-**9**[14] was obtained in 96% *ee* and 90% yield (Scheme 2).[10] However, with 0.5 equivalents of (−)-**2**, protonation was incomplete and afforded, after silylation and hydrolysis, (*S*)-**9** in 55% *ee*. The failure of "autocatalysis" is easily rationalized by the much weaker acidity of **9** (at C(2)) than that of **6**. To circumvent this problem, we then tested the combination of catalytic amounts of (−)-**2** with external achiral (or racemic) proton donors. Various CH-, OH-, and SH-acidic compounds, all of which are more acidic than **6** and **9** (at stereogenic center) by several orders of magnitude, were tested and shown to be effective.[15] For example, the catalytic enantioselective protonation of **8**(Li) with 0.2 equivalents of (−)-*N*-isopropylephedrine ((−)-**2**), followed by the addition of 0.85 equivalents of phenyl-2-



Scheme 2. Enantioselective protonation of **8**(Li) with stoichiometric or catalytic amounts of (−)-**2**.

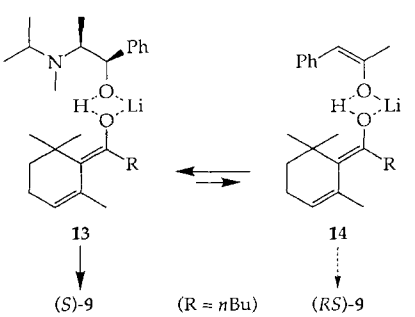
Telefax: Int. code + (22) 780-3436



propanone (**10**), afforded (*S*)-**9** with 94% *ee* and 94% yield,[16] and use of 0.1 equivalent of (−)-**2** gave (*S*)-**9** with 85% *ee*.

The aforementioned concept was also successfully applied to the protonation of thiol ester enolate **12**(Li).[2, 3] The following example is described in a patent application from 1992,[3] and is the first published enantioselective enolate protonation with substoichiometric amounts of chiral proton donor. Racemic thiol ester **11** was deprotonated with 1.5 equivalents of *n*BuLi in THF/hexane at −100 °C. The resulting enolate **12**(Li) was protonated with (−)-**2** (0.5 equiv). Slow addition of **10** (1.55 equiv) in THF (40 min), stirring at −100 °C (75 min), and gradual warming to −10 °C (25 min) afforded (*S*)-**11** in greater than 98% *ee* and 81% yield. Thus, diminishing the amount of (−)-**2** from 2 equivalents[2a] to 0.5 equivalents results in less than 1% loss of enantioselectivity.[17]

11 **12**(Li) (*S*)-**11**

As proposed in previous publications,[2] we suggest that a tight transition state-like complex **13** is formed. This chiral enol/enolate "hybrid" (simplified representation)[18] undergoes an irreversible stereocontrolled C protonation. Complex **13** (R = *n*Bu) can be formed directly by proton transfer from **10** to a chiral enolate complex **8**(Li)/(−)-**2**(Li).[18] Alternatively, the enolate **8**(Li) may be O-protonated by **10** to give an achiral complex of type **14** (or the enol).[19] If the conversion of **14** to (*RS*)-**9** is much slower than that of **13** to (*S*)-**9**, rapid equilibration of achiral complex **14** (or the enol) and chiral complex **13** ensures successful enantioselective C protonation. Presumably, the nitrogen of (−)-**2** participates in and accelerates this proton transfer.

13 **14**

(*S*)-**9** (R = *n*Bu) (*RS*)-**9**

Experimental Procedure

(*S*)-**9**: A solution of **1** (1.0 g, 6.66 mmol) in THF (20 mL) was cooled to −100 °C (Et_2O, liquid N_2) and treated with 1.5 M *n*BuLi in hexane (4.60 mL, 6.66 mmol). The temperature was slowly raised to −70 °C (30 min). Then (−)-**2** (0.275 mg, 1.33 mmol) in THF (3 mL) was added in 1 min (−70 → −60 °C). This was followed by dropwise addition of **10** (0.76 g, 5.70 mmol) in THF (5 mL) over 8 min. The temperature was allowed to reach −5 °C over 30 min. The mixture was poured into stirred 5% aqueous HCl and extracted with Et_2O. The organic phase was washed successively with H_2O, saturated $NaHCO_3$, and saturated NaCl, dried (Na_2SO_4), evaporated, and twice distilled bulb-to-bulb (oven temperature 40–70 °C/0.05 Torr). A mixed fraction of (*S*)-**9** and **10** (1.41 g; 850 mg of (*S*)-**9**), and 450 mg of pure (*S*)-**9** ($[\alpha]_D^{20} = -449$ (*c* = 0.03 in $CHCl_3$), 94% *ee*) were obtained.[9] Yield: 94%. Basification of the acidic aqueous phase allowed quantitative recovery of (−)-**2**. [1–3]

[8] a) *E*/*Z* ratios determined by NOE experiments on the corresponding silyl ethers. b) **5** (*E*/*Z* ≈ 98:2) was obtained by fractional distillation (b.p. 80 °C/2 Torr).
[9] Determined by gas chromatography on either permethylated β-cyclodextrin in OV-1701 or a Megadex column (Megadex Capillary Columns Laboratory, Legnano, Italy).
[10] (*Z*)-free enolate is expected to give ≥98% *ee* (experiments underway).
[11] In a control experiment, (*S*)-**6** does not protonate **3**(Li) enantioselectively in the absence of (−)-**2**.
[12] Lower amounts of (−)-**2** gave a slower and less selective reaction.
[13] Other syntheses: K. Mori, M. Amaike, M. Itou, *Tetrahedron* **1993**, *49*, 1871, and ref. [1] and [2a].
[14] $[\alpha]_D^{20} = -454$ (*c* = 0.04 in $CHCl_3$). Determination of absolute configuration: (*S*)-α-cyclogeranic acid [2a] was converted into the acid chloride ($(COCl)_2$, CH_2Cl_2, 0 → 20 °C); alkylation by addition of *n*BuLi (THF, −78 °C).
[15] For the test experiments, **8**(Li) (prepared from **1** and *n*BuLi at −78 °C) was successively treated at −50 °C with (−)-**2** (0.5 equiv) and an achiral (or racemic) proton donor (0.5 equiv): (±)-**6** (94% *ee*), phenyl-2-propanone (**10**) (94% *ee*), (±)-ethyl 2-acetyl-4-methyl-4-pentenoate (93% *ee*), ethyl acetoacetate (90% *ee*), thiophenol (90% *ee*), 2,6-di-*tert*-butyl-4-methylphenol (90% *ee*), H_2O (90% *ee*), pivalic acid (90% *ee*), acetic acid (85% *ee*).
[16] Likewise, use of easily accessible (+)-**2** [1] afforded (*R*)-**9** (94% *ee*).
[17] With 0.2 equivalents of (−)-**2**, (*S*)-**11** was obtained with 81% *ee*.
[18] Possibly, these complexes are further aggregated with chiral or achiral ligands (see ref. [2c]).
[19] When an equimolar mixture of **10** and **8**(Li) was stirred at −50 °C for 15 min, and quenched with Me_3SiCl, the only silyl enol ether isolated was (*Z*)-1-phenyl-2-trimethylsilyloxy-1-propene. The catalytic, enantioselective protonation of **8**(Li), followed by silylation, affords the same (*Z*)-silyl enol ether. A mechanism invoking prior proton exchange between (−)-**2**(Li) and **10** is less likely, as preliminary experiments have shown that these proton transfers are slow and unselective (*E*/*Z* mixtures after silylation).

Unchallenged Excellence in Inorganic Chemistry

Houben-Weyl. Methoden der Organischen Chemie. Band E 15, Teile 1–3. En-X- und In-X-Verbindungen. 4th Edition, supplementary volumes. Edited by *H. Kropf* and *E. Schaumann*. Thieme, Stuttgart, 1993. Part 1: pp. 1–1200, Part 2: pp. 1201–2530, Part 3: pp. 2531–3946, hardcover DM 6600.00, subscription price DM 5940.00.—ISBN 3-13-218504-3/3-13-797504-2/3-13-797604-9

The Houben-Weyl series of over 100 volumes has an unchallenged position at the peak of excellence in the secondary literature of chemistry. This high standard is based on a unique combination of comprehensiveness (practically every known compound class and reaction type is covered by a volume of Houben-Weyl), reliability (errors are rare), and consistency (the arrangement of the contents follows the same principles in all the volumes). It can be said at the outset that these supplementary volumes on ene-X and yne-X compounds entirely fulfill one's high expectations based on the earlier volumes.

Supplement E 15, which is in three parts and is the work of 26 authors, treats the full range of activated multiply-bonded systems that result from substitution by one or more oxygen- or nitrogen-containing groups. Part 1 begins with a lengthy chapter by H. Frauenrath on enol derivatives (enol esters, acetals, and ethers), followed by chapters on alkenyl hydroxyamines (K. Bott), boroenol ethers (A. Pelter), silylenol ethers (S. Pawlenko), and metal derivatives of enols (G. Klar, R. Kramolowski). The second half of Part 1 is devoted to alkene derivatives with one nitrogen-containing substituent, including detailed chapters on enamines (P. Rademacher), enehydrazines (A. J. Bittner, P. Rademacher), enazides (K. Banert), nitrosoalkenes (K. Bott), azoalkenes (J. G. Schantl), and nitroalkenes (E. Haslinger).

Part 2 is mainly concerned with 1,1- and 1,2-disubstituted alkenes with oxygen- and/or nitrogen-containing groups as substituents. There are chapters on derivatives of 1,2-enediols and 2-aminoenols (H. Kropf, F. Wöhrle), oxocarbones and semioxocarbones (H. Frauenrath), and ketene acetals and their derivatives (C. G. Bakker, J. W. Scheeren, H.-G. Heinen, W. Kantlehner et al.). Substantial contributions on ketenes (E. Schaumann, S. Scheiblich), ketene imines (H. Perst), and heteroketene acetals (H.-G. Heine, W. W. Mergen, W. Kantlehner) form the end of Part 2 and the beginning of Part 3. This continues with chapters on mono- and diheteroketenes (E. Schaumann, S. Scheiblich), tetraheterosubstituted alkenes (H.-G. Heine), and heterosubstituted allenes and butatrienes (R. W. Saalfrank, C.-J. Lurz, K. Banert). The volume ends with a detailed treatment of ynol ethers and ynamines by G. Himbert.

The arrangement of subject matter within the chapters follows the usual pattern. First the methods of preparation of a class of compounds are described in detail, with a distinction between methods based on synthesizing the carbon skeleton and those in which it is already available from elsewhere; in contrast conversion reactions are only described for representative examples. There are frequent cross-references to other Houben-Weyl volumes, and the work includes a comprehensive bibliography, a subject index arranged in the usual way, and (especially pleasing) an author index. The formula schemes are excellent, especially where stereochemical details have to be shown. The use of bold type to highlight the structural feature under discussion is very useful. Despite a thorough search I found scarcely any printing errors (an exception is Si instead of S on p. 598). The style of writing too is mostly above reproach; the few minor slips (such as that on p. 466: "Acidität der Enolform") are excusable. On the other hand, the terms regio- and stereoselectivity and regio- and stereospecificity have not always been used with the necessary care (pp. 176, 432, 461). From the standpoint of reaching an international readership it is, of course, a disadvantage that this supplement, like all its predecessors in the Houben-Weyl series, is in German. The editors' expressed intention to follow the example of Beilstein by publishing the fifth edition in English is therefore to be welcomed.

What other improvements could be made? In the view of this reviewer, the identification of sections by a mixture of Roman and Arabic numerals and of Latin and Greek letters is confusing and irritating; this is more of a hindrance than a help in finding one's way around the work, and should be replaced by a consistent decimal classification in future volumes. A more worrying problem is the use of the special Houben-Weyl nomenclature, which sometimes reveals serious deficiencies. For example, α,β-unsaturated ketones are described throughout the world as enones, but in Houben-Weyl they are called 3-oxo-alkenes. Consequently there is no entry in the index for 2-cyclohexenone. Another criticism is that the reader is subjected to a flood of unnecessary hyphens (e.g., "Chlor-trimethyl-silan"). However, these shortcomings do not detract from the very favorable overall verdict on Supplement E15: its perfection fully meets the high standard of Houben-Weyl, and no chemistry library that is to be taken seriously can afford to be without it.

Asymmetric Synthesis of Natural Products. By *A. Koskinen*. Wiley, Chichester, 1993. 234 pp., paperback £ 16.95.—ISBN 0-471-93848-3

A wide choice of titles on asymmetric synthesis and stereochemistry by well-known authors has recently appeared in the books market. This seems to be a common phenomenon when an area of research reaches a certain stage in its devel-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

opment at which it is worthwhile to review the overall picture and take stock. Such a situation applies in the case of this book by Ari Koskinen, in which he describes methods for asymmetric synthesis, illustrated by examples of successes in the field of natural products. The development of such methods has now reached a stage which is leading not just to individual applications but to progress in natural products syntheses on a broad front, and this in turn is contributing positively to advances in basic principles.

In his introduction the author is concerned to impress on the reader the importance of natural products chemistry, especially by describing examples in the field of pharmaceuticals. The enormous variety of natural products is well illustrated by dozens of structures which, like the schemes appearing later in the book, are excellently drawn and well set out. The examples range from very simple odor and flavor substances through pheromones and antibiotics to complex molecules such as cyclosporin, vitamin B_{12}, and palytoxin. The author offers his readers (or listeners, since the book is based on a lecture series) a highly original selection of examples with the aim of stimulating their interest in the subject. The brief sketch of the history of natural products in medicine (regrettably only four pages long) also contributes to that aim.

This is followed by a short (26-page) account of the basic principles of stereochemistry, explaining the concepts of chirality, topology, and asymmetric synthesis. The author evidently wished to ensure that the reader's understanding of the subsequent chapters should not be hindered by a lack of knowledge of the fundamentals of stereochemistry and nomenclature. In the limited available space he has been able to cover only the basic essentials of conformational analysis and the stereochemical descriptors. Nevertheless, the use of the terms *threo* and *erythro* is discussed, as well as examples of nonlinear effects. Thus the book is intended mainly for readers who already have some familiarity with the basic ideas of stereochemistry. It is pleasing to find that stereoelectronic effects are treated from a modern standpoint using clearly presented orbital models.

Chapter 3 (55 pp.) describes basic methods of asymmetric synthesis. Here again the treatment is limited to the essentials, covering reactions of carbonyl groups (nucleophilic addition, alkylation, enolate chemistry, Michael addition) and of olefins (epoxidation, hydroxylation, hydroboration, and the Diels–Alder reaction). The introduction to the effects of steric hindrance ("allylic strain") on the course of reactions and to the Cram and Felkin–Anh models could appropriately have been included in the first chapter. However, these topics have been very skillfully and effectively incorporated into the next section on reductions and alkylations of carbonyl compounds. The basic principles of the Felkin–Anh model are treated too briefly; experience has shown that students have difficulty in understanding the distinction between this and the Cram model. I also feel that the Sharpless epoxidation and enantioselective *cis*-hydroxylations should have been covered in more detail in view of their dominant role as reagent-controlled reactions. The Corey model to explain the high enantioselectivity of *cis*-hydroxylations should be well within the scope of advanced students, and also provides a good teaching opportunity for explaining the principles of catalysis in asymmetric reactions. The surveys giving formulas with the most important reagents, catalysts, and ligands, together with the names of the relevant authors, are very useful. In many cases typical *ee* values that can be obtained are also given. Here, however, it would have been helpful to include short tables showing the range of selectivities actually achieved.

The fourth and longest chapter (126 pp.) describes examples of syntheses of natural products in the areas of carbohydrates, amino acids and peptides, nucleosides and nucleotides, polyketides, isoprenoids, shikimic acid, and alkaloids. Here again, rather than assuming previous knowledge, the author explains the structure, biosynthesis, and pharmacological importance of each class of substances. Synthetic reaction schemes with detailed explanations of the individual steps are generally accorded an importance equal to that of descriptions of important compounds belonging to the class under discussion. A rigid and systematic connection with the earlier method-orientated chapters is not attempted; instead these are to be regarded as setting the scene and preparing the reader. In a book of this limited size the range of examples cannot, of course, be very comprehensive, but the author has skillfully presented a very good selection. This main part of the book can be regarded as a short introduction to modern natural products chemistry which is complete in itself.

Considering the wealth of information presented and the many structures shown, the incidence of errors has been kept reasonably low. Most of these are trivial; however the omission of the free radical dots in describing the mechanism of the endiin antibiotics (p. 13) makes this difficult to understand. This very reasonably priced book can be thoroughly recommended for all undergraduate and graduate students, as well as researchers and lecturers, who wish to learn about modern trends in natural products synthesis.

Two Books on Solid Catalysts

Organic Chemistry Using Clays. By *M. Balogh* and *P. Laszlo*. Springer, Berlin, 1993. 184 pp., hardcover DM 188.00.—ISBN 3-540-55710-5

Catalysis over clays is an attractive alternative to the well established conventional chemical methods for many chemical transformations. The applications of clays in organic synthesis are summarized here in 17 chapters, each illustrated with formula schemes and supported by a comprehensive and up-to-date bibliography. The book is intended for organic as well as catalysis chemists.

Chapter 1 is concerned with electrophilic aromatic substitutions. The main emphasis is on alkylations, halogenations, and nitrations of arenes. Chapters 2 and 3 describe various types of addition and elimination reactions, respectively. Chapter 4 is devoted to oxidation of hydrocarbons and alkyl groups, ammoxidation reactions, dehydrogenation of aliphatic hydrocarbons, and oxidation of alcohols, thiols, sulfides, and amines. Chapter 5 deals with two types of aromatization reactions, including, for example, dehydrogenation of cycloalkanes. Chapter 6 deals with the hydrogenation of carbon–carbon multiple bonds, hydrogenation of aromatic rings, and reduction of carbonyl and other functional groups. Chapter 7 discusses the use of montmorillonite and bentonite clays in the synthesis of hydrocarbons and heterocyclic compounds. Diels–Alder reactions are known to be catalyzed by Lewis acids, and the use of clays as catalysts for these reactions is described in Chapter 8. The importance of clays in isomerization reactions is illustrated in Chapter 9. Chapter 10 deals with the dimerization of alkenes, reactions of heterocycles, and oxidative couplings of arenes. Montmorillonite, super-filtrol, and clayfen catalysts are used for these reactions. The next chapter is concerned with rearrangement reactions of arenes, illustrated by well chosen examples. Chapter 12 discusses the con-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1818-1892 $ 10.00+.25/0

densation reactions of alcohols and thiols, coupling reactions of aromatic compounds, and aldol condensations. Chapter 13 deals with the thermal and hydrolytic decomposition of a wide variety of pesticides, which is very important from the viewpoint of protection of the environment; examples of the degradation of pesticides and decomposition of organic peroxides are discussed. Chapter 14 summarizes reactions of carbonyl compounds, the CO group being probably the most versatile functional group in organic chemistry. The reactions described include the formation of acetals and ketals, condensation reactions with amines and anilines, Knoevenagel condensations, and carbonyl group deprotection. Reactions of carboxylic acids and derivatives with alcohols, arenes, and ethylene are described in Chapter 15. Chapter 16 describes synthesis of amino acids, polymerization of amino acids, reactions of nucleotides, and formation of peptides from amino acid adenylates. Lastly, Chapter 17 contains the miscellaneous reactions which are not discussed in the previous chapters. The book ends with a glossary and subject index.

Balogh and Laszlo have produced a book that sets new standards. They inform the readers expertly, comprehensively, and without unnecessarily lengthy detail about the capabilities and range of applications of the various clay catalysts described. The book is nicely written and each chapter contains a separate list of references. It can be recommended unreservedly for the chemist working in academia or industry who wants detailed information about the applications of clay catalysts in organic synthesis.

Zeolite, Clay and Heteropoly Acid in Organic Reactions. By *Y. Izumi, K. Urabe* and *M. Onaka*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. 166 pp., hardcover DM 128.00.—ISBN 3-527-29011-7/1-56081-700-3

This book by Y. Izumi, K. Urabe and M. Onaka describes the applications of solid catalysts in organic reactions. It contains three chapters with 350 references, giving a detailed survey of the state of research on this topic up to the end of 1991.

The first chapter comprises three sections giving a brief introduction to organic reactions on zeolites and montmorillonite clay. Each section (except the introduction) is divided into subsections discussing different reactions. The topics covered are the use of acid and base sites of zeolites in the *O*-alkylation of alcohols to ethers, *N*-monoalkylation of aniline derivatives, ring opening of epoxides, regioselective bromination with adsorbed bromine on zeolite, aldol reactions, Michael addition reactions, addition of ester enolates to ynoates, and carbon–carbon bond forming reactions.

Chapter 2 is devoted to clays which are potential catalysts in organic synthesis. After a short introduction to clays, this chapter discusses the structure and composition of clays, factors determining their catalytic efficiency, and new catalytic aspects of synthetic clays. Other topics covered are the selective hydroisomerization of n-hexane, selective dehydrogenation of cyclohexane, selective etherification of n-butyl alcohol, selective hydrolysis of chlorobenzene to phenol, and metathesis reaction of propene.

Chapter 3 discusses the usefulness of heteropoly acids in organic synthesis. This chapter describes the fundamental chemistry of heteropoly acids, and their uses in acid–base and redox molecular catalysis for various types of organic reactions.

The authors have succeeded in providing the reader with a lot of information regarding organic reactions over solid catalysts. The summary tables, reaction schemes, and literature references make it easier for the reader to get more deeply involved in this wide-ranging field of research and facilitate quick access to the original papers.

The book is a useful addition to the literature on zeolite, clay, and heteropoly acid in organic reactions. To those who are seriously interested in organic reactions using solid catalysts, I can recommend reading this neat and well written book.

Comprehensive Handbook on Hydrosilylation. Edited by *B. Marciniec*. Pergamon, Oxford, 1992. 754 pp., hardcover £ 150.00.—ISBN 0-08-040272-0

This book edited by Bogdan Marciniec is an extension of the Polish version of *Hydrosilylation*, published in 1981. The present monograph aims to provide a complete coverage of the literature from 1965 up to the beginning of 1990. Over 1360 literature references and 750 patents are included. The volume is divided into two parts. The first part is a critical survey of the scope and application of hydrosilylation reactions. The second part is a truly extensive tabulation of published hydrosilylation reactions from 1965 to 1990.

Part I consists of six chapters which deal with the systematic trends of the hydrosilylation reaction, focusing on catalyst, silane, and unsaturated substrate. Chapter 1 is a very brief introduction discussing the rationale and organization of the subject matter and its relation to other reviews in the field. Chapter 2 is a survey of mechanistic aspects of the hydrosilylation reaction including free radical, acid and base catalysis, and transition metal catalyzed reactions. Chapter 3 deals with the reactivity of the major classes of unsaturated organic compounds and their utility in the synthesis of organosilicon compounds. This chapter is organized by compound class with separate discussions of alkenes, dienes, alkynes, carbonyls, and other functional groups. The effects of substituents on the organosilane reagents with regard to reaction rate and regio- and stereoselectivity are described in Chapter 4. The chapter also includes practical applications to the synthesis of organosilicon monomers. Chapter 5 is a short discussion of the hydrosilylation reactions of unsaturated organosilicon compounds, which are important both as models for activated curing processes and as routes to the synthesis of carbosilane oligomers and polymers. Finally, Chapter 6 covers some practical applications of the hydrosilylation reaction including the role of organosilanes as coupling agents and as reducing agents for organic substrates. The use of hydrosilylation in polymer modification is also discussed. The topics covered in Part I are very generously illustrated by examples, but sometimes these get in the way of the guiding principles. Also numerous typographical errors, nomenclature lapses, and hard-to-read figures make this section of the book difficult for browsing or casual reading.

Part II of this volume is a nearly exhaustive compilation of hydrosilylation reactions from 1965 to 1990, and includes both literature and patent references. The 425 pages of data are organized into tables which list initial reagents, reaction conditions (catalyst, temperature, time, solvent, etc.), products with yields, and references. The primary division of the tables is according to trisubstituted silanes of increasing complexity (Si, C, and H numbers), followed by the type and complexity of unsaturated organic substrates (C and H numbers). The table is keyed to a separate bibliography giving the appropriate literature references. Patents are identified not only by the patent number

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/1818-1893 $ 10.00+.25/0*

but also by an abstract number in *Chemical Abstracts* or *Ref. Zh. Khim.* Also included in this part of the volume is a key to abbreviations for solvents and functional groups and a glossary containing structural diagrams for some of the more complex organic substrates and products. Perhaps one of the greatest weaknesses of this type of tabular presentation is the constant need to move back and forth between the main table and the supporting glossaries. This is particularly relevant since many of the abbreviations are nonstandard (for example, *c* stands for chloroform), and for complex structures it is necessary to constantly refer to a glossary for structures which are identified only by numbers in the main table. However, this tabulation is a commendable feat and many will find this section of the book by far the most useful.

The treatment of hydrosilylation in the first six chapters is largely by detailed examples, and consequently it would not be a good introduction for the novice and should not be used as a textbook. However, the wealth of information which is presented in this volume should be of tremendous value to the practitioner of the hydrosilylation reaction, whether it be in an industrial or academic setting. As such, this book is an indispensable reference source.

Iron–Carbene Complexes. (Series: Scripts in Inorganic and Organometallic Chemistry, Vol. 1.) Edited by *W. Petz*. Springer, Heidelberg, 1993. 202 pp., paperback DM 68.00. —ISBN 3-540-56258-3

The celebrations were premature! Anyone who hoped that this new series from the Gmelin-Institut für Anorganische Chemie would make it possible to build up a "home Gmelin" at a realistic and affordable cost will be bitterly disappointed. The initial concept, which is again stated in the preface to the first volume of this series, sounds very good: "...the new Gmelin series will review selected areas of inorganic and organometallic chemistry in textbook style. It will provide the lecturer, the advanced student, and the research chemist with a digest of the main features of each topic." As the first topic the publishers have chosen iron–carbene and iron–vinylidene complexes in which the iron atom also has a η^5 ligand (C_5H_5 or one of its derivatives). This is a sensible restriction when one considers that the systematic preparation and study of Fischer carbene complexes has now been going on for nearly thirty years, and it is no longer realistic to expect the whole of this extensive subject, with all the possibilities of central metal atom and substitution pattern, to be covered in a single monograph. The area treated here corresponds exactly to the volume of the original *Gmelin-Handbuch der Anorganischen und Metallorganischen Chemie* with the title "Organoiron Compounds B16a", containing about 260 pages.

To anyone familiar with the density of data in Gmelin, the task of producing a "digest of the main features" of this subject must seem rather like trying to write a short summary of the national postcode index. Practically all the shortening needed to compress the subject into 200 pages for the new publication *Iron–Carbene Complexes* has been achieved by taking out the formula index completely and eliminating all the literature references and the journal citations from the text of the original Gmelin (although, curiously, on the bottom line of p. 168 the last of the references has survived the massacre of its brothers).

However, this has severely reduced the book's potential readership. Specialists working on iron or other carbene complexes, after a first nibble at a topic, need to be given direct access to the original publications. One can perhaps envisage the book being used as a quick reference source for spectroscopic and X-ray structural data, but this use is greatly hindered by the incompleteness of the numerical data and the lack of a detailed overall index. Lecturers and students seeking a general overview of carbene complexes (or even one confined to iron as the central metal atom) will quickly abandon this book, since despite the declared aim of producing a work in "textbook style", this is clearly not that but a collection of data. The few general comments included at the beginnings of individual chapters are either too superficial or so brief that they cannot be understood without relevant previous knowledge.

In this connection one must also mention the many printing errors. In many cases parentheses are either missing or too many in number, and more seriously there are numerous spelling mistakes and incorrect formulas, sometimes altering the meaning. Examples are "$RHC{=}CNCH_3$" instead of $RHC{=}NCH_3$ (p. 32) and "Cp-(CO)(^{2}D)FeC=CH" instead of Cp(CO)-(^{2}D)FeC≡CH (p. 55), and on page 122 a rotational barrier is given as 7712 kJ/mol instead of 77 ± 2 kJ/mol. The "one-protein resonances" referred to on page 104 are presumably one-proton resonances.

There are also many errors in the figures. In Figures XII and XIII (p. 54) the cyclopentadienyl ligand is shown as "H_5C_6" instead of H_5C_5, and the Fp-containing sidechain of compound XXVIII on page 98 has an extra carbon atom. Although errors such as these only cause a shake of the head, the incorrect caption "(*S,S*)-chiraphos" under Figure IV (p. 184), which actually shows the *R,R* isomer, is inexcusable. Other errors that need no further comment are the description of the diastereomeric complexes VII and VIII (p. 27) as "enantiomeric cations", and the labeling of the abscissa in the figure on page 55 as "Wavenumber in nm".

Another source of annoyance is the lack of a glossary explaining the abbreviations used in the book, as also are the repeated explanations of familiar compound name abbreviations (e.g., dppe on pages 7, 10, 47, 178, 181, and 182), and the use of the same abbreviation for different groups (e.g., Fp* is used to represent $(C_5Me_5)(CO)_2Fe$ on pp. 104, 124, and 125, $(C_5H_4Me)(CO)_2Fe$ on pp. 117 and 123, and $(C_9H_7)(CO)_2Fe$ on pp. 123 and 124). The cross-references too show little sign of having been carefully checked. As well as references to the wrong chapters (pp. 114, 126, 158, 167), there are others mentioning chapters that do not even exist (pp. 152, 158, 197) and methods of preparation that are not given ("Method IV" on pp. 118, 121). These and many other errors are quite unacceptable, especially in a book of only 202 pages.

The verdict after looking through *Iron–Carbene Complexes*, which is also to be regarded as an initial sample for the new series *Scripts in Inorganic and Organometallic Chemistry*, is clear. By carrying out some intensive work on correcting the errors, providing a formula index for the whole work, and including all the references to original publications, the authors and the publishers would be performing a valuable service, not least to themselves.

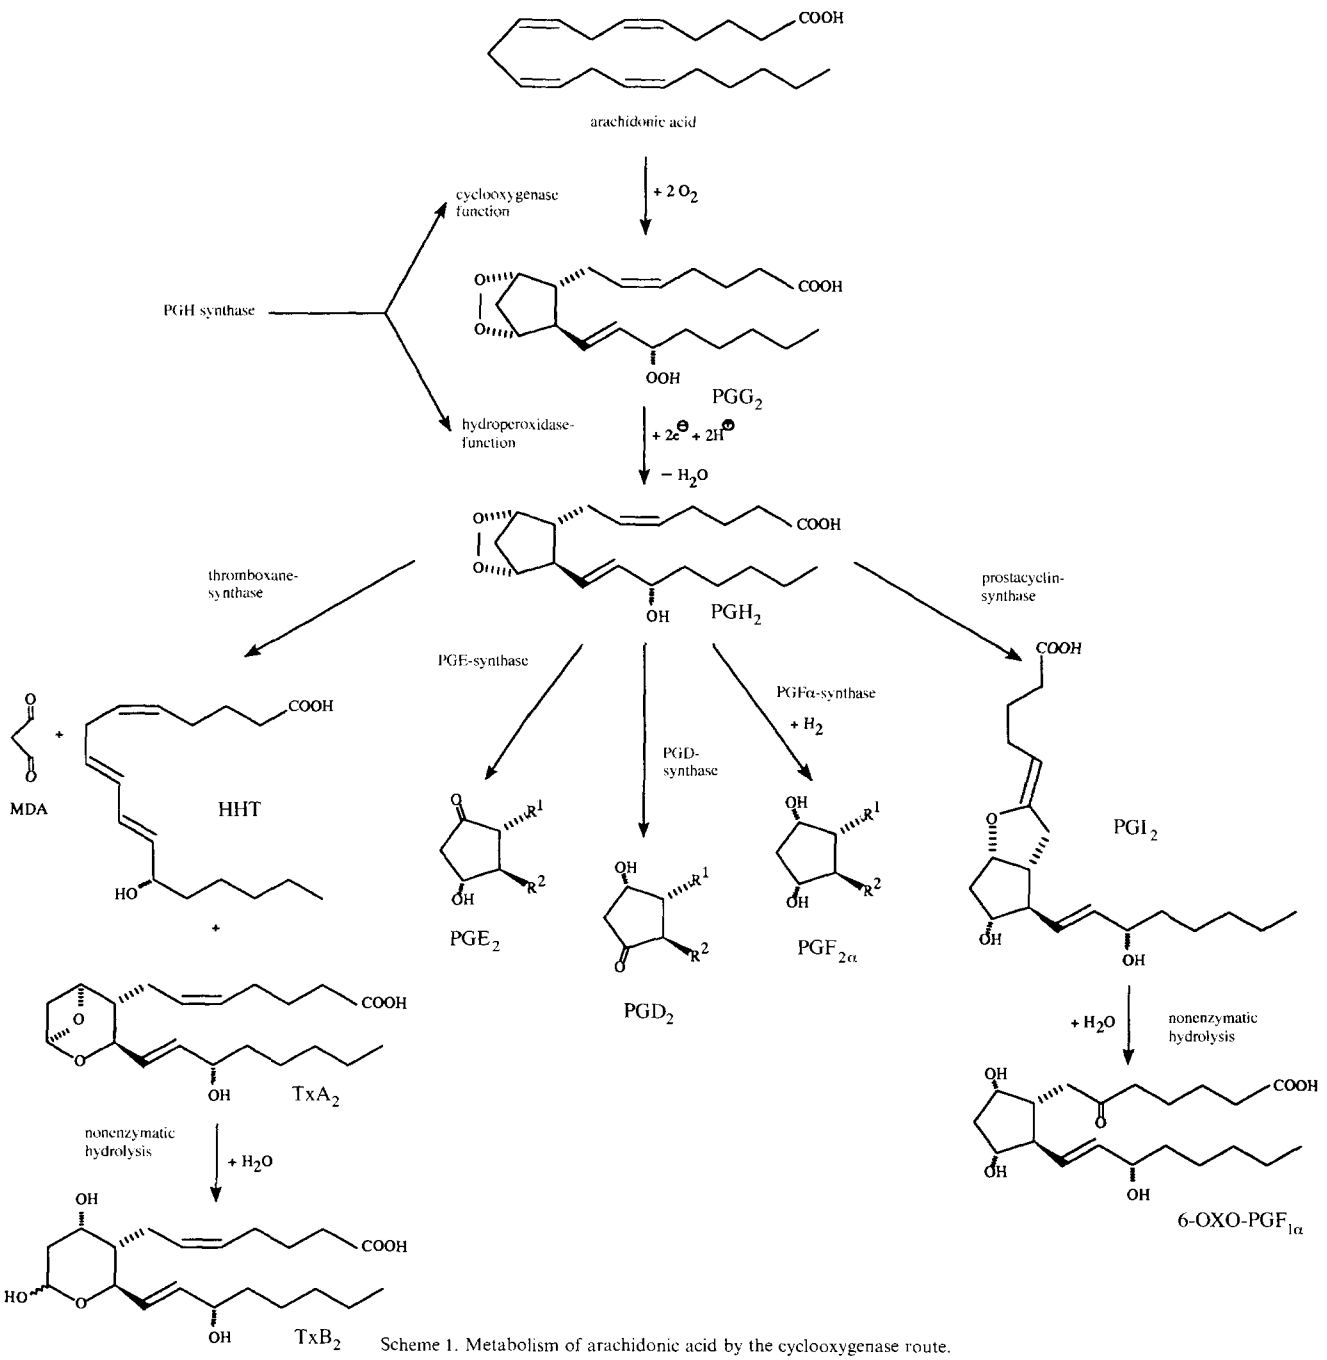
Prostacyclin and Thromboxane Synthase: New Aspects of Hemethiolate Catalysis

Volker Ullrich* and Roland Brugger

The arachidonic acid metabolites thromboxane A_2 and prostacyclin are highly potent regulators of cell physiology. They are both formed by enzymatic rearrangement of the 9,11-epidioxy prostaglandin H_2 catalyzed, however, by thromboxane and prostacyclin synthase, respectively. The two enzymes have been isolated, sequenced, and characterized as hemethiolate ("P450") enzymes. The different isomerization products can be explained on the same catalytic principle by a different ligation of the heme centers with the two epidioxy oxygens atoms. This requires different conformations for substrate binding at the active site, which is substantiated by the different inhibitors and amino acid sequences of the enzymes. In a hypothesis which has mechanistic principles in common with the P450-monooxygenases and the allene oxide synthases, oxy radicals are formed first and rearrange to carbon radicals. These could then rapidly be converted into carbocations by the ferrylthiolate or iron(III)thiyl structures formed as intermediates.

1. Introduction

The prostaglandins form a family of signalling molecules that communicate between cells of a given organ (autacoids). They mediate key events in inflammation, autoimmune diseases, or shock syndromes, but also in physiological regulation associated with growth, differentiation, parturition, or sleep (for reviews see [1–7]). Hence pharmacological research has focused on their pathways of biosynthesis and inhibition, and also on their mode of action. Like steroid hormones, prostaglandins are not stored and secreted but synthesized and released on demand. They are formed and degraded much more rapidly than steroids, and since they act exclusively within organs, only their degradation products rather than active prostaglandins can be found in blood or serum. Because of this and their low concentrations in tissues, the analysis, the structural evaluation and the chemical synthesis of prostaglandins have been a challenge (for reviews see [8–9]).



The biosynthetic pathways in higher organisms start out from arachidonic acid (5*Z*, 8*Z*, 11*Z*, 14*Z*)-icosatetraenoic acid), which on account of its four double bonds and abundance of allylic hydrogens offers a large biosynthetic potential.[10] Arachidonate is readily available from biological membranes after activation of phospholipases. The second step is then the conversion of arachidonate into 15-hydroxy-9α,11α-epidioxy-prosta-5,13-dienic acid (PGH_2).[11] This requires two enzymatic activities, that of cyclooxygenase and of a hydroperoxidase, which are colocated on PGH-synthase (see Scheme 1).

The detailed mechanism of PGH-synthase is still unknown, but the initial step of the cyclooxygenase reaction must involve hydrogen atom abstraction at C-13 of arachidonic acid, followed by isomerization with shift of the radical to C-11, dioxygenation, cyclization, and a second dioxygenation at C-15.[11] The resulting 15-hydroperoxyl radical is then reduced to the hydroperoxide (PGG_2) by the initially abstracted hydrogen atom. Thus, we are dealing with a radical reaction that is initiated, propagated, and terminated at the active site of cyclooxygenase. We shall meet this elegant principle of shielded radical catalysis at active sites of enzymes again with thromboxane and prostacyclin synthase.

The PGH_2 molecule contains the relatively weak epidioxy bond that can be opened for subsequent isomerization reactions leading to the five different prostaglandins (Scheme 1). It is obvious that prostaglandins D_2 and E_2 are formed after a heterolytic cleavage of the O–O bond by a nucleophilic mechanism. However, the biosynthesis of prostacyclin (PGI_2) and thromboxane (TxA_2) with the formation of the oxygen-containing heterocycles appears more complex. After labeling experiments with ^{18}O had established the isomerization character of both reactions,[12,13] mechanisms of heterolytic cleavage of the epidioxide and rearrangements to TxA_2[14] and PGI_2[15] have been proposed. Such chemistry requires an efficient stabilizing catalyst to prevent carbonyl formation from the positively charged oxygen atom. This led us to suggest an involvement of heme since heme containing thiolate ligands in the cytochrome P450 monooxygenases can transfer oxygen atoms from hydro-

Scheme 1. Metabolism of arachidonic acid by the cyclooxygenase route.

Volker Ullrich, born on September 5, 1939, in Wetzlar/Lahn, Germany, studied chemistry at the University of Giessen from 1958 to 1962 (Diplom under P. Ehrlich on nitride halides of barium) and obtained his doctorate in 1964 under Hj. Staudinger. He spent terms for research at the University of Philadelphia (R. W. Estabrook) and in Dallas before habilitating in the Faculty of Medicine at the University of Giessen in 1969 on the mechanism of monooxygenases. In 1971 he accepted the chair of Physiological Chemistry in the Faculty of Medicine at the University of the Saarland and in 1983 at the University of Constance, where he also was Prorektor from 1991 to 1993. He is active in the Deutsche Forschungsgemeinschaft and member of the Gesellschaft Deutscher Chemiker and the European Society of Biochemical Pharmacology among others. His main research interests are the chemistry and biochemistry of oxygen and their implications in the pharmacological field.

peroxides to organic substrates.[16, 17] This working hypothesis could be verified by making use of the characteristic P450 spectra which allowed us to isolate the two isomerases for converting PGH_2 into TxA_2 and PGI_2.[18]

In this review we briefly summarize our data and those of other groups, and focus on a comparison of the two enzymes that share a substrate and a catalytic site but form two different products with entirely different, and even antagonistic, pharmacological properties; PGI_2 is a potent vasodilatory and platelet-antiaggregatory prostanoid, whereas TxA_2 is vasoconstricting and strongly platelet-aggregating.[2] Our results have suggested biosynthetic mechanisms for the two compounds that have led to new insights on the principles of hemethiolate catalysis for other enzymes of this superfamily.

2. Isolation and Spectral Characterization

PGI_2 is primarily produced by the endothelium of blood vessels,[19] which therefore served as the starting material for purification.[20] In accordance with literature, the PGI_2-synthesizing enzymatic activity was associated with the endoplasmic reticulum obtained as the microsomal cell fraction.[21] Difference spectroscopy indeed revealed the presence of a P450 (= hemethiolate) protein with its characteristic carbon monoxide difference spectrum at 450 nm after treatment with sodium dithionite.[22] Enzymatic reduction by $NADPH_2$ could not be observed, which indicates that the P450 protein could not act as a monooxygenase. Solubilization of porcine aortic microsomes with detergents resulted in still active preparations, which could be further purified by affinity chromatography on a column packed with a stable CH_2–O analogue of PGH_2 (U46619),[23] by immunoaffinity chromatography,[24] or by classical methods (R. Brugger, unpublished). This purified fraction from the aorta yielded a homogeneous protein after SDS-polyacrylamide gel electrophoresis with a molecular weight of about 52 kDa and a PGI_2-synthase activity of about $3\ s^{-1}$.[25] Other enzyme parameters are listed in Table 1.

Thromboxane A_2 is released from blood platelets, which are thus a suitable starting material for the isolation of the isomerase. Hammarström and Falardeau[28] have already used it when they localized the synthesizing activity in the microsomal fraction. We identified a P450 protein in the same fraction, solubilized it with detergents, and further purified it to homogeneity.[29] On SDS gels it showed a band at 59 kDa and converted PGH_2 into TxB_2, the stable hydrolysis product of TxA_2. TxB_2 has a molecular activity of about $27\ s^{-1}$. Since the enzyme forms a second product, as will be discussed later, the molecular activity has at least to be doubled.

Table 1. Properties of PGI- and TxA-synthases.

	PGI synthase [23–25]	TxA synthase [25–28]
molecular weight, SDS gel [Da]	52000 (bovine), 49200 (porcine)	58800 (human), 53000 (porcine)
molecular weight from sequences	56600 (bovine) [a]	60500 (human), 58220 (murine)
$\lambda_{abs.}$ [nm] (ox.)	417, 532, 568	418, 537, 570
$\lambda_{abs.}$ [nm] (red. + CO)	424, 451, 545	424, 450, 545
g-tensors (EPR spectrum)	2.42, 2.25, 1.90	2.41, 2.25, 1.92
isoelectric points [pH] [b]	4.8–5.0 (bovine), 5.1 (porcine)	4.8 (human)

[a] T. Tanabe, S. Hara, A. Miyata, R. Brugger, V. Ullrich, unpublished. [b] R. Nüsing, R. Brugger, V. Ullrich, unpublished. [c] TxA_2 + HHT.

It is well established that the heme group in cytochrome P450 monooxygenases is linked to the thiolate group of a cysteine residue, which causes unusual spectral characteristics in the optical and the EPR spectra.[30–34] The spectral features in Figure 1 were redrawn from data published on the most thoroughly investigated camphor 5-monooxygenase from *Pseudomonas putida*.[35, 36]

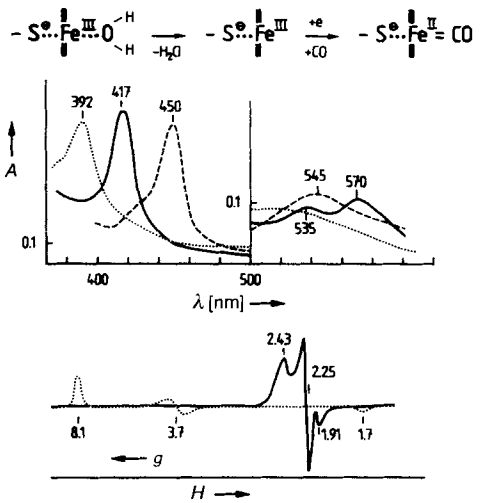

Fig. 1. Spectral characteristics of intermediates in reactions of cytochrome $P450_{CAM}$. Visible spectrum: —— Fe^{III}–H_2O complex, ····· five-coordinate high-spin Fe^{III}, ---- Fe^{II}–CO complex.

The oxidized iron(III) cytochrome P450 is low spin with an unusually narrow splitting of the g-tensor.[37] The Soret band of this species peaks at 417 nm, and by a comparison with heme models[38] as well as from the X-ray structure of $P450_{CAM}$,[39, 40] it contains water at the sixth coordination site. Upon addition of their substrates, which are generally lipophilic, the spectra of P450 monooxygenases change dramatically: EPR shows that the blue shift of about 26 nm in the Soret band is due to the generation of a high-spin five-coordinate iron center.[41] Upon reduction by sodium dithionite in the presence of carbon monoxide, the Soret band shifts to 450 nm. Denaturation of the protein or protonation of the thiolate ligand leads to inactive "P420" enzymes with Soret bands at 420 nm where they are located in most hemoproteins.[42]

Both PGI-synthase and TxA-synthase contain one heme molecule per polypeptide chain and show exactly the same optical and EPR properties as P450 monooxygenases, except that addition of the substrate PGH_2 does not cause the conversion into a high-spin complex, probably because the water ligand is replaced by the epidioxide ligand. In agreement with this assumption, only very subtle spectral changes are observed.[22] As shall be mentioned later, certain other substrate analogues are able to generate the complex containing a five-coordinate iron center.

Hence, all properties of a catalytic hemethiolate site are present in both isomerases. In agreement with the postulated role of the heme, it remains in the Fe^{III} state and need not be reduced enzymatically since no reduction of O_2 is required, in contrast to the P450 monooxygenases. Even the chemical reduction by dithionite in the presence of CO is slow and incomplete.

3. Amino Acid Sequences of the Enzymes

According to the spectral data, PGI- and TxA-synthases clearly belong to the hemethiolate superfamily of enzymes, which includes an ever-growing number of more than a hundred monooxygenases.[43] According to the proposed nomenclature, different families of hemethiolate proteins are defined when the amino acid sequence homology is less than 40%, an arbitrarily chosen value.

The sequences of these synthases were recently established in cooperation with the group of T. Tanabe in Osaka.[44] Human TxA-synthase has 533 amino acids, with homologies to several P450 enzymes but not exceeding 36% as established with human nifedipine monooxygenase (P450IIIA4). This was independently confirmed by Ohashi et al.[45] The recently published sequence of the murine enzyme showed 78% homology with that of the human protein.[26]

Interestingly, cysteine 479 could be identified by alignment as the ligand likely to coordinate to the heme group, and the 10 amino acids toward the N terminus from this cysteine were found to be identical with those of human steroid-17α monooxygenase from adrenals. Thus the P450 or hemethiolate nature could also be verified by the sequence data, and TxA-synthase can be considered as the first and so far only member of a new P450 family.

The sequence of PGI-synthase was expected to be highly interesting, since the use of the same substrate as TxA-synthase suggested a close relationship. The 500 amino acids exhibited a moderate homology of 31% with human cholesterol 7α-monooxygenase. Since only one cysteine was present close to the C terminus, the thiol group that binds heme must belong to this amino acid. The sequence around this heme binding site had some homology with several other P450 monooxygenases and with TxA-synthase. Very surprisingly however, the total homology between PGI- and TxA-synthase was only 16%, which is a statistical value. Therefore PGI-synthase also forms a new family within the hemethiolate proteins, and no phylogenetic relationship seems to exist between the synthases despite their close functional relationship. This was puzzling, but since the enzymes generate two different products from the same substrate, the clue to the unexpected differences could reside in a different folding of the active site. Indeed, inhibitor studies indicate large differences in the substrate binding site.

4. Substrates and Inhibitors

Since at present neither X-ray studies nor two-dimensional NMR spectroscopy are possible for either enzyme, conclusions with regard to substrate binding and the catalytic mechanisms must come from indirect evidence. Chemical modifications of the substrate PGH_2 and their spectral interactions with the heme chromophore, as well as inhibitor studies, provide sufficient information on the active site and the mechanisms involved.

In Table 2 substrates and products for the two enzymes are compared. The main physiological substrate is certainly PGH_2, which is fully converted into prostacyclin and detected as its hydrolysis product 6-oxo-$PGF_{1\alpha}$.[46] It has long been known that TxA-synthase forms not only TxA_2, but also (12*S*)-hydroxy-(5*Z*,8*E*,10*Z*)-heptadecatrienoic acid (HHT) plus malondialdehyde,[47] in fact to a similar or even greater extent (see Scheme 1). Since the latter products are also derived from a chemical fragmentation of the PGH_2 molecule with transition metal ions, they were not at first considered to be formed by the enzyme. However, the isolated enzyme as well as the enzyme expressed in the baculovirus system also generate 50–70% of fragmentation products.[48] Hence HHT is indeed an enzymatically generated product, and any proposed reaction mechanism must include its formation.

Table 2. Substrate specificity and metabolites of PGI- and TxA-synthases.

Substrates	TxA-synthase metabolites		PGI-synthase metabolites	
PGH_1	–	HHD	..	HHD
PGH_2	TxA_2	HHT	PGI_2	–
PGH_3	TxA_3	Δ^{14}-HHT	PGI_3	..
PGG_2	15-OOH-TxA_2	12-OOH-HHT	15-OOH-PGI_2	–
8-*iso*-PGH_2	–	8-*cis*-HHT	..	8-*cis*-HHT
(13*S*)-PGH_2	..	(10*S*)-HHT	–	..
15-oxo-PGH_2		KHT	15-oxo-PGI_2	KHT

A pharmacologically interesting substrate is PGH_3 (identical to PGH_2 except for an additional double bond between C-17 and C-18), which is the cyclooxygenase product of icosapentaenoic acid. Both isomerases can use PGH_3 as a substrate and convert it into PGI_3 or TxA_3. The latter acts as weaker agonist on the TxA_2-receptor for the contraction of smooth muscles and for platelet aggregation.[49] PGI_3 exhibits a similar potency to PGI_2. Therefore, a fish oil diet rich in icosapentaenoic acid has been claimed to have beneficial effects for patients susceptible to cardiac infarct.[50] Interesting results are observed with the corresponding PGH_1 (identical to PGH_2 except for the lack of the double bond between C-5 and C-6). A prostacyclin PGI_1 cannot be formed since the essential Δ^5 double bond is lacking. However, the fragmentation products (12*S*)-hydroxy-(8*E*,10*E*)-heptadecadienoic acid (HHD) and malondialdehyde are formed exclusively with a molecular activity of about 30 s^{-1}, that is, about ten times faster than PGI_2 from PGH_2. Surprisingly, as reported in the literature,[14, 51] TxA-synthase cannot convert PGH_1 to TxA_1 but again only to HHD and malondialdehyde. A chemical reason for the importance of the Δ^5 double bond is not evident in this case, but it is assumed that the carboxylate side chain would be a very sensitive determinant for substrate fixation at the active site. Interestingly, the molecular activity of thromboxane-synthase with PGH_1 is about the same as for TxA_2 plus HHT formation from PGH_2. This finding supports the view that HHT is derived from a common intermediate and suggests that for TxA-synthase the cleavage of the O-O bond is

rate-limiting, whereas for the slower reaction in the case of PGI-synthase, the kinetic limitation occurs at a later step. Further important information can be derived from use of the isomer 8-*iso*-PGH_2 as a substrate, which leads only to the fragmentation products and therefore documents how crucial the correct placement of the α side-chain is for the ring closure reaction of PGH_2 to give PGI_2.

Complementary information was obtained from inhibitor studies. Efforts to synthesize TxA-synthase inhibitors as highly specific platelet-antiaggregatory drugs has led to a variety of tightly (mostly stoichiometric) binding compounds. From the structure–activity relationships of these substances the orientation of the PGH_2 substrate at the active site of TxA-synthase could be deduced.[52, 53] Invariably, all tightly binding inhibitors contain a basic nitrogen atom that coordinates to the sixth ligand position of the iron center of the heme, and a lipophilic side chain containing a carboxylate group that extends about 10 Å at an angle of about 60° from the heme plane (Fig. 2).

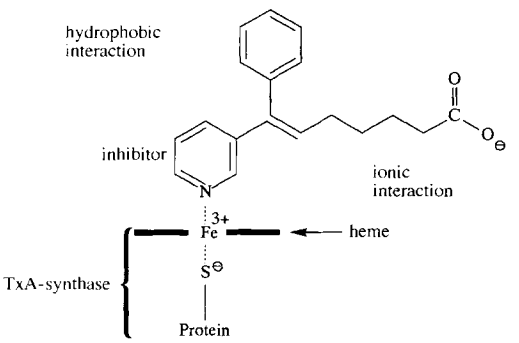

Fig. 2. Binding of inhibitors to the sixth coordination site of TxA-synthase.

From these studies developed the concept that the PGH_2 molecule binds with the epidioxy bridge at the iron atom, and that the side chain occupies the same position as the carboxylate side chain of the inhibitors. Among all compounds tested, the complex between the heme protein and a pyridine derivative with an appropriate carboxylate side chain in the *ortho* position did not display the typical N-ligand binding spectrum but a Soret band at 390 nm, indicative of a high-spin five-coordinate iron center. Such spectral behavior is in accord with weak binding to the active site but not to the heme iron because of steric hindrance of the *ortho*-substituted pyridine moiety. Since the spectrum indicates a free sixth ligand position, the endogenous ligand was obviously displaced. This ligand is probably a water molecule, which has been detected by X-ray analysis in the spectrally identical camphor monooxygenase.[39, 40]

According to spectra, none of the inhibitors of TxA-synthase, not even imidazole or simple pyridine derivatives, interact with PGI-synthase to inhibit this enzyme.[25, 53] This certainly is the prerequisite for their potential therapeutic application, since otherwise the beneficial effects of PGI-synthase would also be eliminated by TxA-synthase inhibition. Conclusions about the steric architecture of the active site of PGI-synthase are possible: low affinity for imidazole or pyridine ligation indicates a very limited space at the sixth coordination position of the iron center. A cyclopropylamine derivative (*trans*-2-phenylcyclopropylamine) was reported as an inhibitor of PGI-synthase, and, according to the spectral shifts, must coordinate through the nitrogen atom. Another nitrogen-containing compound, minoxidil (6-(1-piperidyl)-2,4-diaminopyrimidine-3-oxide), induces similar spectral changes and high binding affinity (K_S = 2.4 μM), but its inhibition of enzyme activity is weak (IC_{50} = 90 μM).[54] From these two examples of N-ligands it can be concluded that the sixth coordination site of iron in PGI-synthase is accessible only for nitrogen compounds with side chains extending almost perpendicular to the Fe–N coordination axis. Applied to the binding of PGH_2 to the active site, this conclusion implies an antiparallel orientation of the carboxylate and alkyl side chains; hence a completely different stereochemical conformation for PGI-synthase and TxA-synthase active sites would result (Fig. 3).

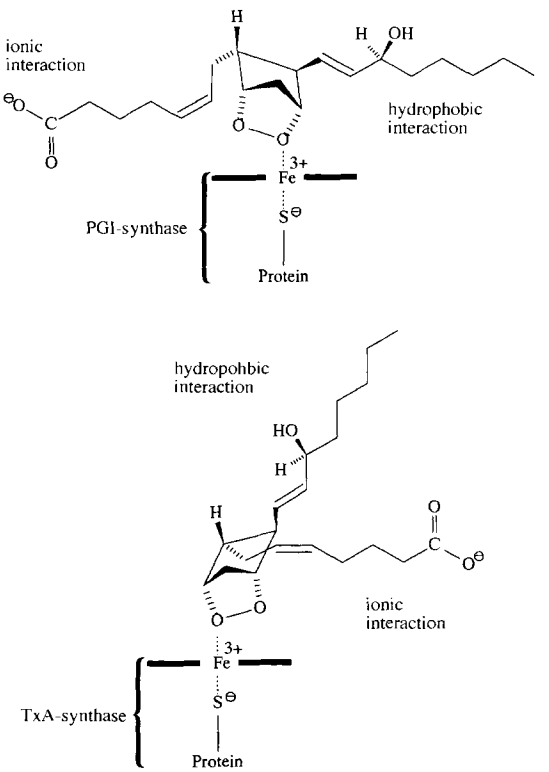

Fig. 3. Binding of the substrate to the active sites of PGI- and TxA-synthases.

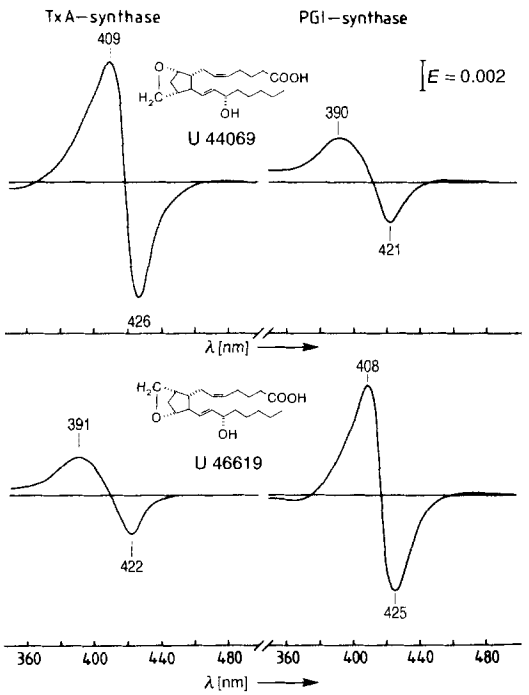
5. Mechanistic Studies and Hypotheses

All attempts to explain the mechanisms of rearrangement from PGH_2 to PGI_2 or TxA_2 must start out with a cleavage of the O-O bond. A heterolytic cleavage leads to a positively charged oxygen atom either at C-9, which could easily form PGI_2,[15] or at C-11 to yield TxA_2.[14] No experimental evidence for a polar mechanism could, however, be obtained,[55] and indeed, the generation of a charged oxygen atom at the active site without immediate isomerization of PGH_2 to PGD_2 or PGE_2 would be highly unlikely.

The remaining mechanism of homolytic cleavage of the O-O bond was first postulated by Turner and Herz,[56] whose pro-



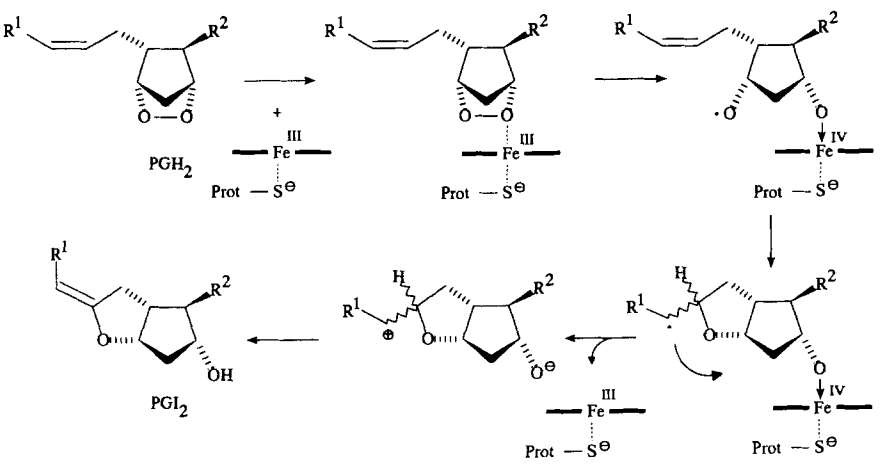


Fig. 4. Difference spectra (visible range) of complexes from solubilized TxA- and PGI-synthase and the PGH_2 analogues U44069 and U46619.

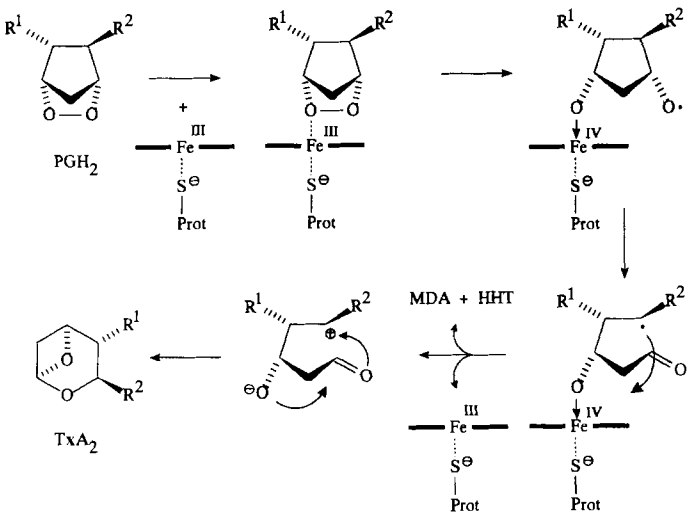
posed splitting agent was Fe^{II}. The resulting Fe^{III} ion could serve as the oxidizing agent for the conversion of the intermediate radical at C-5. The assumption that iron is the catalyst for the epidioxy cleavage was compatible with our later discovery of a hemethiolate group at the active site, but a reduction of Fe^{III} in the heme can be excluded. Either the electron-donating properties of the Fe^{III}–hemethiolate group facilitated heterolytic splitting and the stabilization of a positive oxygen atom,[57] or the homolytic cleavage was assisted by the Fe^{III} form. Spectral investigations with stable PGH_2 analogues[25] demonstrated indirectly that homolytic cleavage was more likely.

The concept of stable substrate analogues as inhibitors of the PGH_2 isomerases seemed reasonable and had led to the early synthesis in pharmaceutical research of several analogues of PGH_2, including among others U46619 and U44069, in which the O–O group was substituted by a CH_2–O bridge.[58] These two isomers inhibited both PGI- and TxA-synthase, but influenced the spectra differently (Fig. 4).[25] Whereas U46619 produced a ligand-type difference spectrum with TxA-synthase, U44069 resulted in a typical "high-spin" spectrum with a peak at 390 nm. With PGI-synthase the situation was reversed. From this it could be concluded that the Fe^{III} ion coordinated to the 9-position in TxA-synthase but to the 11-position in PGI-synthase.[25]

If PGH_2 and its analogues bind tightly, the replacement of a coordinating oxygen atom by a methylene group would result in a five-coordinate iron center as in the enzyme–substrate complexes of P450 monooxygenase.[32]

Because of this unexpected discrimination of the two epidioxy oxygen atoms by both enzyme's catalytic sites, an interaction between Fe^{III} and the oxygen atom at C-11 was postulated in the complex between PGH_2 and PGI-synthase. This precluded a heterolytic cleavage with complexation by Fe^{III} of an oxygen cation and left only the homolytic scission facilitated by spin–spin coupling of the Fe^{III} ion to the 11-O radical; the free oxygen radical at C-9 is then the species that attacks the Δ^5 double bond[25] (Scheme 2).



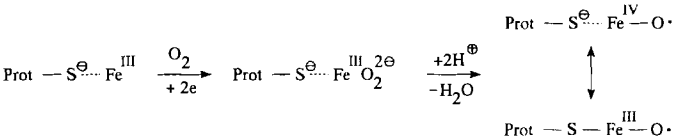
The resulting carbon radical at C4 is oxidized by the now formally Fe^{IV} species, and after migration of a proton from C-5 to 11-O, PGI_2 is formed. This mechanism agrees with the observed substrate specificity: ring closure occurs only when an *E*- or *Z*-configurated Δ^5 double bond in the α side chain between C-5 and C-6 has the same steric orientation as the epidioxy group at the cyclopentane ring.[25, 51] Any changes in the alkyl side chain seem to be irrelevant. Interestingly, PGH_1 (lacking the Δ^5 double bond) and 8-*iso*-PGH_2 are both converted into their respective fragmentation products HHD and 8-*cis*-HHT and malondialdehyde (Table 2). These products confirm that splitting of the epidioxy bridge is the initial step, which leads to fragmentation of the molecule if the appropriate steric orientation of the α-side chain is lacking.

According to the spectral data obtained with TxA-synthase, the heme iron coordinates to the oxygen atom 9-O of PGH_2, and the homolytic scission results in a free oxygen radical at C-11 (Scheme 3). This intermediate undergoes ring cleavage with formation of a radical at C-12 as already suggested by Turner and Herz.[56] As in PGI_2-synthase, the radical can be oxidized by the Fe^{IV} center to a carbocation, which then undergoes electrophilic rearrangement.[25]

The fact that 13,14-dihydro-PGH_2 fragments exclusively into HHD and malondialdehyde supports this mechanism, because the Δ^{13}-double bond would be required for an allylic stabilization of the radical at C-12. Fragmentation also occurs with PGH_1, 8-*iso*-PGH_2, and $\Delta^4(E)$-PGH_1,[51] which underlines the results of studies with inhibitors in which the binding of the α

side chain to the active site was an important factor. A characteristic feature of TxA-synthase is the formation of HHT and malondialdehyde as well as TxA_2 even with the physiological substrate PGH_2. At least 50% and up to 70% of PGH_2 is converted into these products for which no physiological role has yet been found. However, they are clearly formed enzymatically, and the intermediate from which they are derived is very likely the C-12 radical. Fragmentation would be unavoidable if the subsequent electron transfer (or a bonding orbital-overlap of the iron center and the carbon radical) is not fast. It remains to be seen whether the fragmentation products of TxA-synthase are just by-products of an imperfect enzyme or whether they fulfill a still unknown function in the signalling pathway.[59]

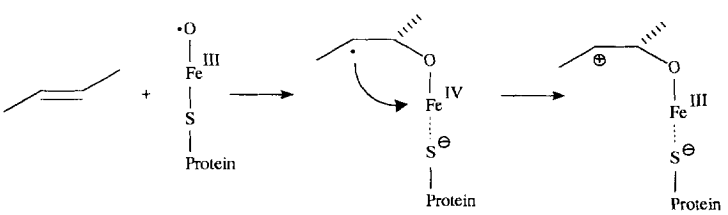
A comparison of the proposed mechanisms for PGI and TxA-synthase reveals the same basic principles of homolytic epidioxy cleavage assisted by spin coupling of Fe^{III}, rearrangement to a carbon radical, and, most importantly, the electronic interaction (oxidation or Fe–C bond formation) between the resulting carbon radical to the $[S-Fe-OR]^{3+}$ entity. Strict steric control of this step is essential, because as outlined in Figure 3, it requires two very different orientations of the PGH_2 molecule relative to the catalytic heme group.



Scheme 3. Mechanism of TxA_2 biosynthesis. R^1: $CH_2-CH=CH-(CH_2)_3-CO_2H$; R^2: $CH=CH-CHOH-(CH_2)_4-CH_3$.

The very low homologies in the sequences of the enzymes would imply that folding of the polypeptide chains to form the active site must be very different. One explanation for this could be found in the concept of evolutionary mobile modules and motifs in proteins.[60] Presumably it was the phylogenetic need to develop entirely different foldings in the tertiary structures that led to the use of different polypeptides from preexisting steroid monooxygenases as building blocks for the protein domains of the two synthases.

6. Common Principles of Hemethiolate Catalysis



Spectroscopic properties and sequence analysis showed the close relationship of TxA- and PGI-synthase with the hemethiolate monooxygenases, in spite of their different enzymatic functions. A closer mechanistic investigation reveals that monooxygenases contain an additional function in the two-electron transfer to O_2 with the generation of an intermediate peroxo complex which eliminates water to give an oxenoid complex as the "active oxygen species"[61–63] (Scheme 4).

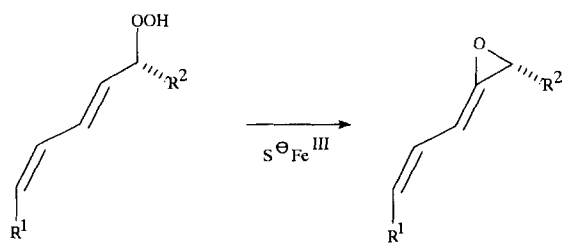
Scheme 4. Oxygen activation through formation of an oxenoid complex between cyctochrome P450 and oxygen.

In earlier work we mimicked all properties of the active oxygen intermediate by adding the oxygen atom donor, iodosylbenzene, to oxidized P450-monooxygenases.[64] This led to the development of model systems consisting of transition metals with iodosylbenzene.[65,66] Since the oxygen transfer with P450-monooxygenases involves the Fe^{III} state, it should also take place at the hemethiolate catalytic site of both synthases if an appropriate PGH_2 analogue is present as a substrate. With U46619 (see Fig. 4) and TxA-synthase in the presence of iodosylbenzene, two hydroxylated products could be detected by GC-MS, which, besides other products, were also formed in a hydroxylating system consisting of liver microsomal cytochrome P450's, $NADPH_2$, and oxygen.[67] Apparently the hemethiolate center of TxA-synthase exhibits the same oxygen transfer properties as that of monooxygenases.

This close analogy to the monooxygenases allows speculation about additional roles of the hemethiolate group in monooxygenase catalysis. Because of the radical attack of the active oxygen species at the monooxygenase substrates, a radical intermediate is expected, which, in case of an epoxidation at the double bond, would have to be oxidized either to a radical cation or to an intermediate iron–carbon bond (Scheme 5).

Scheme 5. Mechanism of epoxidation with heme-activated oxygen.

Unlike hydroxylations with OH radicals, no free radical intermediates have been detected in the enzymatic reaction. The electron transfer or the "rebound" process must thus be extremely fast, as only this would ensure enzymatic stereospecificity.

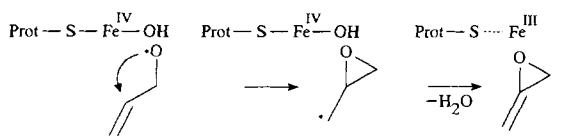


Comparison of this reaction sequence with the rearrangement process to PGI_2 or TxA_2 (Schemes 2 and 3) highlights the requirement for an immediate electron transfer step (Scheme 5). Accordingly, we propose that the unusual redox properties of

the hemethiolate site guarantee a very rapid uptake of an electron from a carbon-centered radical intermediate. That this occurs by a concerted pathway involving an iron–carbon bond is less likely because of the steric situation at the heme and the fragmentation seen with TxA-synthase. This fragmentation would be a typical consequence of a free radical pathway. Furthermore, some experiments with monooxygenases describe a partial racemization at the asymmetric carbon during hydroxylation, which again favors a free though short-lived carbon radical.[68]

7. Wider Implications of Hemethiolate Catalysis

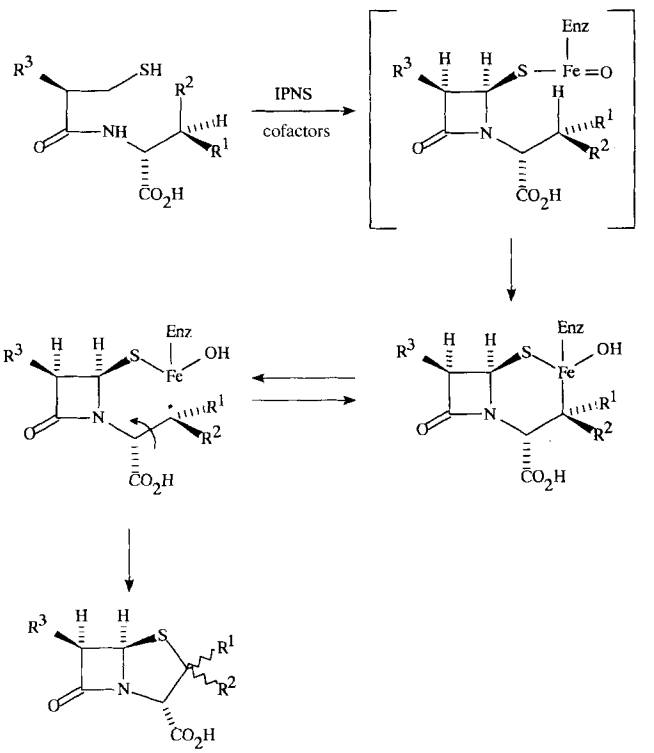
The hemethiolate-catalyzed monooxygenations and the two rearrangement processes consist, in essence, of a primary step in which an oxygen radical is formed, which then attacks the substrate by a radical mechanism. In a third step a carbon-centered radical is oxidized either by electron transfer to the formal heme–Fe^{IV} center or through formation of an intermediate iron–carbon bond.



Recently a third type of P450-catalyzed reaction was described in which fatty acid hydroperoxides are converted into allene oxides by a hemethiolate enzyme from plants, corals, or starfish oocytes (Scheme 6).[69] According to the general path-

fatty acid hydroperoxide allene oxide

Scheme 6. The allene oxide synthase. R^1: C_7H_{14}–COOH; R^2: C_5H_{11}; ref. [69].



way postulated for hemethiolate catalysis, the rearrangement should proceed by a homolytic O-O bond cleavage, attack by the oxyradical at the adjacent double bond, and oxidation of the C radical (Scheme 7).

Scheme 7. Postulated mechanism of the hemethiolate-catalyzed rearrangement of fatty acid hydroperoxide to allene oxide.

The analogies between the epoxidations catalyzed by hemethiolate monooxygenases and the epidioxy rearrangements are apparent.

From the postulated sequence of events in hemethiolate mechanisms it is not implied that the iron is dependent on porphyrin as ligands. Many ironthiolate structures could exhibit similar properties. A good example may be the penicillin biosynthesis (Scheme 8), which has been thoroughly studied.[70] Here the nonheme $iron^{II}$ of isopenicillin N-synthase (IPNS) coordinates to the thiol group of the substrate and with molecular oxygen forms an oxenoid complex in which the oxygen has sufficient radical character to abstract the tertiary H atom of the valine residue. Spin–spin coupling between the resulting Fe^{IV}

Scheme 8. Mechanism of penicillin-N biosynthesis from ref. [71]; $R^1 = CH_3$, $R^2 = CH_3$, $R^3 = NH$–CO–$(CH_2)_3$–$CH(NH_2)$–COOH.

species and the carbon radical was postulated, but since the stereochemical integrity of the carbon center was lost (scrambling of R_1 and R_2),[71] the reaction is likely to proceed without iron–carbon bond formation. Again the final ring closure may result from a rebound process or an electron transfer to the Fe^{IV} species followed by an electrophilic rearrangement. The basic principles of postulated ironthiolate catalysis can thus be recognized in this desaturative cyclization.

No detailed studies are available on the mechanism for the chlorination of organic compounds with activated C-H bonds, catalyzed by chloroperoxidase, another hemethiolate enzyme.[72, 73] However, since H_2O_2 is the required cosubstrate and the chloride ion is bound at the active site,[74] the chlorination may also involve hydrogen atom abstraction from the substrate followed by electron transfer with subsequent addition of the chloride ion.

In summary, it appears that whenever an ironthiolate center combines with oxygen compounds that have an elevated oxidation potential, interesting S-Fe-O entities arise which initiate radical reactions followed by immediate electron transfer, with the result that radical chain reactions are avoided. This offers an excellent basis for enzyme catalysis. An application to homoge-

neous catalysis is hampered by the fact that thiolate ligands are by themselves candidates for oxygen or electron transfer, but appropriate shielding may open interesting possibilities in heterogeneous catalysis.

Our own contributions to this work have been supported over many years by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Our former colleagues M. Haurand, M. Hecker, and R. Nüsing are thanked for their contribution to this research. We also appreciate the cooperation with the research group of T. Tanake (Osaka, Japan).

Toxicity of Chlorinated Organic Compounds: Effects of the Introduction of Chlorine in Organic Molecules

Dietrich Henschler*

Industrial "chlorine chemistry" is accused of polluting the environment with its products and having adverse effects on health. The accusation has been followed by the demand that this ill-defined branch of chemistry be simply abolished, a demand which has been repeated vigorously now for years. It grew out of misgivings such as those summarized here: 1. A number of polychlorinated cyclic compounds are very stable and highly lipophilic so that they accumulate in the environment and affect mankind through the food chain. Prominent examples are chlorinated pesticides, biphenyls, dibenzodioxins, and dibenzofurans. 2. Many chlorinated compounds are toxic for man and animals. Their genotoxicity (mutagenicity and carcinogenicity) plays a role in risk assessment; more and more chlorinated organic compounds are being shown to be carcinogenic and classified accordingly.

To date there are no comprehensive reviews of the toxicology of chlorinated organic compounds. The present treatise is the result of an attempt to analyze the situation systematically. It makes generalizations as to the kind and degree of toxicity of the most important classes of chlorinated organic compounds and elaborates recommendations for reduction and avoidance of risk during production, occupational handling, and general use.

1. Introduction

The present review is the condensed version of a detailed documentation,[1] which is to appear simultaneously as a monograph; wherever necessary in the text below, reference is made to this detailed account of the original data.

The study was based on the following questions:

1. What is the effect of the introduction of chlorine substituents on the toxicity of organic compounds?
2. Is there a defined relationship between the number of chlorine substituents introduced and the kind and degree of toxic effects in specific homologous groups of compounds?
3. Is it also possible to establish general rules for the effect of number and position of the chlorine substituents introduced on the toxicity of organic compounds of different classes?
4. Is it possible to identify "toxophoric" groups in chlorinated organic compounds and could such knowledge be used for purposes of risk reduction and avoidance when developing new chemical products?
5. What are the molecular mechanisms responsible for the toxicity or increases in toxicity of chlorinated organic compounds?

Not all classes of chlorinated organic compounds were analyzed systematically in this study; a selection had to be made because of the differing and often inadequate amounts of data available. An initial overview of this extensive field revealed that relationships within classes are clearest in the series of chlorinated alkanes, alkenes, and alkynes. Data are also available—although not as plentiful—for chlorinated derivatives of benzene and phenol. The analysis concentrates on these five large classes of compounds.

Polychlorinated polycyclics such as the insecticides, DDT, lindane, aldrin, and dieldrin, polychlorinated biphenyls, polychlorinated fatty acids, and polychlorinated dibenzodioxins and dibenzofurans are not analyzed systematically in this review. These classes of compounds have been the subject of numerous systematic studies in recent years; the reader is referred to the relevant monographs and reviews. However, since these polychlorinated polycyclics share significant toxicological features which distinguish them, especially with respect to their carcinogenic potential, from the aliphatic and monocyclic compounds, their features are discussed separately in Section 14.

The analysis of toxicology and risk assessment is based on the following criteria: acute toxicity, subacute and subchronic toxicity, chronic toxicity, genotoxicity in the form of mutagenic and carcinogenic effects, and reproductive toxicity. Neurotoxicity and allergic effects could not be studied systematically because such data are available for only few compounds. The cases where such kinds of effect are known to be associated with the

introduction of chlorine into organic compounds are mentioned in the text.

2. C–Cl Bonds: Chemical Reactivity and Toxicological Properties

The presence of a chlorine–carbon bond affects the chemical properties of organic compounds and also has consequences on their toxicological behavior:

- The electron-withdrawing effect of chlorine, like that of other electron-withdrawing elements (e.g. F, O, N, P), increases the electrophilicity of the C atom to which it is attached. This facilitates or enables nucleophilic attack (with displacement of chlorine) on sp^3 carbon atoms; neighboring H atoms (α-position) and C–H bonds (β-position) are more highly polarized and H^+ elimination is facilitated.
- The relatively low binding energy of the C–Cl bond in alkanes (326 kJ mol^{-1}) results in relatively high chemical reactivity.
- The introduction of chlorine substituents makes organic compounds more lipophilic, facilitating interactions with hydrophobic sites, for example, in enzymes, and promoting enzymatic biotransformation in general.
- The inductive and/or mesomeric effects of a chlorine substituent influence the neighboring C–C sequences; the toxicological consequences depend on the class of compound involved:

  In alkanes the C–C bond becomes more labile so that oxidative attack can cleave bonds and result in radical formation.

  In alkenes the C=C bond is stabilized; this favors the insertion of oxygen to form reactive oxiranes during enzymatic oxidative attack because direct substitution is impeded or no longer possible. The situation is similar in arenes.

  In alkynes the reactivity of the C≡C bond is increased; this favors addition reactions.
- A chlorine substituent in allylic position is a good leaving group and facilitates the formation of resonance-stabilized carbocations which, by covalent binding to nucleophilic sites in biochemical structures, can produce primary toxic lesions and, in particular, genotoxic changes.

Thus it may be deduced that the introduction of chlorine substituents into organic compounds generally leads to increased chemical and biological reactivity and so to increased toxicity. In cases where enzymes activate chlorinated organic compounds to toxic intermediates, however, the situation is further complicated by the fact that the enzymes are not uniformly distributed, neither in the organism, nor in organs, nor in subcellular compartments. Because of the necessity to eliminate metabolic waste products, higher terrestrial organisms are equipped with enzyme systems which make lipophilic compounds more water-soluble and thus more readily eliminated in the urine. Thus lipophilicity is a prerequisite for this kind of enzymatic conversion; the enzyme apparatus is equipped with lipid membranes with appropriate solvent properties. The introduction of chlorine substituents into organic compounds generally makes them more lipophilic. Therefore it is to be expected that, in spite of their frequently increased chemical stability, chlorinated organic compounds are converted enzymatically more readily than their chlorine-free analogues.

The effects of all of these individual factors on chemical reactivity and toxicity have been studied in several series of homologous and analogous compounds, sometimes in detail. However, since, on the one hand, numerous other factors also influence the effects and, on the other, the enzyme systems involved have not yet been studied systematically, particularly, in warm-blooded organisms and their mechanisms of action are not fully understood, the effects of introducing chlorine into organic compounds may be predicted only to a very limited extent. Therefore, tests in appropriate biological systems are generally required to confirm or disprove such predictions.

3. Chlorinated Methane Derivatives

Methane is considered to be physiologically inert; toxic reactions are therefore not expected under the usual test conditions. Some of the few early inhalation studies have shown that methane first has effects on the organism when the concentrations in the inhaled air are above 50%. These effects are ascribed to lack of oxygen which can be prevented by increasing the partial pressure of oxygen in the inhaled test mixture. When sufficient oxygen is present, methane can be shown to have very weak central depressive (anesthetic) effects.

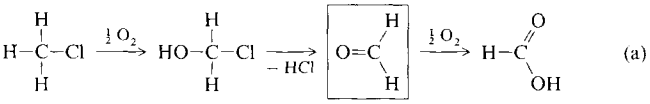
Dietrich Henschler, born 1924 in Glösa, studied medicine at the Universität Würzburg and obtained his doctorate in 1953 with a thesis on the laxative anthranol/anthraquinone glycosides. In 1953 he joined the Department of Pharmacology at the Universität Würzburg and obtained his "Habilitation" under W. Neumann with a thesis on structure-activity relationships and mechanisms of action of neurotoxic triaryl phosphates. In 1964 he became Associate Professor and in 1965 was appointed Professor of the new chair of Toxicology and Pharmacology at the Universität Würzburg. From 1969 onwards, he was chairman of the DFG Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area (MAK Commission). His work has centred on studies of the molecular toxicology of chlorinated organic compounds, especially chlorinated vinylic structures, and mechanisms of the organ specificity of cancerous manifestations. He is co-author of the leading text book in his field and of a series of toxicological monographs on hazardous substances at the workplace.

For all methane derivatives the introduction of chlorine results in toxic activity with various kinds of effect on the organism.[1]

The toxicology of a great number the chlorinated methanes has been studied intensively. Table 1 shows a synopsis of the results obtained in the various kinds of toxicity tests.

Acute toxicity: The LC_{50} and LD_{50} values obtained cannot generally be compared directly[1] because of non-uniform test conditions (different animal strains, exposure times, observation periods, etc.). The order of toxicity shown in the table was estimated taking these parameters into account. Differences in the order of toxicity for different administration routes (Table 1) may be explained in terms of the mechanisms of action involving different metabolic activation reactions (see below); the extent to which such reactions occur also depends on the administration route. The values given in Table 1 for the order of toxicity permit semiquantitative comparisons.

Chronic toxicity: Little data is available for a comparative evaluation. The MAK values (maximum workplace concentrations) shown as a guide demonstrate the influence of the number of chlorine substituents on the toxicity of the compounds. Dichloromethane appears not to fit into the series; this is illusory, resulting from the fact that only this MAK value is based on an acute effect (increase of the level of carboxyhemoglobin).



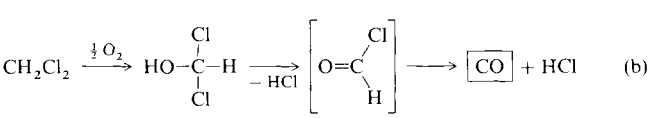
Mutagenicity: This is described in more than 80 publications; for all four compounds positive findings have been published. However, for trichloromethane and tetrachloromethane, negative results predominate numerically in bacterial tests (Ames test). Apart from chloromethane, all these compounds require metabolic activation to become mutagenic.

Carcinogenicity: All four chlorinated methane derivatives have yielded positive results in both mice and rats. There are also negative results but they can be ascribed to inadequate dose levels. The overall carcinogenic potency of the chlorinated methanes is relatively weak. At present, all these compounds are classified in Category IIIB[*] in the "List of MAK and BAT Values"[2] (see Table 6).

Reproductive toxicity: Tests revealed no evidence of prenatal toxicity except with chloromethane, which induced cardiac malformations.

Mechanisms of action: The toxicological mechanisms of action of the four chlorinated methane derivatives are fundamentally different. They account for both the kinds of toxicity and for the relative degrees of toxicity of these substances, especially for the differences in genotoxicity, in terms of the different chemical nature of the metabolically formed reactive intermediates.

Chloromethane is converted oxidatively by cytochrome P450 enzymes to formaldehyde[3] [Eq. (a)] which has been shown in in vitro test systems to be mutagenic. It is also conceivable that chloromethane itself has direct alkylating action; this could, however, not be distinguished unequivocally from the effects of formaldehyde.

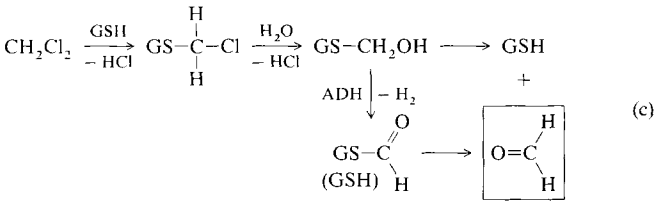


(a)

Table 1. Toxicity of chlorinated methanes: semiquantitative comparison on the basis of original data (given in detail in ref. [1]). Order of toxicity: 1 is the most toxic, 4 is the least toxic.

		CH_3Cl	CH_2Cl_2	$CHCl_3$	CCl_4	Comments
Acute toxicity	inhalation	1	4	3	2	order of toxicity, determined as LC_{50} or LD_{50} values
	ingestion	2	3	1	4	
	intraperitoneal	[a]	2	1	3	
	subcutaneous	[a]	1	2	3	
Chronic toxicity (critical toxicity)	MAK value/ $mL\,m^{-3}$	50 (kidney, male fertility)	100 (CO Hb level)	10 (kidney, liver)	10 (liver, kidney)	MAK value not comparable for CH_2Cl_2 because based on an acute effect
Mutagenicity						for $CHCl_3$ and CCl_4 mainly negative results
point mutations		+	+	(+)	(+)	
chromosomes aberrations		+	+	+	+	
cell transformations		+	+	+	+	
Carcinogenicity		+	+	+	+	results of carcinogenicity studies heterogeneous, positives all weak
Reproductive toxicity		+	(−)	(−)	(−)	(−) = only maternal toxicity + = cardiac malformations

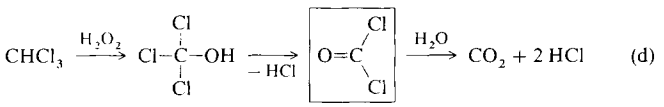
[a] Not determined.



The situation is quite different for dichloromethane. This substance is also a substrate for P450 enzymes [Eq. (b)]. Formyl chloride which is the formal product of this reaction decomposes, however, to yield HCl and CO, and the latter determines

(b)

[*] Carcinogenic substances are summarized in Group III. This group is subdivided into A1, A2, and B (see Tables 4, 5, and 6).



the toxicity by causing carboxyhemoglobin formation.[4] Genotoxicity is not associated with this metabolic pathway but, in addition to the oxidative (P450) metabolic pathway, there is also a reductive pathway[5] [Eq. (c)] involving coupling to glutathione (GSH).

(c)

The chloromethyl glutathione formed is considered to have alkylating activity and this would account for the genotoxic effects of dichloromethane.[6] However, this adduct is also converted to the mutagen, formaldehyde, by alcohol dehydrogenases (ADH). In any case, the demonstration of mutagenicity of dichloromethane in the Ames test requires the addition of glutathione and the enzyme glutathione transferase.[7] It has been suggested recently that the lung tumors observed in mice can be attributed to the presence of certain glutathione transferases which have a high specificity for dichloromethane coupling; these glutathione transferases are not found in other species.[8]

The oxidative action of cytochrome P450 on trichloromethane yields phosgene (carbonyl chloride)[9] [Eq. (d)] which,

(d)

being an acid chloride, is considered to have mutagenic properties; however, these have not yet been demonstrated for phosgene itself because of methodological problems.

The mechanism of the oxidative activation of carbon tetrachloride is again different since no C–H bond is available in this compound; activated oxygen formed by cytochrome P450-dependent monooxygenases (Mfo) cause the homolysis of a C–Cl bond [Eq. (e)] and formation of a trichloromethyl radical[10] which can produce genotoxic effects by binding to DNA.

(e)

Summary: All chlorinated methane derivatives have central anesthetic effects. This property, which is already present in methane although so weakly that it can be demonstrated only with difficulty, becomes marked with the introduction of chlorine, and increases with the number of chlorine substituents in the molecule. Trichloromethane (chloroform) was used as an anesthetic in surgery for almost one and a half centuries. The introduction of chlorine into the methane molecule, however, also opens the way for metabolic attack which results in toxic effects in other organs with all four chlorinated derivatives; the toxic effects are quite different in each case: chloromethane produces central nervous degeneration, dichloromethane carboxyhemoglobin formation, and trichloromethane and tetrachloromethane liver and kidney damage. Although the enzymatic activation yields different reactive metabolites from each of these compounds, all four have genotoxic properties, the prerequisite for their demonstrated carcinogenicity.

4. Chlorinated Ethane Derivatives

Ethane also has central anesthetic properties which, although somewhat more pronounced than those of methane, are still too weak for them to have been useful for medical purposes. The introduction of chlorine increases the anesthetic effects markedly;[11] chloroethane was used for a time as a mild anesthetic for short operations.

Acute toxicity: Studies in which the substance was administered by inhalation have been carried out with all the chlorinated ethanes apart from 1,1-dichloroethane and hexachloroethane, in most cases with rats. The acute toxicity of the derivatives, measured as LC_{50} values,[11] decreases in the order:

1,1,2,2-tetrachloroethane $\geqq$ 1,1,2-trichloroethane > pentachloroethane > 1,2-dichloroethane $\gg$ 1,1,1-trichloroethane $\gg$ chloroethane

In mice too, 1,1,2,2-tetrachloroethane is the most toxic derivative. The oral toxicity has been studied much less frequently than the inhalation toxicity but, where comparisons are possible, they confirm the order of toxicity seen in the inhalation studies. Similarly, the few LD_{50} values available for intraperitoneal, subcutaneous, and dermal administration are in accordance with the above order. The large difference between the toxicities of 1,1,2-trichloroethane and 1,1,1-trichloroethane is significant (four-hour LC_{50} values in the rat 2000 and 18000 $mL\,m^{-3}$, respectively, with similar differences for oral and intraperitoneal toxicity). This difference results from the fact that the metabolism of 1,1,2-trichloroethane yields the reactive intermediates chloroacetyl chloride and dichloroacetaldehyde, whereas 1,1,1-trichloroethane produces the much less toxic metabolites trichloroethanol, trichloroethanal (chloral), and trichloroacetic acid.

Chronic toxicity: Studies have been carried out for only a few chlorinated ethanes so that a systematic comparison of the long-term toxicity of all the members of this series is not possible. Here too, the MAK values[2] provide the best available measure of toxicity since long-term exposure to low concentrations of all of the compounds leads to toxic effects in parenchymatous organs, especially the liver. The data shown in Table 2 reveal a characteristic trend; the former MAK value of 1000 $mL\,m^{-3}$ for chloroethane was withdrawn recently because the substance has been shown to be carcinogenic.

The difference in the chronic toxicities of 1,1,1-trichloroethane and 1,1,2-trichloroethane, as for the acute toxicities, is a result of differences in metabolism. In addition, the data indicate that the chronic toxicity in this series of compounds increases drastically with the number of chlorine substituents.

Table 2. MAK values of chlorinated ethane derivatives [2].

Substance	MAK value/ mL m^{-3}	Target organs
chloroethane	[1000] [a]	lung, liver
1,1-dichloroethane	100	liver, kidney
1,1,1-trichloroethane	200	liver
1,1,2-trichloroethane	10	liver, kidney
1,1,2,2-tetrachloroethane	1	liver
pentachloroethane	5	liver
hexachloroethane	1	liver

[a] This value was withdrawn recently because the substance has been shown to be carcinogenic.

Mutagenicity: Tests on the mutagenic properties have been carried out with all the chlorinated ethanes. Positive results for mutagenicity were obtained with all the compounds except one, in every case after metabolic activation. This statement is not affected by the fact that for some of the compounds both positive and negative test results have been published; such inconsistent results are not unusual with substances which develop their mutagenic properties only after metabolic activation. The activation mechanism has been elucidated for 1,2-dichloroethane (see below). The only exception in this series of compounds is 1,1,1-trichloroethane which is converted metabolically via trichloroethanol and chloral to trichloroacetic acid; these metabolites are only weakly or not mutagenic; elimination of chlorine, which would yield reactive intermediates, does not occur.

Carcinogenicity: 1,2-dichloroethane has been shown to be unequivocally carcinogenic (A2 see also Table 5) in animal studies. Chloroethane (B, see Table 6), 1,1,2-trichloroethane (B), and 1,1,2,2-tetrachloroethane (B only in mice) are suspected carcinogens. Pentachloroethane and hexachloroethane have also proved to be carcinogenic. The mechanism of action for 1,2-dichloroethane has been shown[111] to involve coupling with glutathione (GSH) and formation of an episulfonium ion which has alkylating properties [Eq. (f)].

$$ClCH_2-CH_2Cl \xrightarrow[-HCl]{GSH} ClCH_2-CH_2-SG \longrightarrow \begin{matrix} H_2C \\ | \\ H_2C \end{matrix}\!\!>\!\!SG \qquad (f)$$

Summary: Like the chlorinated methanes, the chlorinated ethane derivatives have central anesthetic effects (anesthesia) which increase with the number of chlorine substituents. Accordingly, the acute toxicity also increases with the number of chlorine substituents up to four, and then decreases. The chronic toxicity is even more clearly dependent on the number of chlorine substituents, increasing up to six substituents; liver cell damage is the principle symptom of intoxication. In the series of chlorinated ethanes, as in the methanes, introduction of chlorine results in genotoxic activity. There are fewer positive mutagenicity results than with the chlorinated methane derivatives but this is most likely a matter of chance. Six of the chlorinated ethanes are carcinogenic; the mechanism demonstrated for 1,2-dichloroethane involves metabolic formation of an episulfonium ion after coupling with glutathione. The only non-genotoxic member of the series is 1,1,1-trichloroethane; this may be ascribed to the metabolic stability of the CCl_3 group.

5. Chlorinated Ethene Derivatives

Because of their industrial importance, chlorinated ethenes have been the subject of by far the most toxicity tests. Like methane and ethane, ethene has central anesthetic properties which are much more marked; ethene has been used as an anesthetic in clinical trials. Here too, chlorine substituents increase the anesthetic effects significantly;[1] trichloroethene was used for a long time as a mild anesthetic in obstetrics.

Ethene can be activated in oxidative metabolism to a genotoxic oxirane. The introduction of chlorine increases this kind of effect.[1]

Acute toxicity: All the chlorinated ethene derivatives, apart from 1,2-dichloroethene, have been studied in inhalation tests in both mice and rats and, in some cases, also in hamsters.[1] In this series of substances too, the LC_{50} values cannot be compared directly because of different exposure times and observation periods. However, the order of toxicity in both the mouse and rat is clear:

1,1-dichloroethene > tetrachloroethene > trichloroethene ≫ monochloroethene

The mouse is particularly sensitive to the renal and hepatic toxicity of 1,1-dichloroethene. The order of toxicity reflects the anesthetic effectiveness of the substances; that is, the cause of death in these studies was respiratory failure and/or circulatory collapse.

In acute oral toxicity tests, *trans*-1,2-dichloroethene was studied as well. The order of toxicity (LD_{50} values) found for the substances was different in mice and rats:

Mouse: 1,1-dichloroethene > *trans*-1,2-dichloroethene > trichloroethene ≫ tetrachloroethene

Rat: *trans*-1,2-dichloroethene ≧ 1,1-dichloroethene > tetrachloroethene > trichloroethene

Thus, the mouse is much more sensitive to trichloroethene than the rat to tetrachloroethene. These differences cannot yet be explained.

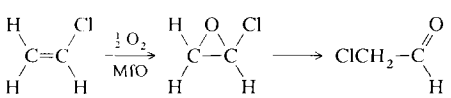
After intraperitoneal administration, the order of toxicity of these substances is largely the same in the mouse and rat:

trans-1,2-dichloroethene > trichloroethene > tetrachloroethene

Chronic toxicity: Chlorinated ethene derivatives have been studied intensively with regard to their chronic toxicity on inhalation because of the great practical importance of these substances. With all the compounds, the primary effects are liver and/or kidney damage which is most marked with 1,1-dichloroethene. This is reflected in the MAK values[2] (Table 3).

The dependence of chronic toxicity on the number of chlorine substituents is not as clear for the ethene derivatives as for chlorinated alkanes; this is a result of differences in the metabolic bioactivation reactions (see below).

Table 3. MAK values of chlorinated ethene derivatives [2].

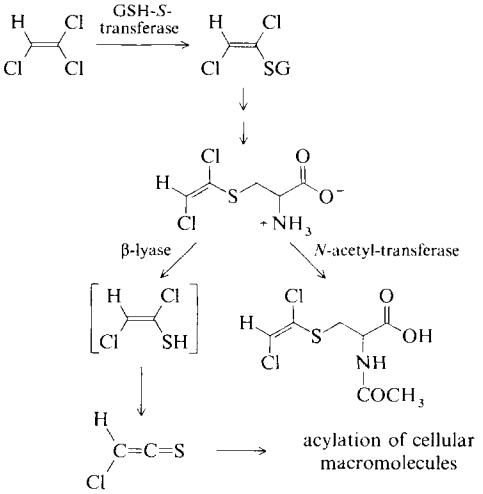


Substance	MAK value/ mL m^{-3}	Target organs
chloroethene (vinyl chloride)	[100] [a]	liver, kidney
1,1-dichloroethene	2	kidney
1,2-dichloroethene (*cis* and *trans*)	200	liver, kidney
trichloroethene	50	liver, kidney
tetrachloroethene	50	liver, kidney

[a] This value was withdrawn recently because the substance has been shown to be carcinogenic.

Mutagenicity: Numerous mutagenicity tests have been carried out on chlorinated ethene derivatives. None of the compounds is mutagenic as such; the activity develops after metabolic activation. Chloroethene, 1,1-dichloroethene, 1,2-dichloroethene, and trichloroethene are activated oxidatively and then yield positive results in mutagenicity tests. Trichloroethene and tetrachloroethene are activated by coupling with glutathione (the mechanism is described below). Thus indirect mutagenicity has been demonstrated for all the chlorinated ethene derivatives.

Carcinogenicity: The carcinogenicity of vinyl chloride has been demonstrated unequivocally in both man and experimental animals. In exposed workers, an otherwise very rare hemangiosarcoma of the liver was observed; it is not certain whether the substance is also a lung carcinogen. In experimental animals, tumors at several other locations were seen as well as the same kind of hepatic hemangiosarcomas. That vinyl chloride is carcinogenic suggested that all chlorinated ethenes could have carcinogenic potential. The suspicion has, however, not yet been confirmed in any other case as it has for vinyl chloride. 1,1-Dichloroethene, trichloroethene, and tetrachloroethene are classified in Category IIIB in the "List of MAK and BAT Values"[2] but the carcinogenicity of these substances is only weak. With trichloroethene and tetrachloroethene, a low incidence of kidney carcinomas was observed in rats. Recent observations suggest that trichloroethene also causes kidney tumors in man after long-term high-level exposure.[18] The mechanism may be explained in terms of a specific kind of metabolic transformation (see Scheme 1).



Mechanism of action: All chlorinated ethene derivatives are converted to reactive oxiranes by metabolism with cytochrome P450-dependent monooxygenases. The oxiranes can alkylate or acylate essential macromolecules, either directly or after intramolecular rearrangement to chlorinated aldehydes or acyl chlorides. The mechanism has been most intensively studied with vinyl chloride[12] [Eq. (g)].

(g)

In this manner, 1,1-dichloroethene is converted to chloroacetyl chloride, 1,2-dichloroethene to dichloroacetaldehyde, and tetrachloroethene to trichloroacetyl chloride.[13] With trichloroethene there are two possible rearrangement products, trichloroacetaldehyde and dichloroacetyl chloride; the formation of trichloroacetaldehyde (chloral) is thermodynamically favored.[13]

Trichloroethene and tetrachloroethene are not only metabolized by the oxidative pathway but also by a reductive pathway involving coupling to glutathione. This results in a complex sequence of additional activation steps which terminates in the formation of chlorinated thioketenes,[14] electrophilic species which have recently been shown to react with DNA[15] (Scheme 1).

Scheme 1. SG = glutathionyl.

The glutathione adduct formed in the primary step of this sequence is converted by cleavage of glutamic acid and glycine to the cysteine adduct which can either be *N*-acetylated to form the mercapturic acid, which is readily eliminated in the urine, or be enzymatically cleaved by β-lyase to yield a reactive thiol. Dehydrochlorination of the thiol yields the thioketene derivative.[16] The β-lyase is present in particularly high levels in the renal tubules and this accounts for the marked organ specificity associated with this class of compounds (renal carcinomas). The cysteine derivatives of trichloroethene, tetrachloroethene, dichloroacetylene, and hexachlorobutadiene are highly mutagenic.[17]

Summary: Ethene has central anesthetic activity which increases after the introduction of chlorine depending on the number of chlorine substituents. All chlorinated ethene derivatives have more or less severe toxic effects and some are genotoxic. In every case, these effects result from the action of metabolically formed reactive intermediates. The main metabolic pathway involves addition of oxygen to the olefinic bond to yield highly electrophilic oxiranes. These can rearrange to chlorinated aldehydes or acyl chlorides; acyl chloride formation is to be seen as a detoxication reaction. Chloroethene, 1,1-dichloroethene, and trichloroethene have clearly genotoxic and to different extents carcinogenic effects. In addition, trichloroethene and tetrachloroethene are metabolized by reductive processes which begin with the coupling to glutathione and end with the formation of electrophilic thioketenes. This metabolic pathway is responsible for the renal carcinogenicity of these substances. Recent

studies seem to confirm the renal carcinogenic activity of trichloroethene in man.[18]

6. Chlorinated Ethyne Derivatives

Acetylene (ethyne) has much more pronounced central anesthetic effects than ethene. The introduction of chlorine into the molecule, however, makes it so unstable that the expected (increase in) central anesthetic activity can no longer be demonstrated. Instead, dichloroacetylene has unique neurotoxic effects: it damages selectively the fifth cranial nerve (*N. trigeminus*). Dichloroacetylene is a frequent contaminant (degradation product) of trichloroethene or 1,1,2,2-tetrachloroethane; in such mixtures it is relatively stable.[19]

The acute inhalation toxicity of dichloroacetylene is extremely high: the six-hour LC_{50} value for the mouse is only 19 mL m^{-3}, the four-hour LC_{50} value for the rat is 55 mL m^{-3}.[20]

Dichloroacetylene is one of the most powerful known carcinogens. Exposure of mice and rats to a dichloroacetylene concentration of 9 or 14 mL m^{-3} for six hours, once or twice weekly, results in a high incidence of cystadenocarcinomas and cystadenomas of the kidney.[21] The mechanism of action involves enzymatic coupling with glutathione (GSH) to form 1,2-dichlorovinylglutathione, formation of the cysteine derivative, and its cleavage by β-lyase,[22] as has been described already for trichloroethene (see Section 5, Scheme 1).

7. Chlorinated Propane Derivatives

There is much less data available for this class of substances[1] than for the C_1 and C_2 compounds so that the general effects of introducing chlorine into the molecule are less clearly documented. However, propane itself has been tested for acute toxicity on inhalation; the 15-minute LC_{50} value is said to be more than 800 000 mL m^{-3}.

Acute toxicity: The four-hour LC_{50} values for the chlorinated propane derivatives tested in the rat can be compared directly and reveal the following order of toxicity:

1,2,3-trichloropropane (550 mL m^{-3}) > 1,1,2-trichloropropane (2000) > 1,2-dichloropropane (2900) > 1,1-dichloropropane (4000) > 1,1,1-trichloropropane (8000)

Once more, the 1,1,1-trichloro compound is the least toxic, a result of the stability of the trichloromethyl group to metabolic transformation. The chlorinated propane derivatives are more toxic than the corresponding ethane derivatives.

The relative acute oral toxicity of the chlorinated propane derivatives corresponds essentially with that seen after inhalation. However, 1,2,3-trichloropropane, tested in the rat in a comparative study with 1,2,2-trichloropropane, 1,1,2-trichloropropane, 1,1,1-trichloropropane, 1,2-dichloropropane, and 1,1-dichloropropane, is conspicuous for its very low oral LD_{50} value; it is only one third of the values found for 1,2,2-trichloropropane and 1,1,2-trichloropropane.

Subchronic and chronic toxicity: Very few studies of subchronic and chronic toxicity of chlorinated propanes have been carried out so that comparisons as for the other groups are not possible. There are MAK values[2] (now withdrawn) for 1,2-dichloropropane (75 mL m^{-3}) and 1,2,3-trichloropropane (50 mL m^{-3}). Neither value is adequately grounded but their dimension and order do confirm the general rule in the series of chlorinated alkanes that the toxicity increases with the number of chlorine substituents. The target organs identified in subchronic studies were liver and kidney.

Mutagenicity and carcinogenicity: 1,2-dichloropropane and 1,2,3-trichloropropane have, because of their industrial importance, been tested for mutagenicity and carcinogenicity. The theory of oxidative metabolism[12] with subsequent dehydrochlorination (formation of chlorinated acetones, aldehydes, or acyl chlorides) suggests that genotoxic activity is to be expected. The expectation has been fulfilled for 1,2-dichloropropane in individual tests and for 1,2,3-dichloropropane in most tests. In a long-term carcinogenicity study, 1,2-dichloropropane was not carcinogenic in the rat and weakly carcinogenic in the mouse (hepatocellular adenomas and carcinomas). 1,2,3-Trichloropropane, on the other hand, was clearly carcinogenic in both rat and mouse.

Summary: It may be concluded that in the group of propane derivatives as well, the introduction of chlorine into the molecule increases all toxic effects and produces genotoxicity.

8. Chlorinated Propene Derivatives

Some of the chlorinated propenes have been the subject of intensive toxicological study because of their use as pesticides (1,3-dichloropropene) or as starting materials for industrial syntheses (allyl chloride, 3-chloropropene).[1] The introduction of a chlorine substituent into an allylic position results in the formation of bifunctional agents in which not only the olefinic group plays a role, but also the chlorine as an active leaving group.[23] This has significant consequences for the toxicological behavior of the substances.

Acute toxicity: Several inhalation studies in the mouse and rat yielded LC_{50} values[1] in the following order of toxicity:

2,3-dichloropropene > 1,3-dichloropropene (*cis* and *trans*) > 3-chloropropene ≫ 2-chloropropene and 1-chloropropene

The situation for oral toxicity is a little different:

2,3-dichloropropene > 1,1,2,3-tetrachloropropene > 1,3-dichloropropene > 1,2,3-trichloropropene > 3-chloropropene ≫ 1-chloropropene

The few results available after intraperitoneal, subcutaneous, and dermal application are essentially consistent with the above order.

Chronic toxicity: There are only few comparable studies available. They indicate that 1,3-dichloropropene (technical mixtures and also the separated isomers) is about twenty times more toxic than allyl chloride. The mechanisms leading to the chronic toxicity have not been explained. It is not clear whether glutathione depletion, which plays an important role in the acute toxicity, is also significant for the chronic toxicity of these substances.

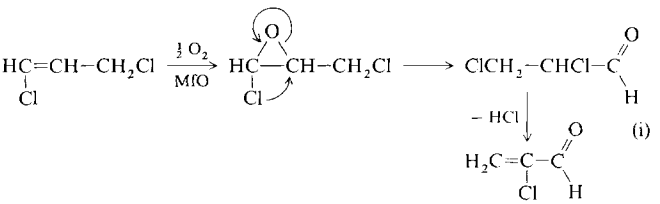
Mutagenicity: The mutagenicity of chlorinated propenes has been studied systematically.[24] All of the compounds in this

class which have a chlorine leaving group in allylic position are direct mutagens. The carbocation formed is resonance-stabilized and can alkylate nucleophilic reaction sites in essential macromolecules including DNA; some DNA adducts have been characterized.[25] Methyl substitution in any possible position increases the mutagenicity drastically.[24] Likewise, the introduction of a second chlorine substituent increases the mutagenicity to up to one hundred times that of allyl chloride.[23] The order of mutagenic potency found is as follows:

cis-1,3-dichloropropene > *trans*-1,3-dichloropropene ≫ 2,3-dichloropropene

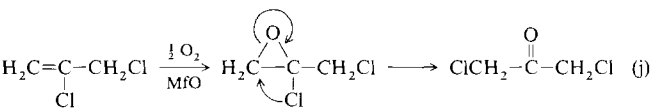
Metabolic oxidation of the double bond to yield the oxirane, followed by intramolecular rearrangement, produces chloroacetone derivatives which are among the most powerful mutagens.[26]

Benzyl chloride ((chloromethyl)benzene) may also be seen as a chlorine-activated allyl compound; it is several times more mutagenic than allyl chloride.[24]



Carcinogenicity: A carcinogenic potential must be expected for the whole group of chlorinated propenes because they have all been shown to have genotoxic activity. To date, allyl chloride and 1,3-dichloropropenes of various grades of purity have been tested for carcinogenicity after oral administration. Allyl chloride was not carcinogenic in the rat and weakly carcinogenic in the mouse; it induced tumors in the forestomach, that is, at the site of contact with the biological material. This is as would be expected from the proposed mechanism of action (direct alkylation). 1-Chloropropene also produced forestomach tumors in mice. 1,3-Dichloropropene (technical mixture contaminated with 1% epichlorohydrin (1-chloro-2,3-epoxypropane)) yielded highly positive results in the rat and mouse and produced tumors in the stomach and the liver (rat) and also in the lung and urinary bladder (mouse). This marked carcinogenic activity has been ascribed to oxidation products in the technical mixture. The highly purified substance was no longer mutagenic and the addition of antioxidants to the technical mixtures largely prevented the formation of such oxidation products. Whether the carcinogenicity of the substance under practical conditions can be prevented by such measures is not known and does not seem very likely.

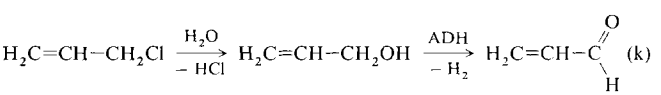
Mechanism of action: As already described in Section 4, the presence of the excellent leaving group (chlorine) in allylic position permits the formation of stable carbocations, as in the model case of allyl chloride [Eq. (h)]:



$$H_2C{=}CH{-}CH_2Cl \longrightarrow [H_2C{=}CH{=}CH_2]^+ + Cl^- \quad (h)$$

The stability of these cations has been calculated for a large number of homologous and analogous propene and butene derivatives;[23] it correlates well with the alkylating and mutagenic potency of the compounds.[24] DNA adducts have also been identified.[25]

In addition, the olefinic bond in chloropropene derivatives can be epoxidized by mixed function oxygenases (Mfo). The resulting oxiranes and the aldehydes and ketones formed by rearrangement are alkylating principles, for example, for 1,3-dichloropropene[26] [Eq. (i)] or for 2,3-dichloropropene [Eq. (j)].



(i)

(j)

A third mechanism involves the hydrolysis of the allyl chlorine bond and subsequent oxidation of the alcohol to acrolein (2-propenal) [Eq. (k)]:

(k)

Acrolein, a bifunctional agent, attacks nucleophilic sites, for example, in DNA, by Michael addition[25] and so produces promutagenic DNA damage.

Thus there are three activation mechanisms which form highly alkylating and mutagenic intermediates from acrolein, chloroacrolein, and 1,3-dichloroacetone or the analogous compounds.[27] Which mechanisms are involved in specific cases is mainly determined by the simultaneously occurring enzymatic deactivation reactions; dominant is coupling to glutathione followed by formation of mercapturic acids which can be excreted in the urine.

Summary: The introduction of chlorine into propene, which itself is only weakly toxic, yields highly reactive compounds. As resonance-stabilized carbocations, these can alkylate essential biological macromolecules; alternatively, highly mutagenic products can be formed after enzymatic oxidation of the olefinic bond to yield oxiranes which rearrange to chlorinated aldehydes or ketones. Accordingly, all the chlorinated propene derivatives have been shown to be mutagenic and the few which have been tested to date in long-term animal studies have been found carcinogenic (1-chloropropene, 3-chloropropene, *cis*-1,3-dichloropropene, and *trans*-1,3-dichloropropene).

9. Chlorinated Butane Derivatives

Inhaled butane also has central depressive action; the effect is much more marked than that of propane. The four-hour LC_{50} value found for butane in the mouse was 282 $mL\,m^{-3}$ and in the rat 273 $mL\,m^{-3}$.[28] Introduction of chlorine into the molecule increases the toxicity in every respect.[1] The cytotoxicity of the chlorinated butanes is caused by metabolic activation products.

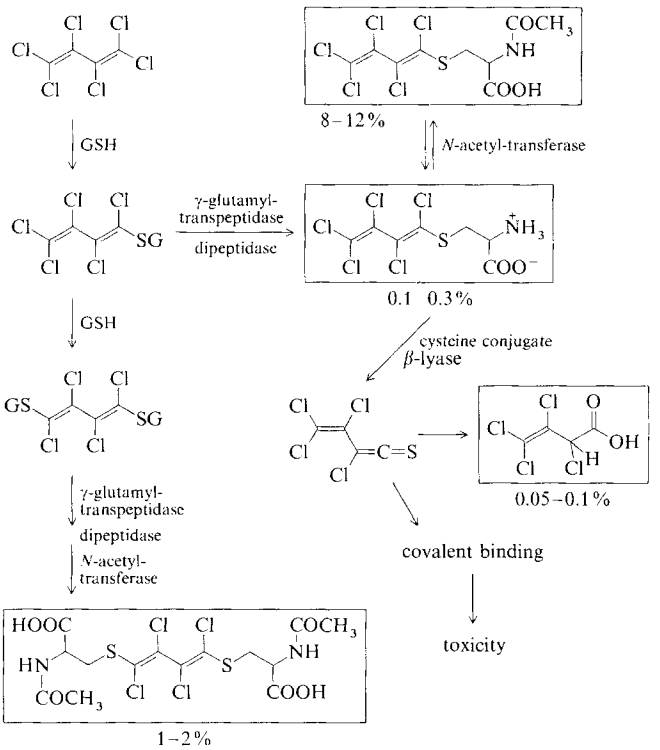
Acute toxicity: This has been investigated mainly after oral administration. The LD_{50} values[1] demonstrate that the toxicity increases with the number of chlorine substituents as follows:

2-chlorobutane > 1,1-dichlorobutane > 1-chlorobutane > pentachlorobutane ≫ hexachlorobutane > 1,2,3,4-tetrachlorobutane

Chronic toxicity: Insufficient data are available for this class of substances to make comparisons.

Genotoxicity: To date genotoxicity studies have been carried out with five chlorinated butane derivatives. Negative results were obtained with 1-chlorobutane and 1,4-dichlorobutane and weak positive results with *sec*-butyl chloride and *tert*-butyl chloride. 1,2,3,4-Tetrachlorobutane induced chromosomal aberrations in vivo. Thus a clear statement as to the mutagenic effects of the group as a whole is not possible.

Carcinogenicity: Studies have been carried out to date only with monochloro derivatives. Negative results were obtained with 1-chlorobutane after oral and intraperitoneal administration to mouse and rat; weak positive results were seen after intraperitoneal administration of *sec*-butyl chloride or *tert*-butyl chloride to the mouse.



Summary: In spite of the paucity of data for the chlorinated butane derivatives, it may be concluded that the introduction of chlorine into the butane molecule increases the central depressive effects and the cytotoxicity; genotoxicity develops but apparently less markedly than in the propane, ethane, and ethene derivatives.

10. Chlorinated Butene Derivatives

The members of this class of compounds which are of particular interest are 1,3-butadiene, because of its use as the monomer, and hexachlorobutadiene, because of its great stability in the environment. In oxidative metabolism, 1,3-butadiene is converted to vinyl oxirane and then to 1,2:3,4-diepoxybutane (bioxirane);[29] both oxiranes are powerful mutagens.[30] Accordingly, in an inhalation study, 1,3-butadiene has been shown unequivocally to be a powerful carcinogen.[31]

Hexachlorobutadiene, however, is not subject to oxidative metabolism, unlike the analogous tetrachloroethene. On the other hand, a vigorous substitution reaction with glutathione (GSH) catalyzed by glutathione transferases takes place; both the monoadduct and diadduct with glutathione have been identified.[32] The subsequent peptidase-mediated cleavage of glycine and glutamic acid yields the cysteine adduct which is either converted by acetylation to the mercapturic acid, which is excreted in the urine, or by β-lyase-catalyzed cleavage to the reactive thiol. The thiol is converted—in analogy with the mechanism demonstrated for trichloroethene and tetrachloroethene (cf. Section 5, Scheme 1)—to the thioketene derivative, the ultimate mutagen (Scheme 2).

Since these processes take place largely in the renal tubules, when hexachlorobutadiene is fed to rats in long-term studies it induces highly organ-specific renal carcinomas.[33] Logically, hexachlorobutadiene has proved to be a powerful mutagen in bacterial tests, provided they were carried out in the presence of GSH and GSH transferase.[34]

Scheme 2. Urinary metabolites are in boxes.

11. Chlorinated Benzene Derivatives

Benzene is one of the toxicologically most intensively studied substances. It has three main kinds of action: a depressive effect on the central nervous system (anesthesia), liver damage, and depression of the hematopoietic systems which can lead to the development of various kinds of leukemia. Benzene is a relatively powerful human carcinogen. The introduction of chlorine into the benzene ring has very different effects on the three kinds of action of benzene: the (acute) central nervous depression is increased, the liver damage—at least with the derivatives with less chlorine substituents—is reduced, and the carcinogenicity is prevented.[1] Because of their considerable industrial importance, most chlorinated benzene derivatives and their isomers have been studied extensively.

Acute toxicity: The LC_{50} and LD_{50} values obtained in studies of the acute toxicity of benzene cannot be compared directly because of the very different conditions under which the studies were carried out. However, for all the administration routes used (inhalation, oral, other parenteral forms) the picture is similar: the toxicity increases with the number of chlorine substituents introduced into the molecule. Pentachlorobenzene and hexachlorobenzene exhibit a kind of toxicity not seen in the members of this series with less chlorine substituents: disturbance of porphyrin metabolism and a specific kind of liver damage.

Chronic toxicity: These substances have hardly been tested but all members of the series have been investigated in subchronic studies. Administered in the diet to rats and mice in three-month or six-month studies, the following order of toxicity was observed:

pentachlorobenzene > 1,2,4,5-tetrachlorobenzene >
1,2,3,5-tetrachlorobenzene > all trichlorobenzenes >
1,4-dichlorobenzene ≥ 1,2-dichlorobenzene ≥ monochlorobenzene

Thus the toxicity, measured here as the no observed effect level (NOEL), increases with the number of chlorine substituents.

Mutagenicity: The mutagenicity of all of the chlorinated benzene derivatives has been studied in a wide variety of different test systems. Apart from a few positive results which, on critical assessment, appear dubious or which are not acceptable because of inappropriate methods, the results obtained were all negative. Thus the chlorinated benzenes are neither direct nor indirect mutagens.

Carcinogenicity: In long-term carcinogenicity studies, negative results were obtained with chlorobenzene in mice and female rats, and questionably positive results in male rats. With 1,2-dichlorobenzene only negative results were obtained. 1,4-Dichlorobenzene induced a particular kind of renal carcinoma in male rats; this effect is said to be specific to this species and sex of animal and irrelevant for man;[35] the mechanism can be considered to involve effects on porphyrin metabolism on the one hand and hormone balance on the other. This applies in particular to hexachlorobenzene which is not mutagenic and may be classified as a non-genotoxic carcinogen.[36]

Summary: Substitution of the benzene ring with chlorine increases the acute and chronic toxicity in line with the number of chlorine substituents; the leukemogenic effects of benzene, however, are suppressed. This is probably a result of changes in the production of genotoxic metabolites which are considered to determine the leukemogenic activity of benzene: oxidative ring opening (with muconaldehyde as the genotoxic principle) and formation of 1,4-benzenediol (hydroquinone) derivatives.[37]

12. Chlorinated Phenol Derivatives

The literature on chlorinated phenols is very extensive and includes a wide variety of toxicological studies. The most important data have been assembled and evaluated in two monographs from IPCS (International Program of Chemical Safety, World Health Organization).[38] Because technical products containing unknown amounts of toxicity-determining impurities were tested in most of the studies, the conclusions cannot all be considered to be final. However, a clear picture does emerge from a review of the data available at present.

Toxicity: The introduction of chlorine susbstituents increases the toxicity of phenol enormously, not only the acute toxicity but also the subchronic and chronic toxicity. Here too, the increase in toxicity correlates with the number of chlorine substituents introduced into the molecule. As the number of chlorine substituents in the molecule increases, inhibition of oxidative phosphorylation becomes a predominant mechanism of toxic action; the other mechanisms are still largely unclear.

Mutagenicity: Tests of the mutagenicity have been carried out with practically all the chlorinated phenol derivatives and their isomers. The results are not consistent. However, negative findings predominate; some of the positive findings can be ascribed to the presence of impurities. It seems justified to conclude that there is no convincing evidence that the chlorinated phenols have genotoxic properties.

Carcinogenicity: Studies have been carried out with three chlorinated phenols, all with oral administration of high doses. 2,4-Dichlorophenol administered orally to mice and rats proved not to be carcinogenic. With 2,4,6-trichlorophenol[39] and pentachlorophenol,[40] however, positive results were obtained in both rodent species. Pentachlorophenol is clearly more effective than the trichloro compound. In addition, in the mouse skin test, monochlorophenol, dichlorophenols, and trichlorophenols have been shown to have tumor-promoting activity.[41] These results indicate that trichlorophenols could induce tumor formation by a non-genotoxic mechanism (see Section 14). The actual toxicological problem with the chlorophenols is contamination with polychlorinated dibenzodioxins and dibenzofurans.

13. The Significance of Chlorine Substituents in Organic Compounds on the Mutagenicity and Carcinogenicity

Of all the kinds of toxic effect (acute and chronic toxicity, neurotoxicity, reproductive toxicity, and genotoxicity), mutagenic and carcinogenic effects are clearly of most significance. This conclusion, which also reflects the more than proportional intensity of present-day toxicological testing and classification activities, is based on the following facts:

- The classical understanding of mutagenic and carcinogenic effects defines them as irreversible in principle. On the one hand, they are a result of covalent interaction of foreign substances with the genetic material (DNA bases); on the other, in spite of the ability of the organism to repair such chemically distinct DNA lesions, in practice some of them always remain unrepaired since repair mechanisms also operate according to high order kinetic functions. Thus accumulation of such primary lesions is observed after repeated and long-term exposure.
- Thresholds for mutagenic and typical carcinogenic effects cannot be determined either experimentally or from theoretical considerations. The usual kind of threshold concentrations considered to have no adverse effects on health (such as MAK and MIK values) can therefore not be established because every exposure concentration, however formulated, includes a certain residual risk which is rarely quantifiable.
- After transplacental distribution, systemic carcinogens can cause cancerous changes in the developing foetus which are first manifested after birth, during the juvenile stage, or even later.
- It is conceivable that genetic damage in the germ cells could result in transfer of damaged genetic material to later generations. Although such events have not yet been observed in man, they have been produced in animal studies, admittedly only under extreme conditions.
- Most cancers diagnosed today are resistant to therapy. In spite of enormous research efforts, significant progress in tumor therapy is not to be expected in the foreseeable future.

– Cancer is considered more important than other diseases as widespread in the population because of the great suffering it entails for the patient and the patient's family.

Chlorinated organic compounds make up a large proportion of the chemicals known to be germ cell mutagens and to cause cancer. The most important German list of carcinogenic substances[42] distinguishes between three categories, A1, A2, and B. If one includes in the assessment the substances suspected of causing cancer (category B in the "List of MAK and BAT Values"), which is justifiable for purposes of comparison, the compounds containing chlorine (about 50) currently make up more than one third of the substances classified in this list as carcinogens or suspected carcinogens.

The chlorinated organic compounds in the current "List of MAK and BAT Values" are shown in Table 4 (clearly carcinogenic in man (A1)), Table 5 (clearly carcinogenic in animal studies (A2)), and Table 6 (suspected carcinogens (B)). Review of the other large list of carcinogenic substances, the collection of monographs of the International Agency for Research on Cancer[43] in Lyon, adds another twelve chlorinated organic substances (partly mixtures) (Table 7).

Table 4. Chlorinated organic compounds shown to be carcinogenic in man (Category IIIA1).

bis(2-chloroethyl)sulfide	α-chlorinated toluenes: (mixture of
chloromethyl methylether	benzoyl chloride, (chloromethyl)benzene,
bis(chloromethyl)ether	(dichloromethyl)benzene,
4-chloro-*o*-toluidine	(trichloromethyl)benzene),
vinyl chloride	*N*-methyl-bis(2-chloroethyl)amine

Table 5. Chlorinated organic compounds shown to be carcinogenic in animal studies (Category IIIA2).

α-chlorinated toluenes (see Table 4)	1,3-dichloro-2-propanol
1-chloro-2,3-epoxypropane	1,3-dichloropropene (*cis* and *trans*)
chlorofluoromethane	dimethylcarbamoyl chloride
N-chloroformylmorpholine	epichlorohydrin (1-chloro-2,3-epoxypropane)
1,2-dibromo-3-chloropropane	4,4′-methylenebis(2-chloroanilin)
dichloroacetylene	pentachlorophenol
3,3′-dichlorobenzidine	2,3,7,8-tetrachlorodibenzo[*b*,*e*][1,4]dioxin
1,4-dichloro-2-butene	2,3,4-trichloro-1-butene
1,2-dichloroethane	1,2,3-trichloropropane

Table 6. Chlorinated organic compounds which are suspected carcinogens (Category IIIB).

allyl chloride	dichloromethane
chlordane	1,2-dichloro-1-methoxyethane
chlordecon	1,2-dichloropropane
chlorinated biphenyls	α,α-dichlorotoluene [a]
chloroethane	diethylcarbamoyl chloride
chloro-*N*-hydroxymethylacetamide	heptachlor
chloromethane	hexachlorobutadiene
3-chloro-2-methylpropene	1,1,2,2-tetrachloroethane
1-chloro-2-nitrobenzene	tetrachloroethene
1-chloro-4-nitrobenzene	tetrachloromethane
chloroparaffins	1,1,2-trichloroethane
chlorthalonil	trichloroethene
5-chloro-*o*-toluidine	trichloromethane
1,1-dichloroethene	α,α,α-trichlorotoluene [a]

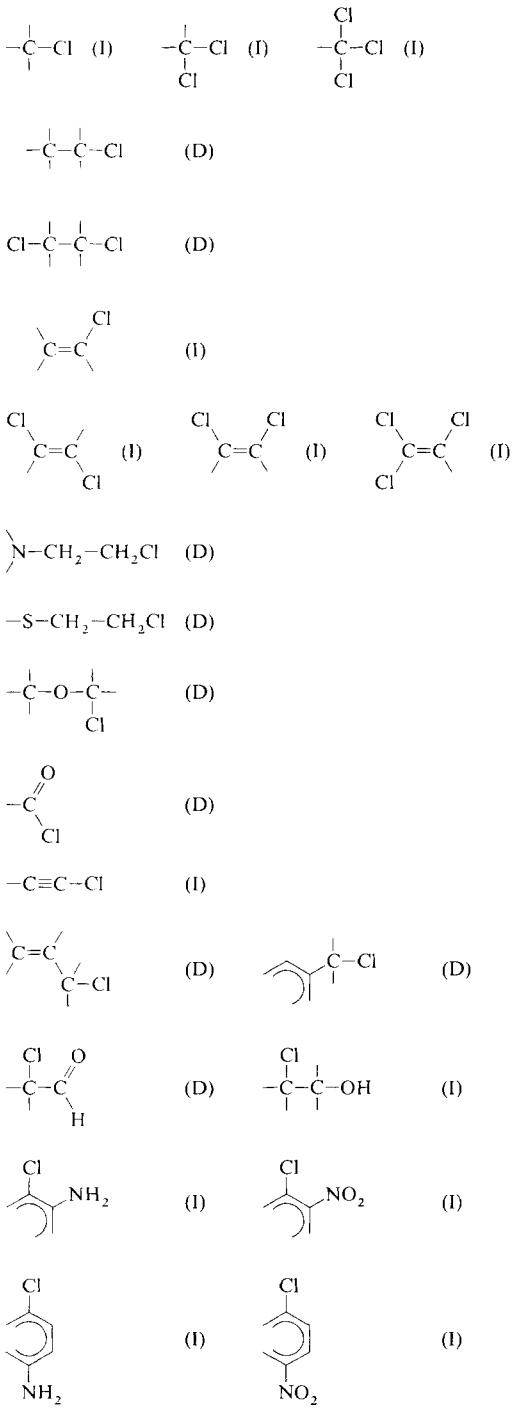
[a] See Table 4 and 5.

Table 7. Additional chlorinated organic compounds which are listed as carcinogens by IARC (IARC = International Agency for Research on Cancer).

N,*N*′-bis(chloroethyl)nitrosourea
1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea
chlorinated phenols
chlorinated phenoxyacetic acids
4-chloro-*o*-phenylenediamine
3,3′-dichloro-4,4′-diaminodiphenylether
dichlorvos
hexachlorobenzene
hexachlorocyclohexane
melphalan
metronidazole
mirex
products of the chlorination of drinking water

When evaluating such lists it must be borne in mind that only a very small proportion of chlorinated organic compounds has been tested for carcinogenicity. In the past, interests and constraints have led to more or less randomly distributed testing of such compounds. An attempt at a systematic approach has been introduced with the German Chemicals Act but the effects of this act, especially for substances which have long been in use, are not to be expected in the immediate future.

Consideration of chlorinated organic compounds with mutagenic and carcinogenic properties reveals a number of molecular fragments which can be made responsible for the genotoxic effects. The mechanisms involved—when they are known—have been discussed already in the appropriate sections of this review. In every case, the mechanisms involve the reaction of electrophilic moieties with nucleophilic sites in biologically important macromolecules, more rarely with low molecular weight cell components (e.g., glutathione, see Schemes 1 and 2). Only few genotoxic chlorinated organic compounds are inherently electrophilic (direct genotoxicity); mostly the electrophilic forms are produced during metabolism in the organism (indirect genotoxicity).



The molecular fragments which have been identified to date as having genotoxic activity are shown in Table 8. They are of particular importance in the conception of protective and avoidance strategies for regulatory measures and for the search for suitable alternative substances with less or no genotoxic activity.

A knowledge of which groups are toxophoric can be useful during product development. It forms a basis for prediction of whether or not genotoxic effects are to be expected. Such hypotheses, however, always require testing in biological systems since, as emphasized in Section 2 of this review, the numerous enzymes and conversion steps involved, especially during metabolic activation of substances in the organism, are highly complex and therefore poorly predictable. The hypothesis can, however, often be proved valid or invalid by a mutagenicity test in a simple model system.

14. Non-Genotoxic Carcinogenic Chlorinated Organic Compounds

Some of the chlorinated organic compounds found to be carcinogenic in animal studies stand out from the majority in that they do not have mutagenic effects. In the organism, they do not

Table 8. Chlorine-containing molecular fragments with genotoxic properties. (D = direct, I = indirect).

undergo metabolic transformation of relevance for their toxicity, unlike the genotoxic substances for which metabolic transformation involving cleavage of the C–Cl bond is a prerequisite for their activity. Although it is not always clear where an individual compound belongs, because the literature contains a few positive results of mutagenicity studies together with the numerous negative ones, mechanistic considerations make it possible to define this class of compounds clearly. It contains the polychlorinated cyclic hydrocarbons of the following types:

- polychlorinated dibenzodioxins and dibenzofurans
- polychlorinated biphenyls
- insecticides such as DDT and related compounds, hexachlorobenzene, hexachlorocyclohexane, heptachlor, chlordecone, chlordan
- pentachlorophenol
- longer chain chloroparaffins

The points which become apparent on consideration of the toxicology of these groups of compounds are detailed below.

- In the carcinogenicity studies with animals, very high doses, compared with the kinds of exposure found for man, were always necessary before carcinogenic effects were obtained at all.
- Severe inflammatory and degenerative symptoms were always seen in the experimental animals, especially in the organs in which cancer developed.
- The tumor incidence was never particularly high, and always lower than that found with the chlorinated organic compounds with genotoxic properties.
- The tumors developed on average much later than with other typical carcinogenic substances.
- The tumor locations were rather unspecific; tumor types characteristic for a particular substance, like liver hemangiosarcomas after chloroethene exposure, for example, did not develop in any case.
- Epidemiological studies have not been able to find clear correlations between exposure and cancer for any of these groups of substances, although carried out on a large scale and supported relatively well by exposure data. Recently, it has been claimed that tetrachlorodibenzodioxin (TCDD) causes a significant increase in tumor incidence, but it is only just a significant increase in the incidence of tumors of a kind which are anyway frequent and the increase is very small, at most marginal. The results of this one study[44] are in contrast with those of several others which did not find a statistically significant increase.[45–48]

The above features have led to the conclusion that the mechanisms of tumorigenesis operating with these substances must be fundamentally different from those found with genotoxic substances. Although the details of the mechanisms have not been elucidated for any of the substances, it seems justified to assume that the prerequisite for induction of cancer is severe organ or tissue damage, the massive cell death and subsequent cell replacement resulting in marked proliferative activity. Cell and tissue proliferation are accompanied by high rates of cell division. Cell division is indispensable for the transmission of genetic damage.[49] Since higher organisms experience constant very low levels of primary genetic damage resulting from all kinds of environmental factors,[50] the effect of increased proliferation is to increase the probability of the final manifestation of such damage in the form of tumors. Effects on hormone balance and immune status are considered to play an important role; such effects have been described in detail for DDT and related substances and for TCDD and polychlorobiphenyls (PCBs).

These mechanistic considerations result in the hypothesis that the carcinogenic effects of this type of substance cannot be expressed in the absence of cytotoxicity and increased cell proliferation, hormonal imbalance or disturbances of the immune system. There are threshold values for the induction of such changes and these can be determined with sensitive biological methods. On this basis it is possible to determine for these nongenotoxic chlorinated organic compounds threshold levels which do not cause impairment of health, cancer formation included.

15. Structure–Activity Relationships

In the present study, a series of representative homologous and analogous groups of chlorinated compounds has been evaluated because they are considered to throw light on structure–activity relationships. It was not intended to attempt to cover the whole field including uncommon substances or groups. Although the present investigation has not included some possibly important groups, conclusions which apply to chlorinated organic compounds in general may be drawn.

1. The introduction of chlorine into organic compounds is almost always associated with an increase in the toxic potential. Only rarely does chlorination produce no increase or even a decrease in effects. This observation applies for all kinds of toxic effect (acute, subchronic and chronic toxicity, reproductive toxicity, mutagenicity, and carcinogenicity).
2. There is also a tendency to an increase in toxicity with the number of chlorine substituents in a molecule; this can be seen as a general rule but a less stringent one than that for the effect of introducing chlorine in the first place.
3. The introduction of chlorine into the molecule frequently gives the substance new properties. New acute and subchronic effects are seen mainly in the parenchymatous organs (especially liver and kidneys, less often in the spleen), circulatory system, and central nervous system.
4. With the introduction of chlorine into the molecule, most of the organic substances discussed here become mutagenic and/or carcinogenic.
5. There is a wide variety of mechanisms of genotoxicity of chlorinated organic compounds. In most cases, the substance must be activated by metabolism in the organism to yield electrophilic intermediates which are able to bind covalently to essential macromolecules, especially DNA. Only relatively few kinds of compound can produce genotoxic effects directly, without metabolic activation (in particular, alkylating agents).
6. A considerable proportion of the chlorinated organic compounds which have been studied has carcinogenic activity. The proportion cannot be determined exactly because chlorinated organic compounds have not been tested systematically.
7. Carcinogenic chlorinated organic compounds can be divided into two fundamentally different groups: chlorinated aliphatic (and olefinic) hydrocarbons with short chain lengths (and, as a rule, high vapor pressures) are mostly carcinogenic because of their genotoxic activity, whereas polychlorinated cyclic compounds induce tumor formation by cytotoxic, never by genotoxic mechanisms. In the latter group, tumor induction always requires very high doses which also cause other kinds of damage.
8. Within groups of closely related chlorinated organic compounds (homologous and analogous series) where the toxicity is uniformly associated with a common chemically identifiable molecular fragment, it is possible to predict whether toxic effects (including genotoxic effects) will occur or not. With heterogeneous series of compounds (that is, with chemically different toxophoric groups), however, or in groups where several mechanisms of toxicity play a role, the predictability is much more restricted. This is mainly because a multitude of enzymatic activation and deactivation reactions can occur with the one molecule, often simultaneously, and can be dependent on or independent of each other.
9. There is one significant exception to the rules given in paragraphs 1. and 4. above: the introduction of chlorine into benzene suppresses its notorious and considerable leukemia-inducing effects. Presently available data indicate that this applies for all members of the extensive group of chlorinated benzene derivatives.

16. Conclusions: Strategies for Risk Assessment and Remedies for Toxicological Problems

For some time now, people have been demanding that "chlorine chemistry" be abolished totally and justifying this demand, on the one hand, with the high toxicity and carcinogenicity of some chlorine compounds together with their ability to accumulate in the environment, especially in food chains and, on the other, with the argument that chlorinated organic compounds are man-made, synthetic, foreign for the human organism and the rest of the biosphere; life processes have not been able to adapt to and develop defense mechanisms against these substances, as they have for numerous natural toxins.

The latter argument is not valid. To date, at least 1500 chlorine-containing compounds are known to be produced not only by plants, microbes, and other primitive organisms but also by higher animals.[51] Intensive research in this field extends the list constantly. The list of natural substances does not include highly chlorinated and perchlorinated hydrocarbons; these generally highly lipophilic and persistent substances which accumulate in certain environmental compartments are only known as synthetic chemicals at present. However, there are numerous genotoxic chlorinated and brominated organic compounds from natural sources with which a wide of variety of living organisms has always had to cope. Examples include tetrachloroacetone, polyhalogenated propenes, tetrabromo-2-propanol, dibromo-1-propanol, dichloroacetamide, polychlorinated terpenes, polychlorinated biphenyls, polychlorinated phenols.[51]

The risks associated with these toxic substances will continue to exist because it is practically impossible to regulate such natural processes—unlike the processes of synthetic chlorine chemistry. Some of these natural chlorine compounds function as hormones in certain living organisms.[52] When they are produced as defensive agents, for example, as antibiotics, they can

accumulate in very high concentrations in certain tissues of the producing organisms. Some prominent chlorine compounds, chloromethane, for example, are produced in much larger quantities in nature than synthetically, especially by primitive marine organisms[53] but also by higher plants.[54]

Chlorinated organic compounds are associated with two kinds of risk which are particularly important for the discussion of effects on health and the environment: the accumulation in certain environmental compartments as a result of high stability and lipophilicity, and the production of genotoxic effects resulting in cancer. There are solutions to the problems associated with both these kinds of risk.

- In spite of their high stability and persistence, polychlorinated cyclic compounds can be eliminated from the animate and inanimate world by means of a number of natural physical, chemical, and biological deactivation mechanisms. Of particular importance is UV irradiation;[55] microbial elimination of chlorine also plays an important role.[56, 57] Thus the remedy for the problem posed by this type of compound lies in the avoidance or large-scale reduction of deposition of the substances in the environment. One of the most sensitive criteria for the accumulation of polychlorinated compounds in the environment is seen in their transfer from a series of food chains into mother's milk. The most recent analyses carried out by the "Bundesgesundheitsamt" (German Federal Health Office) demonstrate that as a result of the now long-term reduction in the deposition of such substances in the environment, the levels of hexachlorobenzene, hexachlorocyclohexane, DDT and its metabolites, and polychlorinated biphenyls in mother's milk have decreased by up to half an order of magnitude during the last ten years.[58] There are other examples too. The effectiveness of such avoidance strategies can be monitored precisely these days with analytical chemical procedures and appropriate indicators. Here the situation could be improved further by appropriate research, and political support for such measures is necessary.
- Where genotoxic chlorinated organic compounds are handled, it is necessary to develop new avoidance strategies or improve existing ones. One kind of strategy involves the development of alternative substances without genotoxic activity or with much less activity. For certain classes of compounds, structure–activity relationships like those described in the specific sections of this review are already available; for other classes of compounds they could and should be developed further. Another kind of strategy involves the reduction of occupational and non-occupational exposure to the substances to harmless levels by improving respirators and personal protective clothing and by encapsulation of production processes. A classical example of the application of this kind of strategy is chloroethene (vinyl chloride). The first case of cancer (hemangiosarcoma of the liver) among PVC-polymerization workers was reported in 1974.[59] One year later the old plants in the Federal Republic of Germany had been exchanged for new ones, the exposure levels at the workplaces were reduced to comply with a hastily established TRK value (technical exposure limit)[60] and the vinyl chloride monomer levels in PVC products were reduced to safe concentrations. On these three levels, the PVC problem has been solved for synthesis, production, and use; partial solutions have been found for waste disposal.
- Effective recycling can reduce environmental damage or even avoid it completely in some areas. A systematic treatment of this field goes beyond the intentions of the present review and beyond the competence of toxicologists. None the less, it should be mentioned that modern cleaning systems, for example, for degreasing metals or dry-cleaning of clothing, are closed systems in which the volatile chlorinated hydrocarbons such as trichloroethene and tetrachloroethene are recovered completely without any significant loss of substances into the air.
- Particularly hazardous substances should no longer be produced or used. Careful quantitative risk assessment is required to determine which substances are particularly hazardous. At present, this is possible only for some chlorinated organic compounds. Toxicology and environmental chemistry, however, have produced the armory of methods required for such comparative risk assessment. They must just be used systematically in the various application areas. Here deficiencies remain and require the attention of scientific research, on the one hand, and of the political decision makers on the other.
- The most important aspect of avoidance strategies as they affect chlorinated organic compounds is the establishment and application of threshold values. Such thresholds are well-established for the workplace, the ambient air, for foods and drinking water. For non-genotoxic substances they may be based exclusively on health-determined criteria. For genotoxic substances it is also possible to justify the establishment and use of threshold values based on health effects. For mutagenic and carcinogenic substances, it is not possible to deduce non-effective threshold concentrations from the results of animal studies or from the theory of action of such substances. Finite doses always retain a finite effect which is generally not measurable in the low dose region and which at best can be estimated by means of more or less arbitrary arithmetic operations which are associated with errors of several orders of magnitude.[61] The application of a threshold value in such cases is thus always associated with a residual risk, albeit a small one. Such a threshold value can therefore not be established on the basis of scientific arguments alone. It requires political consensus as to the acceptable level of residual risk. There are two principles which may be applied when making such decisions: that of minimum risk (value as low as technically, analytically, and socio-economically feasible) and that of relative risk. The former, with its many compromises, is applied in the establishment of TRK values. The principle of relative risk compares the estimated residual risk with other risks; a political decision as to the acceptable increase in risk above the background of "unavoidable" risk will consider the increase in relation to the totality of risks and attempt to keep it in proportion. For chlorinated organic carcinogenic compounds it is self-evident that the acceptability be oriented on the exposure to naturally occurring compounds. Although in recent times the principle of establishing threshold levels has been subject to increasing criticism as an "end of pipe" approach, it is—compared with the others mentioned above—still the best established and most important instrument for

preventing adverse effects of exposure. It is also the instrument with the most readily comprehensible possibilities and limitations because it is based--in general and for the specific hazardous substance—on a great deal of knowledge and experience, on a data base which is generally not or only partially available for the alternative substances which would have to be introduced to replace any of those forbidden completely.

Thus, research into cause and effect has produced useful and tested instruments for risk recognition, evaluation, and reduction: exclusion of particularly persistent and dangerous substances, reduction of exposure of man and other living organisms, reduction of deposition in the environment, and the establishment of harmless threshold concentrations with monitoring procedures. These can be put to use for chlorinated organic compounds in the same way as for all kinds of potentially hazardous chemicals.

This review was suggested and promoted by the Verband der Chemischen Industrie, Frankfurt am Main, Germany, to whom I am indebted for valuable help with references.

Bolaamphiphiles: From Golf Balls to Fibers**

Gregory H. Escamilla and George R. Newkome*

A bolaamphiphile is simply defined as a molecule in which two or more hydrophilic groups are connected by hydrophobic functionalities (Scheme 1). Other terms such as bolaform amphiphile[1] or arborol[2] have been used to describe molecules possessing this architecture. Bolaform electrolytes or bolytes, a term introduced by Fuoss and Edelson in 1951,[1] are structurally similar, except the hydrophilic groups are ionic.[3] Since Fuhrhop and Mathieu[4] reported the synthesis and self-assembly of several bolaamphiphiles, other researchers have explored applications of this basic architecture. A search of current literature demonstrates the potential of bolaphiles, short for bolaamphiphiles, for the preparation of ultrathin monolayer membranes, the inclusion of functional groups into membranes, and the disruption of biological membranes, which could lead to therapeutic agents,[5,6] as well as their use as "antisense" agents,[7,8] as catalysts in reactions,[9-11] and as models for the membranes found in thermophilic archaebacteria.[12]

Scheme 1. Examples of bolaphiles; the basic elements are polar head groups (shaded) and lipophilic spacers (**1** from ref. [13], **2** from ref. [5], **3** from ref. [3]).

In natural membranes bolaform amphiphiles have chiral head groups, which are different in size and thus react stereoselectively with guest molecules.[3] In non-natural membranes binding sites can also be present,[9,22] or other functional groups can be incorporated such as redox- and/or photo-active moieties.[4] The repertoire of bolaamphiphiles is not limited to assemblies such as membranes and vesicles; specific "two-directional" arborols can form gels,[2,13-15] rods and tubules are formed by α-L-lysine-ω-aminobolaphiles.[16] When polymerizable functionalities are included either in the head groups or within the hydrophobic spacer, routes to extended covalently linked domains are opened up.[17,18]

Nontraditional structures (e.g., aqueous gels) result when noncovalent forces are coupled with a proper molecular architecture. The series of two-directional arborols synthesized by Newkome et al. demonstrates this variation on the theme of self-assembly.[13,14] In the proposed model of the aggregated structure one arborol is stacked upon the next; the hydrophobic chains

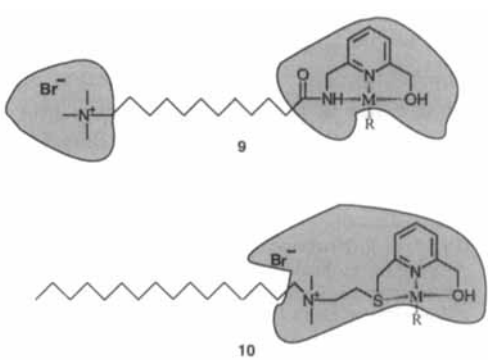
overlap and the hydrophilic hydroxyl groups are oriented out toward the aqueous solution (Fig. 1). Hydrogen bonding between the polar end groups and water results in a semisolid matrix. This proposed model is supported by the long fiberlike structures seen in electron micrographs of these assemblages.[13] As with micelle formation, there is a minimum spacer length needed for gelation to occur; for a saturated spacer this length is eight methylene units.[14] Aqueous mixtures of *N*,*N*′,*N*″,*N*‴-tetrakis[2-hydroxy-1,1-bis(hydroxymethyl)ethyl]hexadec-8-yne-1,1,16,16-tetracarboxamide and [18]crown-6 ether form particles rather than fibers, as evidenced by electron micrographs of resulting gels.[19] The rods and tubules described by Fuhrhop et al. follow an analogous pattern to the two-directional arborols.[16] When the racemic form of the lysine bolaphile **4** was used (Scheme 2), no rod or tubule formation was noted; in contrast, the racemate of the extended bolaphile **5** produced supramolecular assemblies identical to those formed by the pure enantiomers. The effect of configuration in molecular monolayers was shown to depend on membrane curvature in the same manner as in bilayers.[16]

Scheme 2. The unsymmetrical bolaphiles synthesized by Fuhrhop et al. for the generation of monolayer rods and tubules.

Fuhrhop et al. demonstrated[20] that placing quinone moieties in either the head groups or within the hydrophobic spacer resulted in redox-active membranes. The unsymmetrical bolaamphiphile **6** (Scheme 3) is a model of electron acceptors in photosynthesis and forms vesicles evident in electron micrographs. In the anticipated membrane organization all the quinone moieties should be located on the vesicle exterior. This assumption was confirmed by quantitative reduction of the quinone moieties with borohydride; since the reagent does not diffuse through lipid membranes, these "membrane quinones" must be part of the vesicle exterior.

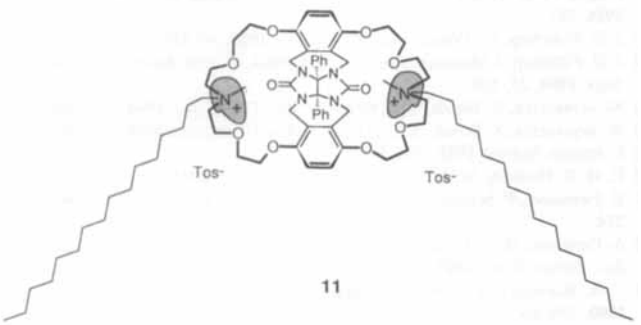
The anthraquinone-based bolaphiles **7** or **8** could not form homogenous membranes due to steric interactions (Scheme 3). Bolaphiles **7** or **8** could, however, be integrated into host membranes formed by dihexadecylphosphate and dimethyldioctadecylammonium bromide. This bolaamphiphile fixed the quinone functionality at the center of the membrane and served as a model for pool quinones.[20] Electron transfer was further



Scheme 3. The unsymmetrical bolaphile **6** was used to fix the quinone functionality at the surface of a micelle. **7** and **8** were used to position the quinone moiety within the membrane.

demonstrated by light-induced charge transfer between cationic porphyrins dissolved in water and membrane-bound anthraquinone bolaphiles.[21]

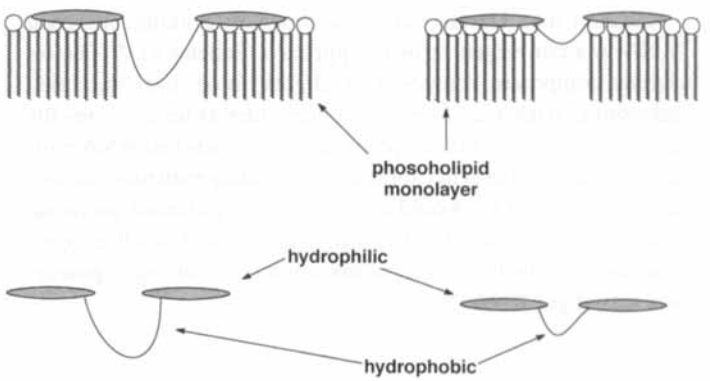
Bunton et al. proved that α,ω-bis(trimethylammonium) bolaphiles catalyze the spontaneous hydrolysis of 2,4-dinitrophenylphosphates.[11] The rate of hydrolysis was enhanced by micellar bolaphiles, and this rate enhancement followed the greater organization seen in vesicles formed by surfactants possessing longer spacers. Bolaphiles with hexadecane and dodecane spacers did not form micelles but small clusters instead, and the rate enhancement achieved was much lower than that with micelle-forming surfactants.[11]



Fornasier et al. used metallomicelles formed from bolaphiles and surfactants with only one head group as catalysts for the cleavage of *para*-nitrophenyl picolinate.[9] Micelles generated from pyridine bolaphiles and Cu^{II} or Zn^{II} (Scheme 4) enhanced the rate of cleavage. As a comparison, the micelles generated from 6-{[2-(*n*-hexadecyldimethylamino)ethylthio]methyl}-2-(hydroxymethyl)pyridine bromide were not as effective catalysts. Increased electrostatic repulsion between the ammonium group

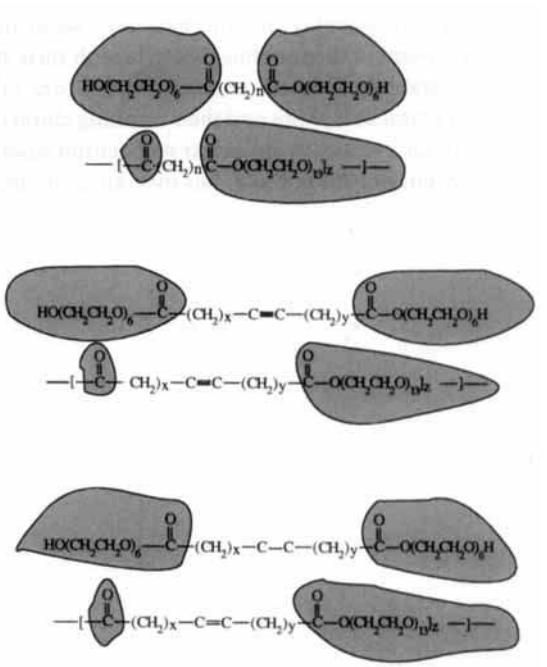
Scheme 4. The proximity of the charged head group to the binding site in **10** slows chelation of the metal relative to that with bolaphile **9**. M = Cu^{II}, Zn^{II}; R = *para*-nitrophenyl picolinate.

and the metal ion site explains the difference in effectiveness of the bolaform versus classical micelle. The crux of the catalytic process is formation of a ternary complex consisting of substrate, metal, and bolaform amphiphile as ligand.[9] These micelles demonstrate substrate discrimination, in other words, the correct substrate geometry is required for catalysis. Accordingly, no catalytic enhancement was found for the hydrolysis of the isomeric nicotinate and isonicotinate esters.



Nolte et al. recently reported[22] a functional vesicle formed by an assembly of hosts (Scheme 5) capable of binding guests such as resorcinol and 4-(4′-nitrophenylazo)resorcinol. In order

Scheme 5. Representation of bolaphile **11** used by Nolte et al. to prepare a functionalized vesicle.



to maintain the hydrophobic binding site at the exterior of the vesicle, the authors used two quaternary nitrogen atoms each having a long alkyl chain. The rigidity of the binding site holds the charged nitrogen atoms apart and fixes the binding site near the plane of the nitrogen atoms and therefore the vesicle surface. Typical for lipids, the hydrophobic alkyl chains served to form the membrane interior. Interactions of solvent, binding sites, charged nitrogen atoms, and hydrophobic alkyl chains together govern the vesicular morphology, which was likened to a golf ball because of to its spherical shape and dimpled surface.[22] The golf ball analogy is completed by the concave shape of the binding site in the host. Examination of a cast film by X-ray diffraction yields a clear periodicity of 53 Å, which is approximately the length of two fully extended hexyldecylamine chains. Also, binding studies suggest that only half the total number of binding sites are able to interact with the guest. These data indicate a bilayer membrane with a thickness of approximately 53 Å.

Jayasuriya et al.[5] hypothesized that bolaform amphiphiles could be tailored to provide an optimal geometry for membrane disruption. Variation of either head groups or spacer could provide a "tunability" to target certain microorganisms. The bolaphiles[5] were proposed to disrupt membranes by insertion of their hydrophobic spacers into the lipid layer, which would cause a mismatch of the preferred geometries of the bolaphile and lipid. When more such interruptions occur, the membrane would become more destabilized (Scheme 6). Spacers with central triple or double bonds were made with the expectation that these functionalities would increase the disruptive capability of the bolaform amphiphiles. For alkane spacers ranging from decane to eicosane maximum activity was observed with pentadecane. In the olefinic analogues the geometry and position of the double bond were less important in determining membrane disruption than the overall length of the spacer. Similarly, the position of unsaturation was not important for the acetylenic bolaphiles.[5] A general trend was that maximum activity required an increase in spacer length when moving from saturated to olefinic to acetylenic spacers.

Scheme 6. Mechanism proposed by Jayasuriya et al. for the destabilization of a membrane by the insertion of the hydrophobic spacer of a bolaphile into the phospholipid layer and the resulting local defect.

The use of polymeric strings of bolaamphiphiles in membrane disruption was described by Jayasuriya et al. (Scheme 7).[6] The membrane disruptive activity of the polymeric bolaamphiphiles or "supramolecular surfactants" is up to 10^3 times greater than that of the monomeric analogues.[6] The precise origin of this amplification is not yet understood; however, several factors were proposed. Since the polymeric bolaamphiphiles have covalent linkages, the "bolaamphiphile defects" will be localized in the membrane and a high local concentration will be achieved. Domains of the supramolecular surfactant within the bilayer will be in equilibrium with nonaggregated membrane-bound

Scheme 7. Membrane-disruptive bolaphiles and their polymeric analogues.

polymers. Repeat unit defects in the polymer are intrinsically more disruptive than the free monomer.[6] A polyester very similar to these "supramolecular surfactants" exhibited substantial protection for human CD4 + lymphocytes against HIV-1 during in vitro studies.[6] Thus a new route to nonionic membrane-disrupting agents is opened, in which activity and specificity can be tailored by molecular design.

Hudson and Damha have succeeded in making branched RNA in a convergent-growth approach (Scheme 8).[8] The resulting compound composed of oligothymine units, modified adenosine spacers, and terminal nucleotides as head groups fits the description of a bolaamphiphile. These branched RNA molecules could be useful in capturing and binding matching nucleotide sequences. This would allow access to potential antisense agents or ligands for affinity purification of the branch recognition factors, which catalyze the maturation or splicing of precursor messenger RNA.[8]

Scheme 8. An RNA-based bolaphile synthesized by Hudson and Damha.

Beyond these initial examples, basic questions remain concerning the conformation of bolaamphiphiles within micelles.[23] There is evidence that a bent conformation is adopted,[24] but micelles have been observed with very small hydrophobic cores and others are sometimes seen in electron micrographs with diameters that correspond to the length of the bolaphile.[23, 25] Among the many subjects for further exploration in the area of molecular self-assembly are the naturally occurring bolaamphiphiles found in thermophilic bacteria with their stereochemistry and stability in harsh environments. More robust membranes or chiral bolaphiles and their resulting chiral membranes could provide avenues to molecular recognition based on stereochemistry not only at one site, but over an entire membrane.[3]

Bolaamphiphiles, like cascade macromolecules,[26] have gained increasing attention recently, since they may offer insight into micellar systems that can mimic enzymes, act as therapeutic agents, or serve as tools in the investigation of molecular recognition and assemblages. Schenning's golf ball and the other examples described here illustrate the course Lehn set for supramolecular chemistry—structures alone are not the goal but rather the expression of a desired chemical, biological, or physical property.[27]

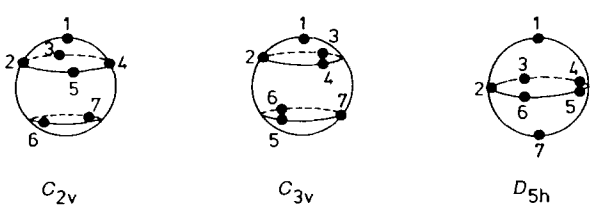
Molecules and Ions with Heptacoordinated Central Atoms



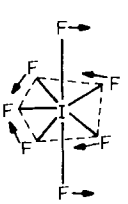
Rolf Minkwitz*

Since the valence-shell electron-pair-repulsion (VSEPR) model was developed to predict molecular structures, it has proved to be a strong stimulus for advances in structural chemistry. Key concepts to illustrate this are "stereochemical activity of lone pairs" or "steric demand of single and multiple bonds".

Heptacoordination is currently the focus of investigations by K. O. Christe et. al.,[1, 2] K. Seppelt et. al.,[3, 4] and J. K. Cockcroft et. al.[5, 6] So far it is only known for IF_7, ReF_7, and OsF_7, and the latter decomposes already at temperatures above 170 K.

Not until K. O. Christe et. al. characterized the "naked fluoride", the significance of which was previously highlighted[7] in this journal, could the anions $[XeF_5]^-$[8], $[OIF_6]^-$, $[TeF_7]^-$, $[OTeF_6]^{2-}$,[9] $[CH_3TeI]^{6-}$, and $[(CH_3)_2TeF_5]^-$[3] be prepared. Monomeric and/or unchelated complex cations with the coordination number (CN) 7 around the central atom are unknown.

For molecules and ions with coordination numbers 5 and 7 around their central atoms, we find many parallels with respect to their structural diversity and their intramolecular dynamics. For CN 5, calculations, which take into consideration that electrostatic repulsions occur between ligands, allow two polyhedra, the trigonal bipyramid and the square pyramid. Their difference in energy is small and they can be interconverted by a succession of angular shifts according to the Berry pseudorotation mechanism. For CN 7, three polyhedra with only small energy differences and minimum energies for the C_{2v} and C_{3v} structures[10] have been calculated under the same assumptions (Scheme 1).



Scheme 1.

The results of earlier IR spectroscopic investigations[1] on IF_7 had been consistent with a pentagonal-bipyramidal stucture of the molecule. This assumption was confirmed by electron diffraction in the gas phase[11] in spite of much uncertainty in the structural data. Crystal structure analyses performed by K. Seppelt et. al. on salts with the $[TeF_7]^-$, $[CH_3OTeF_6]^-$, $[(CH_3O)_2TeF_5]^-$,[3] and $[OIF_6]^-$ anions give a more refined picture.[2] Without exception, these anions are distorted pentagonal bipyramids with slightly shortened bonds to the axial ligands. The large methoxy ligands and the oxygen atom in $[OIF_6]^-$ also occupy axial positions. The distortion relates to the fluorine atoms in close contact around the pentagonal base. They avoid steric crowding by arranging themselves above and below the theoretical plane of the pentagon.

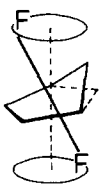
Details of this puckering can be studied in the crystal structure of ReF_7, which has been determined at 1.5 K by T. Vogt, A. N. Fitch, and J. K. Cockcroft, by using high-resolution powder neutron diffraction.[6] The mean displacement of the equatorial F atoms from the ideal ring plane is 0.17 Å and the mean deviation from perpendicular of the angle between axial and equatorial Re–F bonds is 6.2°. The average $Re-F_{eq}$ and $Re-F_{ax}$ bonds are 1.851 and 1.823 Å, respectively, that is the axial bonds are 1.4% shorter. The F_{ax}-Re-F_{ax} angle is 174.6° in the crystal and 172.5° in the gas phase, as determined by electron diffraction analysis.[12] The crystallographic point symmetry of the molecule is C_1, but within experimental error it has a mirror plane, so that the molecular symmetry is C_s. Because of strong deviations of the distorted pentagonal bipyramid from ideal D_{5h} symmetry, the molecular structure at 1.5 K is interpreted as a frozen-in state of the pseudorotational motion.

In a remarkable paper by K. O. Christe, E. C. Curtis, and D. A. Dixon, problems of heptacoordination are discussed for IF_7 as the most-studied prototype. On steric grounds, there is no high-symmetry arrangement of five ligands with normal bond lengths in a plane. Therefore, dynamic ring puckering occurs with large vibrational amplitudes, comparable to the vibrational ring motion in cyclopentane. This "ring puckering", also termed "Bartell-type pseudorotation" by K. O. Christe, has an unexpectedly low vibrational frequency (59 cm^{-1} (0.17 kcal mol^{-1})), which means that there are thermally activated overtones even at very low temperatures. Unfortunately, these vibrations (E_2'' in D_{5h}) are neither IR nor Raman active and can be detected only indirectly in the form of very low-intensity combination bands.

All F atoms in neutral molecular fluorides and fluoro anions with CN 7 are equivalent by NMR spectroscopy. Aside from the very fast ring-puckering mechanism, this equivalence is attributed to a much slower fluxionality between the axial and the equatorial ligands according to the Berry mechanism. The lifetime of a single configuration for IF_7 is estimated to be 2.7×10^{-3} s. The exchange starts from a deformation mode at 265 cm^{-1}, and the activation energy corresponds to a multiple of this frequency. The ligand exchange motion as such is best described as a combination of the out-of-phase axial and equatorial deformation modes (described by the symmetry coordinates S_6 and S_7), accompanied by an out-of-plane twisting mode of the remaining three equatorial F atoms (Scheme 2).

Scheme 2.

In the $[OIF_6]^-$ ion, the O atom avoids the equatorial position because of a partial double bond and thus inhibits axial–equatorial fluxionality. Additionally, in crystalline $[(CH_3)_4N][OIF_6]$, the puckering of the equatorial F atom plane is static rather than fluxional, since interionic H ··· F contacts hinder the vibrations. Questions about the true structure of molecules with strong



[*] Prof. Dr. R. Minkwitz
Fachbereich Chemie der Universität
D-44221 Dortmund (FRG)
Telefax: Int. code + (231)755-3771

fluxionality can only be answered with respect to the method of measurement and its corresponding time scale.

According to ab initio calculations at different theoretical levels, IF_7 in its minimum potential[1] has an undistorted D_{5h} symmetry. Indicative of this is the absence of microwave transitions and of a permanent dipole moment. Also, temperature-dependent crystal structure analyses of $[(CH_3)_4N][OIF_6]$ show that the ring puckering diminishes with falling temperature, that is the arrangement of the equatorial F atoms approaches the arrangement in a plane.

Normal coordinate analyses of IF_7, $[OIF_6]^-$, and $[XeF_5]^-$ give a picture of the vibrating molecule or ion. They are dynamically rather than statically distorted, and on average also have D_{5h} symmetry. According to force-field calculations, the equatorial (in-plane) deformation force constant is in good approximation a measure of the steric hindrance of the ligands in the pentagonal plane. Crowding increases with decreasing bond length and decreasing size of the central atom. It also increases with increasing size of the ligand and increasing temperature.

Because in electron diffraction in the gas phase the time scale is very short, such investigations register only average structures with an equilibrium symmetry between C_1 and C_s. Not only is the equatorial ring puckering evident, but also an inclination of the axial F atoms away from the ideal 180° angle towards approximately 171° for IF_7[1] and 172.5° for ReF_7.[12] Through the dynamic ring puckering in the pentagonal plane, these axial F atoms experience a non-uniform repulsion in such a way that they are each dynamically forced aside by the closest lying ligand (Scheme 3). In other words, the dynamic equatorial puckering gives rise to a coupled in-phase precession of the axial F atoms, which had earlier been interpreted by Bartell as a static inclination. We now know that it is a consequence of the dynamic ring puckering.

Scheme 3.

Molecules and ions with a heptacoordinated central atom do not adopt the minimum-energy structures of a capped prism (C_{3v} symmetry) or a capped octahedron (C_{2v} symmetry) as predicted by VSEPR theory. They rather reside on a slightly raised saddle point of the energy hypersurface, where they adopt a pentagonal-bipyramidal structure with D_{5h} symmetry. K. Seppelt has pointed out[3] that of the possible structures for compounds with coordination numbers 5, 8, and 7, the arrangement with the highest symmetry is also the most common one, and not the minimum-energy structure. This seems to be a general principle for the for the formation of such structures.

As regards chemical bonding, K. O. Christe et. al. have proposed a model,[11] in which the five pentagonal ligands are bound through $p_{x,y}$ hybrid orbitals from the central atom in a semiionic six-center, ten-electron bond. The axial ligands are mainly covalently bonded through two sp_z hybrid orbitals.

$Rb_3[Nb_6SBr_{17}]$, the First Compound Containing an Isolated Trigonal-Prismatic Niobium Cluster**

Hermann Womelsdorf and H.-Jürgen Meyer*

The chemistry of reduced niobium halides is rich in clusters with differing structures. The niobium atoms form trigonal (Nb_3Br_8[1]), rhombic ($Cs[Nb_4Cl_{11}]$[2]), and tetrahedral (NbSeI[3]) clusters. The dominant structural motif, however, is that of the octahedral niobium cluster of the Nb_6X_{12} (X = F, Cl, Br) and of the Nb_6X_8 type (X = I[4]).[5] The binary halides Nb_6Cl_{14}[6] and Nb_6F_{15}[7] (analogous bromine compounds are not known), ternary compounds such as $In[Nb_6Cl_{15}]$[8] and $K_4[Nb_6Cl_{18}]$[9] as well as quaternary compounds such as $In_2Li_2[Nb_6Cl_{18}]$[10] and $CsEr[Nb_6Cl_{18}]$[11] all crystallize with Nb_6X_{12} type structures. The existence of an isolated trigonal-prismatic niobium cluster was suggested previously;[12] and with $Rb_3[Nb_6SBr_{17}]$, such a compound has now been synthesized and characterized for the first time.

In the crystal structure of $Rb_3[Nb_6SBr_{17}]$,[13] 18 bromine atoms are coordinated to the trigonal-prismatic, sulfur-centered Nb_6S unit (Fig. 1). Six of these bromine atoms lie above the six

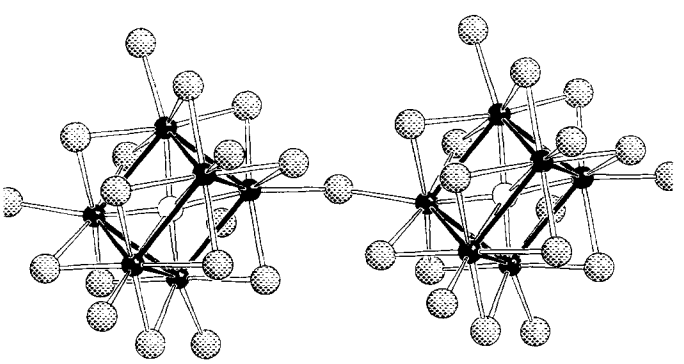

Fig. 1. Chains formed by linkage of the $[Nb_6SBr_{18}]^{4-}$ units through bromine atoms.

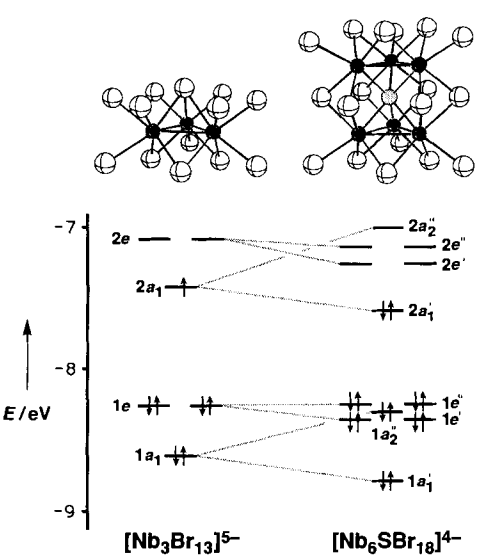
edges of the triangular faces of the prism at a distance (Nb–Br) of 257–261 pm, and a further six bromine atoms lie above the rectangular faces at a distance of 266–269 pm. The remaining six bromine atoms occupy terminal positions above the corners of the prism at a distance of 268–279 pm. The bromine atoms are nearly hexagonally close packed, and the niobium atoms occupy—analogous to the Nb_3Br_8 structure—the octahedral holes, from where they are slightly shifted towards one another. The $[Nb_6SBr_{18}]^{4-}$ units are linked through two terminal bromine atoms to form chains; the longest of the Nb–Br distances (279 pm) is found here. The Rb ions are situated between the chains of cluster molecules. Each Rb ion is surrounded in a nearly anticuboctahedral manner by twelve bromine atoms.

The Nb_6 cluster has a distorted trigonal-prismatic structure with Nb–Nb distances of 328 pm along the edges of the rectangles (here and in the following this term is assigned to those edges of the rectangles which are perpendicular to the planes of the triangular faces). The sulfur atom is located almost exactly in the center of the prism (the Nb–S distances are about 237 pm). The Nb–Nb distances along the edges of the triangle (295–298 pm, mean: 297 pm) are longer than those in Nb_3Br_8[1] by about 7–10 pm and correspond to the value usually found for octahedral niobium bromide clusters.[14] The Nb–Nb distances along the edges of the rectangles are rather long (328 pm) when compared to those in octahedral niobium clusters. Thus, the question arises whether Nb–Nb interactions occur along the edges of the rectangles of the prism.

MO calculations[15] on a $[Nb_6SBr_{18}]^{4-}$ unit show that the fourteen electrons available to the cluster for Nb–Nb bonds fill both the Nb–Nb bonding orbitals, which form the triangles, and those which are assigned to the edges of the rectangles. Indeed, small positive overlap populations (edges of the triangles: 0.25; edges of the rectangles: 0.05) are found between the niobium atoms of the edges of the rectangles. The energy level scheme of the $[Nb_6SBr_{18}]^{4-}$ unit can be constructed based of the MO analysis of a $Nb_3Br_{13}^{5-}$ unit[12] from the Nb_3Br_8 structure. This is illustrated in Figure 2, which shows the splitting of the niobium (d) energy states into—with respect to the interactions along the edges of the rectangles—bonding, nonbonding, and antibonding combinations in $Rb_3[Nb_6SBr_{17}]$. A relative measure for the bonding Nb–Nb interactions along the edges of the rectangles



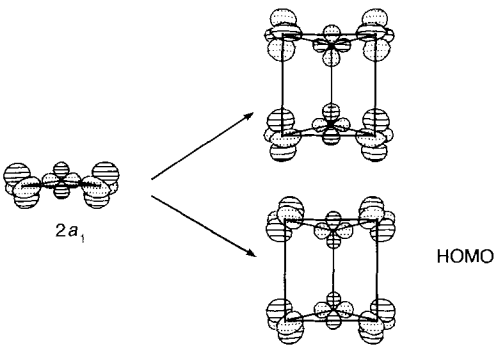


Fig. 2. Comparison of the filled d energy states of $Nb_3Br_{13}^{5-}$ [12] (left) with those of $[Nb_6SBr_{18}]^{4-}$ (right). The energy levels are labeled accoring to idealized C_{3v} and D_{3h} symmetry.

is the splitting of the a_1 states of two Nb_3 clusters (Fig. 2). The combinations of the $2a_1$ orbitals are shown in Scheme 1.

Scheme 1. The formation of a bonding (HOMO) and an antibonding combination (top) from $2a_1$ orbitals of two Nb_3 units.

The Nb_3 triangles of the trigonal-prismatic unit are held together by strong Nb–S bonds, whose states, like those of Nb–Br bonds, are lower in energy than those metal states shown in Figure 2. Weak Nb–Nb bonds strengthen this effect.

In centered clusters the interstitial atom is formally considered either as an electron donor or an electron acceptor. Zr_6CCl_{14}[16] serves as an example for the former. Here the electrons of the carbon atom are added to the cluster electrons: 6×4 (Zr) -14 (Cl) $+4$ (C) $=14$ electrons for metal–metal bonds. Centered clusters are rare for "electron-richer" metals; an example is the trigonal-antiprismatic Mo_6 unit in $Mo_6O(OEt)_{18}$ (16 electrons),[17] in which the oxygen center acts as an electron acceptor. In $Rb_3[Nb_6SBr_{17}]$ the number of electrons available to the cluster for metal–metal bonds is fourteen (6×5 (Nb) $+3\times1$ (Rb) -17×1 (Br) -2 (S) $=14$). Consideration of the MOs for $Rb_3[Nb_6SBr_{17}]$ confirms this, since the seven highest occupied energy states almost exclusively consist of Nb(d) states without noteworthy contributions from sulfur. Thus, the sulfur atom in the center of the cluster is an electron acceptor. Nevertheless, it can be assumed that without the interstitial sulfur atom, as for example in $K_4[Nb_6Br_{18}]$,[14] the Nb_6 prism is less stable than the competing octahedron.

$Rb_3[Nb_6SBr_{17}]$ is the first niobium cluster with an isolated trigonal-prismatic building block. The structural principle of a trigonal-prismatic, sulfur-centered niobium cluster was previously indicated in the structure of Nb_6I_9S,[18] where the sulfur atom resides in a distorted trigonal-prismatic environment formed by the triangular faces of two neighboring Nb_6 clusters.

Experimental Procedure

$Rb_3[Nb_6SBr_{17}]$ was obtained by the reaction of RbBr (124 mg), niobium (74 mg), $NbBr_5$ (345 mg), and sulfur (8 mg). The starting materials were weighed under an argon atmosphere in a glove box and placed into a niobium ampoule, which was sealed and afterwards melted in an evacuated quartz glass ampoule. The reaction mixture was allowed to react over a period of five days at 800 °C. $Rb_3[Nb_6SBr_{17}]$ was obtained as the main product (ca. 70%) in the form of black crystals. The remaining material consisted of fluffy crystals of the $Cs[Nb_3Br_7S]$ type.[19] $Rb_3[Nb_6SBr_{17}]$ is relatively stable in air and is also resistant against moisture for quite some time.

O-Glycoside Syntheses under Neutral Conditions in Concentrated Solutions of $LiClO_4$ in Organic Solvents**

Herbert Waldmann,* Gerd Böhm, Uschi Schmid, and Herbert Röttele

Glycoconjugates have crucial functions in many important biological processes.[1] The development of efficient methods for the directed syntheses of tailored complex glycosides, which could, for example, be used to study these processes, is therefore of great importance, in particular in medicinal chemistry.[2]

Reliable routes for the syntheses of glycosides are the diverse variations of the Koenigs–Knorr reaction,[3] in which glycosyl halides must be activated by heavy metal salts. Furthermore, the transformations with glycosyl fluorides[4] and with trichloroacetimidates according to Schmidt et al.,[5] in which in both cases the glycosyl donor is activated by Lewis acids like $BF_3\cdot OEt_2$, and with thioglycosides, which are transformed into reactive glycosyl donors with alkylating agents,[4, 6] are particularly powerful methods for the chemical synthesis of oligosaccharides.

However, numerous polyfunctional glycoconjugates that are target compounds in complex oligosaccharide syntheses contain many reactive functionalities as well as acid- and base-labile glycosidic bonds. For example, the recently described total synthesis of the oligosaccharide part of calicheamycin γ_1^I[7] had to take into accout the high reactivity of nucleophilic amino and sulfide groups, and the synthesis of benzyl-protected fucosyl glycosides

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

was often substantially hampered by their high sensitivity to acid.[8] It is therefore desirable to develop methods for the chemical synthesis of O-glycosides that require very mild, and preferably neutral, conditions without the use of toxic and expensive heavy metal salts or other promoters like alkylating agents.

The concept behind our method was that the detachment of the leaving group X from glycosyl donors like **1**–**7** should be initiated by a solvent that could stabilize any potential glycosyl cation that might arise as intermediate (Scheme 1). The results of Grieco et al. and other research groups on the acceleration of cycloadditions and rearrangements[9] suggested that concentrated solutions of $LiClO_4$ in organic solvents might fulfill this criterion. We report now that these reaction media favor the formation of glycosyl cations from various glycosyl donors and thus are eminently suitable for O-glycoside syntheses under very mild conditions.

The model glycosyl donors **1**–**7** were used for the development of the method. Donors **1**–**5** have benzyl protecting groups that cannot influence the course of the synthesis through neighboring group effects. As leaving group X at the anomeric center, the halides Br^-, Cl^-, and F^-, trichloroacetimidate,[10] and diphenylphosphate[11] were employed. The stability of a benzylideneacetal group under the conditions of our synthesis method was studied with compound **7**.[12] The O-pivaloylated glucosyl phosphate **6**[12] was selected as acyl-proctected glycosyl donor in which the acyl protecting group at O-2 directs the steric course of the glycosylation. Model glucosyl acceptors were the simple aliphatic alcohols **8**–**10**, the aromatic alcohol **11**, the serine derivative **12**, the steroid **13**, the monosaccharides **14** and **15**, and the disaccharide **16**. The solvents were Et_2O, CH_2Cl_2, $CHCl_3$, and CH_3CN.

The glycosyl donors **1**–**7** react with the glycosyl acceptors **8**–**16** in concentrated solutions of $LiClO_4$ in the organic solvents without addition of promotors or reagents to form the O-glycosides **17** (Scheme 1, Table 1). According to preliminary experiments on the influence of the $LiClO_4$ concentration on the course of the reaction, the best results were achieved in 1 M solutions; all further investigations were performed at this concentration.

Scheme 1. Synthesis of O-glycosides in 1 M solutions of $LiClO_4$ in organic solvents.

Table 1. Results of the O-glycoside syntheses.

No.	Glycosyl donor	Glycosyl acceptor	Solvent	Yield [%] [a]	Anomeric ratio (α:β) [b]
1	**1** (X = Br)	**8**	Et_2O [c]	61	1:1
2	**2**	**10**	Et_2O [c]	63	2:1
3	**3**	**10**	Et_2O	79	1:1
4	**3**	**9**	Et_2O	63	1:1
5	**3**	**11**	Et_2O	56	1:1
6	**3**	**12**	Et_2O	50	1:1
7	**3**	**14**	Et_2O	45	1:1
8	**4**	**8**	CH_3CN	95	1:2

14	**7**	**15**	CH_2Cl_2	48	5:1
15	**5**	**8**	CH_2Cl_2	47	1:4
16	**5**	**10**	CH_2Cl_2	36	1:7
17	**5**	**13**	CH_2Cl_2	42	1:2
18	**6**	**8**	CH_2Cl_2	68	only β
19	**6**	**13**	$CHCl_3$	56	only β
20	**6**	**14**	$CHCl_3$	54	only β

[a] Based on chromatographically purified glycoside **17**. All glycosides **17** were identified in $CDCl_3$ solution by ^1H NMR spectroscopy (250 or 400 MHz). [b] Determined by integration of the relevant signals in the ^1H NMR spectra of the anomeric mixtures or by HPLC. [c] 1 equiv CsF was added as scavenger for acid.

Considering that under these mild conditions the glycosyl donors are not additionally activated, for example through the formation of better leaving groups at the anomeric center, and that the two reactants are always employed in equimolar amounts, the yields of **17** are satisfactory to high. The halogenoses **1** can for instance be employed as benzyl-protected donors (Table 1, no. 1), but higher yields are recorded if the trichloroacetimidates **3** and **4** are used. Particularly surprising is the finding that the glycosyl fluoride **2**, which usually can be activated only by strong Lewis acids like $BF_3 \cdot OEt_2$, and the alcohol **10** react to form the O-glycoside in high yield (Table 1, no. 2). With the α-configurated trichloroacetimidate **3**, the desired glycosides are obtained as 1:1 mixtures of the two anomers (Table 1, nos. 3–7), and with the β-imidate **4** as well as with the β-configurated glycosyl donor **7**, the α-glycosides are in general formed predominantly (Table 1, nos. 9–14). Distinct excesses of β-**17** were achieved with the benzyl-protected α-diphenyl-

phosphate **5** (Table 1, nos. 15–17). The solvents Et_2O, CH_2Cl_2, and $CHCl_3$ influence neither the magnitude nor the kind of the anomeric ratio. However, if the β-trichloroacetimidate **4** is treated with **8** in the solvent CH_3CN,[13] which stabilizes the glycosyl cation, the β anomer is in excess in contrast to the situation in CH_2Cl_2 (Table 1, nos. **8** and **9**). Thus with the trichloroacetimidate or diphenyl phosphate residue as leaving group at the anomeric center of the glycosyl donor and in the presence of benzyl protecting groups that are not capable of exerting neighboring group effects, the stereoselection in the synthesis of O-glycosides **17** can be deliberately steered to either direction. On the other hand, the pivalic acid ester in **6** participates anchimerically in the glycosylation, with the result that, as expected, the β-glycosides are formed with this glycosyl phosphate (Table 1, nos. 18–20).

The examples in Scheme 1 and Table 1 indicate that not only glycosides of simple aliphatic and aromatic alcohols can be formed under mild conditions and without additional promoters by our method reported here, but hydroxyamino acids and steroids can also be glycosylated and disaccharides synthesized successfully. Moreover the method is suitable for the construction of larger glycoconjugates, as the coupling of **4** with the disaccharide **16**, which yields the desired trisaccharide with satisfactory results, shows (Table 1, no. 13).

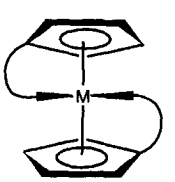
Doubly Bridged *rac*-Metallocenes of Zirconium and Hafnium**

Wolfgang A. Herrmann,* Marcus J. A. Morawietz, and Thomas Priermeier

Dedicated to Professor Wolfgang Hilger on the occasion of his 65th birthday

Since the discovery of stereospecific Ziegler–Natta polymerization with metallocene catalysts,[1] interest has concentrated on the optimization of the catalytic properties by variation of substituents.[2] Only recently was attention also turned to the *rac*/*meso* problem in the synthesis of *ansa*-metallocenes;[3] nevertheless, all concepts cling to the classical route [Eq. (a)].

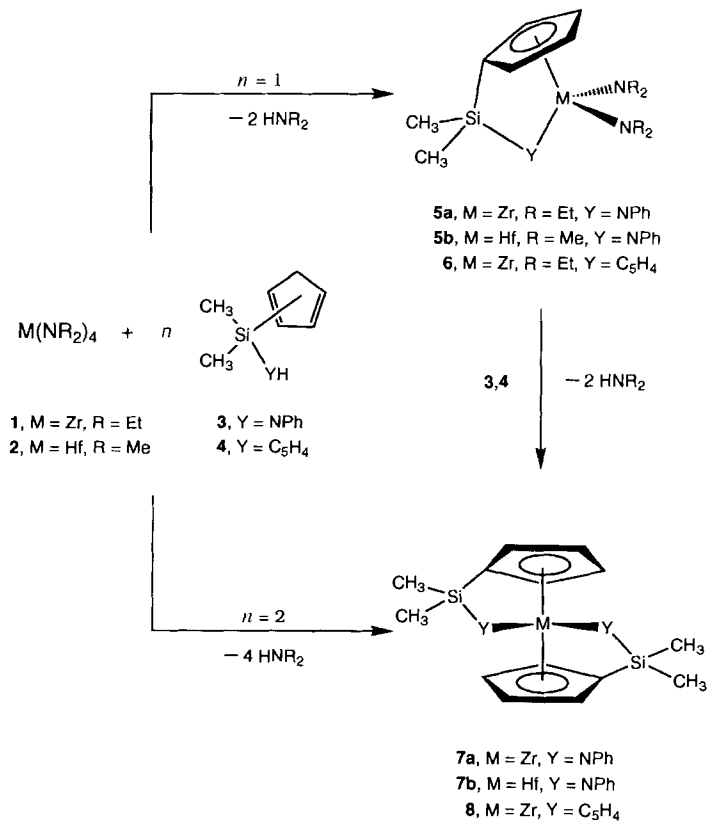


Disadvantages of this pathway are the required removal of the salt and the mostly moderate yields. Moreover, mixtures of *rac*/*meso* diastereomers are produced, which can often be separated only by several crystallization steps.

(a)

M = Ti, Zr, Hf
X = SiR'_2, $CR'_2CR'_2$
M' = Li, Na
R,R' = alkyl, aryl

In this communication we describe a salt-free synthesis in which the *rac*/*meso* isomer problem does not arise, and new metallocenes of the constitution of type **A** can be simply and universally prepared as potential catalysts. The concept is based on the treatment of homoleptic metal amides $[M(NR_2)_4]$ with functionalized cyclopentadienes.



A

If zirconium and hafnium tetraamides **1** and **2** are treated with one equivalent of cyclopentadienyldimethyl(*N*-phenylamino)silane (**3**)[4] or bis(cyclopentadienyl)dimethylsilane (**4**)[5a] in toluene, two amide ligands are substituted (yields >98%, Scheme 1).

Scheme 1. Synthesis of the metallocenes **5**–**8**.

The products **5** and **6** are susceptible to hydrolysis and very soluble in halogen-free organic solvents. The complexes **5** are oils, whereas **6** is a yellow solid crystallizable from *n*-hexane. As the ^{1}H, ^{13}C, and ^{29}Si NMR spectra show, **6** has a mirror plane.

The exhaustive exchange of the amide residues can be achieved either by treatment of **5** and **6** with the ligands **3** or **4**, respectively, or through quantitative substitution directly from the tetraamides **1** and **2** (Scheme 1).[6a] The *rac* configuration of the doubly bridged amido metallocenes **7** was proven by ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy. They are solids sensitive to hydrolysis and can be crystallized from apolar solvents. The crystal structure analysis confirms, in principle, the C_2 symmetry

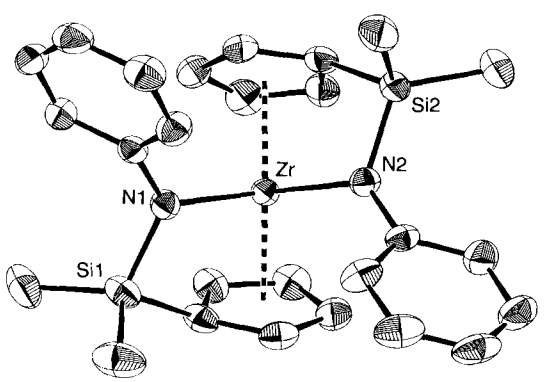

Fig. 1. Molecular structure of **7a** in the crystal (PLATON representation). Selected distances [pm] and angles [°]: Zr–Z1 220.7, Zr–Z2 221.7, Zr–N1 213.7(2), Zr–N2 212.7(2); Z1-Zr-Z2 133.0, N1-Zr-N2 106.48(8). Z1: Center of the cyclopentadienyl ring C11, C12, C13, C14, C15; Z2: Center of the cyclopentadienyl ring C31, C32, C33, C34, C35.

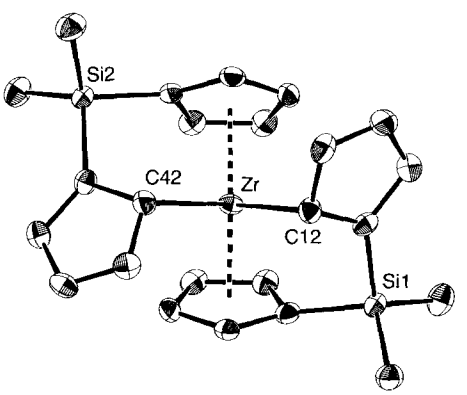
determined in solution, but the complex is slightly distorted in the crystal as a result of packing effects (Fig. 1).[6b, c]

It is striking that the twofold bridging and the steric bulk of the phenyl substituents cause no substantial distortion of the framework. Consequently the metallocenes **7** display the same characteristic features of common metallocenes like $[(C_5H_5)_2ZrCl_2]$ and $[Me_2Si(C_5H_4)_2ZrCl_2]$. The distances between the metal ion and the centers (Z) of the cyclopentadienyl rings in **7a** are 221 and 222 pm, in the typical range for a Zr–Z distance.[5b, c] The similarity is emphasized by the Z-Zr-Z′ angle of 133.0°, which may be compared with the usual value of between 125.4 and 128.3°.[5b, c]

The bis(cyclopentadienyl) ligand **4**, like **3**, can substitute either two or four amide ligands of **1**. Complete ligand exchange yields **8** almost quantitatively after sublimation. Like the complexes $[M(C_5H_5)_4]$[7] of titanium, zirconium, and hafnium, the *ansa* analogue **8** has a dynamic structure in solution. The ^{1}H and ^{13}C NMR spectra feign a fourfold η^5-coordination. The AA′BB′ splitting for monosubstituted cyclopentadienyl rings and the singlet for the CH_3 protons of the bridge remain unchanged to 163 K. In the crystal **8** is not $(\eta^5)_3$:(η^1)-coordinated like $[Zr(C_5H_5)_4]$,[7b] but $(\eta^5)_2$:$(\eta^1)_2$-coordinated like $[Ti(C_5H_5)_4]$[8a] and $[Hf(C_5H_5)_4]$[8b] (Fig. 2).[9]



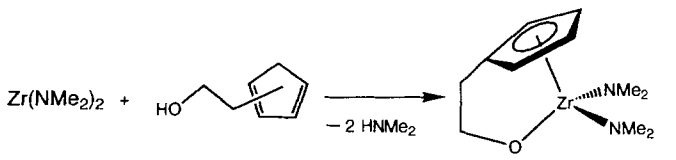


Fig. 2. Molecular structure of **8** in the crystal (PLATON representation). Selected distances [pm] and angles [°]: Zr–Z1 220.2, Zr–Z2 219.5, Zr–C12 245.5(3), Zr–C42 246.3(2); Z1-Zr-Z2 129.6, C12-Zr-C42 82.74(9). Z1: Center of the cyclopentadienyl ring C21, C22, C23, C24, C25; Z2: Center of the cyclopentadienyl ring C31, C32, C33, C34, C35.

This coordination behavior of a bridging bis(cyclopentadienyl) ligand is new in metallocene chemistry. Complex **8** is a model for an intermediate that is discussed in the formation and isomerization of metallocenes.[10] Like **7a**, compound **8** also does not have perfect C_2 symmetry as a result of packing effects. The Zr-η^1–C bonds are unusually long (245.5 and 246.3 pm). The characteristic Z-Zr-Z′ angle is 129.6°.

According to our results the treatment of homoleptic metal amides with nondeprotonated bidentate derivatives of cyclopentadiene is advantageous for the synthesis of metallocenes of type **A** and a promising alternative to classical transmetalation. Besides the easy access to *ansa*-metallocenes, new metallocenes with fixed C_2 symmetry are selectively accessible through this amide route and the principle of double bridging. This concept has substantial advantages over the former syntheses of *rac*-metallocene complexes: a) high stereoselectivity, that is, no *rac*/*meso* separation; b) quantitative yield; c) simple precursors and ligands accessible by common procedures in few steps; d) one step less, because deprotonation of the ligand is not required. The

complexes **7** are catalysts for ethylene and propylene polymerization if methyl aluminoxane (MAO) is used as activator.[11]

With this new method π ligands with alcoholate functions can also be introduced, as the example of **9** shows: this compound arises quantitatively from the complex $[Zr(NMe_2)_4]$ and the ligand $C_5H_5CH_2CH_2OH$ with loss of dimethylamine, which, as in the other cases, escapes as gas during the reaction [Eq. (b)];[12] this favors formation of the product.

(b)

9

Extension to other functionalized π-arene complexes of the early transition metals and rare earth metals, as well as to elements of the fourth main group, seem promising.[13]

Experimental Procedure

5a: Compounds **1** (569 mg, 1.5 mmol) and **3** (323 mg, 1.5 mmol) were each dissolved in toluene (10 mL), and the solutions were mixed at −78 °C. After the reaction mixture had warmed to 25 °C, it was heated at reflux for 3 h. The solvent was then removed under vacuum, and **5a** is obtained as dark red oil. Yield 665 mg (99%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): δ = 0.55 (s, 6H; $Si(CH_3)_2$), 0.87 (t, 12H, ^3J(H,H) = 6.7 Hz; $N(CH_2CH_3)_2$), 3.12 (dt, 4H, ^3J(H,H) = 6.7 Hz; $N(CH_2CH_3)_2$), 3.27 (dt, 4H, ^3J(H,H) = 6.7 Hz; $N(CH_2CH_3)_2$), 6.32 (t, 2H, ^3J(H,H) = 2.4 Hz; C_5H_4), 6.41 (t, 2H, ^3J(H,H) = 2.4 Hz; C_5H_4), 6.81 (t, 1H, ^3J(H,H) = 7.3 Hz; *p*-H), 7.02 (d, 2H, ^3J(H,H) = 7.3 Hz; *o*-H), 7.21 (t, 2H, ^3J(H,H) = 7.3 Hz; *m*-H); $^{13}C\{^1H\}$ NMR (100.4 MHz, C_6D_6, 25 °C, TMS): δ = 0.5 (s; $Si(CH_3)_2$), 15.6 (s; $N(CH_2CH_3)_2$), 43.5 (s; $N(CH_2CH_3)_2$), 108.9 (s; C_5H_4), 115.1 (s; C_5H_4), 118.9 (s; *o*-C), 121.5 (s; C_5H_4), 124.3 (s; *p*-C), 129.2 (s; *m*-C), 155.3 (s; C_6H_5); ^{29}Si NMR (DEPT, 79.5 MHz, C_6D_6, 25 °C, TMS): δ = −20.3 (s; $Si(CH_3)_2$); IR (neat): $\tilde{\nu}$ [cm^{-1}] = 3070 m (ν(=CH)), 3046 m sh (ν(=CH)), 2861 s (ν(C−H)), 997 s (ν_{sym}(N−C_2)), 575 m (ν(M−N)); MS (CI): *m/z* (%): 448 (100) [M^+], 432 (13) [M^+−CH_4], 376 (45) [M^+−NEt_2], 303 (6) [M^+−NEt_2−$HNEt_2$], 216 (4) [$(Me_2Si(C_5H_5)(NHC_6H_5)H)^+$].

6: Compounds **4** (376 mg, 2 mmol) and **1** (759 mg, 2 mmol) were each dissolved in 10 mL toluene and cooled to −78 °C. At this temperature the dissolved ligand was added dropwise. After the mixture had warmed to room temperature, it was stirred for 16 h. The solvent was removed under vacuum, and **6** was recovered as analytically pure yellow solid. Yield 840 mg (99%). ^{1}H NMR (400 MHz, C_6D_6, 30 °C, TMS): δ = 0.40 (s, 6H; $Si(CH_3)_2$), 0.96 (t, 12H, ^3J(H,H) = 6.7 Hz; $N(CH_2CH_3)_2$), 3.17 (q, 8H, ^3J(H,H) = 6.7 Hz; $N(CH_2CH_3)_2$), 5.77 (t, 4H, ^3J(H,H) = 2.4 Hz; C_5H_4), 6.51 (t, 4H, ^3J(H,H) = 1.8 Hz; C_5H_4); $^{13}C\{^1H\}$ NMR (100.4 MHz, C_6D_6, 30 °C, TMS): δ = −5.1 (s; $Si(CH_3)_2$), 14.7 (s; $N(CH_2CH_3)_2$), 47.7 (s; $N(CH_2CH_3)_2$), 109.8 (s; C_5H_4), 112.5 (s; C_5H_4), 117.3 (s; C_5H_4); ^{29}Si NMR (DEPT, 79.6 MHz, C_6D_6, 30 °C, TMS): δ = −15.9 (s; $Si(CH_3)_2$); MS (CI): *m/z* (%): 420 (48) [M^+], 405 (4) [M^+−CH_3], 347 (100) [M^+−$HNEt_2$], 276 (3) [M^+−$HNEt_2$−NEt_2]; IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3010 w (ν(=CH)), 2960 vs (ν(C−H)), 1001 m (ν_{sym}(N-C_2)), 566 m (ν(M-N)).

7a: Compound **3** (430 mg, 2 mmol) dissolved in 10 mL toluene at −50 °C was added dropwise to a solution of **1** (379 mg, 1 mmol) in 10 mL toluene at −78 °C. The reaction mixture was allowed to warm to 25 °C and then heated at 120 °C for 12 h. The solvent was removed under vacuum, and **7a** remained as light yellow solid. Yield: 0.512 g (99%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): δ = 0.37, 0.45 (s, 6H; $Si(CH_3)_2$), 5.65 (q, 2H, J(H,H) = 2.4 Hz; C_5H_4), 5.89 (q, 2H, J(H,H) = 1.8, 3.0 Hz; C_5H_4), 5.95 (q, 2H, J(H,H) = 1.8, 2.4, 3.1 Hz; C_5H_4), 6.17 (q, 2H, J(H,H) = 1.8, 3.1 Hz; C_5H_4), 6.89 (t, 1H, ^3J(H,H) = 7.3 Hz; *p*-H), 6.96 (d, 2H, ^3J(H,H) = 7.9 Hz; *o*-H), 7.20 (t, 2H, ^3J(H,H) = 7.3 Hz; *m*-H); $^{13}C\{^1H\}$ NMR (100.4 MHz, C_6D_6, 25 °C, TMS): δ = −2.3, 1.0 (s; $Si(CH_3)_2$), 112.3 (s; C_5H_4), 113.5 (s; C_5H_4), 113.6 (s; C_5H_4), 117.0 (s; C_5H_4), 118.7 (s; *o*-C), 121.3 (s; C_5H_4), 124.3 (s; *p*-C), 128.9 (s; *m*-C), 157.1 (s; C_6H_5); ^{29}Si NMR (DEPT, 79.5 MHz, C_6D_6, 25 °C, TMS): δ = −20.5 (s; $Si(CH_3)_2$); MS (CI): *m/z* (%): 516 (100) [M^+], 501 (14) [M^+−CH_3]; IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3062 w, 3023 m, 2948 s, 1585 s, 1477 s, 1260 vs, 1252 s sh, 920 s, 816 vs.

8: Compounds **4** (376 mg, 2 mmol) and **1** (379 mmol, 1 mmol) were each dissolved in 10 mL toluene and cooled to −78 °C. At this temperature the ligand was added dropwise. After warming to 25 °C the mixture was stirred for 16 h. The solvent was removed under vacuum, and the yellow-orange residue sublimed under high vacuum. Compound **8** was isolated as a yellow-orange solid at 70 °C and 2×10^{-4} Torr. Yield 440 mg (95%). ^{1}H NMR (400 MHz, C_6D_6, 30 °C, TMS): δ = 0.37 (s, 12H; $Si(CH_3)_2$), 5.70 (t, 4H, ^3J(H,H) = 1.8 Hz; C_5H_4), 5.86 (t, 4H, ^3J(H,H) = 2.4 Hz; C_5H_4); $^{13}C\{^1H\}$ NMR (100.4 MHz, C_6D_6, 30 °C, TMS): δ = −2.4 (s; $Si(CH_3)_2$), 111.8 (s; C_5H_4), 118.0 (s; C_5H_4), 124.5 (s; C_5H_4); ^{29}Si NMR (DEPT, 79.6 MHz, C_6D_6, 30 °C, TMS): δ = −17.6 (s; $Si(CH_3)_2$); MS (CI): *m/z* (%): 462 (100) [M^+], 186 (10) [$Me_2Si(C_5H_4)(C_5H_5)^+$].

Compounds **5b** and **7b** were prepared analogously.

[11] On interaction of complexes **7** with MAO the C_2-symmetry need not necessarily be lost. According to present knowledge, it is more likely that the cleavage of the M–N bond affords an active, *rac*-species in which the amide function resides on the activator. Complex **7** is a good example with which to study such possibilities. Because of the reactive (protolyzable) M-N bond in **7**, the catalyst is possibly fixed to alumoxane surfaces. Experiments on this subject are under way.

Iron-Promoted, Regio- and Stereoselective Allylic Substitutions for the Synthesis of Alkenyl Sulfones Substituted at C-3**

Dieter Enders,* Bernd Jandeleit, and Gerhard Raabe

Catalytic and stoichiometric reactions of transition-metal π complexes containing unsaturated organic ligands are of growing significance in the development of countless preparative methods in organic synthesis.[1] Auxiliaries based on metal complexes are used in functionalization reactions primarily because of their ability to activate and to influence facial differentiation and stereoselection.[2] Complexes containing allyl ligands, which act as stabilized carbocation equivalents, have recently been of particular preparative interest owing to their enhanced reactivity towards nucleophiles. Alkyl-, aryl-, and acceptor-substituted (η^3-allyl)tetracarbonyliron(1 +) complexes undergo addition reactions with a multitude of soft carbon and heteroatom nucleophiles. Functionalization of the allyl unit proceeds with regio- and, above all, stereocontrol.[3] Demetalation ultimately yields complex and stereochemically well-defined target molecules. The scope of this type of reaction, in both its stoichiometric and catalytic variations, has now been extended by the use of other transition metals apart from iron, in particular, palladium,[4] molybdenum,[5] nickel,[6] and copper.[7]

Acceptor-substituted, cationic (π-allyl)carbonyliron complexes **A**[8] in their diastereo- and enantiomerically pure form are preparatively useful as intermediates in asymmetric synthesis. Here, **A** acts as an a^4-synthon **B** with planar chirality; an umpolung[9] of classical d^4-reactivity is observed.

We now report on iron-promoted, regio- and stereoselective allylic substitution reactions of 1-phenylsulfonyl-substituted (η^3-allyl)tetracarbonyliron(1 +) tetrafluoroborate, which exhibits planar chirality. Sulfonyl-substituted allyl compounds of high enantiomeric purity are obtained by this method. Key steps in the synthesis are the diastereoselective complexation of $Fe(CO)_4$ with the easily accessible, enantiomerically pure sulfone (*S*)-**1**[10] to give the neutral η^2-olefin complex (1*R*, 2*S*, 3*S*)-**2** and the transformation of **2** into the enantiomerically pure, cationic iron complex with planar chirality (1*R*, 2*S*, 3*R*)-**3**. Regioselective addition of carbon and nitrogen nucleophiles to **3** followed by oxidative decomplexation provides access to highly enantiomerically enriched, alkenyl sulfones **4** substituted with a wide range of substituents at the allylic position (Scheme 1, Table 1).

Scheme 1. Synthesis of the (η^3-allyl)tetracarbonyliron(1 +) complex with planar chirality (1*R*, 2*S*, 3*R*)-**3**, and its reactions with C- and N-nucleophiles to give the 3-substituted sulfones **4**; a) $[Fe_2(CO)_9]$ (1.3 equiv), *n*-hexane, CO atmosphere, 3 d; b) fractional crystallization from ether/*n*-hexane; c) HBF_4 (1.2 equiv), ether, 30 °C; d) nucleophile (2.5–5 equiv), CH_2Cl_2 or THF, −78 °C to room temperature, 8 h or CH_3NO_2, room temperature, 24 h; e) $(NH_4)_2Ce(NO_3)_6/H_2O$ (4 equiv), 8 h or I_2/ether (4 equiv), 8 h.

Table 1. Iron-promoted allylic substitutions for the preparation of sulfones **4** substituted at C-3.

4 [a]	Nucleophile	Nucleophile/Complex	Reagents/Conditions	Yield [%] [b]	*ee* [%] [c] (Config.)

stable by comparison to similar sulfonyl- or sulfinyl-substituted olefin and diene complexes.[12] A particularly characteristic feature in the NMR spectra of **2** is the upfield shift of the signals of the atoms at the β position of the alkenyl system relative to

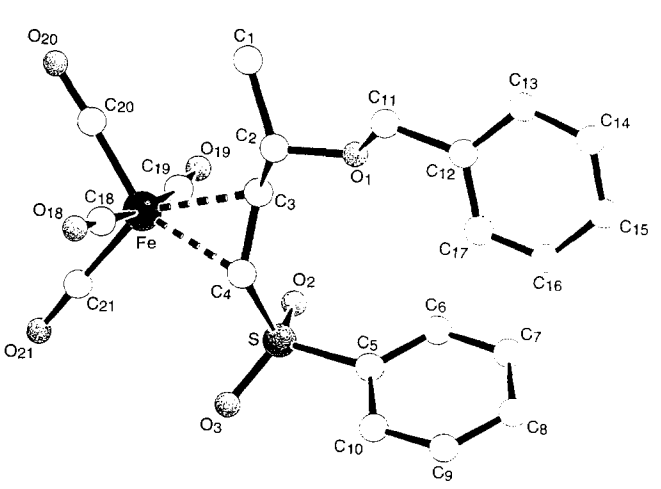

Fig. 1. Crystal structure of (1*R*, 2*S*, 3*S*)-**2** (SCHAKAL representation) [14].

those at the α position (^{1}H NMR: H_α: $\delta = 3.86$, H_β: $\delta = 3.29$; ^{13}C NMR: C_α: $\delta = 66.70$, C_β: $\delta = 57.96$). The crystal stucture of complex **2** is illustrated in Figure 1.[13]

Whilst the structural parameters of the equatorially substituted (η^2-olefin)Fe(CO)$_4$ fragment, which adopts a distorted trigonal bipyramidal geometry, are typical of this type of complex,[3m, 12, 16, 17] some structural aspects of the complexed ligand merit closer inspection. The SO_2Ph unit is twisted away from the Fe(CO)$_4$ moiety (C2-C3-C4-S −137(1)°); the terminal methyl group is, on the other hand, inclined slightly towards the Fe atom (C1-C2-C3-C4 −151(1)°). The "W-shaped" geometry adopted by the ligand fixes the *syn* arrangement of the methyl and sulfonyl groups with respect to β-hydrogen atom in the resulting cationic complex **3**. As a result of the single configuration at the 3-position, one side of the double bond unit is selectively blocked by the Fe(CO)$_4$ moiety, which lies *trans* to the OBn leaving group. This is of crucial importance to the course of reaction. In related cyclic systems, an "antisteric" *cis* complexation[3m, 17] seems to be kinetically favored; hence, the preference for the *trans* arrangement observed here can be explained by thermodynamic equilibration.

The cationic (η^3-allyl)tetracarbonyliron complex with planar chirality (**3**) was generated by precipitation of the (η^2-olefin)iron complex **2** from ether on addition of excess anhydrous tetrafluoroboric acid at 30 °C (Scheme 1).[11b] The OBn group was cleaved in this reaction. The complex was isolated in 96% yield and in virtually isomerically pure form (*de*, *ee* > 98%) as a moderately air-stable, pale yellow powder. The isomeric purity was determined from the signals in the ^{1}H NMR spectrum corresponding to the terminal methyl groups, which have clearly distinguishable chemical shifts (^{1}H NMR: (1*R*, 2*S*, 3*R*)-**3**: $\delta = 2.13$; (1*R*, 2*S*, 3*S*)-**3**: $\delta = 1.77$).[11b, 16] The ^{1}H NMR signal of the β-hydrogen atom shows coupling constants $^3J_{H\beta/H\gamma}$ and $^3J_{H\beta/Hx}$ of 12.4 and 10.1 Hz, respectively, which are characteristic for an *anti* arrangement; both the methyl and sulfonyl groups are thus *syn* to the β-hydrogen atom (Table 2). The transformation of (*S*)-**1** into (1*R*, 2*S*, 3*R*)-**3** therefore proceeds with inversion of the stereogenic center at the 3-position.

The nucleophilic additions were carried out by adding between 2.5 and 5 equivalents of nucleophile (lithium dimethylmalonate, silyl enol ether, secondary amine, electron-rich arene) in an appropriate solvent to a suspension (in CH_2Cl_2 or THF) or solution (in CH_3NO_2) of the cationic iron electrophile **3** at −78 °C and room temperature, respectively (Scheme 1, Table 1). The progress of reaction could be easily followed, since the suspended cationic iron complex gradually dissolved to give the soluble, neutral η^2-olefin complex. The nucleophilic arenes were added as solutions in CH_3NO_2; the reaction was complete after 24 h. Oxidative cleavage of the iron with aqueous ceric ammonium nitrate solution or, in the case of the arene-substituted compounds, with an iodine solution in ether affords, after workup and purification, 3-substituted alkenyl sulfones **4** of high enantiomeric purity (Table 1). The nucleophile added stereoselectively *anti* to the Fe(CO)$_4$ moiety[18] and regioselectively at the 3-position relative to the sulfonyl group. Thus, the overall reaction sequence proceeded with almost complete transfer of chirality (*ee* ≥ 96%) and retention (double inversion) with respect to the stereochemistry of the starting material. The absolute configurations indicated are based on the assumption of a uniform reaction mechanism and on an X-ray structure analysis of **4h**.[19] The coupling constants $^3J_{trans}$ between the olefinic protons in **4a–j** of 15.0–15.4 Hz confirm that neither olefinic nor allylic isomerization takes place under the reaction conditions in the sequence.

The strategy described above, namely, stereoselective chirality transfer (central → planar → central chirality) in (π-allyl)iron complexes synthesized from enantiomerically pure precursors that are readily available from natural products or enzymatic

reactions,[20] provides an efficient access to highly enantiomerically enriched alkenyl sulfones with a range of substitution patterns at the 3-position. This class of compound is of increasing importance.[21] By varying the starting material ((*S*)- or (*R*)-hydroxycarboxylic acids and aldehydes[20]), the double bond geometry of the ligand (*E* or *Z*), and the nucleophile, an extensive spectrum of products should become available.

Experimental Procedure

(1*R*, 2*S*, 3*S*)-**2**: A solution of $[Fe_2(CO)_9]$ (3.64 g, 13.0 mmol) and (*S*)-**1** (3.03 g, 10.0 mmol) in anhydrous *n*-hexane (150 mL) under argon was saturated with carbon monoxide. The suspension was stirred for 3 d at room temperature under carbon monoxide with exclusion of light. The mixture was diluted with anhydrous ether (100 mL) and filtered through Celite, which was then washed with ether. The clear yellow solution was concentrated under reduced pressure to between a third and a quarter of the original volume and was then fractionally crystallized at −25 °C. The pale yellow precipitate was washed with *n*-hexane (−20 °C) and dried under vacuum. A second crop was obtained from the mother liquor. Overall yield 3.24 g (69%).

(1*R*, 2*S*, 3*R*)-**3**: Complex **2** (4.70 g, 10.00 mmol) was dissolved in anhydrous ether (100 mL) under argon at 30 °C. A solution of HBF_4 in ether (54%, 1.64 mL, 12.0 mmol) was added dropwise with rapid stirring. After 2 h, the mixture was filtered, and the slightly yellowish solid was washed with anhydrous ether and dried under vacuum. Yield 4.32 g (96%). Analytically pure (1*R*, 2*S*, 3*R*)-**3** was obtained by fractional recrystallization from nitromethane solution with cold ether.

Procedure for the nucleophilic addition of lithium dimethylmalonate, silyl enol ethers, and secondary amines to (1*R*, 2*S*, 3*R*)-**3**: A suspension (10 mL per mmol of complex) of **3** (0.450 g, 1 mmol) in CH_2Cl_2 (silyl enol ethers, secondary amines) or THF (lithium dimethylmalonate) was treated at −78 °C with a solution of the nucleophile (2.5–5 equiv) in the appropriate solvent (1–2 mL). The reaction mixture was allowed to warm slowly to room temperature. A soluble neutral complex was obtained. For the oxidative decomplexation, the reaction mixture was treated with aqueous $(NH_4)_2Ce(NO_3)_6$ solution (4 equiv) and stirred for 8 h at room temperature. After extraction with CH_2Cl_2 and separation of the organic phase, Fe^{III} ions were removed from the latter by successive washing with saturated NH_4F solution (10 mL) and saturated NaCl solution (10 mL). The solution was then dried over $MgSO_4$, concentrated under reduced pressure, and purified by flash chromatography (silica gel, petroleum ether/ether mixture) to afford compounds **4a–g** in analytically pure form.

Procedure for the addition of electron-rich arenes to (1*R*, 2*S*, 3*R*)-**3**: A solution of **3** (0.450 g, 1 mmol) in CH_3NO_2 (10 mL per mmol of complex) was reacted at room temperature under carbon monoxide with a solution of the nucleophile (3–5 equiv in 1–2 mL). After 24 h, the mixture was diluted with an eightfold volume of ether, and the organic phase washed with saturated NaCl solution. Oxidative decomplexation was achieved by stirring at room temperature with I_2 (4 equiv) for 12 h. Excess I_2 was removed by shaking with $KHSO_3$ solution (10%, 10 mL). Additional workup as described above yielded compounds **4h–j** in analytically pure form.

α-Aryliodonio Diazo Compounds: S_N Reactions at the α-C Atom as a Novel Reaction Type for Diazo Compounds

Robert Weiss,* Jörg Seubert, and Frank Hampel

Three fundamental reaction types account for the versatility of diazo compounds as reagents in organic chemistry: S_E reactions at the α-C atom, carbene generation, and cycloadditions. Although this class of compounds and their reactions have been known for well over 100 years,[1] no examples of an S_N reaction at the α-C atom with retention of the diazo function have been reported.[2] This type of reaction would require functionalization of the α-C atom of the diazo compound with a potent nucleofuge. Since the aryliodonio function is such a nucleofuge,[3] we thought that the previously unknown α-aryliodonio diazo compounds would be suitable for the realization of this type of reaction. As we report here, this proposed type of reaction succeeded.

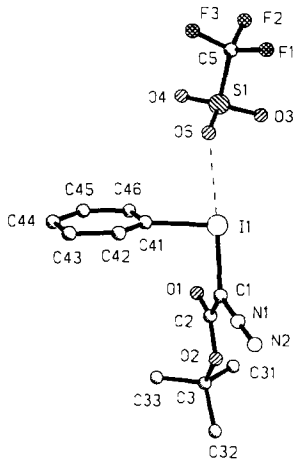
The title compounds, the first α-aryliodonio diazo compounds, are easily accessible via bis(onio)-substituted aryliodine(III) salts such as **1**, which we described recently.[4] Compound **1** reacted rapidly at room temperature with *tert*-butyl diazoacetate (**3**) and ethyl diazoacetate (**4**) to give the corresponding α-aryliodonio diazo compounds **5** and **6**, respectively (path A, Scheme 1).

Scheme 1. $OTf^- = CF_3SO_3^-$.

Both compounds were obtained along with protonated pyridine after precipitation with Et_2O. Subsequent fractional recrystallization provided both compounds in analytically pure form.

The same compounds were also prepared directly according to path B (Scheme 1) by the Lewis acid mediated (Me_3SiOTf) reactions of (diacetoxyiodo)benzene **2** with **3** and **4**. Salts **5** and **6** were obtained in good yields and without interfering impurities;[6] however, one additional mole equivalent of the diazo compound was consumed.[7]

The crystal structure of **5**[8] (Fig. 1) shows the typical T-shaped structure of iodine(III) compounds; the electronic requirements of the iodine center are met by the weakly coordinating anion (OTf^-; I1–O5: 2.705 Å) as a third ligand.[9] The C1–N1 distance (1.309 Å) and the N1–N2 distance (1.125 Å) are within the range expected for diazo compounds.[10] The C1-N1-N2 axis is almost linear (179.7°), which is also typical. The I1–C41 and I1–C1 bonds (2.112 and 2.050 Å, respectively) and the C1-I1-C41 angle (95.0°) are within the standard range for iodonio ylides, for example.[11]



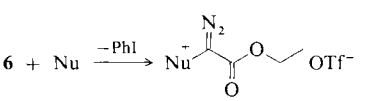


Fig. 1. Crystal structure of **5**. Important bond lengths [Å] and angles [°]: I1-C1 2.050(5), I1-C41 2.112(5), I1-O5 2.705(4), C1-N1 1.309(8), N1-N2 1.125(7), C41-I1-O5 82.4(2), C1-I1-C41 95.0(2), C1-I1-O5 177.0(2), N2-N1-C1 179.7(5).

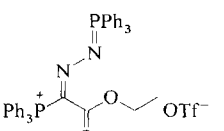
This novel substitution pattern in a diazo compound causes an umpolung of the reactivity of the α-C atom. Thus nucleophilic substitutions can be carried out at the α-C atom for the first time. The reaction of **6** with a series of neutral nucleophiles under mild conditions (room temperature) led to the α-onio-substituted diazo compounds **7**–**11** [Eq. (a)].



(a)

7 **11**

$-Nu^- =$ **7**: $-\overset{+}{N}$ **8**: $-\overset{+}{S}Me_2$ **9**: $-\overset{+}{A}sPh_3$ **10**: $-\overset{+}{S}bPh_3$ **11**: $-\overset{+}{N}Et_3$

The reaction with triphenylphosphane as the nucleophile proceeded further; phosphonio phosphazine **12**, which was previously prepared by Regitz et al. in a different approach,[12] formed regardless of stoichiometry and reaction conditions.

All new compounds can be stored at room temperature with exclusion of moisture and are easy to handle. The yields and spectroscopic data are given in Table 1.

12

If one considers the tendency of diazo compounds to eliminate N_2 and convert into carbenes, then this new class of compounds is in principle the synthetic equivalent of carbyne cations $RC:^+$. This aspect is under current investigation.

Experimental Procedure

All reactions were conducted under nitrogen and in anhydrous solvents.

Synthesis of **5** and **6** from **1**: A suspension of 2 mmol of **1** in 20 mL of CH_2Cl_2 was treated with 2.1 mmol of **3** or **4**. After 10 min Et_2O was added to the clear yellow

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1919-1952 $ 10.00+.25/0

solution and a mixture of **5** or **6** and protonated pyridine precipitated. The latter was removed by fractional recrystallization from CH_2Cl_2/Et_2O.

Synthesis of **5** and **6** from **2**: A solution of 2.5 mmol of **2** in 20 mL of CH_2Cl_2 was treated with 2.5 mmol of Me_3SiOTf. Then 6 mmol of diazo ester **3** or **4** was added dropwise, which was accompanied by release of N_2. 30 min after N_2 release had stopped, Et_2O was added and **5** or **6** precipitated. Both compounds were removed by filtration, washed, and dried at 0.01 Torr.

Synthesis of **7**–**12**: A solution of 2 mmol of **6** in 20 mL of CH_2Cl_2 was treated with 2.5 mmol of the appropriate nucleophile. After 1 h the corresponding products were precipitated by addition of Et_2O, removed by filtration, washed with Et_2O, and dried at 0.01 Torr.

Table 1. Yields and spectroscopic data of compounds **5**–**12** [a]. Correct C,H,N analyses were also obtained.

5: Yellow powder; yield: 84% [b]; ^{1}H NMR (CD_3CN): $\delta = 1.46$ (s, 9H; CH_3), 7.58 (t, 2H; H-3/H-5 Ph), 7.75 (t, 1H; H-4 Ph), 8.10 (d, 2H; H-2/H-6 Ph); ^{13}C NMR (CD_3CN) [c]: $\delta = 28.14$ (CH_3), 87.00 ($C(CH_3)_3$), 117.63 (C-1 Ph), 121.70 (q, ^1J(C,F) = 320 Hz; CF_3), 133.05 (C-3/C-5 Ph), 134.25 (C-4 Ph), 136.24 (C-2/C-6 Ph), 160.86 (CO); IR: $\tilde{\nu}$[cm^{-1}] = 2100 (N_2), 1700 (CO).

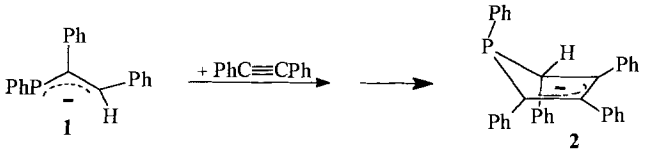
Diastereoselective Reaction of a 1-Phosphaallyl Anion with an Alkyne: Structure of an Isolated Dihydrophospholyl Anion and Stereospecific Protonation to Give 2,3-Dihydrophosphole**

Edgar Niecke,* Martin Nieger, and Peter Wenderoth

Dedicated to Professor Reinhard Schmutzler on the occasion of his 60th birthday

Polar cycloaddition reactions are well documented for 2-aza- and 1,2-diazaallyl "anions" and have proved to be successful for the construction of heterocycles.[1] This reaction sequence is used particularly for the synthesis of 3,4-dihydro-2*H*-pyrroles, pyrrolidines, and pyridene derivatives.[2] In contrast, corresponding cycloaddition reactions of allyl anions are rare and are limited to compounds whose substituents are capable of stabilizing the negative charge in the 2-position.[1, 3]



In the context of work on phosphaallyl anions[4] we recently reported on a surprisingly simple synthesis of the phosphindolyl system.[5] We have now extended our investigations on 1-phos-

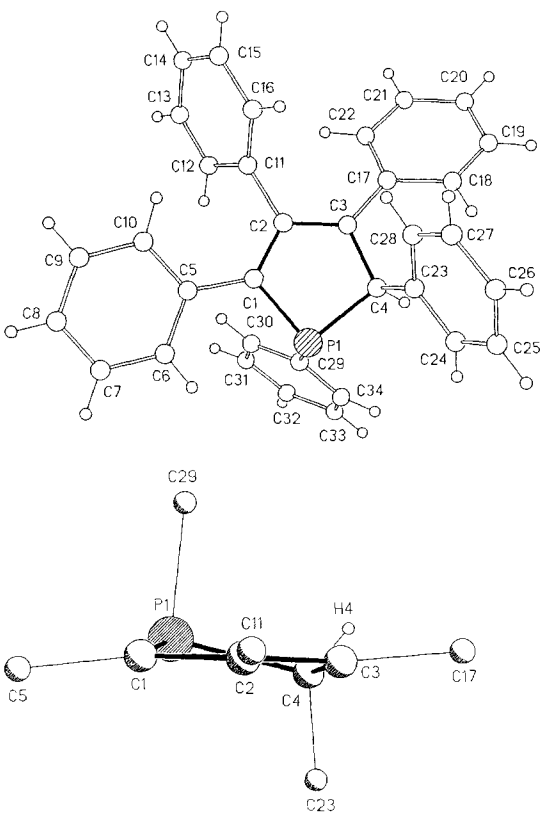
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

phaallyl systems to cycloaddition reactions and have successfully synthesized and structurally characterized a heterocyclic system with a noncomplexed allyl anion as the central building block. The existence of separate ion pairs for allyl anionic systems has to our knowledge only been demonstrated by NMR spectroscopic investigations.[6]

The equimolar reaction of the 1-phosphaallyl anion **1** with tolane, which is accompanied by a change in color from purple to deep red, leads to the formation of an anion **2**. This can be isolated as **2**·Li(dme)$_3$ in the form of extremely air-sensitive crystals.[7]

The lithium salt of the dihydrophospholide **2** crystallizes in the chiral space group $P2_12_12_1$.[8] The lithium ion resides in an octahedral environment coordinated by three solvent molecules (DME). The shortest distances to the anion lie in the range of van der Waals contacts and thus confirm the presence of separate ions in the crystal. The anion has the absolute configuration P1: *S*, C4: *S* in the single crystal chosen for the structure analysis. The five-membered ring has a slightly twisted envelope conformation with the phosphorus atom at the vertex (Fig. 1).



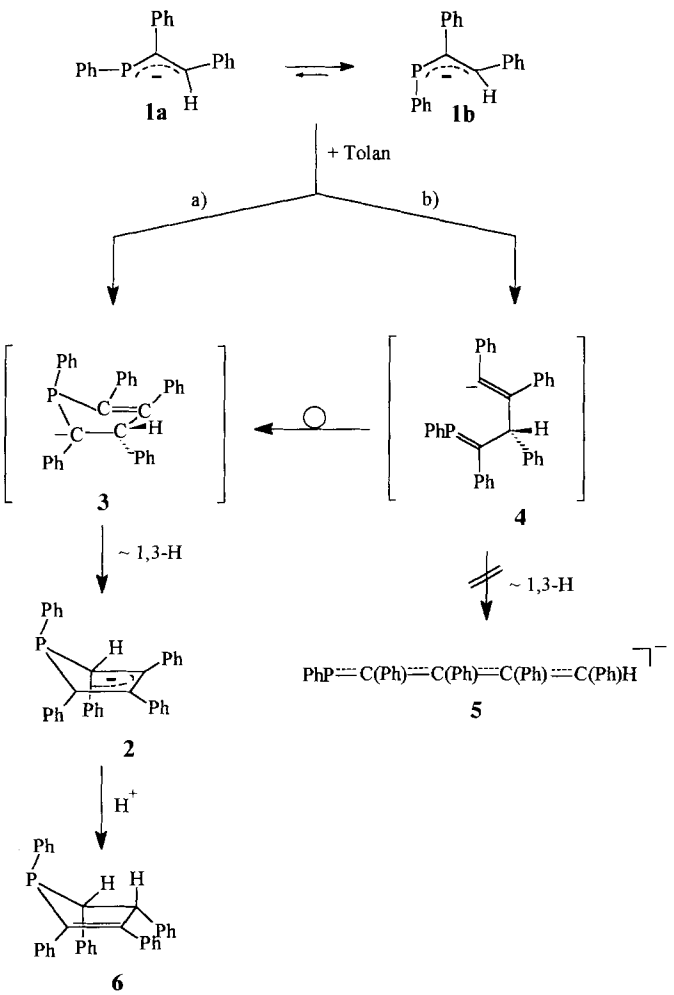


Fig. 1. Crystal structure of the anion of **2**·Li(dme)$_3$. Selected bond lengths [pm] and angles [°]: P1-C1 177.4(6), P1-C29 184.7(6), P1-C4 187.1(6), C1-C2 141.2(8), C2-C3 139.5(8), C3-C4 154.2(8); C1-P1-C29 102.0(3), C1-P1-C4 92.0(3), C4-P1-C29 99.2(3), C2-C1-C5 130.5(6), C2-C1-P1 110.4(5), C5-C1-P1 119.0(5), C3-C2-C1 117.0(5), C3-C2-C11 120.5(6), C1-C2-C11 122.4(6), C2-C3-C17 130.2(6), C2-C3-C4 111.9(6), C17-C3-C4 117.8(5).

Three of the five phenyl substituents (on C1–C3) are arranged propellerlike about the framework of the ring. The phenyl group at the phosphorus atom adopts a "flag pole" position and is orientated *trans* with respect to the substituent on C4. The allylic structure C1–C3 results from the short distances (C1–C2 141.2(8); C2–C3 139.5(8) pm), which, like the innercyclic angle at C2 (117.0(5)°), lie in the range of values typical for allyllithium complexes.[11] The bonds from these atoms to the *ipso* carbon atoms of the phenyl groups (C5, C11, and C17) correspond to single bond lengths (146–148 pm) between sp^2-hybridized carbon centers. As expected the distances of C4 to C3 and to C23 (154–155 pm) are longer. The bond lengths P1–C4 and P1–C29 (187.1(6) and 184.7(6) pm, respectively) correspond with the expected values for this combination of elements, in contrast, the P1–C1 bond is significantly shorter than expected (177.4(6) pm). This indicates a stabilization of the negative charge with the participation of the phosphorus atom.[12]

No evidence for the formation of an intermediate is obtained by following the reaction **1** → **2** by ^{31}P NMR spectroscopy in the temperature range $-60 < T < 25$ °C. The exclusive formation of one product (^{31}P NMR: $\delta = 36.8$) indicates a reaction path,[13] in which following the cycloaddition the anion **3** containing a localized double bond is stabilized by a *suprafacial* [1,3]-H shift to give the allylic system **2**. Investigations on the mechanism of the cycloaddition of allyl anions to (*E*)-stilbene[13b] lead to the belief that also for **1** the thermodynamically more unfavorable (*Z*,*Z*) isomer[4] **1a** takes part in the reaction.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/1919-1954 $ 10.00+.25/0

For a multistep reaction[14] it must be assumed that the acyclic "anion" **4** generated in the first step of the reaction rapidly cyclizes and thereby prevents the formation of a 1-phosphapentadienyl anion **5**.[15]

Regardless of the course of the reaction by path (a) or (b) the formation of only one product implies the highly stereoselective course of the reaction, and the occurrence of pairs of enantiomers is to be expected. The presence of a racemic mixture is supported by the protonation of **2** to give the corresponding 2,3-dihydrophosphole **6**,[16] which occurs strictly regio- and stereospecifically with the formation of one product, in which both enantiomers are present in the equal amounts.[17]

The composition and constitution of **6** can be derived from the high resolution mass spectrum (molecular peak) and the results of multinuclear NMR measurements. The double bond in the 4-position is confirmed by the two resonances in the olefinic region ($\delta = 142.2$, $J_{C,P} = 8.8$ Hz, and 147.4, 13.7 Hz), whose chemical shifts, like the size of the couplings to the phosphorus nucleus, correspond to known values for 2,3-dihydrophospholes.[18] The geometry of the two ring hydrogen atoms cannot be derived unambiguously from the ^{1}H NMR data ($\delta = 4.9$, $J_{H,P} = 6.9$ Hz, and 4.5, 8.3 Hz; $J_{H,H} = 8.3$ Hz), however, in a kinetically controlled reaction the protonation should lead to a *cis* arrangement of the hydrogen atoms.

Investigations into the dipolar cycloaddition of 1-phosphaallyl anions with heteropolar multiple bonding systems are currently in progress.

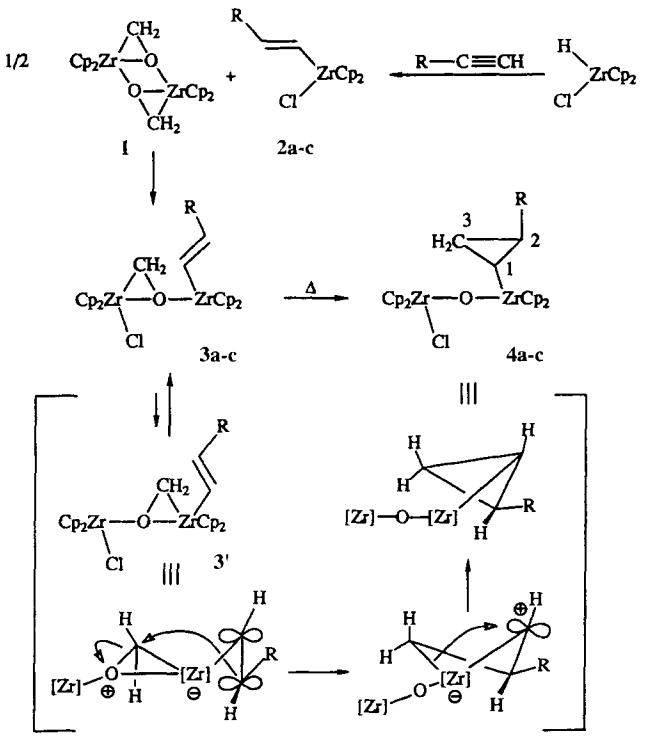
Cyclopropanation by Methylene Transfer from (η^2-Formaldehyde)zirconocene Complexes**

Gerhard Erker,* Stefanie Schmuck, and Maximilian Bendix

Dedicated to Professor Thomas Kauffmann on the occasion of his 70th birthday



Multinuclear (η^2-formaldehyde)zirconocene complexes have some properties that are reminiscent of the chemistry of methylene on metal oxide surfaces.[1] Thus, [{(η^2-CH_2O)$ZrCp_2$}$_2$] (**1**)[2] reacts similarly to diazomethane[3] with catalytic amounts of triethylborane to give a smooth CH_2 transfer and methylene oligomerization. After oxidative workup of the resulting product mixture of alkylborane compounds, a Poisson distribution of 1-alkanols $HO(CH_2)_nC_2H_5$ with a degree of oligomerization n of up to 15 is obtained.[4] A natural extension of this work was to test whether the CH_2 groups of **1** could also be transferred to simple alkenes with cleavage of the good zirconocene oxide leaving group and thus produce cyclopropanes. Although with complex **1** such a direct transformation was not possible, this cyclopropane formation took place at a binuclear μ-oxozirconocene complex that bears a Zr–O bridging CH_2 group and a σ-bound alkenyl ligand simultaneously at the metal oxide matrix.

We have shown that **1** reacts with the metallocene chlorides [Cp_2MCl_2] of zirconium and hafnium to yield the dinu-

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Alfried-Krupp-von Bohlen-und-Halbach-Stiftung.

clear [μ-(O-η^1:C,O-η^2-formaldehyde)]metallocene complexes [$Cp_2Zr(Cl)(CH_2O)MCp_2(Cl)$].[5] We have now used this reaction type to prepare the corresponding dinuclear metallocene complexes **3** from **1** and the (σ-alkenyl)zirconocene chlorides **2** (Scheme 1). The alkenyl complexes **2** were synthesized by hydrozirconation of the alkynes.[6]

Scheme 1. **a**: R = n-C_4H_9; **b**: R = n-C_3H_7; **c**: R = H.

The reaction of dimer **1** with (*E*)-1-hexenylzirconocene chloride **2a** was conducted in [D_8]tetrahydrofuran and monitored by ^{1}H and ^{13}C NMR spectroscopy. At room temperature the new compound **3a** is formed rapidly, and 30% is present together with the starting materials after 17 h.

The existence of a three-membered $ZrCH_2O$ ring in **3a** is deduced unambiguously from the typical ^{13}C NMR spectrum[7] (CH_2: δ = 68.6, ^1J(C,H) = 153 Hz). The complex **3a** could not be obtained in higher yields, because it undergoes a subsequent reaction at longer reaction duration or higher temperature. In this reaction the methylene group adds to the adjacent alkenyl unit to form a zirconium-substituted cyclopropane. We prepared the product **4a** directly in about 60% yield by reaction of **1** with **2a** in toluene at 90 °C (4 days) (see Table 1). According to the ^{1}H NMR spectrum of **4a**, the two substituents are *trans* at the cyclopropane ring, that is, the reaction proceeds with retention of the configuration of the starting compound **2a**.

The corresponding (σ-cyclopropyl)zirconium complexes **4b, c** arise on treatment of **1** with (*E*)-1-pentenylzirconocene chloride (**2b**) or vinylzirconocene chloride **2c**, respectively. In both cases monitoring the course of reaction by NMR spectroscopy makes direct detection of the intermediates **3a** and **3b** possible. The reaction of **1** with the acetylene–hydrozirconation product **2c** is, relative to the other two reactions (with **2a, b**), substantially less selective, and apart from the cyclopropylmetallocene complex **4c**, [$Cp_2Zr(Cl)$–O–$ZrCp_2(Cl)$] is also obtained in about 30% yield.

Table 1. Experimental details for the reaction of **1** with the alkenyl(chloro)zirconocenes **2a–c** as well as NMR data of complexes **3** and **4**.

3a (obtained from a 55:15:30-mixture of **1**, **2a** and **3a**, prepared from **1** and **2a** at 80 °C after 8 h, spectroscopic characterization): ^{1}H NMR ([D_8]THF): δ = 7.12 (dt, ^3J = 18.0, ^4J = 1.3 Hz, 1H, Zr-CH=), 6.23 (s, 10H, Cp), 5.87 (s, 10H, Cp), 5.80 (dt, ^3J = 18.0, ^3J = 6.3 Hz, 1H, Zr-CH=C*H*-), 2.42 (s, 2H, $ZrOCH_2$), 2.05 (m, 2H, =CH-CH_2-), 1.46–1.39 (m, 4H, -CH_2CH_2-), 0.97 (br. t, 3H, CH_3); ^{13}C NMR (C_6D_6): δ = 175.3 (^1J(C,H) = 123 Hz, Zr-CH=), 144.2 (^1J(C,H) = 147 Hz, Zr-CH=*C*H), 112.5 (^1J(C,H) = 174 Hz, Cp), 108.9 (^1J(C,H) = 174 Hz, Cp), 68.6 (^1J(C,H) = 153 Hz, $ZrOCH_2$), 39.0, 32.2, 22.9 (CH_2), 14.4 (CH_3).

4a: Synthesis from 400 mg (0.80 mmol) **1** and 540 mg (1.60 mmol) **2a** in 15 mL toluene (4 d, 90 °C). Recrystallized from toluene at −18 °C, yield: 550 mg (58%) **4a**, M.p.: 138 °C, $C_{23}H_{33}ClOZr_2$ (591.5): calcd. C 54.83, H 5.62; found C 54.34, H 5.53; IR (KBr): $\tilde{\nu}$ = 3102, 3087, 2959, 2919, 2868, 1723, 1637, 1441, 1262, 1098, 1016, 800, 735, 609 cm^{-1}; ^{1}H NMR (C_6D_6): δ = 5.98, 5.97, 5.90, 5.86 (s, each 5H, Cp), 1.72, 1.26 (m, each 1H, 4-H, 4-H'), 1.57 (m, 2H, CH_2), 1.44 (m, 2H, CH_2), 1.02 (br. t, 3H, CH_3), cyclopropyl: 1.02 (m, 1H, 2-H, hidden by CH_3 signal, identified by COSY), 0.87 (m, 1H, 3-H'), 0.66 (m, 1H, 3-H), −0.19 (m, 1H, 1-H); coupling constants: ^2J(3-H, 3-H') = 3.0, ^3J(1-H, 2-H) = 7.6 Hz, ^3J(1-H, 3-H') = 6.7 (*trans* coupling), ^3J(1-H, 3-H) = 10.0 (*cis* coupling), ^3J(2-H, 3-H) = 3.0 (*trans* coupling), ^3J(2-H, 3-H') = 7.5 Hz (*cis* coupling); ^{13}C NMR (C_6D_6): δ = 113.7 (^1J(C,H) = 172 Hz, Cp), 111.4 (^1J(C,H) = 172 Hz, Cp), 111.3 (^1J(C,H) = 172 Hz, Cp), 38.6 (^1J(C,H) = 122 Hz, CH_2), 36.5 (^1J(C,H) = 132 Hz, Zr-cyclopropyl-*C*H), 33.5 (^1J(C,H) = 127 Hz, CH_2), 25.6 (^1J(C,H) = 157 Hz, cyclopropyl-C-2), 23.4 (^1J(C,H) = 124 Hz, CH_2), 19.3 (^1J(C,H) = 158 Hz, cyclopropyl-C-3), 14.5 (^1J(C,H) = 121 Hz, CH_3).

3b (from a 29:28:43-mixture of **1**, **2b** and **3b**, prepared from **1** and **2b** at 80 °C after 8 h, spectroscopic characterization): ^{1}H NMR (C_6D_6): δ = 7.19 (dt, ^3J = 18.0, ^4J = 1.3 Hz, 1H, Zr-CH=), 5.98 (s, 10H, Cp), 5.72 (s, 10H, Cp), 2.40 (s, 2H, $ZrOCH_2$), 2.23 (m, 2H, =CHCH_2), 1.55 (m, 2H, CH_2), 1.06 (br. t, 3H, CH_3). 4b: Synthesis from 250 mg (0.50 mmol) **1** and 340 mg (1.00 mmol) **2b** in 20 ml toluene (4 d, 90 °C), product precipitated from toluene at −18 °C, yield 340 mg (59%) **4b**, contains about ca. 10% nonidentified impurity, m.p. 121 °C, $C_{26}H_{31}ClOZr_2$ (577.4): calcd. C 54.08, H 5.41; found C 52.02, H 5.49; IR (KBr; $\tilde{\nu}$ = 3086, 2969, 2926, 2869, 1716, 1625, 1440, 1352, 1262, 1101, 1017, 802, 738, 610 cm^{-1}; ^{1}H NMR (C_6D_6): δ = 5.98(s, 5H, Cp), 5.97(s, 5H, Cp), 5.85 (s, 10H, 2Cp), 1.68, 1.22 (m, each 1H, 4-H, 4-H'), 1.53 (m, 2H, CH_2), 1.05 (br. t, 3H, CH_3), cyclopropyl: 1.05 (m, 1H, 2-H, hidden by CH_3 signal, identified by COSY), 0.86 (m, 1H, 3-H'), 0.65 (m, 1H, 3-H), −0.21 (m, 1H, 1-H); coupling constants: ^2J(3-H, 3-H') = 3.7, ^3J(1-H, 2-H) = 7.0 (*trans* coupling), ^3J(1-H, 3-H') = 7.6 (*trans* coupling), ^3J(1-H, 3-H) = 10.0 (*cis* coupling), ^3J(2-H, 3-H) = 3.7 (*trans* coupling), ^3J(2-H, 3-H') = 7.5 Hz (*cis* coupling); ^{13}C NMR (C_6D_6): δ = 113.7(2 Cp), 111.4 (Cp), 111.3 (Cp), 41.1 (CH_2), 36.5 (^1J(C,H) = 133 Hz, Zr-cyclopropyl-CH), 25.4 (^1J(C,H) = 155 Hz, cyclopropyl-C-2), 23.9 (CH_2), 19.3 (^1J(C,H) = 155 Hz, cyclopropyl-C-3), 14.7 (CH_3).

3c (from a 20:20:60-mixture of **1**, **2c** and **3c**, prepared from **1** and **2c** at room temperature in THF, spectroscopic characterization): ^{1}H NMR ([D_8]THF): δ = 7.52, 6.14, 5.54 (ABX, $^3J_{trans}$ = 19.5, $^3J_{cis}$ = 14.5, ^2J = 3.9 Hz, each 1H, Zr-CH=CH_2), 6.22 (s, 20H, Cp), 2.37 (s, 2H, $ZrOCH_2$); ^{13}C NMR ([D_8]THF): δ = 185.6 (^1J(C,H) = 120 Hz, Zr-CH=), 127.3 (^1J(C,H) = 153 Hz, ^2J(C,H) = 6 Hz, Zr-CH=*C*$_2$), 113.2 (Cp), 109.3 (Cp), 64.8 (^1J(C,H) = 153 Hz, $ZrOCH_2$).

4c: Synthesis from 300 mg (0.60 mmol) **1** and 338 mg (1.20 mmol) **2c** in 40 mL toluene (6 d, 90 °C), product isolated from toluene at −20 °C, yield 400 mg (44%) **4c**, contains ca. 30% [$(Cp_2ZrCl)_2O$]. ^{1}H NMR (C_6D_6): δ = 5.96 (s, 10H, Cp), 5.82 (s, 10H, Cp), cyclopropyl: 1.01 (m, 2H), 0.64 (m, 2H), −0.20 (m, 1H); coupling constants: ^2J = 3.0, ^3J(1-H, 2-H) = 7.6 (*trans* coupling, ^3J(1-H, 2-H') = 9.8 (*cis* coupling), ^3J(2-H, 3-H) = 4.3 (*trans* coupling), ^3J(2-H, 3-H') = 9.7 Hz (*cis* coupling); ^{13}C NMR (C_6D_6): δ = 113.7 (Cp), 108.0 (Cp), 26.5 (^1J(C,H) = 129 Hz, Zr-cyclopropyl-CH), 11.1 (^1J(C,H) = 155 Hz, cyclopropyl-CH_2).

Detailed studies to elucidate the mechanism of this cyclopropanation at the metallocene oxide framework have yet to be performed. However, we assume that the primarily formed compound **3** is in equilibrium with the isomer **3'** through a dyotropic rearrangement.[7, 8] In **3'** the methylene group to be transferred approaches very close to the alkenyl acceptor at the Zr–O–Zr template. Moreover the μ-oxobis(zirconocene) unit is a good leaving group, and the CH_2 group bridging the Zr and O atoms is activated for nucleophilic attack by the adjacent oxonium-type oxygen atom. Formation of a C–C bond between the alkene and the CH_2 group with cleavage of the C–O bond of the

three-membered Zr, O, C ring, followed by a 1,2-alkyl shift from the zirconium atom to the neighboring former alkene carbon atom (see Scheme 1) readily explains the formation of the cyclopropanation product **4** with the observed stereochemistry.

These reactions add to the examples of small organic units which approach each other and react at the molecular Zr–O–Zr metal oxide template stabilized by cyclopentadienyl ligands.[3, 9] Perhaps the chemistry of such molecular compounds can indeed shed some light on the possible individual steps of reactions at metal oxide phases in heterogeneous catalysis.[10]

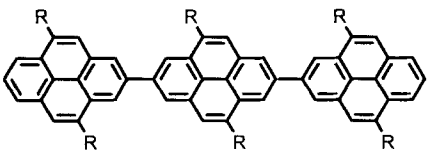
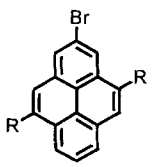
2,2′-Bipyrenyl and *para*-Terpyrenyl—A New Type of Electronically Decoupled Oligoarylene



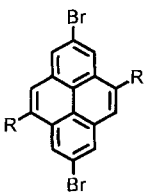
Martin Kreyenschmidt, Martin Baumgarten, Nikolay Tyutyulkov, and Klaus Müllen*

Preparative,[1] stereochemical,[2] and physical aspects[3] of biphenyls and oligophenylenes have received much attention. The frontier orbitals at the bridgehead centers have large atomic orbital coefficients, characteristic of biphenyl[4] and of related biaryls.[4–7] This causes a pronounced electronic interaction through the formal single bond, which decreases with increasing twisting around the bond. However, a stereoelectronic situation that is fundamentally new exists if the molecular orbital coefficients of the bridgehead centers are almost zero, and consequently the rings are electronically decoupled to a first approximation. The 2,2′-bipyrenyls **1** and the analogous *para*-terpyrenyls **2** fulfill this requirement.

Here we describe the synthesis of compounds **1** and **2**, which were unknown until now, and prove that the electronic interaction of the pyrene subunits differs substantially from that in other biaryls and oligoaryls. An important experiment is the charging of the aryl units with one electron each, which, in the case of the title compounds, gives oligoradicals.



1

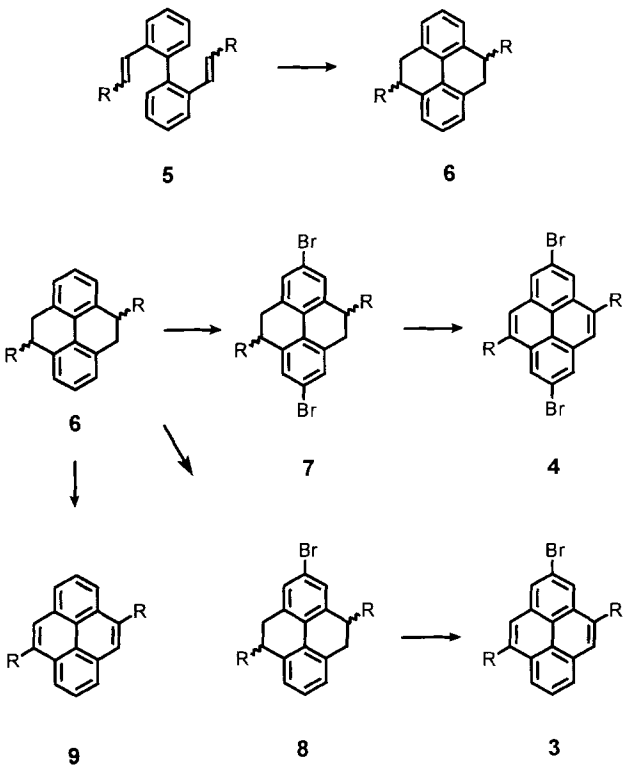


a: R = H
b: R = *n*-octyl
c: R = *n*-pentyl

2

2-Bromopyrenes **3** and 2,7-dibromopyrenes **4** are possible starting compounds for pyrene–pyrene coupling. However, such halogen compounds cannot be prepared by simple substitution at the pyrene. A further difficulty of the targeted syntheses of **1** and **2** from **3** and **4**, respectively, is the expected low solubility of the extended benzenoid systems; the inclusion of alkyl chains is thus necessary to increase the solubility, as in **3b**, **c** and **4b**, **c**, respectively.

a: R = H
b: R = *n*-octyl
c: R = *n*-pentyl



3 **4**

The highly soluble pyrene derivatives **3b**, **c** and **4b**, **c** were synthesized by the route outlined in Scheme 1.

2,2′-(Bis-1-dec-1-enyl)biphenyl (**5b**) is synthesized from either *n*-nonal and 2,2′-bis(triphenylphosphoniomethyl)biphenyl dibromide[8] (EtOH, EtONa, 70 °C, 4 h, 70%) or from diphenaldehyde[9] and nonyltriphenylphosphonium bromide (THF, *n*BuLi, −60 °C, 52%) by the Wittig reaction. The photochemical cyclization of **5b**, which exists as an isomeric *cis*–*trans* mixture, in hexane at 254 nm by irradiation with an 80 Watt Hg low-pressure lamp leads to 4,9-di-*n*-octyl-4,5,9,10-tetrahydropyrene (**6b**)[10] in 80% yield after purification by chromatography. Pyrene **6b** is converted to 2,7-dibromo-4,9-di-*n*-octyl-4,5,9,10-tetrahydropyrene (**7b**) by a new method of catalytic bromination with 5% Pd or Pt on activated carbon, each with two equivalents of Br_2 in *N*,*N*-dimethylformamide (DMF), at room

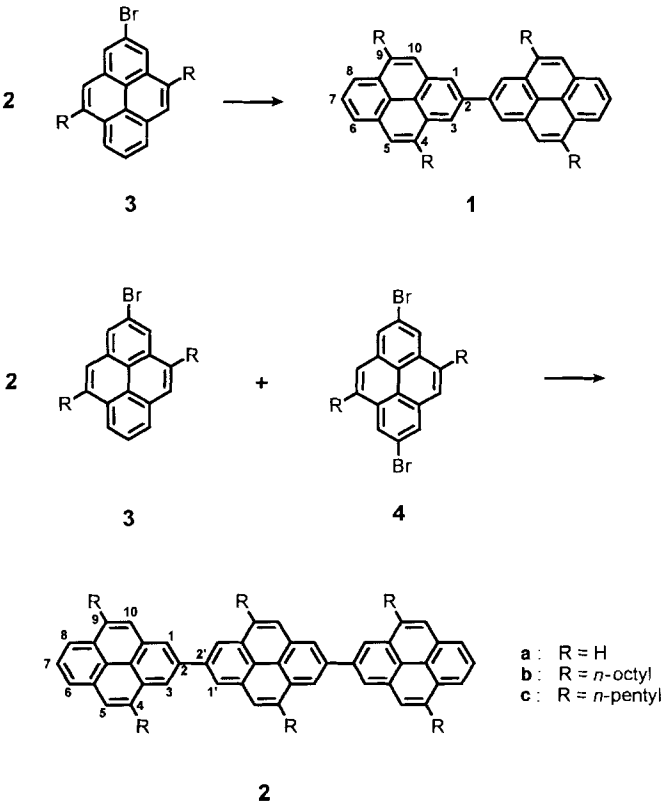
temperature and a reaction time of 12 h. After bromination at the benzyl positions with *N*-bromosuccinimide, **7b** is aromatized to form **4b** in 60% yield (after column filtration and recrystallization twice from benzene) by addition of 1,8-diazabicyclo[5.4.0]-7-undecene in CCl_4. The di-*n*-pentyl compound **4c** and the 2-bromo derivatives **3b, c** are prepared in a similar way. The model compound 4,9-di-*n*-octylpyrene (**9b**) is obtained in 82% yield on aromatization of **6b**.



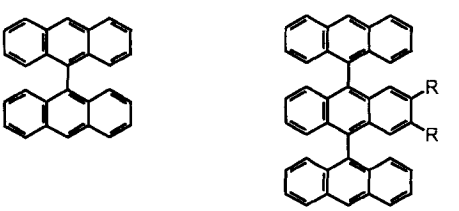
Scheme 1.

The bipyrenyl **1b** was obtained in 95% yield by coupling **3b** with $[Ni(cod)_2]$ according to Yamamoto (Scheme 2).[11] The *para*-terpyrenyl **2b** was synthesized analogously by reaction of two equivalents of **3b** and one equivalent of **4b** (53%). Compounds **1b** and **2b** were purified by size exclusion chromatography.

The interruption of the conjugation by bridging at positions at which atomic orbital coefficients are almost zero in **1** and **2** is shown in the electronic absorption spectra. The λ_{max} values of compounds **1b** and **2b** and of the monomeric model compound **9b** are shifted relative to one another by only a few wavelengths (0–9 nm, Table 1). Thus the oligopyrenyls differ significantly from oligoarylenes with a similar steric arrangement (biphenyl: $\lambda_{max} = 249$ nm and *para*-terphenyl: $\lambda_{max} = 279$ nm) and resemble to 9,9′-bianthryl (**10**) and higher oligo-9,10-anthrylenes in which a conjugation barrier is achieved by positioning the subunits orthogonally (**10**: $\lambda_{max} = 391$ nm; 2′,3′-dihexyl-9,10-trisanthrylene (**11**): $\lambda_{max} = 403$ nm[12]).

To investigate the "electronic decoupling" for the charged states too, compounds **1b** and **2b** were reduced chemically (potassium/THF) and electrochemically (tetrabutylammonium hexafluorophosphate/THF) and then characterized by ESR

Scheme 2.



spectroscopy and by cyclic voltammetry. The cyclic voltammetry investigations, do indeed show that the first reduction potentials E_1 are virtually independent of the number of pyrene units (**1b**: $E_1 = -2.24$ eV, **2b**: $E_1 = -2.27$ eV). Furthermore, the

Table 1. Selected physical and spectroscopic data of **1b**, **2b**, and **9b**.

1b: MS (FD, 8 kV) *m/z* 850.5 [M^+]; ^{1}H NMR (500 MHz, $CDCl_3$ 30 °C): δ = 8.77–8.6 (d, ^4J(H,H) = 1.3 Hz, 4H; H1, H3), 8.34–8.16 (2 d, ^3J(H,H) = 7.85 Hz, ^3J(H,H) = 7.45 Hz, 4H; H6, H8), 8.05–7.98 (2 s, 4H; H5, H10), 8.02 (t, ^3J(H,H) = 7.7 Hz, 2H; H7), 3.41 (dt, ^3J(H,H) = 7.75 Hz, 8H; CH_2), 1.94–2.05 (m, 8H; CH_2), 1.55–1.61 (m, 8H; CH_2), 1.25–1.47 (m, 32H; CH_2), 0.83–0.9 (m, 12H; CH_3); UV/VIS (CH_2Cl_2): λ_{max} (ε) = 350 nm (100957), 333 nm (48615), 294 nm (112920), 251 nm (28850).

9b: UV/VIS (CH_2Cl_2): λ_{max} (ε) = 344 nm.

charging of each pyrene subunit with one electron leads to only low Coulomb repulsions, which is deduced from the potential differences for dianion formation in **1b** ($E_1-E_2 = 0.16$ eV) and trianion formation in **2b** ($E_2-E_3 = 0.07$ eV). The first reduction potentials of 9,9'-bianthryl (**10**, $E_1 = -2.15$ eV) and of the corresponding trisanthrylene **11** ($E_1 = -2.16$ eV) also hardly differ. In the case of oligo(*para*-phenylenes), however, the first reduction potentials decrease with increasing number of phenylene rings because of the pronounced interaction between rings,[14-15] and a significant Coulomb interaction occurs on increasing the charge.

Remarkably, the formation of the dianion $\mathbf{1b}^{2-}$ does not lead to a diamagnetic state as in the dianions of biphenyl, 1,1'-binaphthyl and 3,3'-biperylenyl,[16] but to a diradical that shows a typical axially symmetric zero field splitting D = 7.90 mT = 73.78×10^{-4} cm^{-1} in frozen solution (T = 130 K). For $\mathbf{2b}^{2-}$, a zero field splitting of D = 7.83 mT = 73.24×10^{-4} cm^{-1} is measured that is almost equal to that of $\mathbf{1b}^{2-}$. The Coulomb interaction between the singly charged pyrene units in the dianion of **2b** is therefore so weak that the adjacent and not the two terminal pyrene units are charged (Fig. 1).

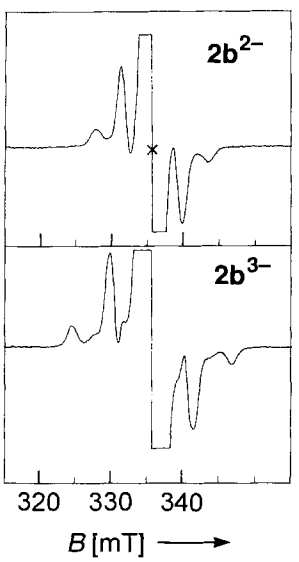

Fig. 1. ESR spectra for the bi- and triradicals $\mathbf{2b}^{2-}$ and $\mathbf{2b}^{3-}$ (THF/K; T = 150 K). The central signal (×) originates from contributions of the monoradical in the biradical.

Further reduction finally leads to the trianion with a quartet state $\mathbf{2b}^{3-}$ in which the zero field coupling D ($S = 3/2$) = 5.53 mT = 51.68×10^{-4} cm^{-1}. Also characteristic of the higher spin multiplicity are the considerably less intense signals of the forbidden $\Delta m_s = 2$ transitions. Therefore, the oligopyrenyls are converted into oligoradicals by charging, but the dipole interaction between the pyrene units is only about half as large as between the anthracene units in bis- and trisanthrylene (**10** and **11**, respectively) with $D(S=1) = 15$ mT and $D(S = 3/2)$ = 11.2 mT.[13]

For the di- ($\mathbf{1b}^{2-}$) and triradicals ($\mathbf{2b}^{3-}$), it is uncertain whether a ferromagnetic or antiferromagnetic exchange interaction is present. The spin multiplicity of the ground state in the dianion of $\mathbf{1b}^{2-}$ cannot be directly determined by Hund's rule, because the half-occupied HOMOs in the anions are localized on nonoverlapping lobes of atomic orbitals, and consequently the direct exchange interaction J_{dir} disappears as part of the effective exchange interaction to a first approximation. For the indirect exchange interaction J_{ind}, an antiferromagnetic interaction with a singlet-triplet energy difference of $E_T - E_S$ = 0.032 eV has been determined while taking the configuration interaction into account.[17-18] Also for the polyanion radical of the corresponding polymer[19] calculations suggest that J_{ind} (= −0.01 eV) provides the main contribution to the effective antiferromagnetic exchange interaction.

The temperature dependence of the intensity of the ESR signals from 4–100 K was therefore investigated for experimental proof of the nature of the interaction in the di- and triradicals $\mathbf{1b}^{2-}$, $\mathbf{2b}^{2-}$, and $\mathbf{2b}^{3-}$. An antiferromagnetic coupling for the intramolecular interaction between the charged pyrene subunits was proven since only monoradical contributions are detected at 4.5 K and components of the zero field splitting only become visible after further thermal excitation from 20 K for diradicals and 40 K for triradicals.

The linkage of pyrene units in the 2- and the 2- and 7-positions leads to an electronic decoupling and offers the possibility for oligoradical formation. However, it does not make a ferromagnetic interaction possible, unlike in *meta*-phenylene-bonded oligo- and polydiradicals.[20] The compounds in the title **1**, **2**, and **9** stimulate further studies in various ways: In physical studies, further criteria for the electronic decoupling of the pyrene units in **1** and **2** will be investigated; for instance, the possibility of a light-induced separation of charge in 1,1'- and 2,2'-bipyrenyl.[3b] In the preparative field, the transition from **1** and **2** into the analogous polymers is an obvious research goal.

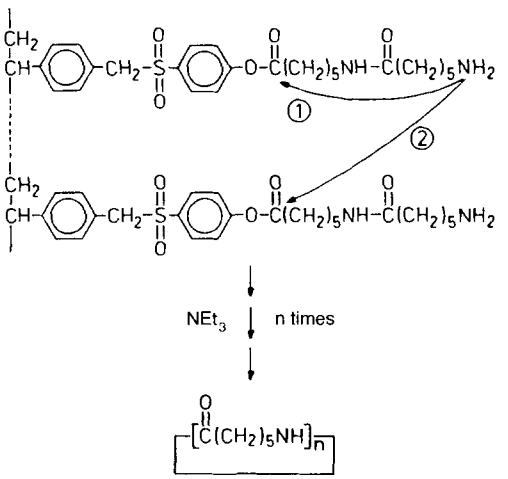
Ring Closures on Polymeric Supports—Formation of Extremely Large Macrocycles by Intrapolymeric Cyclooligomerizations**

Manfred Rothe,* Manfred Lohmüller, Ulrich Breuksch, and Günter Schmidtberg



Dedicated to Professor Theodor Wieland on the occasion of his 80th birthday

The question of the spatial separation of functional groups within polymers is one of the most important current topics in chemistry on polymeric supports. Ideally, in insoluble, cross-linked polymers with low loading the reactive groups within the support, which has considerably reduced flexibility, are sterically isolated so that they can no longer interact. Under these conditions reactive, support-bound compounds should behave like those at high dilution.[1] In contrast, we report here on polycondensations and subsequent cyclizations within cross-linked polymeric supports, which for the first time led to the formation of polymeric rings.

The problem of the spatial separation of functional groups has been investigated in the last few years in various areas of organic chemistry. Steric isolation was detected in the case of the immobilization of resin-bound transition metal catalysts[2] and short-lived species (arynes),[3] as well as in the monofunctionalization of bifunctional molecules.[4] In other cases mainly intrapolymeric interactions between the functional groups occur, especially in ring closures on polymeric supports, which should avoid the large amounts of solvent required for reactions under high-dilution conditions. Thus, the cyclization of tri-, tetra-, and pentapeptides covalently bound to cross-linked polystyrene gave—in contrast to literature results[5, 6]—at best only low yields of cyclic monomers, which should have been formed owing to steric isolation of the individual peptide chains on the support. Instead, cyclic di-, tri-, and tetramers were the predominant products;[7] in other cases only cyclic dimers were found.[8]

In order to investigate the extent of the cyclooligomerization of support-bound linear compounds and test the new approach for the synthesis of very large rings, we used the polymer-bound oligoamide ε-aminohexanoyl-ε-aminohexanoic acid. We found that intrapolymeric reactions occur to an unexpected extent with formation of macrocycles consisting of at least 300 atoms.

Polystyrenes with a low degree of cross-linking (1% divinylbenzene; Bio-Beads S-X1, Bio-Rad, Munich (FRG)) served as the polymeric support, which was converted to the polymeric sulfide derivative by chloromethylation and reaction with *p*-mercaptophenol.[6] The support was subsequently esterified by treatment with the *tert*-butyloxycarbonyl(Boc)-protected dimer of ε-aminohexanoic acid in the presence of carbodiimide and 4-dimethylaminopyridine (loading 0.9 mmol g^{-1}). Oxidation of the sulfur atom with *m*-chloroperbenzoic acid[6] provided the corresponding sulfone and thus an oligoamide active ester of *p*-sulfonylphenol (Scheme 1). The Boc protecting group was removed with trifluoroacetic acid, and the protonated amino group was neutralized with an excess of triethylamine. At the same time, the suspended, polymer-bound, active ester cyclized in dimethylformamide, a good swelling solvent, at room temperature. The cyclic caprolactam oligomers[9, 10] that formed spontaneously are cleaved from the support upon ring closure and go into solution; in contrast, linear oligocondensation products remain bound to the support and thus cannot interfere in the isolation even of macrocycles with polyamide-like properties. Small amounts of ninhydrine-positive, linear oligoamides were removed by ion exchange in trifluoroethanol (TFE); these oligoamides go into solution in the workup by base-catalyzed solvolysis of unreacted active ester groups.

Scheme 1. $n = 2,4,6,\ldots 38,40$.

The mixture of cyclic oligoamides (69% yield) was separated by gel permeation chromatography (GPC) on Sephadex LH 20 in TFE, as well as on the mg scale by semipreparative HPLC on RP 18 phases (LiChrospher 100, 5 μm, Merck, Darmstadt) with a TFE/water gradient. All polymer-homologous rings were shown to be pure by analytical HPLC (Superspher 100, 4 μm, Merck, Darmstadt). The monodisperse cyclo(oligoamide)s with the structure *c*-$[NH(CH_2)_5CO]_{2n}$ with $n = 1-20$ were characterized by FD and electrospray (ESI) mass spectrometry. The largest monodisperse ring isolated was the cyclo(tetracosamer) of caprolactam composed of 40 monomer units (280 ring atoms, $M_{calcd} = 4526.4$, ESI-MS: $m/z = 4527$ $[MH^+]$). Even higher cyclic oligomers were detected by HPLC. Previously, monodisperse, HPLC-pure cyclic oligoamides of nylon-6 up to the hexamer were obtained only by ring closure in solution under high-dilution conditions.[9, 10] This demonstrates the importance of cyclization on polymeric supports in synthesis. Since the low solubility of caprolactam oligomers composed of ten and more units is similar to that of the corresponding linear polyamide (nylon-6), they can be separated considerably better from the noncyclized chains with the new method than by ring closure in solution; thus these compounds could be isolated for the first time.

The melting points of most of the cyclic oligomers (Table 1) are considerably higher than that of the corresponding linear polyamide (225 °C), but decrease with increasing ring size; the melting points of oligomers with more than 280 ring atoms reach the value of the polymer. These findings are significant with regard to the use of macrocycles as monodisperse models for chain folding in polymers.

Intrapolymeric reactions with formation of cyclic oligomers occur as soon as the reaction starts. Very large rings are formed

[**] Linear and Cyclic Oligomers, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 239) and the Fonds der Chemischen Industrie. We thank Dr. F. Eisenbeiss, E. Merck, Darmstadt, for providing us with HPLC material. Part 28: M. Rothe in *Chemistry and Physics of Macrocycles* (Eds.: W. Fischer, R. C. Schulz, H. Sillescu). VCH, Weinheim, **1991**, p. 39.

mainly on long reaction times (ca. 48 h). As expected, first attempts at cyclization on cross-linked polystyrenes with very low loading (0.024 mmol g^{-1} Boc-di-ε-aminohexanoyl polymer), that is with a dilution 40 times higher, did not provide the extremely large rings. However, a remarkably high degree of intrapolymeric reactions was still found with formation of cyclic oligomers consisting of up to ten monomer units corresponding to a fourfold oligomerization.[11] In all cyclizations on the support a markedly higher degree of oligomerization was achieved than in the reactions with the same concentration in solution. Apparently, the grafted oligoamides are present in higher local concentrations on the support than in homogeneous solution.

Table 1. Cyclic oligoamides of ε-aminohexanoic acid with 1–40 monomer units (n).

[a] The extremely large rings with $n > 20$ were also identified by plotting the elution volume from the HPLC analysis versus lg M; as expected, the values of all the rings form a line. The line formed by the values of the corresponding linear oligoamides has a markedly different slope. The IR spectra are in accord with the assigned structure. They become more and more similar with increasing ring size and are identical for rings from $n = 12$ on.

Our results thus show that cyclizations on polymeric supports are better suited for the preparation of very large rings with more than 100 ring atoms than for the synthesis of small cyclic monomers. Rings of this large size could be obtained previously only in the cycloalkane series by hydrogenation of macrocyclic oligoalkynes.[12] Their ready formation by the oligomerization of α,ω-dialkynes according to Sondheimer et al. [13] is based on the principle of "rigid groups": the drastic restriction of the conformational flexibility of the oligomer chains formed favors ring closure for suitable conformations. Our method for the synthesis of very large rings with several hundred ring atoms by cyclization of polymer-bound chains on highly loaded supports with a low degree of cross-linking can also be applied, however, to chains with high conformational flexibility, for example long oligoamides, for the formation of still larger rings.

In conclusion, the polymeric supports previously used with a low degree of cross-linking are apparently not rigid enough to force the steric isolation of functional groups, provided that the reactions are not faster than the movement of the polymer chains. On the contrary, the occurrence of extensive intrapolymer reactions proves that synthesis on supports is not synthesis simply on a solid phase but rather on highly solvated, flexible polymer chains.

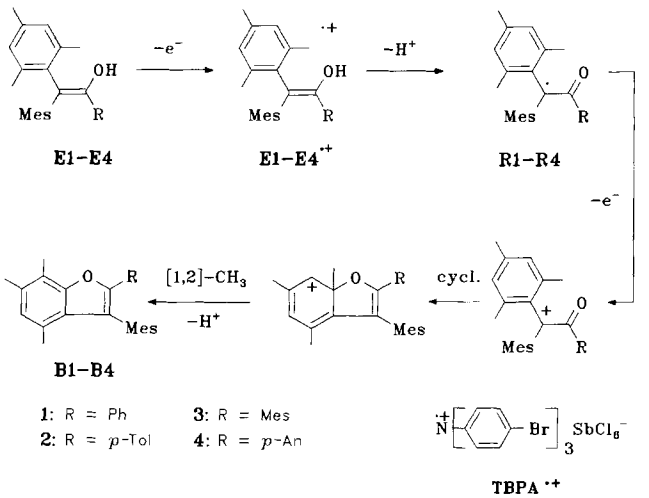
The First Spectroscopic Identification of an Enol Radical Cation in Solution: The Anisyldimesitylethenol Radical Cation**

Michael Schmittel,* Georg Gescheidt,* and Maik Röck

Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday

Although the conversions of ketones and their tautomeric enols in many useful reactions have, for a long time, played an important role in preparative organic chemistry, the first reports about the reactions of the corresponding keto[1] and enol radical cations in solution[2] have only recently appeared. Thus, enol radical cations probably play an important role in reactions of the ribonucleotide reductase[3] and diol dehydratase,[4] and it is highly likely that they are also involved in the α-umpolung of ketones induced by electron transfer[5] and in the synthesis of benzofurans[6] by the oxidation of stable enols. However, these reactive species could, up until now, only be directly detected in the matrix[7] or in the gas phase.[8]



The results of mechanistic investigations[6] on the reactivity of enol radical cations indicate that, in accordance with the high acidity and analogous to phenol radical cations, the main reaction path is a fast deprotonation. Since it can be inferred from thermochemical cycles[9] that the tendency towards deprotonation of enol radical cations should decrease with decreasing oxidation potential of the enol, we have synthesized electron-rich enols of the Fuson type, which have been investigated ex-

tensively by Rappoport et al.[10] These systems can be converted to the corresponding benzofurans[6] under one-electron oxidation conditions, however, up until now, the mechanism shown in Scheme 1 could only be confirmed indirectly.

Scheme 1. Mes = 2,4,6-trimethylphenyl, *p*-An = 4-methoxyphenyl.

While the cyclic voltammograms for enols **E1**–**E4** in acetonitrile show irreversible oxidation waves at low scan rates,[11] above 1000 Vs^{-1} they exhibit an increasingly stronger partial reduction wave which we assign to the reduction of the enol radical cation (Fig. 1). The enol radical cation **E4**$^{\cdot+}$ with a lifetime τ (at room temperature) of 4×10^{-4} s in acetonitrile (Table 1) and 1.9×10^{-2} s in dichloromethane proved to be the longest lived system and therefore we have concentrated on the investigation of **E4** in dichloromethane.

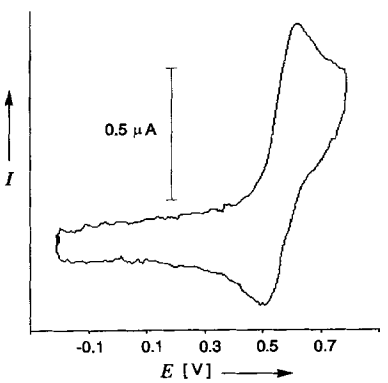

Fig. 1. Cyclic voltammogram (room temperature, versus ferrocene/ferrocenium) for the oxidation of enol **E4** at 2000 Vs^{-1} in acetonitrile.

Cyclic voltammetric investigations on **E4** and [D_1]**E4** in dichloromethane confirmed, for the first time, that an enol radical cation in solution was being detected. First of all the cyclic voltammograms of **E4** in the presence of 0–10 equivalents of trifluoroacetic acid were investigated. Within the detection limits neither the oxidation nor the reduction current was influenced at the applied scan rates. This is in accordance with the high acidity of **E4**$^{\cdot+}$ so that protonation of radical **R4** with formation of **E4**$^{\cdot+}$ cannot occur. When, however, the experiment was carried out in the presence of 7.5 equivalents[12] of deuterated trifluoroacetic acid the reduction current rose markedly. This finding can only be explained by the formation of [D_1]**E4** which is more slowly dedeuterated after one-electron oxidation because of a primary kinetic isotope effect. Through a simulation of the cyclic voltammograms[13] at scan rates of 14–500 Vs^{-1}, k_H/k_D could be determined to be 2.7 ± 0.5 (Fig. 2). Moreover, the primary isotope effect convincingly explains the effect of the solvent on τ, since acetonitrile is more basic than dichloromethane.

Table 1. Results of the fast-scan cyclic voltammetric investigations of enols **E1**–**E4** in acetonitrile or dichloromethane at room temperature. The potentials are related to the ferrocene/ferrocenium system.

Enol	$E_{1/2}$ [V]	pK_a [a]	ΔE_p [V]	v [Vs^{-1}]	i_{pc}/i_{pa} [b]	τ [b, c] [s]	τ [c, d] [s]

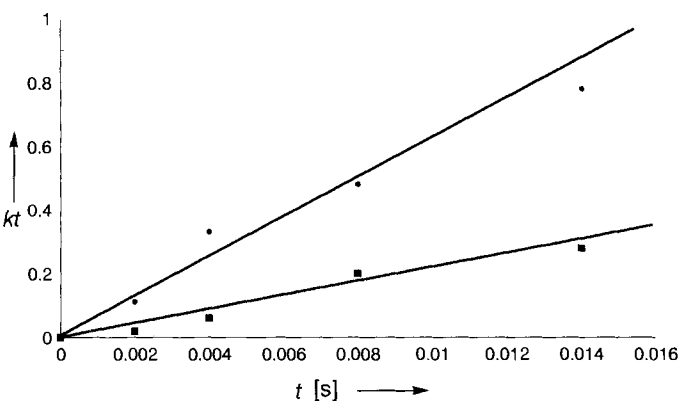

Fig. 2. Plot of the kinetic parameter kt [13] against t for **E4** (● k_H) and [D_1]**E4** (■ k_D) at room temperature.

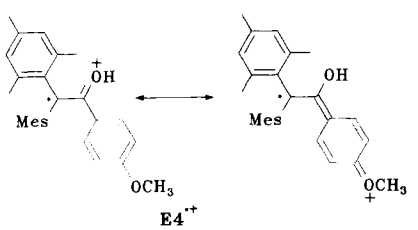

The detection of the enol radical cation **E4**$^{\cdot+}$ by ESR and ENDOR spectroscopy (ENDOR = Electron Nuclear DOuble Resonance) became possible by the one-electron oxidation of **E4** with tris(*p*-bromophenyl)aminium hexachloroantimonate in dichloromethane at −78 °C (persistence ca. 20 min); advantageously, neither of the subsequent products of the enol oxidation, that is the radical **R4** and the benzofuran radical cation **B4**$^{\cdot+}$, were present in detectable concentrations. Whereas the ESR spectrum consisted of a single unresolved signal the hyperfine coupling constants a_H of the protons could be determined by ENDOR spectroscopy. Although the multiplicities of the a_H cannot be established due to the unresolved ESR signals,[14] it is nevertheless possible to obtain structural information about **E4**$^{\cdot+}$. The highest a_H values agree very well with those of the dimesitylmethyl radical **R5**[14, 15] (Table 2). Thus, the a_H values 0.306 and 0.226 mT can be assigned to the *para*- and *ortho*-methyl groups of a mesityl substituent, while the next two a_H values[14] can be assigned to the corresponding positions of the other mesityl substituent. This reflects a marked "diphenylmethyl radical character" of **E4**$^{\cdot+}$. A much smaller spin popula-

Table 2. ENDOR and VIS spectroscopic data for the radical cations **E4**$^{\bullet+}$ and [D_1]**E4**$^{\bullet+}$ compared with that for **R4** and the dimesitylmethyl radical **R5**. The a_H values are arranged in order of size.

Radical	a_H [mT]						λ [nm]
E4$^{\bullet+}$	0.307	0.226	0.151	0.109	0.080	0.052	520, 404
[D_1]**E4**$^{\bullet+}$	0.308	0.229	0.150	0.107	0.076	-	520, 404
R5 [a]	0.338	0.215	0.145	-	-	-	
R4	0.227	0.203	0.170	0.111	0.088	-	572 (sh), 427

[a] See ref. [15], p. 636; a_H for the single proton is 1.157 mT.

tion in the remainder of the molecule is indicated by the ESR/ENDOR investigation of the deuterated derivative [D_1]**E4**$^{\bullet+}$. All the a_H values remain virtually unchanged, and the smallest coupling constant of 0.052 mT vanishes; it can, therefore, be assigned to the enol proton.[16] These findings corroborate a twisted geometry for **E4**$^{\bullet+}$ along the C(1)–C(2) double bond, which is also consistent with the results of AM1 geometry optimizations.[17] In addition the angle between the dimesitylmethyl and the hydroxy(*p*-methoxybenzyl) units is about 30°, and the C(1)–C(2) distance is 1.45 Å. The positive charge is stabilized in the latter segment of the molecule, while the spin population predominates in the dimesitylmethyl moiety. This finding is consistent with the considerably longer lifetime of **E4**$^{\bullet+}$ compared to **E1**$^{\bullet+}$ to **E3**$^{\bullet+}$, since the anisyl substituent is able to stabilize the positive charge very effectively (Scheme 2).

Scheme 2.

Such a structure is additionally supported by comparison with radical **R4** which is available from one-electron oxidation of the enolate.[18] The a_H values assigned to the dimesitylmethyl unit of **R4** (Table 2) are considerably smaller than those of **E4**$^{\bullet+}$ and mirror a more efficient spin delocalization in the α-carbonyl radical **R4**.[19] The clear distinction between radicals **E4**$^{\bullet+}$ and **R4** is also evident from the absorption spectra[20] measured simultaneously with the ESR spectra (Table 2). In this respect the spin density corresponds to that in enol ether[21] and ketene silyl acetal radical cations.[22]

The data presented here allow the existence of enol radical cations in solution to be definitively established for the first time. In addition the high acidity and the primary kinetic isotope effect confirm that these species react preferentially by deprotonation. In view of the widely accepted mechanism of action for ribonucleotide reductase[3] it will be interesting to see whether deprotonation is also the main reaction path for enol radical cations in aqueous solutions.

Interfacial Chem.* **1989**, *270*, 43–59, gold microelectrodes with diameters of 5, 10, and 25 μm, electrolyte: 0.1 M tetra-*n*-butylammonium hexafluorophosphate, enol: 7 mM.
[12] Addition of more than 7.5 equivalents of deuterated trifluoroacetic acid did not increase the reduction current, which indicated that **E4** was completely converted to [D_1]**E4**. ^{1}H NMR investigations independently confirmed the facile H/D exchange of the hydroxy protons of **E4** in the presence of CF_3COOD.
[13] For the simulation with D. Gosser's program an $E_{qr}C_{irr}$ mechanism with $k_{het} = 0.1$ cm s^{-1} was assumed: D. K. Gosser, Jr. *Cyclic Voltammetry*, VCH, New York, **1993**. A working curve (i_{pc}/i_{pa} versus kt) was prepared from the peak current ratio of the simulated curves (determined according to Bellamy's method: A. J. Bellamy, *J. Electroanal. Chem. Interfacial Electrochem.* **1983**, *151*, 263) from which by plotting kt versus the time t (t: time required to scan from $E_{1/2}$ to E_i the rate constants k_H or k_D were obtained (R. S. Nicholson, I. Shain, *Anal. Chem.* **1964**, *36*, 706).
[14] The determination of the multiplicities of a_H by comparison of the spectral width of simulated and experimental ESR spectra did not give an unambiguous result largely because the expected high multiplicities (e.g. two or four almost equivalent *ortho*-methyl groups on the mesityl substituents) led to very flat edges of the ESR signal. A satisfactory agreement between the experimental and the simulated spectrum is obtained when the following mutiplicities are used (**E4**$^{\bullet+}$, a_H[mT]): 0.307 (3H), 0.226 (6H), 0.151 (3H), 0.108 (6H), 0.080 (2H), 0.052 (1H). This indicates an unequal distribution of the spin population in the two mesityl groups as well as a very small spin population in the OH and the anisyl groups. This finding is in agreement with the spin distribution calculated by INDO based on AM1 optimized geometry (cf. ref. [17]).
[15] A. Berndt, Carbon Radicals with Conjugated π systems in *Landolt-Börnstein, Magnetische Eigenschaften freier Radikale*, Springer, Berlin, **1977**, Chapter 4.
[16] Detection of the ^{2}H-ENDOR signal is not possible because of the small a_D value of about 0.007 mT.
[17] According to UHF-AM1 calculations (M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc.* **1985**, *107*, 3902-3909) the energy potential of **E4**$^{\bullet+}$ is very flat, which is not surprising given the almost unhindered rotation of the MeO and OH groups and the many rotamers of the mesityl groups. Independent of these conformations we always found the deviation of the ethene fragment from planarity described in the text and the markedly elongated double C(1)=C(2) bond. The INDO calculations based on these geometries confirm a large proportion of the spin density in the dimesitylmethyl part: on average, the a_H of the *o*-methyl groups in one mesityl part are, for example, predicted as 0.32 mT, in the other as 0.15 mT. For the *p*-mesityl groups the results for a_H are 0.32 and 0.17 mT, respectively. According to INDO, the a_H in the anisyl group and in the OH groups are < 0.12 mT, whereas the a_H of the OH proton is between about 0.04 and 0.12 mT depending on the conformation of the freely rotating hydroxyl group. Considering the size and low symmetry of **E4**$^{\bullet+}$ the agreement between theoretical and experimental values is very satisfactory.

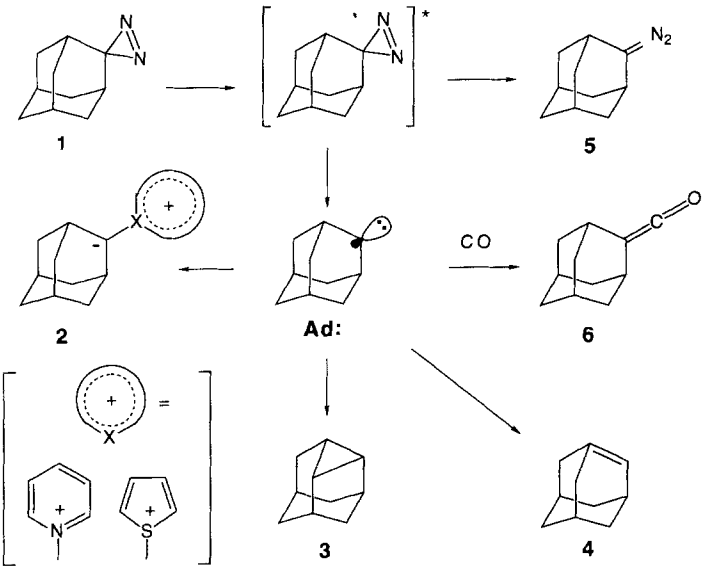
Matrix Spectroscopy of 2-Adamantylidene, a Dialkylcarbene with Singlet Ground State**



Thomas Bally*, Stephan Matzinger, Leo Truttmann, Matthew S. Platz,* and Scott Morgan

Identification of the ground state multiplicity (singlet S or triplet T) of carbene intermediates is of fundamental interest to synthetic, mechanistic, and theoretical chemistry. The issue is straightforward to resolve for triplet carbenes, which are persistent at cryogenic temperatures. In this case detection of the triplet state and assessment whether this is the ground state of the carbene or if it is thermally accessible from a singlet ground state species at the temperature of the experiment is unambiguous with EPR spectroscopy.[1] Unfortunately, failure to observe a triplet EPR spectrum does not constitute proof that a certain carbene has a singlet ground state, because the triplet may not be formed at all or be short-lived, even at cryogenic temperatures.

Dialkylcarbenes present a particular challenge in that they may rapidly decay by 1,2- or 1,3-insertion reactions to form olefins and cyclopropanes, respectively, even at cryogenic temperatures.[2, 3] Therefore, until recently only di-*tert*-alkylcarbenes could be observed directly in matrices (that is, not as trapping products), and these were found to possess triplet ground states.[4] In 1992 Sheridan et al. reported the spectroscopic identification of the first directly observed singlet dialkylcarbene, dicyclopropylcarbene,[5] where migration of the β-H atoms is prevented by keeping the corresponding C–H bonds perpendicular to the empty p-orbital through strong hyperconjugation of the latter with the Walsh MO's of the cyclopropyl moieties.[6] This hyperconjugation also favors the singlet state and may kinetically stabilize the carbene.

A similar geometrical constraint is realized in 2-adamantylidene (**Ad:**), which should therefore also be reasonably resistent to [1,2] H shift at cryogenic temperatures. Photolysis of adamantane-2-spiro-3′diazirine (**1**) under several low-temperature conditions failed to produce a triplet EPR spectrum, but **Ad:** can be intercepted by olefins and by pyridine or thiophene to form the ylides **2** (Scheme 1).[7] As the kinetics of this ylide formation are not influenced at room temperature by oxygen, an excellent trap of triplet carbenes, it was concluded that **Ad:** has a singlet ground state and that the triplet must lie at least 4.8 kcal mol^{-1} higher in energy.[7, 8] Finally, **Ad:** isolated in β-cyclodextrin was recently found to rearrange spontaneously to 2,4-dehydroadamantane (**3**) at room temperature.[9]

Herein we report the spectroscopy of **Ad:** in an argon matrix. Our results confirm that **Ad:** has a singlet ground state. In particular, we have found a characteristic absorption band of **Ad:**, which may be of general use in identifying other hydrocarbon carbenes with singlet ground states.

Scheme 1.

The difference spectrum in Figure 1 shows how a broad band with $\lambda_{max} \approx 620$ nm appears at the expense of the sharp diazirine peaks at 330–370 nm upon 30 minutes irradiation at 365 nm of **1** isolated at 10 K in an argon matrix. At the same time the IR

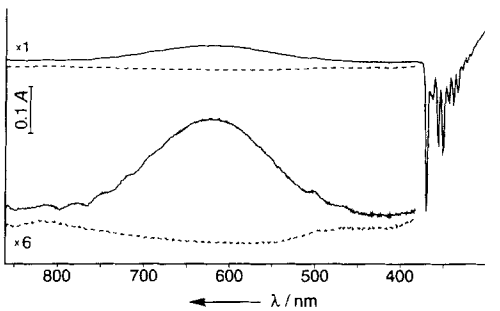


Fig. 1. UV/Vis difference spectra illustrating the formation of **Ad:** by 365 nm photolysis of **1** (solid lines) and the subsequent bleaching of **Ad:** by irradiation at $\lambda > 540$ nm (dashed lines). A = absorbance.

spectrum shows an increase of a group of intense peaks around 2050 cm^{-1}, which are indicative of a diazo moiety. Upon photolysis of this sample through a 540 nm cutoff filter for another 30 minutes, the broad visible band and some of the new bands in the IR spectrum disappear in concert (Fig. 2), while a new group of peaks arise which are identical to those of authentic **3** in argon; the diazo peaks remain unaffected.

If CO is added to the matrix containing **1**, formation of the 620 nm band after 365 nm photolysis is partially suppressed (Fig. 3), while the IR spectra show new features at 2110 cm^{-1}, the region typical of ketene groups, in addition to those of the diazo compound.

As in the experiments without CO, the 620 nm band could be bleached, and **3** was formed, albeit in smaller overall yield. In contrast, annealing of the CO-doped matrices led to an increase of the ketene absorptions (rather than those of **3**) at the expense of those of the primary photoproduct. Annealing the sample at 35 K after complete photolysis of **1** has no effect on the spectra.

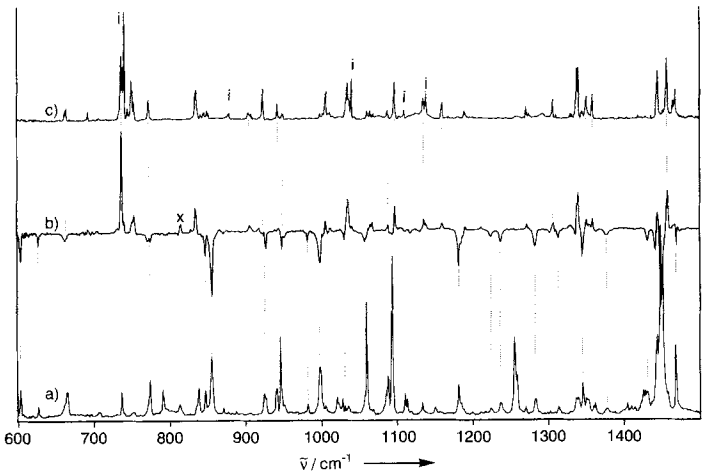

Fig. 2. a) IR spectrum after complete photolysis of **1** at 365 nm; b) difference spectrum after photolysis of sample of spectrum a at $\lambda > 540$ nm. Peaks pointing down are assigned to bleached **Ad:**, those pointing up (except for the band marked x) to newly formed **3**; c) IR spectrum of authentic **3** (bands marked "i" denote a small impurity).

These results provide strong evidence that the photoinduced rearrangement of **1** to diazoadamantane **5** is accompanied by the formation of **Ad:**. Both the appearance of ketene **6** in matrices containing CO (in part upon annealing) and the photochemical transformation to **3**, a known thermal rearrangement product of **Ad:** at room temperature,[9] can most readily be explained if **Ad:** is the carrier of the broad 620 nm absorption and the associated IR bands.

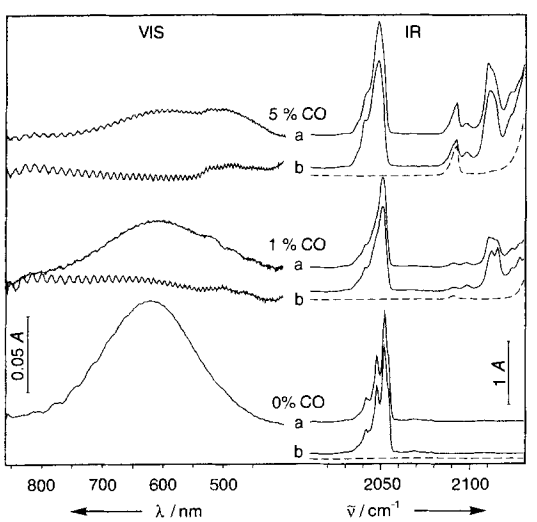

Fig. 3. EA and IR difference spectra illustrating the effect of CO concentration on the yield of **Ad:** and ketene **6**. Also seen in this spectrum is the formation of diazo compound **5**. Spectra **a** are obtained after 365 nm photolysis of **1**, and **b** after annealing at 25 K for 6 minutes. The dashed spectra are before 365 nm photolysis.

With regard to the question of the ground state multiplicity of **Ad:** we note that singlet dicyclopropylcarbene shows a similarly broad band with $\lambda_{max} = 490$ nm,[5] and that $^1CH_2$ has a weak transition with a long vibrational progression whose vertical component lies at about 1.5 eV (820 nm),[10] which corresponds to excitation of an electron from the sp hybrid lone pair to the empty p orbital. Conversely, $^3CH_2$ as well as triplet dialkylcarbenes do not absorb above 300 nm.[4, 11]

We have carried out ab initio CASSCF quantum chemical calculations[12] on the $^1A_1$ and $^3B_1$ states of **Ad:** as well as on tautomers **3** and **4**. The results are summarized in Figure 4. According to these calculations, the triplet state of **Ad:** is 3.1 kcal mol^{-1} more favorable. However, the stability of triplet states of alkylcarbenes is overestimated (or that of singlet states underestimated) by about 6 kcal mol^{-1} at this level of theory, and large basis sets and methods for efficient recovery of dynamic correlation effects are needed to remedy this.[14, 15] Therefore we see no contradiction between this result and the experimental energy difference of at least 4.8 kcal mol^{-1} in favor of ^{1}**Ad:**.[8] More importantly, both **3** and **4** are distinctly more stable than **Ad:**, but the reaction that gives **3** is much more exothermic, which may explain its exclusive formation from **Ad:** isolated in β-cyclodextrin.[9] The [1,2] hydrogen shift leading to **4** appears to be effectively prevented by keeping the empty p orbital on the carbene perpendicular to the migrating C–H bond.

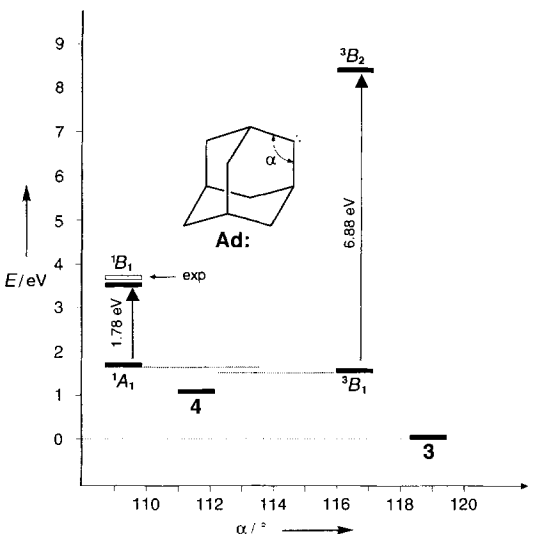

Fig. 4. Energy level diagram for **Ad:**, **3**, and **4** from 6-31G* CASSCF calculations [12]. The first excited states of singlet and triplet **Ad:** were calculated by the CIS procedure [16].

With the CASSCF-optimized geometries, CIS calculations[16] yielded a vertical excitation energy for ^{1}**Ad:** of 1.78 eV (695 nm), whereas the first excited state of ^{3}**Ad:** was predicted to be 6.88 eV (180 nm). Although the former energy is about 0.2 eV too low, the calculations clearly support the assignment of the 620 nm band to ^{1}**Ad:** (rather than ^{3}**Ad:**).[11] Apparently, alkyl substitution does not induce a major shift in this transition, and hence other singlet dialkylcarbenes should show similar bands which may facilitate their identification.

Experimental

1 was prepared according to literature procedures [18]. A sample of **3** was kindly provided by Prof. Udo Brinker (State University of New York at Binghamton) who also shared his recent data with us prior to their publication. The apparatus and procedure for matrix isolation experiments has been previously described [19]. 0.1 Torr (approximately the equilibrium vapor pressure at room temperature) of **1** were mixed with 100 Torr of argon in a 2.2 L bulb from which 80 Torr (approximately 10 mM Ar) were deposited on a CsI window held at 20 K for 2 h. Compound **1** was photolyzed with a 500 W medium-presssure mercury lamp fitted with a 365 nm interference filter; conversion of **Ad:** to **3** was achieved with a 1 kW argon resonance lamp and a 540 nm cutoff filter. Calculations were carried out with the 6-31G* basis

set using the GAUSSIAN92 [17] and GAMESS (US) programs [20] on SGI and IBM workstations.

[11] We have also carried out INDO/S calculations (using geometries optimized with ab initio methods) on **3** and **4** which indicate that neither compound should show visible absorptions and hence cannot be the carriers of the 620 nm band.
[12] Complete active space multireference SCF including the sp hybrid orbitals and the p atomic orbital at the carbene center in the active space. The closed-shell singlet states of carbenes require a [2,2] multireference wavefunction for a correct description. For the $^3B_1$ states of **Ad:**, this amounts to a single-determinant ROHF calculation. For **4** ("adamantene") that has biradicaloid character due to its twisted double bond [13], the active space included the π and π^* MO's, whereas **3** was treated at the single-determinant ROHF level. Unconstrained geometry optimizations were carried out for all species and states considered. The $^3B_1$ state of **Ad:** converged in this procedure to a structure of C_2, symmetry, and the closed-shell $^1A_1$ state to a distorted C_s geometry that, however, lies only 0.03 kcal mol^{-1} below the C_{2v}-constrained minimum. As expected, **3** has C_s symmetry and **4** is unsymmetrical.

[14] a) M. M. Gallo, H. F. Schaefer III, *J. Phys. Chem.* **1992**, *96*, 1515; b) an excellent discussion of the factors influencing the S/T gap in methylcarbene has recently been provided by S. Khodabandeh, E. Carter, *ibid.* **1993**, *97*, 4360.
[15] We have calculated the S/T gap in methyl- and dimethylcarbene at the same level of theory used for our calculations on **Ad:**, both at their equilibrium geometries (where the angle α at the carbene carbon center is 105 and 110° for the singlets, respectively, and 129° for the triplets of both compounds) and also by fixing the angle α at the value it adopts in optimized ^{1}**Ad:** (109.5°) and ^{3}**Ad:** (116.5°), respectively. Thus, the calculated S/T gap in methylcarbene is 10.2 kcal mol^{-1}, that is, some 6 kcal mol^{-1} too high [14], and it reduces to 8.4 kcal mol^{-1} at the **Ad:** valence angles. For dimethylcarbene the S/T gap is 6.1 and 3.6 kcal mol^{-1}, respectively. Subtracting the approximately 6 kcal mol^{-1} error (from methylcarbene) yields a preference for the triplet ground state in dimethylcarbene (at the **Ad:** valence angles) of 2–3 kcal mol^{-1}, which should be similar in **Ad:**, in agreement with experiment.

3,3′-Bis(dicyanomethylene)-4,4,4′,4′-tetramethyl-2,2′-bithiolanylidene, a Compound Containing the Fundamental Chromophore of Thioindigo: (*E*/*Z*) and Valence Isomers, Thermo- and Photochromism**

Andreas Pawlik, Walter Grahn,* Axel Reisner, Peter G. Jones, and Ludger Ernst

Dedicated to Professor Christian Reichardt on the occasion of his 60th birthday

The reversible interconversion of the *E*/*Z* isomers of thioindigo **1a** (X = oxygen, Scheme 1) has been thoroughly investigated in solution and in the adsorbed state.[1, 2] Possible applications of the photochromism of **1a**, particularly for optical data storage and the conversion of solar energy, have stimulated considerable work.[2] The valence isomer pair (*Z*)-**1**/**2** should show a stronger photochromism than the (*E*/*Z*) isomers **1**. However, *cis*-thioindigo (*Z*)-**1a** cannot be transformed into the corresponding heteroanalogous cyclohexadiene **2a**. In contrast, the indigoid dyes **1b** (X = sulfur)[3] and **1c** (X = dicyanomethylene)[4] cannot be isolated and occur exclusively in the form of the 1,2-dithiine **2b** and cyclohexadiene **2c**, respectively.

Scheme 1. Thioindigo dyes **1** [**1a**: X = O; **1b** [3]: X = S; **1c** [4]: X = $C(CN)_2$], their valence isomers **2** [**2a**: X = O; **2b** [3]: X = S; **2c** [4]: X = $C(CN)_2$], and corresponding systems **3** with the fundamental chromophore of indigo [**3a** [6]: X = O, *n* = 1; **3b**: X = S, *n* = 1; **3c** [8]: $C(CN)_2$, *n* = 1; **3d** [9]: X = O, *n* = 2].

This is certainly due in part to the gain in π stabilization energy through the benzothiophene unit. This kind of stabilization is impossible for the dicyanomethylene analogue **3c**[5] of 2,2′-bithiolanylidene **3a**,[6] a compound having the fundamental chromophore of thioindigo. Quantum mechanical calculations (PM3[7]) underline this: the heats of formation for (*E*)-**3c** and (*Z*)-**3c**, 202.1 and 202.2 kcal mol^{-1} respectively, are approxi-

mately equal and only a little greater than that of valence isomer **5** (185.5 kcal mol^{-1}; see Scheme 2).

We report here on our synthesis of **3c**, its characterization by spectroscopy and X-ray crystallography, and its isomerization into *E*/*Z* and valence isomers.

The starting material for the synthesis of **3c** (Scheme 2) was the unknown 3-(dicyanomethylene)-4,4-dimethylthiolane (**4**),[8] which was prepared from 4,4-dimethylthiolan-3-one[6] and malonitrile in 38% yield. Oxidation of **4** with 2,3-dichloro-5,6-dicyano-*para*-benzoquinone (DDQ) gave **3c** as metallic black-green crystals in 73% yield.

According to X-ray analysis, **3c** occurs as a 1:1 mixture of the racemic *E*/*Z* isomers (*E*)-**3c** and (*Z*)-**3c** (Fig. 1).[10] In contrast to (*E*)-**3a**,[11] which has a planar chromophore, (*E*)-**3c** is quite twisted in order to reduce the strong steric interactions between the dicyanomethylene and *gem* dimethyl groups. As in **3a**, the thiolane rings in **3c** are considerably folded: (*Z*)-**3c** has almost an ideal envelope conformation—atoms C4 and C4′ lie outside the plane of the other atoms; in (*E*)-**3c** this is the case for atoms C3a and C3b. The central double bond b (Scheme 2) in (*Z*)-**3c** is twisted by 13°; in (*E*)-**3c** it is *syn* pyramidalized; C2a and C2b lie outside of the best plane through S1a, S1b, C3a, and C3b by 16 and 18 pm, respectively. The d,d′ bonds are only slightly twisted. The helicity of the chromophores is indicated by the large torsion angles about c,c′ (with b and d,d′, 46.5 and 55.4° for (*E*)-**3c**, and 32.6 and 28.2° for (*Z*)-**3c**).[10]

Scheme 2. Synthesis and consecutive rearrangement of **3c**. Photochromism of the pairs **5**/**3c** and **6**/**7**.

What is the ratio of isomers in solution? According to the ^{1}H NMR spectrum, (*E*)-**3c** and (*Z*)-**3c** are no longer present in equimolar amounts in solution (ratio major isomer/minor isomer about 4:1, assignment was not possible). Both show nonequivalent methyl and methylene groups, indicating that they are not planar. By using two-dimensional exchange spectroscopy (EXSY)[12] it is possible to observe the conversion of the *E* into the *Z* isomer (via the transition state structure with orthogonal molecular halves), as well as the interconversion of the enantiomers of the nonplanar *E* and *Z* forms (via the planar transition state structure).[13]

After two hours in refluxing xylene, **3c** gave a mixture of **5** as pale yellow crystals (3%) and **6** as yellow crystals (73%). The remainder is unreacted **3c**. Refluxing in toluene produced **5** and **6** in almost equal amounts, but the conversion of **3c** was only 30%. **5** can be reconverted into **3c** by irradiation with 333 nm light. Irradiating **6** with 420 nm light gave the orange valence isomer **7**, which can be reconverted into **6** thermally (20 h at 150 °C in 1,1,2,2-tetrachloro[D_2]ethane) in 37% yield and also photochemically (436 nm) in roughly 17% yield; the isosbestic points lie at 282, 300, 346, and 428 nm (see Scheme 2).[14]

The structures of **5** and **6** were confirmed by X-ray crystallography (Fig. 2).[10] The bonds involved in the isomerizations are listed in Table 1. Of interest is the long C–C single bond e in **5**, which reduces the steric interactions of the geminal cyano groups.[15] As expected, **6** is present as a racemate (chiral center at C3).[10]

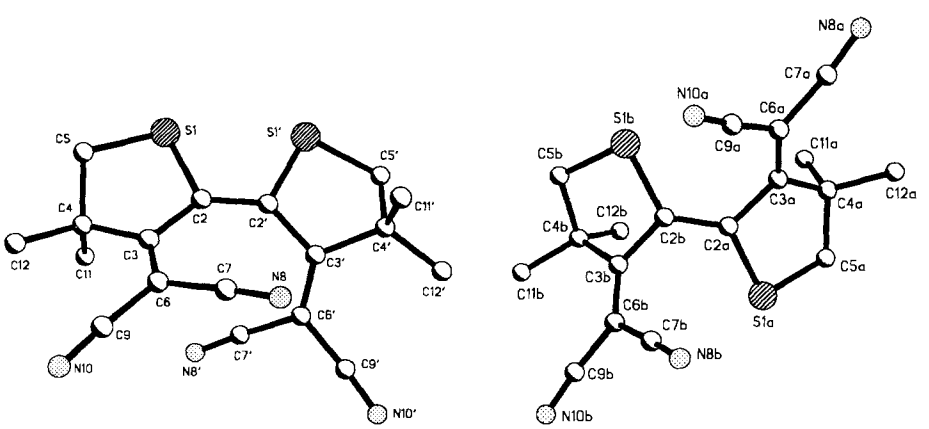

Fig. 1. Structures of one enantiomer of (*E*)-**3c** (right) and of (*Z*)-**3c** (left) in the crystal of **3c** [10].

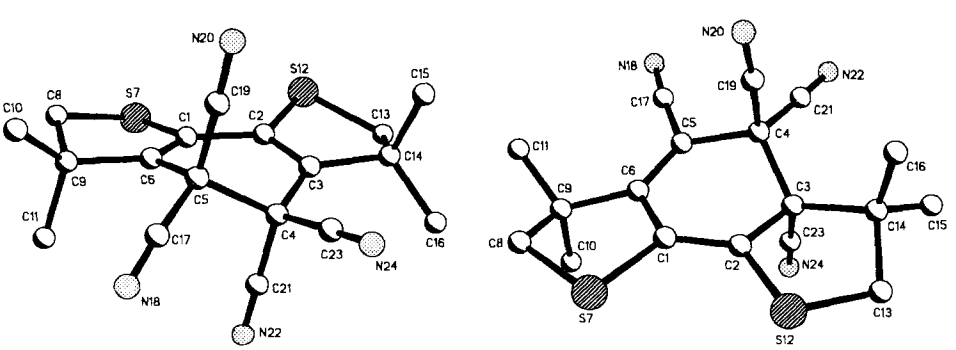

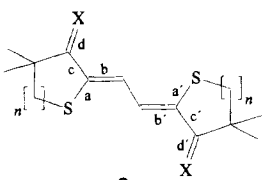

Fig. 2. Crystal structure of **5** [10] (left) and **6** [10] (right).

Table 1. Compounds **3a**, (*E*)-**3c**, (*Z*)-**3c**, **5**, and **6**: Lengths of the bonds involved in the isomerization [pm] (for a–e see Scheme 2).

Cmpd.	Bond				
	a a′	b	c c′	d d′	e
(*E*)-**3a** [11]	173.5(4)	137.2(7)	148.4(5)	121.6(5)	
(*E*)-**3c** [10]	175.6(3)	135.6(4)	145.8(4)	135.5(4)	
	176.0(3)		147.2(4)	134.7(4)	
(*Z*)-**3c** [10]	176.5(3)	137.1(4)	146.0(4)	135.9(4)	
	175.5(3)		146.2(4)	135.0(4)	
5 [10]	174.3(2)	145.5(2)	133.4(3)	151.9(2)	159.5(2)
	174.9(2)		133.5(3)	152.5(2)	
6 [10]	175.2(5)	132.3(7)	145.3(7)	134.6(7)	155.3(7)
	172.7(5)		152.0(7)	156.0(7)	

The NMR spectra of **5** are indicative of high symmetry, which is lost on conversion into **6**. The ^{1}H NMR spectrum of the valence isomer **7** shows two singlets for the *gem* dimethyl groups and also for the methylene groups. All the carbon nuclei, with the exception of the *gem* dimethyl groups in each ring, show different chemical shifts. In addition the characteristic signal of the nitrile-substituted C3 in **6** is missing. The unsymmetrical ring-opened structure of **7** is in accord with these results.

The vinylogous compound **8c** is important for the characterization of the chromophore of **3c** and was therefore synthesized[8] by condensation of thiolane **4** with *N*,*N*′-(1,2-ethandiylidene)bis(cyclohexylamine) (Scheme 3).[16]

8

Scheme 3. The next highest homologues of **3**, the vinylogous systems **8** [**8a** [6]: X = O, *n* = 1; **8c** [8]: X = C(CN)$_2$, *n* = 1; **8d** [9]: X = O, *n* = 2].

In contrast to **3c**, **8c** is present in the crystal solely in the (*Z*,*Z*) form shown, which corresponds to the *E* configuration of **3c** (Scheme 3). The dye **8c** has inversion symmetry with a planar central butadiene unit. The bonds d and d′ are slightly twisted by 13°. In comparison to (*E*)-**3c** the torsion angles in the chromophore about c and c′ (22°) are less than half as large in **8c**.[10]

The vinylogous dye **8c** shows typical indigo properties: low solubility in organic solvents and high thermal stability (m.p. 268–272 °C).

Comparison of the longest measured UV/VIS bands of (*E*)-**3a** and **8a** with the corresponding new dyes **3c** and **8c** shows that replacement of the carbonyl oxygen atom by a dicyanomethylene group produces a strong bathochromic effect (Table 2).[17] On going from **3c** to the next highest homologue **8c** there is drastic batho- and hyperchromism, while the change from (*E*)-**3a** to **8a** is accompanied by the low hypsochromism typical of indigoids.[18] How can this difference be explained?

Table 2. Experimental UV/VIS data for **3a**/**c**/**d** and **8a**/**c**/**d** and calculated UV/VIS data (PPP [20]) for **3c**/**8c**.

Cmpd. [8]	λ_{max} [nm] (ε_{max}) Ethanol	λ_{max} [nm] (ε_{max}) PPP	Cmpd. [6]	λ_{max} [nm] (ε_{max}) Ethanol	Cmpd. [9]	λ_{max} [nm] (ε_{max}) Methanol

[a] In ethanol.

Unlike (*E*)-**3a** and **8a**, (*E*)-**3c**, (*Z*)-**3c**, and **8c** do not have a planar chromophore. The dihedral angles about the thiolane bond c,c′ calculated by PM3,[7] 53° [(*E*)-**3c**] and 39° [(*Z*)-**3c**], are in good agreement with the values determined by X-ray crystallography. Similar torsion is produced in indigo chromophores when the thiolane ring in **3a** is changed to a six-membered ring, as in **3d** (Table 2).[9] The result is hypsochromism, in agreement with the results from HMO calculations.[19] The measured bathochromism in going from **3d** to **8d** is a result of the smaller twist of the chromophores, as is also the case in going from **3c** to **8c**, and not an atypical indigo property.

In order to determine which isomer, (*E*)- or (*Z*)-**3c**, predominates in solution, we calculated the UV/VIS absorption maxima using the PPP method (Table 2).[20] The measured and calculated values for the **3c** mixture in solution are in satisfactory agreement, if the (*Z*)-**3c** isomer predominates. This is less twisted and should therefore absorb at a longer wavelength than the corresponding *E* isomer.

Of note is the large photochromism of 176 nm of the valence isomers **3c**/**5** in cyclohexane. As expected the longest wavelength maximum of **5** (λ = 324 nm) is blue-shifted by 62 nm relative to the corresponding thioindigo valence isomer **2c**.[4] Owing to the donor/acceptor substitution of the butadiene unit in **6**, its longest wavelength absorption maximum is shifted bathochromically by 98 nm in comparison to **5**. Ring opening of **6** to form **7** results in an increase in the acceptor strength and thus a further bathochromic shift of 16 nm.

The formation of valence isomers **5**, **6**, and **7** from **3c** can be regarded as a sequence of pericyclic reactions. (*Z*)-**3c** is converted by an electrocyclic reaction to cyclohexadiene **5**, which can be reconverted to (*Z*)-**3c** by electrocyclic ring opening. The appreciable steric interference in **5** is then reduced by the [1,5]-sigmatropic shift of a nitrile group resulting in **6**. This type of nitrile group migration in cyclohexadienes has been thoroughly studied.[21] Photochemical ring opening of **6** leads to the valence isomer **7**, which is in equilibrium with **6** by a thermal or photochemical ring closure. The valence isomer pairs **5**/(*Z*)-**3c** and **6**/**7** represent new structure types for the photochromic system that relies on the electrocyclic conversion of 1,3,5-hexatriene into 1,3-cyclohexadiene.[22] Important compounds containing this system include the dimethylenesuccinic anhydrides (fulgides)[23] and 1,2-bis(hetero)arylethenes,[24] which are the subjects of continuing studies and optimization for practical uses in optical information technology.

Experimental Procedure

To a solution of **4** (3.57 g, 20.0 mmol) [8] in 250 mL of dry CH_2Cl_2 containing 1 mL of dry pyridine was added DDQ (4.77 g, 21.0 mmol) in portions over 10 min at 0 °C. The reaction mixture was stirred for 1 h, then warmed to room temperature. A further 5 mL of dry pyridine was added, and the reaction mixture was stirred for another 3 h. After addition of 250 mL of CH_2Cl_2, the mixture was extracted with 10% NaOH (aq) (3 × 150 mL). Finally the organic phase was washed with water until neutral and dried over Na_2SO_4. After removal of solvent the residue was chromatographed on silica (200 g silica gel "60", 63–200 μm, Merck, Darmstadt; CH_2Cl_2). Recrystallization from cyclohexane/$CHCl_3$ 3:1 gave **3c** (2.56 g, 73%) [25].

3c: M.p. 184–186 °C; ^{1}H NMR (–60 °C): major isomer: δ = 3.23, 2.96 (both 1 d, J = 11.3 Hz, CH_2), 1.68, 1.39 (both 1 s, CH_3); minor isomer: δ = 3.25, 2.93 (both 1 d, J = 11.1 Hz, CH_2), 1.68, 1.29 (both 1 s, CH_3); IR: $\tilde{\nu}$ = 2225 cm^{-1} (CN); UV/VIS: λ_{max} (ε) = 498 nm (7300), 342 (17000) [cyclohexane]; 514 (6700), 346 (14900) [chloroform]; 512 (6200), 342 (12600) [acetonitrile]; 516 (6900), 346 (14700) [ethanol]; 508 (6800), 342 (14300) [acetic acid]; 534, 350 [KBr]; EI-MS: *m*/*z* (%): 352 (100) [M^+].

4: Fine, colorless needles, m.p. 23–24 °C; ^{1}H NMR: δ = 3.97 (s, 2H; 2-H), 2.90 (s, 2H; 5-H), 1.56 (s, 6H; CH_3); ^{13}C NMR: δ = 190.5 (C3), 112.0 (CN), 110.6 (CN), 82.2 [*C*(CN)$_2$], 50.0 (C4), 47.8 (C2), 40.8 (C5), 25.7 (CH_3); IR: $\tilde{\nu}$ = 2233 cm^{-1} (CN); UV/VIS: λ_{max} (ε) = 308 nm (500), 240 (12800) [acetonitrile]; EI-MS: *m*/*z* (%): 178 (100) [M^+].

5: Pale yellow rods, m.p. 154–155 °C; ^{1}H NMR: $\delta = 3.31$ (s, 4H; CH_2), 1.56 (s, 12H; CH_3); ^{13}C NMR: $\delta = 138.5$ (s), 119.8 (s), 109.3 (s), 50.3 (s), 48.3 (t), 43.2 (s), 24.3 (q); IR: $\tilde{\nu} = 2242\ cm^{-1}$ w (CN); UV/VIS: λ_{max} (ε) = 352 nm (1400, sh), 332 (3900, sh), 322 (4900), 316 (4600, sh), 276 (2000), 234 (9400) [cyclohexane]; 356 (1500, sh), 324 (4800), 276 (2600), 232 (9700) [acetonitrile]; EI-MS: *m/z* (%): 352 (74) [M^+], 337 (100) [$M^+ - CH_3$].

6: Yellow crystals, m.p. 198–201 °C; ^{1}H NMR: $\delta = 3.45$ and 3.09 (both a d, $^2J = 11.5$ Hz, both 1H; CH_2), 3.24 and 3.13 (both a d, $^2J = 11.2$ Hz, both 1H; CH_2), 1.77 (s, 3H; CH_3), 1.67 (s, 3H; CH_3), 1.65 (s, 3H; CH_3), 1.52 (s, 3H; CH_3); ^{13}C NMR: $\delta = 165.1$ (s), 134.4 (s), 130.4 (s), 112.8 (CN), 112.3 (CN), 110.8 (CN), 109.4 (CN), 93.2 (s), 59.7 (s), 52.8 (s), 48.9 (s), 47.4 (CH_2), 46.8 (CH_2), 39.9 (s), 25.9 (CH_3), 25.0 (CH_3), 24.8 (CH_3), 23.1 (CH_3); IR: $\tilde{\nu} = 2205\ cm^{-1}$ (CN); UV/VIS: λ_{max} (ε) = 420 nm (10500), 292 (7400), 240 (7700) [cyclohexane]; 426 (9900), 294 (7600), 242 (8200) [acetonitrile]; EI-MS: *m/z* (%): 352 (64) [M^+], 337 (100) [$M^+ - CH_3$].

7: Thick orange oil; irradiation of **6** in $CDCl_3$ with a Hg high-pressure lamp (photostationary equilibrium **6**/**7** = 1:1) and subsequent preparative thin-layer chromatography (silica gel "60 PF", Merck, 1.5 mm thick layer; toluene) provided **7** in 36% yield. ^{1}H NMR: $\delta = 3.271$ (s, 2H; CH_2), 3.267 (s, 2H; CH_2), 1.52 (s, 6H; CH_3), 1.40 (s, 6H; CH_3); ^{13}C NMR: $\delta = 150.3$ (s), 148.8 (s), 136.4 (s), 132.6 (s), 116.5 (s), 114.1 (s), 112.0 (s), 110.765 (s), 110.762 (s), 95.2 (s), 54.2 (s), 51.3 (s), 48.2 (CH_2), 46.2 (CH_2), 25.3 (CH_3), 24.3 (CH_3); IR: $\tilde{\nu} = 2231$, 2205 cm^{-1} (CN); UV/VIS: λ_{max} (ε) = 460 nm (6700, sh), 436 (8000), 312 (6000), 260 (8200) [cyclohexane]; 454 (6600), 312 (5900), 258 (7700) [acetonitrile]; EI-MS: *m/z* (%): 352 (48) [M^+], 337 (100) [$M^+ - CH_3$].

8c: Copper-colored crystals, m.p. 268–272 °C (decomp.); ^{1}H NMR: $\delta = 7.90$ (s, 2H; CH), 3.05 (s, 4H; CH_2), 1.61 (s, 12H; CH_3); IR: $\nu = 2222$, 2210 cm^{-1} (CN); UV/VS: λ_{max} (ε) = 568 nm, 552 (sh), 336 [cyclohexane, saturated]; 580 (20500), 340 (11000) [chloroform]; 560 (21300), 334 (10700) [acetonitrile]; 564 (18100), 336 (10000) [ethanol]; 650, 578, 344 [KBr]; EI-MS: *m/z* (%): 378 (100) [M^+].

A Thermally Stable Peroxocopper(II) Complex with Unusual μ_4-Coordination of the Peroxo Ligand**

Jörg Reim and Bernt Krebs*

Dedicated to Professor Philipp Gütlich on the occasion of his 60th birthday

Dioxygen transition metal complexes[1] have not only interesting spectroscopic and structural properties;[2] they also play a significant role in the catalytic oxidation of organic compounds[3] and in biological systems.[4] Most contain copper or iron centers that are responsible for the transport of oxygen and its subsequent reactions. Typical examples from the field of copper proteins are catechol oxidase[5] (which catalyzes the oxidation of *o*-diphenols to the corresponding *o*-quinones), tyrosinase (the longest known monooxygenase),[6] and hemocyanin[7] (the O_2 transport protein in arthropods and molluscs). They belong to the type III copper proteins, which are characterized by an antiferromagnetically coupled dicopper(II) site (EPR-silent). To understand the mechanistic, structural, and electronic aspects of oxygen binding to the copper(I) centers of the deoxy forms of these proteins model complexes for Cu^I/O_2 systems have been investigated in solution at low temperatures, in particular by Karlin et al.[8] In 1988 they crystallized the first cop-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

per-dioxygen complex and characterized it by X-ray crystallography.[9] The structure consists of two mononuclear copper(II) units bridged by a *trans*-μ-1,2-peroxo ligand. A dinuclear copper(II) model complex synthesized by Kitajima et al.,[10] which contains a planar μ-η^2:η^2-peroxo group and is likewise stable only at low temperatures, simulates the spectroscopic, magnetic, and structural properties of oxyhemocyanin. A recently reported crystal structure of the protein[11] also shows this type of coordination for the peroxo ligand.

We now present the first report on the synthesis and crystal structure of a peroxocopper(II) complex with unusual μ_4 coordination of the peroxo ligand, which is stable at room temperature. On treatment of $Cu(ClO_4)_2 \cdot 6H_2O$ with the new tridentate ligand 4-methyl-2,6-bis(pyrrolidinomethyl)phenol (HL), dark green crystals of the salt of **1** precipitate in the presence of air from a methanolic solution to which triethylamine and 3,5-di-*tert*-butylcatechol (3,5-DTBC) had been added.

$[Cu_4L_2(O_2)(OMe)_2(ClO_4)]ClO_4 \cdot MeOH$ **1**

The structure of the cation of **1** is depicted in Figure 1.[12] Figure 2 shows its central coordination unit for greater clarity.

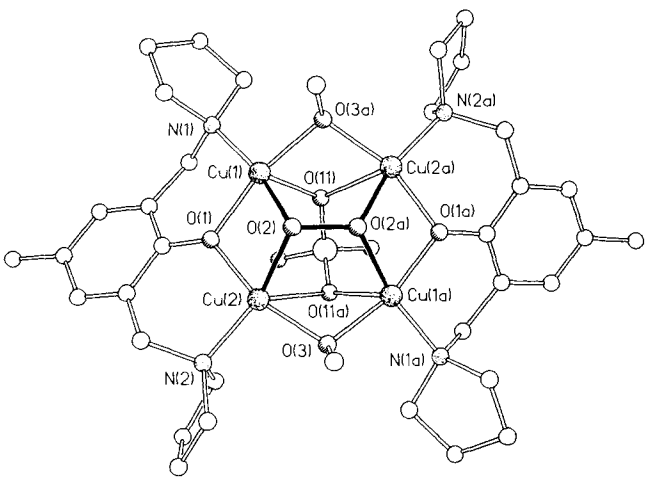

Fig. 1. Crystal structure of the cation of **1**.

In the center of the molecular cation, which lies on the twofold crystallographic axis, are four copper(II) ions forming an almost planar rectangle (dihedral angle 7.5(1)°). The longer sides [Cu(1)···Cu(2a) of 3.030(2) Å] are bridged by a methanolato ligand and the shorter sides [(Cu(1)···Cu(2) of 2.994(2) Å] by the μ-phenoxo unit of the deprotonated ligand L^-. The pyrrolidine groups of the L^- ligand are bound as terminal ligands to each of the copper atoms. Above the rectangle a peroxo group is bound end-on in a fourfold bridging μ_4-$(\eta^1)_4$ coordination at a distance of 1.008(2) [O(2)] and 1.078(2) Å [O(2a)] from the best Cu_4 plane. A perchlorate ligand situated below the Cu_4 rectangle is similarly bound to all four metal centers through O(11) [to Cu(1) and Cu(2a)] and O(11a) [to Cu(1a) and Cu(2)]. The copper atoms are thereby coordinated with typical Jahn-Teller distortion in a square-pyramidal environment; the perchlorate oxygen atoms occupy the apexes of the pyramid. The perchlorate ligand is bound unsymmetrically to the Cu_4 center; the axial bond lengths differ widely [2.411(3) Å for Cu(1)-O(11) and 2.693(3) Å for Cu(2)-O(11a)]. In contrast to these relatively long distances, the other Cu-O and Cu-N bond lengths vary between 1.920(3) for Cu(2)-O(3) and 2.006(3) Å for Cu(1)-N(1), thus lying in the usual range for copper(II) coordination compounds. The coordinated dioxygen unit has a characteristic O-O length for a peroxide O_2^{2-} of 1.453(4) Å.[2, 9, 10] The remarkable μ_4-coordination of the peroxo ligand described here was previously only observed in a tetranuclear Mo complex[13a] and in a hexanuclear Fe complex.[13b] Whereas in the first example the peroxo ligand also lies above the M_4 plane, the O_2^{2-} in the second example is bound in such a way that the O atoms are in a planar environment. This O_2^{2-} structural unit is also under discussion for tetranuclear Mn complexes in photosystem II[14a] as intermediate in the oxidation of water.[14b]

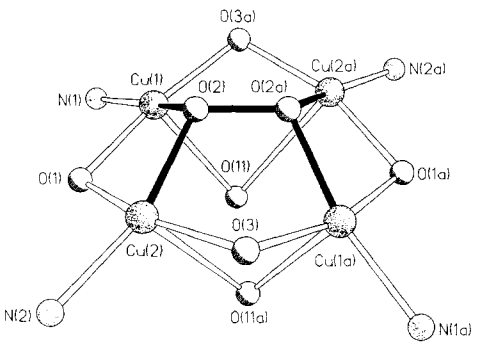

Fig. 2. Central coordination unit of the cation of **1**. Selected distances [Å] and angles [°]: Cu(1)-O(1) 1.939(2), Cu(1)-O(2) 1.961(2), Cu(1)-O(3a) 1.932(2), Cu(1)-N(1) 2.006(3), Cu(1)-O(11) 2.411(3), Cu(2)-O(11a) 2.693(3), Cu(2)-O(1) 1.941(3), Cu(2)-O(2) 1.939(2), Cu(2)-O(3) 1.920(3), Cu(2)-N(2) 1.986(3), Cu(1)···Cu(2) 2.994(2), Cu(1)···Cu(2a) 3.030(2), O(2)-O(2a) 1.453(4); Cu(1)-O(1)-Cu(2) 101.0(1), Cu(1a)-O(3)-Cu(2) 103.8(1), Cu(1)-O(11)-Cu(2a) 72.6(1), Cu(1)-O(2)-Cu(2) 100.3(1), Cu(1)-O(2)-O(2a) 113.7(2), Cu(2)-O(2)-O(2a) 113.8(2).

Another interesting structural feature is the μ-ClO_4^- unit. The perchlorate ion acts as bridging ligand in only relatively few complexes. In most of these cases it coordinates to two metal centers; up to now it has been characterized as tridentate ligand by X-ray crystallography in only two cases.[15] As far as we know, **1** is the first complex in which the perchlorate occurs as a fourfold coordinating ligand.

The synthesis of **1** forms part of our studies on the preparation of new functional models for the active site of catechol oxidase. They have previously led to some dinuclear copper(II) complexes with new tridentate ligands, the catecholase activity of which in solution is under investigation.[16] Under the basic reaction conditions described here, a Cu_2L^{3+} unit dimerizes with coordination of methanolate, peroxide, and perchlorate ions to form **1**. In the presence of coordinating anions an aggregation of complexes of this type is a favored reaction and leads, for example with halide or carboxylate groups, to similarly tetranuclear μ_4-oxo complexes.[17] For the formation of the peroxo complex **1**, a reduction of O_2 to O_2^{2-} is necessary. 3,5-DTBC acts as electron donor and is oxidized to quinone. If this electron transfer is mediated by copper(II) complexes, a copper(I) complex will be formed initially on oxidation of the catechol, and subsequently reoxidized by O_2 to the copper(II) form.[18] Detailed studies in solution are under way to elucidate the exact course of the reaction leading to **1**.

Experimental Procedure

HL: *p*-Cresol (5.41 g, 50 mmol) and pyrrolidine (7.82 g, 9.1 mL, 110 mmol) were dissolved in ethanol (60 mL). The solution was treated with 36% formaldehyde

solution (8.9 mL, 115 mmol), stirred for 24 h under reflux, and then evaporated to dryness under vacuum. The residue was washed with 10% sodium carbonate solution (40 mL). This solution was extracted three times with ether, which was subsequently dried over sodium sulfate. The ether was removed under vacuum. Yield: 11.4 g (83%); yellow oil; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.80$ (m, 8H), 2.23 (s, 3H), 2.59 (m, 8H), 3.70 (s, 4H), 6.85 (s, 2H); MS (70 eV): $m/z = 274$ [M^+], 257, 203, 188, 175, 160, 134, 105, 91, 84, 79, 70, 56, 43; correct elemental analysis.

1: $Cu(ClO_4)_2 \cdot 6H_2O$ (186 mg, 0.5 mmol) was dissolved in methanol (30 mL), and HL (69 mg, 0.25 mmol) was added. After addition of triethylamine (300 mg, 3 mmol) and 3,5-DTBC (56 mg, 0.25 mmol), dark green crystals of **1** precipitate. Decomposition above 330 °C; UV/Vis (dichloromethane): $\lambda_{max}(\varepsilon\ [M^{-1}cm^{-1}/Cu_4]) =$ 285 nm (11 680), 387 nm (6850), 420 nm (shoulder), 587 nm (370); determination of ν(O-O) has not been possible as **1** decomposes in the Raman laser; magnetic measurement: antiferromagnetic coupling, $\mu_{eff} \approx 0.9\ \mu_B$ (300 K); correct elemental analysis.
